EDITOR BIOGRAPHY

Philip A. Schwartzkroin received his Ph.D. in Neurological Sciences from Stanford University in 1972, and carried out postdoctoral work at the Institute of Neurophysiology in Oslo, Norway. He was on the faculty at University of Washington (1978–2001), in the Departments of Neurological Surgery and Physiology/Biophysics. He is currently Professor in the Department of Neurological Surgery at University of California, Davis, where he holds the Bronte Endowed Chair in Epilepsy Research, and is an Affiliate of the UC Davis Center for Neuroscience.

Dr. Schwartzkroin's research has focused on cellular mechanisms of seizures and epilepsy. He has received a number of awards for his laboratory efforts, including two NIH Javits Awards, the American Epilepsy Society Research Award, and a Guggenheim Fellowship. Dr. Schwartzkroin has published over 150 peer-reviewed research articles and numerous book chapters, and has edited several books on epilepsy topics. Although a basic scientist, Dr. Schwartzkroin has throughout his career been associated with clinical departments, and has established important interactions with both basic science and clinical colleagues. He has played a major role in the national and international epilepsy community (past-president of the American Epilepsy Society, past chair of the International League Against Epilepsy's Commission on Neurobiology), and is a recipient of the ILAE/IBE Ambassador for Epilepsy Award. He is currently co-editor-in-chief of the journal *Epilepsia*.

INTRODUCTION

Research in today's epilepsy laboratories is exciting, evolving, and full of interesting twists and turns. Epilepsy has been recognized as a common human disorder for thousands of years. But modern research into its underlying bases has been ongoing, I would argue, only since the middle of the 20th century. Nonetheless, the epilepsy research field boasts an intriguing and productive history. As with most disorders, and certainly for disorders of the nervous system, discovery of mechanisms and improvement in treatment have been a function of technical advances – which in turn have moved research efforts toward ever more detailed and revealing analysis. Because of the complexity of the nervous system, and because of the many different forms that epilepsy may take, research in this field lends itself to different conceptual and technical approaches. It attracts the involvement of those with interests at very basic levels of analysis (e.g., the "hard-core" basic scientists who are interested in "explanations" at the level of genes and molecules) as well as those whose interests are more "clinical" in nature (i.e., those interested in "net output" behaviors, both normal and pathological). Any search of current research activities in the epilepsy field confirms the breadth and variety of epilepsy-related laboratory work. In addition, even a superficial reading of the literature shows the value of epilepsy-related research for opening windows to normal brain function - through which one can begin to see the connections between, and shared mechanisms of, normality and pathology. For anyone interested in the brain, in the general area of neuroscience, and in an opportunity to explore an endlessly fascinating set of puzzles, epilepsy research provides many rewards.

My initial introduction to epilepsy research was in the laboratory. It didn't take long for me to be "hooked," but it did require some hands-on experimental time. Given the need for such exposure, I've struggled with the question of how one can convey that experimentally-generated enthusiasm to someone who's never been in a laboratory, who is in the initial stages of considering a commitment to research or is pondering a focus for his/her laboratory efforts. For a number of years, I've also been frustrated by my inability to provide a satisfying response to an all-too-common question: "Where can I find out about what's going on in epilepsy research?" This type of query comes regularly from students and fellows, from clinical colleagues, from potential colleagues and collaborators outside the epilepsy field who are seeking a reference to current basic research activities. One could, of course, simply direct these individuals to PubMed or to one of the excellent "textbooks" on epilepsy (mostly clinically oriented). But neither of these alternatives is very helpful, especially if one would like to encourage the questioner to become more interested and involved in the laboratory.

My solution to this frustration has been to try to bring many of the current studies in basic epilepsy under one roof - thus, this volume. We've called it an "encyclopedia," but it certainly isn't an encyclopedia in the classical sense. In particular, it does not pretend to be a comprehensive overview of everything (A-Z) in the epilepsy research field. Rather, the collected articles cover a broad selection of topics, contributed by some of the most active epilepsy research groups in the world. These selections were solicited specifically to answer the question "What's going on in epilepsy research today?" My goal is not to cover all potentially relevant themes, but rather to offer representation in this "encyclopedia" to those who have contributed significantly to the field – to share their goals, insights, and progress.

It might be interesting for the reader to note that my preliminary table of contents did not look like the Table of Contents that now introduces this encyclopedia. The initial version was more like something one might see in a textbook, starting with articles at the "micro" level (cellular/molecular features of cells), progressing through synaptic and circuit considerations, and ending with articles focusing on the "net output." I believed that this type of organization could present a rationally-ordered overview of the field. However, as I began to go through the articles that were eventually submitted, I was reminded of my starting motivation – to offer the reader a volume that reflects the major areas of today's research effort in the epilepsy research arena. The current Table of Contents does mirror current research emphases. And the encyclopedia offers the interested reader (including non-experts) a collection of short and focused articles that provide a real sense of the modern research field - What's exciting? What are the key technical approaches? What are the important questions?

We sent out invitations to hundreds of the most active investigators in the field. Each author was asked to frame the question or issue that drives his/her research, to provide some background that puts the research into an historical context, and to describe (briefly) some of the methods that are currently used for this line of work. Authors were then encouraged to identify recent results – from their own laboratories or from others – that are exciting and promising, and to discuss where this line of research should go in the future – the goals, challenges, and potential for clinical application. In short, I asked each author to write an article as though he/she were talking to a prospective laboratory recruit (a graduate student, a postdoctoral fellow, or a collaborative colleague) in a way that would convey the interest and excitement that draws us (as epilepsy scientists and clinicians) toward a career in this area of research. As one might predict, each author has approached this charge in a way that reflects his/her own interests, approach to research, and laboratory personality. While we've tried to make the format of these articles relatively uniform, the style and substance of each article are unique to the laboratory of origin.

Of course, as with any project of this sort, there are always hurdles, objections, and problems. One significant problem – a major concern for me in thinking about the magnitude of this effort - is that much of material collected in these articles is likely to be out of date in a few years. To address this issue, we plan to produce this Encyclopedia in an easily accessible and readily update-able electronic form. My hope from the start was that the material presented here will be updated on a regular 2–3 year cycle, with new results entered, and new areas of research described on a regular basis. Another equally thorny problem was what to include – or exclude. As you can see from the title of the encyclopedia, the emphasis has been on "basic research." But determining exactly what "basic" (and "research") means is a little tricky, especially in a field like epilepsy in which basic and clinical aspects are so intertwined; indeed, epilepsy research has always been what it is now fashionable to call "translational." The coverage of the current volume therefore expresses, in large measure, my own scope of interests; perhaps more accurately, the topics are very much a function of my circle of professional colleagues - those who agreed to participate and the topics they chose to write about. The holes in the current volume – and there certainly are some – include areas in which there is little current activity, but also topics that might have been covered by "other" sets of authors.

We anticipate that this encyclopedia will serve as a useful reference tool for a broad range of readers - laboratory scientists and clinicians, students, fellows, and well-established investigators. Students and young investigators should be able to use this volume to discover potential areas for establishing their own research efforts. Scientists and clinicians with already-established research programs can use the Encyclopedia as a tool for guiding their students and trainees, as an easy way of "keeping up," and even as a source of practical hints that will help them plan their own future studies.

I hope you find this Encyclopedia of Basic Epilepsy Research useful and informative. I've certainly learned a lot from putting it together. For those of you who have contributed to the volume, I thank you for your interest and involvement – and I look forward to your support when I approach you for updates and/or additions. For those of you who have ideas for new articles, whether stemming from your own research or from other laboratories, please contact me with your suggestions. If this Encyclopedia is to fulfill its mission, it needs to be a dynamic, evolving, interactive tool. We are committed to making it work that way.

Introduction

Absence epilepsy was previously studied in chemical seizure models, in which absence seizures were pharmacologically induced either by systemic or local administration of drugs (such as low doses of pentylenetetrazole (PTZ) in rats or mice, or penicillin in cats). Pressure from society to abandon neurophysiological studies in cats, and the discovery that many (mainly albino) rats show spontaneously-occurring seizures, led to the development of genetic absence rodent models, such as the Genetic Absence Epileptic Rats from Strasbourg (GAERS) and the Wistar Albino Glaxo rats from Rijswijk (WAG/Rij). All individuals of these strains show an age-dependent increase in the expression of spike-and-wave discharges (SWDs) in their electroencephalogram (EEG), the hallmark of absence seizures. SWDs seen in these rodent models are similar to SWDs seen in absence epilepsy in humans. They are accompanied by mild clinical symptoms, which in rats include accelerated breathing, movements of the vibrissae, incidental twitches of fine facial muscles, and eye blinks. The interictal EEG of the rats appears to be normal. The SWDs appear suddenly on a normal background EEG and are bilaterally symmetrical, which is consistent with the view that absence seizures are generalized over the entire cortex of the brain, although SWDs are not well expressed at the occipital cortex. The topographical distribution of spike and wave differs: the spike is more clearly expressed in the frontal part of the cortex, while the wave is more pronounced in the occipital and parietal cortices. Differences in the topography of the spike and wave have also been described in human patients.

Background

Many early studies were designed to validate these genetic models as models of absence epilepsy. Pharmacological or predictive validity (how well outcomes of drug studies in the model predict the action of drugs in patients) was investigated by testing antiepileptic drugs (AEDs), known to be effective or ineffective against absence seizures in humans. These studies showed that specific anti-absence and broad spectrum AEDs reduce SWDs, while drugs known to aggravate absence seizures in humans do the same in these rodent models. Considering these outcomes, pharmaceutical companies now use WAG/Rij and GAERS to predict whether new compounds are effective in absence epilepsy or may aggravate absence seizures. Face validity was confirmed by the similar morphology of SWDs (clear negatively directed spikes followed by negative waves) in humans and in rats, by similarities in topographical distribution of SWDs in

rat and human, and by the frequency dynamics of long- and short-lasting spike-and-wave discharges in humans and rats. Other similarities include the occurrence of SWDs in relation to the state of vigilance, the identical circadian pattern of SWDs, the provocative effects of sleep deprivation, and the corresponding clinical manifestations. Finally, construct validity was shown by establishing the identical behavioral and concomitant electrophysiological correlates of absences in humans and rats. This demonstration focused on a key symptom of generalized epilepsy, the decrease of consciousness or responsiveness accompanying an electroencephalographic seizure. Evoked potentials are excellent indicators of the state of the brain since the amplitude and latency of various components of these potentials are modulated by sleeping and waking. Evoked potentials can be used in order to describe the state of the brain during SWDs. Auditory and visual evoked potentials recorded during wakefulness and REM sleep are similar, while slow wave sleep enhances and delays the various components. Interestingly, evoked potentials during SWDs mimic those made during slow wave sleep (but accompanied with more afterdischarges), suggesting that the state of the brain during SWDs is similar to that during slow wave sleep. Similar to the reduced responsiveness seen during slow wave sleep, the animal is less responsive during SWDs than during wakefulness and REM sleep. Comparison of the errors made in a time estimation task, by WAG/Rij rats and by children with absence seizures, show that both species underestimate the passage of time when seizures occur. These results demonstrate that decrease in the level of consciousness is a fundamental characteristic of absence seizures in both absence epileptic children and in rodent models.

Studies using genetic rodent models have been used to examine fundamental neuronal mechanisms of epilepsy. In absence models, the cortico-thalamic network and its constitutive elements have received most attention in in vitro experiments, and a few neurophysiologic single cell and intracellular studies have been carried out in vivo. The neuroanatomical pathways of the circuitry are well known. Thalamo-cortical and cortico-thalamic cells – both with collateral afferents to the reticular thalamic nucleus (RTN), and with inhibitory projections from the RTN to the thalamo-cortical cells and GABA-ergic cortical interneurons – are the primary pathways involved in the generation and propagation of seizure activity. Early neurophysiologic studies indicated a critical role of the thalamus (including the RTN), since local field potentials showing SWD-like patterns were found there. Also, in thalamic structures, multiple unit activity is synchronized with the spike of the SWD (as recorded with cortical local field potentials). Whether the thalamus, and in particular the RTN, is also the initiator of the rhythmic oscillations (as has been proposed by the cortico-reticular theory) is less clear. Critical experiments, such as surgical isolation of the RTN, have not yet been done in genetic models. Chemical and electrolytic lesions are difficult to carry out and interpret, since it is often uncertain, for example, that intra-RTN injections of drugs are restricted to the RTN. This experimental point is important considering that the RTN contains only GABA-ergic cells and that the thalamus contains mainly glutamatergic ones. In favor of the important role of the RTN (at least in rodent models) in absence seizures is the up-regulation of the T-type Ca^{2+} channels in the RTN in GAERS, the increased density of the α_1 2.1 Ca^{2+} subunit current in the RTN in WAG/Rij rats, and the complete lack of the α_3-GABA subunit immuno-reactivity at the inhibitory synapses of the RTN in these rats. The lack of immunoreactivity for a GABA subunit is particularly interesting, considering that deletion of the β_3 subunit in the RTN of knockout mice renders that part of the thalamus defective, showing a reduced inhibitory efficacy. Further, recurrent inhibitory connections act as a desynchonizer of oscillatory activity in normal RTN, but this function is much reduced in mice and rats with a defective RTN.

Methods

Absences cannot be reliably established from clinical signs only. It is imperative to record the cortical EEG in freely moving animals in order to quantify the number of seizures and to evaluate the effect of various experimental manipulations, such as systemic or local administration of drugs. The implantation of chronic epidural or subcortical electrodes for EEG recording, and of cannulas for intracerebral injections of drugs, is a standard technique. Amplifiers with a high common mode rejection ratio, differential EEG recording, and impedance modifiers placed as close to the animals head as possible, contributes to the recording of a clean, artifact-free EEG in freely moving animals.

Methodological caveat: Outcomes of strain comparative studies (epileptic vs. non-epileptic controls) are difficult to interpret since a found difference cannot directly be ascribed only to the fact that one strain has epilepsy and the other not. Only when the epileptic rat is genetically identical to its control, and the control is without seizures, the interpretation of results from these studies is straightforward. In order to circumvent the interpretation problem, one can take advantage of the fact that young adult WAG/Rij rats (c.a. 2 months of age) do not have SWDs, while all 6-month-old rats show many SWDs. A difference in findings between 2- and 6-month-old WAG/Rij rats can be due either to the presence/absence of seizures, or to the age difference. In order to control the age difference, one can include 2- and 6-month-old rats of a non-epileptic strain – for example, ACIs which show no or very few SWDs at 2 and 6 months of age. Differences between

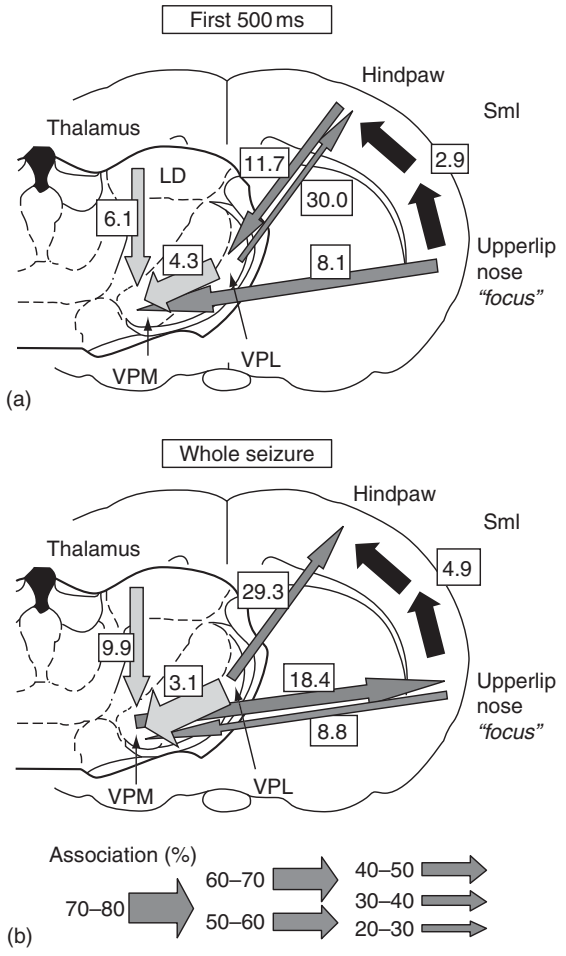

Figure 1 Summary of the cortico-cortical (represented by black arrows), intra-thalamic (light gray arrows), and cortico-thalamic (dark gray arrows) interdependencies during spontaneous absence seizures in the WAG/Rij rat as established by the nonlinear association analysis of a representative WAG/Rij rat (10 seizures were analyzed). The thickness of the arrow represents the average strength of the association, and the direction of the arrowhead points to the direction of the lagging site. The values represent the corresponding average time delays in milliseconds. (a) The relationships as found for the first 500 ms of the generalized seizure showed a consistent cortical focus in the peri-oral somatosensory cortex (SmI), because this site consistently led the other cortical recording sites. The hind paw area, for instance, was found to lag by 2.9 ms on average with respect to this focal site. Within the thalamus, the laterodorsal (LD) nucleus was found to consistently lead other thalamic sites. The ventroposterior medial (VPM) nucleus was found to lag behind the ventroposterior lateral (VPL) nucleus, with an average time delay of 4.3 ms. Concerning cortico-thalamic interrelationships, the cortical focus site consistently led the thalamus (VPM), with an average time delay of 8.1 ms. Within the somatosensory system of the hind paw, the (nonfocal) cortical site led the thalamic site (VPL) during three of 10 seizures; the thalamus led the cortex during one seizure, whereas for the other six seizures no direction of the delay could be established. (b) The relationships as found when the whole seizure is analyzed as one epoch. The same cortical focus as during the first 500 ms was found consistently. Compared with the first 500 ms, the time delay from the cortical focus with respect to the non-focal cortical sites has increased. Furthermore, the strength of association between VPL and VPM has increased. The direction of the cortico-thalamic couplings has changed. For the non-focal cortical sites, the thalamus was found to lead during all seizures. For the focal cortical site, the cortex was found to lead during two seizures, whereas the thalamus was found to lead during seven seizures. Reproduced from Meeren HK, Pijn JP, van Luijtelaar EL, Coenen AM, and Lopes da Silva FH (2002) Cortical focus drives widespread corticothalamic networks during spontaneous absence seizures in rats. *Journal of Neuroscience* 22: 1480–1495, with permission from Society for Neuroscience.

younger and older WAG/Rij rats that are not present in the control strain can then be more readily ascribed to epileptogenesis or to the presence of seizures.

Recent Results

A Cortical Focus in Generalized Absence Epilepsy

The role of the cortex in the generation of spike-and-wave discharges has been investigated using cortical spreading depression techniques to transiently deactivate the entire cortex. During cortical deactivation, recordings have been made of the cortical and thalamic EEG in freely moving GAERS and WAG/Rij rats. In GAERS, the corpus callosum has additionally been transected. At the height of spreading depression, when cortical inactivation is complete, SWDs are abolished in both the cortex and the thalamus. Spike-and-wave discharges reappear after a long recovery period, first in the cortex and later in the thalamus. This demonstration shows that a functionally-intact cortex is a prerequisite for spike–wave generation. Moreover, after callosectomy, the vast majority of SWDs are no longer bilaterally symmetrical, although occasionally bilateral synchronous SWDs are seen. Obviously, the intra-thalamic circuitry alone is not sufficient to generate SWDs, and each hemisphere contains an oscillatory system.

Older studies in cortical slices of WAG/Rij rats showed both increased excitation and reduced inhibition in parts of the frontal cortex, and neurochemical studies show an expanded distribution of NMDA-mediated responses in the cortex of GAERS. These neurobiological studies received new momentum after the discovery of a focal zone involved in the genesis of epileptiform activity in the cortex of WAG/Rij rats. Detailed studies of interrelationships between local field potentials, quantified by means of advanced signal analysis methods of nonlinear association, yields a direct measure of the degree of correlation between the events recorded at different sites (i.e., it gives an indication of the degree of functional coupling between the underlying neuronal populations) (**Figure 1**). In addition, the method provides a time delay between signals. Together, these two parameters deliver evidence

about 'driver-response' relationships between the respective neuronal populations. The outcomes of the analyses of the cortico-thalamo-cortical, intra-thalamic, and cortico-thalamic network in WAG/Rij rats showed that absence seizures (in contrast to what has generally been assumed) have a cortical focal zone of initiation in the peri-oral region of the somatosensory cortex. The activity quickly spreads from this zone over the cortex to the thalamus. Therefore, it seems that the thalamus is only secondarily involved. Moreover, thalamo-cortical cells are only weakly active during SWDs, providing a resonant circuitry that sustains the cortical discharges. During the first 500 ms of SWDs, the cortical focus is consistently found to lead its thalamic counterpart. Thereafter, cortex and thalamus alternately lead and lag in an unpredictable way. These data suggest that the peri-oral region of the somatosensory cortex is the site at which a spike of each new cycle is originally generated. The large-scale synchronization appears to be mediated by the fast propagation of seizure activity from this focal site through cortico-cortical networks. The paroxysmal oscillation within the cortico-thalamic loop is then initiated. Once the oscillation has been set in motion, the cortex and thalamus form a unified oscillatory network in which both structures drive each other.

Several laboratories have now confirmed the existence of a focal cortical initiation zone for SWD in WAG/Rij rats and in GAERS. Pharmacological studies have shown that ethosuximide administered in the focal zone is more effective than injections in the RTN or the ventral basal complex of the thalamus. Even phenytoin, a drug known to enhance SWDs when injected systemically, reduced SWDs after local injections in the cortical focal zone (**Figure 2**). Injections of ethosuximide at other cortical locations are much less effective. Other investigators have found a specific increase in functional magnetic resonance imaging signals in the peri-oral somatosensory cortex during SWDs. These new discoveries have not only revived the classical debate about the origin of absence seizures, the identification of a specific cortical brain region from which the seizures are initiated has led to an attempt to determine why this zone is more excitable than other cortical zones. An up-regulation in the

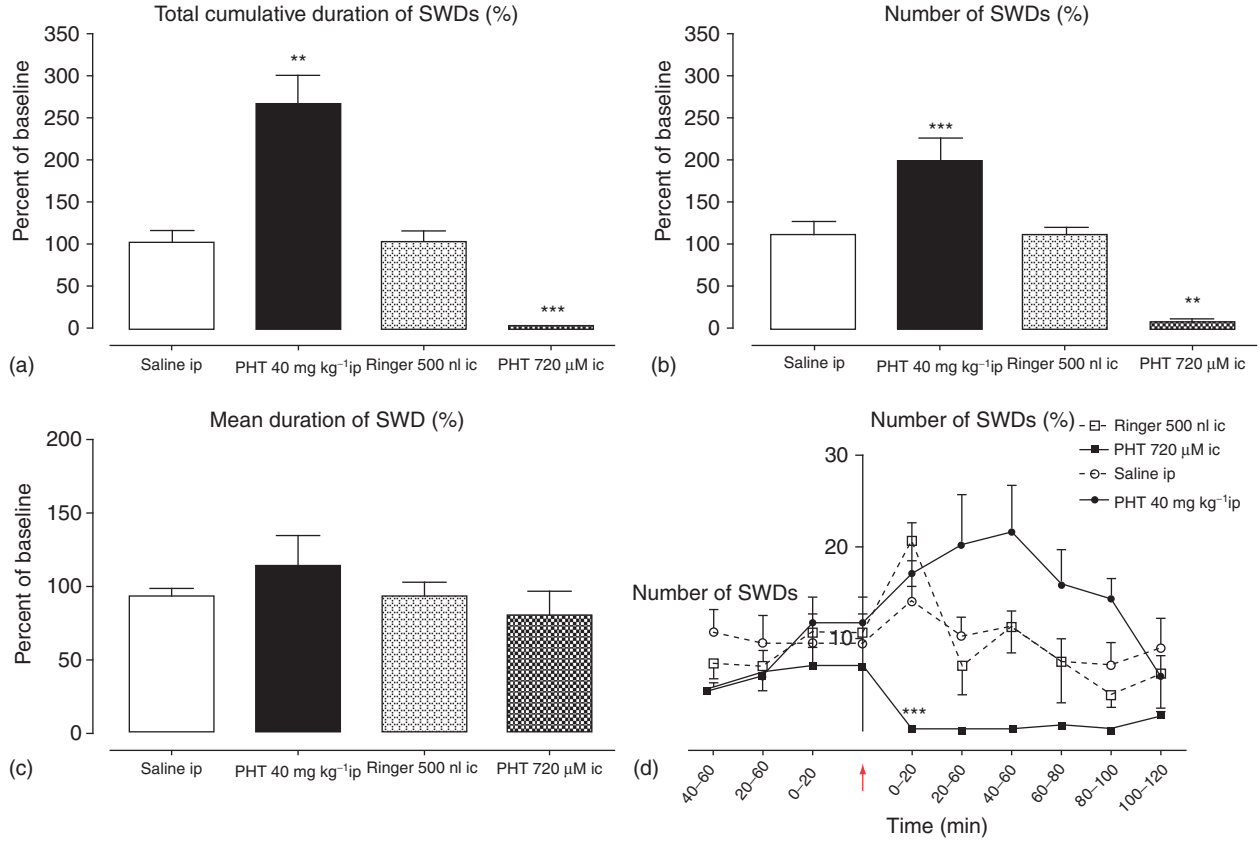

Figure 2 Effect of Phenytoin on total cumulative duration (a) number (b) and mean duration (c) of SWDs throughout 2 h post injection and the number of SWDs per 20 min intervals (d) before and after i.p. and intracortical (i.c.) injections in WAG/Rij rats in the deeper cortical cell layers ($n = 7$). $^{**}P < 0.01$; $^{***}P < 0.001$. expression of a subtype of Na^+ channels is specifically found in this region, and there are changes in I_h channels (which play a crucial role in the burst firing mode of thalamic and cortical neurons). Neurophysiologic in vivo studies in GAERS, specifically aimed at the cortical initiation zone, have shown that epileptic discharges are initiated in neurons of layers 5 and 6. These neurons, which show a distinctive hyperactivity associated with membrane depolarization, lead the firing of distant cortical cells during the epileptic discharge. Consistent with their ictogenic properties, neurons located in this focus exhibit inter-ictal and pre-ictal oscillations that are converted into an epileptic pattern. These pyramidal neurons of deep layers of the focal cortical site display an inter-ictal subthreshold and suprathreshold activity that is markedly higher than that of neurons located in the upper layers. This sustained firing, composed of a mixture of single discharges and high-frequency intrinsic bursts, has a regular pattern. Consistently, short periods (0.2–1.2 s) of small-amplitude rhythmic membrane potential fluctuations, generating periodic firing during inter-ictal epochs, are observed in deep layer neurons. Throughout an absence seizure, the firing of layer 5 and 6 neurons systematically precedes the discharge of superficial neurons. Hyperactivity of deep layer neurons is specific to the focus, and the hyperactivity of deep layer neurons in the somatosensory cortex is specific for epileptic animals.

A disregulation of inhibitory and excitatory synaptic systems may also participate in the generation of SWDs. The peak conductance of the fast component of inhibitory synaptic responses is reduced in deep layers of the focal cortical zone of WAG/Rij rats, documented in cortical-thalamic slices of WAG/Rij rats showing an increase in synaptic excitability mediated by NMDA receptors. Focal electrical stimulations elicit a late, large-amplitude, NMDA-dependent synaptic depolarization that can trigger repetitive firing. A similar stimulating protocol in control Wistar rats produces only a monophasic synaptic depolarization that can trigger only a single action potential. These recent neurophysiologic data obtained in GAERS and WAG/Rij rats provide a firm underpinning of the cortical focus theory of absence epilepsy. The excitatory cortico-thalamic inputs from cortical layers 5 and 6 (of the initiation zone) are stronger than in non-epileptic animals, and they impinge upon the RTN with its decreased propensity to dampen oscillations. These changes in intrinsic and synaptic properties facilitate resonances and spread throughout the thalamus, and propagation back to the cortex.

Circuitries

A further elaboration of the cortical focus theory requires a better understanding of the local and global mechanisms of absence epilepsy, as well as of the spread of epileptic activity over the cortex. We have hypothesized that the epileptic focus in the peri-oral region of the somatosensory cortex interacts with functionally and anatomically related regions – i.e., the adjacent parietal and frontal (sensory and motor) areas, creating an oscillatory loop that generates SWDs. If this occurs, then the onset of SWDs is associated with a significant increase of fronto-parietal coherence (and less significant changes of coherence between distant and functionally divergent areas, such as the fronto-occipital and parieto-occipital areas). Coherence, like correlation, is a measure of the interdependency of two signals; a high correlation suggests coupling of the signals. In our experiments, coherence is calculated from local field potentials recorded from various epidural and thalamic electrodes, placed intra- and inter-hemispherically in WAG/Rij rats. Coherence coefficients can also reveal intra-thalamic and cortico-thalamic synchronization, and shows whether the thalamus indeed exhibits a resonance circuitry of cortical SWDs. We have found that the onset of SWDs is associated with a strengthening of both unilateral and bilateral intracortical and unilateral thalamo-cortical interactions. A significant increase of cortico-cortical, cortico-thalamic, and thalamo-thalamic coherence is detected in frequencies from 5 to 60 Hz. The highest increase of coherence is obtained in two frequency bands – around a mean frequency of SWDs 10 (8–11.5 Hz) and of its first harmonic band of 20 (16–21.5 Hz) (**Figure 3**). Moreover, the anterior cortical areas have an intrinsic propensity to hypersynchronize, which facilitates unilateral and bilateral propagation of SWDs over anterior cortical areas. The trans-hemispheric cortical coherence is significantly higher than the intra-hemispheric cortico-cortical and cortico-thalamic and thalamo-thalamic coherence. This extensive increase of bilateral synchronization, and the peculiar profile of trans-hemispheric coherence, may imply the crucial involvement of the corpus callosum in the pathophysiology of absence seizures.

Strikingly, a SWD-related decrease of coherence is found in a narrow low-frequency band (<5 Hz), limited to cortico-cortical couples formed by the peri-oral region of the somatosensory cortex and the thalamo-thalamic pair. Since a similar pattern of coherence changes is seen in the cortical and thalamic local oscillatory networks, it appears that there is a common neurophysiologic mechanism controlling intra-thalamic and intracortical synchrony. The onset of SWDs is associated with a higher functional coupling throughout cortico-cortical, thalamo-thalamic and cortico-thalamic associative pairs. This increase of oscillatory synchrony is topographically and frequency specific, suggesting that a functional relationship explicitly distinguishes different oscillatory circuits. This finding suggests that there is nonhomogeneous spread of SWD over thalamo-cortical system, and is

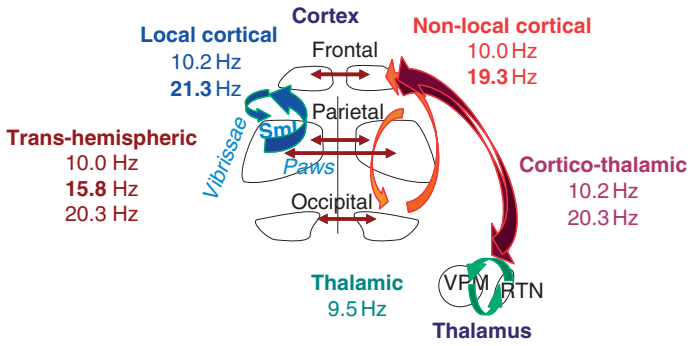

Figure 3 Outcomes of coherence analyses of local field potentials as produced in cortico-thalamo-cortical circuits. Five resonant circuits are identified during a SWD. The first circuit is at or near the site of origin, the parietal cortex. The second one is the trans-hemispheric network, it connects the two hemispheres; the third one is the nonlocal cortical network, it associates the parietal cortex with the occipital cortex; the fourth and fifth are the cortico-thalamic-cortical reverberating and local thalamic activity. The dominant oscillating frequency is around 10 Hz and its harmonic 20 Hz, the trans-hemispheric circuit has an additional 15 Hz oscillation. Reproduced from Sitnikova E and van Luijtelaar G (2006) Cortical and thalamic coherence during spike–wave seizures in WAG/Rij rats. *Epilepsy Research* 71: 159–180, with permission from Nature Publishing Group.

inconsistent with the former viewpoint that spike–wave seizures occur without localizing features.

Genotype-Environmental Interactions

Although generalized seizures (including absences) have a genetic origin, it can be clinically relevant to know how the genotype and the environment interact to modulate and shape the epileptic phenotype. To study this interaction, we subjected the WAG/Rij and a non-epileptic control inbred rat strain (ACI), which differ significantly in their genetic seizure susceptibility, to various environmental manipulations during different stages of development. We also exposed pregnant WAG/Rij mothers to PTZ, WAG/Rij pups were exposed to maternal deprivation and neonatal handling, weaned ACI and WAG/Rij rats were housed in either an enriched of impoverished condition in the period that SWDs start to emerge (0–60 days post weaning) and when they become fully mature (70–130 days post weaning). The EEGs of these ACI and WAG/Rij rats were recorded when they were adult. The outcomes of the pregnancy study show that repeated pentylenetetrazole (PTZ) injections during pregnancy protect WAG/Rij rats against SWDs and PTZ-induced seizures until about 70 days of age; older rats are more sensitive than younger WAG/Rij rats to a challenge with PTZ. Next, it was found that the occurrence of seizures was only minimally affected by housing conditions, suggesting that SWDs are mainly controlled by genetic factors. However, different seizure characteristics, such as number and mean duration of SWDs, have a different heritability and show a different sensitivity to the environment.

Kole and coworkers have established that the changes in the HCN1 subunit, a subtype of I_h channels, precede the development of SWDs, that WAG/Rij rats have more intrinsically burst firing neurons in the deep cortical layers than non-epileptic control Wistar rats, and that the loss of the dendritic I_h in WAG/Rij might form the basis for the initiation of the spontaneous seizures in the focal zone. Manipulations during the weaning period (such as maternal deprivation and neonatal handling before weaning) are accompanied by an increase in the expression of HCN1 and a decrease in SWD; notably, these manipulations during this early developmental period are more successful in changing the epileptic phenotype than the same manipulations later in life. These findings suggest that manipulations early in life, that alter seizure activity and I_h channels in the cortex, are critically involved in the pathogenesis of absence epilepsy. Further, interventions based on the prevention of, or compensation for, the loss of I_h channels might provide a new therapeutic avenue for absence epilepsy.

Interaction between Various Types of Epilepsy

The treatment of complicated mixed forms of epilepsy is one of the most challenging tasks confronting the clinical epileptologist. The suppression of one kind of paroxysms can be accompanied by the aggravation of other seizure types. Whether and how a seizure type develops in the presence of another type is completely unknown. We have taken two approaches to investigate whether there is an interaction between two different seizures types. In the first line of research, WAG/Rij and control rats were selected for their audiogenic sensitivity. Behavioral and neurochemical differences in some monoamines, as measured in extracted tissue immediately after exposure to the sound stressor, were investigated. The presence of absence seizures correlates with novelty-induced anxiety,

in which the limbic circuitry seems to be involved. Sound stress activates the 5-HT system differently in the different subject groups: audiogenic-sensitive rats and rats with only absences display predominantly a reaction in the thalamus, whereas non-epileptic rats show the highest response in the frontal cortex. The highest thalamic response occurs in rats with absence epilepsy, with much smaller changes in audiogenic sensitive control rats. We conclude that the brain 5-HT-ergic response to stress depends on the type of epileptic pathology.

A second approach to the interaction between two seizure types has made use of the kindling model. Both GAERS and WAG/Rij rats show peculiarities in the kindling process when compared with control rats. While controls are fully kindled after 12–15 electrical stimulations in the amygdala, GAERS remained at the initial stage 2 of kindling even after 30 sessions, with no motor seizures observed. Moreover, the duration of the afterdischarge after the kindling stimulus is shorter in GAERS. WAG/Rij rats are also more difficult to kindle; it takes more sessions before some of them reach the end stage 5 of kindling. Resistant rats have more SWDs, preceding the kindling sessions. Thus, it appears that kindling of genetic absence epileptic rats is strongly suppressed – perhaps because of the daily occurrence of a large number of absence seizures of these rats. This result suggests that the limbic system is changed in these genetically absence rats – which is perhaps surprising considering that SWDs occur in the cortico-thalamo-cortical circuitry and that mechanisms of its pathology and the consequences of the seizures are thought to be restricted to cortex and thalamus (without effects in the limbic system).

Behavioral Studies Show a Comorbidity with Depression

Using these genetically absence epileptic rats, we have described their behavioral characteristics, their performance in learning and memory tests, as well as their coping with stressful events Earlier studies showed only minimal behavioral differences from controls in WAG/Rij rats, some disturbances in reference memory in WAG/Rij rats, and (surprisingly) improved avoidance learning in GAERS. In experiments with graded novelty stress, WAG/Rij rats show a locomotor hyper-response to mild environmental stress, but they react with remarkable passive behavior to stronger emotional stress (from which they cannot escape). Further behavioral tests by Sarkisova showed that WAG/Rij rats exhibit depressive-like features, such as increased immobility in Porsolt's forced swim test and decreased sucrose intake (anhedonia). Interestingly, WAG-Rij rats exhibit normalization of this behavior after chronic (but not acute) treatment with antidepressant drugs. These findings validate the WAG/Rij strain as a genetic absence model with comorbidity for depression. In all, it is proposed that WAG/Rij rats are more vulnerable to stress than control rats and have depressive-like symptoms.

Behavioral and neurochemical studies have also been done in order to investigate putative causes and mechanisms of the increased vulnerability to the depressive-like phenotype. A hyper-response to amphetamine is found, similar to results in anhedonic depressive patients. The hyper-response to amphetamine might be due to a high reactivity in the mesolimbic dopaminergic system. The sensitivity for the dopamine agonist, apomorphine, is also enhanced, suggesting that the dorsal striatum is involved. Also, indices of activity of the 5-HT system are found to be reduced in the forebrain of WAG/Rij rats, while the 5-HT response to inescapable sound stress is enhanced in the thalamus. Based on these observations, it has been proposed that absence epileptic rats are more vulnerable to stress in which the 5-HT system is involved, and that they represent a model for mild depression in which the dopaminergic system also seems to be involved. The outcome is clinically relevant, considering that both the absence seizures and the depressive symptoms need to be treated in depressed epileptic patients.

Future Challenges

Progress in science is guided by theories, and a new theory on the origin of the electroencephalographic absence seizures – the cortical focus theory for absence epilepsy – has been derived from work on genetic animal models of SWD epilepsy. An immediate challenge is to test this theory in humans, with the same and other signal analytical tools as used in rats. The MEG, with its moderate spatial and high temporal resolution – alone or in combination with EEG – is well-suited for such studies of the cortical spreading of absence seizures. The fMRI technique, with it excellent spatial resolution, can be used for studying the role of the thalamus in humans. However, based on work presented here, it seems that a unifying theory is still missing. A theory is needed in which the various findings – such as the up-regulation of the various types of Ca^{2+} channels, the anomalies of I_h, and the lack of some of the GABA-subunits in the RTN – are integrated.

The genes mutated in absence epilepsy have not been identified – although different mutations in a gene termed CACNA1H have been associated with childhood absence epilepsy. Not all patients with CAE have mutations in this gene. Therefore, the hunt for the genes controlling absence epilepsy is still open. Candidate genes might come from analysis of the genetic rat models. Interestingly, linkage analyses in GAERS and WAG/Rij rats results in the identification of different chromosomal locations. Micro-array technology may help to identify the expression levels of specific genes in the focal zone of the absence models; the

specificity of the expression should be tested in the peri-oral zone of non-epileptic control rats. By including young, still not epileptic, WAG/Rij rats in such a study, it is possible to discriminate between genes that are affected by the disease rather than by the cause.

Molecular studies are helping to identify the effects of genetic deficits and its consequences, and to specify brain areas and their interconnections involved in the pathogenesis of epilepsy. The discovery of the subunits forming a large variety of GABA and glutamatergic ionophoric ion channel gated receptors with different distribution profiles, and the many subclasses of metabotropic glutamate receptors and neuromodulators, provide a broad panorama of means to target selectively and specifically the affected brain regions. Data from knockout mice are helpful and supplementary. To illustrate this point, it is worth noting that mice missing the mGlu4 receptor are completely resistant to the induction of absence seizures. These mGlu4 receptors are present presynaptically in cortico-thalamic neurons in the RTN and cortex. A positive allosteric modulator of this receptor, PHCCC, enhances dose-dependently, absence seizures, as shown by Ngomba and coworkers. This finding suggests that the mGlu4 receptor antagonist might be a new tool for targeting SWDs. Besides reducing seizures, treatment strategies that will slow or halt the progressive nature of epilepsy and prevent the development of epilepsy in susceptible individuals, are needed. One recent example was recently proposed by Blumenfeld's group, that found that ethosuximide in the drinking water of weaned animals delays the expression of the absence seizure for many weeks.

Increased $GABA_A$ Receptor-Mediated Transmission in Typical Absence Seizures

Introduction

A typical absence episode is a nonconvulsive epileptic seizure that consists of a sudden and relatively brief impairment of consciousness occurring concomitantly with a generalized and synchronous 'spike and slow wave discharge' (SWD) paroxysm at 2.5–4 Hz in the EEG. Typical absence seizures are part of the complex clinical and EEG presentation of many idiopathic generalized epilepsies (IGEs). It is only in childhood absence epilepsy (CAE) that these seizures are the sole neurological symptom and are not accompanied by either metabolic, neuropathological, or other neurological deficits.

Typical absence seizures are genetically determined, and the classical 2.5–4-Hz SWD trait of different IGEs has been shown to be inherited in an autosomal dominant manner. Indeed, there is a strong consensus in describing the occurrence of (typical) absence seizures as a familial disease with a complex genotype, and increasing evidence suggests that they may represent a complex channelopathy of multifactorial genetic background. As far as the pathophysiology of human absence seizures is concerned, there is also a general consensus, based on some old invasive studies and more modern noninvasive imaging investigations, that the EEG manifestation of SWDs of typical absence originates from abnormal electrical activities in reciprocally connected thalamic and cortical territories – i.e., in what is generally referred to as the thalamocortical loop.

Among the various molecular genetic alterations that have in recent years provided support for the idea of IGEs as channelopathies, abnormalities in voltage-dependent Ca^{2+} channels and $GABA_A$ receptors ($GABA_A$Rs) have undoubtedly been of primary significance. In particular, different mutations in the $\gamma 2$ or δ subunits of the $GABA_A$R have been detected in different IGE cohorts, and the proteins resulting from these mutant genes have been shown to give rise to a decreased $GABA_A$R function. However, the probands in all these studies had an epileptic phenotype much more complex than that in typical absence seizures alone. To complicate the matter further, it has not been possible to detect, in every expression system, the potential alterations that these mutant proteins exert in $GABA_A$R function. It is only in linkage studies of probands with only typical absence seizures that the regions coding for $GABA_A$R subunits (namely $\alpha 5$ and $\beta 3$) have been highlighted as susceptibility loci. Thus, notwithstanding the attractive hypothesis of a decreased $GABA_A$R-dependent transmission in typical absence epilepsy, the difficulties in recruiting cohorts with a pure absence seizure phenotype and the inherent drawbacks of studying mutant proteins in expression systems that lack the normal complement of $GABA_A$R subunits might explain why direct and conclusive evidence of a $GABA_A$R loss-of-function in typical absence seizures is still missing.

Background

A decreased $GABA_A$R function in typical absence seizures has also been suggested on the basis of studies in animal models, but a critical analysis of these data indicates that the evidence in support of this hypothesis is far from conclusive. Although no change in the electrophysiological properties of cortical $GABA_A$R-mediated inhibitory postsynaptic potentials (IPSPs) had apparently been found in the feline penicillin model, indirect evidence indicating reduced $GABA_A$R function has been reported in the neocortex of two inbred models of absence epilepsy, the genetic absence epilepsy rats from Strasbourg (GAERS) and the Wistar albino Glaxo/Rij (WAG/Rij) rats.

$GABA_A$Rs in the thalamus have also been implicated in the pathophysiology of absence seizures, since $GABA_A$ antagonists applied to thalamic slices have been shown to transform sleep spindle activity into abnormal oscillatory discharges at 2–3 Hz. Furthermore, direct evidence of a role for $GABA_A$Rs in the nucleus reticularis thalami (NRT), one of the intrathalamic sources of GABAergic afferents to the main sensory thalamic nuclei, has come from the observation of hypersynchroneous 3-Hz firing in thalamic slices of $GABA_A$R $\beta 3$ subunit knockout mice. However, two major drawbacks affect these and many other experimental studies in the field. First, the phenotype of the genetic and pharmacological models that have been used for these studies does not simply show (typical) absence seizures and associated SWDs, but also includes a variety of other neurological symptoms (and in some cases neuropathological abnormalities), including ataxia, dystonia, and tonic–clonic seizures. This complexity clearly makes any attempt to draw direct and solid cause–effect relationships

between the observed genetic, biochemical, or electrophysiological abnormalities and the occurrence of SWDs or absence seizures extremely difficult. Second, the 'abnormal' low threshold Ca^{2+} potential (LTCP)-dependent, high-frequency burst of action potentials observed in thalamocortical (TC) neurons in some of these studies in thalamic slices (which contain either one of the main sensory thalamic nuclei alone or together with the NRT) has been interpreted as if it resembles SWD paroxysms. In reality, however, in both in vivo rat and cat models, the activity of the vast majority of single TC neurons in sensory thalamic nuclei during spontaneous SWDs consists of rhythmic (and in synchrony with each spike and wave complex), composite $GABA_A$ IPSPs that are superimposed on a tonic hyperpolarization, with only an occasional single, or doublet, action potential. Thus, although the overall output of the TC neuron network during spontaneous SWDs in vivo would indeed contain short synchronous discharges originating from this occasional firing, the single TC neuron does not show strong, LTCP-dependent, high-frequency bursts of action potentials.

In an attempt to overcome the interpretational difficulties associated with results originating from models with a complex phenotype, we and other groups have focused our work on GAERS, an inbred model of typical absence seizures, and on the γ-hydroxybutyric acid (GHB) model, which, when systemically injected in normal Wistar rats, also reproduces a substantially pure absence seizure phenotype. In addition, we have concentrated our investigation on the basic properties of single cells and synaptic potentials, since it has not yet been possible (to the best of our knowledge) to accurately reproduce the SWD paroxysms observed in vivo in thalamic, cortical, or thalamocortical slices. Surprisingly, our studies in both GAERS and GHB models have produced results that are consistent with a $GABA_AR$ gain-of-function in typical absence seizures.

Methods

In our laboratories, we use the GAERS rats since this is one of the best-established models of typical absence seizures with no additional neurological or neuropathological abnormalities. The epileptic phenotype of this inbred strain becomes evident only during periods of quiet wakefulness, and consists of SWDs in the EEG that are accompanied by behavioral arrest and rhythmic twitching of the vibrissae and facial muscles. Muscle tone in the neck is sometimes diminished, inducing a gradual and slight lowering of the head. The pharmacological profile of the GAERS seizures very closely matches that of the human condition: In particular, ethosuximide and valproate abolish, whereas carbamazepine and phenytoin aggravate, the seizures. Also similar to the human condition is the thalamocortical origin of SWDs in GAERS, with the hippocampus and cerebellum being devoid of any ictal activity. Another advantage of the GAERS model is the availability of a corresponding, well-characterized, inbred strain of nonepileptic control (NEC) rats, which are devoid of absence seizures. In contrast to typical absence seizures in humans (or at least to classical CAE), however, the frequency of SWDs in GAERS is 7–9 Hz, and the seizures persist during adulthood.

The attractiveness of the GHB model arises not only from the fact that it is possibly the best-established and best-characterized pharmacological model of typical absence seizures, but also that it too shows an almost pure absence phenotype when GHB is injected within appropriate doses in different species, from mice and rats to cats and monkeys. Thus, GHB-induced absence seizures consist of behavioral arrest, facial myoclonus, and vibrissal twitching; these behaviors are invariably accompanied by the EEG appearance of SWDs, which originate in thalamocortical territories and have a pharmacological profile very similar to that of the human condition. Another interesting feature of the GHB model, and one that strongly supports the study of GHB actions in thalamic slices for understanding the pathophysiological mechanisms of absence seizures, is that direct intrathalamic injection of GHB in a main sensory thalamic nucleus (the ventrobasal, VB, complex) of freely moving rats elicits a behavioral and EEG absence phenotype that is almost indistinguishable from that observed following the systemic injection of GHB. In contrast to the human condition, the GHB model clearly lacks the spontaneity and recurrent nature that are characteristic of the epileptic condition. Also, the frequency of SWDs is the same as that in humans when GHB is injected in cats and monkeys (about 3 Hz), but is 7–9 Hz in mice and rats.

Electrophysiological recordings combined with single-neuron staining are used in our laboratories to investigate the electrical abnormalities that are present in GAERS or are induced by application of GHB in normal Wistar rats. Together with EEG recordings in freely moving animals, we also investigate the biophysical properties of single neurons and their synaptic responses using brain slices obtained from the key areas of the thalamocortical loop, i.e., the somatosensory cortex or thalamic nuclei (mainly the VB and the NRT). Either patch clamp recordings are used to assess the biophysical properties of voltage- and transmitter-gated channels, or sharp microelectrode recordings are obtained to investigate the spontaneous or synaptically evoked activity in single neurons or neuronal networks. Isolation of voltage- and transmitter-gated channels is achieved using pharmacological agents. In particular, $GABA_A$ inhibitory postsynaptic currents (IPSCs) or IPSPs are isolated by adding to the perfusion medium the ionotropic glutamate receptor antagonists, DL-2-amino-5-phosphonovaleric acid (DL-APV) (50 μM) and 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) (10 μM), while glutamatergic excitatory postsynaptic currents (EPSCs) or excitatory postsynaptic potentials (EPSPs) are isolated by adding the $GABA_A$ antagonist gabazine (10 μM) and the $GABA_B$ antagonists CGP55845A (100 nM) or CGP35348 (1 mM).

Recorded cortical and thalamic neurons are identified by the presence of their characteristic electrophysiological or morphological features, and electrical stimulation is used to activate the synaptic pathways present in a slice.

Recent Results

Difference in $GABA_A$ IPSC Properties of GAERS and NEC Rat Neurons are Nucleus-Specific

Striking differences between NEC rats and preseizure GAERS are present in the properties of the mIPSCs recorded in NRT neurons. In this nucleus, mIPSCs have a 67% higher frequency, a 25% larger amplitude, and a 40% faster decay in GAERS than in NEC rats (Figure 1(a)–1(c)). These differences in mIPSCs are not the results of differences in either basic electrical or anatomical properties, since the passive membrane properties and the morphological features of dye-injected NRT neurons in GAERS and NEC rats are identical. In addition, differences between GAERS and NEC rats are evident in the presynaptic control exerted by $GABA_B$ autoreceptors on mIPSCs recorded in NRT neurons. Thus, although the $GABA_B$ agonist (±)baclofen (1–10 μM) reversibly decreases the frequency (but not the amplitude) of the $GABA_A$ mIPSCs in all NRT neurons tested, its potency is lower in GAERS than in NEC rats

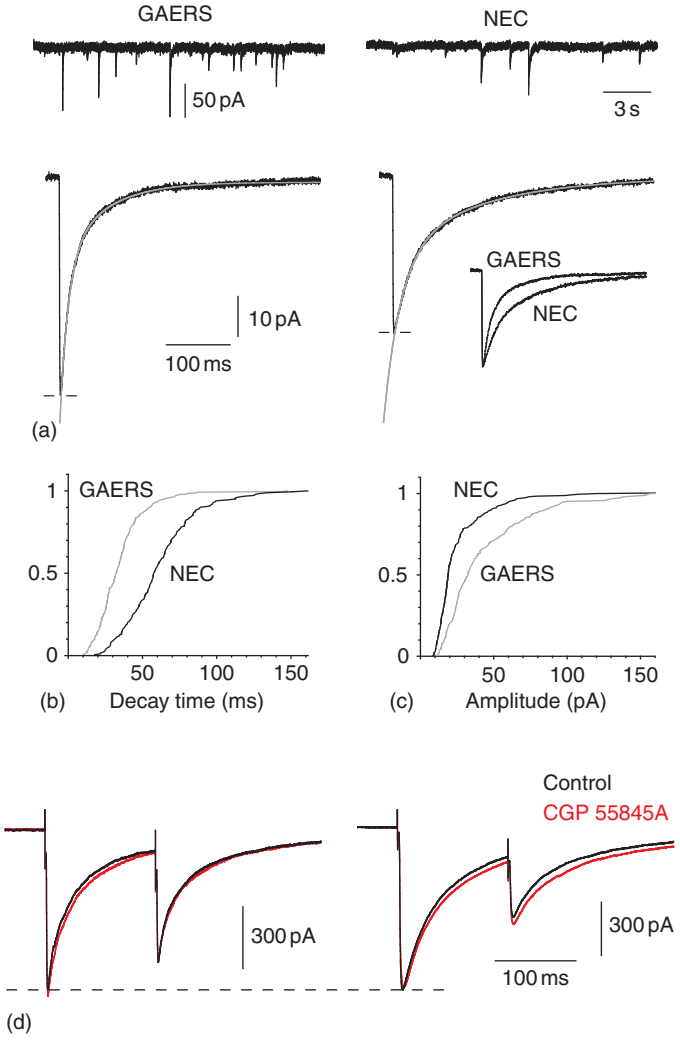

Figure 1 $GABA_A$ IPSCs in NRT neurons of GAERS and NEC rats. (a) Top: mIPSCs in GAERS and NEC NRT neurons. Note the higher frequency and amplitude of mIPSCs from GAERS than from NEC rats. Bottom: Averaged mIPSCs show the larger amplitude and faster decay of these synaptic currents in GAERS than in NEC rats. The two mIPSCs are scaled and superimposed in the inset. (b) Cumulative distribution of the decay time constant shows a faster kinetics of mIPSCs in GAERS NRT neurons (grey) than in NEC (black) NRT neurons. (c) Cumulative distribution of the amplitude shows a larger amplitude of mIPSCs in GAERS NRT neurons (grey) than in NEC (black) NRT neurons. (d) Superimposed, averaged $GABA_A$ IPSCs evoked by intra-NRT stimulation using a 140-ms paired-pulse protocol in control conditions (black) and during application of 100 nM of CGP 55845A (red) in GAERS and NEC NRT neurons. Note the smaller paired-pulse depression in GAERS than in NEC rats, and the lack of effect of CGP 55845A in both strains. Reproduced from Bessaïh T, Bourgeais L, Badiu CI, *et al*. (2006) Nucleus-specific abnormalities of GABAergic synaptic transmission in a genetic model of absence seizures. *Journal of Neurophysiology* 96: 3074–3081, with permission from American Physiological Society.

(ED_{50} of 1.6 and 0.8 μM, respectively). Moreover, baclofen maximal efficacy is 25% lower in GAERS, although no difference exists in its threshold concentration (1 μM) between GAERS and NEC rats. In both strains, the baclofen effect on mIPSCs is fully antagonized by the specific $GABA_B$ receptor antagonist CGP55845A (100 nM).

In contrast, in pyramidal and nonpyramidal cortical neurons of layers 2 or 3 and in TC neurons of the VB, $GABA_A$ mIPSCs have similar rise time, amplitude, frequency, and decay time constant in GAERS and NEC rats. Moreover, no difference between the two strains is detected in the action of (±)baclofen (1–10 μM) in VB TC neurons. As for NRT neurons, the effect of baclofen observed in every cortical and TC neuron tested is reversible and is antagonized by CGP 55845A (100 nM).

Since the $GABA_B$ autoreceptor sensitivity of NRT mIPSCs is different between GAERS and NEC rats, and because in some brain areas, including the thalamus, paired-pulse depression has been shown to be in part due to the activation of presynaptic $GABA_B$ autoreceptors, we used this stimulation protocol to investigate the strength of evoked $GABA_A$R-mediated inhibition. Indeed, paired-pulse depression of evoked IPSCs is significantly smaller (46%) in GAERS NRT neurons than in NEC NRT neurons (**Figure 1(d)**), but similar between TC neurons of the two strains. However, in both TC and NRT neurons of GAERS and NEC rats, CGP55845A (100 nM) and CGP35348 (1 mM) fail to affect the paired-pulse depression of the evoked IPSCs.

In summary, these data in a well-established genetic model of typical absence seizures indicate that one important component underlying the expression of these seizures may be related to subtle alterations in the kinetics and paired-pulse depression of phasic (i.e., IPSCs) $GABA_A$R-mediated inhibition specifically in the NRT. In this respect, our results are in agreement with the subtle abnormalities in $GABA_A$R function resulting from human mutations in genetically simple IGEs. Also, the decreased paired-pulse depression in GAERS clearly indicates that in a well-established model of typical absence seizures, there is a clear gain-of-function in $GABA_A$R-mediated transmission. This result suggests caution in extrapolating to the human condition the significance of experimental results obtained in the presence of full loss-of-function of $GABA_A$Rs that globally involves cortical and thalamic nuclei.

From a pathophysiological perspective, the smaller paired-pulse inhibition of GAERS would undoubtedly play a major role in allowing the expression of the strong, LTCP-mediated bursts of action potentials that are present in GAERS NRT neurons during SWDs. Indeed, computer simulations carried out in NRT network models that contain the $GABA_A$ IPSCs properties highlighted earlier has shown that a simulated 'GAERS NRT network' has an increased excitability compared with a simulated 'NEC NRT network,' and responds to random inputs with a resonance output at the very same frequency of the spontaneous SWDs observed in GAERS in vivo. Finally, the presence of these NRT-specific abnormalities in GAERS at a time prior to seizure onset suggests that alterations in the fine-tuning of GABAergic phasic inhibition (i.e., IPSCs) may be of epileptogenic significance.

Effects of GHB on Excitatory and Inhibitory Synaptic Potentials Recorded in VB TC Neurons

As mentioned earlier, the importance of studying the detailed mechanisms of GHB on TC neurons derives from the fact that this agent when directly injected in the thalamus of freely moving animals, elicits SWDs and behavioral components identical to those observed following systemic injection. Together with a $GABA_B$R-mediated hyperpolarization of TC neurons (**Figure 2(a)**), GHB is also capable of reversibly and dose-dependently decreasing the amplitude of sensory EPSPs and corticothalamic EPSCs in all TC neurons (**Figure 2(b)–2(e)**). This reduction is fully antagonized by CGP 56999A (100 nM) or CGP 35348 (1 mM), and is therefore likely due to activation of presynaptic $GABA_B$ autoreceptors present on these afferents (**Figure 2(f)**). The threshold concentration of GHB against the corticothalamic EPSCs is 250 μM, whereas the maximal effect (57% reduction) is obtained with 10 mM.

GHB also reversibly decreases the amplitude of NRT-derived $GABA_A$ IPSCs with a similar potency as against the EPSCs, but at low concentrations (250 μM–1 mM), it is not effective on all recorded IPSCs (**Figure 2(b) and 2(c)**). In particular, 250 μM of GHB produces an effect in <10% of neurons, whereas at 0.5–1 mM it only decreases (by 25–30%) half of the IPSCs tested (**Figure 2(d) and 2(e)**). However, application of 10 mM of GHB induces a 54% decrease in every TC neuron tested. Although the GHB-induced reduction of the NRT-derived IPSCs is always fully antagonized by CGP 56999A (100 nM), in order to exclude the possibility that the afferents generating the GHB-insensitive IPSCs lack presynaptic $GABA_B$ autoreceptors, we applied baclofen following washout of GHB in 10 of the 31 neurons that were insensitive to 500 μM or 1 mM of GHB (**Figure 2(e)**). In all these neurons, (±) baclofen (5–10 μM) decreased the IPSC amplitude by the same amount as in those neurons where GHB was active.

Controversies still exist with respect to the involvement of putative GHB receptors in the central actions of GHB, including its ability to elicit absence seizures. The results of additional electrophysiological experiments in the thalamus, however, strongly question the selectivity and usefulness of putative GHB receptor agonists and antagonists, such as NCS 356, *trans*-4-hydroxycrotonic acid, and NCS 382. Thus, the apparent block of GHB-elicited SWDs by NCS 382 in vivo should be treated with extreme caution, since it may result from any of its nonspecific actions in the thalamus. Indeed, the putative GHB agonist

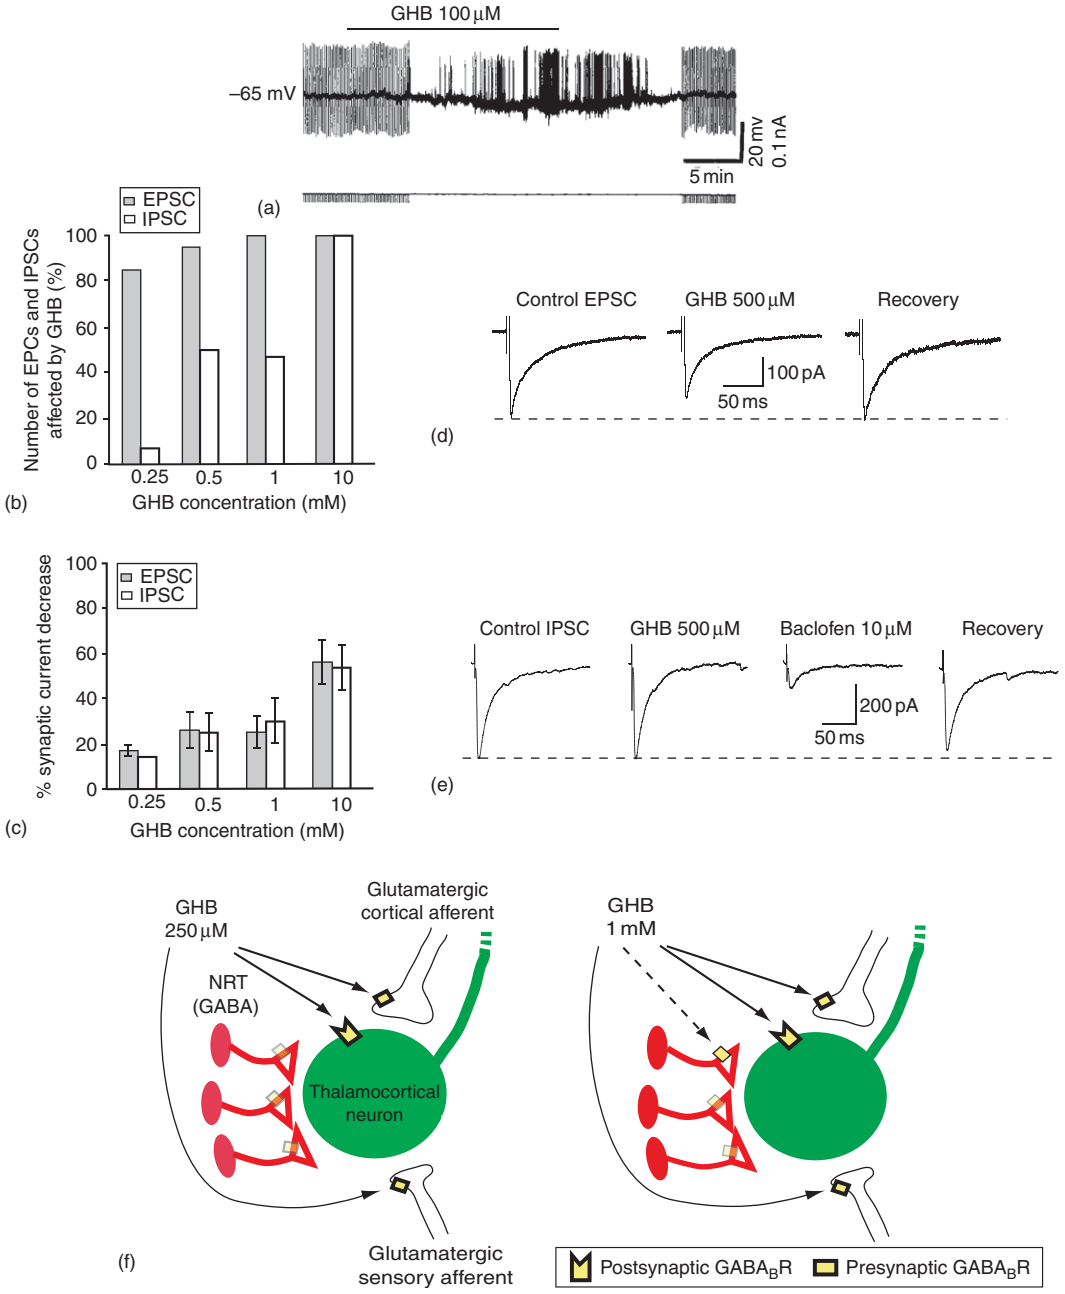

Figure 2 Effects of GHB on thalamic neuzones. (a) A small concentration of GHB hyperpolarizes this TC neuron (top trace). Downward deflections represent voltage responses to rectangular current pulses (bottom trace). (b) Percentage of corticothalamic EPSCs and NRT-derived IPSCs affected by different GHB concentrations. Note that whereas almost all EPSCs are affected by GHB (0.25–1.0 mM), a much smaller proportion of IPSCs are sensitive to these concentrations. At 10 mM, all EPSCs and IPSCs are decreased by GHB. (c) Effect of different GHB concentrations on the amplitude of EPSCs and IPSCs. No difference in the decrease elicited by GHB is observed between corticothalamic EPSCs and those IPSCs that are sensitive to GHB. (d) Example of a corticothalamic EPSC that is reversibly decreased by a low GHB concentration. (e) Example of an NRT-elicited $GABA_A$ IPSC that is unaffected by a low GHB concentration, but markedly decreased by baclofen. (f) Schematic of GHB action in the thalamus and the location of $GABA_BRs$. Presynaptic $GABA_BRs$ are negatively coupled to both glutamate and GABA release. Increasing GHB concentrations (1 mM) affects a greater number of presynaptic $GABA_BRs$ on the GABA-containing nerve terminals of nucleus reticularis thalami (NRT) neurons (highlighted yellow presynaptic $GABA_BRs$), while all presynaptic $GABA_BRs$ on the glutamate-containing cortical and sensory afferents are activated even by 250 μM of GHB. Therefore, the increased inhibition that results from this imbalance between excitatory and inhibitory synaptic drive, together with the hyperpolarization of thalamocortical (TC) neurons mediated by postsynaptic $GABA_BRs$, would increase neuronal excitability, as occurs during absence seizure paroxysms. Note that 240 μM of GHB is the threshold brain concentration for the EEG appearance of SWDs. (b)–(e): Reproduced from Gervasi N, Monnier Z, Vincent P, *et al*. (2003) Pathway-specific action of γ-hydroxybutyric acid in sensory thalamus and its relevance to absence seizures. *Journal of Neuroscience* 23: 11469–11478, with permission from Society for Neuroscience.

trans-4-hydroxycrotonic acid has been shown to be unable to elicit SWDs when injected in vivo. On the basis of all the available data, therefore, it is safer to consider the GHB model of typical absence seizures as one that involves the direct activation of $GABA_B$, and not GHB, receptors.

In summary, together with previous data from our laboratories, the present results indicate that low (250 μM to 1 mM) GHB concentrations, similar to the brain GHB levels required to elicit SWDs in freely moving rats, has two effects on TC neurons of the VB (**Figure 2(f)**): (1) the hyperpolarization of TC neurons by direct activation of postsynaptic $GABA_B$Rs and (2) the decrease in the amplitude, by a similar potency and by direct activation of presynaptic $GABA_B$ autoreceptors, of all sensory and corticothalamic EPSCs, but only 40% of the $GABA_A$ IPSCs. On the basis of these results, and since SWDs can be elicited in vivo by direct injection of GHB into the VB, we suggest that a substantial component of the mechanism underlying the generation of SWDs by systemic GHB is due to an imbalance of the physiological excitatory and inhibitory drives to TC neurons in favor of an increased inhibition. In other words, GHB would not only slightly hyperpolarize TC neurons and decrease their afferent corticothalamic and sensory excitatory volleys, but would also leave the TC neuron population with a substantial proportion of unaltered NRT phasic (i.e., IPSCs) inhibition, thus helping to impose the periodic NRT-derived inhibition that sculptures the electrical behavior of TC neurons during the SWD paroxysm.

Therefore, both in the GAERS and GHB models, a brain area-specific, $GABA_A$R gain-of-function appears to be implicated in the generation of typical absence seizures. Of course, in the GHB model, this is brought about by activation of $GABA_B$Rs (**Figure 2(f)**), whereas in the GAERS model it could be the result of genetic abnormalities of $GABA_B$Rs and/or $GABA_A$Rs or indeed of compensatory alterations in these two types of GABARs that occur as a consequence of mutations or expression in other genes or proteins.

Future Goals

It will be important to characterize the molecular substrate (s) underlying the different properties of $GABA_A$ IPSCs in the GAERS NRT, since this information may provide important leads for the genetic abnormalities that underlie the human condition. In this respect, mIPSC properties of normal animals have been ascribed by various studies to different expression levels of either α1, α3, β1, γ2L, and/or γ2S subunits of the $GABA_A$R. Interestingly, a recent study has highlighted a specific loss of the α3 subunit at the GABAergic synapses in the NRT of WAG/Rij rats. However, other parameters (i.e., receptor density, subcellular localization, occupancy, and phosphorylation) could underlie the observed IPSC differences between preseizure GAERS and NEC rats. Moreover, before conclusively excluding the presence of any alterations in cortical $GABA_A$Rs of GAERS, GABAergic transmission in deep cortical neurons should be studied, since abnormalities in these synaptic potentials have been described in deep layer pyramidal neurons of WAG/Rij rats, and pyramidal neurons in layer 5 or 6 of the somatosensory cortex have been suggested as potential initiators of the SWD paroxysm in both GAERS and WAG/Rij rats.

The sensitivity to $GABA_B$R agonists and antagonists is now considered one of the essential criteria to be fulfilled by any absence epilepsy model. It is therefore important to fully understand the mechanism underlying the differential response of GAERS and NEC rats' IPSCs to baclofen in NRT neurons, also in view of the fact that an increased expression of both $GABA_B$R1 and $GABA_B$R2 has been reported in the somatosensory cortex, VB, and NRT. Also, as far as the GHB model is concerned, it would be important to systematically investigate the actions of this agent on the basic properties and synaptic potentials of NRT and cortical neurons. In fact, any differential sensitivity of intra-NRT and/or intracortical $GABA_A$R-mediated inhibition (similar to that we have uncovered in the VB) should not be discounted when attempting to understand the full proabsence mechanism of action of GHB.

Finally, it is important to stress here that $GABA_A$R-mediated inhibition does not only consists of phasic activity (i.e., IPSCs) but also of a 'tonic' component. The tonic $GABA_A$R current that underlies this type of inhibition originates from the activation of extrasynaptic $GABA_A$Rs, and has already been shown to play a role in a number of physiological functions. Although originally described in cerebellar and hippocampal neurons, a tonic $GABA_A$ current has now been detected in TC and some cortical neurons, but it is absent in thalamic interneurons and in NRT cells. It is feasible that this tonic $GABA_A$ current might be responsible for the tonic hyperpolarization that characterizes the activity of TC neurons during spontaneous SWDs in different models of typical absence seizures, including the GAERS.

Undoubtedly, the notion that typical absence seizures involve a gain-of-function in $GABA_A$R-mediated transmission, in contrast to the traditional view of a reduced $GABA_A$R-mediated inhibition, is further strengthened by our preliminary data showing a larger tonic $GABA_A$ current in TC neurons of GAERS than of NEC rats.

Oscillations in Thalamocortical Networks and the Putative 'Initiation Site' of Typical Absence Seizures

Introduction

A typical absence episode is a nonconvulsive epileptic seizure that consists of a sudden and relatively brief impairment of consciousness, occurring concomitantly with a bilaterally synchronous 'spike and slow wave discharge' (SWD) paroxysm at 2.5–4 Hz in the EEG. Typical absence seizures are part of the complex clinical and EEG presentation of many idiopathic generalized epilepsies (IGEs), but in childhood absence epilepsy, these seizures are the only neurological symptom and are not accompanied by either metabolic, neuropathological, or other neurological deficits.

Typical absence seizures are genetically determined, and the classical 2.5–4 Hz SWD trait of different IGEs has been shown to be inherited in an autosomal

dominant manner. Indeed, there is strong consensus in describing the occurrence of (typical) absence seizures as a familial disease with a complex genotype, and increasing evidence suggests that these seizure disorders may represent a complex channelopathy of multifactorial genetic background.

There is also a general consensus about the pathophysiological nature of human absence seizures. On the basis of some old invasive studies and more modern non-invasive imaging investigations, investigators have determined that the EEG manifestation of SWDs of typical absence originates from abnormal electrical activities in reciprocally connected thalamic and cortical territories – i.e., in what is generally referred to as thalamocortical (TC) networks (see schematic circuitry in **Figure 2(a)**). However, the precise contribution of cortex and thalamus to the generation of SWDs is not known, and the detailed evolution of the membrane potential in cortical, TC, and nucleus reticularis thalami (NRT) neurons (**Figure 2(a)**) during SWDs is still ill-defined. In addition, the notion that typical absences are truly 'generalized' from the very start of the EEG paroxysm has been recently challenged by the observation that seizure onset is associated with paroxysmal activation of discrete, often unilateral, frontal cortical regions.

Many experimental investigations have tried to address some of these issues. In particular, the use of appropriate absence models and the improvements associated with both in vivo electrical recordings and drug injection in localized brain regions has started to provide some novel and interesting data. Two clear indications are now emerging: first, that the intracellular activity of TC neurons during SWDs greatly differs among various thalamic nuclei; and second, that the (oro)-facial region of the primary somatosensory cortex temporally leads other cortical areas and the thalamus in the expression of the SWDs of typical absence seizures.

Background

The proposed major contribution of the thalamus to the SWD generating mechanisms, and the potentially critical role of the GABAergic system in absence seizures, have resulted in numerous studies investigating the electrical activity resulting from the block of this neurotransmitter function in the thalamus. Bath-application of $GABA_A$ antagonists to ferret thalamic slices containing the isolated (from the cortex) TC-NRT network has been shown to lead to highly synchronous oscillatory discharges at 2–3 Hz in every TC neuron of primary sensory thalamic nuclei; these discharges are generated by the rhythmic recurrence of $GABA_B$ IPSPs and low threshold Ca^{2+} potential (LTCP)-dependent, high-frequency bursts of action potentials. Similarly, abolition of $GABA_A$ receptor function (following knockout of the $GABA_A$ β3 subunit) results in hypersynchronous burst firing at 3 Hz in mouse thalamic slices containing viable connections between TC and NRT neurons.

The abnormal membrane potential oscillations and firing patterns observed in these and similar investigations conducted in the isolated thalamus have been interpreted as if they resemble those occurring during SWDs. There is no direct evidence, however, that this is the case. Indeed, in contrast to these in vitro results, the essential contribution of $GABA_A$ receptors to the activity of TC neurones of primary sensory thalamic nuclei during spontaneous SWDs in vivo has been highlighted using localized iontophoretic application of specific $GABA_A$ antagonists in Wistar Albino Glaxo/Rij (WAG/Rij) rats, a well-established genetic model of absence epilepsy. Also, phasic GABAergic transmission (i.e., $GABA_A$-IPSPs) is unaltered in both TC and neurons of upper cortical layers in Genetic Absence Epilepsy Rats from Strasbourg (GAERS), another well-established genetic model of absence epilepsy. Moreover, intracellular recordings in the cat in vivo have clearly shown that the activity of the vast majority (about 90%) of single TC neurons in primary sensory thalamic nuclei during spontaneous SWDs consists of rhythmic sequences of composite $GABA_A$-IPSPs that occur in synchrony with each spike and wave complex, and which are superimposed on a tonic hyperpolarization; only occasionally is a single action potential, a doublet, or a burst, of action potentials present during this sequence. Thus, although the in vitro experiments demonstrate the ability of the isolated TC-NRT network to generate abnormally synchronized membrane potential oscillations and correlated high-frequency bursts of action potentials when $GABA_A$ receptors are blocked, this scenario is quite different from that observed during spontaneous SWD paroxysms in the cat in vivo.

Still, since the spontaneous SWDs in cats were suggested to be probably the consequence of multielectrode penetrations, and their pharmacological profile has not been investigated, we have now used in vivo intracellular recordings to characterize the evolution of the membrane potential of both cortical and thalamic neurons during spontaneous SWDs in GAERS. Also, following the report of a potential cortical 'initiation site' in experimental absence seizures, we investigated in the same model whether localized application of ethosuximide (ETX) in this and adjacent cortical regions is effective in abolishing SWDs, and compared these results with those obtained after ETX injection either in the NRT or in a primary sensory thalamic nucleus (i.e., the ventrobasal (VB) complex).

Methods

The GAERS is one of the best-established genetic models of typical absence seizures, which shows no additional

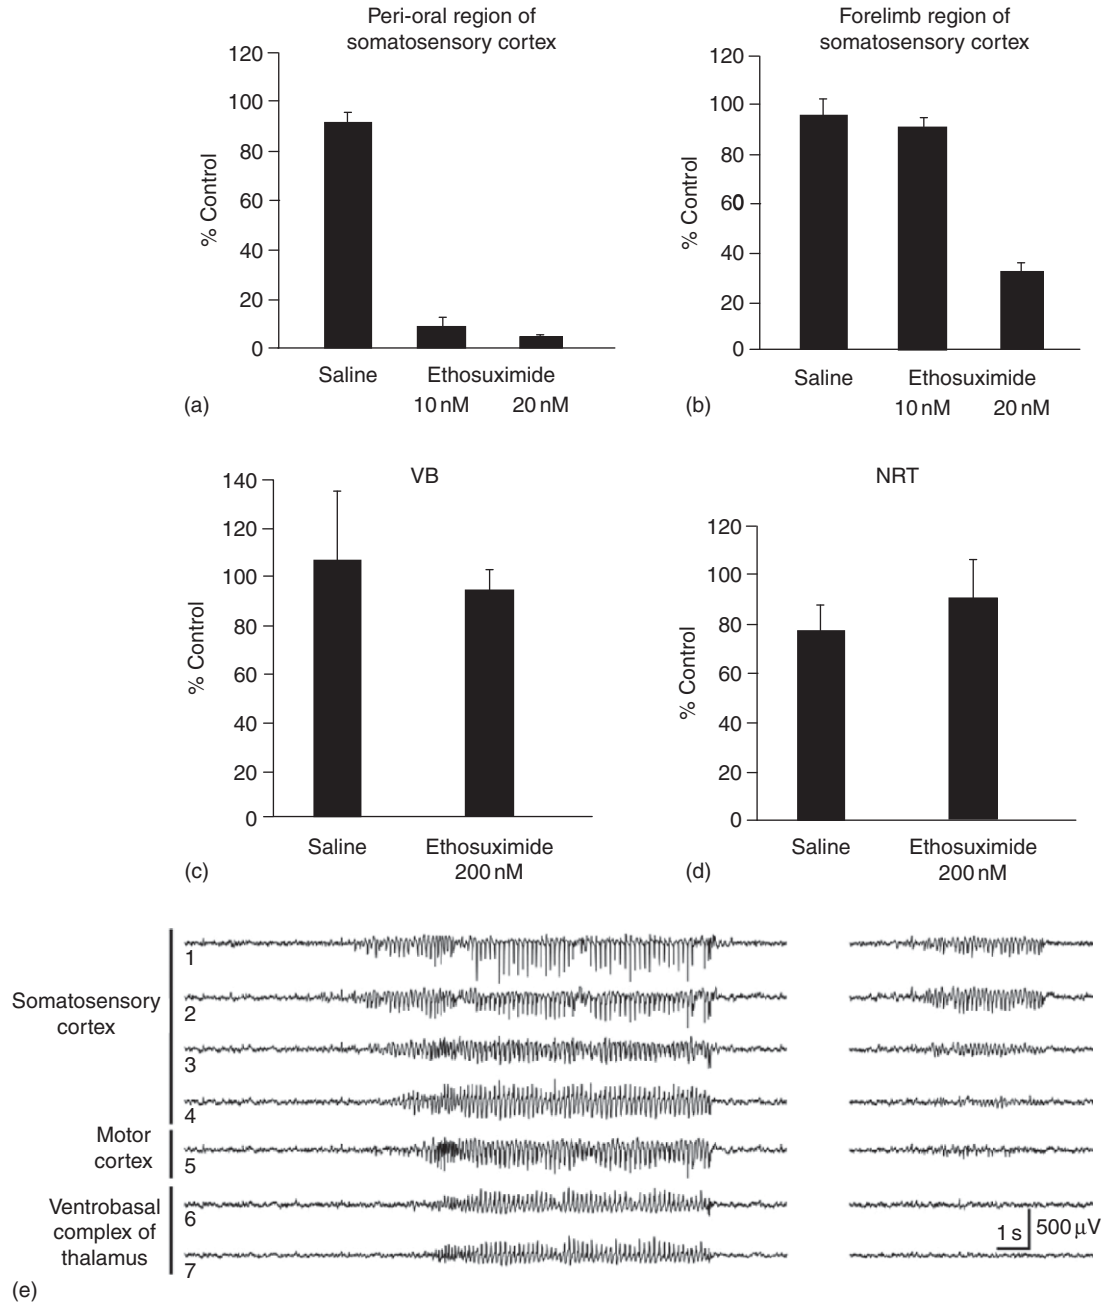

Figure 1 Cortical initiation site for SWDs in GAERS: pharmacological and electrophysiological evidence. ETX abolishes SWDs when bilaterally infused in the perioral region of the primary somatosensory cortex (a), but has no, or a much smaller, effect when it is administered either in the forelimb region of the primary somatosensory cortex (b), the VB thalamic nucleus (c), or the NRT (d). The plots show total time of SWD duration calculated over a 30 min period immediately following ETX injection as the percentage of that observed in the 30 min immediately preceding the injection. (e) Simultaneous local field potential recordings in the indicated cortical and thalamic areas during spontaneous SWDs in freely moving GAERS. The appearance of the paroxysm in the facial region of the primary somatosensory cortex (traces 1–4) precedes that in the other regions. The traces on the right show a SWD in somatosensory cortex that is not accompanied by paroxysmal activity in the VB thalamus complex. Reproduced from Polack PO, Guillemain I, Hu E, Deransart C, Depaulis A, Charpier S 2007 Deep layer somatosensory cortical neurons initiate spike-and-wave discharges in a genetic model of absence seizures. *Journal of Neuroscience* 27: 6590–6599, © with permission from Society for Neuroscience.

neurological or neuropathological abnormalities and fulfills all the accepted criteria for an absence model. The epileptic phenotype of this inbred strain only becomes evident during periods of quiet wakefulness, and consists of SWDs in the EEG that are accompanied by behavioral arrest and rhythmic twitching of the vibrissae and facial muscles. Muscle tone in the neck is sometimes diminished, inducing a gradual and slight lowering of the head.

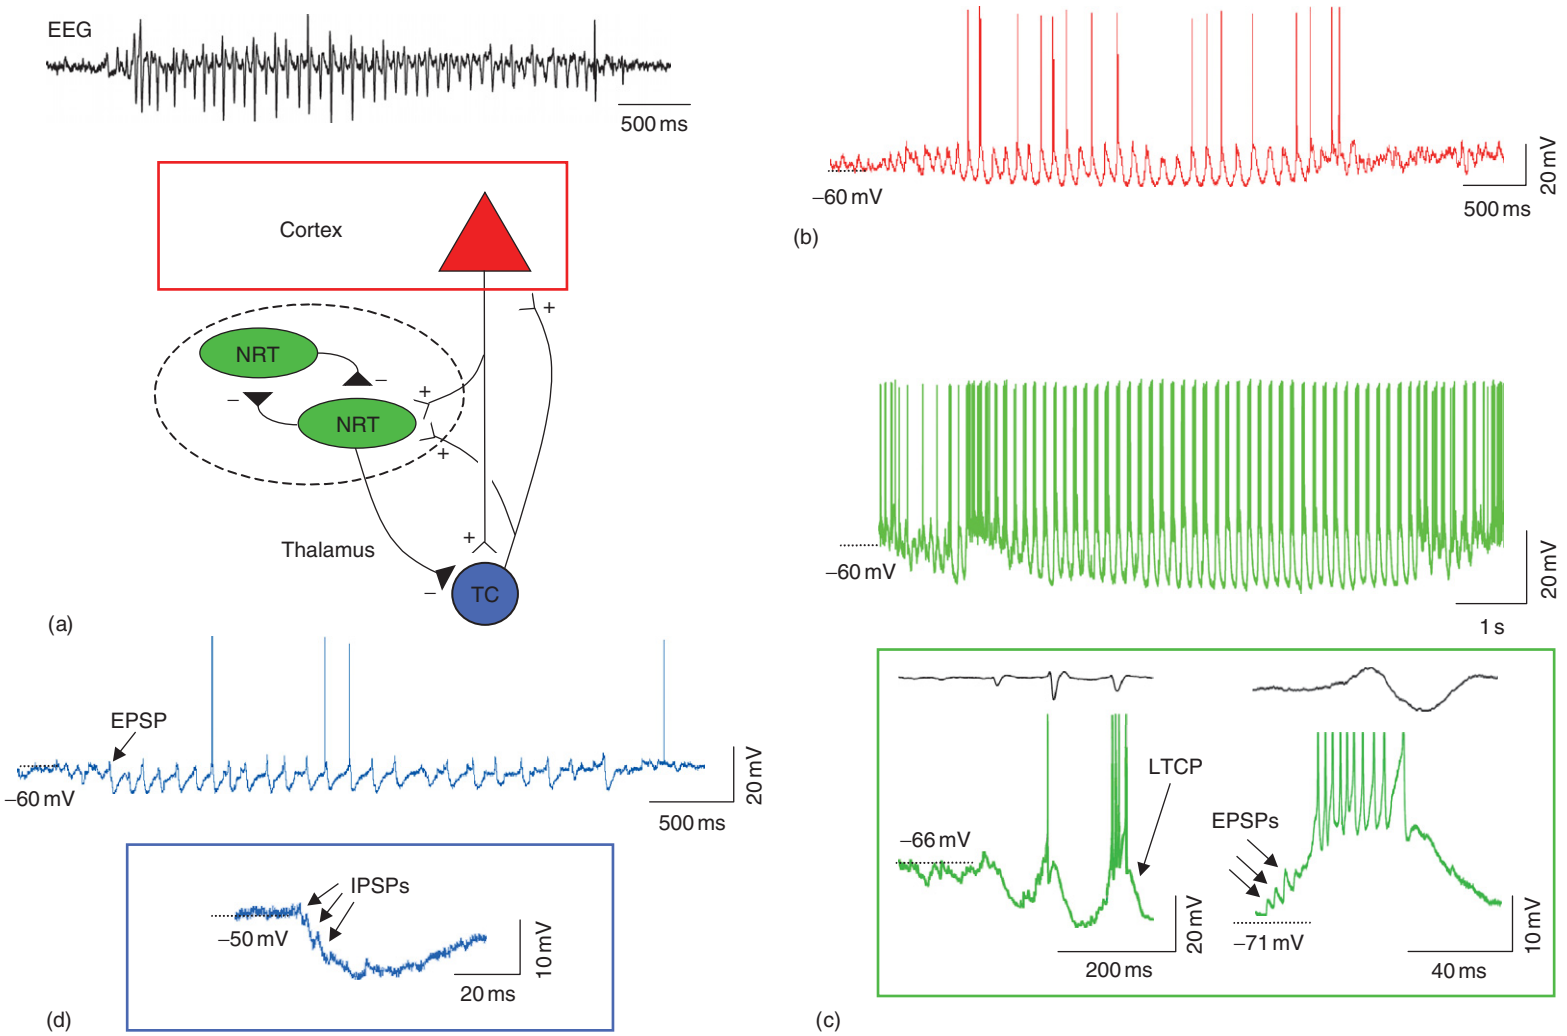

Figure 2 Intracellular activity of cortical and thalamic neurons during spontaneous SWDs in GAERS. (a) Typical SWD (top) and schematic diagram of the thalamocortical loop (bottom). The colour code of the neurons is maintained in the intracellular records of (b)—(d), which are all from GAERS. TC: thalamocortical neuron; NRT: thalamic reticular nucleus neuron; +: excitatory synapse;-: inhibitory synapse. (b) Activity of a layer 5 cortical neuron during a SWD. Note the rhythmic depolarizations that are present in synchrony with each EEG spike. (c) Activity of an NRT neuron during a SWD. Note the presence of robust, high-frequency bursts of action potentials crowing the LTCPs. Insets below are enlarged traces showing the LTCP and the EPSPs that precedes it. (d). Activity of a TC neuron in the VB thalamic complex during a SWD. Note the presence of a tonic hyperpolarization that lasts for the whole duration of the SWDs, and the presence of rhythmic sequences of composite IPSPs (inset below) in synchrony with each EEG spike. Reproduced from Crunelli V and Leresche N (2002) Childhood absence epilepsy: Genes, channels, neurons and networks. *Nature Reviews Neuroscience* 3: 371–382, with permission from Nature Publishing Group.

The pharmacological profile of these seizures very closely matches that of the human condition. In particular, ETX and valproate abolish, whereas carbamazepine and phenytoin aggravate, spontaneous seizures in GAERS. Also, similar to the human condition is the thalamocortical origin of their SWDs, with the hippocampus and cerebellum being devoid of any ictal activity. Another advantage of the GAERS model is the availability of a corresponding, well-characterized, inbred strain of nonepileptic control (NEC) rats, which are devoid of absence seizures. In contrast to typical absence seizures in humans (or at least in classical childhood absence epilepsy), however, the frequency of SWDs in GAERS is 7–9 Hz, and the seizures persist during adulthood.

We use scalp EEG recordings to monitor the occurrence of spontaneous SWDs while we simultaneously sample the evolution of the membrane potential in different types of thalamic (NRT, and TC neurons in the VB) and cortical neurons with independently mounted sharp microelectrodes. As SWDs are abolished by systemic or inhalation anesthetics, animals are kept under neuroleptanesthesia using fentanyl and haloperidol; to obtain long-lasting stable intracellular recordings, the rats are immobilized with gallamine triethiodide and artificially ventilated. In some experiments, neurobiotin is present in the extracellular and intracellular electrodes to allow subsequent morphological analysis of the recorded neuron(s).

For application of drugs in discrete brain areas in freely moving animals, we use either reverse microdialysis or microinfusion via probes or cannulae, respectively, which are positioned in the region of interest. Drugs are applied while we monitor the occurrence of spontaneous SWDs with scalp EEG electrodes in freely moving GAERS. In these experiments, each animal serves as its own control; that is, the spontaneous SWDs observed after drug injection are calculated as the percentage of those observed before drug infusion.

Recent Results

Cortical Area – Specific Action of ETX

Following the report of an initiation site of SWDs in the perioral region of the somatosensory cortex of WAG/Rji rats, we investigated whether this locus represents a preferential site for the action of one of the most commonly used antiabsence drugs, ETX. Indeed, microinfusion or injection of ETX by reverse microdialysis in this region of the primary somatosensory cortex of freely moving GAERS leads to an almost immediate (<30 min) cessation of spontaneous SWDs and the behavioral components of the seizures (**Figure 1(a)**). The onset of this effect is similar in strength and timing to the block observed following ETX systemic injection. Interestingly, a less marked response is observed when even higher concentrations of ETX are applied to the forelimb region of the primary somatosensory cortex (**Figure 1(b)**), and no effect occurs when the injection site is in the primary motor cortex. In contrast, ETX applied either in the NRT or the VB has no effect on SWDs within the first 30 min following injection (**Figure 1(c)** and **1(d)**), while a partial block (about 50%) is observed at later times (30–60 min after injection) and when using higher concentrations.

By providing solid evidence on a primary cortical site of ETX effect, these results stress the substantial importance of cortical T-type Ca^{2+} channels, persistent Na^{+} channels and Ca^{2+}-activated K^{+} channels in the anti-absence action of this anti-absence drug, compared to the too often over-emphasized role of the thalamic T-type Ca^{2+} current. As described in the next section, in fact, it is only in motor thalamic nuclei that there appears to be a substantial activation of T-type Ca^{2+} channels during SWDs, and the T-type Ca^{2+} channel-mediated LTCPs that are present in NRT neurons during SWDs are not a primary target for the action of ETX, since the block of SWDs following its localized injection in this thalamic nucleus is only partial and delayed.

Moreover, our results on ETX provide indirect support for the existence of a cortical initiation site of absence seizures in GAERS, which is located in the same region as the one directly demonstrated to exist in WAG/Rij rats. This finding is supported by recent data from another group that has now directly shown the existence of an initiation site in the facial region of the primary somatosensory cortex of GAERS (**Figure 1(b)**). Interestingly, short SWDs could be observed in this region even in the absence of any paroxysmal activity in the adjacent motor cortex or in the thalamus (right traces in **Figure 1(b)**); in these instances, the short SWDs were not associated with any behavioral abnormalities. The clear demonstration of a cortical initiation site in experimental absence seizures adds strength to the emerging observations of a similar lack of generalization at the start of human absence seizures – although in the latter case, the leading cortical areas appears to be in mesial frontal and orbital frontal regions.

Intracellular Activity of Cortical Neurons

The major component of the intracellularly recorded activity of cortical neurons of GAERS during SWDs consists of rhythmic depolarizations that occur in phase with the EEG spike and emerge from what appears as a hyperpolarizing envelope (**Figure 2(b)**). These rhythmic depolarizations probably involve the contribution of T-type Ca^{2+} channels (at least in some cortical cells), and their waveform is drastically different from the classical paroxysmal depolarizing shifts of convulsive epilepsies, West syndrome, and Lennox-Gasteau syndrome. The recent characterization of an initiation site of SWDs in the

facial region of the somatosensory cortex of GAERS and WAG/Rij has allowed comparison of the activity of cortical neurons in this area, and with those of other cortical regions. These recent results indicate that GAERS pyramidal neurons in layer 5/6 of the cortical initiation site have a higher and more regular firing rate, and a more depolarized membrane potential – compared with layer 2–4 cortical neurons in the same area and to layer 5/6 cells in the adjacent motor cortex. Indeed, a higher excitability and more depolarized membrane potential of layer 5/6 neurons in the cortical initiation site was also observed when these features were compared with layer 5/6 neurons of the same facial region of the somatosensory cortex of nonepileptic Wistar rats. Also, in the GAERS initiation site, the firing of layer 5/6 neurons clearly precedes that of both layer 4 and layer 2/3 neurons, as had already been shown by another group.

Intracellular Activity of NRT Neurons

During SWDs, the strong volley generated by the synchronous firing of corticothalamic neurons, together with the convergence of the corticothalamic input, results in bursts of EPSPs in NRT neurons. Each burst of EPSPs, with the help of a preceding hyperpolarization, generates a strong LTCP in correspondence to each EEG spike (**Figure 2(c)**). In turn, this large LTCP evokes a prolonged burst of 7–12 action potentials, with an average intraburst frequency of up to 350–400 Hz (inset in **Figure 2(c)**). An increased T-type Ca^{2+} current and a smaller paired-pulse depression of $GABA_A$-receptor-mediated IPSPs have been reported to occur in NRT neurons of preseizure GAERS, compared with NEC. It is likely that these abnormalities will also be present in GAERS later in life, when they could markedly contribute to the generation of the aberrant firing of these neurons during SWDs.

Intracellular Activity of Thalamocortical Neurons

The strong inhibitory output of the NRT arrives onto TC neurons of the VB a few milliseconds after the corticofugal volley (i.e., one synapse difference - see diagram in **Figure 2(a)**). Thus, the ictal activity of the vast majority (>90%) of TC neurons in the primary sensory nuclei consists of rhythmic sequences of composite $GABA_A$-IPSPs (in phase with the EEG spike) (**Figure 2(d)**), that are superimposed on a tonic hyperpolarization that lasts for the whole duration of the SWD. The intrasequence frequency of these IPSPs tightly matches that of the action potentials in the NRT burst. Also of interest is the fact that an EPSP can at times be seen to closely precede the sequence of $GABA_A$-IPSPs (inset in **Figure 2(d)**), probably because in these instances the corticofugal volley arriving onto the TC neurons is not fully abolished by the NRT inhibition. This sequence of intracellular events is supported by two findings: the more powerful excitatory action exerted by the corticofugal afferents on NRT than on TC neurones, and the strong (up to 12 action potentials), high-frequency burst observed in NRT neurons at each EEG spike (inset in **Figure 2(c)**). Only very rarely are LTCPs observed during SWDs in the intracellular records of TC neurons in primary sensory thalamic nuclei (i.e., the VB) of GAERS, and also rare are the instances of extracellularly recorded bursts of action potentials with characteristics similar to those mediated by LTCPs.

Similar findings have been recently reported by another group for TC neurons of the ventrolateral nucleus of GAERS. The extracellularly recorded firing of TC neurons in this nucleus is characterized by occasional single action potentials and almost no bursts. In contrast, extracellular recordings in TC neurons of the ventromedial nucleus show short, high-frequency bursts of action potentials, reminiscent of those generated by LTCP-mediated bursts. Indeed, intracellular recordings in TC neurons of the ventromedial nucleus highlight clearly evident LTCPs in correspondence to a substantial number of EEG spikes.

The presence of a LTCP in TC neurons of the ventromedial nucleus could at least in part explain why mice with selective knockout of α1G, the gene that encodes for the most prevalent T-type Ca^{2+} channel subunit that is present in TC neurons, are resistant to pharmacologically induced SWDs. More likely, however, is the possibility that the inability to elicit SWDs in α1G knockout mice results from the lack of T-type Ca^{2+} channels in those cortical layer 5/6 neurons which, as indicated previously, temporally lead thalamic and other cortical neurons in the expression of the SWD paroxysm.

Future Goals

Although the discovery of a cortical initiation site for spontaneous SWDs in the two best-established genetic models of typical absence seizures (i.e., GAERS and WAG/Rij) stresses the cortical origin of this experimental paroxysm, the precise contribution of subcortical structures to the full generalization of SWDs remains to be elucidated. In this respect, the presence of clear differences in the intracellular activity of TC neurons among thalamic nuclei during SWDs warrants systematic investigations of the potential alterations in intrinsic and synaptic conductances that might underlie these differences. It would also be of interest to characterize the activity of intralaminar thalamic nuclei during SWDs, as they provide important subcortical and thalamocortical loops for the spreading of the absence paroxysm.

Another goal, both in GAERS and WAG/Rij, would be to carry out a systematic characterization of the biophysical properties of the intrinsic and synaptic membrane

currents of neurons in the initiation site of the primary somatosensory cortex, in particular in those cortical layer 5/6 neurons where the abnormal activity associated with a SWDs appears to precede that of layer 2–4 neurons. Some of these data is already available (at least for WAG/Rij) from the work of other groups, including an increased excitability mediated by NMDA receptors, a smaller I_h, a reduced $GABA_B$ receptor expression, and a decrease in paired-pulse depression of $GABA_A$-IPSPs. Unfortunately, only the latter two findings were recorded in the cortical initiation site. Moreover, these studies should ideally be carried out both prior and after seizure onset to determine whether any alteration in synaptic or intrinsic conductances are either the consequence, or the cause, of the absence paroxysm.

Finally, it would also be important to assess why different cortical regions, i.e., somatosensory vs. frontal cortex, are the initiating sites in rodent vs. humans, respectively. In both human and experimental studies addressing this issue, it will remain important to consider that the primary genetic alterations could not be necessarily confined to the cortical initiation site. In this respect, uncovering a cortical initiation site as well as studying the intracellular activity of cortical neurons in genetic mouse models with SWDs (i.e., stargazer, lethargic, tottering, etc.), though their phenotype also includes other neurological deficits, might be of help as the underlying primary genetic abnormality of these mouse models is well characterized.

Thalamic Neurons and Networks Related to Absence Epilepsy

Introduction

Oscillations in the thalamocortical network are central to a number of neurocognitive functions, including attention, cognition, perception, memory, wakefulness, and sleep. Several apparently unrelated neurological and psychiatric conditions, including depression, dystonia, neurogenic pain, Parkinson tremor, spasm, tinnitus, and epilepsy, are characterized by the occurrence of slow resonant interactions between thalamus and cortex. These interactions seem to be based on increased inhibition, deafferentation, and/or discrete changes in cellular properties (e.g., ion channel expression) of thalamic neurons, and have been attributed to a new class of syndromes called thalamocortical 'dysrhythmia.' Since natural and pathological oscillations are based on the same network architecture and cellular elements, a key question is why naturally occurring oscillations transform (either by hypersynchronization of physiological oscillations or by gradual evolution from physiological oscillations) into pathological oscillations.

A prominent example of these syndromes is absence seizure activity. Absence epilepsy is an idiopathic, generalized, and non-convulsive form of epilepsy with an as yet unknown polygenic background. A typical absence episode consists of a sudden epileptic seizure associated with severe impairment of consciousness. While the interictal electroencephalogram (EEG) appears normal, the ictal EEG is characterized by waxing and waning phases of bilateral, synchronous 2.5–4.0-Hz spike and slow-wave discharges (SWDs). These ictal episodes can be accompanied by minor motor clonic movements or automatisms. Although SWDs appear to have sudden onset and offset, gradual modulation in α-frequency has been observed in patients just prior to SWDs, indicating a transition state. Absence-related SWDs occur mainly during immobile, inattentive wakefulness and drowsiness. Normal consciousness returns immediately following the cessation of SWDs. Absence seizures have a unique pharmacological response profile, with effective seizure control with ethosuximide (ETX) or valproate. In contrast, drugs effective in focal seizures (such as carbamazepine and vigabatrin) are either ineffective or aggravate absence seizures. As defined by the current International League against Epilepsy (ILAE) classification, typical absence seizures are an integral part of several types of idiopathic generalized epilepsies, including childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME), and generalized tonic–clonic seizures (GTCS) – all of which display complex, partially overlapping phenotypes. It should be noted that the following considerations primarily relate to CAE.

Background

CAE has a Genetic Basis

CAE is genetically determined with incomplete penetrance and complex autosomal dominant inheritance of the SWD trait. Linkage studies, twin studies, and genetic defects in rare families all point to a predominant genetic etiology of CAE. A number of gene mutations localized to the voltage-gated Ca^{2+} channel $Ca_V2.1$, the $GABA_A$ receptor γ2 subunit gene, and the low-threshold (T-type) Ca^{2+} channel $Ca_V3.2$, have been identified in CAE families. A number of additional susceptibility loci and polymorphisms in various types of ion channels, transmitter receptors, and other proteins have also been described, although the linkage to CAE is not always clear (see **Table 1**).

The Thalamocortical Network – General View

The thalamocortical network is the neuronal substrate for the generation and maintenance of SWDs. Defined types of thalamic neurons possess intrinsic pacemaker properties and are synaptically interconnected in functional loops which facilitate recurrent, synchronized network oscillations (see **Figure 1**). The neuronal elements of the thalamic network are composed of three basic cell types, excitatory thalamocortical relay (TC) neurons and two classes of inhibitory cells, namely, neurons of the thalamic reticular nucleus (NRT) and local circuit interneurons (not illustrated here). TC neurons and NRT neurons have extensive synaptic connections between each other, thereby creating a recurrent intrathalamic loop. Relay nuclei are subdivided into two major types, often termed 'specific' and 'higher order.' The specific nuclei contain first order relay neurons which carry signals from the sensory periphery and lower brain centers to the neocortex, mostly in a topographically organized fashion. One example is the dorsal lateral geniculate nucleus (dLGN), which receives afferents from the retina and sends axonal projections to the visual cortex. 'Higher order' nuclei may, in addition or exclusively, contain higher order relay neurons, which

[a]Alterations mainly relate to polymorphisms including nucleotide exchange and insertion.
[b]Alterations typically relate to changed mRNA and protein expression in epileptic rat models.
Some changes could be defined for specific thalamic cell types. Note that some changes are only found in young animals before the onset of seizures. GABA, γ-aminobutyric acid; nAChR, nicotinic acetylcholine receptor.

receive incoming messages from the cortex and relay these messages from one cortical area to another. One example of an 'higher order' thalamic nucleus is the lateroposterior nucleus. Furthermore, 'unspecific' nuclei include the intralaminar nuclei (containing, for instance, the centromedial, paracentral and centrolateral nucleus), which represent a mixed group of cells receiving ascending afferents from the anterolateral system (concerned with thermal and nociceptive stimuli) or from motor cortex, and sending their axons to widespread cortical and striatal areas. They also receive massive monosynaptic input from the brainstem, and thereby are considered to mediate widespread neuronal excitation and arousal.

Thalamic Cell Types

TC neurons

TC cells are a population of excitatory neurons (see Figure 1) that are segregated in specific thalamic nuclei, each associated with different aspects of arousal and consciousness (e.g., sensorimotor processing and higher order and associational roles like attention, cognition, and perception). Mutual excitatory connections between relay cells are rare within and between thalamic nuclei. TC cells possess an intrinsic predisposition for oscillatory activity or resonant activity. The characteristic 'rebound' spiking in TC neurons following inhibition, associated with a Ca^{2+}-dependent low-threshold spike (LTS) (post inhibitory rebound potential) whose activation requires a conditioning membrane hyperpolarization, has been known for a long time. The LTS is a long-lasting depolarization, carried by a low-threshold activated T-type Ca^{2+} current (I_T), which triggers a burst of conventional Na^+/K^+ action potentials and can drive oscillatory activity in the thalamocortical network (see Figure 1, inset). Only recently, genes for three members of a family of T-type Ca^{2+} channels were identified and cloned – $Ca_V3.1$, $Ca_V3.2$, and $Ca_V3.3$. In addition, a number of splice variations have been found that give rise to Ca^{2+} currents with different voltage-dependent properties. One splice variant of $Ca_V3.1$, namely, $Ca_V3.1a$, is highly expressed in TC neurons. The crucial role of T-type Ca^{2+} channels in the generation of reciprocal thalamocortical burst firing and LTS generation in TC neurons is emphasized by knock-out mice lacking $Ca_V3.1$. TC neurons of $Ca_V3.1$ null mutants fail to show rebound burst activity, and unlike wild-type controls, are insensitive to pharmacologically induced SWDs. Moreover, cross-breeding of $Ca_V3.1$ knock-out mice with mice revealing absence epilepsy with ataxia abolishes SWDs in the progeny. This result indicates that a reduction of the T-type Ca^{2+} current – in this case produced by reducing the gene dosage – has an antiepileptic effect.

A second membrane current is of crucial importance for oscillatory activity in the thalamocortical system.

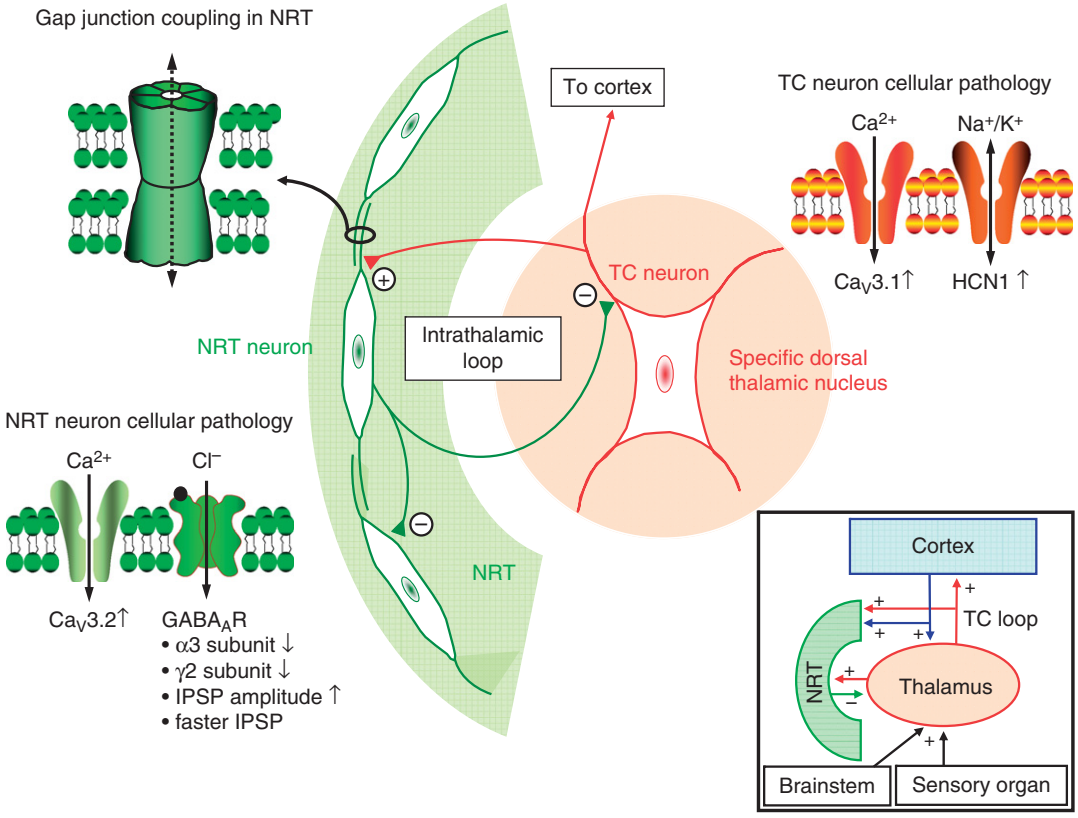

Figure 1 Simplified scheme of the thalamic network. The inset shows the general connectivity of the thalamocortical network including driving inputs from sensory organs and modulating inputs from the ascending brainstem system. Neurons of the nucleus reticular thalamic (NRT) are shown in green. A thalamocortical relay neuron is shown in red. Some of the cellular pathologies found in rat models are shown as membrane sketches near the cells. NRT neurons reveal reciprocal inhibition and electric coupling via gap junctions (see upper left membrane sketch). The latter is regarded as a pro-oscillatory mechanism. +, excitatory connection; −, inhibitory connection; GABA, γ-aminobutyric acid; IPSP, inhibitory postsynaptic potential; TC, thalamocortical.

The hyperpolarization-activated cation current (also called pacemaker current), I_h, possesses unique properties – including dual gating by membrane voltage and cyclic AMP (cAMP) – which make it a candidate for regulation of neuronal activity in a functional range not easily covered by other membrane conductances. In the thalamic synaptic network, there is an active contribution of I_h to the generation of rhythmic activity. The properties of I_h have been analyzed in detail in TC neurons of specific thalamic nuclei (e.g., the dLGN), where it has been shown to act as a cellular pacemaker, and through interplay with the T-type Ca^{2+} current generates slow-rhythmic burst discharges at delta frequencies (1–4 Hz). Furthermore, activation and de-activation of I_h in TC cells are critical for the temporal patterning of low threshold spikes interacting with GABAergic synaptic inputs from the NRT, thereby contributing to the typical waxing and waning of thalamic network oscillations, evident as sleep spindles or SWDs. Regulation of the voltage-dependence of I_h activation through the intracellular adenylyl cyclase/cAMP system, therefore, is considered an important mechanism for the control of oscillatory activity during the sleep-wake cycle. Four members of a gene family encoding mammalian hyperpolarization-activated, cyclic nucleotide-gated cation channels (HCN1–4) have been cloned; they are thought to assemble to form homomeric and/or heteromeric functional channels. The kinetics, voltage-dependency, and cAMP-sensitivity of the channels and the corresponding I_h are largely determined by the particular subunit composition.

A third membrane current with an important role in the integrative properties of TC neurons during burst-firing patterns is a persistent, non-inactivating component of the Na^+ current (I_{NaP}), which influences amplitude and latency of low-threshold Ca^{2+} potentials.

Interneurons

About 20–25% of the cells in some thalamic nuclei (e.g., dLGN) of most species are local circuit interneurons, which contain the inhibitory transmitter GABA. Although these cells are endowed with critical oscillation-related membrane currents such as I_T and I_h, and reveal intrinsic oscillations, the role of thalamic interneurons in thalamocortical rhythmicity is not clear. Because of limited

synaptic connectivity with other thalamic elements (i.e., they receive little input from either TC neurons or NRT neurons), investigators have hypothesized that interneurons have no major role in generating recurrent thalamocortical oscillations but contribute primarily to the processing of sensory inputs. Indeed, the specific expression of the splice variation $Ca_V3.1$-bc and the $Ca_V3.3$ isoform seems to give rise to an I_T with voltage-dependent and kinetic properties largely overlapping with a fast transient outward current (I_A), thereby limiting the generation of an LTS in these interneurons.

NRT neurons

The third neuronal population involved in thalamic rhythm generation is the population of NRT neurons, which are confined to a shell-like nucleus that surrounds mainly the anterior and lateral aspects of the dorsal thalamus (see Figure 1). The NRT is composed entirely of GABAergic neurons that express $Ca_V3.2$ and $Ca_V3.3$ T-type channels. The properties of NRT T-type Ca^{2+} currents are specifically different from those expressed in TC neurons and interneurons, in that they show much slower current kinetics and more depolarized voltage-dependency. These properties allow NRT neurons to generate burst firing patterns from resting membrane potential. The T-type channels in NRT neurons seem to be primarily localized in dendrites and thus can boost efferent signals to these cells, including those arriving from TC neurons or cortical neurons. Knockout mice for $Ca_V3.2$ and $Ca_V3.3$ have not yet been reported, so the primary mediator of burst firing in NRT neurons remains unknown. Activation of the T-type channels results in an electrogenic depolarization; functional interaction with Ca^{2+}-dependent membrane channels (like Ca^{2+}-activted nonspecific cation channels (I_{CAN}) and K^+ channels (I_{KCa})) and rhythmic oscillations of the membrane potential trigger bursts of Na^+/K^+-mediated spikes. Compared with TC cells, the burst generated by NRT neurons is not so stereotyped and is often of a longer duration and higher frequency.

Neurons of 'unspecific' intralaminar nuclei

Data are limited regarding the intrinsic and synaptic properties of intralaminar thalamic neurons, particularly in relation to SWDs. Experimental animal studies have shown burst firing of intralaminar neurons correlated with SWDs on the EEG, similar to the bursts seen in TC neurons of specific thalamic nuclei and the NRT, although firing is not so stereotyped and is often delayed. Clinical studies have demonstrated that electrical stimulation of defined intralaminar thalamic nuclei (in particular, the centromedial nucleus) can reduce or aggravate absence seizure activity, depending on the stimulation paradigm.

The Intrathalamic Loop: TC Neurons – NRT

Reciprocally connected excitatory TC neurons and inhibitory NRT neurons give rise to a synaptic loop consisting of GABAergic inhibitory contacts (from NRT axons onto TC neurons) and axon collaterals from TC neurons onto NRT neurons (that form excitatory synaptic contacts with NRT neurons) (see Figure 1). One important function of this loop is to generate and sustain network oscillations. Inhibitory output resulting from rhythmically bursting NRT neurons leads to activation of $GABA_A$ and/or $GABA_B$ receptors on TC neurons and the generation of postsynaptic inhibitory potentials (IPSPs). The membrane hyperpolarization of the IPSP deinactivates $Ca_V3.1$ channels, and upon termination of the IPSPs, a rebound burst of action potentials is generated. Reciprocal connectivity in the circuit ensures that the burst output of TC neurons is transmitted back to NRT, to excite NRT cells via ionotrophic glutamate receptors, thereby renewing the recurrent network activity. The strong activity induced by burst firing in both cell types ensures robust synaptic output with every oscillatory cycle. This type of network oscillation can occur spontaneously in an isolated thalamic slice preparation. Furthermore, pharmacological manipulations that block synaptic excitation, synaptic inhibition, or T-type channel function completely abolish intrathalamic oscillations in slices. During absence epilepsy, NRT neurons and TC neurons have a propensity to fire in a synchronous, phase-locked manner during every SWD complex. However, both the probability of firing and the number of action potentials during the SWD complex are much lower in most TC neurons than in NRT neurons. The SWD-related inhibition of TC neurons is thought to represent the neuronal substrate for the drop in sensory responsiveness during absence seizures. During absence-related inhibitions, TC neurons show very limited responsiveness to prethalamic signals and so cannot relay peripheral signals to the cerebral cortex.

Synchronized Thalamocortical Oscillations

The thalamus is capable of initiating and sustaining network oscillations. However, the intrathalamic network is considerably more complex than the paired inhibitory–excitatory connectivity described above (and shown in Figure 1). There is considerable synaptic convergence and divergence at all the cellular connections, such that individual NRT neurons inhibit multiple TC neurons and receive inputs from several TC neurons. With this extensive lateral spread of activity, a small local network oscillation can recruit neighboring cells, leading to the generation of widespread thalamic synchronous oscillations in slices. Synchronized oscillatory electrical activity of groups of neurons occurs in vivo during various behavioral states, with sleep and seizures being prominent examples. These synchronous

oscillations can be detected with EEG recordings; two EEG rhythms that reflect this type of activity of thalamocortical networks are sleep spindles and SWDs. During sleep spindles a limited number of the neurons participate in the network oscillation, thereby generating individual spindle waves which are variable in duration and amplitude, and recruit variable populations in diverse cortical areas. By contrast, SWDs are characterized by spiking in the underlying cellular networks that is strongly synchronized within a given cycle of the oscillation and across multiple cortical areas. Thus, bilaterally synchronous SWDs reflecting widespread thalamocortical synchrony are the characteristic sign of generalized absence epilepsy.

Methods

A number of experimental animal models of absence epilepsy have been described. They can be roughly divided into models of seizure generation and models of epilepsy. In the former, seizures are induced in nonepileptic animals by applying chemical or electrical stimuli resulting in SWDs accompanied by behavioral arrest. Important examples are the feline generalized penicillin epilepsy model (FPGE; involving the intramuscular injection of large doses of penicillin to cats) and the γ-hydroybutyrate (GHB) model (involving the application of GHB or the prodrug γ-butyrolactone to thalamic nuclei). Models of epilepsy make use of animals with spontaneous, recurrent seizures. These models seem to better account for the integral nature of various types of absence epilepsies, the polygenic background, and the pathophysiology of the underlying synaptic network. Two genetic rat models, termed Genetic Absence Epilespsy Rats from Strasbourg (GAERS) and Wistar Albino Glaxo Rats from Rijswik (WAG/Rij), were independently derived from inbreeding of the Wistar strain. Their genotypes are not known, although there is some evidence of an autosomal-dominant inheritance of the SWD trait and a polygenic background that may modify seizure characteristics. The absence phenotype is similar in both strains (although subtle differences have been reported for the developmental and electrophysiological profile of the seizures) and largely resembles that in human CAE. The SWDs occur spontaneously on a normal EEG (mostly during quiet wakefulness) and are associated with a severe reduction in sensory responsiveness and a mild facial myoclonus; there are no major neuropathological abnormalities. Furthermore, classic absence antiepileptic drugs (ethosuximide, valproate) suppress SWDs, whereas drugs specific for convulsive or focal seizures (carbamazepin, phenytoin) are ineffective or aggravate SWDs in these rats. Differences from human CAE relate to the higher frequency of the SWDs (7–11 Hz), the relatively late appearance of absence seizure activity during development, and the persistence of SWDs through rat 'adolescence.'

A number of mutant mice models, involving the genes encoding different subunits of high-threshold Ca^{2+} channels (e.g., ducky, leaner, lethargic, rocker, stargazer, tottering), the Na^{+}/H^{+} antiporter (slow-wave epilepsy mouse), adapter-like proteins (mocha), and SNAP-25 (coloboma) are considered less relevant to the human situation because of their monogenetic mode of inheritance and the presence of significant neurological deficits normally not present in CAE (e.g., ataxia, hyperactivity).

Because the relative roles played by the different components of the thalamocortical system in the generation of SWDs are still a matter of debate, experimental models with different network connectivity (i.e., thalamic, cortical, and thalamocortical models) have been developed, thereby helping to assess their specific contributions and to investigate the mechanisms underlying the generation and spread of SWD-like activity in this brain structure. The ferret dLGN and the associated section in the NRT nucleus have proved particularly useful. A sufficient part of the synaptic network is preserved in a slice preparation in vitro to generate spontaneous, recurrent, spindle-like activity, and this pattern of activity can be acutely transformed into SWD-like activity upon pharmacologic manipulation of $GABA_A$ receptors. Similarly, a rodent in vitro thalamic slice preparation has been developed that contains interconnected neurons of the ventrobasal thalamic complex (VB) and the NRT, and which is capable of generating sustained low-frequency (2–4 Hz) oscillations. This horizontal thalamic slice provides a preparation that allows straightforward analyses of genetic mutations or pharmacologic interventions on intrathalamic rhythmicity. To further account for the joint contribution of both thalamus and cortex to the generation of SWDs, in vitro preparations including both parts of the forebrain (i.e., thalamus and cortex) have been developed. The rodent thalamocortical slice was introduced as a suitable system for studying the physiology and pharmacology of the thalamocortical synapse and for exploring the synaptic circuitry of the somatosensory cortex. This thalamocortical slice preparation is a reproducible model that enables investigators to analyze thalamocortical synchronization and to understand the pathogenesis of absence epilepsy.

Recent Results

Pathophysiological Mechanisms of CAE

Clinical evidence indicates that absence seizures are associated with states of decreased vigilance, such as drowsiness. In the early FPGE model, it was observed that SWDs on the EEG developed gradually from sleep spindles during early stages of slow-wave sleep. More recent studies in GAERS suggest that SWDs may originate in a cortical focus and

develop from a more wake-related natural thalamocortical sensorimotor oscillation (medium-voltage, 5–9 Hz oscillations in the somatosensory system of rats during quiet immobile wakefulness). In addition to these different observations according to which 'naturally-occurring' activity represents 'embryonic' SWDs, there have been extensive studies of mutant mice, genetic rat models, and the in vitro slice preparation that have generated the following scenario:

1. The neurons and synaptic interconnections of the thalamocortical system that normally sustain rhythmic activities during slow-wave sleep or sensorimotor oscillations are also critically involved in the generation of SWDs.
2. Seizure activity arises from a concerted interaction within this network, with initiation sites most likely residing in the cortex. The cortico-thalamocortical loop plays a pivotal role in the generation and synchronization of SWDs at an extended spatiotemporal scale. Importantly, neither cortical nor thalamic networks alone can generate or sustain SWDs, and influences exerted by brain structures other than the thalamocortical system can modulate SWD generation. Studies of various models, including GAERS and WAG/Rij, have indicated that spontaneous SWDs occur first in the somatosensory cortex and then invade other cortical and thalamic areas. Pathophysiological mechanisms in the cortex may involve an increase in excitatory synaptic transmission mediated via *N*-methyl-D-aspartate (NMDA) receptors, a decrease in GABAergic inhibition, and/or an altered expression of HCN1.
3. Cortical SWDs reach the NRT via corticofugal fibers. The response in NRT neurons consists of bursts of excitatory postsynaptic potentials (EPSPs) and a regenerative LTS crowned by a burst of fast action potentials. The overall response is synchronized burst activity in NRT neurons, which coincides with the SWDs on the EEG. Pathophysiologic alterations (see **Figure 1**) that have been reported with respect to SWD generation include: an increase in strength of corticofugal inputs; an increase in I_T amplitude associated with an increased expression of the $Ca_V3.2$ subunit in NRT neurons; increased and faster $GABA_A$ IPSCs; decreased expression of the $GABA_A$alpha3 subunit; and changes in the strength of $GABA_A$ receptor- and gap junction-mediated synaptic interactions involved in synchronization of local synaptic networks.
4. Circuitry within the thalamus promotes recurrent network activity as described above. An imbalance of $GABA_B$ over $GABA_A$ receptor-mediated inhibition has been reported to shift activity in TC neurons toward SWD-like discharges, although $GABA_A$ receptor-mediated influences dominate during spontaneous SWDs in rat genetic models, and the balance between $GABA_A$ and $GABA_B$ seems to relate to the prevailing frequency of the SWDs (3–5 Hz in humans versus 7–11 Hz in most animal models). Slightly different conclusions have been reached by investigators studying different models with respect to the relative contribution of LTS-related burst firing and of $GABA_A$ potentials to the SWDs in TC neurons. Further pathophysiological mechanisms in TC neurons may be related to an increased HCN1 and $Ca_V3.1$ expression, resulting in prolonged and enhanced burst activity (see **Figure 1**).
5. Thus, genetically determined, absence-related SWDs are the result of hypersynchronized, rhythmic excitations and inhibitions that result from complex intrinsic, synaptic, and network mechanisms in thalamus and cortex. A number of alterations found in genetic rat models characterize CAE as a 'transcriptional channelopathy.'

Pharmacology of CAE

The pharmacological target of typical absence drugs, especially ETX, has been a matter of long-standing controversy. In line with the I_T dependence of thalamocortical slow oscillations, the mechanism of action of ETX had initially been attributed to a reduction of this current in TC neurons. Subsequent work has failed to reproduce the finding of ETX induced I_T reduction by therapeutically relevant concentrations (0.25–0.75 mM). Instead, the mechanism of ETX action has been attributed to a reduction of I_{NaP} and the Ca^{2+}-activated K^+ current (I_{KCa}). Recently, the issue was readdressed by showing that a specific I_T antagonist was able to inhibit thalamic oscillations in vitro, and by showing that ETX blocks cloned I_T channels expressed in HEK-293 cells. A systematic comparison of ETX effects between thalamic cell types from epileptic and nonepileptic rat strains points to a possible solution to this controversy: (i) Combined effects of ETX on several membrane currents (I_T, I_{NaP}, I_{KCa}) may account for the full anti-absence action of therapeutically relevant ETX concentrations. (ii) The inhibition of I_T in several cell types, especially those important for network synchronization, must be considered. (iii) The dependency of ETX action on membrane potential and stimulation frequency may enhance I_T inhibition.

Future Challenges

Further studies are needed to address a number of important issues: (1) The genetic basis of CAE must be further elucidated – for instance, through identification of candidate genes that convey a predisposition to the generation of SWDs. (2) The mechanisms that lead to the altered expression of otherwise normal ion channels remain to be

identified. (3) Of special interest is the investigation of the role of intralaminar thalamic nuclei to the SWDs generation, as these nuclei are ideally positioned to spread activity within the thalamocortical system. (4) An interesting question is whether the mechanisms of SWD generation are characteristic of, and/or critical for, other types of thalamocortical dysrhythmia. (5) In more general terms, future studies must unravel the mechanisms that transform normal brain activity into SWDs. These mechanisms likely involve widespread neuronal changes that predispose epileptic individuals to develop hypersynchronous phenomena in the thalamocortical system.

Introduction

Primary generalized epilepsies occur in ~0.2% of the population under 25 years of age and are characterized by a major genetic component. The ictal manifestations in these patients show some degree of variability. However, the common clinical marker is a short (<30 s) period of loss of contact with the surrounding environment (i.e., the 'absence') accompanied by a stereotyped electro-encephalographic (EEG) discharge of spike-and-wave (SW) complexes at approximately 3 Hz (**Figure 1** (**a**)). This discharge has several distinctive features, including (i) generalized onset with bilateral synchrony; (ii) non-progressive pattern (i.e., similar SW complexes occur throughout the discharge); and (iii) sudden termination with no ensuing postictal depression. SW discharges can diminish the prospects of a satisfactory life, and may in some individuals develop into tonic–clonic seizures that

identified. (3) Of special interest is the investigation of the role of intralaminar thalamic nuclei to the SWDs generation, as these nuclei are ideally positioned to spread activity within the thalamocortical system. (4) An interesting question is whether the mechanisms of SWD generation are characteristic of, and/or critical for, other types of thalamocortical dysrhythmia. (5) In more general terms, future studies must unravel the mechanisms that transform normal brain activity into SWDs. These mechanisms likely involve widespread neuronal changes that predispose epileptic individuals to develop hypersynchronous phenomena in the thalamocortical system.

Introduction

Primary generalized epilepsies occur in ~0.2% of the population under 25 years of age and are characterized by a major genetic component. The ictal manifestations in these patients show some degree of variability. However, the common clinical marker is a short (<30 s) period of loss of contact with the surrounding environment (i.e., the 'absence') accompanied by a stereotyped electro-encephalographic (EEG) discharge of spike-and-wave (SW) complexes at approximately 3 Hz (**Figure 1 (a)**). This discharge has several distinctive features, including (i) generalized onset with bilateral synchrony; (ii) non-progressive pattern (i.e., similar SW complexes occur throughout the discharge); and (iii) sudden termination with no ensuing postictal depression. SW discharges can diminish the prospects of a satisfactory life, and may in some individuals develop into tonic–clonic seizures that

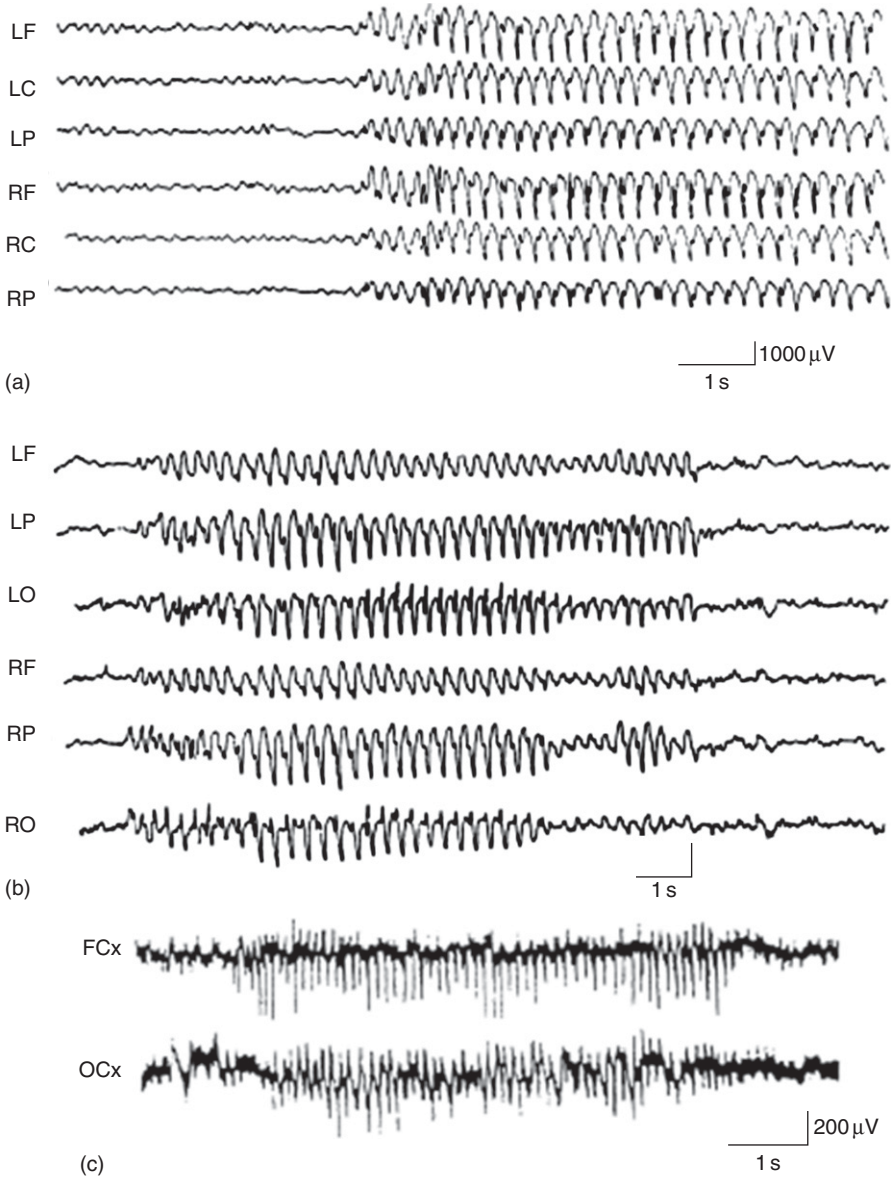

Figure 1 EEG traces of generalized SW discharges obtained from a patient (a), from a cat injected with i.m. penicillin injection (b) and from a WAG/Rij epileptic rat (c). These recordings are similar for the generalization at onset and throughout the discharge, the nonprogressive feature of the pattern and the absence of postictal depression. Abbreviations in this figure are: C, central; Cx, cortex; F, frontal; L, left; P, posterior; O, occipital; R, right. are resistant to medications. Hence, understanding the pathophysiogenesis of SW discharges remains an important challenge in epilepsy research.

Background

Generalized SW discharges were reproduced experimentally by Jasper and Droogleever-Fortuyn over 60 years ago. The discharge was recorded during low-frequency stimulation of midline and intralaminar thalamic nuclei in the cat, suggesting that the SW pattern may have a subcortical origin ('centrencephalic hypothesis'). However, this view was later challenged by the discovery that bilateral application of convulsants to the frontal cerebral cortex of cats and monkeys could produce a similar pattern of generalized, 3 Hz SW activity. In addition, in the photosensitive baboon (*Papio papio*), investigators identified a cortical origin of the electrographic activity characteristic of this genetic model of generalized

epilepsy. This evidence, along with an extensive review of clinical data, led Gloor in 1968 to propose the term 'generalized corticoreticular epilepsy' to reconcile the centrencephalic and cortical hypothesis.

Choosing the proper animal model is of paramount importance in the pursuit of the mechanisms of absence seizures. SW discharges have been widely studied in normal brains treated with either convulsants or electrical stimuli. The EEG and behavioral patterns resulting from these manipulations reasonably approximate the human condition (**Figure 1(a)** and **1(b)**). However, the genetic component of primary generalized epilepsies suggests that genetic animal models are more likely to give insight into the brain alterations leading to SW discharges. Interestingly, rat genetic models (not yet completely defined in terms of their genetic background) present ictal behavioral and EEG manifestations similar to those seen in absence seizure patients (**Figure 1(c)**). These models include the Genetic Absence Epilepsy in Rats from Strasbourg (GAERS) and the Wistar Albino Glaxo rats of Rijswijk (WAG/Rij). SW discharges recorded in these rodents have electroclinical (**Figure 1(c)**) and pharmacological profiles that closely resemble absence epilepsy in humans.

Methods

Feline Generalized Penicillin Epilepsy

Acute experiments were performed under neuroleptic analgesia in awake cats immobilized with gallamine triethiodide. Surface EEG was recorded from both hemispheres while 'local' EEG signals and single-unit activities were simultaneously obtained by each of two tungsten microelectrodes, one placed in the cortex (anterior part of the middle suprasylvian gyrus) and the other in the thalamus (nucleus lateralis posterior/pulvinar). Stimulating electrodes were positioned in the deep cortical layers to identify thalamic neurons as thalamocortical (i.e., antidromically activated) or as cortical targets (i.e., orthodromically activated). The activity of pairs of single neurons, one located in cortical areas 5 and 7 and the other in the dorsal thalamus, was studied during generalized SW discharges induced by intramuscular (i.m.) injection of large penicillin doses (350 000 IU kg^{-1}). All data (i.e., cortical surface, intracortical and thalamic EEG, and cortical and thalamic single-unit activity) were fed to a computer after analog-to-digital conversion. Thalamic and cortical action potentials were processed through window discriminators.

The WAG/Rij Rat Model of Generalized Epilepsy

Rats of the inbred WAG/Rij strain display hundreds of spontaneous seizures per day characterized by bilaterally generalized SW discharges arising abruptly from normal background EEG. At the time of surgery, rats were 16–22 month old. Epidural and depth electrodes for EEG recordings were stereotactically implanted during surgery under pentobarbital anesthesia. Spontaneous field potentials were recorded in freely moving WAG/Rij rats until a large number of spontaneous SW discharges were obtained. These data were used for the signal analysis. To estimate the degree of association between two signals and the corresponding time delay, the nonlinear correlation coefficient was calculated as a function of time shift between the two signals. Field potential recordings were also obtained from nonepileptic control rat thalamocortical slices maintained in vitro and superfused with medium containing 4-aminopyridine.

Results

Contribution of Cortical and Thalamic Networks to SW Discharges

Studies of cats injected intramuscularly with penicillin have demonstrated that functional and anatomical integrity of thalamus and cortex is required for the generation of generalized SW discharges. Depression of thalamic activity transiently abolished both normal spindle and SW activity in this model of absence seizures. Further, SW discharges did not occur when the thalamus was deprived of connections with the neocortex following surgical decortication. Finally, penicillin-induced SW discharges in the intact cat brain were blocked (and replaced by spindles in both thalamus and neocortex) when cortical excitability was reduced by spreading depression. Similar evidence has been obtained from studies with genetic rat strains of absence seizures. Experiments performed in cats in Steriade's laboratory have also identified a major role of neocortical networks in the generation of slow SW discharges typical of the Lennox–Gastaut syndrome.

Single unit extracellular and intracellular recordings have provided further insight into the mechanisms underlying the SW discharges. Both in cats treated with penicillin (**Figure 2(a)**) and in genetic rodent models (**Figure 2(b)** and **2(c)**), the spike of the SW complex is associated with a marked increase in firing probability in cortex and thalamus, while a reduction in firing probability (to virtually zero) is present during the wave component. In addition, intracellular recordings from cortical projection cells in the feline penicillin model have shown that the spike of the SW complex reflects summated EPSPs induced by incoming thalamocortical volleys, while the wave component is mirrored by depression of firing because of a long-lasting, membrane hyperpolarization (**Figures 2(b)** and **3**). A similar sequence of intracellular potentials also occurs during SW discharges in GAERS (**Figure 2(c)**) and WAG/Rij rat cortical and thalamic cells. It is, however, unclear

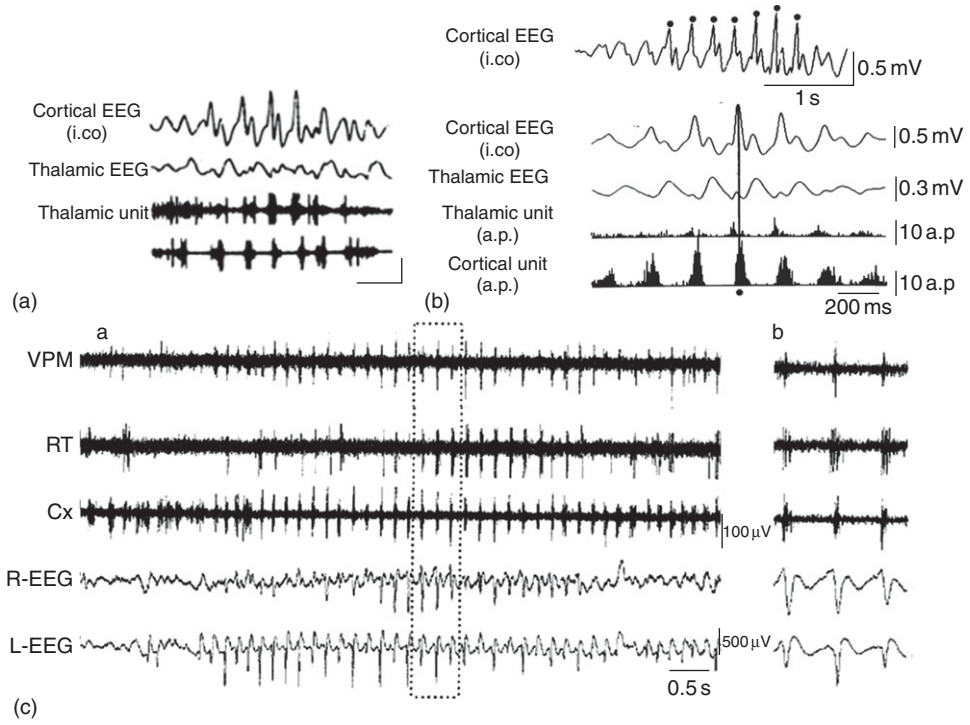

Figure 2 (a, b) EEG-unit correlation for a cortical and a thalamocortical neuron during SW discharges recorded in a cat injected with i.m. penicillin. In (a), raw data of the EEG and single-unit activities; in (b), EEG averages and histograms of single unit activity triggered by the negative peaks of the cortical EEG spikes. Note that both cortical and thalamic units correlate with oscillations between marked increase in firing probability during the *spike*, and a reduction of this probability of firing to virtually zero during the *wave* component of the SW discharge. (c) SW discharges recorded in a GAERS rat from units in the thalamus (RT, rostral reticular nucleus and VPM, ventroposteromedialis) and in the cortex (Cx) and bilaterally from the EEG. Cb: Inset demonstrates the temporal relationship of SW discharges and burst-like unit activity at an enlarged time scale. Parts (a, b) reproduced from Avoli M, Gloor P, Kostopoulos G, and Gotman J (1983) An analysis of penicillin-induced generalized spike and wave discharges using simultaneous recordings of cortical and thalamic single neurons. *Journal of Neurophysiology* 50: 819–837; Part (c) reproduced from Seidenbecher T, Staak R, and Pape HC (1998) Relations between cortical and thalamic cellular activities during absence seizures in rats. *European Journal of Neuroscience* 10: 1103–1112.

whether the hyperpolarization occurs through conventional GABA inhibitory mechanisms.

Thalamic Networks and SW Discharge Rhythmogenesis

The corticothalamic projection to the ventrobasal thalamus consists mainly of small modified pyramidal cells located in layer VI, and in part by larger pyramidal cells located in the lower layer V. Anatomical studies have demonstrated that layer VI cortical neurons, but not those in layer V also send collaterals to the reticular thalamic nucleus. Most of the inhibitory control exerted on thalamocortical relay cells originates from the reticular thalamic nucleus, which is composed entirely of GABAergic neurons that are excited by corticothalamic and thalamocortical afferents. Reticular thalamic neurons are endowed with a pronounced low-threshold (termed also T-type) Ca^{2+} current that causes rhythmic action potential bursting. The volley of action potentials, traveling along the reticular cell axons, induces $GABA_A$ and $GABA_B$ receptor-mediated hyperpolarizing IPSPs in thalamocortical neurons. In thalamocortical neurons, another T-type Ca^{2+} current triggers bursts of action potentials as the membrane potential hyperpolarization (associated with the IPSPs induced by the reticular thalamic nucleus input) decays toward the resting membrane level. In addition, a noninactivating Na^{+} current acts synergistically with the T-type Ca^{2+} current in these cells, contributing to an increased frequency of burst firing. Bursts of action potentials in thalamic principal neurons then excite neocortical cortical cells that in turn re-excite nucleus reticularis neurons via corticothalamic connections.

It is well established that these events lead to the rhythmic activity that paces sleep spindles, and a similar hypersynchronous thalamo-cortico-thalamic mechanism may pace burst firing in thalamocortical cells to frequencies characteristic of the SW discharges of absence epilepsy. The synchronization of thalamocortical and corticothalamic networks can be easily appreciated in vitro by stimulating with 4-aminopyridine slices in which the reciprocal cortical and thalamic connections are preserved (**Figure 4**). A malfunctioning of these networks in

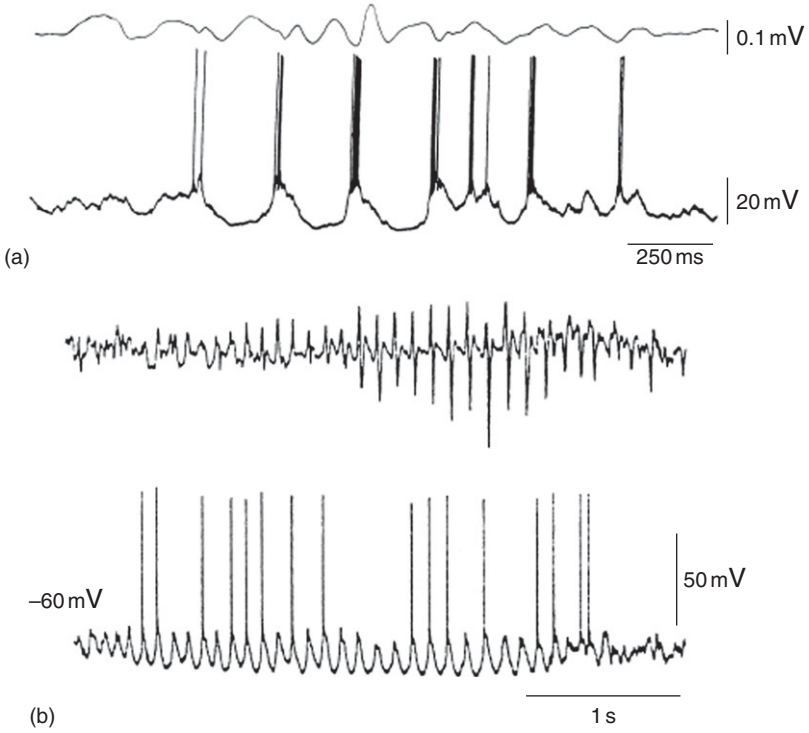

Figure 3 (a) EEG (uppertrace) and intracellular potentials (lower trace) recorded during a SW discharge in a cat injected i.m with penicillin. Note that the *spike* is associated with a depolarization that triggers action potentials, while the *wave* of the SW complex is associated with a hyperpolarization of the membrane. (b) Rhythmic depolarizations are present in the intracellular recording (bottom trace) performed at resting membrane potential from a cortical neuron during the occurrence of a SW discharge recorded in the EEG (upper trace) from a GAERS rat. Part (a) reproduced from Giaretta D, Avoli M, and Gloor P (1987) Intracellular recordings in pericruciate neurons during spike and wave discharges of feline generalized penicillin epilepsy. *Brain Research* 405: 68–79; Part (b) reproduced from Charpier S, Leresche N, Deniau JM, Mahon S, Hughes SW, and Crunelli V (1999) On the putative contribution of $GABA_B$ receptors to the electrical events occurring during spontaneous spike and wave discharges. *Neuropharmacology* 38: 1699–1706.

generalized epilepsy is supported by several pieces of evidence. First, as already mentioned, spindles and SW discharges disappear in cats treated with i.m. penicillin when the thalamic activity is transiently depressed. Second, selective lesioning of reticular thalamic nucleus permanently abolishes SW activity in GAERS animals. Third, the low-threshold Ca^{2+} current is overexpressed in isolated reticular nucleus neurons isolated from GAERS. Fourth, microinjection of $GABA_A$ or $GABA_B$ receptor agonists into thalamic relay nuclei increases the duration of SW discharges in the GAERS model and in other genetic models of primary generalized epilepsies, while microinjection of $GABA_B$ receptor antagonists abolishes SW discharges. Finally, deletion of the $GABA_A$ receptor β_3 subunit – which is mainly restricted to the reticular nucleus in rodents – markedly reduces $GABA_A$ receptor-mediated inhibition in reticular (but not in thalamocortical relay) cells, and causes a marked increase of the oscillatory synchrony of thalamocortical relay neurons. The mutual recruitment of thalamic and cortical networks during generalized SW rhythmogenesis has also been investigated in computational models. In these studies, investigators have shown that the burst responses of thalamic neurons, as well as the properties of $GABA_B$ receptor-activated conductances, are critical in generating SW discharges.

Role of Cortical Networks in SW Discharge Initiation

According to the evidence outlined in the previous section, the interaction between reticular and thalamocortical cells projecting to the cortex, along with the reciprocal corticothalamic connections, provides the anatomical and functional substrate for SW discharges. It remains, however, to be established where the initiation of these epileptic discharges resides. Are there initiation sites in the cortex, or does neocortex just act as a passive by-stander to a rhythm elaborated within the thalamus? Although the evidence obtained in the feline generalized penicillin model indicates that the occurrence of generalized SW discharges require hyperexcitable neocortical networks, a definitive answer to how absence seizures are initiated, and then generalize within the brain, has been provided by studying WAG/Rij rats. By employing nonlinear association analysis of the EEG signals recorded from thalamus and neocortex, investigators have demonstrated that SW activity originates

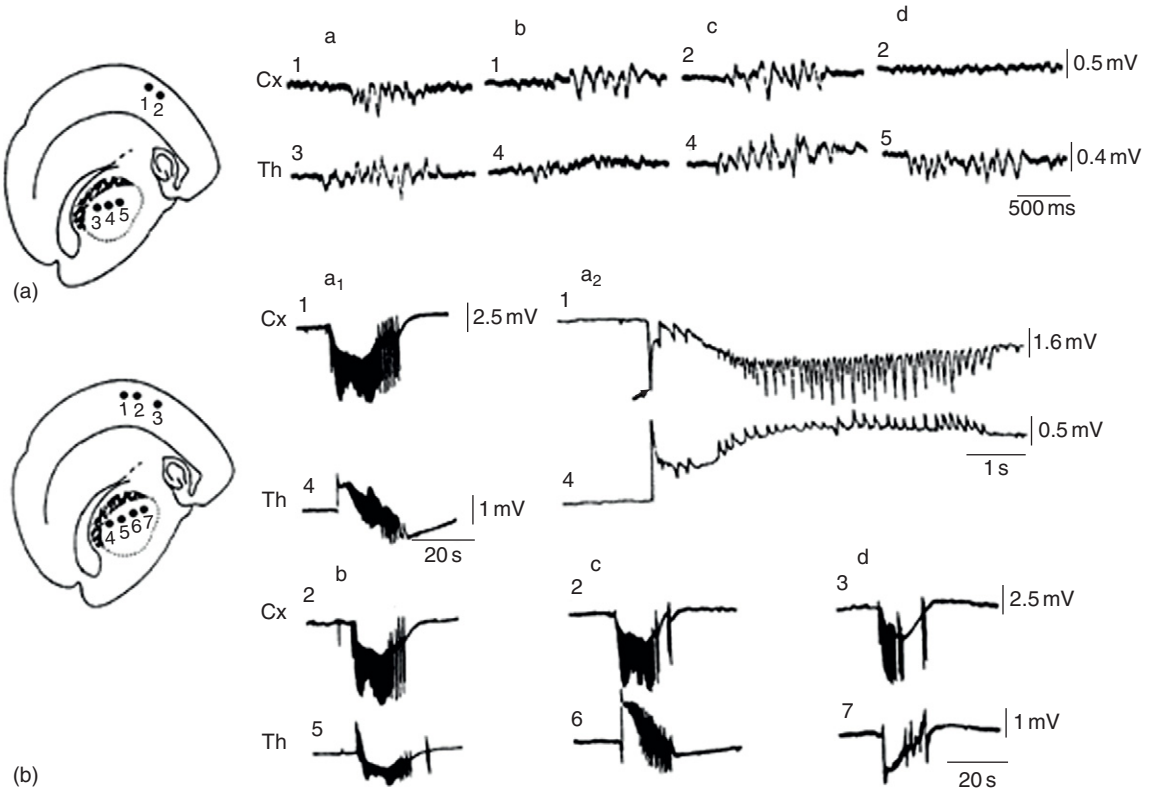

Figure 4 Spontaneous field potential activity induced by low (a) and high (b) concentrations of 4-aminopyridine in the thalamocortical slice preparation. Position of the recording electrodes in the frontoparietal cortex (Cx) and in thalamus (Th) is numbered in the two inserts. (a) Rhythmic field potential oscillations occur in cortex and thalamus during application of low (0.5 μM) concentrations of 4-aminopyridine. Note that these field potential oscillations are synchronized in cortex and thalamus in panels a and c, while synchronization is no longer observed when the recording electrode is moved by <500 μm in either structure (panels b and d). (b) Spontaneous ictal discharges induced by large doses (100 μM) of 4-aminopyridine. These prolonged epileptiform events are characterized in both cortex and thalamus by an initial tonic phase that is followed by recurring rhythmic discharges (a1 and a2). This pattern is characterized by a high degree of synchronicity between thalamus and cortex even when the recording electrodes are repositioned at distances >1.5 mm (panels b, c, and d). In a2, the ictal discharge is illustrated at a faster time base showing that the onset of the discharge is characterized by a negative- and positive-going potential in cortex and thalamus, respectively. Reproduced from Biagini G, D'Antuono M, Tancredi V, *et al*. (2001) Thalamocortical connectivity in a rat brain slice preparation: Participation of the ventrobasal complex to synchronous activities. *Thalamus and Related Systems* 1: 169–179.

from a 'consistent cortical focus' that overlaps with the perioral region of the somatosensory cortex (**Figure 5**). These findings were later confirmed also in GAERS rats. Consistent with this view, in slices of the ferret lateral geniculate nucleus, other investigators have shown that the frequency of the rhythmic oscillations generated by geniculate neurons is controlled by the patterns of activation of corticothalamic inputs (which in these experiments were mimicked by electrical stimulation of corticothalamic fibers).

Mechanisms of Cortical Hyperexcitability in Absence Seizures

Given the earlier results, an obvious question is: 'What mechanisms contribute to neocortical hyperexcitability in genetic rodent models of absence seizures?' Recent studies have begun to shed light on this issue, revealing that both nonsynaptic and synaptic mechanisms are altered in absence epileptic animals as compared with nonepileptic controls. SW discharges have been identified in mice carrying spontaneous mutations in genes belonging to the family of high-threshold voltage-gated calcium channels, such as *Cacna1a*^{tg} ('tottering' mouse), *Cacnb4*^{lh} ('lethargic'), *Cacna2d2*^{du} ('ducky'), and *Cacng2*^{stg} ('stargazer'). Single point mutation in the sodium/hydrogen exchanger (NHE1) gene (*Slc9a1*^{swe}), abolishing its transcription, also causes SW discharges and absence seizures. Interestingly, impairment in the expression (−50%) of the synaptic vesicle-associated protein SNAP25 is also associated with SW discharges in 'coloboma' mice (*Cm*, *Snap25*). In addition, the deletion of the *Hcn2* gene, which abolishes the I_h current, also leads to an absence epilepsy phenotype.

Recently, a new mouse model harboring the R43Q mutation of the $GABA_A$ subunit γ_2, found in an Australian family affected by absence epilepsy and febrile seizures,

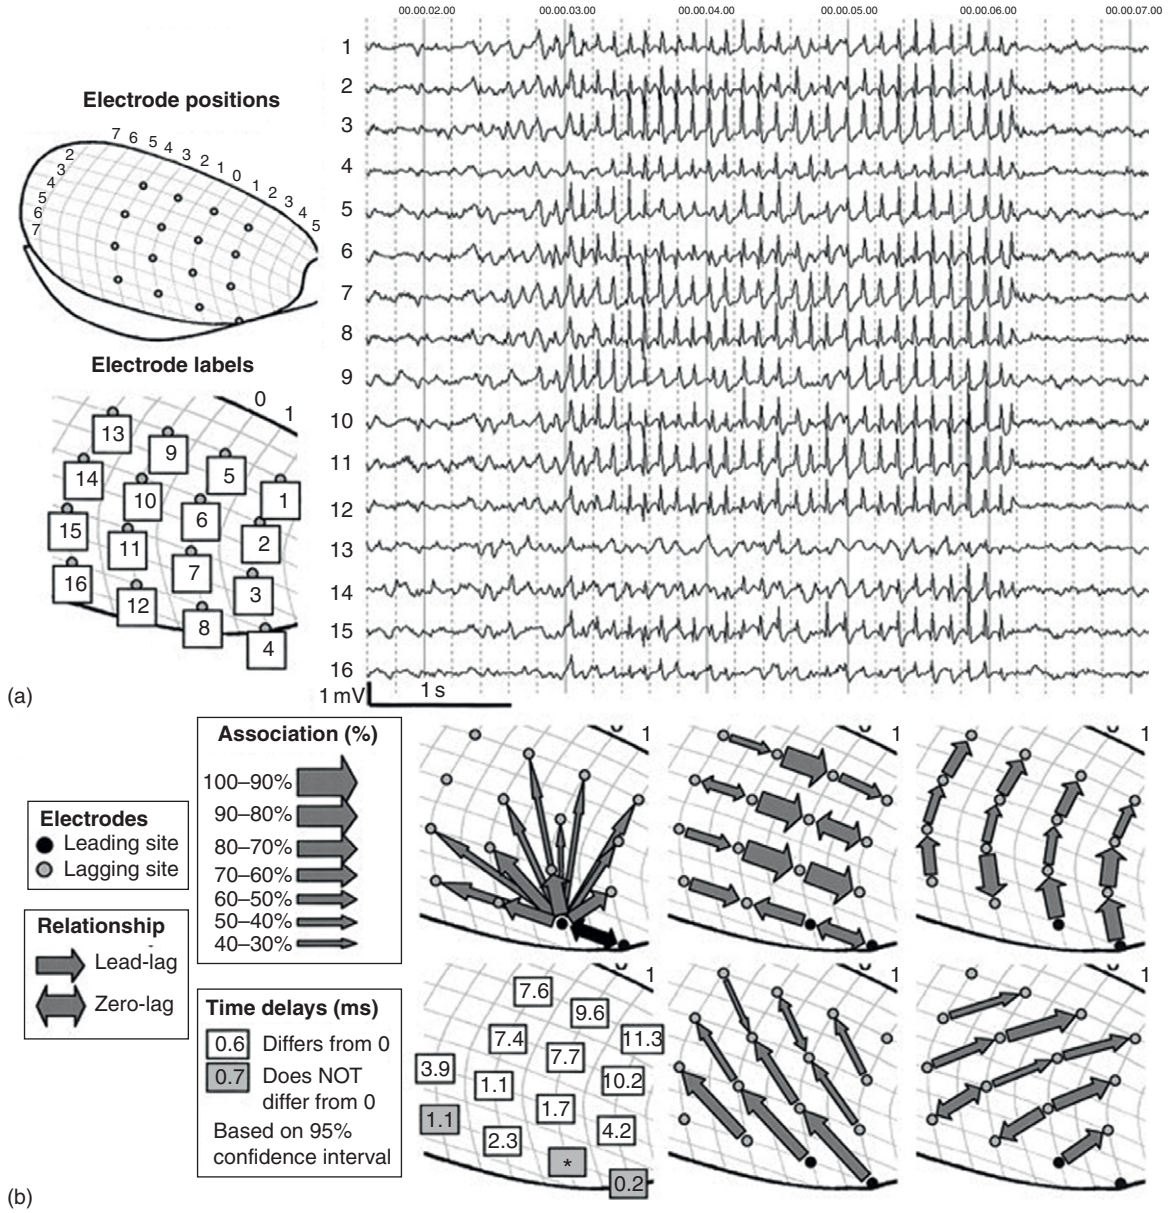

Figure 5 Identification of neocortical epileptic foci in WAG/Rij rats. (a) Electrographic seizure recorded with a cortical grid that covers the lateral convexity of the neocortex. The position of the electrodes and their labels are illustrated on the left. Note that the discharges are visible in each tested position. Note also that the potentials present with larger amplitude in the rostroventral locations, whereas they are minimal in the caudal positions (13–16). (b) Representations by arrows of the results of the nonlinear association analysis from five different perspectives. The thickness of the arrow represents the strength of the association, and the direction of the arrowhead points to the direction of the lagging site. Electrodes corresponding to positions 4 and 8 (black dots) identify the leading sites. The numbers depict the average time delays (in milliseconds) over 10 seizures with respect to electrode 8. Reproduced from Meeren HK, Pijn JP, van Luijtelaar EL, Coenen AM, and Lopes da Silva FH (2002) Cortical focus drives widespread corticothalamic networks during spontaneous absence seizures in rats. *Journal of Neuroscience* 22(4): 1480–1495.

was developed. Seizures in this model appear at approximately 3 weeks of age and are mirrored by reduced $GABA_A$-mediated currents in cortical pyramidal neurons. No changes were found in reticular and ventrobasal thalamic neurons, pointing to a selective reduction of neocortical inhibition. Accordingly, GABA receptor-mediated inhibition is slightly reduced in the neocortex of WAG/Rij rats, where deep layer neurons generate hyperexcitable synaptic responses that appear to be caused by NMDA receptor activation. Paired-pulse depression of excitatory and inhibitory potentials is decreased in epileptic WAG/Rij rat neocortical slices, suggesting a process involving

activation of presynaptic $GABA_B$ receptors. Molecular and immunohistochemical analysis has also demonstrated a reduced expression of the mRNA encoding some $GABA_B$ receptor subunits, as well as the respective proteins. Therefore, diminished function of presynaptic $GABA_B$ receptors may make epileptic WAG/Rij neocortical networks hyperexcitable by increasing inhibitory and, perhaps to an even greater extent, excitatory transmitter release. Interestingly, $GABA_{B(1)}$ knockout mice also generate various types of epileptiform activity, including absence seizures. However, early studies in GAERS and WAG/Rij rats have shown that injecting $GABA_B$ receptor antagonists into the thalamus (or introducing it systemically) can block absence seizures. It is unclear whether these results reflect changes in the molecular properties of $GABA_B$ receptors within the GAERS and WAG/Rij thalamocortical circuits or rather a pharmacological effect based on the ability of $GABA_B$ receptor antagonism to reduce slow hyperpolarizing IPSPs (and thus low-threshold Ca^{2+} currents) in thalamocortical relay cells. Attempts to exploit these findings in order to develop therapeutic procedures in humans have thus far failed.

Pharmacological Treatment of Absence Seizures

Drugs used for treating absence seizures fall into two classes: broad spectrum and specific antiabsence agents. The broad spectrum antiepileptic drugs are effective in the treatment of generalized absence seizures, in addition to their better known activity in partial and generalized tonic–clonic seizures. In contrast, specific antiabsence drugs have little or no effect on other seizure types. Broad spectrum antiepileptic drugs such as lamotrigine, topiramate, and valproate act, at least in part, through state-dependent block of voltage-gated Na^+ channels. Interestingly, a similar mechanism of action is shared by antiepileptic drugs such as phenytoin and carbamazepine that are effective in partial epilepsies but ineffective in absence seizures.

The basis for a distinct spectrum of clinical efficacy for lamotrigine, topiramate, and valproate is unclear, although one may consider (i) subtle differences in the way these drugs modulate voltage-gated Na^+ channels, (ii) region-specific differences in sensitivity to the various agents, or (iii) mechanisms other than Na^+ current modulation. Specific antiabsence drugs, such as ethosuximide, methsuximide, and dimethadione, are known to act by reducing T-type Ca^{2+} currents in thalamocortical relay neurons and in neurons of the nucleus reticularis thalami, thus preventing burst firing and abolishing the rhythmic thalamocortical synchronization that paces SW discharges. However, ethosuximide also reduces bursting in thalamocortical neurons while increasing their tonic firing, an effect accompanied by inhibition of noninactivating Na^+ currents (but no effect on transient Na^+ currents, and a decrease in the activity of Ca^{2+}-activated K^+ channels).

It is also established that barbiturates lack antiabsence activity whereas benzodiazepines are highly effective as antiabsence agents. This differential efficacy may be due to differences in $GABA_A$ receptor subtype expression in thalamocortical relay and thalamic reticular neurons. Indeed, $GABA_A$ receptors on thalamocortical neurons fail to respond to clonazepam, whereas $GABA_A$ receptors on inhibitory cells of the thalamic reticular neurons are sensitive. As a consequence, clonazepam enhances recurrent inhibitory strength within the reticular nucleus, leading to reduced inhibitory output from these cells. This reduction, in turn, causes a decreased propensity of neighboring inhibitory neurons in thalamic reticular nucleus to fire synchronously and produce the powerful inhibitory synaptic responses that are presumably required for SW synchronization. Barbiturates do not show such a differential action, which may account for their lack of antiabsence activity.

Conclusions and Directions for Future Research

Overall, the expression of generalized SW discharges seen in animal models of absence seizures requires the function of reciprocally interconnected thalamic and cortical networks. This experimental evidence is consistent with data obtained from patients with absence seizures, in whom SW discharges were seen to occur simultaneously in cortex and thalamus. It is reasonable to propose that enhanced corticothalamic outputs make GABAergic cells in the thalamic reticular nucleus fire action potential bursts that are more intense than under normal conditions; these increased bursts cause extended IPSPs in thalamic relay cells, thus slowing their pacing frequency and producing recruitment of a larger number of cortical and thalamic neurons – which leads to SW activity. While the rhythmicity of SW appears to arise from properties of thalamic neurons, the initiation of the absence seizure discharge appears to reside in specific cortical neuronal populations.

Evidence from animal models suggests that $GABA_B$ receptors are dysfunctional in absence seizures. The resultant weakened presynaptic control should lead to an augmented release of inhibitory transmitter, which in turn may depress interneuron excitability and thus cause disinhibition of corticothalamic neurons. In addition, this condition is associated with, and perhaps may cause, the functional overexpression of NMDA receptor-mediated mechanisms. The increased release of GABA should activate postsynaptic $GABA_B$ receptors, thus producing robust

hyperpolarizing IPSPs that contribute to de-inactivate low-threshold Ca^{2+} conductances, which in turn facilitate rhythmic bursting. In line with this view, $GABA_B$ receptor antagonists injected either into the thalamus or systemically, block absence seizures in both GAERS and WAG/Rij rats. It remains unclear whether the changes in $GABA_{B(1)}$ subunit expression, and thus the decreased function of $GABA_B$ receptors, are genetically determined (and thus developmentally regulated) or whether they are the consequence of on-going SW discharge activity. The development of radioligands that can be imaged by positron emission tomography (PET) could allow a better understanding of these mechanisms both in the animal models and in patients. The confirmation of the present findings, by applying PET analysis to generalized seizures, could lead to further experiments aimed at establishing whether antiepileptic drug pretreatment (i.e., before the appearance of SW discharges) can influence the interplay between GABAergic and glutamatergic control systems. When proved to be of pathophysiological importance in patients, $GABA_B$ and NMDA receptors could be rationally targeted by the respective specific drugs.

Introduction

The prevalence and incidence of epilepsy increase significantly in the elderly (people older than 60 years). In addition, the aging population has a significantly higher chance of developing status epilepticus. These, and other related factors, may be expressed in two ways: (1) The expression of existing seizures and epilepsy (both inherited and acquired) may change as a function of the changes associated with aging; and (2) Seizures and epilepsy may occur de novo, sometimes as a result of conditions associated with aging such as stroke, brain trauma, tumors, and neurodegenerative disorders. Since aging is not a condition of the CNS alone, aging-associated changes in other organ systems (such as in liver metabolic capacity and renal clearance) may have important effects on the way a patient's antiepileptic medication is metabolized or cleared, thus affecting seizure expression.

The population of elderly persons worldwide, especially in developed countries, is increasing at a high rate. Trends predict that by 2050, the population over 60 years of age will comprise more than 30% in many countries (Figure 1). This increase calls for new and innovative diagnostic and treatment options for elderly patients with epilepsy. Increased needs in patient care should also be reflected in enhanced research in this area. Yet, there remains an alarming gap between the increasing numbers of elderly people with either new or modified seizures and basic research in the field. A recent study suggested that between 1965 and 2003, there were only 30 scientific articles investigating the condition of seizures in the aging brain. From 2003 through 2006, a few additional studies pushed up the number of papers up to about 50. Finally, in 2007, a volume of International Review of Neurobiology appeared that was devoted to this topic. Even with this modest surge in research, a critical mass of knowledge of basic mechanisms leading to significant improvements in seizure diagnosis and treatment in elderly patients has not been achieved. The need is pressing.

Seizures in the elderly are further confounded by the fact that age cannot be simply used as a covariant or grouping variable. Physical conditions of elderly people may be very different even within the same age group. A 60-year-old person with poor health and physical condition may be at a higher risk of seizures than an 80-year-old person in excellent health. Thus, it seems that, as in the case of the early postnatal development, aging studies need to be carried out in several distinct age groups of experimental animals to fully appreciate different conditions associated with aging in humans with seizures. Models of seizures in aged animals should also include some of the underlying conditions frequently occurring in the elderly. That is, the models should include stroke or brain injury within the context of an aging brain, to better mimic the human situation.

Background

Studies on animal models performed so far have investigated, both in vivo and in vitro, mechanisms of seizures and epilepsy in aged rats with normal as well as impaired brain. Unfortunately, some of these studies have sometimes generated inconsistent findings.

To make studies on rodent models relevant to human aging, it is important to define 'aged' in rats. With a life expectancy between 750–850 days, rats beyond 600 days of age can be considered aged. In studies using the kainic acid model to induce seizures in adult and aged rats, there were no differences in peak severity of status epilepticus. However, the progression through seizure stages was

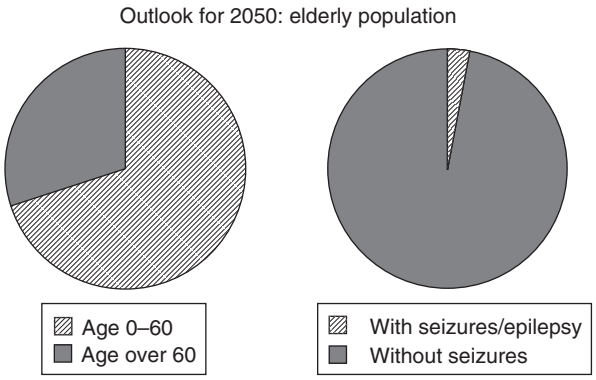

Figure 1 Projected proportion of the elderly population in 2050, along with the projected number with seizures and epilepsy. The proportion of persons 60 years old and older is estimated to exceed 30% of the world's population by the year 2050 (left). The average incidence of seizures and epilepsy ranges from 1.5% in 60 year olds to 4.5% in 80 year olds. Thus, the average incidence can be estimated at 3% of the population older than 60 years (right). As the world's population will reach 9.5 billion by 2050, there will be about 85 million elderly people with seizures worldwide, representing a major diagnostic and treatment challenge.

different; aged rats reached each seizure stage earlier than adult rats, suggesting an increased susceptibility in the aged brain. In contrast, in the hippocampal kindling model, aged rats kindled more slowly (i.e., required more kindling stimulations to reach the criterion of five generalized stage 5 seizures) than adult rats. Despite this slower kindling rate, aged rats displayed longer afterdischarges and faster propagation of epileptiform activity to the contralateral hemisphere.

An in vitro model focused on the features of the hippocampal circuitry to account for age-related differences in susceptibility to kainic acid (KA)-induced seizures. In hippocampal slices, the frequency of inhibitory postsynaptic potentials in granule cells is significantly decreased in aged rats than in adult rats. Further, perforant path stimulation at 5 Hz for 10 s produces multiple population spikes in granule cells as a response to a single stimulus in about 40% of aged rats but in none of adult rats, indicating an impairment of dentate gyrus filtering as a function of age.

Some studies focused on the effects of stroke (using the model of middle cerebral artery occlusion: MCAO) on the development of seizures with aging. One year after after MCAO, there was no evidence of behavioral or EEG seizure activity in the region of the occlusion. More recent studies have employed photothrombotic brain vessel occlusion, with Rose Bengal stain and transcranial illumination of a relatively restricted area of the neocortex. Spontaneous seizures in rats subjected to this injury developed only in few cases (7/36) over a period of 10 months after the insult. However, other studies have reported that 35–100% animals exhibit seizures 4–10 months after cortical photothrombosis, with seizures occurring up to several times per day.

An in vitro model system of stroke-induced epilepsy used glutamate-induced injury in hippocampal neuronal cultures. Neurons that survived yet incurred damage (a correlate of penumbra neurons in stroke) developed epileptiform discharges and network oscillations that persisted throughout their life in culture. This model has potential for studying the mechanisms associated with stroke-induced epilepsy, since the culture model is easily accessible for electrophysiologic, biochemical, and imaging studies.

Methodology

Both mice and rats are used in seizure models. Mice are more commonly used to study genetic modifications that alter seizure susceptibility, while rats are more appropriate for acute seizure models. However, none of the models described in the following sections have been explored and utilized systematically in aged animals.

Mice

One of the convenient mouse models for studies of seizures and epilepsy in aging may be the senescence-accelerated mouse (SAMP8). This mouse is often used in geriatric research, and information gleaned from such studies might aid investigations of epilepsy during aging. Another mouse strain potentially useful for aging studies is the metallothionein-III (zinc-binding protein) knockout mouse. Of course, aged common mouse strains (such as BDF1 mice and C57BL/6J) should also be investigated in epilepsy research.

Rats

Aged (i.e., >600 days old) Sprague-Dawley, Long-Evans, and Fisher 344 rats are more sensitive to KA-induced seizures than adult rats. These findings are consistent with the human condition of increased seizure susceptibility with aging. Other convulsants, such as pentylenetetrazole and strychnine, have also been used to study seizure susceptibility in aged rats, and invariably indicate that aged rats develop seizures at lower thresholds than younger adult animals.

KA-Induced Seizures

Seizures are elicited usually using systemic injection of aqueous solution of KA (with pH adjustment), a neurotoxic analog of glutamate with preferential effects on the limbic system. To elicit clonic seizures without loss of righting (sometimes termed 'limbic seizures') that evolve

into status epilepticus, a bolus dose of KA is administered intraperitoneally. In adult rats, the effective dose is between 10–20 mg kg^{-1}, while mice usually require a higher dose (between 20–40 mg kg^{-1}). An alternative approach is to infuse graded doses of KA into the tail vein, usually 2.5–5 mg kg^{-1} in rats every 5–20 min until seizures occur.

Pentylenetetrazole (PTZ)-Induced Seizures

Seizures are elicited most commonly by a bolus dose of subcutaneous aqueous solution of 50–100 mg kg^{-1} in both rats and mice. This dose results in blockade of the $GABA_A$ receptor via the TBPS (*t*-butylbicyclophosphorothionate) site in the chloride channel. If the dose used is at the lower end of the range, PTZ induces bilateral clonic (myoclonic) seizures of face and forelimbs without loss of righting. With higher doses, these seizures progress to tonic-clonic seizures of all four limbs with loss of righting. As in the case with KA, graded PTZ doses can be delivered intravenously, allowing the determination of seizure threshold.

Strychnine-Induced Seizures

Seizures are elicited by injection of strychnine solution (aqueous; 1 mg ml^{-1}), usually intraperironeally, at a dose range of 1–4 mg kg^{-1} in both rats and mice. Strychnine induces tonic-clonic convulsions with loss of righting and prominent hyperextension, including the tail ('Straub-tail').

Kindling

Kindling is a process by which subconvulsant electrical stimuli, delivered at intervals (usually daily) to various brain structures (e.g., olfactory bulb, amygdala, perforant path), eventually cause local seizure activity (afterdischarge) that can progress to limbic seizures and finally to generalized seizures. The classic protocol for kindling uses electrical stimuli at 50–60 Hz for 1–2 s delivered via electrodes in the amygdala or hippocampus, with 24-h interstimulus intervals. The stimulation that evokes a kindled seizure will cause seizures even weeks or months later.

Results

Data from experiments performed on aged animals provide information about the seizure propensity of the aged brain. Studies carried out so far have been consistent with observations made on the human population, attesting to the increased incidence and prevalence of seizures and epilepsy as a function of age. These studies will also provide information about the conditions leading to these age-related changes in seizure susceptibility.

Mice

The SAMP8 mouse displays increased susceptibility to KA seizure-induced damage compared with the animals of the same age without the 'aging mutation,' but few studies have used this model to study seizures and epilepsy in aging. Similarly, aged metallothionein-III knockout mice are more susceptible to KA seizure-induced damage than the wild-type age-matched controls. Finally, within common mouse strains (BDF1 and C57BL/6J), aged animals display increased susceptibility to PTZ- and KA-induced seizures.

Rats

In aged Long-Evans rats, administration of KA elicits increased release of aspartate, glutamate, and norepinphrine compared to adult controls. This enhanced neurotransmitter release in response to KA might underlie the increased seizure susceptibility seen in aged subjects (compared adult control rats). Other differences seen in the aged rats' response to KA include a delayed c-fos expression and altered regulation of microtubule associated protein and axonal-growth associated protein. However, more research is necessary to determine whether these changes are a consequence of seizures themselves. Future studies should concentrate not simply on whether the aged brain is more susceptible to seizures (we already know this to be the case), but why the aged brain is more seizure susceptible. Such information might improve treatment options for elderly patients.

Future Goals

Several goals should be addressed promptly in research on aging and epilepsy. First, we need to collect significantly more descriptive information about seizures in aged animals, to correlate with human data. Second, experiments need to move beyond description into mechanism. Only at that point will we be able to identify potential therapeutic interventions that might target age-related modifications of brain structure and function. In that regard, the efficacy of antiepileptic drugs needs to be studied in parallel with the earlier-mentiond experiments, always keeping in mind the need for appropriate adult controls.

There are some big challenges to achieving these goals. Research on aged animals is expensive because of the steep costs of purchasing aged animals or maintaining adult rats into senescence. The distinction between causation and association must be considered carefully in experiments on epileptogenesis during aging. Investigators must keep in mind the difference between reactive

seizures (possibly with lower seizure threshold as a function of various age-related neural changes) versus the development of the epileptic state. Data must be interpreted in the context of ongoing age-related brain changes as well as aging in other organ systems. For example, is it possible that the higher susceptibility to KA-seizures in aged rats partially reflects age-related liver metabolic changes?

Despite those challenges, there is an enormous opportunity to explore and define age-related changes in seizure susceptibility and epileptogenesis, as this field has been ignored (with a few notable exceptions) in experimental laboratories. With the burgeoning population of elderly citizens, the need to understand and develop new treatment modalities is urgent.

Introduction

Epidemiological studies reveal that the elderly (individuals $\geq$ 65 years of age) exhibit the highest incidence/prevalence for seizure disorders, with estimates suggesting that 4–5% of the geriatric population is affected compared to 1% of the total population. Seizure disorders are the third most common neurological disorder in the elderly and a major factor in aging-related mortality and morbidity. Moreover, the incidence/prevalence of geriatric epilepsy is likely to be underestimated; differences in the behavioral manifestations and electrographic characteristics of seizures observed in the elderly, compared to those seen in the younger adult population, can complicate diagnosis, and epileptic seizures can be misdiagnosed as several other common age-related conditions if EEG-video monitoring is not employed. While available antiepileptic drugs (AEDs) are generally effective in the elderly age group, complications frequently arise due to increased drug sensitivity, altered pharmacokinetics, complex drug interactions due to multidrug regimes, and a decreased reliability of the elderly to accurately self-report symptoms. Taken together, these facts are alarming since demographic data indicate that the elderly are the most rapid growing segment of the population. In response to these data, the Epilepsy Foundation released a position paper in 1996 detailing this impending public health crisis.

To elucidate the mechanisms that contribute to aging-related epileptogenicity, it is first important to assess whether specific forms of epilepsy are observed preferentially in the elderly (since different forms of epilepsy entail different neural networks), and whether specific antecedents precede the onset of these seizures. Data suggest that

seizures (possibly with lower seizure threshold as a function of various age-related neural changes) versus the development of the epileptic state. Data must be interpreted in the context of ongoing age-related brain changes as well as aging in other organ systems. For example, is it possible that the higher susceptibility to KA-seizures in aged rats partially reflects age-related liver metabolic changes?

Despite those challenges, there is an enormous opportunity to explore and define age-related changes in seizure susceptibility and epileptogenesis, as this field has been ignored (with a few notable exceptions) in experimental laboratories. With the burgeoning population of elderly citizens, the need to understand and develop new treatment modalities is urgent.

While available antiepileptic drugs (AEDs) are generally effective in the elderly age group, complications frequently arise due to increased drug sensitivity, altered pharmacokinetics, complex drug interactions due to multidrug regimes, and a decreased reliability of the elderly to accurately self-report symptoms. Taken together, these facts are alarming since demographic data indicate that the elderly are the most rapid growing segment of the population. In response to these data, the Epilepsy Foundation released a position paper in 1996 detailing this impending public health crisis.

To elucidate the mechanisms that contribute to aging-related epileptogenicity, it is first important to assess whether specific forms of epilepsy are observed preferentially in the elderly (since different forms of epilepsy entail different neural networks), and whether specific antecedents precede the onset of these seizures. Data suggest that

complex–partial seizures are most commonly seen in the elderly. Complex–partial seizures generally involve temporal lobe onset (e.g., hippocampal formation). As for etiology, a number of common aging-related complications, including cerebrovascular insult, metabolic disturbance, and Alzheimer's disease, have been identified as precipitating antecedents; these epilepsy cases are referred to as symptomatic. However, in more than 40% of cases, no proconvulsive antecedent can be identified. These cases are referred to as idiopathic/cryptogenic geriatric epilepsy, and have led to the hypothesis that aging of the central nervous system (CNS) itself may be epileptogenic.

Based on these clinical findings, our laboratory has begun to test the hypothesis that anatomical and electrophysiological changes occur in the CNS during aging that can directly increase seizure susceptibility. We have chosen the hippocampal formation as our model system, given the predominance of complex–partial seizures in the elderly. We postulate that these aging-related changes occur normally, but are benign in the majority of individuals. However, if a secondary insult (e.g., strokes and ischemia, pathological aging) occurs, it can allow these usually benign aging-related changes to manifest more robustly, resulting in abnormal neuronal synchronization (i.e., a seizure). Further, in some subjects these aging-related changes may be more severe, and thus could subsequently contribute to spontaneous seizure generation. This later scenario could contribute to the aging-related increase in idiopathic/cryptogenic epilepsy. There are many other questions regarding geriatric epilepsy that are currently unanswered and are clinically very important; for example, why do seizure characteristics (behavior and EEG activity) change with age?

Background

The rationale for our central hypothesis is based on data from numerous laboratories that have studied the neurobiology of aging. These studies revealed that a myriad of physiological factors that can affect neuronal synchronization and excitability are altered with age. For example, changes have been reported in: (1) dye coupling (i.e., an anatomical change that could represent an increase in electrotonic coupling), (2) extracellular volume, (3) synaptic connectivity, (4) receptor and channel properties, (5) the number and/or functionality of specific types of neurons, (6) potassium and calcium buffering, and (7) the efficacy of neuromodulatory systems. Many of these changes appear to be proconvulsive in nature (e.g., decreased extracellular volume, decrease in the number of glutamic acid decarboxylase immunoreactive neurons), while others appear to be antiepileptogenic (e.g., increased afterhyperpolarization, decreased NMDA receptor-mediated efficacy/activity). However, minimal research has focused on determining the net effect of all these aging-related changes on seizure susceptibility, or how each specific aging-related change affects neuronal synchronization and excitability.

To date, in vivo and in vitro studies examining age-related susceptibilities to epileptiform activity have described apparently contradictory findings (**Table 1**). For example, while repetitive afferent stimulation in vivo (kindling) leads to prolonged afterdischarges in aged animals, the rate of kindling is retarded. Further, while aged animals are more susceptible to systemic kainate treatment, they are more resistant to nicotine-induced seizures. These examples illustrate the need for caution when interpreting data, since the various manipulations used to induce epileptiform activity can activate different neuronal networks, resulting in different types

Table 1 The effect of aging on convulsant induced epileptiform activity

Proconvulsive stimulus	*Affect of Age*
In vivo	
Electroshock	Increased threshold for minimal and maximal evoked seizures in BDF1 mice
Electrical stimulation/ kindling	Discharges are of longer duration; propagation to contralateral side is increased; however rate of kindling is slower
Kainic acid	Decreased threshold; preseizure behavioral manifestations are exacerbated; shorter latency to onset for all classes of seizures/ status
Nicotine	Delayed onset; seizures are abbreviated
Pilocarpine	Decreased threshold
Pentylenetetrazol (PTZ)	Threshold in mice is increased; in rats, a higher incidence and longer duration of generalized convulsions can occur; whether seizure onset differs in rats is controversial
Strychnine	Increased sensitivity and increased mortality
Aminooxyacetic acid (AOAA)	Decreased responsiveness; threshold for convulsions is higher
In vitro	
Zero-Mg^{2+}	Spread and conduction velocity of epileptiform activity is decreased
4-aminopyridine; 4-AP	Spread and conduction velocity of epileptiform activity is decreased
Kainate	Reduced threshold and longer duration events
Repetitive stimulation	Increased susceptibility for generating epileptiform activity in hippocampal slices
Bicuculline	Increased susceptibility for paroxysmal depolarizing shifts in dentate granule cells

of seizures (e.g., complex–partial versus generalized) that involve different mechanisms. In this regard, aging does not affect all types of seizures comparably. For example, while complex–partial seizures are observed commonly in the aging clinical population, generalized seizures are uncommon. Additionally, the underlying mechanism(s) whereby a specific treatment elicits seizure activity may be altered with age in either a pro- or anticonvulsive fashion. Thus, it is not surprising that the rate of kindling and the rate of propagation of epileptiform activity in vitro (in zero-Mg^{2+} artificial cerebrospinal fluid) are retarded in aging animals, since aging is associated with a decrease in NMDA receptor-mediated activity.

Methods and Results

In Vivo Electrophysiology: Susceptibility to Kainate-Induced Seizures and Status Epilepticus

In our laboratory we chose to focus on how aging affects the susceptibility to kainic acid-induced seizure/status epilepticus, since: (1) aging humans also exhibit increased susceptibility to kainate analogs (i.e., domoic acid) and (2) the hippocampus, which is often associated with complex–partial seizures, is highly susceptible to kainate. Additionally, previous studies report that aged rats (>20 months), compared to adults, were more likely to: (1) generate generalized seizures at lower doses of the convulsant and/or (2) display a shorter latency to the onset of stereotypical behaviors associated with nongeneralized seizure activity. While these findings are consistent with aged rodents exhibiting an enhanced seizure susceptibility, such data are not straightforward since generalized seizures do not directly reflect temporal lobe activity, and the stereotypical behaviors associated with complex–partial limbic seizures (wet-dog shakes, head bobbing, teeth gnashing) are difficult to identify accurately with behavioral monitoring if concurrent EEG recordings are not performed. Consequently, experiments were performed to examine the behavioral and electroencephalographic progression of seizures and status epilepticus in adult and aged Fischer 344 rats, using a modified repetitive-kainate treatment protocol coupled with concurrent video and EEG monitoring. These studies revealed that aged rats, compared to adults, exhibit: (1) a greater propensity for wet-dog shakes, a behavior that requires dentate and limbic activation, (2) a shorter latency to onset for all classes of seizures/status epilepticus, including those associated with limbic activation, and (3) a reduction in the power of higher frequency EEG activities (12.5–35 Hz) during the progression of kainate-induced status. These findings are consistent with conclusions from earlier studies, that aged subjects have an enhanced susceptibility to kainate-induced complex–partial seizures and that the temporal lobe may become more epileptogenic with age. Furthermore, the change in EEG activity could reflect a change in network dynamics associated with seizure onset and susceptibility. In addition to the finding that aging affects the susceptibility to kainate-induced seizures, several groups have recently demonstrated that the consequences of kainate-induced status are also dramatically altered with age. For example, aged rodents exhibit a greater degree of cell loss and oxidative stress following kainate-induced status than adult animals. Additionally, the level of status-induced gene expression (e.g., for voltage gated calcium channel subunits) may also be altered in aging animals.

In Vitro Electrophysiology: Susceptibility to Kainate-Induced Epileptiform Activity

Conclusions that can be drawn from these in vivo studies are limited, however, since the relative contribution of aging-related changes in pharmacokinetics (i.e., altered blood–brain barrier, renal clearance) versus pharmacodynamics (altered CNS network activity) cannot been delineated. Subsequently, additional preliminary in vitro experiments were performed to assess whether the intrinsic capacity of the aged CNS (hippocampus) to generate epileptiform activity is increased. In one series of experiments, we examined whether the concentration of kainate required to elicit spontaneous and evoked epileptiform activity differed in hippocampal slices from adult (6–8 months) versus aged (22–30 months) Fischer 344 rats. Field potential recordings were obtained in stratum pyramidale of CA3 while sequentially increasing kainate concentrations (12.5–100 nM) were applied. Hippocampal region CA3 was examined in this study due to its high susceptibility to kainate-induced epileptiform activity. These experiments revealed that lower kainate concentrations were required for the generation of evoked and spontaneous epileptiform activity in slices from aged animals. Moreover, when the characteristics of the spontaneous epileptiform events were compared between groups (at 50 nM, a kainate concentration that elicited epileptiform activity in an identical percentage of aged and adult slices), aged slices exhibited longer duration discharges. Additionally, preliminary data from power spectral and wavelet analyses revealed that dramatic difference also exists in the power and time course of certain spectral components during an epileptiform discharge (**Figure 1**). These preliminary data suggest that network dynamics may differ between age groups during the generation of epileptiform activity and illustrate the need for more rigorous quantitative analysis. Taken together, these in vitro experiments suggest that aging-related pharmacodynamic changes in the hippocampus contribute to both the increase in susceptibility to kainate-induced seizures in vivo, and (potentially) to the differences in EEG

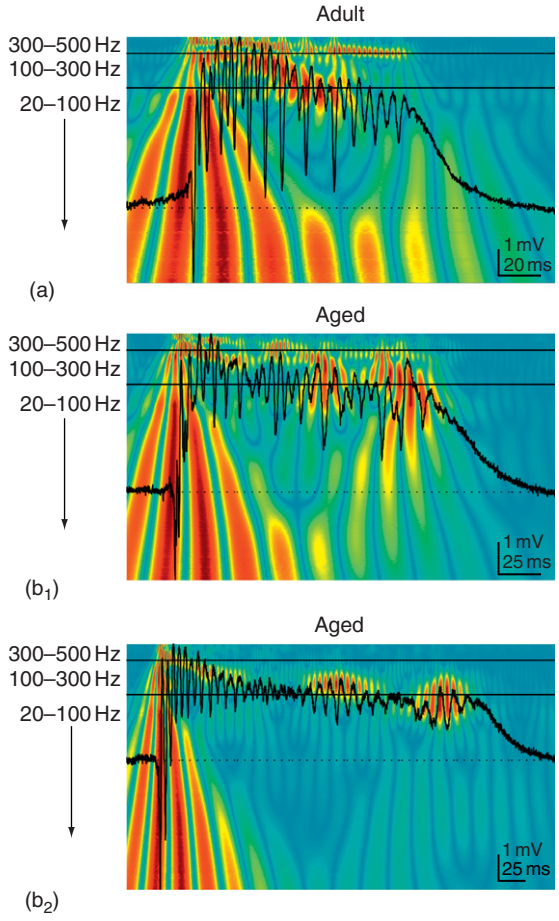

Figure 1 Preliminary time-frequency analysis indicates marked differences in both the time course and composition of the spectral components of epileptiform discharges in a subpopulation of aged slices compared to adults. Shown are representative scalograms from continuous wavelet transforms of individual discharges from adult and aged F344 rats. (a) In the adult, robust high frequency oscillations (HFOs > 200 Hz) are prominent throughout the course of the discharge. (b_1) A subset of aged slices shows a similar profile of HFOs. (b_2) However, in the remaining slices from aged rats, HFO activity is dramatically reduced during an epileptiform discharge.

characteristics. Since kainate activates both glutamatergic and GABA-ergic networks, these results are likely to reflect an aging-related change in the balance of excitatory/inhibitory circuits in the hippocampus, the net effect of which reflects the extent to which these local circuits are activated. Whether aging-related changes in pharmacokinetics (renal clearance and blood–brain barrier permeability) also contribute to the in vivo phenomenon cannot be ruled out and requires further investigation.

In Vitro Electrophysiology: Dentate Gating

In addition to these in vitro kainate studies, we were interested in determining whether more physiological manipulations could also reveal an enhanced susceptibility to epileptiform activity in the aged CNS. For these experiments, hippocampal slices from adult and aged Fischer 344 rats were used. A stimulating electrode was placed in the molecular layer of the dentate gyrus to activate the perforant path and field potential activity was monitored in stratum pyramidale of CA3 in order to assess whether the flow/propagation of neuronal activity through the entorhinal–dentate–CA3 pathway was altered. Several groups have shown that a disruption in the capacity of the dentate gyrus to gate/filter afferent activity impinging onto the hippocampus is associated with converting a normal hippocampus into an epileptic one. In this regard, recent data indicate that the aged dentate appears to be hypometabolic, a condition also observed in patients with temporal lobe epilepsy where dentate gating is thought to be altered.

After an initial characterization of this pathway with single stimuli, a 5-Hz stimulus train (10-s duration) was delivered to the molecular layer with evoked activity monitored during and after the train. As shown in **Figure 2**, slices from adult rodents and the majority of the slices from aged rats exhibited minimal change in field potential activity during the train; only small amplitude (<1 mV) secondary and/or tertiary population spikes were occasionally seen. In contrast, in 30% of the aged slices, prolonged field postsynaptic potentials were generated that were superimposed with significant population spike activity (population spikes >1 mV). These events resembled interictal-like epileptiform activity (**Figure 2**). Moreover, when spontaneous activity was monitored in slices following the train, nearly all of these hyperexcitable aged slices generated interictal-like discharge (**Figure 2**); either no spontaneous activity or only small amplitude positive field potential shifts (that were typically devoid of superimposed activity) were observed in slices from adult animals and the remaining aged animals. Thus, it appears that the propagation of information through the dentate gyrus is altered in a proconvulsive manner during aging in some animals, and can result in the generation of epileptiform activity in hippocampal region CA3.

This finding is fascinating since the percentage of aged rats that exhibited epileptiform activity following molecular layer stimulation is similar to that of aged animals with cognitive decline. It is plausible that a decline in dentate gating function can result in the generation of epileptiform activity in CA3 of aged subjects. Since the entorhinal-dentate-CA3 pathway is involved with the encoding of afferent input, such aberrant activity could potentially interrupt the processing of novel information. In this regard, it is interesting to note that place cell recordings in rodents report a preferential increase in basal activity in CA3 of aged animals with cognitive decline, as compared to adult and aged cognitively intact animals. It is possible that the aberrant activity we observe in hippocampal slices from a subpopulation of aged rats could be an in vitro correlate of this

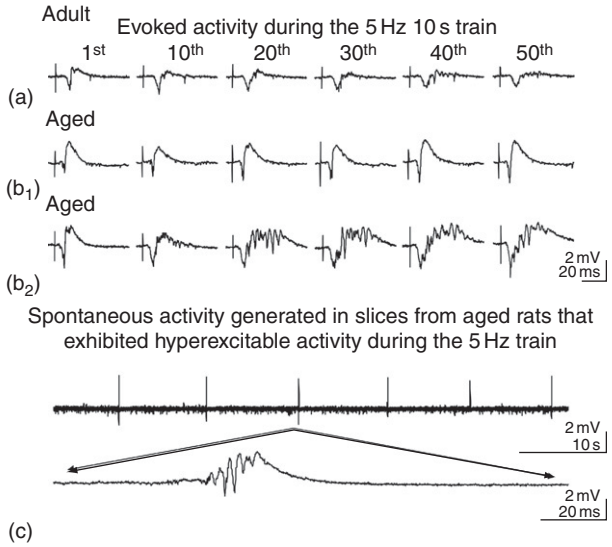

Figure 2 In a percentage of aged slices, the capacity of the dentate to filter afferent input is altered. (a) In slices from adult Fischer 344 rats, repetitive stimulation in the molecular layer of the dentate elicited minimal change in the field potential response of CA3. (b_1) The majority of slices from aged rats exhibited a similar response to 5 Hz stimulation as was observed in adult slices. (b_2) However, in approximately 30% of aged slices multiple population spikes evolved in CA3 during the train. (c) Further, nearly all of the aged slices that exhibited hyperexcitable activity during the 5-Hz train developed spontaneous interictal like events.

in vivo phenomenon. Experiments are currently underway in our laboratory to assess this possibility and determine the relative contribution of aging-related changes in the dentate gyrus and CA3 to this decline in dentate gating during aging.

In Vitro Electrophysiology: Intrinsic and Synaptic Properties of Dentate Granule Cells

To examine whether aging-related changes in dentate physiology contribute to the breakdown in dentate function, experiments were performed using field potential and whole cell patch recordings in slices from adult and aged Fischer 344 rats. Field potential recordings revealed comparable responses to single and paired lateral perforant path stimuli (10–100 ms interpulse interval) in both age groups. In contrast, repetitive stimulation at 5 Hz for 10 s revealed a dramatic aging-related difference. Specifically, while the slices from adult animals and the majority of the slices from aged animals (60%) exhibited a suppression of population spike amplitude during the train, the remaining 40% of the slices from aged animals generated hyperexcitable activity consisting of multiple population spikes. This response pattern was seen in almost the same percentage of aged animals that exhibited epileptiform activity in CA3 during and after molecular layer stimulation, and thus further supports the contention that dentate gating is compromised with age.

While the properties that underlie the capacity of the dentate to filter afferent input are unclear, several factors are likely to be involved. First, granule cells have a relatively hyperpolarized membrane potential and strong spike frequency adaptation. Second, the dentate gyrus has an extensive inhibitory system and a paucity of recurrent excitatory interconnections. Third, there exists a unique relationship between the mossy fibers (granule cell axons) and the CA3 region; the axons of the granule cells preferentially synapse onto inhibitory (versus excitatory) neurons in CA3. Given these possibilities, we examined whether the intrinsic and/or network properties of the dentate granule cells change with age. In general, the intrinsic membrane properties that we examined were preserved, including resting membrane potential, action potential width, time constant, and input resistance. Further, paired-pulse field potential recordings and whole cell recordings of polysynaptic evoked inhibitory postsynaptic potentials in granule cells suggested that the efficacy of short-loop feedback inhibition – provided by the basket and chandelier interneurons – was not significantly altered. In contrast, a decrease was noted in the frequency of spontaneous inhibitory postsynaptic potentials, which was interpreted to reflect a decrease in the degree of inhibitory input onto the distal dendrites of dentate granule cells. This phenomenon could, in part, explain the change in responsiveness of the aged dentate gyrus to 5 Hz lateral perforant path stimulation. Specifically, the interneurons that project onto the distal dendrites of granule cells are localized in the dentate hilus and become activated by the granule cells following afferent input. In turn, these interneurons release GABA onto the distal dendrites of granule cells; this effect would be expected to decrease input resistance and thereby shunt/suppress subsequent afferent input. If this 'long-loop' feedback inhibitory circuit in the dentate is impaired, repetitive afferent input could summate in granule cells and elicit a hyperexcitable response. In agreement with these electrophysiological findings, anatomical data on the dentate gyrus of aged rats indicate that a subclass of interneurons in the hilus is either decreased in number or exhibits a decline in glutamic acid decarboxylase (GAD) levels which could dramatically affect interneuron function since GAD is the major enzyme involved with GABA synthesis. Further, this affected subclass of interneurons (which appear to include those that contain somatostatin and/or neuropeptide y) can regulate afferent input and have been proposed to play a major role in information processing. This subclass of interneurons has also been reported to be lost and/or decreased in number in temporal lobe epilepsy. Ongoing experiments in our laboratory are focusing on understanding the mechanisms associated with this decrease in inhibitory tone.

In addition to observing aging-related changes in inhibition in the dentate gyrus, our experiments revealed that

the degree of recurrent excitatory interconnections also was enhanced with age. Specifically, following disinhibition (the $GABA_A$ receptor antagonist bicuculline was added to the bathing medium), aged granule cells preferentially exhibited prolonged large amplitude excitatory postsynaptic potentials that resembled epileptogenic paroxysmal depolarizing shifts (PDSs). Although the exact cellular players contributing to this aberrant circuit are unknown, current source density studies indicate that hilar stimulation can elicit an additional inward current flow in the vicinity of the inner molecular-granule cell layer – a location which is consistent with the presence of an additional excitatory input. Further, several studies suggest that mossy fiber distribution can change with age. While additional experiments are required to identify the cellular players that are involved with creating this novel recurrent excitatory activity, these data indicate that the balance of excitation vs. inhibition is disrupted during aging. These changes are likely to contribute to the aging-related decline in dentate gating function and subsequently could result in enhanced seizure susceptibility and potentially a decline in cognitive function.

Future Directions

The experimental data presented in this article support the hypothesis that proconvulsive changes occur normally in the CNS during aging and can contribute to an enhanced susceptibility for epileptiform activity in the hippocampal formation. However, whether such aging-related changes also contribute to the increased incidence of symptomatic geriatric epilepsy is unclear. What data are available on this question come from a thrombosis study, using the photosensitive dye rose Bengal to induce experimental infarcts. These experiments revealed that while all postmature Fischer 344 rats can develop seizures, regardless of age or infarct location, aged animals were more likely to develop seizures following a comparable insult than adults. This scenario could arise if the balance of excitation/inhibition is already altered in aged animals and the ischemic/hypoxic episode further aggravates this balance (e.g., due to a disconnect of excitatory input onto inhibitory interneurons). Additional support for our central hypothesis comes from studies on transgenic murine models of Alzheimer's disease. A number of such models exists that express human amyloid precursor protein with or without other transgenes that express anomalous proteins found in humans with Alzheimer's disease. An increase in seizure susceptibility and/or spontaneous epileptiform activity has been reported in several of these models, and data from at least one model suggest that the increase in seizure susceptibility can occur prior to the development of amyloid plaque deposits (one of the histopathological hallmarks of Alzheimer's disease). If Alzheimer's disease is viewed as 'accelerated aging' as some have proposed, then it is plausible that changes in local neuronal networks arise in these animals at an abnormally early age, and contribute to the change in seizure susceptibility prior to plaque formation. Additional experiments are however required to directly test this possibility. Moreover, as Alzheimer's disease progresses, it is plausible that more detrimental changes arise in local neuronal circuitry which further increases seizure susceptibility.

In future, additional experiments are needed to rigorously test the hypothesis that aging-related changes in local excitatory and inhibitory circuitry underlie the increase in cryptogenic and symptomatic epilepsy in the elderly. These studies can take advantage of the vast array of animal models that exhibit enhanced or decreased life span, as well as models of pathological aging. Further, it will also be critical to examine how aging-related changes in neuronal dye coupling (electrotonic coupling), extracellular volume, ionic buffering, and intrinsic neural properties contribute to the generation of epileptiform activity in models of normal and pathological aging.

Poststroke Epilepsy and the Aged Brain

Kevin M Kelly, Allegheny General Hospital, Pittsburgh, PA, USA

Introduction

The prevalence and incidence of unprovoked seizures and epilepsy increase in the elderly, and first occurrence rates for epilepsy in the elderly are higher than for any other age group. Etiologies associated with this increase include cerebrovascular disease, brain tumors, toxic or metabolic disturbances, dementia, and trauma. Of these etiologies, ischemic cerebrovascular disease is the dominant cause of epilepsy in the elderly, accounting for 25–50% of all cases; approximately 15–20% of the elderly who experience a stroke will develop epilepsy. The most important risk factor for developing epilepsy after an ischemic stroke is the involvement of the cerebral cortex. Lacunar, subcortical, and posterior circulation infarcts are rarely associated with the development of epilepsy. In general, poststroke epileptic seizures are considered focal in onset and frequently arise in close proximity to the area of infarcted tissue. To date, numerous clinical studies have detailed the epidemiology of late-onset epilepsy and have underscored the importance of stroke as the primary cause of new-onset epilepsy in the elderly. In contrast, there is little understanding of the pathophysiological mechanisms of aged brain following stroke that cause or predispose to the development of epileptic seizures. The reason for this poor mechanistic insight is clear-the limited development of standard animal models of poststroke epilepsy.

Background

Despite the longstanding and widespread use of arterial occlusion models of cerebral ischemia to study postlesional pathophysiology, neuroprotection, and functional outcomes, these studies typically have not reported evidence of seizures in lesioned animals. This apparent lack of seizure activity may be related to relatively brief periods of observation (from the time of ischemia to animal sacrifice is typically hours to days), and little or inadequate behavioral monitoring (seizures may occur but be nonconvulsive). Middle cerebral artery occlusion (MCAO) is a standard in vivo large artery occlusion model employed by numerous laboratories to cause focal cerebral ischemia and infarction. MCAO is most commonly performed by insertion of a filament in the artery to cause its occlusion (intraluminal filament model). Another technique, injection of endothelin-1 near the MCA, induces spasm of the artery and resultant ischemia. Similar to MCA-distribution strokes in humans, MCAO can produce a large cortical and subcortical infarct ipsilateral to the occlusion, which is characterized by an infarct core and a surrounding volume of partial cellular injury and death (i.e., the ischemic penumbra). In most rat strains, distal MCAO does not generate a consistent size or distribution of infarct because of the animals' overall vascularity. Importantly, the hippocampus of rats can lie within the region of ischemic injury because it is perfused by the posterior cerebral artery, which can be blocked by MCAO; in humans, the hippocampus is supplied by the anterior choroidal and posterior cerebral arteries, which are typically unaffected by occlusion of the MCA. In order to produce infarction of the cerebral cortex that spares subcortical structures and hippocampus, investigators have used a combination of transient unilateral MCA and common carotid artery (CCA) occlusion (MCA/CCAO). This technique in young Long-Evans rats typically results in moderately large cortical infarcts ($\sim$100 mm^3) of reproducible size and location, while sparing injury to the hippocampus. For these reasons, MCA/CCAO may be a preferred technique for large vessel occlusion applied to the study of poststroke epilepsy.

An alternative to large vessel occlusion models of stroke is the model of cortical photothrombosis, which induces cortical infarcts with reproducible area, depth, and location. The photothrombosis model is based on a class of light-sensitive molecules and the reactions they undergo following photic stimulation. One such molecule is rose bengal, a derivative of fluorescein, which can be injected directly into the circulation. Molecules of rose bengal become excited following absorption of photons (peak absorption, 562 nm), typically activated in brain vasculature in the photothrombosis model by an external light beam that is focused on and penetrates the animal's translucent skull and underlying cerebral cortex. This excitation stimulus results in the transition of the molecules from their ground state to a triplet state. Direct reaction of the triplet state molecules with molecular oxygen creates an excited singlet state species of molecular oxygen; singlet oxygen can directly peroxidize certain cell membrane components, such as unsaturated fatty acids and proteins, and likely cause discontinuities (microruptures) in the endothelia of the pial vasculature thereby triggering platelet aggregation at those sites. These defects promote vasogenic edema, which can compress the underlying cortical vasculature and thereby increase

the size and extent of the evolving infarct. The typical infarct is a sharply circumscribed, wedge-shaped necrotic lesion occupying the entire depth of the cortex. This method is well characterized, relatively non-invasive, produces highly reproducible infarcts, and allows for the selective placement of infarcts in well-defined cortical areas. For these reasons, photothrombosis is an attractive alternative to large vessel occlusion techniques as a means to study poststroke epilepsy.

Methods

Photothrombosis

Photothrombosis of young adult and aged rats is performed after the animals are anesthetized with ketamine and xylazine and placed in a stereotaxic frame. A midline scalp incision is made, and the scalp is retracted laterally. Rose bengal (20 mg/kg) is injected through a catheter into the left femoral vein over 2 min, as the brain is stimulated through the intact skull for 10 min by an argon laser-activated light beam. The laser is turned on immediatedly before the rose bengal is injected. The injected volume is based on the weight of the animal (typically about 250 μl); laser time is based on the half-life of the rose bengal ($\sim$ 6 min). The incident beam is $\sim$5 mm wide and focused 1.8 mm posterior to the bregma and 2.8 mm lateral to the midline, corresponding to the area of the left sensorimotor cortex. The laser stimulation protocol generates cortical infarcts of approximately 25 mm^3. The skull is cooled by continuous airflow from a fan to prevent heat-mediated tissue injury. Body temperature is monitored and maintained at 37 °C using a thermoregulated pad. After stimulation, the catheter is removed, and the wound is sutured. Animals receive a subcutaneous injection (5 ml) of lactated Ringer's solution immediately after surgery and each day postoperatively until adequate hydration and nutrition are ensured.

MCA/CCAO

Focal cortical ischemia in young adult and aged rats can be induced by transient or permanent occlusion of the ipsilateral MCA and CCA. For transient MCA/CCAO, after surgical exposure of the MCA, a wire is placed underneath it, the artery is then lifted, and the wire is rotated clockwise; the CCA is occluded using atraumatic aneurysm clips. After 3 hours, reperfusion is established by first removing the aneurysm clips from the CCA, and then rotating the wire counterclockwise and removing it from beneath the MCA. Animals that display reduction of cerebral profusion following ischemia, to less than 15% of the pre-ischemic value, typically demonstrate relatively reproducible cortical infarcts in the distribution of the left MCA. The technique of permanent MCA/CCAO is essentially the same as that of transient MCA/CCAO except that the arteries are ligated with silk sutures followed immediately by surgical closure of the animal. Postoperative supportive measures similar to those used in the photothrombosis model are utilized.

Video-EEG

Three recording screws are placed parasagitally, on each side of the skull, to sample neocortical activities symmetrically. Screw placement are: +2.0 mm from bregma/2.25 mm lateral; −3.0 mm from bregma/275 mm lateral; and −7.0 mm from bregma/2.75 mm lateral. Qualitative video-EEG analysis is performed off-line by a complete visual examination of the EEG recordings, and ictal behaviors are classified by a modification of the Racine scale. EEG interictal activities are distinguished from ictal activities based on waveform morphology and frequency, and the associated absence or presence of behavioral change, respectively.

Recent Results

Photothrombosis

Beginning in the late 1990s, our laboratory sought to determine whether a rodent model of cerebral infarction could result in epileptic seizures; at that time, no model of poststroke epilepsy existed. Because large cortical strokes are most likely to be associated with poststroke epilepsy clinically, we wanted to produce large isolated neocortical infarcts (intentionally not including hippocampus so as to keep the analysis as straightforward as possible) that were relatively easy to generate and reliably reproducible in size and distribution. We chose to explore use of the photothrombosis technique - i.e., photochemically-induced cortical thrombosis and brain infarction, using the photosensitive dye rose bengal. In our initial exploratory study, we used photothrombosis to determine whether animal strain or age, or infarct size or location, were critical variables for the development of epileptic seizures. Fischer 344 (F344) rats at 2, 6, 12, 24, and 30 months of age, and Sprague-Dawley (SD) rats at 2 and 6 months of age underwent photothrombosis creating either large or small focal infarcts overlying left hemisphere anterior frontal, midfrontal, frontoparietal, or parietal areas. The consequences of these lesions were analyzed by video-EEG and morphological techniques. Our main finding was that epileptic seizures were recorded in young adult rats ($<$ 2 months of age) 2 months after lesioning the frontoparietal cortex with large photothrombotic infarcts that extended to the cortical-subcortical interface. These seizures were characterized behaviorally by motor arrest and appeared to originate electrically in the peri-infarct area. Small cortical lesions were essentially ineffective in producing seizures.

Importantly, class 3 convulsive seizures (Racine scale) were observed in a small number of 12- and 24-month old animals lesioned with large infarcts in anterior frontal and frontoparietal areas.

Based on the electrobehavioral findings obtained in our initial study, we designed a parallel study to assess potential long-term changes in cortical $GABA_A$ receptors following photothrombosis. Cell death is largely confined to the volume of the wedge-shaped infarct created by photothrombosis (i.e., there is little cell death beyond the margins of this area). Therefore, we were able to examine the entire hemisphere from both sides (each side separately) for this analysis. Using young adult SD animals, hemispheric cortical $GABA_A$ receptor α_1, β_1, and γ_{2S} subunit mRNA expression was quantified by RT-PCR; these studies indicated that large cortical infarcts resulted in a long-lasting differential expression of the subunit mRNAs in ipsilateral cortex; since some animals became epileptic and others didn't, this mRNA expression in ipsilateral cortex was variably associated with the epileptic state. In a subsequent study designed to assess the early time course of cortical $GABA_AR$ α_1 subunit mRNA and protein expression following photothrombosis, we found that $GABA_AR$ α_1 subunit mRNA levels were decreased ipsilateral and contralateral to the infarct at 7 days, but were increased bilaterally at 30 days, whereas $GABA_AR$ α_1 subunit protein levels were unchanged compared with shams; however, at 30 days, $GABA_AR$ α_1 subunit protein expression in lesioned animals was significantly increased within proximal and distal regions of perilesional cortex compared with distal cortical areas contralaterally. Taken together, these exploratory studies suggested that the photothrombosis model could be used confidently to tailor specific neocortical infarcts to study molecular, cellular, and network alterations, such as short- and long-term changes of $GABA_ARs$, as potential formative mechanisms of poststroke epileptogenesis.

Based on the results of our early studies, we standardized our photothrombosis protocol and characterized the electrobehavioral properties of young adult SD rats during 6-month video-EEG monitoring following lesioning of the sensorimotor cortex. We initially focused on young adult animals in order to validate and standardize the model upon which subsequent aging studies are now performed (studies in progress). With our standardized protocol, 50% of lesioned animals developed focal epileptic seizures ipsilateral to the cortical infarct, characterized by rhythmic spike-wave discharges with or without behavioral change; class 4 seizures were observed in 1 lesioned and 1 naïve control animal as well. Epileptic animals demonstrated increased delta, theta, and low beta range power ipsilateral to the infarct that reliably distinguished them from lesioned nonepileptic and control animals. In a follow-up study, we used neuropeptide Y (NPY) protein expression to assess anatomical changes in the brains of both epileptic and nonepileptic animals after the 6-month monitoring period, and found that lesioned epileptic animals with frequent seizure activity demonstrated significant increases of NPY protein expression in the cortex, CA1, CA3, hilar interneurons, and in granule cells of the dentate gyrus. Additionally, activated astroglia were detected in the cortex and hippocampus of animals exhibiting seizure activity. In general, NPY protein expression and morphological changes after cortical photothrombosis were region- and pathological state-dependent, indicating that significant anatomical changes extended beyond the lesioned cortex in epileptic animals. These observations confirm at least histological evidence of hippocampal involvement; preliminary EEG monitoring with depth electrodes suggest that seizure activity (e.g., class 2 and 3 seizures) is of limbic origin.

In a recent study by a different group, late seizures were assessed in adult Sprague-Dawley rats following photothrombosis. Video-EEG recordings were obtained around-the-clock for 7 to 14 days, at 2, 4, 6, 8, and 10 months post-lesioning. They recorded convulsive seizures in 18% of lesioned animals, with an average seizure frequency of 0.39 seizures/day and a mean seizure duration of 117 seconds. Latencies to the first recorded seizure ranged from 71 to 297 days. Histological analysis of lesioned brains revealed that infarct depths varied from cortical layer I to VI in epileptic animals; epileptic animals demonstrated light mossy fiber sprouting in the inner molecular layer of the dentate gyrus, both ipsilateral and contralateral to the lesion. These findings provided clear evidence of convulsive seizure activity that developed over long periods of time following cortical photothrombosis and were associated with anatomical changes in the hippocampus, similar to changes observed in models of status-epilepticus-induced limbic epilepsy. These results have substantially extended the findings from previous studies of the photothrombosis model and provide clear justification for continued use of the model to explore mechanisms of poststroke epileptogenesis. Because of the aging-related findings obtained in our initial study using the photothrombosis model, ongoing studies have been designed to use young adult and aged F344 rats to determine whether age is a critical or contributing factor in generating epileptogenesis after lesioning. **Figure 1** demonstrates use of an argon-activated laser beam to generate a cortical infarct in an aged animal.

Arterial Occlusion Models

Recent studies using young SD rats and video-EEG recordings have shown that multiple ipsilateral or generalized electrographic seizures (provoked seizures from the acute effects of lesioning) could be recorded within the first 2 hours following transient intraluminal filament-induced MCAO without change in the animal's behavior. In separate studies, using similar techniques adapted to long-term recordings, lesioned young animals

were monitored up to 1 year post-lesioning; these animals did not show evidence of either EEG or behavioral seizures. However, a subsequent study using endothelin-1-induced MCAO demonstrated epileptic seizures in 1 of 26 lesioned animals, associated with an infarct of the ipsilateral basal ganglia. To date, no study using the MCAO model has demonstrated evidence of reproducible poststroke epilepsy.

Over the last several years, our laboratory has sought to develop an arterial occlusion model of poststroke epilepsy.

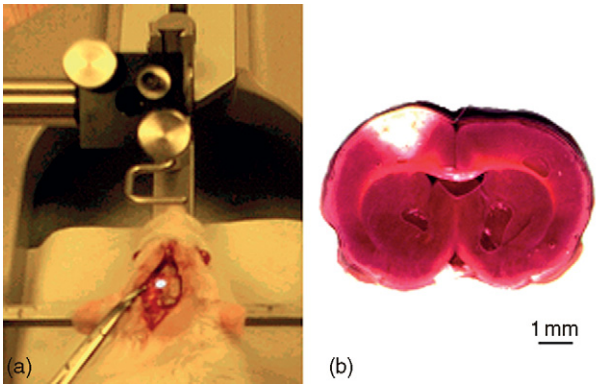

Figure 1 Photothrombosis. (a) Placement of an argon laser beam on the exposed skull of a rat overlying the left sensorimotor cortex. (b) TTC-stained coronal slice of brain performed 24 hr after lesioning of a 20 mo old animal. From Kelly (2006).

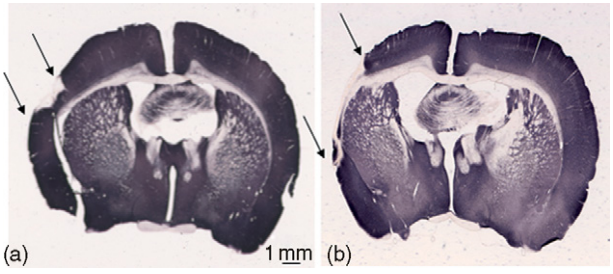

Figure 2 MCA/CCAO. MAP-2 immunostained coronal sections of a 4-month old (a) and a 20-month old (b) animal 2 months after lesioning. Arrows demarcate a smaller infarct in (a) compared with (b). From Kelly (2006).

Our efforts were guided, in part, by the results of previous studies using MCAO. Our initial study consisted of MCA/CCAO and sham-operation in young Long-Evans rats, followed by intermittent video-EEG monitoring for 6 months. Disappointingly, these studies failed to demonstrate poststroke epilepsy in any animal. Because of this result, and similar to our ongoing studies using the photothrombosis model, current studies in our laboratory using the MCA/CCAO model have focused on a comparison among 4-, 12-, and 20-month old F344 rats to determine whether age is a critical or contributing factor in generating poststroke epilepsy. Figure 2 illustrates cortical infarcts created by the MCA/CCAO technique; infarct morphometry indicates a trend to larger infarct volumes in aged animals compared with young adult animals. Figure 3 demonstrates a class 5 seizure in an aged animal followed by sudden death (probably caused by cardiorespiratory failure during the prolonged seizure.

Future Goals

Animal models of cerebral ischemia have had relatively limited development for the study of epileptogenesis and the epileptic state. Goals and challenges for the future broadly include: 1) elucidation of the elements of available experimental models that are necessary and sufficient for them to work reliably for the study of poststroke epilepsy; 2) development of new and improved animal models; and 3) bringing new investigators into the field of study. Basic methodological issues that require exploration and refinement for an improved understanding of poststroke epileptogenesis include the role of: 1) critical brain areas for ischemia/infarction; 2) animal age; 3) MCAO with or without CCAO, and transient vs. permanent occlusion; and 4) different types of recording techniques (e.g., depth, epidural, or skull electrodes, and cabled vs. telemetry systems). Advances in these areas will enable and inform more focused studies to determine: 1) the principal elements of lesion-induced network changes; 2) how excitatory and inhibitory neurotransmission changes during epileptogenesis; 3) the functional

anatomy of seizure initiation and propagation; and 4) the electrobehavioral properties of a potentially dynamically evolving epileptic state.

Anticonvulsant Drugs as Neuronal Network-Modifying Agents

Introduction

Despite decades of research, it is still not really understood how anticonvulsant drugs act to control epilepsy. The action of anticonvulsants on neurons observed in vitro likely contributes to the ability of anticonvulsants to prevent seizures. However, exactly how to translate these findings from the dish (in vitro) to the intact brain is problematic. One reason for this quandary is that the mammalian brain contains billions of neurons, and a true

understanding of the complexity of drug action requires studying the intact brain. It is now agreed that neuronal networks play important roles in seizures, including those seizures that were considered to be strictly localized (focal) in nature. Neuronal networks in the intact brain have the capability to exhibit 'additional' properties that arise from neuronal interactions between nuclei within the network. These 'new' properties that arise from the intact network are called 'emergent properties,' and recent findings indicate that anticonvulsant drugs can act selectively on these properties to exert their therapeutic effects. Therefore, CNS drugs – including those agents that are currently classified as anticonvulsants – are well described as '*neuronal network-modifying agents*.' A major reason for proposing such a new drug classification is that many anticonvulsants are also effective in chronic pain disorders and certain psychiatric disorders, such as anxiety and mania, as well as epilepsy. Each of these disorders involves neuronal networks in the brain.

Background

Approaches to Understanding CNS Drug Mechanisms

Early in the development of CNS drugs, investigators realized that most agents exert therapeutic effects by selective actions on neurons in a specific brain site rather than by acting globally on all neurons. An example of this neuropharmacology paradigm is the theory that sedative-hypnotic drugs produce sleep by selective actions on the brainstem reticular formation, a wakefulness center. This theory has not been disproved. However, it was superseded by a new paradigm, based on the fact that most CNS drugs affect neurotransmitter receptors or ion channels, which consist of several distinct subunits. Receptors and channels consist of different subunit combinations that are distributed differentially in different brain nuclei. The current neuropharmacology paradigm indicates that drugs interact most strongly with specific subunit combinations and exert their effects on the brain regions that contain a high concentration of neurons expressing that specific subunit combination. However, many of the reported selective subunit effects of drugs have been hard to confirm, and the therapeutic relevance of subunit selectivity remains to be established. An example is the anticonvulsant drug, gabapentin, which selectively affects a specific subunit combination in Ca^{2+} channels (P/Q type) in spinal cord neurons in vitro. This selective targeting has not been consistently confirmed, however, and no effect was observed on the same type of Ca^{2+} channel in hippocampal neurons in vitro. One possible reason for these inconsistencies is that neurological and psychiatric diseases are mediated by neuronal networks rather than single CNS neurons. Networks of neurons have additional emergent properties at which drugs can potentially act – properties that may not be present on the same neurons in vitro.

Network Perspective on Brain Function

The complex functions of the CNS involve distributed neuronal networks. For example, a network has been identified that mediates normal locomotion. New neuronal network connections can be formed to support increased brain function, as seen in learning. Many brain malfunctions involve disrupted neuronal network functions, as in Parkinson's disease. Other brain malfunctions are due to the formation of abnormal neuronal networks, for example mossy-fiber sprouting that occurs in some forms of epilepsy.

Neuroanatomy provides knowledge about the connections between brain neurons, but a neuronal network differs from the neuroanatomy of a pathway. Functional studies indicate that many anatomical connections, when activated physiologically, only result in subthreshold responses. These subthreshold responses can reach threshold under pathophysiological conditions, resulting in the creation of a specific disease network. Such findings have led to the idea that CNS diseases are largely governed by what could be termed the 'Law of Conservation of Networks.' That is, pathophysiology of CNS diseases may involve abnormal interactions between existing networks. For example, audiogenic seizures (AGS), as described later, involve the normal auditory network interacting abnormally with the normal network for locomotion to produce the motor (convulsive) seizure. Thus, the convulsion is in response to over-stimulation of the auditory pathway, which extensively activates the locomotor network that is only minimally activated under normal conditions (such as the acoustic startle response). Many mechanisms are known to control network function (**Table 1**).

Networks in Epilepsy

As noted earlier, all forms of epilepsy involve a distributed epileptic network rather than abnormal neurons in one brain location. This view is based on studies of small networks in vitro, animal models of temporal lobe epilepsy, human intracranial EEG, and human and animal brain imaging. Imaging is one of the currently most useful approaches to networks. However, the minimum time scale that is achievable with imaging is too great to observe brain changes that occur during a seizure, which is itself relatively brief. Imaging does not indicate the nature (inhibition or excitation) of neuronal firing changes, which are the critical events underlying elaboration of the seizure. Although imaging is very useful to indicate brain changes associated with neurological or psychiatric disease, imaging data do not tell us if the

observed changes are essential, ancillary, or compensatory to the disease process, nor can it be determined if the observed changes are excitatory or inhibitory. Direct observation of neuronal firing changes, recorded with extracellular microelectrodes in behaving animals, that occur before and during the seizure provides a millisecond time scale of events, and provides details about the presence of excitation or inhibition during the seizure – thus allowing observation of the dynamic function of a network. The effects of drug treatments have also elucidated mechanisms of network function in epilepsy.

Current Classification of Anticonvulsant Drug Mechanisms

The current mechanisms of anticonvulsant drug action, which were largely determined in vitro, include effects on neurotransmitter receptors or ion channels primarily. Enhancement of the inhibitory action of γ-aminobutyric acid (GABA) at $GABA_A$ receptors is thought to contribute in a major way to the anticonvulsant effects of barbiturates, benzodiazepines and tiagabine, and this action may contribute to the anticonvulsant effects of valproic acid and gabapentin. Block of sodium channels is another important anticonvulsant drug mechanism for phenytoin, carbamazepine, oxcarbazepine, and lamotrigine. Antagonism of specific types of calcium channels is another mechanism of anticonvulsant drug action, including ethosuximide and gabapentin. Blockade of glutamate receptors has also been observed with barbiturates, felbamate, and lamotrigine. Many anticonvulsant agents exert multiple actions at the single-cell level. However, the actions of these anticonvulsants have had minimal evaluation in seizure networks, and the limited seizure network research that has been done has shown differential effects on neurons within specific nuclei of the associated networks. Such differential effects may be particularly relevant to therapeutic mechanisms when the doses given to the intact animal do not greatly exceed those required to produce anticonvulsant effects (in the same animal). By limiting the doses, the nontherapeutic (adverse) effects that are exerted by all anticonvulsants in excessive doses are reduced or eliminated, as discussed later.

Audiogenic Seizures

Seizure models in animals have played a key role in the discovery of all antiepileptic drugs. In vitro testing *cannot* replace animal models, because it cannot model the entire spectrum of pharmacodynamic actions required for seizure blockade, does not provide information about the pharmacokinetics that occur in intact organisms, and avoids toxicological effects that may be induced in the intact animal.

A few animal models have well-established neuronal networks. These include an induced model of epilepsy – electrical kindling, which is a model of temporal lobe epilepsy produced in normal animals by repeated electrical stimulation in sites such as the amygdala. Genetics plays a major role in a number of human epilepsies, and in several animal models – e.g., genetically absence-prone rats (GAERs), which model absence epilepsy, and genetically epilepsy-prone rats (GEPRs) and Wistar audiogenic rats (WARs), which model generalized convulsive seizures. (GEPRs discussed below are the severe seizure strain (GEPR-9s), and work done in the moderate seizure strain (GEPR-3) is not included here.) GEPRs are abnormally sensitive to many seizure induction methods, including those evoked by loud sounds; such seizures are called AGS. There are many different rodent forms of naturally-occurring AGS, and several gene knockout mouse strains also exhibit AGS susceptibility. AGS susceptibility can also be induced in previously nonsusceptible rodents with a variety of treatments, including withdrawal from ethanol in ethanol-dependent rats. In all forms of AGS, high-intensity acoustic stimulation results in ictal behaviors that include wild running, clonus, and/or tonus, followed by postictal depression of behavior (much like that seen in generalized tonic–clonic seizures in humans). In human epileptic patients, generalized clonus and tonus occur, but these convulsions are rarely evoked by acoustic stimuli, although they may be evoked by visual stimuli. This sensory difference between humans and rodents may be due to the fact that rodents, unlike humans, are nocturnal and rely less than humans do on the visual system. Many anticonvulsant drugs have been developed using AGS models, and the anticonvulsant effect of levetiracetam was initially observed in an AGS model but not in the standard models.

Neuronal Network for AGS

AGS models provide very specific experimental advantages for network determination and functional studies. There is exact stimulus control – especially of intensity, which allows external control of seizure induction and the ability to evaluate responses to stimuli that are below and above the seizure threshold. Research on the neuroanatomy and neurophysiology of the auditory system is well developed. This established background can be readily applied to AGS, including potential candidate sites within the auditory pathway to evaluate for involvement in AGS as well as computer analysis methods for evaluating neuronal responses. A list of methods that are being used to evaluate neuronal networks is found in Table 2. The methods primarily emphasized in the author's lab are discussed here.

Methods

Chronic Surgical Implantation

An anesthetized rat is implanted stereotaxically with a cannula guide tube or microwire implant in the nuclei of interest. An antibiotic is given to minimize postoperative infection.

Focal Microinjection

One week after surgery, the rats are tested for AGS susceptibility, using an electric bell ($\geq$100 dB sound pressure level (SPL)) in a sound-attenuating chamber. One day later, the cannulae are inserted, and vehicle or active drug (in a volume $\leq$ 1 µl) is infused, using a microsyringe and infusion pump. AGS susceptibility is tested at appropriate times based on the drug's pharmacokinetics.

Extracellular Neuronal Responses

The microwire electrode assembly consists of a connector attached to several 13-µm diameter insulated tungsten wires. One week after implantation, neuronal firing in a nucleus is recorded from the rat, maintained in a clear plastic cylinder inside a sound-attenuating chamber. Tone burst stimuli (12 kHz, 100-ms duration, 5-ms rise–fall, at 0.5- or 1-Hz stimulation repetition rates) are presented. Neuronal firing in response to acoustic stimuli is recorded initially at intensities below that which will initiate AGS and then at seizure-inducing parameters. Neuronal firing and behavior are videotaped (split-screen) simultaneously during AGS. The data prior to AGS are analyzed using computer-based single unit discrimination methods to isolate recordings with a ratio of $\geq$3 to 1 to the background activity. The data are analyzed using post stimulus–time histograms, and quantified neuronal firing changes are statistically compared.

Chronic neuronal recordings are instituted after a network site is putatively identified using imaging techniques and/or focal microinjection to determine whether blockade of the site affects AGS. This assessment involves microinjecting an inhibitory substance, such as a $GABA_A$ receptor agonist or a NMDA receptor antagonist. If the results of this treatment indicate that the seizure can be reduced or blocked reversibly with such drugs, this site will be evaluated in other ways, including electrical stimulation and/or microinjection of an excitatory substance (such as a $GABA_A$ receptor antagonist or an excitatory amino acid receptor agonist) to mimic network activation. If the latter approaches render a normal animal susceptible to the seizure, this result is interpreted to confirm the importance of the structure as a requisite part of the seizure network.

The AGS is triggered using pure tone stimuli at 12 kHz, which is the most sensitive frequency for seizure induction in rats. The use of acoustic attenuators precisely controls stimulus intensity, which allows the neuronal responses to acoustic stimuli below the threshold for seizure induction to be evaluated (since only high intensities trigger seizures). The animals are not anesthetized, which is important since anesthetics significantly alter network properties and can prevent seizures. The neuronal response changes and simultaneous behavior changes are observed before, during, and after seizure. The convulsive seizures in GEPRs exhibit a stereotypical pattern of wild running followed by tonus, and culminate in tonic hind-limb extension (TE); the convulsive behaviors are rated using the seizure severity scale of Jobe. Extracellular neuronal recording in awake, behaving rats indicates if the neurons in a given site, which was previously implicated in the AGS network, change their activity associated with convulsive behaviors. If the results of this experiment suggest an important role of this structure, in vitro experiments on this site are evaluated.

Table 2 Methods of seizure network identification

Anatomical studies (e.g., c-fos, 2-deoxyglucose imaging)

Chronic neuron electrophysiology & behavior in vivo
Combined stimulation and neuronal recording in network sites in vivo
In vitro patch or sharp intracellular recordings to determine cellular mechanisms

Recent Results

Establishing Inferior Colliculus as the Consensus AGS Initiation Site

An example of the earlier-mentioned evaluation of a network site is the experimentation done on the inferior

colliculus (IC) in AGS. A consensus has been reached, through the work of a number of laboratories, that the IC plays a critical role as the site for seizure initiation of AGS. The consensus is based on the application of a variety of techniques (described earlier) in the most thoroughly studied AGS models, GEPRs, and WARs, and also in normal rats made susceptible to AGS during ethanol withdrawal. The major defect that leads to AGS susceptibility in GEPRs is the reduced effectiveness of GABA-mediated acoustically-evoked inhibition in IC neurons. This reduced inhibition allows high-intensity acoustic stimuli to overdrive IC neurons, which in turn results in excess activation of neurons in sensorimotor brainstem sites to which the IC projects (deep layers of superior colliculus (DLSC), periaqueductal gray (PAG), and pontine reticular formation (PRF)) (**Figure 1**). Thus, excessive activity in the normal auditory network abnormally activates the locomotor network, which projects to the spinal cord and produces the convulsive behaviors.

Neuronal responses to acoustic stimuli in each of the AGS network sites in GEPRs are significantly greater than in normal animals, even in response to stimuli below the seizure threshold (**Figure 2**). The firing patterns of neurons in the AGS network during the seizure change dramatically in each site. However, the patterns are consistently different in each site, as the seizure progresses, depending on the type of convulsive behavior that is occurring.

AGS Network Hierarchy

Neuronal recording studies indicate that the seizure network operates hierarchically during AGS; that is, intense activation of each network nucleus occurs in a consistent and specific order preceding each convulsive behavior (**Figure 3**). IC neurons fire most intensely just prior to and during AGS initiation, while neurons in DLSC fire most intensely as the wild running is beginning. PAG and PRF neurons fire most intensely just prior to and during tonic–clonic behavior, and PRF neurons fire most intensely just prior to and during TE. During postictal depression, only neurons in the PRF remain active until recovery of the righting reflex, when neurons in all sites become active again. These findings suggest that the network hierarchy begins with IC dominance (greatest change from preseizural firing), but the DLSC becomes dominant during wild running. Then the PAG and PRF become dominant during tonic behavior, while the PRF dominates during TE.

Anticonvulsant Drug Action on the AGS Network

As noted earlier, abnormal acoustically-evoked neuronal firing prior to seizure occurs in all AGS network nuclei of the GEPR, and the effects of several anticonvulsant drugs on these elevated neuronal responses were evaluated in

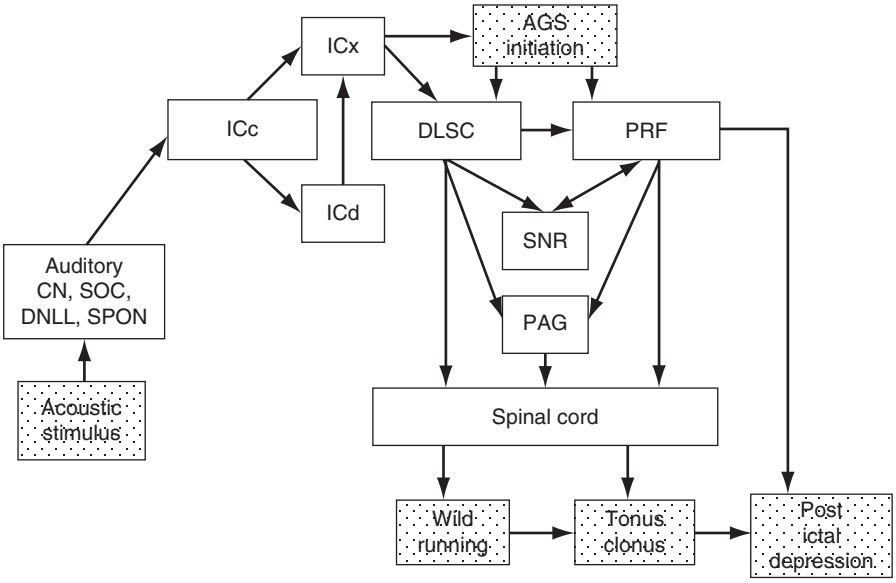

Figure 1 Diagrammatic representation of the major nuclei of the neuronal network that subserves audiogenic seizures (AGS) in GEPRs. The inferior colliculus (IC) central nucleus (ICc) in the midbrain receives input from the lower nuclei in the auditory pathway and initiates AGS via projections to the IC dorsal nucleus (ICd) and particularly to the IC external nucleus (ICx). The ICx projects the sensory input to the motor output nuclei. These include the deep layers of superior colliculus (DLSC), which initiate wild running, and the periaqueductal gray (PAG) and pontine reticular formation (PRF), which are dominant in triggering the clonic and/or tonic phase via their projections to the spinal cord. The PRF is the only region active during postictal depression. The substantia nigra reticulata (SNR) may exert a gating role for elaboration of the convulsive behavior. CN, cochlear nucleus; DNLL, dorsal nucleus of lateral lemniscus; SOC, superior olivary complex; SPON, superior periolivary nucleus. Modified from Faingold, CL **Figure 1** of Jasper's Basic Mechanisms of the Epilepsies, 3rd edn., *Advances in Neurology* 79, Chapter 18: Neuronal networks in the genetically epilepsy-prone rat, pp. 311–321, 1999, with permission from Lippincott.

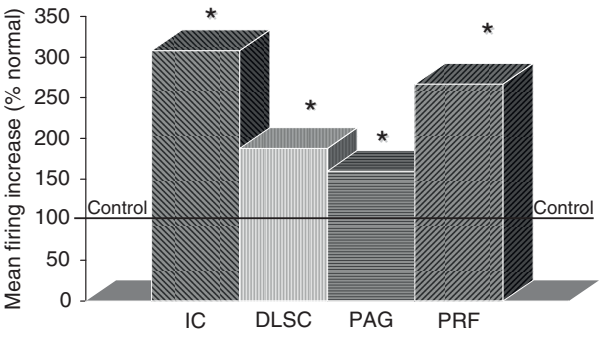

Figure 2 Mean neuronal firing increases in GEPRs (as percentage of normal rat neurons) in nuclei in the AGS network. Neuronal firing was evoked by stimuli (12 kHz, 90–110 dB SPL) that are below the seizure threshold in inferior colliculus (IC), deep layers of superior colliculus (DLSC), periaqueductal gray (PAG), and pontine reticular formation (PRF). All responses were significantly greater than control at $^*p < 0.05$ level (student's *t* test).

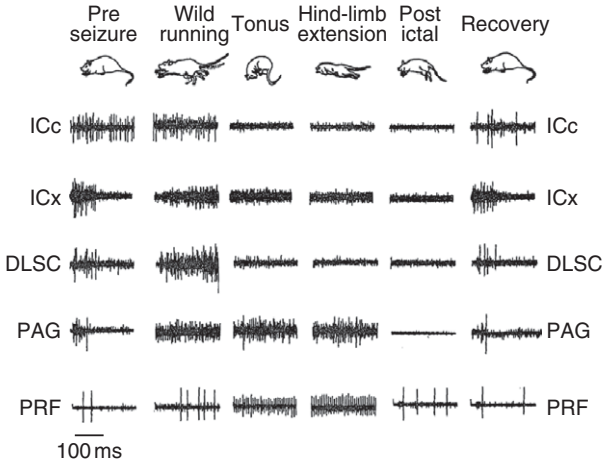

Figure 3 Composite behavioral activity in genetically epilepsy-prone rats (GEPRs) and typical examples of sequential neuronal firing patterns in the audiogenic seizure (AGS) network nuclei. These include the inferior colliculus central nucleus (ICc), inferior colliculus external nucleus (ICx), deep layers of superior colliculus (DLSC), ventrolateral periaqueductal gray (PAG), and pontine reticular formation (PRF). The *preseizure* normal behavior and neuronal responses to the acoustic stimulus in GEPRs just before AGS initiation are shown on the left with burst firing in ICc and ICx as the initial events. Neurons in the DLSC begin to fire at a high tonic rate just prior to the onset of *wild running*. DLSC firing continues at the rapid tonic rate during AGS, and ceases abruptly at the onset of postictal depression. PRF and PAG activity show slow but tonic rates of firing. The PRF and PAG exhibit rapid tonic firing just prior to the loss of righting reflex and entry into *tonus* and tonic *hind-limb* extension. The tonic extension is followed by postictal depression and the neuronal firing in all areas but the PRF ceases, whereas activity in the PRF slows its firing rate. All areas but PRF remain silent until the end of the postictal depression when *recovery* of the righting reflex occurs and neuronal responses begin to revert toward pre-AGS firing patterns in all areas. (Stimulus: 12 kHz, 100-ms duration, 5-ms rise–fall, 95–100 dB SPL). Reprinted from Faingold, CL **Figure 3** of Jasper's Basic Mechanisms of the Epilepsies, 3rd edn., *Advances in Neurology* 79, Chapter 18: Neuronal networks in the genetically epilepsy-prone rat, pp. 311–321, 1999, with permission from Lippincott.

these seizure network nuclei in awake, behaving GEPRs. The anticonvulsant drugs examined thus far (at doses that effectively reduce AGS) exerted differential effects on acoustically-evoked neuronal firing of neurons in each network nucleus (see **Table 3**). As noted earlier, the network appears to operate hierarchically. This hierarchy of network sites suggests that the site in the network at, or closest to, the seizure initiation site in IC is likely to be a critical site for drug action when it is administered at the lowest effective dose (to determine the most sensitive therapeutic target). This view is based on the previous findings that inhibitory substances ($GABA_A$ receptor agonists or NMDA receptor antagonists) will completely block AGS when focally microinjected into each network site. Competitive NMDA receptor antagonists are effective anticonvulsants against many forms of experimental seizures, including AGS in GEPRs. Systemic administration of these agents at anticonvulsant doses, prior to seizures, results in significant reduction of IC neuronal responses to acoustic stimuli at all stimulus intensities, suggesting that competitive NMDA receptor antagonists act in the AGS network at or afferent to the IC. However, an uncompetitive NMDA receptor antagonist, MK-801 (dizocilpine), did not alter the responses of IC neurons, despite the fact that it blocked AGS in very low doses.

Tiagabine blocks cellular uptake of GABA, prolonging its action. Systemically administered tiagabine blocked AGS in GEPRs, but unlike the competitive NMDA receptor antagonists, significant IC neuronal firing reduction prior to seizure was seen only at high acoustic intensities. The time course of the reduced IC neuronal firing paralleled that of AGS suppression with tiagabine, suggesting that tiagabine enhanced that form of $GABA_A$ receptor-mediated inhibition in IC neurons that is prominent at high acoustic intensities. However, other anticonvulsant drugs, including phenytoin, do not affect IC neuronal responses to acoustic stimuli at doses that block AGS, indicating that their actions are exerted at network sites efferent to the IC.

The PAG and PRF are implicated in the generation of tonic convulsive behaviors. AGS in GEPRs that culminate in TE, and elevated acoustically-evoked rapid tonic and/or burst neuronal firing, immediately preceding TE, have been observed in these brain sites. Phenytoin can block AGS completely, but lower doses of this agent can block the TE phase of AGS selectively. Anticonvulsant doses of phenytoin induce consistent changes in PAG and PRF neuronal firing and behavior in GEPRs. Phenytoin in doses that selectively suppressed TE did not consistently

Table 3 Drug Action on Neurons in Audiogenic Seizure Network

Brain Site	*Drug*	*Drug action*	*Effect in vivo*
IC	AP7	competitive NMDAR antagonist	firing down (all intensities)
	CPP	competitive NMDAR antagonist	firing down (all intensities)
	tiagabine	GABA uptake inhibitor	firing down (high intensities)
	ethanol	$GABA_A$ enhancement, NMDA antagonist	firing down (high intensities)
	MK-801	uncompetitive NMDA antagonist	no effect
	phenytoin	Na^+ channel blocker	no effect
PAG	phenytoin	Na^+ channel blocker	firing down *
	MK-801	uncompetitive NMDA blocker	no effect
	lamotrigine	Na^+ channel blocker	firing down
PRF	phenytoin	Na^+ channel blocker	firing down
	MK-801	NMDA channel blocker	no effect

Abbreviations: IC = inferior colliculus, PAG = periaqueductal gray, PRF = pontine reticular formation; * depending on dose
(Adapted from Faingold CL, Progress in Neurobiology, 72:55–85, 2004; Table 1, page 70, Reprinted with kind permission from Elsevier)

alter PAG neuronal responses to acoustic stimuli prior to seizure, but the same doses of phenytoin resulted in significant suppression of PRF preseizural acoustically-evoked neuronal firing and suppressed firing during seizure as well. Doses of phenytoin, which completely blocked AGS, significantly reduced PAG acoustically-evoked neuronal firing and more greatly decreased PRF firing. These results suggest a critical role for PRF, but not for PAG neurons, in the generation of tonic convulsive behaviors of AGS. The suppression of PAG and PRF neuronal firing induced by phenytoin, associated with complete seizure blockade, is consistent with vital roles for both structures in the seizure network. The differential suppressive effect of phenytoin on both preseizural and seizural neuronal firing in PRF as compared with the lack of effect on PAG firing indicate that this experimental approach can identify the most sensitive therapeutic target for anticonvulsant drug action. For an anticonvulsant drug to completely block seizures, however, actions on multiple network sites or on critical circuits within the network are needed, to significantly affect the emergent properties of the seizure network. MK-801 administration did not consistently affect preseizural PRF, PAG, or DLSC acoustically-evoked neuronal firing, despite blocking AGS in GEPRs. The substantia nigra reticulata (SNR) is implicated in the seizure network for several types of seizures, including AGS, and is also implicated in networks subserving normal locomotion. MK-801 induced a significant increase of neuronal firing in SNR neurons concomitant with suppression of AGS. However, MK-801 exerted little effect on action potential firing rates in response to electrical stimuli over a broad range of stimulus intensities when perfused directly onto SNR neurons in slice studies in vitro, despite using high concentrations (up to 200 μM) in vitro. These findings suggest that the significantly increased firing induced by systemically administered MK-801 is an effect on the emergent properties of the AGS network, critically involving SNR neurons. How can a drug produce a major effect on specific neurons in vivo, but not produce this effect on the same neurons in vitro? As noted earlier, there are a number of mechanisms that control network function. In the intact unanesthetized brain in vivo, all of these mechanisms are present. However, in vitro, many of these mechanisms are absent.

If we examine the influences exerted on neurons in a specific brain site, such as the IC, we can see that there are numerous influences, some of which are shown in **Figure 4**. When IC neurons are studied in in vitro brain slices, many of these influences are eliminated or greatly modified (**Figure 4**). Also, achieving an appropriate concentration of the drug in vitro is highly problematic. An 'amplification' phenomenon occurs in vivo, so that much smaller concentrations of drugs affecting seizures are needed in vivo as compared with in vitro to obtain the same effect, as demonstrated by the lab of Narahashi.

The possibility that functioning brain networks possess emergent properties has led to the hypothesis that these properties themselves are potentially critical targets for the action of CNS drugs. This hypothesis, in turn, has led to the idea that '*the intact brain is greater than the sum of its cells*.' When neurons are isolated (in vitro) from their network, regional selectivity of drug action can be lost. In this situation, a neuron in vivo may be affected by a given drug, but the same drug may not affect the same neuron in vitro, as seen with MK-801. Conversely, the emergent property theory also suggests that a neuron may not be affected by a given drug in vivo, even if the same drug has clear effects on the same neuron in vitro – which is observed with ethanol. Thus, the network can actually alter the sensitivity of neurons to a drug, as seen in data comparing the regional effects of ethanol in vivo and in vitro from the lab of Breese.

Neuronal networks may be responsible for conferring the selectivity of drug action. Most CNS drugs at therapeutic concentrations involve selective actions on neurons in a specific site within the brain. However, this selectivity is not due solely to the intrinsic properties of those neurons, and this selectivity may change when the neuron is isolated from the network. The human brain is estimated

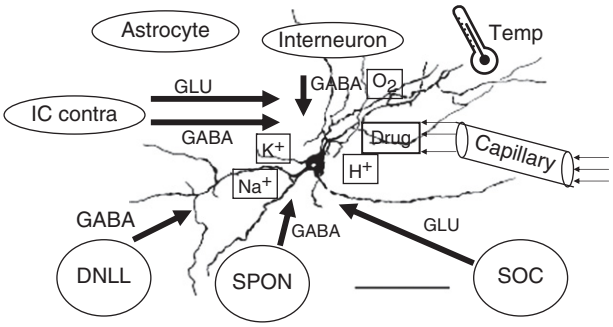

Figure 4 A diagram showing many of the important network-related influences exerted on an inferior colliculus (IC) neuron in vivo. The synaptic inputs to IC neurons include those from the pons via the superior olivary complex (SOC), which projects glutamate (GLU)-mediated excitation onto IC. Inhibitory γ-aminobutyric acid (GABA)-mediated inputs project onto IC neurons from the dorsal nucleus of the lateral lemniscus (DNLL) and the superior periolivary nucleus (SPON). There are also extensive descending inputs to IC (not shown). A number of these inputs, including those from DNLL, SPON, and SOC are eliminated, and many others are significantly modified when the IC undergoes preparation of the slice. Thus, the drug is delivered to the neuron via a capillary in the intact animal, but is directly perfused onto the neuron in vitro. The elements in the extracellular milieu, including the levels of Na^+, K^+, H^+, and O_2, are subject to physiologically-mediated changes in the intact animal but are largely controlled by the experimenter in the slice preparation, as is the temperature. Certain of the influences on IC neurons remain at least partially intact, including the excitatory and inhibitory projections from the contralateral (contra) IC, inhibitory GABAergic input from interneurons and input from local astrocytes contained within the slice. Elimination and alteration of the network-related influences on IC neurons can result in altered effects of any drug in vivo as compared with those exerted by the same agent in vitro, as seen in our studies. The anatomical part of the figure is reprinted from **Figure 2B** of Li Y, Evans MS, and Faingold CL (1999) Synaptic response patterns of neurons in the cortex of rat inferior colliculus. *Hearing Research* 137: 15–28.

to contain 50–100 billion neurons and over a trillion synapses. Several nuclei have been shown to become organized into complex interconnected systems or networks that perform complex functions in health and disease. Network function is subject to 'complexity theory' – i.e., when the multitude of elements in a complex system interact, new and unexpected properties can emerge due, in part, to self-organization. Based on complexity theory, a network can confer emergent properties on a neuron or set of neurons, and those properties can be a selective target of CNS drug action.

Networks and CNS Pathophysiology

As noted earlier, CNS neuronal networks can exhibit emergent properties. Specific elements within these networks may be a major therapeutic target on which CNS drugs exert their pharmacological effect. These network properties are in addition to any specific intrinsic properties of a particular type of neuron in a specific brain site. The net drug effect in an intact organism is the sum of all the actions exerted on various levels of these networks by the drug, and may vary by dose, particularly toxic doses. It is well-known that many neurological and psychiatric diseases are mediated by networks of brain nuclei. A drug's effect may be exerted on multiple networks or common elements of these networks.

Anticonvulsant drugs successfully treat seizure disorders, but many of these same drugs are effective in treating chronic pain disorders and psychiatric diseases – e.g., anxiety disorders and manic-depression (bipolar disorder). Each of these disorders is thought to be subserved by specific brain networks. The gate theory of pain involves an example of an early-described neuronal network in the spinal cord, and brain imaging has identified a neuromatrix that is activated in chronic pain syndromes. Imaging differences are seen between patients in pain and pain-free individuals, and many of these differences are reversible with effective drug therapy. A number of anticonvulsant drugs (e.g., carbamazepine, phenytoin, pregabalin, and gabapentin) effectively treat chronic pain syndromes. These agents may act by altering the properties of the neuronal network involved in the pathophysiology of pain.

Brain imaging techniques have also identified pathophysiological networks in psychiatric disorders, such as anxiety, that express major differences between anxious patients and normals – and many of these differences are also reversed with successful therapy. Evidence suggests that anticonvulsant drugs (e.g., valproate, lamotrigine, pregabalin, and gabapentin) may be effective in treating anxiety disorders.

Future Directions

This neuronal network approach adds another dimension to the understanding of how anticonvulsants produce their antiseizure effects. Additional experimentation is required to develop the usefulness of this approach fully. A catalog of the variety of emergent properties that exist in epileptic neuronal networks, in a number of seizure models, is needed to establish the general applicability of the mechanisms. There is a hierarchy of levels within the nervous system where this concept may apply. Whether the network-modifying mechanism is always involved in drug actions on epilepsy needs to be evaluated. This emergent property approach was developed in the GEPR, and additional anticonvulsants need to be evaluated in this model. More comparisons between in vitro and in vivo effects of the same agent are needed. The generality of this approach needs to be tested in closely related seizure models, such as the moderate seizure strain of the GEPR (GEPR-3) and ethanol withdrawal

models that exhibit similar AGS. Then the mechanisms need to be examined in other seizure models to identify whether differences and similarities occur. This methodology can generate a compendium of emergent targets for drug action. This approach is potentially important for the development of improved drug treatment for epilepsy – and a similar approach may be applicable to other CNS diseases, such as anxiety and pain, to determine if there are common actions.

Seizure networks are subject to plasticity, which may result in the expression of additional emergent properties. For example, a partial seizure model initially involves a relatively circumscribed neuronal network, but if the seizure secondarily generalizes, the seizure network expands and additional properties emerge. These properties may be additive with the original emergent properties. Blockade of these separable emergent properties may require drugs with different actions. Alternatively, effective anticonvulsants may act at multiple levels. Phenytoin, for example, acts on isolated sodium channels, which can be considered the 'ground level' in the hierarchy of emergent properties. However, phenytoin also acts on emergent properties at higher organizational levels in vivo, including specific network nuclei, as seen in the studies cited earlier where it selectively targets PRF neurons within the AGS network.

Identification of how anticonvulsants affect the emergent properties subserving seizure pathophysiology is vital in order to identify drugs that more selectively target these properties. This study applies this approach by investigating network mechanisms for seizure control during AGS, and evaluating anticonvulsant drug actions on neurons in the nuclei of the network. These studies are yielding a detailed understanding of the way this seizure network functions, and how anticonvulsant drugs modify these mechanisms. The results of initial studies indicate that specific sites within the intact network are most sensitive to therapeutic doses of a given drug; this site sensitivity may be different with each specific anticonvulsant examined, since even drugs with similar mechanisms of action can act at different brain sites.

Antiepileptic Drug Mechanisms

Introduction

A seizure is defined as a single episode of neurological dysfunction arising from abnormal neuronal discharge, and can lead to clinically overt changes in motor control, sensory perception, behavior, or autonomic function. Epilepsy is a condition of recurrent spontaneous seizures arising from such aberrant electrical activity within the brain. Epileptic seizures are divided into two broad groups, depending on their site of origin and pattern of spread. Partial or focal seizures arise from a localized region of the brain, and the associated clinical manifestations relate to the function ordinarily subserved by that area. Focal seizures can remain localized, but can also spread to adjacent cortical areas and potentially involve the entire cortex. In contrast, primary generalized seizures begin with abnormal electrical discharges in both hemispheres simultaneously, and critically involve reciprocal connections between the thalamus and neocortex.

Epileptic seizures reflect enduring alterations in structure and function required to support abnormal neuronal firing. At a cellular level, two hallmark features of epileptiform activity are neuronal hyperexcitability and neuronal hypersynchrony. It is important to understand that a single abnormally discharging neuron is insufficient to produce a clinical seizure. For a seizure to manifest electroclinically, there must be synchronous activity of large populations or networks of neurons. Notwithstanding this important context, determination of the mechanisms of action of antiepileptic drugs (AEDs) usually begins with, or is reduced to, modulation of membrane-bound ion channels.

The neuronal cell membrane is populated by a variety of ion channels that convert chemical signals into electrical activity. As such, ion channels have traditionally been regarded as the 'currency' of neuronal excitability. A variety of chemical signals act through ligand-gated and voltage-gated ion channels to generate excitatory or inhibitory signals, which may be subthreshold or suprathreshold for subsequent action potential initiation – which in turn give rise 'downstream' to action potential-propagated neurochemical signals. Traditionally, there are three major classes of molecular targets believed to be relevant for limiting epileptic activity. These include: (1) voltage-gated sodium and calcium channels; (2) γ-aminobutyric acid ($GABA_A$) receptors; and (3) ionotropic glutamate receptors. Clinically useful antiepileptic AEDs exert their effects principally on one or more of these targets.

Background

Voltage-Gated Ion Channels

Sodium channels

Each sodium channel exists as a complex of polypeptide subunits. There is a major α-subunit and one or more β-subunits, which influence the kinetic properties of the α-subunit. Voltage-dependent sodium channels are activated upon membrane depolarization and underlie the fast upstroke of the action potential. The sodium current is a self-limiting process in that the channel inactivates within milliseconds, thus terminating the action potential. Repolarization of the neuronal membrane primes the sodium channel for subsequent activation. The kinetics of the onset and recovery from inactivation allow sustained, high-frequency action potential firing during normal and epileptic activity. Under normal conditions, there is an additional mechanism in the form of 'slow' inactivation that prevents excessive action potential firing. Slow inactivation occurs during prolonged depolarizations, in which full onset and recovery occur over several seconds. Consequently, these lengthy depolarizations can participate in the termination of repetitive action potential bursts.

Upon the decay of the transient sodium current, a remaining or 'persistent' sodium current (I_{NaP}) is observable and constitutes less than 4% of the total sodium current. It has been proposed that the non-inactivating I_{NaP} is either produced by the overlap between activation and inactivation voltage ranges of sodium channels (resulting in a 'window current') or generated by sodium channels entering an infrequently visited open state that lacks fast inactivation. In any case, the voltage range of I_{NaP} activation is immediately subthreshold for action potential initiation, and is thus repeatedly crossed during an action potential train. Accordingly, I_{NaP} occupies a unique position, and its presence or absence can regulate repetitive firing and the spread of hyperexcitability.

Calcium channels

Similar to other voltage-dependent ion channels, calcium channels are macromolecular protein complexes composed of multiple subunits that form a calcium-permeable pore activated by depolarization. There are two broad families of calcium channels, high voltage-activated (HVA) and low voltage-activated (LVA). As the name suggests, HVA calcium channels (L-, R-, P/Q-, and N-types) require strong membrane depolarization to induce opening, and are

predominantly responsible for the regulation of calcium entry and neurotransmitter release from presynaptic axon terminals in response to the arrival of an action potential. LVA calcium channels (T-type) are named as such because they can be activated by small depolarizations of the plasma membrane. T-type calcium channels regulate neuronal firing by participating in bursting and intrinsic oscillations. Thus, given their roles, both HVA and LVA calcium channels represent important targets in the modulation of neuronal excitability.

Synaptic Excitation

Neuronal excitation in the central nervous system is mediated by ionotropic glutamate receptors (i.e., α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid or AMPA, kainate, and *N*-methyl-D-aspartate or NMDA) and metabotropic glutamate receptors (see **Figure 1**). Inhibition of excitatory glutamatergic neurotransmission would appear the most obvious way to limit excessive excitatory activity, and this conceptual notion has been supported by many in vivo and in vitro preclinical studies. However, in clinical trials, selective glutamate receptor antagonists – while efficacious – have been hampered by unacceptable side-effects. Of the currently available AEDs, only two are known to exert activity, in part, on ionotropic glutamate receptors – and none interact principally with metabotropic glutamate receptors.

Synaptic Inhibition

Neuronal inhibition in the central nervous system is primarily achieved by the presynaptic release of the neurotransmitter GABA, which binds to ionotropic $GABA_A$ and metabotropic $GABA_B$ receptors. $GABA_A$ and $GABA_B$ receptors mediate fast and slow inhibition in the brain, respectively. During normal neuronal activity, communication between inhibitory GABAergic interneurons and excitatory glutamatergic neurons provides the critical balance necessary to prevent the development of synchronized epileptiform discharges – discharges that would naturally arise in an unchecked, recurrently connected

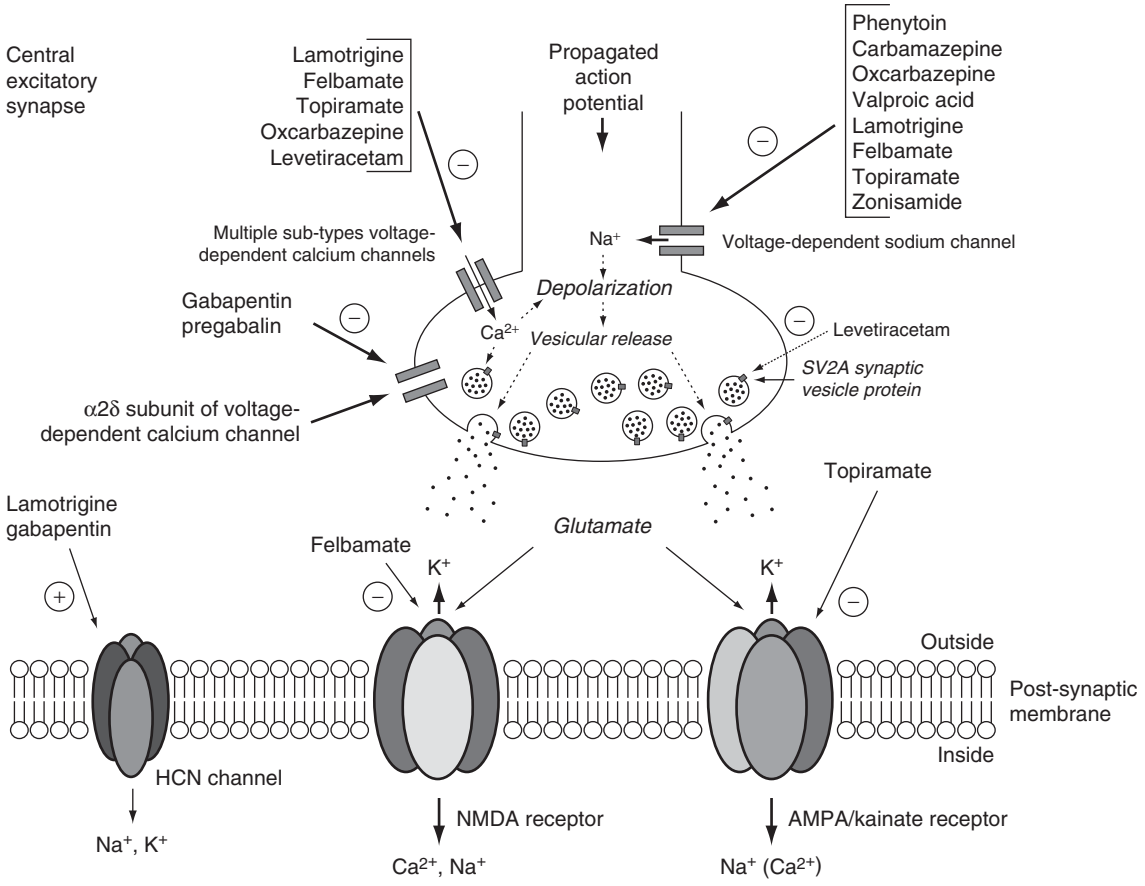

Figure 1 Schematic representation of an excitatory synapse in the central nervous system, and the putative major sites of action of various antiepileptic drugs (AEDs). Plus or minus signs denote activation/potentiation or inhibition, respectively. NMDA, *N*-methyl-D-aspartate; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid; HCN, hyperpolarization-activated cyclic nucleotide-regulated cation channels. excitatory network. However, the role of inhibition with respect to epileptiform activity is not simple. For example, it appears that inhibitory neurotransmission may actually participate in the synchronization of large populations of neurons and the subsequent propagation of seizures to adjacent brain regions. Thus, AEDs that act principally to augment GABAergic neurotransmission may prevent the initiation of epileptiform activity; however, such agents may also – in some cases – exacerbate the synchronization and spread of seizure activity, notably in thalamocortical circuits. There are several distinct ways that GABAergic inhibition can be augmented: (1) increased $GABA_A$ and $GABA_B$ receptor function; (2) enhanced GABA synthesis and decreased degradation; and (3) inhibition of GABA re-uptake into neuronal and glial cells (see **Figure 2**).

Methods – AED Screening

Traditionally, the antiepileptic activity of compounds is first identified in animal models of seizures. Screening by the Anticonvulsant Drug Development (ADD) Program at the University of Utah has contributed to the successful development of nine second-generation AEDs: felbamate (1993), gabapentin (1994), lamotrigine (1994), fosphenytoin (1996), topiramate (1996), tiagabine (1997), levetiracetam (1999), zonisamide (2000), and oxcarbazepine (2000). The ADD program employs a testing paradigm of a battery of animal models to determine efficacy against different seizure types. The 'opening-gate' screens are maximal electroshock (generalized tonic-clonic seizures), subcutaneous pentylenetrazol administration (generalized absence epilepsy), and the 6-Hz psychomotor seizure test (potential therapy-resistance). After a compound proves efficacious in one of these models, furthers tests are performed to characterize its anticonvulsant potential against audiogenic seizures, limbic seizures, and acute clonic seizures. These additional tests reveal whether a compound has a narrow or broad spectrum of anticonvulsant activity. Although the current process for AED discovery has been largely successful, the anticonvulsant screening paradigm is a dynamic flow chart – so that the ADD Program continually evaluates new animal models for possible incorporation into the screening process.

Once a new AED is identified, a wide array of techniques are available to determine its possible mechanisms of action, including (but not limited to) binding studies, imaging, electrophysiology, molecular biology, and molecular

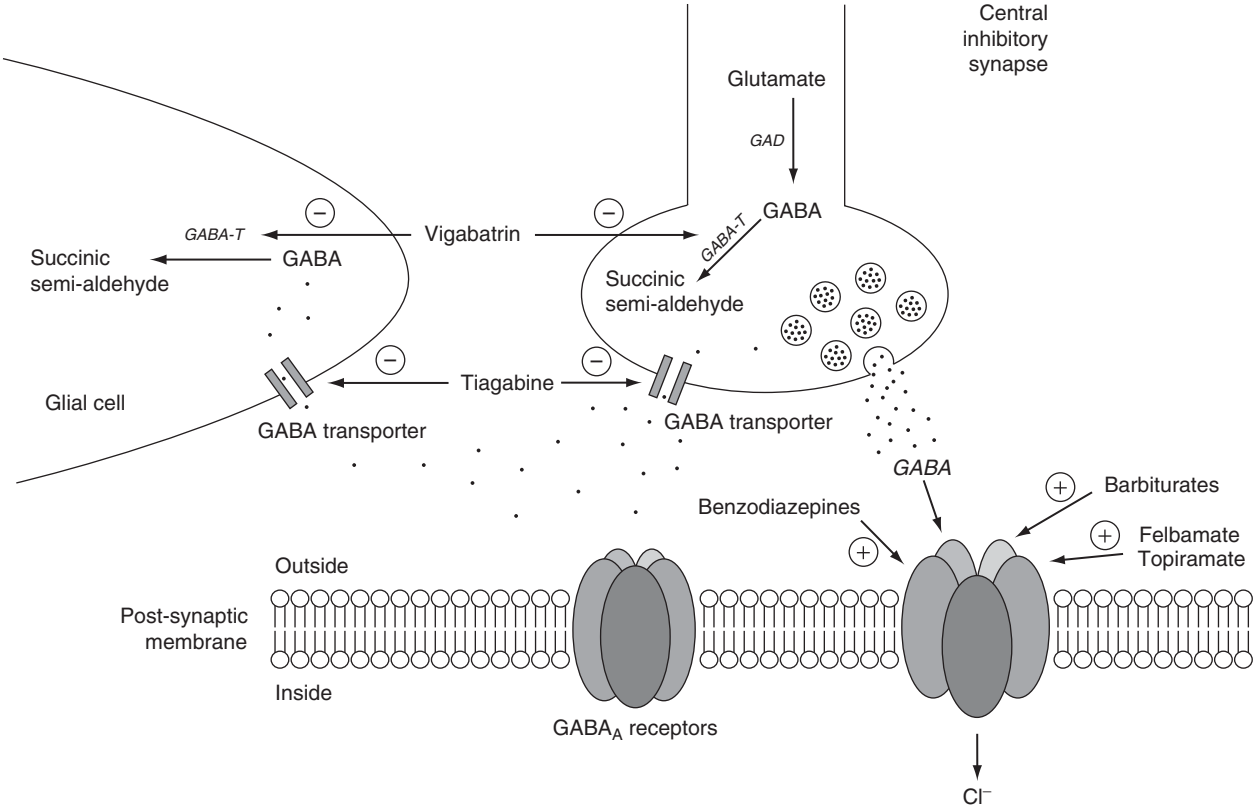

Figure 2 Schematic representation of an inhibitory synapse in the central nervous system, and the putative major sites of action of various antiepileptic drugs (AEDs). genetics. Competitive binding studies determine the specificity of the interaction between a radiolabeled AED and its binding site(s) by examining the ability of various neurotransmitters, hormones, or even other drugs to compete for the binding site(s). If no radiolabeled AED is available, then the inverse experiment can be performed using radiolabeled neurotransmitters, hormones, or drugs with known binding sites. However, this technique has limited or no sensitivity if the AED binding site is completely novel.

In recent years, high-throughput fluorescent imaging techniques (e.g., FLIPR-fluorometric-imaging plate reader, Molecular Devices, Union City, CA) have been used to ascertain test drug effects on cellular calcium concentration or membrane potential. Typically, these experiments are performed by adding a receptor agonist, such as the neurotransmitter glutamate, or depolarizing agent, such as potassium, to induce a change in fluorescence; then the effectiveness of varying concentrations of a drug of interest, in either reducing or preventing the change in fluorescence, is quantified. Understandably, these experiments, when performed using isolated cultured primary neurons, have low specificity and are unable to reveal a putative binding site for the AED, thus providing limited information about mechanism of action. Specificity is increased if the study uses a cell line expressing individual recombinant ion channels or receptors.

Electrophysiological evidence remains the 'gold standard' for discerning AED mechanism(s) of action, even though this approach is time-consuming and labor intensive. Fundamentally, electrophysiological techniques record changes in voltage or current in a group of neurons, within individual cells, or associated with single ion channels. These experiments are generally performed in vitro with acutely dissected brain slices or cultured neurons. Extracellular recordings provide information about AED effects on population events and provoked epileptiform activity. Whole-cell patch clamp techniques allow the investigator to determine AED effects on the single-cell resting membrane potential, input resistance, action potential characteristics (i.e., threshold, duration, and peak), and action potential firing characteristics (i.e., frequency, adaptation, and repetitive firing susceptibility). Furthermore, AED effects on specific voltage- and ligand-gated ion channels are resolved by isolating ionic currents, by changing the membrane potential or applying a receptor/channel agonist. Once a particular channel is identified as an AED target, single channel recording techniques establish AED effects on channel opening and closing kinetics and detail the exact manner in which the AED modulates ion channel function.

The disciplines of molecular biology and molecular genetics have become essential in establishing and determining AED binding sites on specific molecular targets. Molecular biology techniques have provided the technology to overexpress a known ion channel in a cell line that is essentially devoid of endogenous voltage- and ligand-gated channels. Combined with electrophysiology, such molecular approaches provide unequivocal evidence of AED action. Site-directed mutagenesis of ion channel proteins permits a detailed map of the molecular binding site for the AED. Molecular genetics has allowed investigators to identify specific mutations in particular ion channels that are associated with various epilepsies (i.e., GEFS+ type 1 and 2, childhood absence, and many others). Studies of the functional consequences of such natural mutations have been possible using site-directed mutagenesis and gene knockout and knock-in technology. AED modulation of these mutated ion channels can be assessed, and possibly correlated to refractoriness to individual AEDs. The growing structural and functional characterization of AED molecular targets, and increasing understanding of how AEDs modulate these targets, provide a framework for creating improved epilepsy therapies, and have encouraged many investigators in their attempts to develop drugs with specific molecular targets.

Recent Results

Voltage-Gated Ion Channels

Sodium channels

Several AEDs effective in the treatment of partial-onset epilepsy (i.e., phenytoin, carbamazepine, oxcarbazepine, lamotrigine, zonisamide, felbamate, topiramate, and valproate) inhibit voltage-gated sodium channels and block sustained, high-frequency, repetitive firing of neurons. Most of these AEDs appear to inhibit sodium channels in a voltage- and use-dependent manner (i.e., the block is more effective at depolarized rather than hyperpolarized potentials, and the potency of the block increases with increasing action potential frequency or prolonged depolarizations). These observations suggest that these AEDs act in a manner similar to, or modulate the kinetics of, slow inactivation – thus accounting for the selective block of high-frequency firing without affecting normal neuronal action potential discharge.

Phenytoin, carbamazepine, topiramate, ethosuximide, and valproate may additionally inhibit the non-inactivating, persistent sodium current that results from the overlap between activation and inactivation voltage ranges. As mentioned already, the persistent sodium current constitutes less than 4% of the total sodium current, but modulation of this current by AEDs may regulate epileptiform activity due to current activation in the voltage range immediately sub-threshold for spike initiation.

Calcium channels

HVA calcium channels consist of one α_1 subunit (with 7 known subtypes) that forms the channel pore, and various auxiliary subunits (including the $\alpha_2\delta$ subunit).

Two structural analogues of GABA (gabapentin and pregabalin) are effective in the treatment of partial seizures, and have been shown to interact with $\alpha_2\delta$-1 and $\alpha_2\delta$-2 auxiliary subunits. Interestingly, despite strong evidence for this unique site of action, neither gabapentin nor pregabalin has been consistently shown to exert an effect on calcium currents. This result is perhaps not surprising since $\alpha_2\delta$-1 and $\alpha_2\delta$-2 auxiliary subunits can combine with many of the 7 subtypes of HVA α_1 subunits, yielding tremendous heterogeneity in molecular composition – and hence, pharmacosensitivity. Even so, gabapentin and pregabalin can decrease presynaptic neurotransmitter release, at both inhibitory GABAergic and excitatory glutamatergic synapses. In contrast, various subtypes of HVA channels are inhibited by phenobarbital, levetiracetam (N-type), lamotrigine (N- and P/Q-types), felbamate (L-type), oxcarbazepine (N-type), and topiramate (L- and R-type), reducing neurotransmitter release in most cases.

Absence seizures are a unique seizure type associated with brief lapses of consciousness that begin and terminate abruptly, and are a result of generalized spike-wave discharges seen on the scalp electroencephalogram (EEG). Absence seizures reflect widespread and heightened phase-locked oscillations between excitation (i.e., spike) and inhibition (i.e., slow wave) in mutually connected thalamocortical networks. T-type calcium channels generate low-threshold calcium currents that depolarize the membrane and trigger bursts of action potentials. Such excitatory bursts are believed to underlie the 'spike' portion of a generalized spike-wave oscillation. Inhibition of T-type calcium channels by the AEDs ethosuximide, valproate, and zonisamide terminates the 3-Hz spike-wave discharges and correlates with efficacy in the treatment of generalized absence seizures. However, whether augmentation of T-type calcium currents is essential for the genesis of absence seizures remains somewhat controversial.

Synaptic Excitation

NMDA receptors are macromolecules formed by co-assembly of an obligatory NR1 subunit and at least one type of NR2 subunit. Felbamate, at therapeutically relevant concentrations, inhibits NMDA-evoked currents in hippocampal neurons and appears to be a low-affinity open channel blocker. Studies conducted in in vitro expression systems have demonstrated that felbamate is a more potent antagonist of NMDA receptors containing NR2B subunits. The NR2B subunit is abundantly expressed in the immature brain and largely restricted to the forebrain in the adult. These expression patterns may explain the effectiveness of felbamate in pediatric epilepsies and low neurobehavioral side-effects in adults.

As the primary mediators of fast excitatory neurotransmission, AMPA and kainate receptors have differential but important roles in seizure genesis and spread. The AED topiramate has been demonstrated to inhibit both AMPA- and kainate-receptor mediated currents. Kainate receptors are particularly interesting as AED targets because they are not restricted to postsynaptic membranes; they can also be found on presynaptic axon terminals. Presynaptically, activation of kainate-receptors modulates glutamate release and inhibits GABA release. As such, kainate-receptor mediated inhibition represents a very potent mechanism of seizure termination. Like other ligand-gated ion channels, AMPA- and kainate-receptors are composed of various subunits, and topiramate is selective for GluR5-containing kainate-receptors.

Synaptic Inhibition

$GABA_A$ receptors are oligopentameric, macromolecular protein complexes consisting of a variety of subunits that form a pore selectively permeable to chloride and bicarbonate ions. Biophysical and pharmacological properties of $GABA_A$ receptors are determined by their inherent subunit composition. In general, pharmacological blockade and enhancement of $GABA_A$ receptors causes seizures and attenuates seizures, respectively. The AEDs phenobarbital, diazepam, felbamate, and topiramate have been experimentally shown to modulate $GABA_A$ receptors in differential ways to augment inhibitory neurotransmission.

$GABA_A$ receptor function can be enhanced by increasing the channel conductance and/or open state of the channel (either channel 'burst frequency' and/or open state duration). Accordingly, the barbiturate phenobarbital increases mean open duration, the benzodiazepine diazepam increases open state frequency without affecting duration, and topiramate increases both open state and burst frequency and duration. Felbamate has been demonstrated to enhance GABA-mediated currents in hippocampal and cortical neurons, and although the precise effects on single channel kinetics remain unclear, there is evidence to suggest a barbiturate-like action.

Studies of $GABA_A$ receptors expressed in oocytes or mammalian cells, and comprising different subunit combinations, have revealed subunit-specific modulation of $GABA_A$ receptors by AEDs. Diazepam binds to a recognition site juxtaposed between the α and γ subunits, and enhances GABA activation of most receptors comprised of an $\alpha\beta\gamma$ subunit combination with varying affinities; however, it is ineffective for $\alpha_{4\text{ or }6}\beta\gamma$ combinations. Very high concentrations of diazepam are able to directly activate and enhance receptors comprised of only $\alpha\beta$ subunits. Therapeutic concentrations of topiramate enhance $\alpha\beta_{2\text{ or }3}\gamma_2$ combinations and directly activate $\alpha_4\beta_3\gamma_2$, whereas higher concentrations of this AED directly activate $\alpha\beta_{2\text{ or }3}\gamma_2$ combinations and inhibit $\alpha\beta_1\gamma_2$ combinations. Studies utilizing the *Xenopus* oocyte expression system indicate that a therapeutic concentration of felbamate (300 μM) exclusively enhances $GABA_A$ receptors

comprised of $\alpha_{1 \text{ or } 2}\beta_{2 \text{ or } 3}\gamma_2$, and is either ineffective or inhibits every other subunit combination tested. In contrast, phenobarbital positively modulates every $GABA_A$ receptor subunit combination, although potency does depend on α and β subunit subtypes. It is safe to speculate that such subunit specificity, along with possible variations in local AED concentrations, may contribute to the unique anticonvulsant profile of each AED and its effectiveness against particular seizure types.

$GABA_B$ receptors are coupled via a guanosine 5′-triphosphate-binding protein to calcium or potassium channels. The GABA structural analogue, gabapentin, has been reported to modulate inwardly rectifying potassium channels and N-type calcium channels via preferential interaction with $GABA_B$ receptors containing $GABA_{B1a}$ subunits. Gabapentin's subunit specificity was initially thought to contribute to its anticonvulsant activity by selectively reducing excitatory neurotransmitter release with a simultaneous sparing of inhibitory neurotransmission. However, subsequent studies have been unable to replicate these findings-with failure to identify binding at radioligand sites related to $GABA_B$ receptors, failure to demonstrate an inhibitory effect on gabapentin actions by $GABA_B$ receptor antagonists, and failure to prevent gabapentin action by co-application of the $GABA_B$ agonist, baclofen.

Ambient levels of extracellular GABA are controlled by enzymes involved in the GABA life cycle and GABA uptake by transporters. Two pyridoxal-5′-phosphate-dependent enzymes, glutamate decarboxylase (GAD) and GABA transaminase (GABA-T) are involved in GABA synthesis and degradation, respectively. The AED vigabatrin (γ-vinyl GABA) is a GABA analogue that has no activity on GABA receptors, but acts by inhibiting GABA-T, which results in significant elevations in brain GABA levels. Vigabatrin increases ambient extracellular GABA either by reversal of GABA transporters, or by shifting the concentration equilibrium to a value that supports increased extracellular GABA as a result of the marked elevation in intracellular GABA, or by effects on GABA uptake that are unrelated to GABA-T. Other GABA analogues, such as gabapentin and pregabalin, were once thought to enhance GAD and inhibit GABA transferase, resulting in increased GABA concentrations – but subsequent studies have disproved these interactions at therapeutically relevant drug concentrations. The GABA transporter, GAT1, is inhibited by the AED tiagabine, resulting in prolonged postsynaptic inhibitory currents that are enhanced during repetitive interneuron activation, activity that is expected to occur during epileptiform discharge. The increase of ambient GABA through any of these mechanisms would be expected to act on $GABA_A$ and $GABA_B$ receptors. However, the anticonvulsant consequences are more likely due to effects on extrasynaptic rather than synaptic GABA receptors, given the relatively higher GABA affinity and lower desensitization properties of extrasynaptic GABA receptors.

Additional Molecular Targets

HCN channels

Another important ion channel involved in the regulation of thalamocortical rhythmicity is the hyperpolarization-activated cation channel (HCN channel), responsible for the so-called I_h or h-current. HCN channels are highly expressed in neuronal dendrites (and to a lesser extent in the soma) in both thalamus and hippocampus, are activated by hyperpolarization, and produce a depolarizing current carried by a flux of Na^+ and K^+ ions. This depolarization helps to bring the resting membrane potential toward the threshold for T-type calcium channel activation.

Importantly, unlike other voltage-gated conductances that are classified as either inhibitory or excitatory, h-currents are both inhibitory *and* excitatory. HCN channels possess an inherent negative-feedback property. That is, hyperpolarization produces an activation of HCN channels, which then leads to depolarization and immediate de-activation of these channels. The net effect of HCN channel activation is a decrease in the input resistance of the membrane, which is a measure of the voltage change produced by a given synaptic current. H-currents tend to stabilize the neuronal membrane potential toward the resting potential against both hyperpolarizing and depolarizing inputs.

The relevance of HCN channels in the pathogenesis of absence seizures was recently underscored by the experimental finding that deletion of a specific HCN isoform results in absence epilepsy and sinus dysrhythmia in mice. Furthermore, lamotrigine, an AED that is highly effective against absence seizures, enhances activation of dendritic h-currents in hippocampal pyramidal neurons by shifting the voltage-dependent activation towards depolarized potentials. Increasing I_h reduces input resistance, length constant, and temporal summation, and suppresses action potential initiation by dendritic inputs. Gabapentin has also been shown to enhance I_h amplitude by increasing the channel conductance, which results in a slight membrane depolarization and reduced input resistance.

Potassium channels

Potassium channels represent a large and heterogenous family of ion channels, and generally function to dampen neuronal excitation by inducing membrane hyperpolarization. Hence, they represent a natural target for AED development. Previously, it was thought that none of the AEDs available for clinical use today act directly on voltage-gated potassium channels. However, recently

published studies implicate potassium channels as part of the mechanism of action of several AEDs. For example, topiramate induces a steady membrane hyperpolarization mediated by a potassium conductance, whereas levetiracetam blocks sustained repetitive firing by paradoxically decreasing delayed rectifier voltage-gated potassium currents. Phenytoin inhibits A-type potassium channels by increasing the probability of the inactivated state. Delayed rectifier and A-type potassium channels participate in membrane repolarization after an action potential and play a role in determining the frequency of repetitive firing. Presumably, inhibition of either potassium channel slows membrane repolarization, thereby decreasing sodium channel de-inactivation, and effectively preventing responses to fast depolarization by limiting the frequency of repetitive firing. Lamotrigine and zonisamide also inhibit A-type channels, but at supra-therapeutic concentrations.

Carbamazepine, at therapeutically relevant concentrations, blocks recombinant rat brain small conductance, calcium-activated potassium channels which underlie the slow after-hyperpolarization of action potentials that mediate the phenomenon of spike frequency adaptation. In contrast, large conductance, calcium-activated potassium channels participate in spike repolarization and fast hyperpolarization, and are activated by zonisamide in a manner that shifts voltage sensitivity to less positive potentials and decreases mean closed durations, thereby increasing open probability. Interestingly, polymorphisms and mutations in small and large conductance, calcium-activated potassium channels, respectively, are associated with generalized epilepsies.

As described above, the multitude of different types of potassium channels predicts diverse actions of AEDs on potassium conductance. This diversity of actions is illustrated by the AED retigabine, an investigational compound with broad efficacy in animal seizure models, which enhances activation of KCNQ2 and KCNQ3 potassium channels. This mechanism of action is particularly intriguing given that mutations in genes encoding these potassium channel subunits have been linked to a rare form of inherited epilepsy, benign familial neonatal convulsions.

Carbonic anhydrase inhibition

Several AEDs, including acetazolamide, topiramate and zonisamide, act either principally or in part by inhibiting certain carbonic anhydrase isoforms. The clinical use of carbonic anhydrase inhibitors covers the last half century, but it is unclear how anticonvulsant effects are achieved with these agents. Interestingly, the demonstration that carbonic anhydrase II knockout mice have decreased susceptibility to pentylenetretrazole (PTZ)- and fluorothyl-induced seizures emphasizes the relevance of this family of enzymes in modulation of neuronal excitability. Inhibition of brain carbonic anhydrase results in an increase in total CO_2 concentrations in neurons, and increased pH and a decreased HCO_3^- concentration in neuroglia. One downstream effect of intracellular alkalinization by acetazolamide is an up-regulation of I_h in thalamocortical neurons due to a shift in voltage-dependent activation of HCN channels to more positive potentials. This pH-mediated up-regulation of I_h results in decreased membrane responses to hypepolarizing stimuli and a reduced ability to generate rebound calcium-mediated spikes. These changes also lower interstitial K^+ concentration, as well as pH. It is well known that a reduction in extracellular K^+ leads to diminished neuronal excitability, but the impact of decreased extracellular pH is less clear, despite the fact that – depending on subunit composition – extracellular protons can block NMDA receptor-mediated excitation and enhance $GABA_A$ receptor function.

Synaptic vesicle protein

One of the newest AEDs has challenged our conceptual understanding of relevant mechanisms of action. Unlike traditional agents, levetiracetam failed two standard screening tests in animals – the maximal electroshock (MES) and PTZ seizure threshold tests – yet had a profound effect in retarding amygdala kindling in rats. Levetiracetam's principal molecular target, originally identified as a specific high-affinity neuronal binding site, was recently shown to be a specific synaptic vesicle protein, SV2A, which is involved in neurotransmitter release. The functional consequences of an interaction between SV2A and levetiracetam remains to be elucidated. However, a putative augmentation by levetiracetam can be tentatively hypothesized based on the observation that mice lacking SV2A have severe seizures.

Future Directions and Challenges

This last example cearly illustrates that we have yet much to learn about mechanisms underlying seizure genesis and epileptogenesis. Certain molecular targets, such as $GABA_A$ receptors, are widely regarded as relevant to the clinical effects of AEDs such as barbiturates and benzodiazepines. And there is an emerging consensus that the clinical activity of many AEDs across a broad spectrum of seizure types may be a consequence of the multiplicity of molecular actions for any given AED. For example, topiramate's actions on voltage-gated sodium and calcium channels, combined with its effects on both $GABA_A$ and glutamate receptors, are consistent with efficacy against multiple seizure types.

Yet despite their diverse molecular actions, current AEDs fail to 'cure' or modify the disease process. Rather, they are effective in most patients in eliminating the major symptom – seizures – by dampening neuronal excitation, synchronization, and spread of seizure activity. Little experimental evidence exists to support the notion that

these drugs are truly 'antiepileptogenic' or 'antiepileptic' (i.e., prevent the development or maintenance of the epileptic state). As epileptogenic mechanisms become better understood, an important goal will be to design more specific and rational interventions to treat the disease as well as the symptoms.

Introduction

Seizures and epilepsy are a consequence of neuronal hyperexcitability resulting from a variety of mechanisms. These include genetic or acquired alterations in ion channel function, aberrant network connectivity resulting from neurogenesis and axonal sprouting, enhancement of excitatory glutamatergic synaptic transmission, and reductions in inhibitory (GABAergic) synaptic transmission. The predominant mechanism(s) of hyperexcitability are likely to vary between the different types of epilepsy syndromes (e.g., idiopathic generalized epilepsy, temporal lobe epilepsy (TLE), posttraumatic, or poststroke epilepsy, postinfectious epilepsy, and tumor- or mass-associated epilepsy). However, drugs that augment $GABA_A$ receptor function (phenobarbital, benzodiazepines) are among the most potent and reliable agents used to prevent or acutely treat seizures in almost every type of epilepsy syndrome. Their effectiveness and versatility make the GABAergic system an attractive target for pharmacologic modulations that would be effective for chronic treatment of a variety of types of epilepsy.

GABA is the primary inhibitory neurotransmitter in the brain. GABAergic inhibition in the brain occurs as a result of presynaptic release of GABA that acts on postsynaptic $GABA_A$ receptors to transiently open Cl^- channels, resulting in a hyperpolarizing inhibitory postsynaptic potential (IPSP). GABA released from presynaptic terminals also acts on pre- and postsynaptic $GABA_B$ receptors – G-protein-coupled receptors that exert several effects,

these drugs are truly 'antiepileptogenic' or 'antiepileptic' (i.e., prevent the development or maintenance of the epileptic state). As epileptogenic mechanisms become better understood, an important goal will be to design more specific and rational interventions to treat the disease as well as the symptoms.

Introduction

Seizures and epilepsy are a consequence of neuronal hyperexcitability resulting from a variety of mechanisms. These include genetic or acquired alterations in ion channel function, aberrant network connectivity resulting from neurogenesis and axonal sprouting, enhancement of excitatory glutamatergic synaptic transmission, and reductions in inhibitory (GABAergic) synaptic transmission. The predominant mechanism(s) of hyperexcitability are likely to vary between the different types of epilepsy syndromes (e.g., idiopathic generalized epilepsy, temporal lobe epilepsy (TLE), posttraumatic, or poststroke epilepsy, postinfectious epilepsy, and tumor- or mass-associated epilepsy). However, drugs that augment $GABA_A$ receptor function (phenobarbital, benzodiazepines) are among the most potent and reliable agents used to prevent or acutely treat seizures in almost every type of epilepsy syndrome. Their effectiveness and versatility make the GABAergic system an attractive target for pharmacologic modulations that would be effective for chronic treatment of a variety of types of epilepsy.

GABA is the primary inhibitory neurotransmitter in the brain. GABAergic inhibition in the brain occurs as a result of presynaptic release of GABA that acts on postsynaptic $GABA_A$ receptors to transiently open Cl^- channels, resulting in a hyperpolarizing inhibitory postsynaptic potential (IPSP). GABA released from presynaptic terminals also acts on pre- and postsynaptic $GABA_B$ receptors – G-protein-coupled receptors that exert several effects,

including opening potassium channels to produce slow hyperpolarization. These forms of GABA signaling are referred to as phasic inhibition. In contrast, ambient extracellular GABA concentrations ($[GABA]_0$) act in a tonic manner on extrasynaptic $GABA_A$ receptors to cause persistent Cl^- currents, termed tonic inhibition. GABA transporters on neurons and glia serve to terminate synaptic events, limit crosstalk between neurons from GABA molecules diffusing away from synapses, maintain ambient [GABA] at appropriately low concentrations, and provide a means for neurons to reclaim synaptically released GABA for repackaging into synaptic vesicles. Thus, GABA transporters are important pharmacologic targets that modulate both phasic and tonic GABAergic inhibition in the brain. GABA transporters can also operate in the reverse direction, and thus can become an important source of GABA release. In this article, we review the types of GABA transporters, their relevance to epilepsy, and the anticonvulsant drugs that target them.

Background

GABA Transporter Function, Subtypes, and Cellular Localization

GABA transporters are Na^+- and Cl^--dependent symporters that translocate one GABA molecule, two Na^+ ions, and one Cl^- ion per thermodynamic reaction cycle. GABA may be moved into cells against its concentration gradient by this coupled translocation due to the energy stored in the steep transmembrane concentration gradient for sodium established by the Na^+/K^+-ATPase. GABA transporters are electrogenic, moving one net charge into cells during an uptake cycle, and therefore are voltage-dependent. Although GABA transporters may primarily work in the "forward" direction (i.e., moving GABA into cells), they may also work in the reverse direction, releasing GABA into the extracellular space. The direction and magnitude of GABA transport is dependent on the transmembrane concentration gradients of transported substrate and membrane potential. GABA transporters under control conditions have a reversal potential (the membrane voltage at which transport reverses direction) near typical resting membrane potentials of neurons, allowing GABA transporters to easily operate in reverse and release GABA with relatively minor membrane potential changes. During synaptic events, when extracellular GABA may transiently reach as high as 1 mM, GABA transporters will work exclusively in the forward direction. In contrast, elevations in intracellular sodium or membrane depolarization lead to favorable thermodynamic conditions for reverse transport and release of GABA into the extracellular space. As there are continuous fluctuations in membrane potential, ion concentrations, and GABA concentrations during normal brain function, it is predicted that the rate and direction of GABA transport would constantly change as the conditions vary. GABA transporters also play an important role in regulating the level of ambient $[GABA]_0$, and under normal conditions attempt to clamp this level at around 90–250 nM – which is in the range of concentrations necessary – to activate high-affinity extrasynaptic $GABA_A$ receptors that cause tonic inhibition.

GABA transporters belong to the superfamily of Na^+- and Cl^--dependent co-transporters. There are four cloned isoforms: GAT1–3 and the betaine/GABA transporter-1 (BGT-1). BGT-1 differs from the other GABA transporters in that it translocates 3 Na^+ ions during each thermodynamic reaction cycle. GAT-1 is the primary neuronal GABA transporter, but can also be expressed in astrocytes. GAT-1 is concentrated in presynaptic terminals, where its surface expression is dynamically regulated by $[GABA]_0$ and neural activity. GAT-2 expression in brain is greatest in leptomeningeal cells, although there is also some expression of GAT-2 in astrocytes. GAT-3 is the primary GABA transporter expressed in glial cells, and exists in perisynaptic and extrasynaptic glial membranes. BGT-1 expression is seen in glia, to a lesser degree than GAT-3, and in extraneural tissue including liver and kidney.

GABA Transporter Pharmacology

Pharmacologic agents that inhibit GABA transport have been indispensable tools in the study of GABA transporter function. Early antagonists of GABA uptake were the GABA analogs β-alanine, guvacine, and nipecotic acid (NPA). NPA is a nonselective GAT inhibitor that also induces GABA release through a process termed 'heteroexchange.' Many of the GABA transporter antagonists subsequently identified have been the result of chemical modifications to NPA or guvacine. These chemical modifications include addition of lipophilic groups to allow transfer of putative antieleptics across the blood–brain barrier; however, these modifications have also affected the pharmacologic action of these molecules, yielding highly selective inhibitors for specific GABA transporter subtypes. Commonly used research tools to selectively inhibit the neuronal GABA transporter GAT1 include the compounds SKF-899761 and NO-711 (also known as NNC-711). Tiagabine is also a relatively selective GAT1 antagonist. The compound SNAP-5114 is selective for GAT2 and GAT3. Antiepileptic drug development is an active field that has identified additional compounds with varying specificities for GABA transporters that promise to extend the list of research tools and potential therapeutic agents.

Electrophysiology

The study of GABA transporters and the effects of antiepileptic drugs on these molecules often employ

electrophysiologic measurements of membrane voltage or current from neurons in tissue culture or acute brain slices. These recordings are carried out most frequently with patch clamp methods. Patch clamp recordings allow the identification of both phasic and tonic forms of GABAergic inhibition, and allow the assessment of the effects of GABA transporter antagonists on these forms of inhibition. The effects of drugs that stimulate GABA release via GABA transporters may also be detected with patch clamp recordings often as increased tonic inhibition.

Measurements of GABA

Measurements of human brain GABA concentrations in vivo have been made with two different approaches. One approach is invasive and involves sampling of extracellular fluid with microdialysis catheters placed in or near an epileptic focus of a patient undergoing intracranial EEG investigations (as part of a presurgical evaluation for medically-refractory epilepsy). These samples can then be analyzed by high-performance liquid phase chromatography (HPLC) to determine GABA concentrations. This technique also provides the ability to perfuse the area of tissue under study with test solutions, including solutions with elevated K^+ to stimulate neurotransmitter release and those with zero Ca^{2+} to reduce vesicular release of neurotransmitter. A noninvasive approach that has been applied specifically to the study of antiepileptic drug effects on brain GABA concentrations is magnetic resonance spectroscopy (MRS). This method allows quantification of whole brain GABA concentrations (intracellular vs. extracellular GABA cannot be distinguished). Within study protocols, MRS has allowed investigators to determine the effects of some antiepileptic drugs (gabapentin, vigabatrin, valproic acid) on brain GABA concentration, both in control and in epileptic subjects, and at various time points following a single test dose of drug.

Results

GABA Transporters in Epilepsy

GABA transporters are active participants in the regulation of phasic and tonic inhibition. By controlling the time course of synaptic events and ambient [GABA], GABA transporters influence inhibitory tone and the excitation-inhibition balance in the brain. This balance is disrupted in epilepsy, leading to seizures. The roles of GABA transporters in epilepsy are complex. There is support for altered GABA transporter expression and function in both human and experimental epilepsy. These reported alterations include both downregulation and upregulation of GABA transporter number, altered patterns of expression, and diminished uptake capacity.

Surgery is an effective treatment for epilepsy that is refractory to medications, and tissue obtained during these therapeutic procedures has provided an opportunity to study the cellular and molecular properties of human epileptogenic tissue. In human TLE with hippocampal sclerosis (HS), GAT1 expression is reduced in the granule cell layer of dentate gyrus and the pyramidal cell layer (see **Figure 1(a)**). If this downregulation of GAT1 occurred in isolation, it might be expected to prolong IPSPs and promote elevations in ambient [GABA], thereby providing a compensatory, anticonvulsant increase in GABAergic inhibition in the setting of a hyperexcitable, epileptic neural network. However, in TLE with HS, the decrease in GAT1 may be due to cell death and loss of GABAergic terminals, so the anticonvulsant effect of GAT1 loss could be overshadowed by the proconvulsant effect of a reduction in GABA synapse number. Complicating conclusions about how a reduction in GAT1 expression might affect excitability, GABA transporters readily operate in the reverse direction in response to the membrane depolarization and elevation of intracellular sodium that occurs in neurons during high-frequency firing. Consistent with this reversal, measurements of extracellular GABA in human hippocampus (with microdialysis catheters) have shown that GABA is released during seizures and this GABA release is due, in part, to Ca^{2+}-independent, nonvesicular release of GABA by reversal of transporters. In this role, as a source of GABA release, GABA transporters exert an anticonvulsant effect which would be diminished by GABA transporter downregulation. Indeed, the reduction of GAT1 immunoreactivity seen in TLE with HS is associated with less GABA release during seizures (and in response to exogenous glutamate) compared to the contralateral, nonepileptogenic hippocampus (see **Figure 1(b)** and **(c)**). Electrophysiological measurements from human hippocampal tissue with HS have confirmed GABA transporter downregulation. During whole-cell recordings, the responses to exogenous GABA are prolonged in tissue with HS and the responses to NPA, a nonselective GAT inhibitor that induces GABA release, are attenuated (see **Figure 1(d)**). These results demonstrate reduced GABA transporter function (including GABA release) in at least one form of human epilepsy (i.e., TLE with HS). GABA transporter expression is reduced in genetically epilepsy prone rats as well.

Although the importance of GABA transporter downregulation in epileptogenesis and seizures is not firmly established, our consideration of GAT1 downregulation in TLE with HS illustrates the duplicitous nature of GABA transporters in regulating excitability and the conflicting effects produced by pharmacologic inhibition of GABA transporters. The inhibition of GABA transporters delays the removal of synaptically released GABA thereby prolonging IPSPs – an anticonvulsant effect – while at the

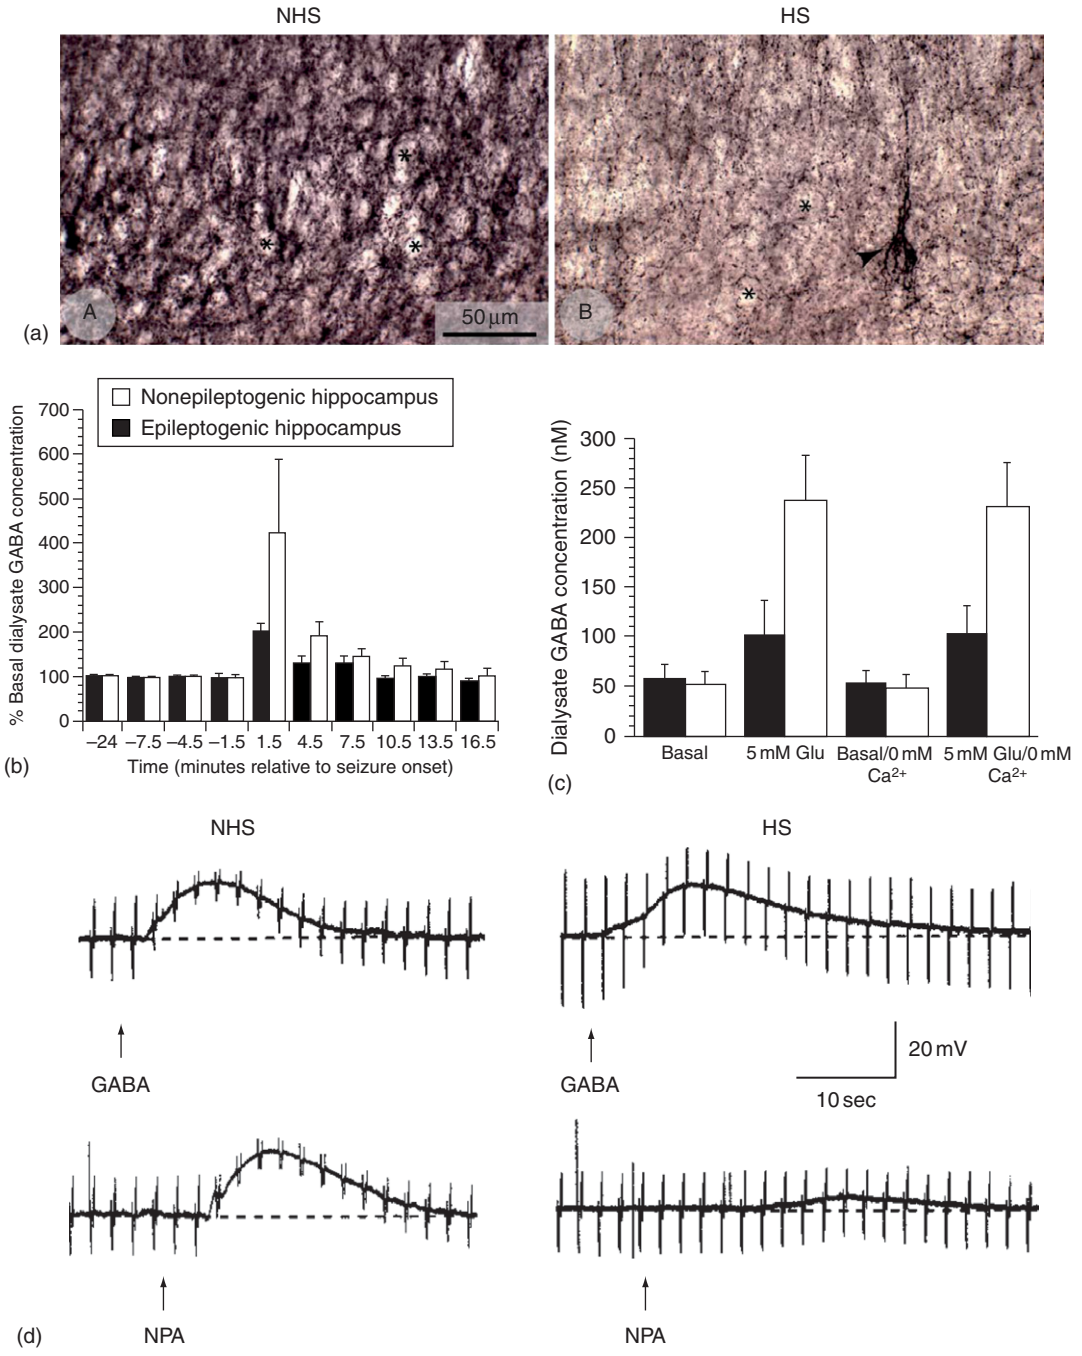

Figure 1 GABA transporter expression and function in human temporal lobe epilepsy with hippocampal sclerosis (HS). (a) Micrographs of immunohistochemical labeling for the GABA transporter GAT-1 in granule cell layer of human dentate gyrus. Tissue from a patient with a temporal lobe tumor but no hippocampal sclerosis (left, ''NHS'') showed diffuse labeling surrounding granule cell somata (asterisks). In contrast, in TLE with HS (right, ''HS'') immunostaining is reduced and only rare granule cells displayed immunostaining (arrowhead). Reproduced from Lee TS, Bjornsen LP, Paz C, Kim JH, *et al*. (2006) GAT1 and GAT3 expression are differently localized in the human epileptogenic hippocampus. *Acta Neuropathologica* 111: 351–363, with permission from Springer-Verlag. (b) Microdialysis catheter measurements of extracellular GABA during spontaneous seizures from human temporal lobe in vivo. GABA release during seizures is reduced in the hippocampus in which secondarily-generalized seizures originated (epileptogenic hippocampus). Reproduced from During MJ and Spencer DD (1993) Extracellular hippocampal glutamate and spontaneous seizure in the conscious brain. *The Lancet* 341: 1607–1610, with permission from Elsevier. (c) Microdialysis catheter measurements of extracellular GABA under basal conditions and during glutamate stimulation with or without extracellular calcium. GABA release in response to glutamate is primarily due to Ca^{2+}-independent, nonvesicular release and is reduced in epileptogenic hippocampus. Same legend as for part (b). Reproduced from During MJ, Ryder KM, and Spencer DD (1995) Hippocampal GABA transporter function in temporal-lobe epilepsy. *Nature* 376: 174–177, with permission from Nature Publishing. (d) The effects of exogenous GABA and NPA on

same time reducing nonvesicular GABA release – a proconvulsant effect. The situation is made even more complex by the presence of $GABA_A$ receptors on both principal cells and inhibitory interneurons, the variety of GABA transporter subtypes with different cellular localizations, the regulation of GABA transporter surface expression by extracellular GABA itself, and the fact that $GABA_A$ receptor activation can sometimes be depolarizing. Which action of GABA transporter inhibition (anticonvulsant or proconvulsant) dominates? Clinical and experimental studies have shown that drugs that selectively inhibit GAT1 are effective in reducing seizure occurrence, supporting the utility of this approach to treat epilepsy. Additionally, several effective antiepileptic drugs work indirectly through GABA transporters by modifying intracellular GABA metabolism thereby promoting GABA release and increasing ambient extracellular GABA concentrations. Moreover, some antiepileptic drugs exert a variety of anticonvulsant effects and have GABA uptake inhibition as part of their mechanistic profile.

GABA Transporters and Antiepileptic Drug Action

Tiagabine

Tiagabine is a structural analog of NPA, with an additional hydrophobic chain that allows for delivery across the blood brain barrier and alters the pharmacologic specificity of tiagabine. Tiagabine is the only direct GABA transporter inhibitor approved for clinical use, with an indication as adjunct therapy for partial epilepsy. It is effective in preventing seizures in several animal models of focal and generalized epilepsy (e.g., amygdaloid kindling, pentylene–tetrazol, audiogenic seizures). Tiagabine preferentially inhibits uptake by GAT1, but is active at other GABA transporters at higher concentrations (10^{-4} g mol^{-1}). GAT1 inhibition with tiagabine prolongs the time course of evoked IPSPs in hippocampal pyramidal cells without influencing IPSP amplitude (see **Figure 2(a)**). Tiagabine and other GAT1-selective inhibitors have little or no effect on the amplitude or time course of miniature synaptic potentials; presumably diffusion is sufficient to 'terminate' miniature IPSPs (due to smaller numbers of GABA molecules) without engaging GAT1. In hippocampus, selective GAT1 inhibition can also sometimes result in elevation of ambient [GABA] and increased tonic inhibition. These observations suggest that, tiagabine exerts its anticonvulsant actions through modulation of both phasic and tonic inhibition. In addition to its efficacy in patients and in animal models, tiagabine inhibits evoked epileptiform activity of single hippocampal neurons in situ (see **Figure 2(b)**).

Vigabatrin

Vigabatrin is an example of an antiepileptic drug that works indirectly through GABA transporters. GABA transporters are controlled by the transmembrane gradients of transported substrate and membrane potential. Elevation of cytosolic [GABA] is one perturbation that alters GABA transporter equilibrium, which in turn potentiates nonvesicular GABA release and leads to higher values of ambient [GABA]. Cytosolic GABA is normally degraded by the enzymatic action of GABA transaminase. Vigabatrin acts by irreversibly inhibiting GABA transaminase, causing elevation of GABA concentrations in vivo and in vitro. Vigabatrin, paradoxically, reduces the frequency and/or amplitude of IPSCs, demonstrating that enhancement of phasic inhibition does not underlie the anticonvulsant action of vigabatrin. Rather, the anticonvulsant action is due to enhancement of tonic inhibition. During perforated patch clamp recordings from hippocampal neurons, in the absence of extracellular calcium to block vesicular GABA release, tonic GABA receptor-mediated currents are enhanced in a time- and concentration-dependent manner by vigabatrin (see **Figure 3(a)** and **(b)**). Most importantly, pretreatment with the GAT-1 blocker NO-711 prevents the enhancement of tonic currents and IPSC amplitude reduction that are induced by vigabatrin, indicating that GABA is released by reverse transport. The elevation of ambient [GABA] caused by vigabatrin can desensitize some classes of $GABA_A$ receptors on neurons, and this desensitization may be the basis of the reduced amplitude and frequency of phasic synaptic events observed following vigabatrin treatment.

Gabapentin and pregabalin

Gabapentin and pregabalin are alkylated GABA derivatives that are effective in the treatment of seizures and neuropathic pain. Although these drugs are structurally similar and have overlapping clinical utility, it is not established that they share all the same mechanisms of

membrane potential of human hippocampal neurons recorded *in situ* after excision. Neurons in epileptic tissue with HS (right, ''HS'') have prolonged responses to exogenous GABA (intracellular chloride concentration is high in these experiments so GABA is depolarizing) and heteroexchange GABA release due to NPA is reduced compared to neurons from tissue with no HS (left, ''NHS''). These results demonstrate a decrease in function of the GABA transporter in HS, with less transporter-mediated GABA uptake and GABA release. Reproduced from Partrylo PR, Spencer DD, and Williamson A (2001) GABA uptake and heterotransport are impaired in the dentate gyrus of epileptic rats and humans with temporal lobe sclerosis. *Journal of Neurophysiology* 85: 1533–1542, with permission from American Physiological Society.

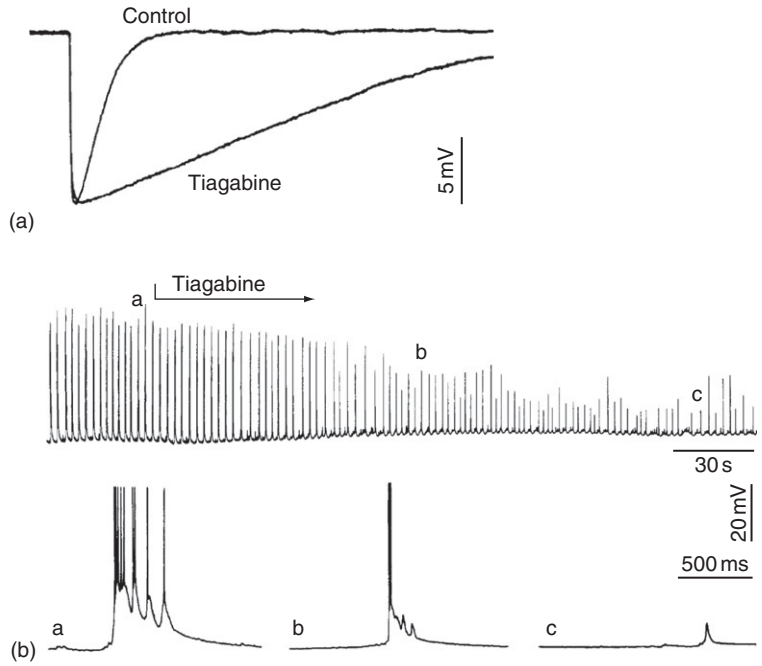

Figure 2 The GAT-1 inhibitor tiagabine prolongs inhibitory postsynaptic potentials (IPSPs) and inhibits epileptiform discharges. (a) Whole-cell recordings of IPSPs in a hippocampal neuron. Tiagabine prolonged IPSPs without affecting amplitude. (b) Whole-cell recording of epileptiform bursting induced by elevated K^+ (8.5 mM) from a hippocampal neuron in organotypic slice culture. This form of hyperexcitability is inhibited by tiagabine (25 μM). The bottom panel illustrates portions of the record from the top panel on an expanded time base, indicated by the letters. Reproduced from Thompson SM and Gahwiler BH (1992) Effects of the GABA uptake inhibitor tiaganine on inhibitory synaptic potentials in rat hippocampal slice cultures. *Journal of Neurophysiology* 67: 1698–1701, with permission from American Physiological Society.

action. Gabapentin, being the older of the two drugs, has been more extensively studied. The precise mechanism of action underlying the anticonvulsant effect of gabapentin (and pregabalin) is not known. The finding that gabapentin can antagonize presynaptic, voltage-sensitive calcium channels containing the α2δ subunit, thereby limiting neurotransmitter release, has focused attention on this mechanism as the action underlying the therapeutic effects of both gabapentin and pregabalin in epilepsy and pain. However, considerable data exist in support of gabapentin also causing effects on the GABAergic system. Gabapentin stimulates glutamic acid decarboxylase in vitro (GAD, the GABA synthetic enzyme) and gabapentin administered to patients in vivo rapidly (within 1 h) increases mean brain GABA concentration to 283% of control values (as determined with MRS). Gabapentin has no acute effects on GABA receptors themselves, but potentiates heteroexchange (transporter-mediated) release of GABA induced by NPA from axons and from hippocampal neurons in slices (see **Figure 4(a)**). This result could be explained by gabapentin's stimulation of GAD and increased cytosolic [GABA], a direct modulatory action on GABA transporters, or an increase in surface expression of GABA transporters. An increase in cytosolic [GABA], with a resultant change in GABA transporter equilibrium and elevated ambient [GABA], is a plausible hypothesis, because gabapentin also increases tonic inhibition of hippocampal neurons 2–3-fold following prolonged treatment (see **Figure 4(b)**). Interestingly, the effects of gabapentin and vigabatrin on tonic inhibition are synergistic. GABA transporters undergo regulated redistribution between the surface membrane and the intracellular compartments in response to a variety of stimuli (e.g., elevated extracellular GABA and depolarization). Gabapentin and pregabalin both induce a similar redistribution of GABA transporters to plasma membrane. Incubation of hippocampal neurons with gabapentin or pregabalin for two hours doubles the uptake of [^{3}H] GABA (see **Figure 4(c)**). These effects are not observed with acute application of drug during the assay period. Biotinylation experiments to define the intracellular and membrane fractions of GAT1 during western blotting demonstrated that the enhanced GABA uptake is due to mobilization of GAT1 to the plasma membrane (see **Figure 4(d)**). Independent of gabapentin's actions on calcium channels, its effects on the GABAergic system would be expected to contribute to its antiepileptic action via elevated GABA concentrations, enhanced transporter reversal, and increased tonic inhibition. The increase in plasma membrane GABA transporter number could

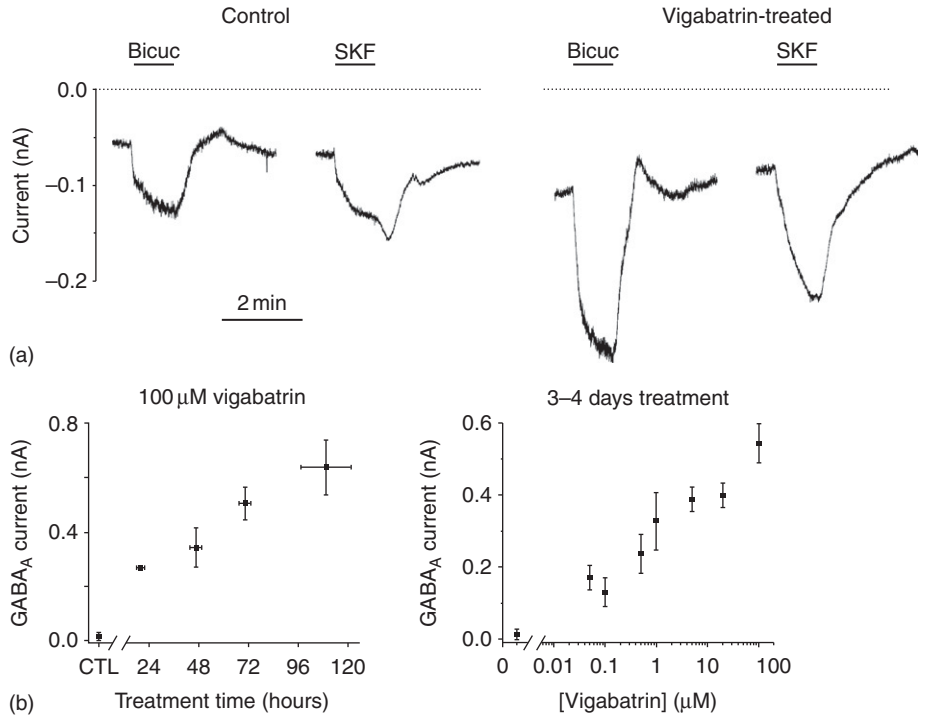

Figure 3 Vigabatrin increases ambient [GABA] and tonic inhibition through GABA transporter reversal. (a) whole-cell currents of hippocampal neurons recorded at −60 mV using gramicidin-perforated patch clamp techniques. Bicuculline, a $GABA_A$ receptor antagonist, blocked a tonic, outward current. The tonic currents were 2–3-fold larger after treatment with vigabatrin (100 μM) for 7 days. Tonic currents under control conditions and following vigabatrin treatment were blocked by the GAT1 inhibitor SKF-89976A indicating that GABA efflux was mediated by reversal of the GABA transporter. (b) Time and concentration dependence for vigabatrin potentiation of tonic inhibition in hippocampal neurons. Note that the effect of vigabatrin is very slow to develop (days), but occurs with as little as 50 nM. Reproduced from Wu Y, Wang W, and Richerson GB (2001) GABA transaminase inhibition induces spontaneous and enhances depolarization-evoked efflux via reversal of the GABA transporter. *Journal of Neuroscience* 21: 2630–2639, with permission from Society of Neuroscience.

shorten the duration of IPSCs (a proconvulsant effect), but perhaps more importantly would enhance nonvesicular GABA release during intense neural activity such as occurs during seizures (an anticonvulsant effect).

Valproic acid

Valproic acid is an anticonvulsant drug effective against focal and generalized epilepsy syndromes, with several well-characterized antiepileptic mechanisms of action that include Na^+ and Ca^{2+} channel inhibition, as well as modulation of GABA metabolism. As is the case with gabapentin and vigabatrin, alterations of GABA metabolism are expected to work indirectly through GABA transporters (potentiation of nonvesicular release, elevation of ambient [GABA]). Elevations of whole brain GABA levels are seen with valproic acid treatment, and valproic acid has in vitro activity against GABA metabolizing enzymes. These in vitro activities include stimulation of GAD (GABA synthetic enzyme) and inhibition of GABA transaminase (GABA degradative enzyme). Additionally, valproic acid has been reported to directly inhibit GABA transport of GAT1-transfected oocytes.

Future Directions

GABA transporter isoforms in the brain have unique cellular localizations and identifying pharmacology. The expression and function of GABA transporters are altered in some forms of epilepsy. GABA transporters serve to terminate synaptic events; their pharmacologic inhibition prolongs IPSPs and can increase tonic inhibition. Drugs such as tiagabine that directly inhibit the neuronal GABA transporter GAT1 exert their antiepileptic effect through this mechanism. GABA transporters exist near equilibrium at typical resting membrane potentials of neurons and operate in the reverse direction to release GABA under appropriate conditions including during spontaneous seizures. Several antiepileptic drugs (gabapentin, pregabalin, vigabatrin, and valproic acid) work indirectly through GABA transporters by increasing intracellular GABA, thereby altering GABA transporter equilibrium and leading to increased ambient [GABA] through facilitation of GABA release.

Future research promises to expand our knowledge of the changes in the expression and function of the different GABA transporter isoforms in epilepsy. This information

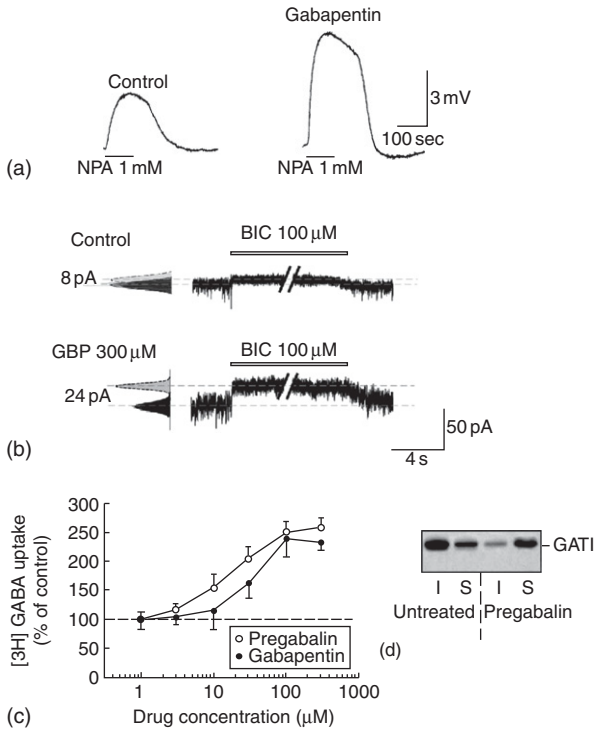

Figure 4 Gabapentin and pregabalin, alkylated GABA derivatives, potentiate nonvesicular release of GABA by GABA transporters, increase tonic inhibition, enhance GABA uptake, and increase membrane surface expression of GAT1. (a) Membrane potential of rat optic nerve axons during nipecotic acid (NPA, 1 mM) application. Pretreatment of nerves with gabapentin (100 μM) for 1 h robustly potentiated the release of GABA induced by NPA. Gabapentin had no effect on depolarization produced with exogenous GABA. Axons maintain high intracellular Cl^- concentrations so GABA responses are depolarizing. A similar response occurs in neurons in hippocampal slices. Reproduced from Kocsis JD and Honmou O (1994) Gabapentin increases GABA-induced depolarization in rat neonatal optic nerve. *Neuroscience Letters* 169: 181–184, with permission from Elsevier. (b) Tonic membrane currents of hippocampal neurons. Pretreatment of neurons with gabapentin (300 μM) for 36–48 h (bottom panel) produced a threefold increase in tonic inhibition compared to control neurons (top panel). Insets on left are all point histograms of current recordings before and during bicuculline application used to define the tonic, $GABA_A$ receptor mediated current. Reproduced from Cheng VY, Bonin RP, Chiu MW, Newell JG, MacDonald JF, and Orser BA (2006) Gabapentin increases a tonic inhibitory conductance in hippocampal pyramidal neurons. *Anesthesiology* 105: 325–333, with permission from American Society of Anesthesiologists. (c) Gabapentin and pregabalin both produce an approximately twofold increase in GABA uptake. Shown are dose–response curves for GABA uptake by hippocampal neurons. Neurons were incubated in drug for 2 h. (d) Immunoblot of biotinylated, surface (S) and nonbiotinylated, intracellular (I) GAT1 protein. Pretreatment with pregabalin for 2 h produced a shift of GAT1 protein from the intracellular to the surface fraction. will advance our understanding of the roles and function that GABA transporters play in health and disease. Antiepileptic drug development has focused on identifying new specific inhibitors of GABA transporter isoforms that may be employed, not only as research tools but also as medical therapy. The development of specific inhibitors for GABA transporter isoforms has the potential to allow recognition of previously underappreciated mechanisms in epilepsy, such as the betaine–GABA transporter (BGT-1). Better defining the pro-convulsant versus the anticonvulsant roles of GABA transporters may lead to more efficacious pharmacological treatments that block the former and enhance the latter.

Local Delivery of Antiepileptic Drugs

F Bannout and R S Fisher, Stanford Comprehensive Epilepsy Center, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Medical therapy for epilepsy is unsatisfactory in about one-third of treated patients. Increasing dosage of medication increases efficacy, but also leads to toxicity. One strategic approach to this conundrum is development of local drug delivery to regions of brain involved in generation of seizures. Local delivery would allow relatively high and effective concentrations, but with minimization of side effects. Side effects intrinsic to the action of the drug on local circuits – for example, impairment of memory with delivery of drug into the hippocampus – would theoretically remain. However, side effects that are incidental to the antiepileptic mechanism – such as hepatotoxicity, suppression of blood counts, kidney stones, and possibly some neurological side effects – would be attenuated by local delivery.

Background

Local delivery of drug to CNS has been employed in clinical practice for pain (epidural or subdural morphine) and spasticity (epidural baclofen). Wafers (which slowly release agent into a resection bed of a tumor), and by catheter delivery into brain, enhanced by convection/pressure have been used in the chemotherapy of brain tumors. Delivery of antiepileptic drugs to the neuraxis has not yet been employed for seizure patients. For this procedure to become a reality in epilepsy therapy, methods to deliver a compound to a seizure focus – or, alternatively, to a part of brain that influences the excitability of a seizure focus – will be needed. Treatment must be shown to be both safe and effective. In the case of devices that deliver drug to brain, safety and efficacy must be demonstrated both for the drug and for the device.

Two general strategies could be used for local drug delivery. One would supply drug on a regular dosing schedule. The other would deliver drug in response to a seizure, or perhaps on command of a supplementary device (not yet available) that is able to predict the imminent onset of a seizure.

Several routes of direct administration of drugs to the brain have been considered, with different degrees of invasivity, ranging from intravenous infusion of liposomes or circulating prodrugs to devices or catheters implanted in brain tissue or cerebrospinal fluid (CSF). **Table 1** shows a few promising approaches to drug delivery to the CNS.

Methods/Results

Seizure-Activated Prodrugs

A prodrug is in an active compound that circulates harmlessly until activated by some metabolic process or clinically relevant event. The commonly used AED oxcarbazepine is, in fact, a prodrug for its monohydroxy derivative, which is the active form. Fosphenytoin is a prodrug of phenytoin, less irritating for intravenous injection. However, metabolic conversion of these two existing AEDs confers no special advantage in terms of penetration or concentration in the brain. One drug that does confer such a potential advantage for epilepsy is under testing, in the form of phosphatidycholine-valproic acid (DP-VPA). The phosphatidylcholine moiety attached to the valproic acid molecule renders the drug inactive until a phospholipase, released at a seizure focus, cleaves the drug to active valproic acid. In animal models, this drug did not block the first seizure, but impeded development of subsequent seizures, presumably because of accumulation of valproic acid at the site of seizure initiation. Clinical trials are underway. A 28-day double-blind crossover trial documented a 30% reduction in seizure frequency compared with placebo, an improvement that is comparable with the results of adding oral valproate to a drug

Introduction

Medical therapy for epilepsy is unsatisfactory in about one-third of treated patients. Increasing dosage of medication increases efficacy, but also leads to toxicity. One strategic approach to this conundrum is development of local drug delivery to regions of brain involved in generation of seizures. Local delivery would allow relatively high and effective concentrations, but with minimization of side effects. Side effects intrinsic to the action of the drug on local circuits – for example, impairment of memory with delivery of drug into the hippocampus – would theoretically remain. However, side effects that are incidental to the antiepileptic mechanism – such as hepatotoxicity, suppression of blood counts, kidney stones, and possibly some neurological side effects – would be attenuated by local delivery.

Background

Local delivery of drug to CNS has been employed in clinical practice for pain (epidural or subdural morphine) and spasticity (epidural baclofen). Wafers (which slowly release agent into a resection bed of a tumor), and by catheter delivery into brain, enhanced by convection/pressure have been used in the chemotherapy of brain tumors. Delivery of antiepileptic drugs to the neuraxis has not yet been employed for seizure patients. For this procedure to become a reality in epilepsy therapy, methods to deliver a compound to a seizure focus – or, alternatively, to a part of brain that influences the excitability of a seizure focus – will be needed. Treatment must be shown to be both safe and effective. In the case of devices that deliver drug to brain, safety and efficacy must be demonstrated both for the drug and for the device.

Two general strategies could be used for local drug delivery. One would supply drug on a regular dosing schedule. The other would deliver drug in response to a seizure, or perhaps on command of a supplementary device (not yet available) that is able to predict the imminent onset of a seizure.

Several routes of direct administration of drugs to the brain have been considered, with different degrees of invasivity, ranging from intravenous infusion of liposomes or circulating prodrugs to devices or catheters implanted in brain tissue or cerebrospinal fluid (CSF). **Table 1** shows a few promising approaches to drug delivery to the CNS.

Methods/Results

Seizure-Activated Prodrugs

A prodrug is in an active compound that circulates harmlessly until activated by some metabolic process or clinically relevant event. The commonly used AED oxcarbazepine is, in fact, a prodrug for its monohydroxy derivative, which is the active form. Fosphenytoin is a prodrug of phenytoin, less irritating for intravenous injection. However, metabolic conversion of these two existing AEDs confers no special advantage in terms of penetration or concentration in the brain. One drug that does confer such a potential advantage for epilepsy is under testing, in the form of phosphatidycholine-valproic acid (DP-VPA). The phosphatidylcholine moiety attached to the valproic acid molecule renders the drug inactive until a phospholipase, released at a seizure focus, cleaves the drug to active valproic acid. In animal models, this drug did not block the first seizure, but impeded development of subsequent seizures, presumably because of accumulation of valproic acid at the site of seizure initiation. Clinical trials are underway. A 28-day double-blind crossover trial documented a 30% reduction in seizure frequency compared with placebo, an improvement that is comparable with the results of adding oral valproate to a drug

regimen. Such trials may or may not lead to release of this particular agent, but they do serve as an interesting proof-in-principle for prodrugs acting at the seizure focus. Further understanding of metabolic activities that are relatively specific to a seizure focus would be useful, since such an understanding might provide other targets for local therapy at the seizure focus (e.g., in the form of agents blocking a focus-specific enzyme).

Carrier Vehicles

Carrier vehicles encapsulate drugs in an inert shell in order to enhance pharmaceutical potency and reduce toxicity in nontarget tissue. These vehicles include conventional liposomes, chemically modified liposomes, microsomes, and polymeric nanoparticles. A liposome is a spherical vesicle composed of a phospholipid and cholesterol bilayer membrane, encapsulated in an aqueous solution. Liposomes are able to carry both hydrophilic solutes as well as hydrophobic chemicals. The lipid bilayer fuses with the cellular membranes to release the contents of the liposome into the tissue, typically over a period of days to weeks, with permeability of the drug depending upon factors such as particle size, pH, osmolality, and other adjustable factors. Liposomes become particularly interesting when coupled to a targeting mechanism – e.g., based on immune affinity or receptor binding (**Figure 1**). The liposomes then can be injected systemically, home to a target of interest, and slowly deliver high concentrations of medications in the region of interest. One example of such use is liposomal doxorubicin for treating hepatic tumors; this delivery method provides significantly reduced systemic and cardiac toxicity.

Local perfusion by catheter

Mori and associates studied the efficacy of liposomal phenytoin in an amygdala seizure focus in the rat, induced by injecting dibutyryl-cAMP and ethylenediaminetetraacetic acid into amygdala and bilateral sensorimotor cortex. Two doses of liposomal phenytoin, given intravenously at 40 mg kg^{-1} at a time 30 and 60 min after injection of cAMP, were able to suppress interictal and ictal amygdalar discharges for up to 170 min. Labeling liposomes with horseradish peroxidase demonstrated preferential accumulation of liposomes in the amygdalar seizure focus. Amiloride is a sodium ion exchange inhibitor with efficacy against animal models of seizures. Its use, however, is limited, since it produces systemic hyperkalemia when conventionally injected. However, Ali and associates showed that liposomal amiloride, delivered intravenously in mice, can inhibit chemically induced seizures, without producing significant hyperkalemia.

Microsomes are conceptually similar to liposomes, but are fabricated from colloidal matrices of polymers. Investigators have recommended that nanoparticles (liposomes or microsomes) should have particle diameter less than 100 nm, and should participate in receptor-mediated transcytosis across brain capillary endothelial cells in order to penetrate into brain. A better technique to enhance carrier-mediated transport across the blood–brain barrier (BBB) is to link a liposome to an antibody, such as OX26, which piggybacks on a transport mechanism for iron into the brain. Several other antibodies and transporter processes are candidates for assisting penetration of nanoparticles into brain. The antigenic targets that would be most useful for putative AEDs presently are unknown, and fabrication of liposomal antiseizure preparations can be technically challenging.

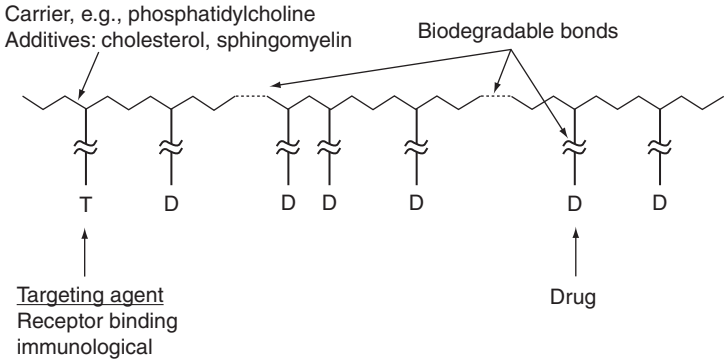

Figure 1 A general structure of a polysome or microsome. Liposomes are colloidal particles composed of phospholipid molecules assembled in a cell membrane-like bilayer or a multilayer sheet-disk configuration. Microsomes use artificial polymers, such as polysorbate to package the drug (D). A targeting agent (T) can be an affiliated receptor binding compound or antibody that will adhere to the desired target tissue.

CSF Delivery Methods

The BBB protects brain from the systemic microenvironment. Most of the AEDs in current use are lipophilic, so they can pass the lipid component of the BBB membrane. Drugs that do not cross the BBB are not suitable candidates for systemically administered epilepsy therapy. In the special case of status epilepticus, consideration might be given to using mannitol to transiently open the BBB for nonlipophilic medications. One example in the clinical literature entails use of mannitol to deliver higher doses to brain of systemically administered chemotherapy in patients with brain tumors. This approach is so far a theoretical possibility; no such candidate drug for treatment of status epilepticus is in clinical use.

The most direct way to reach the CSF is to place a catheter into ventricles or the subarachnoid space, partially bypassing the BBB. Medication can be administered directly through the catheter or by an implanted programmable infusion pump. This approach has been used in clinical practice for antibiotics, chemotherapy, spasticity, and pain. Laboratory investigations have also looked at intrathecal or intraventricular administration of AEDs. For example, intraventricularly administered phenobarbital and carbamazepine were shown to attenuate amygdala-induced seizures in rats; phenytoin inhibited seizures, but only for the first 15 min after administration. A subsequent study showed that intraventricular valproic acid inhibited both partial and generalized seizures in the amygdala-kindled rat. We have shown that fluorothyl-induced seizures in rats were delayed by a prior 5-day infusion of gabapentin into ventricle by an implanted osmotic pump.

Medication administered into ventricles does not quickly penetrate brain parenchyma. A study of ^{111}In diethylenetriamine pentaacetic acid placed in human ventricles showed that the drug reaches the cisterna magna in 5 min, the lumbar cord in 30 min, and the Sylvian cisterns in 50 min. Penetration to brain deep nuclei by passive diffusion requires several hours or longer. This observation suggests that intraventricular administration of AEDs would not be suitable for responsive therapy to a detected seizure, unless the focus were to be located very near the ventricle. Medications can be administered to the CSF space via a lumbar spine catheter, thereby eliminating risk of direct brain trauma from the procedure. However, the degree to which thecally administered drug penetrates and mixes with ventricular CSF is uncertain, since CSF flow is ventriculo-pedal. Intrathecal administration of pain medications may obviate this problem by having effects directly on spinal cord neuronal systems.

Implanted Slow-Release AEDs

The concept of implanting slow-release forms of medications into the brain was pioneered in the treatment of glioblastoma, with polymer matrix wafers containing BCNU (carmustine). Implantable biodegradable microspheres also have been studied in brain tumor patients as another method to provide sustained drug delivery; for example, 5-fluorouracil-loaded microspheres have been surgically implanted into the tumor bed of patients with an unresectable glioma. The CSF and the blood concentration of the drug were found to be negligible. Phenytoin can be conjoined to a poly-ε-caprolactone microcarrier to make stable dissolvable particles, which might be of use for treating seizures.

The wafer polymer concept has been adapted, experimentally, to treat seizures in a rat model of epilepsy produced by focal application of cobalt to neocortex. Phenytoin was prepared in an ethylene–vinyl acetate (EVAc) controlled-release polymer and surgically implanted over the seizure focus. Phenytoin was released for over a year, with a calculated total release time of 3.5 years. Implantation of polymer loaded with phenytoin reduced both EEG epileptiform activity and behavioral seizures compared with inert polymer controls. Implantation of slow-release AEDs provides potential benefits in terms of high concentrations of drug at a relevant brain site, with low concentrations – and therefore low side effects – elsewhere. The technique also has disadvantages. Drug release from the wafer is nonlinear over time. With narrow therapeutic/toxic ratios for many AEDs, this factor could pose a problem in dosing. Many of the AEDs have low potency and poor solubility in water, making it necessary to design large volume wafers. Finally, the need to replace the polymer via a craniotomy every few years is a serious practical limitation. Trials in epilepsy patients may await solutions to these concerns.

Epidural Drug

Epidural placement of a drug reservoir may be less traumatic than is subdural or intraparenchymal placement of drug. An additional advantage of epidural delivery is use of a defined space surrounded by bone and dura to assist with localization of the drug over the intended target. Disadvantages include inability to approach sites remote from the convexities of brain, and limited penetration through dura. Proof-in-principle of epidural drug administration was shown by our laboratory, and developed by others in studies of a neocortical seizure focus in rats. A cup was surgically implanted over intact parietal lobe dura, and later filled with convulsant acetylcholine or anticonvulsant phenobarbital. Starting with phenobarbital prevented subsequent acetylcholine-induced seizures. Phenobarbital administration following acetylcholine terminated seizures within 2.5 min. In another study, these investigators showed that epidural GABA could prevent acetylcholine-induced seizures, but could not terminate them once they were developed.

Human dura mater is about one-third of a millimeter thick, which would be expected to present much more of a barrier to drug penetration than does the thinner rodent dura. This barrier would obviously be a disadvantage for acute administration of antiseizure medications, but it might be less of a problem for chronic administration – where, for example, epidural medication is known to work for pain control.

Local Perfusion by Catheter

Catheters can deliver AEDs from a reservoir associated with a programmable infusion pump to the region of a seizure focus in brain. Such a strategy has, to date, been used in animal models of epilepsy but not in the clinical setting. Injection of the excitatory amino acid antagonist 2-amino-7-phosphono-heptanoate into substantia nigra, entopeduncular nucleus, or piriform cortex blocks seizures produced by pilocarpine injection in rats. Infusion of 2% lidocaine into deep prepiriform cortex of rat blocks seizures induced by bicuculline.

We have further examined laboratory methods to deliver putative antiseizure medications directly to a seizure focus. Interictal spikes in rat neocortex, produced by the GABA-antagonist bicuculline methiodide, can be reduced to about 2% of baseline levels by applying diazepam to the seizure focus via an epidural cannula (**Figure 2**). Ictal events in rats, produced by cobalt and pilocarpine, could be eliminated or delayed by diazepam applied to the seizure focus. Systemic levels of diazepam were insufficient to account for the antiseizure action. Diazepam infusion also was able to prevent epileptiform activity when administered to the region of the seizure focus in advance. Left hippocampus was implanted with an injection catheter in 15 rats, along with hippocampal and surface EEG recording electrodes. Diazepam was then injected into hippocampus, followed 5 min later by bicuculline. Compared with control vehicle, diazepam reduced numbers of interictal spikes and numbers of electrographic and behavioral seizures, and increased latency to those seizures that did occur. The naturally occurring neuromodulator adenosine, which suppresses synaptic activity via the A1 receptor, can produce a similar prophylactic action when infused via a hippocampal cannula prior to administration of bicuculline methiodide into the same cannula.

The process of focal antiseizure drug application can be coupled to seizure detection. In an experiment in our laboratory, neocortical interictal spikes and behavioral-

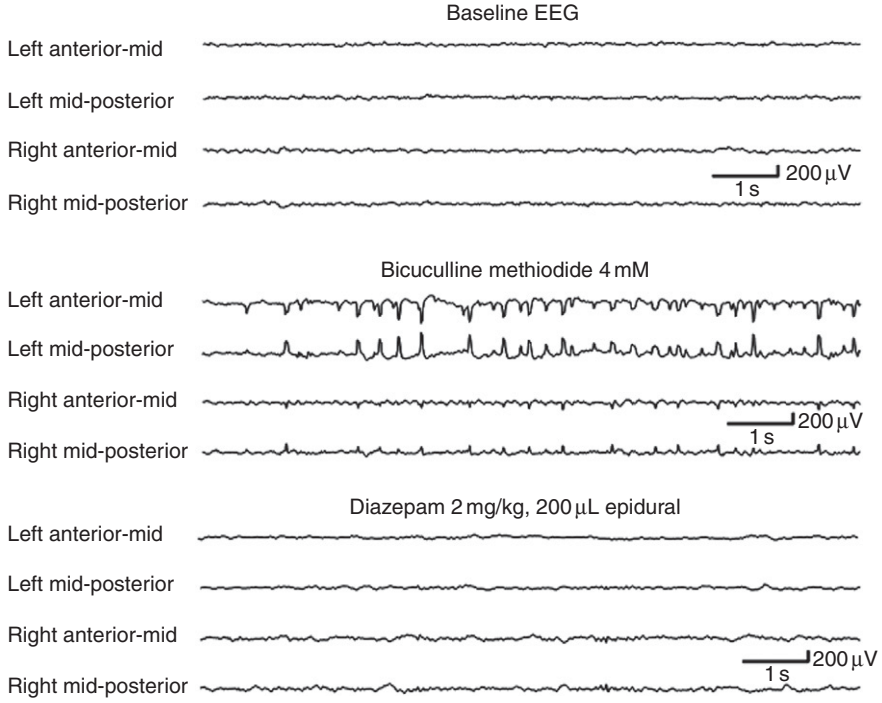

Figure 2 Each panel shows four channels of EEG recorded from bone screws implanted into rat skull, two from the left and two from the right. Anterior, mid and posterior refer to screw placement in the anterior–posterior dimension. The convulsant GABA antagonist, bicuculline methiodide (BMI) 4 mM is placed in the epidural space adjacent to the 'left mid' electrode. Compared with baseline in the top four EEG channels, administration of BMI can be seen to produce frequent left epileptiform spikes. In the bottom panel, administration of diazepam, a GABA-A receptor allosteric modulator and clinical AED, eliminates the spiking within a few minutes.

electroencephalographic seizures were created by epidural bicuculline methiodide in a rat. Bone screws placed near the seizure focus detected the ictal EEG activity by a digital seizure detection algorithm, and then triggered an external programmable infusion pump to deliver diazepam to the same epidural space. Diazepam administration occasionally shortened the detected seizure, but more often depressed regional EEG activity and eliminated emergence of other seizures (within the 40-min duration of the experiment). Mean numbers of seizures were reduced from 2.9 for vehicle-treated control animals to 0.2 for diazepam-treated animals. This paradigm might be expected to work even better if coupled with seizure-prediction algorithms that are now under development.

Reduction of epileptiform activity by local infusion of antiseizure medicines is established in principle, but several important issues need resolution before the technique is adopted clinically. First, what is the best drug, one that is both effective and safe, even if it spreads beyond the expected infusion area? Diazepam would fail these criteria, because its pH in solution is very alkaline, and because it can depress brainstem respiratory centers. A suitable drug for direct brain infusion has two advantages over usual candidate AEDs: it need not be orally absorbed and it need not be able to cross the BBB. Peptides might therefore make good candidates for focal infusion. Second, will the drug lead to tolerance or even a rebound effect, with more seizures at times of non-infusion? Continuous infusion with GABA for a few days, followed by cessation, leads to a withdrawal model of epilepsy. Muscimol, in contrast, seems not to produce such a rebound. Third, can the drug be distributed to relevant tissue? Passive diffusion is a slow process, requiring hours or days. If drug is carried away from the site of interest by bulk CSF flow or vascular uptake, then adequate concentrations may never be achieved.

Convection-enhanced delivery (CED) is a method of delivering drug by bulk flow driven by pressure, usually provided by a continuous infusion pump. Penetration into brain substantially exceeds that of simple diffusion. Chemotherapeutic agents have been administered to patients by CED. Infusion of the GABA agonist, muscimol, into the globus pallidus interna has been used without complication in a patient with Parkinson disease, to transiently relieve contralateral rigidity and bradykinesia. Distribution of muscimol was studied in monkey hippocampus after administration by an infusion pump and implanted hippocampal catheter. Autoradiography and MRI imaging of brain water demonstrated a 'teardrop' of muscimol distribution, with backflow along a space around the catheter pathway through hippocampus. Drug distribution was substantially greater than could be accounted for by passive diffusion. This backflow can be useful for drug distribution through an elongated brain structure, but if greater localization to the catheter tip is desired, then a reflux-free cannula may be of use. CED has not yet been used for treatment of clinical epilepsy.

Other Techniques

Two additional techniques, brain cell transplants and gene therapy, have potential for focal chemical delivery to a region of seizure production in brain, but are beyond the scope of this review. Those interested can see references in Further Reading.

Directions for Future Research

Several problems must be solved before local delivery of AEDs to brain will become a practical clinical approach. The main problem is one of drug distribution. Passive diffusion of a drug is very slow, and even slower if drug is metabolized in brain or taken up into venous blood. Recent experiments on convection-enhanced drug delivery may partially solve this problem. Penetration through the BBB for large liposomes, microsome, or virosomes remains a limiting factor. Recent research linking these delivery vehicles to proteins that are actively transported into brain is promising, but amount of drug so delivered remains small.

A second problem to be solved is managing possible compensatory changes in brain receptors that are exposed chronically to high concentrations of drugs. Research will be required to characterize long-term effects of drug exposure on brain excitability. Future research must show that local drug perfusion or carrier delivery does not result in a 'rebound' of increased excitability when drug delivery is interrupted.

The third major issue is selection of the best drug or drugs for local delivery. A useful drug needs to act where it is delivered and stay away from brain regions where it might have negative effects (e.g., on brainstem cardiorespiratory reflexes). Currently used AEDs are brought to market, in part, because of availability with oral administration and absence of deleterious peripheral metabolism. These concerns are not obvious limitations with optimal design of drugs for direct delivery to brain tissue. Therefore, a useful antiepileptic drug for local delivery to brain is likely to be a novel agent or an existing agent used in a new way.

Pathways of Drug Diffusion into the Epileptic Brain

Introduction

The central nervous system (CNS) is protected by physical and vascular barriers – namely, the skull, the blood-to-CSF, and the blood–brain barriers (BBB). While the skull protects the brain from mechanic insults, the BBB protects the brain from potentially harmful substances present in the bloodstream, while at the same time supplying the brain with the nutrients required for proper functions (**Figure 1(a)**). The BBB strictly regulates the brain penetration of drugs and controls the trafficking of cells of the immune system from the blood into the brain. Failure of these barriers is often associated with CNS pathologies (e.g., malformations of cortical development (MCD), brain tumors, epilepsy, and multiple sclerosis). Due to the presence of such complex, yet delicate mechanisms of protection, pharmacological targeting of CNS pathologies is challenging. Effective treatment often requires new approaches to drug delivery in order to outwit vascular barriers. Several neurological diseases are refractory to drug treatment. For example, while long-term antiepileptic drug (AED) treatment is the standard therapeutic approach to block seizure occurrence in epileptic patients, a significant number of patients consistently fail to respond to AEDs. The probability of seizure freedom becomes very low if the administration of three (or more) AEDs, given alone or in combination, fails to control seizure activity – hence the term 'multiple drug

Pathways of Drug Diffusion into the Epileptic Brain

Introduction

The central nervous system (CNS) is protected by physical and vascular barriers – namely, the skull, the blood-to-CSF, and the blood–brain barriers (BBB). While the skull protects the brain from mechanic insults, the BBB protects the brain from potentially harmful substances present in the bloodstream, while at the same time supplying the brain with the nutrients required for proper functions (**Figure 1(a)**). The BBB strictly regulates the brain penetration of drugs and controls the trafficking of cells of the immune system from the blood into the brain. Failure of these barriers is often associated with CNS pathologies (e.g., malformations of cortical development (MCD), brain tumors, epilepsy, and multiple sclerosis). Due to the presence of such complex, yet delicate mechanisms of protection, pharmacological targeting of CNS pathologies is challenging. Effective treatment often requires new approaches to drug delivery in order to outwit vascular barriers. Several neurological diseases are refractory to drug treatment. For example, while long-term antiepileptic drug (AED) treatment is the standard therapeutic approach to block seizure occurrence in epileptic patients, a significant number of patients consistently fail to respond to AEDs. The probability of seizure freedom becomes very low if the administration of three (or more) AEDs, given alone or in combination, fails to control seizure activity – hence the term 'multiple drug

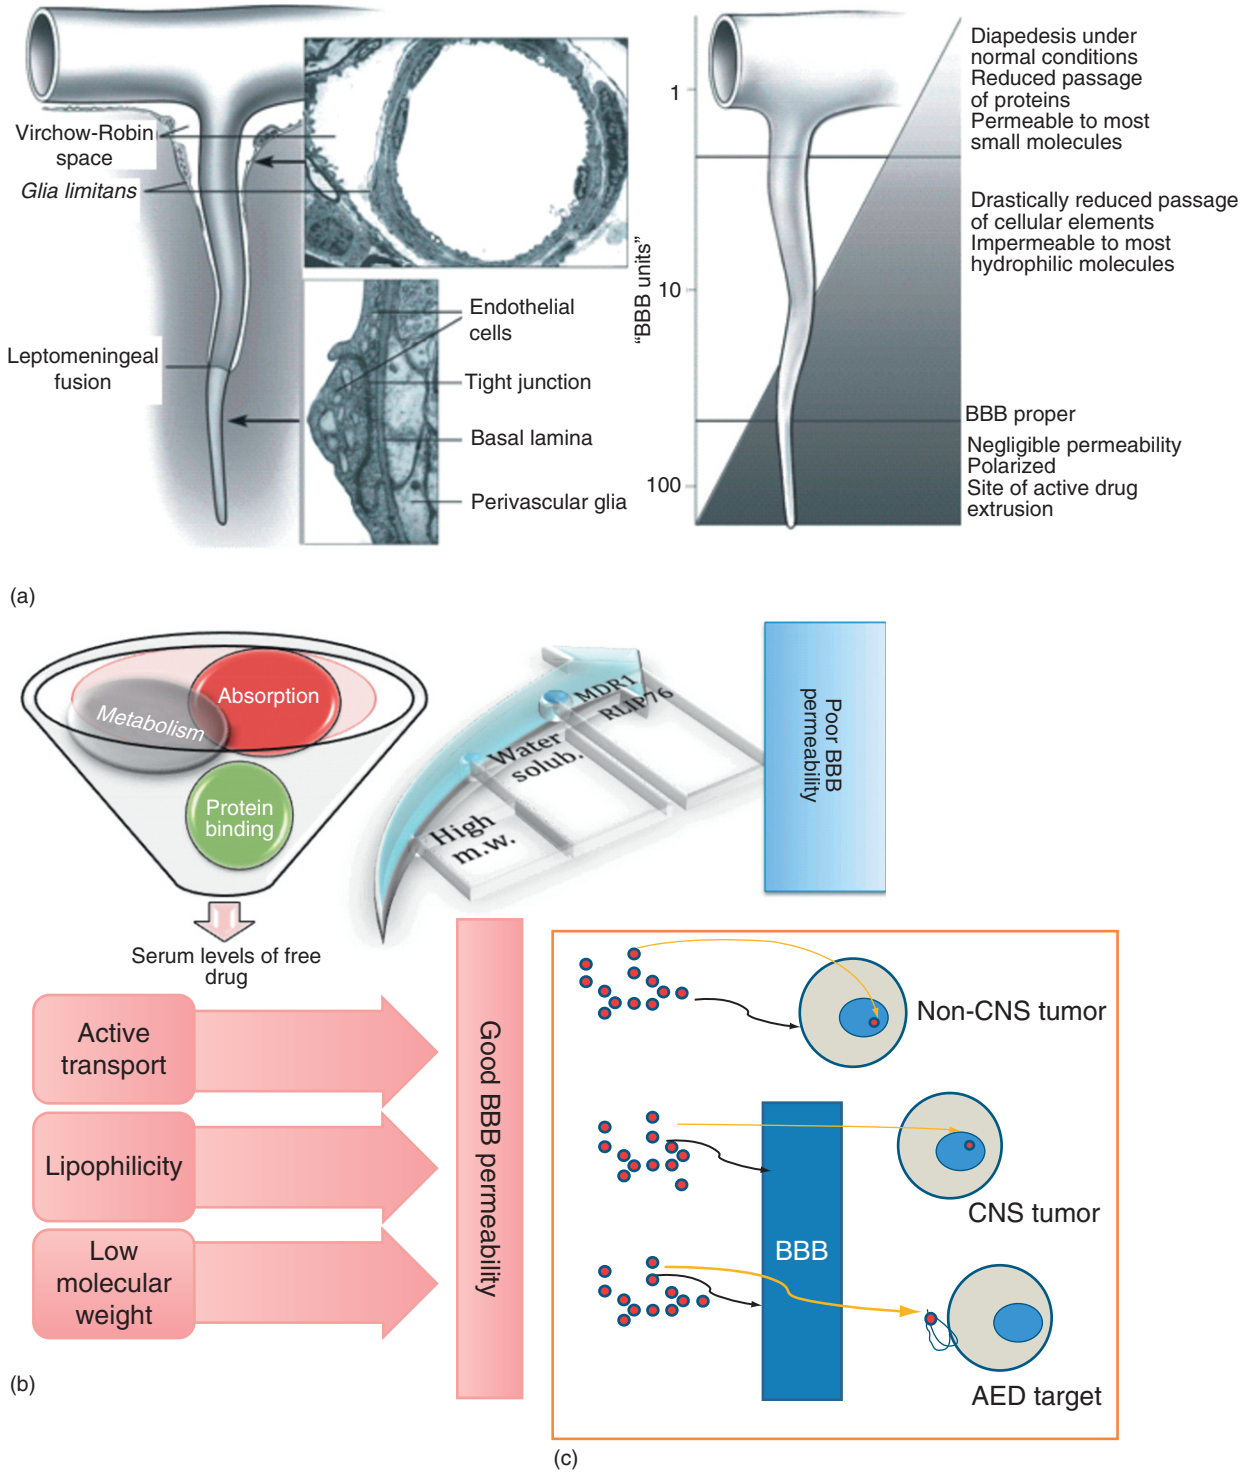

Figure 1 (a) Endothelial cells constitute the BBB. These cells are oriented perpendicular to the direction of blood flow and are exquisitely sensitive to shear stress. Several known contributory factors leading to CNS disorders are believed to act, at least in part, by direct damage to the endothelial cell layer. While the morphological appearance of brain microvascular endothelial cells at the light microscopy level is not dissimilar from their systemic counterpart, it is known today that several distinct submicroscopic and physiological features endow unique properties to these cells. Since both cerebral and systemic microvascular endothelial cells are exposed to comparable levels of shear stress, it is evident that mechanisms other than exposure to blood flow alone must be involved in the process of inducing peculiar BBB properties in undifferentiated endothelial cells. As shown in the *inset*, perivascular glial cells are ideally situated for abluminally influencing the endothelium and it is now accepted that the 'BBB organ' is constituted not only by endothelial cells, but by glial end feet as well. Current understanding of the mechanisms of neuroimmunological interactions of specialized cells with the BBB has also suggested involvement of both perivascular pericytes and microglia as active components

Table 1 Mechanisms supporting the pharmacokinetic hypothesis of multiple drug resistance

	Previous data available?

resistance.' In these cases, neurosurgical resection of the epileptic tissue often represents the last alternative to seizure control. In the past ten years, several new AEDs have been released, but no major reduction in the overall percentage of drug-resistant patients has been achieved. This situation underscores the nonspecificity of the drug refractory process, suggesting that a broad-range/general mechanism can affect the efficacy of all the available AEDs. In this article, we attempt to summarize the possible impediments and determinants of successful drug delivery into the epileptic brain.

Background – Drug-Resistance in Epilepsy

In the normal brain, several mechanisms regulate, directly or indirectly, penetration of drugs to their site of action in the brain (**Figure 1**). These mechanisms include metabolic transformation by specialized enzymes, binding of drugs to serum protein, drug transporters at the BBB, and transformation of 'prodrugs' into active forms. Drug resistance in epilepsy is further complicated by the variable nature of the pathophysiological process, the possible evolution of resistance over time, and the individual sensitivity to drugs (congenital or acquired). Two general hypotheses – pharmacokinetic and pharmacodynamic – have been proposed to explain refractoriness to AEDs. This article focuses particularly on the pharmacokinetic hypothesis.

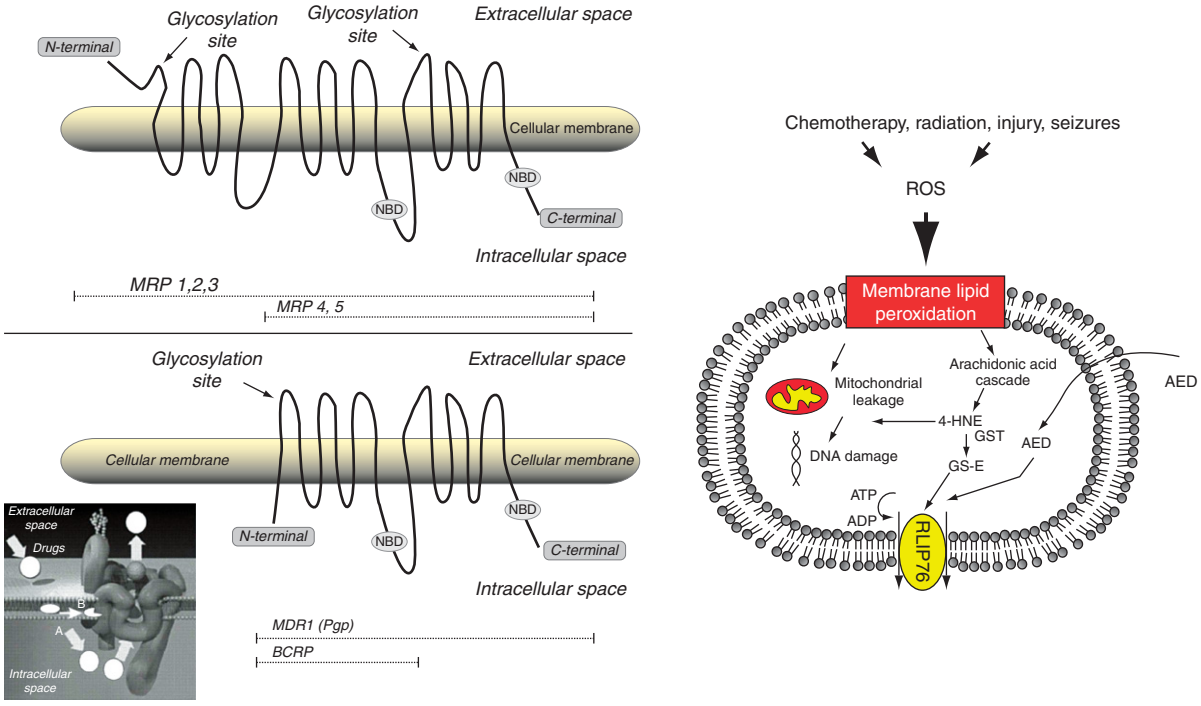
Altered AED Brain Distribution – The Pharmacokinetic Hypothesis

Drug resistance in epilepsy may occur if AEDs are extruded into the vascular bed before entry into the brain. In this respect, molecular and functional studies have implicated several drug transport proteins at the BBB and blood–cerebrospinal fluid barrier as potentially important factors in the development of drug-resistant epilepsy. The pathways of drug brain penetration are dictated by a number of factors involving the intrinsic physical properties of the drugs and their interactions with 'drug resistance proteins' expressed at the BBB (**Figure 1(a)** and **1(b)**). Moreover, the BBB itself can undergo anatomical and functional modification as a result of an underlying pathology and development of disease-related symptoms. Indeed, seizures themselves may influence drug distribution in the brain parenchyma. In human epilepsy, a plethora of pathological changes have been observed in the epileptic zone and surrounding brain. These changes involve the cerebrovasculature, neurons, and glial cells. Many investigators now ascribe altered AED penetration in the brains of drug resistant patients to the over-expression of drug resistance transporters at the BBB (**Table 1**). However, due to the complexity of the epileptic pathology, other phenomena may play an important role in AED resistance.

ATP-Binding Cassette ABC Proteins

ABC-drug transporters identified in the brain are cell membrane proteins that play an important role in regulating entry into the CNS of a large variety of clinically relevant drugs (**Figure 2**). These proteins were initially discovered and characterized for their ability to confer resistance of cancer cells to chemotherapeutics. Indeed, the best-studied phenomenon of CNS drug resistance relates to brain tumor pathology. In brain tumors, mechanisms of drug extrusion similar to those observed in epileptic brain have been described. Specifically, over-expression of multidrug transporters protein (ABC-binding cassette) has been demonstrated for both tumoral cells resistant to chemotherapy and epileptic brain tissues resistant to AED treatment. In particular, over expression of *p*-glycoprotein (MDR1) was observed at the endothelium of brain

of the BBB. Of relevance is also the fact that not all brain endothelial cells form a 'BBB proper' and that a gradient of tightness exists, with passage of blood-borne cells and substances being minimal in the distal parenchymal portion of the vessels and maximal in pial vessels. Also relevant for drug diffusion studies is the fact that capillaries and presumably venules interface lumen with brain cells, while pial vessels and in general larger vessels are surrounded by CSF. (b) Pathways and determinants of drug diffusion into brain. See text for details. (c) Schematic representation of intrinsic and extrinsic (pharmacodynamic) drug resistance.



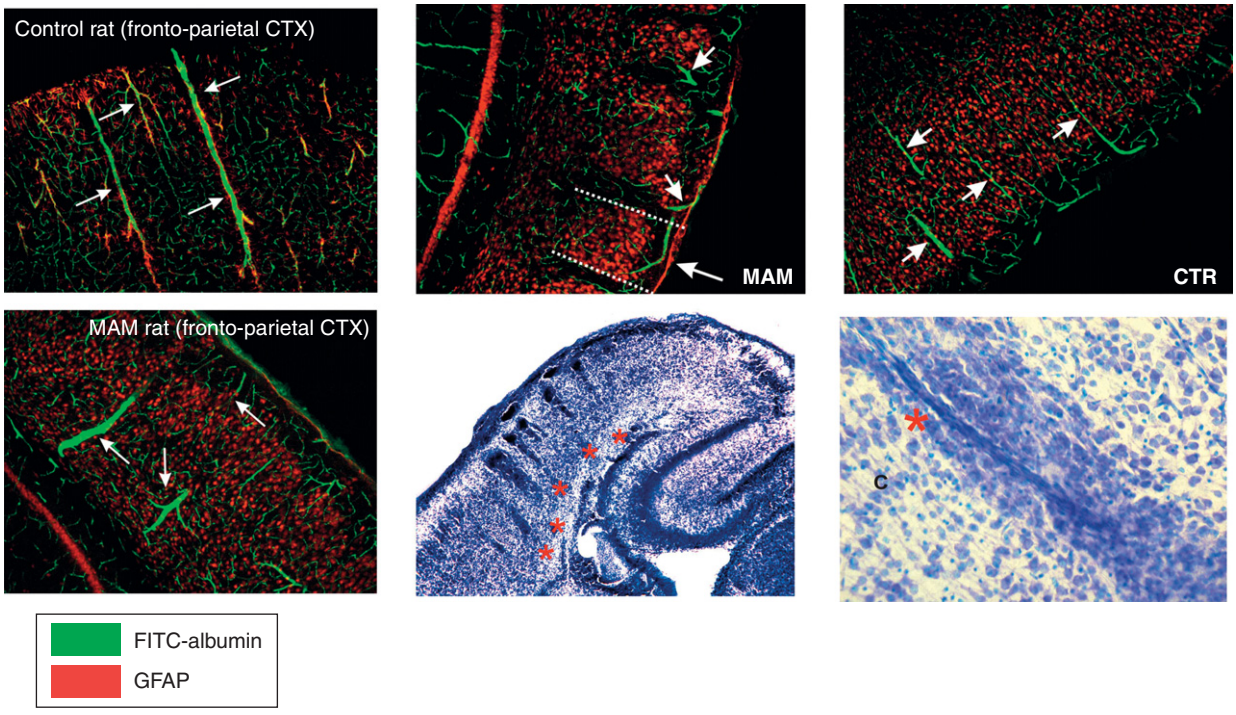


Figure 2 ABC and non-ABC transporters contribute to active drug extrusion from the epileptic brain. *Left panel:* Molecular structure of MRPs, BCRP, and MDR1 transporters. Note the variable length of transmembrane spanning elements and the 'flippase' mechanism of drug binding and extrusion (*inset*). The *right panel* depicts the hypothesis linking metabolic activity and toxic byproducts to RLIP76 (or ABC) transporters. Note that drug transport is fueled by ATP hydrolysis and is driven by intracellular events independent from the presence of the transported drug.

specimens obtained from drug resistant epileptic patients or animal models of epilepsy (Figure 2). There is, however, a significant functional difference between expression of drug transporters in tumoral cells and in refractory epileptic tissue (Figure 1(c)). In particular, while cancer cells may express 'intrinsic drug resistance' that prevents the cellular drug uptake and the subsequent interaction with the nuclear target, resistance to AEDs is more commonly ascribed to abnormally low AED accumulation in the brain extracellular space. The functionally relevant overexpression of drug transporters (limiting the AED brain penetration) occurs at the BBB level, not at the targeted cells (neurons). Further, in contrast to chemotherapic agents for the treatment of cancer cells, AED act on targets present on the membrane surface of cellular targets – so a hypothetical overexpression of drug-transporter on the neuronal cell membrane is unlikely to influence the pharmacologic effect of AED (Figure 1(c)).

RLIP76: A New Model of Multiple Drug Resistance?

Transport mechanisms for the exclusion of toxic xenobiotics and their metabolites from the cellular environment are crucial for living organisms. This trafficking of toxins and their metabolites is an energy dependent, primary active process, involving the hydrolysis of nucleotide triphosphates (ATP or GTP), while transferring substrate molecules across the cell membrane, against a concentration gradient of the substrate. While these transport mechanisms constitute an important part of the cellular defense machinery, they also pose a formidable threat to the efficacy of chemotherapy, including AED efficacy.

RLIP76 is a protein cloned previously as a Ral-effector and Ral-GAP that bridged the Ras and Ral pathways. RLIP76 also displayed GAP activity towards Rho/Rac G-proteins (Figure 2). In independent studies seeking the genetic identity of DNP-SG ATPase, a multispecific transporter protein, investigators established the identity of DNP-SG ATPase as RLIP76. The catalytic activity of RLIP76 and its function in transporting a number of xenobiotic compounds have also been demonstrated. The relevance of these findings to drug-resistance is based on the relatively promiscuous nature of RLIP76 with respect to substrate; numerous amphiphilic chemotherapy drugs can function as transported substrates. Recently published evidence supports a role for RLIP76 in drug resistant epilepsy. RLIP76 is expressed in brain tissue, preferentially in the luminal surface of the endothelial cell. RLIP76 has been shown to be capable of transporting phenytoin and carbamazepine, thus indicating a possible role of this transporter in drug resistant epilepsy (Figure 2).

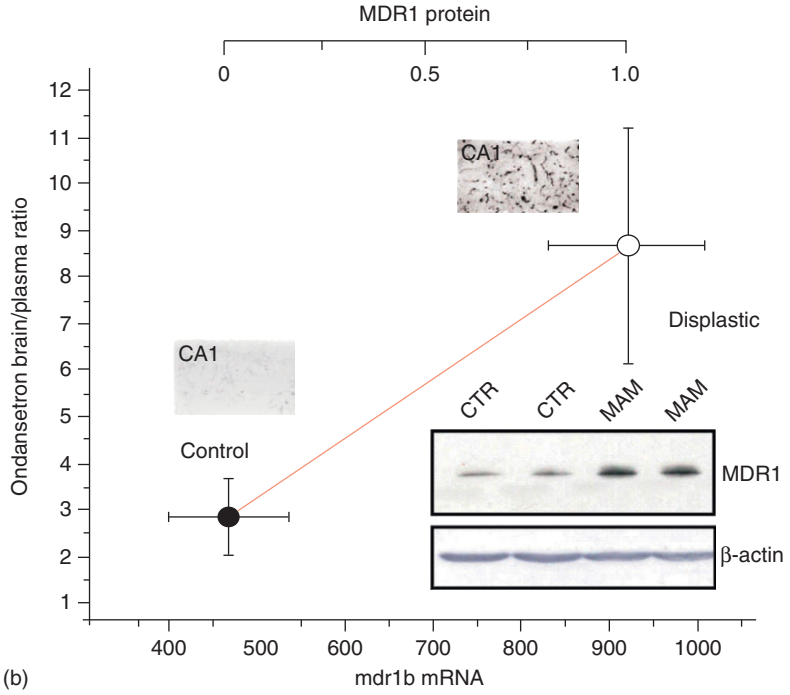

Figure 3 (a) Morphological comparison of a normal and dysplastic BBB in control and MAM rodents. The truncated vessels present in the frontal portion of the cortex are suggestive of inadequate perfusion and therefore of uneven delivery of xenobiotics present in the blood stream. Similar pattern is observed in the temporal cortex. Note how the vessels are interspersed to malformed regions, resulting in morphologically distinct regions of neurovasculature. Loss of glial, neuronal and vascular radiality is also observed in dysplastic brain. The Cresyl violet stained sections depict the appearance of early postnatal MAM brain sections emphasizing the abnormal relationship between neuronal and vascular (*asterisks*) elements. (b) Direct relationship between MDR1 expression levels and drug levels in CNS cast a doubt on MDR1's role in drug extrusion in dysplastic brain. MDR1 levels were measured by RT-PCR and western blotting in dysplastic regions of MAM-treated and control brain. Drug levels were measured by HPLC. Note that increased expression of MDR1 was associated with *elevated* drug levels, suggesting that MDR1 does not participate significantly to drug extrusions in dysplastic regions.

Methods

Prenatal Exposure to Methylaxozymethanoic Acid and Immunohistochemistry

Prenatal exposure to methylaxozymethanoic acid (MAM) at E15 interferes with proper neuronal migration and cerebral vessel formation. These structural alterations assume a characteristic phenotype (neurovascular ectopias and BBB leakage) in the adult animals. We assessed the pattern of drug brain penetration in these animals compared to controls. Interestingly, overexpression of the multidrug resistance protein, MDR-1, at the BBB was discovered in these animals. The MDR-1 substrate, ondansetron, was used to evaluate the relevance of BBB damage and MDR-1 overexpression to drug brain penetration.

For prenatal exposure to MAM, pregnant Sprague–Dawley rats received two injections of MAM (15 mg kg^{-1} of maternal body weight, i.p., in sterile saline, 12 h apart) on day E15. Prenatally exposed adult rats were anesthetized with isofluorane. After surgical exposure of the ribcage, the midline thoracic cutis was incised and the sternum opened. The apex of the left ventricle was cannulated with a 24-gauge polyethylene catheter (BDInsyte, BDVialon, Becton Dickinson, Mountain View, CA, USA), and perfused (1 ml/min) with a FITC–albumin (1% in 0.1 M phosphate-buffered saline). The right atrium was incised to prevent elevation in systemic blood pressure. Immediately following perfusion, animals were decapitated and the brains removed. Brains were fixed for 24 h in 10% formalin solution, then cryoprotected in 30% sucrose solution for 2 days. Frozen brain samples were mounted on a cryostat and cut in the coronal plane at 35 μm thickness. Sections were collected and floated in 0.1 M phosphate buffer solution (PBS) and mounted on positive-charged, glass slides (Fisher Scientific, Pittsburgh, PA). Sections were dried and processed with cresyl violet and/or fluorescence to visualize blood vessels and cells. Immunostaining was performed as described earlier (see Further Reading). The primary antibodies used were: mouse anti-NeuN monoclonal antibody (1:500); mouse anti-GFAP monoclonal antibody (1:200); the secondary antibody was Texas-Red dye conjugated Affinipure donkey anti-mouse IgG (1:100).

MDR1 Western Blot, RT-PCR and HPLC Quantification of Ondansetron (Figure 3(b))

Briefly, MDR1 mRNA levels were evaluated by RT-PCR, while protein expression was quantified by western blot and anatomically localized by immunohistochemistry. The MDR-1 substrate, ondansetron, was injected intravenously at the dose of 1 mg kg^{-1} in MAM-treated and control rats. Animals were sacrificed 30 after and blood and brain collected. Sample preparation and high performance liquid chromatography (HPLC) analysis are described in the Further Reading section. We have correlated the levels of expression of MDR-1 with the brain-to-plasma ondansetron ratio measured in MAM-treated and control rats.

Intracarotid Injection of Hyperosmolar Mannitol

A hyperosmotic bolus of mannitol is injected directly in the carotid artery, provoking a rapid opening of the BBB (within few seconds). This technique allows the study of the effect of acute BBB damage on physiological parameters such as brain electrical activity, as recorded by EEG. Adult male Sprague–Dawley rats were used for this procedure. After anesthesia, a 2–3 cm vertical incision was made from the suprasternal notch to below the chin. After exposure of the sternothyroid muscle, the common carotid artery was exposed and was separated from the posteriorly placed vagal nerve. After exposure of the bifurcation of internal and external carotid arteries, a silk tie (3-0, Ethicon, 24″) was looped around the external branch of the carotid artery (ECA), while a microclamp was positioned ready at the common artery (CCA). In temporal sequences the following steps were then performed within 2–3 min: (1) clamp the CCA; (2) ligate the distal ECA, leaving approximately 5 mm stump proximally; (3) insert the polyethylene catheter (27 gauge) into the proximal stump of the ECA towards the bifurcation; (4) tighten the silk tie around the catheter; (5) inject a hyperosmolar mannitol solution (1.4 M bolus in saline, 0.1 ml s^{-1}, 2 ml); (6) remove the catheter and ligate the proximal stump of the ECA; and (7) release the clamp at the CCA. Sham procedures were conducted using identical protocol and injecting 2 ml of sterile PBS instead of the mannitol hyperosmolar solution.

Radiolabeled Chemical Injection and Quantification

^{3}H-sucrose, ^{3}H-deoxyglucose, ^{14}C-phenytoin, and C^{14}-diazepam (1 μ Cu, Sigma Aldrich) dissolved in 500 μl of saline were injected after sham procedures (with isoosmolar PBS) or after BBB disruption (BBBD) through the intracarotid catheter. These drugs were chosen based on their dissimilar lipophilicity (sucrose and glucose being very idrophylic, diazepam and phenytoin liphophylic); therefore, they have dissimilar tendencies to distribute between plasma and brain. We have examined how this intrinsic physical property would affect drug brain distribution in the presence (or not) of a damaged BBB. Three minutes after BBBD, peripheral blood was drawn from the left heart ventricle, and the brain dissected out (including frontal, parietal, and occipital cortex and cerebellum). Radioactivity was determined by a β-counter Beckman-Coulter. Brain samples were weighted and homogenized with ice-cold solubilizing buffer (10 mM Tris–HCl, pH 7.4, 1 mM EDTA, 150 mM sodium chloride, 60 mM octylglycoside) using a glass potter (150 μl of solution per 10 mg of tissue). Radioactivity in brain was normalized

by tissue weight. Radioactivity counted in serum was normalized by volume. Brain-to-plasma ratio for each drug was then calculated from these values.

FITC–Albumin and Fluorescent Doxorubicin Injection

A microangiographic technique based on the injection of fluorescent probes enables confocal visualization of the entire brain micro- and macrovasculature. Simultaneous observation of functional changes in BBB permeability was also possible with utilization of appropriate microangiographic molecules. To this end, fluorescent albumin was used, since albumin does not extravasate abluminally if the BBB is intact. The fluorescent albumin solution was prepared by reconstituting 500 mg of bovine desiccate albumin–fluorescein isothiocyanate (FITC–albumin, MW 69 KDa; 12 mol mol^{-1} albumin; Sigma, St. Louis, MO) in 50 ml of phosphate-buffered saline (0.1 M PBS) lacking magnesium and calcium ions. Presence of vascular leakage was evaluated by visual inspection and by confocal microscopy. A solution containing 10 mg ml^{-1} of FITC–albumin and red fluorescent doxorubicin (1 μM) was injected as described above. Doxorubicin is used as a small red fluorescent tracer (MW 540 Da).

Recent Results – BBB in Epilepsy and its Role in Mediating Drug Resistance

In addition to the overexpression of multidrug transporter proteins, other morphological and functional modifications can occur at the BBB, all of which perhaps contributing to the phenomenon of drug resistance. In the mammalian cortex, the cortical vasculature is characterized by organized large radial vessels that branch out into a homogeneous network of capillaries; in the hippocampus, a region-specific vascular density (CA1 > CA3) has been reported. Medically intractable epilepsy is often associated with malformations of cortical development (MCD). Even though the term MCD includes a number of brain pathologies, each characterized by a peculiar morphological neuronal appearance and architecture, a propensity to generate seizures is often observed in dysplastic regions. One common model of MCD is obtained by prenatal exposure of rats to the antimitotic agent methylazoxymetanoic acid (MAM). The resulting structural abnormality in MAM-exposed animals mimics the periventricular nodular heterotopias observed in human dysplastic brain. Importantly, vascular dysplasia is also observed in this model. Altered angioarchitecture in brain heterotopic areas (**Figure 3(a)**, GFAP, NeuN, and FITC–albumin staining) includes the loss of the cortical radial vessels in the frontal and temporal cortex and the presence of tortuous side-branched vessels. Regions of leaky BBB are also commonly observed in these models.

Overexpression of MDR1 in Dysplastic BBB: Overall Relevance to Drug Brain Penetration

Recently, overexpression of MDR1 was demonstrated in dysplastic regions of MAM-treated rats, leading to the hypothesis that MDR1 overexpression in heterotopic brain areas may represent a response to aberrant brain development. Overall, analysis of vasculature within heterotopic brain regions in MAM-exposed rats showed significant changes in the intrinsic expression of MDR1, vascular malformation, and the presence of concomitant BBB damage. When evaluating the functional consequences of these observations for drug brain penetration, investigators also observed a general increase in the brain-to-plasma ratio of the MDR1 substrate, ondansetron, compared to control (**Figure 3(b)**) (ondansetron is an antiemetic drug which is known to be transported by MDR1). This observation led to the apparent paradox of increased brain expression of MDR1 in the vasculature *and* increased drug levels of an MDR1 substrate in the brain. These findings suggest that in addition to MDR1, there must be other powerful mechanisms that control drug uptake in dysplastic brain.

BBB Leakage and Epilepsy: MRI Findings

Is there a link between leakage of the BBB and seizure/epilepsy pathology? Several studies have shown BBB damage during or immediately after seizures. A profound remodeling of the cerebrovasculature associated with leakage and extravasation of serum proteins, in consequence of spontaneous seizures, are observed in rodent models of temporal lobe epilepsy. Moreover, it was recently demonstrated that angiogenesis occurs in human TLE (as well as in rodent models of TLE) in consequence of seizures. In particular upregulation of VEGF in neurons, accompanied by an increase in vascular density, has been described after acute, short or long-lasting seizures. Once initiated, the angiogenic processes increase progressively, even in the absence of seizure activity, as observed during the latent period (e.g., in pilocarpine-treated rats), or after single short seizures induced by electroconvulsive shock. Conversely, it has also been repeatedly shown that BBB leakage promotes seizures or epileptogenesis. Whatever the temporal relationship between BBB leakage and seizures, it is clear that epileptic brain is characterized by an abnormal blood–brain interface.

Integrity of the BBB and presence of edema can be evaluated with MRI techniques. Specifically, structural changes at a cellular level can be assessed by diffusion-weighted imaging (DWI), which calculates the extent of passive water motion or diffusivity (apparent diffusion coefficient, ADC). Curiously, contradictory data have

been obtained when evaluating the changes in brain water perfusion in rodent models and in epileptic patients. DWI analysis in animal studies has demonstrated an early and transient decrease of water diffusivity during provoked status epilepticus or sustained seizures. Pre- and postictal human studies, using DWI or diffusion tensor imaging (DTI), have also shown (in some cases) transiently decreased local diffusivity. However, diffusion studies have demonstrated areas of significantly *increased* diffusivity, during the interictal period, in patients with partial epilepsies.

BBB Leakage, Edema, Protein Binding, and Drug Diffusion

Substantial progress has been made in the understanding of the pathophysiology and mechanisms involved in the changes of BBB permeability. In many diseases that affect the brain, the cerebral endothelium plays an active part in the disease process, with the BBB becoming disrupted, or modified, in such a way that there is a dramatic increase in vascular permeability. Theoretically, there are several ways by which various molecules can pass the endothelium, including intercellular routes, vesicular transport, or direct transcellular penetration through damaged endothelium. BBB dysfunction may be a cause or consequence of a particular disease process. Diseases in which increased BBB permeability has been reported include neoplasia, ischemia, hypertension, dementia, epilepsy, infection, multiple sclerosis, and trauma.

The effect of a disease on BBB function will secondarily affect cerebral blood flow and vascular tone in the brain, which then may further influence transport of substances across the BBB. A question of great significance is whether, in certain neuropathological conditions, the BBB disturbance constitutes the *primary* pathogenic factor, which then triggers a sequence of events molding the final pathological state. A notable consequence of BBB damage is cerebral edema, which may be classified into two major types: vasogenic or 'wet' edema, and cellular cytotoxic or 'dry' edema.

The extravasation of plasma proteins resulting from a weakened BBB causes vasogenic edema. When considering the formation of vasogenic edema, it is not clear how water extravasates through a leaky blood-brain barrier under conditions where total brain osmolarity is not substantially different from the osmolarity of serum (**Table 2**). By pure diffusion motion, protein will escape across a leaky blood brain barrier from the blood into the brain according to their chemical gradient (see **Figure 5**). However, it is very unlikely that additional extravasation of other ionic solutes will drive sufficient water to account for brain swelling, since total ionic concentrations (and therefore osmolarity) in serum and brain are very similar (**Table 2**). Since vasogenic brain swelling is nevertheless commonly observed under conditions of impaired BBB function, mechanisms other than osmolarity differential between the two tissues may play an important role. In the case of epilepsy, it is well known that a significant shift of ions, from the intracellular (neurons) to the extracellular compartment, accompanies and follows seizures. For example, during seizures, extracellular potassium accumulation reaches levels that exceed 10-fold changes from baseline. This increased extracellular osmolarity may thus drive more water from blood to brain, initiating a self-sustaining process leading to brain edema.

Table 2 Ionic concentrations and osmolarity in serum and brain

	Brain	*Serum*	*Ratio*
Total osmolarity (mOsm l^{-1})	295	295	1
Glucose (mg dl^{-1})	60	90	0.66667
Na (meq l^{-1})	138	138	1
K (meq l^{-1})	2.8	4.5	0.62222
Ca (meq l^{-1})	2.1	4.5	0.4375
Mg (meq l^{-1})	0.3	1.7	0.17647
Cl (meq l^{-1})	119	102	1.16667
pH	7.33	7.41	0.98

The early process of vasogenic edema formation may also *initiate* seizures. In the presence of a leaky barrier (in nonepileptic brain), protein extravasation occurs very early after BBBD (**Figures 4** and **5**). For yet unknown reasons, albumin extravasation itself promotes pro-epileptogenic events. These events may be sufficient to trigger seizures, followed by water influx into the brain driven by increased osmolarity of the extracellular space.

Protein Binding and pH

From the earliest observations on AED accumulation in the brain, it became obvious that binding to serum protein is a crucial step regulating the passage of AED across the BBB. pH also represents an important determinant of drug pharmacokinetic properties, influencing the drug association/disassociation with serum proteins and affecting the penetration of the drug across the blood brain barrier. For example, **Figure 4(a)** depicts a cholinergic drug that is impermeant across the BBB because of a charge present on the molecule. This charge, however, is not present in the neutral form of the molecule, which exists at equilibrium with the ionic form (these two forms of the drug coexist according to the Henderson–Hesselbach equilibrium). Only the uncharged form of the drug will permeate the BBB and accumulate in the brain. As a result, the drug levels will constantly increase in the brain, in spite of steady levels in the serum. The importance of this fact, combined with protein binding (**Figure 4(b)**), has not been fully appreciated in studies of multiple drug resistance to AEDs. A consequence of seizures is a change in brain interstitial pH. Depending on the chemical properties of a given AED, changes in pH could determine a shift in the dissociation equilibrium of the drug, therefore affecting the

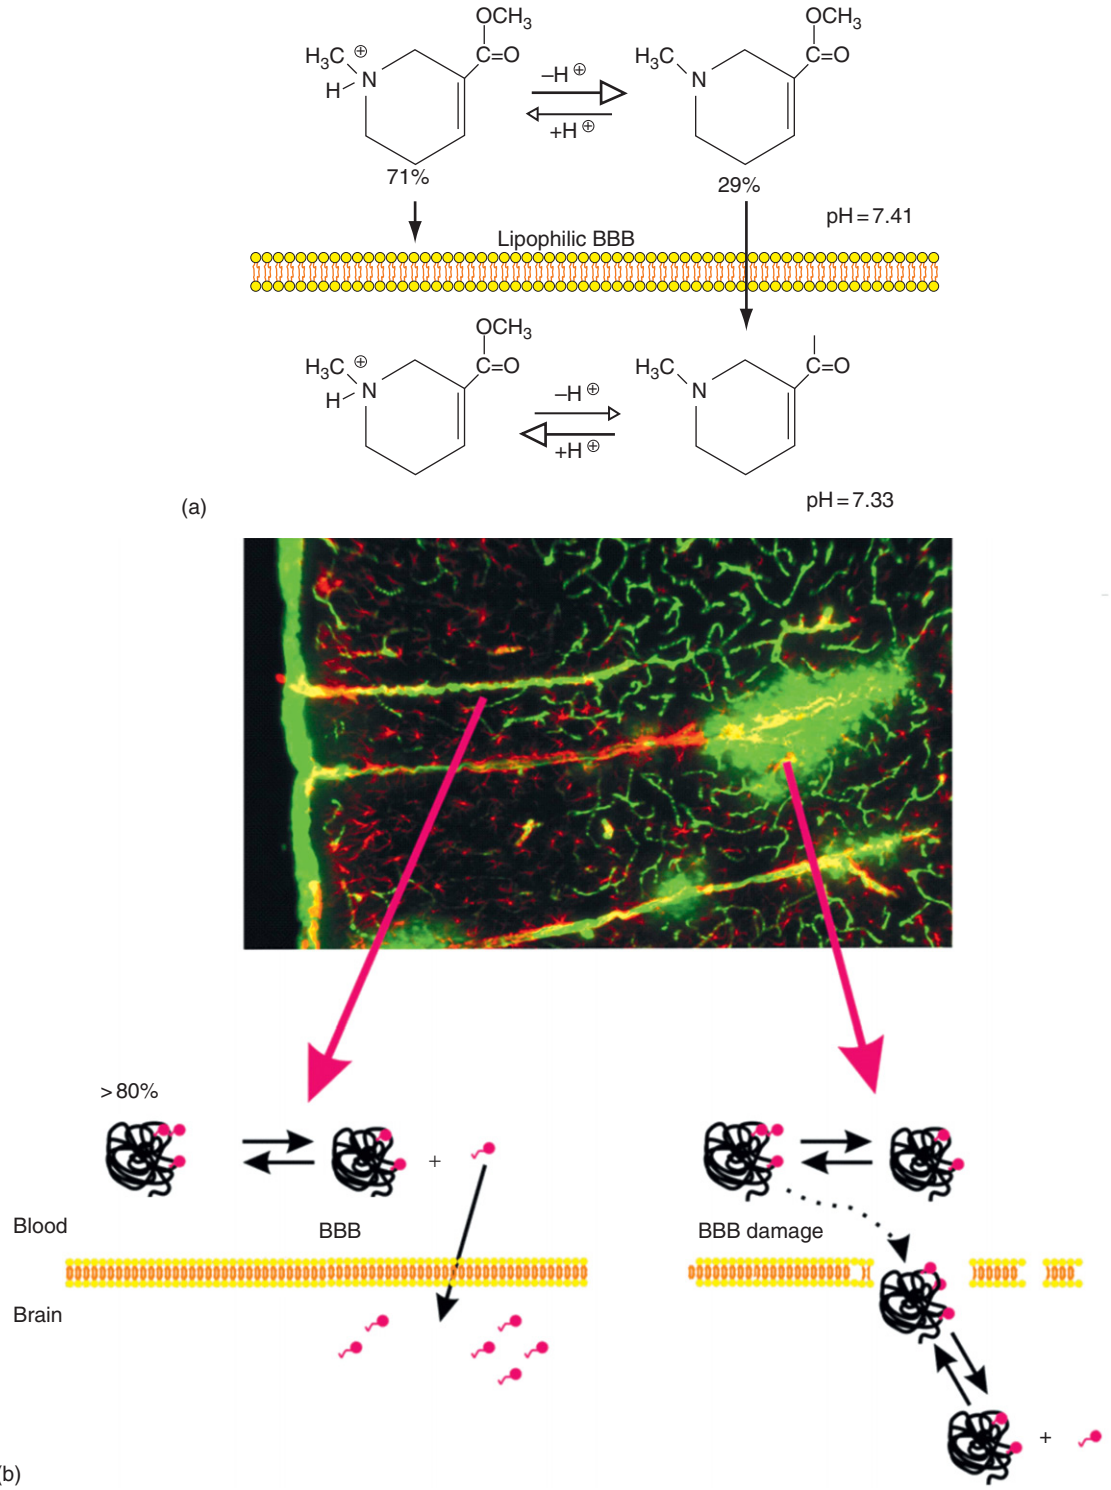

Figure 4 Effect of pH and protein binding on drug permeation across the BBB. (a) Protonation favors BBB passage of drugs by conversion into a nonpolar form. (b) BBB leakage and protein extravasation *decrease* the free drug levels if the drug is tightly bound to serum protein. In regions of intact BBB (green vessels filled with FITC–albumin; neurons are stained in *red*) the intravascular protein binding favors the unbound form since the latter is constantly removed from the equilibrium. This promotes CNS free drug levels higher than those in serum. Conversely, when protein leakage occurs, the CNS freed drug will drop to serum levels. The picture depicts BBB leakage observed in rat brain after exposure to pilocarpine.

overall binding to protein and partition across the lipophilic endothelial cell membrane.

Brain Edema and Drug Delivery in Epileptic Brain

It has been long suspected that seizures may induce cell edema. Routine MR techniques allow detection of focal cortical and hippocampal swelling after prolonged seizures in the area of the seizure focus. T_2-weighted imaging often shows focal increased signal intensity. The signal increase may involve cortical or limbic structures, particularly the hippocampus where posticta changes can be unilateral or bilateral. Similar results are obtained with diffusion weighted imaging, which usually overlaps with T_2-imaging

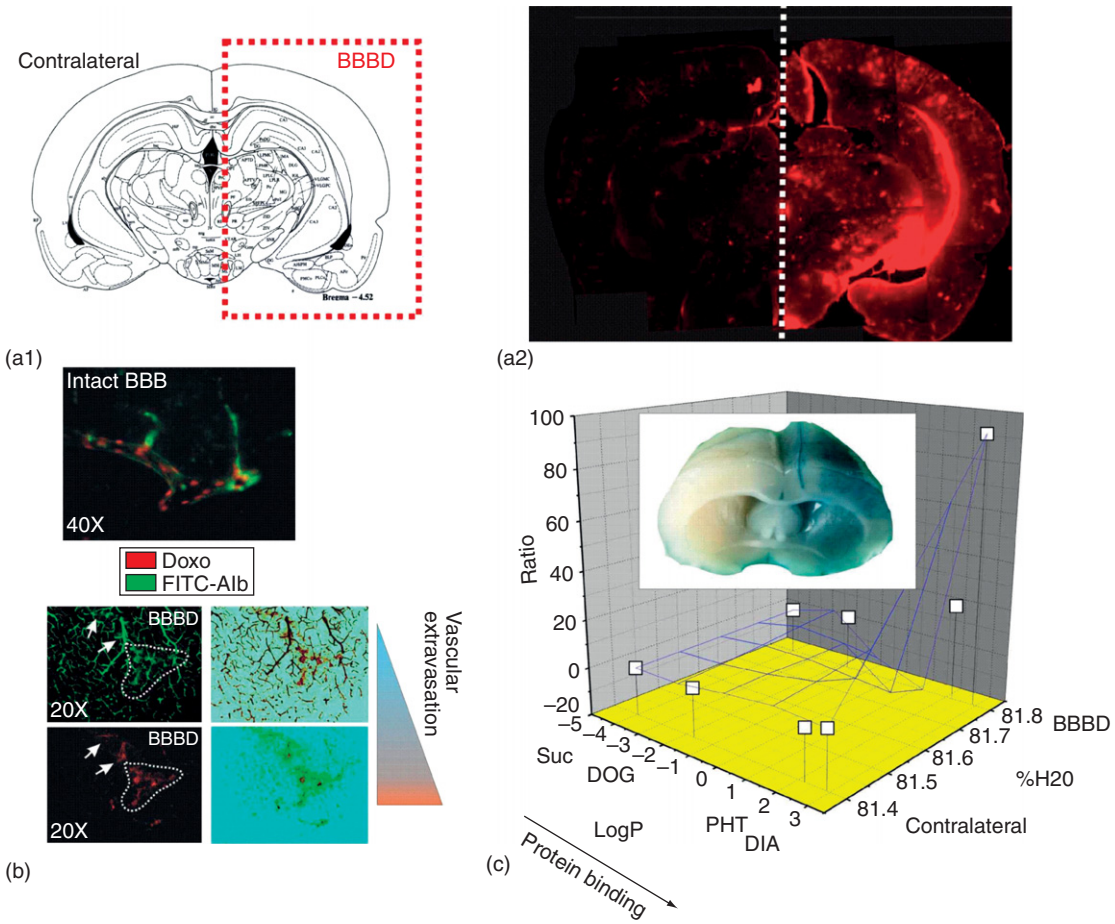

Figure 5 Effect of BBB osmotic disruption on protein and drug brain influxn. (a1–2) Hemispheric disruption promotes widespread leakage of serum albumin (in *red* due to binding to intravascular Evans Blue, which emits a red fluorescent signal). (b) Visualization of protein (FITC–albumin, in *green*) and the lipophilic drug doxorubicin (DOXO, in *red*) extravasation in regions of intact or leaky BBB. Note that intravascular protein and drug fail to migrate across an intact BBB, while protein and drug extravasate in the same spot when the BBB is breached. This is due to the tight binding of serum protein to drugs. At serum pH doxorubicin is 94% bound to plasma protein. Protein binding values (% fraction bound) are normally given as the percentage of the total plasma concentration of a drug that is bound to all plasma proteins. In most cases, binding to plasma proteins is reversible, and the concentration of the free and bound species of the drug at equilibrium may be expressed as: Free drug + Free Protein ↔ Drug protein complex. The total plasma concentration of the drug is expressed as the sum of the percent of free drug and the percent bound. Total plasma concentration = Free drug + Drug bound to protein. Depending upon whether the drug is a weak or strong acid or base, or is neutral, it can bind to a single blood protein, or to multiple proteins (e.g., serum albumin, acid–glycoprotein or lipoproteins). The most significant protein involved in the binding of drugs is albumin, which comprises more than half of all blood proteins. Albumin can interact with acidic or basic drugs in the plasma by van der Waals dispersion forces, hydrophobic bonding, hydrogen bonding, and ionic interactions. Under most conditions, the stability of the albumin-drug complex depends on pH. The drug/protein complex does not permeate phospholipid bilayers, including capillary the BBB. After much of the free drug has been cleared by the metabolic and excretory processes, the reversible drug/protein complex serves as a depot to replenish the concentration in vivo. For these reasons, drugs with high protein binding activity values tend to have a greater half-life compared to those with lower values. (c) Tridimensional graph showing the relationship between lipophilicity (log *P*), protein binding (arbitrary values indicated by the arrow), water content and drug uptake (ratio brain:plasma). Note the brain water content increased modestly after BBB disruption (BBBD) compared to the contralateral, intact hemisphere. However, under conditions of BBBD, the effect of protein extravasation (*e.g.*, part (b)) caused a massive influx of *bound* drug. Given the considerations given above, this will paradoxically result in *lower free drug levels.*

findings. Both types of imaging suggest cytotoxic edema, resulting from a metabolic mismatch between available energy and the demand to clear extra- and intracellular ion accumulation resulting from seizure activity.

MRI images have also been studied in animal models of temporal lobe epilepsy, where changes similar to epileptic human brain have been reported. Early after a seizure, changes may be detected by DWI in humans and animal models; T_2-weighted changes and swelling appear slightly later and may persist for a few days. The assumption that these changes reflect consequences of seizure activity was recently challenged by studies showing that changes seen in pilocarpine-treated animals may actually reflect brain cytotoxic or vasogenic edema occurring *prior* to epileptic seizures. It has also been shown that traumatic or chemical/iatrogenic disruption of the BBB may *lead* to seizures. **Figure 5** shows an example of brain drug permeation after osmotic opening of the BBB, induced by intracarotid injection of a hyperosmolar bolus of mannitol. Note that the disrupted BBB allows a rapid extravasation of Evans blue-proteins (in *red* in the fluorescent microscope image in A2). Also note that fluorescently labeled doxorubicin (DOXO, **Figure 5(b)**) is internalized by endothelial cells at the BBB when the BBB is intact, while extravasation occurs when the BBB is disrupted (BBBD). Panel (c) shows the effect of BBBD on the extravasation of other drugs and compounds of different lipophilicity (indicated by log *P*). These results show that:

1. Protein extravasation is an early consequence of BBBD.
2. No significant changes in water brain content take place immediately after BBBD.
3. Lipophilic drug *apparent* permeability is increased by BBBD, resulting from protein bound drugs accumulating into the extravascular compartment.

Does this situation apply to epileptic brain? This question was assessed in lithium–pilocarpine or pilocarpine models (**Figure 4(b)**). In animals injected with these agents, but *before* occurrence of status epilepticus, leakage of the BBB was observed. It is thus likely that the effects on drug accumulation in epileptic brain will follow patterns similar (i.e., apparent permeability increase) to those seen after intentional BBBD (**Figure 5(a)**). The results shown in **Figure 5** also suggest that penetration of lipophilic drugs (phenytoin and diazepam) is higher in regions of disrupted BBB integrity. Under these circumstances the extravasation of lipophilic drugs could be favored by the influx into the brain of serum proteins, the latter acting as carriers and favored by a positive serum-to-brain concentration gradient. However, CNS drugs can interact with neuronal targets only when present in the brain as free, therefore not bound to serum proteins. Such alteration of the equilibrium between free and bound drug in the CNS could affect the efficacy and the interaction with CNS targets.

Future Directions

This brief summary of the factors involved in drug permeation from the bloodstream into the brain focuses on several features that are believed to hamper the efficacy of drug treatments targeting the CNS, such as AED therapy. Multiple drug resistance to CNS drugs remains an important issue, particularly, while dealing with seizure disorders. Our data, and other considerations discussed above, shed light on the importance of brain environment and blood-brain barrier integrity in determining drug distribution to the brain. The data presented here were limited to nonepileptic animals; further studies are required to evaluate the role of BBB damage, serum protein extravasation, and changes in parenchymal water content in affecting the disposition of free AED in the epileptic brain.

Introduction

Without a specific etiological understanding of the pathogenesis of seizures and epilepsy, approaches to drug therapy would be directed towards the control of symptoms – that is, the suppression of seizures. The treatment of choice in epilepsy is chronic administration of antiepileptic drugs (AEDs), and the treatment aim is to keep the patient seizure-free without interfering with normal brain function. A major goal in epilepsy research is to develop drugs with higher anticonvulsant efficacy and less toxicity than the existing drugs. The mechanisms of action of the currently marketed AEDs are still not completely understood. They finally involve alteration of the balance between neuronal excitation and inhibition. The immediate challenge is to establish the relative importance of individual mechanisms to the overall antiepileptic effect of each drug. During the past decades, a large number of new AEDs and improved formulations of older, 'first generation' drugs have been marketed worldwide. However, the proportion of intractable or difficult-to-treat patients has not changed substantially following the introduction of these new or improved drugs. The probability of intractability largely depends on the type of seizures and epilepsy, with complex partial seizures having the poorest prognosis of all seizure types in adults. A major obstacle in developing new strategies for treatment of pharmacoresistant epilepsy is that the biological basis of pharmacoresistance is only poorly understood. Most of the currently available AEDs and promising drugs in development have been identified by empirical screening in acute seizure models. However, it is increasingly recognized that drug targets in 'genuine' epilepsy models (i.e., models with chronic, spontaneous seizure occurrence) are modified or completely changed during epileptogenesis. Thus, there is a growing trend to test drugs in animal models that resemble specific types of epilepsy. This more focused approach allows development of new compounds with higher selectivity and efficacy for the altered targets in the epileptic brain. Furthermore, the study of the pathophysiological processes in epileptogenesis in proper animal models may yield new concepts for drug development. This article deals with current concepts of anticonvulsant drug action, new pharmacological targets and approaches (pharmacokinetic–pharmacodynamic (PK–PD) modeling), methodological aspects in determining the ultimate in vivo efficacy of drugs in specific animal models of epilepsy, and rational design of synergistic drug combinations.

Background

AEDs: Neurochemical Profiles and Mechanisms of Action

At the cellular level, three basic mechanisms of action of AEDs are now recognized: modulation of voltage-dependent ion channels (Na^+, Ca^{2+}, and K^+); enhancement of inhibitory neurotransmission (principally by GABA); and attenuation of excitatory (particularly glutamate-mediated) transmission. It is increasingly apparent that many of our AED compounds possess multiple mechanisms and cellular effects. Since epilepsies are, by definition, a group of disorders rather than a single disease entity, it is not surprising that the currently employed AEDs display such a range of pharmacological actions. In addition, many

Introduction

Without a specific etiological understanding of the pathogenesis of seizures and epilepsy, approaches to drug therapy would be directed towards the control of symptoms – that is, the suppression of seizures. The treatment of choice in epilepsy is chronic administration of antiepileptic drugs (AEDs), and the treatment aim is to keep the patient seizure-free without interfering with normal brain function. A major goal in epilepsy research is to develop drugs with higher anticonvulsant efficacy and less toxicity than the existing drugs. The mechanisms of action of the currently marketed AEDs are still not completely understood. They finally involve alteration of the balance between neuronal excitation and inhibition. The immediate challenge is to establish the relative importance of individual mechanisms to the overall antiepileptic effect of each drug. During the past decades, a large number of new AEDs and improved formulations of older, 'first generation' drugs have been marketed worldwide. However, the proportion of intractable or difficult-to-treat patients has not changed substantially following the introduction of these new or improved drugs. The probability of intractability largely depends on the type of seizures and epilepsy, with complex partial seizures having the poorest prognosis of all seizure types in adults. A major obstacle in developing new strategies for treatment of pharmacoresistant epilepsy is that the biological basis of pharmacoresistance is only poorly understood. Most of the currently available AEDs and promising drugs in development have been identified by empirical screening in acute seizure models. However, it is increasingly recognized that drug targets in 'genuine' epilepsy models (i.e., models with chronic, spontaneous seizure occurrence) are modified or completely changed during epileptogenesis. Thus, there is a growing trend to test drugs in animal models that resemble specific types of epilepsy. This more focused approach allows development of new compounds with higher selectivity and efficacy for the altered targets in the epileptic brain. Furthermore, the study of the pathophysiological processes in epileptogenesis in proper animal models may yield new concepts for drug development. This article deals with current concepts of anticonvulsant drug action, new pharmacological targets and approaches (pharmacokinetic–pharmacodynamic (PK–PD) modeling), methodological aspects in determining the ultimate in vivo efficacy of drugs in specific animal models of epilepsy, and rational design of synergistic drug combinations.

Background

AEDs: Neurochemical Profiles and Mechanisms of Action

At the cellular level, three basic mechanisms of action of AEDs are now recognized: modulation of voltage-dependent ion channels (Na^+, Ca^{2+}, and K^+); enhancement of inhibitory neurotransmission (principally by GABA); and attenuation of excitatory (particularly glutamate-mediated) transmission. It is increasingly apparent that many of our AED compounds possess multiple mechanisms and cellular effects. Since epilepsies are, by definition, a group of disorders rather than a single disease entity, it is not surprising that the currently employed AEDs display such a range of pharmacological actions. In addition, many

less well-characterized mechanisms may also contribute to the anticonvulsant effect of a given compound.

Excitation and inhibition are considered the prerogatives of glutamate and GABA. We, among others, correlated different types of chemically and electrically induced limbic seizures in rats with substantial increases in extracellular hippocampal glutamate and GABA levels caused by increased network activity during the initial stages of a seizure. These data are consistent with earlier human microdialysis studies in which seizure-associated increases in extracellular hippocampal glutamate and GABA were reported. These neurochemical changes presumably have a profound impact on the further course of a seizure. Increased glutamatergic excitation is considered a major cellular mechanism underlying seizure initiation, spread, and maintenance, while increased GABAergic inhibition is widely viewed as an anticonvulsant response in the epileptogenic tissue. We have used these neurochemical changes routinely as a biomarker for increased network activity, and have been able to demonstrate that a wide variety of AEDs (phenobarbital, carbamazepine, valproate, lamotrigine, and topiramate) and experimental compounds with anticonvulsant properties (adenosine-1 agonists, kainate antagonists, a group I metabotropic glutamate antagonist, angiotensin IV, somatostatin) suppress pilocarpine-induced increases in extracellular hippocampal glutamate and/or GABA. Moreover, we recently demonstrated that while increased hippocampal extracellular glutamate concentrations do not induce seizures per se, a pre-existing elevation in extracellular glutamate may aggravate seizures induced by subsequent intrahippocampal administration of a chemoconvulsant. However, whether glutamate and GABA increases can indeed effectively modulate seizure generation and spread – or are only an epiphenomenon – remains controversial. Studies in animal seizures models have often yielded conflicting data; sometimes no changes or even a decrease in glutamate and/or GABA were reported during seizures. Moreover, activation of different glutamate receptors subtypes differently affect seizure activity.

Monoaminergic receptors are widely distributed throughout the brain, and are expressed in almost all networks implicated in the regulation of seizures. Activation of dopamine, serotonin, and noradrenaline receptors is known to modulate seizure susceptibility in epilepsy models (both in vitro and in vivo). Despite convincing data, this class of neurotransmitters has not received much attention. Perhaps the lack of consensus in the field about which receptors and signalling pathways mediate the anticonvulsant effects may contribute to this relative lack of interest.

In recent years, more selective agonists and antagonists have become available, allowing a more reliable evaluation of the role of different monoaminergic receptor subtypes in seizure control. Recently, we demonstrated that increases in exogenous hippocampal dopamine or serotonin levels can have profound anticonvulsant effects in the focal pilocarpine model for limbic psychomotor seizures. These anticonvulsant effects were restricted to a well-defined anticonvulsant concentration range and were shown to be mediated by D_2 and 5-HT_{1A} receptor stimulation. Subsequently, we showed that GBR-12909, a highly selective dopamine reuptake blocker, and citalopram, a selective serotonin reuptake blocker, were anticonvulsant in the focal pilocarpine model. At the anticonvulsant threshold concentrations for both these compounds, significant increases in respectively endogenous hippocampal dopamine or serotonin levels within the previously determined anticonvulsant concentration ranges were observed. Moreover, our group was able to demonstrate that hippocampal dopamine and serotonin increases are an important constituent of the anticonvulsant mechanism of action of oxcarbazepine and its active metabolite 10,11-dihydro-10-hydroxycarbamazepine. These transmitter changes were defined as biomarkers for the anticonvulsant efficacy of these compounds. Our data are consistent with previous results showing that therapeutically relevant concentrations of many marketed AEDs, and of experimental compounds with antiepileptic properties, increase extracellular levels of dopamine and/or serotonin in brain areas involved in epileptogenesis. Preliminary results from our group also indicate that potent anticonvulsant effects can be achieved by increasing noradrenergic signaling in the hippocampus.

Genetic approaches have been increasingly coupled with physiological and pharmacological approaches in epilepsy research. Transgenic and knockout mice with modified monoaminergic signaling have provided new models for the study of the monoaminergic system in epilepsy. Currently, the role of at least D_1, D_2/D_3, $5HT_{1A}$, $5HT_{2C}$, $5HT_3$, 5HT7, α_1, α_2, and β subtypes of dopamine, serotonin and noradrenalin receptors in epileptogenesis and seizure propagation has been described using such models. However, discrepancies between the different experimental approaches, as well as differences in experimental results, hamper the interpretation of the relationship between neurochemical alterations and seizure activity – and this relationship merits further research. It appears that each modification of the factors that characterize excitation and inhibition is model-, time-, area-, and pathway-dependent. Some modifications appear as proepileptic within one brain region, experimental model or neuronal pathway, while others will appear as antiepileptic. Due to the large number of factors that can be modified, the resulting behavior of the neuronal network is difficult to predict.

Methods

Upon its introduction in the early 1970s, the microdialysis technique rapidly became a widely accepted method in

the neurosciences. This technique has made the extracellular brain compartment experimentally approachable without causing major physiological and anatomical disturbances in neuronal tissue.

Microdialysis probes can collect endogenous neurotransmitter substances, released from nerve endings in the vicinity of the probe, as well as drugs that reach the brain following systemic administration (**Figure 1**). This process takes place at the distal end of the microdialysis probe where the physiological perfusion fluid equilibrates with the surrounding extracellular tissue fluid via passive diffusion down a logarithmic concentration gradient. As the direction of the concentration gradient is governed by the difference in concentration through the membrane, microdialysis can also be used to administer exogenous substances (local delivery), while endogenous compounds are concurrently recovered. These features make the in vivo intracerebral microdialysis technique an elegant tool to unravel unidentified mechanisms of action and identify 'the mechanisms that matter' of marketed AEDs. Since the extracellular space is the biophase for drugs acting on cell-surface-bound drug targets, the microdialysis technique enables the investigator to continuously monitor the effect of AED administration – e.g., on extracellular endogenous components such as neurotransmitters, neuropeptides, etc. Insertion of a microdialysis probe into the seizure focus allows the investigator to characterize the neurobiological and metabolic changes that accompany seizures. The dialysate is obtained before, during and after drug treatment, so that each animal serves as its own control. Brain accessibility and blood-brain barrier passage of systemically applied drugs can be studied, giving crucial information concerning target site drug pharmacokinetics. Simultaneously their pharmacodynamic effects can be evaluated.

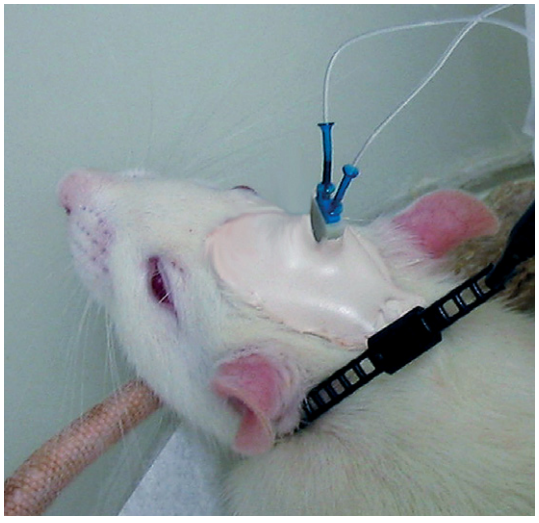

Figure 1 Freely moving rat with stereotactically implanted microdialysis probe in the dorsal hippocampus.

The term 'pharmacokinetics' (PK) refers to the time-concentration relationship of a drug in the body, and encompasses absorption, distribution, metabolism and excretion processes. Pharmacodynamics (PD) describes the mechanisms by which drugs exert their biochemical and physiological effect in the living organism. Although the magnitude of the pharmacological effect is related to the concentration at the site of action, in the past PK and PD were often studied and used separately for optimizing dosing recommendations. However, the usefulness of these disciplines is limited if viewed in isolation. PK–PD modeling links the concentration-time profile to the intensity of a pharmacological response, usually expressed as a biomarker or surrogate end point. It therefore allows better description of the complete time course of the desired and/or undesired effects in response to drug therapy. It enables the elucidation of causative relationships between drug exposure and response, and the characterization of the sequence of events leading to the observed drug effect. Mechanistic and empirical PK–PD models are available. These models can be descriptive and/or predictive of the time course of PD effect. Predictive models, when properly developed, may be used to guide or adjust doses and regimens, add evidence to the certainty of the decision to allow market access, and provide a better understanding of outcomes from clinical benefit studies. Population PK–PD modeling is primarily based on the nonlinear mixed-effects regression models, and allows the characterization of dose-concentration-effect relationships in populations rather than individuals, thereby providing investigators with the opportunity to identify and account for sources of inter-individual PK and/or PD variability.

Recent Results

New Pharmacological Targets and Approaches

The growing understanding of the pathophysiology of epilepsy, including the breakthroughs in genetics that have defined the fundamental defects of many epilepsy syndromes, and the structural and functional characterization of the molecular targets, provide new opportunities for rational AED development. Potential antiepileptic targets include voltage-gated ion channel subunits (α2-δ Ca^{2+} channel subunits, A- or M-type voltage-gated K^+ channels, α Na^+ channel subunits, hyperpolarization-activated cyclic nucleotide-gated cation channel subunits), SV2A synaptic vesicle protein, connexins, plasma membrane and vesicular glutamate and GABA transporters, and glutamate and GABA receptors. We screened different subtype-selective ionotropic and metabotropic glutamate receptor ligands in animal epilepsy models, and monitored the concomitant neurochemical changes in extracellular hippocampal

glutamate and GABA levels as biomarkers for increased network activity. The subtype-selective GLU_{K5} kainate receptor and metobotropic mGlu1a and mGlu5 antagonists were shown to completely suppress complex partial seizures, while mGlu2/3 agonists only offered partial anticonvulsant effects.

Neuropeptides are appealing targets for the study of basic mechanisms of seizure initiation and arrest, and for the development of novel approaches for epilepsy treatment. They are modulators of the traditional neurotransmitters, contained in large dense-core vesicles within neurons and in brain areas involved in epileptogenesis. Since neuropeptides are preferentially released in response to bursts or high frequency firing neuronal firing, neuropeptide systems seem extremely relevant targets for epilepsy research. Seizure activity causes important region-specific temporal variations in expression of virtually every neuropeptide (and related receptors), as seen dramatically in the hippocampal formation. In a recent pharmacological study, we reported the anticonvulsant properties of angiotensin IV and somatostatin-14. The effects of both angiotensin and somatostatin were mediated via somatostatin receptor-2 activation. In accordance with our earlier data showing the importance of the monoaminergic system in seizure suppression, hippocampal monoaminergic transmission was demonstrated to be an important constituent of the anticonvulsant mechanism of action of both peptides. A substantial amount of evidence has implicated neuropeptide Y in the control of seizure activity. Its anticonvulsant activity is generally accepted to arise from a negative modulatory effect on glutamatergic synaptic transmission via presynaptic Y_2 receptor-mediated inhibition of voltage dependent Ca^{2+} currents. In a recent study we demonstrated that neuropeptide Y-mediated increases in hippocampal dopamine is a complementary anticonvulsant mechanism of action. The hippocampal dopaminergic effect was shown to be mediated via sigma 1-receptors activation. During the past decade, many other neuropeptides, such as galanin and dynorphin, have emerged as powerful endogenous anticonvulsant peptides and/or neurotropic factors that modulate seizure-associated neurodegenerative and neuronal plastic changes. Due to degradation by peptidase-catalysed breakdown and sparse blood-brain barrier permeability, peptides are generally poor candidates for future therapeutic agents. However, non-peptidergic ligands for peptide receptors may offer new opportunities as potential antiepileptic treatment strategies.

One of the mechanisms that has emerged as a credible potential factor in refractory epilepsy is impairment of drug penetration into the brain by efflux transporters. It has been hypothesized that over-expression of efflux transporters at the blood-brain barrier prevents AEDs from reaching sufficiently high brain concentrations, despite adequate plasma levels. Certain efflux transporters have been found to be transiently upregulated (over-expressed) following experimentally-induced seizures. It is of major clinical interest to evaluate whether AEDs are substrates for these transporters. If that is the case, over-expression of multidrug transporters in epileptogenic brain tissue is likely to result in reduced drug penetration into brain parenchyma and could critically contribute to pharmacoresistance in epilepsy. We evaluated the impact of p-glycoprotein and multidrug resistance-associated protein blockade on the brain distribution of oxcarbazepine and its active metabolite. Efflux transporter impairment resulted into increased extracellular brain levels of both compounds, as measured by intracerebral microdialysis. Also, the pharmacodynamic effects on hippocampal monoamine levels were potentiated, resulting in increased anticonvulsant activity. Over the last years, most of the marketed antiepileptic compounds were proven to be efflux transporter substrates (with exception of levetiracetam). Thus, co-administration of AEDs and efflux transporter blockers may be a new potential treatment strategy.

Alteration of Drug Efficacy in Epileptic Animals

Two hypotheses have been put forward to explain the phenomenon of pharmacoresistance. The first states that the drug does not reach the target in sufficient quantity, as has been ascribed above. The second states that drug targets in the brain have been altered in a way that they do not respond to the administered drug. Indeed, ample evidence can be found in the literature for changes in ion channel properties, as well as in GABA, glutamate and other receptors. If the target has disappeared altogether or has changed so drastically that it does not respond to the drug under investigation, it is obvious why the drug does not exert an antiepileptic effect. However, it should be noted that in every type of epilepsy, whether responsive to the current armentarium of AEDs or not, there may be differences – compared to the non-epileptic brain – in properties of receptors, ion channels, and other targets. These differences may appear small, and only moderately affect interaction of the drug with its target. However, their net effect on brain excitability may nevertheless be significant.

Unfortunately, most of our AED drug candidates are screened primarily in models of acute seizures induced in essentially non-epileptic brain, and the results from these tests may be misleading when extrapolated to the types of epilepsy for which the drugs were designed. Pharmacological investigations should preferably be carried out in animal models that properly reflect the type of epilepsy of interest. In fact, the same principles apply when mechanisms of drug action are investigated in in vitro preparations such as hippocampal slices. When selecting an animal model for pharmacological studies, or perhaps

even developing a new model, the relevance of the model for the type of epilepsy of interest is receiving increasing attention. Several interesting models now exist. The most widely used model is induction of status epilepticus by chemical or electrical means in rodents, which develops in a matter of weeks into spontaneous epilepsy. The associated neurochemical changes and synaptic reorganization in the animals closely mimic those seen in mesial temporal lobe epilepsy in humans. But there are other important model systems. Genetic models (e.g., GAERS and Wag/Rij rats) display spontaneous seizure resembling absence epilepsy and exhibit a similar pharmacology. Hyperthermia induced in immature animals can elicit complex febrile seizures. And rat pups exposed in utero to methylazoxymethanol acetate (MAM) develop dysplasia-associated epilepsies. Validation of a model is an important issue. Therefore, the selected animal model should display a profile of responsiveness to AEDs similar to the human type of epilepsy under study.

The ultimate proof of efficacy of a drug is its capacity to suppress spontaneous seizures. However, reliable determination of a change in seizure frequency can pose a major problem. For example, it is known that during status epilepticus, the anticonvulsant effects of diazepam and phenobarbital rapidly decrease. Whether this process continues in the latent period following status epilepticus is an important question, but measuring changes in frequency is not an option because, by definition, seizures do not occur in this period. To allow assessment of progressive decreases in anticonvulsant effect of a drug during the latent period, one needs to elicit seizures artificially or use a quantitative method that reflects the mechanism underlying the anticonvulsant action (e.g., enhancement of GABAergic inhibition).

An attractive method for determination of seizure threshold is to stimulate the brain with ramp-shaped electrical pulse trains. Stimulation up to the threshold determination lasts only 10–15 s and the procedure can be repeated at intervals as short as 5 min. Therefore, this method allows determination of the time course of drug action. An alternative is the use of a biomarker that either reflects the interaction of the drug with the target or the seizure susceptibility of the brain. The intrinsic efficacy and potency of benzodiazepines to enhance $GABA_A$-mediated inhibition, for example, is reflected in the increase in the β-frequency band in the EEG. This effect provides an extremely convenient measure of pharmacological effect, because the EEG can be recorded continuously, without the need to elicit seizures. Using this method, it was possible to demonstrate that midazolam almost completely looses its efficacy during the latent period following status epilepticus. Other useful biomarkers include endogenous molecules or metabolites that can be measured in the brain by microdialysis, MRI, or another appropriate method. It is important that, when using this type of biomarker, its relation to the anticonvulsant effect is thoroughly validated.

Characterization of Concentration-Effect Relationships of AEDs: Pharmacokinetic and Pharmacodynamic Modeling

It seems trivial to state that the efficacy of a drug does not only depend on the interaction with its target but also on the PK of the drug. Nevertheless, it is surprising how little attention is paid in the literature to this important aspect of drug efficacy. Searching for synergistic drug combinations revealed that more than half of the studies ignored brain concentrations altogether. Absorption from the gut, metabolism in the liver or elsewhere, renal excretion, distribution to various tissues, passage over the blood-brain barrier (and vice versa) determine how much or how little of the AED will reach its target in the brain. PK can be affected by interaction with other drugs, chronic medication, or disease progression. Induction of liver enzymes and upregulation of efflux transporters at the blood-brain barrier are obvious examples of mechanisms that contribute to a drug's PK. Thus, it is in general insufficient to determine the time of peak drug effect in a control animal and assume that this value is also valid under pathological conditions.

Because of these obvious difficulties, an integrated study of the relationship between the PK and PD (PK–PD) of a drug can be a powerful tool in characterizing drug effects. First of all, PK–PD modeling provides quantitative information about the range of concentrations over which a drug is effective. More interestingly, PK–PD modeling can be used to compare efficacy in different models of epilepsy, to establish the influence of age and gender, to study the influence of disease progression or the efficacy of drug combinations, to confirm or reject whether effects observed in vitro indeed contribute to the in vivo effect, and so on. Advanced PK–PD-modeling is a discipline in itself, but it begins with well-controlled dosing, and measuring effects and concentrations in plasma simultaneously. If possible, target tissue concentrations should be measured as well.

The concentration-effect relations of drugs acting on $GABA_A$-receptor-mediated inhibition have been studied in this way, using the increase in β-activity as the pharmacodynamic endpoint. By giving a bolus dose sufficient to saturate all receptors, and measuring EEG during the elimination of the drug, the whole range of concentration and effect can be covered in a single experiment. For this purpose, the rapid elimination of drug in rodents is a considerable advantage. Using this approach, we found that the concentration-effect relation of benzodiazepines and tiagabine could be described by a sigmoidal E_{max} model, and that their in vivo potency (EC_{50}) and efficacy

(E_{max}) correlated well with the in vitro affinity and efficacy. In kindled animals and in rats with spontaneous absences, midazolam exhibited the same potency but the efficacy was 25–30% lower than in control animals. In rats subjected to status epilepticus by injection of kainic acid, the decrease in efficacy was more dramatic, progressing from 50% at day 4 after status to 75% at day 14. In contrast, tiagabine was equally effective in control animals, kindled animals (perhaps even more effective), and in kainic acid-treated rats. Alphaxalone, a neurosteroid also acting on $GABA_A$-receptors, even exhibited a slightly increased efficacy in kainic acid-treated rats. This result suggests that epilepsy (and/or its development) selectively modifies specific $GABA_A$-receptors by altering subunit composition and thereby the effect of different drugs. This idea is consistent with numerous histochemical and electrophysiological studies.

Another application of PK–PD modeling is to use parameters derived from the modeling in order to monitor disease progression. For example, using PET, we have been able to determine specific binding (B_{max}) and affinity (K_D) for flumazenil (**Figure 2**). As PET is a non-invasive technique, it offers the opportunity to monitor the time course of changes in receptor density and affinity in relation to epilepsy development, anti-epileptogenic treatment, etc. Also, it should be noted that effective concentrations in animals and man are often remarkably similar, despite huge differences in required dosages. In other fields, PK–PD modeling has been used successfully to predict efficacy in humans from pre-clinical data, and such approaches should also be used for epilepsy research. For inspiration the reader should consult the literature on PK–PD modeling.

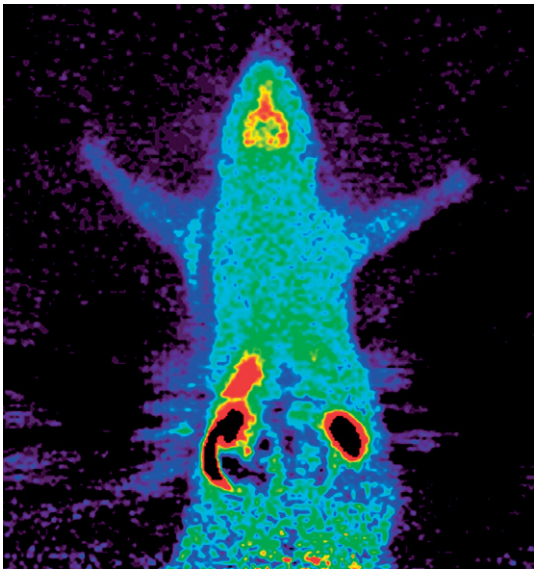

Figure 2 Positron Emission Tomography in a rat. Uptake of a tracer amount of ^{11}C-flumazenil in the brain can be easily seen and reflects mainly binding to the $GABA_A$ receptor. Combined with plasma concentration data, PET data have been used to model plasma and brain pharmacokinetics of flumazenil and to determine K_D and B_{max}.

Synergistic and Antagonistic Interactions of AED Combinations

From a therapeutic point of view, selective compounds might be interesting because of their potentially limited side-effect profile. However, it has been suggested that the failure of several rational therapeutic strategies, aimed towards more selective drugs, is related to the fact that absolute selectivity for one target may not be desirable for a multifactorial disease such as epilepsy. Most clinically efficacious AEDs act by a multitude of mechanisms, so that a rational combination of mechanisms in a single drug – e.g., generated by combinatory chemistry – may be a more successful strategy for creating novel broadly-acting AEDs than the development of highly selective compounds.

Nevertheless, highly selective compounds remain important tools for investigation. To design single drugs combining multiple mechanisms, one should ideally know which mechanisms to combine. On theoretical grounds, it can be expected that combining compounds acting at different targets provide the highest chance of creating an effective interaction, where the benefit would reflect a synergism for the anticonvulsant effect or antagonism for adverse effects. For this purpose, examining the combined effect of highly selective compounds would be ideal, because it will allow identification of the proper targets.

Characterization of the efficacy of combinations of two drugs, let alone three or more, is an experimental challenge, and interpretation of the data is fraught with pitfalls. Combinations may be synergistic only over a limited concentration range, or even more complex, be synergistic over one range and antagonistic over another. Consequently, complete characterization of the interaction requires investigation of the entire concentration range over which the drugs are active. This task may become prohibitive when only one effect point can be measured in an individual animal. Furthermore, pharmacokinetic interactions, choice of the animal model, and method of analysis can influence the outcome of the study. However, if it is possible to determine multiple effect points and concentration data in individual subjects, complete characterization becomes feasible. Furthermore, sophisticated study designs, developments in methodological tools such as surface response analysis (which allows examination of interactions over a range of concentrations), and population PK–PD analysis (which takes into account, and actually takes advantage of, various sources of variability) have come to the investigators' aid.

Given the fact that many patients clearly benefit from combination therapy, it is likely that favorable

interactions exist. Nevertheless, sound clinical evidence to support this view is still lacking. In experimental studies, the number of combinations that can be made is unlimited, and many claims for synergistic anticonvulsants can be found in the literature. In about half of the experiments, the PK are not considered and it is therefore impossible to conclude whether pharmacodynamic interactions occurred in these experiments. Considering only the more properly designed studies, it is not yet entirely clear which properties in an anticonvulsant drug favor synergism. Nevertheless, some trends have become visible. The majority of studies, in which AMPA antagonists (and also NMDA antagonists) formed part of the combination, reported synergistic effects. As the AMPA and NMDA antagonists were combined with agents either acting on multiple targets or blocking Na^+-channels, there is still no definitive proof that postsynaptic glutamate receptors favor synergism, but these receptors are certainly good candidates. Similar results were obtained for compounds acting on presynaptic glutamate receptors, but only a few studies have been carried out with these compounds.

There is accumulating evidence that synergism can occur in a restricted range of concentrations. This understanding was demonstrated quite early for a number of registered AED combinations. Increasingly, brain concentrations are also taken into account in such combinatorial analysis. In a number of cases where favorable interactions were observed, the synergism had to be attributed to an increase in brain concentration, rather than a pharmacodynamic interaction. Such results indicates that brain PK (regional distribution, metabolism, blood-brain barrier transport) may have a decisive influence. Combinations may not only suppress seizures in an all-or-none manner. In a study with tiagabine and lamotrigine, we demonstrated by quantitative behavioral analysis that over a limited concentration range, certain seizure components were selectively suppressed. This result illustrates that the nature of seizures, and thereby their severity, can be modified by drug combinations. Finally, optimization of rational drug synergism may be more effective in controlling seizures than either drug alone. It is encouraging that increasing attention is paid to potential adverse effects when using drug combinations. This concern is important, because combinations will be successfully introduced into clinical practice only when synergistic anticonvulsant effects are not spoiled by increased adverse effects.

Conclusion – Directions for the Future

Despite the substantial progress in understanding the pathophysiology of the epilepsies, many patients remain refractory to currently available pharmacological treatments. More effective, innovative therapeutic agents are therefore urgently needed. In the future, screening in animal models will probably remain the engine that drives AEDs discovery. Inclusion of truly epilepsy models, which closely mimic the human disease state in a battery of tests for early stage characterization, is necessary for the further unraveling of the processes involved in epileptogenesis and the identification of new potential pharmacological targets. Additionally, a complete characterization of the primary and secondary mechanisms of action of existing AEDs, and the recognition of the antiepileptic 'mechanisms that matter' may offer new opportunities for rational (combinatory) drug design and optimization of rational drug synergism. The development and validation of biomarkers, which can be used to monitor the natural course of epileptogenesis as well as anticonvulsant activity of drugs, and advances in pharmacokinetic-pharmacodynamic modeling, are indispensable for optimizing the analysis of the in vivo efficacy of new pharmacological interventions and treatment strategies.

Introduction

Despite the introduction of 11 new antiepileptic agents over the past 20 years, and unprecedented advances in our knowledge of how those drugs work at the cellular level, at least 30% of epilepsy patients continue to experience seizures on otherwise optimal therapy. Even amongst those patients who achieve seizure control, a significant proportion can expect dose-related adverse effects to impact upon their quality of life. For the most part, modern antiepileptic agents are associated with fewer and less severe side effects; they have simpler pharmacokinetics and fewer drug interactions; but they have largely failed to improve the outcome, at least in terms of efficacy. As a result, still more new antiepileptic drugs are required.

Background – Drug Discovery

In order to understand why recent drug development in epilepsy has been relatively unsuccessful, it is important to review the strategies employed in each case. Starting with vigabatrin, which was first licensed in the UK in 1989, and ending with rufinamide, the most recent addition to the antiepileptic armamentarium, three principal approaches are evident: target-orientated design, structural modification, and random screening.

Amongst modern antiepileptic agents, vigabatrin and tiagabine are the sole products of target-orientated design, fulfilling their intended purpose of enhancing γ-aminobutyric acid (GABA) mediated neurotransmission by selective inhibition of GABA metabolism via an action on the enzyme GABA-transaminase, and of GABA re-uptake via an action on the GAT-1 transporter, respectively. Other new drugs are products of a structural modification strategy which is based on chemical adaptation of both exogenous and endogenous neuroactive compounds. For example, gabapentin and pregabalin are analogs of the inhibitory neurotransmitter GABA, and oxcarbazepine is a carbamazepine derivative, designed to bypass the epoxide metabolite believed to be responsible for many of the adverse effects of the parent compound. Finally, there are several new antiepileptic agents (such as topiramate, levetiracetam, zonisamide, and rufinamide) that have arisen from random screening of libraries of molecules. This category also includes lamotrigine, which might more accurately be defined as the product of a candidate screening program, albeit based on the incorrect assumption that antifolate compounds might prove useful in the treatment of epilepsy.

Target-orientated design is likely to yield a single mechanism drug with high specificity which can be tailored to defects in the epileptic brain (where known), but may be inadequate for a heterogeneous disorder such as epilepsy. To date, efforts at target-orientated drug design for epilepsy have foundered, most likely because targets were selected on the basis of a hypothesis rather than on direct evidence. Structural modification relies on the established activity of the parent molecule and provides an opportunity to improve on specific aspects of efficacy and/or tolerability. It could be argued that this approach is unlikely to change the spectrum of activity, unlikely to benefit those who are unresponsive to the medications upon which any novel compound is based, and employed predominantly to limit perceived commercial risk. Random screening has been the most successful drug development strategy in recent years, identifying several agents

Preclinical Drug Development in Epilepsy

Introduction

Despite the introduction of 11 new antiepileptic agents over the past 20 years, and unprecedented advances in our knowledge of how those drugs work at the cellular level, at least 30% of epilepsy patients continue to experience seizures on otherwise optimal therapy. Even amongst those patients who achieve seizure control, a significant proportion can expect dose-related adverse effects to impact upon their quality of life. For the most part, modern antiepileptic agents are associated with fewer and less severe side effects; they have simpler pharmacokinetics and fewer drug interactions; but they have largely failed to improve the outcome, at least in terms of efficacy. As a result, still more new antiepileptic drugs are required.

Background – Drug Discovery

In order to understand why recent drug development in epilepsy has been relatively unsuccessful, it is important to review the strategies employed in each case. Starting with vigabatrin, which was first licensed in the UK in 1989, and ending with rufinamide, the most recent addition to the antiepileptic armamentarium, three principal approaches are evident: target-orientated design, structural modification, and random screening.

Amongst modern antiepileptic agents, vigabatrin and tiagabine are the sole products of target-orientated design, fulfilling their intended purpose of enhancing γ-aminobutyric acid (GABA) mediated neurotransmission by selective inhibition of GABA metabolism via an action on the enzyme GABA-transaminase, and of GABA re-uptake via an action on the GAT-1 transporter, respectively. Other new drugs are products of a structural modification strategy which is based on chemical adaptation of both exogenous and endogenous neuroactive compounds. For example, gabapentin and pregabalin are analogs of the inhibitory neurotransmitter GABA, and oxcarbazepine is a carbamazepine derivative, designed to bypass the epoxide metabolite believed to be responsible for many of the adverse effects of the parent compound. Finally, there are several new antiepileptic agents (such as topiramate, levetiracetam, zonisamide, and rufinamide) that have arisen from random screening of libraries of molecules. This category also includes lamotrigine, which might more accurately be defined as the product of a candidate screening program, albeit based on the incorrect assumption that antifolate compounds might prove useful in the treatment of epilepsy.

Target-orientated design is likely to yield a single mechanism drug with high specificity which can be tailored to defects in the epileptic brain (where known), but may be inadequate for a heterogeneous disorder such as epilepsy. To date, efforts at target-orientated drug design for epilepsy have foundered, most likely because targets were selected on the basis of a hypothesis rather than on direct evidence. Structural modification relies on the established activity of the parent molecule and provides an opportunity to improve on specific aspects of efficacy and/or tolerability. It could be argued that this approach is unlikely to change the spectrum of activity, unlikely to benefit those who are unresponsive to the medications upon which any novel compound is based, and employed predominantly to limit perceived commercial risk. Random screening has been the most successful drug development strategy in recent years, identifying several agents

with a broad spectrum of clinical activity. However, this approach is laborious and expensive. As far as screening is concerned, mechanism of action is largely irrelevant (and may remain undiscovered), with success dependent on the models employed in the screening protocol, and with a significant potential for useful compounds to be discarded prematurely.

Methods

Models

Irrespective of the method employed for compound discovery, preclinical evaluation of efficacy and toxicity typically follows a standardized, if not specifically regulated, path. The efficacy and neurotoxicity of new antiepileptic agents are initially established in a series of experimental models. The most commonly employed models for evaluation of efficacy include the maximal electroshock (MES) and subcutaneous pentylenetetrazol (sc PTZ) tests, and the kindled rat. More recently, the 6-Hz psychomotor seizure test has gained favor as a high throughput model which can identify those compounds that are inactive in both of the two primary screening modalities (MES and sc PTZ).

Maximal electroshock

In the MES test, animals receive a short, supramaximal electrical stimulus sufficient to induce tonic extensor seizures of the hind limbs. Electrical stimuli are applied through either ear-clip or corneal electrodes and are delivered by a constant current apparatus. Typical stimulation parameters are 0.2 s of rectangular positive (or square-wave) pulses at 60 Hz, with a pulse width of 0.4 ms. A current of 50 (mice) or 150 mA (rats) is generally sufficient to induce tonic extension of the hind limbs in the majority of naive animals, although some rodent strain differences are observed. Tonic hind limb extension is an 'all or none' phenomenon against which the effectiveness of test compounds can be evaluated by measuring the percentage of protected animals in any given treatment group.

Pentylenetetrazol

PTZ is a chemical convulsant agent which produces seizures following systemic administration and is used extensively for the investigation of the anticonvulsant effects of novel drugs. The sc PTZ test involves the subcutaneous administration of PTZ at a dose (CD_{97}) which is known to elicit convulsions in 97% of naive animals. The CD_{97} varies according to species and strain, and is routinely determined prior to any new series of drug studies. The most common CD_{97} in mice is 85 mg kg^{-1}. PTZ-induced seizures are characterized by an initial 'absence-like' immobility, followed by brief myoclonic jerks, sustained myoclonus, and finally generalized clonic seizures with a loss of the righting reflex. Use of higher doses can result in tonic extension of the hind limbs. Evaluation of anticonvulsant efficacy is most commonly performed by comparing the time to the first generalized seizure with loss of the righting reflex in drug- and vehicle-treated animals.

Kindled rat

Kindling is a phenomenon by which daily electrical stimulation of a specific brain region (usually amygdala or hippocampus), with a fixed and initially subconvulsive current, results in progressive sensitization and precipitation of epileptic seizures. The procedure involves stereotaxic, surgical implantation of a unilateral, bipolar stimulating and recording electrode, followed by daily stimulation for upwards of 15 days. The behavioral response to kindling evolves through five stages (stages I–V): stages I and II are characterized by immobility and twitching of the vibrissae, and by facial clonus and head nodding; stage III is characterized by unilateral forelimb clonus; and stages IV and V are associated with rearing and bilateral forelimb clonus, and with generalized clonic seizures and a loss of the righting reflex, respectively. Once animals reach stage V (after approximately 15–21 stimulations) they can be considered fully kindled, and their increased sensitivity to stimulation prevails for several months. Antiepileptic efficacy can be assessed against various components (threshold, amplitude, duration) of the electrographic response to kindling stimuli (otherwise known as the after-discharge), or more commonly by measuring protection against fully kindled, stage V seizures. Antiepileptogenic activity, or the ability to retard or prevent the development of seizures, can also be investigated by drug treatment in the kindling acquisition phase and comparison of the time to nth stage V seizure.

6-Hz psychomotor seizures

The 6-Hz psychomotor seizure model is a variation on the MES test. It employs a more modest current (32 mA) applied, via corneal electrodes, at lower frequency (6 Hz) over a longer period (3 s). The 6-Hz test generates a much less severe response than the traditional MES, with only brief clonic seizures followed by stereotyped behaviors (jaw-chomping, whisker-twitching) against which the efficacy of candidate compounds can be assessed. As discussed earlier, this model has recently been incorporated into screening protocols in order to identify compounds (such as levetiracetam) with antiepileptic potential but which are inactive in the conventional MES and sc PTZ tests.

Other efficacy models

Additional experimental models may be employed to examine the spectrum of preclinical efficacy and thereby

facilitate comparison with established antiepileptic drugs. These models may include (but are not necessarily restricted to): the audiogenic-seizure sensitive mouse (DBA/2 or Frings), which experience generalized clonic seizures on exposure to loud bell-ringing; the bicuculline and picrotoxin tests, both of which are chemical convulsant agents administered subcutaneously to elicit generalized convulsions in a similar manner to the sc PTZ test but with different mechanisms of epileptogenic action; and the intravenous pentylenetetrazol (iv PTZ) threshold test, which can be employed to investigate the ability of candidate compounds to elevate (or lower) the seizure threshold as achieved by a slow, intravenous infusion of PTZ, with the time to first appearance of seizure manifestations recorded.

Neurotoxicity models

Neurotoxicity is most often determined by the rotarod test, which involves placing experimental animals (usually mice) on a 2.5-cm diameter rod, rotating continuously at 6 rpm. Control animals are able to maintain their equilibrium on the rotating rod for prolonged periods of time, whereas those treated with neurotoxic doses of candidate compounds are more likely to fall. Neurological impairment is generally indicated by loss of equilibrium (falling) in three consecutive tests performed over a 1-min period. Additional investigations of drug-related neurotoxicity include the horizontal screen test (where animals are placed on an inverted horizontal wire mesh), the positional sense test (where one hind-limb is deliberately lowered over the edge of the table), the gait and stance test (where animals are observed for overt signs of ataxia, abnormal gait, stupor, somnolence, etc.), and the muscle tone test (in which experienced investigators can identify a lack of skeletal muscle tone during simple handling).

Formulations

Solubility of test compounds is an issue in preclinical studies and can influence the dose range, route of administration, and choice of vehicle. Antiepileptic drugs are necessarily lipophilic, in order that they cross the blood-brain barrier; however, this characteristic can limit their solubility in aqueous solutions. For informal studies, individual investigators may choose to dissolve candidate compounds in either distilled water or 0.9% saline or in organic solvents such as polyethylene glycol, dimethyl sulfoxide, or Tween 80. Ethanol should be avoided as it possesses anticonvulsant properties in its own right. For more formal investigations, such as those described under the Antiepileptic Drug Development (ADD) program (below), candidate compounds are routinely dissolved or suspended in a standardized vehicle, such as 0.5% methylcellulose solution, to ensure reproducibility and comparability of findings. Test compounds are most often administered either orally or intraperitoneally in a volume adjusted according to both body weight and species (e.g., mice, 0.01 ml per gram body weight; rats, 0.04 ml per gram body weight). Chemoconvulsant agents (such as PTZ or bicuculline) and test compounds should be administered by different routes to avoid unforeseen interactions at the level of absorption.

Analyses

Data derived from preclinical screening are generally expressed in a series of values, such as the median effective dose (ED_{50}; the dose at which 50% of animals are protected from seizures), the median toxic dose (TD_{50}; the dose at which 50% of animals exhibit neurotoxicity), the time of peak effect (time since drug administration at which maximal efficacy or neurotoxicity is observed), and the protective index (PI; ratio of median toxic dose to median effective dose). All of these measures allow comparison with previously reported data. PIs give an indication of the relative separation between effective doses and those at which side effects are likely to be observed. They may be useful in predicting whether a novel compound is likely to possess clinical utility; for example, a PI of around 1.0 is often thought to be predictive of little or no efficacy at tolerable doses. It is important to note, however, that PIs can be manipulated to show novel drugs in a preferential light by selecting the efficacy model in which the candidate compound is most potent and the neurotoxicity model in which it is least potent.

The ADD Program

In response to changes in legislation governing the licensing of new medications, and the resulting hiatus in antiepileptic drug development in the 1960s and early 1970s, the ADD Program was instituted by the United States National Institute of Neurological Disorders and Stroke in 1974. Since then, the ADD program has screened more than 30 000 compounds submitted by academic and pharmaceutical company chemists from across the globe. It is currently based at the University of Utah, under the direction of Professor H. Steve White.

The ADD program currently comprises three principal evaluation stages – termed: identification, quantification and differentiation – and so-called 'further studies,' investigating proconvulsant potential, and mechanisms of action (**Table 1**). Initial identification of anticonvulsant efficacy is undertaken in the MES and sc PTZ models, performed at 30 min after intraperitoneal (mice) or oral (rats) administration of 30–300 mg kg^{-1} doses of the candidate compound. Those agents which fail to demonstrate any efficacy under these conditions are further evaluated in the 6-Hz psychomotor test, 30 min after a single intraperitoneal dose of 100 mg kg^{-1} in mice. Compounds which fail this initial identification stage are generally discarded.

Table 1 Overview of testing procedures in the Antiepileptic Drug Development program

1. Identification
   a. Mouse (i.p.)
      Dose range: 30, 100, and 300 mg kg^{-1}
      Tests: MES, sc PTZ, rotarod
      Time of tests: 30 min and 4 h
   b. Rat (p.o.)
      Dose: 30 or 50 mg kg^{-1}
      Tests: MES (30 mg kg^{-1}) or sc PTZ (50 mg kg^{-1}) plus minimal neurotoxicity
      Time of tests: 15 min, 30 min, 1 h, 2 h, and 4 h
   c. Mouse (i.p.) – only performed for compounds inactive in 'a' and 'b' above
      Dose: 100 mg kg^{-1}
      Test: 6 Hz
      Time of test: 15 min, 30 min, 1 h, 2 h, and 4 h
2. Quantification
   a. Mouse (i.p.)
      Determination of TPE: MES, sc PTZ, 6 Hz, rotarod
      Determination of ED_{50}: MES, sc PTZ, 6 Hz
      Determination of TD_{50}: rotarod
   b. Mouse (p.o.)
      Determination of TPE: MES, sc PTZ, rotarod
      Determination of ED_{50}: MES, sc PTZ
      Determination of TD_{50}: rotarod
   c. Rat (p.o.)
      Determination of TPE: MES, sc PTZ, minimal neurotoxicity
      Determination of ED_{50}: MES, sc PTZ
      Determination of TD_{50}: minimal neurotoxicity
3. Differentiation
   a. Mouse (i.p.)
      Determination of ED_{50} in sc bicuculline model
      Determination of ED_{50} in sc picrotoxin model
      Determination of ED_{50} in Frings audiogenic seizure-sensitive mouse
   b. Rat (i.p.)
      Determination of ED_{50} against stage V seizures in amygdala kindled rat
      Determination of ED_{50} against spike-wave discharges in γ-hydroxybutyrate model of absence
4. Further studies
   a. *Proconvulsant potential*
      Mouse (i.p.)
      Dose: Single dose of investigational agent at TPE and ED_{50}
      Test: Determination of seizure threshold following timed i.v. infusion of PTZ
   b. *Mechanism of action*
      (i) Patch-clamp electrophysiology studies (voltage-gated sodium and calcium channels and ligand-gated ion channels; NMDA, AMPA/kainate, GABA)
      (ii) Electrophysiological recording from synaptically coupled neuronal pairs

6 Hz, 6-Hz psychomotor seizure test; AMPA, α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid; ED_{50}, median effective dose; GABA, γ-aminobutyric acid; i.p., intraperitoneal; i.v., intravenous; MES, maximal electroshock; NMDA, *N*-methyl-D-aspartate; p.o., oral; PTZ, pentylenetetrazol; s.c./sc, subcutaneous; TD_{50}, median toxic dose; TPE, time of peak effect.
Adapted from White HS, Woodhead JH, Wilcox KS, *et al*. (2002) Discovery and preclinical development of antiepileptic drugs. In: Levy RH, Mattson RH, Meldrum BS, and Perucca E (eds.) *Antiepileptic Drugs*, 5th edn., pp. 36–48. Philadelphia: Lippincott, Williams & Wilkins.

Those drugs which demonstrate efficacy in one or more of the initial experimental screens then undergo more detailed quantification of their efficacy and neurotoxicity. First, time of peak effect is established in both mice (intraperitoneal and oral administration) and rats (oral administration only), with a single dose of candidate drug evaluated in multiple models (MES, sc PTZ, 6 Hz, rotarod) at a variety of time points. Thereafter, ED_{50} in MES, sc PTZ and 6-Hz tests, and TD_{50} in the rotarod test, are determined at time of peak effect, again using two species (mice and rats) and two administration routes (intraperitoneal and oral). Finally, compounds are submitted for differentiation studies where their efficacy (ED_{50}) in a host of experimental models (such as the kindled rat, bicuculline and picrotoxin tests, audiogenic-seizure sensitive mouse, and γ-hydroxybutyrate-induced spike-wave seizures) is determined at the time of peak effect following intraperitoneal administration.

Novel drugs may undergo additional studies of their proconvulsant potential using the iv PTZ threshold test. The likelihood of their being associated with pharmacological tolerance (pharmacokinetic or pharmacodynamic) is also investigated using a repeated administration protocol. Mechanisms of action are explored using patch-clamp analysis focused on multiple voltage- and ligand-gated ion channels, such as sodium channels, calcium channels, GABA receptors, and glutamate receptors – which represent the primary pharmacological targets for existing antiepileptic agents. Paired-pulse recording in monosynaptically connected neurones, to investigate in vitro effects on membrane potential, action potential generation, and neurotransmitter release, can also be performed.

This extensive characterization provides information not just about whether the submitted compound is active or inactive, but also about the extent and range of its efficacy and neurotoxicity in comparison with other antiepileptic drugs, an indication of its PI, preliminary evidence regarding its mechanism of action, basic pharmacokinetic knowledge, and an indication of possible doses for use in initial human studies. The ADD program, as described earlier, has been instrumental in the development of all eleven modern antiepileptic drugs.

Additional Investigations

In addition to assessment of efficacy and neurotoxicity in animal models, all new candidate compounds for epilepsy are required by regulatory authorities to undergo detailed toxicological investigation (**Table 2**). This procedure generally involves acute tests using single drug doses, and two series of prolonged tests employing daily oral administration of three different drug doses to two different species (usually rats and dogs) for a minimum period of 14 days (short-term toxicology) and between 6 and

24 months (long-term toxicology). Routine toxicology investigations attempt to uncover biochemical and morphological abnormalities associated with prolonged drug exposure; additional, so-called 'special tests' specifically focus on behavioral, teratogenic and reproductive effects, and the potential for carcinogenicity. Animals in long-term studies undergo regular blood analyses, electrocardiograms, neurological and ophthalmological assessment, and a full postmortem at study termination. Teratogenicity is evaluated in detail, by physical and behavioral examination of the offspring of chronic drug-exposed females – from delivery, through weaning, growth, pubescence, and sexual maturity. Mutagenicity, as an indicator of potential carcinogenicity, is evaluated in vitro using the Ames test, in which mutagens can induce a reverse mutation in a specific strain of Salmonella bacterium, allowing it to grow on histidine-free medium.

Predicting Clinical Activity from Preclinical Models

Attempts have been made to use efficacy in preclinical models as a predictor for the potential spectrum of clinical activity, with the correlation based largely on pharmacological sensitivity to established antiepileptic drugs (Table 3). The MES test, responsive to carbamazepine and phenytoin, is reported to indicate activity against generalized tonic–clonic seizures. In contrast, the sc PTZ model is believed to reflect efficacy against generalized absence and/or myoclonic seizures and is principally sensitive to ethosuximide, sodium valproate and benzodiazepines. Finally, the kindled rat, proposed to predict utility in partial epilepsies, identifies a wide range of established antiepileptic agents (including carbamazepine, phenytoin, sodium valproate, barbiturates and benzodiazepines) with efficacy against various electrographic and behavioral components of the kindling response, including protection against fully kindled, stage V seizures.

Experience with modern antiepileptic drugs has, however, called this simplistic extrapolation of preclinical seizure protection into question. Several newer compounds, including topiramate, levetiracetam, and zonisamide, possess a broad spectrum of clinical activity, including at least anecdotal efficacy in absence epilepsies – and yet all are inactive in the sc PTZ test. In contrast, tiagabine has potent anticonvulsant effects in the sc PTZ model, but can make clinical absence seizures worse. Thus, drugs that are active in multiple preclinical models do not necessarily have clinical efficacy against multiple seizure types or in multiple epilepsy syndromes. This experience most likely reflects the fact that the majority of preclinical models currently used for drug development purposes are models of a single seizure – and as such, do not adequately mirror the chronic, recurrent and unpredictable nature of the clinical disorder.

Table 2 Routine toxicological assessment during drug development

1. Acute treatment
   a. Median lethal dose (LD_{50} or equivalent) in rodents
   b. Pyramiding single dose studies in dogs
   c. Local effects on rabbit skin (only for agents to be used topically)
2. Repeated treatment
   a. Subchronic (up to 3 months) using rats and dogs and three dose levels
   b. Chronic (6 months to 2 years) using rats and dogs and two or three dose levels
3. Special investigations
   a. Effects on fertility and reproduction
   b. Teratogenicity
   c. Carcinogenicity and mutagenicity
   d. Behavioral effects
   e. Interactions with other chemical agents

Future Studies

Current screening procedures in the ADD program (and elsewhere) may not be adequate to identify all potentially useful antiepileptic drugs. For example, levetiracetam was originally discarded by the ADD program due to its lack of efficacy in both MES and sc PTZ models; its

Table 3 Correlation between the efficacy of established antiepileptic drugs in selected preclinical models and their clinical spectrum of activity

	Clinical seizure type		
	Generalized tonic–clonic seizures	*Generalized absence/myoclonic seizures*	*Partial seizures*
Maximal electroshock test	PB, PHT, CBZ, VPA	–	–
Subcutaneous pentylenetetrazol test	–	ESM, VPA, BZDs	–
Kindled rat (stage V seizures)	–	–	PB, PHT, CBZ, VPA, BZDs

BZDs, benzodiazepines; CBZ, carbamazepine; ESM, ethosuximide; PB, phenobarbital; PHT, phenytoin; VPA, sodium valproate.

effectiveness was only revealed after subsequent screening in the kindled rat and audiogenic-seizure sensitive mouse. This failure prompted the subsequent incorporation of the 6-Hz psychomotor test into the ADD screening protocol, for those compounds which are unsuccessful in the initial identification phase. Whether other such compounds have slipped through the net, or are likely to do so in the future, is unclear. It is almost impossible, however, given the costs and high throughput nature of screening, to guard against all such eventualities.

The relatively modest impact of modern antiepileptic agents, at least in terms of efficacy, has lead to the suggestion that the clinical utility of novel compounds is unlikely to improve, unless the models used for their identification and characterization are updated. This is the so-called 'old models identify old drugs' argument, which questions the almost exclusive continued use of experimental seizure models such as the MES test, first developed in the 1930s and employed in the identification of phenytoin, in modern screening protocols. From a pharmacological perspective, using a limited number of traditional models as the primary screen for drug development may indeed favor certain mechanisms of action at the expense of novelty. Current evidence, however, does not support this assertion. Prior to the development of modern antiepileptic agents, there were no compounds with selective effects on high-voltage activated calcium channels (i.e., gabapentin) or on GABA transporters (i.e., tiagabine). These agents are examples of structurally novel drugs, with unique and selective pharmacological effects, that are active in at least one traditional seizure model. Thus, old models can identify new drugs; whether those drugs have better efficacy than their more established counterparts is another issue.

Drug resistance is one of the most significant problems in the clinical management of epilepsy. At least 30% of patients fail to respond to treatment with currently available medications. New drugs are required to meet this therapeutic deficit, but whether they are likely to be identified by traditional screening protocols is debatable. It may be necessary to introduce a second tier of screening, using specific models of drug resistant epilepsy, to distinguish generic anticonvulsants from those with potential efficacy in refractory epilepsies. Several such models have been described in recent years. The 6-Hz psychomotor seizure model has, on occasion, been promoted as a model of therapy-resistant epilepsy, on the basis that it is relatively insensitive to sodium channel blockers (such as phenytoin and lamotrigine), but more responsive to compounds with multiple mechanisms of action (such as sodium valproate and levetiracetam). Other models of drug resistant epilepsy, such as the phenytoin-resistant kindled rat, are more technically demanding and less suitable for high throughput screening. This model is an extension of the traditional kindling model, with animals selected and bred on the basis of response to phenytoin against fully kindled stage V seizures. If phenytoin nonresponders are employed in subsequent drug studies, they are invariably less sensitive to treatment with the majority of established and modern antiepileptic drugs than their responsive counterparts. Whether such models can be accommodated in screening protocols, and perhaps more importantly, whether they genuinely represent human refractory epilepsy, remains to be determined.

Another target for drug development in the epilepsy field, albeit somewhat further removed from contemporary practices, is epileptogenesis or the process of acquiring epilepsy following some unspecified neuronal insult. The search for such a drug is, to some extent, the holy grail of epilepsy therapy – focusing on the notion that 'at risk' individuals might be treated in a prophylactic manner to prevent the development of chronic seizures. Several models of epileptogenesis already exist, despite the fact that the clinical problem is yet to be delineated. The ability of a drug to prevent or retard the development of stage V seizures in the kindled rat model has been suggested to demonstrate antiepileptogenic potential. More clinically representative models are those in which recurrent, unprovoked seizures develop after a short period of acutely provoked status epilepticus, induced by either chemical (e.g., pilocarpine) or electrical stimulation. Understanding the processes ongoing in the 'latent period' between initial insult and seizure onset, which in these models may be weeks or months and which in humans may be twenty years and more, has the potential to identify novel drug targets. Several current antiepileptic agents can retard kindling acquisition, and some have been proposed to possess disease-modifying effects in post-status epilepticus models. As yet, however, there is no drug which can effectively prevent the development of chronic seizures in animal models.

Irrespective of the direction of drug development in the epilepsy field in the coming years, it is imperative that screening protocols remain robust and reliably predictive of clinical activity in general. They must also be sufficiently sensitive to identify compounds with novel mechanisms of action and sufficiently flexible to accommodate technically demanding models of drug resistant epilepsy and epileptogenesis. The recent and ongoing re-evaluation of drug development strategies in epilepsy should help to ensure that future treatments are targeted at the areas of greatest need.

Summary

Despite the introduction of eleven new antiepileptic drugs in the past 20 years, drug development in the field of epilepsy continues apace. All new compounds undergo rigorous examination in a series of experimental models prior to first human use. Preclinical studies are designed

to identify anticonvulsant activity, and thereafter to quantify the experimental efficacy and neurotoxicity of individual agents. Knowledge of potency and range of efficacy can facilitate comparisons with established drugs, and additional investigations may yield information about pharmacology, pharmacokinetics, and possible clinical activity. Preclinical toxicology is a statutory requirement of drug development and provides important information about long-term safety. The drug development process in epilepsy must constantly evolve to ensure that future generations of antiepileptic drugs are superior to those currently available, and to prioritize those areas of clinical epilepsy and those patients in greatest need.

Basic Mechanisms of Neuronal Injury from Seizures and Status Epilepticus

Introduction

Epilepsy is one of the most common neurological conditions, occurring in up to 1% of the adult and 2% of the pediatric populations. In addition, ~40% of patients with epilepsy have seizures that are refractory to treatment. This large population of patients is having recurrent seizures on a regular basis, despite the best of neurological care. It is essential to understand the potential risks to the brain of episodic seizures and to determine whether repeated seizures in this population of patients can lead to neuronal damage and brain injury. This article evaluates the evidence supporting the question of whether clinical and in vitro recurrent seizures or epileptiform events can cause neuronal damage. The results of this article indicate that recurrent seizures do not cause neuronal damage.

Status epilepticus (SE) is a prolonged seizure condition representing a major medical and neurological emergency, and is associated with a significant morbidity and mortality despite aggressive treatment protocols. In vivo studies are complicated by compensatory environmental changes in the brain that are characteristic of living systems. Changes in glucose utilization, hormonal production, extracellular fluid composition, and the involvement of other physiological processes, for example, may vary under different conditions that induce SE. These changes alter the environment of neurons under study, complicating the mechanistic assessment in vivo of whether continuous seizure discharges alone – or other related physiological effects – cause neuronal damage and death. Evaluating the effects of epileptiform activity per se on electrophysiological and metabolic functions is very difficult at the single neuron level in vivo, since it is not possible to carefully control the neuronal environment during seizure activity in the whole animal. Studies from our laboratory have investigated the effects of electrographic epileptiform discharges on neuronal viability in an in vitro model, in order to elucidate the mechanisms of seizure-induced cell death. Although the neuronal cultures do not have anatomical connections as seen in the intact brain, and do not display clinical seizures, epilepsy and SE in hippocampal neuronal cultures have been routinely used to characterize biochemical, electrophysiological, and molecular mechanisms underlying these conditions.

Background

It has been well established that SE is associated with neuronal death. This neuronal damage is dependent upon multiple variables, including the location of seizure

foci, seizure duration, age, and genetic susceptibility; there are, in addition, many exacerbating factors, such as the underlying etiology of the seizures – e.g., hypoxia and ischemia. Pioneering studies by Meldrum and coworkers, in ventilated baboons, provided the first evidence that prolonged electrographic seizures (SE) alone, in the absence of underlying systemic physiological complications, could cause neuronal death. There is now strong evidence that SE can cause significant neuronal damage, especially in the limbic system, in both animal models and human patients. Evidence is now accumulating especially from in vivo models of epilepsy, suggesting that neuronal death is associated with an initial epileptogenic insult and not with later spontaneous seizures that do not develop into SE. Understanding the effects of epileptiform discharges on neuronal viability and pharmacology of neuronal death is important in developing therapeutic strategies for treating SE and epilepsy.

The results presented in this paper provide direct evidence that self-limited seizure activity does not injure neurons, but that SE can cause neuronal injury and death if the electrographic epileptiform activity continues for a significant duration. These studies confirm the findings and implications of human and animal studies, and provide the first direct documentation in an in vitro model that the electrographic epileptiform activity associated with periodically recurring seizures does not cause neuronal injury or death.

Methods

Hippocampal Neuronal Cultures

We conducted studies on primary mixed hippocampal neuronal cultures prepared as described previously (see Further Reading), with slight modifications. In brief, hippocampal cells were obtained from 2-day postnatal Sprague-Dawley rats (Harlan, Frederick, MD) and plated at a density of 2×10^5 cells cm^{-2} onto a confluent glial bed on 35-mm grid cell culture dishes (Nunc, Naperville, IL) previously coated with poly-L-lysine ($0.05\,mg\,ml^{-1}$). Cultures were maintained at 37 °C in a 5% CO_2/95% air atmosphere and fed twice weekly with neuronal feed. These mixed cultures were used for experiments from 13 days in vitro following neuronal plating.

Hippocampal Neuronal Culture Model of SE

Continuous epileptiform activity, identical to electrographic discharges recorded from neurons from whole animal models of SE, were induced in the neuronal cultures by exposing the cultures to a solution containing no added $MgCl_2$ (low Mg^{2+}). Culture maintenance medium was replaced with physiological recording solution with or without $MgCl_2$. In low Mg^{2+} condition, all neurons manifest continuous high voltage epileptiform discharges at a frequency of 8–12 Hz; this activity meets the criteria for electrographic SE. Using this model of SE, we directly compared cultures that manifested continuous epileptiform discharges with cultures maintained under control conditions. SE was observed in the experimental cultures until restoration of physiological recording solution (containing 1 mmol $MgCl_2$), giving the investigators precise control of the duration of SE. Cultures were studied during constant perfusion of fresh low Mg^{2+} or control solutions over the culture plates, using a gravity feed perfusion system (Warner Instrument Corp., Hamden, CT) at the rate of $2\,ml\,min^{-1}$. Continuous perfusion did not disrupt the neurons and provided a complete exchange of the experimental media every 1 min.

Hippocampal Neuronal Culture Model of Epilepsy (SREDs)

The hippocampal neuronal culture model of spontaneous recurrent seizures (SREDs) manifests spontaneous recurrent synchronized epileptiform activity that is essentially identical to that seen in intracellular recordings from neurons in a seizure focus of an intact animal. In this in vitro model of epilepsy, SREDs were induced in the neuronal cultures by exposing them for 3 h to a solution containing no added $MgCl_2$ (low Mg^{2+}). At the end of this 3-h period, low Mg^{2+} treatment was terminated by gently washing the cultures with 3×1.5 ml of minimum essential medium, and the cultures were returned to the maintenance medium (incubated at 37 °C under 5% CO_2/95% atmosphere). SREDs developed in these neuronal cultures after ~12–24 h and lasted for the lifetime of the culture.

Whole-Cell Current-Clamp Recordings

Whole-cell current-clamp recordings were obtained from individual neurons in culture. Briefly, cell culture dishes were mounted on the stage of an inverted microscope (Nikon Diaphot, Tokyo, Japan). Patch electrodes with a resistance of 2–4 mΩ were pulled on a Brown-Flaming P-80C electrode puller (Sutter Instruments, Novato, CA), fire-polished, and filled with a solution containing (in millimoles): 140 K^+ gluconate, 1.1 EGTA, 1 $MgCl_2$, and 10 Na-HEPES; pH 7.2; osmolarity adjusted to 290 ± 10 mOsm with sucrose (pBRS). Whole-cell recordings were carried out using an Axopatch 200B amplifier (Axon Instruments, Foster City, CA) in current-clamp mode. Data were digitized via Digidata 1322A (Axon Instruments, Foster City, CA) and transferred to VHS tape, using a PCM device (Neurocorder, New York, NY), and then played back on a DC-500 Hz chart recorder (Astro-Med Dash II, Warwick, RI).

Neuronal Death Assay

Neuronal death at various time points after low-Mg^{2+} or control media exposures was assessed morphologically as well as determined using fluorescein diacetate (FDA)–propidium iodide (PI) microfluorometry. Neurons labeled with FDA or PI were quantified using Ultraview (Perkin Elmer Life Sciences), and percent neuronal death was calculated as the number of neurons labeled by PI divided by the sum of the number of neurons labeled by PI and FDA.

Data Analyses

One-way analysis of variance (ANOVA), followed by post hoc Tukey test or Kruskal–Wallis variations of ANOVA, were performed where appropriate to evaluate neuronal cell death. Data are reported as mean ± SEM. Paired *t*-tests were utilized to compare differences in neuronal death data between the fluorescent techniques and phase contrast microscopy. Each neuronal culture plate was treated as $n = 1$; a minimum of three determinations were obtained on each plate, and a mean cell death was obtained. Net neuronal death was calculated by comparing neuronal death in the experimental conditions with that observed in sham control groups in order to adjust for cell death because of handling artifacts. Data were analyzed using SigmaStat 2.0 and plotted using SigmaPlot 8.02 (SPSS Inc., Chicago, IL).

Results

The SE and SRED models have allowed us to carefully control the external environment of the neuronal networks and thus rigorously determine if SE or SREDs alone can induce neuronal death. This experimental approach provides a careful evaluation of the effects of different patterns of electrographic activity on the viability of a population of neurons, compared with neurons under identical conditions without seizure activity.

SE in Hippocampal Neuronal Cultures

Exposing hippocampal neurons in culture to low Mg^{2+} caused the induction of large, long-duration synaptic potentials with multiple action potentials, evolving into high-frequency burst discharges. Figure 1(b) illustrates a 30 min recording from a neuron after 3 h of exposure to low Mg^{2+}. The resultant spike discharges were sustained for the entire low Mg^{2+} exposure. Expansion of the time scale indicated that spike frequency occurred at 8–15 Hz. This high-frequency spiking continued throughout the 9-h period of low Mg^{2+} treatment. Following retoration of the normal Mg^{2+} level to the media, these spontaneous discharges immediately stopped. Recording from a control neuron showed occasional spontaneous action potentials (Figure 1(a)).

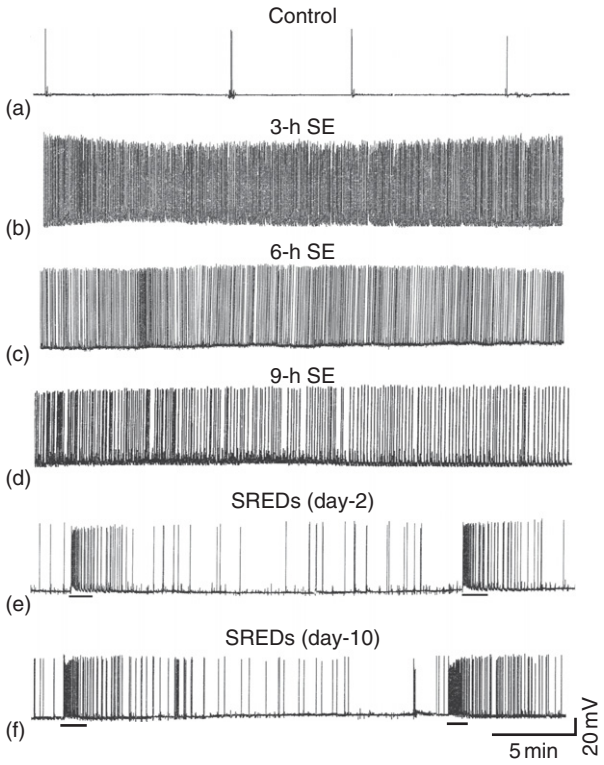

Figure 1 Continuous high-frequency epileptiform discharges and SREDs in cultured hippocampal neurons. (a) Representative current-clamp recording from a control neuron showing occasional spontaneous action potentials. (b–d) Representative current-clamp recordings during low Mg^{2+} treatment showing induction of tonic high-frequency epileptiform bursts (abbreviated SE in the figure) from neurons subjected to 3, 6, and 9 h of low Mg^{2+} exposure respectively. Tonic high-frequency spiking was observed at all the timepoints. Although a little slowing of spike activity is sometimes observed at later time points, the spike frequency was still >3 Hz and meets the criteria of SE. (e) A continuous 30-min recording from a representative neuron 2 days following an initial 3-h exposure to low Mg^{2+} solution. Two SREDs or spontaneous seizure episodes lasting ~60–80 s can be seen in this time frame (denoted by black bars beneath each episode in the trace). (f) A continuous 30-min recording from a representative neuron 10 days following an initial 3-h exposure to low Mg^{2+} solution. These SREDs at 10 days after initial injury with low Mg^{2+} are identical to the SREDs seen 2 days after low Mg^{2+}-induced high-frequency spiking (e) and demonstrate that the SREDs phenotype lasts for the life of the neurons in culture in this model. Reproduced from Deshpande LS, Lou JK, Mian A, Blair RE, Sombati S and DeLorenzo RJ (2007) In vitro status elipticus but not spontaneous recurrent seizures cause cell death in cultured hippocampal neurons. *Epilepsy Research* 75: 171–179, with permission from Elsevier.

SREDs in Hippocampal Neuronal Cultures

SREDs or seizure events were observed, using whole-cell current-clamp recording techniques, in neurons in cultures 2 days after a 3-h, low-Mg^{2+} treatment. Two SREDs lasting between 1 and 1.5 min are shown in Figure 1(e) and were observed in a continuous 30-min recording. These SREDs are characteristic of the epileptiform phenotype and were observed for the life of the neurons in

culture after the initial insult with low Mg^{2+}. Thus, SREDs were also observed even at 10 days after initial SE insult (Figure 1(f)). SREDs started and stopped spontaneously had durations between 1 and 3 min, and occurred at frequencies of up to 2–6 episodes every hour. We have shown previously that SREDs produced in cultured neurons manifest electrographic properties, neuronal population synchronicity, and anticonvulsant sensitivity analogous to comparable features observed in vivo. Age-matched control neurons revealed 'normal' baseline activity consisting of intermittent action potentials. SREDs were never observed in control neurons, and there were no significant differences in membrane potential and input resistance between control and epileptic neurons.

Increasing Durations of SE and It's Effect on Neuronal Cell Death

Experiments were initiated to investigate the effects of increasing durations of SE on hippocampal neuronal cell death (Figure 1). In order to standardize the method for cell death assessment, in the first set of experiments low Mg^{2+} exposure was continued for 0 or 12 h, at the end of which neuronal cultures were washed with solution containing normal Mg^{2+} concentrations (2 mmol) and cell death was measured using FDA–PI staining. Figure 2(a) shows representative fluorescent images from neurons before (0 h) and after (12 h) exposure to low Mg^{2+}-induced SE. Intravital staining with FDA–PI in cultures that

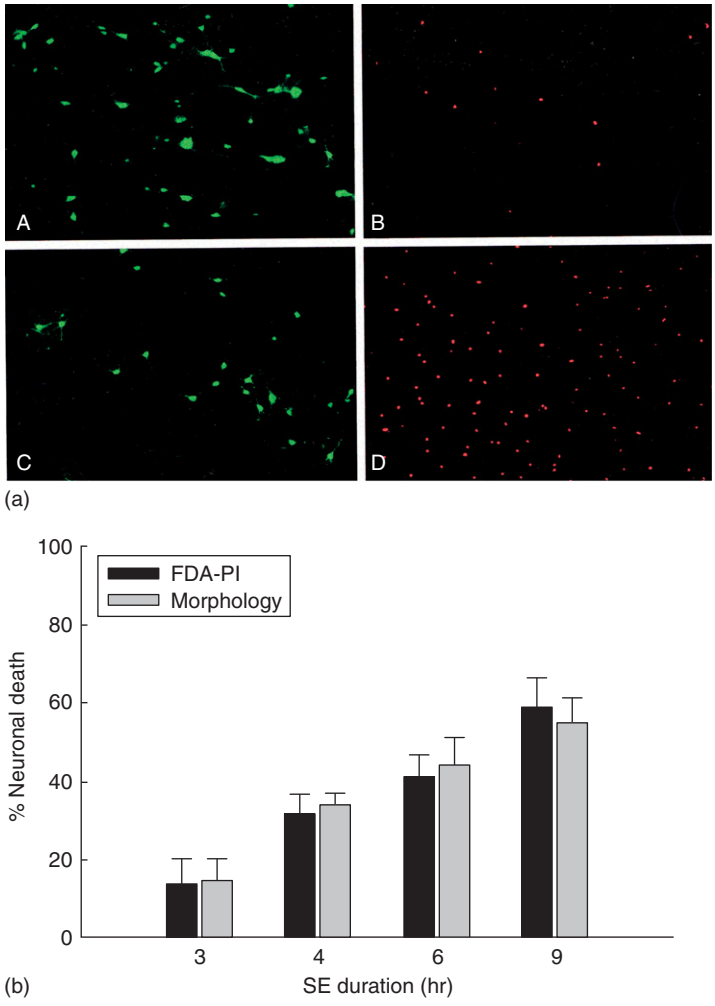

Figure 2 Neuronal cell death as a function of seizure duration. (a) Representative images of neurons at 0 and 12 h of low Mg^{2+}-induced high-frequency spiking. Frame A: FDA staining of viable neurons at 0 h ($n = 49$). Frame B: PI staining of nuclei of nonviable neurons in the same field as A at 0 h. Frame C: FDA staining of viable neurons at 12 h of low Mg^{2+} exposure ($n = 32$). Frame D: PI staining of nonviable neurons in the same field as C at 12 h of low Mg^{2+} exposure. (b) Comparison of neuronal cell death after 3, 4, 6, and 9 h exposure to low Mg^{2+} solution (abbreviated SE in the figure). Percentage neuronal cell death is dependent on the duration of exposure to low Mg^{2+} solution in culture. Gray bars represent cell death assessed by visual examination of neuronal morphology. Black bars indicate cell death examined using FDA–PI intravital staining as described in Materials and Methods. Differences between the two techniques were not statistically significant (paired *t*-test). FDA–PI staining was performed 24 h after exposure to low Mg^{2+} solution for these studies. Reproduced from Deshpande LS, Lou JK, Mian A, Blair RE, Sombati S and DeLorenzo RJ (2007) In vitro status elipticus but not spontaneous recurrent seizures cause cell death in cultured hippocampal neurons. *Epilepsy Research* 75: 171–179, with permission from Elsevier.

were not exposed to low Mg^{2+} conditions exhibited a preponderance of cells fluorescing green and few fluorescing red (Figure 2(a), panels A and B). Cultures that were exposed to low Mg^{2+} conditions displayed a decrease in FDA (green) staining brightness and corresponding increase in PI (red) fluorescence (Figure 2(a), panels C and D).

Neuronal cultures were then subjected to varying durations of exposure to low Mg^{2+} (3, 4, 6, and 9 h), after which time cell death was quantified using the FDA–PI staining. To rigorously control for the validity of the FDA–PI staining method, we also quantified neuronal viability by morphological assessment in the same fields of neurons. Paired *t*-tests were used to compare differences in neuronal death data between the fluorescent techniques and phase contrast microscopy. As shown in Figure 2(b), the results from both the FDA–PI fluorescent dye staining and the neuronal morphology techniques were consistent (not statistically divergent). Since the FDA–PI technique was accurate and required less time to perform, it was used for the subsequent neuronal viability measurements.

Increasing durations of exposure to low Mg^{2+} caused the percentage of neuronal death to increase correspondingly (Figure 3(a)). Cell death increased from ~10–15% after 3 h of SE to 55–60% after 9 h of exposure. After 12 h of SE, ~80% of the neurons appeared to have died. Control culture neuronal death was determined to be ~18%. This amount of cell death represented neuronal injury because of handling effects of the cultures; the control cultures were subjected to the same handling procedures (including removal of media, washing with pBRS, and maintenance in pBRS) and for the same durations that were used for the low Mg^{2+} time course cultures. The cell death values reported in Figure 3(a) were adjusted for control cell death in order to reflect net cell death occurring from low Mg^{2+} treatment alone, in the absence of these handling artifacts. Differences in neuronal death between control and low Mg^{2+} conditions were not significant at 0, 1, and 2 h time points, but were significant for low Mg^{2+} durations of 3–12 h ($p < 0.001$, Figure 3(a)). In order to quantify the correlation of cell death and duration of SE, a linear regression analysis was performed. As shown in Figure 3(b), the percent neuronal cell death correlated significantly with the duration of exposure to low Mg^{2+} ($r^2 = 0.972$, $p < 0.001$). These results demonstrate a significant relationship between duration of SE and the degree of neuronal death.

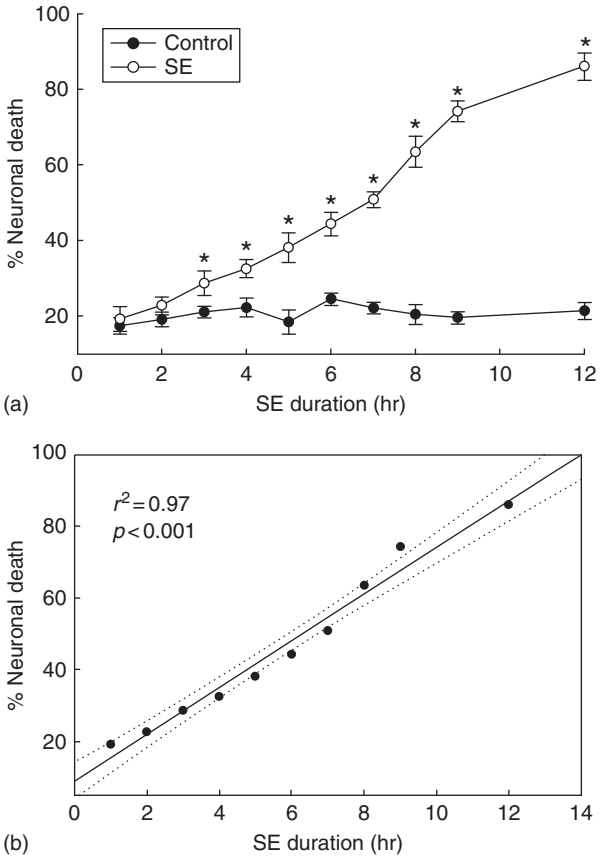

Figure 3 Correlation between duration of low Mg^{2+}-induced high-frequency spiking and neuronal cell death. (a) There was a time-dependent increase in neuronal cell death in cultures exposed to increasing durations of low Mg^{2+}-induced high-frequency epileptiform discharges (abbreviated SE in the figure) ranging from 0 to 12 h (n = 6–9 at each time point tested). Black circles (●) indicate sham controls. Open circles (○) represent percent cell death from low Mg^{2+}-exposed cultures. Statistically significant differences were observed for all the time points starting at 3 h following exposure to low Mg^{2+} solution (*$p < 0.001$, one-way ANOVA). (b) Linear regression analysis of neuronal cell death and duration of exposure to low Mg^{2+} solution gave an r^2 value of 0.97 ($p < 0.001$). Dotted lines represent 95% confidence interval limits. Reproduced from Deshpande LS, Lou JK, Mian A, Blair RE, Sombati S and DeLorenzo RJ (2007) In vitro status elipticus but not spontaneous recurrent seizures cause cell death in cultured hippocampal neurons. *Epilepsy Research* 75: 171–179, with permission from Elsevier.

Accumulation of Glutamate or Other Metabolites into the Media do not Cause Neuronal Cell Death

It is important to rule out the possible neurotoxic effects of the accumulation of glutamate or other metabolites in the media on the time-dependent low Mg^{2+}-induced neuronal cell death. Therefore, experiments were performed using a perfusion system to continuously perfuse fresh low Mg^{2+} medium over the culture plate. Glutamate was measured before and during low Mg^{2+}-induced SE. The glutamate concentration in the media alone was not detectable, and when media was replaced with pBRS, the glutamate concentration in neuronal culture was estimated to be $<1\ \mu mol\ l^{-1}$ (also essentially not detectable). The glutamate concentration was then measured at various time points in the presence of the low Mg^{2+} solution. The concentration of glutamate steadily rose to a maximal level of 5–6 $\mu mol\ l^{-1}$ at the longest durations of SE. Upon continuous perfusion with a low Mg^{2+} solution, the glutamate concentration throughout the duration of

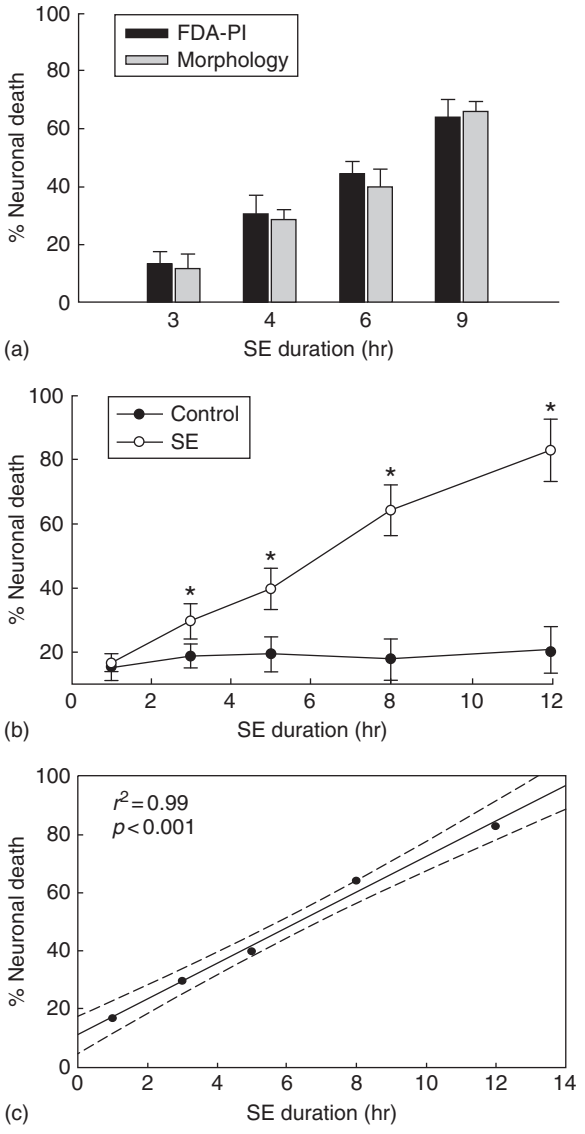

Figure 4 Accumulation of glutamate or other metabolites into the media do not cause cell death. Low Mg^{2+}-induced possible accumulation of glutamate or other metabolite in the culture media was prevented by continuously perfusing culture plate with fresh low Mg^{2+} solution throughout the duration of experiment using gravity feed perfusion system. (a) Both FDA–PI (black bars) and morphological assessment (gray bars) procedures still revealed a time-dependent increase in neuronal cell death as the result of continuous high-frequency epileptiform discharges (abbreviated SE in the figure), despite continuous perfusion of low Mg^{2+} perfusion media. (b) Time-dependent increase in neuronal cell death with increasing durations of exposure to low Mg^{2+} solution despite continuous perfusion of fresh low Mg^{2+} perfusion media. Low Mg^{2+} solution was perfused throughout the duration of experiment ranging from 0 to 12 h (n = 6–10). Black circles (•) indicate sham controls. Open circles (○) represent percent cell death from low Mg^{2+}-exposed cultures (abbreviated SE in the figure). Both control and low Mg^{2+}-exposed neurons were subjected to similar perfusion protocol. Significant differences were observed for all the time points starting at 3 h following exposure to low Mg^{2+} solution (*$p < 0.001$, one-way ANOVA). (c) Linear regression analysis of neuronal cell death and duration of high-frequency epileptiform discharges under constant low Mg^{2+} perfusion conditions (abbreviated SE in the figure) gave an r^2 value of 0.99 ($p < 0.001$). Dotted lines represent 95% confidence interval limits. Reproduced from Deshpande LS, Lou JK, Mian A, Blair RE, Sombati S and DeLorenzo RJ (2007) In vitro status elipticus but not spontaneous recurrent seizures cause cell death in cultured hippocampal neurons. *Epilepsy Research* 75: 171–179, with permission from Elsevier.

experiment was maintained at not detectable levels (i.e., <1 μmol l^{-1}). Although our perfusion system cannot effectively remove synaptic glutamate, it prevented the build up of glutamate (or other materials) in the neuronal culture media and thus maintained a constant environment for the neurons during SE.

Figure 4 demonstrates that despite the continuous perfusion of fresh low Mg^{2+} solution, neuronal death increased with increasing durations of SE (in comparison with control neurons). Similar to the nonperfusion experiments (Figure 3), both FDA–PI staining and morphological methods demonstrated an increase in neuronal death as a function of time (Figure 4(a) and 4(b)). We did observe a small decrease in cell death with increasing durations of SE when fresh low Mg^{2+} solution was continuously perfused throughout the duration of the experiment (compared with the nonperfusion conditions). This decrease in cell death was highest at the longer time points; however, this reduction in cell death (<3–5%) did not reach statistical significance. As previously shown, there was a significant correlation between percent neuronal death and duration of SE in the continuous perfusion experiments ($r^2 = 0.99$, $p < 0.001$, Figure 4(c)). These experiments indicate that SE alone, and not the build up of glutamate or other seizure-released metabolites, was responsible for neuronal death during low Mg^{2+}-induced SE.

SREDs do not Cause Cell Death

These studies were conducted to evaluate the effects of SREDs that occur several times per hour, for the life of the neurons in culture, on neuronal survival. Neuronal cultures were first shown to generate SREDs (using patch clamp electrophysiology); SREDs were observed in the cultures at all the time points tested (Figure 1(e) and 1(f)). To allow the cells to recover from the initial 3-h low Mg^{2+} exposure, we conducted experiments starting 2 days after the initial insult. Figure 5 presents the effects of SREDs on neuronal death. Using both the FDA–PI staining and morphological assessment methods, we observed that SREDs did not cause a significant increase in cell death in comparison with age-matched control cultures (Figure 5(b)). Moreover, there was no significant correlation between percent neuronal death and time of exposure to SREDs ($r^2 = 0.26$, $p = 0.3$, Figure 5(c)). Cell death in age-matched control cultures was 4–6%; this percent cell death was lower than that observed for the

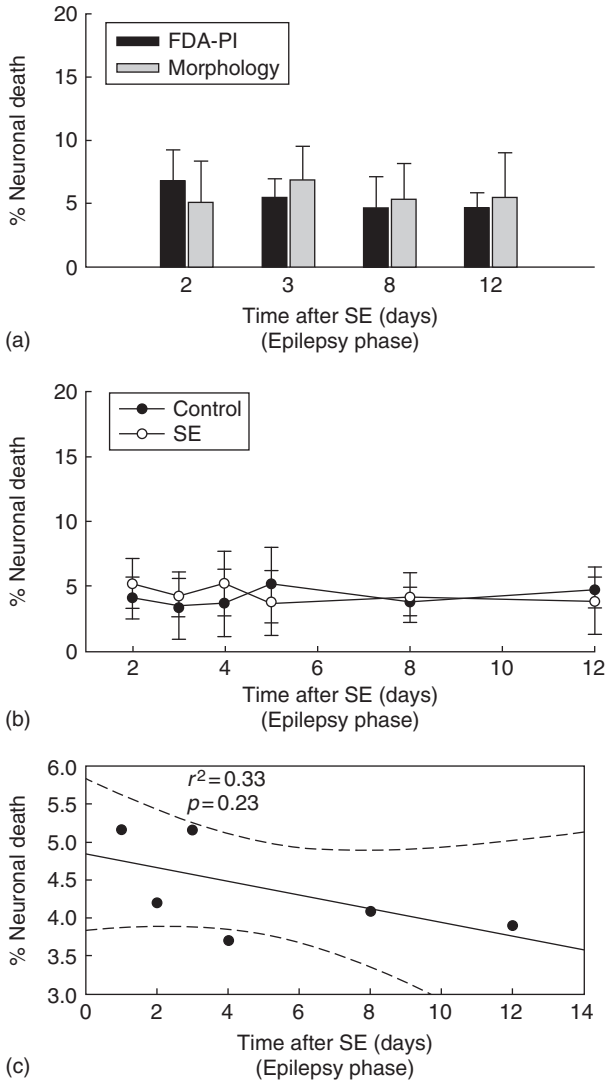

Figure 5 Spontaneous recurrent seizures do not cause neuronal cell death. (a) FDA–PI staining (black bars) and morphological assessment (gray bars) procedures revealed no increase in percent cell death with longer exposure to SREDs. (b) The amount of cell death in SREDs cultures was similar to age-matched control cultures and did not increase with time. Thus there was no increase in neuronal cell death in SREDs phase with time. The cell death in control cultures was around 4–6% and was lower than the control conditions for the pBRS-washed cultures due to the lack of washing and handling of the neurons and the direct assessment of the cell death in culture maintained in media without manipulation. (c) Linear regression analysis revealed no significant correlation ($r^2 = 0.26$, $p = 0.3$) between neuronal cell death and time of exposure to SREDs in cultures. Reproduced from Deshpande LS, Lou JK, Mian A, Blair RE, Sombati S and DeLorenzo RJ (2007) In vitro status elipticus but not spontaneous recurrent seizures cause cell death in cultured hippocampal neurons. *Epilepsy Research* 75: 171–179, with permission from Elsevier.

control conditions in the pBRS-washed cultures, presumably due to the lack of washing and handling of the neurons (i.e., we measured cell death in the control culture that were maintained without manipulation).

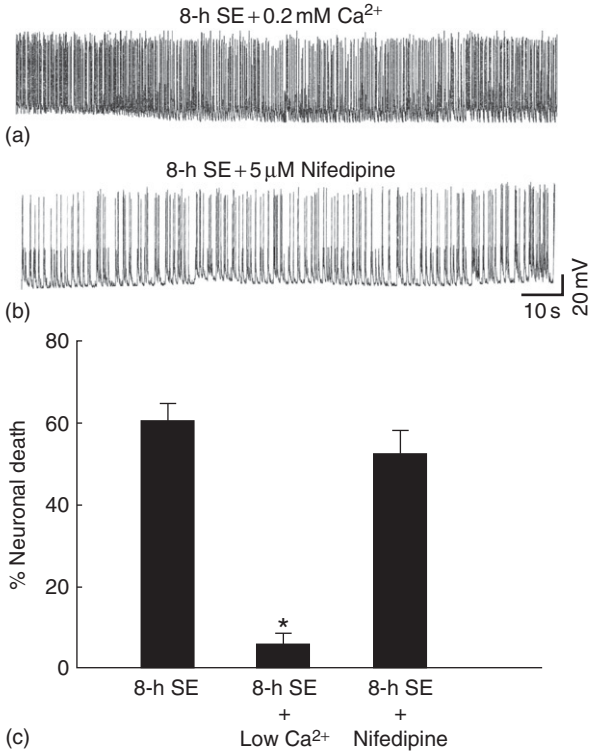

Figure 6 In vitro SE-induced neuronal death is dependent upon extracellular calcium. (a) Representative current-clamp recording from a neuron subjected to low Mg^{2+}-induced SE in the presence of low Ca^{2+} (0.2 mmol). Lowering extracellular Ca^{2+} had no effect on low Mg^{2+} induced high-frequency spiking. (b) Representative recording from a neuron treated with nifedipine (10 μmol) during low Mg^{2+}-induced SE. Similar to low Ca^{2+} condition, nifedipine treatment did not affect low Mg^{2+}-induced high-frequency spiking. (c) Neuronal death assessment revealed that lowering extracellular Ca^{2+} significantly attenuated net neuronal cell death compared to 8-h SE alone group (*$p < 0.001$, one-way ANOVA). In contrast, percent neuronal death was not significantly different between 8-h SE and nifedipine-treated cultures. Modified from Deshpande LS, Lou JK, Mian A *et al*. (2008) Time course and mechanism of hippocampal neuronal death in an in vitro model of status elipticus: Role of NMDA receptor activation and NMDA dependent calcium entry. *European Journal of Pharmacology* 583: 73–83.

Role of Ca^{2+} in SE-Induced Neuronal Death

Reduced extracellular Ca^{2+} (0.2 mmol) during low Mg^{2+} treatment significantly attenuated net neuronal death when compared with 8-h SE controls (**Figure 6(c)**). Lowering extracellular Ca^{2+} had no effects on the expression of low Mg^{2+}-induced SE (**Figure 6(a)**). SE durations of 8 h with 2 mmol Ca^{2+} ($n = 9$) resulted in 60.2% ± 5.03% neuronal death; in contrast, in cultures treated with low Ca^{2+} and low Mg^{2+} solution for 8 h ($n = 6$), net neuronal death was determined to be 4.05% ± 3.03% (when controlled for sham treatment). These experiments indicate that SE-induced neuronal death is dependent upon influx of extracellular Ca^{2+}.

To investigate the route of this Ca^{2+} entry, we used concentrations of well-characterized voltage gated Ca^{2+} channels inhibitors shown to be effective under our conditions. Treatment with nifedipine (5 μmol, $n = 6$) appeared to slow down low Mg^{2+}-induced high-frequency spiking (**Figure 6(b)**), but it did not significantly reduce neuronal death compared with untreated 8-h SE cultures (**Figure 6(c)**). Similarly, the T-type voltage-gated Ca^{2+} channel blocker ethosuximide (1 mmol) did not significantly prevent cell death due to SE in this model (data not shown). It was not possible to evaluate the effects of some of the other voltage-gated Ca^{2+} channel inhibitors, such as ω-conotoxin, because electrophysiological studies showed that these agents effectively blocked synaptic transmission and also prevented low Mg^{2+}-induced SE (data not shown). However, the lack of effects of nifedipine and ethosuximide on reducing cell death from SE supports the interpretation that Ca^{2+} entry through voltage-gated Ca^{2+} channels is not playing a significant role in causing cell death.

Role of Glutamate Receptor Subtypes in SE-Induced Neuronal Death

Treatment with the AMPA/kainate glutamate receptor antagonist CNQX (10 μmol, $n = 6$) had no significant effects on percentage of neuronal death compared with 8-h SE cultures (**Figure 7(d)**). Exposure to the metabotropic glutamate receptor antagonist mCPG (250 μmol, $n = 6$) did not significantly reduce neuronal death after 8-h of SE (**Figure 7(d)**). Treatment with the AMPA/kainate glutamate receptor antagonist NBQX (10 μmol, $n = 6$) did result in a small decrease in neuronal death from of 8-h SE ($p < 0.05$). In the current-clamp studies, we found that NBQX considerably slow down low Mg^{2+}-induced high-frequency epileptiform spiking (**Figure 7(a)–7(c)**). Thus, its reduction of the severity of SE may have contributed to its minor, but significant effect in reducing neuronal death.

Treatment with the NMDA receptor antagonist MK-801 (10 μmol, $n = 6$) produced a marked reduction in net neuronal death to 9.5% ± 3.36%, a figure that represented approximately an 80% decrease in neuronal death compared with 8-h SE cultures not treated with MK-801 (**Figure 8(c)**). Treatment with D-APV (25 μmol, $n = 6$) also reduced net neuronal death, to 13.2% ± 2.02%. Treatments with APV or MK-801 had no effects on the expression of low Mg^{2+}-induced SE (**Figure 8(a) and 8(b)**). These results demonstrate that during in vitro SE, extracellular Ca^{2+} that enters neurons through the NMDA receptor pathway is coupled to the molecular cascades that initiate neuronal death.

Discussion and Future Directions

This study provides a direct demonstration, in a controlled environment, that continuous electrographic epileptiform activity, but not spontaneous recurrent epileptiform discharges, caused cell death in hippocampal neurons in culture. We observed a strong correlation between duration of SE and subsequent neuronal death. However, there was no significant correlation between the time of exposure to SREDs and neuronal death. In fact, aside from the cell death associated with the initial exposure to low Mg^{2+}, there was no increase in neuronal death in cultures manifesting SREDs compared to age-matched control cultures for the life of the neurons in culture. SE-induced neuronal death was also found to be dependent upon extracellular Ca^{2+}, since reducing the driving force for Ca^{2+} entry, by lowering extracellular Ca^{2+}, significantly attenuated neuronal death. SE-mediated neuronal death was reduced by NMDA receptor channel blockade, while

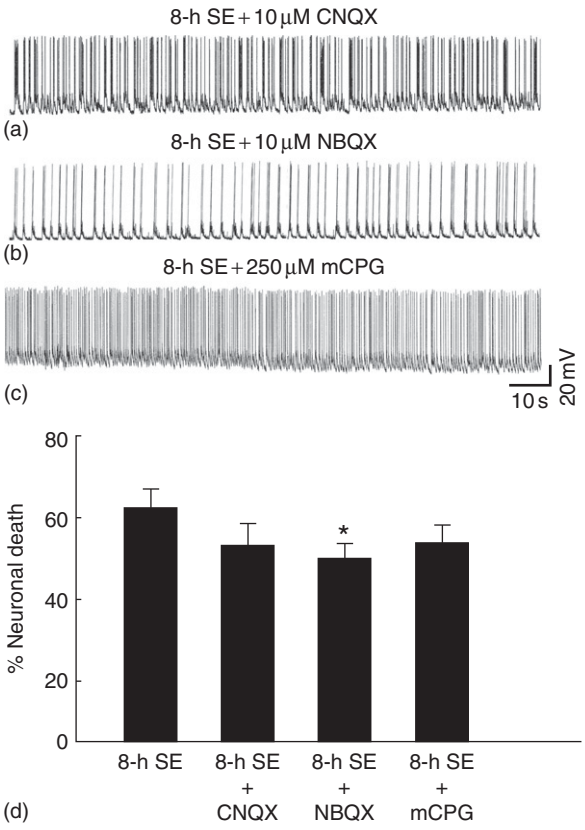

Figure 7 Role of glutamate receptor subtypes in SE-induced neuronal death. (a–c) Representative current-clamp recordings from neurons subjected to treatment with various glutamate receptor antagonists during low Mg^{2+}-induced SE-like activity. Treatment with AMPA/KA receptor antagonist CNQX (10 μmol) or NBQX (10 μmol) did slow down low Mg^{2+}-induced high-frequency spiking. But the spike frequency was still >3 Hz that meets the criteria of SE. Similarly, the metabotropic glutamate receptor antagonist mCPG (250 μmol) also had no effects on SE-like activity. (d) Neuronal death assessment revealed that there were no statistically significant differences between CNQX and mCPG-treated cultures and 8-h SE alone cultures. However, a small but significant reduction in neuronal death was observed upon NBQX treatment (*$p < 0.01$). Modified from Deshpande LS, Lou JK, Mian A *et al*. (2008) Time course and mechanism of hippocampal neuronal death in an in vitro model of status elipticus: Role of NMDA receptor activation and NMDA dependent calcium entry. *European Journal of Pharmacology* 583: 73–83.

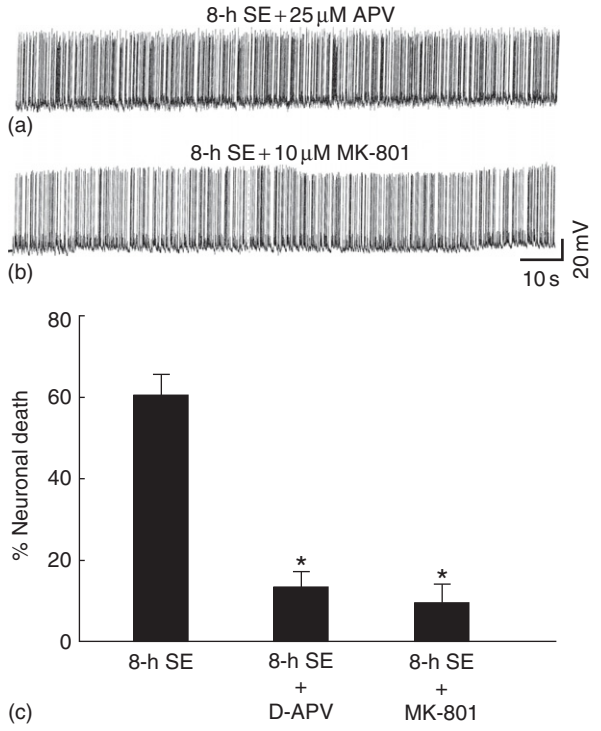

Figure 8 SE-induced net neuronal death is NMDA receptor dependent. (a, b) Representative current-clamp recordings from neurons subjected to treatment with NMDA receptor antagonists during low Mg^{2+}-induced SE. Treatment with APV (25 μmol) or MK-801 (10 μmol) had no effects on low Mg^{2+}-induced high-frequency spiking. (c) In contrast, there was a significant reduction in net neuronal death when these NMDA receptor antagonists were present throughout the duration of SE as compared with 8-h SE controls (*$p < 0.001$). (2008) Time course and mechanism of hippocampal neuronal death in an in vitro model of status elipticus: Role of NMDA receptor activation and NMDA dependent calcium entry. *European Journal of Pharmacology* 583: 73–83.

neuroprotection afforded by blockade of non-NMDA glutamate receptor subtypes or voltage-gated Ca^{2+} channels appeared to be minor.

The results are generally consistent with animal and human data that demonstrate that neuronal cell death is associated primarily with SE and not with recurrent seizures. For example, in vivo studies using rat models of SE-induced temporal lobe epilepsy suggest that cell death is only associated with the initial injury from SE, but not with the subsequent spontaneous recurrent seizures. However, there are data showing that even a few evoked seizures in kindled rats produce TUNEL-positive responses in hilar neurons, and that hippocampal neuronal loss increases with increasing numbers of kindled seizures. Clinical studies have demonstrated conflicting results, with reports of increased serum and CSF levels of neuron-specific enolase, a marker of neuronal injury, after spontaneous seizures. However, a recent population-based, longitudinal quantitative MRI study of 179 patients with epilepsy showed that progressive regional or global cerebral damage was not a consequence of epileptic seizures. Furthermore, a separate quantitative postmortem study of the human hippocampus (from patients with chronic epilepsy) showed that seizures do not inevitably cause neuronal loss. Our studies support these findings and indicate that epileptic seizures do not cause neuronal damage by themselves.

Neuronal injury secondary to SE is the consequence of excessive neuronal excitability and synaptic activity, with high-frequency epileptiform discharges resulting in depolarizing shifts of membrane potential, free-radical production, neuronal metabolic overload, and elevations in extracellular glutamate. Although several microdialysis studies in humans and animals have shown significant elevations in extracellular glutamate during SE, others studies have failed to show such increases in extracellular glutamate during SE. It is well established that prolonged exposure to glutamate can kill neurons, and it has been suggested that increased glutamate in the extracellular space may account for neuronal death associated with SE. Although our experiments with continuous perfusion throughout the duration of high-frequency spiking cannot lower the synaptically trapped glutamate, our measurements do show that this perfusion manipulation can lower and prevent buildup of glutamate in the extracellular media. Under these conditions, the possible neurotoxic effects of extracellular accumulation of glutamate (and other substances) are eliminated. The cell death that occurs under these perfusion conditions is, therefore, a result of excessive synaptic activity. These findings are consistent with the observation that prolonged SE caused by the electrical stimulation of the perforant pathway (presumably involving excessive synaptic activity) can damage postsynaptic neurons. In addition, it has also been reported that increasing durations of kainic acid-induced SE – to the point of neuronal injury – cause cell death in the absence of a measurable increase in extracellular glutamate concentration. Taken together, these results further stress the importance of limiting seizure duration during SE to prevent brain injury.

Our data support the previous research that showed neuronal death after SE to be excitotoxic in nature. Thus, glutamate-mediated activation of NMDA receptors results in excessive influx of Ca^{2+}, which triggers various NMDA receptor-coupled neurotoxic signaling cascades, some of which (e.g., the activation of proteases, neuronal nitric oxide synthase, ceramides and poly(ADP-ribose) polymerase-1) cause cell death. The induction of these pathways may contribute to a positive feed-forward cycle that results in increased levels of intracellular Ca^{2+}, with subsequent energy failure and neuronal death. The neuroprotection we observed upon NMDA receptor antagonism or lowering extracellular Ca^{2+} could possibly result from inhibition of these neurotoxic cascades. These results are consistent with earlier in vivo studies from our laboratory, and those reported by others, that while NMDA receptor inhibition does not stop on-going SE

activity, the blockade of NMDA receptor signaling pathways is sufficient to attenuate SE-induced neuronal death. Interestingly, prolonged activation of the NMDA receptor transduction pathways during SE is also thought to underlie the permanent plasticity changes in neurons responsible for the expression of epilepsy.

Determining the effects of recurrent seizures in humans or animals is complicated by several factors, such as age, type of convulsant stimuli or seizure type, treatment with antiepileptic drugs, and numerous other clinical variables. The results from this study demonstrate that the hippocampal neuronal culture system provides a powerful in vitro model that allows for careful evaluation of the effects of seizures on neuronal viability – in the absence of various confounding factors. Understanding the molecular mechanisms mediating neuronal death due to continuous epileptiform may provide new insights into the development of novel therapeutic agents to prevent neuronal injury during SE. Future studies should be directed at not only controlling seizure activity, but in preventing the damaging manifestations of prolonged electrographic seizure activity. The results of our study provide a pharmacological framework within which to develop novel therapeutic interventions to prevent neuronal injury during seizure activity. Development of agents that can protect the brain during prolonged seizure activity offer new hope for the prevention of brain injury from SE.

Excitotoxicity and Neurodegenerative Disease

Introduction

Glutamate is the predominant excitatory neurotransmitter in the central nervous system (CNS). Almost all excitatory neurons in the CNS are glutamatergic, and it is estimated that over 70% of all cortical nerve-endings release this excitatory amino acid (EAA). Glutamate is one of the most abundant chemicals in the mature human brain at an average intracellular concentration of 11 mM. Excessive levels of glutamate can be toxic to neurons,

which in culture can be killed by bathing in as little as 10–40 μM of glutamate. Excitotoxicity is the prolonged or overstimulation of glutamate receptors (GluRs), subsequently allowing the excessive influx of calcium (Ca^{2+}). Cytoplasmic Ca^{2+} is then responsible for the activation of a myriad of Ca^{2+}-dependent enzymes – including protein kinase C, phospholipase A2 and C, Ca^{2+}/calmodulin-dependent protein kinase II, nitric oxide synthase, and other proteases and endonucleases – all of which have the potential to destroy neurons. During excitatory synaptic transmission, the levels of glutamate can rise 1000 fold in the synaptic cleft. Glutamate is cleared from the synapse mainly by astrocytic EAA transporters (EAATs). The EAATs prevent excessive amounts of glutamate remaining in the synapse to overstimulate GluRs. A balance of excitatory and inhibitory neurotransmission is also necessary to protect neurons from potentially excitotoxic insults. Inhibitory neurotransmitter receptors mainly act to hyperpolarize the membrane, preventing propagation of the excitatory postsynaptic current. γ-aminobutyric acid (GABA) is the major inhibitory neurotransmitter of mammalian CNS.

Glutamatergic neurotransmission is complex and multifaceted, and perturbations in any aspect of glutamate or GABA release, signaling, clearance, or cycling may lead to excitotoxic neurodegeneration. Both the GABAergic and glutamatergic neurotransmitter systems are implicated in epileptogenesis, as well as other neurodegenerative diseases where excitotoxicity is purported to play a role in the pathogenesis of neuronal death. Examples of such diseases are Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS), Huntington's disease (HD), Parkinson's disease (PD), stroke, and hypoxia/ischemia.

AD is the commonest neurodegenerative disease. AD patients have an increased risk of epilepsy, particularly in younger onset cases. It is estimated that 10–22% of AD patients suffer from seizures. Although the pathogenesis of the two diseases may be different, the pattern of disease pathology of AD and temporal lobe epilepsy (TLE) affects similar regions of the brain, early stages manifesting in the hippocampus. The pattern of neuronal damage is also very similar, affecting pyramidal neurons and causing axon-sparing lesions and dendritic pruning. The ingestion of domoic acid from blue mussels can induce seizures and produces region-specific neuronal damage similar to AD and epilepsy. Domoic acid is able to act as a neurotoxin probably because of its structural similarity with glutamate. The common features of AD and TLE pathologies with those produced by domoic acid could indicate a link in the pathogenesis of two separate neurodegenerative diseases through excitotoxicity. It has also been postulated that the link between the two diseases (i.e., the high frequency of seizures among AD patients) may arise because of the neuron loss in AD. Loss of pyramidal neurons in the hippocampus and neocortex may lead to the development of a seizure focus. The loss of normal balance between excitation and inhibition plays a role in the pathogenesis of both diseases. Published work reporting evidence of this imbalance, and future experimental strategies to delineate a synaptic role, will be discussed.

Background

The assessment of glutamate in autopsy tissue is problematic as it is both a neurotransmitter and a metabolic intermediate. Glutamate is a major product of the Krebs cycle in brain, and immunohistochemistry (IHC) does not distinguish transmitter and metabolic glutamate. Delineation of glutamatergic neurons by IHC can only be performed on perfusion-fixed tissue, and so a biochemical correlate of pyramidal neuron dysfunction in postmortem brain is difficult to establish. Reports of reduced levels of glutamate and aspartate in AD cerebral cortex and hippocampus are confounded by the rapid rise in glutamate levels that occurs after death. The ability to distinguish one pool of glutamate from the other in experimental systems currently remains elusive. For this reason, studies have mainly focused on molecules directly affected by glutamate, such as receptors and transporters. Excitotoxicity can occur through excessive glutamate release, implicating a synaptic dysfunction as is postulated to occur in epilepsy, through inefficient glutamate clearance as is evident from ALS, or through changes in GluR composition allowing hyperexcitation of neurons leading ultimately to excitotoxic cell death. In some neurodegenerative disorders with a more complex etiology, such as AD, it is possible that the pathogenesis involves a combination, if not all, aspects of excitotoxic glutamate build-up. Common to all neurodegenerative diseases, where excitotoxicity is the putative cause of neuronal death, is regional-specific neuronal damage as part of the pathology. It is possible that the intrinsic regional balance between excitatory and inhibitory systems may be the determinant.

Transporters

There are five major types of glutamate transporter, or EAAT. Transporters localized to astrocytes include EAAT1 and EAAT2. The latter is responsible for the majority of glutamate uptake in the CNS. EAAT3 is localized to somata and dendrites of neurons but in extrasynaptic sites. EAAT4 is found in cerebellar Purkinje cells and EAAT5 is specific to retina.

The EAATs are responsible for the fast efficient clearance of glutamate from the synaptic cleft, where glutamate is converted to glutamine via glutamine synthetase. Glutamine is then transported back into neurons, where it is reconverted into glutamate and packaged into synaptic

vesicles by the vesicular glutamate transporters (VGLUTs), of which three have been isolated and characterized.

Glutamate transporters and glutamine synthetase have been implicated in the pathogenesis of epilepsy and other neurodegenerative diseases, particularly AD and ALS.

Glutamate uptake in AD-affected cortex is reduced than in controls. However, attempts to correlate this reduction in transport efficacy with distribution and abundance of the different EAATs by IHC or immunoblotting techniques has led to conflicting reports. EAATs have been more directly implicated in other neurodegenerative diseases, particularly epilepsy and ALS. Mice lacking EAAT2 displayed spontaneous epileptic seizures, and other mice treated with antisense probes to EAAT3 or EAAT1 showed increased epileptic activity. Reduced glutamate transport and EAAT2 expression has been observed in ALS motor cortex. Some studies have found higher levels of EAAT2 splice variants in ALS that may contribute to the reduction in EAAT2 expression. Overrepresentation of EAAT2 splice variants present in hippocampus and temporal cortex has also been found in TLE patients. Aberrant EAAT1 expression has been found to occur in neurons that form neurofibrillary tangles as evidenced by tau expression in AD brain. These studies implicate abnormal glutamate transporter expression or function in the pathogenesis of neurodegeneration.

Receptors

GluRs play a more direct role in excitotoxic neurodegeneration typical of epilepsy and other neurodegenerative disorders. Many of the current pharmaceuticals available to treat epilepsy act on either the glutamate or GABA receptors. GABA is the major inhibitory neurotransmitter in the mammalian CNS. There are two major classes of GABA receptors. $GABA_A$ receptors are ligand-gated ion channels made up of many subunits that are responsible for rapid inhibitory effects by allowing the influx of Cl^-. $GABA_B$ receptors are G protein-coupled receptors that hyperpolarize the neuron by increasing K^+ conductance. $GABA_B$ receptors are also able to decrease Ca^{2+} entry and have a slow inhibitory effect. Both types of GABA receptor have the ability to counterbalance the effects of GluR activation. Disruptions to GABAergic transmission favoring excitation may lead to seizures and excitotoxic neuronal death.

There are two major classes of GluRs: metabotropic and ionotropic. Metabotropic GluRs (mGluRs) are G protein-coupled receptors divided into three groups – group I, II, and III. Activation of mGluRs raises intracellular Ca^{2+} stores from the endoplasmic reticulum. mGluRs can contribute to excitotoxicity by raising Ca^{2+} concentration or by prolonging depolarization of the neuron, thereby activating *N*-methyl-D-aspartate (NMDA) receptors.

Ionotropic glutamate receptors (iGluRs) are the largest group, and are generally named after their specific ligands: kainate, α-amino-3-hydroxy-5-methyl-isoxazole-4-propionate (AMPA), and NMDA. Of these receptors, the NMDA receptor plays the most direct role in excitotoxicity, due to the receptor's Ca^{2+} channel properties. Overactivation of any of these receptors leads to epileptic seizures, and also has the ability to kill neurons.

GluRs have been the most popular target for pharmaceutical intervention in neurodegenerative disorders. GluR agonists show proconvulsant properties, whereas antagonists have been found to have anticonvulsant properties. Similarly, with the glutamate transporters, attempts to correlate the distribution and abundance of GluRs with disease states have been met with mixed results. Anticonvulsant drugs that have been successful in treating and attenuating seizure activity commonly ameliorate aspects of hyperexcitability. GluR antagonists are important in this category, but agonists of GABA receptors also have anticonvulsant properties. Conversely, GABA receptor antagonists induce seizure activity. Severe alcohol withdrawal may produce seizures, supposedly due to its action on the $GABA_A$ receptor.

Previous studies measuring the levels of GluRs in human autopsy brain have shown varying results: some report an increase, some a decrease, and others no change. Splice variants have also been described for the NR1 subunit of the NMDA receptor. NR1 subunit mRNA transcript variants containing an N-terminal cassette were found to be more abundant in affected regions of the AD brain than areas of the brain relatively unaffected by AD (and controls). This result was supported by immunoblotting results detecting the NR1 N-terminal cassette variant protein. Areas susceptible to AD damage also showed lower levels of NR2A and NR2B subunits compared with the homotropic area in controls. The mRNA transcripts of the NR2A and NR2B subunits were concordantly lower in affected areas of the AD brain than in controls. This finding would seem to suggest that the composition of the receptor, not its abundance, is important for susceptibility to excitotoxic insults.

Synaptic Dysfunction

There is evidence of synaptic dysfunction in epilepsy and AD. Riluzole, a drug used to treat ALS, has been suggested as a candidate antiepileptic drug. One of the pharmacological effects of riluzole is the inhibition of G protein-dependent synaptic glutamate release. In AD, synaptic loss is the best correlate of cognitive decline that characterizes the clinical symptoms of the disease. Neurodegenerative disorders where excitotoxicity may underlie the neuronal loss all share synaptic pathology. A study to delineate and characterize the regionally specific pathology of these disorders by categorizing the aberrant function of excitatory or inhibitory synapses, or whether these changes are specific to pre- or postsynaptic

terminals, could focus efforts of pharmaceutical intervention of glutamate-mediated neuronal death.

Methods

In our laboratory, we aim to study the synaptic pathology of excitotoxicity in neurodegenerative diseases in human autopsy brain tissue. Frozen brain tissue obtained at autopsy can be stored and assayed for a variety of markers, together with IHC from formalin-fixed tissue. The extent of nerve-terminal loss may be assessed in situ by measuring markers specific to the synapse. We have initiated a study that uses sensitive and specific assays for pre- and postsynaptic markers for (a) nerve-terminals in general and (b) excitatory terminals specifically. If the study can be extended to selective markers of GABA terminals, a 'map' of excitatory and inhibitory terminals could be constructed. Most studies on synaptic proteins in neurodegenerative diseases have focused on presynaptic markers for densities of terminals in the brain areas studied. Since neurons may receive inputs from different brain areas, quantitating presynaptic markers could be misconstrued because the afferents may differ in their origins. Rarely have studies measured the abundance of postsynaptic markers in neurodegenerative diseases, which would provide a better measure of local neuronal loss. If both presynaptic and postsynaptic markers are assessed, the numbers of synaptic contacts might be quantitated, at least in principle. Also by categorizing markers specific to excitatory or inhibitory synapses, and identifying these markers with their subsynaptic localization, a complete picture of excitotoxic synaptic dysfunction in neurodegenerative disease could be obtained.

Recent Results

General Presynaptic Markers

Synaptophysin is an integral membrane protein localized to synaptic vesicles. It is thought to comprise part of the pore complex, which forms when the vesicle fuses with the presynaptic membrane. It is a specific and sensitive marker for synaptic terminals. Synaptophysin concentrations are reportedly reduced in certain brain areas of AD. However, our IHC and ELISA data suggest that the reduction is not great, certainly not to an extent consonant with local neuronal loss. This emphasizes the extrinsic origin of many terminals.

Dynamin I is enriched in the presynaptic terminal and accounts for over 0.4% of total brain protein. Ca^{2+} influx inactivates dynamin I during neurotransmitter release until the vesicles are recycled. We investigated the levels of dynamin I in AD brain concurrently with synaptophysin and found no difference compared with controls.

Glutamatergic Presynaptic Markers

A key to excitotoxicity will be the ability to delineate excitatory terminals and to quantitate them relative to the total. Three distinct isoforms of the VGLUT (VGLUT1–3) have been cloned, characterized, and had specific antibodies raised against them. VGLUT1 and 2 divide distinct subpopulations of excitatory synapses. The third isoform, VGLUT3, overlaps in distribution with the other two isoforms in some brain areas. While not as abundant as VGLUT1 and 2, VGLUT3 colocalizes with markers of cholinergic and serotonergic synapses in certain areas. VGLUT1 and 2 are diminished in AD frontal cortex, which correlates with cognitive decline. Animal models of epilepsy have shown an increase in VGLUT1 in the hippocampus. In a study of hypoxic ischemia in rats, VGLUT1 immunoreactivity was significantly elevated in both hippocampi following insult; the levels of VGLUT2 were unaltered. It is reported that 14% of patients with hypoxic brain injury develop epilepsy. The elevation in VGLUT1 could signify the onset of increased transynaptic glutamate release. This difference between the two diseases shows a difference in pathogenesis. The increase in VGLUT in epilepsy could signify an overload of glutamate or an increase in glutamatergic terminals. The opposite effect in AD, albeit in a different area, could signify a loss of glutamatergic terminals, implying a different mechanism for excitotoxicity.

Two protein isoforms distinguish inhibitory presynaptic terminals from excitatory presynaptic terminals. Complexin I regulates inhibitory neurotransmitter release and complexin II regulates excitatory neurotransmitter release. They are cytosolic, acidic membrane proteins associated with synaptic vesicle docking to the presynaptic membrane that decreases neurotransmitter release. Complexin I and complexin II have 84% amino acid sequence identity in mammalian brain tissue. Complexin I mRNA is preferentially expressed in axosomatic synapses, which are mainly inhibitory, while complexin II mRNA is mainly expressed in axodendritic and axospinal synapses, which are typically excitatory. We found that both complexins were significantly decreased in hippocampus, inferior temporal cortex, and occipital cortex in AD cases compared with those in controls. The loss of complexins in AD was in contrast to the unchanged levels of dynamin I and synaptophysin, markers of presynaptic terminals. The ratio of complexin II to complexin I was unchanged between AD cases and controls. This result indicates a loss of regulation of neurotransmitter release in AD in preserved presynaptic terminals.

Loss of regulation in vesicular glutamate release might also increase synaptic glutamate concentrations. The ratio of complexin II to complexin I in hippocampus favored complexin II highly; inferior temporal cortex also favored compexin II (but to a lesser extent than

hippocampus), but occipital cortex favored complexin I over complexin II. This pattern may signify a regional susceptibility to excitotoxic insults in neurodegenerative diseases, such as AD, which rarely affects occipital cortex, which is commonly one of the most spared brain regions. Similarly, hippocampus is the earliest and one of the most affected regions in AD. Inferior temporal cortex is also commonly affected in AD. Both these regions showed significantly lower levels of complexin I and II compared with the homotropic area in controls. This result shows the potential role of vesicular glutamate exocytosis regulation in excitotoxicity and neurodegenerative disease and is worth investigation in epilepsy.

N-cadherin belongs to a large family of cell adhesion proteins. It is implicated in neurite outgrowth, synaptic junctional complex formation, and maintenance of the synapse. It is located at the synapse both in the presynaptic terminal and on the postsynaptic membrane, where it colocalizes with synaptophysin, synapsin I, PSD95, and GluR1. N-cadherin interacts with the cytoskeleton via β-catenin. Immunological studies have shown the staining of N-('neural') and E-('epithelial') cadherin to be mutually exclusive; some synapses are negative for both. Hippocampal cell culture studies have shown the segregation of N-cadherin from general synapses to excitatory synapses during maturation of the cell, suggesting that N-cadherin is specific for excitatory synapses. In AD tissue (as compared with that of controls), we found higher levels of N-cadherin in hippocampus, inferior temporal, and occipital cortex, albeit not significantly overall. We then investigated its binding partner β-catenin. The levels of β-catenin were significantly more abundant in AD cases, especially in hippocampus. β-catenin is also able to translocate to the nucleus, where it activates transcription factors. The concordant increase in N-cadherin and its associate β-catenin in AD could signify dysfunction of excitatory synapses, or an increase in the density of excitatory synapses in AD. Such dysfunction would require confirmation by IHC. Similar results have been obtained investigating the levels of N-cadherin in animal models of epilepsy. An increase in both N-cadherin protein and mRNA were observed in the hippocampus of rodents after induced seizures. Interestingly, an increase in β-catenin was observed in the hippocampus of chemically-induced seizures in rodents.

The Postsynaptic Region

An electron-dense thickening at the synaptic junction is termed the postsynaptic density (PSD). Most postsynaptic proteins isolated from the PSD are associated with neurotransmitter receptors. Proteins enriched in the PSD include fodrin, tubulin, actin, Ca^{2+}/calmodulin-dependent kinase II (CaMKII), and the neuroligins 1–3. Neuroligins are brain-specific membrane proteins with biochemical and structural features indicative of heterotypic cell adhesion. They associate with various splice variants of β-neurexins. Drebrin is enriched at the postsynaptic terminal where it binds actin. Excitatory synaptic terminals in adult mammalian CNS are held in place by an asymmetric junctional complex, termed type I PSDs. The protein PSD95 (SAP90) binds to the NR1 subunit of the glutamate-NMDA receptor. It has been implicated in the assembly of some of the components of the PSD and in receptor targeting and localization.

A major component of the PSD is the brain-specific α subunit of CaMKII, which, with the β-subunit, has been estimated to comprise 2% of total protein in rodent hippocampus and 1% of total protein in forebrain. CaMKII interacts with the NR2B subunit of the NMDA receptor as well as with PSD-95. Other substrates of the enzyme include GluR1 of AMPA receptors, SynGAP, F-actin, and densin-180. These associations have implicated CaMKII in long-term potentiation (LTP), neuronal plasticity, and memory formation. The levels of αCaMKII were unaltered in AD hippocampus compared with those in controls. One study had reported an increased level of αCaMKII in epileptic dentate gyrus, but another study had suggested a decrease of αCaMKII in epileptogenic brain tissue in another form of epilepsy. Activation of receptors and enzymes by CaMKII is implicated in epileptic neuronal damage as this kinase is activated by Ca^{2+}. Increases of intracellular Ca^{2+} are a by-product of GluR activation.

Hippocampal drebrin levels were shown to be lower in AD cases than in controls. The concentration of synaptophysin in that study did not differ, in agreement with our own studies. This result is unexpected if it is supposed that neuronal loss should lead to retrograde degeneration of axons. One explanation for this finding is that an initial axonal degeneration might be followed by a florid regrowth, as a compensatory process in the diseased tissue. The failure of these regenerate terminals to re-form appropriate connections may be a substrate of the clinical dementia and language malfunctions that are characteristic of AD. As a marker of dendritic spines, investigation of drebrin in epilepsy and other neurodegenerative disorders affecting dendrites could provide valuable insight into the disease pathogenesis.

A tubulin binding protein, gephyrin, is associated with glycine and GABA receptors and anchors them in clusters at inhibitory postsynaptic membranes. Inhibitory postsynaptic terminals are structurally different from excitatory PSDs and are named type II PSDs. Investigation of gephyrin as a marker of inhibitory postsynaptic terminals would be a great asset to AD and epilepsy research, and is worthy of future investigation. Fewer gephyrin-labeled puncta have been reported in a rodent model of epilepsy, indicating a decreased inhibitory content in the disease.

Future Challenges

To date, these changes in synaptic proteins indicate a significant role for glutamatergic synapses in the pathology of neurodegenerative disorders. The markedly lower abundance of the complexins in AD, and the area-specific variation in their excitatory to inhibitory ratio distribution, demonstrate a potential predictor of area-specific damage in AD. Excitatory synaptic junction protein N-cadherin and its binding partner β-catenin are elevated in AD and epilepsy. This result could indicate a novel pathway of excitatory synaptic dysfunction in neurodegenerative diseases. Further investigation by IHC is required to determine the specific subcellular localization of the increase.

The approach outlined could also be applied to disease progression. Charting the disease severity or progression that occurs in many neurodegenerative diseases, with the distribution and abundance of specific synaptic proteins, could aid in the determination of the specific elements that correlate with disease symptoms. This strategy could isolate the initial stages of the pathogenesis, and direct focused pharmaceutical intervention.

Introduction

Seizures, particularly when prolonged (status epilepticus) or repeated (pharmacoresistant epilepsy), can damage the brain. Injury is found acutely in humans after status epilepticus, and neuroimaging and neuropathology suggest hippocampal changes may progress over time in some temporal lobe epilepsy (TLE) patients. Experimental modeling shows cognitive deficits brought about by repeated seizures relate to the extent of seizure-induced neuronal death. Neuronal death may also contribute to the pathogenesis of acquired epilepsies. There appears to be a critical threshold of neuronal loss within the hilar or CA3 subfields that when breached leads to permanently enhanced hippocampal excitability and manifestation of epileptic seizures. Understanding how to protect the brain against neuronal death after seizures is, therefore, a key area of basic epilepsy research, with significant therapeutic implications.

Future Challenges

To date, these changes in synaptic proteins indicate a significant role for glutamatergic synapses in the pathology of neurodegenerative disorders. Introduction

Seizures, particularly when prolonged (status epilepticus) or repeated (pharmacoresistant epilepsy), can damage the brain. Injury is found acutely in humans after status epilepticus, and neuroimaging and neuropathology suggest hippocampal changes may progress over time in some temporal lobe epilepsy (TLE) patients. Experimental modeling shows cognitive deficits brought about by repeated seizures relate to the extent of seizure-induced neuronal death. Neuronal death may also contribute to the pathogenesis of acquired epilepsies. There appears to be a critical threshold of neuronal loss within the hilar or CA3 subfields that when breached leads to permanently enhanced hippocampal excitability and manifestation of epileptic seizures. Understanding how to protect the brain against neuronal death after seizures is, therefore, a key area of basic epilepsy research, with significant therapeutic implications.

Excitotoxicity and Seizure-Induced Neuronal Death

In the early 1970s, Meldrum and colleagues demonstrated that evoking seizures in primates replicated patterns of damage found in the hippocampus of TLE patients. Other work, particularly by Olney's group, provided mechanistic explanations. The prolonged or sustained activation of ionotropic glutamate receptors during seizures gates pathologic sodium and calcium entry. Neuronal death may result directly from osmotic stress and cell lysis, or follow secondary signaling cascades. The latter include calpain- and cathepsin-mediated proteolysis of structural proteins and essential enzymes, and DNA damage resulting from DNase II and neuronal nitric oxide synthase activity. Consistent with this hypothesis of glutamate-initiated cell death pathways, studies have shown that administration of glutamate receptor antagonists block or attenuate seizure-induced neuronal death and epileptogenesis.

Background

Seizures and Apoptosis Signaling Pathways

Despite this progress, disrupting glutamatergic signaling has major side effects in rodents and humans, including psychosis and neurotoxicity; further, glutamate antagonists have failed in clinical trials as neuroprotectants in other disorders. In addition, not all cell death after seizures appeared to fit the necrotic/excitotoxic hypothesis. Seizure-induced neuronal death could be reduced by inhibition of new protein synthesis. Moreover, seizure-damaged neurons were found to be positive for DNA fragmentation, and glutamate receptor antagonists failed to influence the numbers of such cells after brief seizures. Furthermore, morphological features of apoptosis as well as necrosis were present in seizure-damaged hippocampus. Questions therefore emerged about whether seizures activated apoptosis signaling pathways, whether such activation contributed to neuronal death (or epileptogenesis), and the relevance of these cell death pathways to human epilepsy. Over the past decade, experimental modeling and analysis of clinical material by a number of laboratories have furnished answers to some, but not all of these questions.

Apoptosis proceeds via one of two main pathways. The intrinsic (mitochondrial) pathway is triggered by DNA damage, endoplasmic reticulum stress, serum withdrawal, or perturbed calcium homeostasis. These changes are 'sensed' by Bcl-2 homology (BH) domain 3-only proteins which target and neutralize antiapoptotic members of the Bcl-2 family, facilitating multidomain Bax/Bak to undergo conformational change/activation. This pathway culminates in release of cytochrome *c* from mitochondria, which binds and activates the apoptotic protease activating factor 1 (Apaf-1). In turn, this complex recruits and activates caspase-9, a member of the cysteine aspartate-specific protease family. Caspase-9 cleaves and activates caspase-3, which then cleaves key substrates, triggering DNA fragmentation and cell demise. Caspase activity may be constrained by inhibitor of apoptosis proteins (IAPs), a molecular brake that is overcome by another mitochondria-originated protein, Smac/Diablo.

The extrinsic pathway is mediated by surface-expressed death receptors of the tumor necrosis factor (TNF) family (e.g., Fas and the p55 TNF receptor). Intracellular adaptor proteins containing death domains such as Fadd and Tradd associate with the receptors and form a molecular scaffold (death-inducing signaling complex) that enables recruitment of caspase-8. Activated caspase-8 can directly cleave caspase-3 or trigger the mitochondrial pathway by cleaving and activating the BH3-only protein Bid.

Methodological Approaches

Our laboratory uses in vivo and in vitro models of seizure-induced neuronal death, alongside analysis of patient material. Our in vivo model of status epilepticus is based around a focal elicitation approach that was originally developed by Ben Ari et al. Kainic acid (KA) is injected into the rat (or more recently, mouse) amygdala to generate seizures and a focal, ipsilateral lesion within hippocampal CA3/CA1. We perform quantitative EEG in our studies and find this of value for identifying electrographic correlates of damaging versus benign seizure activity, or associations with gene responses. We also use an in vitro seizure model, where hippocampal neurons are chronically cultured in a glutamatergic block; wash-out of the blocker triggers seizure-like activity. This model allows us to exploit some experimental techniques not possible in vivo. Tissue from these models is used to characterize spatiotemporal changes in apoptosis-associated gene expression after seizures, and to measure enzyme activity, protein–protein interactions, and subcellular localization of key players in the cell death cascade. Histological approaches include analysis of neuronal loss or DNA fragmentation – and assessment of intervention efficacy. Finally, clinical material from TLE patients enables us to validate experimental model findings and gain insight into translational relevance.

Results

Important Results to Date

Key discoveries

Our first contribution to the field came from two simultaneous discoveries in the laboratory at the University of Pittsburgh in the late 1990s. Having observed DNA

fragmentation in CA3 neurons after seizures, we investigated cytochrome *c* release in our model and detected rapid translocation into the cytoplasm within ~2 h. The seizure-damaged hippocampus also contained activated caspase-3, and we found that in vivo infusions of a putative caspase inhibitor protected against neuronal death in the hippocampus. At the same time, we were collaborating with Robert Clark and Neurological Surgery to look at apoptosis-associated genes in human neocortex removed during surgery for intractable seizures in patients with TLE. We found patient samples contained higher levels of procaspase-3 and cleaved caspase-3. The inflammatory caspase-1 was also cleaved in these samples, and Bcl-2 was over expressed. We interpreted these observations to mean that caspases and apoptosis-associated signaling molecules were altered in patients most at risk of progressive neuronal loss in hippocampus, and this interpretation was supported by findings in experimental models showing that prolonged seizures recapitulated some of these responses.

Intrinsic or extrinsic?

Studies moved next to the question of the route to caspase-3 activation. We expected the mitochondrial/caspase-9 pathway would be involved because elevated intracellular calcium, a consequence of seizure activity, had been shown to directly release cytochrome *c* from isolated brain mitochondria. We found that seizures induced formation of the so-called apoptosome complex, of cytochrome *c* with Apaf-1, and caspase-9 was cleaved and activated. However, so too was caspase-8. In fact, the early onset of the caspase-8 pathway and the protection afforded by its inhibition suggested an important role, and one we later found was conserved during seizure-induced neuronal death in vitro. The mechanism of caspase-8 activation after seizures remains puzzling, but probably is death receptor mediated because death-inducing signaling complexes form rapidly after experimental seizures and are even detectable in a TLE patient's hippocampus. Results from independent laboratories have since supported this unexpected mix of the intrinsic and extrinsic pathways in experimental models, and the robust protection afforded by several caspase inhibitors. Our studies of resected hippocampus from TLE patients have shown that both cleaved caspases 8 and 9 are present.

Other roles for caspases?

Not all laboratories have confirmed our findings. Fujikawa's group has shown DNA fragmentation can be weak and caspase processing absent in some models of generalized seizure-induced neuronal death. In addition, even where independent laboratories have confirmed seizures cause processing or activation of caspases, the temporal profile can vary. While our group detected responses within the first 4 h postseizure, other groups (e.g., Pitkanen's laboratory at the University of Kuopio) have shown later changes that extend into the period of epileptogenesis. These differences may be partly due to technical and model-specific factors. Whatever the basis for such differences, these experiments have identified nonlethal roles for caspases. Limited proteolysis or restriction of activated caspases to specific cell sites appears to enable sublethal activity, and this activity may underlie restructuring and the mechanism of ischemic tolerance. Such sublethal activity could explain the presence of cleaved caspases 2, 3, and 9 within neuronal processes in hippocampal sections from patients with TLE. Experimentally, caspases 2 and 6 are also overexpressed in regions of neuronal restructuring during epileptogenesis. Thus, roles for caspases extend beyond regulation of cell death into other areas of potential importance in epileptogenesis.

Bcl-2 proteins: Upstream determinants of seizure-induced cell death?

The significance of Bcl-2 family proteins for seizure-induced neuronal death (see **Figure 1**) was first indicated by the finding that neurons in *bax* knockout mice were resistant to glutamate and KA. However, convincing evidence that Bax is activated by seizures in vivo has not yet been presented, although we have detected mitochondrial clustering of Bax after seizures in vivo. Instead, BH3-only protein responses have been more completely explored. Seizures activate Bad, which dissociates from 14–3–3 and binds antiapoptotic Bcl-xl, an event thought to enable Bax activation. Interestingly, the neuroprotective effect of the ketogenic diet was recently linked to suppression of the Bad pathway. Seizures also induce Bim upregulation, a much more potent BH3-only protein, one that appears to target antiapoptotic Bcl-w in rat and mouse hippocampus. Bid is also an early responder after seizures in vivo, although calpain can also cleave Bid during excitotoxic insults. Reports from other laboratories support broad and early involvement of BH3-only proteins after seizures.

Transcriptional control?

Several transcription factors associated with apoptosis are activated by seizures. The most studied is p53, although the specific genes involved in effecting p53-induced neuronal death after seizures are still unknown. Mice deficient in p53 are protected in the short term against cell death after seizures, although when followed at later recovery points this protection may dissipate. Protection is also seen using pharmacologic approaches to target p53. Interestingly, levels of p53 are elevated in hippocampus from TLE patients.

We had rather discounted a role for transcription factors after studying the Bad-Bcl-xl pathway because all the components were constitutively expressed in hippocampus and activated without expressional changes. However,

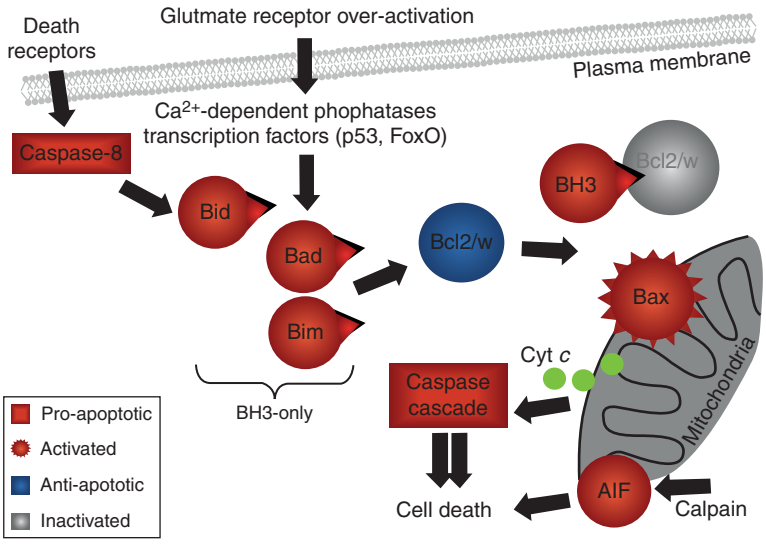

Figure 1 Cartoon depicting possible triggers and routes for apoptosis signaling after status epilepticus. Glutamate activates BH3-only proteins via calcium (Ca^{2+})-dependent phosphatases or transcription factors. Death receptors are also activated by damaging seizures, leading to caspase-8 and Bid cleavage. BH3-only proteins target and neutralize antiapoptotic Bcl-2 family proteins and enable Bax activation. Thereafter, apoptogenic substances including cytochrome *c* (cyt *c*) and AIF are released from mitochondria, activating caspase-dependent or independent cell death.

subsequent studies on Bim showed seizures rapidly activated FoxO transcription factors, and blocking this activation was found to be neuroprotective. Also interesting, protein kinase B/Akt protected cortical regions in this model by suppressing FoxOs such that when Akt was inhibited, cortical Bim expression increased and more cell death resulted. Significantly, Akt activity is elevated and FoxOs/Bim suppressed in patient hippocampus, suggesting potentially adaptive responses that could limit vulnerability to cell death. New data also suggest additional complexity in transcriptional control of Bim involving c-Jun *N*-terminal protein kinase.

AIF and caspase-independent pathways

An interesting development has emerged for calpains, traditionally linked to neuronal necrosis, as effectors of caspase-independent apoptosis. Chen's group at the University of Pittsburgh recently showed that activated calpain I can trigger apoptosis inducing factor (AIF) release from mitochondria and neuronal death, bypassing Bcl-2 proteins and caspases. This finding is relevant to seizure-induced injury, since mice overexpressing the calpain inhibitor calpastatin or deficient in AIF are partly protected against seizure damage in vivo. However, we found that the nuclear fraction from human TLE hippocampus contained significantly elevated levels of the caspase-activated DNase (CAD) compared with matched autopsy controls, while nuclear levels of AIF were not different between TLE patient samples and controls. This result suggests that caspase-dependent rather than caspase-independent apoptosis pathways are more important for ongoing pathogenic processes in chronic TLE.

Recent Results

Findings from Bcl-w knockouts

Since a pharmacological approach in the area of Bcl-2 family proteins was limiting functional studies, we developed relevant mouse models. We had found that intraamygdala KA caused seizure damage in mice that involves ipsilateral CA3 and CA1, strong DNA fragmentation, and some morphological features of programmed cell death. Early cytochrome *c* release and caspase processing were also conserved. We next carried out studies on antiapoptotic Bcl-w, since this gene had been identified as a target of Bim and we had other experience with Bcl-w. Seizures in normal mice caused bidirectional regulation of Bcl-w, depending on the severity of the seizure; Bcl-w increased after brief seizures that did not cause neuronal damage, but decreased/inactivated after damaging seizures. Levels of Bcl-w in hippocampus from our TLE patient cohort were also higher than autopsy controls, suggesting frequent seizures in humans also alter expression. Critically, mice deficient in *bcl-w* displayed significantly more hippocampal cell death after seizures than mice with normal *bcl-w*. Unexpectedly, we detected another difference between *bcl-w* knockout and wild-type mice: earlier polyspike seizure onset in *bcl-w* knockout mice. The difference was small, a few minutes, and not sufficient to explain the differences in histological injury. However, it implied that Bcl-w protein may have novel functions to explore. We next overexpressed Bcl-w in hippocampal neurons in vitro and performed patch clamp recordings which determined that Bcl-w overexpression significantly enhanced fast γ-amino-butyric acid (GABA) currents. These data suggest that Bcl-w can promote inhibitory neurotransmission.

This makes Bcl-w an attractive target in epilepsy, being both neuroprotective and potentially seizure-suppressive.

Other findings in experimental models

Recent work has focused on assessing the functional significance of BH3-only proteins on epileptogenesis. In *bim* deficient mice (from the Villunger laboratory), brain development appears normal (Figure 2a) and the mice undergo seizures after intra-amygdala KA as their wild-type (Figure 2a) littermates. Our early results suggest that loss of this gene influences seizure-induced neuronal death, with fewer DNA damage-positive cells in the vulnerable CA3 subfield compared with wild-type mice (Figure 2a). We have now used video and EEG telemetry to follow the emergence of epileptic seizures in wild-type mice in our model (Figure 2b). Our experiments reveal all mice

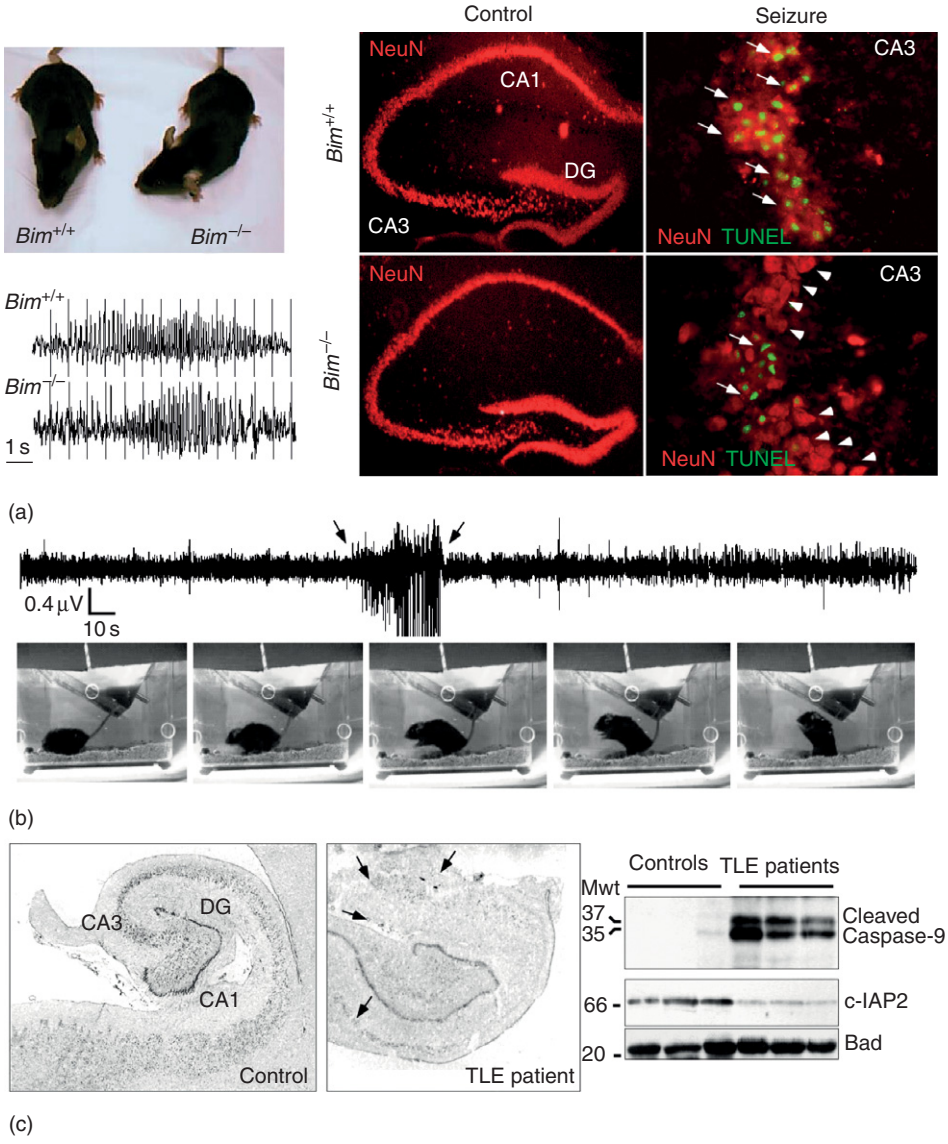

Figure 2 (a) Photographs of wild-type (*bim*$^{+/+}$) and *bim*-deficient (*bim*$^{-/-}$) mice and below, representative EEG traces of seizures following kainic acid (KA). Immunohistochemistry panel to the right shows hippocampi from (left panels) control and (right panels) seizure-damaged wild-type and *bim*-deficient mice. Wild-type mice display extensive TUNEL-positive neurons (arrows) in the CA3 subfield, while a proportion of neurons survive in *bim*-deficient mice (arrowheads). (b) An epileptic seizure captured using EEG-telemetry in a mouse that underwent prolonged seizures induced by KA. Panels below show sequential video stills depicting behavioral features. (c) Representative images of a nissl-stained hippocampus from an autopsy control (provided by the University of Maryland Brain & Tissue Bank) and a pharmacoresistant TLE patient. Note the evident neuronal loss (arrows) in the patient specimen. Western blot panel to the right shows expression of mitochondrial/intrinsic pathway proteins in the cytoplasmic fraction from three controls and age/gender-balanced TLE samples. Note presence of cleaved caspase-9 and lower antiapoptotic c-IAP2 levels. The Bad levels confirm loading. The authors gratefully acknowledge the unpublished data, courtesy of Hatazaki S, Mouri G, Murphy B, Paucard A, Schindler C, Thompson S, and Woods I.

injected with intra-amygdala KA developed epilepsy within 5 days. This resource will support screening mice deficient in apoptosis-associated genes for epileptic phenotype and it will be interesting to determine whether a different (perhaps milder) form of epilepsy develops in *bim* or other BH3-only deficient mice post *status epilepticus*.

Recent human material analysis

Some questions remain from our studies of TLE patient hippocampus. While we had detected some caspase-9 cleavage in the microsomal fraction of patient hippocampus, we were aware that this was not the compartment in which the protein was likely to be most enriched. Data in **Figure 2c** show representative autopsy control and TLE patient hippocampi and recent analysis of the cytoplasmic fraction. Western blots show there are significant levels of cleaved caspase-9 in TLE patient brain compared with autopsy controls (**Figure 2c**). Moreover, levels of c-IAP2, a potential negative regulator of caspase activity, are lower in the TLE samples than autopsy controls (**Figure 2c**). Levels of Bad in this fraction are similar between the TLE group and autopsy controls. These new findings extend the case that caspase activity may be present in hippocampus from refractory TLE samples.

Future Goals

Progress is still required in several areas. The cell type(s) in which apoptosis signaling is modulated in human TLE hippocampus is poorly characterized. Is pro- and antiapoptotic signaling occurring in the same or different cells, and are these mainly neurons? Beyond this, we must test whether blocking proapoptotic signaling has any protective effects against epilepsy development after *status epilepticus*. Using long-term EEG recordings we have found that mice neuroprotected by a brief (preconditioning) seizure given a day before *status epilepticus* developed five times fewer epileptic seizures than nonpreconditioned mice subject to *status epilepticus*. The degree of neuroprotection in BH3-only protein deficient mice after status epilepticus could be similar, so we would expect to observe antiepileptogenic effects. In summary, research on the molecular mechanisms of cell death after seizures has identified roles for apoptosis-associated signaling in experimental and, probably, human epilepsy. This has provided important insights into the pathophysiology of seizure damage and led us toward discovering potential routes to antiepileptogenesis.

Neuronal Injury and Progressive Cell Damage

L E Mello and L Covolan, Universidade Federal de São Paulo, Sao Paulo, Brazil

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Life and death are not dichotomies, but the extremes of a continuum. At the cellular level, a wide range of phenomena that are often forgotten and not investigated temporally interconnects these two poles. The complete picture of these phenomena requires analysis on a time scale different from that used to analyze the changes that take place after an insult is inflicted to injure tissue and cells. The biochemical, morphological, and functional consequences of an injury can be assessed quickly – at the millisecond level – as well as over the course of many years or decades. Cellular, molecular, and network changes in various neurons and glial cells have been proposed as critical factors for the development of epileptogenesis, and may also contribute to the progression of the seizure disorder (maintenance of recurrent spontaneous seizures).

Cause or Consequence Debate

The 'chicken or egg' debate on whether seizures are a cause or a consequence of brain damage is one of the oldest issues in epilepsy research. The association of epilepsy with brain damage and hippocampal sclerosis – a characteristic pattern of lesion which includes neuronal cell loss and gliosis in the hilus of the dentate gyrus and CA1 and CA3 regions – was first described by Bouchet e Cazauvieilh in 1825. On one hand, these neuropathological findings related to epilepsy have been extensively studied; on the other hand, the trigger of these neurobiological events, and whether/how these initial pathological findings are associated (or not) with the subsequent network plasticity changes, still remain unsolved. Just as epileptogenesis is perceived as a dynamic process, developing with variable latency after an identifiable insult (such as head trauma, status epilepticus (SE), brain tumor, infection, or anoxia), the processes of cell and tissue injury (and death) should also be viewed not as static but rather as dynamic processes.

Background

For a long time, assessment of the changes taking place after an epileptogenic or epileptic (ictal) events was mostly based on histology. Typically, after the death of a patient or upon the termination of a laboratory experiment, brain tissue would be processed with various histological techniques. Early work in this area usually relied on Nissl-stained sections of brain tissue, and provided cell counts of specific brain areas. The results from such analysis provide information about the number of remaining cells and thus, by comparison with cell counts from normal tissue, indicate the amount of cell loss. This approach, although able to establish whether or not there has been damage to the tissue, does not provide any information about when this damage occurred. In particular, in human epilepsy patients, this approach does not indicate whether tissue damage is cause or consequence of the epileptic process. For that insight, investigators have turned to experimental models of epilepsy, since animals can be examined histologically at various time points after injury. Furthermore, with the advent of the surgery as a clinical treatment for epilepsy, tissue from patients – at different ages, with different lengths of seizure history, with different seizure types, and seizure frequencies – became available. It was shown that hippocampal cell densities in mesial temporal lobe were not reduced in psychomotor epileptic patients with extrahippocampal foci consisting of tumoral tissue. Variables in seizure histories were not correlated with Ammon's horn cell densities, suggesting that sclerosis preceded the seizures, and that the seizures did virtually no significant further damage to hippocampus.

This new era of investigation has provided a wealth of information, but has generated only indirect evidence to shed light on the chicken or egg dilemma. It was only with the application of magnetic resonance imaging (MRI), to visualize the brains of living persons (and laboratory animals) over time, which finally gave rise to direct evidence on this issue. Particularly, with respect to experimental studies on small animal models, the limited spatial resolution of MRI has been problematic. The emerging clinical picture from imaging studies is that there is a small but progressive process of neural damage associated with length of seizure history and with seizure frequency. MRI data, while providing important insights, has also generated additional previously unimagined possibilities. For example, it was found that some close relatives of patients with familial mesial temporal lobe epilepsy show MRI changes, including atrophy of specific brain structures – and yet not have electroencephalographic abnormalities or seizures. The authors of that study concluded that evidence of hippocampal sclerosis is not necessarily related to seizure severity, and may occur in individuals who never had seizures. In addition,

these observations strongly indicated that hippocampal sclerosis in familial mesial temporal lobe epilepsy is not a consequence of recurrent seizures and is determined by a strong genetic predisposition. Given the heterogeneous nature of even a seemingly uniform condition such as mesial temporal lobe epilepsy, it is clear that the relationship between neuronal damage and seizures is likely to be determined by the specific nature of each distinct epileptic syndrome.

Similarly, initial biochemical analyses of epileptic tissue provided only static pictures of the ongoing changes. The possibility of addressing these changes in the same subject over time allows further advances in our understanding of the complex relations between epilepsy and neuronal damage. Neuron-specific enolase (NSE) is a marker of neuronal injury; elevated NSE correlates with neuronal death (as seen with histology) in animal models of SE. Studies using NSE support the idea that seizures (and not only overt SE) can cause neuronal injury.

As expressed in the opening of this article, not all cells will die immediately as a consequence of an epileptic seizure. Rescuing those cells that are killed at short latency after a seizure may be impossible. Conversely, it may be feasible to repair, or bring back to normal function, cells that have been injured but not lethally wounded. Indeed, while most studies have concentrated on the presence of cell loss, few are dedicated to the issue of cell injury. Evaluating what cells are injured by repeated seizure-related events – and particularly assessing what biochemical changes take place in those cells – might give rise to novel measures for halting the progressiveness of an epileptic condition. That is, it is as important to assess cell injury as to describe cell degeneration (death).

Methods

In our laboratory, we have taken advantage of a highly sensitive silver staining technique (Gallyas or argyrophil III) for the assessment of cell injury. This technique stains cells that have been injured in the preceding hours – only some of which will die in the near future. As expected, what cells will die and what cells will survive is a function of damage type and intensity. For example, not all rodent models of SE lead to degeneration of dentate granule cells. Indeed, silver staining technique stains dentate granule cells in rats subjected to pilocarpine-induced SE but not those subjected to kainic acid-induced SE.

Given the Golgi-like nature of most of the elements stained with Gallyas technique, it is often possible to describe the cell type that has been damaged (e.g., basket, pyramidal, mossy cell, fusiform cell). This technique, therefore, provides not only information about the number of damaged elements (neurons or glia) and their topographic distribution, but also on cell morphology. In addition, the level of contrast that is obtained allows us to detect even a single injured cell in a brain section. The fact that the technique does not rely on fluorescent dyes provides an additional advantage, as the marker is 'permanent.' Our work with this technique clearly demonstrates that it stains fibers and cell bodies of both glial and neuronal elements. A major concern is that this highly sensitive staining approach can easily provide false positive results if proper care is not taken with perfusion and with tissue processing.

Recent Results

We first compared the regional distribution of selectively vulnerable neurons, and the temporal evolution of neuronal injury, after pilocarpine- and kainate-induced SE. Pilocarpine SE leads to greater damage at shorter latencies than kainic acid. Few neurons were silver-stained two hours after kainate-induced SE, as compared to many silver-stained cells in most neocortical, hippocampal, amygdaloid, and hypothalamic structures in pilocarpine SE animals. For both models, most damage took place from 8 to 24 h after SE onset. Importantly, although some silver-stained cells do not eventually die as a consequence of SE, it is not clear that surviving cells would show full functional recovery. That is, after a brain injury some neurons would die acutely, whereas other neurons might die over a protracted period of time, during which they could contribute to seizure genesis. In fact, it was shown in pilocarpine-treated animals that surviving neurons in the dentate granule cell layer display substantial changes in their morphology; these changes vary over time, starting with an initial spine loss, followed by recovery and plastic changes in spine shape and density, and culminating in dendritic spine degeneration many months after SE induction. Similarly, we demonstrated distorted morphology of surviving interneurons in the hippocampus of animals subjected to pilocarpine-induced SE.

In slice studies, investigators have shown that orthodromic activation of CA1 neurons evoked only a single, stimulus-graded population spike in control slices, the same stimulus produced an all-or-none burst of population spikes in slices from epileptic animals (i.e., animals that underwent pilocarpine-induced SE). Assessment of the intrinsic firing patterns of CA1 pyramidal cells determined that in control slices, the vast majority (97%) were regular firing cells – in contrast to only 53% regular spiking cells in slices from epileptic animals. The remaining 47% of the pyramidal cells had become intrinsic bursters. The discharge of spontaneously active CA1 bursters anteceded the population discharge, whereas most other pyramidal cells began to fire conjointly with the first population spike in the field potential epileptiform burst. Thus, spontaneous bursters were suggested to be

the likely initiators of spontaneous population bursts in these slices. The authors concluded that the dramatic upregulation of intrinsic bursting in CA1 pyramidal cells, particularly the de novo appearance of Ca^{2+}-dependent bursting, could contribute to the epileptogenicity of the hippocampus in the pilocarpine model of epilepsy. Our data are consistent with this view, and further suggest that neurons that are silver-stained following SE might become those permanently altered bursters. By developing a means to pinpoint which cells will be altered by the lesional event, we hope to provide a way to more readily evaluate strategies to prevent these changes.

We then showed that even the much milder chronic spontaneous recurrent seizures that follow pilocarpine-induced SE are able to trigger neuronal injury. Animals were sacrificed from 1 to 6 h after either single or multiple seizures. Silver-impregnated dark neurons were never found in control animals or in epileptic animals that had no behavioral seizures in the 8 h prior to sacrifice. After spontaneous seizures, dark (injured) neurons were mostly interneurons and were present in hippocampus (CA1 stratum radiatum), amygdala, piriform cortex, and other limbic structures. Animals with multiple seizures had a higher number of dark cells than animals with single seizures. These results suggested that even single generalized spontaneous tonic–clonic seizures could induce long-lasting morphological changes, and are consistent with the idea that epilepsy is a progressive disorder where one seizure begets the next.

The smaller number of neurons stained after a single seizure led our group to question whether SE would trigger some sort of adaptative process, analogous to the so-called ischemic tolerance. Indeed, as hypothesized counts of silver-stained cells, using the Gallyas (argyrophil III) method, revealed a markedly lower neuronal injury in animals submitted to reinduction of SE as compared to rats exposed to a single episode of pilocarpine-induced SE. This effect could be explained by either (or both) of the following considerations: (1) The first SE would remove the vulnerable cells, leaving behind resistant cells not affected by the second SE; (2) The first SE would confer increased resistance to the remaining cells, analogous to the process of ischemic tolerance. Counting of Nissl-stained cells, to differentiate between these alternative mechanisms, indicated that different neuronal populations reacted differently to SE induction. For some brain areas, most if not all of the vulnerable cells were lost after an initial insult, leaving only relatively resistant cells and little room for further damage or cell loss. For some other brain areas, in contrast, our data supported the hypothesis that surviving cells might be modified by the initial insult, which conferred a sort of excitotoxic tolerance. As a consequence of both mechanisms, subsequent insults (regardless of their intensity) after an initial intense insult resulted in very little damage.

Evidence for resistance to damage conferred by previous epileptic activity has been shown in several experiments by different groups. However, in all of these studies, assessment of the effects of a second lesional event was always performed within a short time interval after the first insult. For example, preconditioning animals by intrahippocampal kainic acid administration produced significant neuroprotection against a second intrahippocampal kainic acid dose administered from 1 to 7 days later – but not 15 days after the first injection. In our study, however, we allowed a period of many months to pass between the initial major lesional event and the induction of a second SE. Under these conditions, the lack of an extensive lesion after the second SE was not due to a lower degree of the second insult compared to the first. Accordingly, our data could be seen as indicative of neuroprotection or excitotoxic-induced tolerance. The possibility that there was simply a lack of vulnerable cells to be damaged by the second SE was not supported by our counts of the number of silver-stained cells relative to the number of available neurons (Nissl-stained).

Thus, our data suggest that in some neuronal populations there is a tolerance to damage that is induced by pilocarpine SE and may extend for over 15 months after the initial insult. In addition, this 'tolerance' to further damage does not seem to increase or diminish as a consequence of repeated spontaneous seizures, irrespective of the frequency of these latter seizure events. The protection conferred by the initial SE event was able to partially withstand even a second SE bout 6 months later. Our findings may be relevant to the clinical studies that attempt to determine under which conditions neuronal damage is a cause or a consequence of seizures. Knowledge of the factors influencing such tolerance might be relevant to the development of neuroprotective strategies.

The lack of significant neuronal loss and neuronal damage by repeated seizures (when they occur) does not imply that those repeated seizures do not harm the patient. Indeed, not only might those repeated seizures have a tremendous impact on a person's ability to have a normal life, but also (more importantly within the context of this article) may negatively affect cognition. Even though repeated seizures do not necessarily lead to increasing overt neuronal injury, these events may alter synaptic plasticity and have consequences on other physiological functions (as extensively demonstrated in kindling studies).

Future Goals

The answer to the chicken or egg dilemma may vary depending on the epileptic syndrome or animal model considered. A major challenge ahead is to dissect the biochemical bases underlying these different responses to injury shown by different neuronal populations.

For example, how does this excitotoxic tolerance develop? In our previous experiments, we did not evaluate whether excitotoxic tolerance would develop after a less intense SE or even after just a single seizure. In the event that excitotoxic tolerance does develop after a single seizure, we must then evaluate how long the tolerance will last and to what extent different neuronal populations might be protected.

Another goal is to evaluate whether the modulation of neuronal injury would affect the epileptogenic process. To this end, as discussed earlier, there is evidence that multiple SE events, triggered in subsequent days and at a controlled level of intensity, result in very little damage. This model, however, has not yet been evaluated with the Gallyas silver staining technique for detecting injured neurons or with other means of assessing neuronal stress. The model of two controlled priming SE episodes, followed by one full-blown SE episode, is associated with no cell loss and yet with the emergence of epilepsy (e.g., spontaneous recurrent seizures). Is neuronal injury (and not only of cell death) also blocked in the repeated SE model? Presumably not, as the animals do become epileptic. What is the biochemical cascade associated with this injury process, and what is its temporal progression? Given that, despite the lack of neuronal loss, animals subjected to the titrated model of SE induction still develop spontaneous seizures, it is relevant to investigate neuronal injury in this model and to determine whether we are able to modulate the injury – and thus modulate the epileptogenic process.

A basic concept in epileptology is that upon the death of certain cell populations the remaining cells reorganize, and this reorganization may contribute to epileptogenesis and ictogenesis. Is the loss of a nearby neuron, or the loss of a component in a neuronal circuit, what triggers the changes in the surviving neurons? To what extent is it relevant that the surviving neurons are injured (but not killed) by the initial precipitating injury? We are currently exploring several pathways (e.g., NMDAR-induced cell swelling, the recruitment of Ca^{2+} stores, and their modulation by BDNF) associated with the changes in the biochemical machinery of the cells that result from excessive excitation. Therefore, as important as understanding what cells degenerate in epilepsy, it is critical to understand what cells are damaged but do survive and serve as the locus of epileptogenic plastic changes.

Neuronal Injury from Seizures: Influence of Models, Development and Genetics

Introduction and Background

The earliest observation linking seizures to brain injury is generally attributed to Bouchet and Cazauvielh who reported on hippocampal abnormalities in an autopsy series on patients who had epilepsy. Decades later, Sommer described a characteristic pattern of neuronal injury in the hippocampus of epileptic patients that has been called Ammon's horn sclerosis (AHS). These descriptions preceded a detailed knowledge of the ultrastructure of the brain and involved gross inspections of brain specimens. The epilepsy-related lesion suggested in these early reports – now also referred to as mesial temporal sclerosis (MTS) – was first described in detail by Margerison and Corsellis based on a study of 55 autopsy specimens of patients with known epilepsy confirmed by clinical electrophysiology data. It involved cell loss and gliosis in the Sommer sector (CA1), along with a major but variable part of the end folium (previously referred to as CA4, but the current preferred appellation is 'hilus') and the dentate gyrus. An illustration from their classic paper is reproduced as Figure 1, to show the typical lesion as well as to mark the historic description of seizure-related hippocampal pathology. Their study could not clearly resolve the controversy as to whether hippocampal sclerosis is the cause or the result of temporal lobe epilepsy. Detailed discussion of the evidence supporting either point of view is not within the scope of this article, but we refer the reader to a review by Sutula and Pitkänen (see Further Reading section), in which the authors review important evidence from animal and human studies. They suggest that regardless of a possible etiologic role of pre-existing structural abnormalities, progressive seizure-induced neuronal injury can occur and that it may be modified by genetic and environmental factors. Improvements in high resolution neuroimaging modalities such as high field magnetic resonance imaging provide us with an opportunity to study patients prospectively and undertake careful documentation of seizure density and duration for correlation with quantitative analysis of findings from imaging.

Meldrum and colleagues were the first to demonstrate that seizures themselves, in the absence of systemic factors, produce brain injury. In their classic study, baboons were intubated, ventilated, and paralyzed – and then subjected to prolonged seizures. The brain damage seen subsequent to these seizures could not be attributed to respiratory arrest, and thus was interpreted as a direct response to seizure activity. Subsequently Nevander and colleagues confirmed similar findings in a study involving well-oxygenated rats. These observations were explained by the emerging concept of excitotoxicity; that is sustained and repetitive depolarization of neurons led to a massive influx of calcium into the cell, triggering a cascade of events leading to cell death. Theses studies showed that even careful clinical management of systemic

factors – for example, during status epilepticus (SE) – is insufficient to protect neurons. Aggressive management of on-going seizure activity, including meticulous detection of electrographic (but subclinical) seizures, is important for optimal outcome. In recent years, this concept of seizure management is also beginning to take hold with respect to seizures and SE in the neonatal settings.

While seizure-induced injury usually encompasses widespread regions of the brain, a great deal of research has focused on the hippocampus, no doubt in part triggered by the availability of surgically resected hippocampi from patients undergoing epilepsy surgery. In parallel, animal models were studied in an attempt to replicate the human lesion. There is considerable variability in the lesion among humans, but the diagnosis of hippocampal sclerosis is readily made – not only by the pathologist but also by the neuroradiologist – during the early evaluation of the epilepsy patient.

Methods

Experiments subjecting animals to SE produced by chemoconvulsants (like kainic acid or pilocarpine) can reliably produce hippocampal sclerosis in rodents. Kainic acid has been injected into the hippocampus (or amygdala) in some models, but systemic administration of these drugs is most common. A variation of the pilocarpine model involves pretreating animals with lithium chloride, which reduces the dose of pilocarpine needed to induce status epilepticus and to improve 'consistency' in results. Continuous electrical stimulation of the hippocampus has also been employed in different paradigms, including that involving perforant path stimulation to produce self-sustained status epilepticus; seizure activity is considered to be self-sustaining when seizures continue even after the provocative stimulus is withdrawn. Mazarati and colleagues showed that 30 min of electrical stimulation of the angular bundle resulted in seizures that continued for hours. This method has the advantage of not involving chemicals, that may be inherently neurotoxic, to produce experimental SE.

Neuronal injury has been demonstrated using a variety of histological techniques. Degenerating neurons can be identified by staining with hematoxylin and eosin or fluoro-jade blue. Tissue studies have also employed TUNEL staining and immunohistochemical studies for various caspase proteins to elucidate the mechanisms underlying neuronal injury

Investigators have shown that hippocampal sclerosis can also be demonstrated after repeated kindling stimulations, suggesting that even repeated brief seizures (rather than SE) can contribute to chronic loss of neurons and hippocampal sclerosis. These studies also highlighted the selective vulnerability of the hippocampal neuronal populations to seizure-induced injury. Neuronal loss was demonstrated in the CA1 and the hilus of the dentate gyrus after only three kindling-induced generalized tonic–clonic seizures, but there was no discernible cell loss in the somatosensory cortex even after 150 seizures.

These models have been studied extensively to demonstrate seizure-induced brain injury following SE or repeated seizure activity, as well as to evaluate subsequent molecular, cellular and network plasticity that may contribute to epileptogenesis. In addition, studies have been reported that attempt to evaluate the evolution of cognitive and behavioral comorbidities that follow this seizure insult, and if those are associated with seizure-related cell damage.

Recent Results

Seizure-Induced Neuronal Demise – Apoptosis or Necrosis?

A number of studies have attempted to define the seizure-related brain damage in terms of apoptosis or necrosis. Review of the literature suggests that this discussion is clouded by semantic inconsistencies. Original definitions of these distinct types of cell death were based on early morphologic changes accompanying tissue injury.

Many reports (see Henshall and Simon in Further Reading and in this volume) have described apoptotic cell death following both brief seizures as well as SE in rodent models. Most of these reports concluded that seizure-related cell death was apoptotic, based on the demonstration of a number of biochemical markers typically associated with apoptosis, including enhanced expression of either the message or protein product corresponding to such cell death-associated mediators as p53, Bax, activated form of various caspases, and the demonstration of oligonucleosomal DNA cleavage (as shown by DNA 'laddering'). The most common histological marker for apoptosis has been TUNEL staining, which reflects double-stranded DNA cleavage. Now we know, however, that TUNEL positivity is not specific to apoptosis.

The classical description of apoptosis as a distinct mode of cell death was based on morphological descriptions based on electron microscopy (EM). The EM findings for apoptosis are dramatically distinct from those for necrosis. As summarized by Fujikawa, the morphologic findings in most neurons after a bout of status epilepticus appear to correspond to necrosis, even though many biochemical markers reflecting the initiation of programmed cell death can be demonstrated. This form of cell death has therefore been referred to as 'programmed neuronal necrosis.' Interestingly, it does not appear to be unique to seizures as the provocative insult, since it has also been demonstrated in a hypoxic–ischemic model.

The molecular events pertaining to cell death following seizure(s) seem to be represented along a continuum, and depend upon the intensity/duration and/or frequency of seizures. Very brief seizures may induce a phenomenon that has been termed 'preconditioning' which affords relative neuroprotection from a subsequent event in the short term. With more prolonged or frequent seizures, cell death may ensue with prominent DNA laddering, suggestive of an 'apoptotic' mode of cell death. When the same provocation for producing seizures is titrated to yield a more rapid onset and continuous seizure activity, a necrotic appearing morphology and biochemical markers of death have been noted.

Some studies have noted that a given insult can produce an apoptotic morphology in the dentate granule cells but a necrotic morphology in the pyramidal cells of the Ammon's horn. This apparent paradox may be related to the fact that many of the affected dentate granule cells are newborn (i.e., there is ongoing neurogenesis in the dentate gyrus). It has been estimated that a large majority of the newly born cells undergo apoptotic death, and that this process is enhanced by seizure activity. Thus, at least in the dentate, apoptosis is correlated with the developmental immaturity of newborn cells, recapitulating the normal role of apoptosis during development.

Regardless of the morphology of seizure-induced death of neurons, the identification of a large number of molecular targets can contribute to the development of neuroprotective strategies. A number of targets involve the so-called 'intrinsic' pathways, set in motion by the dramatic seizure-related rise of intracellular calcium and the consequent disruption of intracellular organelle (mitochondria, endoplasmic reticulum) function. In addition, 'extrinsic' pathways – for example, involving the activation of surface receptors of the tumor necrosis factor (TNF) super-family can also play important roles. Ligands for the latter include TNF-α, Fas ligand, and the TNF receptor apoptosis-inducing ligand (TRAIL). There is a great diversity of potential targets for neuroprotective strategies, including the TNF receptors indicated earlier, the receptors for excitatory amino acids, the intrinsic pathway-associated organelles (e.g., mitochondria-related targets), the cellular elements involved in oxidative injury, etc. Indeed, this diversity suggests that effective neuroprotective strategies may have to address more than one specific target, and a 'neuroprotective cocktail' approach may emerge.

Seizure-Induced Neuronal Death in the Developing Brain – Influence of Models

Experiments involving kainic acid (KA)-induced status epilepticus in immature animals formed the basis for the initial impression that the developing (immature) brain does not undergo the classic seizure-induced injury to the dentate hilus and Ammon's horn that lead to hippocampal sclerosis. Investigators initially reported that rats younger than postnatal day 17 or 18 were relatively protected from seizure-induced injury (although injury from systemic KA-induced seizures was demonstrated in immature rabbits). However, it was noted that the administration of corticotropin-releasing hormone (CRH) to rat pups of postnatal age 10 (P10) resulted in severe seizures and extensive hippocampal injury. Such injury could not be reproduced in mature animals, even at much higher doses of CRH. Thus, the relative lack of vulnerability in immature rats appears to be both species- and model-specific.

Treatment of P10 rabbits with pilocarpine following pretreatment with lithium produced hippocampal injury similar to that produced by KA. Our laboratory undertook a systematic study of the lithium–pilocarpine model in rat pups of different ages. The pattern of injury varied with age, with CA1 most vulnerable in the P14 animals; injury to the hilus and CA3 became prominent by P21. Anatomic evidence of synaptic reorganization, as evidenced by mossy-fiber sprouting, was seen in animals several weeks after SE at P21 in this model, but not in those subjected to SE at P14. The vulnerability of CA1 in the very young animals (P14) in this model has assumed special significance, in the light of emerging human data confirming abnormal signal in the CA1 region of some children after prolonged febrile convulsions. With this model, we also observed neuronal injury outside the hippocampus – in the amygdala, thalamus, cortex, caudate, and other regions. Injury to the thalamus was clearly discernible even in the P14 pup, but involvement of the cortex and amygdala was minimal at this age and steadily increased with brain maturation.

Studies of electrically induced status epilepticus (stimulation of the perforant path) have also provided evidence for injury in immature animals, but have also confirmed that such injury in immature animals is substantially milder than that encountered in adult animals.

Inflammation could be an important modifier of seizure-induced neuronal injury in the developing brain. When P10 animals are subjected to experimental hypoxia, they develop seizures but do not display neuronal injury. However, the neurologic outcome of newborns with hypoxia–ischemia as measured by microcephaly, cerebral palsy, etc. was worse in the subgroup of infants that experienced electrographic seizures in a study that matched the groups for Apgar score, initial pH, and base deficit; these observations suggested that the presence of seizures added to the hypoxic–ischemic injury. Another study that investigated brain injury in hypoxic–ischemic newborns, using signal changes in magnetic resonance spectroscopy for *N*-acetylaspartate (NAA), a marker of neuronal viability, confirmed an association between neonatal seizures and brain injury. The apparent disconnect, between the lack of brain injury as seen in experimental hypoxia–ischemia with seizures and the clinical consequence of hypoxia–ischemia when accompanied by

seizures, may be explained by the role of inflammation that commonly accompanies hypoxia–ischemia and seizures in clinical situations.

Our laboratory subjected P7 and P14 rat pups to lithium–pilocarpine SE after exposure to the bacterial endotoxin, lipopolysaccharide (LPS), a common experimental provocateur of inflammation. The CA1 vulnerability we had demonstrated in this model in the P14 animals in our earlier study was robustly enhanced by pretreatment with LPS (Figure 2). However, the dentate granule cells, hilus, and neurons in sector CA3 were unaffected. Even the P7 pup, usually resistant to neuronal injury in this model, showed selective CA1 injury following the combined LPS pilocarpine treatment. This enhancement of neuronal injury in the CA1 occurred in LPS-treated animals undergoing SE, even though LPS treatment did not result in increased temperature or prolongation of SE. Animals treated with LPS alone, but not subjected to SE did not show any injury.

An important link in humans connecting inflammatory signaling, early febrile seizures, and hippocampal sclerosis (with temporal lobe epilepsy) is suspected to be a specific polymorphism involving the interleukin-1β–511T allele. Our data support important interaction between inflammation and seizure-induced neuronal injury in the developing brain.

Genetic Influences

Some understanding of the role played by the genetic background in determining the vulnerability of the brain to seizure-induced neuronal injury has emerged in recent years. Schauwecker and Steward showed that SE induced by KA produced excitotoxic cell death in the CA3 and CA1 sectors of the Ammon's horn in 129/SvEMS and FVB/N strains of mice, in the same pattern as seen in rats. However, C57BL/6 and BALB/c mice showed considerable resistance to seizure-induced neuronal injury (although they exhibited comparable seizures); they exhibited excitotoxic cell death only at very high doses of KA, and only in a very restricted brain region. The C57BL/6 and BALB/c inbred strains appear to possess gene(s) that confer(s) protection from KA-induced excitotoxicity. The results reported in some articles describing the contribution of specific genes to cellular vulnerability, based on gene disruption manipulations, may have been confounded by the back-crossing process involved in generating the null hybrids. Consequence of null mutations should best be studied in mice with a pure genetic background. This important discovery also raises the hope, however, that we may understand the role of human genes in determining susceptibility to seizure-induced neuronal injury. Findings by Schauwecker and colleagues

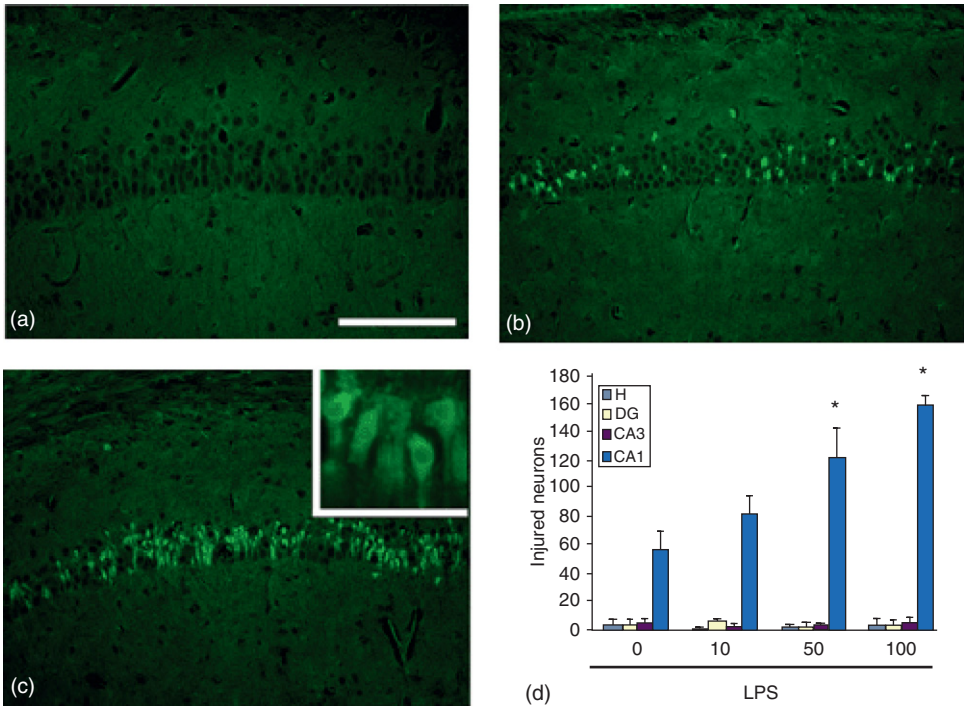

Figure 2 Lipopolysaccharide (LPS) plus pilocarpine (PC) induced hippocampal injury in 2-week-old rats. (a) LPS 100 μg kg^{-1} + vehicle lacks discernible CA1 neuronal injury; (b) vehicle + 60 mg kg^{-1} PC results in cell damage that becomes significantly more pronounced with (c) LPS 100 μg kg^{-1} + 60 mg kg^{-1} PC. High magnification inset in (c) demonstrates injured CA1 neurons with eosinophilic cytoplasm, irregularly shaped cell bodies and pyknotic nuclei. Scale bar is 200 μm for (a–c), 40 μm for inset. Graph (d) shows the mean hippocampal counts (± SEM) of damaged neurons with varying doses of LPS (0, 10, 50, and 100 μg kg^{-1}) + 60 mg kg^{-1} PC 24 h after SE. *$p < 0.05$ LPS0 vs. LPS50 or LPS100. H, hilus; DG, dentate granule cell layer.

provide a basis for reconciling at least some of the controversies in human data pertaining to the question of whether chronic epilepsy leads to ongoing neuronal injury.

Directions for Future Research

Knowledge gained from research on the mechanisms of seizure-induced neuronal injury is expected to influence the design of studies to investigate neuroprotection in the clinical setting. The diversity of targets, both extracellular (membrane receptors and ion-channels) and intracellular, suggests that multiple processes may have to be targeted simultaneously to achieve meaningful neuroprotection. Different clinical settings and different developmental stages may dictate distinct 'neuroprotective cocktails.' Laboratory studies should attempt to identify and include relevant variables that modify seizure-induced neuronal injury. Furthermore, increasing knowledge about the role of genetic background in conferring neuroprotection has the potential to be leveraged for the design of clinical interventions that could be based on the targeted activation of specific genes towards transcription and translation into neuroprotective factors.

The Ontogeny of Seizure-Related Programmed Cell Death in the Developing Brain

Introduction and General Overview

Due to controversies regarding the meaning of specific terms that are used to describe different forms of cell death, it is helpful to start by defining these terms.

Necrosis is a process involving cell death associated with the presence of specific cytoplasmic and inflammatory changes. These cytoplasmic changes consist of mitochondrial swelling, destruction of organelles, dilatation of endoplasmic reticulum (ER), and disruption of the plasma membrane leading to release of intracellular contents and inflammation. Nuclear chromatin is small, irregular, and dispersed within the intact nuclear membrane. Necrosis occurs as an independent process but may also occur in late stages of apoptosis, especially when energy reserves of the cell are depleted.

Apoptosis was originally described as a series of well defined and stereotyped morphologic changes in dying cells. It has features that are mainly specific to the nucleus. Typical features include cell shrinkage, phosphatidylserine exposure, formation of apoptotic bodies, and maintenance of organelle integrity with condensation and fragmentation of DNA. DNA fragmentation occurs in a two-step process. First, it is degraded into high molecular weight fragments, with chromatin condensation seen around the nuclear membrane. Second, DNA is degraded into smaller oligonucleosomal fragments (low molecular weight fragments). In its most classical form, apoptosis is seen when caspase 3 is activated. Detection of apoptosis is conventionally based on the use of two techniques, terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) that detects double stranded DNA fragments, and the agarose gel electrophoresis that detects 180 bp DNA fragments in the pattern known as DNA 'laddering.' These techniques were thought at one time to be specific for apoptotic cell death detection. However, both TUNEL positivity and DNA laddering may be present in apoptotic and necrotic cells.

The classic apoptotic pathway (Type II apoptosis) of cell death involves cleavage and activation of caspases which lead to oligonucleosomal DNA fragmentation. Apoptosis inducing factor (AIF) mediates caspase-independent cell death with DNA fragmentation of the type that results in HMW fragments ~50 kb (Type I apoptosis) rather than LMW fragments 200–1 000 bp (Type II apoptosis). Unlike Type II, Type I apoptosis is not detected by TUNEL staining and on agarose gel electrophoresis DNA 'laddering' is absent.

'Apoptosis like programmed cell death (PCD)' is a form of PCD with chromatin condensation that is less complete than in apoptosis, and with appearance of phagocytosis-recognition molecules before lysis of the plasma membrane. Most published forms of caspase-independent apoptosis, as well as some of the caspase-dependent apoptosis – such as tumor necrosis factor (TNF)-induced death of MCF-7 cells – fall into this class (i.e., apoptosis-like PCD).

Programmed necrosis (or necrosis-like PCD) is a form of PCD that occurs in the absence of chromatin condensation. It is a passive process of cell death in which there is rapid neuronal death, necrotic morphology, and activation of terminal steps of PCD (e.g., caspase activation and/or double stranded DNA breaks). It usually involves caspase-independent signaling pathways. Seizure-induced neuronal death is morphologically necrotic, but also includes programmed processes such as DNA laddering. A subgroup of necrotic PCD models are often described as involving 'aborted' apoptosis; that is, a standard apoptosis program is initiated, then blocked at the level of caspase activation, and finally terminated by alternative caspase-independent routes.

Programmed necrosis-like death or necroptosis as defined by Degterev *et al.* (2005) is a caspase-independent cell death mechanism. It is initially stimulated by the activation of Fas/TNFR family of death domain receptors that can trigger either extrinsic pathway of apoptosis or necroptosis. But in necroptosis Fas/TNFR family can induce cell death even when caspases are inhibited. Cell death under these conditions lacks the typical features of apoptosis and looks more like necrosis.

Autophagy (Greek, to eat oneself) is an intracellular degradation of cytoplasmic constituents within lysosomes. A portion of cytoplasm, including organelles, is enclosed by a phagophore, an isolation membrane, to form an autophagosome. The outer membrane of the autophagosome fuses with the endosome first and then with the lysosome, and the internal material is degraded. Although autophagy is commonly induced by necroptosis, both processes are independently regulated and in general necroptosis is distinct from autophagy and independent of autophagy for cell death execution. Autophagy has also a role in cell survival pathway under some circumstances such as starvation and growth factor deprivation.

Programmed cell death is a term sometimes used interchangeably with apoptosis. However, programmed necrosis

and autophagy are also programmed events. Thus, PCD is divided into apoptosis (type I PCD), autophagy (type II PCD), and programmed necrosis (type III PCD).

Background

The commitment to cell death depends on the activation of many signaling pathways.

Caspase-Dependent Pathways

The 14 members of the caspase family have been identified to be closely involved in the apoptotic process of the cell. These caspases are categorized as 'initiator caspases' (caspases 1, 2, 4, 5, 8, 9, 10, and 14) and 'effector caspases' (caspases 3, 6, and 7) based on their specific role in the apoptotic pathway. The two best-documented caspase-dependent pathways include the intrinsic and extrinsic pathways.

Intrinsic Pathway

The intrinsic pathway is activated by cell stressors that disturb the intracellular organelle function, such as elevated intracellular Ca^{2+} levels, growth factor (GF) withdrawal, chemotherapeutic agents, irradiation, or reactive oxygen species. These stressors lead to the activation of the proapoptotic Bcl-2 family proteins (such as Bax) and then to the release of cytochrome-*c* from the mitochondrial intermembrane space into the cytosol. In the presence of dATP, cytosolic cytochrome-*c* binds to the apoptotic protease-activating factor-1 (Apaf-1) and recruits an initiator caspase – caspase 9 – to form the apoptosome complex. This complex gives rise to an activated caspase 9, which in turn activates caspase 3 that initiates the execution phase of the cell death pathway. Caspase 3 activates caspase-activated DNase (CAD), which cleaves the DNA into 180-bp fragments (DNA laddering). CAD was found to be activated 48 h after kainic acid (KA)-induced status epilepticus (SE) (for 2 h); however, DNA fragmentation was first observed 24 h after SE, suggesting that another DNase might be involved in the early DNA fragmentation. Interestingly, caspase 3 was found not to be activated in injured neurons after SE, suggesting that either another enzyme activated CAD or another DNase is involved in the DNA fragmentation. The release of cytochrome-*c* and the fate of the cell are determined by the balance between antiapoptotic proteins (Bcl-2, Bcl-x, and Bcl-w) and the proapoptotic proteins (Bid, Bad, Bim, Bax, and Bak) of the Bcl-2 family. After KA-induced SE, Bad is dissociated from the protein 14-3-3 and dimerizes with Bcl-x. Bax, which is normally bound to Bcl-x, is then displayed and translocates to the mitochondria to release cytochrome-*c*. KA-induced SE also upregulates the dephosphorylation (active form) of the transcription factors of the forkhead in rhabdomyosarcoma (FKHR) family, including FKHR and FKHR-like-1 (FKHRL-1), which are translocated to the nucleus to upregulate Bim expression. In turn, Bim dimerizes with Bcl-w, triggering the release and activation of Bax.

The ER is the second important site (mitochondria being the first) for the initiation of the intrinsic apoptotic pathway. The activation of inositol (1, 4, 5) tris phosphate/ryanodine receptor, or the blockade of the sarcoplasmic/endoplasmic Ca^{2+} ATPase (SERCA), initiates Ca^{2+} release that instigates Ca^{2+}-dependent protease activation and apoptosis. The ER is also known to be connected, both physically and biochemically, with the mitochondria, so that any ER stress can lead to mitochondrial Ca^{2+} accumulation and dysfunction.

In addition, other factors such as ceramide may be involved. Ceramide, which causes PCD when added to neuronal cultures in vitro and when stereotaxically injected in the hippocampus in vivo, has been shown to increase during SE (Table 1 and Figure 1). Data from our lab indicate that these increases are at least partially secondary to sphingomyelinase activation. Administration of C2-ceramide causes apoptotic cell death in cultured rat cortical neurons and in SH-SY5Y human neuroblastoma cells. This process is associated with upregulation of active

Table 1 Hippocampal TUNEL and Hoechst stains and ceramide levels in different models of SE

Model and age	*TUNEL positivity*	*Hoechst #33342 (DNA clumping)*	*Increased ceramide levels*
Adult KA	+	+	+
P35 KA	+	+	+
P7 KA	–	–	–
Adult KA + MK-801 (1 mg/kg)	–	N/A	–
Adult KA + MK-801 (5 mg/kg)	–	N/A	–
Adult LiPC	+	+	+
Adult LiPC + MK-801 (0.2 mg/kg)	–	–	–
P21 LiPC	+	+	+
P7 LiPC	+	+	+

Note that models in which PCD occurs (positive TUNEL fluorescence and Hoechst DNA clumping) are accompanied by an increase in ceramide levels.

TUNEL, Hoechst and Ceramide procedures were performed 30 h after onset of SE that lasted >3 h. '+' indicates that $p < 0.05$ compared to sham manipulated controls (original data were reported previously: Mikati *et al.* (2003); Daderian R, Rizk E, El Dada S, Zeinieh M, Kurdi R, Harb S, Rahmeh A, Usta J, Dbaibo G, El Sabban M, and Mikati MA (2005). NMDA receptor activation results in ceramide increases and in apoptosis in lithium pilocarpine SE. *Epilepsia* 46(Suppl 6): 207). N/A = not applicable.

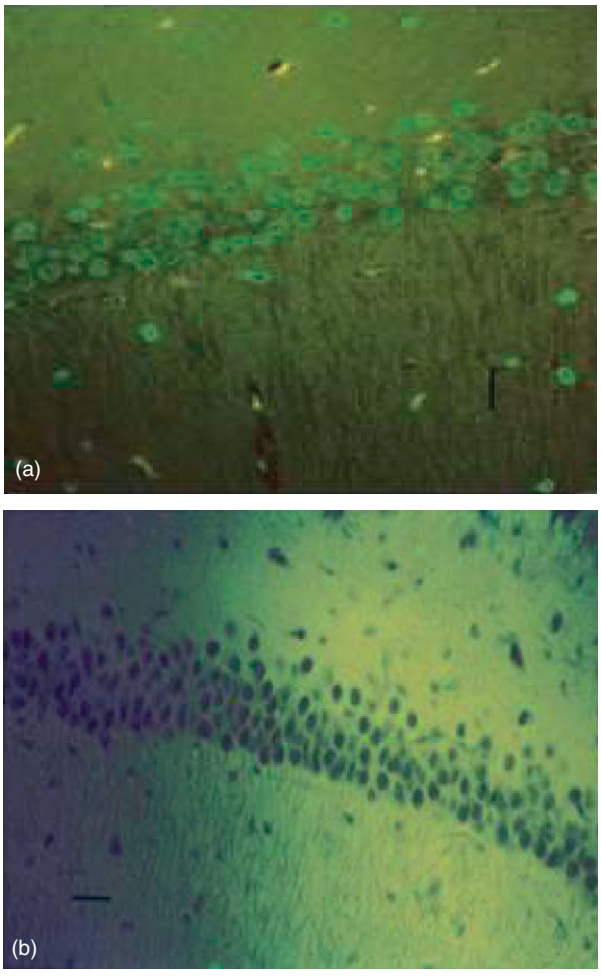

Figure 1 (a) TUNEL stain of the CA1 region of an adult rat injected with C2-ceramide (biologically active ceramide) as compared to (b) an adult rat injected with C2-dihydroceramide (biologically inactive ceramide). Scale bar, 20 μm. Note disruption of CA1 architecture and TUNEL positivity (yellow-light green fluorescence) induced by C2-ceramide (see also Mikati *et al*. 2003).

caspases 3 and 9, but without changes in active caspase 8 protein levels. The stereotaxic injection of the biologically active C2-ceramide results in increases in inositol triphosphate (IP3) levels in the hippocampus 2 h after injection (Figure 2). Ceramide has been shown to elevate IP3 levels in non-neural tissues. It has also been shown that IP3 increases in the hippocampus at 30 min, and peaks at 1 h following KA administration in mature animals. Type-III IP3 receptor activation contributes to PCD processes in T-lymphocytes and CHO cells by releasing intracellular Ca^{2+} stores from ER, and transmitting Ca^{2+} signals into mitochondria – thus activating the apoptotic mechanism. Thus, it is possible that ceramide exerts its effects through IP3 elevations. However, further studies are needed to prove or disprove this hypothesis, particularly since ceramide can have multiple other intracellular effects.

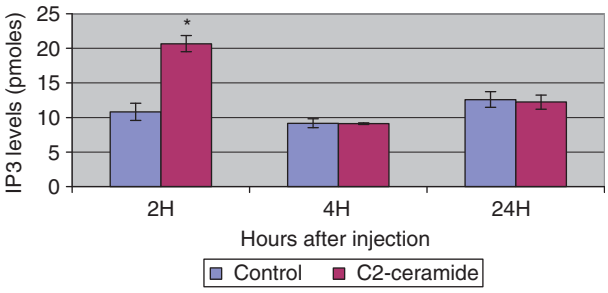

Figure 2 IP3 levels at 2, 4, and 24 h post vehicle and C2 ceramide injection. Data expressed as mean ± SE. $^*p < 0.05$ compared to control groups.

Extrinsic Pathway

The extrinsic pathway is initiated after the activation of 'cell death receptors', that is, after the binding of the ligands TNFα to TNFR1, FasL to Fas (CD95), and TNF receptor apoptosis inducing ligand (TRAIL) to TRAILR1 (DR4) and TRAILR2 (DR5). Once these receptors are activated, the cell death signal is propagated inside the cell by FADD (Fas associated protein with a death domain) recruitment in case of the Fas receptor, or TRADD (TNF-R1-associated death domain) recruitment in the case of the TNFR1. This recruitment then leads to activation of caspase 8, which will induce the apoptotic pathway either by cleaving and activating the effector caspases 3, 6, and 7 or by Bid. Cleaved or truncated Bid (tBid) dimerizes with Bax, resulting in the release of cytochrome-*c*, thus bridging the extrinsic and the intrinsic pathways.

Caspase-Independent Pathway

This cell death pathway, triggered by NMDA receptor activation, includes poly(ADP-ribose) polymerase-1 (PAPRP-1) activation, which produces AIF and endonuclease (Endo G) release and their translocation from the mitochondria to the nucleus, which in turn results in large-scale (50 kb) DNA cleavage and internucleosomal (180 bp) DNA fragmentation (DNA laddering), respectively. These changes are evident when KA is administered intra-hippocampally or systemically in mice. Also, calpain I, a cytoplasmic calcium-dependent cysteine protease, triggers Bid cleavage; tBid translocates to the mitochondria causing the mitochondrial release and translocation of AIF and EndoG to the nucleus.

Methods

Different techniques have been used in order to determine different types of cell death. The most common techniques used are terminal deoxynucleotidyl transferase-mediated biotin-dUTP nick-end labeling (TUNEL), ISEL, Hoechst 3342 staining, agarose gel electrophoresis

of DNA, and electron microscopy (EM). TUNEL is used to detect DNA fragmentation, but can only detect oligonucleosomal DNA breaks with 3′-OH ends (TUNEL and ISEL are similar in that they can only detect oligonucleosomal DNA breaks with 3′-OH/5′-P ends). TUNEL was initially thought to be specific for apoptosis; however, some studies have shown that TUNEL-positive cells had necrotic morphology – i.e., the case of cells dying through programmed necrosis. The Hoechst 33342 nuclear stain (DNA-sprcific dye bis-benzimide) allows the in situ detection of chromatin condensation, which constitutes one of the morphological features of apoptosis. Agarose gel electrophoresis of DNA is used to determine the type of DNA fragmentation: If oligonucleosomal bands separated by approximately 200 bp (also known as DNA 'laddering') is observed, one can conclude that the cell is dying either through apoptosis or programmed necrosis. If a DNA smear pattern is apparent, then necrosis is the mechanism by which cells are dying. EM gives a detailed characterization of the dying cell by analyzing the different compartments of the cell, particularly the nucleus and its components.

Recent Results – Ontogenic Differences in SE Induced Apoptosis/Necrosis

Several studies have shown that mature and immature rats are often affected differently by SE. Immature animals have often been shown to be resistant to the development of neuronal injury even after severe KA-induced SE. However, a number of recent studies have indicated that the immature brain does exhibit apoptosis and/or necrosis after undergoing different types of experimental SE. These results show that the relative resistance of the immature brain to SE-induced apoptosis/necrosis is model-dependent.

Pilocarpine and Lithium-Pilocarpine Models

In these models, the administration of convulsant doses of pilocarpine (with or without lithium) produces widespread apoptotic and necrotic neuronal injury in adult as well as in immature rats. Animals at different ages show region-specific differences in types of cell death. The immature brain appears to be more likely to manifest apoptotic cell death, whereas the mature brain is likely to manifest necrosis. The pattern, the localization, and the severity of neuronal injury in this model are age-dependent, as demonstrated in studies of 2-, 3-, and 4-week-old rat pups (and adult rats) 24 h after LiPC-induced SE. The damage seen in 2- and 3-week-old pups appeared to involve both necrosis (as evidenced by the eosinophilic cells) and apoptosis (as assessed by different techniques such as TUNEL staining, visualization of fragmented nuclei under fluorescence microscopy of ethidium bromide-stained sections, EM, and DNA electrophoresis). In the 2-week-old pups, necrotic cells were predominant in the CA1 subfield, whereas the apoptotic cells were predominant in the CA1 region, in subiculum and in thalamus. In the 3-week-old animals, necrotic cells were evident in the CA1 and CA3 hippocampal subfields, in the hilus, and in granule cells of the dentate gyrus; the apoptotic cells were seen only in the inner layer of the dentate granule cells and in a few thalamic neurons. In the 4-week-olds and in adult animals, only necrotic cells were apparent in the hilus, CA3, CA1 and granule cells. In adult rats at 24 and 72 h after 3 h of LiPC-induced SE, there was necrotic cell death in the hippocampus, amygdala, and piriform, entorhinal, and frontal cortices, despite the presence of DNA laddering in these regions 24 and 72 h after SE and the presence of positive TUNEL staining in some of the regions 72 h after SE. The results of these and other studies suggest that LiPC-SE produces neuronal injury with the morphological features of necrosis rather than apoptosis, and that internucleosomal DNA cleavage and other PCD phenomena can be activated by SE in neurons which become necrotic. Pups, 7–9 days old, subjected to three consecutive episodes of SE-induced by systemic pilocarpine injections showed apoptotic cell death, evaluated by TUNEL staining, in the hilus, granule cells, and thalamus 24 h after the last SE episode. In the LiPC model, the mechanism of SE-induced damage in the mediodorsal thalamic nucleus at P12 was shown to be necrotic rather than apoptotic. This conclusion was based on evidence using several different techniques, including EM, TUNEL staining (negative), caspase 3 and cytochrome-*c* immunocytochemistry (negative) in the thalamus, and OX-42 immunostaining (positive) of microglial cells in the central and lateral segments of medidorsal nucleus (supporting the idea of inflammation in the damaged area). After 2 h of seizures induced by LiPC in 2-week-old rat pups, semi-thin, toluidine blue-stained sections showed extensive neuronal injury in the CA1 region, and EM showed that most of these cells have a necrotic morphology. However, 24 h after 2 h of seizures, the majority of neurons in the CA1 had an apoptotic morphology. This result suggests that the same seizures kill different neurons in the same population of CA1 subfield at different rates and by different processes.

In another study, P19 and adult rats were treated with LiPC subcutaneously and intra-abdominally to evoke SE. The presence of the apoptotic neurons, using TUNEL staining, was detected in the CA3 of hippocampus, dentate gyrus, and cortex of the temporal lobe, starting 30 min (and lasting up to 8 h) after SE. Although the count of total dead neurons was higher in normal infant rats than in adult rats, the count of TUNEL-positive neurons in mature brain remarkably increased and exceeded that in immature brain at 30 min after hypoxia. There is also an increase in the expression of p53 in the

immature and adult rat following LiPC-induced SE. Induction of p53 occurred in the hippocampal subfields, piriform cortex, amygdala and thalamus at P15, P21 and in adult rats after LiPC-induced SE, but was maximal in P21 rats. Double-labeling experiments revealed that p53 was co-localized with NeuN and with TUNEL positivity. Our group demonstrated that LiPC-induced SE results in ceramide increases and in TUNEL positivity in the hippocampi of both adult and P21 rats (Table 1). LiPC-induced DNA fragmentation was maximal in the CA1 subfield in both age groups. These combined findings may be important because several studies have shown the relationship between ceramide and p53, both of which are involved in apoptotic signaling pathways. Even though this relationship has not yet been investigated in SE, ceramide has been shown to trigger p53-dependent apoptosis in fibrosarcoma tumor cells and in SKN-SH cells. In addition, in human glioma cells treated with etoposide (a DNA topoisomerase II inhibitor), p53 activation was shown to modulate ceramide generation by neutral sphingomyelinase activation.

Kainic Acid Model

The type of seizure in this model depends very much on the mode of administration of KA. Apoptosis commonly occurs in the immature brain after stereotaxic injection of KA into the brain, but this pattern is not the case after intraperitoneal injection (i.p.). The latter is probably a better model of SE, as the injury associated with systemic KA injection may be more closely related to SE rather than to the direct effects of KA itself. Whether KA is stereotaxically injected or given i.p., adult rats often show necrotic morphologic changes with DNA fragmentation probably representing programmed necrosis.

The types of neuronal loss after intracerebroventricular infusion of KA (10 or 50 nmol) to P7 rats have been investigated. Brain sections were examined at several neurodevelopmental time points (P8, P14, P25, P40, P60, and P75) to assess neuronal loss, and to search for evidence of necrosis and apoptosis. This analysis showed that KA administration caused both immediate and delayed hippocampal neuronal damage in the CA1 and CA3 subfields. The effect of KA was dose-dependent, and the delayed neuronal damage occurred through apoptosis. Another study investigated the effect of a single bilateral intracerebroventricular infusion of KA (50 nmol in 1.0 µl) on neurodegeneration in P7 pups. Progressive loss of neurons in the CA1 and CA3 subfields of the hippocampus, at P14, P25, P40, and P60, was detected. TUNEL staining showed apoptotic cells mainly in the CA3 subfield, and the TUNEL-positive cells decreased with age. Twenty-four and seventy-two hours after 3 h of KA-induced SE in adult rats produced necrotic cell death in the hippocampus, amygdala, and piriform, entorhinal, and frontal cortices, despite the presence of DNA laddering in these regions 24 and 72 h after SE and positive TUNEL staining in some of the regions 72 h after SE. The authors concluded that KA-SE induces neuronal injury with the morphological features of necrosis rather than apoptosis. Moreover, neuronal cell death with morphological features of necrosis was found at 12, 24, and 48 h after KA administration to adult rats, in the entorhinal and piriform cortices, basal amygdala, certain thalamic nuclei, and CA1 region of the hippocampus. In addition, a small number of apoptotic-like cells were observed in the same regions, using in situ labeling of nuclear DNA fragmentation. Typical necrotic cells were not stained with this method. A single intra-septal injection of kainate in adult rats induced apoptosis in the medial septum and amygdala, while the lateral septum exhibited a lower but significant incidence of apoptotic cells. TUNEL staining revealed a time-dependent sequential apoptotic cell death in hippocampal pyramidal cells. During the first two days postinjection, apoptosis in the hippocampus was only evident in the CA3 region. At 5 days postinjection, the apoptotic changes extended to the CA4 region, and at 10 days postinjection to the whole CA1 pyramidal cell region. Our group demonstrated that, in both adult and P35 rats, the administration of a convulsant dose of KA (15 mg/kg i.p) induces severe seizures and produces changes indicative of PCD (TUNEL positivity, DNA clumping in Hoechst 33342 staining) and ceramide increases in the hippocampus. The morphology of the injured cells was usually necrotic, and TUNEL positivity was present in only a few of the injured cells. These histological changes were the most severe in the CA3 and CA1 subfields. In immature P7 pups, the administration of a convulsant dose of KA (3 mg/kg) produced severe seizures, but did not induce increases in ceramide levels nor hippocampal PCD 30 h after KA injection, as assessed by TUNEL and Hoechst 33342 staining (Table 1). Of note is that young animals do not manifest the late stages of SE after KA (as seen in older animals) and require smaller doses to manifest seizures. These differences in the stages of SE may, thus, underlie the above reported differences in the presence or absence of injury and in the type of injury noted after KA-induced SE. Thus, the type of injury in the KA model depends on the mode of administration which may influence the severity of the seizures and mechanism of excitotoxicity.

Perforant Path Stimulation Model

In this model, the mature and the immature brains manifest similar types of cell death mostly consistent with programmed necrosis, although more apoptotic changes are probably seen in the immature brain. Perforant path stimulation, in P14-P16 rat pups, causes extensive hilar

cell and mild CA3 pyramidal cell necrosis evaluated at 2 and 24 h after stimulation. In situ end-labeling (ISEL) stain performed 2 h after the end of 16 h of stimulation reveals an intense band of positively labeled eosinophilic cells in the granule cells of the dentate gyrus, while control animals show no in situ end-labeling in that area. The positively labeled cells are not seen 24 h later, suggesting that they are rapidly scavenged apoptotic cells. In adult rat hippocampi, prolonged afferent perforant path stimulation produces neuronal death in all hippocampal subfields, particularly in the hilus. Degenerating hilar neurons and pyramidal cells exhibit the morphological features of necrosis, while degenerating granule cells exhibit all the morphological features of apoptosis after 24 h of perforant path stimulation.

Corticotropin Releasing Hormone Model

The morphologic alterations of neurons 16 h after SE induced in P10 and P11 rat pups by the neuropeptide, corticotrophin-releasing hormone were investigated. The morphological features of the degenerating neurons in the pyramidal cell layer of the CA3 region were suggestive of apoptosis, as assessed by EM and osmium tetroxide (showing dense staining of the degenerating neurons). In adult rats, CRH produces seizures, but does not cause any neuronal degeneration. In addition, the doses needed to induce seizures in adults are much higher than doses needed in infant rats.

Homocysteic Acid Model

The morphologic changes in the cerebral cortex and hippocampus of P12 pups, at 6 days after generalized clonic-tonic seizures induced by bilateral intracerebroventricular infusion of homocysteic acid (HCA) (600 nmol/side), were examined. In the granule cell layer of the dentate gyrus, neurons with fragmented nuclei in various stages of degeneration were detected (using Hoechst staining), and displayed the features of apoptotic death. This hypothesis was fully supported by results of the EM analysis.

Flurothyl Inhalation Model

In this model, the immature brain was shown to manifest both types of cell death – apoptosis and necrosis – whereas the mature brain manifested only necrotic cell death. When P20 rats were subjected to seizures by daily flurothyl inhalation for 6 days, edema, degeneration, and necrosis of nerve cells in cerebral cortex were observed, accompanied by inflammatory cell infiltration and apoptosis. Flurothyl-induced SE in adult rats leads to necrosis of the substansia nigra pars reticulate (SNPR), globus pallidus (GP), neocortex, thalamus, hippocampus, and amygdala. Histopathological damage was assessed by celestine blue and acid fuchsin stains.

Hyperthermia Model

In this model, in which, febrile seizures are induced by a hyperthermal bath with 40–45°C water, the immature brain was shown to manifest both types of cell death (apoptosis and necrosis) whereas the mature brain manifested only apoptotic cell death. Febrile seizure (FS) induced by hyperthermia results in necrosis in the hippocampal CA1 region in P21 rats, as assessed by EM. In contrast, 10 recurrent febrile seizures (induced once every 2 days) in P21 rats induced an increase in apoptotic cells in the hippocampal CA1 neurons as detected by TUNEL. P10 rats subjected to hyperthermia (up to 41–42 °C) by using a regulated stream of moderately heated air to induce seizures, show an abundance of argyrophilic neurons in the central nucleus of the amygdala and in the CA1 and CA3 pyramidal cell layers 24 h later. Neuronal injury in this model is not associated with significant DNA fragmentation (as detected by ISEL). Neurons in the hippocampal CA1 region and dentate gyrus of adult rats subjected to FS exhibited increased mitochondrial volumes with vacuoles, condensed matrix, and apoptotic bodies.

Future Directions

From all of the above data, we can conclude that both apoptosis and necrosis can occur in the developing brain following SE. In some models, including LiPC and intracerebroventricular KA, CRH and Homocysteic acid models, the developing brain is more likely to manifest apoptosis whereas the mature brain manifests necrosis. In these models the predominance of apoptosis in the developing brain may be related to its reliance on glycolysis (with a resultant resilience against energy failure), and to the constitutive and higher expression of many of the apoptotic factors (e.g., cyclin-dependent kinases, caspases, and immediate early genes) which reduce energy requirements for the apoptotic process and consequently favors apoptosis over necrosis. In other models, such as perforant path stimulation, flurothyl inhalation, and hyperthermia, necrosis – with or without apoptosis – has been observed in the immature brain. This variability suggests specific vulnerabilities of the developing brain to different types of SE.

Although significantly elucidated in the adult brain, the mechanisms of SE-induced apoptosis and necrosis are still not completely understood and remain to be investigated in the developing brain. Specifically, the Bcl-2 family proteins, cytochrome-*c*, caspases 3, 6, 7, 8, and 9, AIF, Fas receptor, and others that have been shown to be important in PCD in the adult brain, have not

been investigated in the developing brain. There is some evidence, as reviewed above, that PCD in the developing brain in the LiPC model, as in the adult brain, may involve activation of p53- and ceramide-related pathways. The mechanisms leading to the vulnerability of specific cell types, at specific ages, in specific SE models leading to apoptosis, are still also largely unknown and await further investigation. Additionally, one of the questions in need of further investigation in immature animals is whether – and more importantly, how – apoptosis and necrosis related mechanisms can coexist in the same degenerating cell in the brain? How does one process (i.e., apoptosis or necrosis) lead to another? It also remains to be determined whether SE-induced PCD – in any of the above models – results from activation of a single pathway or (more likely) by activation of multiple simultaneous and inter-related pathways. Despite the many questions that remain to be answered, it is clear that SE-induced cell death manifests significant age-, cell type-, region-, and model-related differences. And that apoptosis is an important mode of neuronal injury in the developing brain.

Attention Deficit Disorder and Epilepsy in Children

R Schubert, New York Methodist Hospital, East Pavilion, Brooklyn, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction and Background

Epilepsy and attention deficit disorder with and without hyperactivity (ADHD/ADD) are highly prevalent in children and adolescents. The CDC estimates that 4.4 million youths aged 4–17 have been diagnosed with ADHD by a healthcare professional, and as of 2003, 2.5 million youth aged 4–17 were receiving medication treatment for the disorder. The current prevalence of ADHD in the United States is about 5%. The association between ADHD/ADD and epilepsy has been well established since 1955, when Ounsted first reported an elevated incidence of children with hyperactivity in his population of 830 children with epilepsy. Behavior problems of all kinds are 4.8 times more common in children with epilepsy than in the general population, and are still about 2.5 times more common in children with recurrent seizures than in children with non-neurological chronic illnesses such as asthma. The incidence of ADHD/ADD is elevated in children with epilepsy not only when compared with the general population, but also when compared with children with other chronic neurological disorders, as first reported in Rutter's Isle of Wight study. Since then, numerous publications have documented prevalence rates of ADHD/ADD of about 30–40% in children with epilepsy. One recent study noted that ADHD was the most common comorbidity of children with intractable epilepsy referred for presurgical evaluation. The majority of studies have also shown an increased incidence of ADHD/ADD in children with newly diagnosed idiopathic epilepsy. Interestingly, the association between new-onset epilepsy and ADHD is limited to the predominantly inattentive type of ADHD, not the hyperactive or combined types. The diagnosis of ADD predates the diagnosis of epilepsy in most cases. Seizure type, etiology, sex, or seizure frequency at diagnosis do not affect this association, but attentional problems become more frequent over time in children with uncontrolled seizures and persistent interictal abnormalities. Several authors have postulated that ADHD is the most frequent behavioral disorder in children with epilepsy. This association has far-reaching consequences, and has a great impact on social and academic functioning. Children with ADHD and epilepsy have lower academic outcome, lower adaptive scores, and a three-times greater likelihood of lowered health related quality of life than children with epilepsy but without attentional or behavioral problems.

Methods

The diagnosis of ADHD is still made clinically, predominantly by using observer behavior rating scales. Supportive information can be provided by formal neuropsychological testing and continuous performance tests. PET and functional MRI (fMRI) are utilized as research tools. A wide variety of behavior rating scales are available. Commonly used scales include Conner's rating scales, Vanderbilt scales, SNAP-IV, Aschenbach scales, and Child Behavior Checklist. These scales screen for core symptoms of inattention,

hyperactivity, and impulsivity. Most also provide information on oppositional defiant behaviors and symptoms of conduct disorder, as well as an overview of classroom academic performance. Assessments via rating scales are typically made by parents and teachers, although adolescent and adult self-rating scales are also utilized. Shorter follow-up rating scales are used to monitor treatment response. Additional observer and self-rating scales are sometimes used to screen for co-morbid disorders, such as anxiety, depression, and mood dysregulation.

Continuous performance tests are computerized tests of attention. Typically, a series of varying shapes, pictures or letters flash on the screen, and the test subject has to click a mouse button whenever the correct figure appears. The tests typically measure errors of omission (not clicking at the appropriate stimulus) – which correlate with inattention, and errors of commission (clicking when you shouldn't click) – which correlate with impulsivity. Time needed to click and variability of response time are also measured. These measures are typically increased in individuals with ADHD. Formal neuropsychological testing provides additional evidence of frontal lobe dysfunction by demonstrating deficits of working memory, planning, sorting, and shifting attention between sensory modalities.

Summary of Current Research Results

Epidemiology

The prevalence of ADHD in epilepsy populations is quite high. Further, compared with ADHD in the general population, ADHD in epilepsy populations shows some interesting differences. As noted earlier, the purely inattentive type of the attention deficit disorder is much more common in children with both chronic and newly diagnosed epilepsy than in children without epilepsy. Although in the general population ADHD is 4 times more common in boys than in girls, there is no gender predilection in children with epilepsy – perhaps reflecting the much higher proportion of the predominantly inattentive type in epilepsy, which is more common in girls than in boys.

Diagnosis

Continuous video-EEG monitoring has become the gold standard for the diagnosis of epilepsy and characterization of seizure type. Unfortunately, no similarly reliable tool exists for the diagnosis of ADHD, which is generally made based on behavior rating scales. These scales are sometimes augmented by more detailed neuropsychological testing and continuous performance tests, but this type of testing is time-consuming and expensive and difficult to perform in children with developmental disabilities. Symptoms of ADHD and epilepsy can overlap. For instance, daydreaming could be due to absence or partial complex seizures, postictal impairment or inattention. In children with confirmed epilepsy, continuous video EEG-monitoring may be necessary to determine whether a particular clinical event is due to breakthrough seizures or untreated ADHD. Children with ADHD but without epilepsy have a higher incidence of interictal spikes than seen in the general population, leading to further diagnostic confusion. In spite of the high prevalence of ADHD in children with epilepsy, it is advisable to proceed with caution and to re-evaluate the diagnosis repeatedly over time, particularly if the response to treatment is poor.

Pathophysiology

The pathophysiology of ADHD in the general population is thought to be related to dysfunction of dopaminergic and noradrenergic circuits in the prefrontal cortex and subcortical areas. Dopaminergic pathways are involved in inhibition and motor control, while noradrenergic pathways are involved in arousal and maintenance of attention. Causes for dysfunction in these systems are usually genetic, although environmental factors may contribute. To be sure, behavioral disturbances of all kinds, in individuals with epilepsy, are due to a complex interaction between biological and psychosocial factors. Biological factors include neuronal cell loss owing to frequent seizures, disruption of vital brain circuitry at critical periods of development, medication side effects, sequelae of frontal lobe epilepsy surgery, and postictal depression of brain activity. Biological factors can be permanent, such as congenital brain malformations, consequences of head trauma or perinatal asphyxia, etc. Biological contributions may also be transient (i.e., 'state dependent'), such as postictal impairment, sleep disruption from seizures, medication side effects, or postictal impairments. Psychosocial factors include family dynamics and dysfunction, disruption of family life due to the seizures, psychosocial stigmatization, and restriction of activities due to seizures. It is a major challenge of research in this area to try to evaluate how, and to what extent, each of these factors are responsible for a particular child's impairment. A meta-analysis of 46 studies from 1988 to 2003 showed that while behavioral problems of all kinds were significantly increased in children with epilepsy, attentional, thought, and social problems were specifically related to epilepsy rather than family factors or the presence of chronic illness. The fact that ADHD/ADD diagnosis precedes the diagnosis of epilepsy in a significant number of cases suggests that common biological factors cause both disorders, at least in some cases.

Role of Interictal Discharges

The effect of interictal discharges on cognition and attention has come under increasing scrutiny in the past 20 years. Impairment of cognitive functioning was first demonstrated

in childhood absence epilepsy. In the 1980's, transient cognitive impairment (TCI) was demonstrated to occur during both generalized and focal interictal discharges. Focal spikes specifically impaired cognitive functioning in the area(s) involved in spike generation. Interictal spiking of all kinds can also impair attention indirectly, by lowering quality and quantity of sleep. Some studies suggested that these effects can be reversed with anticonvulsant therapy, but those results have been inconclusive. Children with ADHD (but no diagnosed epilepsy) have an increase in epileptiform abnormalities on interictal EEGs when compared to the general population, particularly rolandic spikes. The incidence of interictal spikes may be as high as 30% in this population, compared to an incidence of 3.5% in typically developing school age children. This observation raises the question of whether treatment of these abnormalities can improve neurodevelopmental outcome. One study of a small number of children with interictal spikes, but no clinical seizures and various neurodevelopmental disorders including ADHD, found an 80% improvement in developmental outcome with chronic anticonvulsant therapy. Many anecdotal reports are consistent with these results, but there are no controlled studies with large numbers of children.

Some recent studies suggest that prolonged focal epileptic activity during sleep may permanently impair learning. Frontal lobe executive functioning, which is also impaired in ADHD/ADD, appears to be particularly vulnerable to disruption by interictal spiking during childhood – i.e., during the period of greatest neuronal plasticity. Even temporal lobe epilepsy may permanently affect frontal lobe functioning in children, by disrupting temporal lobe input to the frontal lobes during a critical period of neuronal maturation.

Research on the Interaction of the Type of Epilepsy and ADHD

Benign childhood epilepsy with centrotemporal spikes (BCECT)

Numerous studies have shown a very high prevalence of cognitive and behavioral dysfunction in benign childhood epilepsy with centrotemporal spikes (BCECT). This association is sufficiently well-established so that BCECT is no longer thought of as a 'benign' epileptic syndrome. Furthermore, BCECT probably represents one of a spectrum of rolandic epilepsies, ranging from benign to severe. Typical BCECTS represents the mildest form of this disorder, atypical benign partial epilepsy or pseudo-Lennox syndrome is in the intermediate part of the spectrum, and Landau–Kleffner syndrome is at the severe end. The presence of rolandic discharges is associated with increased impulsivity in children with ADHD/ADD. Several detailed studies of neuropsychological performance in children with rolandic discharges have shown that cognitive and behavioral dysfunction is related to duration and anatomical distribution of interictal spiking rather than to number or duration of clinical seizures. Transient impairments of attention and learning have been demonstrated in direct relationship to frequency of interictal spiking in children with BCECTS. One study suggested that attention is impaired with children with right-sided or bilateral rolandic discharges, as opposed to children with purely left-sided focal discharges. Other studies have shown that morphology of the epileptic dipole is related to cognitive and behavioral problems. Specifically, discharges with a frontal-temporal dipole had fewer cognitive problems than children with focal central, temporal or centrotemporal discharges. Studies of small numbers of children suggest that these effects are reversible with anticonvulsant therapy, but results have been conflicting and have not been sufficiently striking to cause a change in treatment guidelines for children with BCECT. Permanent cognitive dysfunction may be related to the significant increase in interictal spiking during non-REM sleep, particularly if this occurs during critical periods of development of fronto-temporal circuits. BCECT and related epilepsy syndromes may be associated with electrical spike-wave during sleep (ESES); persistence of ESES for more than two years is associated with permanent cognitive and behavioral changes, even after remission of the epilepsy and normalization of the EEG.

Temporal lobe epilepsy

Temporal lobe epilepsy (TLE) has primarily been associated with an impairment of memory, which is generally already present at the time of diagnosis. Neuropsychological studies have shown impairments of frontal lobe executive functions in children with TLE, most likely due to interruption of fronto-temporal circuits.

Frontal lobe epilepsy

Frontal lobe epilepsy has not been studied as extensively as BCECT, but the literature that exists suggests the presence of significant attentional problems. One retrospective study of 21 children with non-lesional frontal lobe epilepsy demonstrated ADHD/ADD in 2/3 of the population, while half of the children had cognitive impairments. Another study evaluated 16 children with frontal lobe epilepsy via an extensive neuropsychological test battery and continuous performance testing. The authors found significant impairments of attention and inhibition when compared to children with temporal lobe and childhood absence epilepsy. Frontal lobe seizures can also present with ictal behaviors which are difficult to distinguish from ADHD, such as screaming, kicking and flailing of the extremities (so-called 'hyperkinetic seizures'). Video EEG-monitoring may be necessary to arrive at the correct diagnosis.

Occipital lobe epilepsy

Idiopathic occipital lobe epilepsies are associated with visuoperceptual problems, lowered IQ, and behavioral

problem such as anxiety and depression, but not with ADHD/ADD.

Idiopathic generalized epilepsies

Childhood absence epilepsy very often presents as school failure, and causes significant impairment of attention if untreated. However, deficits of attention have been demonstrated even in children with well-controlled absence and generalized tonic clonic seizures. Adolescents with juvenile myoclonic epilepsy (JME) may have personality changes and even personality disorders, although the literature has been conflicting on this point. These patients have been described as impressionable, easily influenced and unreliable – features that have been attributed to subtle frontal lobe dysfunction. ADHD/ADD has not been specifically associated with JME, although one recent study of 50 patients with juvenile myoclonic epilepsy demonstrated widespread dysfunction on a detailed neuropsychological test battery, which included tests of attention and executive function.

Severe epilepsies of childhood

Severe epilepsies of childhood have long been associated with poor cognitive outcome and behavioral problems, typically following a developmental regression at the time of onset of seizures. Hyperactivity and attentional problems are particularly common in infantile spasms, severe myoclonic epilepsy of infancy, Lennox Gastaut syndrome and Landau Kleffner syndrome. These patients usually are treated with polytherapy, which may further contribute to behavioral and attentional impairments. The etiology of these impairments is uncertain, and does not appear to be related to specific seizure frequency or EEG patterns. The behavioral problems improve over time when the seizures remit, but permanent impairment is the rule. It has been shown that early initiation of treatment improves cognitive outcome in infantile spasms. Generally, poor behavioral and cognitive outcome correlates with early seizure onset, particularly if seizures start in the first year of life.

Effect of Anticonvulsants on ADHD

Anticonvulsants can affect behavior and attention in children with epilepsy, although this effect may be subtle and may be overshadowed by the positive effects due to reduced seizure-frequency. Increased rates of hyperactivity and distractibility were initially demonstrated for the older anticonvulsants, particularly phenobarbital. One study of 109 children with febrile seizures, who were treated with phenobarbital and had therapeutic anticonvulsant levels, showed a significant increase in hyperactivity. However, subsequent controlled studies in individuals with partial complex seizures only showed subtle effects on attention and concentration, once results were controlled for seizure frequency and anticonvulsant levels. Among the newer anticonvulsants, cognitive complaints–including impairment of attention–are particularly common with treatment with topiramate, although slow titration reduces this symptom considerably. Levetiracetam has behavioral side effects as high as 10%, including increase in aggression and irritability, but has not been shown to significantly affect attention. Lamotrigine has been shown to have no adverse effect on attention and may have favorable effects on mood and behavior. However, lamotrigine, gabapentin and tiagabine have been reported to cause absence status, which can imitate the inattentive type of ADHD. Gabapentin may cause somnolence and has been reported to cause increased aggression in children with developmental disabilities. Oxcarbazepine does not appear to cause any impairment of attention or behavior when compared to children treated with carbamazepine or valproate.

Behavioral side effects of anticonvulsants are generally thought to be more common with polytherapy than with monotherapy, regardless of the anticonvulsant used, although one recent study didn't find any differences in behavioral scores of children treated with 0, 1, 2 or 3 anticonvulsants. Negative effects on attention and behavior can be diminished by a slow titration schedule and decreases in dosage. Drug effects on behavior must be distinguished from the so-called 'release phenomenon,' which refers to the appearance of hyperactivity in children that were previously oversedated due to frequent, uncontrolled seizures.

Does ADHD resolve when epilepsy is treated? State-dependent biological factors such as postictal impairment, medication side effects, and postictal psychosis contribute significantly to the attentional problems in children with epilepsy. Studies have shown progression of these effects over time, and raises the question of whether attentional problems and associated executive dysfunction may be reversible–if the underlying epilepsy is successfully treated, particularly if complete seizure control is achieved quickly. Similarly, impairment of family dynamics due to the child's chronic illness would also be expected to improve when the seizures are controlled. So far, this result has not been documented in the medication literature. The consensus is that ADHD should be treated separately, with appropriate medications.

Treatment of ADHD in Children with Epilepsy

There are no treatment guidelines for children with ADHD/ADD and epilepsy, but treatment of ADHD symptoms is clearly justified considering that ADHD/ADD contributes significantly to the morbidity of epilepsy in children. A stepwise approach seems warranted in view of the complexity of ADHD/ADD in this population. Children with behavioral and attentional problems should

be evaluated further for degree of seizure control, the presence of nocturnal interictal discharges, and anticonvulsant side effects. They also should be evaluated for proper educational placement (as is the case for children with ADHD/ADD without seizures). Behavioral measures (e.g., reward systems, timers, and other devices to improve focusing, homework trackers, and so on) should be implemented when these evaluations indicate their appropriateness. Medications used to treat ADHD in children with epilepsy are the same as those used in children with ADHD alone, including stimulants such as methylphenidate and dextroamphetamine, and the non-stimulant medication atomoxetine. Controlled trials have proven the efficacy of stimulants, in particular methylphenidate, for children with ADHD. Methylphenidate has also repeatedly been shown to be effective and safe in many studies (of small numbers) of children with epilepsy and of children with interictal abnormalities but without clinical seizures. It should be noted, however, that some investigators have found that methylphenidate may increase the risk of breakthrough seizures in children with uncontrolled epilepsy (although the numbers of children studied were very small). One recent review of the atomoxetine clinical trials database and the atomoxetine postmarketing spontaneous adverse event database did not show an increased incidence of seizures in children who were treated with atomoxetine versus methylphenidate versus placebo. There are no controlled trials of the use of atomoxetine in children with epilepsy. There is very little literature on amphetamine products, but there is no evidence to suggest that these medications increase the risk of epilepsy when used in therapeutic doses. Only buproprion has been associated with an increased risk of epileptic seizures.

Challenges for the Future

Assessment of ADHD in Epilepsy Populations

There are many problems involved in assessing ADHD/ADD in children with epilepsy. The lack of objective measures is a major issue. Behavior rating scales and their cutoff scores haven't been validated in epileptic populations and are prone to observer biases. Continuous performance tests are an attempt at objective measurement of behavior and attention, but they only measure one type of attention (generally sustained attention) and represent only a snapshot of the individual's behavior and attention. They also require at least some cooperation from the child, making them difficult to use in developmentally disabled populations. These measures are unable to adjust for marked fluctuations of behavior and attention, such as can occur owing to postictal state, interictal discharges, medication side effects, and even motivation or lack of sleep. The ideal assessment tool would provide a reliable, objective and quantifiable measure of attention and behavior over time. Results should correlate with educational and social outcome, as recorded on quality of life studies and reviews of academic achievement. Modern imaging tools, which assess state-dependent changes in cerebral blood flow, metabolism, oxygenation, and neurotransmitter status, might be able to fulfill this role.

Role of Interictal Activity

The assessment of the role of subclinical seizures, and interictal spikes without clinical seizures, is another major challenge. There is increasing evidence that treatment of interictal spikes may improve long-term developmental outcome, but there are to date no well-controlled studies of large numbers of children. We need guidelines to determine when to initiate treatment, which treatment is beneficial, when to stop treatment, and how to determine that treatment has been successful or has failed. Should children with interictal abnormalities be treated, regardless of the presence or absence of developmental impairments? Should only nocturnal spikes be treated or only specific focal interictal spikes? Should treatment be continued until the EEG normalizes? How long would one monitor these patients to determine that treatment has been successful?

Other Questions

Other questions which need to be answered include:

1. Which biological factors contribute most significantly to the high incidence of ADHD/ADD in children with epilepsy?
2. Is the mechanism of ADHD in epilepsy different from ADHD in non-epileptic patients? If so, should different treatment approaches be used?
3. Is ADHD in children with epilepsy reversible if treated early?
4. Does treatment of epilepsy improve attentional problems in selected populations?
5. Finally, can we develop standardized assessment and treatment guidelines for children with ADHD/ADD and epilepsy?

Behavioral and Cognitive Comorbidities

R Caplan, UCLA David Geffen School of Medicine, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

To get a better understanding of how a chronic illness involving the brain impacts the development of children's behavior, a study has been made on psychopathology in children with epilepsy. Given the association of cognitive difficulties with behavioral and emotional problems in the general population of children and the high rate of behavioral problems in children with mental retardation, we were interested in determining if children with epilepsy with average intelligence have specific behavior problems related to their epilepsy, comorbid cognitive problems, and effects of seizure variables.

In the first stage, these mainly phenomenological studies addressed three main questions. First, do children with epilepsy have a wide range of behavior problems similar to children in the general population and children with chronic illness involving the brain, such as head trauma or are certain psychiatric disorders overrepresented in these children? Second, what role does IQ play in the psychopathology of children with epilepsy? Third, how do seizure variables contribute to both behavioral and cognitive comorbidities in pediatric epilepsy?

To answer these questions, it has also been necessary to conduct studies that address methodological issues, such as the quality of the behavioral information derived by using different diagnostic tools and informants, as well as how to assess the effects of seizure variables when they are interrelated and also associated with cognition. Most recently I have examined the relationship of psychopathology and subtle cognitive impairments with structural abnormalities using magnetic resonance imaging (MRI) in children with epilepsy.

Background

In 1970, Rutter and colleagues' pivotal Isle of Wight epidemiological study demonstrated increased psychopathology in children with epilepsy, a wide range of psychiatric diagnoses, and an association between type of epilepsy and type of psychiatric diagnosis. Thus, children with temporal lobe epilepsy were described as hyperactive, antisocial, and aggressive, particularly if they had left sided foci. Children with childhood absence epilepsy (CAE) were thought to have neurotic traits, but no other behavioral disturbances.

Behavioral and Cognitive Comorbidities

R Caplan, UCLA David Geffen School of Medicine, Los Angeles, CA, USA

Introduction

To get a better understanding of how a chronic illness involving the brain impacts the development of children's behavior, a study has been made on psychopathology in children with epilepsy. Given the association of cognitive difficulties with behavioral and emotional problems in the general population of children and the high rate of behavioral problems in children with mental retardation, we were interested in determining if children with epilepsy with average intelligence have specific behavior problems related to their epilepsy, comorbid cognitive problems, and effects of seizure variables.

In the first stage, these mainly phenomenological studies addressed three main questions. First, do children with epilepsy have a wide range of behavior problems similar to children in the general population and children with chronic illness involving the brain, such as head trauma or are certain psychiatric disorders overrepresented in these children? Second, what role does IQ play in the psychopathology of children with epilepsy? Third, how do seizure variables contribute to both behavioral and cognitive comorbidities in pediatric epilepsy?

To answer these questions, it has also been necessary to conduct studies that address methodological issues, such as the quality of the behavioral information derived by using different diagnostic tools and informants, as well as how to assess the effects of seizure variables when they are interrelated and also associated with cognition. Most recently I have examined the relationship of psychopathology and subtle cognitive impairments with structural abnormalities using magnetic resonance imaging (MRI) in children with epilepsy.

Background

In 1970, Rutter and colleagues' pivotal Isle of Wight epidemiological study demonstrated increased psychopathology in children with epilepsy, a wide range of psychiatric diagnoses, and an association between type of epilepsy and type of psychiatric diagnosis. Thus, children with temporal lobe epilepsy were described as hyperactive, antisocial, and aggressive, particularly if they had left sided foci. Children with childhood absence epilepsy (CAE) were thought to have neurotic traits, but no other behavioral disturbances.

In terms of seizure variables, most early studies reported a relationship between poor seizure control and behavioral problems in children with epilepsy. Yet, several of these studies included children with mental retardation and difficult to control early onset epilepsy. Furthermore, follow-up studies on surgically treated and medically treated children have not confirmed that seizure control was related to behavior problems. In addition, a cross-sectional study found no difference in parent reports of behavior problems in children with generalized epilepsy and complex partial seizures (CPS).

Regarding cognition, Camfield *et al.* (1984) and Rutter *et al.* (1970) found that the behavioral deficits of children with epilepsy were associated with the severity of their neuropsychological deficits. Nevertheless, subsequent studies have not separated out the effect of IQ, as well as its relationship with both seizure variables and psychopathology. Our studies, therefore, focused on ascertaining the role of this variable and its possible interaction with seizure variables in the behavioral problems of these children.

From the methodological perspective, studies in child psychiatry have identified differences in the behavioral information obtained using different informants (e.g., children, parents, and teachers) and instruments (e.g., structured psychiatric interviews, self-report instruments, parent, or teacher questionnaires). In terms of the informant, children and adolescents frequently do not share 'internalizing' symptoms, such as depression, anxiety, fears, suicidal ideation, hopelessness, helplessness, hallucinations, and delusions with their parents. Alternatively, parents are a better source when measuring acting out, irritable, and aggressive behavior with poor judgment in the child or adolescent. The informant's emotional state, age, and gender also can affect the type of information provided. For example, parents with a history of depression tend to overdiagnose depression in their children. Although anxious parents are more sensitive to the child's emotions and fears, they might also worry about behaviors in their children that would otherwise be considered normal. Adolescents are more likely to report depression than children, particularly if they are females.

Some informant differences are specifically pertinent to epilepsy. Some parents of children with epilepsy misinterpret behavioral phenomena as seizures while others might mistake manifestations of seizures as behavior problems. For example, parents might report what might appear to be unprovoked irritability as a child being 'out of it' and having a seizure. Alternatively, parents might interpret repeated brief loss of consciousness in CAE as the child being distractible and having attention deficit hyperactivity disorder (ADHD).

Regarding diagnostic instruments, structured psychiatric interviews, and some questionnaires yield DSM-IV diagnoses, whereas most self-report, parent, and teacher questionnaires provide information on behavioral/emotional symptoms. Concerned that parent questionnaires might not identify all the children who have psychiatric diagnoses, we, therefore, compared psychopathology findings with parent questionnaires to those of structured psychiatric interviews.

Additional methodological concerns relate to the effects of seizures on behavior. Thus, some studies have examined individual variables, such as type of epilepsy, seizure control, seizure frequency, duration of illness, antiepileptic drugs (AEDs), and their relationship to behavioral measures, and others have devised a severity measure. However, early onset of epilepsy is confounded by poor seizure control, increased seizure frequency, AED polytherapy rather than monotherapy, longer duration of illness, and prolonged seizures, as well as lower IQ score. Ascertaining which aspects of seizures are related to behavior, therefore, necessitates conducting studies on large population of children and use of statistical techniques, such as principal component analysis to identify independent variables.

Finally, the rationale for our imaging studies was based on increasing evidence for structural and functional abnormalities in children with ADHD, depression, anxiety disorders, and psychosis who do not have epilepsy. We applied these techniques to identify the neural circuits and substrates associated with psychopathology in children with epilepsy, and to determine if abnormalities in these circuits reflect effects of the underlying neuropathology, seizures, and IQ.

Methods

Subjects

These studies included 103 CPS and 80 CAE children, aged 5.1–16.3 years with IQ scores of 70 and higher and 101 normal children. CPS subjects had to have cryptogenic epilepsy and CPS, as defined by the International Classification of Epilepsy, and at least one seizure during the year prior to the child's participation in the study. Children with a clinical history of CPS, but no EEG evidence for focal epileptic activity were also included in the study sample. The study inclusion criteria for each CAE subject were a diagnosis of CAE, absence seizures induced by hyperventilation, at least one seizure in the year prior to participation in the study, and EEG evidence of 3 Hz spike and wave. We excluded patients with a mixed seizure disorder, previous epilepsy surgery, atypical spike and wave complexes, juvenile myoclonic epilepsy, generalized tonic–clonic seizures, a structural MRI abnormality but not those with mesial temporal sclerosis, a neurological illness other than epilepsy, chronic medical illness, imaging evidence for structural brain abnormalities, a metabolic disorder, a hearing disorder, mental retardation based on school/classroom placement, and bilingual

speakers of American English who did not attend English speaking schools or speak English at home.

To include control children from a wide range of ethnic and socioeconomic status backgrounds similar to that of the CPS and CAE groups, we recruited the normal control subjects from four public and two private schools in the Los Angeles community. We excluded children with diagnoses of neurological, psychiatric, language, and hearing disorders in the past from the study.

Procedures

Psychopathology: We determined the presence/absence and type of DSM-IV diagnoses using the *Schedule for Affective Disorders and Schizophrenia for School-Age Children, Epidemiologic Version,* and the *Present and Lifetime Version*, administered separately to each child and parent. Parents completed the *Child Behavior Checklist (CBCL)* and children filled out the *Child Depression Inventory (CDI)* and the *Multidemnsional Anxiety Scale (MASC) for Children.*

Cognition: The *Wechsler Intelligence Scale for Children-Revised (WISC-R)* and the *Wechsler Intelligence Scale for Children-3rd edition (WISC-III)*, administered to children generated Full Scale, Verbal, and Performance IQ scores.

Imaging: All subjects underwent brain MRI scans at 1.5 T. Tissue was segmented and total brain, frontal lobe, frontal parcellation and temporal lobe volumes, hippocampus volumes, and amygdala volumes were computed.

Results

Range and Type of Behavior Problems in Children with Epilepsy

Using a structured psychiatric interview administered separately to the child and parents, we found high rates of psychiatric diagnoses in children with CPS and children with CAE, children with epilepsy recruited from community and from epilepsy centers compared to normal children (Table 1). In both CPAS and CAE the most frequent diagnosis was ADHD followed by anxiety/mood disorders and then both ADHD and anxiety/depression. Among the children with anxiety/depression, 62% had anxiety disorders, 24% depression, and 14% both anxiety disorder and depression diagnoses. We also found high rates of suicidal ideation in 20% and suicidal plans in 37% of our sample, particularly in children with both ADHD and anxiety/depression diagnoses.

Unlike other psychiatric diagnoses, we diagnosed psychosis in children with CPS not CAE, and made this diagnosis in less than 10% of these children. However, a long-term follow-up study of children following hemispherectomy for early onset intractable epilepsy, most of whom had mental retardation, demonstrated psychosis in 33%. We also diagnosed autism and autism spectrum disorders infrequently in the CPS and CAE groups with average IQ in contrast to the high rate of these disorders in children with epilepsy with mental retardation.

Table 1 Psychiatric Diagnoses in CPS, CAE, and Normal Children

	CPS	*CAE*	*Normal*
N	103	80	101
Psychiatric Diagnosis	56%	57%	15%
ADD*	17%	23%	6%
Affective/Anxiety	14%	18%	7%
ADD + Affective/Anxiety	23%	12%	2%
Other	2%	4%	0%
No diagnosis	56%	43%	85%
CBCL T > 60			
Total	40%	35%	12%
Internalizing	42%	35%	16%
Externalizing	19%	26%	7%

*Attention deficit disorder.

Associated Variables

A principal components analysis of seizure variables in a large sample of 101 children with CPS demonstrated no significant relationship between four epilepsy components (e.g., age of onset/duration, seizure frequency/number of AEDs, history of prolonged seizures or febrile convulsions, localization, and lateralization of epileptic activity on EEG) and psychiatric diagnosis. Although the prolonged seizure/febrile convulsions and the seizure frequency/AEDs components of the principal components analysis were significantly related to IQ in CPS children, Verbal IQ was a robust predictor of psychopathology above and beyond the seizure effects. With both epilepsy and IQ variables in the model, significantly more CPS children with lower Verbal IQ scores had a psychiatric diagnosis and CBCL scores in the clinical/borderline range.

In contrast, in the CAE group, duration of illness and seizure frequency predicted the presence of a psychiatric diagnosis, as well as the type of psychiatric diagnosis, ADHD, and anxiety disorder diagnosis. Being on AED treatment predicted parent total and internalizing CBCL scores in the clinical/borderline range whereas longer duration of illness was related to higher CBCL externalizing scores. Unlike the CPS group, increased duration of illness was significantly related to lower Verbal IQ scores, and AED treatment, whether monotherapy or polytherapy, was associated with lower Full Scale, Verbal, and Performance IQ scores.

Our findings are remarkable as they demonstrate similar rates and types of psychopathology, as well as IQ in children with a focal and a generalized type of epilepsy but different profiles of associated variables. These different profiles imply that despite similar end points, different mechanisms underlie the psychopathology and

IQ of children with CPS and CAE who have average intelligence.

In addition, the robust association of Verbal IQ with psychopathology in CPS and between emotional maladaptation and school performance in children with epilepsy and in the general population underscore the importance of ruling out subtle learning disorders in CPS children with behavioral disturbances. Subtle difficulties with verbal cognition might also reflect poor use of language to problem solve and manage emotional and behavioral responses. Furthermore, these findings point to a possible role for the underlying neuropathology in both the Verbal IQ and psychopathology of children with CPS.

The frontal lobe, thalamus, and impaired 5HT metabolism are implicated in both absence seizures and anxiety disorders. The high rate of anxiety disorder diagnoses in CAE might reflect prominent involvement of the frontal lobe in the neuropathology underlying CAE, response of this brain region to effects of ongoing seizures, and the child's feeling of lack of control and increased anxiety with repeated episodes of loss of consciousness over a prolonged period. Similarly, the frontal lobe has been implicated in both ADHD with and without epilepsy and probably plays a role in this frequent CAE comorbidity.

Longer duration of illness and AED treatment in CAE children with cognitive comorbidities also imply possible adverse effects of continued uncontrolled CAE on children's cognitive skills. These findings might also reflect the developmental effects of CAE on maturation of the frontal lobe and thalamus, brain regions involved in the neuropathology of CAE, and in cognition.

Instruments, Informants

Parent CBCL scores identified behavioral problems in only 40% of CPS and CAE children who had a psychiatric diagnosis. However, having a K-SADS diagnosis significantly predicted clinically relevant CBCL scores. Our findings suggested that parent based CBCL scores appear to be more helpful identifying children who are more behaviorally deviant but not children whose behavioral/emotional difficulties are less obvious.

Comparison of the sensitivity (i.e., correct classification of children with a diagnosis) and specificity (i.e., correct classification of children without a diagnosis) of the parent CBCL with the CDI and MASC child self-report questionnaires in identifying children with structured interview based anxiety disorder and depression diagnoses revealed good sensitivity for the MASC (84.2%) but low sensitivity of the CDI (50%), CBCL internalizing scores (45%), and CBCL anxiety/depression scores (40%). These instruments, other than the CBCL anxiety/depression scores (91.7%), had low specificity (60%–74%). The combined MASC, CDI, and anxiety depression factor score of the CBCL provides a 87.5% sensitivity and the CBCL anxiety depression factor score a 91.7% sensitivity. Screening children with epilepsy for mood and anxiety disorder diagnoses should, therefore, involve a combination of instruments to avoid false negative (i.e., missing children with anxiety/depression diagnoses) and false positives (i.e., making these diagnoses in children who do not have them).

Unmet Mental Health Needs

These high rates of psychiatric diagnoses together with low treatment rates in only 33% of these children highlight the unmet mental health needs of children with epilepsy. Absence of mental health care was associated with younger age of the children, less parental education, limited number of AEDs (i.e., one or none), and higher verbal IQ. Children with CAE and a single psychiatric diagnosis were also less likely to have mental health treatment. We concluded that these findings highlighted the need to educate parents and clinicians about the undiagnosed behavioral comorbidities of pediatric epilepsy, particularly if children are younger, less severely ill, and have CAE, traditionally considered a 'benign' form of epilepsy.

Psychopathology and Brain Volumes

Children with CPS have significantly larger white matter volumes of the temporal lobe, smaller gray matter volumes of the orbital frontal gyrus, no difference in amygdala volumes, and smaller hippocampal volumes compared to age and gender matched normal children. In terms of the relationship of these volumes with psychopathology, CPS children with a psychiatric diagnosis have significantly smaller white matter volumes of the inferior frontal gyrus controlling for effects of seizure variables and IQ. These inferior frontal gyrus findings are interesting given our prior findings that Verbal IQ is a robust predictor of psychopathology in these children, the central role of this brain region in syntax, semantics, phonology, and higher-level linguistic functions, and recent clinical evidence for higher level linguistic deficits, disruptive disorder diagnoses, and externalizing behaviors in children with CPS. Together these findings implicate the inferior frontal gyrus in the behavioral and cognitive comorbidities of pediatric CPS. Of note, Hermann and colleagues recently demonstrated increased frontal lobe gray matter volumes in a large population of children with new onset epilepsy that was related to ADHD diagnoses and not seizure variables.

We had predicted that total and frontotemporal brain volumes in CPS children would be related to IQ. However, we found this relationship in the normal children not in those with CPS. Age (not IQ) was associated with these volumes in the CPS group both with and without seizure variables in the model. Although cross-sectional, this

finding implies that brain development in CPS might alter the normal association between IQ and cortical volumes. Given the small sample size, we were unable to examine if these volumes were associated with an interaction effect of psychopathology and IQ.

Similar to findings in children with depression and anxiety disorders without epilepsy and adults with temporal lobe epilepsy and depression, the CPS children with anxiety disorder/depression diagnoses had significantly larger left amygdala volumes than those without these diagnoses. Seizure variables were unrelated to these findings. However, despite evidence for involvement of the hippocampus in pediatric depression unrelated to epilepsy, we found no relationship of these volumes with either the presence of a psychiatric diagnosis or IQ.

Conclusions and Future Directions

The association of psychopathology with both subtle cognitive deficits involving verbal skills and smaller white matter volumes of the inferior frontal gyrus, a brain region involved in integrating language and cognition, together with the abnormal lack of a relationship between IQ and fronto-temporal volumes in CPS attests to the integral involvement of the underlying neuropathology in the behavioral problems of these children. These findings also imply that behavioral and cognitive comorbidities are part and parcel of pediatric CPS. Increased left amygdala volumes in the children with anxiety and depression diagnoses further supports this conclusion.

In contrast, the relationship of seizure variables (i.e., frequency, duration, number of AEDs) with the psychopathology of the CAE group implies that in this disorder ongoing seizures might contribute to behavioral problems. However, prominent involvement of the frontal lobe in this disorder underscores the importance of our ongoing neuroimaging studies of this brain region to advance our understanding of how the underlying neuropathology might be associated with the comorbid behavior problems in pediatric CAE.

Our future directions include prospective studies in CPS and CAE examining age-related changes in psychopathology and their relationship with changes in seizure variables, cognitive/academic performance, and multimodal imaging findings (e.g., functional magnetic resonance imaging, magnetic resonance spectroscopy, diffusion tensor imaging, morphometry). To ascertain if the psychopathology and cognitive comorbidities of children with epilepsy reflect 'familial/genetic' factors, we are comparing psychopathology, cognition, and brain structure of the siblings of children with CPS and CAE to those of the probands and normal children. Finally, we are also examining possible barriers to mental health care in children with epilepsy.

Introduction

Focus of Our Research and Why It is Important

The focus of our research program is to identify factors that account for the high rates of behavior problems in children with epilepsy. These research goals are important for three major reasons: First, children with epilepsy are almost five times more likely to have behavior problems than children from the general population and over two times more likely than children with other chronic physical conditions. Second, these behavioral comorbidities in children with epilepsy are stressful for parents and disruptive to families. In interviews with parents of children with new-onset seizures, parents reported that dealing with their children's behavior problems was a major source of worry and an area for which they were in need of professional help. In recent studies, parenting problems were related to stress arising from the parents' attempt to manage the behavior of their child with epilepsy. Third, these behavioral difficulties in children with epilepsy are enduring and result in significant social morbidity with aging. As children with epilepsy pass through adolescence and into young adulthood, they are more likely to leave school early, be either unemployed or underemployed, and be unmarried. In the very few available longitudinal studies, investigators found that adults with childhood-onset epilepsy had more psychiatric difficulties, more unemployment, and lower rates of marriage than the general population. In summary, behavior problems in children with epilepsy are common, disruptive to the family, and lead to later social problems.

What Kinds of Problems Do Children with Epilepsy Have?

Findings from descriptive studies consistently show higher rates of internalizing behavior problems (i.e., symptoms of anxiety, depression, social withdrawal) than externalizing behavior problems (i.e., acting out, conduct problems). A recent meta-analytic study provided the most definitive statement on the nature of the behavior problems that are found in children with epilepsy. In this meta-analysis of 46 studies, behavior problems in children with epilepsy were contrasted to those in the general population, in healthy siblings, and in children with other chronic childhood conditions. Children with epilepsy were found to differ more from healthy controls than either children with other chronic conditions or their healthy siblings. Common problem areas for both children with epilepsy and those with other chronic physical conditions were: social withdrawal, somatic complaints, anxiety/depression, delinquency, and aggression. Interestingly, many of these problems fall under the rubric of internalizing problems, suggesting that having a chronic illness leads to more social withdrawal, worry, and symptoms of depression. The similarity in problems between these two groups suggests that some of the problems that children with epilepsy experience might be related to having a chronic physical condition. Areas in which children with epilepsy had more difficulties than the other groups were attention problems, thought problems, and social problems. Notably, none of these problem areas is a type of internalizing problem. Overall, these findings suggest that having epilepsy affects behavior beyond that associated with living with a chronic illness.

Background

The major goal of our research program has been to identify factors that might explain the high rates of behavior problems in children with epilepsy. We propose that understanding which factors are associated with the problem can provide important information on which to base interventions to prevent or reduce these problems. We have identified four broad categories of variables (see Table 1) as potential causes of behavior problems: (a) neurological dysfunction; (b) seizure condition variables; (c) neuropsychological deficits; and (d) poor child and family response to the condition. Each of the potential causes of problems is briefly reviewed below.

Neurological Dysfunction

Neurological dysfunction is a known risk factor for behavioral difficulties. Children with mental retardation or intellectual disability have very high rates of behavior problems. Epidemiological studies showing that children with neurological conditions such as epilepsy have higher rates of behavioral problems than children without central nervous system involvement; such studies provide indirect evidence that neurological dysfunction is a potential cause of behavioral problems. Additional support for the relative importance of underlying neurological problems comes from

Table 1 Risk factors for behavioral comorbidity in children with epilepsy

I. Neurological dysfunction
A. Central nervous system abnormality
B. Neurological disorder in addition to epilepsy
II. Seizure condition variables
A. Age of onset and duration of epilepsy
B. Seizure type and epileptic syndrome
C. Seizure control/frequency
D. Epileptiform discharges on EEG
E. Antiepileptic drug side effect
III. Neuropsychological deficits
A. Intellectual disabilities
B. Learning disorders
C. Cognitive deficits
IV. Child and family variables
A. Parental psychopathology
B. Family dysfunction
C. Child attitude toward illness
D. Child social skills

studies of new-onset epilepsy. For example, in recent studies by our research team and others, children were found to display behavioral problems *before* the first seizure was recognized – in other words, prior to other potential causes such as side effects of antiepilepsy drugs (AEDs) or poor psychosocial responses to dealing with epilepsy. It is important to study neurological dysfunction in order to increase our understanding of why children with epilepsy have behavior problems.

Seizure Condition Variables

Because seizures are the defining characteristic of epilepsy, a large number of studies have investigated different seizure variables (e.g., age of onset, seizure frequency, seizure type, and epilepsy syndrome) for relationships with behavior problems in children with epilepsy. Findings have varied greatly, with some authors finding support for greater seizure frequency being associated with more behavior problems but other authors showing no association. A major conclusion from a recent review of the literature was that seizure variables were not consistently related to behavior problems (across the studies surveyed), regardless of study design and sample. One possible explanation for the mixed findings is that seizure variables such as time of onset, seizure type, and epilepsy syndrome are interrelated and confounded. As a result, findings could vary if only one seizure variable was studied (e.g., age of onset), especially in a small sample.

Nevertheless, there is evidence that children with symptomatic syndromes experience more cognitive deficits and behavioral disruptions than children without such symptomatic syndromes. Because neurological dysfunction is strongly associated with symptomatic syndromes, neurological dysfunction might account for the relationship between syndrome and behavior problems.

An important seizure-related variable that has received much attention is AED treatment. Prospective studies have not found support for a relationship between AEDs and behavior problems. For example, in a study comparing behavior from before and after stopping AED treatment, only a decrease in tiredness was found. A major conclusion from this study was that AED monotherapy does not have an impact on behavior.

To summarize, although studies do not show consistent relationships between seizure variables and behavior problems, the mixed findings might be explained by study design and variables studied. Prospective studies tend to show fewer associations between seizure variables and behavioral comorbidities than do cross-sectional studies. Moreover, some seizure variables are related to neurological dysfunction, making it difficult to clearly identify the relevant causal mechanism.

Neuropsychological Deficits

As previously mentioned, behavioral problems are most common in children with epilepsy who also have intellectual deficits. In one of the very few studies on the occurrence of psychiatric disorders in children with both epilepsy and intellectual disability, ~60% were found to have at least one psychiatric diagnosis. These exceedingly high rates of psychiatric diagnoses provide indirect empirical support for a relationship between cognitive functioning and behavior problems. Moreover, this study is consistent with the epidemiological studies showing the highest rates of behavioral comorbidities in children with both epilepsy and other neurological deficits. In addition, studies exploring predictors of behavior problems in children with epilepsy showed that those with intelligence in the low normal range had more problems than those in the average and high normal intelligence ranges.

Children with epilepsy have more cognitive deficits than their healthy siblings or the general population. In a study of children with complex partial epilepsy and their siblings, children with epilepsy performed significantly worse across seven cognitive domains (verbal memory, nonverbal memory, language, academic achievement, problem solving, mental efficiency, and motor skills). Only a few studies have explored the relationship between cognitive deficits and mental health problems in children with epilepsy. When global neuropsychological functioning was explored for relationships with mental heath problems, a moderate correlation was found, with poorer cognitive functioning being associated with more mental health problems. In studies in which children with epilepsy were placed into high or low cognitive functioning groups, children in the low functioning group had significantly more behavior problems. Finally, in the few

studies in which specific areas of cognitive functioning were explored for relationships with mental health comorbidities, low verbal IQ was related to greater behavioral disruption. In summary, although there are relatively few studies in this area, findings consistently show a moderate positive relationship between neuropsychological deficits and behavior problems in children with epilepsy.

Child and Family Variables

Research on child and family variables as they relate to child behavior problems has increased substantially in the last decade. Most of the studies have focused on family variables, however, and only a few have explored child variables. One probable reason is that there are fewer epilepsy-specific instruments available to measure child variables. Interestingly, almost all of the family studies that have included both seizure variables and family variables as predictors have found family variables to be more strongly related to behavior problems than were seizure variables. However, most of these studies were cross-sectional in nature and focused on children with chronic epilepsy, so it is almost impossible to know whether problems in the family preceded or followed problems in the children.

Two approaches have primarily been used to explore relationships between family variables and child behavior problems, group comparison studies, and within-group correlational studies. When comparisons were made to control families or families of children with other physical conditions, families of children with epilepsy showed more family dysfunction, disturbed parent–child interactions, and maternal depression. In the within-epilepsy sample of correlational studies, a number of variables have been associated with behavioral comorbidities, including greater family stress, fewer family resources, disturbed parent–child interactions, and poor family adjustment to the epilepsy. In one of the few prospective correlational studies that explored parenting variables, our research team found that an increase in parent emotional support to the child (over the first 24 months after the first seizure) predicted less child anxiety and fewer depression symptoms at 24 months after seizure onset.

Our research team is one of the few groups that has focused on how child perceptions related to epilepsy are related to child mental health functioning. We found that fewer negative beliefs about having epilepsy were associated with more positive self-concepts and fewer symptoms of depression. In a study of symptoms of depression in adolescents with epilepsy, we found negative attitudes toward having epilepsy and beliefs in an unknown or external locus of control (i.e., that events are controlled by luck or external forces and not the actions of the affected individual) had the strongest associations with depressive symptoms.

Methodological Approaches

How have Behavior Problems been Measured?

Child behavior problems have primarily been measured using parent-completed questionnaires. Although a few studies have used structured interviews with children to measure psychopathology, most have relied on either parent or teacher report of the child's behavior. The most commonly used instrument is the Child Behavior Checklist (CBCL). The CBCL contains 118 items on which parents rate their children's behavior on 3-point scales: 0 (Not True), 1 (Somewhat or Sometimes True), and 2 (Very True or Often True). A number of versions of the scale are available for use with different ages (e.g., preschool, school age, young adult) and for other raters such as teachers. The CBCL provides a total score, two broad factor scores, and eight syndrome scores. The internalizing behavior problems factor is composed of three syndromes: anxious/depressed, somatic complaints, and withdrawn. The externalizing behavior problems factor is composed of two syndromes: delinquent behavior and aggressive behavior. The three syndromes scores that are not included in either of these two broad factors are social problems, thought problems, and attention problems. All CBCL instruments are well-validated and have had extensive research carried out to develop norms for age and gender for each of the scores. In addition, CBCL instruments have been translated into other languages. Because the CBCL is commonly used in several countries, it has facilitated comparisons across studies internationally. Despite the many advantages of the scale for assessing behavior in children with seizure disorders, some of the individual items on this instrument reflect behaviors that might be directly related to seizures (i.e., more of a reflection of acute seizure-associated behavioral changes). To address this potential weakness, our research team has used structured interviews and asked parents not to rate any behavior that might be related to their child's seizures or that occurs in close proximity to a seizure (i.e., behavior that occurred directly before, during, or directly after a seizure). Another potential weakness of this instrument is that the CBCL measures children's problem behaviors, but does little to assess areas of positive child adaptation.

What are the Most Common Designs?

Because both the frequency and the nature of behavior problems have been well-described, cross-sectional descriptive studies of behavior problems have been decreasing in number and are no longer needed. Likewise, cross-sectional studies that compare behavior problems in

children with epilepsy with other illness groups are not needed, because it is well established that children with epilepsy fare worse in specific areas. In contrast, studies are needed that delineate specific factors associated with or predict behavior problems in children with epilepsy. Early studies in this area had cross-sectional designs and focused on children who had had epilepsy for a number of years. Although these studies showed associations of neurological, seizure, cognitive, and family variables to child behavior problems (as described earlier), their designs limited their ability to determine the temporal order of the relationships (i.e., when the behavioral problem arose relative to the onset of seizure activity). In the past two decades, more studies have been conducted that had longitudinal or prospective designs. Once predictors of behavior problems are identified from these studies with strong designs, interventions to reduce or prevent problems can be developed and tested in randomized clinical trials.

Important Recent Results

In the past decade, prospective studies investigating a comprehensive set of predictors in large samples of children with new-onset seizures have been carried out and have yielded new and unexpected findings. In particular, a number of studies have demonstrated that behavior problems actually precede the onset of seizures and the diagnosis of epilepsy. In a prospective study of children who had a first recognized seizure, our research team collected parent ratings of their children's behavior in the 6 months prior to the first seizure and found that 32% of children already had behavior problems. Other investigators have found that children with a diagnosis of Attention Deficit Hyperactivity Disorder (ADHD) are at greater risk for developing seizures. Findings from these studies have led to a sea change in the conceptualization of the causes of behavior problems. If behavioral comorbidities precede seizure onset, it is unlikely that side effects of medications and poor family adjustment to epilepsy are responsible for these behavior problems.

Future Research Challenges

Although descriptive studies have categorized the types and frequency of behavioral comorbidities in children with epilepsy, many questions remain to be answered if we are to develop interventions to reduce behavioral comorbidities. We need to delineate further the underlying mechanisms for behavioral comorbidities. Although neurological dysfunction is a known risk factor, little is known about neurological function changes over time – and how such changes might be related to changes in behavior problems. In this regard, recent imaging studies are revealing evidence of progressive changes that may be important for cognitive and behavioral functioning. Studies are needed to understand which specific domains of neuropsychological function are related to behavior problems. Although some studies of change in intelligence have been carried out, more comprehensive batteries that test multiple domains of neuropsychological functioning over time will provide a more complete picture of the relationships between cognitive functioning and behavioral comorbidities. Once specific domains have been identified, interventions can be developed to address specific cognitive deficits. Newer antiepileptic drugs appear to have fewer cognitive and behavioral side effects than do traditional AEDs; however, adequate methodological studies of the positive and negative cognitive and behavioral effects of these AEDs are still needed. In addition, pharmacogenetics studies have the potential to provide a better understanding of which patients are at risk for adverse behavioral effects from particular medications. Studies are also needed to clarify the physiological mechanisms through which depression and ADHD increase the risk of seizures (as well as epilepsy). Finally, studies are needed in the area of child and family factors, including investigations that identify risk and protective factors as well as those that test interventions aimed at reducing behavioral comorbidities.

Introduction

Numerous clinical studies have identified cognitive and behavioral effects following seizures. These seizure consequences include deficits in intelligence, learning and memory, heightened anxiety, and altered emotional and affective responses. Seizures in infants and young children had previously been thought to cause fewer and less-significant cognitive sequelae than equally severe seizures in the adult brain, but it is now appreciated that seizures at any age can lead to persistent adverse effects on the brain, including increased susceptibility to subsequent seizures and deficits in cognition and behavioral function. Even children with 'benign' childhood epilepsies have a significantly higher incidence of memory, attention, and intellectual dysfunction than those without epilepsy. Factors that influence cognitive outcome include the age of seizure onset, the number and timing of seizures, seizure frequency and severity, and seizure type, syndrome, or etiology. Cognitive assessment in children with epilepsy can be complicated by preexisting deficits in cognition and behavior, making it difficult to discern whether seizures or their treatment are primary or secondary causes of the dysfunction.

Seizures during development present a paradox. Seizure threshold is low in the young brain, with seizures occurring in response to much smaller convulsant stimuli than in adults. At the same time, seizure-induced behavioral and cognitive consequences, though measurable, are less profound in the immature brain than those seen after seizures in mature animals. However, careful consideration of the effects of seizures on the developing brain have revealed that this paradox is more apparent than real; i.e., the young nervous system actually does sustain seizure-induced cognitive deficits in distinct and significant ways. The sensitivity of the brain at all ages to the deleterious effects of seizures necessitates a concerted effort to avoid, or at least minimize, those adverse effects.

Animal models are useful in addressing some of the questions that evade experimental analysis in patients. Many of the seizure variables discussed earlier can be controlled in animal models. For example, seizure etiology plays a major role in outcome, but it is difficult in humans to separate the effects of seizures from the consequences of the brain pathology that caused the seizures. The creation of etiology-specific neonatal seizure models is necessary to increase our ability to compare animal models with human data. However, increasing evidence suggests that seizures can engender adverse effects on the developing brain, regardless of etiology or model. Further, while prolonged seizures unequivocally result in adverse long-term cognitive consequences, the effects of frequent, brief seizures are also associated with deficits (not discussed in this article). Recognition of cognitive and behavioral comorbidities and their relationship to various seizure types and ages of occurrence poses both challenges and opportunities for early intervention.

Introduction

Numerous clinical studies have identified cognitive and behavioral effects following seizures. These seizure consequences include deficits in intelligence, learning and memory, heightened anxiety, and altered emotional and affective responses. Seizures in infants and young children had previously been thought to cause fewer and less-significant cognitive sequelae than equally severe seizures in the adult brain, but it is now appreciated that seizures at any age can lead to persistent adverse effects on the brain, including increased susceptibility to subsequent seizures and deficits in cognition and behavioral function. Even children with 'benign' childhood epilepsies have a significantly higher incidence of memory, attention, and intellectual dysfunction than those without epilepsy. Factors that influence cognitive outcome include the age of seizure onset, the number and timing of seizures, seizure frequency and severity, and seizure type, syndrome, or etiology. Cognitive assessment in children with epilepsy can be complicated by preexisting deficits in cognition and behavior, making it difficult to discern whether seizures or their treatment are primary or secondary causes of the dysfunction.

Seizures during development present a paradox. Seizure threshold is low in the young brain, with seizures occurring in response to much smaller convulsant stimuli than in adults. At the same time, seizure-induced behavioral and cognitive consequences, though measurable, are less profound in the immature brain than those seen after seizures in mature animals. However, careful consideration of the effects of seizures on the developing brain have revealed that this paradox is more apparent than real; i.e., the young nervous system actually does sustain seizure-induced cognitive deficits in distinct and significant ways. The sensitivity of the brain at all ages to the deleterious effects of seizures necessitates a concerted effort to avoid, or at least minimize, those adverse effects.

Animal models are useful in addressing some of the questions that evade experimental analysis in patients. Many of the seizure variables discussed earlier can be controlled in animal models. For example, seizure etiology plays a major role in outcome, but it is difficult in humans to separate the effects of seizures from the consequences of the brain pathology that caused the seizures. The creation of etiology-specific neonatal seizure models is necessary to increase our ability to compare animal models with human data. However, increasing evidence suggests that seizures can engender adverse effects on the developing brain, regardless of etiology or model. Further, while prolonged seizures unequivocally result in adverse long-term cognitive consequences, the effects of frequent, brief seizures are also associated with deficits (not discussed in this article). Recognition of cognitive and behavioral comorbidities and their relationship to various seizure types and ages of occurrence poses both challenges and opportunities for early intervention.

Background

This article focuses on contributions of the kainic acid (KA) model in studying cognitive and behavioral consequences of seizures early in life. In this chapter, 'early life' refers to the first 2–3 weeks of life in rodents, which correlates with several parameters of brain development during the first few months to about 3 years of age in humans.

Various models of developmental epilepsy have contributed to our understanding of the consequences of seizures during this vulnerable time period. For example, seizures caused by convulsant stimuli as diverse as pilocarpine, tetanus toxin, hypoxia, and hyperthermia have been demonstrated to lead to deficits in spatial learning, memory, and other cognitive functions. Seizures induced by hyperthermia (resembling human febrile seizures) or by deprivation of oxygen (mimicking hypoxia ischemia) are examples of acquired brain pathology causing epilepsy. Other epilepsy models involve genetic lesions or focal cortical dysplasia. In comparison, KA is an exogenous convulsant agent that, though working via a specific glutamate receptor subtype (KA receptors), is not a naturally occurring stimulus. KA is a glutamate analog that has been used as an experimental convulsant since the 1970s. The main advantage of KA as a developmental epilepsy model is not that it mimics a specific clinical scenario, but rather, that it causes – via overactivation of a physiologically relevant glutamate receptor subtype – exquisitely age-dependent neuronal dysfunction at the cellular, synaptic, network, and behavioral levels. It is worth emphasizing that none of the developmental epilepsy models cause epilepsy or its adverse consequences by killing neurons, implying that any long-term impact is due to developmentally-specific alteration of cell proliferation or migration, ion channel function, receptor formation and subunit composition, synapse formation, circuit connectivity, or other cellular or subcellular pathology.

Age-related effects of KA seizures are summarized in Table 1. In adult rats, parenteral administration of KA results in a well-defined sequence of changes leading to epileptogenesis, i.e., the creation of the epileptic state. Three phases in this process are recognized: initial status epilepticus (SE) lasting hours, a latent period of days to weeks, and finally the development of spontaneous recurrent seizures (SRS). Each phase is characterized by specific cellular and morphological changes. SE is defined as seizure activity for 30 min or longer. KA administration initially causes limbic seizures, beginning with immobility and staring, leading to unilateral limb clonus, and eventually culminating in generalized tonic–clonic convulsions. After recovery from SE, adult rats develop spontaneous brief limbic seizures over the next few weeks to months, defining a chronic epileptic state. Physiological and cellular changes underlying KA-induced epileptogenesis, not all of which are fully defined, include altered synaptic inhibition, increased excitability due to effects on ion channel and neurotransmitter function, new recurrent excitatory circuits (sprouting of hippocampal mossy fibers), and neuronal death in vulnerable hippocampal regions (dentate hilus, subfield CA3). The pattern of neuronal loss resembles that in human mesial temporal sclerosis, the pathological basis of temporal lobe epilepsy (TLE). As such, the KA model in adult rats mimics human TLE and has been used to study several aspects of the human syndrome. Of relevance here, rats treated with KA as adults develop profound cognitive and behavioral impairments in spatial learning and memory, exploration and activity level, and emotional responses to handling with heightened aggressiveness.

In contrast to the adult syndrome, KA administered to developing rats (under 3 weeks of age) causes SE but seizure-induced cell death is minimal, axonal reorganization involves the CA3 region but not mossy-fiber sprouting, and neurogenesis is decreased. While some differences in seizure semiology are seen at different ages (e.g., tonic–clonic convulsions preceded by repetitive scratching under P20, and wet dog shakes over P20), equally intense electrographic seizure activity is seen

Table 1 Comparison of kainic acid seizures in developing and adult rats

	Immature ($p < 20$)	*Adult ($p > 60$)*
Status epilepticus features	Immobility, staring → repetitive scratching → tonic–clonic activity	Immobility, staring → wet dog shakes → forelimb clonus → tonic–clonic activity with rearing, falls
Spontaneous recurrent seizures	No	Yes
Neuronal death	None	Dentate hilus, CA3, CA1
Axonal reorganization – DGL (mossy fibers), CA3 IPL	Some	Significant
Dentate granule-cell neurogenesis	Variable results: Both increases and decreases reported	Increased
Increased susceptibility to subsequent seizures	Some	Significant
Cognitive deficits	See Table 2	Significant

DGL, dentate granule layer; IPL, infrapyramidal layer.

across ages. Under 2–3 weeks of age, KA seizures do not lead to SRS, and cognitive sequelae of KA-induced SE in immature rats are not nearly as dramatic as in adult rats. Yet, these cognitive impairments, though subtle, certainly occur and are strongly age dependent. Therefore, the cognitive impairments in immature rats occur in the absence of structural or morphological changes, suggesting that channels, receptors, or neurogenesis alter network excitability enough to engender long-lasting functional changes. As mentioned earlier, other developmental epilepsy models share this feature of minimal cell death secondary to seizures.

Early studies showed that KA seizures were associated with cognitive impairments only when occurring after 3 weeks of age, about the time that excitatory glutamate neurotransmission matures. However, recent studies necessitate a revision of that concept. Not only do seizures very early in life lead to cognitive deficits, they also interrupt the ongoing processes necessary for the development of normal excitability and neurologic function.

Recently, Cornejo *et al.*, showed that even a single seizure episode induced by KA in the neonatal period (P7) caused subsequent lifelong cognitive impairment by altering synaptic plasticity. Rats undergoing KA-induced seizures on P7, and later tested on P60 in a hippocampal-dependent radial-arm water maze task, had decreased working and episodic memory, without any mossy-fiber sprouting or change in dendritic spine density. In the CA1 region, long-term potentiation was decreased and long-term depression was increased. The authors attributed the cognitive deficits to alteration in the expression of NMDA receptor subunits (NR2A) and a synaptic scaffolding protein (PSD95). These dramatic results, if confirmed, have profound implications on the mechanisms of early-life seizure consequences.

Clinically, at least 30–40% of children who experience a seizure will have another seizure. Animal models facilitate investigations of whether a prior seizure 'sensitizes' the brain to make it easier to generate a subsequent seizure (and hence, lead to cumulative cognitive risks). In one such a 2-hit model reported by Koh *et al.*, rats underwent KA seizure on both P15 and P45, or on P45 only. When tested as adults, rats that had an initial KA seizure at a young age (P15) exhibited more severe cognitive deficits in spatial learning and memory than rats undergoing a KA seizure only on P45. Presumably, the initial seizure altered network excitability significantly such that the second insult (the KA-induced seizure on P45) occurred in an already compromised brain.

Methodology

We have used the KA model to mimic partial complex seizures with secondary generalization. The consequences of KA-induced SE in adult rodents include damage to hippocampal neurons in a similar distribution as seen in TLE, the occurrence of SRS with limbic features, and distinct learning and memory deficits, especially involving hippocampal-based functions such as special learning and memory. In developing animals, KA elicits all of those consequences but they are less severe than those seen after seizures in adulthood. Therefore, research is focused on the mechanisms by which KA induces damage at each age, why glutamate is less toxic to the immature brain, and why the young brain shows some resistance to the deleterious effects of KA seizures.

The overall protocol employed by several studies using the KA model entails administration of age-specific doses of KA intraperiteonally (i.p.) to rats of various ages. Initial SE is assessed in terms of severity and duration. Later, spontaneous seizure frequency is monitored, either by visual observation or using a variety of video-EEG recording techniques. Subsequently, parameters of the SE and subsequent spontaneous seizures can be correlated with behavioral and histological analyses.

Behavior and cognition can be assessed using a variety of tests of cognition and memory, including the Morris water maze and radial-arm maze (both assess hippocampal-based spatial learning and memory), open field (measures exploratory behavior in a novel environment), handling (assesses stress responses), elevated plus maze (assesses anxiety level), etc. Each of these tests is designed to address specific questions, and is essential to apply each test appropriately.

The Morris water maze (and its variations) deserves special mention because of its common usage in laboratories studying cognitive effects of seizures. This test involves the ability of an animal to use visual cues in its environment to locate and escape onto a small platform in a pool of water. The time and swim path taken by the animal over repeated trials is recorded and compared among experimental groups. Importantly, the acquisition portion of the water maze (when a hidden platform is present) measures spatial learning and memory; the 'probe' test (with the platform removed and the rat's search pattern analyzed) measures retention of that memory. Numerous variations of the water maze have been devised to address specific cognitive questions. For example, in the recent study by Cornejo *et al.*, performance of control rats and KA-seizure rats was similar on the standard water maze and 4-trial radial-arm water maze. The authors then explored cognitive abilities of the two groups in further detail, using a variation called the 2-trial radial-arm water maze. In this version of the test, rats learn the location of a hidden platform on one trial and then are tested to see if they remember its location 4 h later in a single additional trial; the test measures episodic-like memory for a single event. In the Cornejo *et al.*, study, rats with neonatal seizures made significantly more errors in finding the platform (showing defective episodic-like memory); they also took longer to find the platform and

more often re-entered an incorrect arm (both measures of working memory). Therefore, a single episode of neonatal seizure activity was sufficient to produce robust, lifelong deficiencies in episodic and working memory, but these deficits only became apparent when a specialized testing paradigm was employed.

It is important to recognize that the water maze is not a test of general intelligence or cognitive ability, but rather, a specific measure of spatial memory and learning, which is dependent upon integrity of the hippocampus. Other tests mentioned earlier often have their own anatomical substrates. To conclude that a treatment or intervention has an effect on cognition, the investigator must consider the coordinated appraisal of multiple behavioral tests.

Results

In our recent experiments (Table 2), rats experienced an episode of KA-induced SE on various postnatal (P) days from P1 to P24, and were then tested as adults (P90–100) on several behavioral tests. On a radial-arm maze test designed to assess short-term spatial learning and memory, all groups of rats exhibited impaired performance in terms of latency to achieve criteria (learning bait location) over repeated trials (compared with age-matched controls that received saline rather than KA and did not undergo seizures). Radial-arm maze testing showed an increased number of reference errors in KA-treated rats, suggesting impaired short-term spatial memory. Similarly, rats receiving KA at the early ages and later tested as adults in a standard version of the Morris water maze took significantly longer to find the hidden platform (acquisition test) and spent less time swimming in the target quadrant (probe test) than did non-KA-treated controls. Deficits varied inversely with age of SE (worst in P24-treated rats). On the elevated plus maze, a measure of anxiety, rats with KA seizures were significantly more anxious, preferring to remain in closed arms of the maze. Finally, the open field test was used to assess locomotion and exploratory behavior; there was no difference in open field behavior between controls and KA-treated rats (KA at any age), suggesting that the differences in anxiety in the plus maze were not secondary to differences in motor activity. Therefore, these results provide additional support for the concept that seizures early in life can produce long-term impairment in certain cognitive and behavioral functions. Recent physiological studies (Sayin and Sutula, unpublished) suggest that reduced inhibition in the dentate gyrus, as measured by paired-pulse inhibition, correlates with these cognitive effects. Similarly, Lynch *et al.*, previously showed that lifelong cognitive deficits in rats treated with KA between P1 and P24 correlated with enhanced dentate gyrus paired-pulse inhibition as well as with decreased long-term potentiation, suggesting a permanent seizure-induced alteration of neuronal plasticity.

Table 2 Some cognitive deficits reported after early-life KA seizures in rats

- Impaired long-term spatial memory in Morris water maze
- Impaired short-term spatial memory in radial-arm maze
- Impaired working and episodic memory in 2-trial radial-arm water maze
- Increased aggressiveness on handling test
- Increased anxiety in elevated plus maze
- No difference in exploratory activity in open field test

Future Goals

The long-term goal of research in this field is to elucidate the mechanisms by which seizures at various ages induce long-term cognitive and behavioral damage, in order to intervene and hopefully prevent such damage. In approaching this daunting task, it is important for investigators to acknowledge the differences between seizure-induction methods and experimental protocols across laboratories, and hopefully work out a means for examining those differences. Further, the presence of critical periods during brain development and stage-specific maturational factors are clearly important and need to be elucidated. The KA model is but one of numerous seizure-induction techniques that can yield useful information about the mechanisms and consequences of seizures during development.

One area of research that could provide practical benefit in the developmental epilepsies is environmental enrichment. This idea is based on the concept that the quality and quantity of external stimulation (availability of novel, interesting objects for exploration, presence of other animals for socialization, etc.) can prevent or even reverse expected seizure-induced cognitive impairment. Enriched environments have been associated with reduced seizure damage and fewer deficits in visual spatial learning. Mechanisms for such neuroplasticity need to be determined, and could involve genetic or cellular signaling pathways in different brain regions. It will be important to establish which aspects of environmental enrichment are sufficient and which aspects are necessary for adaptive neuroplasticity. The effects of neuroprotective factors such as brain-derived neurotrophic factor (BDNF), changes in synaptic efficacy, and stabilization of neuronal structure could all be critical factors, as could alteration of specific early genes or transcription factors that can be up-regulated or down-regulated after seizures.

Limitations to the use of animal models, and of the KA model in particular, need to be acknowledged. The absence of SRS after KA is a major impediment for its usefulness as an epilepsy model in the developing brain, but this disadvantage also holds true for all the other convulsant techniques used in developing rodents. Any

single model is insufficient to explain the diversity and rich variability of developmental epilepsy. Yet, each model offers the opportunity to address specific questions, and together they can increase our understanding of the complex relationship between seizures and behavior. For example, we obviously cannot model language in animal models – even though language is one of most sensitive measures of cognitive impairment in children with epilepsy. Is there a surrogate function testable in rats?

The opportunity to prevent seizure-induced cognitive damage has widespread implications for the lives of children. The comorbidities in children with epilepsy include numerous psychological, physical, and educational impairments. We need to understand the effects of seizures on already established cognition as well as seizure-induced alteration of new learning and memory formation. It is important to recognize and address these comorbidities in addition to the seizures themselves, and to devise innovative ways in which the lives of these children can be improved. The goal of basic research is to figure out how to exploit the natural resiliency of the brain's immature neural circuitry to avoid epileptogenesis and its adverse consequences.

Introduction

Epidemiological studies indicate that there is a high rate of mental retardation and learning disabilities in individuals with epilepsy. In many cases, both the epilepsy and the cognitive impairment will have a common cause, such as a metabolic disorder, congenital brain malformation, or brain trauma. However, there is also evidence that in some individuals, the epilepsy itself may cause either temporary or permanent interictal (i.e., between seizures) learning problems.

It can be argued that memory is one of the most essential higher brain functions, since it provides continuity in time, personal history, and awareness. Memory is often impaired in patients with epilepsy. Cross-sectional and longitudinal analyses of memory performance in a large series of patients with epilepsy have shown a high risk of episodic memory impairment.

The mechanisms responsible for the high incidence of memory impairment in individuals with epilepsy are not entirely clear. As with other cognitive problems, the memory impairment may be secondary to the underlying pathology responsible for the seizures. However, the temporal lobe, and particularly structures of the mesial temporal lobe, is highly susceptible to seizure-induced cell loss, and patients with temporal lobe epilepsy appear to be at particularly high risk for memory deficits. There is also evidence that in some patients, recurrent seizures can lead to progressive changes in cognitive function, most notably memory.

While seizure-induced cell loss in the hippocampus may account for some of the cognitive impairment in patients with temporal lobe epilepsy, there are indications that seizures may cause functional impairment without necessarily causing cell loss. For example, patients with idiopathic generalized epilepsy perform worse than controls on a range of memory tests, including face recognition, word recognition, verbal recall, and complex figure recall. This observation supports the contention that memory deficits in epilepsy may be due to neuronal dysfunction secondary to epileptic activity rather than due to macroscopic lesions in the temporal lobes.

Understanding the pathophysiological basis of seizure-induced cognitive deficits is critical to the development of therapies that will prevent the deficits. While the human condition clearly differs from that occurring in animals, human studies are often difficult to interpret because of the large number of variables associated with human epilepsy. Neuropsychological outcome in individuals with epilepsy may be influenced by factors such as etiology; age of onset; duration of the disorder; seizure type, frequency, and severity; concomitant disorders; genetic background; and treatment. Studies on animal models allow investigators to control many of these variables, such as age, seizure type, frequency, and antiepileptic drug therapy. Indeed, the widespread use of animal models has led to many fundamental insights into seizure-induced changes in the brain.

Background

Because of costs and convenience most investigators have used rodent models. While these models provide considerable insight into pathophysiological mechanisms, results from these studies must be interpreted cautiously for their relevance to the human condition. Subtle cognitive and behavioral changes are difficult to measure, and higher cortical function such as language and abstract thinking cannot be studied in rodents.

A large number of animal models have been employed in epilepsy research. Most animals models have been used to induce a single seizure (usually prolonged – e.g., status epilepticus) or recurrent repetitive seizures. Chemoconvulsants and electrical stimulation have been widely used in adult rodents, although recently a larger number of genetic models have been employed. Genetic models often are complex, since the animals may have structural, functional, or developmental issues beyond the seizure phenotype. In addition, there may be considerable differences among strains with regard to seizure susceptibility and outcome.

Methods

Status Epilepticus (SE) Model

Induction of seizures

SE is induced in our laboratory with the lithium–pilocarpine. Lithium chloride is given intraperitoneally 18 h before an intraperitoneal injection of pilocarpine ($34\,mg\,kg^{-1}$) to induce SE. Systemic injection of pilocarpine produces severe seizures within 30 min, progressing into SE in almost all rats. Two hours after the onset of SE, pentobarbital ($30\,mg\,kg^{-1}$) is given intraperitonally to stop the seizures. Following recovery from the SE, rats are returned to the

animal care facility for a minimum of one month before they are implanted with electrodes or undergoing behavioral testing.

Water maze

While a variety of tests can be used to assess learning and memory, one of the most popular is the Morris water maze, a measure of visually guided spatial memory. In the water maze, the animal uses visual clues to learn the location of a platform submerged below the water line in a tank of water. The primary outcome measure is the time it takes for the rat to find the platform. Although rats swim well, they would prefer to be out of the water and will seek the platform to avoid swimming.

As used in our laboratory, test animals are placed in a 2 m in diameter tank filled with water (Figure 1). Four points on the rim of the pool are designated north (N), south (S), east (E), and west (W), thus dividing the pool into four quadrants (NW, NE, SE, SW). An 8×8 cm plexiglass platform, onto which the rat can escape, is positioned in the center of one of the quadrants, 1 cm below the water surface.

Following a day of habituation where the rats are placed in the swimming tank without a platform present, rats are trained for 24 trials (six trials a day over 4 days) to locate and escape onto the submerged platform. The latency from immersion into the pool to escape onto the platform is recorded for each trial, and the observer also manually records the route taken by the rat to reach the platform. One day after completion of the last latency trial, the platform is removed and animals are placed in the water maze in the quadrant opposite to where the platform had previously been located. The path and time spent in the quadrant where the platform had been previously placed is recorded. In this part of the water maze, the probe test, normal animals typically spend more time in the quadrant where the platform had been previously located than in the other quadrants.

The Morris water maze is a test of hippocampal-dependent spatial memory, which parallels episodic memory in humans. While intact hippocampus function plays a major role in the test, lesions in other brain regions, including neocortex, retrosplenial cortex, striatum, basal forebrain and cerebellum, can alter water maze performance. The testing procedure used during the 4 days of locating the hidden platform provides a measure of both working memory and reference memory. The animal uses working memory to know which areas of the tank have been visited while trying to find the platform, and uses reference memory to know where the platform was previously placed.

Place cell recordings

In addition to behavioral tests, pathophysiological mechanisms responsible for seizure-induced memory impairment in epilepsy can be assessed using electrophysiological measures. Hippocampal place cells fire selectively in specific and restricted locations (place fields) as rodents move through open environments. Field location, size, and shape are specific to each cell and each environment, and fields cover the surface of the environment homogeneously. In normal rats, for a given environment, the place field for a given cells remains unchanged, evenbetween exposures separated by months. Hippocampal cells 'learn' to encode the salient features of experience through *N*-Methyl-D-Aspartate (NMDA) receptor-dependent synaptic plasticity mechanisms, and this rapid and persistent neuronal encoding is a crucial step toward the formation of long-term spatial memory. Since there is a strong relationship between place cells activity and the ongoing navigational behavior of rats, it is believed that such signals provide the animal with a spatial representation in order to navigate efficiently within the environment. Place cells therefore serve as powerful surrogate markers for assessing spatial memory.

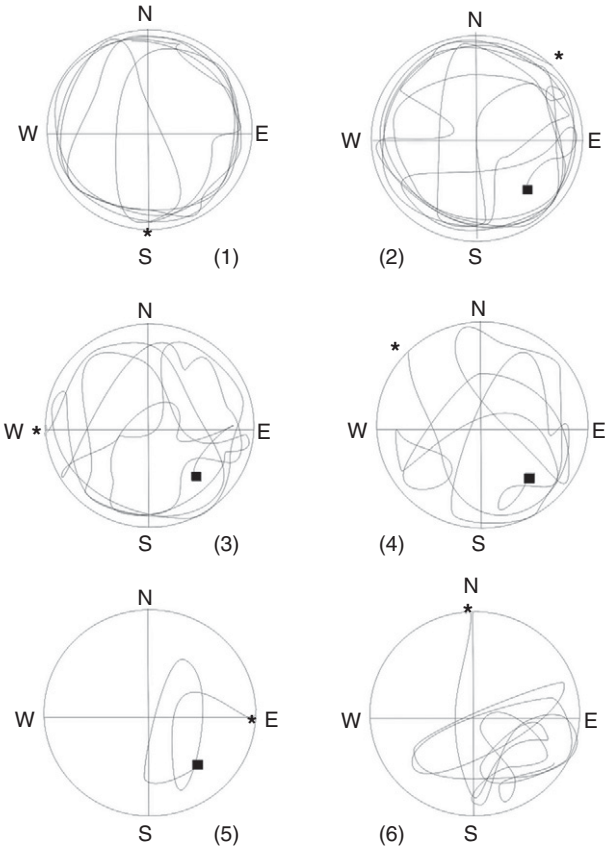

Figure 1 Example of swimming path during water maze testing. During the first day the rat is placed in the water maze without the platform present to habituate the rat to the environment. On days 2–5 the rats are placed in randomized starting spots in the water maze and the time and path taken to find the submerged platform is recorded. On the sixth day the platform is removed and the time the rat spends in the quadrant where the platform had previously been located is recorded.

We use special microdrives to place eight tetrodes (a group of four 25 µm nichrome electrode wires twisted together) in the CA1 region of hippocampus. Tetrodes allow excellent signal detection and cell discrimination, and also allow recording from several cells simultaneously. The signal coming from the headstage preamplifiers is differentially amplified 10 000 times and the acquired waveforms are sorted off-line using a computer program.

For these place cells experiments, rats are fitted with a light-emitting diode (LED) on its head, which enables rat movement (and direction) to be tracked with an overhead TV camera. Action potentials from individual cells are recorded as the animal chases food pellets randomly distributed on the floor of a cylinder 76 cm in diameter (**Figure 2**). The floor area is divided into 'pixels.' A sheet of white cardboard occupies 90° of inside arc of the cylinder and is the only polarizing stimulus. The total time the LED is detected in each pixel and the number of action potentials (spikes) fired in each pixel is accumulated. A time-averaged firing rate distribution is calculated by dividing the number of spikes in each pixel by the dwell time in that pixel. Color-coded firing rate maps are then used to visualize positional firing distributions. Pixel rates are coded in the sequence: yellow, orange, red, green, blue, and purple, in order from lowest to highest firing frequency. The firing rate is exactly zero for yellow pixels.

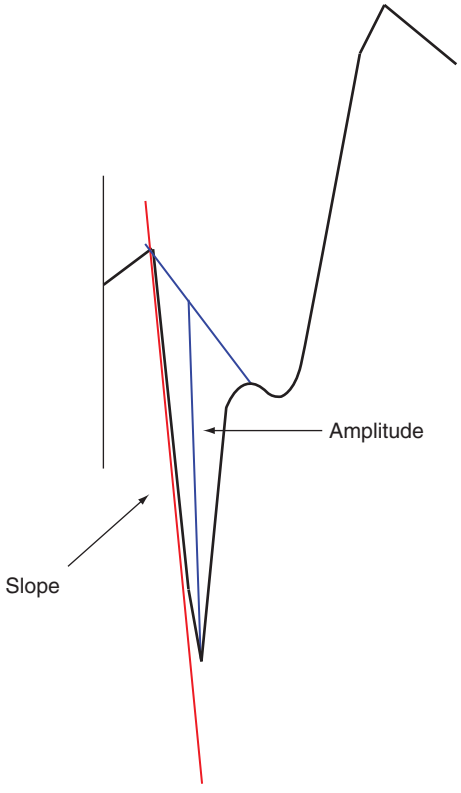

Figure 2 Example of an evoked fEPSP in CA1 following stimulation from the contralateral CA1. The slope and amplitude measurements of the initial negative deflection are shown.

For the pyramidal neurons that show location-related firing of spikes, we assess the following characteristics: (1) Coherence: This measure is a two-dimensional nearest-neighbor autocorrelation, calculated by listing the firing rate in each pixel and the average firing rate in its eight nearest neighbors. Coherence is the z-transform of the correlation between these lists and estimates the local smoothness of the positional firing pattern; (2) Firing rate: The number of spikes firing per second; (3) Information content: Information content is a measure of the amount of information (in bits) conveyed about spatial location by a single action potential emitted by a single cell; (4) Field size: Size of the place cell field in pixels; (5) AP rate: firing frequency of action potentials; and (6) Center rate: Rate of spikes firing in the center of the firing field.

Serial Seizures Model

Seizure induction

Serial seizures are induced by flurothyl, which readily induces generalized seizures following inhalation. Rats are placed in a plastic container (length = 28 cm, width = 18 cm, height = 26 cm) and liquid flurothyl (2,2,2-trifluoroethyl ether) is delivered through a plastic tube and dripped onto filter paper in the center of the chamber. Experimental rats are exposed to flurothyl until tonic extension of both the forelimbs and hindlimbs is observed. Rats are then quickly removed from the chamber and allowed to recover in room air until the animals return to their baseline activity level. After recovery, they are returned to their cages. Rats are allowed at least 2 h of rest between induced seizures. Rats received flurothyl-induced seizures at the rate of two times per day for 5 days.

Long-term potentiation

Another electrophysiological method useful in studying seizure-induced changes in memory is long-term potentiation (LTP). Since enduring spatial memory and stable place fields each depend upon synaptic plasticity mechanisms that normally rely on the same NMDA-receptor mediated events, LTP appears to be a useful measure of seizure-induced changes in plasticity.

Rats are implanted with bipolar 125 µm wires twisted together in the dorsal hippocampus. The recording electrode is implanted in the CA1 region on the left and the stimulating electrode in the homotopic region in the right stratum oriens of CA1. The stimulus and recording electrodes are positioned so that stimulation produces an extracellular field excitatory post-synaptic potential (fEPSP) which has an initial negative deflection in the recording electrode (**Figure 3**).

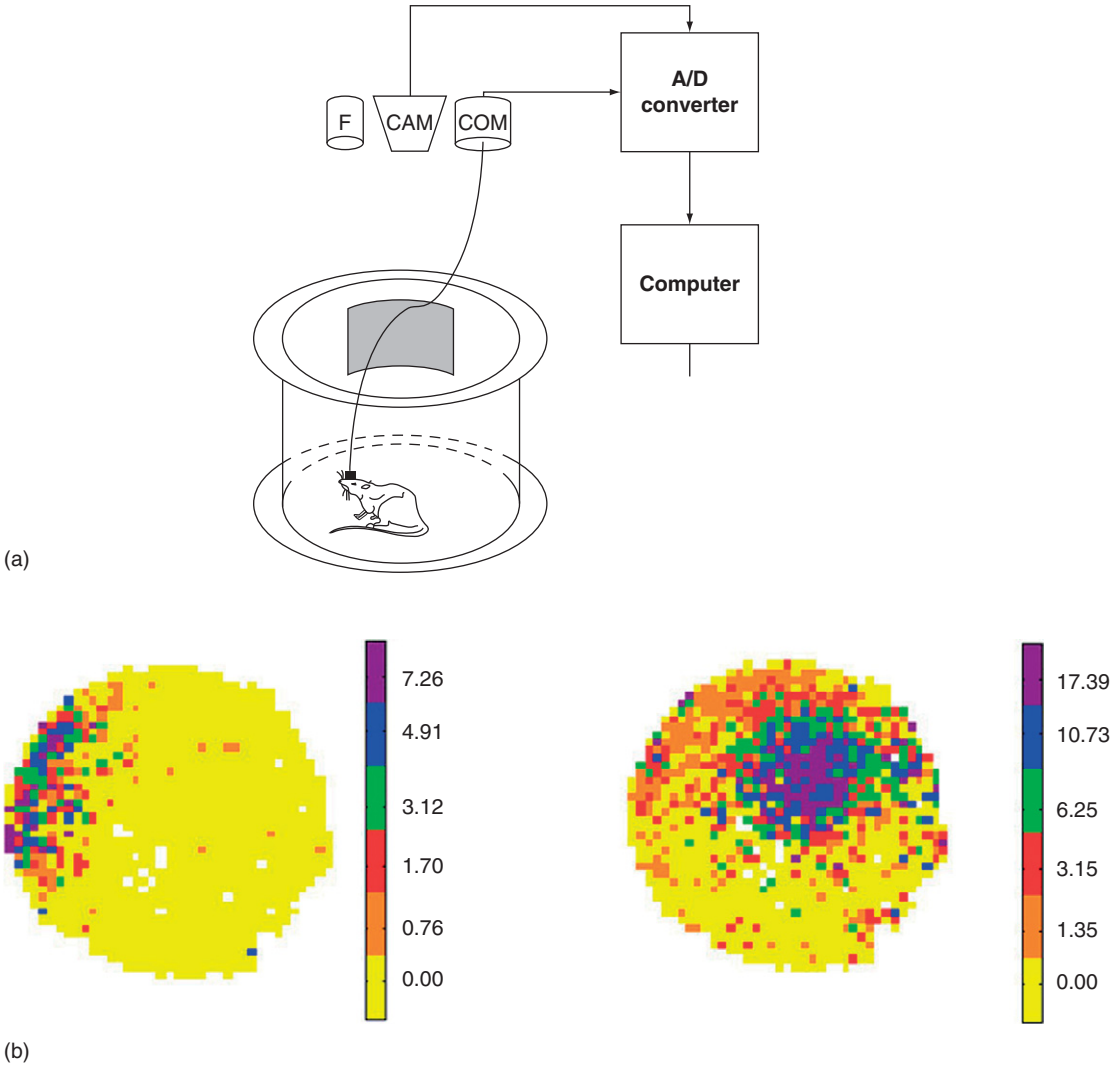

Figure 3 Example of place cell recording chamber and two place cells. (a) Rat has diode on head which allows tracking of position. An orienting card is on the wall of the cylinder. The intracranial electrodes are attached to a cable with preamplifier in place. A food pellet dispenser is attached on the ceiling along with the camera and commutator. The recording system amplifies and digitizes the analog signal and allows the recording of single cell action potentials while also recording position. Food pellets are dispensed randomly about the cylinder which causes the rat to visit all locations in the cylinder. (b) Color-coded firing rate maps were used to visualize firing distributions. Pixel rates were coded in the sequence: yellow, orange, red, green, blue and purple. The firing rate was exactly zero for yellow pixels. Unvisited pixels in the cylinder and pixels outside the cylinder were coded white. In the left hand figure a place cell at approximately 11:00 is shown. In the right hand figure a place cell in the middle of the field was seen.

One week after surgery to implant electrodes, recordings of evoked fEPSPs are initiated. Stimuli consist of 0.2 ms monopolar pulses with an intensity starting at 40–50 μA; intensity is gradually increased until an evoked response is obtained. The threshold intensity is then defined as the lowest stimulus intensity that can evoke a detectable and reproducible excitatory post-synaptic response. An input/output curve is developed to show the change in the output of the neuronal population (EPSP amplitude and slope) over a range of input intensities. Prior to LTP, rats are stimulated every 20 s at an intensity 1.5X greater than threshold, for a minimum of 30 min or until a stable response is obtained. LTP is then induced with a 200-Hz high frequency train (pulsewidth of 0.2 ms, 1 s train duration, stimulus intensity of 1.2X the single-pulse threshold). Following the LTP-inducing stimulus train, responses to single stimuli (delivered using the same parameters as used prior to LTP) are obtained at 5, 10, 20, 30, 60, 90, 120, and 180 min. Synaptic transmission efficacy is assessed by measuring the fEPSP slope and population spikes (PS) amplitude from averaged waveforms before and after the tetanic stimulation (Figure 3). An average of all of the slope and amplitude measurements recorded before the tetanic stimulation is used as the baseline value.

Recent Results

Status Epilepticus Model

Water maze

As found in other studies, rats subjected to SE had significantly impaired performance in the water maze. Both reference and working memory are impaired in these studies. The increased latency to the escape platform was not related to motor deficits or swimming speed.

Place cell recordings

The SE group differed strikingly according to 'coherence' which measures the local smoothness of spatial firing pattern. Numerically, the mean coherence for control place cells of 0.81 ± 0.04 was reliably higher than the mean of 0.50 ± 0.06 for the place cells from the SE rats. Thus, firing field organization is weaker in adult rats subjected to SE earlier in development (in prepubescence). Furthermore, this weaker organization of the spatial firing pattern is not secondary to other firing pattern defects (such as decreased rates or major changes in the positional distribution of place cell discharge) as measured by field area or information content. On the assumption that place cell activity is essential to normal navigational behavior, the decreased coherence helps account for the poorer water maze performance shown by SE rats.

We also asked if the positional firing patterns of the place cells from the SE rats were stable over time. To this end, we ran four recording sessions (within a 7-h period) for each control cell and for each cell from SE rats. Place cells in the control rats appeared stable; their fields remained in approximately the same position and retained their shapes across the four recording sessions. In marked contrast, the positional firing patterns of SE rats often changed considerably over time. These findings indicate that the positional firing patterns for the place cells from the SE rats drift away from their initial states in a time-dependent fashion. The reduced stability of the place cells from the SE rats at short intervals, and the progressive decay of stability at longer intervals, provide additional bases for explaining observed deficits in complex spatial tasks. Thus, adult rats that experienced SE during pubescence had defective place cells.

Serial Seizures Model

LTP

Following 10 flurothyl-induced seizures in our rats, LTP could not be elicited. The impairment in LTP appeared to be 'dose-dependent'; following two flurothyl-induced seizures, the rats had normal LTP.

Water maze

The rats undergoing serial seizures had increased latencies to the platform compared with the controls. The probe test also showed a significant difference between groups, with the serial seizure rats showing less swimming time in the target quadrant than the non-seizure controls.

Place cell recordings

Place cells were recorded 1 day prior to flurothyl-induced seizures, 24 h following the tenth seizure, and 72–128 h following the last flurothyl-induced seizure. All of the rats were behaving normally when they were studied. There were significant decreases in coherence, information content, and center firing rate. When the rats were studied 72 h after the last flurothyl seizure, there was a return of place cell firing patterns to baseline values, except for reduced coherence values. Stability was assessed numerically by computing change in the location of place field center with serial recordings. Stability was substantially impaired following the tenth flurothyl seizure. These changes persisted when the animals were studied >72 h following the last seizures.

Future Goals

Our major goal in understanding the role of seizures in cognitive dysfunction is to determine the precise reasons by which seizures cause cognitive impairment. Clearly, seizures can result in cognitive impairment as measured behaviorally and electrophysiologically (e.g., as seen in single cell place cell recordings and field recordings). While these studies demonstrate that seizures can impair brain function, the remaining challenge is to determine why such impairment occurs. A myriad of changes occur in the brain following seizures. Determining which of these changes result in seizure-induced cognitive impairment is the next step.

Introduction

Of the epilepsies, complex partial seizures are particularly common, with the majority originating in the temporal lobes. There is special interest in this patient group, as they represent a large cohort of persons with surgically curable epilepsies. As such, they have been very carefully studied with advances made in characterizing the neurobehavioral characteristics of localization-related syndromes of temporal lobe origin. The most prominent syndrome is *mesial temporal lobe epilepsy* (MTLE). This disorder is among the most common form of epilepsy and among the most refractory to medical treatment (often intractable by adolescence). Its defining features include an early age of onset (primarily in the first decade), underlying hippocampal sclerosis reflected on magnetic resonance imaging (MRI) as unilateral hippocampal atrophy, and a history not uncommonly including complicated febrile convulsions or other early etiological insults. Other defining symptoms (e.g., clinical semiology, interictal/ictal EEG characteristics) associated with MTLE have been described. Two other localization-related epilepsies of temporal lobe origin have also been described, and include so-called idiopathic, cryptogenic, or MRI-negative temporal lobe epilepsy (here called *MRI-negative TLE*), and lesional (e.g., tumor, stroke) epilepsy of temporal lobe origin.

Background

The most prominent cognitive deficit in MTLE occurs in memory function; this is, due to the effects of the primary epileptogenic lesion. However, it has become apparent that cognitive impairments may often be evident in other cognitive domains, abnormalities that cannot be explained by the primary temporal lobe disturbance. The etiology underlying this distributed cognitive effect is an interesting issue. A long-standing literature has shown associations between clinical seizure features and disrupted cognitive function. Seizure-related contributors to cognitive impairment in chronic temporal lobe epilepsy, as well as in other types of epilepsy, include the underlying etiology of the disorder, adverse effects of medications, seizure frequency and severity, medical complications such as status epilepticus, rate and type of EEG abnormalities, and other factors.

However, recent advances in neuroimaging have provided new perspectives. Alterations in brain metabolism demonstrated by FDG-PET often appear in lateral and mesial temporal lobe, and may also extend to other areas including thalamus, basal ganglia, and frontal and parietal lobes. This associated hypometabolism has been linked to abnormalities in cognition and behavior. Specifically, thalamic hypometabolism has been shown to be associated with memory impairment, and frontal hypometabolism associated with impairment in higher order cognitive abilities and mood disorder.

Especially interesting are quantitative MRI findings. Initial quantitative MRI studies identified atrophy of the hippocampus, followed by reports of abnormalities in related structures including the enthorhinal cortex, fornix, parahippocampal gyrus, amygdala, basal ganglia, and thalamus. Additionally, more distant temporal and extratemporal lobe regions have been implicated, including the

Introduction

Of the epilepsies, complex partial seizures are particularly common, with the majority originating in the temporal lobes. There is special interest in this patient group, as they represent a large cohort of persons with surgically curable epilepsies. As such, they have been very carefully studied with advances made in characterizing the neurobehavioral characteristics of localization-related syndromes of temporal lobe origin. The most prominent syndrome is *mesial temporal lobe epilepsy* (MTLE). This disorder is among the most common form of epilepsy and among the most refractory to medical treatment (often intractable by adolescence). Its defining features include an early age of onset (primarily in the first decade), underlying hippocampal sclerosis reflected on magnetic resonance imaging (MRI) as unilateral hippocampal atrophy, and a history not uncommonly including complicated febrile convulsions or other early etiological insults. Other defining symptoms (e.g., clinical semiology, interictal/ictal EEG characteristics) associated with MTLE have been described. Two other localization-related epilepsies of temporal lobe origin have also been described, and include so-called idiopathic, cryptogenic, or MRI-negative temporal lobe epilepsy (here called *MRI-negative TLE*), and lesional (e.g., tumor, stroke) epilepsy of temporal lobe origin.

Background

The most prominent cognitive deficit in MTLE occurs in memory function; this is, due to the effects of the primary epileptogenic lesion. However, it has become apparent that cognitive impairments may often be evident in other cognitive domains, abnormalities that cannot be explained by the primary temporal lobe disturbance. The etiology underlying this distributed cognitive effect is an interesting issue. A long-standing literature has shown associations between clinical seizure features and disrupted cognitive function. Seizure-related contributors to cognitive impairment in chronic temporal lobe epilepsy, as well as in other types of epilepsy, include the underlying etiology of the disorder, adverse effects of medications, seizure frequency and severity, medical complications such as status epilepticus, rate and type of EEG abnormalities, and other factors.

However, recent advances in neuroimaging have provided new perspectives. Alterations in brain metabolism demonstrated by FDG-PET often appear in lateral and mesial temporal lobe, and may also extend to other areas including thalamus, basal ganglia, and frontal and parietal lobes. This associated hypometabolism has been linked to abnormalities in cognition and behavior. Specifically, thalamic hypometabolism has been shown to be associated with memory impairment, and frontal hypometabolism associated with impairment in higher order cognitive abilities and mood disorder.

Especially interesting are quantitative MRI findings. Initial quantitative MRI studies identified atrophy of the hippocampus, followed by reports of abnormalities in related structures including the enthorhinal cortex, fornix, parahippocampal gyrus, amygdala, basal ganglia, and thalamus. Additionally, more distant temporal and extratemporal lobe regions have been implicated, including the

temporal pole, frontal lobe, and cerebellum. Most recently, abnormalities in cerebral white matter have been reported, including the corpus callosum and distributed regions within the temporal, parietal, and frontal regions, both ipsilateral and contralateral to the affected temporal lobe. In the context of these findings, it is not surprising that reduction of whole brain volume has been reported. With few exceptions, most volumetric investigations have examined a single or limited number of neural structures – as opposed to characterizing a broader and more diverse range of regions and their relative degree of atrophy. Preliminary investigations that do make such comparisons have helped to characterize the degree of abnormality that exists both within and outside the epileptogenic hippocampus (**Figure 1**).

Also striking are recent investigations of cortical thickness, demonstrating diffuse thinning of the ipsilateral and contralateral cortical mantle in unilateral temporal lobe epilepsy (**Figure 2**), as well as diffuse abnormalities in cortical complexity in unilateral temporal lobe epilepsy.

In the studies to be reviewed here, we begin by characterizing and comparing the degree of cognitive pathology in patients with temporal lobe epilepsy to healthy controls, in order to determine the nature and range of cognitive dysfunction both within and outside memory function. It was our hypothesis that given a mean cognitive profile of greater than expected neuropsychological impairment in a group of persons with well-defined temporal lobe epilepsy, there might be distinct subgroups of patients with specific patterns of cognitive impairment (and sparing), and that these cognitive phenotypes would have distinct clinical seizure and MRI volumetric correlates, with varying prospective cognitive courses.

Methods

Our research cohort consisted of 96 patients with well-defined chronic temporal lobe epilepsy and 82 healthy controls, aged 18–60. All research participants underwent comprehensive cognitive assessment (intelligence, language, perception, learning and memory, executive function, psychomotor abilities) and quantitative MR volumetrics of total and lobar gray and white matter volumes. Cognitive performance in the epilepsy subjects was compared to that in the healthy controls after adjustment for age, education, and gender. Volumetric measurements were adjusted for age and total intracranial volume, as is the custom. The cognitive data were later subjected to cluster analysis, and identified groups were related to adjusted volumetric measurements of total hippocampal volume and gray and white matter volumes. Finally, subjects were reassessed after 4 years, and test–retest cognitive trajectories in the epilepsy participants were analyzed via standardized regression-based norms for change.

Results

Patients with chronic temporal lobe epilepsy were compared with healthy controls (**Figure 3**). Impairments were evident in memory function, but this deficit occurred in the context of a cognitive profile notable for generalized cognitive dysfunction, with significant differences between the control and temporal lobe epilepsy patients across all cognitive domains – findings that are inconsistent with the neuropsychological consequences of exclusively hippocampal pathology.

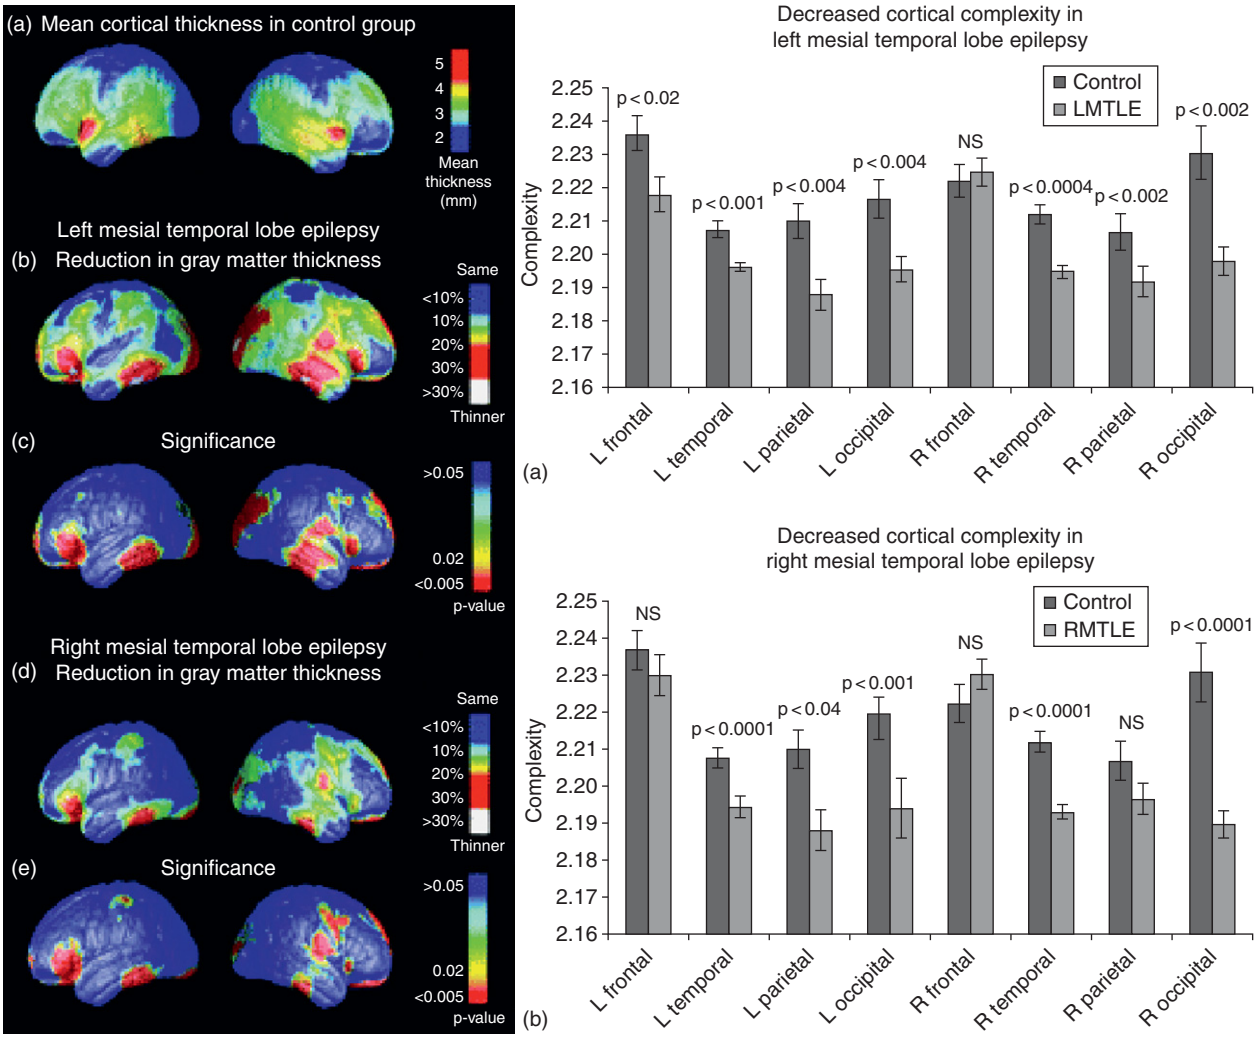

Figure 2 Patterns of cortical thinning in unilateral mesial temporal lobe epilepsy. Lin JJ, Salamon N, Lee AD, *et al*. (2007) Reduced neocortical thickness and complexity mapped in mesial temporal lobe epilepsy with hippocampal sclerosis. *Cerebral Cortex* 17: 2007–2018.

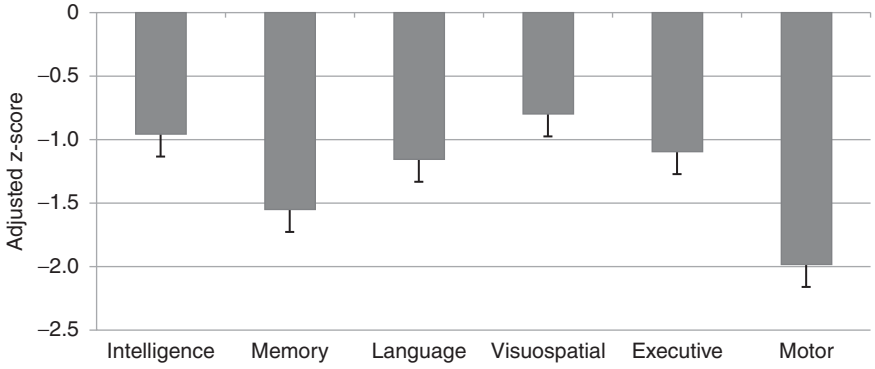

Figure 3 Age, gender, and education corrected *z* scores for patients with temporal lobe epilepsy (solid bars) compared with controls ($z = 0$) (Oyegbile, 2004).

Modal descriptions of patients with epilepsy syndromes are helpful in characterizing general patterns of cognitive performance, but they do not give a sense of the interesting heterogeneity that can be seen within and across epilepsy syndromes. Our experience had been that among patients with ictally confirmed unilateral mesial onset of spontaneous seizures – in whom there was a pathologically confirmed hippocampal sclerosis – there was considerable heterogeneity in individual cognitive profiles (in the context of the above mean cognitive profile). These observations suggested that specific cognitive phenotypes might be represented in such patient groups.

A yet untapped approach to understanding cognitive morbidity in epilepsy is taxonomic in nature. This approach involves addressing the question of whether empirically derived groupings of *patients* with similar profiles of cognitive function can be identified, either within or across epilepsy syndromes. Taxonomies facilitate reliable clustering of individuals into meaningful groups, provide a common language and organizing influence in the field, and set the stage for further investigation of clinical and neurobiological correlates. To date, taxonomic approaches have rarely been used to advance understanding of the neurobehavioral complications of the epilepsies. Toward that goal, rather than grouping patients on the basis of clinical seizure characteristics (e.g., seizure frequency) and examining the relationships of individual clinical seizure characteristics to cognition, one would derive a grouping of patients based solely on their pattern of performance across several cognitive domains and then look for potential electrical or imaging correlates.

We applied cluster analysis to a large sample of patients with temporal lobe epilepsy and identified distinct cognitive subgroups or phenotypes. From a neuropsychological perspective, three distinct cognitive profiles were uncovered (**Figure 4**); Cluster 1 was minimally impaired, Cluster 2 was memory impaired, and Cluster 3 was more diffusely affected – with memory, executive, and psychomotor speed impairments. These distinct groups were then compared across demographic factors, clinical seizure characteristics, quantitative MRI volumetric variables, and cognitive course. A brief description of the cognitive phenotypes is presented here.

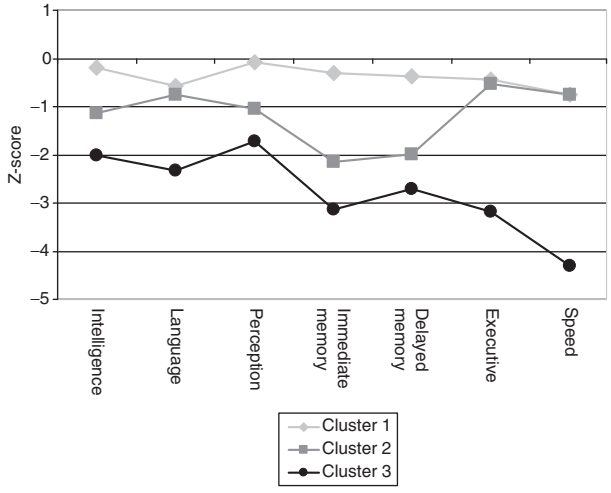

Figure 4 Cognitive profiles in temporal lobe epilepsy. Reproduced from Hermann *et al.*, 2007, with permission of Cambridge University Press.

Cluster 1 (*minimally impaired*) consisted of approximately half (47%) the temporal lobe epilepsy subjects who exhibited the most intact cognition of the three cluster groups. That said, their performance was significantly worse than controls across several cognitive domains, including language, immediate and delayed memory, executive function, and psychomotor speed domains. While statistically significant, the pattern was one of very mild but discernable cognitive dysfunction. These patients were clearly distinct from the other epilepsy subjects, and closest to the healthy controls in terms of cognitive status.

Cluster 2 subjects (*predominantly memory impaired*) consisted of 24% of the patient sample, who exhibited marked impairments in immediate and delayed memory – in the context of significantly poorer performance than controls across all other cognitive domains. That is, memory was the most striking cognitive abnormality, but it occurred in the context of a mild generalized depression of overall cognition compared to controls.

Cluster 3 (*generalized impairment*) consisted of 29% of the temporal lobe epilepsy subjects. They exhibited the poorest cognition across all domains compared with controls, and also demonstrated significantly poorer performance across all cognitive domains compared with both Clusters 1 and 2. The most striking impairments in this group fell in the areas of executive function and cognitive/psychomotor speed. This group exhibited an especially prominent degree of impairment in executive function impairment, which has been an interesting finding in both adults and children with temporal lobe epilepsy.

Thus, an underlying taxonomy characterized by the nature, pattern, and severity of evident cognitive complications can be identified. The clinical correlates of these cognitive phenotypes was then examined by examination of profiles of demographic features (age), clinical seizure features (duration of epilepsy, AED polytherapy), and brain volumetrics (segmented whole brain and lobar tissue volumes, CSF, and hippocampus). In summary, the volumetric findings (**Figure 5**) paralleled the cognitive results. The most intact group (Cluster 1) showed significant hippocampal atrophy with minimal change in other morphometric measurements. As the degree of cognitive impairment increased (Cluster 2–3), there was a pattern of corresponding increase in volumetric abnormality, including greater hippocampal atrophy and culminating in Cluster 3 where there was evidence of widespread volumetric abnormalities. These relationships were examined largely in terms of whole brain volumes (cerebral gray,

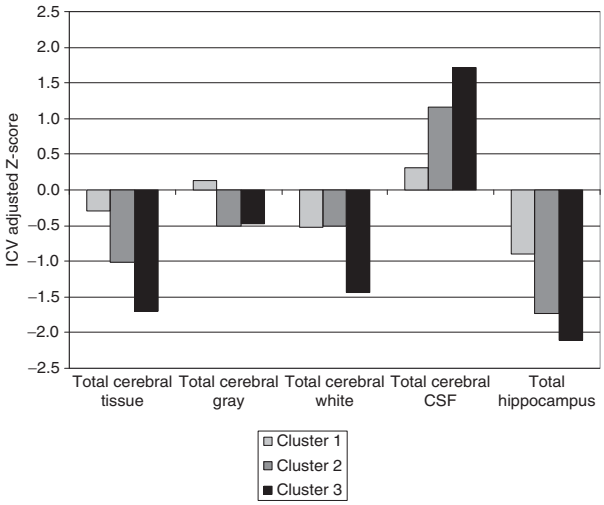

Figure 5 MRI volumetrics in cognitive profile groups. Reproduced from Hermann *et al*., 2007, with permission of Cambridge University Press.

white, and CSF volumes). In the future, we plan to examine more specific relationships, such as those between frontal lobe volumes and tests of executive function.

In addition, the most cognitively impaired group (Cluster 3) was older, had the longest duration of epilepsy, and took more medications than the other groups (especially Cluster 1). There were also meaningful but statistically nonsignificant trends with regard to other clinical seizure features. Cluster 3 had the highest proportions of patients with histories of >50 lifetime generalized tonic–clonic seizures, status epilepticus, and severe initial precipitating injuries. Thus, this appears to be a group that is most likely to have incurred both an earlier neurodevelopmental insult and a more protracted and severe course of epilepsy.

Of considerable interest is the degree to which abnormalities in mental status may progress in the face of an increasingly chronic (longer duration) disorder. The issue of cognitive progression in temporal lobe epilepsy is important, as curative surgical treatments exist but are frequently delayed. Patients with medication-resistant temporal lobe epilepsy often present with considerable cognitive and behavioral handicap when finally referred for surgical consideration – unfortunately, sometimes after decades of unsuccessful medical management.

Prospective cognitive studies of patients with epilepsy date back to the early part of the last century, but these studies are often characterized by rather limited assessment of cognition (often just IQ), the inclusion of mixed seizure types, varying test–retest intervals, lack of control groups, and other methodological shortcomings. More common are cross-sectional studies, which, while informative, suffer from the obvious limitation of providing an indirect evaluation of neuropsychological change over time, cohort effects, and other methodological problems that prevent a clear and unequivocal characterization of the cognitive course of epilepsy. A recent review concluded that progressive cognitive decline does occur in a proportion of patients, and appears to be associated with markers of a difficult epilepsy course (e.g., number of lifetime generalized tonic–clonic seizures).

Progressive changes in cognitive function, especially memory, have been demonstrated in careful prospective investigations by the group in Bonn (Germany). We also found in our sample that over a 4-year prospective period, an abnormal cognitive trajectory was exhibited in approximately 20–25% of patients. A poorer cognitive course was associated with a variety of factors, including demographic features (older age), clinical seizure features (longer duration of epilepsy), MR variables (baseline volumetric abnormalities), and cognitive findings (lower baseline intelligence).

But just as modal cognitive profiles harbor interesting subgroups (as demonstrated in the results of the cluster analysis described earlier), so is the case when considering prospective cognitive change. If we examine prospective cognitive course as a function of our cognitive phenotypes, meaningful differences in their prospective cognitive trajectory can be seen across the cognitive phenotype groups.

As shown in **Figure 6**, the most abnormal cognitive trajectory was observed in Cluster 3 subjects; that is, those who were the most impaired at baseline appeared to be quite vulnerable to ongoing cognitive change. In contrast, the most optimal cognitive course was observed in Cluster 1 subjects – those who were most intact at baseline.

Conclusion and Future Goals

There is a remarkable degree of heterogeneity in the cognitive profiles of patients with a discrete syndrome of epilepsy. This heterogeneity is only just beginning to be characterized and understood. The average cognitive profile of these patients is interesting in that it suggests that despite a relatively focal zone of seizure onset, there can be a remarkably diverse range of cognitive difficulties. These cognitive phenotypes can be identified, and they appear to reflect clear differences in the degree of underlying structural abnormality (as revealed by quantitative volumetrics) as well as clinical seizure features.

Not discussed here, but important, are abnormalities evident in other neuroimaging modalities (voxel-based morphometrry, diffusion tensor imaging and tractography, fMRI), which also demonstrate interesting patterns associated with cognitive abnormality and cognitive reorganization.

Specific aspects of underlying volumetric abnormalites in chronic unilateral temporal lobe epilepsy are likely to contribute to the pattern of generalized cognitive impairment described previously. There is developing evidence

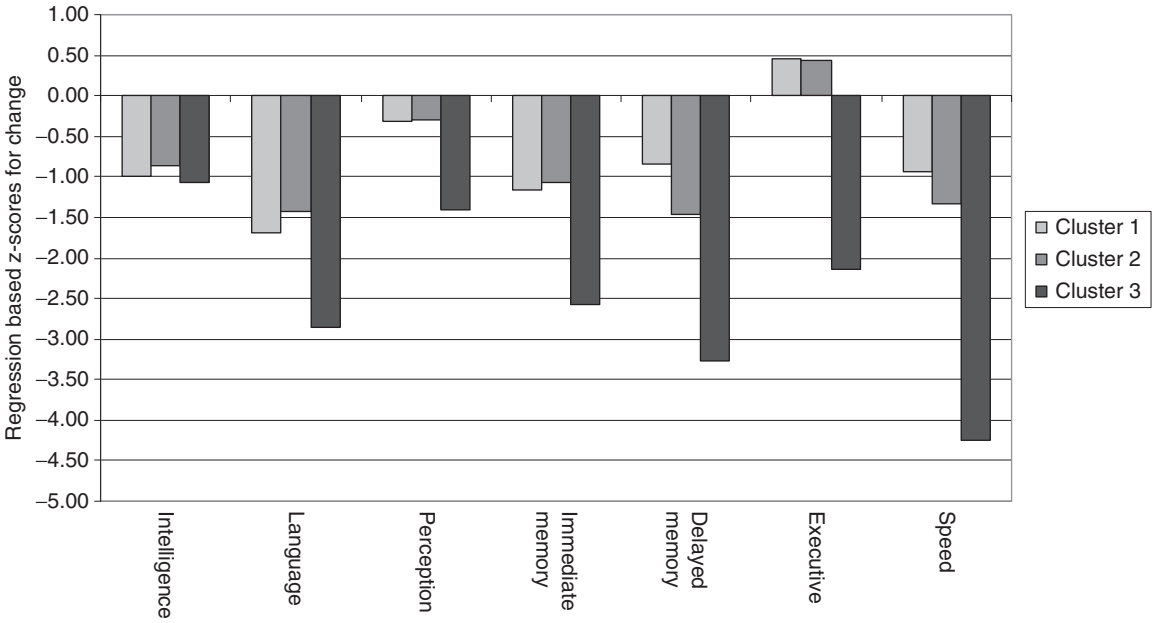

Figure 6 Prospective cognitive trajectories in cognitive phenotype groups. Down going bars represented poorer obtained test performances compared with expected test performances. Reproduced from Hermann *et al*., 2007, with permission of Cambridge University Press.

of specific structure–function relationships linking abnormalities in cognitive processing speed with reduction of total cerebral white matter volume, abnormal procedural memory (classical eyeblink conditioning) with cerebellar atrophy, abnormal confrontation naming with hippocampal atrophy, and impaired aspects of semantic memory with atrophy of the temporal pole. Overall, the image of this *focal* brain disorder is changing, with linkages between distributed abnormalities in brain structure and cognition just beginning to be understood.

In the future, similar approaches could be taken with other forms of localization-related (frontal lobe epilepsy) or idiopathic generalized epilepsies (absence epilepsy). It would prove interesting to identify both shared features (e.g., generally intact cognition) as well as syndrome-specific cognitive patterns (e.g., memory impairment in TLE, executive impairment in frontal lobe epilepsy, attentional disruption in absence epilepsy) and their relative distributions across epilepsy syndromes. These findings would facilitate genotype–phenotype investigations as applied to higher cognitive function and brain structure, as has been undertaken in other disorders.

Introduction

Autism spectrum disorders are a heterogeneous group of neurodevelopmental disorders characterized by impairment in three domains: deficits in verbal and nonverbal communication, impairments in reciprocal social interaction, and the presence of restricted, repetitive behaviors or interests. The term 'autism' is used throughout this chapter to refer to the broader spectrum of autistic disorders, including Asperger's syndrome and atypical autism, with classic autism lying at the more severe end of the spectrum. Autism is associated with significant long-term impairment for affected individuals, and prevalence rates have increased with better recognition of the wider spectrum of more subtle symptoms. Approximately, 10–15% of cases of autism are associated with known medical conditions and 5–10% of those with autism have genetic and chromosomal disorders. The remaining cases are idiopathic with unknown etiology. However, genetic factors appear to be of significant importance, with 3–7% recurrence risk in families of individuals with autism and with twin data strongly suggesting the involvement of multiple interacting genes.

While current evidence robustly points at a genetic etiology for autism, there is also emerging evidence that nongenetic factors may play an equally important etiological role. Autism is clearly recognized as a neurobiological disorder, in part due to early recognition of the

Introduction

Autism spectrum disorders are a heterogeneous group of neurodevelopmental disorders characterized by impairment in three domains: deficits in verbal and nonverbal communication, impairments in reciprocal social interaction, and the presence of restricted, repetitive behaviors or interests. The term 'autism' is used throughout this chapter to refer to the broader spectrum of autistic disorders, including Asperger's syndrome and atypical autism, with classic autism lying at the more severe end of the spectrum. Autism is associated with significant long-term impairment for affected individuals, and prevalence rates have increased with better recognition of the wider spectrum of more subtle symptoms. Approximately, 10–15% of cases of autism are associated with known medical conditions and 5–10% of those with autism have genetic and chromosomal disorders. The remaining cases are idiopathic with unknown etiology. However, genetic factors appear to be of significant importance, with 3–7% recurrence risk in families of individuals with autism and with twin data strongly suggesting the involvement of multiple interacting genes.

While current evidence robustly points at a genetic etiology for autism, there is also emerging evidence that nongenetic factors may play an equally important etiological role. Autism is clearly recognized as a neurobiological disorder, in part due to early recognition of the

association with clinical seizures and abnormalities in the EEG. Epilepsy is the most highly prevalent medical comorbidity with autism. Depending on the population studied, rates of epilepsy in autism range from 11% to 39%, with the highest prevalence being reported by studies of adolescents and young adults, those with moderate to severe learning disabilities, and those with severe receptive language disorders. The likelihood of developing epilepsy in autism increases with age, with a peak incidence before 5 years and in adolescence. Children with autism seem more likely to have partial onset epilepsy than primary generalized epilepsy, and the multiple seizure types seen in association with autism can often be treatment-refractory. The frequency of abnormal (epileptiform) discharges on EEG has been found to be almost twice as high as the frequency of clinical epilepsy, with a wide range of rates reported from 15% to as high as 68%. The abnormalities most reported are focal or multifocal spiking, over the temporal region or more commonly over the frontal areas. Although there are relatively few data on the rates of autism in children with epilepsy, studies suggest that up to one-third of children with epilepsy are at risk of having autism, with the risk highest amongst those with early onset of seizures.

Despite this strong association, the relationship between epilepsy or epileptiform EEG abnormalities and autism is poorly understood. It is possible that epilepsy and autism are separate manifestations of a dysfunctional brain, most likely stemming from genetic vulnerability. It may also be that epileptiform abnormalities interfere with early brain development, thus potentially contributing to cognitive, language, and behavioral dysfunction of an autistic type. The association of both conditions with mental retardation makes the relationship even more complex. There are a number of genetic disorders associated with both autism and epilepsy, including Tuberous Sclerosis, fragile X syndrome, and Rett syndrome. However, it is tuberous sclerosis complex (TSC) that, due to the high rates of mental retardation, autism and epilepsy with which it is associated, offers a unique neurogenetic model for investigating the relationship and testing theories about the brain basis of autism.

Background

TSC is a multisystem autosomal dominant genetic disorder, characterized by widespread tumor-like malformations (hamartomas) of many organs, including the brain, skin, kidney, eyes, and heart. Hamartomas are benign 'tumors' that resemble the tissue that is ordinarily found in the location; however, the tissue is disorganized and malformed and consists of poorly differentiated and immature cells. Mutations which give rise to the disorder occur in the TSC1 gene in 20% of cases and in the TSC2 gene in 80% of cases. The mutations are spontaneous in ~60% of cases while the remaining cases are familial. Individuals with TSC2 mutations may have a more severe form of tuberous sclerosis and more adverse developmental outcomes than individuals with TSC1 mutations. The TSC1 gene is located on chromosome 9q34 and codes for the protein hamartin. The TSC2 gene is on Ch 16p13.3 and codes for the protein tuberin. The complex formed by these proteins acts in the insulin signaling pathway to regulate mTOR and hence S6 Kinase; mutations in TSC1 or TSC2 lead to abnormalities of the tuberin/hamartin complex, dysregulation of mTOR, and possibly other pathways with the final effect being abnormalities in cell growth, differentiation, and migration.

The prevalence of TSC in children is around 1 in 10 000–20 000. Autistic behaviors were first described in TSC in 1932, and recent epidemiological studies of children with TSC have found rates of autism between 43% and 86%, thus demonstrating that not all children with TSC develop autism. There is some evidence that the prevalence of autism may be higher in those with TSC2 mutations compared with individuals with TSC1 mutations. This difference may reflect the increased severity of TSC in those with TSC2 mutations. More severe intellectual impairment also appears to occur in children with TSC2 mutations. The distribution of intelligence quotient (IQ) seems to be bimodal with one peak in the severely impaired range and another in the low average range. The risk of mental retardation is increased in children with early seizure onset, intractable seizures, and infantile spasms. Mental retardation is a correlated feature with autism in TSC, although some individuals of normal intelligence may develop autism or Asperger's syndrome. Approximately, 1–4% of children with autism have TSC.

Neuropathological manifestations of TSC include cortical tubers, subependymal nodules, and in ~10% of cases, subependymal giant cell astrocytomas. Cortical tubers form during fetal life and vary in number and location, but with most individuals having several. They appear to act as foci for epileptic discharges, producing multiple types of difficult to control, often multifocal, seizures.

The majority of patients with TSC will present in childhood and usually with seizures. Epilepsy is a common feature in TSC, with rates of 60–90%. However, not all individuals with TSC develop epilepsy or come to medical attention. Therefore, the true incidence of epilepsy in TSC is unknown. Of those who do develop epilepsy, the most frequent seizure types are infantile spasms and/or partial seizures. Earlier seizure onset is correlated with increasing numbers of cortical tubers. Up to 69% of patients with TSC present with infantile spasms, often in the first year of life and in most cases

between 4 and 5 months of age. TSC is associated with 25% of all cases of infantile spasms. Infantile spasms and associated EEG abnormalities may be atypical in TSC. They are often preceded by partial seizures, although the latter can be missed in the first few months. The majority of children with TSC who have infantile spasms at onset eventually develop partial seizures (partial motor, complex partial) with secondary generalization. Focal or multifocal epileptiform abnormalities on EEG may be found before the onset of seizures and between seizures. Hypsarrthymia on EEG (often with focal features) may also develop. The treatment of epilepsy in TSC is often difficult, with seizures frequently being intractable despite treatment with many different antiepileptic medications. Poor prognostic signs include multiple seizure types, seizure onset before 1 year, and multifocal EEG abnormalities. Children with TSC and treatment-refractory epilepsy have undergone resective surgery of cortical tubers with variable outcomes.

Methodological Considerations

Although the early studies have provided many important leads and produced some fundamental insights, various methodological challenges and shortcomings have led to some inconsistencies and uncertainties. For example, due to the rarity of TSC, studies have almost inevitably involved small sample sizes, with all the concomitant limitations that stem from this point. Moreover, most of the samples have been based on clinic populations, where possible ascertainment biases may be operating. In addition, data have frequently been collected retrospectively and therefore may be subject to various biases. As such, data suitable for rigorous multivariate analysis, aimed at delineating developmental causal pathways from genetic mutation to neurological, cognitive and behavioral outcomes, are lacking or only just emerging.

Several challenges are also evident in terms of the need to develop suitable standardized measures and protocols for various important manifestations of the disease. For example, the recording and categorization of seizures and the type of epilepsy represents one challenge; similar difficulties can arise when attempting to standardize and interpret EEG recordings. Many similar considerations apply to the identification and measurement of the cerebral changes seen in TSC. New MR imaging techniques that are optimized for tuber identification and mapping are emerging, but there are as yet no agreed 'gold standard' protocols. To fully exploit the potential of any prospective population based studies, there is a need to develop agreed protocols, classification systems, and minimum standards for the collection of high quality epilepsy data, EEG recordings, autism assessments, psychometrics, and neuroimaging.

Results – The Unique Relationship between Autism and Epilepsy in TSC

Autism may develop in individuals with TSC1 or TSC2 mutations, although the risk in individuals with TSC1 mutations appears to be lower. It may be that the risk is also dependent on the nature of the mutation, although this possibility has yet to be established. There is also evidence for nongenetic determinants of development outcomes in TSC. Such evidence, for example, has come from case reports of monozygotic twins in whom quite different developmental outcomes were found despite their identical genetic abnormalities and background. The nongenetic influences may reflect unique environmental effects and/or the random nature of second hit events that give rise to the hamartomatous lesions/cortical tubers.

Different explanations for the pathogenesis of autism in TSC have been postulated. It may be that abnormalities in a specific key brain system (e.g., the social brain network or the mirror neuron system) may give rise to the risk for autism. Alternatively, abnormalities within several different brain systems may be required (the multiple primary deficit hypothesis). According to this latter hypothesis, abnormalities in the social brain system might give rise to social impairments, whereas abnormalities in the frontal regions could underlie the stereotyped and repetitive behaviors. Abnormalities in these brain systems could derive from tuber-related anatomical abnormalities or from the adverse effects of epilepsy on brain development. Lastly, widespread abnormalities in 'connectivity' stemming from the effects of seizures on synaptic development and dendritic arborization may create the increased risk.

Due to the presence of easily identifiable cortical lesions in TSC, investigators have carried out studies in patients with autism and TSC to try to correlate the neurodevelopmental disorder with the location of tubers. One of the first clinical series of cases investigating the distribution of cortical tubers in TSC reported a strong association between the presence of temporal lobe tubers and the development of autism. In this study of 18 TSC patients, the number of tubers in the group overall were greatest in the frontal lobes, followed by the parietal, temporal, cerebellar, and occipital lobes. However eight of the nine patients with autism had temporal lobe tubers, whereas none of those without autism had tubers in this region. In the autistic patients, the lateralization of the temporal tubers was on the left for three patients, on the right for four, with bilateral temporal tubers for the remaining two. There was a history of epilepsy in eight of the autistic and in seven of the nonautistic participants. Overall, the number of tubers was significantly greater in patients with mental retardation. This study provided the first clear evidence between localized, gross structural abnormalities in the brain and the development of autism.

Testable hypotheses for similar studies could be offered by a number of neuropsychological theories of autism. One of these more influential theories was evaluated in a retrospective case study investigating neuroepileptic risk factors of autism in individuals with TSC. The theory proposes that autism is a specific cognitive disorder of 'mind-blindness,' whereby the social impairments associated with autism are due to an inability to read other people's minds. The study hypothesized that such impairment is the end result of a dysfunctional neural network that involved ventral frontal cortex, the amygdala, and temporal lobes. The 'mind-blindness' theory proposes that the inability to follow another person's eye gaze is a core deficit of autism. The processing of information from faces – such as recognition of faces, facial expressions of emotion, and the direction of another person's eye gaze – are recognized to be key functions of the temporal lobes and amygdala within this neural network. Further, the function of detecting another's direction of gaze has been shown to be related to the superior temporal gyrus.

Results from this retrospective case study confirmed that a diagnosis of autism was associated with the presence of cortical tubers in the temporal but not other lobes of the brain. The presence of cortical tubers appeared to be a necessary factor for the development of autism in TSC. However, it was noted that not all individuals with temporal lobe tubers developed autism; therefore, temporal lobe tubers might be necessary but not sufficient for the development of the neurobiological disorder. Contrary to the hypothesis that tubers located in the temporal superior gyrus would be associated with autism, neither the number nor the location of temporal lobe tubers was significantly associated with the development of autism spectrum disorder in this study. Therefore, it was proposed that epileptiform activity in the temporal lobes, rather than the structural abnormalities represented by the tubers, may be the risk factor for the development of autism. Further analysis of the retrospective case study data revealed that outcome was associated with various indices of epileptic activity, including evidence of temporal lobe epileptiform discharges on EEG, the age of seizure onset in the first 3 years of life, and a history of infantile spasms. The study concluded that children with tuberous sclerosis are, therefore, more likely to develop autism when temporal lobe tubers are present and associated with temporal lobe epileptiform discharges as well as early-onset, persistent spasm-like seizures.

These findings support the hypothesis that the developmental timing of seizures influences outcome. In particular, temporal lobe epileptiform activity occurring early in life, at an early critical period, may perturb the normal development of key social cognitive functions within the temporal lobes and finally leads to autism. The key risk period was identified in the first year of life when social behaviors begin to emerge and develop. The risk of developing autism was decreased if seizures began in the second year of life, consistent with the evidence that epilepsy syndromes which begin after 18–24 months are not associated with an increased risk of autism. Idiopathic autism rarely occurs after 36 months. Although a history of infantile spasms was found to be associated with autism, not all children with spasm-like seizures developed autism and not all children with autism suffer infantile spasms. Therefore, infantile spasms appear to be a marker for liability rather than a risk factor. Further analysis in the retrospective case study showed that the risk of developing autism associated with infantile spasms was no longer evident when age to seizure onset and temporal lobe epileptic foci were accounted for.

There is evidence indicating a temporal association between epilepsy and regression of development. Similar evidence has been reported in cases studies of autistic regression in patients with TSC and with either seizures or EEG abnormalities. One such report described a male with TSC at 6 months of age. Before the onset of seizures but after detection of an abnormal EEG, the child was treated with vigabatrin (at 6 months of age) to prevent the onset of seizures. In order to avoid possible visual field defects, vigabatrin was discontinued at 13 months of age. At 21 months, the child developed partial seizures with secondary generalization, as well as infantile spasms. Cognitive and social development were normal until 21 months of age and the onset of seizures, but following the onset of seizures regressed developmentally. The child met the criteria for autism and mental retardation when assessed at 24 months. Such case studies indicate that the onset of epilepsy during an early stage in brain development can be associated with autistic regression and pervasive developmental disorder.

A temporal association between onset of epilepsy and regression in language has also been found in children with regression after a period or normal or near – normal development. In Landau–Kleffner syndrome (rapid loss or previously normal language skills in association with either seizures or epileptiform abnormalities on EEG), some investigators have found that successful treatment of EEG abnormalities may improves the language deficits. An earlier age of onset of seizures has the worst outcome. Recent work has demonstrated some favorable long-term effects of vigabatrin on overall cognitive function, epilepsy, and autistic behavior in children with infantile spasms, with and without TSC. The cessation of spasms with vigabatrin was associated with significant improvement of cognition and behavior in children with TSC; controlling infantile spasms seemed to be a key factor for mental development. Similar results have been reported in children without TSC. Recently, however, vigabatrin has been linked with visual field defects which may limit its use.

Taken together, these lines of evidence support the notion that temporal lobe epileptiform discharges are most strongly associated with autism in TSC when occurring during an early critical period of social development in the brain. However, a causative relationship of epilepsy to autism is yet to be established and the findings are inconsistent, with data from some studies being interpreted as supporting the multiple primary deficit hypothesis or as suggesting abnormalities within the cerebellum as primary. Methodological differences probably underlie some of the inconsistencies in findings.

Future Directions

Most of the evidence to date stems from retrospective studies of clinic populations of children with autism, with or without TSC. As such, findings may have been biased in one way or another. Prospective, longitudinal studies are therefore needed to find out whether early seizures occurring during a critical time of development, specifically increases the risk of developing autism in children. There is also a need to understand whether the risk for developing autism depends on the type and severity of seizures as well as on treatment response. Such an investigation may lead to a better understanding of clinical prognostic indicators and of the neurobiological pathways leading to autism.

To address the above questions, a prospective longitudinal study of children with TSC was planned and has commenced. The study (TS2000 Study) sample comprises a population-based sample of newly diagnosed individuals with TSC, diagnosed in the UK between 2001 and 2006. Systematic longitudinal data are being collected on the natural history, prognostic indicators, and the influence of genotype on developmental outcome. Following diagnosis and recruitment children are evaluated using standardized instruments and their development is monitored and assessed at regular intervals. The aims of the TS2000 Study include determining to what extent the natural history (in terms of intellectual, cognitive, behavioral, and neurological impairments) is related to genotype, gender, mode of presentation; the number, distribution, and type of brain lesions; and the type, severity, and course of seizures in the early years, including response to treatment. Prospective studies that follow infants who are diagnosed with TSC before the onset of seizures are also underway and will be particularly informative. Such longitudinal studies with repeated testing at regular intervals should contribute towards identifying the sequence of unfolding events, thereby clarifying the causal chain.

Treatment studies and trials of antiepileptic medications in TSC could potentially be very informative. The few medication trials to date are small pilot studies highlighting the need for large-scale better randomized control designs. It will be important to identify whether treatment efficacy is associated with the development of autism – which could lead to a change in prescribing guidelines and a better outcome for affected children. Intervention research studies will also be required to elucidate the value of neurosurgical interventions.

Future directions also include further clarification of genotype and phenotype correlates, in relation to the genotype/phenotype analysis of autistic behaviors in TSC. Studies to date have demonstrated that mental retardation is more highly associated with TSC2 mutations. More studies are required to identify whether this association also applies to autism and therefore whether less severe presentations of autistic spectrum disorders might be associated with TSC1 mutations.

Molecular studies of TSC have identified a cascade whereby hamartin and tuberin form a protein complex which inhibits mTOR (mammalian target of rapamycin); abnormalities in this pathway, resulting in higher mTOR activity, are thought to lead to increased cell proliferation and growth. The identification of this pathway has lead to early clinical trials of mTOR inhibitors (e.g., rapamycin) in the treatment of TSC. Early evidence suggests that some of the brain lesions may shrink with drug treatment, and these initial studies are now being followed up with randomized controlled clinical trials – the results of which are eagerly awaited, to determine whether these drugs can improve other outcomes such as seizure severity, intellectual disability, and autistic behavior.

Finally, the high rates of autism in TSC highlight the importance of evaluating these TSC children for autistic behaviors. In fact, higher rates have been reported for autism than for the cardiac or renal abnormalities (for which children with TSC are routinely screened). In order to identify children with autism and the associated long-term impairment, improved assessment procedures for this unique population are required.

Introduction

Language, a fundamental component of social behavior, is a tool for communicating thoughts and feelings. The development of children's linguistic skills extends from the toddler period through adolescence. In parallel, there is a protracted maturation of brain regions involved in language. The extensive nature of this period increases the vulnerability of this developmental process. In addition, the development of language parallels the prolonged, age-related changes in children's behavior, cognition, and social skills. Language, therefore, provides a gateway to studying illness effects not only on children's language itself, but also the child's intelligence, social skills, emotions, behavior, and brain development. As such, it is essential to understand the functional implications of a developmental disorder like epilepsy on language development.

My laboratory has studied how the development of children's use of language, to organize and formulate their thoughts, goes awry in pediatric neurobehavioral disorders such as epilepsy. To this end, we have used clinical psychiatric measures of 'thought disorder.' These higher level linguistic or discourse deficits involve impaired integration of language, cognition, and social behavior. Studies of thought disorder in pediatric epilepsy are important for three main reasons. First, from the neurological perspective, they provide information on how ongoing seizures and the underlying neuropathology impact the development of children's higher level linguistic skills. Second, from the psychiatric perspective, they offer an understanding of the functional implications of higher level linguistic impairments on behavior and emotions in children with epilepsy. Third, from the theoretical perspective, use of a developmental model and neuroimaging techniques in these studies advance our understanding of how epilepsy impacts development.

Background

Thought disorder involves impairment in the form or manner in which a speaker presents thoughts to a listener and is characterized by clinical signs such as illogical thinking, loose associations, incoherence, poverty of content of speech, tangentiality, circumstantiality, and others. Thought disorder represents abnormal organization, control, and processing of thinking; improper use of semantic and relational aspects of speech; and poor use of linguistic context to process and produce speech. Although regarded as a hallmark of schizophrenia, thought disorder (a normal developmental phenomenon in young children) is also found in pediatric neurobehavioral disorders including attention deficit hyperactivity disorder (ADHD), high functioning autism, complex partial seizures (CPS), and childhood absence epilepsy (CAE).

Prior evidence for schizophrenia-like psychosis and thought disorder in adults with temporal lobe epilepsy (particularly left temporal lobe epilepsy) led us to study thought disorder in children with temporal lobe epilepsy. The study was begun to identify brain substrates involved in pediatric thought disorder, such as those seen in childhood schizophrenia. Being conducted on children with cryptogenic epilepsy with CPS and focal EEG findings in the temporal and frontal regions, the study included control groups of children with CAE and normal children. We initially predicted that we would find thought disorder in

Introduction

Language, a fundamental component of social behavior, is a tool for communicating thoughts and feelings. The development of children's linguistic skills extends from the toddler period through adolescence. In parallel, there is a protracted maturation of brain regions involved in language. The extensive nature of this period increases the vulnerability of this developmental process. In addition, the development of language parallels the prolonged, age-related changes in children's behavior, cognition, and social skills. Language, therefore, provides a gateway to studying illness effects not only on children's language itself, but also the child's intelligence, social skills, emotions, behavior, and brain development. As such, it is essential to understand the functional implications of a developmental disorder like epilepsy on language development.

My laboratory has studied how the development of children's use of language, to organize and formulate their thoughts, goes awry in pediatric neurobehavioral disorders such as epilepsy. To this end, we have used clinical psychiatric measures of 'thought disorder.' These higher level linguistic or discourse deficits involve impaired integration of language, cognition, and social behavior. Studies of thought disorder in pediatric epilepsy are important for three main reasons. First, from the neurological perspective, they provide information on how ongoing seizures and the underlying neuropathology impact the development of children's higher level linguistic skills. Second, from the psychiatric perspective, they offer an understanding of the functional implications of higher level linguistic impairments on behavior and emotions in children with epilepsy. Third, from the theoretical perspective, use of a developmental model and neuroimaging techniques in these studies advance our understanding of how epilepsy impacts development.

Background

Thought disorder involves impairment in the form or manner in which a speaker presents thoughts to a listener and is characterized by clinical signs such as illogical thinking, loose associations, incoherence, poverty of content of speech, tangentiality, circumstantiality, and others. Thought disorder represents abnormal organization, control, and processing of thinking; improper use of semantic and relational aspects of speech; and poor use of linguistic context to process and produce speech. Although regarded as a hallmark of schizophrenia, thought disorder (a normal developmental phenomenon in young children) is also found in pediatric neurobehavioral disorders including attention deficit hyperactivity disorder (ADHD), high functioning autism, complex partial seizures (CPS), and childhood absence epilepsy (CAE).

Prior evidence for schizophrenia-like psychosis and thought disorder in adults with temporal lobe epilepsy (particularly left temporal lobe epilepsy) led us to study thought disorder in children with temporal lobe epilepsy. The study was begun to identify brain substrates involved in pediatric thought disorder, such as those seen in childhood schizophrenia. Being conducted on children with cryptogenic epilepsy with CPS and focal EEG findings in the temporal and frontal regions, the study included control groups of children with CAE and normal children. We initially predicted that we would find thought disorder in

the CPS children with left temporal involvement and/or psychotic symptoms (such as hallucinations and delusions) and not in the control groups. However, this study and subsequent studies on larger samples of children demonstrated that, in contrast to our predictions, both children with CPS and those with CAE had thought disorder, irrespective of their psychiatric diagnosis, compared to normal children. In fact, there were no significant differences in the thought disorder of the CPS and CAE groups. Furthermore, evidence for thought disorder in young normal children, and a significantly greater degree of thought disorder in younger CPS, CAE, schizophrenic, ADHD, and high functioning autistic children than in older children with these diagnoses, implied that onset of these abnormalities during active development of children's higher level discourse skills might impair the acquisition of these skills.

These findings underscored the importance of using a developmental model to determine if thought disorder in children with epilepsy reflected effects of on-going seizures, the underlying neuropathology, or both – on the development of children's discourse skills. From the clinical perspective, our results also highlighted the need to determine the functional implications of discourse deficits in children with epilepsy. More specifically, how did these impairments impact or reflect every day life – in terms of the cognitive/academic, behavioral/emotional, and social skills of these children?

Methods

Subjects

These studies included 93 CPS and 56 CAE children, aged 5.1–16.3 years with IQ scores of 70 and higher; 117 normal children were also studied. CPS subjects were diagnosed with cryptogenic epilepsy (as defined by the International Classification of Epilepsy) and had experienced at least one seizure during the year prior to the child's participation in the study. Children with a clinical history of CPS, but no EEG evidence for focal epileptic activity, were also included in the study sample. The study inclusion criteria for each CAE subject were: a diagnosis of CAE, absence seizures induced by hyperventilation, at least one seizure in the year prior to participation in the study, and EEG evidence of 3 Hz spike and wave. We excluded patients with a mixed seizure disorder, previous epilepsy surgery, atypical spike and wave complexes, juvenile myoclonic epilepsy, generalized tonic clonic seizures, a structural MRI abnormality (but not those with mesial temporal sclerosis), a neurological illness other than epilepsy, chronic medical illness, imaging evidence for structural brain abnormalities, a metabolic disorder, a hearing disorder, mental retardation based on school/classroom placement, and bilingual speakers of American English who did not attend English speaking schools or speak English at home.

To include control children from a wide range of ethnic and socioeconomic status backgrounds similar to those of the CPS and CAE groups, we recruited the normal control subjects from four public and two private schools in the Los Angeles community. We excluded children with current or past diagnoses of neurologic, psychiatric, language, and hearing disorders.

Procedures

Thought Disorder

We assessed the four types of thought disorder measures described in children with schizophrenia and presented in Figure 1. The first type, formal thought disorder, represents impaired organization of thoughts and includes illogical thinking (e.g., failure to present the listener with appropriate reasoning in causal and noncausal utterances or contradiction) and loose associations (e.g., unpredictable change in the topic of conversation without preparing the listener for the topic change). The second type, cohesive deficits, involves poor use of linguistic ties, such as conjunctions and referential cohesion that link ideas across sentences. The third and fourth types, deficits in self-initiated repair and revision, respectively, involve impaired use of strategies to correct on-line errors during conversation that occur at the level of the organization of ideas or of the linguistic ties across sentences, word choice, or syntax. As a result of poor organization of ideas, impaired use of cohesive devices, and poor on-line correction of communication breakdown, the listener has difficulty following the reasoning, topic maintenance, ideational contiguity between sentences, and to whom or what the child is referring.

Two raters with no knowledge of the child's neurological diagnoses code videotapes of the Story Game with the Kiddie Formal Thought Disorder Rating Scale (K-FTDS) as we described in detail in previous publications (see Further Readings). During the Story Game, the child hears an audiotaped story about a ghost or an ostracized boy and is presented with structured open-ended questions following each story. The child also chooses to tell a story about a good child, a bad child, the Incredible Hulk, or a witch. The K-FTDS scores are frequency counts of illogical thinking and loose association ratings divided by the number of sentences (clauses) made by the child. Kappa for illogical thinking and the generalizability coefficient for loose associations were 0.75 (SD = 0.15) and 0.66 (SD = 0.01), respectively, in a subsample of 39 epilepsy and healthy subjects.

The cohesion scores, measuring the frequency with which the child used linguistic ties that connect ideas and referents across sentences, include conjunctions,

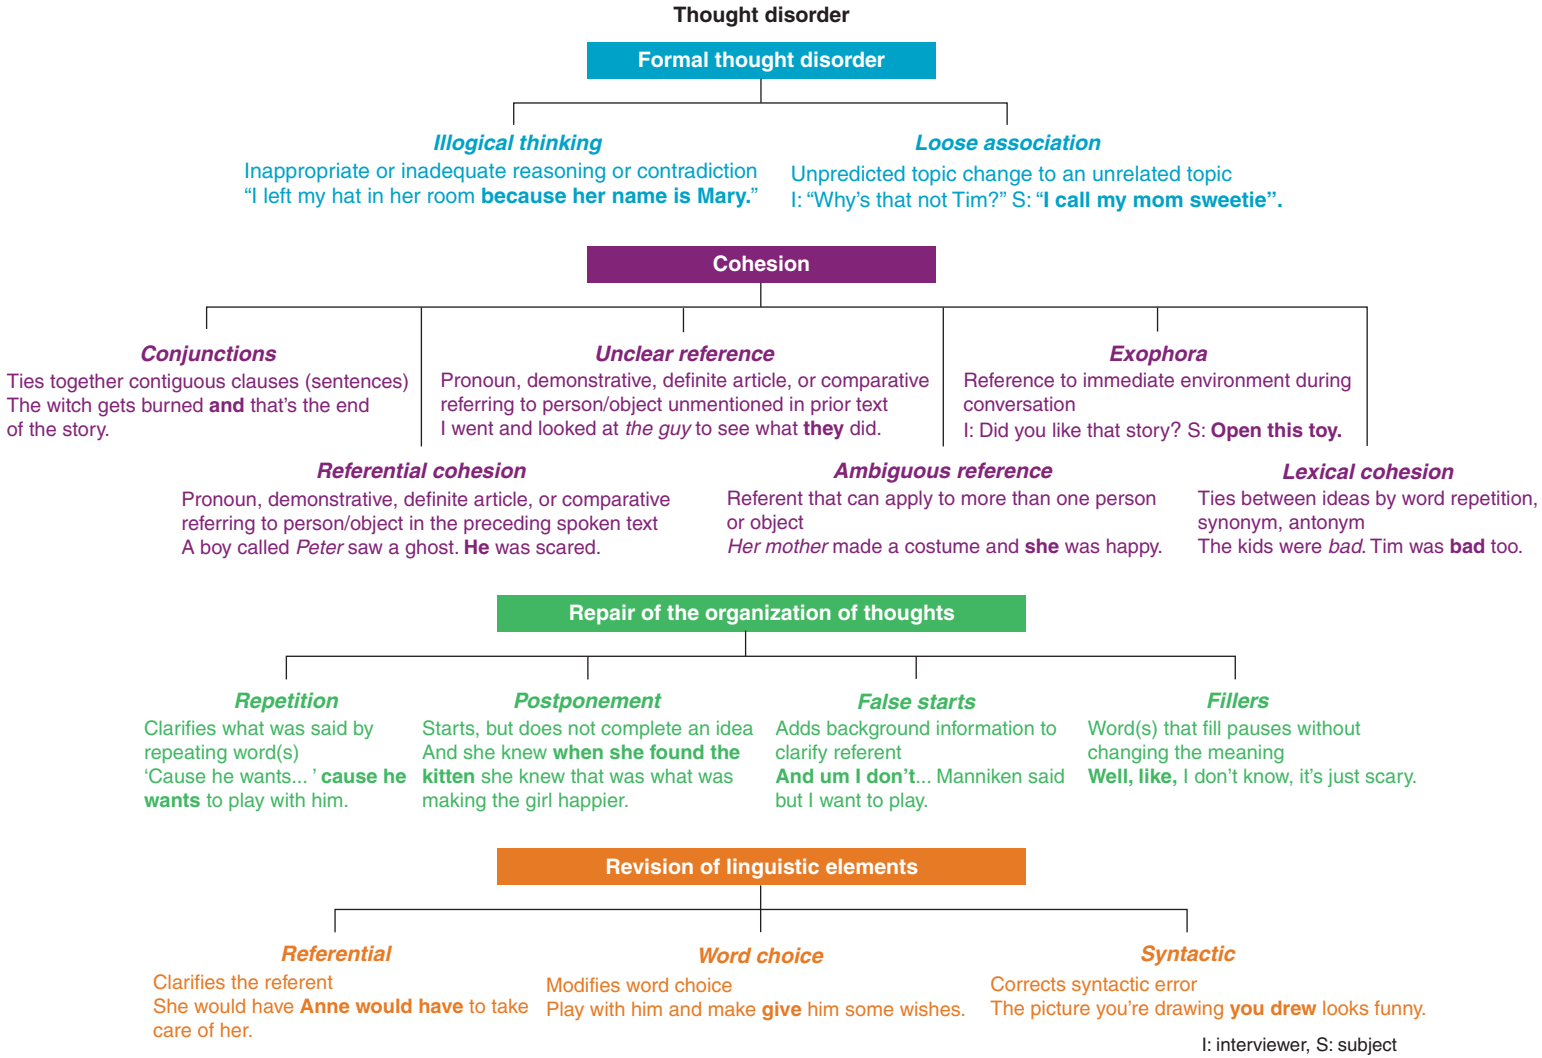

Figure 1 Definition and examples of thought disorder.

referential cohesion, lexical cohesion, ellipsis, unclear reference, ambiguous reference, and exophora (i.e., reference to the immediate environment during conversation). The inter-rater agreement (intraclass correlation) of these scores among a subsample of 31 children was 0.97 for conjunction, 0.96 for referential cohesion, 0.97 for lexical cohesion, 0.99 for ellipsis, 0.99 for unclear/ambiguous reference, and 0.99 for exophora.

The repair scores are frequency measures of how often the child corrects errors in the organization of thoughts (e.g., fillers, false starts, repetition) or linguistic errors (e.g., syntax, semantics, reference) while speaking. Inter-rater reliability (intraclass correlation) for the repair scores was 0.92 in a subsample of 45 children.

Psychopathology

A structured psychiatric interview, the *Schedule for Affective Disorders and Schizophrenia for School-Age Children, Epidemiologic Version (K-SADS-E)* and the *Present and Lifetime Version* (K-SADS-PL*)* was administered separately to each child and parent to determine the presence/absence and type of DSM-IV diagnoses, as detailed previously (see Further Readings). Parents completed the 118 behavior problem items of the *Child Behavior Checklist* (CBCL).

Cognition

The *Wechsler Intelligence Scale for Children – Revised* (WISC-R), and the *Wechsler Intelligence Scale for Children – 3rd edition* (WISC-III), were administered to children to generate Full Scale, Verbal, and Performance IQ scores (see Further Readings).

Imaging

All subjects underwent brain magnetic resonance imaging (MRI) scans in a 1.5-T magnet. Tissue was segmented and the total brain, frontal lobe parcellation (i.e., subregions), and temporal lobe volumes were computed. Using a discourse coherence activation paradigm, previously validated in both normal adults and normal children, children listened to short question–answer dialogs and indicated by key presses whether the answers made sense. Unknown to the subjects, features critical to making this decision were varied so as to challenge either reasoning or topic maintenance. Data were acquired on a Siemens 1.5-T Allegra scanner using an EPI gradient echo sequence (TR = 3000 ms, TE = 25 ms, flip angle = 90°, matrix size 64 × 64, FOV = 20 cm).

Results

The thought disorder in children with CPS and CAE with average intelligence includes: illogical thinking; under-use of cohesive devices that link ideas, people, events, and objects across sentences; and infrequent online monitoring and self repair of errors in the organization of thinking and in the use of syntax, word choice, and reference (**Figure 1**). The younger CPS and CAE children have significantly more thought disorders than the older children with these neurological diagnoses. However, earlier onset of CPS, a history of prolonged or febrile seizures, as well as localization and lateralization of epileptic activity are all related to thought disorder in CPS children. In contrast, the thought disorder in CAE is associated with age, seizure frequency, Verbal IQ, and the type of antiepileptic drug (e.g., valproic acid > ethosuximide). These findings suggest that although CPS and CAE both affect the normal maturation of children's discourse skills, they might to do so through different mechanisms.

From a functional perspective, thought disorder in the CPS group was related to psychopathology, school problems, decreased academic achievement, and poor peer interaction; in the CAE group, thought disorder was related only to school problems. More specifically, children with CPS, with ADHD, and high CBCL externalizing behavior scores had the highest thought disorder scores, lower IQ scores, and poor social skills. Thus, thought disorder appears to be a developmental disability or comorbidity of pediatric CPS and CAE that involves essential areas of the children's functioning.

In CPS children, the association of thought disorder with ADHD, externalizing behaviors, and poor social skills might have important implications for the 'stigma' associated with epilepsy. Children who have difficulty using language to formulate and organize their thoughts are not competent social communicators. Perceiving them as 'different,' their peers might not want to play or interact with them. Thus, children's thought disorder or social communication deficits might underlie certain aspects of the stigma or peer rejection experienced by children with epilepsy. The presence of externalizing behaviors associated with ADHD as well as poor peer interaction and poor academic achievement might further contribute to this perception and to the social difficulties of these children. Thus, certain aspects of the behavior, social, and academic achievement difficulties of children with epilepsy, particularly those with CPS, might reflect their thought disorder-related social communication deficits.

Recent imaging findings demonstrate that the thought disorder of children with CPS is significantly related to smaller orbital frontal and inferior frontal gray matter volumes, increased Heschl's gyrus gray matter volumes, and smaller superior temporal gyrus white matter volumes. These brain regions are associated with language and, like language, undergo protracted maturation. The association of thought disorder with volumes in these brain regions and the relationship of both thought disorder and these

volumes to the age of seizure onset, history of prolonged seizures, and lateralization of EEG in our studies provide additional support for our conclusion that in CPS, thought disorder might represent a developmental disability involving fronto-temporal regions involved in language.

Our fMRI findings (during a discourse coherence paradigm) show that normal children – compared to CPS children – have significantly increased cortical activity in the left inferior frontal gyrus when they use reasoning to make sense of the on-going conversation and in the right temporal region when they assess topic maintenance. Thus, even though the normal and CPS children are performing the task accurately, and are not told how to determine if the conversation makes sense or not, the CPS group engages the inferior frontal gyrus and the right temporal region significantly less than normal children. It remains to be determined, however, if our structural and functional imaging findings represent the effects of on-going seizures or the underlying neuropathology (or both) on the development of these brain regions.

Future Directions

Given the behavioral, cognitive, academic, and social implications of having thought disorder in children with epilepsy, our future studies will examine the change over time in the thought disorder measures of children with CPS and CAE – and how these changes might be related to changes in seizure variables, IQ, comorbid psychopathology, social competence, and brain volumes. We will also use MRI and diffusion tensor imaging to further our understanding of the association of thought disorder with brain function and the structure of white matter, respectively, to identify the neural substrates of thought disorder in these children.

Due to evidence for thought disorder in the families of schizophrenic patients, we are also examining thought disorder in the siblings of children with CPS and CAE. Finally, treatment studies are needed to ascertain the appropriate timing and method (i.e., speech and language, psychopharmcological, and educational treatment) of intervention for thought disorder and related functional impairments in CPS and CAE.

The Relationship of Epilepsy to Other Conditions/Disorders

A F Luat and D C Chugani, Wayne State University School of Medicine, Detroit, MI, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Autism is a neurodevelopmental disorder with onset before 3 years of age, characterized by impairments of reciprocal social interactions, verbal and nonverbal communication, and markedly restricted repertoire of activities and interests. The reported seizure frequency in autistic individuals ranges between 5% and 39%, and the reported prevalence of epileptiform electroencephalography (EEG) abnormalities in children with autism range from 8% to 60.8%. The prevalence of autism in children with infantile spasms is also higher compared to the general population. Autistic regression, a pattern of autistic development observed in 25–30% of cases wherein affected children initially appeared to have normal development (including speech) but then lose skills either social or language or both, has been reported in children with epileptic encephalopathies. The high prevalence of epilepsy in autism (and vice versa) suggests the existence of a common mechanistic basis (and perhaps a causal relationship) between the two.

Background

Serotonin in Autism and Epilepsy

The initial interest in the role of serotonin in autism arose from the demonstration of hyperserotonemia in autistic children, a result that has been replicated and extended, with the recognition that blood serotonin is also elevated in the first degree relatives of autistic children. Serotonin, in addition to functioning as a neurotransmitter, has an important role in brain development. Serotonergic fibers innervate Cajal–Retzius cells (CRC), which are necessary for cortical column development. Furthermore, in experimental studies, investigators found that treatment with the serotonin agonist 5-methoxytryptamine during fetal development led to altered brain reelin levels and abnormal presubicular cortical column development. This observation is consistent with the findings of abnormalities of reelin levels and cortical minicolumns in human autism autopsy brain tissue.

The presence of peripheral blood hyperserotonemia in autism led to investigations of the central serotonergic pathway, by measuring cerebrospinal fluid (CSF) 5-hydroxyindole acetic acid (5-HIAA), the major metabolite of serotonin. These studies, however, did not show consistent findings. To further explore the role of the central serotonergic pathway in autism, the serotonin synthesis capacity in autistic children was evaluated in vivo with positron emission tomography (PET), using the tryptophan analog α[^{11}C]methyl-L-tryptophan (AMT) as a tracer. For nonautistic children, serotonin synthesis capacity was >200% of adult values until the age of 5 years, and then declined toward adult values. In autistic children, serotonin synthesis capacity increased gradually between the ages of 2 and 11 years to values 1.5 times the adult normal values. In addition, unilateral alterations in the serotonin synthesis in the dentatothalamocortical pathway were noted. These data suggest that humans undergo a period of high brain serotonin synthesis during early childhood, and this developmental process is disrupted in autistic children, with some brain regions more severely affected than others. In a study involving a larger group of autistic children, it was shown that subgroups of autistic children can be defined by the presence or absence, and side of cortical asymmetry, in AMT abnormalities; these subgroups differed in terms of language and handedness.

Serotonin and Epileptogenesis

The role of serotonin in epileptogenesis has been demonstrated in both animal and human models. Abnormalities in brain serotonin concentration have been reported in genetically epilepsy prone rat (GEPR). Furthermore, serotonin and selective serotonin reuptake inhibitors have anticonvulsant properties. Investigators have demonstrated that monoamine oxidase A (MAO_A) knockout (KO) mice are more susceptible to seizures, but show reduced epileptogenesis. In human epileptic cortex, high levels of serotonin and 5-HIAA has been noted in spiking regions of the temporal neocortex as compared to nonspiking regions. Serotonergic hyperinnervation of dysplastic human epileptogenic cortex has been described. Using AMT PET scanning, investigators demonstrated (in vivo) increased AMT uptake in epileptic foci as indicated by ictal EEG. These results may indicate increased tryptophan metabolism by either the serotonin or kynurenine pathway.

Considering that serotonergic abnormalities are associated with abnormalities of cortical development and epileptogenesis, it may represent one of the common disturbances in autism and epilepsy and hence may

explain the common association of the two disorders. The association between reelin deficiency (as described earlier for autism) with human temporal lobe epilepsy and lissencephaly reinforces this view of potentially common underlying mechanisms. Reelin dysfunction can lead to neuronal migration disorders that are subsequently often associated with epileptic seizures. An inverse correlation between reelin expression and the degree of granule cell dispersion, in human epileptic hippocampal tissue, has been shown. Similarly, neuronal migration defects have been seen in reelin deficient mice.

Methods

Methods for the studies described here are elucidated in papers included in the Further Reading section.

Results

Rett Syndrome

Rett syndrome (RTT) is a neurodevelopmental disorder primarily affecting females. The syndrome consists of autism, dementia, ataxia, loss of purposeful hand use, and acquired microcephaly that presents after a period of apparent normal development of 6–18 months. The majority of cases are caused by mutations in the X-linked gene encoding methyl CpG binding protein, MeCP2. Mutations in another X-linked gene, cyclin-dependent kinsase-like 5 (CDKL5), have been found in female patients characterized by early-onset encephalopathy and early development of seizures. The phenotype of children with CDKL5 gene mutation overlaps with that of the severe form of atypical RTT or the early seizure variant of RTT (Hanefeld variant) which is characterized by early development of seizures, particularly spasms, with EEG findings of hypsarrhythmia and developmental regression. CDKL5 has highest expression in the brain, thymus, and testes, and is expressed early in development. Investigators have demonstrated that CDKL5 expression in the nervous system overlaps with that of MeCP2 during neural maturation and synaptogenesis. The phenotypic overlap between patients carrying MeCP2 and CDKL5 gene mutations imply that the two genes play a role in a common pathogenic pathway.

Epilepsy has been reported in 50–94% of female individuals with RTT. Likewise, EEG epileptiform abnormalities are common. The EEG is abnormal early in the course, and has been correlated with the clinical staging of the disease. Additionally, both cortical reflex myoclonus and giant amplitude somatosensory evoked potentials have been described in RTT and motor cortex stimulation evokes action potentials at low threshold (with short latency and enhanced duration).

A developmental disorder of synaptogenesis

Neuropathological findings in RTT include low brain weight, reduced neuronal size, and reduced dendritic arborization with relatively preserved neuronal number. Immunohistochemical studies have shown severely reduced levels of the cytoskeletal microtubule associated protein-2 (MAP-2), a dendritic protein necessary for neuronal growth cones extension and dendritic growth. MRI studies show brain atrophy with global reduction of gray and white matter volumes, particularly in the frontal, parietal, and insular cortex. One study involving six girls with RTT, using 2-deoxy [^{18}F] fluoro-D-glucose (FDG) PET, reported relative glucose hypermetabolism in the frontal cortex of the younger children, resembling the pattern seen in normal children of less than 1 year of age; the authors correlated the relative increase in the frontal glucose metabolism with the changes in the excitatory neurotransmitters during the early active stage of the disease and to the EEG frontal lobe abnormalities. Studies of postmortem cerebral cortex of girls with RTT have shown differential expression of a number of genes related to synapses. The onset of decelerated head growth and psychomotor regression during infancy in RTT correlate well with the period of rapid synaptogenesis in normal infants.

The role of MeCP2 gene in synaptogenesis and epilepsy

MeCP2 mediates transcriptional repression through interaction with histone deacetylase and the corepressor Sin3A. It regulates gene expression and chromosomal architecture. In the brain, MeCP2 expression is cell- and region-specific, and tends to correlate with brain maturation; early-developing areas, such as the brain stem and thalamus, express the protein before the cerebral cortex and hippocampus do. Using a mouse model, investigators demonstrated that the expression of MeCP2 increases as neuronal migration progresses, suggesting that it is necessary for neuronal maturation and maintenance. MeCP2 plays a role in synaptic development by regulating the expression of brain-derived neurotrophic factor (BDNF) and Dlx5. MeCP2 binds selectively to the BDNF promoter and functions to repress the expression of BDNF gene. BDNF facilitates excitatory glutamenergic transmission that can also inhibit inhibitory transmission (enhances the release of glutamate and inhibits the release of GABA). Dlx5, a DNA-binding homeobox protein expressed in early-embryonic development, is a protein expressed in virtually all GABAergic neurons and controls genes necessary for GABA synthesis. Abnormal regulation of these two proteins (as presumably occurs with MeCP2 mutations) could account for the dysfunction in synaptic development, synaptic neurotransmission, and the consequent neuronal hyperexcitability noted in RTT.

Altered neurotransmission in RTT

Elevated CSF glutamate has been described in individuals with RTT. One study found age-related changes in the *N*-methyl-D-aspartate (NMDA) receptor densities, with the younger patients having higher densities compared to older patients. Compared with controls, the densities of the NMDA and adenosine monophosphate (AMPA) receptors were higher in the younger RTT. However, in older RTT patients, they were lower than in control. A similar age-related distribution of the AMPA receptor has been shown in the basal ganglia of affected patients. MR spectroscopy showed elevations in the glutamate/*N*-acetylaspartate (NAA) peak in the gray matter, and the reduction of the epileptic seizure in patients with RTT treated with anticonvulsant lamotrigine has been speculated to be due to its inhibition of glutamate release. Inconsistent changes in monoamines have been reported, including increased homovanillic acid (HVA) and 5-HIAA, suggesting increased turnover of dopamine and serotonin (as determined in postmortem brain); in contrast, another postmortem brain study demonstrated reductions in HVA and 5-HIAA. Similarly, studies on the CSF of patients with RTT have shown reduction in the metabolites of serotonin and dopamine in one study, but no difference in the concentration of biogenic amines in CSF in other studies. In MeCP2-null mice, investigators measured the concentrations norepinephrine, dopamine and serotonin and their metabolites, and found a defect in the normal developmental increase of the brain biogenic amine concentrations.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is an autosomal dominant genetic disorder caused by mutations of TSC1 or TSC2 genes. It is characterized by hamartomas in multiple organs, including the skin, brain, kidneys, heart, and the eyes. Epilepsy is its most common neurological feature, occurring in 80–over 90% of cases, often beginning in the first year of life. Infantile spasms have been reported in up to 69% of patients with TSC. Partial seizures may precede, coexist with, or evolve into infantile spasms. In addition, a very high proportion of patients with TSC experience mild to severe behavioral problems, which include autism spectrum disorders (ASD), attention deficit hyperactivity disorder (ADHD), and mild to severe aggression. There is some evidence that the neurological and behavioral problems are less frequent and less severe in individuals with TSC1 mutations and in those in whom a mutation is not detected, compared to those with TSC2 mutations.

Autism in TSC

Autism occurs in 17–61% of individuals with TSC. The incidence of autism in girls with TSC is equal to that in boys with TSC – which contrasts to the fourfold higher incidence of autism in males for the entire population of autistic individuals. Infantile spasms are common in children with TSC who are subsequently diagnosed with autism. One study found that 57% of the children with TSC who had infantile spasms were later diagnosed as autistic, while only 13% of children with infantile spasms from any etiology were autistic. Children with TSC and infantile spasms also have more severe mental retardation than children with any other form of epilepsy. Approximately 10% of non-TSC patients with infantile spasms show decreased glucose metabolism bilaterally in the temporal lobes (superior temporal gyrus and hippocampus) and meet the DSM-IV criteria for autistic disorder. Thus, there appears to be a considerable difference in the prevalence of autism between TSC (57%) and non-TSC (10–13%) children with infantile spasms. Notably, one study found that successful treatment of infantile spasms in children with TSC (i.e., cessation of spasms) led to an increase in developmental quotient and verbal communication, but did not change stereotypy or hyperactivity.

Several imaging studies have shown that 43–100% of autistic TSC patients have cortical tubers in the temporal lobes, whereas all the nonautistic TSC patients were free from temporal lobe tubers – although there have been reports that nonautistic TSC patients have temporal tubers. PET glucose hypometabolism in the nonlesional lateral temporal cortex has been correlated with communication delays and a higher incidence of subependymal nodules adjacent to the caudate nucleus in the autistic group compared to the nonautistic mentally retarded group. These subependymal nodules exhibit increased uptake of AMT on PET scanning, and were associated with increased AMT uptake in the caudate nuclei as well. This observed increased AMT uptake in the caudate nucleus of autistic TSC children may be important in light of the role of the caudate in stereotyped or repetitive behaviors. These investigators hypothesized that increased tryptophan metabolism by the kynurenine pathway results in increased production of quinolinic acid in the caudate nuclei or adjacent subependymal nodules in autistic TSC children, and that this quinolinic acid production might be one mechanism underlying their stereotyped behavior; indeed, infusion of quinolinic acid into caudate nucleus in rats resulted in motor stereotypies. Cerebellar lesions in children with TSC showed decreased glucose metabolism and increased tryptophan metabolism and were associated with higher autistic symptomatology. Purkinje cells in the cerebellum were reported to be decreased in individuals with idiopathic autism. TSC1 and TSC2 proteins, hamartin and tuberin, are expressed abundantly in neurons and astrocytes in the developing and adult cerebellum. In addition, tuberin predominantly localizes to the Purkinje cells. Abnormal expression of hamartin or tuberin in Purkinje cells might

disrupt Purkinje-mediated inhibition and result in an abnormal pattern of glucose and tryptophan metabolism in the cerebellum.

TSC and epilepsy

The generation sites of seizures in TSC have been postulated to include the cortical tubers, as well as microscopic abnormalities, such as microdysgenesis, heterotopic gray matter, and dyslaminated cortical structures. Neuropathological studies show that cortical tubers contain heterogeneous populations of cellular elements, including giant cells, dysplastic neurons, and excessive astrocytes. The neurons typically show simplified dendritic patterns and aberrant patterns of spine morphology. The cytoarchitecture of the cortex surrounding the tubers is typically normal, suggesting that tubers result from a developmental defect that affects a restricted population of neuronal precursor cells. In vivo interictal FDG PET studies have shown that the cortical tubers typically appear as multifocal nodular areas of glucose hypometabolism; the hypometabolism can presumably be attributed to the decreased neuronal number and simplified dendritic pattern in the cortical tubers. FDG PET imaging also detects small cortical tubers, not typically observed on T2-weighted magnetic resonance imaging (MRI), but which were detected using fluid-attenuated inversion recovery (FLAIR).

A relationship between the localization of persistent EEG foci and the site of the major MRI lesions has been observed. Immunohistochemical studies have demonstrated that the dysmorphic neurons in the tubers express a variety of neuronal markers, neurotransmitter receptor subunits, neuropeptides, and calcium binding proteins suggesting that they may actively participate in the generation of partial seizures. Epileptogenic tubers are characterized by high-tryptophan metabolism, whereas nonepileptogenic tubers are characterized by low-tryptophan metabolism. There is evidence that the high-tryptophan metabolism is primarily associated with metabolism by the kynurenine pathway, resulting in increased quinolinic acid, an NMDA agonist. Although this association was seen in the majority of TSC patients with intractable epilepsy, approximately one-third of patients failed to show any areas of increased AMT uptake despite seizure intractability. There is enhanced expression of glutamate NMDA receptors and reduced expression of GABA receptors in epilepsy surgery specimens from patients with TSC.

Conclusion and Directions for Future Research

We have reviewed a number of studies that show the common mechanistic features between epilepsy and autism, particularly in RTT and TSC. Serotonergic abnormalities exist in both autism and epilepsy MeCP2, the gene mutated in RTT, regulates both brain maturation as well as synaptic neurotransmission through BDNF (which facilitates excitatory glutamenergic transmission) and Dlx5 (which controls GABA synthesis). Therefore, abnormalities in the expression of these two proteins (due to MeCP2 mutation) might be contributing to the frequent occurrence of epilepsy in RTT. In TSC patients with either intractable epilepsy or autism, abnormalities in tryptophan metabolism via the kynurenine pathway have been demonstrated. Using PET scanning, increased AMT uptake, has been noted in epileptogenic tubers. Likewise, abnormally increased AMT uptake has been noted in the caudate nucleus as well as in the subependymal nodules of TSC patients with autism. This observation suggests that dysfunction in kynurenine pathway with abnormal production of quinolinic acid could be one of the mechanistic links between epilepsy and autism in TSC.

A complex interaction of genetics, neurobiological, and developmental factors, that lead to an imbalance in neurotransmission regulation, and abnormalities in synaptic functions and connectivity, likely contribute to the frequent occurrence of epilepsy in these conditions. These abnormalities may, at least partially, explain the coexistence of epilepsy with a number of developmental disorders.

Cortical Malformations as a Cause for Epileptiform Activity: The Freeze Lesion Model

H J Luhmann, University of Mainz, Mainz, Germany

Introduction

The six-layered cerebral cortex is generated during the earliest developmental stages in an inside first–outside last pattern (layer VI first–layer II last). Newly generated glutamatergic excitatory pyramidal neurons migrate radially from the ventricular and subventricular zone into the developing cortex, whereas γ-aminobutyric acid (GABAergic) inhibitory interneurons migrate along a tangential path from the medial ganglionic eminence to their final cortical destinations. In humans, this period of neuronal migration peaks between the third to fifth months of gestation.

The neuronal migration process is controlled by a number of genes, and genetic deficits are often the primary cause of severe neuronal migration disorders. These migration disorders induce various brain malformations, such as polymicrogyria, periventricular heterotopia, or lissencephaly, and are often associated with drug-resistant epilepsy. Beside these genetic neuronal migration disorders, nongenetic disturbances such as hypoxic–ischemic encephalopathy or infections may also cause cortical malformations leading to catastrophic epilepsies. Recent clinical observations obtained with high-resolution imaging techniques have demonstrated that neuronal migration disorders are more common than what was previously estimated and that a large population of patients suffering from pharmaco-resistant epilepsy show obvious cortical neuronal migration disorders.

Two questions are of central interest to understand the mechanisms and consequences of early neuronal migration disorders and the manifestation of severe forms of epilepsy: (1) What are the genetic and molecular mechanisms underlying normal and abnormal neuronal migration during early corticogenesis? (2) What are the cellular and neuronal network mechanisms leading to hyperexcitability and epilepsy in a cortical network showing developmental malformations? This article addresses the second question, and provides insights into the molecular, cellular, and network mechanisms underlying epileptiform activity in an animal model of cortical malformations induced by an early focal freeze lesion.

Background

A large number of different animal models have been developed over the last 30 years to study the process of normal and abnormal neuronal migration in the developing cerebral cortex. In utero injection of methylazoxymethanol

acetate into pregnant rats, prenatal cocaine or ethanol exposure, in utero RNA interference knockdown, and genetic models of cortical malformation (such as the 'tish' rat or the Dreher mouse) have been all very instrumental in understanding the causes and consequences of neuronal migration disorders. In 1977, Dvoral and Feit presented a model to induce a well-defined cortical malformation by exposing the cerebral cortex of a newborn rat for a few seconds to a freezing probe. This experimental manipulation produced a cortical freeze lesion that, in the adult rat, was characterized by a focal four-layered neocortex (microgyrus). Further experimental analyses demonstrated that the duration of this freezing insult determines the size and the type of the lesion (**Figure 1**). The neocortical freeze lesion model very reliably reproduces the pathology of certain types of human neuronal migration disorders (polymicrogyria, focal heterotopia, cortical dysplasia, schizencephaly) and can be easily established.

It is not entirely clear how the cortical malformation develops, after the induction of the focal freeze lesion at the day of the animal's birth. In the newborn rat cerebral cortex, the lesion destroys neurons and glia throughout the cortical plate and occasionally the subplate. According to Rosen et al., the pial membrane is not destroyed, and damaged radial glial fibers regrow. Supragranular neurons migrate in the first postnatal days along radial glia through the damaged area, and the newly formed supragranular layer overlies the cell-free area in the microgyric cortex.

Methods

The cortical freeze lesion model can be easily established and generates a reproducible pathology in the mature cerebral cortex. The mortality of this model is low (<5%). Depending on the experimental protocol, the freeze lesion induces a three- or four-layered cortex (microgyrus), focal

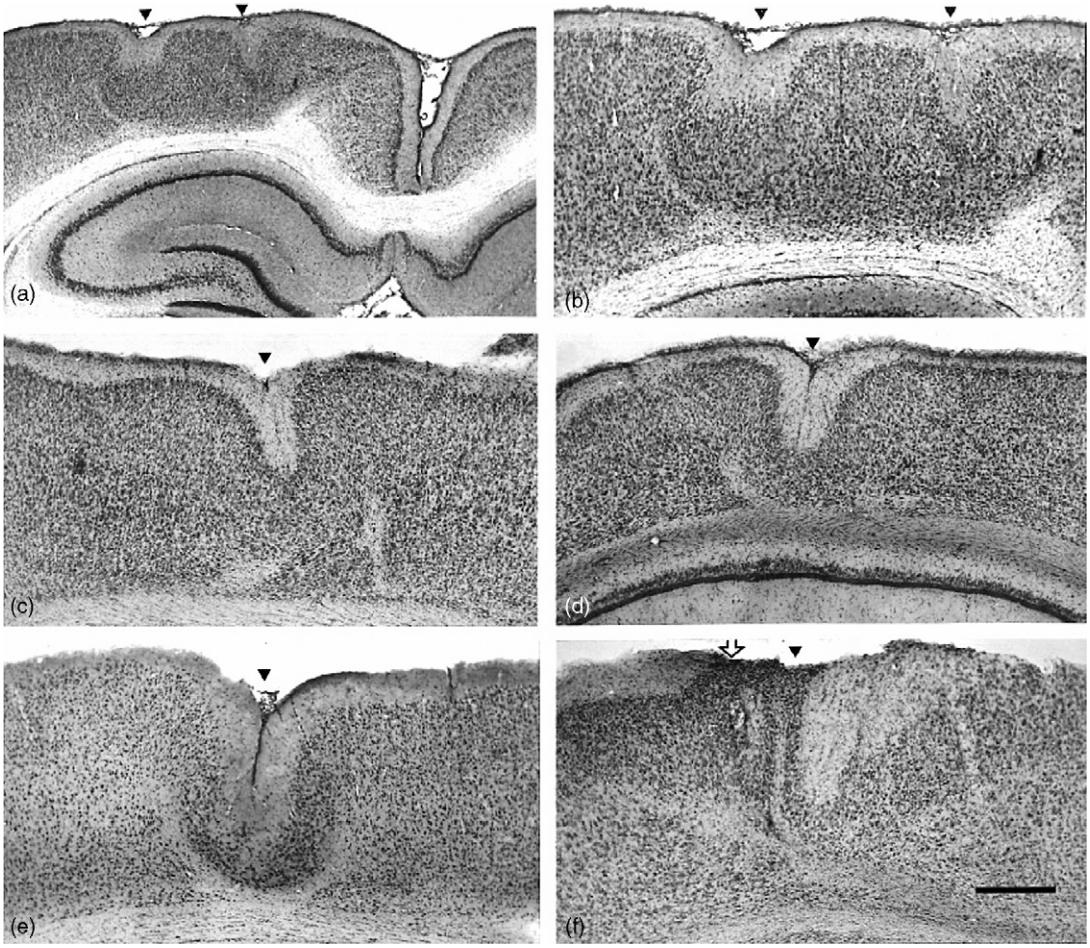

Figure 1 Examples of focal neocortical malformations induced by freeze lesion of the neonatal rat cerebral cortex. Photographs show Nissl-stained coronal sections of the cerebral cortex of adult rats, which received a focal cortical freeze lesion at the day of birth. heterotopia in layer I or a cortical cleft (schizencephaly). This model has been mostly studied in the rat, and to a minor extent also in the mouse. The model has been studied over the last decade by various groups using in vivo and in vitro electrophysiology, in vivo imaging, behavioral tests, immunohistochemistry, receptor autoradiography, molecular biology and neuroanatomical tracing techniques.

The induction of the lesion is relatively easy to perform, and the best reproducible results can be obtained when the lesion is induced during the first 24 h after birth. Cortical migration disorders with a pathology resembling cortical dysplasia, four-layered cerebral cortex, microgyria, or heterotopia in layer I can be obtained when the lesion is induced during the period of neocortical neuronal migration (in rats and mice, approximately up to postnatal day 4). A comprehensive description of the experimental procedure is available in Further Reading.

Recent Results

In vitro electrophysiological studies in different labs have independently demonstrated that the cortical freeze lesion model induces a pronounced hyperexcitability in the developing and mature neocortical network (**Figure 2**). These groups also have provided compelling evidence that the structural lesion does not correlate with the location of the most excitable region, reproducing some

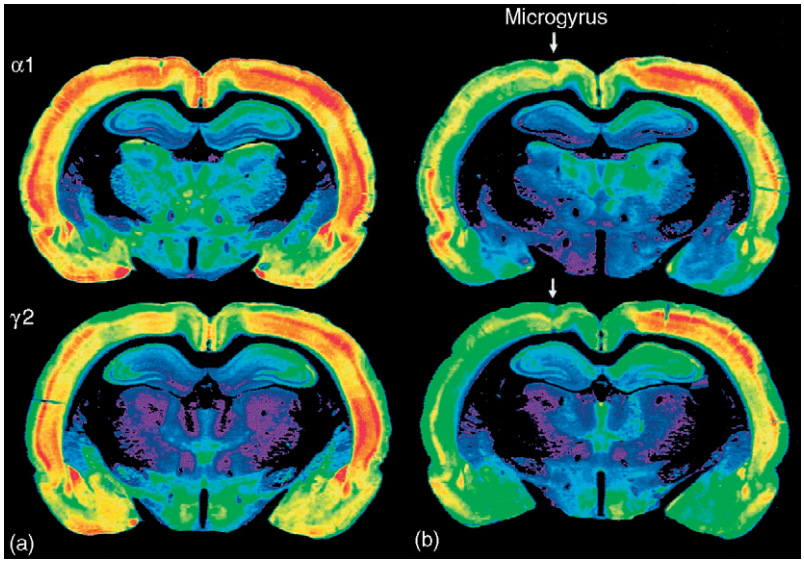

Figure 3 Freeze lesion induced microgyrus and associated widespread down-regulation in α1 and γ2 $GABA_A$ receptor subunits in adult rat cerebral cortex. Color-coded images of whole brain coronal sections immunohistochemically processed for the α1 (upper row) and γ2 (lower row) subunit in sham-operated control rat (a) and adult rat that received a cortical freeze lesion at the day of birth (b). In (b), freeze lesion induced microgyrus is marked by downward arrow. Color code ranges from black for background to violet, blue, green, yellow, and red for most intense signal. Modified from Redecker C, Luhmann HJ, Hagemann G, Fritschy JM, and Witte OW (2000) Differential downregulation of $GABA_A$ receptor subunits in widespread brain regions in the freeze-lesion model of focal cortical malformations. *Journal of Neuroscience* 20: 5045–5053, with permission from Society for Neuroscience.

clinical features of cortical dysplasia associated with pharmaco-resistant epilepsy. In the rat freeze lesion model, epileptiform activity originating from the hyperexcitable region around the lesion propagates (at ~0.06 m s^{-1}) over several millimetres across the neocortex into neighboring cortical areas with a normal histological appearance. Functional modifications in NMDA receptor subunit composition have been described in the rat cortical freeze lesion model and in human cortical dysplastic tissue. Interestingly, the structural lesion is surrounded by a widespread area of GABA and glutamate-receptor reorganization. Quantitative receptor autoradiography demonstrated a widespread and significant reduction in the binding to $GABA_A$ and $GABA_B$ receptors, reflecting a down-regulation in inhibitory receptor number and/or affinity. These observations could be confirmed immunohistochemically by the use of specific antibodies for different $GABA_A$ subunits (**Figure 3**). A widespread regionally differential reduction of the $GABA_A$ receptor subunits $\alpha 1$, $\alpha 2$, $\alpha 3$, $\alpha 5$, and $\gamma 2$ was observed. Furthermore, the down-regulation of $GABA_A$ receptor subunits also involved the ipsilateral hippocampal formation, as well as restricted contralateral neocortical areas, indicating widespread disturbances in the inhibitory neocortical and hippocampal network.

Alterations of glutamatergic receptors in dysplastic cortex are more complex. Quantitative receptor autoradiography demonstrated a significant increase in binding to NMDA, AMPA, and kainate receptors, but immunohistochemically, analyses of four NMDA receptor subunits and two major AMPA- and kainate-receptor complexes did not reveal any remote or widespread changes of glutamate-receptor subunit distribution.

Another controversial issue is the extent to which the widespread down-regulation in $GABA_A$ receptor density and/or affinity and their subunits causes a functional reduction in GABAergic inhibition. Our electrophysiological in vitro recordings from pyramidal neurons in the hyperexcitable region close to the microgyrus have revealed a lack or reduction of stimulus-evoked inhibitory postsynaptic potentials (IPSPs) as compared with the controls (upper row in **Figure 4**), but pharmacologically isolated IPSPs recorded under blockade of ionotropic glutamate receptors (lower row in **Figure 4**) did not reveal a statistically significant difference in IPSP peak

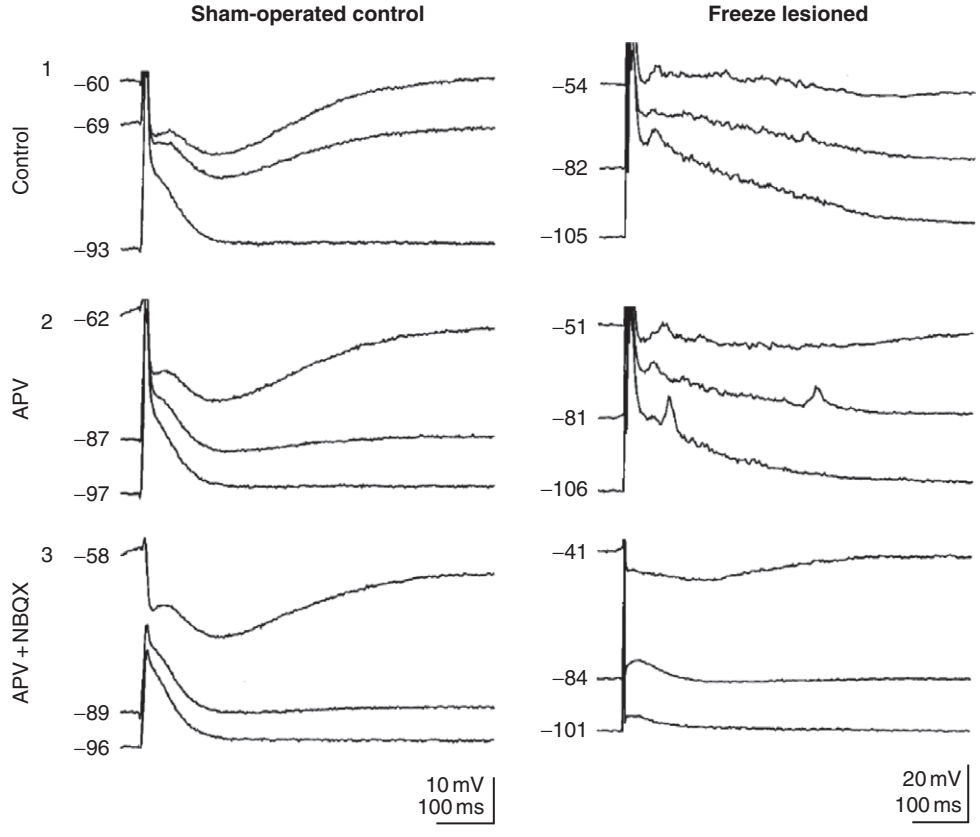

Figure 4 Intracellular recordings from upper layer pyramidal neurons in neocortical slices from sham-operated (left) and freeze-lesioned (right) adult rats. Recordings show stimulus-evoked inhibitory postsynaptic potentials (IPSPs) in normal extracellular solution (upper row), after the addition of NMDA receptor antagonist APV (middle row) and after blocking ionotropic glutamate receptors with APV and NBQX (lower row). Membrane potentials are given for each trace. Modified from Luhmann HJ, Karpuk N, Qü M, and Zilles K (1998) Characterization of neuronal migration disorders in neocortical structures: II. Intracellular in vitro recordings. *Journal of Neurophysiology* 80: 92–102, with permission from The American Physiological Society.

conductances. However, similar experimental analyses by Jacobs and Prince indicate that GABAergic inhibition may be enhanced in the epileptogenic areas. That group has identified, in the paramicrogyral region, an increase in the number of functional excitatory synapses on both interneurons and pyramidal cells, perhaps due to hyperinnervation by cortical afferents originally destined for the microgyrus proper. This disorganization in cortical architecture is associated with an abnormal ingrowth of thalamocortical afferents into layer IV. Rosen *et al.* reported an almost complete lack of thalamocortical or corticothalamic projections between the ventrobasal somatosensory complex in the thalamus and the cortical microgyrus. Furthermore, callosal connections are also disorganized.

A major drawback of the freeze lesion model is the lack of spontaneous epileptic seizures in vivo. Recurrent seizures and status epilepticus have not been described in this model. So far only a lower threshold for hyperthermia-induced seizures and a prolonged ictal manifestation have been reported in freeze-lesioned rats in vivo, suggesting a pathophysiological link between focal cortical dysplasia and atypical febrile seizures.

Future Goals

A major challenge in the future investigation of the cortical freeze lesion model will be a more comprehensive analysis of the EEG or ECoG in freely moving animals that exhibit various extents of cortical malformations. It is currently unclear at which age experimental animals with a cortical freeze lesion might reveal what type of spontaneous seizures or whether seizures can be provoked by systemic application of drugs that lower the seizure threshold. Long-term EEG recordings, preferentially telemetric recordings from freely moving animals, might be most valuable to address this important issue.

It remains to be determined in more detail how the intracortical GABAergic inhibition is modified in the cortical freeze lesion model. The excitatory drive onto certain types of inhibitory interneurons may be enhanced or reduced, the intracellular Cl^- homeostasis might be modified, and the functional consequences of changes in $GABA_A$ receptor subunit composition are also not clear. The differential regulation of the $GABA_A$ receptor subunits is of pivotal interest, since $GABA_A$ receptors mediating conventional synaptic (phasic) inhibition have a different subunit composition as compared with those mediating extrasynaptic tonic inhibition. In many neuronal cell types, tonic inhibition is mediated by δ-subunit containing $GABA_A$ receptors, which are located extrasynaptically. In contrast, phasic inhibition is most likely mediated by synaptic γ-subunit containing $GABA_A$ receptors. These electrophysiological and pharmacological studies would also be valuable in other models of epilepsy.

Epilepsy-Associated Reelin Dysfunction Induces Granule Cell Dispersion in the Dentate Gyrus

Introduction

Ammon's horn sclerosis (AHS) is a hallmark of temporal lobe epilepsy. AHS is characterized by neuronal loss in hippocampal regions CA3 and CA1 and in the hilus of the dentate gyrus, and by granule cell dispersion (GCD). The term *sclerosis* describes a glial hypertrophy accompanying the neuronal loss. The neuron loss is likely to represent excitotoxic cell death associated with increased calcium entry into the cells. This mechanism of cell death is supported by studies showing that intracellular application of calcium buffers prevents excitotoxic cell death of hilar neurons. Neurons in hippocampal region CA2, which is located in between CA1 and CA3, are less vulnerable and are particularly rich in calcium-binding proteins.

The factors that induce a broadening of the granule cell layer – i.e., granule cell dispersion – are less clear. Does increased neuronal activity force the granule cells to leave their normally tightly packed layer? Does seizure activity stimulate neurogenesis in the dentate gyrus, leading to an increase in neuron number and thus to a broadening of the granule cell layer? Does glial hypertrophy in AHS play a role in the development of granule cell dispersion?

In this article, we summarize our recent studies that addressed these questions. In these studies, we used tissue samples from temporal lobe epilepsy (TLE) patients subjected to hippocampal resection for therapeutical reasons. In addition, we used tissue from mice that had received a unilateral hippocampal injection of kainate. By comparing our results in human tissue and in experimental animals, we obtained new insights into the processes leading to the development of granule cell dispersion in epilepsy.

Background – Granule Cell Dispersion in Epilepsy – a Migration Defect?

Granule cell dispersion is best described as an abnormal broadening of the granule cell layer, with many granule cells migrating far into the molecular layer (**Figure 1**). GCD is regularly associated with Ammon's horn sclerosis, but there are also cases of Ammon's horn sclerosis lacking a prominent GCD. There is strong evidence that Ammon's horn sclerosis, the degeneration of neurons in hippocampal regions CA1 and CA3 and in the hilus of the dentate gyrus, represents excitotoxic changes resulting from increased neuronal activity. Does this also hold true for GCD? The neurons that migrate out into the molecular layer do not show signs of neuronal degeneration. Alternatively, is GCD a migration defect of the granule cells during development that eventually leads to epilepsy? It would not be too far-fetched to assume a developmental migration defect, as there are mouse mutants that show a structural phenotype reminiscent of GCD and a functional phenotype of seizures/epilepsy.

A more scattered distribution of the granule cells leads to an overlap of the normally segregated input and output sides of the granule cells. In a densely packed granule cell layer, the input side (i.e., the granule cell dendritic arbors in the molecular layer) is normally separated from the output side (the mossy fiber axons invading the hilus). A loss of this clear-cut lamination will allow more superficially located granule cells to contact dendrites of deeply located neurons, resulting in an increased granule cell-to-granule cell connectivity. Would this aberrant circuitry contribute to increased excitability of the granule cells, resulting in epileptic activity?

One mutant that shows a migration defect similar to GCD is the reeler mouse lacking the extracellular matrix protein, reelin. Reelin is known to be synthesized and secreted by Cajal-Retzius cells in the marginal zones of cortex and hippocampus, and there are severe migration defects in these regions in the reeler mutant. Could it be that GCD in epileptic patients is associated with an altered reelin expression?

As a first step towards a better understanding of GCD, we looked at reelin expression in tissue samples from epileptic patients with GCD and in samples from autopsy controls. These control patients did not suffer from epileptic seizures and did not show Ammon's horn sclerosis and GCD. We measured reelin expression by real-time PCR and quantified reelin-expressing cells using in situ hybridization for reelin mRNA. We found a significant decrease in reelin expression in patients with granule cell dispersion with both methods. Moreover, there was an inverse correlation between the number of reelin mRNA-expressing cells

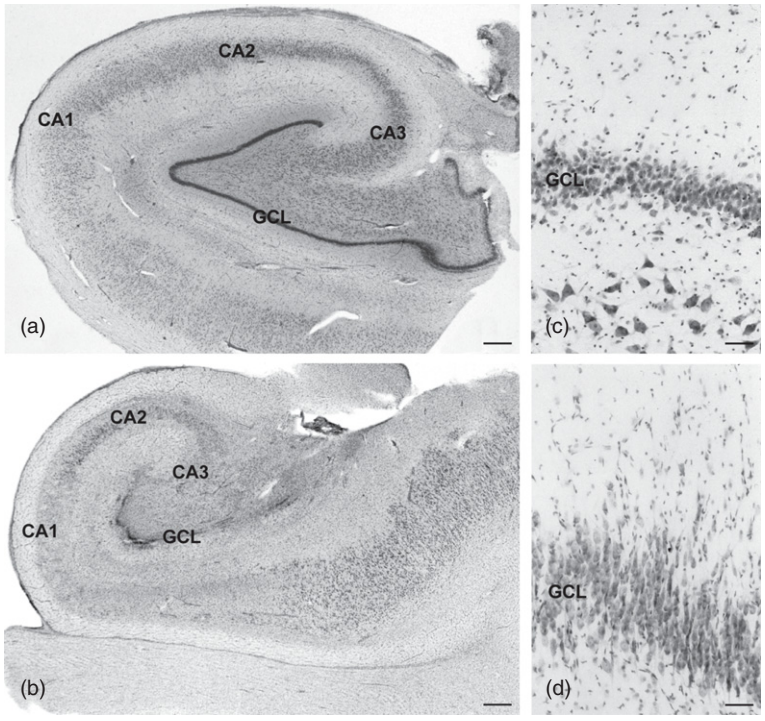

Figure 1 Morphology of normal and epileptic human hippocampus stained with cresyl violet. (a) Human control hippocampus with normal distribution of neurons in hippocampal subfields and in the dentate gyrus, where the granule cells are located in a dense layer. (b) Epileptic human hippocampus with characteristic features of Ammon's horn sclerosis. Selective cell loss is obvious in hippocampal subfields CA1 and CA3. The granule cell layer is dispersed. (c) Granule cell layer of a normal human dentate gyrus. The granule cells are arranged in a densely packed layer. (d) Loss of dense granule cell packing (granule cell dispersion) in temporal lobe epilepsy. Scale bars a, b: 600 μm; c, d: 75 μm. CA1, CA2, CA3, hippocampal subfields; GCL, granule cell layer. in the dentate gyrus and the extent of granule cell dispersion, quantified by measuring the width of the granule cell layer. Although these findings pointed to a role of reelin in the development of granule cell dispersion, they could not clarify whether decreased reelin expression during development had *caused* granule cell dispersion, which in turn led to epilepsy or, alternatively, epileptic seizures interfered with reelin expression, leading to GCD. For obvious reasons, these questions could not be addressed in studies of tissue samples from patients.

Methods

We used tissue samples from TLE patients and a mouse epilepsy model that recapitulates the main histopathological and electrophysiological features of human TLE. A single unilateral injection of the glutamate agonist kainate (KA) into the hippocampus of adult mice induced spontaneous, focal epileptic seizures and Ammon's horn sclerosis, including GCD. We used cresyl violet staining, immunohistochemistry, in situ hybridization, and real-time PCR analysis to monitor cell death, GCD development, neurogenesis, glial cell proliferation, and reelin expression in human tissue and in tissue obtained from kainate-injected mice.

Recent Results

Unilateral Injection of Kainate, an Agonist of the Excitatory Transmitter Glutamate, Results in the Development of GCD in Mice

Increased neuronal activity is associated with an increased release of the excitatory neurotransmitter, glutamate. Thus, glutamate agonists, such as kainate, are often injected into animals to induce epileptic activity. Unilateral injection of kainate into one hippocampus (in mice) was not only found to induce seizure activity but also to lead to Ammon's horn sclerosis with neuronal degeneration in CA1 and CA3 and granule cell dispersion in the dentate gyrus. Interestingly, these degenerative changes are not found on the contralateral, non-injected side.

After a latency period of 2 weeks, the animals developed seizure activity as monitored by EEG recordings. They also developed a prominent granule cell dispersion on the side of kainate injection but not on the contralateral side, indicating that GCD resulted from the injection

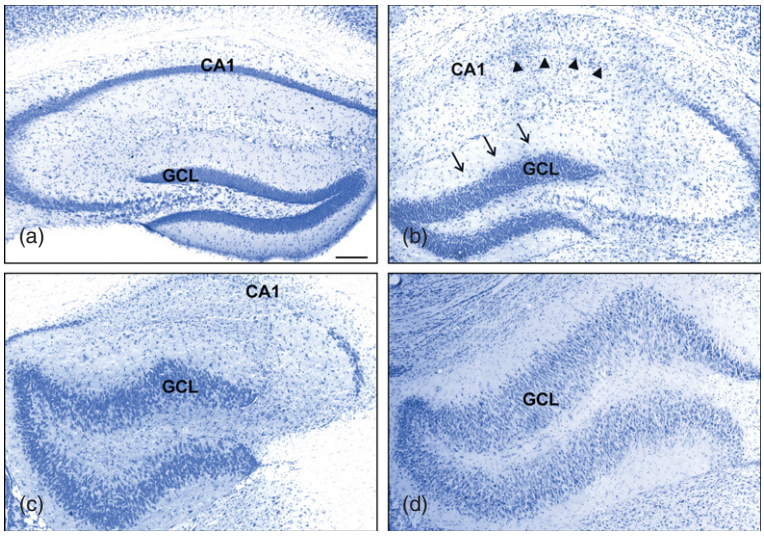

Figure 2 Development of granule cell dispersion induced by unilateral intrahippocampal kainate injection in the adult mouse. Coronal sections of hippocampus were stained with cresyl violet. (a) Contralateral, non-injected hippocampus displaying the normal histology of the hippocampal formation. (b–d) Ipsilateral hippocampus 7 days (b), 21 days (c) and 6 weeks (d) after kainate injection. A progressive dispersion of the granule cells (arrows) is observed. Note neuronal loss in CA1 (arrowheads), CA3, and hilus. Scale bar: 100 μm; GCL, granule cell layer. From Heinrich *et al.*, 2006; copyright by the Society for Neuroscience.

of the excitotoxin. The broadening of the granule cell layer developed progressively; GCD was evident as early as one week post injection and was fully expressed after six weeks (**Figure 2**).

What is the nature of kainate-induced GCD? Is it a migration of fully differentiated granule cells, or does seizure activity increase neurogenesis and aberrant migration of the newly generated granule cells? It is generally accepted that post-migratory neuroblasts that are about to differentiate their dendritic and axonal arbors are no longer able to migrate. How, then, could fully differentiated granule cells migrate out of a densely packed granule cell layer?

In our experimental animals, we were in the position to address these questions by injecting them with bromodeoxyuridine (BrdU), a marker of newly generated cells. We found that neurogenesis was significantly decreased on the side of kainate injection (where GCD occurs) when compared with the non-injected control side (where no GCD was observed). Given the paucity of neurogenesis on the side that shows GCD, we concluded that adult, differentiated granule cells have 'migrated,' and that GCD does not represent an abnormal migration of newly generated granule cells. The cessation of neurogenesis on the side of kainate injection came as a surprise, since studies of other epilepsy models had shown epileptic activity to induce neurogenesis. Further, while neurogenesis had ceased on the side of kainate injection, we noticed an increased gliogenesis, as revealed by double labeling for the astrocytic marker GFAP (glial fibrillary acidic protein) and BrdU. It is reasonable to assume that this increased formation of astrocytes, particularly in the hilar region and in CA1 and CA3, is associated with the excitotoxic neurodegenerative changes observed in these regions. There was also an increase in activated microglial cells, as demonstrated by labeling for the microglial marker Iba1. Studies are in progress to determine the extent to which glial hypertrophy and increased gliogenesis contribute to GCD.

Next, an attempt was made to determine whether or not increased neurogenesis is involved in the formation of GCD in human epileptic patients. To this end we used immunostaining for Ki67, a marker of the cell cycle, in tissue samples from epileptic patients. We were unable to find stained cells among the neurons that had migrated out of the granule cell layer, suggesting that in human epileptic patients, like in kainate-injected mice, granule cell dispersion is not an aberrant migration of young neurons.

Reelin's Role in the Development of GCD

As mentioned earlier, reelin expression was found to be decreased in tissue samples from epileptic patients. This finding pointed to a role of reelin in granule cell lamination, reminiscent of the lamination defects seen in the mouse mutant lacking reelin. However, the dispersed granule cells in the reeler mouse represent a maldevelopment of the granule cell layer, whereas GCD in epileptic patients appears to be a secondary effect associated with seizure activity. Numerous studies have shown that reelin is a molecule important for the normal development of cell and fiber layers in the hippocampus. However, it is

less clear how one might explain a decreased reelin expression in tissue samples of adult epileptic patients.

Animals with unilateral injections of kainate appeared useful in studies of reelin expression associated with GCD. On the kainate-injected side, where GCD developed, we found a dramatic decrease in reelin expression in quantitative real-time RT-PCR studies and by counting reelin mRNA-expressing cells using in situ hybridization (Figure 3). On the contralateral side, where no granule cell dispersion developed, reelin expression was normal when compared with naïve control animals. The findings point to a close relation between reelin expression and the development of GCD, but did not elucidate the underlying mechanisms.

Reelin Keeps Adult Granule Cells in Register

The CR-50 antibody against reelin has proven its usefulness in blocking reelin function in a variety of experimental paradigms. Working with the concept that a decreased reelin expression induces an aberrant migration of granule cells (similar to the aberrant migration of these neurons in reeler mutants), we reasoned that blocking reelin function should lead to granule cell dispersion. We thus used adult naïve mice that received unilateral infusions of CR-50 antibody into one hippocampus via osmotic minipumps for one week. For controls, unspecific IgG was infused. On the side of CR-50 infusion, we observed a significant development of GCD near the infusion site; no development of GCD was observed when unspecific IgG was injected. The results were quantified by measuring the thickness of the granule cell layer and comparing the infused hippocampus with the contralateral one. While no statistically significant differences were observed between the contralateral hippocampus and the ipsilateral hippocampus when unspecific IgG was infused, the thickness of the granule cell layer had significantly increased on the side of

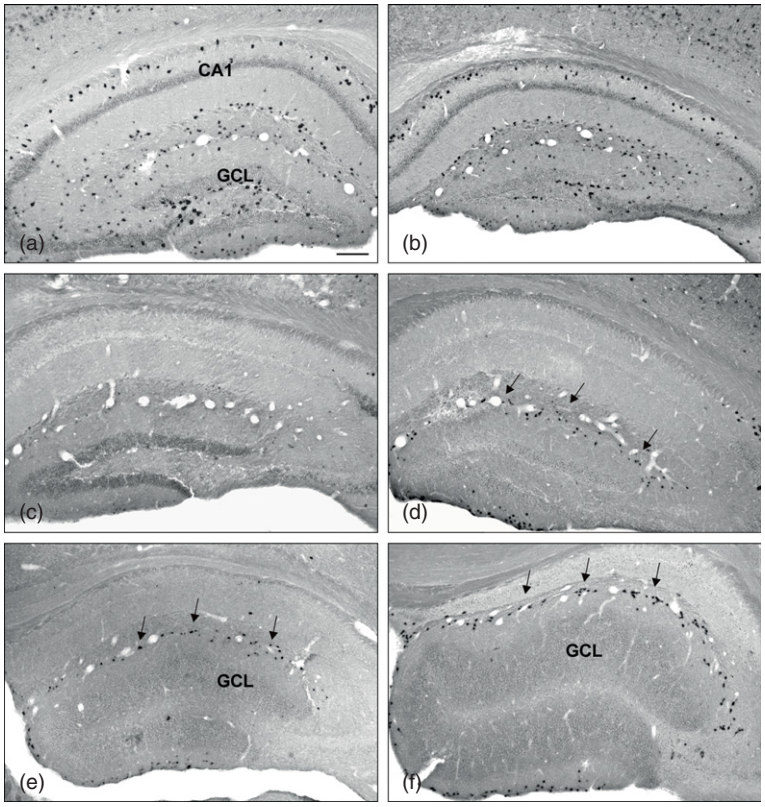

Figure 3 Time course of reelin mRNA expression in the mouse hippocampus after unilateral intrahippocampal kainate injection. Reelin mRNA expressing neurons were localized by *in situ* hybridization histochemistry. (a) Contralateral hippocampus. Many reelin mRNA-positive neurons are present in CA1, CA3, in the hilus, and along the hippocampal fissure. (b) Ipsilateral hippocampus of a saline-injected control mouse two days after injection. The distribution of reelin mRNA-positive neurons is similar to that in (a). (c–f) Ipsilateral hippocampus two days (c), seven days (d), two weeks (e) and six weeks (f) after kainate injection. (c) A dramatic reduction of reelin mRNA expression is evident all over the hippocampus two days after kainate injection. Except a few labeled cells, which are still present along the hippocampal fissure, no reelin mRNA-positive neurons can be detected in CA1 and in the hilus. (d) Seven days after kainate injection, a few reelin mRNA-positive neurons can be observed along the hippocampal fissure (arrows). (e, f) Numbers of reelin mRNA expressing cells remain low along the hippocampal fissure after two (e) and six (f) weeks following kainate injection, in parallel with a progressive development of GCD. GCL, granule cell layer. Scale bars: a–f, 100 μm. Adapted from Heinrich *et al.*, 2006; copyright by the Society for Neuroscience.

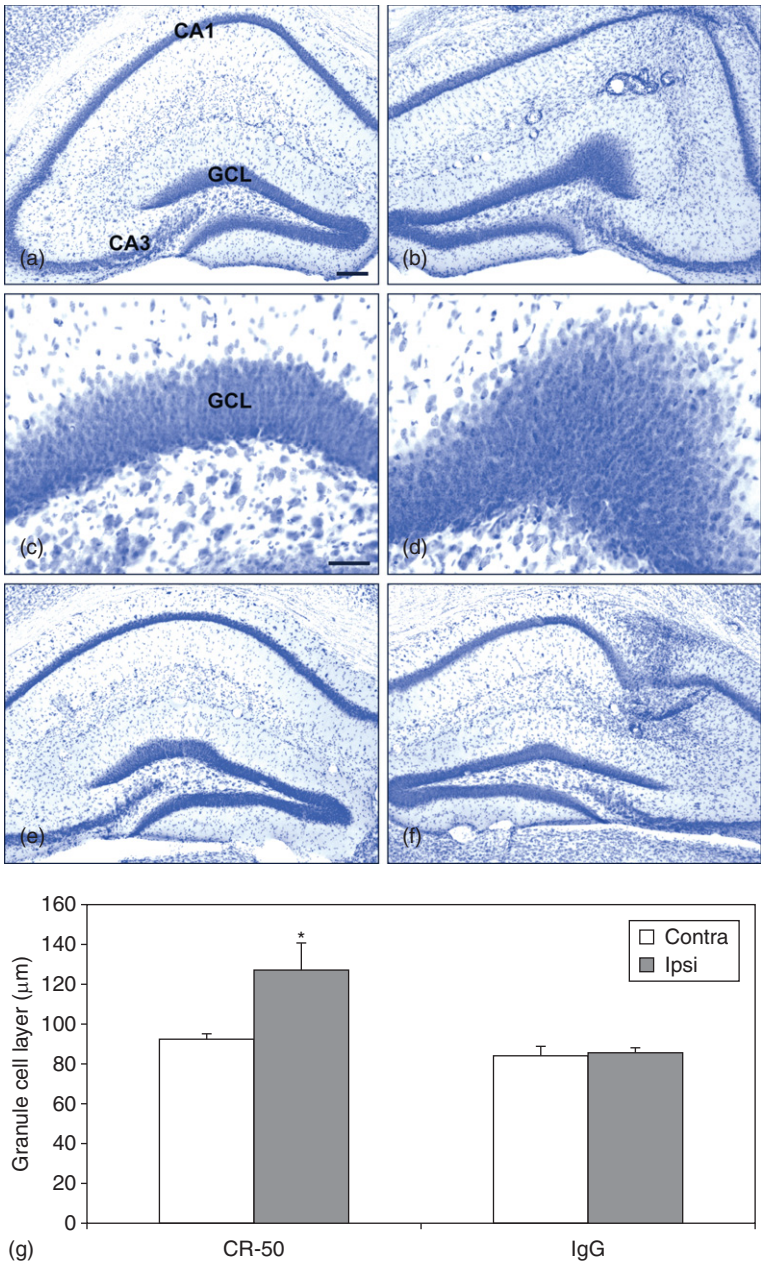

Figure 4 Effect of chronic CR-50 antibody infusion into the dentate gyrus of adult mice. Antibodies were chronically administered by osmotic pumps inserted in the right hippocampus over a period of seven days followed by another seven days of survival. Morphological changes were visualized by cresyl violet staining. Infusion of CR-50 resulted in a massive increase in the width of the granule cell layer (b, d) as compared to the contralateral side (a, c). The widening of the granule cell layer was confined to the site of injection, indicating that a local neutralization of reelin altered the lamination of adult granule cells. No change in lamination was observed after infusion of mouse control IgG (e, f). (e) Contralateral side. (f) Side of IgG infusion. Scale bars: a, b, e, f: 150 μm; c, d: 40 μm. (g) Quantitative evaluation of GCL width in CR-50 ($n = 6$) and IgG-infused hippocampi ($n = 5$). The width of the GCL was measured in the ipsi- and contralateral hippocampus in five sections/animal, and five measurements were taken per hippocampus. Mean values ± S.E.M. are shown. In the CR-50-injected animals, the width of the GCL was significantly increased as compared to the contralateral side ($p < 0.0277$) using the two sample Wilcoxon rank-sum test. Comparisons were of the unpaired two-sided type. Adapted from Heinrich *et al.*, 2006; copyright by the Society for Neuroscience.

CR-50 injection (Figure 4). These results clearly show that the expression of reelin is not only required for the normal development of dentate lamination but for the maintenance of a compact granule cell layer in the adult brain.

Summary and Conclusions

Correlating the results of studies on tissue samples from epileptic patients and in experimental animals and mouse mutants sheds light on the mechanisms leading to granule

cell dispersion in epilepsy. A similar loss in granule cell lamination in reeler mutants and in human GCD prompted our study of reelin expression in tissue samples from patients. The decreased reelin expression we observed in human GCD led us to study reelin expression in an animal model of epilepsy. We found both a decreased reelin expression and GCD only on the side of kainate injection (not on the contralateral control side). Interestingly, there was ongoing postnatal neurogenesis on the contralateral side, but a cessation of neurogenesis on the kainate-injected side. From these findings, we concluded that injection of the glutamate agonist kainate induced seizure activity associated with GCD, paralleled by a decreased reelin expression. A causal link between the development of GCD and decreased reelin expression was found in our experiments with antibodies neutralizing reelin. Infusion of CR-50 antibody, but not of unspecific IgG, was sufficient to induce GCD in adult, naïve mice.

In summary, we propose the following scenario for the development of GCD:

1. Seizure activity in epileptic patients, or in experimental animals induced by unilateral kainate injections, interferes with reelin expression. Since there does not seem to be a substantial death of reelin-synthesizing neurons (very few degenerating Cajal-Retzius cells were observed using Fluoro Jade staining, unpublished observations), we conclude that seizure activity decreases reelin expression.
2. The decreased reelin expression in adult animals or human patients allows mature granule cells to invade the molecular layer. This result is consistent with a 'stop signal function' of reelin. Reelin-expressing Cajal-Retzius cells in the marginal zone of the neocortex and in the molecular layer of the dentate gyrus prevent migrating neurons from invading these zones during development. In reeler mutants lacking reelin, the marginal zone of the neocortex is densely populated by neurons, and the characteristic dense packing of dentate granule cells is lost. Reelin appears to have a similar function in the adult organism: Decreased reelin expression, and thus a loss of the 'stop signal,' allows granule cells to invade the molecular layer. These aberrantly migrating cells were not, in our studies, newly generated neurons but differentiated granule cells.
3. A more general conclusion from these studies is that there are molecules, such as reelin, which are important for the maintenance of the structural organization of the brain. Their malexpression may result in secondary structural changes such as granule cell dispersion. It is tempting to speculate that not only seizure activity, but also a variety of other noxious stimuli, may interfere with reelin expression (or with the expression of other control genes) and lead to structural changes in the adult brain that are reminiscent of developmental defects and contribute to neurological or psychiatric diseases.

Future Directions

Our results have shown that reelin is important for the maintenance of the laminated organization of the dentate gyrus. In epileptic patients with decreased reelin expression, in kainate-injected mice, and in the reelin-deficient mutant reeler, dentate granule cells do not form a compact cell layer but are dispersed. Can the application of reelin rescue granule cell dispersion?

Using slice cultures of reeler mutants as a model, we were able to show that the scattered distribution of the granule cells can be rescued by wildtype co-cultures. On the basis of these findings, we have recently started to treat kainate-injected mice with infusions of recombinant reelin. As described, mice with unilateral injections of kainate develop epileptic seizures and show decreased reelin expression and granule cell dispersion on the injected side but not on the contralateral side. Our first results from experiments to treat these animals with recombinant reelin are very promising. However, there is much to be learned before we will know whether or not reelin treatment constitutes a new therapeutic avenue.

The results reported here have shown that reelin expression is sensitive to epileptic activity. There may be other noxious factors that interfere with the expression of reelin or other molecules important for the maintenance of normal network structure and function. Studies are in progress analyzing potential effects of virus infections on reelin expression. Along this line, it will be important to determine, by molecular approaches, how reelin expression is regulated. Finally, future studies should address the effects of reelin signaling on the cytoskeletal reorganization required for the actual migration process. In spite of increasing knowledge about the signaling cascade activated by reelin binding to its receptors, very little is known about the ways in which reelin acts on the cytoskeleton to control cell movement and arrest.

Focal Malformations of Cortical Development: Pathogenesis and Pathways

P B Crino, University of Pennsylvania Medical Center, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Focal malformations of cortical development (focal MCD), including focal cortical dysplasia with balloon cells, hemimegalencephaly, and gangliogliomа, are highly associated with epilepsy. Despite their prevalence in both pediatric and adult epilepsy populations, little is known about the molecular and developmental pathogenesis of these lesions or their causal relationship with intractable epilepsy. Of particular interest is the fact that focal brain malformations virtually always occur sporadically, with no defined family pedigrees or twin pairs identified to date. Monozygotic twins are typically discordant for these lesions. Only rarely does hemimegalencephaly occur in the setting of another genetic disease (such as Proteus syndrome or tuberous sclerosis), and early attempts at causative gene identification have been unsuccessful.

One attractive hypothesis is that focal brain malformations form as a consequence of a somatic gene mutation occurring during brain development within a cortical progenitor cell. Thus, new experimental strategies must be defined to identify gene mutations within brain tissue rather than in peripheral blood samples. Histopathological similarities between focal MCD and the autosomal dominant disorder tuberous sclerosis complex suggest that the pathogenesis of focal MCD may be related to the mammalian target of rapamycin (mTOR)-signaling cascade. Thus, comprehensive analysis of genes and proteins in this pathway may identify candidate molecules to explain how these lesions form during brain development.

Background

Focal MCD are a common cause of pharmacoresistant epilepsy. In a recent classification scheme, focal MCD were classified as putative disorders of cell proliferation. Tubers in TSC, focal cortical dysplasia with balloon cells (FCD), hemimegalencephaly (HMEG; **Figure 1**), and gangliogliomа (GG) are of particular interest because

Introduction

Focal malformations of cortical development (focal MCD), including focal cortical dysplasia with balloon cells, hemimegalencephaly, and ganglioglioma, are highly associated with epilepsy. Despite their prevalence in both pediatric and adult epilepsy populations, little is known about the molecular and developmental pathogenesis of these lesions or their causal relationship with intractable epilepsy. Of particular interest is the fact that focal brain malformations virtually always occur sporadically, with no defined family pedigrees or twin pairs identified to date. Monozygotic twins are typically discordant for these lesions. Only rarely does hemimegalencephaly occur in the setting of another genetic disease (such as Proteus syndrome or tuberous sclerosis), and early attempts at causative gene identification have been unsuccessful.

One attractive hypothesis is that focal brain malformations form as a consequence of a somatic gene mutation occurring during brain development within a cortical progenitor cell. Thus, new experimental strategies must be defined to identify gene mutations within brain tissue rather than in peripheral blood samples. Histopathological similarities between focal MCD and the autosomal dominant disorder tuberous sclerosis complex suggest that the pathogenesis of focal MCD may be related to the mammalian target of rapamycin (mTOR)-signaling cascade. Thus, comprehensive analysis of genes and proteins in this pathway may identify candidate molecules to explain how these lesions form during brain development.

Background

Focal MCD are a common cause of pharmacoresistant epilepsy. In a recent classification scheme, focal MCD were classified as putative disorders of cell proliferation. Tubers in TSC, focal cortical dysplasia with balloon cells (FCD), hemimegalencephaly (HMEG; **Figure 1**), and ganglioglioma (GG) are of particular interest because

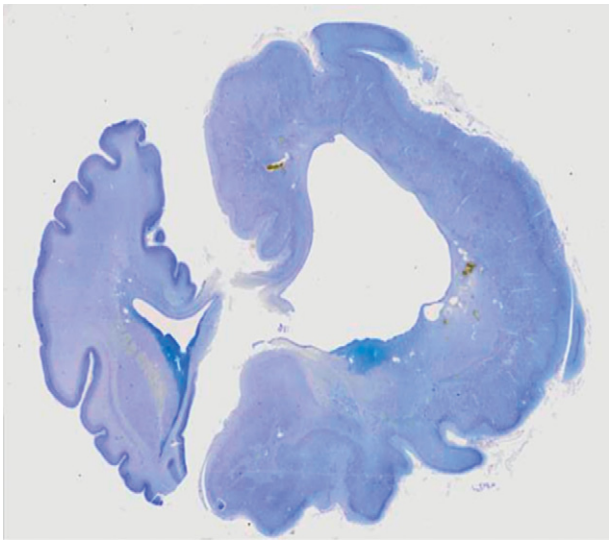

Figure 1 Hemimegalencephaly in a 1-month-old female. Note dramatic enlargement of one hemisphere (specimen courtesy of E. Aronica).

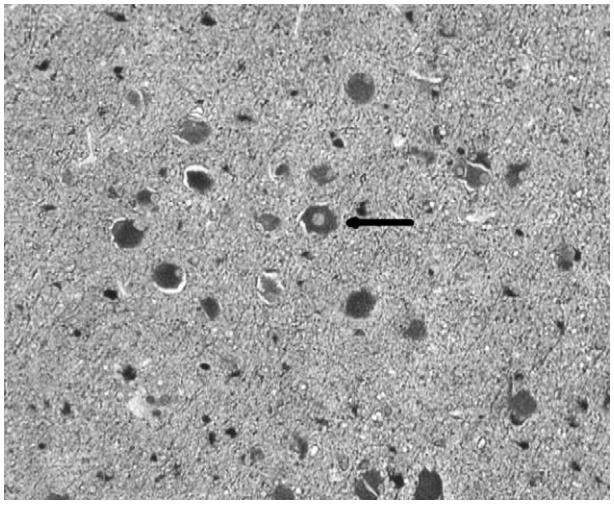

Figure 2 Balloon cells (arrow) in FCD labeled with NeuN antibodies. Note characteristic cytomegaly and laminar disorganization.

these MCD affect restricted regions of the cerebral cortex, share histopathological features, affect children and adults, and are highly associated with intractable epilepsy. TSC is an autosomal dominant disorder resulting from mutations in one or two genes (*TSC1* and *TSC2*), whereas FCD, GG, and HMEG are sporadic disorders that form by unknown mechanisms. It is estimated that 10–30% of resected neocortical epilepsy specimens are diagnosed as FCD. HMEG is highly associated with severe intractable neonatal seizures and infantile spasms, a devastating epilepsy syndrome in infants that often requires urgent neurosurgical intervention. GG represents the most common pediatric tumor associated with intractable seizures. The healthcare impact of these brain malformations (tubers, FCD, GG, and HMEG) is significant, and includes issues such as cost, morbidity, and even mortality.

Histopathology in Focal MCD: A Unifying Feature?

Tubers, FCD, GG, and HMEG are characterized histologically by disorganized or absent cortical lamination, loss of radial neuronal orientation in relation to the pial surface, and the presence of large, dysmorphic neurons ('cytomegalic' neurons). However, a unifying histopathological feature of these developmental lesions is the presence of unique cells that exhibit dramatic cytomegaly; these cells are known as balloon cells (BCs) in FCD (Figure 2) and HMEG, as atypical ganglion cells (AGCs) in GG, and as giant cells (GCs) in tubers.

Morphologically, BCs, AGCs, and GCs are not similar to any known cell types in the normal human cortex. These cell types are larger than dysmorphic, cytomegalic neurons or normal-appearing neurons in FCD, GG, and HMEG and lack the neuronal morphology characteristic of dysmorphic, cytomegalic neurons. The cell soma of BCs is quite large (often exceeding 120 μm) and exhibits a laterally displaced nucleus that may even be multinucleated. Unlike cytomegalic neurons, BCs do not extend clearly defined axons or dendrites and express phenotypic features suggestive of a mixed astrocytic and neural lineage. For example, the expression of neural protein markers such as neurofilament and α-internexin, as well as neurotransmitter receptor subunits and neurotransmitter uptake proteins, suggests a neural phenotype for BCs, AGCs, and GCs. At the same time, the expression of glial markers such as S-100, vimentin, and glial fibrillary acidic proteins in BCs, AGCs, and GCs suggests an astrocytic phenotype. In some cases, cytomegalic cells also express both neuronal and glial markers, suggesting a mixed glioneuronal lineage (or that these cell types can be further delineated into glial- or neural-derived lineage subtypes). The highly aberrant morphologies and phenotype of BCs, AGCs, and GCs suggest that genesis of these cells may be critical to all other histological findings in FCD, tubers, and HMEG.

Intersecting and Parallel Cell Cascades Modulate Cell Size

Recent insights into the roles that the *TSC* genes play in governing cell size and growth have shed light on cytomegaly as a feature of tubers, FCD, and HMEG. The *TSC1* gene encodes the protein TSC1 (also known as hamartin), and the *TSC2* gene encodes the protein TSC2 or tuberin. Hamartin and tuberin form a functional protein–protein complex that modulates several pivotal cellular pathways

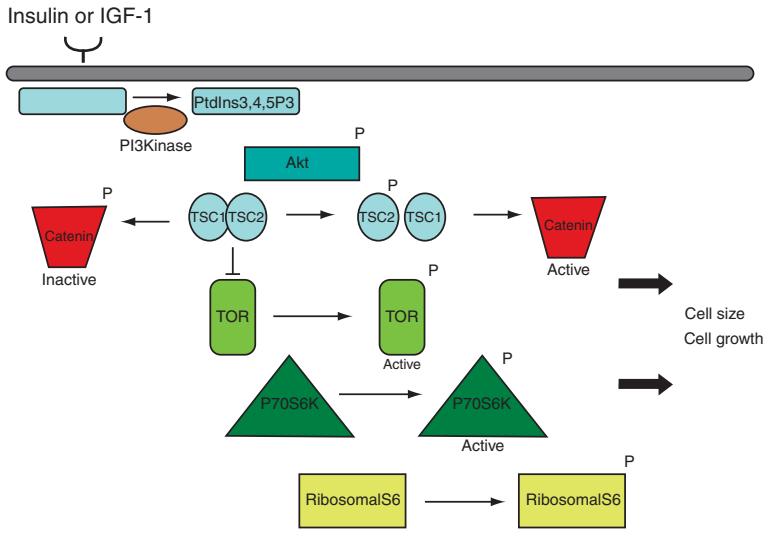

Figure 3 Overview of the TOR and Wnt-1/β-catenin paths. Note that hamartin–tuberin play pivotal negatively modulatory roles in both cascades.

that govern cell size, cell proliferation, and organ growth. For example, the hamartin–tuberin heteromer is a pivotal regulatory complex in the PI3K–Akt–TOR–p70S6-kinase–ribosomalS6 cascade (Figure 3).

Hamartin–tuberin functions downstream from insulin- and insulin-like growth factor receptors, PI3kinase, and Akt to constitutively inhibit the phosphorylation of proteins – including m TOR (mammalian target of rapamycin), p70S6 kinase, and ribosomal S6 – that contribute to ribosomal assembly and protein translation. This inhibition may occur as a direct stepwise cascade or may occur via yet-to-be-identified intermediary steps. Negative modulation of this cascade by the hamartin–tuberin complex results in growth suppression and restricted cell size. When tuberin is inactivated by Akt-mediated phosphorylation in vitro, hamartin and tuberin dissociate, resulting in Rheb (Ras homolog expressed in brain)-mediated phosphorylation of TOR, p70S6kinase, and ribosomal S6 proteins (Figure 3). A similar effect occurs in the setting of loss of function mutations, in either *TSC1* or *TSC2*, that lead to failed heteromer complex formation. For example, enhanced phosphorylation of TOR, p70S6 kinase, and ribosomal S6 is observed in neuroepithelial cells derived from *Tsc2* knockout mice, and increased phospho-ribosomal S6, in particular, has been identified in renal angiomyolipoma cells from TSC patients. Phosphorylation (activation) of TOR, p70–S6-kinase, and ribosomal S6 is observed following tuberin inactivation by Akt-mediated phosphorylation in vitro or in cells lacking tuberin or hamartin in vitro. Loss of function mutation in the Drosophila *dTSC2* mutant *gigas* leads to enlarged ommatidia, head, and wings.

TSC1 and TSC2 have been shown to act as a constitutive inhibitor of the Wnt/β-catenin pathway, which like the PI3K–Akt–TOR–p70S6kinase–ribosomalS6 cascade is pivotal in the regulation of cell growth. β-Catenin is a transcriptional signaling modulator of the Wnt pathway via effects on T-cell factor (TCF)-mediated gene transcription. Wnt binding to its receptor, frizzled, leads to transport of nonphosphorylated β-catenin to the nucleus where it functions as a transcriptional activator. Several downstream genes, including cyclin D1 and c-myc, have been identified that are transcriptionally activated by the Wnt/β-catenin cascade. β-Catenin is active when dephosphorylated, but is targeted for degradation in the cytoplasm after phosphorylation by a GSK-3/APC/axin1 complex at critical residues encoded in exon 3. Binding of Wnt to frizzled leads to phosphorylation of disheveled (dvl-1), which inhibits GSK activity. Total β-catenin protein levels were found to be elevated in TSC2-related renal tumors. The TSC1–TSC2 complex also inhibits Wnt-1 stimulated Tcf/LEF luciferase reporter activity. TSC1 and TSC2 coimmunoprecipitate with GSK3 and axin, suggesting a direct effect of TSC1–TSC2 on β-catenin. Enhanced expression of cyclin D1 mRNA has been reported in single microdissected GCs in tubers, supporting the role of tuberin in β-catenin modulation. Transgenic mice, in which the Wnt/β-catenin pathway was constitutively activated, were shown to exhibit megalencephaly and abnormal cortical gyral patterning. Elevated levels of cytoplasmic β-catenin have been demonstrated immunohistochemically in BCs in FCD. The *PTEN* gene negatively modulates both PI3Kinase-Akt and Wnt/β-catenin pathway activity, and targeted knockout of the PTEN gene in mice leads to megalencephaly and seizures. Finally, recent evidence suggests that the PI3K-mTOR cascade may intersect and function in parallel with three additional cell cascades related to cell

growth or proliferation – the mitogen activated kinase (MAPK)/p42/p44, JNK, and Jak–Stat pathways. These cell-signaling cascades may be activated by PI3K or Akt, bypassing Rheb or p70S6kinase, and lead to phosphorylation of ribosomal S6 protein. There is evidence to support MAPK activation in TSC. Thus, elucidation of select cell cascades – whose direct cellular function is to control cell size – offers a number of compelling candidate molecules that may be involved in the generation of enhanced cell size in FCD and HMEG.

Molecular Mechanism of FCD and HMEG Formation

Clearly, cytomegaly is a pivotal histopathological feature of FCD and HMEG, and likely arises by persistent or aberrant activation of a cell cascade such as the PI3K–Akt–TOR–p70S6kinase–ribosomalS6, Wnt/β-catenin, (MAPK)/p42/p44, JNK, or Jak–Stat pathways. However, FCD does not result from mutations in either *TSC1* or *TSC2*. Thus, it seems plausible that altered regulation, either up- or downstream of the PI3K–Akt–TOR–p70S6kinase–ribosomalS6 or Wnt/β-catenin pathways, may be implicated in the formation of FCD and HMEG, and specifically in the generation of BCs, during brain development.

How might FCD and HMEG form during embryogenesis? We propose that FCD and HMEG likely arise from an abnormality occurring during cell proliferative stages of cortical development. This hypothesis provides a conceptual framework that has driven several novel methodological approaches. Etiologic possibilities, including hypoxia-ischemia, intrauterine infection, nutritional deficit, or environmental toxins such as cocaine or ethanol, have been considered as inciting events responsible for FCD and HMEG. There have been recent studies to suggest that cytomegaly can reflect a reactive process in response to tissue injury. For example, 'mega-neurons' have been reported around the perimeter of porencephalic cysts. These cells are clearly neuronal in that they express neuronal marker proteins and are quite morphologically distinct from BCs. While reactive hypertrophy may reflect an injury process, the cell-specific activation – in TSC – of a cascade clearly linked to enhanced cell size provides highly plausible evidence that activation of these cascades (or a related parallel cascade) contributes to cytomegaly in FCD and HMEG.

Recent speculations have suggested the compelling hypothesis that FCD and HMEG result from a somatic gene mutation occurring during cortical development. No FCD or HMEG pedigrees have been identified, and monozygotic twins appear to be independently discordant for FCD and HMEG. Thus, FCD and HMEG may result from a mutational event occurring in a neural or astrocytic progenitor cell. On the basis of lineage analysis experiments in our lab, we postulate that a somatic gene mutation occurs in a single progenitor cell at a critical stage in cortical development, and that this cell continues to divide and yield progeny carrying a mutant gene. The effect of the gene mutation on these daughter cells would include cytoarchitectural abnormalities, cellular dysmorphism, and laminar disorganization observed in FCD and HMEG.

Somatic mosaicism provides a plausible explanation for the salient features of FCD and HMEG, including sporadic occurrence, histological heterogeneity, and restriction of the lesion to a given brain region or to one hemisphere. First, since a somatic mutation occurs long after meiotic recombination, these events are not germline mutations and thus are confined only to the progeny of cells derived from the original progenitor cell sustaining a mutation. From a practical perspective, this means that causative mutations in FCD and HMEG are not likely to be identified in leukocyte DNA. In addition, these disorders are not heritable. Second, the cellular heterogeneity found in FCD and HMEG suggests that distinct populations of cells may form by separate molecular mechanisms, and thus it is likely that FCD and HMEG contain cells derived from the initial progenitor that sustained a gene mutation that are directly adjacent to other cells born from distinct precursors cells that did not sustain a somatic gene mutation. Third, because the effects of a gene mutation are confined to a restricted population of cells, cytoarchitectural abnormalities remain within a focal brain region. The differences in the amount of cortex that is affected in FCD and HMEG can be accounted for *when* a somatic mutation occurs. For example, an earlier-occurring mutation would, in theory, render an effect on cell morphology and migration over a longer developmental time epoch, and thus lead to a more broad region of abnormality in the cortex (as observed in HMEG). In contrast, a later-occurring mutation might lead to a more focal or restricted region of structural abnormality (as in FCD).

Experimental Methodologies

Since FCD and HMEG are sporadic disorders, it is difficult to implement conventional gene screening approaches in which family pedigrees are collected for genetic analysis. Thus, analysis of DNA extracted from human FCD and HMEG brain tissue specimens provides the most direct avenue to study the molecular pathogenesis of these lesions. While there are numerous animal strains that exhibit cerebral cortical malformations, none contain cellular equivalents of BCs. One clear and highly likely benefit of human studies will be the potential identification of candidate genes that can be targeted for mouse model systems in the future.

Studies to define the pathogenesis of focal MCD include three primary experimental strategies: (1) localization and quantification of individual proteins in focal MCD, using immunohistochemistry and Western assay, (2) analysis of mRNA expression using cDNA and oligonucoleotide arrays, and (3) assaying gene sequence in select MCD specimens obtained during epilepsy surgery or at postmortem examination. Using these three approaches, the expression of specific candidate gene families – such as cytoskeletal elements, neurotrophins, neurotransmitter uptake sites, cell-signaling molecules, and neurotransmitter receptor subunits – that are directly relevant to cortical development and epilepsy has been assayed in FCD and HMEG.

Analysis of focal MCD specimens resected during epilepsy surgery is the most common approach to studying the neurobiology of these lesions. There are several important caveats to analysis of resected specimens. First, the expression of cell-selective protein markers in focal MCD may not demarcate specific cell types or lineages, but instead may reflect aberrant gene transcription or protein translation due to the abnormal phenotype of cytomegalic cells or to up- or downstream changes in the expression of other genes that are distinct from lineage identities. Alternatively, the profound abnormalities of cortical lamination in focal MCD may cause altered expression of protein markers distinct from the molecular events leading to lesion formation. It is conceivable that the presence of seizures alone, or antiepileptic drug exposure alone, can alter protein expression. Thus, comparison with a nonseizure control group is essential. It is also important to keep in mind that differential expression of individual proteins could represent regional expression variability in the normal cortex, so it is essential to compare homologous regions of cortex.

Recent Developments

Over the past 5 years, several key developments have added new insights into our understanding of focal cortical malformations. For example, immunohistochemical analysis of focal MCD specimens resected during epilepsy surgery has identified numerous differentially expressed proteins in focal MCD; some provide new insights into pathogenesis, while others shed light on the mechanisms of epileptogenesis. These results have included information regarding distinct cell-signaling cascades, cell lineage markers, and expression of neurochemical markers such as neurotransmitter receptor subunits and uptake sites.

Perhaps most revealing has been the finding, independently verified in three laboratories, that the mTOR cascade is activated in tubers, FCD, HMEG, and gangliolglioma in a cell-specific fashion. The detection of hyperphosphorylated S6 protein is largely confined to cytomegalic cells in each lesion type. In TSC, the TSC1 and TSC2 proteins are direct upstream negative modulators of mTOR. Thus, the detection of hyperactived mTOR signaling in all four lesion types, as evidenced by hyperphosphrylation of S6 protein (a downstream marker for mTOR activation) provides a potential pathogenic link between these phenotypically similar disorders. The cell specificity of mTOR activation suggests the challenging concept that focal MCD may be a mosaic of cells with differential activation of TOR.

Expression of Phospho-S6 in Focal Malformations: mTOR Cascade Activation

On the basis of known functions of TSC1 and TSC2 and their role in mTOR cascade activation, we have recently found that cells meeting morphological criteria for GCs express phosphorylated p70S6kinase (phospho-S6K) and ribosomal S6 protein (phospho-S6), whereas cytomegalic neurons and astrocytes do not. There is a virtual absence of phospho-S6K and phospho-S6 immunoreactivity in normal control cortex or in nontuber brain regions from postmortem TSC brain specimens, highlighting the specificity of phospho-S6K and phospho-S6 labeling in GCs. These results provide evidence that GCs represent a unique subpopulation in tubers that express phospho-S6K and phospho-S6, and demonstrate a clear association between phosphorylation of p70S6kinase and ribosomal S6 protein and loss of hamartin or tuberin expression.

Phospho-S6 is selectively expressed by BCs in FCD (**Figure 4**), GG, and HMEG – but not in adjacent cytomegalic neurons or astrocytes. The number of phospho-S6-labeled BCs was quite consistent across FCD samples.

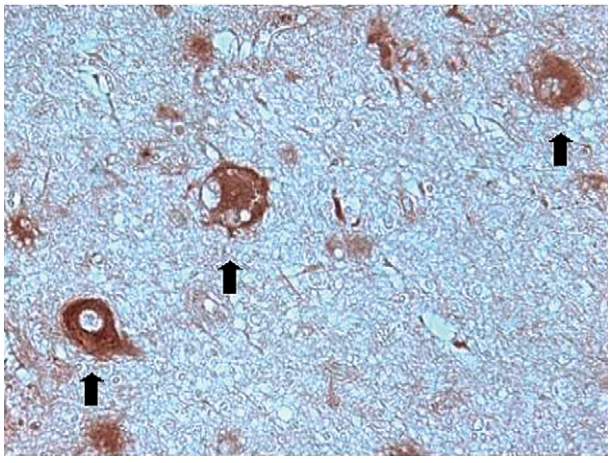

Figure 4 Phospho-S6 expression in BCs (arrows).

As in TSC, phospho-S6 is expressed in a highly cell-specific fashion, suggesting that the pathogenic process leading to lesion formation may not occur ubiquitously but rather in a select subgroup of cells. Thus, if we hypothesize that mTOR hyperactivation is a central mechanism of lesion formation in TSC as well as other focal MCD, then analysis of candidate gene expression and a search for candidate gene mutations must be confined to those cells that express phospho-S6.

Single-Cell Microdissection for mRNA Expression Analysis in Focal Malformations

A pivotal experimental strategy in our lab is the application of single-cell microdissection (Figure 5). Single-cell microdissection permits phenotypic classification of individual cells (by immunohistochemical labeling) so that alterations in gene expression can be determined in defined cell types. Thus, potential contamination of gene expression by the heterogeneous cell types in focal MCD in a homogenate is eliminated.

We have used this approach to define mRNA expression in fixed, paraffin-embedded brain specimens obtained intraoperatively during epilepsy surgery or at postmortem exam. For mRNA amplification studies, single cells are first microdissected using a stainless steel or borosilicate microscalpel driven by a joystick micromanipulator and then aspirated into a second pipette tip (the Eppendorf TransferMan apparatus). An oligo-dT24 primer coupled to a T7 RNA polymerase promoter is used to generate cDNA from poly (A) mRNA with a high-fidelity avian myeloblastosis reverse transcriptase. The cDNA then serves as a template for mRNA amplification incorporating ^{32}PCTP. Radiolabeled mRNA is used to probe large- or small-scale laboratory-generated or commercial cDNA arrays containing candidate genes of interest. We have demonstrated the success and reproducibility of the mRNA amplification protocol in surgical specimens and in postmortem brain tissue despite intervals to autopsy of as long as 18 h.

In a recent study, we used phospho-S6 protein as a marker for GCs and BCs and found that differential expression of 28 candidate genes distinguished BCs from GCs. Gene expression profiles were observed in four patterns, including changes in both GCs and BCs, in GCs alone, in BCs alone, or no change in expression. The expression profile of five mRNAs was identical between GCs and BCs whereas the expression of 12 mRNAs was selectively altered in BCs, and 12 distinct mRNAs were selectively altered in GCs. There was only modest variability among the data points in each cell group, and many of the individual mRNA abundances were similar within each cell type. One interesting finding that supports our hypothesis that activation of select pathways may lead to ribosomal S6 phosphorylation and cytomegaly was that both IGF-1 (insulin-like growth factor-1) and IGF-2 were significantly upregulated in BCs. These growth factors are upstream of PI3K–Akt, β-catenin, MAPK, JNK, and Jak–Stat cascades, and are regulated in a feedback loop by these pathways. A similar study was performed in which differential gene expression was defined in microdissected phospho-S6-labeled cells in FCD. Those investigators reported changes in numerous genes, including the gene for neurofilament, suggesting that the cell specificity of S6 protein phosphorylation is accompanied by cell-specific changes in gene expression.

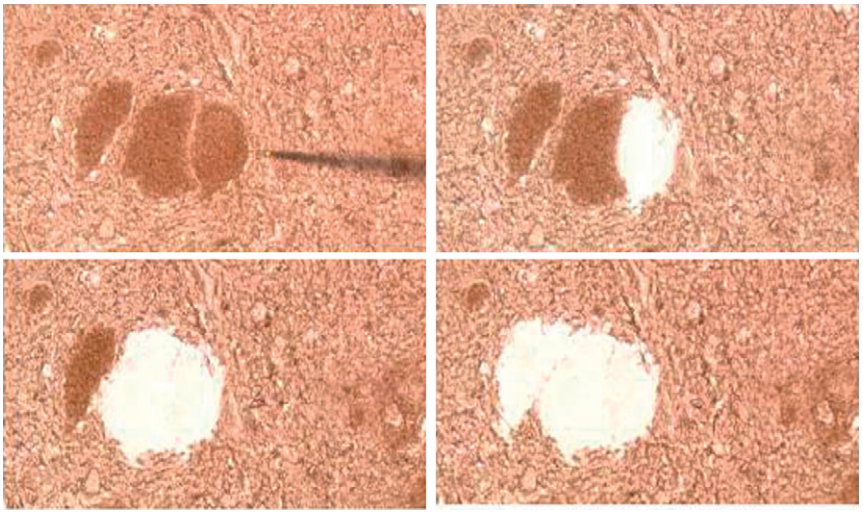

Figure 5 Microdissection of single NeuN immunolabeled cells from FCD sample. Note clean dissection with microscalpel (arrow) and aspiration of single cells in close proximity.

Recent data from our laboratory have used mRNA expression profile analysis to define differential expression of numerous candidate genes in HMEG. These studies were carried out in tissue homogenates, but nonetheless revealed changes in expression of several interesting classes of genes, including neurotransmitter receptor subunits and uptake sites, as well as transcription factors and cell-signaling molecules. We have implemented a functional cluster analysis to look at distinct classes of genes in TSC, FCD, and HMEG, and found that altered expression of genes can be clustered according to four categories (cell adhesion molecules, cell-signaling molecules, growth factors/growth factor receptors, and transcription factors) in these three lesion types.

Differential expression of 16 genes (including mRNAs for glutamate transporter (EAAC1) and receptor subunits (NMDA2C, mGluR5)), growth factor (hepatocyte growth factor), and growth factor receptors (platelet-derived growth factor receptor β, fibroblast growth factor receptor) was detected in GG neurons compared with control neurons. In astrocytes within GG, altered expression of p75NGF, mGluR3, TGFβ3, and Glt-1 mRNAs was detected. These findings demonstrate that altered gene transcription occurs in noncytomegalic cells in focal malformations.

Stem Cell Markers

One consistent finding in focal MCD has been the detection of protein markers in cytomegalic cells that are typically expressed by embryonic neurons or neuroglial precursor cells. For example, vimentin, phosphovimentin, nestin, and CD34 are normally expressed in progenitor cells in early stages of cortical development, but are then shut off in mature cerebral cortex. Over the past 10 years, expression of nestin, vimentin, phosphorylated vimentin, Mcm2, and CD133 has been identified in cytomegalic cells in focal malformations. These data suggest that cytomegalic cells in focal MCD may have failed to fully differentiate, may retain embryonic features, or may indeed represent a unique neural stem cell.

Challenges for the Future

One particular limitation for this research has been tissue specimen availability. It would seem logical for a repository of resected tissue to be generated so that individual samples can be stratified or classified according to tissue pathology or other clinical features. By more completely classifiying tissue samples, the chances of identifying a gene mutation or aberrant cell pathway are dramatically increased. To fully define the pathogenesis of focal MCD associated with epilepsy, additional high-throughput methodologies will be needed to screen for candidate gene mutations. Another limitation is that current technologies to screen for changes in mRNA expression or DNA sequence alterations are limited by paraffin fixation methods. Thus, development of new approaches to aid with in silico analysis of gene expression (or mutation in paraffin-embedded tissue specimens) is of paramount importance.

Morphological and Electrophysiological Properties of Abnormal Cells in Pediatric Cortical Dysplasia Tissue

C Cepeda, V M André, H V Vinters, G W Mathern, and M S Levine, University of California Los Angeles, Los Angeles, CA, USA

Introduction

The cerebral cortex, particularly in early development, is exquisitely sensitive to external insults; in response to such insults, it may become hyperexcitable and capable of generating paroxysmal activity, even though its constituent neurons have no obvious morphological abnormalities. It is thus not surprising that the search for 'epileptic' neurons in cortical or hippocampal tissue has been unsuccessful. Disruption of the balance between excitatory and inhibitory networks is now favored by most scientists as the mechanism by which epileptic activity is generated. However, in focal cortical dysplasia (CD), the presence of abnormal cell types has raised the suspicion that these cells could be epileptogenic.

Focal CD was first described in 1971 by Taylor and associates as a histopathological abnormality in surgical specimens from epileptic patients, characterized by cortical dyslamination, pyramidal cell disorientation, and the presence of abnormal cells – in particular, cytomegalic neurons and balloon cells. Although the potential role of these cells in epileptogenesis had been recognized, technical limitations prevented their electrophysiological characterization. With the introduction, in the 1990s, of infrared videomicroscopy in combination with differential interference contrast optics (IR-DIC), it became possible to visualize individual cells in living brain slices. IR-DIC and whole-cell patch clamp recordings constitute a powerful approach for the characterization of different cellular types in specific brain regions. In CD, this methodology allowed for the first time a systematic electrophysiological characterization of abnormal cells. The in vitro dissociated cell preparation has also been used to characterize, in more detail, abnormalities in ionic channels and receptors in cells from CD tissue. This article will summarize studies, describing some of the properties of these abnormal cells and providing a hypothesis about how CD tissue may be able to generate epileptic discharges.

Background

Electrophysiological recordings from human tissue resected for the treatment of pharmacoresistant epilepsy have been performed for many years. However, after a considerable number of such studies, the evidence for alterations in intrinsic membrane properties of cortical or hippocampal neurons in epileptic tissue was tenuous at best. Attempts to find abnormal cells in CD tissue, even from severe cases, were also unsuccessful, partly because of technical limitations as well as the inclusion of a heterogeneous population of epilepsy cases. Pioneer work by Avoli and associates, mostly in adult surgical patients, showed that CD tissue is particularly susceptible to epileptogenic agents (as compared to tissue resected from temporal lobe epilepsy cases), but tissue susceptibility could not be correlated with the presence of abnormal cells as these studies used blind recording techniques and neuronal staining was not attempted. Other studies also failed to find abnormal cells or synaptic transmission in tissue from children with catastrophic epilepsy, even when cells were intracellularly labeled with biocytin or Lucifer yellow. However, the patient population investigated in these studies was heterogeneous and included multiple pathologies.

Methodological Aspects

The Pathological Substrate in CD

CD is not a homogeneous pathological entity. In fact, several types have been described. To provide a first approximation, the pathology group at UCLA divided CD into mild and severe. More recently, CD has been classified in different subtypes, including CDI, where only architectural abnormalities are found, and more severe cases (where, in addition to cortical dyslamination, the sample contains abnormal cells) – CDIIA (with cytomegalic neurons) and CDIIB (with balloon cells). Even within the same patient, areas removed at surgery have different degrees of abnormality. Tissue typically has been separated into the most and the least abnormal areas, as based on electrocorticographic (ECoG), MRI, and PET studies. Areas with the highest degree of ECoG abnormalities correlate with severely abnormal MRI and pathological findings. Further, successful surgical outcome correlates well with removal of the most abnormal tissue. It is in these highly abnormal samples where the likelihood of finding abnormal cells is very high. Tuberous sclerosis complex (TSC), an autosomal dominant

disease caused by mutations in *TSC* genes (which encode hamartin and tuberin), shares histopathological similarities with severe CD; abnormal cells are abundant, particularly in the vicinity of the cortical tuber.

IR-DIC Optics and Electrophysiological Recordings

Correlative morphological and electrophysiological studies of pediatric CD tissue were first undertaken in our laboratory 10 years ago, with the goal of finding abnormal cellular types in severe CD and other pathological substrates. Individual cells in live tissue slices are visualized with IR-DIC optics. One limitation of this technique is that the age of the tissue plays an important factor. Younger tissue, with less myelination, is more accessible to adequate visualization compared to older tissue. Typically, the tissue samples most accessible to IR-DIC visualization are from patients younger than 5 years of age. Also, the health of the cells and the possibility of maintaining the slices for long periods of time in vitro are best in the young tissue samples. In our cohort, many cases are less than 2 years old (the youngest cases are only 2 months old), which permits electrophysiological recordings under optimal conditions.

Samples of CD tissue are prepared for in vitro analysis using the acute slice preparation approach. It is very important to slice the tissue sample as soon as possible after resection; slices (350 μm) should be cut within 10–15 min after obtaining the sample. The slices are allowed to recover for at least 1 h before recordings are obtained. For current clamp recording, a K^+-gluconate-based electrode solution is used; for voltage clamp recordings, a Cs^+-methanesulfonate-based electrode solution is used. After the recovery period, a slice is placed in a custom-made chamber attached to the fixed stage of an upright microscope. Potentially abnormal cells are visualized (40x lens) and selected for recording. Cytomegalic pyramidal neurons are easy to recognize by their large size, whereas balloon cells are harder to distinguish; they are usually large and round and appear pale.

Recent Results

One of the hallmarks of CD, in nearly all cases, is pyramidal cell disorientation, as manifested by a rotation of the cell body and deviation of the apical dendrite from the normal perpendicular orientation with respect to the pial surface. In some cells, disorientation is very subtle (~15–30° rotation), but in other cases it is more noticeable and complete inversion of the soma is not uncommon. A number of electrophysiological properties of disoriented pyramidal neurons were examined. The basic membrane properties of these cells are very similar to those of normal pyramidal neurons, and the cells do not appear to exhibit signs of hyperexcitability. Although it is possible that disoriented pyramidal neurons display subtle differences in synaptic inputs compared to correctly oriented pyramidal neurons, current evidence indicates that disorientation per se may contribute to – but is probably not a causal factor underlying – epileptic activity. This interpretation is consistent with the fact that a mouse model of cortical migration disorder, the Reeler mouse, does not display spontaneous seizures.

Another type of morphological finding in CD tissue is the presence of pyramidal neurons with tortuous or sinuous neurites. These neurons have normal somata but the apical or basilar dendrites, and sometimes also the axon, display segments that zigzag for variable distances, as though they were unable to find a specific target or pathway during neuritic growth. This feature could be another marker of migration disorder. The role of these neurons in the generation of paroxysmal discharges is still unknown, but electrophysiological recordings did not reveal clear signs of hyperexcitability.

Balloon cells are some of the most bizarre cells in CD tissue. They are found in ~50% of pediatric CD tissue from surgical cases and are very common in TSC and in severe CD (CDIIB). Morphologically, they are reminiscent of fibrillary astrocytes, but some features are more neuronal. They lack dendritic spines and an axon is not visible. They usually display very abundant, tortuous processes that extend for several hundreds of microns and become progressively thinner. Immunocytochemical studies revealed that balloon cells display neuronal and glial markers alone or in combination, suggesting that balloon cells did not 'commit' to a neuronal or glial phenotype and remained undifferentiated. For some time, investigators speculated that balloon cells could be the culprits – i.e., the basis of epileptogenicity – in CD. However, electrophysiological recordings demonstrated that these cells are unable to generate inward currents, do not respond to excitatory amino acids, and do not display spontaneous synaptic activity. In more recent studies, balloon cells were found not to be completely inert; they produced membrane oscillations in the presence of the K^+ channel blocker, 4-aminopyridine, similar to those generated by glial cells. The role of balloon cells in the generation of epileptic activity in severe CD is still an open question. However, based on the fact that these cells are unable to generate action potentials, their role in epileptogenesis is probably only minor.

The presence of cytomegalic pyramidal neurons is another hallmark of CD and occurs in ~60% of pediatric CD cases. These cells are 2–3 times larger than normal pyramidal neurons, and also display very thick processes, including the axon hillock. Spines are present and can be abundant in some dendritic segments, but are scarce in

other dendritic segments. Cytomegalic pyramidal neurons have abnormal membrane properties. Due to their large size, the membrane capacitance and time constants are significantly larger than those of normal pyramidal neurons, and their input resistance is very low. One of the main features of cytomegalic pyramidal neurons is their capacity to generate repetitive calcium oscillations. Because of the practical impossibility to obtain reasonable space clamp in these neurons, the dissociated cell preparation has been used to examine these calcium currents in more detail. These studies suggest that the large inward calcium currents in cytomegalic cells are due to upregulation of calcium channels. We speculate that upregulation of calcium channels gives rise to repetitive calcium oscillations in these cells when they are depolarized. These calcium oscillations could serve as an amplification device for the synchronization of cortical networks and the propagation of epileptic activity. However, these cells are also relatively hyperpolarized and, because of their low input resistance, it is difficult to depolarize these neurons via excitatory inputs. Immunocytochemical studies have revealed peculiar GABAergic basket formations around these neurons, and it has been hypothesized that GABA could depolarize these neurons to generate paroxysmal activity. The *N*-methyl-D-aspartate (NMDA) receptors in cytomegalic pyramidal neurons display reduced Mg^{2+} sensitivity, so that these receptors open (and permit calcium influx) at more hyperpolarized membrane potentials than normal cells – which can also lead to hyperexcitability.

In severe CD, particularly in cases of hemimegalencephaly, we recently described another type of abnormal neuron. Cytomegalic interneurons were found in the areas of greatest abnormality, in close proximity to the cytomegalic pyramidal neurons. The incidence of these cells in surgical material is presently unknown. Cytomegalic interneurons are 2–3 times larger than normal interneurons and can be labeled with GABAergic markers such as GAD, calbindin, and parvalbumin. They are generally basket cells and display increased numbers of dendrites compared to normal basket cells. These cells display some signs of hyperexcitability, such as non-inactivating Na^+ spikes when a depolarizing ramp voltage command is applied. An important feature of some cytomegalic interneurons is that these are the only cells in which spontaneous paroxysmal depolarizing shifts occur in vitro under physiological conditions. It is thus likely that cytomegalic interneurons play an important role in the generation of epileptic activity, assuming that GABA is excitatory in some pyramidal neurons from CD tissue.

Immature-looking pyramidal neurons can be observed in mild and severe CD tissue from patients generally younger than 2 years of age. Although, strictly speaking, these cells are not 'abnormal,' their presence in postnatal tissue was unexpected. They tend to occur in clusters, similar to the clones occurring during early neuroblast migration. Their morphological and electrophysiological properties are typical of immature pyramidal neurons, including incipient dendrites and spines, very high membrane input resistance, low capacitance, fast time constants, and small inward currents. But the main and most remarkable characteristic of these immature neurons is the presence of abundant, rhythmic spontaneous $GABA_A$ receptor-mediated synaptic activity. GABAergic synaptic events are depolarizing and may induce action potentials that can be blocked with bicuculline, a $GABA_A$ receptor antagonist. These observations support the notion that in early development GABA is the main excitatory neurotransmitter and led us to propose that CD tissue displays dysmature properties. Recordings of spontaneous synaptic activity from normal-appearing pyramidal neurons indicated that in CD tissue there is an over-abundance of GABAergic activity (relative to glutamate receptor-mediated activity). Paradoxically, anatomical studies have consistently found that the number of GABAergic interneurons is reduced in CD tissue. How can this reduction in GABAergic cells be reconciled with the observation of relatively high spontaneous GABAergic synaptic activity? One possibility is that synaptic reorganization of the remaining GABA interneurons occurs. Another is that in severe CD cases, cytomegalic interneurons provide rich innervation onto cytomegalic and normal-appearing pyramidal neurons. In fact, the presence of GABAergic basket formations surrounding cytomegalic pyramidal neurons suggests abundant GABAergic innervation and synaptic reorganization in CD tissue. The origin of this innervation is still unknown and could involve both intrinsic as well as extrinsic sources.

Hypotheses attempting to explain the intrinsic epileptogenicity of CD tissue range from those proposing that abnormal neurons can generate epileptic activity to those suggesting involvement of aberrant circuits. Needless to say, a combination of those factors is a more plausible explanation. The idea that cytomegalic pyramidal neurons and/or balloon cells are the generators of paroxysmal discharges has been entertained by several authors. Immunocytochemical studies seemed to support an important role of cytomegalic pyramidal neurons as they demonstrated abnormal expression and assembly of NMDA receptor subunits. That balloon cells could also generate paroxysmal activity was suggested based on morphological studies. However, as shown above, the balloon cells are unable to generate action potentials, and lack synaptic connections and axonal processes. Thus, their role in epileptogenesis can only be indirect. Immature cells are also candidates of hyperexcitable elements in younger, severe forms of CD. High membrane input resistances can amplify incoming signals. Immature properties also include depolarizing GABA

actions, and immunocytochemistry has shown altered expression of chloride transporters NKCC1 and reduced KCC2 in CD tissue. Recently described cytomegalic interneurons, in virtue of their hyperexcitability, have the potential to produce spontaneous depolarizing shifts, making them good candidates for generators of synchronous activity. If GABAergic basket formations surrounding cytomegalic pyramidal neurons are indeed depolarizing, GABA released from cytomegalic interneurons has the potential to activate upregulated calcium channels present in cytomegalic pyramidal neurons, which in turn could generate synchronous oscillations. A tentative scheme of an epileptogenic locus, constituted by a set of abnormal neurons and circuits in a brain with severe CD, is illustrated in Figure 1. In cases of mild CD, which do not contain abnormal cells, the generation of epileptic discharges has to rely on other abnormal functional properties. For example, aberrant excitatory and/or inhibitory circuits as well as abnormal receptor sensitivity in normal-appearing neurons could play important roles.

Directions for Future Research

Many unanswered questions still remain. For us, one of the most important questions is the origin of the abnormal cells in severe CD. When were they generated and, if this occurred during embryonic development, why do they remain in postnatal brains? Our studies suggest that CD is the consequence of abnormalities occurring late in neurogenesis and involve excessive generation of neurons and retention of preplate cells in the molecular layer and subplate regions. This retention could be the product of arrested development and/or decreased apoptosis. The fact that abnormal cells observed in severe CD resemble cells commonly found in the subplate supports our

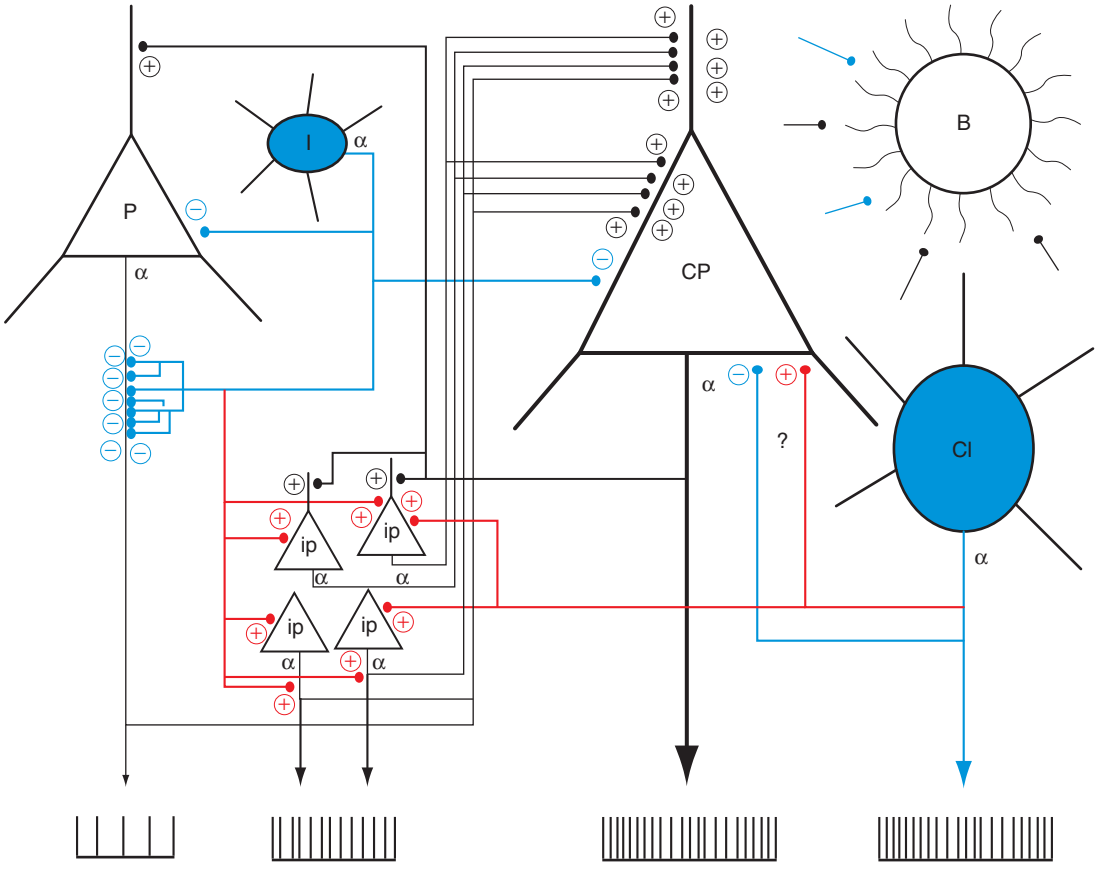

Figure 1 Diagram illustrates network hyperexcitability in an area of severe CD. It is hypothesized that cytomegalic (Cl) or normal GABAergic interneurons (I) generate pacemaker activity able to excite cytomegalic (CP) and immature (IP) pyramidal neurons. These clusters of immature pyramidal neurons, being excited by both glutamatergic (black) and GABAergic (red) inputs generate further excitation onto other pyramidal (P) neurons, thus creating a positive feed-back loop. Once cytomegalic pyramidal neurons are sufficiently depolarized they are able to amplify synchronous inputs and propagate abnormal activity to adjacent cortical areas. Balloon cells (B) do not participate directly as they do not receive synaptic inputs and do not appear connected to other cells. The question mark indicates that the effect of GABAergic inputs onto cytomegalic pyramidal neurons is not yet known. α indicates the axon.

hypothesis. Indeed, it is unlikely that cytomegalic neurons became hypertrophic as a consequence of epileptic activity; cases of mild CD (or other pathologies) also sustain epileptic activity, yet cytomegalic neurons are not observed. A number of studies support the hypothesis that balloon cells and dysplastic neurons are derived from radial glial progenitor cells.

The presence of cytomegalic interneurons in severe CD cases is particularly intriguing. These cells are unique in that they can generate spontaneous depolarizing shifts, making them suitable as generators of synchronous activity. It is interesting that in cell cultures from embryonic rat cerebral cortex, a distinct subpopulation of large GABAergic neurons, which constitute only a minority (<4% of all cultured neurons), is a key element in the generation of synchronous oscillatory network activity. In addition, these basket-like neurons are derived from the primordial plexiform layer and reside in the subplate at the time of birth, placing them in an ideal position to distribute activity in the local networks.

In conclusion, the presence of undifferentiated cells, retained embryonic neurons, immature pyramidal neurons, predominance of GABAergic synaptic activity, etc., all point to the idea that the abnormality in CD tissue is one of cortical dysmaturity. If true, then therapeutic approaches to CD-related epilepsies must take into consideration this important factor. For example, increasing GABA function in CD cases may not only be inadequate but even counterproductive.

Neonatal Progenitor Contributions to Epilepsy-Associated Cortical Malformations: A Hypothesis

J C Platel, V Gordon, and A Bordey, Yale University, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

A recurrent theme in epilepsy research is the contribution of neural progenitor defects to epilepsy-associated malformations of cortical development (MCDs). MCDs are associated with pharmacoresistant, intractable epilepsy, predominantly associated with seizure generation in the temporal lobe. MCDs were referred to as local neuroglial lesions in the 1990s. They include epilepsy-associated tumors and nontumoral malformations that have been recently classified based on the developmental stage (e.g., proliferation, migration, or differentiation) when a defect occurs, and subdivided based on their genetic mutations and/or histopathology.

Although MCDs encompass a broad spectrum of disorders, a subset of MCDs with abnormal glioneuronal proliferation and differentiation share similar molecular, histopathological, and clinical features, suggesting a common mechanism through which they contribute to epileptogenesis. These MCDs have been termed epilepsy-associated glioneuronal malformations, and include gangliomas (GGs), severe focal cortical dysplasia (FCD) with cytomegalic cells (called balloons cells), and tuberous sclerosis complex (TSC). These disorders are thought to result from combined defects in neural progenitor proliferation and differentiation, and neuronal precursor migration. Such defects can result from germline or de novo mutations, embryonic or neonatal insults, or a combination of both. It was initially thought that these defects occurred during embryonic life. However, it is becoming increasingly evident that both gliogenesis and neurogenesis within the subventricular zone (SVZ) in neocortex persist during neonatal life. This period is critical during brain development, since this is the time that infants are first directly exposed to the external environment. However, the contribution of neonatal progenitor defects to epilepsy-associated lesions has not been explored.

We propose to test whether defects in neural progenitors during neonatal life contribute to epilepsy-associated MCDs, and more specifically the MCDs (produced by glioneuronal proliferation and differentiation abnormalities) with known genetic mutations (e.g., of *TSC1* or *TSC2*). The results can then be compared to data obtained in studying defects in progenitor cells during embryonic life. Results from such studies should help us better understand the ontogeny of the epilepsy-associated MCDs and epileptogenic nature of these lesions.

Background

Abnormalities in SVZ-Derived Neural Progenitors Contribute to the Formation of Epilepsy-Prone Lesions during the Neonatal Period

Two relatively recent findings have radically changed our view on embryonic cell development and adult cell plasticity. During embryonic development, radial glia, long thought to serve as mere scaffold for migrating neuroblasts, are now recognized as neural progenitors. They can generate both cerebral cortical neurons and astrocytes. As a result, genetic mutations or insults to radial glia can have dramatic consequences on cortical development. For example, they can affect cell number or morphology, resulting in heterotopia (i.e., misplacement) of cortical neurons. In neonates and adults, it is now well-recognized that neurogenesis persists in two regions: the SVZ along the lateral ventricle (LV) and the dentate gyrus subgranular zone of the hippocampus. This continuing generation of new neurons confers an incredible level of plasticity, at the molecular, cellular, and network levels, to a brain long thought to have a fixed neuronal-cell population. Recent findings suggest a contribution of hippocampal neurogenesis to epileptogenesis, which is the subject of other articles in this volume. The contribution of SVZ neurogenesis and gliogenesis to epileptogenesis or seizure activity remains unclear.

The SVZ contains the largest pool of dividing neural progenitors in the adult mammalian brain, including humans. Neural progenitors generate highly proliferative intermediate progenitors (also called transit amplifying cells), which in turn divide to give rise to neuroblasts. These latter cells migrate along the rostral migratory stream to the olfactory bulb, where they differentiate into interneurons. SVZ cells expressing glial fibrillary acidic protein (GFAP), a marker of astrocytes that is also expressed in human radial glia, act as neural progenitors. In this article, these GFAP-expressing cells in the SVZ will be called SVZ astrocytes for simplicity. It was shown that radial glia transform into SVZ astrocytes during the neonatal period, a process well-known for the transformation of perinatal radial glia into parenchymal astrocytes. Neonatal neurogenesis may provide a relatively 'simple' developmental process, the understanding of which may provide insight into the ontogeny of developmental disorders.

It was reported that seizure activity in pilocarpine-injected adult rats increases neurogenesis to the olfactory bulb and also triggers the production of glioblasts in the SVZ. These glioblasts then migrate into the hippocampus where they differentiate into astrocytes and oligodendrocytes. However, it remains unknown whether SVZ cells contribute to epilepsy-prone lesions or exacerbate seizure activity occurring in the cortex. Gliogenesis within the SVZ is clearly ongoing during the neonatal period. In addition, there is increasing evidence that SVZ neural progenitors produce cerebral cortical interneurons during neonatal life as well as neurons in the piriform cortex in adults.

We propose to examine whether SVZ neural progenitors contribute to the formation of epilepsy-associated MCDs during neonatal life. This is a critical period when genetic mutations or insults could alter the behavior of SVZ progenitors, resulting in aberrant cell production and misplacement. As indicated earlier, our studies use a model of TSC to examine neonatal progenitor contribution to epilepsy-associated MCDs with abnormal glioneuronal proliferation and differentiation (see another article in this volume. for a discussion of another TSC model in which mutations in astrocytes result in seizure activity).

TSC as a 'Model' of Epilepsy-Associated MCDs with Abnormal Glioneuronal Proliferation and Differentiation

MCDs with abnormal glioneuronal proliferation and differentiation share similar clinical, histological, cellular, and molecular features. Clinically, patients with these types of MCDs usually have partial seizures during childhood that are thought to originate from within or surrounding the cortical lesions. In addition, these patients display low rates of remission and high rates of medical intractability. In TSC patients, epilepsy is the most common and devastating complication of the disorder, observed in more than 75% of the patients. Seizures usually begin in infants (during the first year of life, corresponding to $\sim$2 weeks in mice) as infantile spasms that are pharmacoresistant. At the histological level, these malformations display glioneuronal hamartias and benign tumor-like lesions called hamartomas. Hamartias correspond to abnormal cellular arrangements – also called dysplasia, nodules, or tubers when located in the cortex. FCD is characterized by the presence of 'balloon cells,' whereas TSC is associated with 'giant cells' in the cortical tubers (FCD with balloon cells is often indistinguishable from TSC at the histological level). The simultaneous appearance of tumors, the detection of neurodevelopmental antigens in cytomegalic cells, and the predominant occurrence of these defects in the temporal lobe and along the LV (i.e., where neurogenesis persists) suggest a defect of neural progenitor development. Although the presence of tubers in the 20-week-old human fetus suggests a defect during embryonic life, de novo mutations may occur at any time during early brain development and the lesions may progress during neonatal life. There are three types of lesions in TSC: cortical tubers, subcortical heterotopic nodules, and subependymal nodules. The first two are thought to be static (hamartia), although subtle anatomical but functionally important changes are not likely to be detected. The last (hamartoma) one is progressive and may transform into subependymal giant-cell astrocytoma (SEGA) in 15% of the patients. At the molecular level, TSC is an autosomal dominant neurocutaneous disorder with germline or predominantly de novo somatic mutations in one of two genes, *TSC1* or *TSC2*, the protein products of which are hamartin and tuberin, respectively. The tubers display positive staining for these gene products, suggesting a relatively subtle mutation that leads to abnormal function. However, the mechanisms of lesion and giant-cell formation remain unclear. The Knudson 'two-hit' model of tumorigenesis (i.e., second-hit mutation resulting in loss of heterozygosity) is thought to explain SEGA formation (SEGAs display loss of heterozygosity). Interestingly, the other MCDs with abnormal glioneuronal malformation (i.e., FCD and ganglioglioma) also display *TSC1* or *TSC2* polymorphisms. Importantly, these MCDs exhibit dysregulation of signaling pathways downstream of tuberin and hamartin, consistent with the idea of a similar (or common) molecular mechanism of pathogenesis.

Methods

In our laboratory, we are using a combination of technical approaches to achieve two goals: (1) to develop an approach to selectively knock out *TSC1* or *TSC2* in neural progenitors and their progeny during the neonatal period, and (2) to examine whether these specific mutations give rise to abnormal progenitor growth, leading to hamartia (cortical tubers) with giant cells and hamartoma. Results will then be compared with those observed with mutations generated at different embryonic time-points.

To address our first goal, we will take advantage of transgenic mice where the *Tsc1* or *Tsc2* gene is floxed. By in vivo electroporating a plasmid or injecting a virus containing a Cre sequence and a fluorescent protein (e.g., red fluorescent protein, RFP), we can selectively knock out the gene of interest in electroporated or infected cells. To address the second goal, we will perform immunohistochemistry, on RFP-positive cells, to identify different neuronal, glial, and progenitor markers. We will investigate the rate of proliferation of *Tsc1/2*-null neural progenitors in the SVZ by using the mitotic marker, bromodeoxyuridine (BrdU), and determining the number of proliferative cells. The identity and properties of RFP-positive cells will then be determined using the patch clamp technique in acute brain slices containing the SVZ and cortex. These studies are at an

early stage; the in vivo electroporation technique in neonates is presented in the research results below, together with recent data suggesting the contribution of SVZ cells to a freeze-induced cortical lesion in neonates.

Recent Results

Several years ago, we thought of a possible contribution of neonatal progenitors to the formation of cortical lesions based on data using the cortical freeze-lesion model. In this model, a freezing probe was placed on the skull of a postnatal day (P) 1 mouse pup for 5 s, resulting in the formation of a focal lesion in the cortex. Three weeks later, this lesion displayed enhanced hyperexcitability but the mice did not exhibit clinical seizures, consistent with previous studies on freeze-lesioned rats. As shown in **Figure 1(a)**, the lesion is strongly immunoreactive for GFAP. When acute slices from lesioned animals were bathed for 2 h in BrdU, a mitotic marker taken up by cells in S-phase, a stream of cells in the SVZ, along the LV and below the corpus callosum (CC), were marked (**Figure 1(b)**). This result suggested that some proliferative cells were migrating out of the SVZ, possibly toward the lesion.

BrdU could be taken up by dying cells in the slices because of their leaky membranes. However, the predominant labeling in the SVZ and below the CC cannot be explained simply by cell injury because SVZ cells remain healthy in acute slices. These data indicated to us that the SVZ may contribute to 'feeding' cells to the cortical lesion. Although this model is attractive for its simplicity and the formation of a hyperexcitable lesion that resembles a microgyrus, it does not involve genetic defects in the formation of epilepsy-associated MCDs. In addition, it does not offer an easy way to alter gene expression in SVZ cells. We thus decided to develop a model of TSC in which the TSC genes can be selectively knock out in neural progenitors.

We first examined whether neonatal SVZ cells express the *Tsc1* and *Tsc2* gene products, hamartin and tuberin, respectively, using immunostaining. We found that tuberin expression was low or not present in SVZ cells in a P1 section (green labeling in **Figure 2(a)** and **2(b)**). Nevertheless, some glutamate–aspartate transporter (GLAST)-immunopositive cells (red labeling in **Figure 2**) along the ventricle (i.e., either radial glia or newly-formed ependymal cells) expressed tuberin. Neurons in the striatum and the lateral septal nucleus expressed high levels of tuberin, suggesting that tuberin levels become higher as cells differentiate into neurons. SVZ cells, in particular cells along the ventricle (presumably radial glia), expressed hamartin, as did striatal neurons (green labeling in **Figure 2(c)**).

To knock out *Tsc1* or *Tsc2*, we will take advantage of transgenic mice where *Tsc1* or *Tsc2* have been floxed (the floxed *Tsc1* mice ($Tsc1^{C/C}$ mice) are commercially available from Jackson Laboratory). Then, one of three approaches can be used to selectively introduce Cre recombinase into SVZ cells: (1) injection of a viral vector (containing the Cre recombinase cDNA) into the LV that will infect SVZ cells, (2) crossing $Tsc1^{C/C}$ mice with GFAP-Cre^{ER2} or nestin-Cre^{ER2}, where intraperitoneal injections of tamixofen will induce Cre expression and deletion of TSC1 in GFAP or nestin-expressing cells, respectively (GFAP is expressed in SVZ neural progenitors but also in parenchymal astrocytes; nestin is predominantly expressed in SVZ cells in neonate and adult mice), and (3) In vivo electroporation of a Cre recombinase-containing plasmid into neonatal SVZ cells. We decided to use the third method because of its simplicity and efficiency, as already shown by in utero electroporation. As a proof of principle, we electroporated a CAG-GFP plasmid at $4\,\mu g\,\mu l^{-1}$ into P2 SVZ cells. Following anesthesia of pups by hypothermia, a glass pipette (30–50-µm beveled tip) was inserted into the LV. Plasmid ejection and electroporation were performed by applying a positive pressure at the tip of

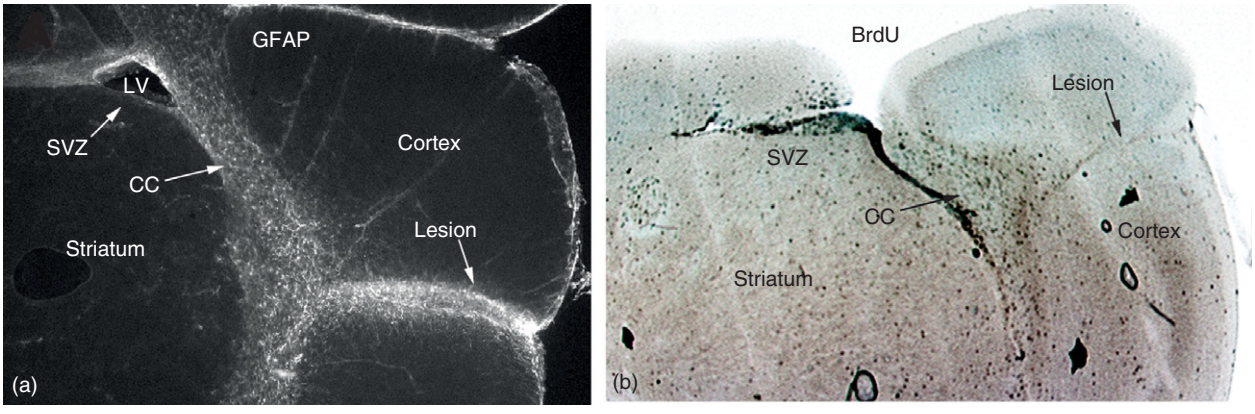

Figure 1 (a) GFAP immunostaining in a mouse coronal section at 21-day post lesion, which was performed at postnatal 1. (b) BrdU immunostaining in a mouse coronal section that was incubated for 2 h in BrdU, fixed, and stained. The section was prepared 18 days post lesion performed at postnatal day 1. CC, corpus callosum; LV, lateral ventricle.

the glass pipette and five 50 ms pulses (150 V) via electrodes placed on top and bottom of the head. Two days post electroporation, SVZ cells (as well as cells on top of the ventricle) displayed strong GFP fluorescence (**Figure 3(a)**). Radial glia were among the electroporated cells, as observed by the presence of GFP-fluorescent and GFAP-immunopositive radial processes crossing the parenchyma and reaching the cortical surface (**Figure 3(b)** and **3(c)**). Thus, electroporation provides a simple procedure by which we should be able to knock out TSC genes in SVZ cells, including radial glia, which are neural progenitors in neonatal mice.

Future Goals

Our immediate goal is to determine whether knocking out *Tsc1* in neonate SVZ neural progenitor cells results in lesion formation in the cortex (i.e., cortical tubers), and whether this lesion is associated with neuronal hyperexcitability, and perhaps clinical seizures or lowered seizure threshold. We also hope to identify cytomegalic cells that display features of the giant cells in TSC patients, as well as the formation of hamartoma along the SVZ (that may transform into SEGA either spontaneously or upon tumorigen exposure). However, we may not find defects in cortical lamination because neonatal neurogenesis is likely restricted to interneuron formation at a time when the cortical layers are already established. In addition, to better mimic the human disorder, it may be important to apply a two-hit injury model. We would then use one of the two following procedures. First, cross *Tsc1* heterozygote mice (noted $Tsc1^{-/+}$) with $Tsc1^{C/C}$ and then perform in vivo electroporation in neonatal $Tsc1^{-/C}$ mice. Interestingly, the $Tsc1^{-/+}$ mice do not develop the neural abnormalities seen in human TSC patients but these mice contain 50% more astrocytes than do littermate control mice. Second, electroporate Cre recombinase-containing plasmids

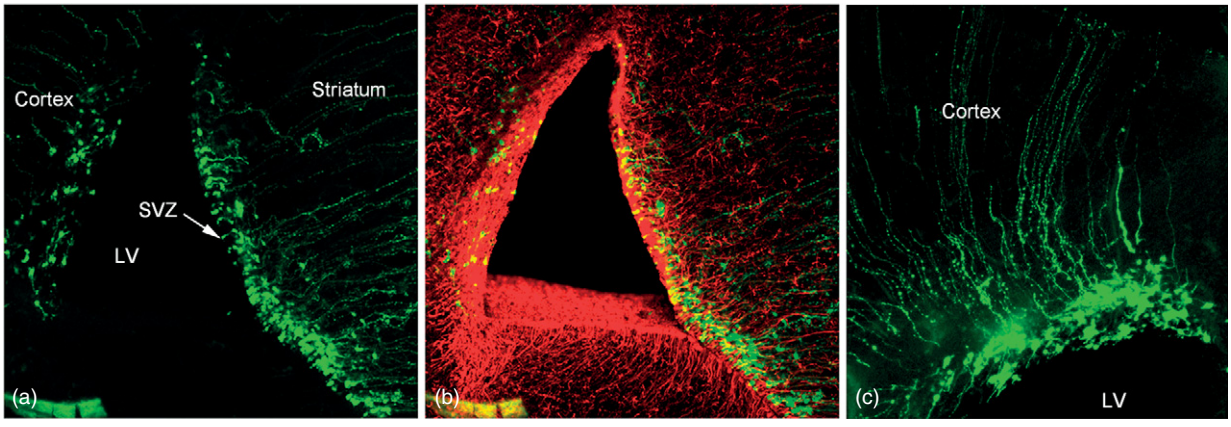

Figure 3 Images of GFP fluorescence (a-c) overlaid with GFAP staining in (b). Photographs were taken 2 day post-electroporation of a CAG-GFP plasmid in P2 mice.

in utero. As not all the cells will receive the plasmid, it could be interesting to apply a second electroporation during neonate life.

Once a lesion has been obtained, a series of experiments could then be performed to histologically characterize them and determine the state of neuronal excitability within and surrounding the lesions. Using immunohistochemistry, the presence of giant cells and proliferation in the lesions will be assessed. An increase in astrocyte proliferation is a common finding in MCDs with abnormal neuroglial proliferation and differentiation. Neuronal excitability can be assessed using electrophysiology or imaging in acute brain slices. In particular, voltage-sensitive dyes have shown tremendous improvement in their sensitivity and could give a more global view of neuronal excitability. Finding cytomegalic cells could help us understand the function of such cells in cortical circuits, and perhaps in hyperexcitability or seizure initiation. Finally, when possible it is important to compare the murine model to the human disease. Immunohistochemistry is the easiest technique to study human tissue, but it is also possible to use imaging in acute slices to better understand the mechanism of seizure initiation and propagation in human tissue (in parallel with the mouse study). Collectively, we hope that establishment of the described model of MCDs will provide a valuable tool to better study the ontogeny of these disorders and the epileptogenesis associated with the lesion. These approaches are critical for designing better diagnostic methods and therapeutic approaches to control seizure initiation or spread in affected children.

Introduction

Cortical dysplasia is defined as 'a malformative disorganization of the cytoarchitecture of the cortex relative to neurons'. It reflects disturbances in normal cortical development, which can be the result of aberrations in processes such as migration, proliferation, pruning of arborization, differentiation, and programmed cell death of neurons. There exists a wide range of histopathological and anatomical variations of human cortical malformations, reflecting the differential influence of the type, timing, and severity of the external insult or genetic mutation. One

in utero. As not all the cells will receive the plasmid, it could be interesting to apply a second electroporation during neonate life.

Once a lesion has been obtained, a series of experiments could then be performed to histologically characterize them and determine the state of neuronal excitability within and surrounding the lesions. Using immunohistochemistry, the presence of giant cells and proliferation in the lesions will be assessed. An increase in astrocyte proliferation is a common finding in MCDs with abnormal neuroglial proliferation and differentiation. Neuronal excitability can be assessed using electrophysiology or imaging in acute brain slices. In particular, voltage-sensitive dyes have shown tremendous improvement in their sensitivity and could give a more global view of neuronal excitability. Finding cytomegalic cells could help us understand the function of such cells in cortical circuits, and perhaps in hyperexcitability or seizure initiation. Finally, when possible it is important to compare the murine model to the human disease. Immunohistochemistry is the easiest technique to study human tissue, but it is also possible to use imaging in acute slices to better understand the mechanism of seizure initiation and propagation in human tissue (in parallel with the mouse study). Collectively, we hope that establishment of the described model of MCDs will provide a valuable tool to better study the ontogeny of these disorders and the epileptogenesis associated with the lesion. These approaches are critical for designing better diagnostic methods and therapeutic approaches to control seizure initiation or spread in affected children.

Introduction

Cortical dysplasia is defined as 'a malformative disorganization of the cytoarchitecture of the cortex relative to neurons'. It reflects disturbances in normal cortical development, which can be the result of aberrations in processes such as migration, proliferation, pruning of arborization, differentiation, and programmed cell death of neurons. There exists a wide range of histopathological and anatomical variations of human cortical malformations, reflecting the differential influence of the type, timing, and severity of the external insult or genetic mutation. One

such variant involves a mutation in the doublecortin gene, which results in the development of subcortical band heterotopia. This disorder is also known as 'double cortex', since there exists a second, abnormally laminated and disorganized layer of cortex (heterotopia) located inferior to the normal-appearing cortex that maintains proper orientation and lamination of its primary neurons.

Studies performed on human brain tissue suggest that dysplastic tissue is hyperexcitable, as compared to surrounding neocortical tissue. However, specific mechanisms responsible for epileptogenic activity associated with cortical malformations remain to be elucidated. It is possible that hyperexcitable dysplastic and heterotopic neurons may be unable to establish their normal synaptic connections with nearby neurons and thus create dysfunctional synaptic activity. It could be at this level of circuitry that the abnormal synchronization of neuronal populations occurs, which in turn may underlie the genesis of epileptiform activity in cortical malformation.

It is important to also consider potential molecular mechanisms that may underlie the epileptogenicity of brains with malformations. Limited studies have demonstrated alterations in the subunits of glutamate and GABA receptors found within human dysplastic cortex. In addition, reduced inhibitory input from interneurons has been demonstrated in dysplastic cortical tissue resected from patients with intractable epilepsy. These alterations and reductions may result in an imbalance between excitation and inhibition, thus leading to a net increase in excitatory drive with epileptogenic potential.

Unfortunately, the amount and types of experimental information collected from human brain samples regarding epileptogenesis in cortical malformations are restricted. The data have suggested some mechanisms; however, the intrinsic limitations encountered when using human samples have impeded rigorous studies to define specific mechanisms. To help answer these questions, experimental, and genetic animal models of cortical malformation have been developed. Although these models do not utilize human tissue, they do provide a greater degree of control, standardized sample collection, the possibility for age-matched experiments, and large sample sizes that allow for statistical analysis of experimental results. In this article, we focus on the genetic model of cortical malformation, known as the 'tish' (telencephalic internal structural heterotopia) rat.

Background

The Tish Rat: Morphology, Genetics, and Development

The brain of the tish rat displays bilateral subcortical heterotopia reminiscent of those found in double cortex. The heterotopia consists of misplaced cortical neurons and glia that retain several basic features of normal neocortex, including topographic connectivity with subcortical targets. However, the heterotopic neurons fail to orient and laminate as in typical neocortex. Overlying the heterotopia is an area of neocortex termed 'normotopic cortex' that is thinner than normal neocortex, but maintains proper orientation and lamination of its primary neurons.

The initial characterization of the genetic disorder in the tish rat indicated that a spontaneous autosomal recessive mutation is responsible for the cortical heterotopia. More recent findings are consistent with an autosomal mutation with partial penetrance. This genetic basis distinguishes the tish rat from human double cortex, which is usually the result of an X-linked mutation.

Investigation into the developmental basis for the subcortical heterotopia in the tish rat has revealed that several important developmental milestones are achieved normally. Similar to control neocortex, only one preplate is formed, and this structure subsequently splits during expansion of the normotopic cortical plate into a single subplate and a marginal zone containing reelin-secreting Cajal–Retzius cells. The heterotopic cortical plate, therefore, forms without a dedicated preplate. In contrast to normal cortical development, the defining feature of tish neocortex is the presence of an additional proliferative zone located below the cortical plate and corresponding to the position of the intermediate zone in normal animals. This second proliferative zone has been shown to incorporate BrdU and to contain mitotic cells; therefore, it is hypothesized to give rise to many of the projection neurons and/or glia within the malformed neocortex. Local interneurons are unlikely to be generated in the heterotopic proliferative zone because they derive from the ganglionic eminences, which do not exhibit a misplaced proliferative zone.

Seizure Activity in the Tish Rat Brain

Spontaneous partial seizures with variable secondary generalization have been documented in the tish rat, which makes it an appropriate subject of study for epilepsy associated with cortical malformations. The distribution and site of seizure initiation zone were examined by using depth electrode recordings and postmortem analysis of c-*fos* mRNA expression to locate regions of aberrant discharge activity during seizures. The results of these studies demonstrated that the overlying normotopic neocortex and heterotopic cortex begin seizure activity almost simultaneously. Electrophysiological experiments using tish brain slices suggest that although epileptiform discharges occur in both brain regions, it is the normotopic cortex that is more prone to exhibit epileptiform activity and is responsible for recruiting the heterotopic area into aberrant discharge activity.

Considering these interesting results, experiments using anterograde and retrograde tracers were performed in order to examine the connectivity between the different regions (heterotopic and normotopic) of the tish cortex and both cortical and subcortical targets. The results show that both the normotopic and heterotopic cortices make functional topographic connections to subcortical targets, including thalamus and spinal cord. These experiments also demonstrated connectivity between the normotopic and heterotopic cortices, thus providing a potential avenue for the spread of epileptogenic discharges between hyperexcitable normotopic cortex and the heterotopia as well as subcortical targets.

Methods

Spontaneous seizure activity has only been noted in tish rats above the age of 30 days. This finding led our laboratory to examine a developmental stage prior to seizure development, specifically animals at 15 days of age (P15), in search of physiological abnormalities that might eventually lead to the development of spontaneous seizures in adult animals.

We used whole-cell patch clamp recordings of pyramidal neurons from live brain slices to characterize GABAergic inhibitory postsynaptic currents (IPSCs) at P15 in the tish brain. Layer V pyramidal neurons were selected from normotopic cortex because they are a major source of efferent projections from the neocortex, and have been implicated in epileptogenesis. In addition, this cell type could be targeted in both the normotopic and heterotopic areas for recordings; the cells in the normotopic area were identified on the basis of size, shape, and laminar position while the cells in the heterotopic area were defined on the basis of size, shape, and position within the outer one-third of the heterotopia. The recordings from these cells were compared with those collected from the same cell type found in wild-type animals of the same background strain, referred to hereafter as control.

By combining patch clamp recordings with pharmacological manipulations, we can isolate events in postsynaptic neurons that result from the action potential-dependent release of multiple GABA-containing vesicles from a presynaptic interneuron, otherwise known as spontaneous IPSCs (sIPSCs). Other pharmacological agents allow us to examine events that result from the action potential-independent release of individual vesicles of GABA at a single synapse from a presynaptic interneuron. These events are known as miniature IPSCs (mIPSCs). By measuring parameters (such as amplitude and frequency) that characterize sIPSCs and mIPSCs, we can gain knowledge about presynaptic activity from interneurons as well as synaptic function at the single synapse level.

Once recordings were completed, the brain slice was fixed and stained for a label that was incorporated into the solution filling the recording electrode. This procedure allowed a post hoc characterization of the morphologies of the cells from which recordings were made. Detailed morphologies of the reconstructed cells could then be established to ensure their consistency with morphology of layer V pyramidal cells.

Immunohistochemical experiments were also performed in order to investigate potential structural foundations of hyperexcitability in tish rat brains. Glutamic acid decarboxylase isoform 65 (GAD-65) is the rate-limiting enzyme in GABA production and is concentrated in the terminals and occasional cell bodies of GABAergic interneurons. Visualization of GAD-65 immunoreactivity allows the investigator to gain insight into the quantity, quality, and location of inhibitory interneuron terminals on principal cells. These types of immunohistochemical experiments also allow us to visualize a wide variety of cellular components that are distributed throughout the different regions of the tish brain. For instance, there are markers for multiple subtypes of inhibitory interneurons, and visualization of these markers provides insight into differential representation of the subtypes of interneurons found in the hetertopic and normotopic neocortices.

Recent Results

Spontaneous IPSCs recorded from normotopic neurons in tish brain slices were smaller in amplitude and less frequent as compared to those recorded from layer V neurons in control slices. The smaller amplitudes could result from a decrease in the occurrence of multiquantal, multiterminal release events in the tish brain compared to controls; however, smaller quantal size cannot be ruled out. In order to determine the quantal size in control and tish normotopic neurons, we measured the amplitude of action potential-independent mIPSCs. The amplitudes of mIPSCs recorded from normotopic neurons and control neurons were similar, indicating that quantal size was comparable in the two populations of neurons. The smaller amplitudes of sIPSCs recorded from normotopic neurons were therefore not due to smaller quantal size but rather due to a reduced number of GABA-containing vesicles being released from interneuronal terminals.

The reduced frequency of sIPSCs suggests that GABAergic terminals from normotopic cortex are not releasing vesicles at the same rate as in control cortex. It is possible that, establishing conditions that increase the probability of vesicle release (i.e., increasing calcium and lowering magnesium concentrations) might overcome this attenuated release from GABAergic terminals onto normotopic neurons. The frequency of sIPSCs recorded from control cells increased in response to these conditions, which reflects a robust increase in the release of presynaptic vesicles from control interneurons. In contrast, sIPSC

frequency was only modestly and nonsignificantly increased in normotopic cells in tish cortex under the same conditions. Thus, despite an enhanced probability of release, the frequency of sIPSCs in normotopic cells did not achieve a level comparable to that recorded from control neurons in standard recording conditions. We then investigated possible mechanisms that might be responsible for abnormal vesicular release.

Neurotransmitter release from presynaptic terminals is mediated by entry of Ca^{2+} into the terminal via voltage gated Ca^{2+} channels. Consequently, we tested whether the expression and/or function of Ca^{2+} channels on GABAergic presynaptic terminals in the normotopic cortex was reduced compared to control cortex. In interneurons, high voltage-activated N-type calcium channels are located specifically on synaptic terminals, are tightly coupled to exocytosis, and play a predominant role in action potential-mediated GABA release. This role for N-type channels contrasts with the situation in other central neurons in which P/Q type channels play a dominant role in synaptic release. One possible explanation for disturbed GABA release from interneuron terminals in tish normotopic cortex is that the expression of N-type channels is altered. Pharmacological experiments confirmed the presence and function of N-type channels in tish normotopic interneuron terminals and indicated that P/Q type channels do not participate substantially in regulating GABA release from terminals innervating layer V pyramidal cells. Thus, a shift of calcium channel subtypes did not occur in the interneurons innervating tish normotopic neurons.

Another plausible explanation for the decrease in presynaptic GABAergic neurotransmission is that fewer GABAergic terminals were making synapses onto normotopic neurons. To test this concept, immunohistochemical techniques were used to visualize GAD-65-positive terminals in control and tish neocortices. These experiments demonstrated that the intensity of GAD-65 immunoreactivity in layer V of the tish normotopic cortex was reduced relative to that observed in control tissue. GAD-65 IR terminals surrounding layer V pyramidal neurons in tish normotopic cortex displayed dispersed, punctate immunoreactivity that was less intense than that seen surrounding control layer V cells. The reduced perisomatic labeling in the tish cortex is consistent with a reduction in the number of GABAergic terminals innervating layer V pyramidal neurons.

This reduction in GAD-65-positive terminals in the tish normotopic cortex could reflect an overall reduction in GABAergic interneurons, a selective reduction in one or more interneuron subtype, and/or an attenuation of immunogenicity for GAD-65 in one or more types of interneuron. To examine these issues, we utilized a previously described classification system that identifies three discrete interneuron populations based on their selective expression of the following markers: parvalbumin, somatostatin, and cholecystokinin. The results demonstrate a selective decrease in parvalbumin-expressing interneurons (see Figure 1), with no significant change in somatostatin- or cholecystokinin-expressing interneurons.

The heterotopia was also examined to assess their electrophysiological and neuromorphological characteristics. The results indicated that: (1) inhibitory synaptic transmission onto large heterotopic pyramidal neurons was somewhat weaker than that observed in large pyramidal neurons in layer V of control tissue; (2) calcium channel expression was similar to that found in control and normotopic cortex; (3) the intensity of the GAD-65 immunoreactivity appeared more diffuse around the heterotopic pyramidal neurons as compared to control, but not as weak as that observed surrounding the tish

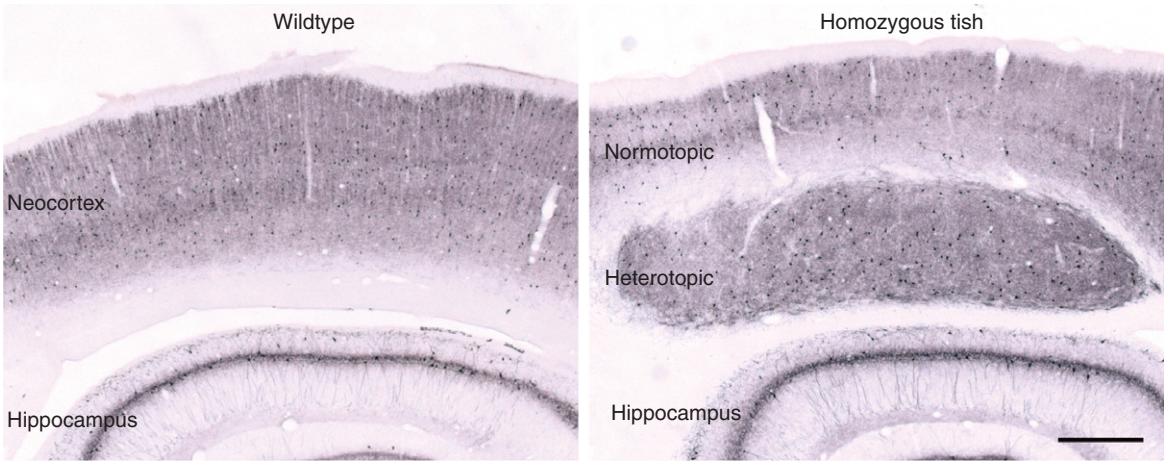

Figure 1 Coronal sections are shown from wild-type and homozygous tish brains stained for parvalbumin immunoreactivity. The tish phenotype is characterized by a thinned normotopic neocortex and an underlying heterotopic neocortex. Fewer parvalbumin-positive interneurons are observed in the tish normotopic neocortex in comparison with the wild-type neocortex.

normotopic layer V neurons; (4) all three subtypes of interneurons were present in the heterotopia of the tish brain, but their distribution appeared more random than in the laminated areas of the neocortex; and (5) a profound reduction of parvalbumin-positive cells was not seen in the heterotopia. These results suggest an overall reduction in GABAergic inhibitory drive on heterotopic neurons, which was less profound than the prominent reduction observed in normotopic neurons.

In summary, these recent results demonstrate that GABAergic synaptic inhibition is reduced in a seizure-prone animal model of cortical malformation. Studies performed in humans and other animal models have implicated disruptions in the GABAergic system, such as altered inhibitory drive, alterations in GABA interneuron populations, changes in $GABA_A$ receptor subunits, and changes in GABA reuptake transporters. A key finding in this unique model is that inhibitory failure of GABAergic innervation onto primary neurons in normotopic and heterotopic cortices actually precedes the onset of seizures. This type of disturbance thus provides not only a mechanism for ongoing seizure activity, but also represents a rational substrate for epileptogenesis in a dysplastic brain.

Future Goals

A question that still remains unanswered is what events precipitate the onset of seizures in tish animals. Alterations in inhibitory drive have been described in immature animals, but it remains to be elucidated whether these changes persist into adulthood, or whether there are further changes that may contribute to the onset of seizures. A rigorous study of adult tish brain inhibitory physiology, similar to that described for P15 animals, will help in further understanding these issues.

Our studies have focused on the presynaptic aspect of the GABAergic synapse; however, the postsynaptic side of inhibitory synaptic function (e.g., $GABA_A$ receptors) remains unexplored. These receptors and related molecular components of the postsynaptic complex represent an important area of study because during normal development of the forebrain, modifications occur in $GABA_A$ receptor subunit mRNA and protein expression that, in turn, influence synaptic transmission. It is plausible that there could be alterations in the $GABA_A$ receptor subunit composition that contribute to altered inhibitory neurotransmission in the tish brain.

The disturbances in interneuron distribution and their innervation of primary neurons are critical features of the seizure-prone tish neocortex. In light of the lengthy tangential migration of interneurons from the ganglionic eminences during embryonic development, it is intriguing to hypothesize that the errors in tish interneuron distribution in the P15 brain could have their origins in disrupted tangential migration. A number of molecules are known to stimulate or otherwise coordinate the process of interneuron migration, including various neurotrophic factors, hepatocyte growth factor/scatter factor, class 3 semaphorins, and the chemokine CXCL12 (also known as SDF-1). In particular, CXCL12 is important for maintaining migrating interneurons in the marginal and subventricular/intermediate zones, allowing them to invade the laminar cortex only after they have reached their appropriate mediolateral position within the cortex. Alterations in CXCL12 gradients via genetic knockout result in dispersal of migrating interneurons, their premature entry into the cortical plate, and their disturbed laminar positioning in the adult animal. These findings highlight the importance of this particular guidance molecule in determining interneuron distribution. Considering that CXCL12 is produced, in part, by neurogenic intermediate progenitor cells in the subventricular zone, and that a malpositioned population of proliferative cells exists in the tish intermediate zone and normotopic cortical plate, the changes in interneuron distribution in tish neocortex may result from errors in CXCL12 gradients caused by heterotopically located intermediate progenitor cells. In an effort to better address this possibility, ongoing and future studies in our laboratory will address the distribution of specific progenitor populations and their contributions to the construction of the neocortex. In addition, since CXCL12 is one of several cortical molecular signals that might regulate the migration and positioning of interneurons, an important goal of future studies will be to define the critical cellular and molecular regulators that are modified in the developing tish cortex.

Finally, the studies so far undertaken on tish brain physiology have focused on GABAergic inhibitory synapses. However, human and animal studies of cortical malformation have also implicated alterations in excitatory neurotransmission in the hyperexcitability associated with epilepsy. It would be worthwhile to investigate alterations in excitatory glutamatergic physiology in the tish brain, as well as structural entities that may underlie abnormalities associated with a disturbance between excitatory and inhibitory influences.

Introduction

Epileptogenesis and plasticity of neuronal networks are two related phenomena because some epileptogenic lesions show clear reorganization of neuronal connections and growth of neuronal elements. This is conspicuous in epileptogenic foci induced by kindling, but even more so in 'post-status epilepticus' (SE) experimental models of chronic epilepsy. In this article we consider, *first*, the relations between kindling epileptogenesis and a classic form of neuronal plasticity, long-term potentiation (LTP). *Second*, we examine the evidence regarding how restructuring of synaptic connections may underlie epileptogenesis. *Third,* we analyze the relations between developmental plasticity and epileptogenesis. *Fourth,* the question of mechanisms of neurogenesis and the role of growth factors is discussed. *Finally* we summarize some conclusions and formulate some open questions that merit being further investigated.

Background

Electrophysiological Evidence for a Relation between LTP and Kindling Epileptogenesis

Experimental evidence support that repeated tetanization (i.e., high-frequency electrical stimulation) of several brain structures, particularly the limbic cortex, at regular intervals, leads finally to the development of an epileptogenic focus. This epileptogenic process is accompanied by a progressive change in evoked synaptic responses that has a striking resemblance to what is seen during the establishment of LTP in vivo. This progressive change has been shown by recording local evoked potentials (EPs) for many hours and even for days after tetanization of the Schaffer collaterals. In particular, potentiation was shown for the synaptic potentials elicited by the stimulation of the Schaffer collaterals, using the paired-pulse paradigm and recording field EPs in the CA1 area. The tetanus consists of a burst of high-frequency pulses, similar to the stimulus used to induce LTP in vivo in the rat, but at somewhat higher stimulus intensity. Using a kindling procedure involving once daily tetanization, investigators (not surprisingly) found that the first tetanic stimulus induced LTP (i.e., an increase in the peak amplitude of the field EP). In one series of experiments, the degree of LTP increased gradually up to the 4th daily stimulation session, but then became variable or nonsignificant. This transient character of LTP, induced in the kindling paradigm, was interpreted by some researchers as indicating that LTP cannot be the 'cause' of kindling epileptogenesis. Nevertheless, LTP may play a role in the initiation of the

plastic processes that eventually lead to kindling epileptogenesis. We find it interesting that the occurrence of epileptiform after-discharges and of the first behavioral signs of seizures takes place at about the same time that the LTP effect appears to saturate and becomes rather variable. At this time, additional changes in the EPs are noted. In particular, the late components of the EP are modified in a manner that has been shown to correspond to a decrease in a population inhibitory postsynaptic potential (IPSP) in the CA1 area. In contrast, in the dentate gyrus, paired-pulse stimulation of the angular bundle shows an increased paired-pulse depression that can be interpreted as a strengthening of inhibition (especially at the septal pole of the hippocampus). Several factors may be involved in this increased inhibition, including sprouting of interneurons, sprouting of granule cell axons that may form synapses preferentially with inihibitory interneurons, or increased number of $GABA_A$ receptors in this region. These findings lead to two main conclusions: First, kindling epileptogenesis and LTP may share some common plastic neuronal changes. And second, kindling epileptogenesis involves additional processes concerning LTP. Thus, kindling cannot be considered just a simple amplification of the same processes underlying LTP, but rather involves *additional plastic changes*, among which a restructuring of synaptic connections plays an important role. There is evidence that ultrastructural changes of synapses may occur in LTP, particularly enlargements of the spine head and shortening of the dendritic spine neck, both changes can be associated with changes in the strength and time course of synaptic currents and intracellular calcium dynamics. In addition, time-lapse imaging has provided the evidence of increases in the density of spines. How these ultrastructural changes are related to the induction or maintenance of LTP is still an open question. In contrast to LTP, however, kindling epileptogenesis is associated with much more prominent and extended morphological changes. In kindled rats, changes in the form of synaptic contacts have been described at the ultrastructural level in the dentate gyrus of the hippocampus; in particular, there is an increase in the ratio of perforated axo-spinous synapses (i.e., synapses with discontinuous postsynaptic densities) to nonperforated synapses. The consequence of this structural change would be, in theory, an increase in the gain of excitatory synapses.

Methods

In most of the experiments described later, the SE model for temporal lobe epilepsy in the rat has been used. In this model, SE is induced by electrical stimulation of the angular bundle or by kainate or pilocarpine injection. The SE is followed by a latent period of about 1–2 weeks (in the case of the electrical stimulation), after which spontaneous seizures start to develop. This seizure progression can be monitored by hippocampal EEG and field potential recordings. Using in situ hybridization and immunocytochemistry at different time points after SE, we can gain some insights into the factors that can contribute to epileptogenesis and seizure progression.

Recent Results

In the 'post status epilepticus' models the occurrence of *sprouting of mossy fibers* and the formation of aberrant mossy fiber synapses onto apical dentate granule cell dendrites in the inner molecular layer of the dentate gyrus (a zone where mossy fiber terminals synapses are not found in normal animals) is an even more conspicuous structural change. These mossy fibers can be viewed by Timm staining for heavy metals (zinc is abundant in these terminals), or by dynorphin-A immunocytochemistry. The sprouting of mossy fibers may contribute to the formation of a recurrent excitatory circuit, which could facilitate the spontaneous recurrence of focal seizures and propagation of the epileptic state. Nevertheless, sprouted mossy fibers may also innervate inhibitory interneurons which, after an initial loss of inhibition following SE, could contribute to recovery of inhibition in this subarea of the hippocampus during epileptogenesis. An interesting new finding is that stimulation of granule cells can cause inhibitory synaptic potentials in postsynaptic pyramidal cells after epileptic seizures (but not before), indicating a change in the neurotransmitter signalling of these cells from purely glutamatergic to a combination of glutametergic and GABAergic effects (refer 'See also' section). This change in phenotypic expression may compensate for the increased excitability associated with mossy fiber sprouting, since the GABAergic transmission of these 'post-seizure' granule cells may hyperpolarize target cells, shunt incoming excitatory signals, and enhance tonic inhibition at both pre- and postsynaptic sites.

In addition to sprouting of mossy fibers, the granule cell layer of the dentate gyrus displays another conspicuous structural change, namely the *dispersion* of the granule cell layer, and the formation of granule cell basal dendrites (which normally appear only in early stages of development). The processes that lead to these structural changes are still unknown. However, recent studies suggested that granule cell dispersion does not result from increased neurogenesis but rather reflects a displacement of mature granule cells, most likely caused by a local deficiency in the protein reelin that is associated with neuronal migration and the development of normal dendritic trees.

Moreover, kindled seizures are also associated with axonal and synaptic remodeling in other subareas of the hippocampal formation, including the hilus of the dentate gyrus, the CA3 and CA1 regions, and the entorhinal

cortex (EC). What induces this abnormal plasticity, characterized by sprouting of axonal collaterals that invade a foreign territory, is still an unsettled issue. Mossy fiber sprouting appears as a reaction to the loss of the normal post-synaptic targets of the mossy fibers, namely the hilar cells. Indeed, in the hilus of the SE rats, there is a severe loss of mossy cells as well as elimination of parvalbumin, claretinin, and somatostatin-immunoreactive interneurons – all cell types that normally receive mossy fiber input.

The occurrence of sprouting in this hippocampal area, may be induced by a transient decrease of the chemorepellant Semaphorin (Sema3A). Sema 3A is normally secreted by axons from the EC and serves to prevent axon collaterals from entering the molecular layer of the dentate gyrus. It is interesting that Sem3A expression is downregulated in a model of temporal lobe epilepsy caused by electrical stimulation that induces 'status epilepticus.' Indeed, shortly after induction of 'status epilepticus,' Sema3A messenger RNA almost disappears in the stellate cells of the EC, although this loss was transient. The downregulation of Sema3A appears concomitantly with an upregulation of GAP-43 in the granule cells. GAP-43 is known to stimulate mossy fiber sprouting and is enhanced in many epilepsy models. Thus, in this temporal lobe epilepsy model, the chemorepellent Sema3A disappears from the molecular layer at the same time as granule cell axons are prompted to form sprouts. We were surprised to know that if the electrical stimulation of the angular bundle, used to induce seizures, does not result in a complete status epilepticus, the downregulation of Sema3A does not occur but the upregulation of GAP-43 does – but there is no sprouting. This result suggests that the downregulation of Sema3A in the molecular layer of the dentate gyrus is a molecular event needed for recurrent mossy fiber sprouting. Also in the SE model induced by kainic-acid injections, the chemorepellant Sema3C content of CA1 has been shown to be downregulated within the first week of epileptogenesis. These findings indicate that an inactivation of the Semaphorin signalling may play a role in the formation of new aberrant synaptic contacts.

Seizure Progression and Selective Neuronal Loss in Parahippocampal Regions

Although mossy fiber sprouting has been proposed to be a prerequisite for chronic seizure activity in experimental temporal lobe epilepsy, and may occur regardless of the kind of initial epileptogenic insult (electrical stimulation, stroke, or percussion injury), the extent of hilar cell death also appears to be an important factor that could contribute to seizure progression, as illustrated in **Figure 1**.

Although most studies have focused on cell death in hippocampus, extensive cell death has also been observed in other limbic regions, including thalamic nuclei, amygdala, and piriform- and entorhinal cortices. Inhibitory GABAergic cells have been reported to be reduced in epileptic foci in both experimental animals and epileptic patients. A subset of GABAergic cells, the parvalbumin (PV) immunoreactive neurons, exert strong perisomatic inhibition and are involved in both feedback and feedforward inhibition. Extensive PV cell loss has been reported in rats that have developed a progressive form of epilepsy and exhibit frequent daily seizures in the chronic epileptic phase. The density of PV-IR neurons is, however, not significantly decreased in the medial EC layer III (**Figure 2(e)**), even though most of the surrounding layer III principal neurons are lost (particularly in rats that develop a progressive form of epilepsy) (**Figure 2(b)**). The disappearance of these principal layer III neurons may leave the PV interneurons without their main excitatory innervation, leading them to become 'dormant,' similar to what has been suggested for basket cells in the dentate gyrus. The decrease of PV-IR neurons in EC layer II (and the less PV 'rich' layers V/VI), together with dormant cells in EC layer III, might have a profound effect on net inhibition in the EC. Under normal circumstances, layer III is thought to act as a powerful 'gate,' limiting the responsiveness of the superficial EC layers. In the absence of this gate, superficial layers may become hyperexcitable to deep layer entorhinal input. Support for this hypothesis has been provided by several electrophysiological studies.

The selective cell loss is less extensive in post-SE rats that did not develop a progressive form of epilepsy (although an occasional seizure can be observed in these rats). Neuronal death is induced mainly by the initial SE (not by later spontaneous seizures), and the loss of PV containing neurons does not progressively increase along with the number of seizures. Therefore, the significant correlation between decreased PV immunostaining and lifetime seizure load appears to be related to the fact that rats with longer SE duration show more extensive cell loss and are more likely to develop a progressive form of epilepsy.

Developmental Plasticity and Epileptogenesis

An interesting possibility to account for epileptogenesis is that the reaction of brain tissue to an epileptogenic insult may cause the neuronal system to recapitulate some mechanisms that were active during its most intense period of plasticity – i.e., during early development. This recapitulation may lead to changes in neuronal systems that are inappropriate for the adult brain, and that become manifest by the occurrence of epileptic seizures, as well as other possible functional impairments. In this respect, a number of interesting changes have been found in epileptic tissue, including the reappearance of embryonic forms of sodium channels, and the appearance GABAergic depolarizing signalling characteristic of early

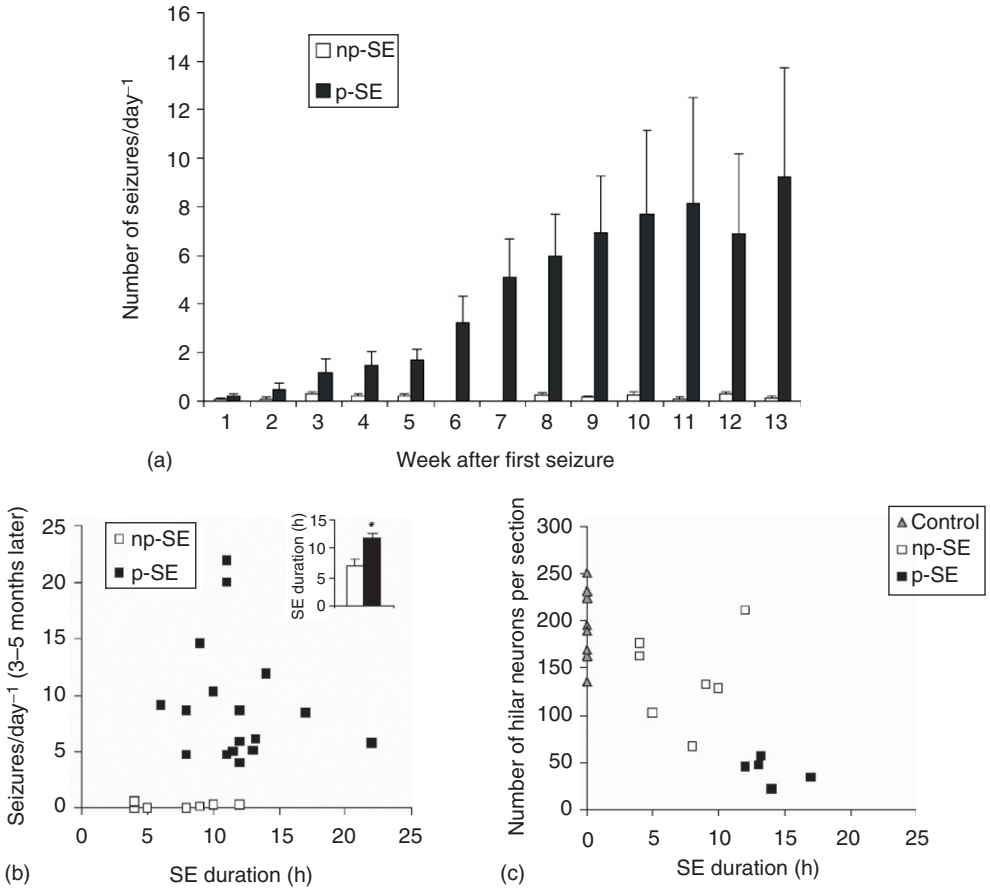

Figure 1 (a) Data from SE rats, induced by repeated electrical stimulation of the angular bundle, that after a latency period develop spontaneous seizures; in some rats seizure development is progressive, with an increase of seizures' frequency and duration (p-SE), but in some other seizures occur only occasionally and do not show a progressive trend (np-SE). (b) Relation between the duration of the SE and the later individual seizure activity in progressive epileptic rats (black squares) and nonprogressive epileptic rats (white squares) during the last week before perfusion. The average group data (inset 1(a)) indicate that rats that displayed a progressive form of epilepsy had experienced a significant longer SE than rats that had a nonprogressive form of epilepsy. (c) Relation between the duration of the SE and the number of hilar Nissl cells at dorsal hippocampus after SE. There is a significant negative correlation ($r = -0.66$, $p < 0.01$) between the duration of the SE and the hilar cell number of the three groups (Adapted from Gorter *et al*. 2003 and van Vliet *et al*. 2004).

development. It has been previously shown that inactivation properties of the fast Na+ ionic current shift to a more depolarized potential after kindling epileptogenesis, and that this feature has some resemblance to sodium current properties in neonatal rat neurons. This finding, in turn, led to an investigation of the cell-specific expression of mRNAs encoding 'neonatal' II and III alpha-isoforms, and a comparison of these isoforms with 'adult' sodium channels (NaCh I, II, III). For these studies, we used in situ hybridization, at different time points after electrically induced seizure activity, in the SE rat brain. Both types II and III sodium channel genes encode two isoforms, as a result of a mutually exclusive splicing of a single exon. This alternative splicing is developmentally regulated. An increased expression of neonatal sodium channels II and III alpha-isoform mRNAs after the induction of status epilepticus was found in neurons of CA1, CA3 and in the dentate granule cell layer. These changes persist, although less intensely, in the chronic phase when rats display spontaneous seizures. In addition, this enhanced expression of neonatal sodium channels II and III was observed also in microglial cells. The increased expression of neonatal isoforms of sodium channels in both neurons and microglia represents a plastic regression to early stages of development. This plasticity may reflect a critical mechanism for enhancing neuronal excitability in the course of epileptogenesis, and may be relevant for the pharmaco-resistance that is frequently found in epileptic patients with mesial temporal lobe epilepsy. Furthermore, a period of status epilepticus can produce other plastic changes in ionic currents. For example, during the latent period of epileptogenesis, most CA1 pyramidal cells that normally fire in a regular pattern acquire low-threshold bursting behaviour, generating high-frequency clusters of 3–5 spikes as their minimal response to depolarizing stimuli. This burst firing pattern is initially

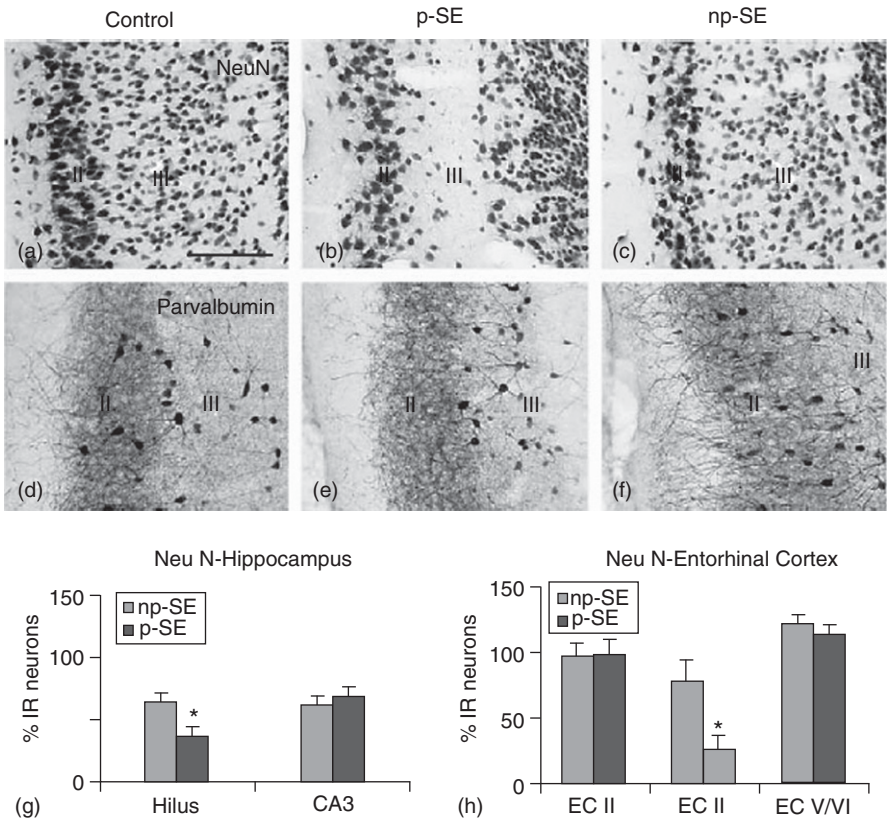

Figure 2 Examples of NeuN ((a)–(c)) and PV ((d)–(f)) immunostainings in the superficial entorhinal cortex (EC) layers (II and III) of a control rat ((a), (d)), progressive post-SE rat (p-SE; (b), (e)), and nonprogressive post-SE rat (np-SE, (c), (f)). Note the preservation of PV-positive staining in layer III in both p-SE and np-SE rats, while NeuN staining is extensively decreased only in p-SE rats. Scale bar in panel a = 250 μm. ((g) and (h)) NeuN densities in various hippocampal and entorhinal areas in rats with progressive and nonprogressive epilepsy (control densities are 100%). A significant decrease was observed in hilus (g) and EC layer III (h) in p-SE rats compared with controls. Np-SE rats also showed reduced NeuN staining in the hilus but not in the EC layer III. (Adapted From van Vliet *et al*. 2004).

mediated by a T-type Ca^{2+} current, but gradually becomes dependent on a persistent Na+ current. This plastic transition may contribute to the development of temporal lobe epilepsy.

Another example of a reiteration of a developmental program is the overexpression of a sodium-potassium chloride transporter (NKCC1) – as evident in subicular pyramidal cells removed from MTLE patients. NKCC1 is known to facilitate the accumulation of Cl^- in neurons, producing a GABA receptor-mediated depolarizing response which is characteristic of the immature brain. The subicular cells of adult epileptogenic tissue appear to reproduce the behavior of the embryonic brain with respect to NKCC1 expression. NKCC1 overexpression has also been found in tissue of epilepsy patients with developmental lesions such as focal cortical dysplasia (type IIB), gangliolioma and hemimegalencephaly. This protein may contribute to the occurrence of seizures. In the electrically induced SE rat model, a gradual upregulation of NKCC1 gene expression was found during the chronic epileptic phase in both CA3 and EC. The switch from depolarizing to hyperpolarizing GABAergic synaptic activity depends not only on the expression of the K-Cl co-transporter, NKCC1 but also of the KCC2 transporter. The latter becomes expressed only a few days after birth in the rat; and it causes the reversal potential of chloride to shift in the hyperpolarizing direction. In this context, it is interesting to note that de-afferentation (e.g., resulting from the neuronal loss) can cause a downregulation of the neuronal KCC2. An increase in expression of brain-derived neurotrophic factor (BDNF) (see later text) may also contribute to the shift of the membrane equilibrium potential for $[Cl^-]$ in hippocampal cells associated with seizures.

Neurogenesis and the Role of Growth Factors

A plastic change associated with epileptogenesis is the enhancement of *neurogenesis* – a process that occurs throughout life in the dentate gyrus, but is highly accentuated after epileptic seizures. Some of the newborn cells mature as adult granule cells and appear to integrate into the local circuits; other cells do not integrate appropriately and appear to be 'displaced.' Newborn granule cells also show increased NKCC1 expression which leads to a

GABA-mediated depolarizing action. The molecular mechanisms responsible for new neurogenesis are still unclear, but neurotrophins are likely contributors. Neurotrophins play a significant role during neural development, and are associated with normal plasticities associated with, e.g., learning and memory. A particularly relevant neurotrophin is the BDNF that acts by binding to the high-affinity receptor tyrosine kinase, TrkB. The activity of BDNF is quite complex; besides the full-length receptor, TrkB, there exist spliced truncated forms (trkB.T1 and trkB.T2), both of which bind BDNF but lack tyrosine kinase activity. These spliced variant receptors inhibit the function of the full-length receptor. The expression of BDNF is enhanced after limbic seizures. BDNF, through Trk receptors, can downregulate KCC2 protein levels in hippocampal neurons. In addition, BDNF decreases the amplitude of IPSCs in hippocampal excitatory neurons, and induces hyperexcitability in the hippocampus. Transgenic (tg) mice overexpressing BDNF also exhibit increased severity of seizures. Furthermore, kindling in BDNF knockout mice is retarded. Finally, the inactivation of the BDNF efficacy, by intraventricular administration of antibodies to trkB receptor, during induction of kindling reduces kindling epileptogenesis. Experiments in mice in which status epilepticus was induced by kainate support the hypothesis that *decreased* BDNF signalling *reduces* epileptogenesis. Furthermore, the potential role of BDNF in mossy fiber sprouting has been addressed by studies in BDNF overexpressing transgenic mice; in these experiments, no difference was seen in induction of mossy fibre sprouting after kainate-induced SE in mice with truncated trkB receptor compared to wild type mice – showing that BDNF is not the primary inducer of sprouting after status epilepticus.

Plastic Changes that are Responsible for the Formation of a Mirror Focus

Many years ago, Morrell hypothesized that a mirror focus may be formed in the course of an epileptic process – i.e., a secondary epileptogenic focus may be formed on the side of the brain contralateral from a primary focal epileptogenic area. This phenomenon of *secondary epileptogenesis* is an example of how in an adult brain plastic changes may be induced in normal tissue by seizure activity in a remote, but connected, brain area. The phenomenon of secondary epileptogenesis is well described in experimental animals but its relevance to human epilepsy has been the subject of controversy. Nevertheless, it has been shown that secondary epileptogenesis is not uncommon in humans, although it does not occur in all cases. An experimental study using an ingenious in vitro preparation, has given new insights into the plastic mechanisms mediating the formation of a mirror focus. Using this preparation (composed of a three compartment chamber in which two intact hippocampi and the connecting fibers are placed), investigators showed that induction of a 'mirror focus' required activation of NMDA receptors as well as persistent changes in GABAergic synapses which became depolarizing due to a shift in the chloride reversal potential (as described above).

Plasticity Related Genes and Epileptogenesis

Microarray studies in animal models of temporal lobe epilepsy yield results that are in general agreement with respect to genes associated with the immune response, inflammation and proteolysis. The expression of these genes is enhanced especially during the first weeks after the 'initial insult.' Another conspicuous change is the decrease or change in expression of various GABA receptor subtypes. In another article, we discuss in more detail the gene expression changes that are related to synaptic plasticity and epileptogenesis (refer 'See also' section).

Future Directions

An initial epileptogenic insult, such as a brain inflammation, trauma, ischemic lesion, or tumor, may cause neuron loss, de-afferentiation of surviving cells, and proliferation of glial cells. These cellular alterations can cause changes in gene expression, promoting inflammatory processes and neurodegeneration, but also the upregulation of neurotrophic factors, such as BDNF, enhanced neurogenesis, and the sprouting of new synaptic connections. This replay of phenomena associated with growth in early stages of development is accompanied by the reappearance of several processes that are characteristic of embryonic phases, such as neonatal forms of sodium channels, of the sodium-potassium chloride co-transporter NKCC1 (with the consequence that GABAergic processes becoming depolarizing), and of GABA expression in normal glutamatergic cells (e.g., the granule cells). These processes are necessary during the early stage of development, where they contribute to the growth and formation of neuronal connections, but become disruptive when they re-appear in the adult brain, where they affect the dynamical equilibrium of the neuronal networks. Thus, conditions that may finally lead to the emergence of epileptic seizures may be created. Thus, we postulate that this kind of epileptogenic lesion results from *plastic developmental changes in reverse direction.* Other processes characteristic of this replay of early developmental stages will likely emerge as more such researches is pursued. A general issue that merits further investigation is how the chain of reactions that goes from the early inflammatory and immunological responses to an initial epileptogenic insult results in a series of plastic changes that revive early stages of development (with respect to ionic channels, neurotransmitter signaling, growth of neural cells and of synaptic connections).

Gene Expression in Immature and Mature Hippocampus After Status Epilepticus

H Chung and S Koh, Northwestern University, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Prolonged seizures or status epilepticus (SE), as well as repeated brief intermittent seizures associated with epilepsy, have been shown to cause neuronal damage. A single systemic administration of kainic acid (KA) in mature rodents causes seizures that can last for several hours, followed by a latency period of about 2 weeks between status and the onset of spontaneous seizures, and finally a chronic epileptic state characterized by spontaneous recurrent seizures. In young rats prior to postnatal day 18 (P18), however, KA injection does not result in spontaneous recurrent seizures or cell death. Rather, these young rats exhibit a limited pathology characterized by a lowered seizure threshold. Studying such age-dependent differences, therefore, offers a strategy not only for understanding epileptogenesis, but also for identifying factors that contribute to seizure

susceptibility in mature animals and neuron-protection in younger animals.

We focused on the contrasting responses of immature and mature brains to the same stimulus, KA-induced seizures, to identify target genes involved in epileptogenesis and cell death processes. We used high-throughput, high-density oligonucleotide gene arrays (microarrays), to study the molecular basis of the detrimental effects of seizures. The comparison between transcriptional changes in immature brain and those in the mature brain following SE may offer insight into mechanisms of neuroprotection against seizure-induced neuronal injury. Some of the highly regulated genes identified in our array analysis were confirmed by a real-time quantitative reverse transcriptase-polymerase chain reaction (qRT-PCR).

Background

Gene Expression Profiling Using Microarray Technology

Advances in both array technology and knowledge of genomic sequences have opened a new way to study the nervous system. One of the benefits of these innovations is high-density oligonucleotide arrays that contain more than 400 000 sequences, typically 25-mers, in $20 \times 20\,\mu m^2$, in a total area smaller than half inch square. We used the Affymetrix Rat Genome U34A GeneChip®, which has 8799 genes and expressed sequence tags (EST) and 16 probe pairs targeted to the most unique regions of genes, a design that increases detection redundancy and specificity.

The array interrogates complex nucleic acid samples and effectively counts the number of different RNA molecules that are present in a sample. The process is highly parallel, as all sequences are counted simultaneously, and is quantitative over a limited range. The relative concentration of a given sequence fragment between two samples can be determined for thousands of genes at a time, based on hybridization reaction and a posthybridization fluorescence scan of the array. Instead of a 'one gene at a time' approach, microarrays allow us to look broadly and to gain a new and broadly-encompassing view of genome-wide changes in neuronal gene expression. This strategy is particularly suitable for a study of complex diseases such as epilepsy, as it is likely that a large number of genes are simultaneously involved in the disease process.

Gene microarray technology has been successfully applied in many areas of medical research, most notably in cancer research to aid in classification, diagnosis, and prognosis predictions. By facilitating the identification of potential therapeutic targets from thousands of genes in a single experiment, array technology provides a new and valuable approach in searching for candidate target genes for epileptogenesis.

Lack of Histopathologic Markers for Epileptogenesis

Beginning within the second week after KA treatment, during the time referred to as the 'latent period,' there is temporal progression of axon growth in the dentate gyrus, which proceeds for several months. This progression is believed to correlate with the onset and peak of spontaneous seizures. A currently influential hypothesis suggests that hippocampal neuronal loss and mossy fiber sprouting play a critical role in the pathogenesis of chronic epilepsy. Recent evidence regarding the relationship between chronic epileptogenesis and hippocampal histopathology, however, has challenged this hypothesis. Studies using rat models have revealed that neither cell death nor mossy fiber sprouting is necessary or sufficient for the generation of spontaneous seizures after SE. These findings suggest that while neuronal injury and mossy fiber sprouting may be common sequelae of SE, and may accompany the epileptogenic process, they do not cause chronic epilepsy. Instead, the epileptogenesis process is preceded by, and may occur as a result of, a cascade of changes in gene expression. Temporal sequences of gene expression may incite a subsequent cascade of cellular events, ultimately leading to the occurrence of cell death, mossy fiber sprouting, and spontaneous seizures. Although molecular, cellular, and physiologic mechanisms operate together to contribute to epileptogenesis, our focus here is on the earliest events detectable following evoked seizures.

Role of Inflammation in Epileptogenesis

The contribution of inflammation in mediating many aspects of disease has been relatively well established. However, we have only begun to explore the involvement of inflammation in the pathogenesis of epilepsy and seizure-induced brain damage. For example, hippocampal sclerosis has been viewed as an inert scar, but recent neuropathological studies of resected hippocampal tissue reveal many hallmarks of active inflammation, such as astrocytic proliferation, microglia activation, and expression of cytokines. These and other findings raise the possibility that seizure-induced glial activation and neuronal degeneration are active and ongoing processes.

Clinical observations also report acute inflammatory reactions after seizures. Active inflammation has been detected not only in prototypical inflammatory epilepsies such as Rasmussen's encephalitis or limbic encephalitis, but also in patients with pharmacoresistant epilepsy of diverse causes. Proinflammatory cytokines, NF-κB, and interleukin 1β (IL-1β) and its signaling receptor IL-1R1 are highly expressed by neurons and glia in temporal lobe epilepsy, focal cortical dysplasia, glioneuronal tumor, and in tuberous sclerosis complex. Increased levels of cytokines such as IL-6, IL-1β, and IL-1-receptor antagonist (IL-1Ra), a

naturally occurring antagonist of IL-1β, have also been detected in plasma and cerebrospinal fluid from patients with recent seizures without evidence of infections. Involvement of the 'cytokine network' has also been implicated in febrile seizures. Whether cytokines contribute directly to pathogenesis of seizures and chronic epilepsy, or the presence of high levels of cytokines merely reflects activation following seizures, cannot be determined from these clinical observations. However, consistent with these clinical findings are related results from experimental studies. In many animal models of epilepsy, acute seizures cause glial activation and increased expression of transcription factors and cytokines that coordinate inflammatory responses. Proinflammatory cytokines can affect neuronal excitability, either directly – by interacting with glutamatergic neurotransmission, or indirectly – by activating gene transcription.

Methods

Phosphate-buffered saline or KA were given to P15 ($3\,mg\,kg^{-1}$) and P30 ($10\,mg\,kg^{-1}$) Long-Evans male rats. These age-specific doses of KA have been determined previously to result in less than 25% mortality while inducing seizures in over 60% of animals. Only animals with nearly continuous seizures for more than 30 min were included in the study. P15 is considered roughly equivalent to human infancy or early childhood. P30 animals were chosen because their response to KA injection is adult-like, with neuronal injury and occurrence of spontaneous seizures, although P30 might be more accurately considered pubescence rather than adult.

We assessed hippocampal mRNA expression using microarrays after KA-induced SE in immature (P15) and mature (P30) rats at five time points (1, 6, 24, 72, and 240 h). For qRT-PCR, separate sets of rats were sacrificed at 1, 6, and 24 h post seizure. Total RNA was isolated from individual hippocampal tissues. For microarray analysis, equimolar quantities of RNAs were pooled from four animals (eight hippocampi) for each sample to average out individual variability present in the rat brain (i.e., single nucleotide polymorphism 'noise'). Each sample was hybridized onto an Affymetrix rat U34A gene chip. Three independent hybridizations were performed per condition per age per time point – a total of 60 chips ($3 \times 2 \times 2 \times 5 = 60$). In our data, each replicate had a correlation coefficient of greater than 0.95, indicating highly reproducible results. Preparation of cRNA, array hybridization, and scanning were performed by an array consortium (NINDS/NIMH Microarray Consortium). Individual RNA samples were not pooled for qRT-PCR.

Microarray data analysis consisted of many levels of quality control and analysis. At the chip level, the fluorescent image of each chip was scrutinized using programs such as dChip (HSPH) (that allowed direct visualization of the chips) and Probe Profiler (Corimbia, Inc., Berkeley, CA) (that detected and corrected saturation artifacts and outliers). MAS, Affymetrix software, generated the raw expression value of each probe set from the scanned image. This expression value, the signal value of intensity, is a quantitative metric calculated for each probe set, representing the relative level of expression of a transcript, upon which further analysis was based. Probe-level analysis relies on the interpretation of probe sets hybridization performance (pairs of 16 perfect match and mismatch 25-mer oligonucleotides per probe sets) as a measure of whether signal intensities are significantly above background and specific to the gene of interest. The detection algorithm uses probe pair intensities and assigns a 'present', 'marginal', or 'absent' as a flag, after comparison to a predefined threshold. For analysis of each gene, normalization was performed by standardizing experiments between real-time biological variations (controls) and alteration in gene expression following KA treatment. First, the averages of the three control replicates were calculated to form the baseline gene expression, by which the signal intensity of each KA-treated probe set was divided. This normalized value of KA replicates, representing fold change from the control, was used for further analysis (see Table 1). GeneSpring (Silicon Generics) was used for normalization, hierarchical cluster analysis, and graphics generation. For group comparison between control and KA-treated samples, statistical analysis (significance analysis of microarrays (SAMs), Stanford University) was used to select genes that were significantly regulated by KA. SAM generates a q-value (our cutoff 0.05) that reflects a false discovery rate.

Results

Selection Process and List of Genes Selected

Selection of genes significantly regulated by KA-induced seizures was carried out in two steps. First, flag selection was performed as described in Methods. By selecting 'present' in at least two replicates out of three, for every time course and for both control and KA-treated samples, we eliminated genes with low precision, those with expression levels too close to the background. Although this was a rather stringent criterion, we found that it allowed us to include most probe sets with reliable and consistent performance, and minimized background noise. Forty to fifty percent of genes were selected by this process of 'scrubbing'. Second, SAM was used for statistical selection with the median false discovery rate (q-value) of less than 5%. Only known genes with greater than twofold changes were included in our list of selected genes. Figure 1 illustrates the selection process.

Table 2 shows the number of genes selected. At 1, 6, and 24 h after KA-induced seizures, there were over twice

as many genes up-regulated in P30 rats than in P15 rats. And in P15 samples, there was a virtual disappearance of genes significantly increased at 72 and 240 h, whereas a substantial number of genes remained up-regulated in P30 samples. The peak of gene expression for both P15 and P30 rats appears to be at 24 h.

Immediate-Early Genes

Gene induction appears to be the preferred process for acute seizure-regulated changes in neuronal function. There was an early wave of gene induction at 1 and 6 h, followed by a second wave of genes that were either induced or repressed at 24 h.

By far the most predominant class of induced genes, more than 80% in both P15 and P30 rats, was transcription factors or immediate-early genes (IEGs). They were turned on en masse at early hours after SE. They included Ania (activity and neurotransmitter-induced early gene)-2, Ania-3, Ania-6a, Ania-7, Arc (activity-regulated cytoskeletal-associated protein), Btg2 (PC3;Tis21), C/EBP (CCAAT/enhancer binding protein), c-fos, Crem (cAMP responsive element modulator, ICER), Egr1 (early growth response1, NGFI-A, zif268, Krox24), Egr2 (Krox20), Homer1a (vesl-1), v-jun, JunB, Narp (neuronal activity-regulated pentraxin), Nr4a1 (nuclear receptor subfamily 4, groupA, member 1, also known as NGFI-B), Nr4a2 (Nurr1), Nr4a3, Plat (tissue plasminogen activator), and Ptgs2 (Cox2). These genes include activity-regulated transcription factors and IEGs capable of modulating signaling cascade or pathways and protein networks. These genes are intimately associated with cellular and synaptic plasticity and can affect many biological processes. They initiate genomic response underlying long-term modification of neuronal physiology at later time points, thus translating a seizure activity into lasting changes in cellular function. In our data set, there were about twice as many IEGs induced at P30 than at P15, a clear indication that the KA-induced seizures exert more transcriptional changes in adult brain (see Table 3).

Table 2 Up-regulated known genes

	1 h	*6 h*	*24 h*	*72 h*	*240 h*

P15 average fold change	0	0.42	0.45	0	0
P30 average fold change	0.46	0.42	0.41	0	0

Inflammation-Related Genes

The transcription factors and IEGs activated at early hours (1 and 6 h), while being crucial regulators of subsequent activity-dependent gene expression, are not unique to KA-induced seizures. Other stimuli such as kindling or brain injury are also known to induce similar transcription factors. Transcripts that are regulated at 24 h and beyond, however, appear to be more stimulus-specific. Most dramatically regulated at 24 h after KA-induced seizures, in both juvenile and adult rats, were inflammation-related genes. Notable were transcription factors known to be early mediators of immune and inflammation responses, as well as cytokines associated with microglial activation. GFAP and vimentin mRNAs were also significantly up-regulated, indicating astrocyte activation. Genes for tachykine, coagulation factor, cell-surface antigens (MHC class II, mast cell), and cell-surface glycoproteins (CD9, CD44, CD63) were also acutely increased after early-life seizures. After KA administration at P30, these inflammation-related genes were increased to a greater extent than at P15 and were often persistently elevated beyond 72 h (Figure 2). High and sustained levels of inflammatory gene expression after KA administration in adult rats contrasts with transient inflammatory response after KA administration in the juvenile counterpart.

Rapid up-regulation of cytokines and complement components implicates microglial activation after KA-induced seizure (Figure 3). Also, significantly increased were small inducible cytokines (Scya2) and tissue plasminogen

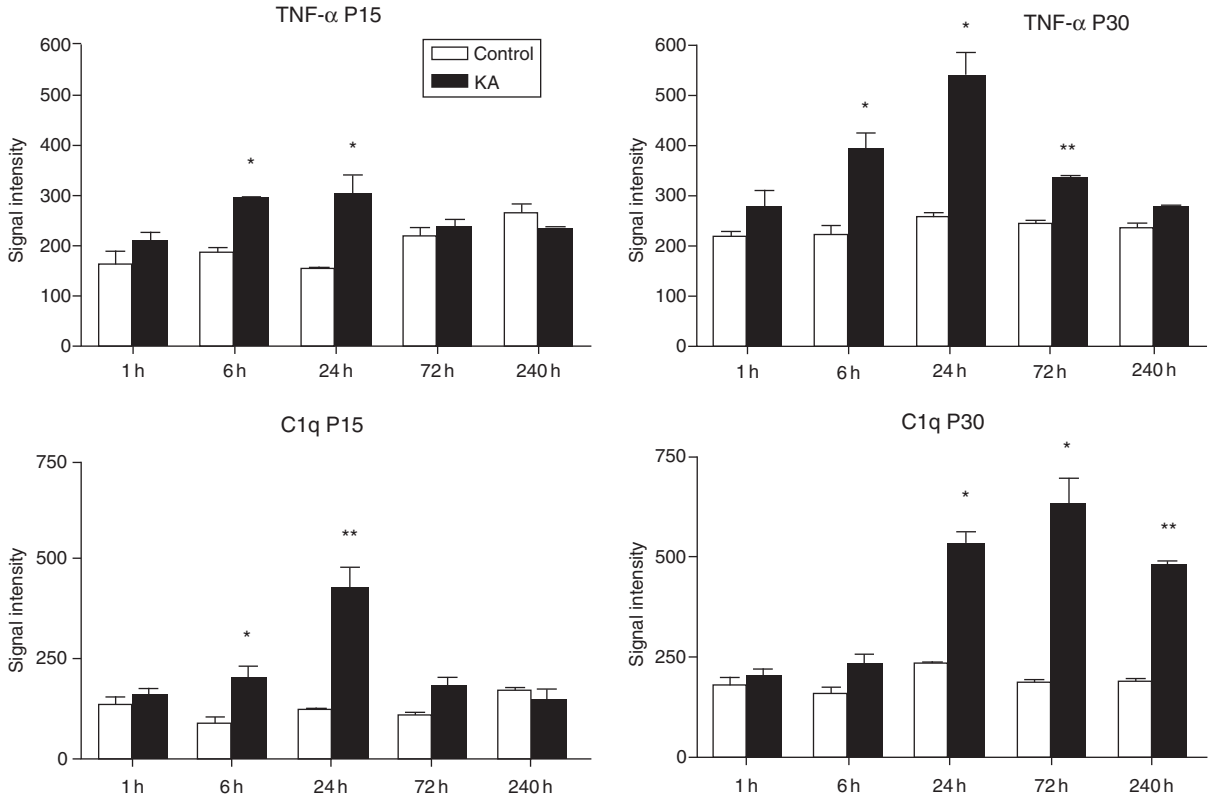

Figure 3 TNF-α and C1q.

activator (tPA or Plat), which showed acute transient increases at 6 and 24 h post KA administration in P15 animals and persistent increases (up to 72–240 h post-KA) in P30 animals. Astrocyte-specific transcripts, such as GFAP, S-100a4, S-100a10, and vimentin, were significantly increased after KA-induced seizures in immature and adult animals. While astrocytic activation was seen as early as 6 h in P15 rats, it was delayed until 24 h in P30 rats – and then remained markedly increased for 10 days, possibly reflecting glial activation following neuron degeneration at later time points in adult rats (**Figure 4**).

Transcripts for proinflammatory cytokines, IL-1β and IL-6, were uniquely increased after KA-induced seizures in adult animals. Delayed increases in MHC class II, C3, immunoglobulin Fc receptor gamma III (FcRgIII), and allograft inflammatory factor 1 (Aif1, marker for activated microglia) mRNA may indicate late transformation of microglia. In an experimental model of autoimmune disease, immune thrombocytopenia (ITP), disease induction requires the presence of low affinity FcRgIII, suggesting a pivotal role of this immunoglobulin receptor in the disease pathogenesis of autoimmunity. Whether FcRgIII

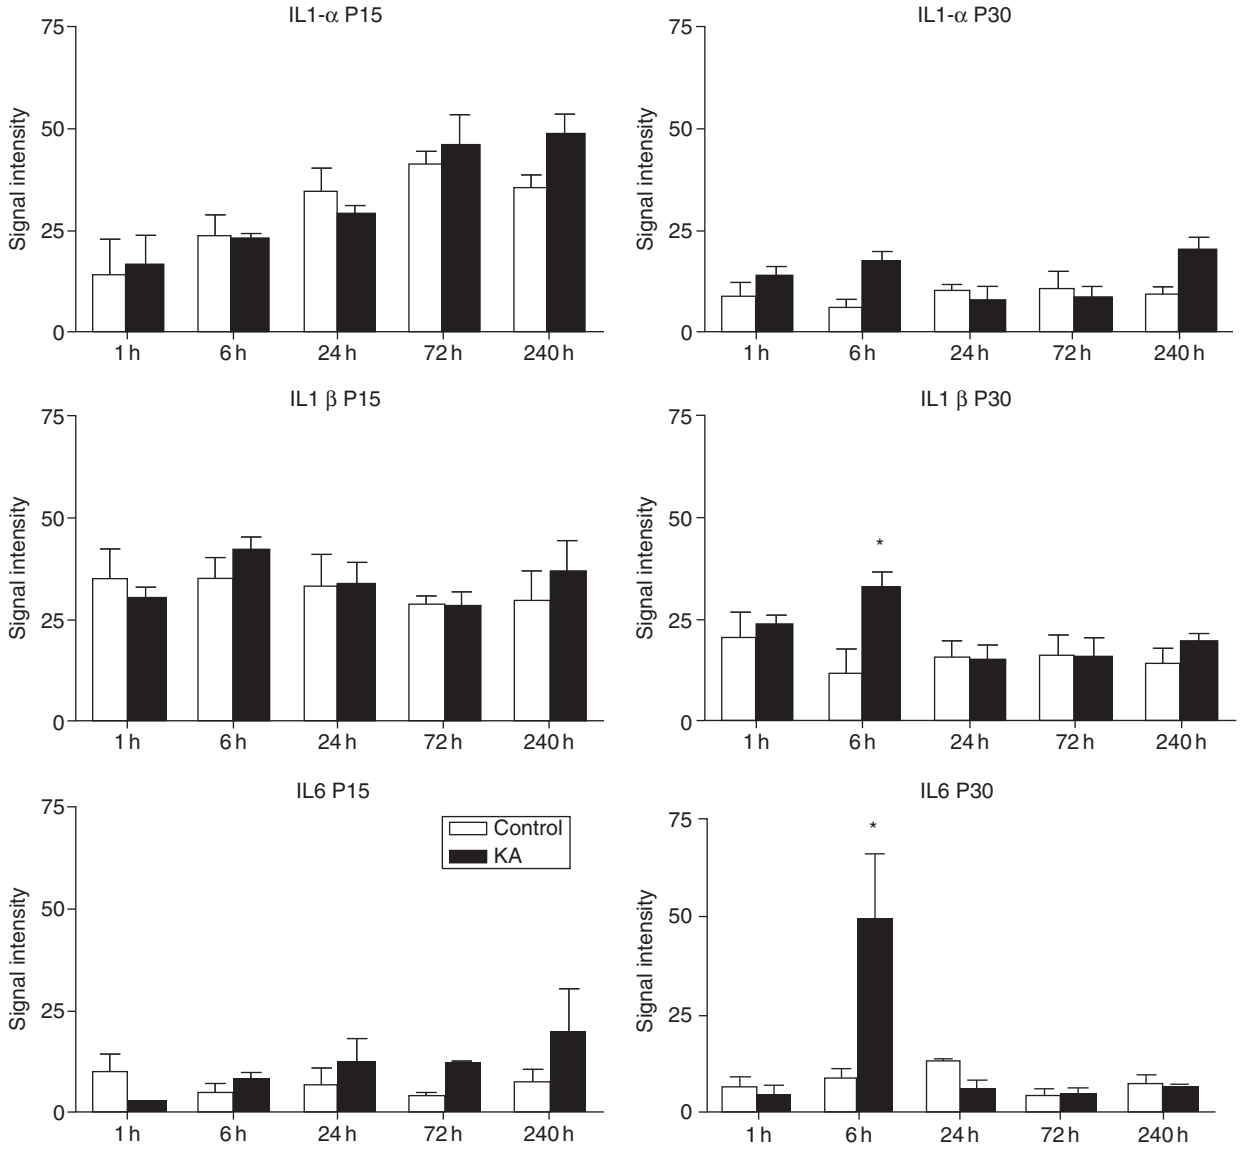

Figure 4 IL-1α, IL-1β, and IL-6.

activation may play a role in immunologic memory, and thus contribute to the long-term effects of early-life KA-induced seizures, remains to be determined.

Validation of Microarray Data

Just as any other technology, the microarray approach has its share of variances associated with various aspects of the process, including experimental design, reagents in hybridization, expression signal normalization, choice of base (house keeping) genes, the algorithm in probe set level analysis and fold change, and statistical methods in gene-level analysis. These variances require validation. There are many ways of validating microarray data, including northern blot, RT-PCR, real-time qPCR, and siRNA; in addition, one can use cross platform validation (i.e., assessing the results with a different microarray platform). Our choice for validation has been qRT-PCR. A relative quantification analytical method was used to analyze the real-time qRT-PCR data, by which the data are normalized to an endogenous reference gene. This normalized value is then used to compare control versus KA-treated samples. Microarray and qRT-PCR data are represented as fold change in KA-treated samples over controls. qRT-PCR results confirmed the expression level trends seen in microarray analysis for all 25 genes that we have examined. Fold changes were often higher in the qRT-PCR reaction than in microarray results, possibly reflecting a greater linear dynamic range afforded by qRT-PCR.

Summary and Future Goals

By using the microarray analysis of time-dependent sequential changes of genes, we found that transcription factors, cytokines, and complement that coordinate inflammatory responses are differentially regulated in juvenile and adult rat hippocampus after KA-induced seizures. Inflammation-related genes comprised the single most abundant functional group that is significantly regulated after KA-induced seizures in the hippocampus of both age groups, and also comprised the majority of genes that remained significantly elevated at 240 h in P30 rats. It is likely that neuronal death provoked further glial activation and a persistent inflammatory response 3–10 days after seizures. As a result, chronic, persistent, and active inflammation appears to occur in adult rats, as evidenced by the presence of mRNA coding for inflammatory cytokines and microglia-associated proteins. Because spontaneous recurrent seizures occur only in adult rats (not in juvenile rats) after KA-induced seizures, it is tempting to speculate that chronic active brain inflammation plays a critical role in future epileptogenesis. Although our results suggest a potential pivotal role of inflammation in spontaneous recurrent seizures and seizure-induced brain damage, they do not prove the causal role of these molecules for subsequent neuronal excitability and degeneration. We need to show the functional consequences of increased inflammatory cells and molecules in seizure-induced brain damage and in the epileptogenic process. That is, we need to demonstrate whether an acute seizure-induced inflammatory response leads to future seizure susceptibility and neuronal damage.

Microarray-based gene expression profiling provides a powerful tool to detect sequence of alterations that occur with time after seizures. Successful application of this method, however, requires the ability to sift through, manipulate, and analyze large volumes of data sets – and then to link them to the biological phenomena. Interpretation of microarray data can thus be a difficult and challenging task. In addition, the sensitivity of microarray technology for detecting genes of interest may be low. Many genes known to be expressed in the brain and important in epilepsy, such as channel genes, may not be reliably detected by this microarray approach. As tissue complexity (number of cell types) increases and transcript abundance (copies per cell) decreases, transcript may be diluted to levels below detection. Biological sensitivity of microarrays can be improved by further microdissection of cell type, such as dentate granule cells within the hippocampus.

As inflammatory responses involve a complex set of interactions, as well as integration among many soluble factors and cells, one must proceed with caution when considering antiinflammatory therapy. Chronic suppression of the inflammatory response may be just as harmful as unchecked chronic inflammation itself. Further, some inflammatory response can both heal and harm the CNS. When appropriately activated and deactivated, inflammation benefits the host defense response by removing damaged cells and promoting repair and recovery. However, uncontrolled or chronic glial responses can actually exacerbate the pathology, inducing further glial activation. When the balance between the beneficial and detrimental effects of activated glia is disrupted, the scales may tip toward neuropathological outcomes. Whether inflammation can be life-preserving or death-promoting appears to depend on the context, timing, and magnitude of the inflammatory reaction. For this reason, there is a concern that antiinflammatory strategies to reduce neuronal damage may interfere with neuronal regeneration and recovery, and thus render the intervention ineffective or even exacerbate the insult. It remains to be determined whether delayed intervention, which allows an early inflammatory response to occur, will maximize the benefit of modulating neuro-inflammation in preventing the seizure-induced epileptogenesis and neuronal injury. It is thus important to perform careful dose–response and time–course experiments to determine the efficacy of anti-inflammatory drugs and to optimize treatment protocol. Intervention in and modulation of the inflammatory response to acute seizures not only offer the potential to develop new neuroprotection strategies, but also allow investigators to examine the inflammatory processes involved in both injury and repair after a seizure.

Introduction

The predominant and often sole abnormality found in surgically resected mesial temporal structures in patients with intractable temporal lobe epilepsy (TLE) is hippocampal sclerosis: severe hippocampal neuron loss and gliosis. Despite early recognition of this characteristic pathology more than 170 years ago, it remains unclear whether hippocampal sclerosis is the cause or consequence of repeated seizures. Perhaps the strongest argument for a causative role of mesial temporal sclerosis (MTS) in epilepsy is the remission of complex partial seizures after resection of sclerotic hippocampus. MTS, however, can result from a variety of insults, including hypoxia–ischemia, Pick's disease, Alzeimer's disease, general paresis, and pellagra – and most of these patients, in whom 'classic Ammon's horn sclerosis' was seen in postmortem material, never experienced seizures (Gloor, 1991).

The age at which an initial insult occurs may be a critical factor in epileptogenesis and hippocampal damage. Falconer was the first (1964) to suggest an etiological connection between genetics, prolonged febrile seizures (the most prevalent form of seizures during first 3 years of life), and subsequent development of MTS. Meencke, in his 1991 neuropathologic survey of age-specific epilepsy syndrome in 52 patients who died of other causes in adulthood, found hippocampal sclerosis in 46% of patients with infantile spasms (average age at onset, 3.5 months) and in 23% of patients with Lennox-Gastaut syndrome (average age at onset, 3.1 years) – but none in patients with childhood absence (average age at onset, 7.5 years) or in patients with juvenile myoclonic epilepsy (average age at onset, 15.5 years). Both clinical and laboratory studies, however, suggest that the immature brain is relatively resistant to seizure-induced brain damage. While early-life seizures may not be sufficient to cause epilepsy and hippocampal damage, molecular and cellular events that accompany early-life seizures may predispose the brain to future seizure-induced damage.

Background

Febrile Seizures and Risk of Later Epilepsy

Of 1706 children with a history of febrile seizures in the cohort of the US National Collaborative perinatal project, the risk of later epilepsy in a 7-year follow-up was 1–10%. In an extended 18-year follow-up study of 678 children with febrile convulsions, the risk of later epilepsy varied from 2.5% to 22%, and rose to 49% if a child had complex febrile seizures, an abnormal neurologic state, and family history of epilepsy. If the first febrile seizure occurred before the child was one-year old, later afebrile seizures and epilepsy were more likely. Preoperative neuropsychiatric evaluation also revealed that the early onset of seizures is correlated with significantly poorer cognitive function in patients undergoing temporal lobectomy for intractable epilepsy. Hippocampal sclerosis is found in only 1–5% of patients with adult-onset TLE compared with 50–80% of those with antecedent seizures, most often febrile, in infancy or early childhood. These studies show that children with febrile seizures are at increased risk for later epilepsy.

It is difficult, however, to distinguish between 'epilepsy triggered by fever' and the febrile seizure itself increasing the risk for later afebrile seizures. Moreover, a common genetic disposition may exist for both febrile seizure and epilepsy. In complex multifactorial disorders such as epilepsy, it is conceivable that both genetic susceptibility and injury (insult, life-event, or exposure) are necessary for

Introduction

The predominant and often sole abnormality found in surgically resected mesial temporal structures in patients with intractable temporal lobe epilepsy (TLE) is hippocampal sclerosis: severe hippocampal neuron loss and gliosis. Despite early recognition of this characteristic pathology more than 170 years ago, it remains unclear whether hippocampal sclerosis is the cause or consequence of repeated seizures. Perhaps the strongest argument for a causative role of mesial temporal sclerosis (MTS) in epilepsy is the remission of complex partial seizures after resection of sclerotic hippocampus. MTS, however, can result from a variety of insults, including hypoxia–ischemia, Pick's disease, Alzeimer's disease, general paresis, and pellagra – and most of these patients, in whom 'classic Ammon's horn sclerosis' was seen in postmortem material, never experienced seizures (Gloor, 1991).

The age at which an initial insult occurs may be a critical factor in epileptogenesis and hippocampal damage. Falconer was the first (1964) to suggest an etiological connection between genetics, prolonged febrile seizures (the most prevalent form of seizures during first 3 years of life), and subsequent development of MTS. Meencke, in his 1991 neuropathologic survey of age-specific epilepsy syndrome in 52 patients who died of other causes in adulthood, found hippocampal sclerosis in 46% of patients with infantile spasms (average age at onset, 3.5 months) and in 23% of patients with Lennox-Gastaut syndrome (average age at onset, 3.1 years) – but none in patients with childhood absence (average age at onset, 7.5 years) or in patients with juvenile myoclonic epilepsy (average age at onset, 15.5 years). Both clinical and laboratory studies, however, suggest that the immature brain is relatively resistant to seizure-induced brain damage. While early-life seizures may not be sufficient to cause epilepsy and hippocampal damage, molecular and cellular events that accompany early-life seizures may predispose the brain to future seizure-induced damage.

Background

Febrile Seizures and Risk of Later Epilepsy

Of 1706 children with a history of febrile seizures in the cohort of the US National Collaborative perinatal project, the risk of later epilepsy in a 7-year follow-up was 1–10%. In an extended 18-year follow-up study of 678 children with febrile convulsions, the risk of later epilepsy varied from 2.5% to 22%, and rose to 49% if a child had complex febrile seizures, an abnormal neurologic state, and family history of epilepsy. If the first febrile seizure occurred before the child was one-year old, later afebrile seizures and epilepsy were more likely. Preoperative neuropsychiatric evaluation also revealed that the early onset of seizures is correlated with significantly poorer cognitive function in patients undergoing temporal lobectomy for intractable epilepsy. Hippocampal sclerosis is found in only 1–5% of patients with adult-onset TLE compared with 50–80% of those with antecedent seizures, most often febrile, in infancy or early childhood. These studies show that children with febrile seizures are at increased risk for later epilepsy.

It is difficult, however, to distinguish between 'epilepsy triggered by fever' and the febrile seizure itself increasing the risk for later afebrile seizures. Moreover, a common genetic disposition may exist for both febrile seizure and epilepsy. In complex multifactorial disorders such as epilepsy, it is conceivable that both genetic susceptibility and injury (insult, life-event, or exposure) are necessary for

disease manifestation. For example, abnormal hippocampal shape and position can be found in healthy controls; however, a significantly greater proportion of such hippocampal abnormality is found in patients with partial epilepsy arising either from a cortical malformation or of a temporal lobe origin. The multiple hit hypothesis for disease expression predicts that the combination of diathesis, early-life brain insults, and later-life stress together can cause an individual to succumb to chronic epilepsy.

Epileptogenic Effects of Early-Life Seizures

Seizures that occur during a critical developmental period of enhanced neuronal excitability can increase long-term seizure susceptibility. Such a susceptibility caused by early-life seizures has been observed in different animal models. Hypoxia-, hyperthermia-, kainic acid- or flurothyl-induced seizures in the immature brain during the first 2 weeks of life cause permanent functional alterations and enhance long-term excitability within the hippocampal neuronal network. Further, intrauterine toxin-induced neuronal migration defects (simulating congenital brain malformations) can act as the first hit and predispose the brain to the damaging effect of seizures later in life.

Cellular and molecular mechanisms behind this heightened susceptibility to injury after early-life seizure remains unknown. Further, we do not understand the cellular and molecular mechanisms responsible for the subsequent occurrence of spontaneous seizures as a consequence of status epilepticus in adult animals. An influential current hypothesis posits that hippocampal neuronal loss and mossy fiber sprouting play a critical role in the pathogenesis of chronic epilepsy. Recent studies scrutinizing the relationship between chronic epileptogenesis and hippocampal histopathology, however, have challenged this hypothesis and shown that neither cell death nor mossy fiber sprouting is necessary or sufficient for the generation of spontaneous seizures after status epilepticus. While neuronal injury and mossy fiber sprouting may be common sequelae of status epilepticus, and accompany the epileptogenic process, they themselves do not appear to cause chronic epilepsy.

Role of Inflammation in Epileptogenesis and Seizure-Induced Neurodegeneration

The contribution of inflammation in mediating many aspects of the disease has been relatively well established for both acute CNS injury (such as cerebral ischemia and traumatic brain injury) and chronic CNS conditions (such as multiple sclerosis, HIV encephalopathy, and cerebral malaria). The active involvement of inflammation in the pathogenesis of epilepsy and seizure-induced brain damage has only recently been explored. Available evidence suggests that proinflammatory and antiinflammatory molecules are synthesized in glia during seizures, in the CNS regions where seizures initiate and spread. Such inflammatory molecules produced in the CNS may have a role in the pathogenesis of epilepsy. Recent studies also indicate (as has been observed in cerebral ischemia or traumatic brain injury) that cytokines may contribute to exacerbation of brain damage after seizures. Activation of resident microglia and subsequent increases in mRNA for cytokines and complements appear to be the key initiating events for seizure-induced inflammatory responses. We hypothesize that the inflammatory reaction provoked by early-life seizures primes the developing brain so that microglia are modified, leading to rapid reactivation by a second seizure in adulthood.

Methods

In our laboratory, we developed a 'two-hit' rodent seizure model in which systemic kainate (KA) or hypoxia was used to induce seizures in early life (postnatal day (P), P10–P21), and a second KA injection was given again in adulthood (P35–P45). The effect of early-life seizures on later seizure susceptibility was measured by examining seizure onset latency and grade of seizure severity in the adult animals. Seizure-induced neuronal injury was also examined using in situ detection of DNA fragmentation. This assay offers cellular resolution and yields dense nuclear staining of fragmented DNA, a robust and quantifiable marker of cell death. To determine whether seizure-induced inflammation plays a direct role in increasing seizure susceptibility after the experience of early-life seizures, we treated rats with minocycline, an inhibitor of microglia activation, for 7 days after the initial seizure. Microglia were subsequently visualized by Aif-1 immunocytochemistry.

Systemic administration of KA, which stimulates a subset of excitatory glutamate receptors, induces prolonged seizures in rodents. KA seizures originate in the hippocampus and cause characteristic patterns of neuronal death that resemble human hippocampal sclerosis. Hippocampal lesions are not due to direct toxicity of KA, but rather due to epileptic activity induced by the intraperitoneal injection of KA, as blocking the epileptic events with diazepam abolishes the neuronal loss. Seizure-induced cellular damage appears to be mediated by excessive excitatory amino acid release, which activates NMDA receptors and voltage-gated Ca^{2+} channels, both of which allow Ca^{2+} influx. The calcium influx then results in a cascade of biochemical changes that subsequently leads to cell death. Seizures induced by KA also cause axonal reorganization referred to as 'mossy fiber sprouting.' Most important, KA-induced status epilepticus is followed by a latent period between injury and the onset of spontaneous seizures, and finally a chronic

epileptic state. In immature rats younger than P18, however, KA injection (or hypoxia-induced seizures) causes neither cell death nor mossy fiber sprouting, although it induces status epilepticus at a dose one third the adult dose per weight. Furthermore, spontaneous recurrent seizures do not develop after status epilepticus until animals reach P20.

Results

Seizures in immature animals may cause subtle functional or molecular changes without causing cell death, and thus alter the response to seizures later in life. In our two-hit rodent seizure model, despite the lack of cell death, animals subjected to seizures during the second week of life become more susceptible to seizures in later life and sustain more extensive hippocampal neuronal injury after the second KA-induced seizure in adulthood (**Figure 1**). Furthermore, we have shown that the priming effect of early-life seizures could be reversed if acute seizures were blocked by an alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/KA-type glutamate receptors antagonist (**Figure 2**).

Recently, we began to examine the role of brain inflammation in mediating the epileptogenic effect of early-life seizures. Our focus was on microglia, resident immune cells in the CNS and the primary source and target of

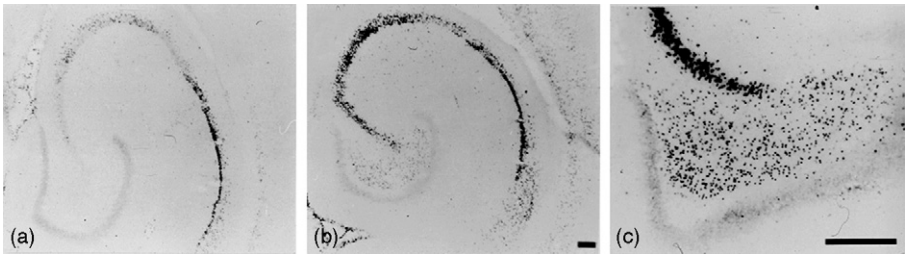

Figure 1 DNA fragmentation in the hippocampus 10 days after KA seizures on P45. (a) Animal treated with saline on P15 and KA on P45. (b) Animal treated with KA at P15 and P45 (KK). many cytokines and chemokines. Within 24 h after KA-induced seizures, we observed retraction of processes and cellular hypertrophy of microglia, suggestive of an activated state. Further, the group that experienced early-life seizures (K/K) had a marked increase in the number of activated microglia compared with a group of control littermates who received single exposure to KA in adulthood (saline/kainate, S/K). These microglia were much larger and formed a complex, web-like network localized within the hippocampus especially over the CA1 region (**Figure 3**). The early experience of KA-induced seizures primed the developing brain such that there was a lowered seizure threshold to the second 'hit' (the KA injection in adulthood), as well as rapid microglial activation associated with that second KA-induced seizure (**Figure 4**). Increased susceptibility to later-life seizures is associated with rapid hyperplastic reactivation of microglia after the second KA. To show a causal link between initial microglial activation and seizure susceptibility, we treated the animals with an inhibitor of microglia activation, minocycline, after the initial (early-life) seizure, and determined whether minocycline reversed this priming effect of early-life seizures. Both increased seizure susceptibility and microglial hyperactivation caused by early-life seizures were abolished by minocycline treatment. Our data thus suggest that microglial activation and brain inflammation occur following KA-induced seizures, and that modulation of the inflammatory responses to seizures could be a target for specific types of pharmacological intervention to block the epileptogenic effect of early-life seizures.

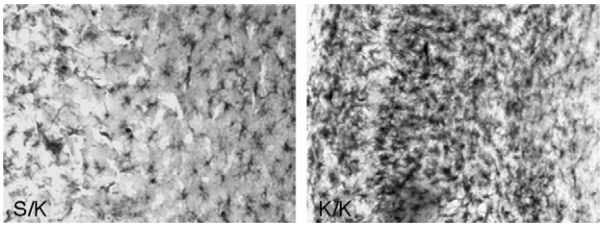

Figure 3 Reactivating effect of an early-life seizure on microglia. The rats were injected either with saline (S/K) or KA (K/K) at P21 and challenged with KA at P35. Microglia activation is increased in K/K.

Work in Progress and Future Goals

We found that the experience of early-life seizures primes the microglia so that a much more robust activation is elicited in response to later-life seizures. Microglial reactivation may be causally related to the epileptogenic effect of early-life seizures. Neuroinflammation provoked by seizures appears to be mediated via activation of resident CNS immune cells, microglia. Sequential propagation and widespread microglia activation have been described in rodent models of acute seizures. As rapid responders, imbalanced or chronic activation of microglia to full-blown phagocytic and potentially cytotoxic cells may *cause* neurodegeneration rather than microglia being activated as a *consequence* of neurodegeneration. In our model, we hypothesize that the experience of early-seizure facilitates this

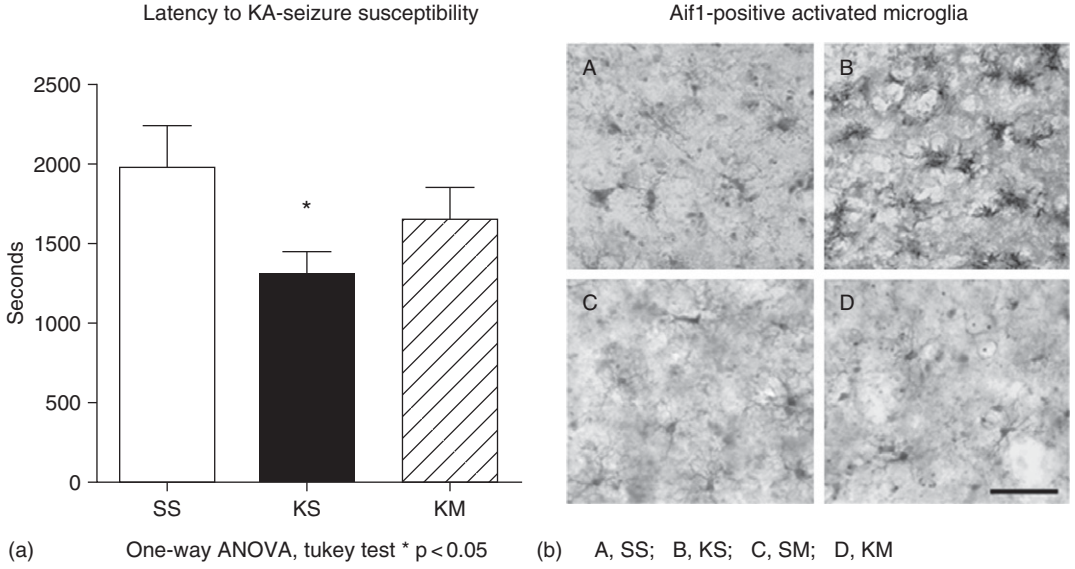

Figure 4 (a) Seizure susceptibility to KA on P35 was increased after KA on P21 (KS), compared with saline treated littermate (SS). This epileptogenic effect of early-life seizure was reversed by treating the animals with daily injection of minocycline for one week (10 mg kg^{-1}, i.p.) (KM). (A) SS: Saline at P21, KA at P35, (B) KS: KA at P21and P35, (C) SM: Saline at P21, minocycline × 7 days, KA at P35; (D) KM: KA at P21, minocycline × 7 days, KA at P35. Scale bar = 100 μm.

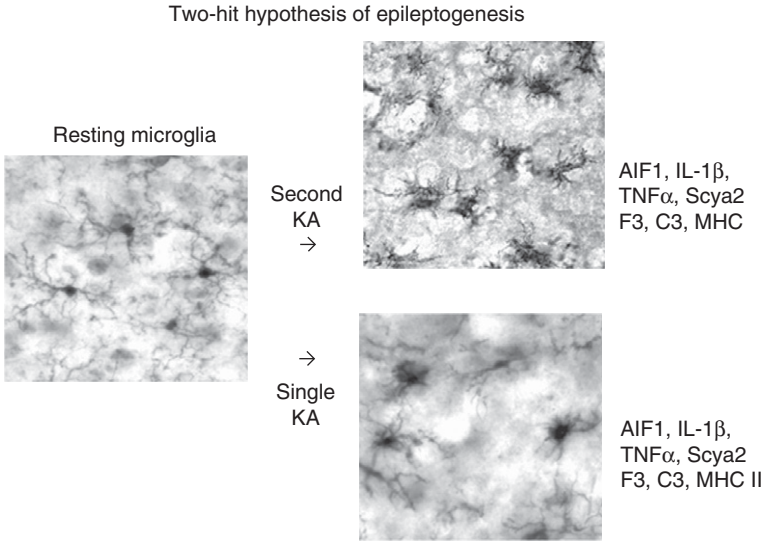

Figure 5 The 'two-hit' model of epileptogenesis.

reactive microgliosis, leading to excessive activation of microglia (Figure 5) and to subsequent increases in susceptibility to seizures. This proposed central role of microglia in seizure-induced neuronal excitability and degeneration suggests that an inhibition of microglia activation may be a potential target for therapeutic intervention. Although anti-inflammatory therapy may be antiepileptogenic, potential risks associated with immune modulation need to be weighed against its benefit.

The role of activated glia as a sensor and a cause of brain injury, as well as a mediator of neuronal excitability and epileptogenesis, will need to be directly assessed both in vitro and in vivo. Pure microglia cultures can be established with relative ease from early postnatal rodent brain. We can take advantage of a transgenic mice, $Cx3cr1^{GFP/+}$, in which all microglia are fluorescently labeled, and establish a neuron–microglia cocultures to demonstrate the contribution of activated microglia in neuronal excitability. Neuronal excitability can be measured by calcium influx (Fura-2-AM, a membrane-permeable calcium-sensitive dye) evoked by an acute application of potassium in the culture bath. Whether activated microglia mediate neuronal hyperexcitability can be tested in vivo with the use of cultured pure microglia. Induction of spontaneous seizures or a lowering of seizure threshold by stereotactic injection of hyperactive microglia into the hippocampus may provide direct evidence that activated microgila can cause seizures.

Patterns of Gene Expression in Epileptogenesis: Micro-Array Studies in Rats

J A Gorter, F H Lopes da Silva, and E Aronica, University of Amsterdam, Amsterdam, The Netherlands

Introduction

To study changes in gene expression of multiple genes, the DNA microarray approach is now the most frequently used technique. A DNA microarray, or gene *chip*, is a collection of microscopic DNA spots – each of which represents a single gene – arrayed on a solid surface. Measurements with DNA microarrays use nucleic acid hybridization under high-stringency conditions. DNA arrays are commonly used for monitoring expression levels of thousands of genes simultaneously. Many epilepsy-related gene-expression studies compare gene expression between normal and epileptic hippocampal tissue. Although this tissue consists of an mRNA mixture of different cell types, expression profiles from selected brain regions can be used to describe changes in local networks. In this article, we focus on the large-scale microarray studies on (para)hippocampal (sub) regions in a rat model for temporal lobe epilepsy. In this model, epilepsy develops a few weeks after electrically induced status epilepticus (SE). To obtain insight into how epilepsy develops after an initial insult, we characterized the temporal profile of changes in gene expression during three crucial stages of epileptogenesis: the acute, latent, and chronic epileptic phases.

Background

Before the existence of microarrays, studies on gene expression related to temporal lobe epilepsy – in animal models – were mainly focused on individual genes that were induced by acute seizures or repeated electrical stimulations that led to an epileptic condition (e.g., kindling). In the late 1980s, many studies appeared (e.g., using in situ hybridization) that described seizure-related changes in gene expression in the rat brain. For instance, shortly after seizure occurrence, a marked upregulation was found in the expression of immediate early genes (IEGs; transcription factors). These IEGs stimulate the expression of genes such as growth factors, and also activate genes associated with apoptosis and stress. For a comprehensive review of the studies that report changes after kainate-induced SE, see Zagulska-Szymczak et al. in Further Reading.

The microarray technique has provided significant insights into the expression of a large number of genes in specific brain regions following a seizure. Tang and colleagues were the first to show the acute coordinate gene-expression changes in the parietal cortex 1 day after kainate-induced SE. They showed that most genes induced by kainate-induced seizures, were also induced by ischemia, intracerebral hemorrhage and hypoglycemia – a finding that suggests that excitotoxicity-mediated injury is common to all of these acute conditions. The rapidly activated genes included genes encoding for heat shock proteins, DNA damage repair proteins, proteases and protease inhibitors, metal ion and free-radical scavengers, and calcium-binding proteins. The induction of Hmox1, ceruloplasmin, GFAP, vimentin, matrix glia protein, and S-100 genes pointed to a generalized response of glial cells in all of these injury conditions.

More recently, special attention has been paid to changes in gene expression at increasingly longer time points after an initial insult, in order to better understand the evolution in time of the process of epileptogenesis. Attention to temporal changes in gene expression is essential in order to understand the dynamics of how the brain becomes epileptic, and can provide insight into the therapeutic potential of a specific target. Using long-term video and EEG observations, investigators have shown that most animals develop epilepsy within a few weeks after an initial SE evoked by injections of kainate or pilocarpine or via electrical stimulations of a specific brain region (often hippocampus or amygdala). In these so-called post-SE models, frequently used to study the development of temporal lobe epilepsy after an initial insult, we can roughly separate three crucial stages of epileptogenesis: (1) the *acute phase*, in which the animals exhibit seizures in the immediate aftermath of the status; (2) the *latent period*, which is characterized by the absence of spontaneous seizures and that ends with the first spontaneous seizure; and (3) the *chronic phase*, in which the animals exhibit spontaneous seizures. A few studies have described gene expression at these different phases of epileptogenesis. One group used the Research Genetics Rat array on whole hippocampal tissue obtained from the amygdala stimulation model of TLE. They studied the gene-expression profile at 1, 4, and 14 days after induction of SE, and showed that several of the differentially expressed genes were associated with neuronal plasticity, gliosis, cellular metabolism, and inflammation. Another group studied differential gene-expression patterns in dentate gyrus (DG) and CA1 hippocampal areas after

pilocarpine-induced SE, using the Affymetrics 34A array. In that study, at 3 days after SE, the majority of upregulated genes were related to mechanisms of cellular stress and injury; a greater degree of gene upregulation was seen in CA1 than in DG. At 14 days after SE, numerous transcription factors and genes involved in cytoskeletal and synaptic reorganization were differentially transcribed. During the chronic stage (>20 days post-SE), expression changes were observed in genes associated with different neurotransmission pathways. Although a direct comparison between these studies is not possible, there was general consensus that inflammation-related genes were also activated after the acute phase following SE.

Methods

Using the Affymetrics Rat RAE 230A, we studied gene expression at three specific stages after electrically induced SE, looking specifically in hippocampal CA3, entorhinal cortex (EC), and cerebellum (CB). Total RNA was obtained from the selected brain regions, quantified, amplified, and labeled according to the Affymetrix Small Sample labelling protocol. Samples were hybridized to the GeneChip. After 16 h of hybridization, the GeneChips were washed and stained on a fluidics station and scanned in a confocal scanner. The expression levels and present/absent calls were calculated for all 15 866 probe sets, with the affy package from Bioconductor in the R program for statistical computing, using the MAS5 algorithm. Comparisons were made between control and experimental samples taken at the same time points; the analysis required at least $p < 0.05$ for a significant difference. Because array analysis deals with large numbers of multiple comparisons, it is necessary to take into consideration the false discovery rate for multiple comparisons. The dataset consisting of the significantly altered genes was entered into GenMAPP (Gene Map Annotator and Pathway Profiler), a computer program that is designed for viewing and analyzing genome-scale data.

Results – Patterns of Gene Expression in the Electrical Post-SE Model

In the post-SE model, CA3 and EC are assumed to belong to the epileptogenic region while CB does not. The time points of our study included 1 day after SE (acute phase), 1 week after SE (latent period), and 3–5 months after SE (when rats exhibit frequent daily seizures). The RAE230A GeneChip contains many more probes (~16.000) than the previous arrays (e.g., the arrays used in the studies mentioned above use <8.000 probes). With that chip, we could demonstrate coordinate changes of groups of genes that belong to specific biological processes or pathways. Using specific web-accessible software for large-scale data analysis, we obtained an overview of the expression of genes that belong to a specific Gene Ontology (GO) term (biological process, molecular function, or structural component) at a specific time point. In this way, dynamic changes at each crucial stage of epileptogenesis could be described in this electrical post-SE model. **Figure 1(a)** shows a global overview of the distribution of up- and downregulated genes in CA3 at the three different phases. The number of genes that were differentially expressed is very high at the acute stage, and progressively decreases over time. Moreover, within a specific process (or function or component), there are genes that are activated but also genes that are downregulated, perhaps reflecting a homeostatic biological response to the molecular SE. The relative expression changes for each process, function, and cellular component (**Figure 1(b)**, pie charts) remain surprisingly stable over time. A similar distribution can be constructed for expression in EC.

To find significant trends during epileptogenesis, the percentage of genes that changed at a specific time point can be calculated for each GO term, and a statistical evaluation can be made. For instance, we ranked the GO terms by a *Z*-score, using the MappFinder program. This analysis reveals that the immune and inflammatory responses, among others, play a prominent role not only during the early phase and latent period but also during the chronic phase.

The Acute Phase (1 Day after SE)

As mentioned earlier, the general consensus is that the inflammatory response plays a prominent role (at least in those brain regions examined to date – mainly the hippocampal and parahippocampal subregions) shortly after SE. In the CA3 and EC regions of the post-SE model, we confirmed maximum activation of processes, such as transcription and translation, cell differentiation, progression through cell cycle, neuropeptide signaling, and immune responses, at this time point. Many genes related to cell adhesion, synaptic transmission, and ion transport have the strongest suppression at this acute phase, in both CA3 and EC. Such changes are not observed in the cerebellum. On the basis of the injury that is caused by SE, it is not unexpected that many acute changes include activation of inflammatory- and proteolysis-related genes. These changes are associated with increased gene expression of GFAP and vimentin, both genes that code for intermediate filament proteins present in astrocytes – which are, together with microglial cells, the main cellular entities in the brain responsible for release of inflammatory and proteolytic proteins. Vimentin expression is almost 10-fold increased at 1 day after SE and remains

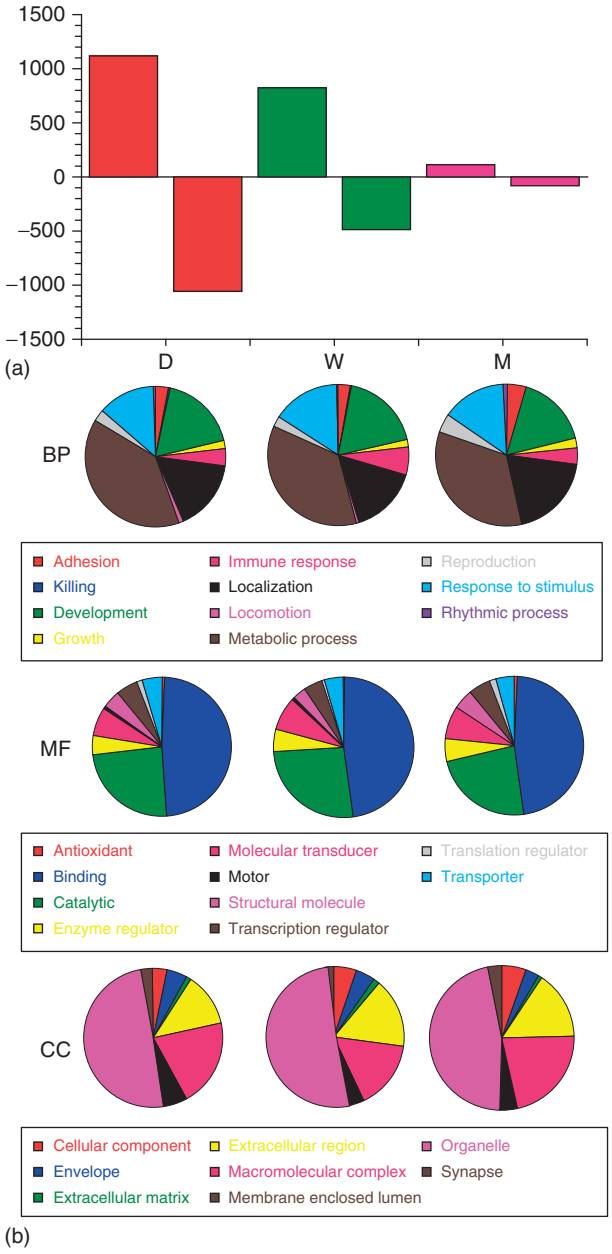

Figure 1 Global overview of the distribution of up- and downregulated GO terms in CA3 at the three different phases at 1 day (D), 1 week (W), and 3–5 months after SE (M: in the chronic phase). (a) Shows that the number of genes that were differentially expressed is high at the acute stage and progressively decreases over time. (b) The relative expression changes in each biological process (BP), molecular function (MF), and cellular component (CC) remain rather stable over time.

significantly increased during all three phases of epileptogenesis. Many genes that are upregulated during the acute phase show a slower time course, with maximum activation at a later time point (e.g., at 1 week; explained later). It should be noted, too, that increased expression of more rapidly activated genes with transient expression might have been missed in our study. Expression of many (but not all) proteases peaked at 1 day; these proteases include cathepsins (*Cts*), caspases (*Casp*), calpains (*Calp*), matrix metalloproteases (e.g., *Mmp9*), tissue-plasminogen activator (*Plat*; which can activate *Mmp9* transcription) and urokinase-plasminogen activator (Plau). *Stat3*, *CD14*, and *Spp1* (Osteopontin – which binds to *CD44* and is responsible for macrophage migration) also peaked at 1 day after SE. Noteworthy, several protease inhibitors were also upregulated, such as cystatins (*Cstb*, *Cstc*), tissue inhibitors of metalloproteases (*Timp1* and *Timp3*), and serine inhibitors (Serpins). The chemokine *CCl2*, which is also involved in macrophage migration, was the most markedly activated gene, while *IL1b* and *IL6* were among the most activated interleukin genes at this acute time point. The process of synaptic transmission is most significantly downregulated in the acute phase. This downregulation could reflect a homeostatic protective response, rather than an epileptogenic response. For example, the downregulation of glutamate receptor activity can help to limit further excitotoxic damage. Downregulation of the expression of these genes does not simply reflect neuronal loss, but consists of a transient repression of gene expression, since ion channel and receptor gene expression largely recover in later phases. The seizure-related increase of several neuropeptides can also be seen as a compensatory response, since several neuropeptides have antiepileptic properties.

The Latent Phase (1 Week after SE)

During the latent phase, which in this electrical post-SE model is relatively short (an average of <8 days), many cytokines, proteases, and their inhibitors were still significantly upregulated – and several of these genes showed maximum expression at this time point (e.g., *Tgfbr2*, *Casp1*, *Casp11*, *Ctsd*, *Ctsl*, *Mmp2*, *Aif1*, *CstC*). The immune response was the most significantly activated process at this time, both in CA3 and EC, which was not surprising considering the maximum microglial activation that can be detected. *IL1a*, *IL18*, *Casp1* expression, already significantly activated at 1 day after SE, peaked during the latent phase. Again, the cerebellum did not exhibit activation of these genes. Increased macrophage activity peaks at this time point as illustrated with Mpeg1 expression. Interestingly many genes belonging to the classical and alternative complement cascade displayed maximum expression at 1 week after SE. Overactivation of this system, which is a key component of the *innate immune* system, can mediate further inflammation and tissue damage. However, most of the significantly repressed genes at this time point are related to neurotransmitter receptor and ion channels, including multiple GABA-receptor subunits.

The Chronic Phase (3–5 Months after SE)

During the chronic phase, when post-SE rats exhibit daily seizures, many genes are still differentially regulated. Although in the acute and latent phases, hierarchical clustering analysis nicely grouped the gene profiles of CA3 and EC together, they were separated in the chronic phase. This 'dissociation' suggests that in the initial phases, the dominant changes are common to CA3 and EC, but in chronic phase, the two areas display distinct area-specific changes. Heat shock protein binding was the only GO term that was significantly upregulated in both CA3 and EC. Upregulation of aquaporin 4 (*Aqp4*), which is associated with a breakdown of the blood brain barrier (BBB), was increasingly evident during epileptogenesis. A few proteolytic and inflammation-related genes were also still activated during this phase (**Figure 2(a)**). Moreover, various 'activity-dependent' genes showed an increased expression after a transient 'silencing' during the latent period. These genes include *Sgk*, *Homer1*, *CryaB*, *Tnfaip6*, *Dnajb9* (*Hsp40*), *Akap8*, *Arf4*, *Slc2a1*, *Ddah1* (involved in nitric oxide biosynthesis), several neuropeptides (e.g., *Sst*, *Npy*, *Trh*, *Crh*, *Penk*, *Gal*), *pafah1b1*, growth factors, including *Bdnf*, *Cntf*, *Vgf*, *Ptgs2* (or *Cox-2*), *Agpt2*, *Egr1*, *Tieg*, and several genes involved in protein transport and folding (**Table 1**). Although some of the 'activity-dependent' genes are

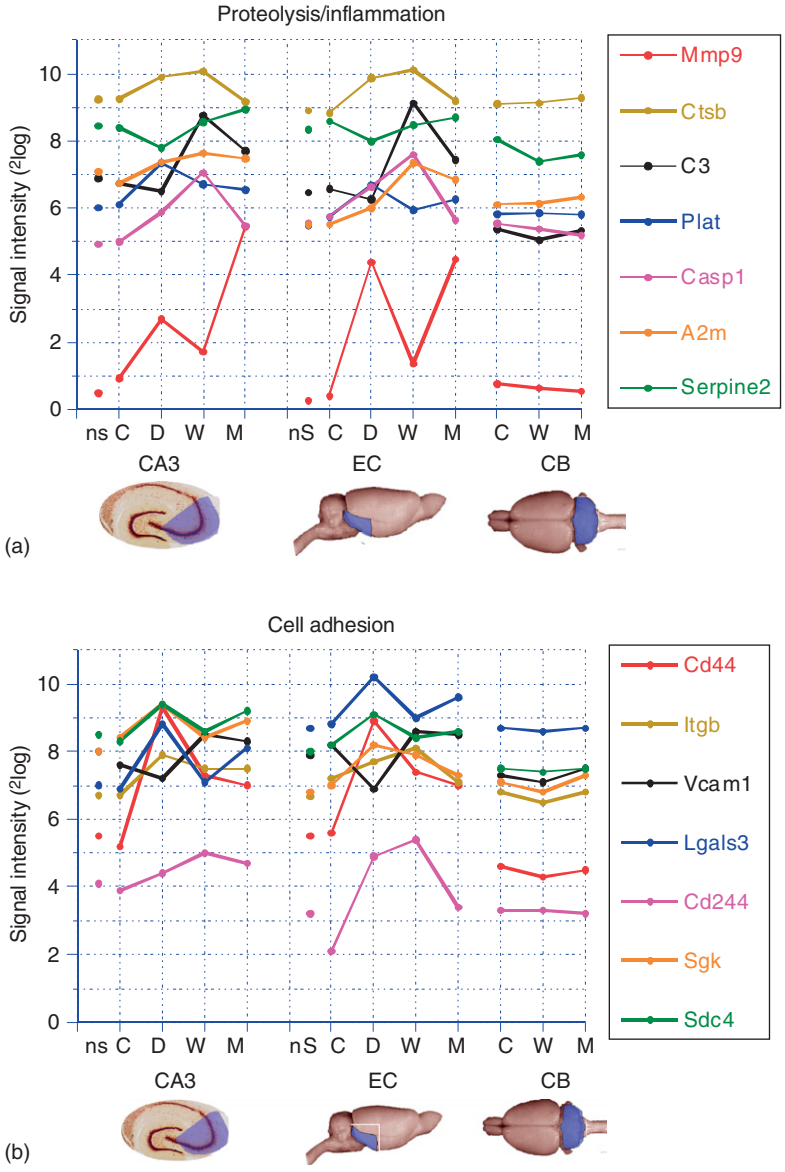

Figure 2 Examples of genes that are significantly activated in CA3 during the chronic phase and that are related to (a) proteolysis, inflammation and (b) cell adhesion. Note that many of the same genes are also activated in EC but not in cerebellum (CB) and that gene expression in stimulated rats that did not exhibit SE after stimulation (nS, 3–5 months after stimulation) were almost similar to controls.

Table 1 Gene symbols and gene names mentioned in this article, with corresponding biological process (BP) and corresponding fold changes at 1 day (D), 1 week (W) and 3–5 months (M) compared to control expression (C) in CA3 region

considered to have antiepileptogenic properties (e.g., *Npy*, *Trh*, *Sst*, *Gal*), several others are proepileptogenic (e.g., *Bdnf*, *Penk*, *Crh*).

Interestingly, cell adhesion (e.g., increased *Vcam1*, various Cd antigens, *Itgb*, *Lgals3*, *Ptprf*, *Raph1*, *Sdc4*) is recognized as an upregulated process during this chronic phase, particularly in CA3. Cell adhesion proteins can promote adhesion and entrance of leukocytes into the brain. In this respect, it is interesting to note that *Cd244*, which is known to be regulated by lymphocytes and monocytes, is significantly upregulated in the chronic phase (**Figure 2(b)**), suggesting that the adaptive immune response could also play a role during this later phase. That the adaptive immune system can play a role in temporal lobe epilepsy is supported by the fact that Cd8-positive lymphocytes are still present in tissue from patients with hippocampal sclerosis. Several proteolytic and complement system-related genes are also still activated in this phase. For example, *Mmp9*, a metalloprotease that is associated with BBB disruption, can indirectly play a proepileptogenic role via entrance of blood proteins through a leaky BBB. *C3*, a complement protein, eventually can lead to formation of the membrane attack complex. Several inhibitors of proteases (e.g., *A2m*) remained strongly upregulated at the same level as during the latent period in both CA3 and EC regions, indicating a continued challenge to counteract the proteolytic activities of Mmps and other proteases.

Genes Associated with Growth, Neuronal Plasticity, Glutamate, and GABA

Epilepsy is often associated with overactivation of genes/proteins that are involved in learning and memory. However, in our study, 'synaptic plasticity' emerged as a significant downregulated process during the acute phase. Further, in the brain regions where cell death and inflammation are prominent – such as in CA3 and EC – the *calcium- and calmodulin-dependent protein kinase activity* (*CamKII*) emerged as a downregulated function during all three phases studied. Absence, or a downregulation, of CaMKII has been related to hyperexcitability and epilepsy. Contrary to what has been reported after long-term potentiation (LTP), there is a decrease in expression of genes related to glutamate and GABA signaling (mainly receptor subunits); 'synaptic transmission' (as reflected mainly in K, Na, Ca channel subunits) also appears to be a downregulated process in the acute and latent phase. These changes probably contribute to an imbalance between GABA and glutamate transmission, and subsequently to instability of the involved networks. Gene expression studies in these global (CA3 and EC) networks, have revealed that, in particular, genes for GABA-receptor subunits involved in tonic inhibition ($\alpha 5$ and δ) are downregulated. In the chronic phase, GABA signaling related gene expression is largely normalized, and there is even a tendency toward overcompensation; compared with control expression, some genes show significantly increased expression – for example, the vesicular inhibitory transporter Viaat (in EC) and the potassium chloride cotransporter *Slc12a2* (Nkcc1; in both CA3 and EC). The latter transporter is also markedly upregulated in subicular neurons of TLE patients. It is thought that the effects of such upregulation are proepileptogenic, since upregulation of Nkcc1 will lead to increased intracellular Cl^- accumulation and consequently to more depolarizing actions of GABA (instead of its more 'normal' hyperpolarizing actions).

The upregulation of the gene encoding Bdnf may be particularly relevant for epileptogenesis, since the mechanism leading to the shift of the membrane equilibrium potential for Cl^- (in hippocampal cells), associated with seizures, may be mediated by an increase in expression of Bdnf. Moreover, there is evidence that Bdnf may alter inhibitory processing in the brain by regulating the balance between phasic and tonic inhibition. We must be aware, however, that the GABA-receptor subunits can be differentially regulated and expressed, depending on the epileptic region under investigation. For instance, there is ample evidence that opposite regulation of receptor subunit expression can exist in CA1 versus dentate gyrus. Therefore, therapeutic strategies aimed at receptors (or any other target) can be region- and even cell-specific, as recently shown in a gene therapy study after pilocarpine-induced SE in rat.

Despite these apparent dissimilarities in gene expression between seizures and LTP, there are also interesting similarities if one looks at individual genes. For instance, as in studies related to learning and memory, many IEGs (*Fos*, *Jun*, *Homer*, *Arc*) are acutely induced, and also in some cases also overexpressed (e.g., Egr1), during the chronic phase of epileptogenesis. Moreover, genes related to growth – such as *Bdnf*, *Vgf*, *Gfra1*, *Tgfbi*, *Tieg*, *Nid67*, *Agpt2*, *Sox11*, and *DcamKII* – are also commonly induced. Some of these genes are associated with morphogenesis and sprouting (*Bdnf*, *Vgf*), others to gliogenesis (*Sox11*), neurogenesis (*DcamKII*, *Nid67*, *Gfra1*, *Pafah1*), and angiogenesis (*Ptgs2*, *Agpt2*). Expression of many of these genes is increased again in the chronic phase (**Figure 3**).

Future Directions-Hypothesis and Potential Targets

From the gene-expression changes that occur in the course of epileptogenesis (as described), we can extract the following picture: The overwhelming acute inflammatory response is reflected in a general and time-dependent activation of multiple genes that code proteases, cytokines, and other inflammatory substances (e.g., cox-2). Expression of these genes can alter the dynamics of

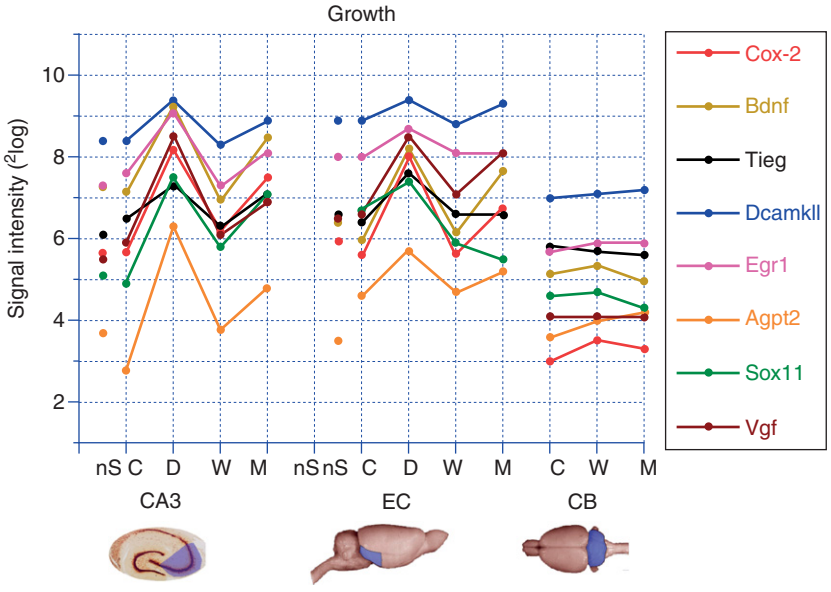

Figure 3 Examples of genes that are significantly activated in CA3 during the chronic phase and that are associated with 'growth.' Note that many of the same genes are also activated in EC but not in cerebellum (CB) and that gene expression in stimulated rats that did not exhibit SE after stimulation (nS, 3–5 months after stimulation) were almost similar to controls.

the neuronal networks, for example, by potentiating glutamate release from neuronal and glial sources. Some overactivated genes (e.g., cox-2, complement and Mmp9) may not only cause parenchymal inflammation but also inflammation of endothelial cells, leading to leakage of the BBB – a feature that can still be present during the chronic phase. Via leakage of blood proteins (e.g., albumin), and via entrance of leukocytes, inflammation will be sustained and will further destabilize neuronal networks and contribute to progression of epilepsy. From this scenario it can be speculated that antiinflammatory treatment, at least in the initial phases when treatment could be directed toward stopping inflammation at the BBB, could help to prevent further progression of the disease.

The microarray studies aforementioned have provided a few suggestions regarding specific targets that may be explored at specific time points during epileptogenesis in order to counteract the epileptogenic process. The relevance of several of these targets (e.g., caspases, metalloproteases, cox-2, complement proteins, cell adhesion proteins) has been, or is presently being tested in animal models for ischemic insults or neurodegenerative diseases (such as multiple sclerosis). Their relevance for epilepsy requires further investigation. Other strategies are also suggested by these gene-expression studies – for example, inhibiting proteins that are induced by seizures and that have proepileptogenic actions by amplifying the actions of glutamate (such as Bdnf and Cox-2) or affecting K^+ channels (Crh). Nkcc1, which regulates intracellular chloride levels and thereby GABA transmitter action, is a potentially interesting target, especially in the chronic phase of epileptogenesis. Genes for GABA-receptor subunits related to tonic inhibition are among the most persistently downregulated, and could be a target for therapy in any phase of epileptogenesis.

Introduction

An essential component of neuron transmission at glutamatergic and GABAergic synapses is removal of the transmitter from the synaptic cleft. Several types of cDNAs encoding high-affinity glutamate transporters have been cloned, including GLAST, GLT, EAAC-1. These glutamate transporters are found in the forebrain. We have examined the regulation of these glutamate transporter proteins in the context of epileptogenesis.

Disruption of inhibition mediated by GABA is one cause for neuronal hyperexcitability leading to convulsive seizures. Extracellular GABA concentration is regulated by specific Na^+-dependent transporter proteins on presynaptic terminals and glial cells. Three subtypes of GABA transporters, designated GAT-1, GAT-2, and GAT-3, have been identified in the rat brain. These transporter proteins modify extracellular GABA concentrations. In earlier studies, we have observed an enhancement of glutamatergic excitatory synaptic transmission efficacy in a spontaneous seizure model, and hypothesized that that enhancement was due to changes in the levels of GABA transporter proteins. We subsequently performed a series of experiments, using quantitative Western blotting, with antibodies specific to individual GABA transporters (GAT-1 and GAT-3) to measure GABA transporter levels (and glutamate levels) during the epileptogenic process.

Background

Models of Epileptogenesis and Transporter Proteins

Repetitive microinjection of glutamate into the amygdala causes seizure generation similar to that found in both kindling and the $FeCl_3$-induced epilepsy model. This observation suggests that the enhancement of excitatory neurotransmitter levels (especially of glutamate) within the limbic system has a critical role in seizure generation. Recent reports suggest that efficacy of long-lasting excitatory synaptic transmission in the kindling model is closely related to extracellular glutamate concentration, glutamate-mediated responses mediated via NMDA receptors, and reduction of GABA-mediated inhibition. However, the molecular and cellular events responsible for these changes remain unknown.

We wondered if enhanced glutamatergic excitatory synaptic transmission in spontaneous seizure models is associated with changes in the levels of glutamate transporter proteins. We performed a series of experiments, using quantitative Western blotting, with antibodies specific to the individual glutamate transporters to test this hypothesis, and to determine if glutamate transporter levels changed over time – reflecting the process of epileptogenesis. We examined the levels of these proteins at various times after $FeCl_3$ injection into the amygdala and correlated those data with the development of chronic seizures.

Experiments using knockdown and knockout of glutamate transporter genes in mice suggest that these proteins are important in epilepsy. Amygdala kindling causes diminished production of GLAST within the piriform cortex and amygdala of kindled rats. This kindling-induced change in GLAST within piriform cortex could result in an increase in extracellular glutamate that would result in increased regional neuronal excitability. This pattern of diminished GLAST production in kindling is identical to the changes in transporter proteins we observed in iron-injected animals with chronic seizures. In contrast to these results from kindling and iron injection models, animals with kainic acid-induced seizures show increased GLAST mRNA in the acute seizure

Introduction

An essential component of neuron transmission at glutamatergic and GABAergic synapses is removal of the transmitter from the synaptic cleft. Several types of cDNAs encoding high-affinity glutamate transporters have been cloned, including GLAST, GLT, EAAC-1. These glutamate transporters are found in the forebrain. We have examined the regulation of these glutamate transporter proteins in the context of epileptogenesis.

Disruption of inhibition mediated by GABA is one cause for neuronal hyperexcitability leading to convulsive seizures. Extracellular GABA concentration is regulated by specific Na^+-dependent transporter proteins on presynaptic terminals and glial cells. Three subtypes of GABA transporters, designated GAT-1, GAT-2, and GAT-3, have been identified in the rat brain. These transporter proteins modify extracellular GABA concentrations. In earlier studies, we have observed an enhancement of glutamatergic excitatory synaptic transmission efficacy in a spontaneous seizure model, and hypothesized that that enhancement was due to changes in the levels of GABA transporter proteins. We subsequently performed a series of experiments, using quantitative Western blotting, with antibodies specific to individual GABA transporters (GAT-1 and GAT-3) to measure GABA transporter levels (and glutamate levels) during the epileptogenic process.

Background

Models of Epileptogenesis and Transporter Proteins

Repetitive microinjection of glutamate into the amygdala causes seizure generation similar to that found in both kindling and the $FeCl_3$-induced epilepsy model. This observation suggests that the enhancement of excitatory neurotransmitter levels (especially of glutamate) within the limbic system has a critical role in seizure generation. Recent reports suggest that efficacy of long-lasting excitatory synaptic transmission in the kindling model is closely related to extracellular glutamate concentration, glutamate-mediated responses mediated via NMDA receptors, and reduction of GABA-mediated inhibition. However, the molecular and cellular events responsible for these changes remain unknown.

We wondered if enhanced glutamatergic excitatory synaptic transmission in spontaneous seizure models is associated with changes in the levels of glutamate transporter proteins. We performed a series of experiments, using quantitative Western blotting, with antibodies specific to the individual glutamate transporters to test this hypothesis, and to determine if glutamate transporter levels changed over time – reflecting the process of epileptogenesis. We examined the levels of these proteins at various times after $FeCl_3$ injection into the amygdala and correlated those data with the development of chronic seizures.

Experiments using knockdown and knockout of glutamate transporter genes in mice suggest that these proteins are important in epilepsy. Amygdala kindling causes diminished production of GLAST within the piriform cortex and amygdala of kindled rats. This kindling-induced change in GLAST within piriform cortex could result in an increase in extracellular glutamate that would result in increased regional neuronal excitability. This pattern of diminished GLAST production in kindling is identical to the changes in transporter proteins we observed in iron-injected animals with chronic seizures. In contrast to these results from kindling and iron injection models, animals with kainic acid-induced seizures show increased GLAST mRNA in the acute seizure

phase (mainly in area CA3), as well as a modest increase in the expression of GLT-1. Of note, we have also seen the same pattern of changes in GLAST and GLT-1 protein during the acute phase (for 5 days) following iron injections.

In tissue obtained during resections of temporal lobes of patients with epilepsy, investigators have found that GLAST protein is reduced compared with the levels seen in control tissue, but observed no significant difference in GLT-1 protein levels. This pattern of transporter change is similar to the pattern we found in rats at 30 days after $FeCl_3$ injection. During the 30 days of our experiment, the level of protein expression of the three types of glutamate transporters changed in a time-dependent manner, with acute elevations in expression followed by collapse in GLAST at +30 days (while all other proteins returned to baseline). In contrast to changes in the glial glutamate transporters that are thought to have a neuroprotective function, neuronal EAAC-1 provides glutamate needed for GABA synthesis. Immunocytochemical studies show colocalization of EAAC-1 on the soma of GABAergic neurons, particularly in the cerebellum. It is tempting to speculate that neuronal glutamate transport may play a significant role in GABA formation, since GABA synthesis depends on uptake on glutamate as a metabolic precursor, with subsequent decarboylation by glutamic acid decarboxylase to form GABA. Introduction of antisense oligonucletides to EAAC-1, with subsequent impaired production of that transporter protein, has led to concomitant decreases in GABA levels, thus linking EAAC-1 with GABA production. Conversely, upregulation of EAAC-1 might be seen as a compensatory response to seizures, with the goal of increasing GABA synthesis in response to excessive glutamate levels.

Methods

In our laboratory, we have combined continuous, online microdialysis and molecular methods to correlate changes in the extracellular concentration of transmitters with alterations in the molecular regulation of transporter proteins. Detailed methods can be found in our previous publications (see suggested readings by Ueda *et al.* and by Willmore *et al.*).

$FeCl_3$-Induced Seizures

Sprague-Dawley rats, weighing between 250 and 280 g, are used for our studies. Surgical procedures are performed, using pentobarbital sodium as an anesthetic (37.5 mg kg^{-1}, i.p.). All experiments are reviewed and approved by the Animal Welfare Committee of our Health Science Center.

Microdialysis and recording from rats are performed in animals prepared with stereotaxic placement of a 22-gauge guide cannula, with the lumen occluded with a stylet and the end positioned just above the left amygdala. We prepare the cannula with a bare-tipped insulated wire affixed to the lip of the guide cannula orifice. After positioning the guide cannula, the stylet is removed and replaced with a fused silica tube (0.075 mm ID, 0.15 mm OD), attached to a microinjection pump (CMA Type 100), which is then lowered into the left amygdala. Animals are injected with 1.5 µl of 100 nmol $FeCl_3 \cdot 6H_2O$, diluted with distilled water, at the rate of 1 µl min^{-1} by microinfusion pump. Our control animals are injected with an equal volume of 0.9% NaCl with pH adjusted with hydrochloric acid to 2.2, to equal the pH of the ferric chloride solution. During injection, and for the following 30 min, we keep animals under continuous EEG recording. Following this recording period, the cannula is removed and animals are allowed to recover.

Animals are killed at designated times – 60 min, 5 days, 15 days, and 30 days – after amygdala injection. After sacrifice, we remove both the left and the right hippocampi, place the tissue in ice-cold PBS buffer, and homogenize the tissue (Polytron PT 3000, Brinkmann) for membrane extraction and immunoblotting.

Immunoblotting and Quantitative Densitometry

To extract a crude synaptic membrane fraction from the hippocampus, we use the method of Danbolt *et al.* Briefly, each hippocampus is homogenized in 1 ml ice-cold 0.32 mol mannitol containing 1 mmol EDTA (pH 7.4), and centrifuged at 1000 *g*<?tfqs- for 10 min at 4 °C. The supernatant is then centrifuged at 27 000 *g*<?tfqs- for 20 min at 4 °C, and the pellet is suspended in 1 ml of hypotonic 1 mmol Tris–HCl containing 1 mmol EDTA. This suspension is centrifuged at 27 000 *g*<?tfqs- for 20 min at 4 °C. The pellet is resuspended in 1 ml of resuspension buffer (100 mmol PBS, pH 7.4, 5 mmol Tris–HCl, 1 mmol $MgSO_4$, 0.5 mmol EDTA, 1% glycerol) and centrifuged at 27 000 *g*<?tfqs- for 20 min at 4 °C. The final pellet is resuspended in 200 µl of resuspension buffer, and is stored at −80 °C. Protein concentrations are determined by the Bio-Rad DC protein assay, using bovine serum albumin as the standard.

Samples of total protein (30 µg each) are solubilized by adding an equal volume of 4% SDS, 20% glycerol, and 125 mmol Tris–HCl, pH 6.8, and boiling them for 5 min. To obtain resolution of both small and large proteins, the samples are analyzed by discontinuous one-dimensional Tris–SDS-PAGE (4% stacking gel and 10% separating gel), using the method of Schagger and Von Jagow. Standard proteins for SDS-PAGE are as follows: phosphorylase (97 kDa), bovine serum albumin (67 kDa), ovalbumin

(43 kDa), carbonic anhydrase (30 kDa), soybean trypsin inhibitor (20.1 kDa), α-lactalbumin (11.4 kDa), and myoglobin residues 1–153(17.2 kDa), residues 1–131 (14.6 kDa).

Proteins from the gel are transferred by electroblotting to 0.2-mm nitrocellulose membrane (Amersham). The nitrocellulose membrane is blocked for 10 min in 10% nonfat milk in PBS buffer containing 1% Tween 20 (PBS-T). Following this washing, the blot is incubated for 2 h in anti-GLT-1, prepared as 0.33 mg ml^{-1} of rabbit affinity-purified antibody raised against the 16 amino acid synthetic peptide RMHDSHLSSEEPKHRN 17–32, corresponding to part of the amino terminus (Alpha Diagnostic Inc, USA). The anti-GLAST, a 0.33 mg ml^{-1} antibody raised against the 15 amino acid synthetic peptide NRDVEMGNSVIEENE, 504–518, corresponds to part of the carboxy terminus, reported by Storck *et al.* (Alpha Diagnostic Inc, USA). The anti-EAAC-1 contains 0.33 mg ml^{-1} of antibody raised against the 14 amino acid synthetic peptide DKSDTISFTQTSQF, 510–523, corresponding to part of the carboxy terminus, reported by Kanai *et al.* (Alpha Diagnostic Inc., USA). These antibodies are suspended in PBS-T containing 0.67% blocking agent. The blot is then washed with PBS-T, incubated with horseradish peroxidase-conjugated goat anti-rabbit IgG for 20 min (1:3000, Chemicon), washed again, and processed for immunoreactivity using enhanced chemiluminescence (Amersham). The blot that is incubated with anti-EAAC-1 is incubated concomitantly with anti-β-tubulin (1:1000, Sigma), using horseradish peroxidase-conjugated goat anti-mouse IgG as secondary antibody for 20 min (1:3000, Chemicon). Densitometry of the immunoblots is used to quantify the changes in expression levels of each transporter protein on the blot. Each blot contains a range of standards of membrane fractions from normal rat brain (7.5–60 μg) that were used to generate a standard curve. The linearity of the relationship between optical density and protein concentration is verified on each film. The transferred blotted membrane fractions are stained with Ponceau-S to verify that each lane is loaded with equivalent amounts of protein. The blots are normalized to β-tubulin for densitometry.

Results

We have found increases in the level of each glutamate transporter at 5 days post-injection. At 15 and 30 days, only GLAST shows downregulation. Increase in EAAC-1 levels continues to 30 days and is seen bilaterally. In contrast, GLT-1 returns to control level at 30 days, bilaterally.

GLAST

We have measured transporter levels in the hippocampus at 60 min after injection of ferric chloride into the amygdala. Measurements were repeated at 5 days post-injection (when spontaneous seizure had their onset) and again at 15 and 30 days after injection. At these later time points, rats injected with ferric chloride have spontaneous, stage 4 seizure behavior. None of the control animals had seizures. Western blotting reveals no change in the levels of GLAST 60 min after injection. Upregulation of GLAST, bilaterally, is observed by 5 days after injection, but at 15 and 30 days after injection GLAST protein immunoreactivity is reduced to 50% of control in both ipsilateral and contralateral hippocampi.

EAAC-1

In contrast to the pattern of GLAST protein, EAAC-1 immunoreactivity is markedly increased at 5 days after injection, particularly contralateral to the injection site. By 15 and 30 days after injection, when experimental rats were experiencing spontaneous seizures, EAAC-1 protein level remained elevated bilaterally.

GLT-1

Immunoreactivity of GLT-1 followed a pattern similar to EAAC-1, with the most pronounced effects of seizures observed in hippocampal regions contralateral to the injection site. However, by 30 days after injection, no significant increases in GLT-1 protein (compared with controls) were detected.

Conclusions and Future Goals

Reuptake of extracellular glutamate has a neuroprotective effect. However, glutamate transporters are capable of moving glutamate in the reverse direction (into the extracellular space), in response to driving forces such as ion gradients or membrane potentials. Reverse transport is thought to result in elevation of extracellular glutamate concentrations following seizures. Thus, an increase in the number of transporter proteins – as may occur associated with seizures – could enhance glutamate efflux and contribute to neuronal hyperexcitability and seizures.

We have been concerned about the initiation of brain injury responses that result in epileptogenesis, and have focused on the role transporter dysfunction as it may explain the collapse of glutamate regulation across various chronic models of epilepsy (amygdala injection of iron salts, kainic acid injection, electrical and PTZ kindling). We continue to evaluate the impact of various antiepileptic drugs on the entire system of transporter regulation, with the belief that such medications may have mechanisms of action that have an impact on the molecular mechanisms of epileptogenesis rather than

affection membrane and synaptic processes that are symptomatic treatments.

Specific Gene Expression Before and After Seizure in Epileptic EL Mice

Y L Murashima, J Suzuki, and M Yoshii, Tokyo Institute of Psychiatry, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In EL mice, ictogenesis can be first seen at about 10 weeks of age. Epileptogenesis, in contrast, is established through the experience of repetitive seizures during development, starting about 20 weeks of age. It has been suggested that an 'abnormal neural plasticity' may play a major role in the establishment of ictogenesis and epileptogenesis, and therefore, can be a potential target for the development of new pharmacotherapies for epilepsy. For example, it has been reported that constitutive neuronal nitric oxide synthetase (n-NOS) and endotherial NOS (e-NOS) are both necessary for the establishment of long-term potentiation (LTP) phenomena. Abnormal LTP-like neural plasticity, and therefore abnormal NOS expression, are likely to play the key roles in the pathogenesis of epileptic disorders. In addition, anti- and proapoptotic factors, as well as neurotrophic factors, have recently been suggested to play crucial roles not only in 'normal' cell development and survival, but also in epileptogenesis.

Continuous immediate early gene (IEG) expression and abnormal γ-aminobutyric acid-ergic (GABAergic) function may also be involved in epileptogenesis in EL mice. It is likely that transiently expressed IEGs are involved in ictogenesis. Further, DNA fragmentation may be associated with the formation of epileptogenesis; in the brain of EL mice, DNA fragmentation without cell loss was observed in the parietal cortex and hippocampus, structures that play the major role in the seizure initiation and generalization (respectively) in this model. The susceptibility of hippocampal neurons to DNA fragmentation increases after experiencing repetitive seizures during development, probably due to a change in the balance between protective (Bcl-2, Bcl-X_L) mechanism and proapoptotic (Bax) pathway inactivation. Drugs that can suppress free-radical generation and protect brain – such as allopurinol (ALP) – may be promising in new antiepileptic agents.

Neurotrophic factors, such as brain-derived nerve growth factor (BDNF), neurotrophin-3 (NT-3), and fibroblast growth factor-2 (FGF-2), may also play a role in

affection membrane and synaptic processes that are symptomatic treatments.

Specific Gene Expression Before and After Seizure in Epileptic EL Mice

Y L Murashima, J Suzuki, and M Yoshii, Tokyo Institute of Psychiatry, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In EL mice, ictogenesis can be first seen at about 10 weeks of age. Epileptogenesis, in contrast, is established through the experience of repetitive seizures during development, starting about 20 weeks of age. It has been suggested that an 'abnormal neural plasticity' may play a major role in the establishment of ictogenesis and epileptogenesis, and therefore, can be a potential target for the development of new pharmacotherapies for epilepsy. For example, it has been reported that constitutive neuronal nitric oxide synthetase (n-NOS) and endotherial NOS (e-NOS) are both necessary for the establishment of long-term potentiation (LTP) phenomena. Abnormal LTP-like neural plasticity, and therefore abnormal NOS expression, are likely to play the key roles in the pathogenesis of epileptic disorders. In addition, anti- and proapoptotic factors, as well as neurotrophic factors, have recently been suggested to play crucial roles not only in 'normal' cell development and survival, but also in epileptogenesis.

Continuous immediate early gene (IEG) expression and abnormal γ-aminobutyric acid-ergic (GABAergic) function may also be involved in epileptogenesis in EL mice. It is likely that transiently expressed IEGs are involved in ictogenesis. Further, DNA fragmentation may be associated with the formation of epileptogenesis; in the brain of EL mice, DNA fragmentation without cell loss was observed in the parietal cortex and hippocampus, structures that play the major role in the seizure initiation and generalization (respectively) in this model. The susceptibility of hippocampal neurons to DNA fragmentation increases after experiencing repetitive seizures during development, probably due to a change in the balance between protective (Bcl-2, Bcl-X_L) mechanism and proapoptotic (Bax) pathway inactivation. Drugs that can suppress free-radical generation and protect brain – such as allopurinol (ALP) – may be promising in new antiepileptic agents.

Neurotrophic factors, such as brain-derived nerve growth factor (BDNF), neurotrophin-3 (NT-3), and fibroblast growth factor-2 (FGF-2), may also play a role in

ictogenesis and epileptogenesis during brain development by promoting abnormal synaptic plasticity. There is abundant evidence of neurotrophic factor expression during the early developmental stages. Another developmental feature studied in EL mice has been cell-cycle phenomena, and particularly how altered cyclins and the corresponding cyclin-dependent kinases (CDKs) are related to the cell proliferation during epileptogenesis. Developmental changes in cyclin and CDK families were examined during cell cycle. As compared with the control DDY mice, we found that the EL mouse shows an upregulation of cell-cycle-specific cyclins or CDKs during early development, suggesting that reentry into cell cycle is promoted prior to the beginning of seizures – perhaps to the presence of high levels of neurotrophic factors.

Background

IEG Expression

Rapid genomic responses to neural activation may play a critical role in long-term synaptic plasticity. Recent work has strengthened this idea by demonstrating that neurotransmitter-induced long-term synaptic plasticity requires RNA and protein synthesis during a critical time window immediately following stimulation. These studies prompted the suggestion that genes, such as *c-fos*, that are rapidly induced by cell-surface-receptor-mediated stimulation by growth factors or neurotransmitters might be involved in the early genomic response underlying long-term synaptic plasticity. Activation of IEGs occur by increased transcription and is thought to represent the primary genomic response to stimulation because it does not require protein synthesis. Several IEGs code for transcription factors. These include members of the *fos* family, which dimerize to form the transcription regulatory complex AP1, as well as *zif*, which is a member of a family of proteins characterized by their DNA-binding domains.

During EL mouse development, IEG expression shifts from one site to another, and the three-dimensional expression area gradually expands, suggesting a change in the regional sites involved in epileptogenesis. These studies also suggest that during development, as well as during repetitive seizures, frequent expression of IEGs and synthesis of Fos and Zif proteins might facilitate synaptic conductivity involved in epileptogenesis. We found that IEG expression after seizures is not related to the seizure pattern per se, but rather to the seizure history, seizure threshold, and developmental state of the EL mouse. Even in the interictal period, EL mice with long seizure histories and very low seizure thresholds demonstrate IEG expression continuously. The IEG expression site is the hippocampal CA1 region, which is the final terminal of various inputs from other areas of the limbic system. We have proposed that the continuous expression of IEGs might play a different role from that of transiently expressed IEGs. During development, as well as through repetitive seizures, the *zif* expression site shifts gradually from the primary input system of the hippocampus (i.e., the pyriform cortex, the entorhinal cortex, and the dentate gyrus) to the hippocampal CA1. We found the *zif* expression site was initially localized to parietal cortex, and was associated with ictogenesis. As *zif* expression became universal, epileptogenesis was established (with weak expression all over the cortex).

NOS Abnormalities

Nitric oxide (NO) is associated with a variety of normal brain functions, including synaptic plasticity. In addition, NO, identified as an Endotherial Relaxing Factor (EDRF), is a potent vasodilator, regulating cerebral blood flow in basal conditions and during certain types of neuronal activation, including seizures. It is also involved in glutamate neurotoxicity. In the central nervous system, NO is synthesized from L-arginine by a Ca^{2+}-calmodulin-dependent NOS that is activated mainly by the stimulation of NMDA receptors. In association with these distinct functions of NO, three isoforms of NOS have been identified: n-NOS, e-NOS, and i-NOS form.

NO has been identified as a source of free-radical oxidants with special relevance to pathological conditions in the brain, since reactive nitrogen intermediates could damage DNA. However, it remains to be seen how seizure activities are regulated by NO in EL mice during development. n-NOS and i-NOS are major and minor components, respectively, of the NO system in EL mice. e-NOS, however, appears to play a minimal role despite the fact that e-NOS appears to be responsible for the NO that mediates an increase in local cerebral blood flow during focal seizures. One might wonder whether the relatively low concentration of e-NOS in EL mouse brain may contribute to the anoxia, and subsequent damage, in those active neurons associated with the epileptic focus complex. NO has been proposed as a retrograde messenger for sustaining LTP, a phenomenon thought to be involved in learning and memory function. Recently, Kandel's group carried out an elegant study in which mice that lacked either n-NOS or e-NOS were shown to have essentially normal LTP, whereas mice deficient in both n-NOS and e-NOS exhibited substantially decreased LTP. This result suggests that both n-NOS and e-NOS are essential for neural plasticity. The process of development of seizure propensity in EL mice has been referred to as 'abnormal plasticity,' based on electroencephalogram studies, biochemical analysis of neurotransmitters, mitochondrial function, and gene expressions. By analogy with the neural plasticity in normal brains, both n-NOS and e-NOS may participate in this abnormal plasticity and further epileptogenesis in EL mice. Given that i-NOS

is more conspicuous than e-NOS, it is also conceivable that excess i-NOS (and subsequent increase in harmful antimicrobial NO) and the relatively lower concentration e-NOS (and subsequent decrease in NO identified as EDRF) may work together to contribute to a complex epileptic focus and ictogenesis.

DNA Fragmentation

An attempt was made to identify the region of EL brain targeted by free radicals as measured by DNA fragmentation. In EL[s] mice, which have experienced seizure induction since the age of postnatal 5 weeks and shown to have a low seizure threshold, DNA fragmentation was detected in the hippocampal CA1 and the parietal cortex (using in situ terminal transferase-mediated dUTP Nick labeling with the aid of alkaliphosphatase and peroxidase). DNA fragmentation was also detected in EL[ns] – animals that never experienced seizure induction and shown to have high seizure threshold. However, the DNA fragmentation in EL[ns] mice was localized to the parietal cortex, and was less intense compared with that of EL[s] mice. EL mice also showed low Cu,Zn-super oxide dysmutase (Cu,Zn-SOD) activities than did control DDY mice. These findings suggest that abnormalities in the region-specific Cu,Zn-SOD isoenzyme activity, which is localized in mitochondria, might produce spatially specific free radicals, leading to DNA fragmentation – a process that might contribute to epileptogenesis.

Proapoptotic and Antiapoptotic Factors

We have hypothesized that excess free radicals might produce DNA fragmentation. The possible free-radical candidates are superoxide and superoxynitrite, a result of decreased Cu,Zn-SOD and increased i-NOS in the brain of EL mice. Ordinarily DNA fragmentation leads to apoptosis. Although IEG expression is usually nonspecific, the expression of localized and continuous IEG expression suggests that some protein cascades occur in situ.

The Bcl family of proteins, and neurotrophic factors, are closely related to cell loss and cell survival as well as to epileptogenesis. We have therefore analyzed, developmentally, their expression in the parietal cortex (seizure initiation site) and in the hippocampus (seizure generalization site) of EL mouse brain. Cell death regulatory genes of the Bcl-2 and caspase families may play a role in ongoing neuropathologic processes in human epilepsy, and offer novel targets as an adjunct to anticonvulsant therapy. The Bcl-2 family of proteins play a crucial role in the regulation of cell death in many eukaryotic systems. The Bcl-2 gene was initially isolated from the t chromosomal translocation found in human B-cell follicular lymphomas, and was subsequently shown to repress cell death triggered by a diverse array of stimuli. However, biochemical process by which Bcl-2 regulates cell death is poorly understood. Bcl-2 family gene products are critical to the integration of cell death stimuli that target the mitochondria. Bcl-X_L has been shown to promote cell survival through the regulation of mitochondrial homeostasis. Bax has been shown to redistribute from the cytosol to the mitochondria during apoptosis; overexpression of Bax can accelerate cell death.

Bcl-2, Bcl-XL, and Bax are apoptosis regulatory proteins, which are variably expressed in brain tissue and are known to be involved in the abnormal plasticity during epileptogenesis. Seizure-induced neuronal damage may involve both excitotoxic and apoptotic (programmed cell death) mechanisms. The expression of proapoptotic Bax and antiapoptotic Bcl-2 are associated with apoptotic phenomena. The ratio of Bax/Bcl-2 expression is increased in the hippocampus by seizures, suggesting that apoptosis of hippocampal inhibitory interneurons may lead to disinhibition in the hippocampus and increased seizure susceptibility.

Neurotrophic Factors

Epileptiform activation can regulate the expression of neurotrophins, and increases or decreases in neurotrophins can affect both epileptogenesis and seizure-related axonal growth. Epileptic seizures increase the expression of BDNF in the hippocampus. Since this neurotrophin exerts modulatory effects on neuronal excitability in this structure, it may play an important role in hippocampal epileptogenesis. Several studies suggest that BDNF can exacerbate seizure development during status epilepticus (SE) and subsequent epileptogenesis in the adult brain. However, there is also evidence for the protective effect of BDNF. To study this controversy, we have studied the developmental changes of expression of neurotrophic factors in EL mouse brain. We found that various neurotrophic factors were over-expressed during the development of EL mice. BDNF showed a biphasic over-expression during 8–12 weeks postnatal, and also around 20 weeks of age – which covers the late period of epileptogenesis. NT-3 (a member of the neurotrophin family of neurotrophic factors important for cell survival, axonal growth, and neuronal plasticity) showed a peak expression from 8 to 12 weeks old, also corresponding to the early period of epileptogenesis. Finally, FGF-2 showed a linear increase in expression with age, and reached a maximum level at 24 weeks (covering the late period of epileptogenesis). Although seizure activity itself also induces expression neurotrophic factor mRNAs and proteins, it is worth noting that the level of NT-3 and BDNF in the hippocampus of EL mice show a significant increase in earlier developmental periods, before the animals exhibit frequent seizures. The high levels of trophic

factors could thus facilitate the induction of cell division-related processes and promote epileptogenesis.

Cell-Cycle Reentry

In proliferating cells, the cell cycle consists of four phases. Gap1 (G_1) is the interval between mitosis and DNA replication that is characterized by cell growth. The transition that occurs at the restriction point (R) in G_1 commits the cell to the proliferative cell cycle. If the conditions that signal this transition are not present, the cells stop the cell cycle and enter G_0, a nonproliferative phase during which growth, differentiation, and apoptosis occur. Replication of DNA occurs during the synthesis (S) phase, which is followed by a second gap phase (G_2) during which growth and preparation for cell division occurs. Mitosis and the production of two daughter cells occur in M phase. A family of cyclins act as regulatory subunits for CDKs that regulate passage through the four phases of the cycle. Altered cyclins, and the corresponding CDK (cyclin D/CDK-4, cyclin E/CDK-2, cyclin A/CDK-2, cyclin A/CDK-1, cyclin B/CDK-1), are related to abnormalities in cell proliferation during early stages of brain development, and may be related to epileptogenesis.

Cytokines or Inflammatory Agents

A variety of cytokines (IL-1b, IL-6, and interleukin 1 receptor antagonist (IL-ra)) are upregulated in the cerebrospinal fluid (CSF) in human temporal lobe epilepsy. IL-1b shows proconvulsant effects (intrahippocampal injection) in the kainate model, although the role of IL-1b in epileptogenesis remains unclear. IL-1b and IL-ra may play a role in altering neuronal network excitability and the associated events. In addition, IL-1ra, IL-6, and tumor necrotizing factor-a (TNF-a) show neuroprotective and anticonvulsant actions at low concentrations, apparently through blocking IL-1r-mediated activity.

Methods

EL Mouse

The EL mouse is an inbred mutant strain that has been used as an animal model of secondarily generalized seizures. The mode of inheritance is autosomal dominant and the penetration rate is 100%. EL mice will show the first seizures at about 10 weeks of age and show frequent seizures after 20 weeks. Several lines of evidence indicate that seizure discharges are initiated in the parietal cortex, and then spread through the hippocampus. These findings have been substantiated by the histochemical and biochemical analyses of glucose utilization and study of inhibitory neurotransmission mediated by GABA. The development of the epileptogenic zone – which mainly consists of the parietal cortex (seizure initiation site) and the hippocampus (seizure propagation and generalization site) – has been hypothesized to be key to epileptogenesis in EL mice.

In Situ Hybrydization and TUNEL Method

IEG (*c-fos* and *zif*) expression in EL mice was developmentally analyzed by in situ hybridization by using ^{35}S. DNA fragmentation was detected by in situ terminal transferase-mediated dUTP Nick end labeling (TUNEL method).

Preparation of Tissues for Immunoblotting Analysis

Immunoblotting analysis was carried for three isoforms of NOS (n-NOS, e-NOS, and i-NOS), proapoptotic Bax, antiapoptotic Bcl-2 and Bcl-X_L, neurotrophic factors (BDNF, NT-3, and FGF-2), cell-cycle reentry proteins (cyclin A, B, D, E, and CDK-1,-2,-4), and cytokines (IL-1a, IL-1b, TNF-a, IL-6, interleukin 1 receptor (IL-1r), and IL-1ra) in EL mice at 4, 6, 8, 10, 12, 15, 19, and 23 weeks of age ($n = 6$ animals per age group). DDY/TIP mice (background strain of EL) at 10 and 20 weeks were used as controls. After decapitation, brains were removed and the hippocampus was dissected out. Homogenates were prepared with 20 mM Tris–HCl buffer (pH 8.0). Just before use, homogenates (with dye for 15% SDS-PAGE gels) were boiled for 3 min and centrifuged for 5 min at 3000 rpm.

Seizures were induced in EL mice once every week (once every 7 days), starting at 5 weeks of age. Cytokines (IL-1a, IL-1b, IL-6, IL-1r, IL-1ra, and TNF-a) were examined by Western blotting in the parietal cortices and the hippocampus). In 15-week-old EL mice, which show seizures once a week regularly, these cytokines were similarly determined 5 min, 2 h, 4 h, 11 h, 24 h, 3 days, and 6 days after the last seizure.

Immunoblotting Procedures and Data Analysis

For the immunoblot analysis, 10% mouse brain homogenates (total protein: 30.0–31.0 μg) were separated by 15% SDS-PAGE and transferred to a PVDF membrane (Millipore, Bedford, MA), blocked and then incubated with primary antibody. After washing, the membrane was incubated with rabbit anti-goat, goat anti-rabbit, or rabbit anti-rat conjugated with horseradish peroxidase (1:10 000) (Sigma), which was followed by a Western blot-chemiluminescence reagent (DuPont NEN, Boston, USA). The luminescence of the membrane was detected using Hyperfilm-ECL (Amersham, Little Chalfont, UK).

The data were semiquantitatively analyzed by using the NIH Image software.

Preparation and Procedure of Labeling Brdu

EL mice of 5, 10, and 20 weeks of age were used ($n = 6$ per age group); DDY/TIP mice at 5, 10, and 20 weeks of age were used as controls. BrdU ($50\,mg\,kg^{-1}$) or vehicle was injected intraperitoneally. One hour after injection, mice were sacrificed and decapitated, brains were removed and frozen in ethanol on dry ice, and then mounted on the cryostat. Thin sections (4–5 μm thickness) were mounted on poly-L-lysine coated glass slides. These sections were further fixed in the ethanol fixative containing 15 mM glycine, at −20 °C, for an hour. Then sections were stained using the 5-bromo-2′-deoxy-uridine Labeling and Detection Kit II purchased from Roche (Penzberg, Germany). Seven sections from each mouse (covering the hippocampus at rostral–caudal distances from bregma −1.7, 1.8, 1.9, 2.0, 2.1, 2.2, and 2.3 mm distance) were obtained. Total positive cells were counted according to layers and statistically compared by t-test. All differences were considered significant at $P < 0.05$.

Recent Results

It has been reported that limbic seizures rapidly induce cytokines (IL-1a, IL-1b, IL-6, TNF-a, IL-1r, and IL-1ra) and related inflammatory mediators. It remains to be seen, however, whether cytokines contribute to the transition from interictal to ictal state. Our recent study was designed to address this issue using EL mice. In the parietal cortex and the hippocampus of EL mice, a significant increase in the level of cytokines was observed when compared with control animals at comparable stages during development. Cytokines were increased predominantly before animals experienced frequent seizures. In the hippocampus of EL mice, at the age of 15 weeks when they show seizures once a week, cytokine levels were highest 6 days after the last seizure. In contrast, peak levels of cytokines were observed 2 h after seizure in the parietal cortex. Cytokines were upregulated just before seizures in the hippocampus, or just after seizures in the parietal cortex.

In the seizure initiation site – the parietal cortex (Pcx), the expression of IL-1a gradually increased and reached a peak level at the age of 10 weeks, the time when the first seizure is seen. In the hippocampus (Hipp), the expression of IL-1a showed a sharp peak at 8 weeks, or just before the first seizure. The expression of IL-1b reached peak level at the age of 10 weeks in Pcx or at the age of 10–12 weeks in Hipp. The IL-6 monomer was expressed most highly at the age of 10 weeks, whereas the dimer was highly expressed at the age of 10 weeks in Pcx and 12 weeks in Hipp. The expression of TNF-a showed a relatively high level from 8 to 15 weeks of age in both Pcx and Hipp. In the case of IL-1r, the expression in Pcx showed a sharp peak at the age of 6–8 weeks, whereas the expression in Hipp showed a maximum peak at the age of 8 weeks and was maintained at a relatively high level during frequent

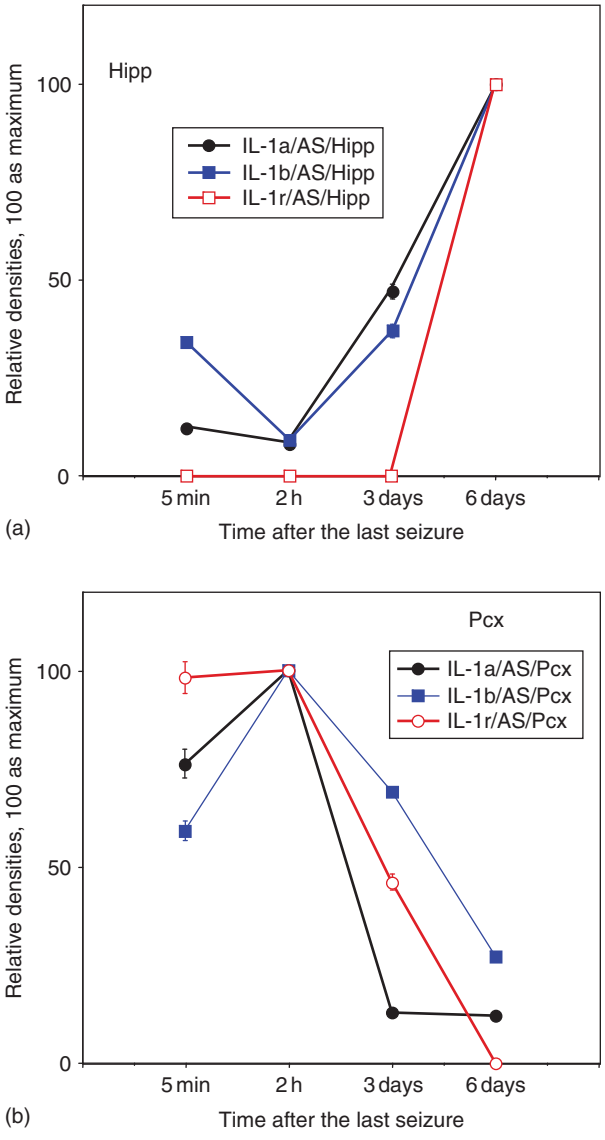

Figure 1 (a) Expression of cytokines after the last seizure in the hippocampus (Hipp), in a 15-week-old EL mouse that exhibited a seizure once a week associated with cage changing. Relative expression of IL-1a,-1b, and-1r. Mean + SEM. The physiological correlates of these changes are as follows: 5 min post-seizure – the EEG has recovered to a pattern similar to that seen before the seizure; 2 h – the absolutely seizure refractory period is over; 3 days – developmental interictal samples were normal; 6 days – just before the next seizure. (b) Expression of cytokines after the last seizure in the parietal cortex (Pcx), using a 15-week-old EL mouse that exhibited seizure once a week associated with cage changing.

seizures. IL-1ra showed a relatively high expression in both Pcx and Hipp from the early ages, from a time before the mice exhibited the first seizure to the later stage of frequent seizures; its peak level was seen at the age of 10 weeks.

In the seizure propagation site (hippocampus), cytokines were expressed at relatively low levels immediately after seizures (**Figure 1(a)**), but were expressed most strongly just before seizures. These results suggest that the upregulation of cytokines in EL mice is associated with triggering of the ictogenesis, rather than as a consequence of frequent seizures. In contrast, the seizure initiation site – Pcx – showed a maximum expression of cytokines immediately after seizures, with expression then gradually decreasing (**Figure 1(b)**).

Cytokines are also induced in forebrain regions where seizures originate and spread in kainate and bicuculline models. Their syntheses in neurons are high when seizure activity is advanced in these models.

Future Goals

The role of cytokines in the seizure initiation site and seizure propagation and generalization site may be different. Several reports have described the upregulation of cytokines after the seizures. However, in the commonly used chemical models of epilepsy or epileptogenesis, it is impossible to determine cytokine expression levels just before a seizure. The mutant EL mouse appears to be a useful model of epilepsy to investigate the transition from the preictal or interictal to the ictal state during development. Our studies suggest that proinflammatory cytokines are increased progressively and periodically in association with both brain development and with seizure activity. A periodic increase of cytokines just prior to a seizure episode may play a role in triggering the ictal activity. That is, alteration in region-specific cytokines may induce ictal activities. Future studies should examine whether inflammatory cytokines work together with other neuronal factors during epileptogenesis, and in the transition from the interictal to the ictal state.

Introduction

The term 'epileptogenesis' refers to the development of an epileptic disorder, and implies abnormal neuronal reorganization occurring over a long period of time following a specific cerebral insult. One of the greatest challenges in epilepsy research is to prevent epileptogenesis in patients at risk or at least to modify the disease process in such a way that the epilepsy that develops is milder or easier to treat. This goal not only requires novel treatment strategies based on understanding the basic mechanisms of epileptogenesis, but also relies on new methodologies to study the epileptogenic process, to follow treatment effects, and to predict outcomes in individual subjects.

Neuronal reorganization during epileptogenesis is composed of a large number of neurobiological changes, including neurodegeneration, neurogenesis, axonal sprouting, axonal damage, gliogenesis, angiogenesis, dendritic plasticity, reorganization of the extracellular matrix, and changes in cellular membranes. All these changes require spatiotemporally orchestrated patterns of gene expression. In principle, these molecular and cellular alterations can serve as targets for the development of bio- and surrogate markers for epileptogenesis.

A biomarker can be defined as a characteristic that is objectively measured and evaluated as an indicator of a normal biological process, pathogenic process or pharmacological response to a therapeutic intervention. A surrogate marker is an indirect measure of disease progression. In a recent NINDS sponsored workshop 'Biomarkers for Epileptogenesis', the three major technological areas that were identified as the most promising in the search for bio- or surrogate markers of epileptogenesis were: imaging, electrophysiology, and 'omics' (e.g., genomics, proteomics, metabolomics).

Here we summarize the strategies and current data available using magnetic resonance imaging (MRI) and proteomics in the search for surrogate markers of epileptogenesis.

MRI-Related Surrogate Markers of Epileptogenesis

Background

MRI is one of the most versatile tools for in vivo visualization of the brain. MRI relies on a physical phenomenon of atomic nuclei called nuclear magnetic resonance (NMR). To create an image, we utilize the NMR signals of hydrogen nuclei in water molecules. The nature of these signals depends on multiple factors conferred by the tissue environment, for example, the local quantity and mobility of water. It is important to note that approximately 60% of an adult's body is water and much of this water lies in soft tissues. This feature of biological tissue composition results in a high signal density for MRI; when this signal is spatially localized (with the help of controllable magnetic field gradients within the MRI scanner), high resolution images with high signal-to-noise ratios are achievable. Typically, small animal MRI has a resolution in the order of 100 μm, which can be optimized to 50 μm using the most advanced hardware and measurement techniques. This resolution is quite remarkable, especially when one considers that the thickness of the granule cell layer in the rat hippocampus is about 50–100 μm. Therefore, neurobiological changes in even a small group of cells in the brain can lead to distinct, measurable changes in the black–white contrast captured within our MR images.

Tissue alterations during epileptogenesis (such as neuronal cell death, gliosis, or axonal alterations) can affect the volume of extracellular space and dynamics of water movement. Importantly, MRI contrast is dependent on the concentration of water in the sample, but is also determined by the nature of the dynamic behavior of water within the timescale of an MRI measurement (milliseconds to seconds). These water dynamics affect the relaxation times T2 (transversal) and T1 (longitudinal) that determine how hydrogen nuclei return toward equilibrium after excitation by a radio frequency pulse. By modifying the NMR excitation and acquisition method, image contrast can be optimized to observe a certain

Introduction

The term 'epileptogenesis' refers to the development of an epileptic disorder, and implies abnormal neuronal reorganization occurring over a long period of time following a specific cerebral insult. One of the greatest challenges in epilepsy research is to prevent epileptogenesis in patients at risk or at least to modify the disease process in such a way that the epilepsy that develops is milder or easier to treat. This goal not only requires novel treatment strategies based on understanding the basic mechanisms of epileptogenesis, but also relies on new methodologies to study the epileptogenic process, to follow treatment effects, and to predict outcomes in individual subjects.

Neuronal reorganization during epileptogenesis is composed of a large number of neurobiological changes, including neurodegeneration, neurogenesis, axonal sprouting, axonal damage, gliogenesis, angiogenesis, dendritic plasticity, reorganization of the extracellular matrix, and changes in cellular membranes. All these changes require spatiotemporally orchestrated patterns of gene expression. In principle, these molecular and cellular alterations can serve as targets for the development of bio- and surrogate markers for epileptogenesis.

A biomarker can be defined as a characteristic that is objectively measured and evaluated as an indicator of a normal biological process, pathogenic process or pharmacological response to a therapeutic intervention. A surrogate marker is an indirect measure of disease progression. In a recent NINDS sponsored workshop 'Biomarkers for Epileptogenesis', the three major technological areas that were identified as the most promising in the search for bio- or surrogate markers of epileptogenesis were: imaging, electrophysiology, and 'omics' (e.g., genomics, proteomics, metabolomics).

Here we summarize the strategies and current data available using magnetic resonance imaging (MRI) and proteomics in the search for surrogate markers of epileptogenesis.

MRI-Related Surrogate Markers of Epileptogenesis

Background

MRI is one of the most versatile tools for in vivo visualization of the brain. MRI relies on a physical phenomenon of atomic nuclei called nuclear magnetic resonance (NMR). To create an image, we utilize the NMR signals of hydrogen nuclei in water molecules. The nature of these signals depends on multiple factors conferred by the tissue environment, for example, the local quantity and mobility of water. It is important to note that approximately 60% of an adult's body is water and much of this water lies in soft tissues. This feature of biological tissue composition results in a high signal density for MRI; when this signal is spatially localized (with the help of controllable magnetic field gradients within the MRI scanner), high resolution images with high signal-to-noise ratios are achievable. Typically, small animal MRI has a resolution in the order of 100 μm, which can be optimized to 50 μm using the most advanced hardware and measurement techniques. This resolution is quite remarkable, especially when one considers that the thickness of the granule cell layer in the rat hippocampus is about 50–100 μm. Therefore, neurobiological changes in even a small group of cells in the brain can lead to distinct, measurable changes in the black–white contrast captured within our MR images.

Tissue alterations during epileptogenesis (such as neuronal cell death, gliosis, or axonal alterations) can affect the volume of extracellular space and dynamics of water movement. Importantly, MRI contrast is dependent on the concentration of water in the sample, but is also determined by the nature of the dynamic behavior of water within the timescale of an MRI measurement (milliseconds to seconds). These water dynamics affect the relaxation times T2 (transversal) and T1 (longitudinal) that determine how hydrogen nuclei return toward equilibrium after excitation by a radio frequency pulse. By modifying the NMR excitation and acquisition method, image contrast can be optimized to observe a certain

parameter, such as water diffusion or blood flow. Tricks to accentuate the contrast include employing contrast agents that modify water relaxation in tissue and/or blood. Contrast agents normally contain paramagnetic substances (such as Gd^{3+} and Mn^{2+}) that predominantly shorten T1 relaxation times to create hyperintensity in T1 weighted imaging. Alternatively, superparamagnetic iron oxide (Fe^{3+}) particles can be utilized to produce negative contrast in T2 weighted imaging.

Perhaps the greatest asset of using MRI in epileptogenesis studies is that it provides safe and noninvasive visualization of the brain. Consequently, MRI can be performed early during the disease process without causing too much burden for the patient, and the pattern and severity of damage can be reassessed and correlated with the long-term functional outcome on an individual basis. Appreciation of interindividual variability in findings makes it possible to identify an array of quantitative MRI changes in each subject that predict poor or favorable outcomes. Moreover, the physical principles of MRI make it suitable for both experimental and clinical studies of epilepsy. The strong magnetic fields involved pose no known threat to humans or animals, and the electromagnetic pulses are within the low energy, radio frequency range, just like those of the airwaves used in broadcasting and communications. Since these low energy pulses have excellent tissue penetration without any hazardous ionizing radiation, MRI can safely be repeated throughout prolonged studies.

Methods and Results

MRI studies predict outcome in animal models of epileptogenesis

In rat studies, epileptogenesis can be triggered by genetically disrupting cortical development, or by introducing a brain insult such as stroke or traumatic brain injury (TBI). However, most of the recent work relies on chemically or electrically induced status epilepticus (SE) (see Further Reading section). MRI studies in these models have aimed at identifying early structural alterations that would correlate with the later risk of seizure (i.e., lowered seizure threshold) or occurrence of spontaneous seizures. Some studies have also used MRI to monitor the effects of antiepileptic compounds on SE and the severity of its consequent structural lesion.

Recent studies have drawn correlations between T2 (see **Figure 1**) or diffusion MRI changes and the risk of epileptogenesis. For example, T2 prolongation in the piriform and entorhinal cortices, seen as early as twenty four hours post-SE in rats, was associated with a higher risk of epileptogenesis later in life. A newer technique, diffusion weighted imaging, can identify lesion development before detection is feasible by T2 weighted imaging. The diffusion MRI measurement is sensitive to small changes in water diffusion, which correlate with the early stages of lesion formation, when there is a decrease in normal diffusion values. Follow-up studies in chemically or electrically induced SE models have demonstrated that delayed secondary changes in both T2 and water diffusion may also develop weeks after SE, taking place either before or during the appearance of spontaneous recurrent seizures. Whether the development of secondary alterations would provide a specific and sensitive surrogate for the appearance of spontaneous seizures after SE requires further exploration.

Interestingly, in a model of posttraumatic epilepsy (PTE), a recent study demonstrated that diffusion in the hippocampus increases between the first and third month post trauma and remains elevated during the remaining 8 months of study. This increased diffusion correlates with a lowered seizure threshold in these animals. Notably, a diffusion decrease (as early as 3 h post insult) and a diffusion increase 23 days after injury were both associated with hyperexcitablity seen in EEG 11 months post injury.

A few studies have attempted to monitor the effects of antiepileptic drugs (AEDs) on SE and consequent structural damage. For example, administration of diazepam 15 min after induction of SE with pilocarpine normalized the diffusion change present during the course of SE, and consequently alleviated the neurodegeneration when assessed 2 weeks later. Similarly, topiramate administration during SE has been reported to alleviate T2 prolongation after SE, and this MRI result was associated with a mild neuroprotective effect.

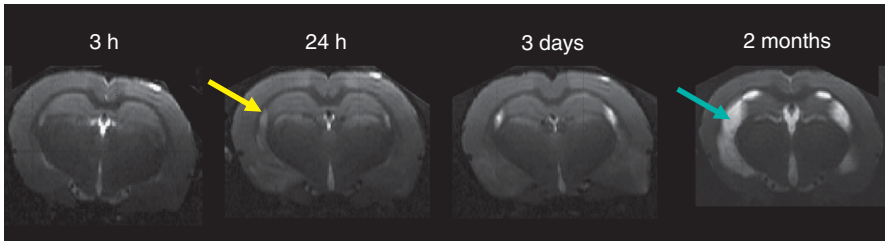

Figure 1 T2 weighted MR images of a rat brain following kainic acid (KA) induced status epilepticus (SE). Images were acquired using a 4.7 T MRI scanner. Images show the course of T2 weighted signal changes after SE. The yellow arrow highlights an edematic lesion forming 24 h after KA injection. The lesion develops into atrophy after 2 months (blue arrow). Images courtesy of Riikka Immonen.

What are the physiological translations of these MRI results? That is, can we already pinpoint the neurobiological substrates that predict epileptogenesis based on MRI information? The interpretation of physiological correlates of MRI relaxation and diffusion changes can be challenging. MRI relaxation and diffusion measurements probe the mobility and interactions of water molecules. In the complex environment inside epileptogenic tissue, it is feasible that many of the physiological changes mentioned earlier are ongoing concurrently. Each will impact on relaxation and diffusion of water to a variable extent. Thus, we cannot unequivocally link MRI changes to any one of the neurobiological processes in a progressive pathology. Nonetheless, it is still possible to use detailed findings from these MRI data to build a surrogate marker – for example, for severity and extent of cytotoxic edema in the brain. In this specific example, an initial diffusion decrease occurs as the extracellular water enters the intracellular space, where diffusion is more restricted. (Actually, net diffusion decrease is a result of multiple factors, including changes in diffusivity of the intracellular and extracellular spaces and extracellular tortuosity – see Further Reading section.) Conversely, a diffusion increase occurs when the cellular barriers that restrict water movements are lost. This happens in regions of substantial cell death, and thus is a common characteristic of most epileptogenic brain insults. Regarding T2 relaxation time changes, a T2 increase is well associated with vasogenic edema, in which there is, by definition, more free water than in healthy tissue. Since free water content positively correlates with T2 relaxation time, we have the basis for another surrogate marker. Importantly, such pathological explanations for these MRI findings from animal studies are normally supported by histological analyses.

A caveat regarding the use of various models in surrogate marker development revolves around the fact that some findings can be model-specific. For example, observation of an early epileptogenic T2 increase in the pilocarpine-induced SE paradigm has been challenged by reports that T2 actually decreases within the first 12 hours after SE was induced with an organophosphate, soman. Clearly, results from different animal models can sometimes be conflicting; thus, the interpretation of MRI findings must be made cautiously and without dependence on single studies or models.

Towards more specific imaging of cellular alterations in epileptogenesis

Since relaxation and diffusion based MRI can describe so many physiological processes which can often be difficult to discriminate, some more specific MRI techniques have recently begun to evolve. One such example, manganese enhanced MRI (MEMRI), has been applied to SE-induced epileptogenesis involving mossy fiber sprouting. Mossy fiber sprouting is present in the dentate gyrus of the hippocampus both in experimental models and human epilepsy. Its precise role in the onset and progression of epilepsy is debated. However, several studies have shown that it is present in the hippocampus, not only after the emergence of epilepsy but also before the appearance of spontaneous seizures. Therefore, mossy fiber sprouting has become an attractive candidate for imaging as a surrogate marker for epileptogenesis. Mossy fibers are extensions of the axons of granule cells in the dentate gyrus. These are extremely difficult to visualize by MRI in animals unless manganese ions (Mn^{2+}) are employed as a paramagnetic contrast agent. After both systemic injection and injection into the entorhinal cortex during epileptogenesis, Mn^{2+} translocates from the terminals of the perforant pathway to the axons of granule cells – that is, to the mossy fibers. This specific labeling brings them enhanced visibility in T1 weighted imaging, enabling the extent of mossy fiber sprouting to be visualized in a region-specific manner. Systemic administration of Mn^{2+} makes the method simple to use in a preclinical setting.

The relatively new technique of diffusion tensor imaging (DTI) is beginning to help complete the epileptogenesis puzzle. This method relies on the principle that water diffuses with the same directionality as that of axons within white matter tracts. The measurement is sensitive to unidirectional diffusion (see **Figure 2**); thus, nerve bundles, and possibly even mossy fibers, could be visualized with greater accuracy and resolution.

Much of this article is focused on structural MRI studies, yet functional magnetic resonance imaging (fMRI) has been used to characterize neuronal activation patterns in seizures. This technique relies on blood oxygenation level dependent (BOLD) contrast, which is derived from a hemodynamic response coupled with neural activity. As brain neurons are activated, their energetic demands create a transient regional increase in blood flow. This event increases the local oxyhemoglobin concentration, and therefore decreases the deoxyhemoglobin concentration at the activated site. As deoxyhemoglobin is paramagnetic, an NMR signal intensity increase occurs around active neurons. fMRI in animal models of epilepsy promises to be a valuable tool for describing the functional characteristics of the epileptogenic brain, and provides an attractive technique for following brain recovery processes and functional improvement in relation to epileptogenesis.

We must continue our efforts to determine whether these new techniques can also help assess the efficacy and safety of antiepileptogenic treatments. Our ability to interpret MRI data will undoubtedly improve as both the MRI technology and our animal models improve. Fortunately, most new or enhanced MRI techniques developed in the laboratory can be applied to clinical MRI scanners in hospitals, facilitating the translational goals of our research.

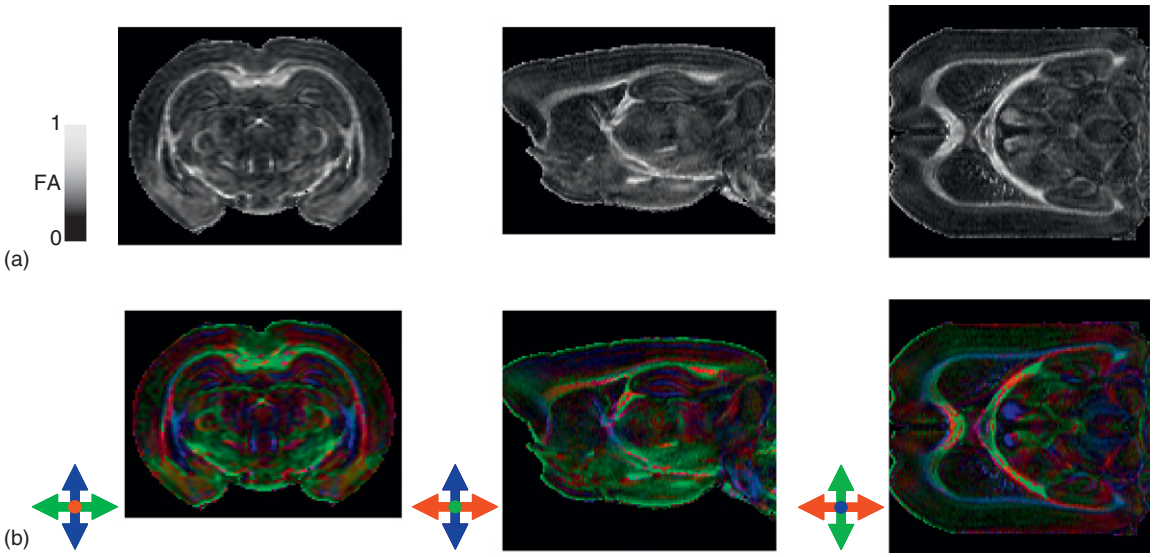

Figure 2 (a) Fractional anisotropy maps (FA) and (b) color-coded fractional anisotropy maps of a healthy rat brain acquired *ex vivo* using a 9.4 T MRI scanner by diffusion tensor imaging (DTI). Coronal, saggital, and horizontal views are presented (from left to right). Fractional anisotropy positively correlates with unidirectional water diffusion, thus white matter tracts have the greatest FA intensity (a). The color-coded maps (b) describe the principle diffusion direction in three dimensions. Maps courtesy of Teemu Laitinen.

Proteomic Approaches to Discovery of Surrogate Markers for Epileptogenesis

Background

The goal of proteomics research is to identify, characterize, and quantify proteins in a biological system. It has been proposed that about 20 000 genes in the genome can encode more than 500 000 proteins. From these proteins, a few thousand can typically be identified at one time using proteomic methods. Despite this 'limited view' of the entire proteome currently available, proteomic techniques can detect minute changes in a given proteome profile, and thus it is possible to identify pathological processes in preclinical investigations or at an early clinical stage of a disease.

Methods

The gel-based two-dimensional (2D) difference gel electrophoresis (2D DIGE) and the mass spectrometry-based isobaric tags for relative and absolute quantification (iTRAQ) are two proteomic methodologies that provide qualitative and quantitative information. These are used for the discovery of epileptogenesis-specific surrogate markers from CSF and/or serum/plasma.

2D difference gel electrophoresis

2D DIGE is the method of choice when complex protein mixtures are to be analyzed (Figure 3). It is a much more sensitive method than classical 2D gel electrophoresis.

2D DIGE is based on labeling of each protein sample of interest (control, treated, and pooled internal standard) with a different fluorophore (Cy3, Cy5, or Cy2) that binds covalently with the epsilon amino group of lysine residues. A clear benefit of the 2D DIGE system is that all three protein samples (Cy3-, Cy5-, and Cy2-labeled) can be separated on the same 2D gel. For example, CSF protein samples from control and epileptic populations are labeled with Cy3 or Cy5 dye, respectively. Next CyDye-labeled protein samples and a pooled internal standard (Cy2) (created by mixing aliquots of all samples to be analyzed) are mixed together and focused according to their isoelectric point on an IPG strip, then separated according to their molecular weight by sodium dodecyl-sulfate polyacrylamide gel electrophoresis (SDS-PAGE). After the 2D run, the gel is scanned using an imaging analyzer, and data obtained from the scanner is processed with DeCyder software (GE Healthcare). DeCyder is a dedicated image analysis software package that utilizes a proprietary codetection algorithm (max triple detection) that allows automatic detection, background subtraction, quantification, normalization, and internal matching of fluorescence images. The use of an internal standard efficiently eliminates gel-to-gel variation and improves the accuracy of quantification between samples from different gels, allowing detection of small differences in protein level, since quantitative analysis is based on relative intensities of fluorescing labels at specific protein spots or labeled standard protein spots. A significant advantage of the DIGE system is that it covers a dynamic detection range of 3–5 orders of magnitude.

After DeCyder software data analysis, the protein spots of interest are picked up from the gel and processed for mass spectrometry (MS) analysis. Each protein spot is

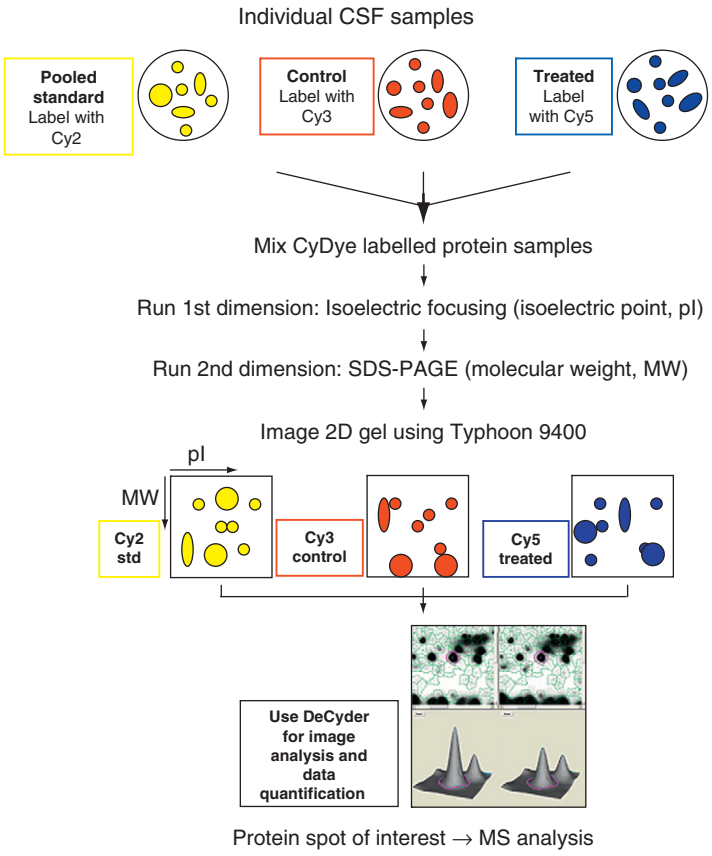

Figure 3 Two-dimensional difference gel electrophoresis (2D DIGE). Experimental design for labeling each individual cerebrospinal fluid (CSF) protein sample with fluorescent CyDye (Cy2, internal standard; Cy3, control; Cy5, treated) and separation of the labeled protein mixture in the first dimension run according to isoelectric point (pI), in which proteins' net charge is zero, and next in second dimension run on SDS-PAGE gel, in which proteins are separated according to their molecular weight (MW). Next, the protein 2D gel is imaged using a Typhoon 9400 laser scanner and data are analyzed with DeCyder software. Finally, a protein spot of interest is picked from the 2D gel and the protein is identified with mass spectrometry (MS).

separately in-gel digested with trypsin protease. Then, proteolytic trypsin digested peptide mixtures derived from a single protein spot are examined by mass spectrometry (Nano-LC QStar or MALDI-TOF/TOF). Finally, the Mascot algorithm is utilized for large-scale protein identification by searching a sequence database using mass spectrometry data.

Isobaric tags for relative and absolute quantification

Mass spectrometry based iTRAQ utilizes up to eight tag reagents, which bind covalently to the amino-terminus of the peptide (Figure 4).

First each control/treated CSF protein sample is separately digested with a proteolytic enzyme. After digestion, peptides are mixed with a specific iTRAQ tag reagent. Next, iTRAQ-labeled peptides are combined and fractionated using isoelectric focusing. Fractionated iTRAQ-labeled peptides are extracted from the IPG strip and processed for mass spectrometry analysis. Ionization of an iTRAQ-labeled peptide leads to fragmentation of the precursor ion using tandem mass spectrometry (MS/MS) and separation of the tag fragment from the peptide. On the spectrum, those fragmented iTRAQ-tag signature ions will show up from 113 to 119 m/z and 121 m/z, in a 'quiet' spectral region. Comparing the relative intensities of each of the tagged peaks with ProteinPilot 2.0.1 software (Applied Biosystems) provides quantitative analysis of the iTRAQ-labeled peptides.

It is important to note that high-abundance proteins should be removed from a complex protein mixture before iTRAQ-labeling, because those high-abundance proteins mask other low-abundance proteins and thus prevent their detection in mass spectrometry analysis. For example, CSF contains much albumin and IgG, and therefore it is beneficial to deplete those proteins from CSF using an albumin and IgG removal kit. This step will highly improve the detection of low-abundance proteins. Another option is to perform prefractionation of the protein sample, prior to iTRAQ labeling, by centrifugation. Also, antibody-based affinity depletion kits that remove

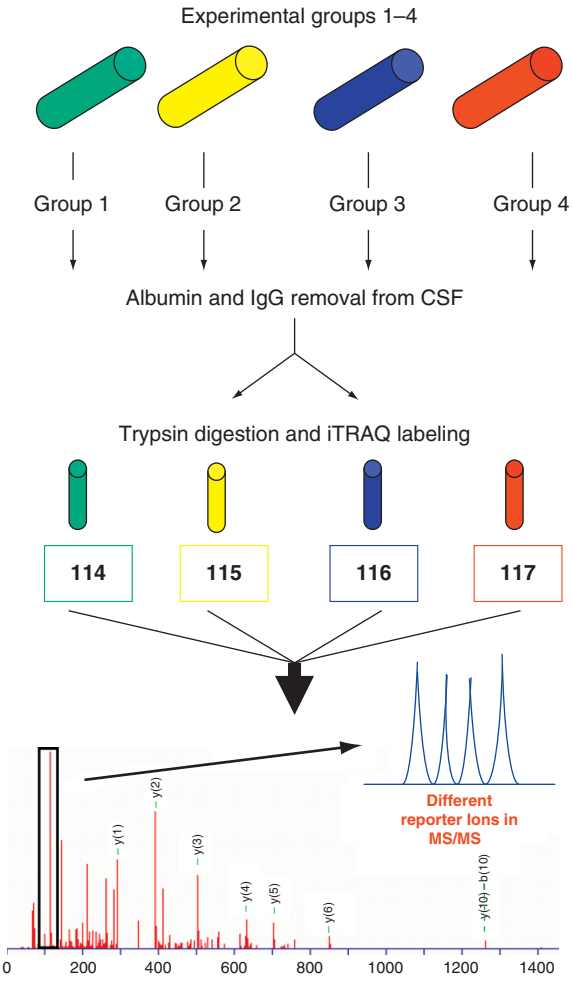

Figure 4 Isobaric tags for relative and absolute quantification (iTRAQ). Experimental scheme for the discovery of surrogate markers for epileptogenesis from rat cerebrospinal fluid (CSF) using mass spectrometry-based iTRAQ methodology. First, high-abundance proteins, such as albumin and IgG, are removed from CSF. Next, proteins are digested with trypsin and trypsin generated peptides are labeled with a specific iTRAQ tag (e.g., 114, 115, 116, and 117). Then iTRAQ-labeled peptides are fractionated with a cation exchange column or isoelectric focusing and analyzed with tandem mass spectrometry (MS/MS). Data can be processed, e.g., with ProteinPilotTM 2.0.1 software (Applied Biosystems).

the 6–12 most abundant plasma proteins and enrich low-abundant proteins are commercially available.

Results – Proteomics Studies During Epileptogenesis

To date, proteomic methods have not been utilized for the discovery of biomarkers for epileptogenesis from CSF or plasma/serum. Published epilepsy articles, which have exploited proteomic approaches in biomarker discovery, have mainly focused on finding tissue specific, epilepsy related protein alterations in the hippocampus and cerebral cortex at early time points. For example, putative biomarkers found in the rat hippocampus at acute (12 h) and later (72 h – latent period) phases in a pilocarpine induced TLE model can be linked to cytoskeletal modifications, altered synaptic function, mitochondrial dysfunction, changed ion channels, and chaperone functions. In turn, when absence seizures were induced by gamma-butyrolactone in mice, researchers concluded that 15 out of 16 thalamic proteins were down-regulated in the group of absence seizure-induced mice. Those down-regulated proteins belonged in the five functionally different groups of cytoskeleton rearrangement, neuroprotection, neurotransmitter secretion, calcium binding, and metabolism. These tissue-derived results provide a hint for developing therapeutic interventions for epilepsy. However, to carry out such studies currently requires surgical operations – so this approach does not provide an easy and noninvasive means of obtaining a useful biomarker.

What does the Future Hold?

It is likely that the use of one technology is not going to provide the sensitivity and specificity that are required for a surrogate marker to be reliably used in the clinic. A more realistic approach is exemplified in the Alzheimer's disease research field, where ongoing studies combine data from several technological platforms – such as MRI and proteomics – to optimize the prediction of outcome. It is likely that the development of surrogate markers for epileptogenesis will require multidisciplinary approaches, especially given the variability of spatiotemporal progression of epileptogenesis after brain injuries (e.g., traumatic brain injury, stroke, infection).

Introduction

GABA is the key inhibitory transmitter in the central nervous system (CNS). Synaptically released GABA activates specific receptors in the membrane; the resulting increase in permeability alters the neuron's membrane potential and excitability. Early electrophysiological data established two types of GABA-mediated synaptic events in central neurons, with different pharmacology and ionic mechanisms. The early inhibitory postsynaptic potential (IPSP) mediated by $GABA_A$ receptors ($IPSP_A$, time to peak about 20 ms) is sensitive to bicuculline, the prototype $GABA_A$ receptor antagonist, i.e is mediated by $GABA_A$ receptors. The late IPSP ($IPSP_B$, time to peak about 150 ms) is sensitive to established antagonists for $GABA_B$ receptors (saclofen, CGP 35348), i.e. is mediated by $GABA_B$ receptors. The receptors mediating these responses have been cloned revealing two molecularly distinct families of receptors.

The $GABA_A$ receptors are pentameric arrangements of subunits, each containing four transmembrane amino-acid helices, essentially forming a cluster of transmembranal protein columns enclosing a central pore. Binding of GABA alters the conformation of the protein, and the resulting change in the central pore allows small anions to flow down their electrochemical gradients. To date, 18 different $GABA_A$-receptor subunits have been cloned. These subunits can be grouped according to sequence homology into 6 α, 4 β, 4 γ, 1 δ, 1ε, and 2 ρ subunits. The stoichiometric composition of subunits governs the pharmacological and biophysical properties of a given $GABA_A$ receptor. Thus, a plethora of distinct $GABA_A$ receptors is present in the mammalian CNS. The composition of $GABA_A$ receptors exhibits regional specificity and developmental changes. It is also subject to activity-dependent alterations.

Functional $GABA_B$ receptors consist of a dimer of heptahelical subunits in the membrane, containing no pathway for the flow of ions; that is, $GABA_B$ is a metabotropic receptor. The extracellular domain of each subunit assumes a structure resembling half a sphere (or 'venus

flytrap'). The intracellular domains of the two subunits form coils adjacent to each other. Binding of GABA to the inside of one subunit's half sphere is conveyed to the inside coil; through a coil–coil interaction, the binding of G-protein to the other coil is enabled. The G-protein in turn interacts with two main effector systems, Ca^{2+} and K^+ channels. For example, a $GABA_B$ receptor-mediated increase in potassium conductance underlies the $IPSP_B$, observed in hippocampal and neocortical pyramidal neurons. A $GABA_B$ receptor-mediated decrease in Ca^{2+} currents, originally observed in dorsal root ganglion cells, also occurs in CNS presynaptic terminals, thereby modulating (for example) the release of GABA in a negative feedback manner. The dimerization of subunits appears to be unique to $GABA_B$ receptors, but other metabotropic receptors share – through different G-proteins – the same effectors. In fact, occlusion experiments using pairs of agonists for metabotropic receptors have demonstrated that binding of two agonists can occur simultaneously at distinct receptors, and can be blocked by different (receptor-specific) antagonists; yet, the combined application of agonists causes no additive effects. The divergence of a given metabotropic receptor to different effectors, together with the convergence of different receptors to the same effector, may enable a complex integration of signaling via various metabotropic receptors.

In the rodent neocortex, blockade of $GABA_A$ receptors (by, e.g., penicillin or bicuculline) inevitably induces paroxysmal depolarization shifts (PDSs) characterized by a large depolarization (about 25 mV), with a barrage of action potentials (APs) atop. These PDSs are regarded as the cellular correlate of the interictal spike of EEG recordings from the epileptogenic cortex. A brief summary of PDS properties produced in this way is instructive for a comparison with the synaptic responses in human epileptogenic cortex (as described later). These PDSs do not gradually increase in amplitude as stimulus intensity rises, but rather occur in an essentially 'all or none' fashion. Moreover, the peak amplitudes of the APs riding on the large depolarization are attenuated at the peak of the PDS and recover as the slow depolarization decays; the resulting troughs in the AP peaks probably is due to a slowed recovery from inactivation of sodium channels. Not surprisingly, drugs augmenting the efficacy of $GABA_A$ receptors (e.g., benzodiazepines) are established anticonvulsants. The data from experiments of $GABA_A$ receptor blockade and facilitation support the concept that a disturbance of $GABA_A$ receptor-mediated inhibition might contribute to hyperexcitability in human cortex. However, detailed patch-clamp analysis of $GABA_A$ receptor-mediated events has revealed no differences between epileptogenic human cortex and normal rat neocortex.

The role of $GABA_B$ receptors in focal epilepsies is less clear. Antagonists of $GABA_B$ receptors have minimal effects on normal excitatory synaptic responses but do prolong the duration of bicuculline-induced PDSs and increase their frequency. Interestingly, $GABA_B$-receptor agonists are also proconvulsant in the neocortex. Most likely, the tonic inhibition mediated by $GABA_B$-receptor agonists is overridden in the neocortex by the depressant effect of $GABA_B$ agonists on GABA release, which in turn attenuates $GABA_A$-mediated inhibition.

Background

Ionic Mechanism of $GABA_A$ Receptor-Mediated Inhibition

The proper functioning of GABAergic inhibition depends not only on the adequate release and the appropriate density of intact $GABA_A$ receptors, but also on the prevailing ionic gradient. This gradient is governed by the distribution of two ion species: the chloride gradient, which is maintained at a more negative level (in adult CNS neurons) than that of the resting membrane potential by the operation of a potassium-coupled chloride outward transport (a neuron-specific isoform of these transporters (KCC2) has been cloned), and the bicarbonate gradient ($GABA_A$-receptor channels are partially permeable to bicarbonate ions with a permeability ratio chloride:bicarbonate of 1:0.2). This small bicarbonate permeability has a marked effect on the reversal potential of $GABA_A$ inhibition, because the bicarbonate gradient across the neuronal membrane is (due to the rapid diffusion of CO_2) governed by the proton gradient, which has an equilibrium potential of about −10 mV. Previous estimates indicate that the partial permeability for bicarbonate, together with the bicarbonate equilibrium potential, causes a difference of about 15 mV between the chloride equilibrium potential and the $GABA_A$ equilibrium potential.

Previous studies on rat hippocampal neurons, as well as on neocortical neurons in human epileptogenic tissue, have demonstrated depolarizing $GABA_A$ responses. A key question concerns the mechanism of this depolarizing $GABA_A$ inhibition. The latter may be due to a reduced outward transport of chloride via KCC2, as occurs in early postnatal stages. The consequence, a shift of the chloride reversal potential (from about −85 mV) toward passive distribution (governed by the resting membrane potential, near −70 mV), may cause a depolarizing $GABA_A$ response because of the partial bicarbonate permeability. Alternative explanations include the following possibilities. First, aberrant $GABA_A$ receptors are expressed during the development of epilepsy and exhibit a different relative bicarbonate permeability, thereby causing the depolarizing $GABA_A$ reversal potential despite unaltered chloride outward transport and bicarbonate gradient. Second, there may be a change in the bicarbonate gradient per se. And third, there may be an upregulation of inwardly directed sodium–potassium-coupled chloride transporters (e.g., NKCC1).

Alterations in $GABA_B$ Receptor-Mediated Inhibition

The role of $GABA_B$ receptors in the initiation and spread of epileptiform activity is unclear. Part of the difficulty in resolving a possible role of $GABA_B$ receptor in epilepsy, apart from the lack of subtype-specific agonists and antagonists, stems from their presence at both postsynaptic and presynaptic sites. Changes in postsynaptic receptors would have different consequences on neuronal excitability than would changes at the presynaptic GABA or glutamatergic terminals.

In the healthy neocortex, synaptic responses evoked by single stimuli are only marginally affected by a blockade of $GABA_B$ receptors. Two possible explanations exist for this observation: First, the $IPSP_B$ is relatively weaker than the $IPSP_A$ and hence the reduction of $IPSP_B$ in the presence of intact $GABA_A$ inhibition has relatively little effect. And, second, the time course is so slow (a peak near 150 ms) that the $IPSP_B$ overlaps only slightly with a normal, brief excitatory postsynaptic potential (EPSP). The $IPSP_A$, by contrast, shortens the EPSP directly. Only when the $IPSP_A$ is attenuated and the resulting PDS lasts for more than 100 ms, is activity seen to be markedly curtailed by the $IPSP_B$. Of particular interest are presynaptic $GABA_B$ receptors that cause a frequency-dependent depression of both $IPSP_A$ and $IPSP_B$ by exerting a negative feedback of GABA on release. The attenuation of $GABA_A$ inhibition exerted through presynaptic $GABA_B$ receptors may therefore contribute to the initiation of epileptiform activity. Concurrently, however, presynaptic $GABA_B$ receptors at excitatory terminals would also reduce excitatory transmission; thus, the net effect of this presynaptic $GABA_B$ influence depends (at least in part) upon the diffusional spread of released GABA to these two sites.

A virtual absence of $GABA_B$ receptor-mediated effects has been demonstrated in the hippocampus in an animal model of temporal lobe epilepsy (self-sustained limbic status epilepticus). Neither $IPSP_B$ nor paired-pulse depression of $IPSP_A$, an index for presynaptic $GABA_B$ receptors, were detected, suggesting that $GABA_B$ receptors are impaired. This finding seems difficult to integrate with the notion that a use-dependent attenuation of $GABA_A$ inhibition contributes to epileptiform activity; according to that notion, robust, frequency-independent inhibition should limit hyperexcitability. However, $GABA_{B1}$-receptor knockout mice present with spontaneous seizures, thus providing some evidence that a lack of $GABA_B$ receptors may indeed contribute to epilepsy.

Methods

All methods have been described previously. In brief, slices from human cortical tissue are cut with a vibratome and stored in beakers containing artificial cerebrospinal fluid (ACSF) equilibrated with carbogen. Individual slices are transferred to a submersion-type chamber, where intracellular recordings with sharp microelectrodes are carried out. The chamber is continuously perfused with ACSF at constant temperature (32 °C). Electrodes are usually filled with a solution containing 1 M potassium acetate and 1 mM KCl (titrated to pH 7.2). In some experiments, electrodes are filled with 1 M KCl solution. Typically we recorded neurons in layer 2 or 3, using standardized protocols to facilitate comparison between the different tissues. Synaptic responses are evoked with stimulus intensities between 2 and 20 V (100 or 200 μs, 2 V increments) in control condition and during application of various drugs. We routinely measured current–voltage relationships with current pulses of incrementing amplitudes (−0.5 to about +1 nA; duration, 600 ms) to evaluate firing properties and neuronal input resistance. A second series of current injections is applied while synaptic responses are elicited with a constant stimulus (usually 12–16 V) to estimate reversal potentials and synaptic conductances. The temporal properties of synaptic responses are evaluated with a paired-pulse paradigm – i.e., two identical stimuli applied at incrementing intervals (50–1400 ms in 50 ms increments, every 10 s). The kinetics of chloride extrusion are evaluated by measuring the amplitudes of synaptic responses following cessation of current injections (0.5, 1, and 2 nA for 0.5, 1, and 2 min) and fitting the recovery with an exponential function.

Recent Results

Alterations in $GABA_A$ Receptor-Mediated Inhibition

Synaptic potentials elicited in human cortical neurons exhibit some similarities to bicuculline-induced PDSs of rodent cortex. In particular, they usually exhibit a steep increase in amplitude with increasing stimulus intensities, in some cases even exhibiting almost 'all or none' behavior. Yet, synaptic responses are, in most cases, devoid of the barrage of APs on top of the slow synaptic depolarization. Therefore, I refer to these synaptic responses in human epileptogenic tissue as DSs. DSs exhibit strong voltage dependence; i.e., they increase with membrane hyperpolarization and decrease with depolarization. In some neurons, the peak of the DS attains the same potential, regardless of the cell's membrane potential preceding the DS, i.e. during the peak of the DS membrane potential is essentially clamped to a certain value. Since the DS peak amplitude also exceeds the threshold for current-induced generation of APs, I assume that the DSs represent a state of such high conductance that it precludes the initiation of APs.

To delineate the receptor mechanisms, we applied D-APV (*N*-methyl-D-aspartate (NMDA)-type glutamate receptor antagonists, usually 20 μM) alone and together with CNQX (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid/kainate-type receptor antagonist, usually 10 μM). D-APV alone caused a slight depression (about 10%) in the amplitudes of the DSs; this result contrasts with earlier observations indicating a marked depression of synaptic responses by D-APV in human epileptogenic cortex. The reported lack of correlation between the magnitude of NMDA receptor-mediated responses and the severity of epilepsy is consistent with our data. The combined application of D-APV and CNQX reduced the DSs to a great extent, but a depolarizing synaptic component remained in some of the neurons. Application of bicuculline (50 μM) eliminated the remaining synaptic depolarization, suggesting that this component of the response is mediated by $GABA_A$ receptors. Quantification of the reversal potential of the remaining component revealed a less-negative value compared with rat cortical neurons (but with a fairly large standard deviation). Further analysis of the data revealed a clear dichotomy between reversal potentials; about half of the human cortical neurons exhibited reversal potentials indistinguishable from those observed in rat cortex, and another half exhibited a reversal potential close to −55 mV. This less-negative reversal potential would suggest a chloride gradient governed by passive distribution near the resting potential together with the partial bicarbonate permeability of the $GABA_A$ channels.

Most recently, I have begun to evaluate the ionic mechanisms for these depolarizing $GABA_A$ responses in human epileptogenic neurons, using intracellular chloride injections to ascertain the methods, parallel experiments were carried out in rat cortical neurons. Recordings from rat neurons with KCl electrodes shifts the $IPSP_A$ peak toward depolarization, with the response merging with the EPSP. In fact, this response looked strikingly similar to those recorded under normal conditions (K-acetate filled electrode) in some of the neurons from human epileptogenic tissues. Chloride loading by current injection resulted in a further increase of the synaptic component. On cessation of the injection current, the amplitudes of the synaptic responses recovered with a time constant of about 10 s, as previously shown in guinea-pig cortex. To reduce ambiguities concerning the kinetics of chloride extrusion, we also evaluated the recovery kinetics of synaptic responses in the presence of CNQX, D-APV, and CGP 55845A (a $GABA_B$-receptor antagonist acting at both pre- and postsynaptic sites). Under these conditions, the time course of recovery from chloride injections was on average similar to the standard conditions (near 10 s).

In human neurons, the time constant of recovery was much larger, on average about 20 s, for both control conditions and in the presence of CNQX, D-APV, and CGP 55845A. Interestingly, 2 of 10 human cortical neurons investigated to date have exhibited a time constant of recovery close to rat neurons (8 s).

Taken together, these data indicate that $GABA_A$ receptor-mediated inhibition is impaired in some neurons of human epileptogenic cortex. However, unlike the bicuculline-model in the rodent cortex, the receptors are unaltered. Instead, the basis for a $GABA_A$ receptor-mediated depolariziation is the altered contribution is the altered ionic gradient. The pathophysiologically altered ionic gradient of $GABA_A$ inhibition in about half of the neurons is probably due to impaired net outward chloride transport as initially reported. A depolarizing $GABA_A$ response generating a high conductance state at the peak would account for the large DS depolarization devoid of APs. This high conductance also suggests that GABA release and the $GABA_A$ receptors are essentially unaltered, as previously shown with patch-clamp recordings in human neurons. However, the crucial change, an altered ionic gradient, would have been undetectable with whole-cell patch-clamp recordings, because the filling solution of the electrodes rapidly equilibrates with the cell's interior and thus determines the intracellular concentration of ions.

$GABA_B$ Receptor-Mediated Inhibition in Human Epileptogenic Cortex

Previous data suggested that the $GABA_B$ receptor-mediated postsynaptic inhibition is rather small in the human epileptogenic cortex. In more recent experiments, we evaluated the properties of $GABA_B$ receptor-mediated inhibition in a larger number of tissue samples and quantified inhibition with established methods. On average, the postsynaptic $GABA_B$ receptor-mediated inhibition was significantly smaller in epileptogenic tissue (about 5 nS) than in human neurons from tumor resections without history of epilepsy (17 nS). To evaluate possible differences in the magnitude of $IPSP_B$ conductance between various clinical groups, we segregated the data according to the leading clinical symptom into tissue from: (1) TLE with Ammon's horn sclerosis, (2) TLE without Ammon's horn sclerosis, (3) tumors with epilepsy, (4) cortical dysplasia, (5) lesion with epilepsy, (6) frontal lobe with epilepsy, and (7) tumors without epilepsy. The $IPSP_B$ conductances in neurons from the groups 1–6 were significantly smaller than those in neurons from non-epileptogenic human tissues but not significantly different from each other. Although there were in each group a few neurons (around 5%) that exhibited fairly large $IPSP_B$ conductances, the data generally indicate a marked depression of $GABA_B$ receptor-mediated conductance in the majority of neurons.

Of course, this apparent conductance also depends on the amount of GABA released and hence the low conductance may be due to insufficient GABA release.

We therefore applied the established $GABA_B$ receptor agonist baclofen at 2 μM, close to the concentration yielding half-maximal effects in the rat neocortex (1 μM), and determined the induced conductance in both human and rat neurons. On average, the baclofen-induced conductance was about half of that induced by synaptic stimulation in both rat and human neurons. We considered the possibility that the average values may be misleading because some neurons may have 'extrasynaptic' $GABA_B$ receptors not accessible by synaptically released GABA, while others may have a reduced release. We therefore compared the conductance increase during the $IPSP_B$ with the conductance increase induced by exogenous baclofen. Plotting the data revealed a very good correlation: Human neurons exhibiting a small $IPSP_B$ conductance also exhibited minimal responses to baclofen. Conversely, neurons with a high $IPSP_B$ conductance also demonstrated large baclofen-induced conductance. On average, the slope was ~2, indicating that in each neuron the $IPSP_B$ conductance was about twice as large as the baclofen-induced conductance. This result indicates that the small $IPSP_B$ conductance is not due to insufficient GABA release, but rather to impairments in postsynaptic receptor function or density. That is, if the small and variable $IPSP_B$ conductances were due to a variation of release, a constant conductance should have been observable, due to the constant level of exogenous baclofen. These data provide functional evidence for a reduced function or density of $GABA_B$ receptors in human epileptogenic cortex, and are consistent with immunohistochemical data from human epileptogenic hippocampus, revealing marginal immunosignals for $GABA_B$ receptors, except in a few neurons. The latter cells would correspond to our finding of a small percentage of neurons in human epileptogenic tissues with large $IPSP_B$ conductance.

To evaluate presynaptic $GABA_B$ receptor-mediated effects, we employed a paired-pulse paradigm in human neurons, and in rat cortical neurons treated with bicuculline (to induce a defined hyperexcitability). In the human cortical neurons, paired stimulation of DSs yielded constant amplitudes at all interstimulus intervals. This constancy was at odds with the pronounced failure of bicuculline-induced PDSs of rat cortical neurons at interstimulus intervals up to about 1 s. At these intervals, a second PDS was virtually abolished and only a small EPSP remained, yielding an average depression of PDS amplitude by 75% (at 200 ms) in rat neurons. We tested our hypothesis that this well-established phenomenon was mediated by $GABA_B$ receptors by applying the $GABA_B$-receptor antagonist CGP 55845A, known to also be effective at presynaptic sites in the cortex. CGP 55845A eliminated the paired-pulse depression of the PDS; PDSs were virtually constant at all interstimulus intervals. Comparison of bicuculline-induced PDSs in rat cortical neurons with the DSs present in human epileptogenic neurons is hampered for several reasons (e.g., amounts of transmitter released) and we therefore also tested the effects of bicuculline in human neurons. Bicuculline converted the DS responses into PDSs, and paired-pulse stimulation revealed failures of PDSs in some neurons, as was the case in rat neurons. However, in other neurons the bicuculline-induced PDSs were only slightly attenuated with interstimulus intervals of, for example, 200 ms. The depression of a second PDS at 200 ms averaged 25% in human neurons, significantly less than that seen in rat neurons. The small attenuation of bicuculline-induced PDSs in human cortical neurons was also antagonized by CGP 55845A.

Our data indicate that both pre- and postsynaptic $GABA_B$ receptors are impaired in the human epileptogenic neocortex. The transient failure of bicuculline-induced PDSs in the rat cortex, eliminated by the $GABA_B$-receptor antagonist CGP 55845A, suggest that $GABA_B$ receptors normally limit the maximal frequency of PDSs. The frequency-independent DSs seen in human cortical neurons from epileptogenic tissues therefore imply that impaired $GABA_B$ receptors may be a cause of seizure activity. This conclusion complements existing data that decreased $GABA_B$ function may be a consequence of epilepsy. Together, the data indicate that deficits of $GABA_B$-receptor function can be both cause and consequence, and thus may form a vicious circle.

Future Goals

The depolarizing $IPSP_A$ in about half of the neurons of human epileptogenic cortex may account for some of the hyperexcitability seen in this tissue. These depolarizing responses probably contribute to the steep increase of synaptic responses with increasing stimulus intensities. This relationship has two conceivable consequences: first, there is a shift of the half-maximal stimulus intensity (i.e., any input will produce a larger synaptic potential); and second, there is a steeper slope of the input–output curve (i.e., any increase in input would cause a supranormal increase of synaptic responses). It remains to be tested whether the alteration of input–output relations correlate with clinical parameters of the patients (e.g., seizure frequency).

The slow recovery of $IPSP_A$ in human cortical neurons, following chloride injections indicates an impeded chloride outward transport. This observation leads to several important questions: which route of chloride flux is impaired, and can this mechanism account for a chloride equilibrium below resting membrane potential? Voltage-activated chloride channels, for instance, may contribute to chloride efflux when chloride is artificially elevated by the injection (if the channels are substantially activated near resting potential), yet such channels cannot easily account for a chloride equilibrium potential below the

resting membrane potential. Nevertheless, characterization of these currents in human and rat neurons is planned. Also downregulation of NKCC1 (usually believed to mediate inward chloride transport) may slow the recovery from injection if it proceeds in a backward fashion at elevated intracellular chloride levels. An upregulation of NKCC1 might shift the balance between inward and outward chloride transport rates and cause depolarizing $GABA_A$ responses – as in hippocampal granule cells – but whether such upregulation could impede chloride efflux is unclear. To further evaluate the mechanisms of disturbed chloride homeostasis in human cortical neurons, we will evaluate the effects of available blockers of chloride fluxes on steady-state levels under normal conditions and on the kinetic of recovery from chloride loading. Together with staining of the recorded neurons (to obtain morphological characterization) and immunohistochemistry, we might resolve the mechanism of depolarizing $GABA_A$ responses.

The reduced efficacy of pre- and postsynaptic $GABA_B$ receptors suggested by our data has two implications pertinent to hyperexcitability. First, the reduced efficacy of presynaptic $GABA_B$ receptors may contribute to larger synaptic responses per se. If tonically activated by ambient GABA, they normally might attenuate the release of GABA and glutamate. Second, the attenuated $GABA_B$-receptor effects have profound consequences for temporal properties of synaptic responses. Previous data suggested that depolarizing $GABA_A$ responses mediate interictal activity of human epileptogenic hippocampus. A similar spontaneous synaptic activity near 1 Hz was observed in some of the cortical neurons reported in this article as well. The $IPSP_A$ conductance decreases rapidly by about 80%, when stimulus frequency is increased from 0.1 to 1 Hz, due to activation of presynaptic $GABA_B$ receptors. Thus, for GABA-depolarizing events to occur spontaneously at frequencies near 1 Hz, not only a depolarizing $GABA_A$ response but also an impaired $GABA_B$-receptor function must be present.

I had previously assumed that the frequency-dependent depression of inhibition via presynaptic $GABA_B$ receptors might be a crucial mechanism for the initiation and spread of epileptiform activity. At first glance, this prediction seems difficult to equate with the present data, indicating impaired presynaptic $GABA_B$ receptors in human epileptogenic cortex. However, the concept of $GABA_B$ participation in seizure initiation and spread may still be valid, if different properties of focal and perifocal tissues are considered. Our data are probably from focal epileptogenic tissue. A disinhibition via presynaptic $GABA_B$ receptors is very unlikely in this case; instead, impaired $GABA_B$ receptors allow repetitive $GABA_A$-depolarizing events to contribute crucially to interictal activity. But in perifocal tissue, containing normally functioning $GABA_B$ receptors, the interictal activity may, at sufficiently high frequency, cause a use-dependent depression of inhibition and facilitate recruitment of larger arrays of neurons. Conceivably, that disinhibition may cause the transition from a small subclinical focus to clinically detectable focal activity.

Acknowledgements

Some of the $GABA_B$-related experiments were done by L. Spilker during her PhD work. I am most grateful to Dr. T.-N. Lehmann for providing the human tissues, to Prof. H.-J. Meencke and his team at the Epilepsiezentrum Berlin–Brandenburg for their care for the patients and their interest in my work, and to Dr. S. Gigout for helpful suggestions on the manuscript.

Differential Alterations of $GABA_A$ Receptors in Epilepsy

J-M Fritschy, University of Zurich, Zurich, Switzerland

Introduction

$GABA_A$ receptors mediate most of the fast synaptic inhibitory transmission in mammalian brain. They belong to the family of ligand-gated ion channels and form multimeric GABA-gated channels selectively permeable to Cl^- and HCO_3^- ions. They are encoded by a large family of subunit genes (α1–6, β1–3, γ1–3, δ, ε, π, θ, ρ1–3), whose differential assembly into receptor complexes gives rise to multiple $GABA_A$ receptor subtypes differing in functional and pharmacological properties. $GABA_A$ receptors are a major target for drugs used clinically for the treatment of anxiety, sleep disorders, muscle spasms, and epilepsy. $GABA_A$ receptors are widely expressed in the CNS, and influence all major brain functions by controlling excitability of postsynaptic neurons and synchronization of neuronal networks.

The convulsant effects of $GABA_A$ receptor antagonists, and conversely the clinically relevant antiepileptic action of classical benzodiazepines such as diazepam, led to the concept that epileptic seizures reflect an imbalance between excitatory and inhibitory transmission in the brain. As a corollary, a deficit in $GABA_A$ receptor-mediated transmission is often suspected as an underlying cause of recurrent seizures.

However, unlike acute drug effects which occur in an intact system, drug effects during epileptogenesis and associated with recurrent seizures in chronic epilepsy likely reflect pathological disturbances that may have multiple origins. Furthermore, the simple view that GABAergic transmission acts like a break to prevent overexcitation of neuronal circuits has been challenged by the highly sophisticated anatomical and functional organization of GABAergic interneurons in cerebral cortex. Furthermore, in epileptic tissue, neuronal networks undergo extensive rewiring that considerably changes the function of interneurons and their control over pyramidal cells. Therefore, the concept of imbalance between inhibitory and excitatory GABAergic/glutamatergic transmission has to be revised, to integrate the fact that the role of GABAergic transmission in epilepsy is much more complex than suggested by simple pharmacological experiments.

This article will address two major issues about the involvement of $GABA_A$ receptors in epilepsy. First, we will discuss the relevance of tonic inhibition mediated by extrasynaptic receptors for the control of neuronal excitability. Second, we will review the recent results indicating that alterations in $GABA_A$ receptor assembly, subunit composition, trafficking, and posttranslational modification can be altered in experimental models of epilepsy and potentially also in patients with epilepsy.

Background

$GABA_A$ receptor-mediated transmission is essential for fine tuning of neuronal networks and generation of rhythmic, synchronized neuronal activities. Conceptually, both a decrease and an increase in GABAergic tone in cortical circuits can facilitate seizure initiation and propagation. In the first case, reduced inhibition might favor hyperexcitability; in the second case, enhanced inhibition might result in hypersynchronization and generation of rhythmic discharges. To establish whether an alteration in $GABA_A$ receptors is linked with epileptogenesis and/or recurrent seizures in chronic epilepsy, one has to consider several mechanisms that altogether determine $GABA_A$ receptor function:

1. Regulation of $GABA_A$ receptor assembly, trafficking, synaptic clustering, and cell-surface mobility. All these processes might be disturbed by mutations in $GABA_A$ receptor subunits and/or associated proteins, which might underlie familial forms of epilepsy. Collectively,

Introduction

$GABA_A$ receptors mediate most of the fast synaptic inhibitory transmission in mammalian brain. They belong to the family of ligand-gated ion channels and form multimeric GABA-gated channels selectively permeable to Cl^- and HCO_3^- ions. They are encoded by a large family of subunit genes (α1–6, β1–3, γ1–3, δ, ε, π, θ, ρ1–3), whose differential assembly into receptor complexes gives rise to multiple $GABA_A$ receptor subtypes differing in functional and pharmacological properties. $GABA_A$ receptors are a major target for drugs used clinically for the treatment of anxiety, sleep disorders, muscle spasms, and epilepsy. $GABA_A$ receptors are widely expressed in the CNS, and influence all major brain functions by controlling excitability of postsynaptic neurons and synchronization of neuronal networks.

The convulsant effects of $GABA_A$ receptor antagonists, and conversely the clinically relevant antiepileptic action of classical benzodiazepines such as diazepam, led to the concept that epileptic seizures reflect an imbalance between excitatory and inhibitory transmission in the brain. As a corollary, a deficit in $GABA_A$ receptor-mediated transmission is often suspected as an underlying cause of recurrent seizures.

However, unlike acute drug effects which occur in an intact system, drug effects during epileptogenesis and associated with recurrent seizures in chronic epilepsy likely reflect pathological disturbances that may have multiple origins. Furthermore, the simple view that GABAergic transmission acts like a break to prevent overexcitation of neuronal circuits has been challenged by the highly sophisticated anatomical and functional organization of GABAergic interneurons in cerebral cortex. Furthermore, in epileptic tissue, neuronal networks undergo extensive rewiring that considerably changes the function of interneurons and their control over pyramidal cells. Therefore, the concept of imbalance between inhibitory and excitatory GABAergic/glutamatergic transmission has to be revised, to integrate the fact that the role of GABAergic transmission in epilepsy is much more complex than suggested by simple pharmacological experiments.

This article will address two major issues about the involvement of $GABA_A$ receptors in epilepsy. First, we will discuss the relevance of tonic inhibition mediated by extrasynaptic receptors for the control of neuronal excitability. Second, we will review the recent results indicating that alterations in $GABA_A$ receptor assembly, subunit composition, trafficking, and posttranslational modification can be altered in experimental models of epilepsy and potentially also in patients with epilepsy.

Background

$GABA_A$ receptor-mediated transmission is essential for fine tuning of neuronal networks and generation of rhythmic, synchronized neuronal activities. Conceptually, both a decrease and an increase in GABAergic tone in cortical circuits can facilitate seizure initiation and propagation. In the first case, reduced inhibition might favor hyperexcitability; in the second case, enhanced inhibition might result in hypersynchronization and generation of rhythmic discharges. To establish whether an alteration in $GABA_A$ receptors is linked with epileptogenesis and/or recurrent seizures in chronic epilepsy, one has to consider several mechanisms that altogether determine $GABA_A$ receptor function:

1. Regulation of $GABA_A$ receptor assembly, trafficking, synaptic clustering, and cell-surface mobility. All these processes might be disturbed by mutations in $GABA_A$ receptor subunits and/or associated proteins, which might underlie familial forms of epilepsy. Collectively,

mechanisms regulating $GABA_A$ receptor synaptic targeting, clustering, and cell-surface mobility are responsible for short- and long-term regulation of the number of receptor molecules available for synaptic transmission.
2. Regulation of receptor properties by posttranslational modification, with phosphorylation being one of the major covalent modifiers. Increasing evidence indicates that chemical modification affects receptor trafficking and cell surface expression, as well as intrinsic functions of the ligand-gated ion channel.
3. Regulation of subunit expression, at the transcriptional and translational level. This mechanism determines the abundance and subunit composition of $GABA_A$ receptors in a given cell type or brain region, and is known to be of relevance for alterations of physiological network function (such as hormonal fluctuations during the ovarian cycle and after delivery), as well as for pathophysiological conditions, including neurological diseases and drug abuse.

GABAergic synaptic transmission is regulated also by modifications affecting presynaptic function (regulation of GABA synthesis, storage, and reuptake; modulation of GABA release probability; etc.) and $GABA_B$ receptors, but these aspects are outside the scope of the present review.

Studies of $GABA_A$ receptors in epilepsy have focused on two major diseases, namely absence epilepsy and temporal lobe epilepsy (TLE). In both cases, alterations of $GABA_A$ receptor expression, pharmacology, and functional properties have been studied in detail over many years. Recent results highlighting novel features will be discussed in more detail in the subsections 'Phasic–Tonic Inhibition' and '$GABA_A$ Receptor Alterations in Epilepsy.' Importantly, changes observed in experimental models need to be compared to alterations taking place in the brain of TLE patients. The availability of tissue resected at surgery from patients with intractable seizures represents an invaluable source for studying the pathophysiology of the disorder. Conversely, the functional consequences of mutations associated with familial forms of epilepsies are not readily amenable for analysis in patients, but can be investigated in recombinant expression systems and in transgenic mouse models. A close link between the clinic and experimental research is, therefore, a prerequisite for successful studies of the mechanisms of epilepsy.

Methods

Experimentally, absence seizures can be genetically determined (GAERS, WAG/Rij rats) or induced pharmacologically; for example, by treatment with a cholesterol biosynthesis inhibitor, AY-9944. TLE is mimicked by induction of a prolonged status epilepticus in mice or rats (either upon repetitive electrical stimulation of sensitive regions of the temporal lobe or by injection of a convulsant, such as kainic acid or pilocarpine), which is followed in most cases by the occurrence of spontaneous recurrent seizures. Kindling, either electrical or chemical, is also used to model TLE in rodents, with the major difference that the animals do not present with recurrent seizures. Despite their usefulness, these models of TLE are limited by the fact that experimental animals have generalized seizures (unlike patients with TLE), and epileptogenesis frequently is accompanied by patterns of neuronal damage, notably in the extrahippocampal regions, that are not observed clinically.

An alternative model of TLE was introduced, in which chronic partial seizures are induced in adult mice upon unilateral injection of kainic acid into the dorsal hippocampus. These mice have a nonconvulsive status epilepticus that subsides spontaneously and is followed by a latent period of about 2 weeks prior to the onset of spontaneous partial seizures. During the latent period and initial chronic phase, extensive neuronal damage occurs in the CA1 region, accompanied by a strong astrogliosis and, most remarkably, a prominent dispersion of dentate gyrus granule cells. The latter feature is reminiscent of the granule cell dispersion occurring in a subset of patients with TLE. All in vivo models are used for a wide range of investigations, including molecular biology, biochemistry, histology, electrophysiology, and behavior. Alterations of $GABA_A$ receptor assembly, localization, and function can be related to distinct stages of epilepsy and can be investigated further by pharmacology and/or genetic manipulation.

Tissue resected at surgery from patients with intractable seizures likewise is amenable to histological, electrophysiological, or biochemical analysis. Thus, the expression of $GABA_A$ receptor subunit genes can be analyzed by in situ hybridization, providing insight into their regional and cellular distribution, as well as relative level of expression. More specific information about the subcellular localization of receptor subunits can be obtained with immunohistochemistry using subunit-specific antibodies. This method cannot distinguish, however, between intracellular and cell-surface proteins and provides no information about 'functional' receptors, which are a heteromeric protein complex located at synaptic sites. Radioligand binding studies, including autoradiography, allows the investigator to distinguish functional receptors (which bind the radioligand), but have limited spatial resolution and do not distinguish among $GABA_A$ receptor subtypes, which differ in subunit composition. For studies of $GABA_A$ receptors, the high affinity and specificity of benzodiazepine site ligands (e.g., ^{3}H-flumazenil) make them very well suited for autoradiography. The major limitation of these studies in tissue obtained from surgery is the lack of appropriate 'control' tissue. Among potential 'control,' alternatives are apparently healthy tissue

resected along with the diseased tissue, resections derived from tumor-related epilepsies, postmortem brain tissue from autopsy, or brain tissue from another mammalian species.

Recent Results

Phasic–Tonic Inhibition

Phasic and tonic neurotransmission are used to discriminate between the short, spatially restricted action of transmitters activating postsynaptic receptors, and the continuous activation of receptors localized peri- or extrasynaptically by transmitter spillover into the extracellular space. Although tonic GABAergic inhibition has been largely overlooked in the past, it might play a major role in modulating neuronal activity, given that most of the total charge transported by ligand-gated ion channels occurs via tonic transmission (due to the prolonged duration of tonic transmission compared to the short channel opening times associated with postsynaptic receptors).

The subunit composition of $GABA_A$ receptors appears to be a major determinant of phasic and tonic GABAergic transmission. The γ2 subunit, which is present in the vast majority of $GABA_A$ receptor subtypes (along with α and β subunit variants), is required for clustering of the receptor at postsynaptic sites. Multiple γ2-containing $GABA_A$ receptor subtypes (also containing α1-, α2-, α3-, and, in part, α5-$GABA_A$ receptor subunits) indeed are clustered postsynaptically in various neuronal populations. A major additional property of the γ2 subunit is to confer diazepam sensitivity to receptor complexes containing these α subunit variants. It is important to note, however, that $GABA_A$ receptors containing the γ2 subunit are not necessarily confined to postsynaptic sites. For instance, most α5-containing $GABA_A$ receptors are extrasynaptic, contribute to tonic inhibition modulated by diazepam, and regulate the excitability of pyramidal cells in neocortex and hippocampus. Consequently, postsynaptic and extrasynaptic receptors formed with the γ2 subunit are diazepam-sensitive and contribute to the pharmacological profile of classical benzodiazepine-site agonists.

Receptors containing the δ subunit, in contrast to the γ2 subunit, appear to be excluded from postsynaptic sites. The δ subunit is associated mainly with the α4 subunit – e.g., in thalamus and dentate gyrus – or the α6 subunit in cerebellar granule cells. These receptors are diazepam-insensitive but are selectively modulated by GABA agonists such as gaboxadol and muscimol as well as neurosteroids, pointing to a possible novel target for drug therapy. Importantly, $GABA_A$ receptors containing the α4 and/or δ subunit exhibit unique functional properties that may contribute to epileptogenesis and recurrent seizures upon altered expression, as occurs in TLE. δ Subunit-null mice exhibit enhanced sensitivity to pentylenetetrazol-induced seizures, but it is not established whether this sensitivity reflects a reduced tonic inhibition in thalamocortical circuits or a reduced availability of binding sites for endogenous neurosteroids with anticonvulsant activity.

Ectopic overexpression of the α6 subunit has been used to assess the functional and pharmacological significance of enhanced tonic inhibition. Such transgenic mice overexpress α1/α6/β/γ2-$GABA_A$ receptors and exhibit a five-fold increase in tonic inhibition in CA1 pyramidal cells. Behaviorally, these mice are essentially normal, but are more sensitive than wild type to the convulsant effects of $GABA_A$ receptor antagonists, suggesting an overall decrease in GABAergic synaptic strength.

$GABA_A$ Receptor Alteration in Epilepsy

Changes in subunit composition

Alterations in $GABA_A$ receptor subunit expression and composition in epilepsy are well documented in human and in animal models. Given the heteromeric structure of $GABA_A$ receptor subtypes, a change in expression of a given subunit is often taken as evidence for a change in subunit composition of $GABA_A$ receptors present in this cell or brain area. However, since the complete $GABA_A$ receptor subtype repertoire of neurons in most brain regions is not yet established, these interpretations need to be treated with caution.

It should be emphasized, furthermore, that many of the studies focusing on transcriptional alterations have not used quantitative methods and did not address the issue whether gene transcription or mRNA half-life were changed. Furthermore, the relevance of these changes for the function of $GABA_A$ receptors is difficult to assess in most studies; the major impact on function of receptor localization, targeting, and regulation must be assessed, in addition to the mere abundance of a given subunit mRNA. There are very few studies, indeed, which have demonstrated a direct correlation between altered $GABA_A$ receptor subunit gene transcription and a corresponding functional alteration.

Changes in $GABA_A$ receptor subunit protein levels are also well documented in the hippocampal formation and neocortex of patients with partial seizures, as well as in a variety of TLE models – mainly using immunohistochemistry. Both a decrease and an increase in specific subunits have been reported. There are some discrepancies among studies, but it is not clear whether they relate to methodological differences in the analysis or are due to differences among the models. Importantly, besides a reduction of $GABA_A$ receptor subunits in regions affected by neurodegeneration, a subunit-specific *increase* has been reported in many studies, notably in the dentate gyrus. It is not known whether this increase leads to abnormal hypersynchronization of neuronal networks or represents a compensatory reaction to protect against recurrent seizures.

Recent experimental studies extend previous work by demonstrating a major contribution of extrasynaptic $GABA_A$ receptors to the changes in inhibitory function that might underlie epileptogenesis and occurrence of chronic recurrent seizures. For example, in the mouse pilocarpine model of TLE, a profound decrease in δ subunit immunoreactivity was observed, correlating with a redistribution of the γ2 subunit from synaptic to perisynaptic sites, where it assembles with the α4 subunit (which is normally associated with the δ subunit). A downregulation of the α5 subunit also occurs in CA1 pyramidal cells of pilocarpine-treated rats, resulting in a loss of diazepam-sensitive tonic inhibition seen upon blockade of GABA reuptake. Despite this change, tonic inhibition is enhanced in pyramidal cells, suggesting compensatory upregulation of other extrasynaptic $GABA_A$ receptors, possibly containing the α4 subunit.

Taken together, changes in $GABA_A$ receptor subunit expression and subsynaptic localization, as occurring in TLE and in experimental models, are open for interpretation. First, it is not established whether they reflect changes in connectivity, for example, due to axonal sprouting and synaptogenesis in response to the selective loss of specific populations of interneurons, or changes in the nature of inhibition received by a given cell type, as determined by the distinct functional properties of specific $GABA_A$ receptor subtypes. The reduction in synaptic receptors in favor of extrasynaptic receptors, as discussed in the previous paragraph, might represent an example of functional reorganization. However, in the pilocarpine model, it has been suggested that perisomatic inhibition of CA1 pyramidal cells is increased, whereas dendritic inhibition is decreased as a consequence of differential cell loss and circuit reorganization. Second, neurogenesis should be considered as an additional factor likely to play an important role in the long-term maintenance of synaptic circuits in the dentate gyrus. The effects of epileptogenesis and recurrent seizures on neurogenesis are still debated. Some reports suggest that seizures enhance neurogenesis, but disturb the migration of new born cells, which ultimately from abnormal circuits. Other reports suggest, on the contrary, that neurogenesis might be suppressed in TLE, notably when the subgranular zone of the dentate gyrus is disrupted due to granule cell dispersion. More information will be required before we understand how $GABA_A$ receptor-mediated transmission is adjusted in epileptic dentate gyrus.

Region-specific changes in $GABA_A$ receptor function and expression have also been reported in models of absence epilepsy. In the pharmacological model of absence seizures induced by neonatal treatment with the cholesterol biosynthesis inhibitor AY-9944, a reduced expression of the α1 and γ2 subunit has been reported, with distinct sex differences and temporal profiles, correlating with the higher incidence of absence seizures in female rats. In the GAERS model of absence, $GABA_A$ receptor-mediated currents are altered selectively in the thalamic reticular nucleus (but not in ventrobasal complex or somatosensory cortex), with mIPSCs exhibiting enhanced amplitude and reduced decay kinetics. Such changes might be accounted for by expression of the β1 subunit. Finally, in WAG/Rij rats, a loss of $GABA_A$ receptor α3 subunit-immunoreactivity has been shown to occur without alteration in mRNA expression in the reticular thalamic nucleus, suggesting a local and highly specific deficit in $GABA_A$ receptor function as a possible cause of absence seizures in these mutant rats.

Changes in $GABA_A$ receptor phosphorylation

Although multiple $GABA_A$ receptors can be phosphorylated by various serine/threonine and tyrosine kinases in vitro and in vivo, the significance of this posttranslational modification for the regulation of $GABA_A$ receptor function and of network properties remains poorly understood. Available evidence indicates that phosphorylation might affect $GABA_A$ receptor channel function as well as trafficking to and from the cell surface and synaptic sites. The net effect of phosphorylation-associated changes can be an increase or a decrease in $GABA_A$ receptor function, depending on the subunit involved and on the balance between kinase and phosphatase activity. Of relevance for epilepsy is the recent report showing a deficit in endogenous $GABA_A$ receptor phosphorylation in tissue resected from patients with partial epilepsies, an abnormality which might favor seizure initiation and propagation. Importantly, in this study, the reduced extent of phosphorylation was not related to an overall decrease of $GABA_A$ receptors in the epileptic focus. Another approach to study potential deficits of $GABA_A$ receptor phosphorylation is to transplant membranes prepared from resected human brain tissue into oocytes. Functional $GABA_A$ receptors are inserted into the oocyte membrane within hours and their properties can be compared to $GABA_A$ receptors present in control, nonepileptic tissue. Such studies have revealed specific alterations in $GABA_A$ receptor phosphorylation selectively in 'epileptic' tissue, but the precise mechanisms underlying these alterations remain to be discovered.

Mutations affecting assembly and trafficking

An increasing number of mutations in $GABA_A$ receptor subunits have been associated with familial idiopathic epilepsies. In recombinant expression systems, these mutations typically affect single channel gating and/or cell surface availability of $GABA_A$ receptors. The precise mechanism underlying seizure generation in most of these cases remains ill-defined. The $GABA_A$ receptor γ2 subunit mutation R43Q associated with $GEFS^+$ has been reported to impair assembly and cell surface expression of $GABA_A$ receptors. The mutation causes an increase in intracortical excitability in patients (compared to

unaffected relatives). Intriguingly, the effect of the mutation was shown to be temperature-dependent, with cell surface expression being reduced in vitro at temperatures higher than 37 °C. However, since most $GEFS^+$ patients do not carry this mutation, such a mechanism alone is not sufficient for explaining the onset of seizures in $GEFS^+$. In fact, other studies have shown that the γ2(R43Q) mutation affects $GABA_A$ receptor cell surface trafficking and subunit composition independently of temperature. Another mutation, α1(A322D), associated with juvenile myoclonic epilepsy, is characterized by reduced subunit expression due to enhanced proteosomal degradation, probably a result of protein misfolding. Finally, mutations in the δ subunit (forming mainly extrasynaptic $GABA_A$ receptors) affect both channel kinetics and cell surface expression, and are associated with GEFS+.

Future Goals

The ultimate goals of experimental epilepsy studies are to better understand the pathophysiology of this disorder and to provide better therapeutic approaches than those available today. Since antiepileptic drugs do not 'cure' epilepsy but only suppress seizures, an ideal treatment strategy would be to prevent epileptogenesis, as least in acquired epilepsies. Since very little is known, yet, about the mechanisms of epileptogenesis, there is a crucial need for developing animal models that allow insight into the changes in neuronal circuits underlying emergence and recurrence of spontaneous seizures following a brain insult. The observation that prolonged seizure activity (status epilepticus) is required in experimental models of TLE for the emergence of recurrent seizures, after a latent phase of several days or weeks, was important for subsequent studies of epileptogenesis. A major question that remains open in relation to epileptogenesis is whether emergence of recurrent seizures at the end of the latent phase represents a failed attempt of the brain to compensate for the detrimental effects of the initial lesion (or status epilepticus) or whether it results from abnormal reorganization of neuronal circuits triggered by the initial lesion. There is no doubt that GABAergic transmission is profoundly affected during the latent phase. A proper answer to this question will hopefully provide guidance for the design of therapeutic strategies aimed at prolonging or curtailing the latent phase.

Regarding $GABA_A$ receptors, there are at least three main goals to achieve: (1) To further our understanding of the significance of $GABA_A$ receptor heterogeneity for proper brain function; (2) To investigate the mechanisms underlying the effects of mutations in idiopathic epilepsies. Here, the main stumbling block is the fact that different mutations can lead to similar phenotypes – or conversely, that a given mutation can generate different phenotypes across individuals; (3) To develop new drugs that take advantage of $GABA_A$ receptor heterogeneity to achieve better efficacy and reduced side-effects (compared to the drugs – e.g., benzodiazepine agonists – in current clinical use.

Introduction

In the adult brain, glutamatergic neurons and synapses provide most of the excitatory drive by means of receptor channel complexes permeable to cations. GABAergic neurons and synapses provide the inhibitory drive by means of receptor channel complexes permeable to anions and particularly chloride. Equilibrium between the operations of both synapse types is instrumental for avoiding seizures and toxicity. A wide range of agents that block GABA signaling induce seizures, and many agents that increase GABA signaling effectively block seizures or even reduce their long-term consequences. In addition, GABAergic neurons play a central role in the generation of behaviorally-relevant network oscillations by means of an extremely complex and diversified pattern of innervation of all the elements of the networks, including the somata and dendrites of principal cells and other GABAergic neurons. Thus, the operation of brain networks relies heavily on a time- and space-dependent activation of excitatory and inhibitory synaptic currents that enable the brain to integrate information and generate the appropriate response by means of network oscillations.

During brain construction, once neurones start their differentiation, they establish functional synapses and start generating signals and patterns that in turn influence the network wiring. The more the neuron matures, the more the genetic program is influenced by activity and signals generated by the neuron and its neighbors. This influence is particularly important in complex brains such as that of the human's, with its 10^{15} synapses. During network construction the neurons may discharge, so some mechanisms for maintaining equilibrium between excitation and inhibition is needed during the process; in this respect, the process is very different from, say, the construction of a car where the engine is ignited only when all the pieces have been put together. The basic question examined in this article is how the brain resolves that equilibrium issue in relation to GABA and glutamate signaling. If GABAergic inhibitory synapses are operative too early, then the process will be retarded because of inhibition and reduction of calcium influxes; if glutamate excitatory influences develop first, then the excitotoxicity may result in injury and lesions. The solution to this problem appears not to be a parallel and general equilibrated/titrated excitatory/inhibitory drive, but rather a unique developmental sequence with an earlier maturation of *excitatory* GABA synapses followed by a later maturation of glutamate synapses. This sequence prevents the possible deleterious sequelae of too early development of inhibitory GABA or excitatory glutamate systems, while still providing the calcium surge needed for maturation and neuronal growth.

These issues are of particular importance for understanding the epilepsies. For example, is the well-established higher incidence of seizures at an early age related to these features? Is it possible that a weaker inhibition, or an early unbalanced excitatory drive, fosters a lower threshold for seizure generation? Do certain developmental features, such as the immature states of neurons, synapses or networks, make the immature brain particularly prone to seizure generation? Answers to these questions would, of course, give important clues as to the means by which treatments should proceed. We shall focus here on the maturation of GABA and glutamate signaling, and evaluate the implications of the unexpected cascade of events initiated by these immature signalling processes on seizures on the developing brain.

Background

Key Findings

A higher $[cl^-]_i$ in immature neurons leads to excitatory actions of GABA (Figure 1)

In 1989, using old fashioned intracellular recording techniques, we recorded hundreds of hippocampal neurons in slices from young rats, and discovered a higher intracellular concentration of chloride ($[Cl^-]_i$) that disappeared progressively around the second week of post natal life. Consequent to the membrane depolarization thus induced by GABA actions at its receptor/channel complex, GABA excites immature neurons and generates sodium action potentials, calcium currents and removes the voltage-dependent Mg^{2+} blockade from NMDA channels in immature neurons, leading to a massive calcium influx. This result is contrary to that seen at more adult stages, where activation of GABA usually reduces calcium influx and the activation of NMDA receptors channels. This property of GABA activation in immature neurons has been confirmed in all brain structures and animal species investigated to date, suggesting that it has been conserved throughout evolution.

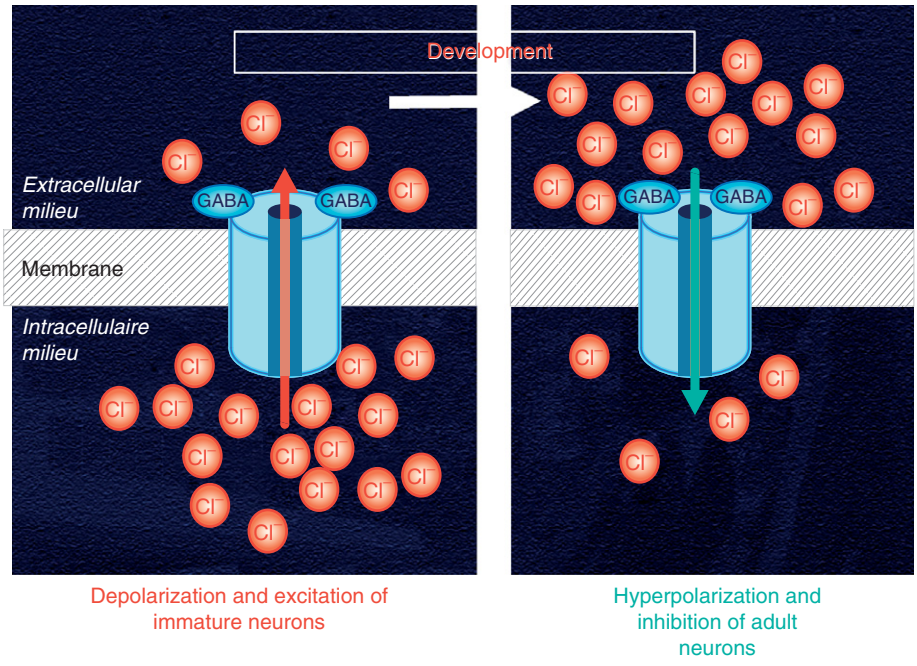

Figure 1 The developmental gradient of $[Cl^-]_i$ and excitatory actions of GABA. A higher intracellular concentration of GABA in immature neurons leads to depolarizing actions of GABA. This action is replaced with maturation and GABA resumes its adult actions.

Early excitatory actions of GABA provide the source of the calcium increase needed for neuronal growth and synapse formation, while avoiding toxic actions of glutamate. The higher concentration of chloride in immature neurons is due to an early expression of a chloride importer (NKCC1) AND a delayed maturation of a chloride exporter. This maturational difference has been observed in various experimental animals, and also in humans, suggesting that these mechanisms are also conserved. Interestingly, the immature chloride gradient has many functional implications, and probably is instrumental in the trophic roles of GABA in neuronal and network maturation. An example of that role is illustrated by the experiment performed by Medina and colleagues, who showed that early transfection of KCC2 in immature neurons (that have a high $[Cl^-]_i$) induces the expected change of the actions of GABA but also augments the formation of GABAergic synapses in the neurons that have shifted their chloride too early. Thus the excitatory actions of GABA, caused by high $[Cl^-]_i$ is an important signal in synapse formation.

The GABA-glutamate sequence: GABA comes first

Earlier studies had shown that GABAergic interneurons divide and mature before principal neurons. We also found that blockers of GABAergic receptors that trigger seizures in adults can block ongoing activity at an early stage. We then recorded and reconstructed a large number of pyramidal neurons and interneurons, and found that GABAergic synapses appear first on both cell types; neurons with few or no dendrites are silent, with no synapses; neurons with a small apical dendrite have only GABAergic postsynaptic currents (PSCs); and only neurons that have both large apical dendrites and basal dendrites have both GABAergic and glutamatergic synapses. The sequence occurs earlier in interneurons than in pyramidal cells; with over 80% of pyramidal cells and less than 20% of intereurons being silent at birth. In both cell types, GABAergic currents provide most of the activity at an early developmental stage.

GABA exerts a paracrinic actions even before synapses have been formed

Immature neurons express functional receptors prior to the formation of synapses. We showed that these neurons that bear receptors but no synapses act as sensors of extracellular GABA, as reflected by the large tonic currents generated by GABA receptor antagonists. In addition, extracellular electrical stimuli induce large slow currents mediated by a non-vesicular release of GABA – only at an early stage of development. This GABA release and the resultant currents have a functional significance, as blocking GABA receptors at this early stage reduces neuronal migration. The implications of this result are reflected by the observation that GABA-acting antiepileptic drugs slow neuronal migration and lead to heterotopic neuronal masses (see later text).

The immature hippocampal network generates a primitive universal pattern

During this earlier series of experiments, we also found that immature rat hippocampal neurons generate – until

the 2nd week postnatal – a pattern of discharge that we called Giant Depolarizing Potentials (GDPs). This pattern is the first synapse-driven pattern in the hippocampus, and consists of large polysynaptic events that provide most of the excitatory activity in these neurons (as long as a substantial proportion of GABAergic synapses are excitatory). GDPs are generated by the depolarizing effects of GABA. The depolarization also removes the voltage-dependent Mg^{2+} block from NMDA channels, thus facilitating the generation of large glutamatergic NMDA receptor-mediated synaptic currents that activate most neurons in the population. GDPs are primitive events that are replaced by behaviorally-relevant patterns. They enable co-activation of neurons that are in different developmental stages. Similar patterns have been observed in a wide range of structures and animal species.

Confirming this sequence in primate neurons in utero

In a parallel study, we performed the first recordings ever made in primate central neurons in utero. These recordings required a Caesarean surgery followed by slices production and determination of synaptic currents, evaluation of spine density, determination of the speed of axonal and dendritic growth, etc. We found a similar earlier formation of GABAergic synapses in the primate hippocampus as seen in the rat, as well as GDPs in both pyramidal neurons and interneurons. The hippocampal CA1 pyramidal neuron in primate has no synapses at mid-gestation, and more than 7000 synapses at birth (some 2 months later). This study provided a detailed description of the general developmental sequence in primate hippocampus, and showed that the basic principles described in immature rodents are valid in primates in utero.

Why have these sequences been kept throughout evolution?

We have suggested that this developmental sequence provides a solution to the need for preserving equilibrium between excitation and inhibition at all times. We hypothesize that the excitatory drive of GABA at an the early developmental stage is sufficient to augment calcium and stimulate neuronal growth – without endangering the integrity of immature cells since E_{rev} for chloride is 30–40 mV below zero (contrary to the much more depolarized E_{rev} for glutamate. In addition, the shunting actions of GABA prevent excessive hyperactivity (but see below). The GDPs, by means of their long-lasting duration, enable immature neurons (which are endowed with few synapses) to fire together with more adult neurons, and thus wire together. This scenario also promotes synaptic plasticity, since summation of currents is more likely to occur with long PSCs. Once the GABA shift occurs and a sufficient density of glutamate synapses has been formed, primitive patterns disappear and are replaced by the plethora of behaviorally-relevant patterns.

The importance of measuring adequately V_{rest} and E_{GABA}

The above observations raise the issue of the importance of adequately measuring the genuine resting membrane potential and reversal potential of GABA. Clearly, if recording methods modify resting membrane potential or $[Cl^-]_i$, the measurement of the excitatory actions of GABA will be invalid. Apparently excitatory actions of GABA have been reported with all possible recording techniques, including extracellular, intracellular, whole cell patch clamp and perforated patch recordings (permeable to cations but not to chloride and thus thought not to affect $[Cl^-]_i$). However, in a recent study, we measured V_{rest} by a non-invasive method. We found that with whole cell and gramicidin perforated-patch recordings, resting membrane potential was −44 mV at postnatal days P0-P2 and −67 mV at P13–15; in contrast, with single NMDA channels recordings, it was −77 mV at both ages. Therefore, V_{rest} is not altered during maturation, and the developmental decrease of the effects of GABA are genuinely due to alterations of $[Cl^-]_i$. More recently, we also measured single GABA channels in cell attached recordings, and confirmed this developmental reduction (from over 25 mM chloride to around 7 mM). These results suggest that invasive techniques, including perforated patch recordings, provide an inadequate estimation of V_{rest}. Computer simulations suggest that depolarized values of invasive recordings could be explained by a shunt through the seal contact between the pipette and membrane.

Generalization of theses features to other brain structures

Extensive studies made by several groups have essentially confirmed the chloride developmental shift in intracellular chloride concentration for most brain structures and animal species. The mechanism underlying these shifts have also been clarified and shown to depend on an early maturation of a chloride importer and a late maturation of a chloride exporter. To the best of our knowledge, there is to date no exception to the early depolarizing actions of GABA. Whether, GABA excites – i.e., generates action potentials – has been more controversial, since GABA also inhibits even when depolarizing because of its 'shunting' actions that tend to clamp V_{rest} at E_{GABA}. However, cell attached extracellular recordings show unambiguously that the depolarization provided by GABA – *at an early stage* – is above the threshold for action potential generation. GABAergic currents have also been shown in many systems to operate first (i.e., before glutamate currents); however, compelling evidence relying on neuronal reconstruction is lacking in most structures. Primitive patterns such as the GDPs have been reported in a wide

range of brain structures, and the GABA shift does play a central role in their generation and/or their termination. More problematic is the relevance of these patterns to the in vivo situation, since various patterns have been reported in pups in vivo; a comparison between the generating mechanisms in vivo and in vitro remains to be performed.

Implications for the epilepsies

As should be clear from the above discussion, immature neurons lack one of the main inhibitory systems characteristic of the adult brain. In addition, other major inhibitory transmitter-gated postsynaptic mechanisms – e.g., $GABA_B$ receptor and other G-protein-mediated activation of K^+ channels – are also late to develop. In contrast, pre-synaptic G-protein-mediated currents (activated via $GABA_B$, 5HT, or A1 receptors) operate at an early stage, suggesting that pre-synaptic inhibition is functional before postsynaptic inhibition. Therefore, during maturation, neurons lack postsynaptic transmitter-gated hyperpolarizing inhibition, and only voltage-gated K^+ currents operate. Given this situation, immature networks may be more prone to seizure generation because of the excitatory actions of GABA.

Studies devoted to estimating the contribution of GABA to neonatal seizures have, however, led to a more complex image. Using non-invasive extracellular field potential and cell-attached recordings in hippocampal slices, we have found a dual action of GABA (**Figure 2**): seizure-like events generated by a high K^+ milieu were reduced by the $GABA_A$ receptor antagonist bicuculline, but at the same time the amplitude of the population spikes was increased – suggesting that GABA exerts dual excitatory and inhibitory actions. Other observations suggest a direct contribution of excitatory actions of GABA to epileptogenesis, as reflected by the powerful antiepileptic actions of bumetanide – a blocker of chloride import that reduces the excitatory actions of GABA and seizures in the developing brain. Excitatory actions of GABA may play an important part in the generation of seizures by developing networks (working together with other factors, including the high input resistance of immature neurons). This possibility does raise a question about the widespread use of GABA facilitators – notably benzodiazepines – to treat early seizures. However, this topic deserves more direct investigation.

The excitatory effect of GABA is also illustrated by the powerful pro-convulsant actions of the cannabinoid agents. Since endogenous cannabinoids exert a negative feed back

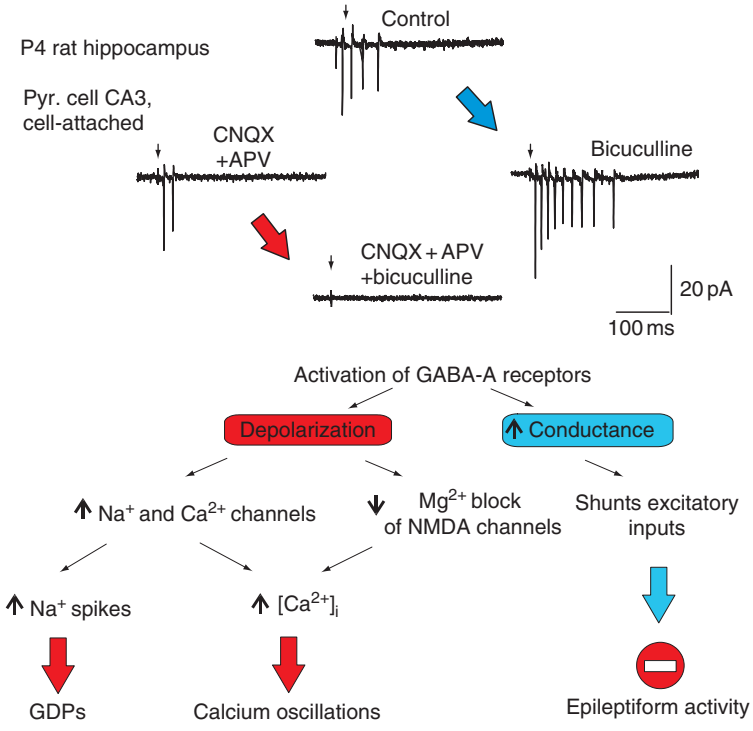

Figure 2 Dual actions of GABA. In an immature hippocampal neuron recorded in a cell attached configuration, ionotropic Glutamate receptor antagonists blocks many spikes generated by an electrical stimulus, however the remaining ones are blocked by a GABA receptor antagonist reflecting the genuine excitatory actions of GABA. In the bottom part, the dual actions of GABA are depicted with on the one hand the depolarizing actions of GABA generating action potentials and calcium currents as well removing the Magnesium block from NMDA channels and on the other, the shunting action of GABA exerting an inhibition that reduces the efficacy of glutamatergic synaptic currents.

on the release of GABA, they should act differently on adult and immature neurons. Blockade of cannabinoid type 1 (CB1) receptors leads to epileptic discharges during maturation, and conversely, activation of CB signaling reduces network activity in vivo and in vitro. Therefore, endocannabinoid signaling maintains population activity within a narrow physiological time window and controls the generation of the primitive GDPs pattern. Disturbing that delicate balance during pregnancy (in either direction) will affect neuronal activity, and blocking these CB1 receptors will contribute to seizure generation in the fetus.

Methods

These studies have used the entire panoply of recording, imaging and morphological techniques in vitro and in vivo. These methods include whole cell voltage and current clamp recordings, as well as the first single channel GABA and NMDA recordings to estimate correctly the resting membrane potential and reversal membrane potential for GABA. Fast imaging techniques were also used to measure alterations of calcium signals and activity in large number of neurons. In vivo studies used extra and intracellular and whole cell recordings in rat pups. A variety of anatomical and histological tools were used, including 3D neuronal reconstructions to determine the relation between neuronal activity and morphological properties.

Recent Results

Maternal Oxytocin Reduces $[Cl^-]_i$ before Delivery and Shifts Transiently GABA to Inhibition (Figure 3)

An interesting illustration of the excitation (E) to inhibition (I) shift in the actions of GABA was recently observed during a study aimed at determining the time course of changes of $[Cl^-]_i$ from embryonic to postnatal stages. We found an abrupt drop of $[Cl^-]_i$ immediately before and after delivery. This transient shift is associated with a transient inhibitory effect of GABA, and is mediated by the maternal hormone oxytocin (which is released to start labor). Thus, the release of maternal oxytociçne both triggers labor and shifts GABA effects from excitatory to inhibitory. The effects are most likely mediated by a reduction of the actions of NKCC1 that imports chloride into neurons. Indeed, whereas oxytocin receptors are present in utero, we did not find oxytocin positive neurons in fetal brain, and in vivo administration of an oxytocin receptor antagonist prevented the E-to-I shift. This mechanism has a neuroprotective action, since fetal neurons are more resistant to anoxo-ischemic episodes when oxytocin receptors are operative (not blocked). Blocking in situ oxytocine receptors also made neurons more readily blocked by anoxic episodes. Using a fast dynamic two-photon imaging process, we determined the sequential maturation of patterns from the embryonic to the post natal stage. We found that the earliest pattern present

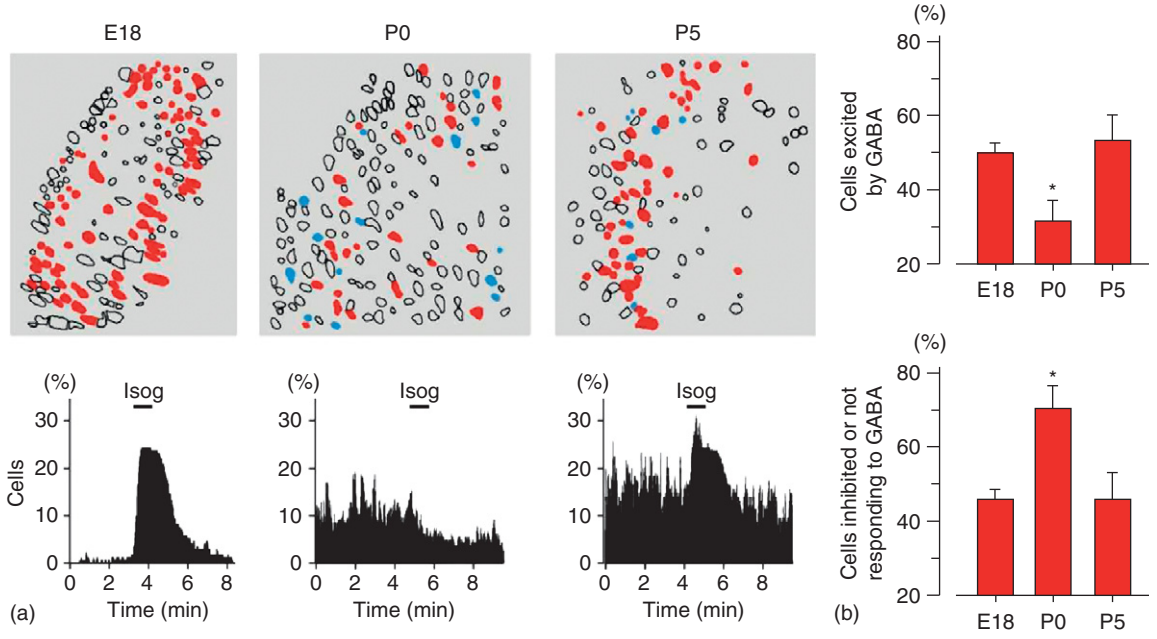

Figure 3 Dramatic shift of the actions of GABA before delivery. A GABA agonist – isoguvacine – excites immature neurons *in utero* (E18) and at P5 as shown in the dynamic imaging of calcium recorded by two photon imaging laser microscopy. In contrast immediately before delivery, the same agent inhibits neurons. The number of neurons excited and inhibited by isoguvacine at these developmental stages is shown at the right side of the figure.

(around delivery) is a calcium plateau oscillation mediated by voltage-gated calcium currents in a small population of neurons connected by gap junctions. This pattern is triggered also during delivery by oxytocine.

These data suggest that the fetus is informed that delivery is to commence, and is protected from labor-associated insults by the ocytocin hormone. This scenario has important clinical implications in relation to preterm deliveries. Indeed, the use of atosiban and other oxytocin receptor antagonist may remove an endogenous neuroprotective mechanism; agents that block peripheral but not central oxytocin receptors may be advantageous. Also, oxytocin agonists may offer interesting tools to reduce neuronal excitability at an early stage.

In Utero Administration of Some Antiepileptic Drugs Affects Neuronal Migration and Dispersion

Since immature neurons express receptors before functional synapses, it is important to examine the functional significance of these receptors – and the possible pathological implications of activating these receptors. In an earlier study, we found that GABA and NMDA receptor agonists generate currents in neurons endowed with no functional synaptic current. GABA – but not glutamate – receptor antagonists also generate a tonic current, suggesting an ongoing release of GABA. In later studies, we found that the lack of effects of glutamate receptor antagonists is due to an early efficient maturation of glutamate transporters. Indeed, glutamate transporters develop before GABA transporters, and if they are blocked, severe seizures are generated. To determine the functional consequences of these receptors and the currents that they generate in neurons that bear no synapses, we tested the effects of various agents on neuronal migration in an in vitro preparation. We found that several drugs – notably antiepileptic drugs that act on $GABA_A$ receptors – retard migration. Interestingly, in vivo administration in rats of some antiepileptic drugs, at concentrations that are similar to concentrations found in pregnant epileptic women during gestation, lead to abnormalities in neuronal and layer organizations. Such results support the relevance of these findings to human disorders in general, and specifically to the effects of antiepileptic regimens during gestation. These observations suggest that GABA-acting agents used during migration may cause migration disorders and heterotopic masses with their well known deleterious sequelae.

Future Goals

The developmental sequences described here have been conserved throughout evolution. These rules have important implications in relation to seizure generation and seizure sequelae. Clearly, major signalling cascades – including those initiated by GABA, but perhaps also by many other molecules – operate differently in neonates and adult. Thus, the development of therapeutic strategies for neonates can only rely on observations obtained in neonatal experimental models. Further, the widespread use of GABA enhancers in treating early epilepsies may not be appropriate – perhaps only partially effective (as some observations already suggest) and potentially pro-epileptic. An important goal of future research is to determine the interactions of GABA and various other molecules to better comprehend the roles of the excitatory and inhibitory (shunting) actions of GABA in neurones endowed with few synapses and poorly developed dendritic arbors.

A second goal of future research is to determine the roles of oxytocin (and other agents released during delivery) on protecting fetal neurons during the birth process form traumatic and anoxic insults. The fetal brain is endowed with oxytocin receptors but apparently not with capacity to synthesize and release the hormone. Oxytocin is known to exert a powerful protective actions on neuronal activity. Understanding the actions of these agents (including, in addition to oxytocin, vasopressine, and catecholamines) is important as it will provide a rationale for better understanding how GABA and chloride are regulated during these unique situations.

In a more general perspective, the developing brain is known to be relatively resistant to cell loss when compared with that of adults. Yet seizures and other insults do lead to long-lasting consequences, suggesting that contrary to adult networks, the pathological sequelae are produced by alterations of the developmental program rather than lesions and neuronal damage. During maturation, many essential processes are activity-dependent and thus may be affected by episodes of hyperactivity or excessive release of transmitters that act via their paracrine actions (even before synapses have been established). The pharmacopoeia of immature neurons must be completely revised in the process of incorporating these new vistas. Widely-used drugs that act on GABA receptors, that are used during gestation and delivery, may deserve more detailed scrutiny.

In sum, the developmental alterations of the actions of GABA provide a unique opportunity for studying how neurons develop and networks are formed, and for evaluating how these processes may be endangered by manipulations that have been validated in adult preparations but not in developing networks.

Introduction

Florey and MacLennan were the first to suggest that 'factor I' was an inhibitory neurotransmitter; after some debate, this compound was identified as the amino acid GABA. Half a century later, we know that GABA released from interneuron terminals activates pre- and postsynaptic GABA receptors in forebrain neurons. These receptors include ionotropic $GABA_A$ and metabotropic $GABA_B$ receptors. $GABA_A$ receptors are receptor-operated channels with a large molecular diversity and a largely somatodendritic expression. Signals mediated metabotropically, by $GABA_B$ receptors, are slower and may be involved in opening or closing somatodendritic channels or in controlling transmitter release from excitatory and inhibitory terminals, via distinct G proteins.

A relation between GABA and seizures first emerged when convulsions were seen in infants fed with a formula that was accidentally deficient in pyridoxine (known also as vitamin B6). Pyridoxine is the coenzyme for the synthesis of GABA from glutamic acid via the enzyme glutamic acid decarboxylase. Moreover, shortly after its identification, GABA was found to prevent seizures, and several molecules that interfere with GABA synthesis and signaling were shown to induce convulsions. Work in the 1970s and early 1980s confirmed a function for GABA receptor-mediated mechanisms in controlling neuronal excitability and thus epileptiform synchronization. Later

GABA$_A$ Receptor Plasticity in Epileptogenesis

Y H Raol and A R Brooks-Kayal, Children's Hospital of Philadelphia, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

It is clear from studies carried out in various animal models and retrospective studies from humans that an initial precipitating event such as status epilepticus (SE) can increase the risk of later development of epilepsy. The process of epilepsy development (epileptogenesis) is complex and multifactorial. Many laboratories, including our own, have focused on understanding the role of γ-aminobutyric acid (GABA) receptor plasticity in epileptogenesis. GABA is the major inhibitory neurotransmitter in the mature brain, and various drugs such as diazepam and barbiturates that enhance GABAergic inhibition are commonly used as antiepileptic drugs. Also, drugs that block GABAergic inhibition can induce seizures in animals, further supporting the potential importance of alterations in GABAergic transmission in epileptogenesis. In this article we will describe the changes that have been observed in GABA$_A$ receptor (GABAR) subunit expression following prolonged seizures in various animal models of epilepsy, and the role these changes may play in epileptogenesis. Also, we will highlight the differences in GABAR subunit expression that occur following SE in adult and developing animals.

Background

GABA is the major inhibitory neurotransmitter in the adult brain. Three types of GABA receptors, GABA$_A$, GABA$_B$, and GABA$_C$, are found in the mature central nervous system. GABA$_A$ and GABA$_C$ are ionotropic receptors, whereas GABA$_B$ is a metabotropic receptor. Most fast synaptic inhibition in the mature brain is mediated by GABARs, whereas slow inhibition is mediated by GABA$_B$ receptors. GABARs are composed of multiple subunits subtypes (α1–6, β1–3, γ1–3, δ, ε, π, θ, and ρ1–3) that form a pentameric anion-selective channel. The most common in vivo subunit composition is two α, two β, and one γ subunit. There is remarkable receptor heterogeneity, with subtype combinations varying in different brain regions, cell types, and during different times in ontogeny. Different subunit subtypes confer distinct functional and pharmacological properties to the receptors.

Several laboratories have studied the changes in GABAR subunit composition in human temporal lobe epilepsy (TLE) and in animal models of TLE. Houser and colleagues have shown that in the CA1 and CA2 areas of the hippocampus there are long-lasting reductions in the α5 subunit of GABARs in pilocarpine-treated animals that develop spontaneous seizures. The α5 subunit is primarily extrasynaptic and is thought to be involved in tonic inhibition in the CA1 area. Lower levels of α5 subunit may thus result in reduction of tonic inhibition. In the molecular layer of denate gyrus, levels of α1, α3, α4, α5, and γ2 increase and levels of δ decrease chronically following SE. In interneurons of dentate gyrus, however, α1 subunit levels decrease and δ subunit levels increase, suggesting that there are cell-specific changes within the same region of the hippocampus. Additional studies from the Houser group suggest that changes in GABA receptor function after SE may depend not only on the levels of different subunits within individual neuronal cell types, but also on the subcellular localization of different GABAR subunits within these cells. Using immunogold labeling, these investigators showed that the subcellular location of γ2 and δ subunits in molecular layer of dentate gyrus was changed in pilocarpine-treated epileptic mice; they found a decrease in δ and an increase in γ2 subunits at perisynaptic locations, and a decrease in γ2 labeling near the center of the synaptic contacts. The change in the location of these subunits correlated with an insensitivity of the tonic current to neurosteroids and reduced phasic inhibition of DGCs in pilocarpine-treated epileptic mice. This impairment in inhibition could play an important role in development of epilepsy in this mouse model of TLE.

Additional support for the role of GABAR alterations in epileptogenesis comes from genetic studies. Mutations in the GABAR subunit γ2 gene (GABRG2) are found in the families with generalized epilepsy with febrile seizures plus ($GEFS^+$) and childhood absence epilepsy with febrile seizures. The γ2 subunit plays important roles in receptor trafficking, clustering, and synaptic maintenance; for example, Macdonald and colleagues found that slight increases in temperature caused impaired trafficking and accelerated endocytosis of α1β2γ2 receptor containing mutant γ2 subunit but not wild-type α1β2γ2 receptor. This finding suggests that some genetic forms of febrile seizures might be associated with reduced inhibition related to temperature-induced internalization of GABARs from the cell surface.

It is known from clinical experience and numerous animal studies that the immature brain is more susceptible to induction of seizures than the mature brain. The increased seizure susceptibility is thought to result from a combination of factors at play in the immature brain, including enhanced excitation and reduced inhibition. Animal model studies also suggest that the outcomes of events such as SE occurring in early-life are different from those outcomes from SE occurring in adult life. For example, almost all animals that experience pilocarpine-induced SE in adulthood exhibit spontaneous seizures following a short latency, whereas rat pups exposed to pilocarpine-induced SE at postnatal day (P) 10 never develop epilepsy in later life. Similarly, there are age-dependent molecular and morphological changes following SE. Effects of early-life SE on GABAR plasticity are different from those found in animals exposed to SE in adulthood. Rocha and colleagues found short-term increases in benzodiazepine ([^{3}H] flunitrazepam) binding in brain regions such as dentate gyrus, amygdala, and piriform cortex after kainic acid-induced SE at P15. However, there was a reduction in benzodiazepine binding in the same brain regions after 35 days. These results were in contrast to what has been found in adult animals, where there was an initial reduction in benzodiazepine binding in various brain regions followed by an increase in benzodiazepine binding 40 days after kainic acid-induced SE. Using in situ hybridization and immunohistochemistry, Holopainen and colleagues found a reduction in GABAR α1 and α4 subunit levels and increases in α2, α3, β3, and γ2 subunit levels in CA1, CA3, and dentate gyrus regions of hippocampus 1 week following kainic acid-induced SE at P9. These studies suggest that developing brain responds to SE differently from mature brain.

Methods

Various animal models of epilepsy are available to study different forms of epilepsy. Our laboratory is interested in studying the mechanism of development of TLE following an initial insult such as SE. SE can be induced by chemoconvulsants such as kainic acid or pilocarpine, or by continuous electrical stimulation administered through intracerebral electrodes. In our laboratory we have used pilocarpine (for adult animals) or lithium–pilocarpine (for 10–20-days-old rat pups) to induce SE. Adult rats were first injected with 1 mg kg^{-1} body weight scopolamine to block the peripheral effect of acetylcholine activation and then, 30 min later, with 385 mg kg^{-1} pilocarpine. Rats that did not exhibit convulsive seizures within 1 h of pilocarpine injection were given a second dose of pilocarpine (192.5 mg kg^{-1}) to produce equivalence in seizures between animals. Diazepam (6 mg kg^{-1}) was administered at 1 h after the onset of SE to stop seizure activity and was administered again every 2 h (3 mg kg^{-1}) until rats stopped seizing. To induce SE in developing rats, rat pups were briefly separated from the mother and injected intraperitoneally (i.p.) with 3 mEq kg^{-1} body weight lithium chloride. Fourteen to 18 h after the lithium injection, pups were again separated from their mother and received i.p. injection with either 60 mg kg^{-1} pilocarpine (SE group) or 0.9% saline (control group). Rats were continuously video-EEG monitored to determine the occurrence of seizures.

To selectively study the change in GABARs subunit expression in dentate granule cells (DGCs), our laboratory has used a single-cell mRNA amplification technique that was modified from the original technique described by Eberwine. For studies of regional RNA expression, subfields of the hippocampus such as dentate gyrus, CA1, and CA3 were microdissected; RNA was isolated, reverse transcribed, and amplified, and then analyzed using reverse Northern blots. T7-(dT)24 primer and SuperScript II RNase H-reverse transcriptase were used for cDNA synthesis, and the AmpliScribe T7 High Yield Transcription kit was used for RNA amplification. The cRNA was purified using the RNeasy MinElute Cleanup kit protocol (Qiagen, Valencia, CA) according to the protocol of the manufacturer. [P 32]dCTP was incorporated into the radiolabeled cDNA probe using SuperScript II RNase H-reverse transcriptase and hybridized for 18 h against a slot blot containing GABR cDNAs (α1–6, β1–3, γ1–3, δ, ε, π, φ).

To determine whether changes observed in mRNA result in changes in protein levels, our laboratory has used Western blotting to quantitatively, and immunocytochemistry to qualitatively, determine the alteration in protein content in various brain regions. For Western blotting, tissue was homogenized in a buffer and homogenates were run on SDS/polyacrylamide gels and then transferred to nitrocellulose. Blots were blocked with 5% milk, incubated with primary antibody (against protein of interest), and then incubated with secondary antibody conjugated with horseradish peroxidase. Protein bands were developed using Super Signal West Pico chemiluminescent substrate

kit (Pierce, Rockford, IL) and quantified using NIH Image software (National Institutes of Health, Bethesda, MD). To carryout immunocytochemistry, brains were cut into thin sections and washed 2–3 times in phosphate buffered saline (PBS) containing 1% Triton. Brain sections were then incubated with goat serum to block nonspecific binding of the primary antibody. The sections were incubated at 4 °C for 48 h with primary antibody (against GABAR subunits), and after washing with PBS sections were incubated with secondary antibody at room temperature. Sections were washed with PBS and covered with mounting medium. Intensity of immunofluorescence was quantified using various methods such as confocal microscopy.

Recent Results

To selectively study changes in GABAR subunit expression and function in DGCs, our laboratory (in collaboration with Coulter and colleagues) has used single-cell mRNA amplification technique combined with whole cell patch-clamp. We found that levels of α1 subunit mRNA decreased whereas levels of α4 subunit increased, beginning 24 h after SE and continuing as the animals became epileptic. The change in subunit expression correlated with a decreased sensitivity to zolpidem augmentation and increased sensitivity to zinc inhibition of GABAR responses. Similar functional and subunit expression changes have been observed in DGCs isolated from surgically resected hippocampus from patients with intractable TLE. The changes in GABAR subunit expression and function in DGCs of epileptic animals precede the development of epilepsy, suggesting that these changes contribute to the epileptogenesis process.

A recent study from our laboratory supports the idea that these GABAR subunit alterations may be critical contributors to epilepsy development. We designed a viral vector that contains the promoter for the α4 subunit gene of the GABAR; this promoter drives the expression of an α1 subunit transgene and enhanced yellow fluorescence protein reporter gene. The viral vector was directly injected into dentate gyrus before SE induction. Following SE, activity of the α4 promoter is upregulated, resulting in enhanced α1 expression in DG. Rats were continuously video-EEG monitored to determine the latency for the development of spontaneous seizures. We found that α1 gene transfer resulted in a threefold increase in mean seizure-free time after SE and a reduction in the number of rats developing epilepsy in the first 4 weeks after SE.

In contrast to adult rats where we found an decrease in α1 subunit in DG following SE, rats that experience pilocarpine-induced SE at P10 show an increase in GABR α1 expression in dentate gyrus and enhanced type I benzodiazepine augmentation of GABA currents. Also, unlike adult animals that uniformly develop spontaneous seizures following SE, none of the rats that had SE at P10 developed epilepsy later in life. Similarly, rats that had experienced SE at P20 have increased GABAR α1 expression in dentate gyrus, and only two-third of the rats develop epilepsy; in the subpopulation that does develop epilepsy, the frequency and severity of the seizures that develop are much less and the latency much longer, than in adults exposed to SE. These changes in GABAR α1 subunit levels in rats that had SE at P20 occurred selectively in the dentate gyrus, preceded the onset of epilepsy, and were not model specific. Also, there was no change in any other GABAR subunits in rats exposed to SE at P20.

Future Goals

Increased neuronal activity associated with induced seizures results in a variety of changes in GABAR-mediated neurotransmission, some of which may contribute to the later development of epilepsy. Going forward, it will be critical to determine which of these changes actually contribute to epileptogenesis and which are adaptive. Also, as the majority of studies have described changes that occur after the development of seizures, additional studies examining receptor changes during the latent period – i.e., prior to onset of epilepsy – are needed. Further, as one of the major goals of epilepsy research is to prevent the development of epilepsy after an initial precipitating event, it will be essential to establish which of the changes that occur during the latent period directly contribute to development of spontaneous seizures. Similarly, identification of the factors resulting in susceptibility or resistance to development of epilepsy following an event such as SE is critical. These studies will require models that generate groups of animals that do and do not develop spontaneous seizures after the insult. One choice for such studies will be developmental animal models of epilepsy, using juvenile animals (P15–P25) where only a subset of exposed animals become epileptic. For example, in the lithium–pilocarpine-induced SE model at P20, 70% of the animals go on to develop spontaneous seizures following a long latency. This model therefore provides a good opportunity to study and compare the receptor activity over time, between the animals that develop epilepsy and those that do not. Finally, in chronically epileptic animals, the effects of spontaneous seizures themselves are difficult to differentiate from those primarily responsible for epileptogenesis. Therefore, a key goal for the future will be to identify a biomarker that can predict which animal will develop epilepsy following an injury, so as to permit us to differentiate critical mediators of epileptogenesis from the secondary effects of spontaneous seizures in susceptible animals.

Introduction

Epilepsy is a disease of complex etiology and multiple molecular mechanisms contributing to its development. The development of temporal lobe epilepsy (TLE) often occurs after a traumatic event to the brain, such as head injury or prolonged seizure activity (status epilepticus, SE). After this initial event, a latent period ensues before recurrent spontaneous seizures (epilepsy) develop. Changes in the expression of multiple genes, including those that encode ligand- and voltage-gated ion channels, have been implicated in the process of epileptogenesis. Several growth or transcription factors are known to be activated by SE, including (but not limited to) brain-derived neurotrophic factor (BDNF), cAMP response element binding protein (CREB), inducible cAMP early repressor (ICER), and early growth response factors (EGRs). Results of multiple studies suggest that these factors regulate gene expression in a way that is pertinent to seizure-induced changes in brain function. This article will introduce each of these signaling elements and provide an overview of their possible roles in gene regulatory pathways that are critical for, or associated with, the epileptic condition. Recent work elucidating specific mechanisms that regulate changes in subunits that assemble to form the major inhibitory neurotransmitter receptor in the brain, the type A γ-aminobutyric acid receptor (GABAR), will then be discussed in detail. Introduction

Florey and MacLennan were the first to suggest that 'factor I' was an inhibitory neurotransmitter; after some debate, this compound was identified as the amino acid GABA. Half a century later, we know that GABA released from interneuron terminals activates pre- and postsynaptic GABA receptors in forebrain neurons. These receptors include ionotropic $GABA_A$ and metabotropic $GABA_B$ receptors. $GABA_A$ receptors are receptor-operated channels with a large molecular diversity and a largely somatodendritic expression. Signals mediated metabotropically, by $GABA_B$ receptors, are slower and may be involved in opening or closing somatodendritic channels or in controlling transmitter release from excitatory and inhibitory terminals, via distinct G proteins.

A relation between GABA and seizures first emerged when convulsions were seen in infants fed with a formula that was accidentally deficient in pyridoxine (known also as vitamin B6). Pyridoxine is the coenzyme for the synthesis of GABA from glutamic acid via the enzyme glutamic acid decarboxylase. Moreover, shortly after its identification, GABA was found to prevent seizures, and several molecules that interfere with GABA synthesis and signaling were shown to induce convulsions. Work in the 1970s and early 1980s confirmed a function for GABA receptor-mediated mechanisms in controlling neuronal excitability and thus epileptiform synchronization. Later

studies, however, challenged this view, showing that (i) epileptiform discharges occur when inhibition is preserved and even enhanced, and (ii) $GABA_A$ receptor-mediated mechanisms are at least partially preserved in animal models of temporal lobe epilepsy. More complex, at times ambiguous, roles for GABAergic signaling in epilepsy have been identified. In particular, recent evidence suggests that mechanisms involving $GABA_A$ receptors may assist, support, or shape epileptiform synchrony in limbic structures.

Background – $GABA_A$ Receptor-Mediated Functions

$GABA_A$ receptor activation opens channels that are permeable to chloride and to a lesser extent to bicarbonate. With a reversal potential ($E_{GABA\text{-}A}$) usually negative to neuronal resting potential, GABA release induces a fast inhibitory postsynaptic potential (IPSP), hyperpolarizing postsynaptic cells and thus suppressing firing. The inhibitory effect is also sustained by an increased membrane conductance responsible for the IPSP 'shunting effect'; consequently, inhibition – that is, a reduction in the likelihood that neurons will discharge action potentials – can also be achieved even without prominent hyperpolarization. Recent evidence indicates that $GABA_A$ receptors also mediate tonic inhibition, mediated by activation of extrasynaptically localized receptors with a distinct subunit composition that endows these receptors with a particularly high affinity for GABA (Semyanov *et al.*, 2004). $GABA_A$ receptors are also expressed at presynaptic sites in some brain regions (including the spinal cord – but their presynaptic existence in the forebrain remains to be proven), and act there to control transmitter release.

Finally, GABA can act as an excitatory transmitter under certain conditions. $GABA_A$ receptor activation depolarizes neurons when the E_{GABA} is positive to resting membrane potential – which may occur due to changes in transmembrane gradients of chloride or bicarbonate. If associated conductance changes are small enough to preclude an inhibitory shunting effect, excitation may result. This 'aberrant' behavior of GABA occurs in immature tissue before an adult chloride homeostasis is established, and also in adult tissue when GABAergic systems are strongly or repetitively activated.

Methods

Findings reported in **Figures 1 and 2** were collected from rat brain slices that were maintained in vitro under standard procedures, and were superfused with a medium containing 4-aminopyridine (4AP) or zero magnesium. Data for **Figure 3** derive from temporal lobe tissue obtained after operations at the CHU Pitié-Salpêtrière, Paris on patients with pharmacoresistant epilepsies of the temporal lobe (tissues with hippocampal sclerosis). All patients gave their informed written consent. Intracellular records were obtained with sharp electrodes filled with 2 M potassium acetate, and extracellular records were made from sharpened tungsten electrodes. Recorded cells were identified by intracellular biocytin staining (biocytin included at 1.6% in the intracellular electrode solution), developed with the avidin–biotin reaction using Avidin-Texas Red. The transporter KCC2 was detected immunohistochemically using standard techniques and a polyclonal antibody made by the laboratory of John Payne. Results shown in **Figure 4** are from human cortical tissue that was obtained during surgery for focal cortical dyspalsia at the Montreal Neurological Institute and Hospital, Montreal, QC. All patients gave their informed written consent. Field potential and extracellular potassium-selective records were obtained using standard techniques (see Further Reading).

Results

$GABA_A$ Receptors and Epileptiform Synchronization in the Limbic System

Blocking $GABA_A$ receptor-mediated inhibition induces epileptiform synchrony in cortical regions. Early data supporting this evidence were obtained in vivo from penicillin application to the neocortex or hippocampus. Later, the use of hippocampal slices opened the way toward work on underlying mechanisms. The activity, induced in vitro by $GABA_A$-receptor antagonists, is similar to the interictal discharges recorded from epileptic patients, consisting of short duration (a few hundred milliseconds) population events. Simulation studies have suggested that strong but sparse recurrent excitatory synapses within a single cortical area can explain the genesis of interictal-like synchrony. Electrophysiological studies confirmed this idea, and showed that suppressing inhibition induces synchrony by permitting transmission in existing – but previously not functional – polysynaptic recurrent pathways. Parallel in vivo studies demonstrated that the appearance of epileptiform activity during electrical stimulation is accompanied by failure of GABA-receptor-mediated increases in membrane conductances, and that the transition between nonconvulsive absence seizures and tonic–clonic discharges is associated with breakdown of intracortical inhibition. Thus, exogenous perturbation of inhibition induces epileptiform activity.

In contrast to this interictal-like discharge, prolonged epileptiform synchronization similar to electrographic seizures is only seen during experimental procedures

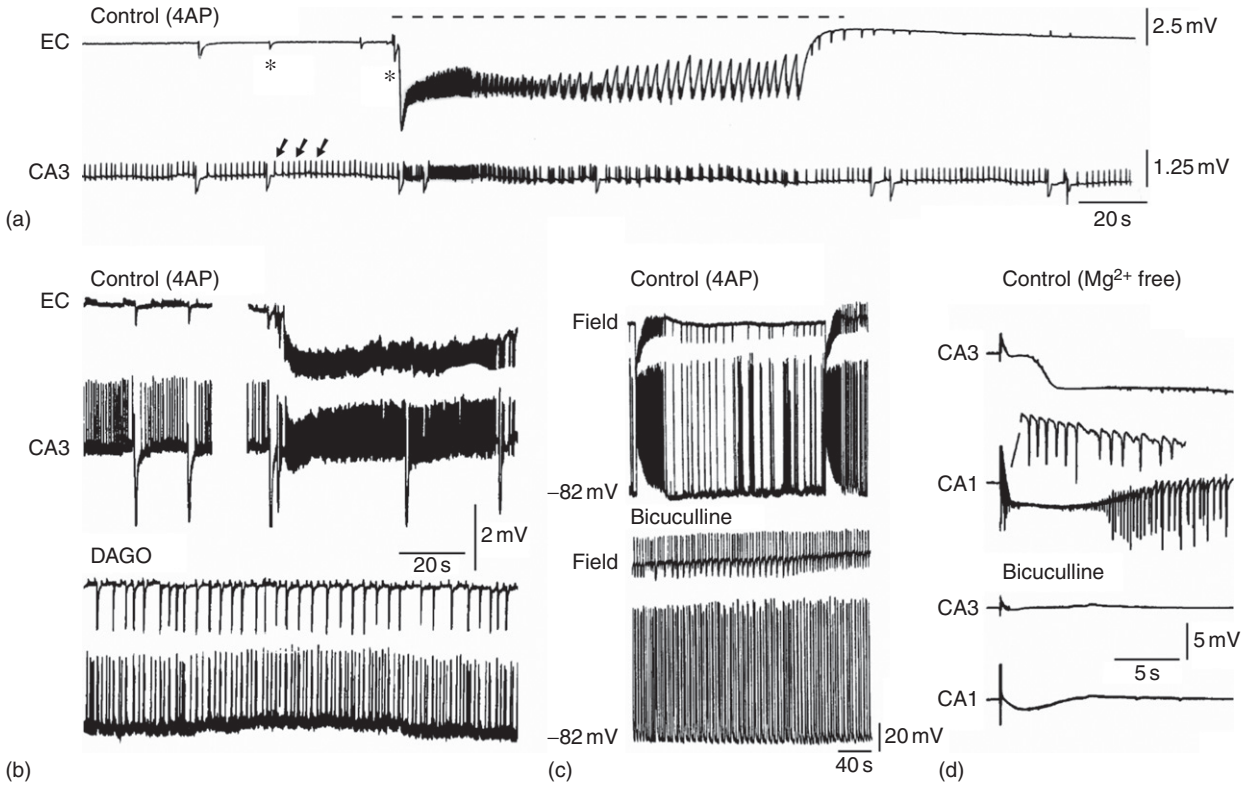

Figure 1 (a) Synchronous epileptiform activity recorded from a combined hippocampus-entorhinal cortex slice bathed with a medium containing 4AP. Note that 4AP induces the appearance of (i) fast interictal-like discharges at around 0.5 Hz (arrows), (ii) slow interictal events at 0.01–0.05 Hz (asterisks), and (iii) ictal discharge (interrupted line). (b) Effects induced by the μ-opioid receptor agonist (D-Ala-2-*N*-Me-Phe,Gly-ol)enkephalin (DAGO) on the synchronous activity recorded in the entorhinal cortex and CA3 area of the hippocampus during application of 4AP; note that DAGO blocks slow interictal events (which can be recognized by their negative-going polarity) and ictal discharge. (c, d) Effects similar to those seen with DAGO are reproduced by the $GABA_A$ receptor antagonist bicuculline on the ictal activity recorded from brain slices superfused with 4AP (c) or with Mg^{2+}-free medium (d), respectively. In (c), field potential and intracellular recordings were obtained from the entorhinal cortex, while field potential was recorded in (d) from the CA3 and CA1 areas of the hippocampus. Note that in the latter experiment the ictal response is preceded by oscillations (inset). Panels (a) and (b) are modified from Avoli M, Barbarosie M, Lucke A, Nagao T, Lopantsev V, and Köhling R (1996) Synchronous GABA-mediated potentials and epileptiform discharges in the rat limbic system in vitro. *Journal of Neuroscience* 16: 3912–3924; panel (c) is from Lopantsev V and Avoli M (1998) Participation of GABAA-mediated inhibition in ictal-like discharges in the rat entorhinal cortex. *Journal of Neurophysiology* 79: 352–360; panel (d) is from Köhling R, Vreugdenhil M, Bracci E, and Jefferys JG (2000) Ictal epileptiform activity is facilitated by hippocampal $GABA_A$ receptor-mediated oscillations. *Journal of Neuroscience* 20: 6820–6829.

that leave inhibition functional or even enhance it. These procedures include the application of 4AP or the removal of Mg^{2+} in acute slice preparations of the hippocampus and entorhinal cortex. Application of 4AP to hippocampal slices from young animals, or to slices including the entorhinal cortex in the adult, induces epileptiform interictal-like discharges presenting at 'fast' (~0.5 Hz, see **Figure 1(a)**, arrows) or rather slow events (0.01–0.05 Hz – see **Figure 1(a)**, asterisks), along with prolonged ictal-like discharges (see **Figure 1(a)**, thick line). While the fast interictal discharges are primarily mediated through excitatory synaptic transmission, both slow interictal-like and ictal, seizure-like events depend on GABAergic processes. In addition, these ictal-like discharges are immediately preceded (and thus presumably initiated) by slow potentials similar to the slow interictal events; they also show a reversal potential close to E_{Cl} and reflect bicarbonate-mediated $GABA_A$ receptor-dependent depolarizing discharge. Critically, ictal discharges – along with the slow interictal events – are blocked by preventing GABA release (e.g., by activating μ-opioid receptors (**Figure 1(b)**)) or by antagonists of the $GABA_A$ receptor (**Figure 1(c)**). These pharmacological maneuvers induce a pattern of robust interictal activity. As illustrated in **Figure 1(d)**, the ictal events that are recorded in hippocampal slices during removal of Mg^{2+} are also markedly reduced by application of the $GABA_A$ receptor antagonist bicuculline.

As illustrated in **Figure 2(a)**, the intracellular counterpart of ictal discharge onset during 4AP application is a long-lasting depolarization that resembles the depolarizations seen in isolation between ictal discharges (i.e., during interictal events) and becomes hyperpolarizing

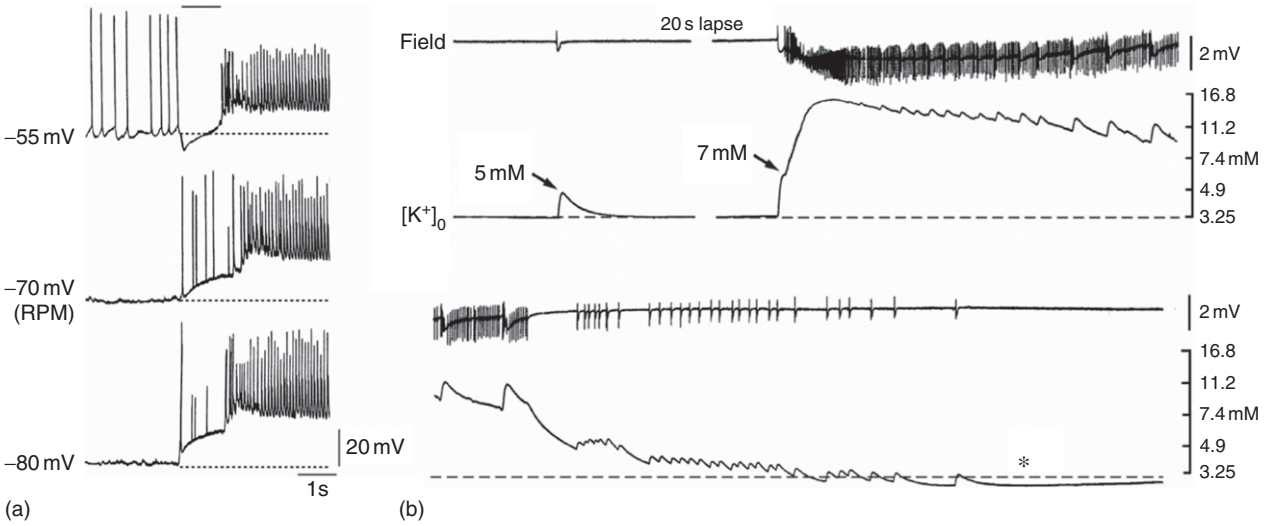

Figure 2 (a) Characteristics of the long-lasting depolarization occurring at ictal discharge onset in a neuron of the medial entorhinal cortex that was recorded with K-acetate-filled microelectrode. Note that when the neuronal membrane is depolarized by intracellular injection of steady positive current (−55 mV) the amplitude of the sustained ictal depolarization decreases while the initial long-lasting depolarization becomes hyperpolarizing as compared with the recording obtained at resting membrane potential (RMP, −70 mV). Note also that when the membrane is hyperpolarized by intracellular injection of steady negative current (−80 mV) both long-lasting depolarization and ictal depolarization increase in amplitude as compared with the sample obtained at RMP. (b) 4AP-induced synchronous activity recorded in the rat entorhinal cortex with simultaneous field potential and $[K^+]_o$ recordings. Note that the slow interictal event (arrow) is associated with a transient increase in $[K^+]_o$ up to around 5 mM while that preceding and apparently leading to ictal discharge initiation is accompanied by an increase of around 7 mM. Panels (a) and (b) are modified from Lopantsev V and Avoli M (1998) Participation of GABAA-mediated inhibition in ictal-like discharges in the rat entorhinal cortex. *Journal of Neurophysiology* 79: 352–360; Avoli M, Barbarosie M, Lucke A, Nagao T, Lopantsev V, and Köhling R (1996) Synchronous GABA-mediated potentials and epileptiform discharges in the rat limbic system in vitro. *Journal of Neuroscience* 16: 3912–3924.

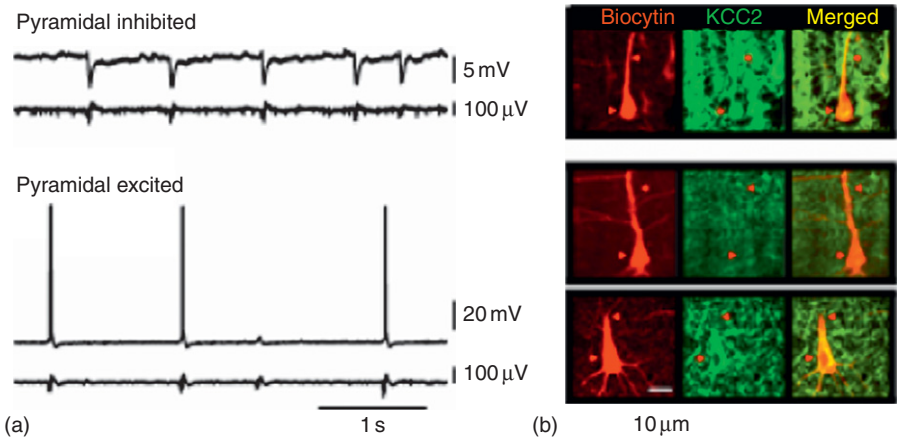

Figure 3 (a) Two different subicular pyramidal cell activities during spontaneous interictal bursts in slices from epileptic patients. Intracellular and extracellular records: In the upper traces the pyramidal cell is inhibited during interictal bursts. The lower traces show a pyramidal cell that is excited and often fires during interictal bursts. (b) Comparison of the expression of the K–Cl cotransporter, KCC2, and pyramidal cell activity during interictal bursts. Six out of six cells showing hyperpolarizing responses expressed KCC2. Four out of seven cells that fired during bursts did not express KCC2. KCC2 was detected in three out of seven cells that depolarized during interictal bursts. Recorded cells were identified by biocytin injection (red); KCC2 expression (green) was detected by immunohistochemistry; in the merged image biocytin and KCC2 expression appears yellow.

during steady injection of depolarizing current. Thus, under these experimental conditions, ictal depolarizations paradoxically originate from a GABAergic event. When GABA$_A$ receptors are activated at high frequency, internal Cl^- increases and a postsynaptic cell depolarization occurs due to the positive shift in reversal potential. Furthermore, the KCC2 transporter starts to operate in reverse, extruding K^+, which further depolarizes neighboring neurons. Application of exogenous GABA is known to increase external K^+ via GABA$_A$ receptor

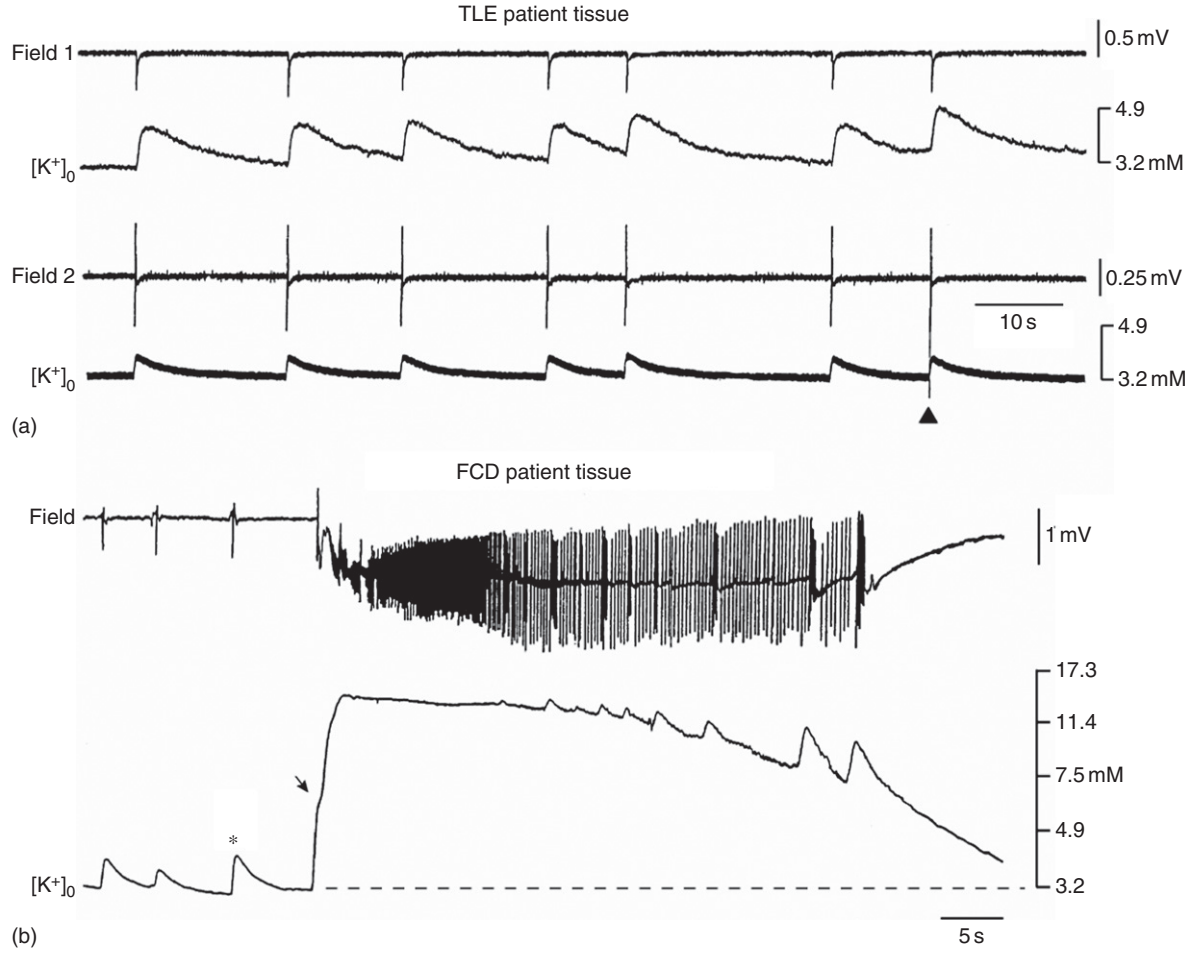

Figure 4 Synchronous activity induced by 4AP in neocortical slices obtained from TLE (i.e., presenting with no architectural anomaly) (a) and FCD patients (b). In both experiments field potential and $[K^+]_o$ recordings were obtained simultaneously at 1000–1500 μm from the pia. Note that only isolated field potential events can be recorded from the TLE neocortical tissue as well as that each of these events is associated with a transient increase in $[K^+]_o$ up to 4.4 mM. $[K^+]_o$ increases up to 4.5 mM accompanying the isolated negative field events (asterisk) but an elevation up to 6.4 mM characterizes the field potential leading to the ictal discharge onset (arrow). Panel (a) modified from Louvel J, Papatheodoropoulos C, Siniscalchi A, *et al*. (2001) GABA-Mediated synchronization in the human cortex: Elevations in extracellular potassium and presynaptic mechanisms. *Neuroscience* 105: 803–813; Panel (b) from D'Antuono M, Louvel J, Kohling R, *et al*. (2004) $GABA_A$ receptor-dependent synchronization leads to ictogenesis in the human dysplastic cortex. *Brain* 127: 1626–1640.

activation. An involvement of GABA-mediated K^+ efflux is supported by the increased external K^+, detected at the initiation of slow interictal events induced by 4AP in young rat hippocampus and rat or mouse adult entorhinal cortex (**Figure 2(b)**). The elevation in external K^+ during the slow event preceding an ictal discharge is consistently higher than that associated with a slow interictal event.

As already discussed, the interictal and ictal-type discharges induced by reducing external Mg^{2+} are similar to those initiated by exposing slices of hippocampus and entorhinal cortex to 4AP. They are also accompanied by depolarizing, bicarbonate-dependent GABA events. Depolarizing GABA-mediated events have been associated with gamma frequency oscillations (30–100 Hz). Inhibitory connections between GABAergic interneurons promote network oscillations at gamma frequencies, which may have a physiological role in learning and memory consolidation. Gamma oscillations may be synchronous over short and long distances. Long-range synchrony is presumably mediated via interneurons, which make long-range connections between hippocampal regions, or between hippocampus and other brain regions – particularly the entorhinal cortex. In the entorhinal cortex, gamma oscillations also appear to be mediated by direct excitation of inhibitory networks, although entorhinal gamma oscillations are blocked by antagonists of glutamate receptors while hippocampal oscillations are not. Both gamma oscillations and ictal events in the entorhinal cortex are blocked by $GABA_A$ receptor antagonists (**Figure 1(d)**).

Intriguingly, gamma frequency discharges may contribute to the emergence of an epileptic focus. In a model of an epileptic 'mirror focus' (based on two connected

hippocampi, one of which was treated with a convulsant), it was recently shown that independent mirror focus activity emerged in the untreated hippocampus only if it received activity in the gamma frequency range from the treated primary focus. More importantly, the emergent activity of the mirror focus was not dependent on glutamatergic signaling but was suppressed by $GABA_A$ receptor antagonists. The clinical observation that neocortical seizures are often initiated in zones that generate gamma oscillations supports the hypothesized role of gamma frequency oscillations as a marker for seizure initiation sites.

Involvement of $GABA_A$ Receptors in Animal Models of Temporal Lobe Epilepsy

A more direct approach to the role of GABA receptors in epileptic disorders is provided by animal models that mimic the spontaneous occurrence of epileptic seizures in temporal lobe epilepsies. As in patients, these models are characterized by Ammon's horn sclerosis together with synaptic reorganization, particularly in the dentate gyrus. While the ability of interneurons to release GABA is intact in most animal models of temporal lobe epilepsy, the function of GABA-mediated inhibition may be changed. Some studies have shown a reduction in $GABA_A$ receptor function in electrically kindled rats, while other studies suggest that a reemergence of ontogenetically immature GABA-receptor expression patterns may underlie epileptogenesis. Recent investigations using kainate and pilocarpine modes have described a reconfiguration of inhibitory circuits that produces an enhanced somatic inhibition, together with reduced GABAergic actions on the dendrites of CA1 pyramidal neurons. The increased somatic inhibition was ascribed to enhanced firing of somat-targeting interneurons, and the decreased dendritic inhibition to degeneration of interneurons producing dendritic input. Computational studies suggest that these differential changes in GABAergic circuits may contribute to the transition from interictal to fast ictal activity.

Changes in Basal Cl^- Homeostasis and Interictal-Like Activity

A different proepileptic alteration in GABAergic signaling has emerged from work on tissue obtained from surgery on patients with pharmacoresistant temporal lobe epilepsies. Several studies have shown that antagonists of $GABA_A$ receptors suppress synchronous population discharges generated by human epileptic tissue in vitro. This observation suggests that GABAergic signaling may contribute, together with glutamatergic transmission, to the generation of interictal-like synchrony. Cellular studies on human tissue slices revealed that the reversal potential for $GABA_A$-mediated synaptic events was depolarizing (with respect to resting potential) in a minority of pyramidal cells of the subiculum, the region in which the interictal synchrony was initiated. Such a depolarized reversal potential is suggestive of a basal change in Cl^- homeostasis. Recordings of IPSP reversal potential in pyramidal cells, together with immunostaining of the same cells, suggest that expression of KCC2 (a K^+–Cl^- cotransporter that contributes to the regulation of internal Cl^-) may be reduced in a subset of subicular pyramidal cells. In this cell group, GABA provides an excitatory drive, which combines with that transmitted via glutamatergic synapses to assure synchrony. In contrast, GABA effects on the majority of pyramidal cells is hyperpolarizing, thus limiting the duration of interictal discharges.

Depolarizing GABAergic responses in pyramidal cells of the epileptic subiculum, and the associated alterations in molecules controlling Cl^- homeostasis, 'recapitulate' events during early postnatal development in rodents. In rat, the Cl^- cotransporter KCC2 is expressed at about 10 days after birth, and until this time GABAergic signaling is depolarizing. Investigators have speculated that the partial denervation of subicular cells in epileptic temporal lobe, due to the sclerosis-induced loss of their presynaptic partners in the CA1 region, induces a return to an immature pattern of Cl^- homeostasis. That mechanisms initiated by glial cells might be involved is suggested by the observation that following damage to afferents in the spinal cord, BDNF liberated by microglia activates trkB receptors leading to a KCC2 downregulation and a depolarizing shift in GABAergic reversal potentials associated with pathological pain responses. Shorter term changes in KCC2 function might also be involved in the rapid kindling-like depolarizing shift of GABAergic responses, as seen in the establishment of a mirror focus in vitro.

$GABA_A$ Receptors and Epileptiform Synchronization in Human Focal Cortical Dysplasia

Taylor's type, focal cortical dysplasia (FCD) is characterized by a localized disruption of normal cortical lamination, with the presence of balloon cells and an excess of large aberrant neurons in the underlying white matter. Seizures in FCD patients are often medically intractable, which makes them candidates for neurosurgical interventions to resect the epileptogenic FCD area. During intraoperative electrocorticography, epileptic activity is often recorded from electrodes overlying the dysplastic cortical area. Immunocytochemical analysis of surgically resected human FCD tissue has revealed a decreased number of presumptive interneurons, but also suggests that the remaining interneurons provide an increased GABAergic innervation to principal cells. Slices of FCD tissue, exposed to 4AP, generate NMDA receptor-mediated ictal discharges as well as isolated, interictal-like synchronous potentials

largely dependant on $GABA_A$ receptor-mediated conductances. 4AP treatment of human neocortical tissue without obvious structural abnormalities induces only interictal-like potentials (**Figure 4**). These data support the view that epileptogenicity is a functional feature of FCD tissue. Furthermore, 4AP-induced activity in FCD slices resembles pre-excision ECoG records made from the dysplastic lesion, and appears to be a specific, sensitive indicator of FCD lesions.

As in the rodent limbic system, ictal-like activity in slices of human FCD tissue treated with 4AP is initiated (and presumably maintained) by mechanisms that depend on $GABA_A$ receptors. These ictal discharges are preceded by negative-going field events similar to those observed in isolation during the interictal period. However, the negative field potentials leading to ictal discharge onset are consistently of larger amplitude than those associated with interictal events, and are often followed by a secondary, slow negative field event from which ictal oscillations emerge. In FCD tissue slices, transient elevations in $[K^+]_o$ occur during slow 4AP-induced interictal events to levels consistently larger than those occurring during synchronous discharges recorded in non-FCD slices obtained from temporal lobe epileptic patients. Furthermore, the increases in $[K^+]_o$ associated with GABA receptor-mediated potentials preceding the onset of ictal discharges are larger than those associated with any field potentials observed during the interictal period. These findings from studies of FCD tissue are similar to those made in immature cortical slices, suggesting that the human dysplastic cortex may revert to – or rather retain – ontogenetically immature properties.

The role of GABA receptor-mediated synchronization in initiating ictal activity in FCD tissue is also supported by pharmacological manipulations that modify $GABA_A$ receptor function. $GABA_A$ receptor antagonism, or activation of μ-opioid receptors to block GABA release from interneuron terminals, suppresses both ictal discharges and GABA receptor-mediated interictal events in FCD slices, and recurrent interictal epileptiform activity reemerges. Conversely, ictal and interictal activity is enhanced when $GABA_A$ receptor function is potentiated with low doses of phenobarbital.

Conclusions and Directions for Future Research

While is there no doubt that blocking GABA receptor function leads to neuronal hyperexcitability and short-lasting epileptiform discharges, evidence obtained from several in vitro models of epileptiform discharge indicates that inhibition can also initiate and sustain ictal discharge depolarizations. It also appears that this mechanism rests on the ability of $GABA_A$ receptor-mediated conductances to depolarize, under specific circumstances, brain cells – thus causing sizeable elevations in $[K^+]_o$. The possibility that activation of $GABA_A$ receptors can initiate epileptic discharge goes beyond the experiments performed in normal animal tissue, as similar mechanisms have been identified in the subiculum of temporal lobe epilepsy patients as well as in human FCD tissue.

GABA$_A$ Receptor Plasticity in Epileptogenesis

Y H Raol and A R Brooks-Kayal, Children's Hospital of Philadelphia, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

It is clear from studies carried out in various animal models and retrospective studies from humans that an initial precipitating event such as status epilepticus (SE) can increase the risk of later development of epilepsy. The process of epilepsy development (epileptogenesis) is complex and multifactorial. Many laboratories, including our own, have focused on understanding the role of γ-aminobutyric acid (GABA) receptor plasticity in epileptogenesis. GABA is the major inhibitory neurotransmitter in the mature brain, and various drugs such as diazepam and barbiturates that enhance GABAergic inhibition are commonly used as antiepileptic drugs. Also, drugs that block GABAergic inhibition can induce seizures in animals, further supporting the potential importance of alterations in GABAergic transmission in epileptogenesis. In this article we will describe the changes that have been observed in GABA$_A$ receptor (GABAR) subunit expression following prolonged seizures in various animal models of epilepsy, and the role these changes may play in epileptogenesis. Also, we will highlight the differences in GABAR subunit expression that occur following SE in adult and developing animals.

Background

GABA is the major inhibitory neurotransmitter in the adult brain. Three types of GABA receptors, GABA$_A$, GABA$_B$, and GABA$_C$, are found in the mature central nervous system. GABA$_A$ and GABA$_C$ are ionotropic receptors, whereas GABA$_B$ is a metabotropic receptor. Most fast synaptic inhibition in the mature brain is mediated by GABARs, whereas slow inhibition is mediated by GABA$_B$ receptors. GABARs are composed of multiple subunits subtypes (α1–6, β1–3, γ1–3, δ, ε, π, θ, and ρ1–3) that form a pentameric anion-selective channel. The most common in vivo subunit composition is two α, two β, and one γ subunit. There is remarkable receptor heterogeneity, with subtype combinations varying in different brain regions, cell types, and during different times in ontogeny. Different subunit subtypes confer distinct functional and pharmacological properties to the receptors.

Several laboratories have studied the changes in GABAR subunit composition in human temporal lobe epilepsy (TLE) and in animal models of TLE. Houser and colleagues have shown that in the CA1 and CA2 areas of the hippocampus there are long-lasting reductions in the α5 subunit of GABARs in pilocarpine-treated animals that develop spontaneous seizures. The α5 subunit is primarily extrasynaptic and is thought to be involved in tonic inhibition in the CA1 area. Lower levels of α5 subunit may thus result in reduction of tonic inhibition. In the molecular layer of denate gyrus, levels of α1, α3, α4, α5, and γ2 increase and levels of δ decrease chronically following SE. In interneurons of dentate gyrus, however, α1 subunit levels decrease and δ subunit levels increase, suggesting that there are cell-specific changes within the same region of the hippocampus. Additional studies from the Houser group suggest that changes in GABA receptor function after SE may depend not only on the levels of different subunits within individual neuronal cell types, but also on the subcellular localization of different GABAR subunits within these cells. Using immunogold labeling, these investigators showed that the subcellular location of γ2 and δ subunits in molecular layer of dentate gyrus was changed in pilocarpine-treated epileptic mice; they found a decrease in δ and an increase in γ2 subunits at perisynaptic locations, and a decrease in γ2 labeling near the center of the synaptic contacts. The change in the location of these subunits correlated with an insensitivity of the tonic current to neurosteroids and reduced phasic inhibition of DGCs in pilocarpine-treated epileptic mice. This impairment in inhibition could play an important role in development of epilepsy in this mouse model of TLE.

Introduction

Epilepsy is a disease of complex etiology and multiple molecular mechanisms contributing to its development. The development of temporal lobe epilepsy (TLE) often occurs after a traumatic event to the brain, such as head injury or prolonged seizure activity (status epilepticus, SE). After this initial event, a latent period ensues before recurrent spontaneous seizures (epilepsy) develop. Changes in the expression of multiple genes, including those that encode ligand- and voltage-gated ion channels, have been implicated in the process of epileptogenesis. Several growth or transcription factors are known to be activated by SE, including (but not limited to) brain-derived neurotrophic factor (BDNF), cAMP response element binding protein (CREB), inducible cAMP early repressor (ICER), and early growth response factors (EGRs). Results of multiple studies suggest that these factors regulate gene expression in a way that is pertinent to seizure-induced changes in brain function. This article will introduce each of these signaling elements and provide an overview of their possible roles in gene regulatory pathways that are critical for, or associated with, the epileptic condition. Recent work elucidating specific mechanisms that regulate changes in subunits that assemble to form the major inhibitory neurotransmitter receptor in the brain, the type A γ-aminobutyric acid receptor (GABAR), will then be discussed in detail. Major alterations in the expression of certain GABAR

subunits are thought to contribute to epilepsy after SE in human TLE patients and in animal models of TLE. Specifically, α1 GABAR subunit mRNA levels decrease and α4 GABAR subunit mRNA levels increase by 24 h after SE, as measured in single dentate granule neurons of the rat hippocampus. These subunit changes are accompanied by a reduction in α1- and an increase in α4-containing synaptic (γ2-containing) GABARs in the dentate gyrus (DG) of the hippocampus. This change in receptor composition may result in impaired inhibition, making the brain more vulnerable to hyperexcitability.

Background

Signaling Proteins Involved in $GABA_A$ Receptor Subunit Regulation

Brain-derived neurotrophic factor

BDNF is one member of the mammalian neurotrophins (NTs). The classical view of NT function includes its effects on the growth and survival of neurons during development through the activation of Trk receptors. Recent studies suggest that the presence of NTs in the adult brain has a striking influence on neuronal excitability. Expression levels of BDNF and TrkB increase in kindling kainic acid (KA) and pilocarpine models of TLE. BDNF mRNA and protein levels are elevated in temporal lobe tissue from human epileptic brains.

Evidence that BDNF upregulation is associated with seizure activity suggests that BDNF may play a role in epileptogenesis. Lindvall and colleagues have shown that $BDNF^{+/-}$ mice show a marked reduction in the rate of kindling development and Scharfmann and colleagues have demonstrated that transgenic mice overexpressing BDNF have more severe seizures in response to KA. McNamara's group showed that intracerebroventricular administration of TrkB-Fc receptor bodies, to sequester endogenous BDNF, inhibits development of kindling, and that kindling development is impaired in conditional TrkB null mice. While evidence clearly points to a role of the TrkB receptor and its ligand (BDNF) in seizure susceptibility, the cellular and molecular mechanisms of BDNF/TrkB promotion of epileptogenesis remain to be fully elucidated. BDNF has been shown to both enhance excitatory synaptic transmission and reduce inhibitory transmission. The mechanisms underlying excitatory synaptic potentiation by BDNF is currently unclear, but could involve the facilitation of neurotransmitter release, phosphorylation of NMDA receptors, and direct effects on ion channels and/or conductances.

Enhanced excitatory neurotransmission by BDNF might also arise indirectly through alteration of the structure and function of GABAergic neurons. Several mechanisms have also been suggested regarding BDNF-induced modulation of inhibitory transmission, which include phosphorylation of the GABAR, alteration of GABAR trafficking, and regulation of subunit gene expression. For details, see suggested readings and discussion below.

Early growth response factors

A growing number of studies demonstrate an association between induction of immediate early genes (IEGs), such as Egrs, and seizure activity. Egrs are a family of four proteins (Egr1, 2, 3, and 4) that share nearly identical zinc finger DNA binding domains and bind to a common Egr response element consensus sequence (EREs), GCG T/GGG GCG. However, studies in Egr1-4-deficient animals illustrate quite divergent physiological roles for each protein. Baraban and colleagues have shown that there is sequential induction of Egr1 and Egr3 transcription factors after electroconvulsive shock (ECS) and gel shift assays demonstrate that Egr1 and Egr3 DNA binding activities follow the same pattern. These findings indicate that Egr1 and Egr3 act in concert to mediate early and late phases, respectively, of the transcriptional response regulated by their cognate response element and may play different regulatory roles.

Our laboratories have also shown induction of Egr family transcription factors after SE, with protein levels of Egr3 increasing in the DG of the hippocampus 24 h after pilocarpine-induced SE. The role that changes in Egrs plays in the process of epileptogenesis remains to be determined. One hypothesis is that Egrs may be critical for differential regulation of ligand-gated ion channel receptors that occurs in TLE patients and in several animal models of TLE. Egr1 has been shown to increase promoter activity and expression levels for several N-methyl-D-aspartate receptor subunits. Egr transcription factors may also play an important role in the regulation of different subunits of GABARs as discussed later.

CREB/ICER

The CREB is another key transcription factor that may mediate observed gene expression changes in epilepsy. CREB is a stimulus-induced bZIP transcription factor that is activated by phosphorylation at its Ser 133 site. Phosphorylated CREB (pCREB) dimerizes and binds to cAMP response element (CRE) motifs on promoters that contain the consensus sequence TGACGTCA. Along with its anchoring binding partner, CREB binding protein (CBP), pCREB upregulates transcription of target genes. Transcriptional regulation through CREB has been implicated in mechanisms of cell survival, plasticity, and learning and memory paradigms. Target genes of pCREB include CREB family members, which consist of cAMP response element modulator (CREM), ICER, and activating transcription factor (ATF). These para- and homologues of CREB also bind CRE elements to

modulate the transcription of particular genes. The CREM gene produces many spliced isoforms that can act as transcriptional repressors or activators. One of these repressor forms is ICER, a group of four proteins made from an internal promoter of the CREM gene. ICER can heterodimerize with CREB and directly block CREB-induced transcription.

Several studies using adult animal models of epilepsy suggest that seizures upregulate CREB or CREM/ICER activity for varying durations. For example, PTZ-induced seizures in adults increase pCREB levels transiently, and electroconvulsive seizures have been found to cause rapid increases of CREM and ICER mRNA expression. Our laboratory, using the pilocarpine model of SE, has found more sustained increases in both pCREB and ICER in the DG of the hippocampus, continuing 1–48 h after SE. This study demonstrated that these increases in pCREB and ICER may mediate the α1 GABAR subunit decreases that occur after SE in the DG, as detailed later. Seizures not only influence CREB phosphorylation, but also influence the association of CREB with CRE sequences on promoters of target genes, a necessary component of CREB transcriptional control. Taken together, these results suggest that increases in the levels or activation state of CREB and its family members, seen after multiple types of seizure induction, may be important mechanisms responsible for the changes in gene expression that occur during epileptogenesis.

Methods

Animal models of epilepsy have been used to study changes in GABARs that occur during the development of spontaneous seizures. In adult rats, the muscarinic agonist pilocarpine induces prolonged seizure activity (SE) and after a latent period of 5–14 days, spontaneous seizures occur in the absence of any provocation. As also occurs in human TLE, GABAR subunit composition is altered in individual DGNs in epileptic rats in this model. We examine tissue from the DG of animals sacrificed during the latent period, and use RT-PCR to examine mRNA levels and Western blotting to examine protein levels of various transcription factors. To better determine if certain transcription factors are regulating GABAR subunit genes, we use chromatin immunoprecipitation (ChIP) to examine if binding of the transcription factor to the subunit gene promoters is increased after SE. To perform ChIP, animals are first perfused with phosphatase inhibitors in saline, then 4% paraformaldehyde, in order to cross-link protein to associated sites on DNA. The DNA–protein complexes are then precipitated with antibodies to the transcription factors of interest: for example, CREB, pCREB, or early growth response factors (EGRs). Once the associated proteins are precipitated with antibodies, the DNA for the α1 CRE or other promoter binding site of interest is detected and quantified with RT-PCR. In our recent studies, we also wanted to detect ICER binding at the α1 CRE site; however, all antibodies to ICER also recognize CREM variants, and so the two transcription factors can only be distinguished by size. We therefore developed a DNA pull-down assay to purify nuclear proteins in DG tissue that specifically recognize the GABRA1:CRE – identified by size using gel electrophoresis. Oligonucleotide duplexes corresponding to GABRA1:CRE and its flanking region are covalently linked to a biotin moiety at their 5′ends, and oligos and their nuclear binding proteins are recovered using magnetic Streptavidin Dynabeads.

Recent Results

Transcriptional Regulation of $GABA_A$ Receptor Subunits

$GABA_A$ receptor α1 subunit gene (GABRA1)

Although many mechanisms of gene regulation remain to be characterized, recent work in our laboratories has established CREB and ICER as critical mediators of GABAR α1 subunit mRNA decreases that occur after SE in the DG. In adult animal models and human TLE, GABAR α1 mRNA levels decrease in DG 24 h to 1 week after SE. Viral delivery of α1 into DG protects rats from development of spontaneous seizures following pilocarpine-induced SE, suggesting that α1 down-regulation is potentially a critical determinant of epileptogenesis. Decreased levels of α1 are accompanied by a reduction in the number of α1-containing synaptic GABARs (as determined by the presence of γ2) and an increase in α4-containing synaptic GABARs. The human α1 promoter contains a functional CRE, making CREB and its family members potential regulators of α1 gene regulation in epilepsy. A study using microarrays to detect changes in multiple mRNAs in response to overexpressed dominant-negative CREB (MCREB) in vivo first suggested that GABRA1 might be regulated by CREB, directly or indirectly. However, it remained unknown whether the CREB system was involved in GABRA1 changes associated with epilepsy. In accordance with previous findings, we found increases in pCREB protein and ICER mRNA and protein in the DG at 1–48 h after SE. Using ChIP and DNA pull-down studies, increased pCREB and ICER binding at the CRE site of GABRA1 were also observed after SE. Further, in vitro studies manipulating CREB and ICER levels showed that overexpression of CREB and ICER together decreases GABRA1 promoter activity in primary hippocampal neurons. In contrast to adults, neonatal rats show increases in α1 levels after SE, and display no changes in pCREB and ICER levels compared with those in controls. These findings suggest that CREB

and ICER are important regulators of seizure-induced GABRA1 changes.

In addition, BDNF has been associated with changes in both α1 and α4 subunit levels associated with epilepsy (discussed later). BDNF treatment of primary hippocampal neurons in culture resulted in similar changes in α subunit levels as observed after SE. After 24 h of BDNF treatment, α1 levels decrease 42% and α4 levels increase 57%. Given the well-documented increases in BDNF that occur after SE, and that CREB has long been associated with BDNF regulation, both of these signaling molecules are likely to be involved in the alteration of GABAR function that occurs in TLE.

$GABA_A$ receptor α4 subunit gene (GABRA4)

GABARs that contain α4 subunits have unique pharmacologic properties such as insensitivity to benzodiazepines and increased sensitivity to zinc blockade. Receptors containing α4 subunits are most often found with the δ rather than γ subunit, in combination with αβ. These α4βδ GABARs are localized to extrasynaptic sites and contribute to tonic inhibition. A minor population of α4βγ2 GABARs are found within DG synapses where they are proposed to affect both the rise time and decay of synaptic currents.

Pharmacological changes in GABAR function in DGCs, including decreased augmentation by type 1 benzodiazepine agonists and increased inhibition by zinc, are observed in isolated DGCs in tissue from both animal models and human TLE. These changes are associated with a marked increase in α4 and decrease in α1 subunit expression. Our studies have shown that the alteration in α4 levels is transcriptionally mediated, and have identified Egr3 as a specific regulator that is responsible for the upregulation of α4 subunit expression. BDNF is believed to be the endogenous signal that induces Egr3 synthesis via a PKC/MAPK-dependent pathway.

These findings are in agreement with the work of Houser and colleagues who observed increases in the levels of α4 and γ2 subunits and decreases in the levels of δ subunits after pilocarpine-induced SE in mice. Taken together, these changes in subunit gene expression may result in a number of functional effects. The loss of δ subunits may lead to a drop in the overall number of extrasynaptic GABARs, decreasing the overall levels of tonic inhibition and lowering the excitatory threshold for affected neurons. In addition, changes in the levels of α4 and α1 subunits suggest that the effect of these changes may extend beyond tonic inhibition and also affect synaptic and/or perisynaptic GABA signaling. Direct evidence for this possibility comes from recent studies in which the decrease in expression of the α1 subunit and increase in expression of the α4 subunit are associated with less α1γ2-containing and more α4γ2-containing $GABA_A$ receptors ($GABA_AR$) in DG after SE. Consistent with these observations, Houser and colleagues reported that there is an increase in the co-localization of α4 and γ2 subunits in DG neurons after SE. The change in receptor subtype from α1βγ2 to α4βγ2 may contribute to epileptogenesis, as α4 containing GABARs have been shown to desensitize rapidly, especially when assembled with β3 subunits. In addition, sensitivity of GABARs to zinc blockade is influenced by the type of α subunit in the receptor complex. GABARs containing the α4 subunit are very sensitive to zinc blockade, as is seen in DGCs of epileptic brain. In epileptic animals, DGCs not only are exposed to a greater amount of zinc as a result of mossy fiber (MF) sprouting accompanying the development of hippocampal sclerosis, but they also undergo a change in GABAR subunit composition that generates a receptor exquisitely sensitive to zinc blockade. Such a change in the sensitivity of GABARs to the zinc released from MF has been hypothesized to contribute to epilepsy development. Whether or not MF sprouting is a necessary prerequisite for TLE, however, is still under intense investigation.

Future Goals

The full range of gene expression changes that are involved in epileptogenesis and the molecular mechanisms that underlie them are just beginning to be characterized. While the transcription factors discussed in this chapter likely compose only a part of the cascade of signaling events that are initiated by seizures, it is clear that BDNF, Egr3, CREB, and ICER play important roles. Recent work characterizing their functions in GABAR α1 and α4 subunit changes in the DG after SE provides an important lead for the future development of molecular therapies. However, the upstream signalers of these pathways, and the exact means through which they confer vulnerability to epilepsy, remain to be further elucidated.

Molecular Pathology of Genetic Epilepsy Associated with $GABA_A$ Receptor Subunit Gene Mutations

Introduction

Idiopathic generalized epilepsies (IGEs) affect about 1% of the population worldwide and are among the most common neurological disorders. IGEs are a group of presumably genetic epilepsies that encompass several different clinical phenotypes, including childhood absence epilepsy (CAE), juvenile myoclonic epilepsy (JME), pure febrile seizures (FS), generalized epilepsy with febrile seizures plus (GEFS+), and generalized epilepsy with tonic-clonic seizures. In neuronal networks, either a 'gain of function' of receptor channels mediating excitatory neurotransmission or a 'loss of function' of receptor channels mediating inhibitory neurotransmission could impair the subtle balance of excitation and inhibition in the brain, thus, leading to disinhibition and seizures.

Genetic advances and functional characterizations of the pathophysiological alterations in receptor channel trafficking and function are changing our understanding of IGEs. It is becoming increasingly clear that genetic mutation of transmembrane ion channels is the underlying cause of many forms of human IGEs, both in large pedigrees and in sporadic cases or de novo mutations. The original conceptualization of epilepsy as merely a loss of channel function or an imbalance between excitation and inhibition is probably oversimplified. The imbalance resulting from channel dysfunction is not sufficient to delineate the pathogenesis of all epilepsy syndromes in which the underlying channel abnormalities have been verified. In this article, we will review the molecular pathology of IGEs caused by $GABA_A$ receptor mutations based on the recent studies.

Molecular Pathology of Genetic Epilepsy Associated with $GABA_A$ Receptor Subunit Gene Mutations

J-Q Kang and R L Macdonald, Vanderbilt University Medical Center, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Idiopathic generalized epilepsies (IGEs) affect about 1% of the population worldwide and are among the most common neurological disorders. IGEs are a group of presumably genetic epilepsies that encompass several different clinical phenotypes, including childhood absence epilepsy (CAE), juvenile myoclonic epilepsy (JME), pure febrile seizures (FS), generalized epilepsy with febrile seizures plus (GEFS+), and generalized epilepsy with tonic-clonic seizures. In neuronal networks, either a 'gain of function' of receptor channels mediating excitatory neurotransmission or a 'loss of function' of receptor channels mediating inhibitory neurotransmission could impair the subtle balance of excitation and inhibition in the brain, thus, leading to disinhibition and seizures.

Genetic advances and functional characterizations of the pathophysiological alterations in receptor channel trafficking and function are changing our understanding of IGEs. It is becoming increasingly clear that genetic mutation of transmembrane ion channels is the underlying cause of many forms of human IGEs, both in large pedigrees and in sporadic cases or de novo mutations. The original conceptualization of epilepsy as merely a loss of channel function or an imbalance between excitation and inhibition is probably oversimplified. The imbalance resulting from channel dysfunction is not sufficient to delineate the pathogenesis of all epilepsy syndromes in which the underlying channel abnormalities have been verified. In this article, we will review the molecular pathology of IGEs caused by $GABA_A$ receptor mutations based on the recent studies.

Background: Mutations in $GABA_A$ Receptor Subunit Genes

$GABA_A$ receptors are the primary mediators of fast inhibitory synaptic transmission in the central nervous system, and are formed by pentameric assemblies of multiple

subunit subtypes (α1–α6, β1–β3, γ1–γ3, δ, ε, π, θ, and ρ1–ρ3) that form chloride ion channels. The most common $GABA_A$ receptors contain two α subunits, two β subunits, and a γ- or δ subunit. $GABA_A$ receptors mediate both phasic, inhibitory synaptic transmission and tonic, perisynaptic tonic inhibition, and several antiepileptic drugs work through enhancement of $GABA_A$ receptor currents.

Mutations or variants associated with IGEs have been reported in $GABA_A$ receptor α1, β3, γ2, and δ subunits (Figure 1). These mutations include missense mutations (GABRA1(A322D), GABRB3(P11S), GABRB3(S15F), GABRB3(G32R), GABRG2(R43Q), GABRG2(R139G), GABRG2(K289M)), as well as nonsense mutations (GABRG2(Q1X), GABRG2(Q351X)), splice donor site mutations (GABRG2(IVS6 + 2T → G)), or frameshift mutations (GABRA1(975delC, S326fs328X) that generate premature termination codons (PTCs). There are also variants of GABR genes that have been identified as seizure susceptibility genes (GABRD(E177A) and GABRD (R220H)). The mutations and variants are located in both exons and introns of the affected subunit genes, and in signal peptides or mature peptides of the affected subunit proteins. The missense mutations have been shown to impair receptor trafficking of mutant receptors to the cell surface and/or to alter receptor channel kinetics. Impaired trafficking of receptors harboring missense mutations has been shown to be due to posttranslational modifications of subunits, such as impaired folding, impaired assembly, glycosylation arrest, endoplasmic reticulum (ER) retention, or accelerated degradation of the mutant proteins by ER-associated degradation (ERAD). The PTC-generating mutations could trigger degradation of mRNA through nonsense-mediated decay (NMD) due to cellular mRNA quality control, thus eliminating production of the mutant protein.

Mutations in $GABA_A$ Receptor α1 Subunits

$GABA_A$ receptor α1 subunit mutation (A322D)

The α1 subunit mutation (A322D), associated with autosomal dominant JME, introduces a negatively charged aspartate into the middle of the M3 transmembrane helix of the α1 subunit at residue A322. It could be predicted that such a nonconserved mutation in a transmembrane domain would destabilize helix formation and alter α1 subunit folding and pentamer assembly. It has been shown that when coexpressed with wild-type β2 and γ2 subunits, the mutant α1(A322D) subunit reduced both total and surface α1 subunit levels, and had an intermediate effect with 'heterozygous' subunit expression (α1:α1 (A322D – 1:1 cDNA ratio). Peak GABA-evoked currents were significantly reduced in both 'heterozygous' and 'homozygous conditions.' The loss of the mutant protein

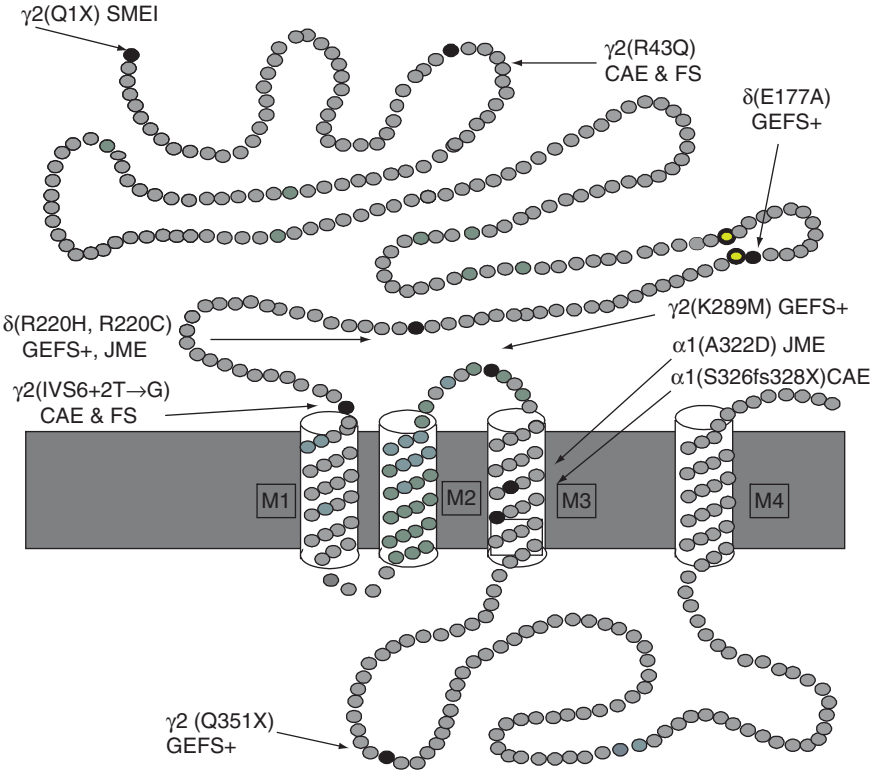

Figure 1 Schematic representation of the $GABA_A$ receptor subunit topology, showing the location of autosomal dominant epilepsy mutations associated with different IGEs.

was due to an ER quality control process, ERAD. A recent study also demonstrated that this mutant protein was subject to rapid degradation through the ubiquitin–proteosome system (Figure 4).

Mutations in GABA$_A$ Receptor β3 Subunits

GABA$_A$ receptor β3 subunit mutations, P11S, S15F, and G32R

Two mutations in β3 signal peptide (exon 1a; P11S, S15F), and a mutation in β3 (exon 2) (G32R) have been associated with CAE. The underlying molecular defect could be abnormal protein expression and/or impaired receptor trafficking, but the mechanism is still under study. Early reports have revealed that heterozygous and homozygous null mutant GABRB3 mice show absence-like features, including the EEG characteristics and pharmacological responses to antiepileptic drugs that are typical for absence seizures. GABRB3 deletion has also been associated with Angelman syndrome in which CAE is present. In addition, a GABRB3 promoter haplotype impairing transcriptional activity has also been associated with CAE. Thus, mutation of the GABRB3 subunit likely contributes to generation of CAE, but this involvement needs to be clarified further.

Missense Mutations in GABA$_A$ Receptor γ2 Subunits

GABA$_A$ receptor γ2 subunit missense mutation, R43Q

The γ2 subunit missense mutation, R43Q, was reported in affected individuals of a large family having both CAE and FS (Figure 1). The functional and cellular consequences of this mutation have been studied extensively from oocyte preparations and mammalian cells to knock-in animals. The data, both in vitro and in vivo, consistently showed reduction of surface γ2 subunit protein with heterozygous expression. We demonstrated that heterozygous expression of mutant α1β2γ2/γ2(R43Q) receptors in HEK 293–T cells resulted in reduced peak current. In vivo in γ2(R43Q) knock-in mice, a small but significant reduction of GABA$_A$ receptors in cortical pyramidal neurons was also observed. Using fusion proteins, in which DNA encoded enhanced yellow fluorescent protein (EYFP) was inserted between amino acids four and five of the mature γ2 subunit (γ2-YFP), we demonstrated (using fluorescence microscopy) that the basis for the reduced surface expression of the mutant protein was ER retention of the mutant protein (Figure 2). Thus, the reduced surface expression of mutant α1β2γ2S (R43Q) receptors was a consequence of receptor ER retention because of impaired protein assembly, folding, and/or trafficking.

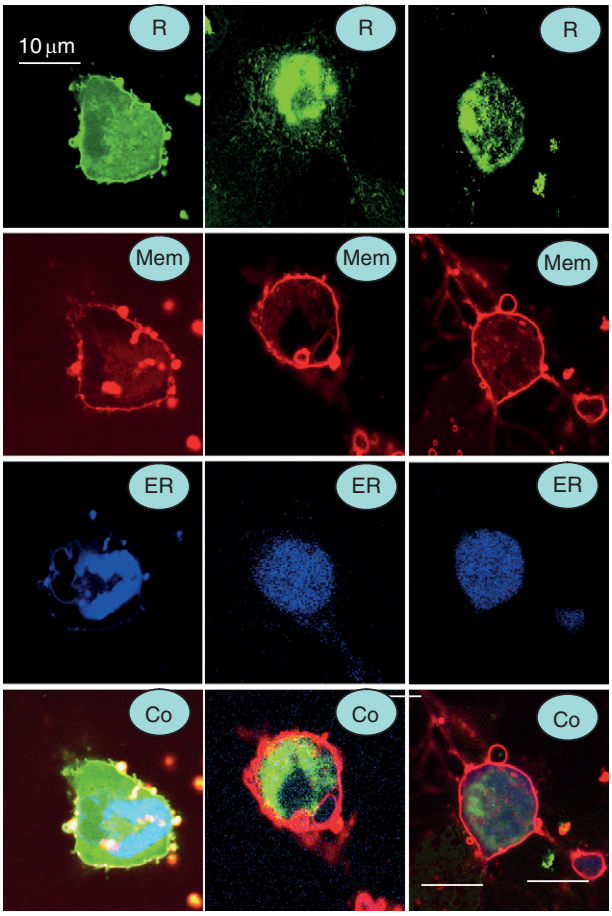

Figure 2 Heterozygous and homozygous α1β2γ2S(R43Q) receptors were retained in the ER. Human α1β2γ2S-YFP wild-type (wt) or α1β2γ2S(R43Q)-YFP heterozygous (het) or homozygous (hom) receptors in COS-7 cells were coexpressed with enhanced CFP-tagged ER marker and labeled with FM4–64 membrane marker. R stands for receptor, Mem for membrane, ER for endoplasmic reticulum and Co for colocalized image. Wt α1β2γ2S-YFP receptors were primarily in the cell membrane. Het α1β2γ2S(R43Q)-YFP receptors were found in both the membrane and intracellular compartments. Hom α1β2γ2S(R43Q)-YFP receptors were primarily found in intracellular compartments with minimal localization on the cell surface. Both het and hom receptors had a fluorescence pattern that was similar in distribution to that of the ER fluorescence pattern. (Modified from Kang J and Macdonald RL (2004) The GABAA receptor gamma2 subunit R43Q mutation linked to childhood absence epilepsy and febrile seizures causes retention of alpha1beta2gamma2S receptors in the endoplasmic reticulum. *The Journal of Neuroscience* 24: 8672–8677).

GABA$_A$ receptor γ2 subunit missense mutation, K289M

A family with an autosomal dominant generalized epilepsy similar to GEFS+ was shown to have a mutation in the GABA$_A$ receptor γ2 subunit, K289M, that is located in the short extracellular loop between transmembrane domains M2 and M3 (M2–M3 loop; Figure 1), a region

implicated in the gating of ligand-gated ion channels. We investigated the effects of this mutation using a rapid application, concentration jump technique (open tip application rise time 1 ms) to apply GABA for brief (2–5 ms) durations and the excised outside-out patch clamp recording technique. We demonstrated that α1β3γ2L(K289M) receptors had faster current deactivation. Single channel currents from homozygous α1β3γ2L (K289M) receptors had mean open times that were one fourth as long as wild-type α1β3γ2L receptor currents, consistent with its more rapid whole cell current deactivation time (Figure 3). Briefly, rapid GABA applications to excised macropatches evoked currents that were similar to inhibitory post synaptic currents (IPSCs). Therefore, reduction of the duration of rapid GABA-evoked current by the γ2L(K289M) subunit mutation suggests that this mutation would result in reduced IPSC duration, thus producing disinhibition that may lead to epilepsy.

$GABA_A$ receptor γ2 subunit missense mutation, R139G

The $GABA_A$ receptor γ2(R139G) subunit mutation was identified in a small FS only pedigree. The R139 residue is conserved among γ2 subunits across species, and basic residues are conserved among other γ subunits. Within the cys-loop family, polar, and charged amino acid residues occur at this position. Residue R139 is located at a highly conserved and likely aqueous accessible part of the amino terminus in a hairpin loop between β sheets 5 and 6. We demonstrated that the mutant α1β3γ2L (R139G) receptors had subtly altered current kinetics and reduced benzodiazepine sensitivity. Future study of the mutant protein maturation and receptor trafficking will further elucidate the molecular defect of this mutation in epilepsy.

Nonsense and Splice Donor Site Mutations in $GABA_A$ Receptor γ2 Subunits

$GABA_A$ receptor γ2 subunit nonsense mutation, Q351X

A γ2 subunit mutation, Q351X, is associated with a family with GEFS+, including two family members with FS and a member with Dravet syndrome. The Q351X mutation is localized in the γ2 subunit intracellular loop between transmembrane domains M3 and M4 (Figure 1) and results in a premature translation-termination codon (PTC) with loss of the downstream 78 amino acids. This mutation was studied by using green fluorescent protein (GFP)-tagged γ2 subunits. The receptor containing this mutation was not expressed on the surface, but was retained in the ER. Consistent with this finding, no GABA-evoked current was recorded from oocytes expressing the mutant receptors. Genetic mutations producing PTCs can result in C-terminally truncated proteins that

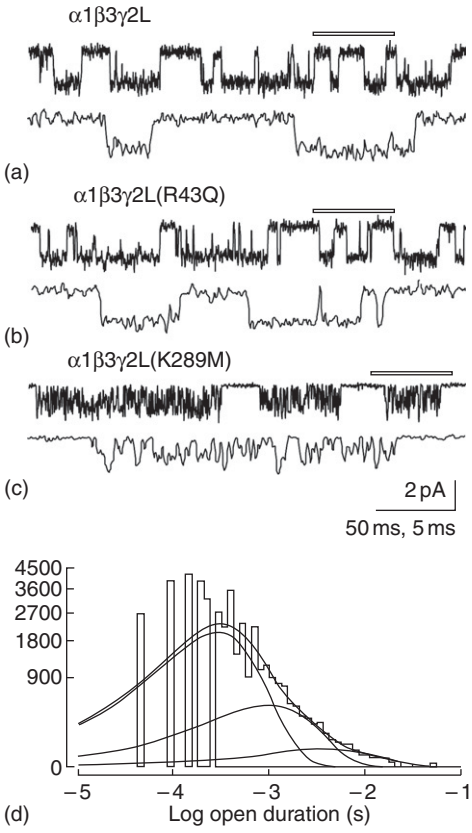

Figure 3 Single channel analysis demonstrated that the mean open time of α1β3γ2L receptor channels was reduced. Single channel recordings obtained in patches held at −75 mV in the presence of 1 mM GABA from wild-type α1β3γ2L receptors (a), α1β3γ2L (R43Q) receptors (b) and α1β3γ2L(K289M) receptors (c). A portion of the top trace in each pair (indicated by the open bar) is expanded below that trace. Calibration bars apply to all three panels. Openings were downward. Similar results were observed from three α1β3γ2L, five α1β3γ2L(R43Q), and seven α1β3γ2L (K289M) patches. (d) Open duration histogram for α1β3γ2L (K289M) single channels. The distribution was best described by the sum of three exponential functions, with each exponential fit shown as a smooth curve. Although three functions were required, the relative contribution of the shortest open state (Leftmost curve) was highest, indicating that the most openings were brief in duration. The time constants were 0.33, 1.17, and 4.54 ms with relative areas 0.81, 0.17, and 0.02 respectively. Data were pooled from seven α1β3γ2L(K289M) patches. Adapted from Bianchi MT, Song L, Zhang H, and Macdonald RL (2002) Two different mechanisms of disinhibition produced by $GABA_A$ receptor mutations linked to epilepsy in humans. *The Journal of Neuroscience* 22: 5321–5327.

can produce dominant negative inhibition on full length proteins, thus potentially harming the cells. Based on the faux 3-UTR model, cellular mRNA quality control mechanisms may also affect γ2(Q351X) subunit expression, but this possibility needs to be clarified. It is also intriguing that there is a great intrafamilial phenotype variation with this mutation; the basis for this variation is unknown.

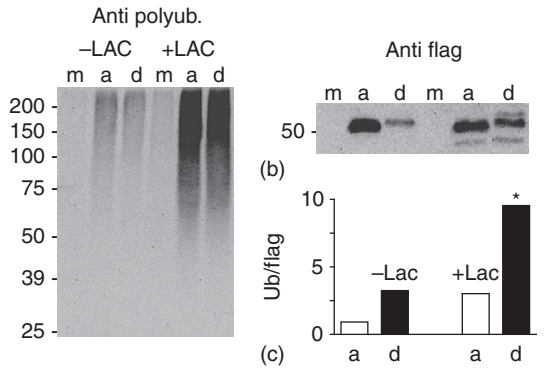

Figure 4 The α1(A322D) subunit was degraded through the ubiquitin–proteosome system.(a) HEK 293T cells were mock transfected (m) or transfected with α1-Flag (a) or α1(A322D)-Flag (d) subunits were incubated in the absence or presence of 10 μm lactacystin ($n \geq 5$) and analyzed by immunoblot that was probed with an antibody directed against polyubiquitin (a) or Flag (b). The relative amounts of polyubiquitinated subunits were plotted (c). The relative amount of polyubiquitinated mutant α1 subunit was greater than the wild-type α1 subunit. Modified from Gallagher MJ, Ding L, Maheshwari A, and Macdonald RL (2007) The $GABA_A$ receptor alpha1 subunit epilepsy mutation A322D inhibits transmembrane helix formation and causes proteasomal degradation. *Proceedings of the National Academy of Sciences* 104(32): 12999–13004.

$GABA_A$ receptor γ2 subunit nonsense mutation, Q1X

A γ2 subunit mutation that introduced a PTC, Q1X, between the signal peptide and mature peptide was identified in a family with severe myoclonic epilepsy of infancy (SMEI). The γ2 subunit mutation, Q1X, would likely trigger NMD, although this has not been demonstrated. However, if the γ2(Q1X) subunit mutation resulted in NMD completely, and if the mutant γ2S subunit does not interfere with transcription of the wild-type γ2S subunit at the mRNA level, no epilepsy would result (as observed in γ2 (+/−) gene deletion heterozygous mice). It is also unclear why in the pedigree, both twins carrying the mutation were diagnosed with SMEI while the father with the de novo mutation was seizure-free. Future studies focusing on gene expression and the completeness of NMD may elucidate the underlying molecular pathology.

$GABA_A$ receptor γ2 subunit splice donor site mutation, IVS6 + 2T → G

The γ2 subunit IVS6 + 2T → G mutation is the first intronic mutation identified in a $GABA_A$ receptor gene. The point mutation in the splice-donor site in the γ2 subunit gene intron 6 (IVS6 + 2T → G) has been identified in a family with CAE and FS (**Figure 1**). The effect of this mutation on $GABA_A$ receptor function is unknown but was predicted to lead to a nonfunctional protein through exon skipping. The predicted exon skipping would result in a new PTC at the fifth and seventh exon junction site. Thus, it is very likely that this prematurely terminated codon may also trigger NMD, thus reducing expression of mutant protein at mRNA level. Therefore, the underlying mechanism for this splice donor site mutation may also be due to haploinsufficiency. In fact, with the NMD-sensitive minigene approach, we demonstrated that the mutant γ2 (IVS6 + 2T → G) minigene only produced a minimal amount of the mutant protein compared with the wild-type γ2 minigene, suggesting that the mutation may activate NMD. Our ongoing research at the transcription level will further elucidate the underlying molecular mechanisms.

$GABA_A$ Receptor δ Subunit Variants (E177A, R220C, R220H)

Monogenic mutations only account for the pathogenesis of a small portion of IGE syndromes. Most of the idiopathic epilepsies are polygenic, requiring additive actions of a set of susceptibility genes. We reported the first $GABA_A$ receptor susceptibility gene, *GABRD*, for IGEs. Two putative missense mutations in *GABRD* were identified: δ(E177A) was detected in a small GEFS+ family, and δ(R220C) was detected in a second small GEFS+ family. Both mutations were heterozygously associated with epilepsy in these pedigrees. In addition, a polymorphic allele, δ(R220H), has been associated with JME patients, but is also found in the general population.

The δ subunit variant, E177A, is adjacent to one of the invariant cysteines that form a disulfide bond, the signature feature of cys-loop receptors. The δ(R220) residue is localized about in the middle between the δ(E177A) variant and the entrance to the first transmembrane domain (M1). The current amplitudes of heterozygous or homozygous receptors harboring either δ(E177A) or δ(R220H) subunits were significantly reduced compared to those of wild-type receptors. The current amplitudes of heterozygous or homozygous α1β2δ(R220C) receptors were not significantly different from those of wild-type receptors, but this finding requires further investigation. Combining both single channel recording and biochemistry data, the basis for the reduced peak current of these δ variant-harboring receptors was determined to be primarily due to the reduced mean channel open time and a small reduction of surface receptor expression.

Methods

Our laboratory uses electrophysiological techniques such as whole cell recording, lifted whole cell recording,

macropatch recording, single channel recording, and slice recording. In addition, we use rapid drug application techniques. With these techniques, we can study the function of any mutant $GABA_A$ receptor composed of various subunit combinations. Toward that end, we have developed a comprehensive $GABA_A$ receptor subunit gene bank.

However, characterization of channel function itself is not adequate to dissect the molecular pathology of these epilepsy mutations. We thus developed numerous other research approaches to study $GABA_A$ receptor subunit mutations at gene, protein, and cellular levels. For each mutation, in addition to electrophysiological study, we run parallel experiments with these additional techniques so as to better understand the molecular pathology of the mutation. At the protein level, these additional approaches include immunoblotting, coimmunoprecipitation, receptor surface biotinylation, immunohistochemistry, and high throughput flow cytometry. We have also generated numerous $GABA_A$ receptor subunit constructs with epitope tags (FLAG, c-myc, HA), including a number of fluorescent protein epitope tags (GFP, YFP, CFP), which allow us to visualize (with confocal microscopy) mutant and wild-type subunit protein trafficking in live cells (**Figure 2**). At the gene level, we have developed real-time PCR (RT-PCR), gene silencing by siRNAs, and BACs (bacterial artificial chromosomes) that contain wild-type human $GABA_A$ receptor subunit genomic sequences. Since expressing BAC constructs in mammalian cells is still problematic, we have initiated studies using transgenic animals that carry the mutations of interest.

Recent Results

Based on our studies, these $GABA_A$ receptor subunit gene mutations could impair neuronal inhibition either through channel gating or receptor trafficking. Our current results suggest that most of the mutations cause reduced receptor subunit biogenesis, including defects in subunit transcription, folding and assembly, or impaired receptor trafficking. These observations are similar to the reports of mutant CFTR in which trafficking-deficient mutations are far more frequent than the mutations with channel gating defects. As shown in **Figure 2**, receptors harboring mutant γ2(R43Q) subunits have a trafficking defect. The YFP-tagged mutant protein was retained inside ER, as indicated by the fact that the membrane/ER fluorescence intensity ratios were significantly lower in both heterozygous and homozygous mutant receptor conditions. Although the mutant $\alpha1\beta3\gamma2$L(R43Q) channel has no gating defect based on our electrophysiology data, the impaired trafficking of the mutant protein suggests that it contributes minimally to synaptic inhibition in a neuronal milieu.

In contrast, receptors harboring mutant γ2(K289M) subunits have a gating defect. As shown in **Figure 3**, mutant $\alpha1\beta3\gamma2$L(K289M) receptor single channel currents had a reduced mean open time. In addition, currents from macropatches excised from cells expressing $\alpha1\beta3\gamma2$L(K289M) receptors displayed accelerated deactivation when evoked with brief, rapid, and saturated GABA concentration. The brief macropatch currents are similar to IPSCs. This reduction of the duration of rapid GABA-evoked current by the γ2L(K289M) subunit mutation suggests that the mutation would result in reduced IPSC durations, thus producing disinhibition that may lead to epilepsy.

What is the cellular fate of those trafficking-impaired mutant proteins that are retained inside ER? Recent studies have demonstrated that the ubiquitin–proteosome degradation of these misfolded and misrouted proteins is a prominent mechanism. Through this mechanism, misfolded proteins are recognized and then dislocated to the cytosol to be ubiquitylated and degraded through a process known as ERAD – ER-associated degradation. A recent study from our laboratory demonstrated that a mutant $GABA_A$ receptor subunit protein could be subject to this ER quality control process. As illustrated in **Figure 4**, the mutant α1(A322D) subunit protein was rapidly degraded by the ubiquitin–proteosome system.

Challenges and Future Directions

In spite of the advances from genetic and functional studies of these epileptic mutations, there are many major challenges remaining in understanding the pathology of these inherited epilepsies. First, it is difficult to obtain a proper and easy-to-carry out experimental model that can adequately reproduce the alterations produced by these mutations in patients. Most of the data to-date are still obtained from studies using heterologous expression in acute transfection systems. The available heterozygous subunit gene deletion mice may reflect the function of a certain gene, but gene knockout may well be different from a loss-of-function mutation. Second, most of the mutations may not be fully penetrant, and there is a great intrafamilial phenotype variation. This variation suggests that there are other modifying genes that influence the development and persistence of the epilepsy, but this possibility needs to be clarified.

Given the complexity of gene transcription and translation, as well as complications involved in receptor trafficking from the ER to cell surface and synapses in neurons, it would not be surprising that mutations in other genes of associated proteins – e.g., chaperones, kinases involved in phosphorylation signaling pathways, etc. – are linked to epilepsy. For example, the non-ion

channel gene mutation in LGI1 has been identified in familial lateral temporal lobe epilepsy, suggesting an additional pathogenetic process in epileptogenesis. It is likely that the concept of ion channelopathy of epilepsy represents only the tip of a gigantic iceberg. Future work directed at the gene expression, protein modification, trafficking, synaptic targeting, and maintenance of cellular homeostasis will eventually present a more accurate picture of epileptogenesis – and hopefully lead to alternative therapeutic approaches.

Pathophysiology of Status Epilepticus

J Kapur, University of Virginia, Charlottesville, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Broadly, status epilepticus (SE) refers to prolonged seizure activity. The International League Against Epilepsy (ILAE) classification of seizures defines status epilepticus as 'a condition characterized by epileptic seizures that are sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epileptic condition.' This definition does not define the duration of seizures necessary for them to be considered unvarying and enduring. Analyses of seizure duration in epilepsy monitoring units suggest that most complex partial seizures last less than 2 min. Prospective studies of new-onset seizures in children also suggest that if a seizure continues for more than 7 min, it is unlikely to end spontaneously (or soon). These observations suggest that seizures lasting more than 5–7 min are unlikely to end spontaneously, and constitute 'enduring' epileptic condition referred to as SE.

There are at least 126 000–195 000 episodes of status epilepticus associated with 22 000–42 000 deaths each year in the United States. The majority of SE patients have no history of epilepsy. In the 30 days following SE, mortality is approximately 25% – a rate that approaches deaths from gunshot wounds, major head trauma, and myocardial infarction. Much of the mortality associated with SE is a consequence of the underlying cause of seizures. However, prolonged seizures themselves add to the mortality. SE-associated mortality is particularly high in the elderly. In infants and children, SE may impact cognitive development and could potentially increase risk for subsequent development of epilepsy.

Neurobiology of SE is as challenging as its clinical aspects. The primary question is as follows: How do seizures rapidly alter brain function so as to become self-sustaining? SE probably reflects a perversion of normal brain plasticity. The limbic system, and particularly

channel gene mutation in LGI1 has been identified in familial lateral temporal lobe epilepsy, suggesting an additional pathogenetic process in epileptogenesis. It is likely that the concept of ion channelopathy of epilepsy represents only the tip of a gigantic iceberg. Future work directed at the gene expression, protein modification, trafficking, synaptic targeting, and maintenance of cellular homeostasis will eventually present a more accurate picture of epileptogenesis – and hopefully lead to alternative therapeutic approaches.

Pathophysiology of Status Epilepticus

J Kapur, University of Virginia, Charlottesville, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Broadly, status epilepticus (SE) refers to prolonged seizure activity. The International League Against Epilepsy (ILAE) classification of seizures defines status epilepticus as 'a condition characterized by epileptic seizures that are sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epileptic condition.' This definition does not define the duration of seizures necessary for them to be considered unvarying and enduring. Analyses of seizure duration in epilepsy monitoring units suggest that most complex partial seizures last less than 2 min. Prospective studies of new-onset seizures in children also suggest that if a seizure continues for more than 7 min, it is unlikely to end spontaneously (or soon). These observations suggest that seizures lasting more than 5–7 min are unlikely to end spontaneously, and constitute 'enduring' epileptic condition referred to as SE.

There are at least 126 000–195 000 episodes of status epilepticus associated with 22 000–42 000 deaths each year in the United States. The majority of SE patients have no history of epilepsy. In the 30 days following SE, mortality is approximately 25% – a rate that approaches deaths from gunshot wounds, major head trauma, and myocardial infarction. Much of the mortality associated with SE is a consequence of the underlying cause of seizures. However, prolonged seizures themselves add to the mortality. SE-associated mortality is particularly high in the elderly. In infants and children, SE may impact cognitive development and could potentially increase risk for subsequent development of epilepsy.

Neurobiology of SE is as challenging as its clinical aspects. The primary question is as follows: How do seizures rapidly alter brain function so as to become self-sustaining? SE probably reflects a perversion of normal brain plasticity. The limbic system, and particularly

the hippocampus (which has been the focus of extensive learning and memory research), appears to play a key role in sustaining SE. Experimental animals subjected to SE become permanently epileptic, and have recurrent unprovoked seizures, suggesting long-lasting plasticity as a consequence of a single event. Understanding SE thus offers a direct benefit in advancing the treatment of patients with SE. Such understanding may also provide an indirect but more generally applicable benefit, since mechanisms of brain plasticity involved in/during SE may play a role not only in the pathogenesis of partial epilepsies, but also in mechanisms of learning and memory.

Background

Animal Models and Functional Anatomy

Several animal models are available to study various facets of SE. These models can be divided into two major categories: chemical convulsant-induced and electrogenic models. The progression of behavioral and EEG changes described in humans has also been demonstrated in both the chemical convulsant model and the electrogenic model of SE in experimental animals, thus validating their use in understanding the pathophysiology of SE. Chemical convulsant models of SE have been useful in determining the systemic effects of generalized convulsive SE, elucidating the functional anatomy of SE, and comparing the efficacy of antiepileptic drugs in treatment. In addition, they are convenient experimental tools. However, in studies of SE based on chemical convulsant-induced seizures, there is an inherent difficulty of separating the effects of the convulsant drug itself from the effects of seizures. Electrical stimulation models of SE are helpful in identifying clearly the effect of prolonged and recurrent seizures in a controlled fashion. Electrogenic models are derived from kindling protocols and involve prolonged electrical stimulation of limbic structures. Prolonged electrographic seizures can be induced in hippocampal slices from young animals, using a combination of electrical stimulation and manipulation of extracellular magnesium concentrations.

Anatomical mapping studies using quantitative autoradiography for radiolabeled 2-deoxy glucose and immunohistochemistry for cfos and c Jun have been performed on the electrical stimulation and lithium/pilocarpine models. These studies consistently demonstrated activation of an interconnected circuit of limbic structures, consisting of entrorhinal cortex, dentate gyrus, areas CA1 and CA3, subiculum and parasubiculum, and basolateral amygdala. When seizures progress from limbic to secondarily generalized tonic–clonic events, there is activation of the substantia nigra, somatosensory cortex, head of the striatum, and midline thalamic nuclei.

SE: The GABA Hypothesis

Almost two decades ago, our laboratory proposed that the self-perpetuating nature of SE is due to its impact on GABA-mediated inhibition. We proposed that seizures reduced GABA-mediated inhibition, which then led to more seizures, setting up vicious cycle. We initially investigated (using the paired pulse inhibition method) the hypothesis that GABA-mediated inhibition collapses during SE. The paired pulse technique primarily measures feedback inhibition of CA1 pyramidal neurons. Briefly, the method involves placement of a stimulating electrode in the CA1/CA3 region of one hippocampus and a recording electrode in the homotopic contralateral CA1 region to record extracellular field potentials in response to the stimuli. When two low-intensity pulses were delivered at short interpulse intervals, the inhibition of the response to the second stimulus depends both on the interpulse interval and on stimulus intensity. At higher stimulus intensities, the inhibition is dependent only on the interpulse interval. Paired pulse inhibition in the 20–70-ms interpulse interval range was enhanced by benzodiazepines and diminished by bicuculline.

The relationship of GABA-mediated paired pulse inhibition in the CA1 region of the hippocampus and evolution of SE was studied. The evolution of seizures is closely correlated to the loss of paired pulse inhibition. All three cholinergic-based (i.e., pilocarpine) models of SE have been studied using the paired pulse inhibition technique. While studies using the paired pulse inhibition method have shown the critical role of reduction of GABA-mediated inhibition in the pathogenesis of SE, they did not reveal the mechanisms underlying the disinhibition. Paired pulse inhibition in the CA1 region of the hippocampus could be reduced by diminished release of GABA or diminished responsiveness of postsynaptic $GABA_A$ receptors. These possibilities are discussed later.

While the release of GABA from neurons during SE has not been studied, extracellular amino acid neurotransmitter levels during SE have been measured. In SE induced by kainic acid, there are decreases in glutamate, aspartate, and glutamine concentrations and increases in GABA concentration in the hippocampus. Walton studied amino acid neurotransmitter levels in SE induced by lithium/pilocarpine during various electrographic stages. Both aspartate and glutamate levels decline in the hippocampus, pyriform cortex, motor cortex, and entorhinal cortex during the early phase of SE, and continue to do so in the late phase. GABA levels, in contrast, rise in early SE and continue to do so in the late stages. It is difficult to interpret these observations since increased GABA levels could represent increased synthesis, diminished release, or diminished breakdown of this neurotransmitter. Similar observations pertain to glutamate and aspartate. More

recent electrophysiological studies have further suggested that extracellular GABA levels may be increased.

Methods

Whole-cell patch clamp recordings of $GABA_A$ receptor currents were obtained from hippocampal neurons (CA1 pyramidal neurons and dentate granule cells). In initial experiments, CA1 pyramidal neurons and dentate granule cells were acutely isolated from hippocampal slices after enzymatic digestion. GABA and drugs were applied via pipettes to elicit $GABA_A$ receptor currents. In later experiments, GABA-mediated IPSCs were recorded from dentate granule cells in hippocampal slices by patch clamp technique. Fast glutamatergic currents were blocked by NMDA and AMPA receptor antagonists. Trafficking of $GABA_A$ receptors from neuronal cell membrane into the cytosol was studied using an antibody feeding technique and a biotinylation assay.

Results

$GABA_A$ Receptor Function in the Hippocampus Diminishes During SE

The possibility that the reduction of GABA-mediated inhibition seen in SE is a consequence of changes in CA1 pyramidal neurons has been investigated. Several possible changes in CA1 pyramidal neurons could reduce the efficacy of GABA in producing chloride currents. The number of $GABA_A$ receptors could be reduced, or the efficacy of GABA in opening the ion channel after binding could be reduced. Whole-cell perforated patch recordings of $GABA_A$ receptor currents were made from acutely isolated CA1 pyramidal neurons from rats that exhibited SE or from naive control rats. The 'perforated patch' method was employed and the electrode solution (except for the tip) contained the pore-forming antibiotic, amphotericin. Recordings of $GABA_A$ receptor currents were conducted in whole-cell voltage clamp mode. These experiments showed that marked reductions of $GABA_A$ receptor currents in CA1 pyramidal neurons occurred during SE that produced loss of GABA-mediated inhibition. A third of all CA1 pyramidal neurons isolated from animals undergoing SE showed no response to GABA in contrast to 7% of neurons isolated from naive animals. These experiments also indicated that during SE, $GABA_A$ receptor currents were reduced by reduction of both conductance and the chloride reversal potential.

These findings suggest that the $GABA_A$ receptor is modified during an episode of SE. $GABA_A$ receptors are regulated by numerous positive (barbiturates, benzodiazepines, and neurosteroids) and negative (picrotoxin, bicuculline, and Zn^{2+}) allosteric modulators. We tested whether prolonged seizures of SE altered drug sensitivity of $GABA_A$ receptors. Seizures induced in rats by administration of lithium (Li) followed by pilocarpine were readily terminated by the benzodiazepine diazepam when administered early during the seizures. However, during status epilepticus, there was a substantial reduction of diazepam potency for termination of the seizures. To determine if the loss of sensitivity of the animals to diazepam was due to an alteration of $GABA_A$ receptor functional properties, whole-cell $GABA_A$ receptor currents were recorded from hippocampal dentate granule cells isolated acutely from control rats and from rats undergoing status epilepticus. $GABA_A$ receptor properties were characterized by determining GABA sensitivity, and the sensitivity of $GABA_A$ receptors to regulation by benzodiazepines, barbiturates, and Zn^{2+}. When compared with those from naive littermates, $GABA_A$ receptor currents from rats undergoing status epilepticus were less sensitive to diazepam and Zn^{2+} but retained their sensitivity to GABA and pentobarbital. These studies suggested that the prolonged seizures of status epilepticus rapidly altered the functional properties of hippocampal dentate granule cell $GABA_A$ receptors.

Mechanism of $GABA_A$ Receptor-Mediated Inhibition

The mechanism of reduction of $GABA_A$ receptor-mediated inhibition is being explored in a number of laboratories. $GABA_A$ receptors undergo a cycle of internalization and insertion into the cell membrane via a clathrin-dependent endocytic process. Internalization of the surface $GABA_A$ receptor correlates with a reduced response to GABA, whereas inhibition of internalization results in an increase in the amplitude of synaptic $GABA_A$ receptor currents. An activity-induced acceleration of the internalization of $GABA_A$ receptors from the cell surface could partially explain the reduction in GABA-mediated inhibition observed during the prolonged seizures of SE. The number of receptors at a synapse is an important determinant of synaptic strength; therefore, a reduction in the total number of postsynaptic $GABA_A$ receptors could result in a decline in GABAergic inhibition.

This rapid loss of $GABA_A$ receptor benzodiazepine sensitivity during seizures has been difficult to explain. Recent studies have suggested that benzodiazepine-insensitive receptors are expressed in hippocampal neurons on extrasynaptic membranes. Furthermore, these receptors appear to mediate a novel form of inhibition called tonic inhibition. We tested whether during SE, there is increased internalization of synaptic, diazepam-sensitive $GABA_A$ receptors, which leaves extrasynaptic diazepam-insensitive receptors on the neuronal surface. A combination of immunocytochemical and electrophysiological studies suggested that cultured hippocampal

neurons expressed two types of $GABA_A$ receptors. One type of receptor, containing α1, α2, β2/3, and γ2 receptor subunits, formed clusters that are present at GABAergic synapses and in extrasynaptic membrane. The second type of receptor, containing the α4, β1, and δ subunits, was diffusely distributed in the extrasynaptic membrane. Using an in vitro model of status epilepticus combined with electrophysiological and cellular imaging techniques, we found that prolonged epileptiform bursting results in a reduction in GABA-mediated synaptic inhibition. Furthermore, we found that the constitutive internalization of $GABA_A$ receptors is rapid and is accelerated by increased activity associated with seizures. Reduction of activity reduced the rate of internalization. These findings suggest that the rate of $GABA_A$ receptor internalization is regulated by neuronal activity, and its acceleration contributes to the reduction in inhibitory transmission observed during status epilepticus. More recent studies demonstrate that the rate of internalization of benzodiazepine-insensitive, extrasynaptic $GABA_A$ receptors containing the δ subunit, which mediate tonic inhibition, is much slower than that of synaptic receptors. During acute status epilepticus, tonic inhibition is preserved and the surface expression of the δ subunit containing receptors is unchanged.

NMDA Receptor Function is Enhanced during Limbic Status Epilepticus

Although abnormal GABAergic mechanisms are involved in the pathogenesis of SE, excitatory transmission mediated by glutamate is essential for spread of epileptiform activity. Glutamate activates multiple subtypes of postsynaptic excitatory amino acid receptors during SE, but studies have focused on the *N*-methyl-D-aspartate receptor. The role of non-NMDA receptors in SE is uncertain. Current evidence suggests that NMDA activation sustains SE and may in part cause the characteristic neuropathologic changes in SE. However, NMDA receptor antagonists fail to block initiation of status epilepticus. NMDA receptor antagonist MK 801 administered prior to or shortly after the onset of kainate-induced or lithium/pilocarpine-induced status epilepticus did not control seizures. Although some authors have reported that seizures were less intense after NMDA receptor antagonist administration, others have reported worsening of electrographic seizures by NMDA receptor antagonists.

Recent studies have demonstrated that prolonged status epilepticus can be treated with ketamine, a clinically available NMDA receptor antagonist; these studies indicate that ketamine is more effective in treatment of prolonged status epilepticus compared with early status epilepticus. NMDA receptor function can be inhibited by multiple mechanisms, including competitive block by drugs such as 3-((*R*,*S*)-2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP), by open channel block at the phencyclidine (PCP) site by MK-801 or ketamine, and by action at the pH-sensitive site by ifenprodil. NMDA receptor antagonists CPP, MK801, and ifenprodil were compared for their ability to terminate prolonged SE. These studies suggested that noncompetitive NMDA receptor antagonists were superior to competitive and allosteric inhibitors of NMDA receptors in terminating prolonged SE induced by electrical stimulation.

The ability of NMDA receptor antagonists to suppress SE varies from model to model. For example, the NMDA receptor antagonist ketamine terminates diazepam-refractory SE generated by electrical stimulation (see earlier sections), but it is ineffective when used alone in SE induced by cholinergic stimulation. Multiple doses of ketamine, ranging from ineffective to toxic, were examined for their efficacy in terminating diazepam-refractory SE in electrogenic model of status epilepticus. Furthermore, the same range of ketamine doses was used in combination with two doses of diazepam. The principal finding of this study was that a combination of diazepam and ketamine rapidly terminated prolonged cholinergic stimulation-induced SE in a synergistic fashion. Diazepam shifted the ketamine dose response (SE termination) relationship to the left and increased the maximal effect of ketamine.

Conclusions and Directions for Future Research

The current working hypothesis for understanding pathophysiology of status epilepticus is that prolonged seizures diminish $GABA_A$ receptor-mediated inhibition by enhancing the internalization of synaptic $GABA_A$ receptors. Seizures also activate NMDA receptors. The relationship between NMDA receptor activation and diminished inhibition is currently under study. Further studies are needed to characterize the mechanism of NMDA receptor activation. The role of AMPA subtype of glutamate receptors in mediating status epilepticus has not been studied in detail and needs to be explored. Clinical therapeutic trials testing the efficacy of drugs acting on NMDA receptors, in treating refractory status epilepticus, would determine whether treatments developed in laboratories can have clinical application.

Plasticity of GABAergic Systems during Epileptogenesis

C Bernard, Université de la Méditerranée, Marseille Cedex 05, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epileptogenesis

An initial insult, be it inherited (i.e., a genetic mutation) or acquired (e.g., brain trauma), is often thought to be causally related to the appearance of temporal lobe epilepsy (TLE). The time interval between the initial insult and the first spontaneous seizure is highly variable (from a couple of hours to decades). It is thus reasonable to propose that modifications in neuronal networks occur during this period. These modifications will eventually favor the emergence of seizures. Such alterations belong to the processes that define epileptogenesis. It is very difficult to study epileptogenesis in humans, since an initial insult, recognized as putting some patients at risk, does not necessarily lead to epilepsy. As a consequence, the results discussed here are derived primarily from animal studies.

Most animal models of TLE are characterized by a chemically or electrically induced initial insult followed by a seizure-free period. Many modifications have been identified just after *status epilepticus* (SE). They include cell death, transcriptional modifications (the expression of hundreds of genes is altered), and posttranslational changes (e.g., modifications of proteins). The impact of these alterations on epileptogenesis remains an open question. It is usually assumed that some of these changes will lead to still further modifications, until an epileptic network is built. In such a dynamical perspective, it seems certain that some of the changes seen during this period are crucial to epileptogenesis (and some may not be). If we can identify the critical (i.e., 'causal') changes, we may be able to interfere with them, and thus delay or stop epileptogenesis. Thus, a related hypothesis states that there is a cascade of deleterious events, and that the earlier we can intervene, the more likely we are to achieve 'antiepileptogenesis.' These hypotheses are very difficult to address experimentally, because of the complex spatio-temporal dimensions of the trauma-induced changes. Alterations occur at several levels – genetic, molecular, cellular, network, and brain region – and they all may evolve over time.

Multiplicity of GABAergic Systems and Functions

Many investigators have focused on the modifications affecting γ-aminobutyric-acid (GABAergic) systems, because GABAergic neurons powerfully control the activity of neurons and neuronal networks. This control has multiple, nonexclusive aspects. When GABA is released by a cell, it will activate $GABA_A$ receptors, leading to a flux of Cl^- and bicarbonate through the associated channels. Because the equilibrium potential for Cl^- is normally close to the cell resting membrane potential, and because the intracellular concentration of Cl^- can be dynamically

Plasticity of GABAergic Systems during Epileptogenesis

Introduction

Epileptogenesis

An initial insult, be it inherited (i.e., a genetic mutation) or acquired (e.g., brain trauma), is often thought to be causally related to the appearance of temporal lobe epilepsy (TLE). The time interval between the initial insult and the first spontaneous seizure is highly variable (from a couple of hours to decades). It is thus reasonable to propose that modifications in neuronal networks occur during this period. These modifications will eventually favor the emergence of seizures. Such alterations belong to the processes that define epileptogenesis. It is very difficult to study epileptogenesis in humans, since an initial insult, recognized as putting some patients at risk, does not necessarily lead to epilepsy. As a consequence, the results discussed here are derived primarily from animal studies.

Most animal models of TLE are characterized by a chemically or electrically induced initial insult followed by a seizure-free period. Many modifications have been identified just after *status epilepticus* (SE). They include cell death, transcriptional modifications (the expression of hundreds of genes is altered), and posttranslational changes (e.g., modifications of proteins). The impact of these alterations on epileptogenesis remains an open question. It is usually assumed that some of these changes will lead to still further modifications, until an epileptic network is built. In such a dynamical perspective, it seems certain that some of the changes seen during this period are crucial to epileptogenesis (and some may not be). If we can identify the critical (i.e., 'causal') changes, we may be able to interfere with them, and thus delay or stop epileptogenesis. Thus, a related hypothesis states that there is a cascade of deleterious events, and that the earlier we can intervene, the more likely we are to achieve 'antiepileptogenesis.' These hypotheses are very difficult to address experimentally, because of the complex spatio-temporal dimensions of the trauma-induced changes. Alterations occur at several levels – genetic, molecular, cellular, network, and brain region – and they all may evolve over time.

Multiplicity of GABAergic Systems and Functions

Many investigators have focused on the modifications affecting γ-aminobutyric-acid (GABAergic) systems, because GABAergic neurons powerfully control the activity of neurons and neuronal networks. This control has multiple, nonexclusive aspects. When GABA is released by a cell, it will activate $GABA_A$ receptors, leading to a flux of Cl^- and bicarbonate through the associated channels. Because the equilibrium potential for Cl^- is normally close to the cell resting membrane potential, and because the intracellular concentration of Cl^- can be dynamically

regulated, the physiological effect of $GABA_A$ receptor activation is context-specific. In adult tissue, activation of perisomatic synapses leads to the hyperpolarization of the membrane. Importantly, a hyperpolarizing action of GABA does not necessarily imply reduced network activity (i.e., inhibition per se), since the coordinated action of perisomatic interneurons can entrain a network into an oscillatory mode. In contrast to perisomatic synapses, the activation of GABAergic synapses on apical dendrites is depolarizing (but not excitatory). Activation of GABAergic synapses on the axon initial segment is depolarizing *and* excitatory. The functional consequences of $GABA_A$ receptor activation are thus dependent upon the cell compartment(s) (initial segment, soma, dendrites) activated, as well as the underlying activity (e.g., oscillations) and (most likely) the type of postsynaptic cell and the specific brain region in question. This complexity is correlated with the heterogeneity of GABAergic neurons in terms of morpho-physiological properties and neurochemical content (tens of GABAergic cell types can be distinguished). For example, most GABAergic neurons in temporal lobe structures have local connectivity, directly controlling local network activity in a cell-type- and brain-state-dependent manner. But there are also GABAergic neurons with long-range connections (spanning different brain regions); the hypothetical role of which is to bind distantly operating networks.

This short presentation focuses on the functional consequences of postsynaptic $GABA_A$ receptor activation. Other important aspects of GABAergic neurotransmission include $GABA_B$ receptors, extrasynaptic receptors (generating a tonic current), and the current shunt effect produced when $GABA_A$ channels are activated. Indeed, one is certainly justified in talking of GABAergic systems – not a single system.

Plasticity of GABAergic Systems

Plasticity within GABAergic systems can occur at all levels of analysis. Modifications may involve gene expression, transcriptional processes, receptors (subunit composition, ability to be translocated to the membrane and to be assembled, anchoring, motility, molecular partners), intracellular medium (Cl^- concentration, phosphorylation processes), extracellular medium (presence of modulators such as benzodiazepines, Zn^{2+}, steroids, etc.), extracellular space, and GABA uptake mechanisms. Upstream, at the presynaptic terminal level, one can distinguish GABA synthesis or recycling, quantal release and content, Ca^{2+} homeostasis, presynaptic terminal excitability, and presynaptic receptors. Further upstream, at the GABAergic neuron level, alterations can be morphological (e.g., axonal sprouting, synaptogenesis or pruning) and functional – i.e., any change affecting the way the GABAergic neuron processes information (e.g., modifications in cell excitability, receptor distribution, and properties). Thus, it is ultimately necessary to take a step backward, and consider not only how the GABAergic cells are embedded in a local network, but also how networks or brain regions *presynaptic* to a given GABAergic network control these GABAergic cells.

Background

Research attempting to assess the state of GABAergic systems during epileptogenesis faces three major difficulties. First, epileptogenesis can only be determined by continuous 24/24-h and 7/7-day video-EEG recordings. Second, the diversity of GABAergic interneurons must be considered. Third, the parameters characterizing the GABAergic circuitry should be adequately chosen. These difficulties make these studies both condition-specific and highly time-consuming.

A large number of studies have been devoted to the characterization of GABAergic systems in the already epileptic animal, in various regions of the temporal pole, and in different experimental models. These studies provide a picture of the state of the system when animals have recurrent seizures. Knowing both the end point of epileptogenesis and the starting point (the state of the system before the initial insult), the strategy for studying epileptogenesis is relatively simple: Determine the temporal profile of the modifications of the chosen parameters. A limitation to this approach lies in the fact that there may not be a real 'end point.' Most studies performed during the 'chronic phase' (i.e., in the epileptic animal) do not take into account the time course of epilepsy progression; further, parameters have been evaluated anywhere between a few days to one year following the first spontaneous seizure. Several experimental models display a progressive sclerosis of the hippocampus, indicating that reorganizations continue to occur once the animal is epileptic. To reduce variability in parameter measurements, an ideal solution would be to evaluate parameters just after the first two spontaneous seizures.

Keeping this limitation in mind, what do we know about the reorganization of GABAergic systems during the chronic (epileptic) period? Morphological studies indicate a specific loss of subpopulations of GABAergic interneurons. Histological and electron microscopy studies performed in the CA1 region demonstrate specific loss of GABAergic synapses on the distal part of the dendritic tree, suggesting the loss of somatostatin-containing O-LM cells, a class of stratum oriens interneurons that project to the lacunosum moleculare (**Figure 1**). The number of GABAergic synapses on the initial segment of pyramidal cells is also decreased, confirming the loss of parvabumin-containing axo-axonic cells. Such reorganization should result in a decreased GABAergic drive, but the functional outcome has been surprisingly difficult to evaluate.

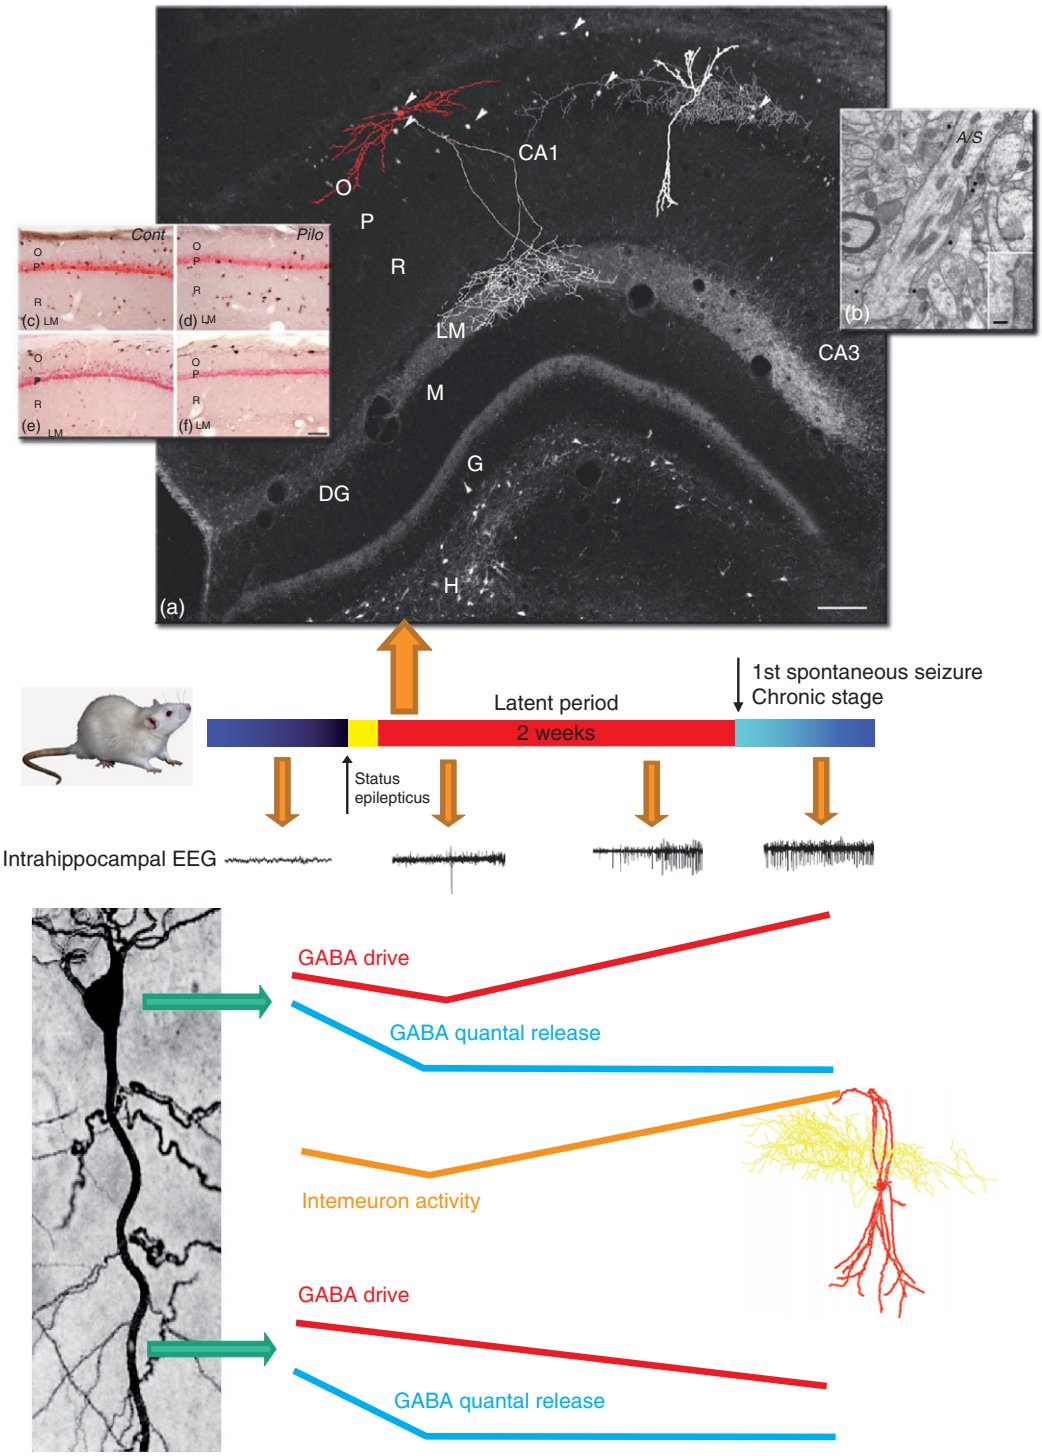

Figure 1 Plasticity of hippocampal CA1 GABAergic pathways in experimental temporal lobe epilepsy. Morphological and physiological parameters are assessed at different times during the latent period and the chronic stage. Morphological analysis (top panel) shows the early loss of O-LM cells and axo-axonic cells (a) 3 days after the pilocarpine-induced *status epilepticus*. (b) Electron microscopy analysis reveals the loss of axo-axonic GABAergic synapses. The loss of GAD-expressing (c, d) and somatostatin-expressing (e, f) interneurons is predominant in CA1 stratum oriens. The middle panel shows the progressive increase in interictal-like activity during epileptogenesis. The bottom panel schematizes the time course of the GABAergic dive and GABA quantal release in the dendritic and somatic compartments in CA1 pyramidal cells at the same time points. Note the transient decrease of the somatic drive and the continuous decrease of the GABAergic drive. Interneuron activity is also modified. For example, after an initial decrease, basket cells become hyperactive.

Physiological studies confirm a decreased GABAergic drive in the distal dendrites of CA1 pyramidal cells, facilitating the transfer of excitatory glutamatergic perforant path inputs coming from the entorhinal cortex. Such a reorganization may qualify as 'proepileptic.' However, the loss of axo-axonic synapses could be considered as 'antiepileptic,' since these GABAergic synapses are excitatory.

The study of the surviving interneurons also provides valuable information about the reorganization of the GABAergic system at the network level. Far from being dormant, the surviving interneurons (including basket cells) are hyperexcitable and hyperactive. An increased glutamatergic drive onto these interneurons contributes to their hyperactivity, showing that glutamatergic networks presynaptic to interneurons are also reorganized. The physiological consequence of basket-cell hyperactivity is an increased GABAergic drive in the soma of CA1 pyramidal cells. However, the functional consequence of this increased drive is difficult to assess, as increased somatic GABAergic drive may mean decreased (increased) firing probability if GABA remains hyperpolarizing (becomes depolarizing), or increased propensity to fire in synchrony. Whether interneuron intrinsic excitability is modified remains to be determined. However, postsynaptic currents in interneurons appear to be modified, suggesting a possible modification in the way they integrate incoming inputs. Such an alteration may modify information processing at the network level, affecting specific functions in a cell-type- and brain-state-dependent manner.

Looking downstream, one needs to consider possible changes in the interneuron output circuitry – e.g., changes in the axonal tree. Whether axonal sprouting occurs for specific interneuron cell types remains debated. There are, however, alterations at the level of presynaptic terminals, including the reduction of GABA quantal release (depending upon the hippocampal region) and a modification of presynaptic receptors.

Finally, major modifications occur at the postsynaptic site. There is a complex reorganization of $GABA_A$ receptors, both spatially (their physical distribution) and functionally (their subunit composition, which determines their biophysical properties and modulation by external and internal compounds). The modifications affecting $GABA_A$ receptors are region-specific, indicating the need for analyses in different networks.

The net functional consequences of these reorganizations are difficult to assess, if only because we still do not have a clear conceptual framework about interneuron function in the normal brain. For example, the functional consequences are likely to be brain-state-dependent and highly variable.

Methods

One strategy used by several investigators – including our laboratory – to determine whether these modifications play a role in epileptogenesis or seizure genesis/propagation is to estimate their time course following the initial insult. Toward that end, we have used pilocarpine-treated rats as an experimental model of TLE. Following an initial SE induced by pilocarpine, animals go through a two-week-long latent (seizure-free) period, until they become 'epileptic' (i.e., have spontaneous recurrent seizures). Continuous 24 h day^{-1}, 7 day $week^{-1}$ video-EEG monitoring is used to relate behavior with electrical abnormalities (ictal episodes and interictal activity). Animals not exhibiting SE following pilocarpine injection, and sham-treated animals, are used for comparison. Animals are sacrificed at different stages during the latent period and during the chronic phase, and directed for morphological and in vitro electrophysiological studies. We have investigated the fate of various classes of interneurons (cell death and synaptic reorganization) using conventional immunohistochemical and electron microscopy techniques, and have tried to correlate morphological alterations with electrophysiological changes. To obtain information about electrophysiological changes, hippocampal CA1 pyramidal cells and different types of interneurons have been recorded in vitro to determine their firing pattern and the properties of their synaptic inputs. In parallel, a computer model able to generate depth EEG-like signals (based on a simplified architecture of the hippocampus) has been used to predict, at the network level, the functional consequences of the physiological modifications identified experimentally. These model-based results are then compared with experimental in vivo recordings.

Recent Results

Using continuous video-EEG recording, we determined that the range between the initial SE and the first spontaneous seizure was 12–18 days. After the first spontaneous seizure, which most of the time was subclinical and limited to the hippocampus, seizures recurred. The state of the GABAergic circuitry was then determined at different time points: 3–5, 5–7, and 7–10 days following the initial SE and during the chronic phase.

The most obvious impact of the initial SE on the CA1 GABAergic circuitry is cell death. According to the classical hypothesis, decreased GABAergic 'inhibition' should be a proepileptic factor. Interneuron cell loss is indeed an early phenomenon that follows SE, but the death of GABAergic cells does not immediately lead to seizure activity. Affected neurons include a subpopulation of somatostatin- and parvalbumin-containing GABAergic interneurons. It is important to stress again that the loss of parvalbumin immunoreactive axo-axonic cells will remove a strong excitatory GABAergic drive onto pyramidal cells. As such, the loss of GABAergic synapses on the initial segment of principal cells may be seen as a 'protective' mechanism during

the early phase of epileptogenesis. The loss of GABAergic synapses on the distal part of the dendritic tree of pyramidal cells (due to the death of somatostatin-containing O-LM interneurons) may have a different functional impact, removing the strong control they exert upon entorhinal cortex glutamatergic inputs.

While the loss of glutamatergic synapses is usually followed by the sprouting of glutamatergic-cell axons and by reactive synaptogenesis, this reaction does not seem to be the case for the GABAergic circuitry. Loss of GABAergic synapses on the initial segment and in the distal part of the dendritic tree is not compensated throughout epileptogenesis and during the chronic phase. Sprouting of GABAergic axons in experimental TLE remains fiercely debated, but direct evidence is still lacking. Sprouting within the GABAergic circuitry has been suggested in tissue from epileptic patients.

What could be the physiological consequence of the loss of GABAergic synapses onto principal cells? Fewer GABAergic synapses should result in decreased functional GABAergic inputs, a hypothesis that can be tested by recording the spontaneous GABA-mediated synaptic activity in pyramidal cells. Since two different cell compartments are involved, we recorded from the soma and the distal dendrites of CA1 pyramidal cells during epileptogenesis. We found that the frequency of spontaneously-occurring GABAergic currents was decreased 3–5 days post-SE, and this decrease persisted throughout the latent period in both the cell compartments. Although the frequency of GABAergic currents remained decreased in the distal dendrites during the chronic phase, it recovered to control (pre-SE) levels in the soma. Although these results correlate with the loss of GABAergic synapses during epileptogenesis, it is important to remember that the frequency of GABAergic inhibitory postsynaptic currents (IPSCs) can also be influenced by many other factors, including the firing behavior of interneurons (which in turn depends upon their endogenous excitability and the synaptic inputs they receive), the probability of GABA release at presynaptic terminals, and postsynaptic $GABA_A$ receptors. We found that the probability of GABA quantal release was decreased by more than 50% at dendritic and somatic GABAergic synapses soon after SE, a phenomenon that persisted during the chronic phase. The loss of GABA quantal release appears to be related to the depletion of the reserve pool of GABA-containing vesicles, not to the loss of GABAergic synapses. Both the loss of synapses and decreased quantal release contribute to decreasing the GABAergic tone during epileptogenesis.

The decrease in IPSC frequency was somewhat compensated by postsynaptic modifications. Consistent with the previously described changes in subunit composition of $GABA_A$ receptors, we found that the kinetics of GABAergic currents were altered during the latent period; slower GABAergic currents compensated for the decreased frequency of GABAergic IPSCs in the soma, but not in dendrites. Interestingly, this modification was transient, as IPSC kinetics returned to pre-SE values during the chronic phase. This late shortening of GABAergic currents resulted in a further decrease of the GABAergic tone in the dendrites, suggesting that there is a gradual erosion of the dendritic GABAergic drive during the course of epilepsy. In the soma, the situation was different as the GABAergic drive was increased during the chronic phase because of the hyperactivity of basket cells, demonstrating that the activity of the surviving GABAergic subnetworks was also modified.

Analysis of the glutamatergic and GABAergic drives received by different classes of interneurons revealed that the GABAergic drive remained unchanged, but that the glutamatergic drive was increased. Such an alteration of the balance between the glutamatergic and GABAergic inputs may contribute to the increased firing rate of interneurons. In keeping with this enhanced activity, the levels of GAD, the GABA synthesis enzyme, were also increased. Glutamate and GABA quantal release, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and $GABA_A$ receptor-mediated current kinetics, and excitability were also modified in a cell-type-dependent fashion; i.e., these measures varied across different interneuron types. It is important to note that several of these modifications have been studied in other TLE models and in other brain regions, and some appear to be model- and region-specific.

A decreased GABAergic drive has been consistently proposed to be causally related to ictogenesis. But decreased GABAergic drive does not appear to constitute a necessary condition for seizure genesis (at least in the CA1 region), for the time window during which the GABAergic drive is maximally decreased is the seizure-free latent period. What, then, are the functional consequences of a decreased GABAergic drive, in particular in the dendrites, during the latent period? Using the computer model described earlier, we found that decreasing the GABAergic drive constitutes a sufficient condition to render the system hyperexcitable, with the occurrence of interictal-like activity. In keeping with this prediction, in vivo recordings revealed the presence of interictal-like activity as soon as 3 days post-SE. As described by others, interictal-like activity increased in frequency during epileptogenesis. Rather than being directly correlated to seizure genesis, a decreased GABAergic drive at the early stages of epileptogenesis may render the system prone to generate interictal-like activity. This activity may, in turn, participate in the construction of a network able to generate seizures.

Future Goals

The results described earlier demonstrate that plasticity of GABAergic systems during epileptogenesis is a very

complex phenomenon. Alterations occur at all levels of analysis, including postsynaptic, presynaptic, cellular, and network levels, in a subnetwork (defined by a given class of interneuron)-dependent manner. To make things more complex, these modifications are time-dependent.

Because there are many different types of interneurons, and because each interneuron type plays a specific role in shaping network dynamics, we have only began to assess the functional consequences of these plastic modifications. Up to now, two broad classes of interneurons have been considered: perisomatic and dendrite-projecting cells. It is now necessary to assess the fate of each cell type. Alterations within a specific GABAergic subnetwork may change specific activity patterns. Future goals include testing the ability of the system to generate physiological activities, including θ and γ oscillations, rhythms that have been associated with many cognitive processes.

Another challenge is to determine whether the interictal-like activity plays a role in epileptogenesis – i.e., whether it is causally related to the construction of an epileptogenic zone. If the occurrence of interictal-like activity is causally related to a decreased GABAergic drive, can we block this pathological activity by boosting GABAergic neurotransmission with conventional antiepileptic drugs as soon as interictal activity appears? Will such a manipulation delay or stop epileptogenesis?

Our results are interpreted within a specific framework that focuses on the inhibitory action of GABA. As pointed out, GABAergic neurotransmission is instrumental for the genesis of oscillatory activities. Whether a system with increased GABAergic drive on the postsynaptic soma is more prone to generate oscillatory activity remains to be tested. A greater ability to oscillate in specific frequency bands may facilitate the emergence of highly synchronized and widespread electrical patterns – such as seizures.

Finally, there is a specific class of interneurons that should be carefully investigated – interneurons with long-range connections. These GABAergic cells have extensive axonal fields spanning different hippocampal and extrahippocampal regions. Some of these long-range connection interneurons contact exclusively other interneurons, while others contact mostly glutamatergic cells. Neurons with long-range connections are believed to play a crucial role in information processing, as they would facilitate the 'binding' of distant brain regions (i.e., coordinate their activities). Hippocampo-septal interneurons (one of these long-range connection cells) survive in epileptic tissue. It will particularly be important to assess the state of these subnetworks, as they may favor synchronization between different brain regions.

Synchrony Through GABAergic Inhibition

Introduction

Activity in the normal brain is synchronized within a variety of network oscillations, the frequency and spatial scale of which vary with behavior. At one extreme are the ultraslow oscillations (<1 Hz) observed during slow wave sleep, which propagate across the entire neocortical mantle and also recruit neurons in the thalamus and striatum. In contrast, the activity within local circuits can display rhythmic synchronization over much shorter time scales, reaching the high gamma-frequency range (80–120 Hz) and beyond. While neuronal networks can generate rhythmic activity exclusively via mutual excitation, brain rhythms across this physiological spectrum are thought to depend upon GABAergic inhibition to both balance excitation and synchronize neuronal activity.

GABAergic neurons comprise a diverse array of anatomically and physiologically distinct neuronal subtypes, which not only make reciprocal connections with excitatory neurons, but also with each other. It is becoming increasingly clear that different GABAergic loops are recruited during different brain rhythms and contribute to their generation and synchronization. Less is known about the precise mechanisms which determine the pattern of recruitment, or how distributed networks can switch between oscillations at different frequencies. Given the complex and dynamic interplay between excitation and GABAergic inhibition, one can appreciate the difficulties in understanding how perturbations in GABAergic signaling might affect brain rhythms, and conversely, what some pathological changes in neuronal synchronization might imply about the status of GABAergic function.

While epileptic seizures are behaviorally-defined phenomena, a cardinal feature is the presence of atypical oscillations in the electroencephalogram (EEG). These ictal oscillations can be comprised of large-amplitude stereotyped events that are apparent even to the untrained observer, but may also be manifested as more subtle abnormalities in rhythmicity, which are inappropriate for a given brain region and behavioral state. Seizures themselves are clearly hyperexcitable events and are commonly assumed to arise from an underlying failure of inhibition to curb runaway excitation. It is known that blocking GABAergic inhibition produces seizures in animal models, but GABAergic signaling remains viable in epileptic tissue from humans and various chronic seizure models. Indeed, it may sometimes even be increased. GABAergic circuits are recruited during seizure activity and are likely to shape the particular temporospatial patterns of ictal activity observed in different epilepsy syndromes. However, this article will explore the possibility that GABAergic signaling could also play a causative role in the generation of pathological synchronization.

Background

Treatments designed to bolster GABAergic inhibition, or directly suppress neuronal excitability, have proved successful in treating many epileptic syndromes. Moreover, it is very rare for such anticonvulsants to exacerbate seizures. At first glance, this situation appears to rule out a major active role for GABAergic inhibition in ictogenesis. However, it should be noted that drugs acting to inhibit the activity of excitatory neurons will have qualitatively similar effects on GABAergic neurons. Moreover, the transition from interictal to ictal activity involves several stages of temporal development, which may have different mechanisms and be subject to different methods of intervention. In the epileptic brain, the primary underlying deficits in neuronal function give rise to seizures only sporadically. Recent developments in computer analyses of EEG signals, designed to help predict ictal onset, show that changes in brain activity can precede seizures by several minutes, even hours. Introduction

Activity in the normal brain is synchronized within a variety of network oscillations, the frequency and spatial scale of which vary with behavior. At one extreme are the ultraslow oscillations (<1 Hz) observed during slow wave sleep, which propagate across the entire neocortical mantle and also recruit neurons in the thalamus and striatum. In contrast, the activity within local circuits can display rhythmic synchronization over much shorter time scales, reaching the high gamma-frequency range (80–120 Hz) and beyond. While neuronal networks can generate rhythmic activity exclusively via mutual excitation, brain rhythms across this physiological spectrum are thought to depend upon GABAergic inhibition to both balance excitation and synchronize neuronal activity.

GABAergic neurons comprise a diverse array of anatomically and physiologically distinct neuronal subtypes, which not only make reciprocal connections with excitatory neurons, but also with each other. It is becoming increasingly clear that different GABAergic loops are recruited during different brain rhythms and contribute to their generation and synchronization. Less is known about the precise mechanisms which determine the pattern of recruitment, or how distributed networks can switch between oscillations at different frequencies. Given the complex and dynamic interplay between excitation and GABAergic inhibition, one can appreciate the difficulties in understanding how perturbations in GABAergic signaling might affect brain rhythms, and conversely, what some pathological changes in neuronal synchronization might imply about the status of GABAergic function.

While epileptic seizures are behaviorally-defined phenomena, a cardinal feature is the presence of atypical oscillations in the electroencephalogram (EEG). These ictal oscillations can be comprised of large-amplitude stereotyped events that are apparent even to the untrained observer, but may also be manifested as more subtle abnormalities in rhythmicity, which are inappropriate for a given brain region and behavioral state. Seizures themselves are clearly hyperexcitable events and are commonly assumed to arise from an underlying failure of inhibition to curb runaway excitation. It is known that blocking GABAergic inhibition produces seizures in animal models, but GABAergic signaling remains viable in epileptic tissue from humans and various chronic seizure models. Indeed, it may sometimes even be increased. GABAergic circuits are recruited during seizure activity and are likely to shape the particular temporospatial patterns of ictal activity observed in different epilepsy syndromes. However, this article will explore the possibility that GABAergic signaling could also play a causative role in the generation of pathological synchronization.

Background

Treatments designed to bolster GABAergic inhibition, or directly suppress neuronal excitability, have proved successful in treating many epileptic syndromes. Moreover, it is very rare for such anticonvulsants to exacerbate seizures. At first glance, this situation appears to rule out a major active role for GABAergic inhibition in ictogenesis. However, it should be noted that drugs acting to inhibit the activity of excitatory neurons will have qualitatively similar effects on GABAergic neurons. Moreover, the transition from interictal to ictal activity involves several stages of temporal development, which may have different mechanisms and be subject to different methods of intervention. In the epileptic brain, the primary underlying deficits in neuronal function give rise to seizures only sporadically. Recent developments in computer analyses of EEG signals, designed to help predict ictal onset, show that changes in brain activity can precede seizures by several minutes, even hours. Immediately prior to the

final transition to a full-blown behavioral seizure, activity must reach a critical state to 'break out' from the epileptic focus; this state in some cases is seen as a flattening of the EEG and emergence of low-amplitude high-frequency oscillations. Of course, the temporal progression towards seizures is different within and between epilepsy syndromes, but the sequence does not appear to be an inevitable cascade. In some patients with intractable temporal lobe epilepsy, as well as in slice models of this type of seizure, it has proved possible to abort the final transition to ictal (or ictal-like) discharges by disrupting synchronization with low-frequency electrical stimulation. Drugs that reduce the overall levels of excitation might prove broadly effective by blocking different aspects of seizure evolution, and thus imply little about the underlying causes.

Current anticonvulsants that produce gross changes in the balance between inhibition and excitation have severe side effects, and more than 25% of epilepsy cases remain drug-resistant. Whether a therapeutic goal proves to be an enhancement or reduction in certain aspects of GABAergic function, the development of more selective and successful treatments will require a more detailed understanding of the functional diversity of GABAergic signaling at the molecular, cellular, and network levels.

GABA Receptor Heterogeneity

GABA acts via two main types of receptors: the ionotropic $GABA_A$ receptors and the metabotropic $GABA_B$ receptors. $GABA_A$ receptors are composed of pentameric assemblies of seven different classes of subunits (α1–6, β1–3, γ1–3, δ, ε, θ, and π), which form ion channels selective for Cl^- and HCO_3^- ions. Not all the possible combinatorial permutations exist in the brain and the rules governing $GABA_A$ receptor assembly and function have been reviewed extensively elsewhere. Suffice it to say that most receptors in mature neurons probably contain either a γ or δ subunit, and that the precise composition determines not only the biophysical properties of $GABA_A$ receptors, but also their cellular localization and pharmacology. For example, δ subunit-containing $GABA_A$ receptors have the highest affinity for GABA, display slow desensitization, and appear to be excluded from synaptic sites. In contrast, $\alpha1\beta2\gamma2$ $GABA_A$ receptors, which are the most abundant in the brain, display a much lower affinity and rapid desensitization, and are localized at synapses.

Benzodiazepines, which are positive allosteric modulators of $GABA_A$ receptors, display powerful anticonvulsant properties. Benzodiazepine-sensitivity is also determined by subunit composition, with binding occurring at the interface between the γ subunit and the α1, α2, α3, or α5 subunits. Switching these α subunits for α4 or α6, or substituting the γ subunit for a δ subunit, eliminates benzodiazepine-sensitivity.

Metabotropic $GABA_B$ receptors display much less diversity. Receptors are composed of either the $GABA_{B1a}$ or $GABA_{B1b}$ subunit isoform, in combination with a $GABA_{B2}$ subunit, to form two types of heteromeric receptors. $GABA_B$ receptors are located both pre- and postsynaptically, where their major respective roles appear to be in regulating transmitter release via the inhibition of Ca^{2+} channels and mediating slow inhibition through the activation of inwardly-rectifying K^+ channels. The subtype of the $GABA_B$ receptor may determine its subcellular localization within a given cell type, but both isoforms can be either pre- or postsynaptic and they cannot yet be distinguished pharmacologically.

Tonic & Phasic GABAergic Inhibition

The activation of synaptic $GABA_A$ receptors, in response to a transient exposure to GABA released from the presynaptic terminals, produces postsynaptic currents with fast rise and decay kinetics, termed phasic inhibition. However, GABA can also escape the synaptic cleft and pool in the extracellular space to activate peri- and extrasynaptic $GABA_A$ receptors and thus generate an 'inhibitory tone.' The ability to detect and transduce such volume transmission requires nonsynaptic $GABA_A$ receptors with a high affinity and low rate of desensitization, and in many brain regions, these criteria appear to be met by δ or α5 subunit-containing $GABA_A$ receptors. While many studies have demonstrated the importance of phasic inhibition for synchronizing neuronal activity, the possible roles of tonic inhibition in modulating network function are yet to be fully explored.

Hyperpolarizing and Depolarizing $GABA_A$ Receptor-Mediated Responses

The response to GABA receptor activation can be hyperpolarizing or depolarizing, depending on the difference between the membrane potential and the reversal potential across the activated ion channel. Unless an experimenter artificially clamps the membrane potential, activation of postsynaptic $GABA_B$ receptors, coupled to K^+ channels, will always lead to hyperpolarization. However, the relationship between the reversal potential across the $GABA_A$ receptor and the neuronal membrane potential varies throughout development, between neurons, and during the course of disease.

In immature neurons, the expression of the NKCC1 chloride transporter produces a net accumulation of intracellular Cl^-, yielding a $GABA_A$ receptor reversal potential positive to the resting membrane potential, and thus enabling GABA to be depolarizing. During the course of development, the expression of the KCC2

chloride transporter becomes upregulated, leading to active extrusion of intracellular Cl^-. Accordingly, in the adult brain, $GABA_A$ receptor-mediated signaling is predominantly hyper-polarizing. However, the expression of KCC2 does not become developmentally-upregulated in at least some classes of GABAergic interneurons and it is likely that the precise nature of GABAergic signaling varies throughout the mature brain.

Recently, there have been several studies suggesting that $GABA_A$ receptors on axonal compartments, including the axon initial segment and presynaptic terminal, may mediate depolarizing responses at resting membrane potentials. This idea harks back to classical electrophysiological studies showing that GABA could produce primary afferent depolarization in the peripheral nervous system. However, as with such studies, it is not yet clear how Cl^- homeostasis is independently controlled in different neuronal compartments, or whether the predominant effect during ongoing activity would be stimulation of release or presynaptic inhibition through inactivation of voltage-dependent conductances.

Rebound Excitation

Even when GABAergic events are hyperpolarizing, they can paradoxically excite neurons by interacting with intrinsic voltage-dependent conductances, thus producing a rebound excitation. An example of this effect is shown in Figure 1, in which GABAergic inhibition across a population of neurons leads to the activation of an intrinsic inward current with a slow time constant (I_h) and subsequently to synchronized rebound firing. GABAergic hyperpolarization could produce similar effects via the deactivation of outward currents, such as I_M, or by the deinactivation of inward currents, such as Na^+ and Ca^{2+} currents.

Diversity of GABAergic Interneurons

Interneurons can be classified into subtypes based on their axonal arborization, with the simplest distinction being those interneurons that selectively target the perisomatic region of excitatory neurons, those that target the dendritic tree of excitatory cells, and those that selectively target other interneurons. Finer distinctions within these broad classes can be made on the basis of intrinsic physiological and synaptic properties, as well as the expression of neuropeptides, calcium-binding proteins, and neurotransmitter receptors. There is increasing evidence that these subtypes of GABAerigc neuron are recruited differentially during different brain rhythms, both within and between distinct brain regions. Moreover, each subtype is thought to modulate different aspects of cellular and network function. We still have a long way to go to link the molecular, cellular, and network aspects of

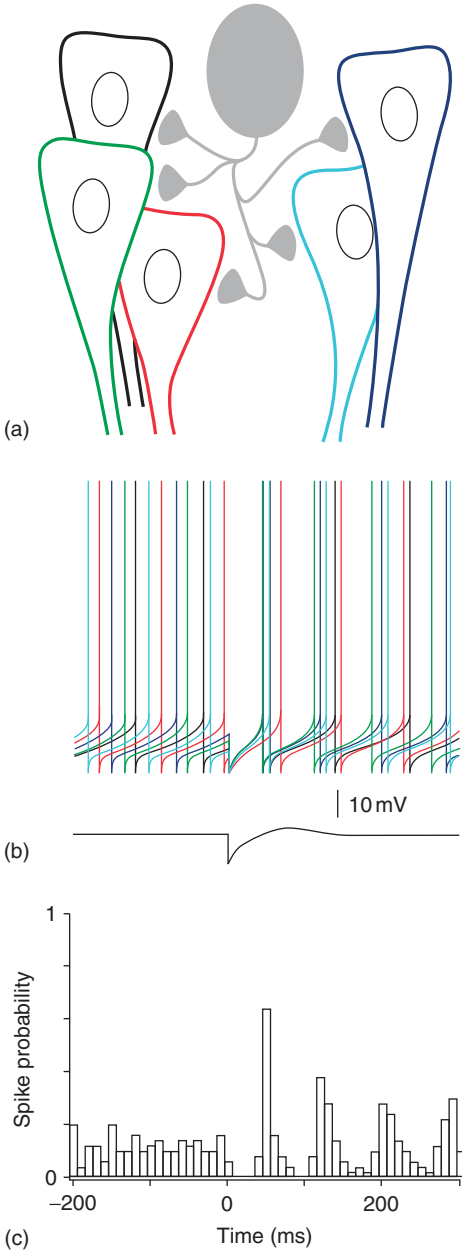

Figure 1 Synchronization via inhibition and rebound excitation. This figure is based on work by Peter Somogyi's laboratory, showing that a single perisomatic-targeting GABAergic interneuron can actively synchronize the spontaneous spiking activity of multiple pyramidal neurons, not only by vetoing spike generation during the period of synaptic inhibition, but also by generating rebound excitation. (a) A single perisomatic-targeting interneuron (grey) makes divergent projections onto a population of pyramidal neurons. (b) A spike in the interneuron produces a $GABA_A$ receptor-mediated inhibitory potential in the pyramidal neurons, which is followed by rebound excitation due to the activation of I_H (lower subthreshold trace). If the pyramidal cells are depolarized to a level that gives spontaneous asynchronous spiking, the postinhibitory rebound induces synchronization over several oscillatory cycles (upper traces). (c) Spike probability histogram centered on the timing of the GABAergic input, and averaged over eight trials, to demonstrate the increase in population synchronization.

GABAergic signaling, but the ability to modulate these GABAergic circuits independently would provide a powerful pharmacological armory for probing neuronal function and also for combatting brain disorders.

Methods

Our laboratory is focused on exploring the multiple facets of GABAergic inhibition using model rodent systems. The various projects take advantage of transgenic mice and chronic disease models to determine both the normal function GABAergic signaling and how these systems change in response to perturbations and contribute to pathogenesis. The analysis of the biophysical and pharmacological properties of different modes of GABAergic signaling is performed routinely using patch-clamp recording from acutely prepared brain slices. How such GABAergic inhibition shapes network activity is explored further in slice models that display intrinsic rhythmic activity and computational models, and with EEG recordings from awake behaving animals.

Recent Results – Evidence for a Causative Role for GABAergic Signaling in Seizure Evolution

While exploring the changes in synaptic transmission and cellular excitability associated with seizures, in both resected tissue samples from human patients and in animal models of epilepsy, it is difficult to distinguish between those changes that predispose the network to seizures and those that represent a homeostatic response to pathological activity. This problem is compounded in patients that have been on extended drug treatments, which are also likely to cause adaptive changes in the neuronal circuitry. Nevertheless, there are a few cases where a role for GABAergic signaling in driving hyperexcitability is emerging.

Interictal Spikes in Mesial Temporal Lobe Epilepsy

The neuronal circuits that are disturbed in epilepsy may give rise to abnormal EEG patterns during the interictal period. These interictal events can be used to localize the seizure focus and aid the diagnosis of the epilepsy syndrome. In focal epilepsies, these EEG abnormalities often include interictal spikes lasting 50–200 ms. Intracranial recordings from patients with mesial temporal lobe epilepsy have shown that interictal spikes do not correlate with massive burst discharges across the neuronal population, but rather suggest that these events are predominantly inhibitory. Indeed, slices of the subiculum resected from these patients continue to display interictal spikes in vitro, where they have been associated with high-frequency firing in GABAergic interneurons and inhibition in the majority of excitatory pyramidal neurons. The small spatially-distributed proportion of pyramidal neurons that do display interictal bursting was found to exhibit decreased KCC2 expression and depolarizing GABAergic responses. The interictal spikes in these slices can be blocked by antagonists of either glutamatergic or GABAerigc receptors, suggesting that interictal spikes are generated by positive feedback loops between interneurons and a selective population of pyramidal cells – an interaction that results in surround inhibition in the bulk of the network.

There is continued debate as to whether interictal spikes represent a pathological state of a network that might be involved in ictogenesis, or whether these events are in fact protective against seizures. Interictal spikes are, by definition, inversely correlated with seizures (i.e., they occur when there are no seizures), but the area of generation of interictal spikes does not always overlap with the determined epileptic focus (i.e., the site of seizure generation). Further, the frequency of interictal spiking has been shown to decrease prior to seizure onset. Greater understanding of the network interactions during the temporal evolution of seizure onset will be required to resolve this relationship between interictal and ictal phenomena.

Changes in Excitability Induced by Febrile Seizures

Complex febrile seizures in children are associated with an increased risk for the development of epilepsy. Experimentally-induced hyperthermia also induces seizures in rat pups and leads to a subsequent reduction in seizure threshold. Interestingly, recordings from hippocampal slices prepared form these animals reveal an enhancement of GABAergic inhibition, without any significant changes in excitatory transmission. A clue as to how such increased inhibition could increase network excitability came from the finding that this change in GABAergic transmission is accompanied by a positive shift in the activation curve of I_h, and thus an enhancement of post-inhibitory rebound firing (see **Figure 1**). Hyperthermia-induced seizures may also lead to other changes in the activity-dependent modulation of GABAergic transmission, but these studies have fostered the idea that increased inhibition might be proictogenic in cortical circuits by promoting both synchrony and hyperexcitability via rebound excitation.

GABAergic Circuits Involved in Thalamocortical Spike-Wave Seizures

Absence epilepsy is characterized by generalized non-convulsive seizures, which are observed in the EEG as periods of repetitive and bilaterally-synchronous ~3 Hz

spike-wave discharges. Understanding the mechanisms underlying absence epilepsy has been aided by several genetic and pharmacological animal models, which display qualitatively similar spike-wave seizures. While there is still debate over the location of seizure focus, there is a general agreement that the stereotypical pattern in the ictal EEG depends on synchronizing mechanisms in the thalamus. A minimal circuit for these paroxysmal oscillations appears to be the reciprocal connections between the inhibitory neurons of the thalamic reticular nucleus (nRT) and the excitatory thalamic relay neurons. In this circuit, excessive synchronized inhibition from the nRT deinactivates T-type Ca^{2+} channels into thalamic relay neurons, leading to rebound bursts and re-entrant excitation. This scenario is consistent with the fact that ethosuximide, which is a clinically-effective treatment for absence seizures, can act to reduce T-type Ca^{2+} currents in thalamic relay cells.

Support for the role of GABAergic inhibition in driving spike-wave seizures comes from the observation that the systemic administration of $GABA_A$ or $GABA_B$ receptor agonists can lead to spike-wave seizures in animal models. Perhaps unexpectedly, benzodiazepines, which augment $GABA_A$ receptor-mediated transmission, have also proved effective in treating both spike-wave seizures in animals and absence seizures in humans. The key to this paradox may lie in the cell type-specific distribution of $GABA_A$ receptor subunits. Many neurons in the nRT appear to be rich in benzodiazepine-sensitive γ-containing $GABA_A$ receptors, while a large number of thalamic relay nuclei contain δ and $\alpha 4$ subunits, which convey insensitivity to benzodiazepines. Therefore, while increased inhibition onto thalamic relay neurons may precipitate absence seizures, benzodiazepines may nevertheless be therapeutic by selectively increasing inhibition within the nRT and thus disrupting pathological synchronization in the thalamic circuitry.

Increased Inhibition in a Mouse Model of Autosomal Dominant Nocturnal Frontal Lobe Epilepsy

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is characterized by frontal lobe motor seizures that arise most frequently during slow wave sleep. Three loci associated with ADNFLE have been mapped to mutant genes coding for the $\alpha 4$ (CHRNA4), $\alpha 2$ (CHRNA2), and $\beta 2$ (CHRNB2) subunits of the nicotinic acetylcholine receptor (nAChR), while candidates genes for alternate loci remain to be identified. Studies exploring the effects of ADNFLE nAChR mutations in heterologous in vitro expression systems have produced inconsistent results, suggesting a variety of changes in receptor properties that lead to both increases and decreases in nAChR function. These differences may reflect the details of expression and the particular experimental paradigms used. More compelling insights come from a set of mouse strains engineered to carry either the ADNFLE $Chrna4^{S252F}$ or the $Chrna4^{+L264}$ mutant alleles; both the homozygous and heterozygous mice carrying these mutations display spontaneous recurrent seizures. Recordings from pyramidal neurons in the frontal cortex of these ADNFLE mutant mice in vitro demonstrate a large increase in nicotine-evoked inhibition, without significant changes in nicotine-evoked excitation. Furthermore, the animals spontaneous seizures can be inhibited by subconvulsive doses of picrotoxin, a use-dependent antagonist of fast GABAergic transmission. It has yet to be shown how this gain of inhibition could lead to paroxysmal activity, but again it has been suggested that synchronization through post-inhibitory rebound bursting may play a role.

Further Goals

One of the future challenges in this area of research will be to understand how a certain change in inhibition, measured at the level of a single cell, translates into the aberrant activity of a local network. Individual neurons may 'titrate' their inhibition by very small amounts, but these small cellular changes can translate into massive pathological alterations of excitability at the network level. Moreover, to understand how inhibition will affect the local network, we will have to study its modulation at the level of each individual network component. More genetic, molecular biological, and optical approaches are needed to alter inhibition or activity in specific neuronal components of the network, thus providing the needed functional insight into generation of epileptic activity. Considering the importance of inhibition in pathological synchrony, it will be well worth the challenge to design new drugs that are effective only against pathological inhibitory activity.

Introduction

The *ARX* gene is a transcription factor, which belongs to a family of paired-class homeobox genes that play a pivotal role in the embryogenesis of all animals, including the development of the central nervous system. *ARX* is a relatively small gene of 12.5 kb, with an open reading frame (ORF) that spans 1686 bp and has an unusually high GC content (72.5%), which complicates polymerase chain reaction (PCR) and sequencing. In the central nervous system, *ARX* is expressed in the cerebral cortex, amygdala, corpus callosum, caudate nucleus and hippocampus, areas implicated in the pathophysiology of seizures, neuropsychiatric disorders, involuntary movements, and learning and memory formation. Studies in humans have demonstrated remarkable pleiotrophy, as several apparently unrelated disease phenotypes have been associated with mutations of this gene. Thus, *ARX* is emerging as one of the most important disease-causing genes on the X chromosome and ought to be considered for routine screening.

One of the disorders in which *ARX* has been implicated is infantile spasms (ISs). ISs are a unique form of seizure disorder, the occurrence of which is limited almost

entirely to infants during the first year of life, and that is refractory to conventional anticonvulsant drugs. ISs are usually associated with developmental retardation or deterioration and a characteristic electroencephalographic (EEG) pattern (hypsarrhythmia) that together configure a syndrome that is also known as West syndrome (WS). The seizure type is defined as an epileptic spasm; it is seen predominantly in infants, although spasms may also occur in childhood or even in adult patients. ISs have multiple causes, and their pathophysiological mechanism is unknown. Infants with developmental brain abnormalities and those who are small for gestational age are more apt to develop spasms. Familial cases are probably the expression of several genetic disorders, some of which are well characterized, including X-linked lissencephaly and band heterotopia, or X-linked mental retardation and ISs due to mutations in the *ARX* gene.

Background

The first three-generation family with an X-linked recessive form of infantile spasms (ISSXs) was described in 1977. Support for an X-linked form of ISs was also provided by reports of monozygotic male twins and male siblings with this condition. Linkage analysis performed in two additional families with ISSX suggested localization to Xp, in a region distal to DXS1068, with a maximum lod score of 2.36. The mapping was confirmed to Xp22.1-p21.3 and the interval containing the candidate gene was refined to 7.0 cM by studying a western Canadian family with X-linked ISs. *ARX* was considered as a candidate gene underlying ISSX primarily on the basis of its expression pattern in fetal, infant, and adult brain.

In 2002, *ARX* was screened in five ISSX families, and mutations were found in four of them. An additional stretch of seven tandem GCG repeats (c.333_334ins$(GCG)_{10+7}$) within the first normal stretch of 10 GCG triplet repeats in exon 2 (resulting in 16–23 polyalanine repeat expansion) was found in two of the five screened families. A third family had a duplication of 24 bp within the second stretch of GCG triplet repeats in exon 2 (428-451dup (24 bp)), causing 12–20 polyalanine repeat expansion. The fourth family was found to have a deletion of 1517 bp, removing 816 bp of intron 4 and 701 bp of exon 5 (IVS4-816_EX5701del). This deletion was predicted to result in an alternative carboxyl terminus of the ARX protein. In the last family screened, no mutations were found.

In addition to patients with ISSX/WS, *ARX* mutations were identified in patients with Partington syndrome, X-linked lissencephanly with ambiguous genitalia, a rare form of X-linked myoclonic epilepsy with generalized spasticity and intellectual disability, and nonsyndromic X-linked mental retardation. The majority of ISSX mutations identified to date (summarized in **Table 1**) are located in exon 2, which is also the largest coding exon, representing 52% of the *ARX* ORF. In particular, 5 of 6 families described to date with ISSX/WS had a polyalanine expansion in exon 2, harboring the 24-bp duplication 428-451dup (which is considered an *ARX* mutation hot spot), or the 23 polyalanine $(GCG)_{10+7}$ repeat expansion. In addition, a 24-bp duplication (441-464dup) has also been found in a patient with cryptogenic WS.

The role of the polyalanine tracts in the ARX protein, and in other proteins in general, is poorly understood. On the basis of their overrepresentation in transcription factors and in homeobox genes in particular, it has been suggested that they play a role in transcription regulation. Among the four polyalanine tracts present in *ARX* gene, two of them – the polyalanine tracts 1 and 2, (both located in exon 2) – have been directly affected by *ARX* mutations. Little is known about the molecular pathology associated with polyalanine expansions, and in order to explain how these mutations in the *ARX* gene cause disease, a series of polyalanine expansions in *Arx* have been generated. Expression studies in COS cell cultures and mouse brain slices showed that these constructs result in nuclear protein aggregation, filamentous nuclear inclusions, and increased cell death. Furthermore, it has been suggested that different *ARX* polyalanine expansion mutations may aggregate differently: while the $(GCG)_{10+7}$ repeat expansion seems to lead to protein aggregates mostly in the cytoplasm, the 428-451(24 bp) duplication seems to favor precipitation of aggregates in the nucleus. Both mutations were also found to be associated with the repression of the transcription of reporter genes.

Methods

The genetic mapping of the ISSX/WS locus was obtained through classic two point and multipoint linkage analysis, using sets of microsatellite markers on chromosome X. PCR amplification and DNA sequencing of the candidate genes present in the region (selected for their expression profile and/or function) allowed investigators to identify *ARX* as the mutated gene. The wide spectrum of phenotypes associated with *ARX* mutations is a reflection of the complexity associated with the ARX protein structure and function. A detailed analysis of the clinical findings of the patient, and an accurate analysis of the family pedigree, are fundamental in order to consider *ARX* genetic testing – in particular, for less severe *ARX* mutations such as trinucleotide expansions in exon 2 or missense mutations outside the homeobox. In fact, these latter mutations cause syndromes without malformations, including ISs, mental retardation with or without seizures, intellectual disability, and myoclonic epilepsy. EEG analysis is also very important, leading to the identification of typical electroclinical features, such as hypsarrhythmia. For the

ISs, X-linked infantile spasms; WS, West syndrome; PRTS, Partington syndrome; EIEE, early infantile epileptic encephalopathy with suppression-burst pattern; EDE, epileptic-dyskinetic encephalophaty.

purpose of genetic testing, genomic DNA is usually extracted from blood samples according to standard procedures; then all coding regions of the gene and the flanking intronic regions are amplified by PCR. PCR products are then analyzed using denaturing high performance liquid chromatography (DHPLC), a fast and reliable technique for screening DNA that can detect variations within minutes, with close to 100% sensitivity and specificity (including single-base substitutions as well as small deletions and insertions in DNA fragments). All the PCR fragments that show an abnormal DHPLC profile are then directly sequenced on an automated capillary sequencer.

Recent Results

Previous reports have described remarkable pleiotrophy among the phenotypes associated with mutations of *ARX*, including several syndromes with or without malformations of the brain. Most patients with ISSX/WS harbor expansions of the two GCG (polyalanine encoding) repeat regions in exon 2 of the *ARX* gene. It is, however, well documented that among these patients there can be considerable variability in clinical presentation, making the phenotypic classification difficult.

Recently, our group broadened the phenotypic spectrum of *ARX* mutations. To investigate the role of *ARX* mutations in cryptogenic ISSX, we performed mutation analysis in 115 boys, including two pairs of brothers, with ISSX and developmental delay. The $(GCG)_{10+7}$ polyalanine expansion was found in six boys from four families (Table 1).

Males carrying the expansion exhibited an epileptic-dyskinetic encephalophaty (EDE), with cognitive impairment, early-onset ISs, and severe generalized dystonia – reflecting the most severe nonmalformation phenotype described in patients with any *ARX* mutation.

A novel observation in this group of severely affected patients is the magnetic resonance imaging (MRI) finding of multiple small foci of abnormal cavitation, possibly reflecting progressive multifocal loss of tissue, in basal ganglia. The basal ganglia have long been implicated in the pathogenesis of dystonia and other movement disorders. Several additional lines of evidence support the hypothesis that abnormalities in basal ganglia might also play a role in the

pathogenesis of ISs. The basal ganglia are, in fact, rich in GABAergic interneurons, the developmental fate of which is known to be influenced by *ARX*. In addition, lesions in subcortical structures, including the basal ganglia, have been implicated in the generation of ISs.

Recently, a novel 33-bp duplication (298_330dup GCGGCA$(GCG)_9$) has been identified in two unrelated patients showing early infantile epileptic encephalopathy with suppression-burst pattern (EIEE, **Table 1**). This epilepsy syndrome is considered as an early variant of ISs; both EIEE and IS patients developed WS.

While early reports in multiplex families suggested that duplication of the second polyalanine tract was the most common mutation of the *ARX* gene, most recent studies (including our own) suggest that expansion of the first polyalanine tract may be more common in sporadic patients. Furthermore, the severity of the phenotypes described in these reports, and the observation that small in-frame c.333_334(GCG) insertions (leading to one to three amino acid expansions of the first polyalanine tract) cause only mild to moderate nonsyndromic mental retardation suggest that expansion of polyalanine tracts is harmful to neurons in a size-dependent manner.

Future Goals

Although the function of polyalanine tracts remains unknown, repeats of several alanine residues are frequent in transcription factors and other proteins with nuclear localization. Recently, the human ARX protein was shown to be a potent transcriptional repressor and, although the domain encompassing polyalanine tract 1 and 2 of *ARX* gene seems not to have a direct role in the repression activity, it has been demonstrated that the expansion of either polyalanine tract 1 or 2 enhances the transcriptional repression activity in a size-dependent manner. This effect could occur by a number of different mechanisms. For example, aggregation of the mutant protein due to polyalanine expansion could result in a loss of transcriptional activity or it could disrupt normal cellular processes due to the aggregates themselves. More systematic studies are needed to better elucidate how polyalanine expansions affect *ARX* function. Toward this goal, the development of mouse 'knock-in' lines harboring the expansion found in children with ISs will provide an essential genetic tool to assess how these mutations affect *ARX* transcriptional repression activity, and will help to clarify the pathogenetic mechanisms leading to the disease. Hopefully, the development of animal models carrying polyalanine expansions will also provide insights regarding the mechanisms by which *ARX* regulates the cell fate (in particular, the fate of GABAergic interneurons) in the developing brain. Valuable insights to address these points will be also obtained from the characterization of the transcriptional activity of the *ARX* gene in patients with polyalanine expansion mutations. Finally, since no neuropathologic studies have been performed so far in boys with polyalanine expansion in *ARX*, such studies should be carried out.

Cytoskeletal Genes and Idiopathic Epilepsies

B Lakaye, L de Nijs, C Léon, and T Grisar, CNCM, University of Liège, Liège, Belgium

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The neuronal cytoskeleton consists of cellular scaffolding or skeleton, contained within the cytoplasm of the perikarion as well as within adjacent neurites (dendrites and axons). In all cells, the cytoskeleton is a dynamic structure that maintains cell shape, enables cellular motion (using structures such as flagella, cilia, and lamellipodia) and cellular division. In nerve cells, it plays important roles in axonal transport (e.g., the movement of vesicles and organelles). The neuronal cytoskeleton is essentially composed of three types of fibrous structures namely, in decreasing order of their diameters, microtubules (15 nm in diameter), neurofilaments (the intermediate filaments of the neurons; 8–12 nm), and microfilaments (7 nm). The constituent proteins include, respectively, polymers of α- and β-tubulin, neurofilamins (NF-L, NF-M and NF-H), and actin.

Some epileptic syndromes are associated with mutations in genes encoding proteins implicated in the dynamic properties of this neuronal cytoskeleton. This article reviews some of these disorders. As will be illustrated, these initial genetic defects often lead to the production of important brain malformations, due to defaults in either nerve cell division or migration occurring during brain development. Brain development is a very complex process that can be divided into three phases: cell proliferation, neuronal migration, and cortical organization. Dynamic rearrangements of cytoskeleton are clearly implicated in all of these steps. Different microtubule-associated proteins (MAPs) and proteins localized at the centrosome – such as doublecortin (DCX), Map1b, Tau, Lis1, dynein, NudE – are implicated in the regulation of microtubule dynamics and have been shown to be essential for brain development. The epilepsies associated with the genetically based disruption of these cytoskeletal elements are often classified as secondary, lesional, or focal – or even 'acquired' epileptic diseases. The epileptogenic mechanisms of such syndromes are therefore also considered to be 'secondary,' with neuronal hyperexcitability due to an abnormal cortical environment – similar to abnormalities associated with other 'lesional' disorders such as tumors or posttraumatic lesions.

However, in some cases such gene mutations may give rise to a nonlesional epilepsy syndrome. In the latter part of this article, we present our strategy for investigating the biological properties of an unknown gene whose mutations are segregated with juvenile myoclonic epilepsies (JMEs), a clear nonlesional, inherited syndrome. While in most cases, such nonlesional epileptic syndromes have been associated with channelopathies, we present evidence to support our conculsion that in some idiopathic generalized epilepsies (IGEs), the mutated gene is not directly coding an ionic channel protein, but rather a protein associated with the cellular cytoskeleton. Specifically, we focus on a gene encoding a protein called EFHC1 (or Myoclonin 1) that has been found to be mutated in some pedigrees suffering from JME.

On the basis of our work on this genetic disorder, we propose that some IGEs are a consequence of electrical disorders due to subtle microdysgenetic lesions within the cortical mantle.

Background – Epileptic Syndromes Associated with Mutated Cytoskeleton Genes

Some epileptic conditions are now identified as phenotypes co-segregating with defaults in genes encoding proteins of the cytoskeleton and/or vesicle membrane trafficking-interacting proteins. These genes are summarized on Table 1.

Periventricular Nodular Heterotopia

Periventricular nodular heterotopia (PNH) is characterized by aggregates or masses of grey matter along the lateral ventricular wall. This disorder is due to an arrest in the migrational progress of neuroblasts from the periventricular zone to the cortical layers (occurring between the seventh and sixteenth gestational weeks) or a failure in programmed cell death of some neuroblasts within the periventricular germinal matrix. The associated epileptic features are variable: seizures may be generalized or focal, suggesting mesial or neocortical temporal and parieto-occipital onset, with the age of onset usually in the mid teens. PNH has an X-linked dominant mode of inheritance. It displays high rates of embryonic hemizygous male lethality, often exhibiting in females a cell-autonomous mosaic phenotype due to random X-inactivation. Neurons expressing the mutant X chromosome fail to migrate, while those having the normal X chromosome migrate normally.

This condition is, in most cases, associated with mutations of the *filamin 1* gene (*FLNA*) that maps to Xq28. The gene is composed of 48 exons, spans a 26-kb genomic region and codes for the F-actin-binding cytoplasmic cross-linking phosphoprotein Filamin A (FLNA).

Table 1 Some epileptic conditions associated with defaults in genes encoding cytoskeleton and/or vesicle and membrane trafficking interacting proteins

Cytoskeleton and vesicle trafficking interacting proteins	*Genes*	*Loci*	*Properties*	*Types of disorders*		*Inheritance*	*Epileptic features*
				Cellular level	*Tissue level*		
Filamin A, alpha	FLNA	Xq28	Actin binding protein 280 Vascular function	Radial migration	Bilateral PNH	X-linked	Epilepsy very frequent (90%) mild to intractable
Doublecortin	DCX	Xq22.3	Microtubulesassociated protein (MAP)	Radial migration	SBH	X-linked	Epilepsy very frequent Onset before 6 months Intractable
Non catalytic subunit of PAF acétylhydrolase isoform Ib	PAFAH1B1 or LIS1	17p13.3	Nuclear migration along microtubules via dynein motor function	Radial migration	Type 1 Lissencephaly	AD	Epilepsy frequent Intractable
ADP ribosylation factor for guanine nucleotide exchange factor 2 (Brefeldin A inhibited)	ARFGEF2	20q13.13	Intracellular vesicular trafficking	Proliferation; radial and tangential migration	PVH and microcephaly	AR	Early onset seizures Infantile spasms

PAF, platelet activaton factor; ADP, adenosine diphosphate; PNH, periventricular nodular hetrotopia; SBH, subcortical band heterotopia or double cortex; PVH, periventricular heterotopia; AD, autosomal dominant; AR, autosomal recessive.

This protein binds other membrane-associated proteins such as integrins, presenilin1 and glycoprotein Iba, and promotes orthogonal branching of actin filaments. Filamin A is thought to act early during development, and could be part of the molecular machinery leading to the 'switch' that permits a neuron to become competent for subsequent migration. FLNA functions also by structuring actin networks at the cell periphery. In PNH, instead of acting at the leading edge of the migrating neuron, FLNA maintains a static focal contact between a stationary neuron and a neighboring radial glial cell.

Subcortical Band Hetrotopia or Double Cortex and Type 1 Lissencephaly

Subcortical band hetrotopia (SBH) and type 1 lissencephaly (LIS) are both cortical malformations secondary to abnormal migration of neurons during early brain development. Lissencephaly consists in an absence (agyria) or various degrees of decrease (pachygyria) of cortical gyration, leading to the development of an abnormally smooth cerebral surface. In lissencephaly, neurons migrate partially toward their proper cortical destination, but subsequent formation of gyri and sulci fails to occur. Subcortical band heterotopia (SBH) is a related disorder in which there are bilateral bands of grey matter found interposed within the white matter between the cortex and the lateral ventricles ('double cortex').

Mutated genes have been found to cosegregate in families with either classical LIS or SBH. One gene responsible for the autosomal form of LIS is *LIS1*, located on chromosome 17p13.3. A second gene, *doublecortin* (*DCX*), is X-linked. Interestingly, mutations in both genes can result in either LIS or SBH; however, the majority of cases of classical LIS are due to deletions or mutations of *LIS1*, whereas the majority of cases of SBH are due to mutations of *DCX*. *LIS1* mutations result in lissencephaly more severe in posterior brain regions, whereas *DCX* mutations result in LIS more severe in anterior brain regions. Epileptic features vary according the site of the malformation. Patients with missense mutations have less severe defects; they may present pachygyria (and only rarely SBH) and much milder neurological and cognitive impairment. Truncating mutations, in contrast, cause severe lissencephaly.

LIS1 was initially identified as the noncatalytic subunit of platelet-activating factor acetylhydrolase Ib (PAF-AH), an enzyme that degrades the bioactive lipid PAF. Experimentally, treatment with a PAF agonist caused a drastic reduction of the migration of cerebellar granule cells in vitro. LIS1 protein function in PAF-AH could, therefore, be related to its essential role in migration. Moreover, LIS1 protein has been shown to colocalize with microtubules and to promote their stabilization. An ortholog of LIS1 in *Aspergillus nidulans*, nudF, mediates nuclear translocation, probably by interacting with microtubules. Thus, LIS1 protein might exert its effects on migration through microtubules.

DCX mutations classically produce a double cortex phenotype in which a second band of cortical neurons appears within the white matter below the normal cortical layers. This gene encodes isoforms of a highly hydrophilic 40-kDa protein containing several potential phosphorylation sites. DCX proteins are homologous to other CNS protein containing a Ca^{2+}/calmodulin kinase domain, suggesting that the DCX may belong to a novel class of intracellular proteins involved in neuronal migration through Ca^{2+}-dependent signaling. In fact, DCX is a microtubule-associated and stabilizer protein, expressed almost exclusively in immature neurons. DCX stabilizes microtubules and inhibits neurite outgrowth during nerve growth factor-induced differentiation. Neuronal precursors start expressing DCX early after exiting the cell cycle, and continue to express DCX for 2–3 weeks as the cells mature into neurons. Downregulation of DCX begins after 2 weeks, and occurs at the same time that these cells begin to express a marker for mature neurons. Due to the nearly exclusive expression of DCX in developing neurons, this protein has been used increasingly as a marker for neurogenesis.

The interaction of both DCX and LIS1 with microtubules may explain the striking similarities between the lissencephalic phenotypes produced by mutations in these two genes.

Methods – The Genotype–Phenotype Correlations in Epilepsy: A Real Way of the Cross

In recent decades, thanks to advances in molecular biology techniques coupled with those in medical diagnosis, many gene mutations cosegregated with inherited neurological diseases have been identified. However, before declaring that any isolated mutation is responsible for the morbid phenotype, a pathophysiological mechanism must also be proposed and demonstrated. Even with the current capabilities for rapid genotyping, elucidation of the genotype–phenotype relationship may require many years of research. This difficulty is particularly true if the properties of the mutated gene have yet to be established. Examples of such obvious difficulties include the *huntingtin* gene in Huntington's disease, *parkin* for Parkinson disease, and *preselinin* in Alzheimer disease. Much work has been carried out to characterize these new proteins, but full explanation of how the gene is related to the relevant morbid process is often still unclear.

In the field of epilepsies, diseases of brain cortical excitability, the story is slightly different. Many of the initial gene mutations detected within families with inherited epilepsy corresponded to proteins known to be involved in the control of neuronal excitability

(i.e., nicotinic and $GABA_A$ receptors). Thus, many of these seizure disorders have been classified as 'channelopathies.' However, despite these important discoveries, studies of these gene mutations have sometimes failed to produce a complete explanation of the clinical picture.

Recently, a generalized idiopathic epileptic syndrome, JME, has been associated, in some families, with mutations in a gene encoding a protein with unknown properties. How should one go about establishing the correlation between the genotype and phenotype in this case? In our laboratory, such research consists of two phases.

The first phase starts by a systematic screening that include the following steps:

1. Understanding/characterizing the phenotype.
2. Establishing the complete sequence of the gene and the protein, and comparing them to sequences in available databases to identify possible regions with known properties.
3. Determining the distribution of the transcript in the adult organism and during development using Northern blot and/or in situ hybridization methods.
4. Generating and validating a poly- or monoclonal antibody against a sequence of the protein in order to estimate its level of translation and its distribution within the organism (and in particular in the brain), both in adulthood and during development. This goal can be achieved using Western blot and/or immunohistochemistry methods.
5. Determining the subcellular distribution of the protein in vitro in cell lines using immunocytochemistry and/or overexpression of protein coupled to fluorescent marker.
6. Identifying the protein partners using yeast two hybrid, pull down and/or immunoprecipitation methods.

Investigations during the *second phase* depend upon the results obtained during the first phase. Within the context of a gene related to an epilepsy phenotype, the studies will obviously focus on brain tissue, with functional electrophysiological experiments used within relevant experimental models in which plausible pathophysiological mechanisms can be tested. Production of a knock-in mouse model, reproducing the human genotype of interest (together with at least a part of the human phenotype) is the 'gold standard' for models studies focused on the role of the target gene in the development of the particular epileptic disease.

Results – An Example of Genotype–Phenotype Work: JME and EFHC1 or 'Myoclonin1'

First Phase

Characterizing the phenotype

JME is the most common form of IGEs and the primary cause of hereditary grand mal seizures. Most reports calculate that JME accounts for 10–30% of all epilepsies. JME is a familial disorder inherited with a complex mode of transmission.

JME phenotypes can be distinguished as two major and two minor subsyndromes. Classic JME (72%) is characterized by the adolescent (13–15 years) onset of myoclonic jerks on awakening, tonic–clonic seizures appearing two years later, with no absence seizures. The second major subsyndrome is characterized by childhood absence evolving to JME (18%). Pyknoleptic absence, with 3 Hz spike and wave complexes and 4–6 Hz spike and polyspike-waves complexes then persist into adolescence, when myoclonias and convulsive seizures appear. The two minor forms consist of adolescent myoclonias, and 'grand mal' seizures with absences that start during adolescence (or even after 18 years), some rare cases being associated with astatic drop attack. Electroencephalographs consistently show diffuse 3–6 Hz multispike wave complexes between seizures and diffuse rapid spikes during actual myoclonias.

To date, 15 chromosomal loci have been associated with JME by linkage analysis. Three genes (below) are known to be involved in different pedigrees of monogenic JME. The first two genes are obviously implicated in the neuronal excitability, whereas the last one is a gene of unknown function.

GABRA1 (EJM5 – 5q34)

This gene encodes the α_1 subunit of the $GABA_A$ receptor. It exhibits an A322D mutation in one French and one large French–Canadian JME family. This mutation results in a lesser amplitude GABA current in vitro, and also reduces the α_1 subunit trafficking at the synaptic level.

CLCN2 (EJM6 – 3q26)

This gene encodes a voltage-gated chloride channel. Mutations (M200fsX231, 74–117del and G715E) have been shown to reduce in vitro the transmembrane chloride gradient, thus potentially reducing GABA inhibition.

EFHC1/Myoclonin (EJM1a – 6p12)

This gene encodes a protein of unknown function. Mutations in EFHC1 seem to be the most common in JME patients. Molecular analysis reveals missense, nonsense, frameshift-deletion and deletion mutations found in six separate cohorts. Mutations appear more commonly in Hispanic JME population from California, Mexico, and Honduras, but also appear in Caucassian families from Italy and Austria.

What can we learn from the gene structure and the encoded protein?

The *EFHC1* gene (EF-hand domain containing 1) is located on chromosome 6p12.3, has a size of 72 kb and encodes a 640 amino acid protein of 73 kDa. This protein

contains three DM10 domains of unknown function and a single EF hand motif. This last sequence is part of protein structure often implicated in calcium homeostasis. In human, alternative splicing at exon 4 generates a splice variant encoding a truncated protein of 278 amino acids, with 240 common to the long transcript.

Distribution of the transcript in various tissues

The distribution of EFHC1 mRNA in various tissues has been verified by quantitative RT-PCR, northern blot and in situ hybridization. EFHC1 transcript is present in all studied organs of adult mouse. It is expressed at high levels in testis, lung, muscle, and thymus. Lower transcription levels were observed in the cerebral cortex, uterus, ovary, stomach, intestine, kidney, liver, and heart.

We also studied the EFHC1 transcript expression during mouse brain development. The expression was highest at E14, and then progressively decreased until 10 days after birth, at which time it stabilized at the adult level. In brain, EFHC1 mRNA is therefore essentially expressed at early stages of development, when nerve cells are dividing and organizing the cortical mantle cytoarchytecture.

The distribution of the transcript is also available on the Allen Brain Atlas web, indicating the presence of the transcript in various neuronal layers, in particular, in hippocampus (dentate gyrus) and cerebellum, as well as in ependymal structures and choroids plexus. In human, Northern blot and EST counting has demonstrated that the transcript is expressed in many tissues (including testis, pharynx, pituitary gland, lymph nodes, bone marrow, kidney, brain, heart, and pancreas at high levels, and many more at lower levels).

Distribution of the protein in various tissues

Using validated antibodies, we started to revisit (previous results were presented with nonvalidated antibodies) the distribution of the protein in the adult mouse brain and during development. Expression of EFHC1 in the adult brain was shown in neurons in the hippocampus CA1, cerebellum, and cerebral cortex. The staining appeared to be localized in the nucleus and in the cytoplasm. Immunostainings using a different antibody also showed the presence of EFHC1 in neuronal cells in the hippocampus and the cortex, with stronger signal in pyramidal neurons. In hippocampal neuronal cells in culture, the same cellular localization was observed; the neuronal processes were also weakly stained. A significant staining was also observed on the border of the lateral ventricles lining with ciliated ependymal cells. These data are in agreement with results from in situ hybridization performed on mouse brain (see the on-line Allen Brain Atlas).

Immunohistochemistry in developing mouse brain shows protein expression at E16, with strong staining at the border of the cerebral ventricles as well as in the choroid plexus. Significant immunostaining was also observed in neocortex, piriform cortex, and striatum. At the subcellular level, EFHC1 antibody recognized principally a cytoplasmic material, quite radially organized. Therefore, not only the quantitative expression but also the subcellular localization of EFHC1 appears to be modulated during development. Western blot has confirmed that the protein expression is also higher during development compared to adult. All together, these findings strongly suggest that EFHC1 may contribute to the development of the nervous system.

Intracellular localization

To study the subcellular distribution of EFHC1, we overexpressed EFHC1 coupled to EGFP, a fluorescent marker, in different cells lines (HEK293, COS7, HeLa, NIH3T3, and neuroblastoma). In interphase cells, the fusion protein was present throughout the cytoplasm and in the nucleus, but was absent from the nucleoli. One, or occasionally two, intensively fluorescent spots were observed close to the nuclei. However, the most prominent characteristic was observed during mitosis, as EGFP–EFHC1 showed a strong colocalization with the mitotic spindle poles and the midbody (the microtubule-based intercellular bridge at cytokinesis). These results suggest the involvement of EFHC1 in cell division, and in particular, in the organization of the mitotic spindle and the midbody.

The localization of the above-mentioned strongly fluorescent spots close to the nucleus, and the presence of two spots in some cells, suggested an association of the protein with the centrosome. To substantiate this hypothesis, we performed colocalizations by using a fluorescent anti-γ-tubulin antibody, a well-established centrosomal marker. We indeed observed a strong colocalization of γ-tubulin with the EGFP–EFHC1 spots in interphase cells and at spindle poles during mitosis. Thus we suggest that EGFP–EFHC1 could be a centrosomal component.

We also compared the distribution of the EGFP-tagged protein with the endogenous EFHC1 using a specific antibody. By indirect immunofluorescence we observed the presence of EFHC1 in the cytoplasm and nuclei during interphase in different cell lines. In interphase cells, intense spots close to the nuclei were detected. These spots were identified as centrosomes using an anti-γ-tubulin costaining. During mitosis, the distribution of the endogenous EFHC1 was the same as the overexpressed protein. The association with the mitotic spindle and the midbody (**Figure 1**) was observed in all above-mentioned cell lines.

EFHC1 contains three DM10 domains of unknown function. To investigate the role of DM10 domains in its association with the mitotic spindle, HEK293 cells were transfected with various truncated forms of EGFP-tagged EFHC1 and processed for immunofluorescent staining

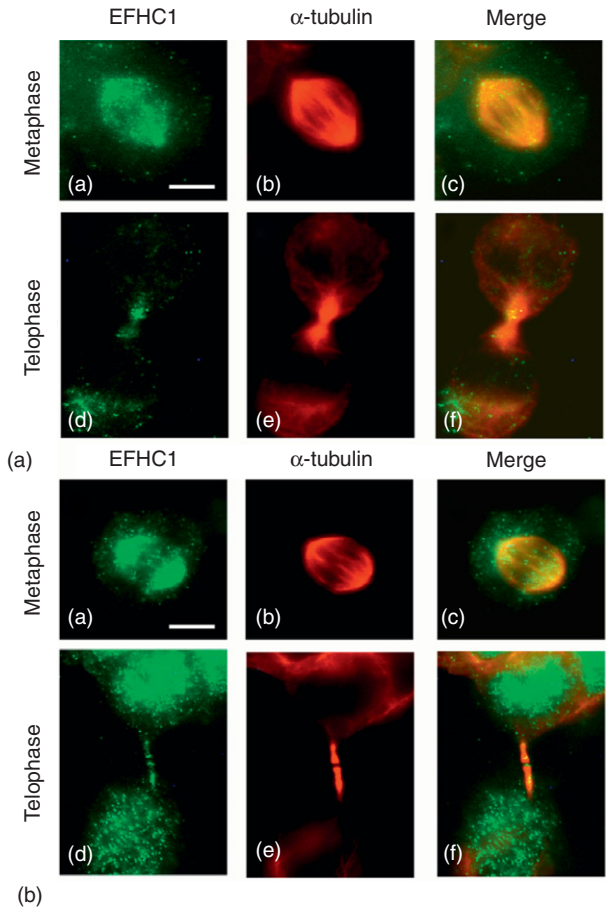

Figure 1 Association of EFHC1 (Myoclonin1) with the mitotic spindle in HEK293 and neuroblastoma cells. HEK293 (A) and N2A (B) cells were immunostained using anti-EFHC1 antibody (a, d, in green) and anti-α-tubulin antibody (b, e, in red) during metaphase (a–c) and telophase (d–f). The corresponding merged images are shown on right panels (c, f). Epifluorescence images. Scale bar: 10 μm. Note the characteristic staining of the midbody in (B-f).

using an anti-α-tubulin antibody. Different EFHC1 chimeras demonstrated their distinct capacities for localization to the mitotic apparatus. All constructs that contained the N-terminal portion of the protein localized to the mitotic spindle and midbody, whereas C-terminal constructs did not. The N-terminal part of the protein, containing only the 92 first amino acids of EFHC1, still associated with the mitotic apparatus; however, the truncated form containing the DM10 domains and EF-hand did not. We therefore conclude that the N-terminal portion is required to address EFHC1 to the mitotic spindle and the midbody.

Protein–protein interaction

To date, interaction between EFHC1 and the C-terminus of R-type voltage-dependent Ca^{2+} channel ($Ca_v2.3$) has been suggested by immunoprecipitation studies. Another potential interacting partner, TEX11 (a testis-expressed sequence of unknown function), has also been proposed after yeast two hybrid experiments. In our hands, preliminary results indicate a specific EFHC1 interaction with nucleoporin 54, creatine kinase B, C18orfl, SUI1, ProSApiP1 and three unknown sequences. However for all of them, additional experiments (such as pull down and immunoprecipitation assays) are needed to confirm these putative interactions.

Second Phase

Taking all the above information together, the role of EFHC1 is still unclear. However, based on these data, we have hypothesized that EFHC1 can either play a role in intracellular calcium signaling and/or in cell division during neuronal development.

Is EFHC1 a calcium sensor?

C-terminal EF-hands are found in neuronal calcium sensors of the calmodulin family, Ca^{2+} ATPase, Ca^{2+} activated K^+ and Ca^{2+} channels, and various novel calcium binding proteins such as calsenilin, DREAM, and KchIP3. By modulating calcium concentrations, the EF-hand superfamily regulates neurotransmitter release, excitability and synaptic plasticity. Comparison of EFHC1 with calcium binding proteins from mammals, *Drosophilia*, *Caenorhabditis elegans*, and yeast revealed significant evolutionary conservation for key residues in the EF-hand motif. A recent study demonstrated that the EF-hand domain of EFHC1 bind to one divalent ion (Ca^{2+} or Mg^{2+}) under reduced condition. Further reports indicated that the overexpression of EFHC1 in hippocampal neurons in vitro induced apoptotic cell-death, which was significantly reduced by any of the mutations. This proapoptotic effect of EFHC1 was assigned to its enhancement of calcium influx through the R-type voltage-dependent Ca^{2+} channel ($Ca_v2.3$). EFHC1 mutations partly reversed this effect. The investigators carrying out those studies suggested that an incomplete reversal of EFHC1-induced calcium influx through $Ca_v2.3$ may be responsible for a precarious state of calcium homeostasis in JME patients. A higher density of neurons with precarious calcium homeostasis could, in theory, enhance a hyperexcitable state. In a sense, this hypothesis is similar to hypotheses suggested for other epileptic syndromes in which channelopathies or ion exchange modifications have been proposed as central causes of the clinical pictures.

Is EFHC1 implicated in the organization of the cytoskeleton?

More interestingly, in 2005, Ikeda et al. found that EFHC1 is a homolog of *Chlamydomonas* axonemal protein Rib72 and is expressed in tissues that have motile cilia and flagella. Since it is known that motile cilia of ependymal

cells are necessary for the correct migration of neuroblasts in the adult mouse brain, the mutations of EFHC1 could produce ependymal ciliary motility defects leading to abnormal GABAergic neuron cytoarchitecture in the neocortex, resulting in epileptogenesis. This hypothesis is supported by recent work demonstrating the presence of EFHC1 in ependymal cells.

As shown above, we have demonstrated that EFHC1 associates with the centrosome and the mitotic spindle through its N-terminal region. These results strongly suggest a role for EFHC1 in the regulation of the cellular cytoskeleton. Consequently, our current efforts have focused on the following questions:

Can EFHC1 plays a role during cell division?
Does EFHC1 have particular interactions with some proteins of the cytoskeleton?
If EFHC1 can participate in cell division, how can it affect CNS function?

Since neuronal precursors are dividing in CNS during the early stage of brain development, what could be the influence of the inactivation of the EFHC1 gene on neuronal proliferation and migration?

We recently started to answer this latter question using the in utero electroporation technique combined with RNA interference (RNAi). In brief, this approach involves an intraventricular injection, in utero, of a DNA plasmid solution, subsequently submitted to a brief electrostatic field. The plasmid is incorporated within the dividing cells along the ventricular wall of an appropriately developing hemisphere, so that the migration patterns can be further observed either in vivo or in vitro (using brain slices), under different conditions. With this technique, we have confirming the subcellular localization of EFHC1, suggesting that EFHC1 could have similar functions in vivo to those previously demonstrated in vitro. Next, we will analyze the effect of EFHC1 loss of function on radial migration. Embryos will be subjected to electroporation with plasmids encoding control shRNA or EFHC1 shRNA along with plasmid encoding EGFP to mark transfected cells. The position of $EGFP^+$ cells in different neocortical subregions will be analyzed four days after electroporation. Our unpublished results look very promising.

Directions for Future Research – Working Hypothesis: IGEs as a Disorder of Neuronal Cell Division or Migration?

Based on all the above-mentioned data, we hypothesize that IGE, as JME, could be due, in part, to subtle neuronal migration disorders. If EFHC1 controls cell division and neuronal migration, a gene mutation causing functional protein abnormalities could lead to subtle migration defects. During the later phases of development, subsequent reshaping of synaptic circuits could lead to progressive epileptogenic characters. Rare and still controversial indications in the literature support this working hypothesis. For example, autopsy studies of a patient with JME have shown cortical and subcortical 'dysplastic' neurons and other subtle abnormalities of intracortical architecture called 'microdysgenesis.' Quantitative MRI studies have demonstrated an increase in cortical grey matter in some JME patients. Such defects could be caused by abnormalities during specific stages of cortical development.

Therefore, the main goal for future research is to determine if JME is indeed a developmental disorder. To answer this question, we will modulate EFHC1 expression during brain development by in utero electroporation combined with RNAi, and study the influence of EFHC1 inactivation on neuronal migration. If any neuronal migration defect is found, we will let the animals carrying such a lesion survive and study (in adulthood) the consequence of these defects on neuroanatomical and electrophysiological properties of the cerebral cortex. We hypothesize that a subtle abnormal migration defect could produce an epileptogenic lesion under these conditions. If this hypothesis is correct, then categorization of all IGEs as classical channelopathies must be revised.

Epilepsy Genes that Do Not Encode Ion Channels

W N Frankel, The Jackson Laboratory, Bar Harbor, ME, USA

Introduction – Non-ion Channel Genes in Human Epilepsy

Epilepsy can be viewed as arising from the inability of the brain to control the balance of excitatory and inhibitory neurotransmission. Since ionic content determines the electrical potential of a cell, proteins that allow the flow of ions across the plasma membrane are the primary determinants of excitability state. Naturally, mutations in the genes that encode these channels are logical candidates for causing disruptions in brain excitability – such as seen in familial idiopathic epilepsies. It is therefore no surprise that two-thirds of the few known genes for idiopathic epilepsy encode ion channels. Still, several known human epilepsy genes do not encode ion channels. Furthermore, since most idiopathic familial epilepsy is genetically complex, the 20 or so known human epilepsy genes are likely to be just a fraction of those that are at play in nature.

It is tempting to consider, as a group, epilepsy genes that do not encode ion channels. As shown in **Table 1**, whether proven or proposed as candidates based on association studies, this group consists of a very small number of genes – too small, in fact, to draw systematic conclusions. However, with ion channels so important for epilepsy, one might at least expect that some of these genes may be directly involved in modifying channel activity. Indeed, this may be the case for *EHFC1*, which encodes a Ca^{2+}-sensing protein that may be involved in regulating the activity of R-type voltage-dependent calcium channels; EFHC1 mutations can cause juvenile myoclonic epilepsy, but the role of calcium channel misregulation in disease is not yet understood. More generally, one can imagine how a candidate gene such as *BRD2*, which is likely involved in gene transcription, may be an upstream regulator of certain ion channel genes. But as noted, we cannot yet draw any general conclusions.

Background – Insight from Epileptic Mice

At the present time, a richer source of information about candidate epilepsy genes is the larger number that renders seizure disorders when mutated in laboratory mice. We can use this group to begin to systematically assess the pathways that can lead to epilepsy. The Mouse Genome Informatics group at The Jackson Laboratory has assembled the world's largest mammalian genetics database, annotating information from all published articles according to mammalian phenotype ontology, and reflecting a community effort to provide standard terms for annotating mammalian phenotypic data.

Given 'seizure' as a search term, the database yields 467 allelic variants, from some 335 independent genes that, when mutated, yield a seizure-related phenotype of one kind or another. When considering relevance to epilepsy, it seems best to limit this set to genes that are associated with spontaneous (or naturally induced – e.g., by routine handling) seizures and for which the experimental evidence is the clearest. Therefore, after excluding mutants that only showed altered seizure threshold (but not spontaneous seizure), after excluding those spontaneous seizures noted in mice over 10 months of age (because some mixed strain backgrounds can exhibit age-related spontaneous seizures due to polygenic effects), and after eliminating several ion channels (but not metabotropic receptors or electroneutral ion transporters), 82 genes remained (**Table 2**). Although only some papers describing these mutant mice have included electroencephalographic evidence of seizure discharge, it is likely that most of these examples are mice that exhibit bona fide tonic–clonic and generalized seizures; the behavioral descriptions usually include characteristic features such as Straub tail, ventral or dorsal neck flexion, jaw clonus, forelimb clonus, loss of balance, and excessive salivation and/or defecation, followed by a quiescent period.

At a glance, the 82 genes appear to represent a rather wide set of cellular processes, ranging from cytostructural (e.g., myosin), to neurotransmitter receptor ($GABA_B$), to synaptic vesicle functions (e.g., synaptojanin-1), to cellular signaling (sonic hedgehog). One advantage of database-friendly annotation is that computational tools can be exploited to gain a systematic overview of how functional classes relate to each other and to the group that defines them (i.e., seizure disorder). Using a prototype visualization tool called VLAD (VisuaL Annotation Display), we can observe how these 82 molecules cluster according to gene ontology (GO) functional annotation (**Figure 1**; *NB*:For the analysis, we also added the few non-ion channel human epilepsy genes listed earlier). The first impression supports the anecdotal observation that a wide variety of functions are encoded by genes associated with seizure disorder in mice. The GO category with the largest number of seizure genes is involved in cellular component organization/biogenesis. Naturally, the composition of this group is very mixed – containing synaptic vesicle component proteins (*Syn1*, *Syn2*, *Snap25*),

Table 1 Non-ion channel genes known or suspected in human idiopathic epilepsy

Epilepsy type	*Gene*	*Encoded protein*	*Biol. Function*	*Chr*
Autosomal dominant epilepsy with partial auditory features	*LGI1*	Leucine-rich repeat LGI family, member 1	Unknown (secreted glycoprotein)	10q24
Febrile seizures	*GPR98 (MASS1)*	G protein-coupled receptor 98	Unknown (membrane protein)	5q14
Febrile seizures	*IMPA1*	Inositol (myo)-1/4 monophosphatase 1	Inositol metabolism	8q21.13-q21.3
Idiopathic generalized epilepsy	*ME2*	Malic enzyme 2, NAD(+)-dependent, mitochondrial	Malate metabolism	18q21
Juvenile Myoclonic Epilepsy	*EFHC1*	EF-hand domain (C-terminal) containing 1	Ca^{2+} binding; regulates VDCC	6p12-p11
Juvenile myoclonic epilepsy	*BRD2*	Bromodomain-containing 2	Transcriptional regulation?	6p21.3

metabolic enzymes (*Sod2*, *Hexa*), as well as genes encoding adaptor complex proteins (*Ap3b2*, *Ap3m2*). However, VLAD also shows the relative significance of each functional category, as a function of the number of seizure genes relative to the number of genes that exist altogether in a GO category. The darker circles in **Figure 1** highlight the more statistically significant groups. The two most significant groups are cell–cell signaling and nervous system development – the latter including transcriptional regulators *Bmi1*, *Emx1*, *Neurod2*, *Otx1*, and *Pten* as well as other cell-signaling molecules. One can imagine several ways in which these genes are crucial for preventing seizures; for example, they may regulate the maturation of cellular networks and synapses, or regulate the expression of ion channel gene transcription directly.

As large as this list may seem, 82 is certainly an underestimate of non-ion channel genes, which, when mutated, can cause epilepsy – especially given the ascertainment bias inherent in the dataset. That is, most alleles are man-made gene knockout mutations, resulting in little or no normal protein. Only a few mutant alleles encode missense or gain of function mutations. In nature, one finds a good mix of both reduced function and altered function. Still, even for the list of 82 genes, an entire encyclopedia would be required to discuss the potential roles of these molecules in epilepsy. As a recent example, we will focus on a new non-ion channel seizure gene, *Brunol4*, which causes a complex seizure disorder in mice.

Methods

Genetic approaches to understanding gene function are often classified in one of two categories: 'forward genetics' and 'reverse genetics.' Forward genetics means simply that the molecular identity of the gene is not known ahead of time, and that 'bottom–up' genetic or genomic methods are used to find it. The canonical 'forward' approach is called *positional cloning*, whereby the causative gene is identified by virtue of its position on a chromosome. Classically, this process consists of 'walking' along the chromosome (from a genetic marker on one side of the chromosomal interval associated with a disease to the other side), characterizing and evaluating molecular variants (e.g., by gene expression or structure analysis) along the way until one is found to be a strong possibility (i.e., a gene likely to be the cause of the disease). This possibility is then independently tested (e.g., by creating and testing a new allele, or performing a rescue experiment, or both). A variant of *positional cloning* is *positional candidate* – a slightly less systematic approach whereby the chromosomal interval or region of interest is known, and researchers make educated guesses about the causative gene – based on the position or nature of a nearby gene – and then evaluate molecular variants. Some transgenic approaches may be considered to be positional candidate – for example, when a transgene inactivates an endogenous gene (as in the case of *Brunol4*, described later); the endogenous gene is then retrieved based on its proximity to the transgene and is evaluated in a similar manner.

'Reverse genetics' is the opposite of forward genetics, in that the gene is already hypothesized to be a candidate for a particular phenotype (e.g., based on other studies) and then is purposefully mutated (e.g., in a 'knockout' or 'knockin' mouse) to test the hypothesis. Most targeted mutation studies in mice to date represent a reverse type of approach.

Recent Results

Complex Seizure Phenotype in *Brunol4* Mutant Mice

In 2007, a new mouse model was described with features of a genetically complex seizure disorder. The most obvious abnormality in heterozygous mutants was recurrent, tonic–clonic, and generalized seizures, which could be precipitated by routine animal care (e.g., moving mice into a clean pen), with onset during middle age (e.g., after 2–3 months). Because the behavioral manifestion of the tonic–clonic component can be quite wild, the mutant

Helt	Hey-like transcription factor (zebrafish)	*Tal2*	T-cell acute lymphocytic leukemia 2
Hexa	Hexosaminidase A	*Tef*	Thyrotroph embryonic factor
Hexb	Hexosaminidase B	*Ube3a*	Ubiquitin protein ligase E3A
Hlf	Hepatic leukemia factor	*Usp18*	Ubiquitin-specific peptidase 18
Htr2c	5-Hydroxytryptamine (serotonin) receptor 2C		

allele was dubbed 'frequent-flyer' (allele symbol *Ff*). Heterozygotes also have a reduced seizure threshold, are slightly hyperactive, and gain more weight later in life compared with wild-type littermates. Interestingly, homozygous mutants (two copies of the transgene) have a much more severe phenotype, including lethality of some mice within the first week of life; those mice that survive show convulsive seizures by 3–4 weeks of age. Moreover, homozygotes that are not on a C57BL/6J strain background display spike-wave discharges (SWD), the hallmark of

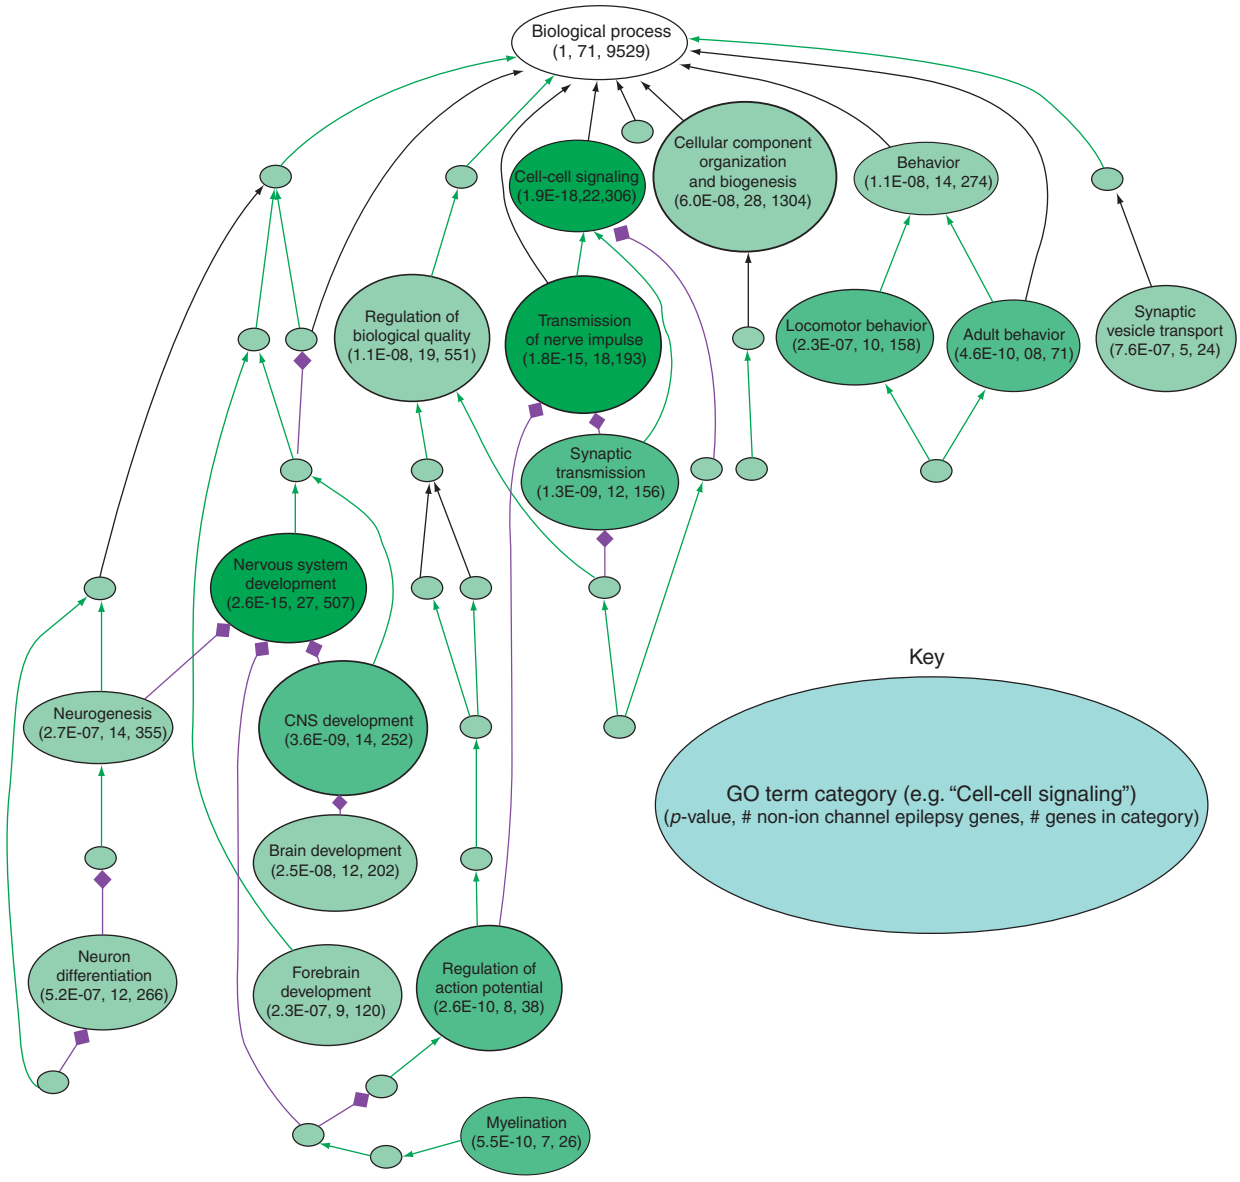

Figure 1 A classification of non-ion channel epilepsy genes using gene-ontology (GO) functional annotation. The prototype clustering tool, VLAD (see text), was used to categorize 82 mouse genes associated with convulsive seizures, and the human non-ion channel epilepsy genes from **Table 1**, according to their GO functional annotation. Individual genes can be members of different categories. The ovals show the categories according to statistical significance (p value obtained from the number of epilepsy genes compared with the total number of genes in a particular GO category). Darker green indicates more significant.

absence epilepsy (**Figure 2**). Gross neuroanatomical abnormalities, such as cell death or hypoplasia, were not found in either heterozygous or homozygous mutant mice, although assessment of specific neuronal populations was not done.

Because the phenotype arose in a strain carrying a non-functional transgenic insertion, and since seizures and the transgene cosegregated with each other, the abnormalities were most likely due to insertional inactivation of an endogenous gene. Genomic sequencing of the transgene insertion site revealed that the inactivated gene encodes the RNA binding protein, BRUNOL4 (Bruno-like 4), and that the effect of transgene insertion was to reduce the amount of steady-state Brunol4 mRNA to a very low level. Subsequent analysis of gene-targeted *Brunol4* null mutants, with the same phenotype, confirmed the gene identity.

Bruno-like RNA binding proteins have been shown, mostly from molecular biology studies, to be involved in multiple aspects of RNA processing such as pre-mRNA splicing, mRNA editing, and RNA stability and translation. There are six Bruno family members in humans and mice, with orthologs in nematode and fruit fly. *Brunol4* is expressed broadly during midgestation, but with maturity the expression becomes limited to the brain and is

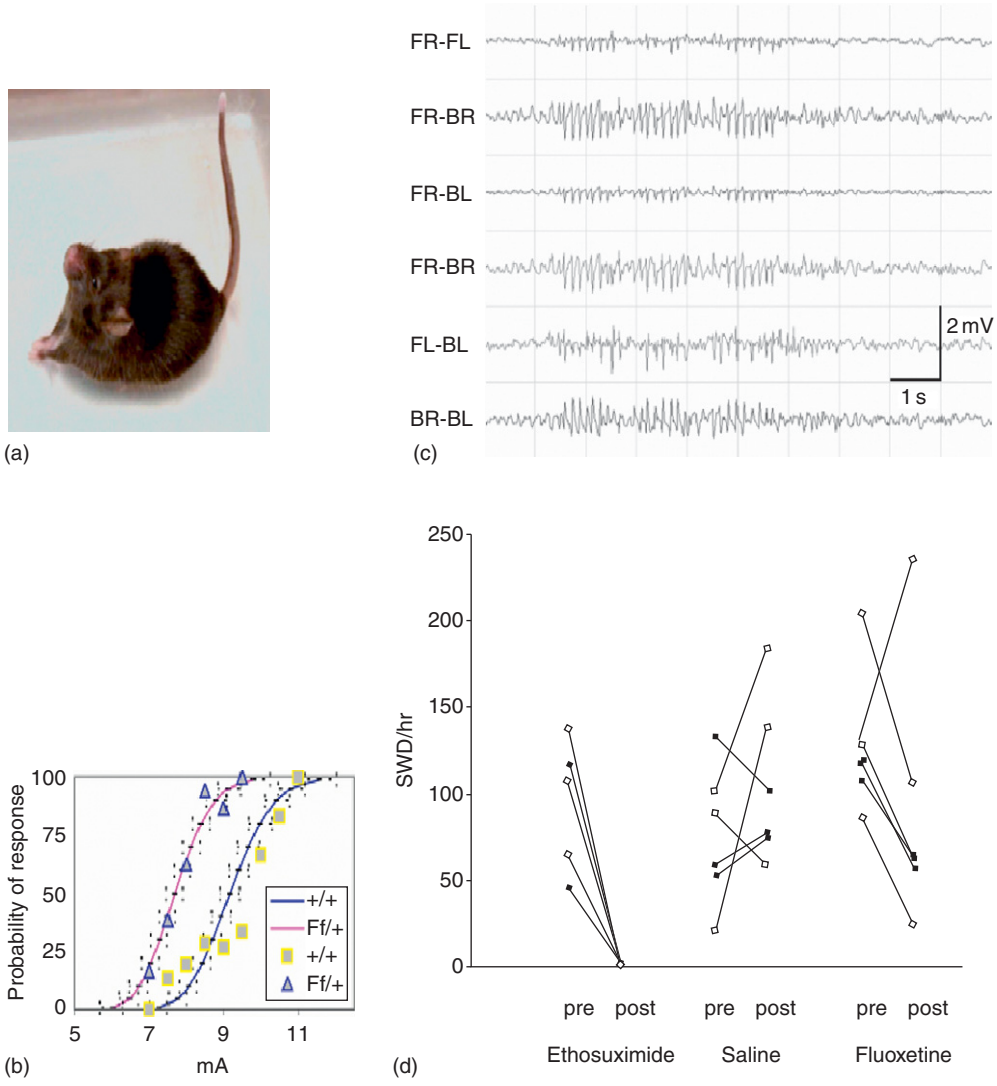

Figure 2 Seizure phenotypes of frequent-flyer mutant mice. (a) The posture of a 3-month-old *Brunol4*$^{Ff/+}$ heterozygote mouse at the beginning of a seizure episode. Note the contraction of the muscles of the neck, ears, and forelimbs and the vertical position of the tail. (b) Reduced ECT of *Brunol4*$^{Ff/+}$ mice. Squares (▫) and triangles (△) indicate individual data points used to construct CC curves in +/+ and *Brunol4*$^{Ff/+}$ mice, respectively. (c) EEG recording from a *Brunol4*$^{Ff/Ff}$ homozygous mouse. Shown are the six differential recordings from four subcranial electrodes, one in each quadrant corresponding to front-right (FR), front-left (FL), back-right (BR), and back-left (BL). These traces correspond to one of the longer spike-wave discharge (SWD) episodes observed. (d) Treatment of SWD in *Brunol4*$^{Ff/Ff}$ homozygous F2 hybrid mice from crosses to FVB (white box) or 129S1 (black). Recording sessions began at least 1 h prior to ethosuximide, saline, or fluoxetine (Prozac) treatment, and the rate of SWD (minimum criteria: ≥0.5-s duration, amplitude ≥2× baseline) was determined and plotted ('pre'). Animals were then injected with drug, monitored for an additional hour, and SWD incidence was recorded (post). Lines between data points correspond to each animal pre- and posttreatment. Only the ethosuximide and fluoxetine results were significantly different comparing treatments (ETX, $p = 0.009$; fluoxetine, $p = 0.019$; saline, $p = 0.804$ matched pairs test). Modified from Yang Y, Mahaffey CL, *et al*. (2007) Complex seizure disorder caused by Brunol4 deficiency in mice. *PLoS Genetics* 3(7): e124.

mostly enriched in the hippocampus – in particular, in the CA3 region. In vitro, BRUNOL4 itself has been shown to bind to U/G-rich intronic sequence and promotes the inclusion of the adjacent exons, at least when measured in cell lines with constructs designed to measure alternative splicing. However, in vivo – i.e., in the whole organism and particularly in the brain – its function is completely unknown.

The discovery that a single gene mutation in *Brunol4* has a striking neurological phenotype presents an opportunity to learn more about the true function of *Brunol4*. But it also raises a question: How can a complex seizure disorder result from a single gene defect in an RNA binding protein? The current hypothesis is that *Brunol4* somehow quantitatively regulates the levels of several different mRNA target genes simultaneously – and in mutants, it is the *combination* of

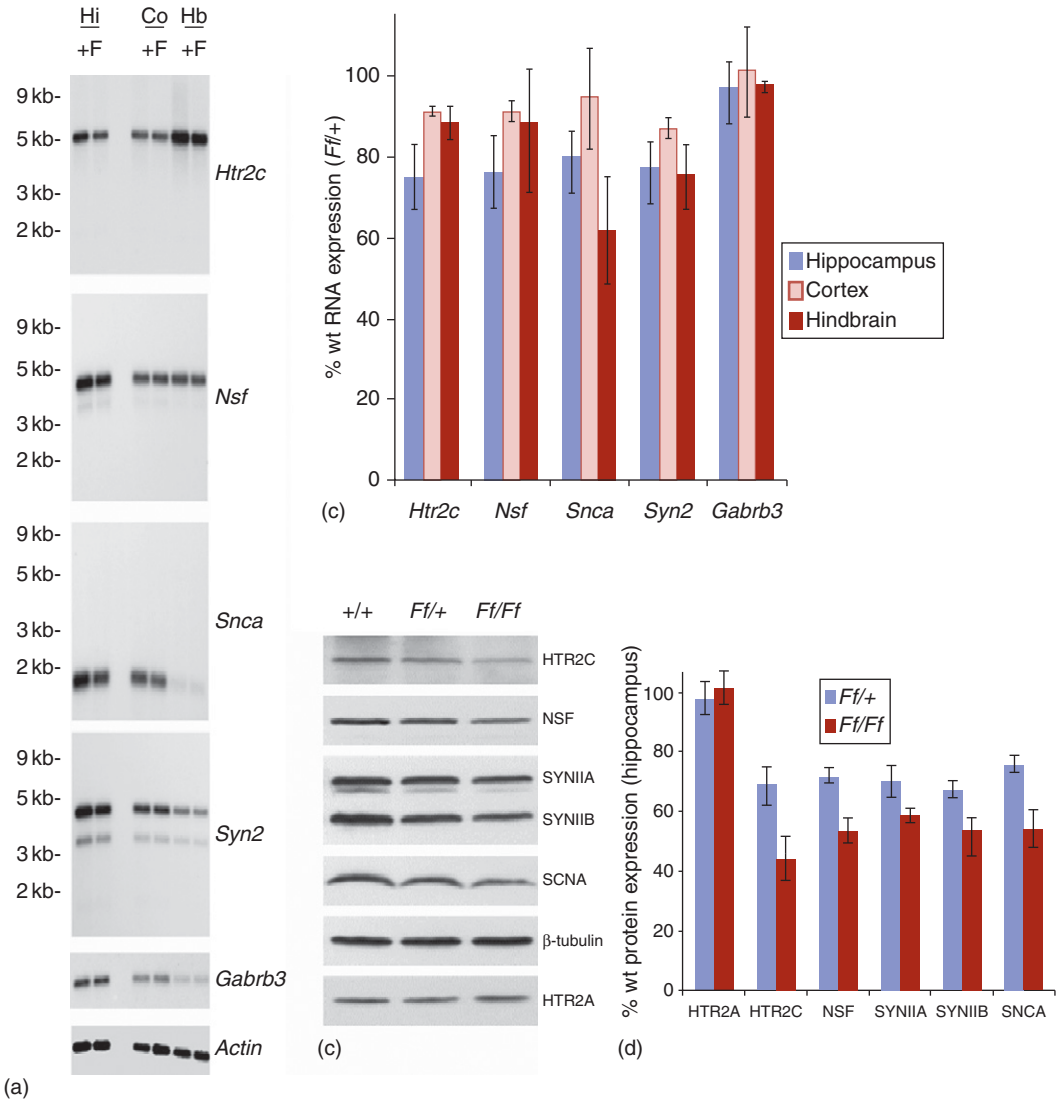

Figure 3 Reduced expression of four candidate genes in *Brunol4*$^{Ff/+}$ brains. (a) Representative images from three independent RNA blots. Sequential hybridization using *Htr2c*, *Nsf*, *Snca*, *Syn2* (experimental), *Gabrb3*, and β-actin (control) probes was carried out on a blot containing poly-A RNA extracted from dissected brain regions. CO, cerebral cortex; Hb, hindbrain; Hi, hippocampus. F, *Brunol4*$^{Ff/+}$; +, +/+. The position of size markers was shown on the left. (b) Histogram summarizing results from northern blots, expressed as % of wild type after normalization to β-actin. (c) Reduced expression at the protein level – western blot for HTR2A, HTR2C, NSF, synapsin II, α-synuclein, and β-tubulin. HTR2A, a molecule with distribution and property similar to HTR2C, was used as a control in addition to β-tubulin. Representative images from experiments with three independent adult mice on a mixed background are shown. (d) Histogram summarizing results from panel (c), in *Brunol4*$^{Ff/+}$ and *Brunol4*$^{Ff/Ff}$ mutants on a mixed background, expressed as % of wild type after normalization to β-tubulin, summarizing data from three independent animals. Error bars throughout are 1 standard deviation. Reproduced from Yang Y, Mahaffey CL, *et al*. (2007) Complex seizure disorder caused by Brunol4 deficiency in mice. *PLoS Genetics* 3(7): e124.

these effects that leads to the seizure disorder. Because the consequence of *Brunol4* deficiency might lead to a decrease in levels of steady-state mRNA(s), genome-wide microarray analysis was performed on brain RNA from homozygous mutants and compared with those of wild-type littermate control mice in order to look for candidate targets. Considering that tens of thousands of transcripts are represented on an array, a surprisingly small number (~75) had significantly lower levels in mutant as compared with control. Four epilepsy-related candidates stood out from this group: *Htr2c* (encoding a serotonin receptor, for which the null mutation has tonic–clonic convulsions, hyperactivity and middle-age weight gain), *Syn2* (encoding synapsin 2, which, when combined with synapsin 1 deficiency, lowers seizure threshold), *Nsf* and *Snca* (two known synaptic proteins also enriched in hippocampus, although heretofore not specifically linked to seizure disorders). The decrease of the mRNAs and protein for these genes was confirmed in mutants, being reduced some 25–40% compared with that in controls (**Figure 3**).

Genes for two of these candidate target mRNAs were already associated with epilepsy in mice. Further, *Htr2c* null mutants are also hyperactive and slightly obese as adults. Still, the relatively modest decrease in *Htr2c* transcripts in frequent-flyer mice with their severe seizure phenotype, in contrast with its complete absence in the knockout, suggests that its quantitative reduction is not sufficient (if it is indeed involved in the seizure phenotype). Moreover, *Htr2c* knockout mice did not have absence seizures, whereas the frequent-flyer homozygotes did. Interestingly, fluoxetine (Prozac®), the 5-HT reuptake inhibitor, partially reduced the incidence of SWD in frequent-flyer mutants, suggesting that the *Htr2c* deficiency was somehow involved in the etiology of SWD in frequent-flyer mice. To gain more direct evidence for the assertion that other genes were also involved in the frequent-flyer seizure syndrome, double-mutant mice (*Htr2c* null, *Brunol4*$^{Ff/+}$) were constructed and their seizure threshold was compared with that of single mutants. This procedure revealed that double mutants had a significantly lower threshold than either single mutant (**Figure 4**) – confirming that additional downstream players (i.e., not just *Htr2c*) in frequent-flyer heterozygous mice affect the seizure threshold. Although this initial study did not resolve whether *Syn2*, *Nsf*, *Snca*, or other potential BRUNOL4 targets were the coconspirators, it is consistent with the likelihood that frequent-flyer mice have a seizure disorder that mimics genetically complex seizure disorders in human idiopathic epilepsies.

Brunol4^{Ff} mutants illustrate, in a striking way, how genes other than those encoding ion channels can cause a complex form of epilepsy. Although many of the 75 downregulated mRNAs seen in animals with this mutation were of unknown function (and have not yet been tested), some of them may also contribute to the phenotype – and none encode ion channels. Still, if *Htr2c* and the other genes indeed contribute to the seizure phenotype associated with *Brunol4*^{Ff} mutant, one can hypothesize that the genetic effect is due to subtle modulation of synapse maturation or function.

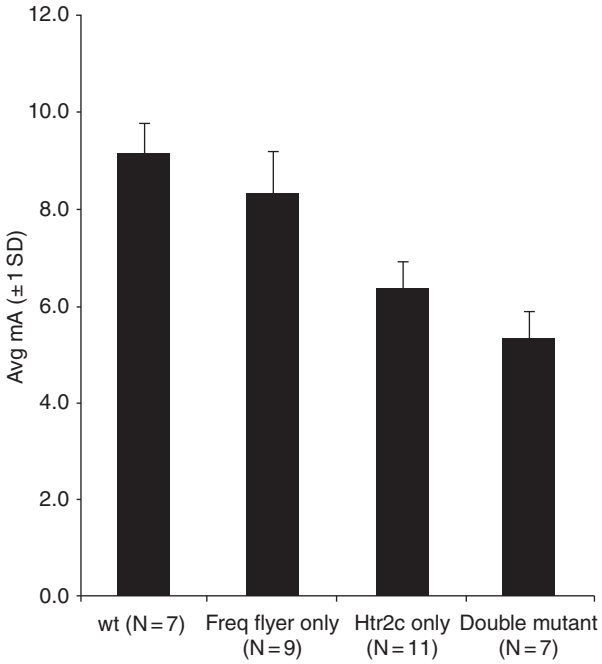

Figure 4 Genetic interaction between *Brunol4* and *Htr2c* for electroconvulsive threshold. Shown is a histogram of average threshold (in mA) to a minimal clonic or maximal tonic hindlimb extension seizure, for wild-type (+/+, +/+), single mutant (*Brunol4*$^{Ff/+}$, +/+ or B6 – *Htr2c*^{tm1Jul}/Y), or double-mutant (*Brunol4*^{Ff}/+; *Htr2c*^{tm1Jul}/Y) littermates from crosses between B6-*Htr2c*^{tm1Jul}/Y and B6-*Brunol4*^{Ff}/+ mice. Directions for Future Research

It is somewhat difficult to chart a specific way forward for understanding the role of non-ion channel genes in idiopathic seizure disorders, short of first identifying all the genetic factors underlying human epilepsy – a daunting, if not impossible task even in the 'postgenome' era. While it seems essential to gain a better understanding of the function of natural variants of ion channels in human epilepsy, the mouse research literature alone clearly suggests that many different types of genes – beyond ion channels – have a role too, including transporters, transcription and RNA processing factors, synaptic proteins, components of metabolism, and many other types of molecules. Furthermore, players at the 'upstream' end of pathway hierarchies, such as *Brunol4*, imply how even just one such gene can have complex consequences on multiple genes that more directly influence excitability. Over the next few years, the genetics research community will undoubtedly be systematically mutating a variety of genes (e.g., in the Knockout Mouse Project, KOMP). These studies will foster and better standardize the assessment of seizure phenotypes in new mutants, so that we can come to a more thorough understanding of what kinds of molecular changes can lead to seizures. In this way, when candidate genes are eventually nominated for more complex human epilepsies, the community will have a better grasp of which ones merit further pursuit in human genetic studies and in studies of potential targets for therapy.

GABRB3 and Childhood Absence Epilepsy

Introduction

γ-Aminobutyric acid is the major inhibitory neurotransmitter in the brain, and the ligand-gated ion channel $GABA_A$ receptors (GABARs) mediate the bulk of rapid inhibitory transmission. Any dysfunction of GABA causes seizures; conversely, several anticonvulsant medications act by enhancing GABA-mediated inhibition. Human epilepsies have an overall prevalence of about 1% across various countries. Amongst these epilepsies are absence or petit mal epilepsies which account for 3–12% of all epilepsies. Mutations in GABAR gamma2 (γ2), alpha1 (α1), and beta3 (β3) subunit genes have now been identified in human childhood absence epilepsy (CAE) sub-syndromes, namely (a) febrile seizures and CAE, (b) juvenile myoclonic epilepsy with CAE, and (c) remitting CAE, respectively. Mouse models of these mutated GABAR subunit genes are consistent with their role in producing inherited human absence epilepsies. This article focuses on the pathogenic role of GABAR beta3 subunit (*GABRB3*) in remitting CAE.

Background

$GABA_A$ Receptors

GABARs are heteropentameric membrane chloride channel proteins composed from a superfamily of 19 related subunit genes. These genes are constituted into a family of about 25 receptor subtypes which exhibit different regional, age-dependent, and subcellular localization. Plastic changes in subunit composition are observed with experience, disease, and chronic drug administration. Each receptor protein molecule contains two copies of an α subunit, two copies of a β subunit, and one other subunit. The γ2 subunit-containing GABARs are primarily synaptically localized and sensitive to benzodiazepines; extrasynaptic, primarily δ subunit-containing GABARs also control neuronal and network excitability (through tonic currents), and are important targets for drugs like anesthetics, ethanol, and neurosteroids. Genetically engineered mice have been valuable in deducing GABAR functions.

GABAR Mutations in Human Idiopathic Generalized Epilepsy (IGE) and Angelman Syndrome (AS)

Mutations in GABAR have been observed in multiple families affected with CAE syndromes. The GABAR subunit α1 has been found to be mutated in several positions within their protein sequences in autosomal dominant juvenile myoclonic epilepsy with CAE (JME/CAE) and in the syndrome of CAE only. Mutations have also been found in the γ2 subunit in the syndromes of febrile seizures with CAE, and generalized epilepsy with febrile seizures (GEFS+) and CAE. Some evidence also implicates the GABAR subunits δ and β3 in CAE. Current studies have investigated the reasons why a heterozygous mutation in these GABAR subunits can alter inhibitory function and produce petit mal seizures. Evidence suggests that in most cases there is reduced GABAR protein expression, reduced physiological inhibition, and hyperexcitability. The explanation for the dominant genetics remains unknown, but can include altered physiological properties of the GABAR channels, reduced trafficking of receptor proteins to the cell surface, and dominant-negative reduction of normal heteropentamer assembly.

An interesting variant on *GABRB3* pathology involves the neurodevelopmental genetic disease Angelman syndrome (AS). AS is associated with an imprinted maternal-inherited mutation in chromosome 15q involving the gene *UBE3a*. The majority of patients have a large deletion that includes, along with *UBE3a*, the GABAR subunit gene cluster α5/β3/γ3; these patients are thus heterozygous for these three subunits, including *GABRB3*. Compared to

Introduction

γ-Aminobutyric acid is the major inhibitory neurotransmitter in the brain, and the ligand-gated ion channel $GABA_A$ receptors (GABARs) mediate the bulk of rapid inhibitory transmission. Any dysfunction of GABA causes seizures; conversely, several anticonvulsant medications act by enhancing GABA-mediated inhibition. Human epilepsies have an overall prevalence of about 1% across various countries. Amongst these epilepsies are absence or petit mal epilepsies which account for 3–12% of all epilepsies. Mutations in GABAR gamma2 (γ2), alpha1 (α1), and beta3 (β3) subunit genes have now been identified in human childhood absence epilepsy (CAE) sub-syndromes, namely (a) febrile seizures and CAE, (b) juvenile myoclonic epilepsy with CAE, and (c) remitting CAE, respectively. Mouse models of these mutated GABAR subunit genes are consistent with their role in producing inherited human absence epilepsies. This article focuses on the pathogenic role of GABAR beta3 subunit (*GABRB3*) in remitting CAE.

Background

$GABA_A$ Receptors

GABARs are heteropentameric membrane chloride channel proteins composed from a superfamily of 19 related subunit genes. These genes are constituted into a family of about 25 receptor subtypes which exhibit different regional, age-dependent, and subcellular localization. Plastic changes in subunit composition are observed with experience, disease, and chronic drug administration. Each receptor protein molecule contains two copies of an α subunit, two copies of a β subunit, and one other subunit. The γ2 subunit-containing GABARs are primarily synaptically localized and sensitive to benzodiazepines; extrasynaptic, primarily δ subunit-containing GABARs also control neuronal and network excitability (through tonic currents), and are important targets for drugs like anesthetics, ethanol, and neurosteroids. Genetically engineered mice have been valuable in deducing GABAR functions.

GABAR Mutations in Human Idiopathic Generalized Epilepsy (IGE) and Angelman Syndrome (AS)

Mutations in GABAR have been observed in multiple families affected with CAE syndromes. The GABAR subunit α1 has been found to be mutated in several positions within their protein sequences in autosomal dominant juvenile myoclonic epilepsy with CAE (JME/CAE) and in the syndrome of CAE only. Mutations have also been found in the γ2 subunit in the syndromes of febrile seizures with CAE, and generalized epilepsy with febrile seizures (GEFS+) and CAE. Some evidence also implicates the GABAR subunits δ and β3 in CAE. Current studies have investigated the reasons why a heterozygous mutation in these GABAR subunits can alter inhibitory function and produce petit mal seizures. Evidence suggests that in most cases there is reduced GABAR protein expression, reduced physiological inhibition, and hyperexcitability. The explanation for the dominant genetics remains unknown, but can include altered physiological properties of the GABAR channels, reduced trafficking of receptor proteins to the cell surface, and dominant-negative reduction of normal heteropentamer assembly.

An interesting variant on *GABRB3* pathology involves the neurodevelopmental genetic disease Angelman syndrome (AS). AS is associated with an imprinted maternal-inherited mutation in chromosome 15q involving the gene *UBE3a*. The majority of patients have a large deletion that includes, along with *UBE3a*, the GABAR subunit gene cluster α5/β3/γ3; these patients are thus heterozygous for these three subunits, including *GABRB3*. Compared to

UBE3a mutations alone, this deletion seems to contribute to a more severe syndrome of mental retardation and epilepsy, typified by atypical absence and myoclonic seizures generalizing to grand mal, as well as a characteristic epileptiform EEG. We ascribe these abnormalities to the reduced expression of GABAR β3. Genes in this region of 15q also show reduced expression with potential functional consequences in autism spectrum disorder.

Methods

Mouse Knockout

Gene targeting in embryonic stem cells was employed to produce a mouse harboring a deletion mutation in the *gabrb3* gene, in a mixed 129/C57 genetic background. These animals were null (knockouts) for the GABAR β3 subunit mRNA and protein in the homozygous −/− animals.

Human Genetics

Probands with remitting CAE (with frequent, 20–200 per day, seizures), and family members, were screened for *GABRB3* mutations using DNA heteroduplex analysis with denaturing high performance liquid chromatography and gene sequencing. Microsatellite markers in the vicinity of *GABRB3* were assessed in all the family members to determine allelic linkage and segregation with the disease phenotype.

Molecular Cell Biology and Physiology

Human *GABRB3* cDNAs mutated in the three residues observed in human CAE patients were expressed in heterologous cells for examination of protein expression, in vitro transcription and translation, with analysis of the glycosylated product, and for functional expression of Cl^- channels using electrophysiological recording.

Results

GABRB3 Mouse Ko

Mice lacking the GABAR β3 subunit have a complex and pathological phenotype that includes epilepsy in the homozygous (−/−) animals. There appears to be little or no compensatory increase in other GABAR β subunits in the knockouts. The seizures have been characterized by EEG and show spike and wave discharges, accompanied by arrested locomotion similar to an absence seizure, beginning at about 2 months of age. The seizures become progressively more frequent with age, not remitting in adult, and the mice exhibit myoclonic jerks during the abnormal EEG. The seizures often are accompanied by a circling behavior in the cage, sometimes becoming frantic with 'whirling dervish' behavior, and sometimes generalizing to tonic-clonic generalized seizures. The EEG includes some absence-like discharges that continue so long that they can be considered nonconvulsive status epilepticus. The seizures, like human absence, respond favorably to ethosuximide and are worsened by carbamazepine; they respond poorly to other clinical antiepileptic medications.

The homozygous β3 knockout mice, but not heterozygotes, clearly show epileptic seizures that resemble human absence and the epilepsy of AS. These animals also show motor incoordination, disturbed rest/activity cycles, and cognitive deficits, possibly also a model of the developmental human genetic disease AS (of which autism is overlapping).

The *gabr3* mouse gene product is expressed widely in brain, especially early in life. It forms heteropentamers with varying α subunits, γ2 or δ, and is enriched in subtypes lacking α1 (which normally partners with β2). These heteropentamers are abundant in GABAergic interneurons, which are therefore low in functional β3. The β3 subunit polypeptide is expressed in the embryonic thalamus and decays to low levels in the adult, except in the thalamic reticular nucleus. Rhythmic activity of inhibitory synapses in the thalamic reticular nucleus and thalamic relay neurons produces synchronous thalamocortical firing typical of sleep spindles; loss of inhibition in one of the two regions, but not both (lack of β3 in the knockout in reticular nucleus but not in the relay cells), increases synchronicity and thus gives rise to the absence seizure activity.

Human Remitting CAE

CAE (petit mal) with remission at adolescence (remitting CAE) is a common idiopathic generalized epilepsy typified by frequent brief loss of consciousness with bilateral 3–4 Hz spike-and-wave without motor convulsions. Family studies have proved inherited distribution of the disorder, consistent with a major gene interacting with additional genetic and environmental factors. Association with the *GABRB3* gene was reported for Austrian CAE patients, and in California we found linkage of genetic polymorphisms near *GABRB3* with remitting CAE. Analysis of the DNA from remitting CAE patients and family members revealed mutations in 4 of 48 families from Mexico and Honduras. These mutations included one heterozygous missense mutation P11S (exon 1A, position 11 in immature polypeptide) that segregated with 4 CAE patients in a two-generation Mexican family, and the same mutation in a singleton from Mexico. We also found a heterozygous missense mutation S15F (exon 1A, position 15 in immature polypeptide) in a singleton from Honduras, and a heterozygous missense mutation G32R (exon 2, position 10 in the mature polypeptide) in 2 CAE diagnoses and 2 abnormal EEG cases in a single family from Honduras. All mutations were absent in 630 controls.

The three versions of mutated *GABRB3* were studied by expression in heterologous cells using immunoblotting, and shown to exhibit no significant difference from wild type. But all exhibited hyperglycosylation in in vitro transcription and translation, and reduced GABAR inhibitory current amplitude, measured by patch clamp recording. All the three mutated gene products appeared to undergo abnormal hyperglycosylation and possibly impaired leader peptide cleavage, leading to reduced assembly and/or trafficking to the cell surface and reduced physiological inhibition consistent with seizure-susceptibility.

Future Directions

How Does GABA β3 Mutation Cause Seizures?

GABAR-mediated inhibition cannot be significantly impaired without dangerous consequences in hyperexcitability, namely seizures. The β3 subunit is a component of about 40% of the adult GABAR and an even higher percentage of GABAR in embryonic and neonatal brain. It is a constituent of the only subtype(s) of GABAR present in certain neurons in critical circuits needed for myriad behaviors. Its function is apparently especially important in the nucleus reticularis of thalamus, and perhaps in hippocampal CA1. Further, the β3 subunit is part of the only GABAR present in a number of regions neonatally and deficiency results in permanently altered wiring and dire consequences such as deficits in cognition, sensorimotor integration, motor coordination, sleep patterns, and seizures.

Preliminary characterization of the mutations in *GABRB3* suggests loss of function via a variety of protein assembly, trafficking, and functional deficits resulting in reduced brain inhibition, even in the heterozygotes (dominance).

The role of GABRB3 in *remitting* absence epilepsy is particularly intriguing. This age-dependent change in seizure expression is probably related to the important developmental role of this gene product. The β3 subunit-containing GABARs are prevalent in the embryonic and neonatal brain. Interestingly, the β3 protein is expressed in neonatal thalamic relay neurons, but not in adult, and the remission of CAE at adolescence may reflect this changing expression pattern, suggesting that the β3 is no longer needed for function in the adult in some circuits that employ this GABAR subtype earlier in life.

How General is the Pathophysiology of GABAR Mutations in Human IGE?

Current information suggests that mutations in GABAR are one of a few molecular genetic mechanisms to explain idiopathic epilepsies. Even more epilepsies are due to channelopathies in general. However, mutations in four different GABAR subunits, α1, γ2, δ, and β3, have now been found in four sub-syndromes of human epilepsies – all of which have in common the presence of CAEs; at least three of these mutations – in γ2, α1, and β3 – segregate in family members affected with CAEs. These subunits are so prevalent that it is difficult to pinpoint the effect of a mutation/deficiency to a specific brain region/circuit, but evidence in both man and mouse suggests a likely thalamocortical involvement, and especially the GABAR in the reticular nucleus of thalamus.

Is Any Therapy (Other Than Gene Delivery) Suggested by the Genetic Lesion?

GABAR functional enhancement is already a strategy for anticonvulsant drug development. The implication of GABAR genes in human IGEs strengthens the rationale to spend more effort on efficacious GABAR-directed medications, and in solving related problems such as tolerance to the anticonvulsant therapeutics after chronic treatment. Development of GABAR subtype-selective drugs that would modulate the appropriate GABAR and circuits while minimizing side-effects (such as sedation, inhibition of learning, intoxication, dependence, and withdrawal) could be particularly valuable. In particular, a beta3-selective drug might be useful and recent advances in GABAR pharmacology suggest that such drugs exist and/or could be developed.

In conclusion, a major and common type of human epilepsy, namely CAE, involves pathogenic mutations in GABAR and should be amenable to anti-seizure medications aimed at these molecular lesions. Further knowledge about the ontogenetic and epigenetic modulation of GABAR molecular lesions could lead to curative strategies to treat absence epilepsies.

Genetic Association Studies in Human Epilepsy and Pharmacogenetics of Antiepilepsy Drugs

R J Buono, Coatesville Veteran's Affairs Medical Center, Coatesville, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Family and twin studies demonstrate that genetic factors are important contributors to the etiology of the majority of human epilepsy phenotypes. Some epilepsy phenotypes are known to be caused by mutations in a single gene, and these disorders are transmitted through families in predictable patterns based on classic Mendelian genetics. Such disorders are very rare, however, with less than 1% of all epilepsy patients acquiring their illness because of a single mutation in a gene of major effect. Current research suggests that the vast majority of patients with common forms of epilepsy acquire their disease because of genetic variation in multiple genes of small effect and that these collectively increase the risk for expressing recurrent seizures. This genetic risk then interacts with environmental factors (i.e., diet, sleep deprivation, alcohol consumption, etc.) to elicit the onset of disease in some individuals. Thus, common forms of epilepsy are considered to be complex trait diseases that are caused by interaction between DNA sequence variations in multiple genes, combined with exposure to environmental factors.

Identification of genetic variants that influence epilepsy susceptibility would be of exceptional value in the field and would open new avenues of research both in terms of diagnostics and treatment. Variants associated with specific epilepsy phenotypes could be used immediately as molecular markers for more accurate diagnosis. More importantly, genetic variations associated with epilepsy would help elucidate those molecular mechanisms that cause disease. An understanding of mechanisms that contribute to the etiology of disease would help identify novel neural pathways and lead to new pharmacological or mechanical interventions devised to improve medical treatment.

Pharmacogenetics is a relatively new field dedicated to identifying genetic variation that can predict response to pharmacologic agents. Currently, antiepileptic drugs (AEDs) and other medications are prescribed based on physician experience alone. In the future, genetic testing will identify DNA sequence variation that can accurately predict drug resistance or risk for an adverse side effect. Since 30% or more of all epilepsy patients are either resistant to, or suffer intolerable side effects from current AEDs, the identification of DNA sequence variation that accurately predicts resistance or adverse effects would revolutionize treatment. Prescriptions could be based on scientific tests with acceptable clinical validity and accuracy, and would eliminate much of the 'trial and error' process currently employed.

Introduction

Family and twin studies demonstrate that genetic factors are important contributors to the etiology of the majority of human epilepsy phenotypes. Some epilepsy phenotypes are known to be caused by mutations in a single gene, and these disorders are transmitted through families in predictable patterns based on classic Mendelian genetics. Such disorders are very rare, however, with less than 1% of all epilepsy patients acquiring their illness because of a single mutation in a gene of major effect. Current research suggests that the vast majority of patients with common forms of epilepsy acquire their disease because of genetic variation in multiple genes of small effect and that these collectively increase the risk for expressing recurrent seizures. This genetic risk then interacts with environmental factors (i.e., diet, sleep deprivation, alcohol consumption, etc.) to elicit the onset of disease in some individuals. Thus, common forms of epilepsy are considered to be complex trait diseases that are caused by interaction between DNA sequence variations in multiple genes, combined with exposure to environmental factors.

Identification of genetic variants that influence epilepsy susceptibility would be of exceptional value in the field and would open new avenues of research both in terms of diagnostics and treatment. Variants associated with specific epilepsy phenotypes could be used immediately as molecular markers for more accurate diagnosis. More importantly, genetic variations associated with epilepsy would help elucidate those molecular mechanisms that cause disease. An understanding of mechanisms that contribute to the etiology of disease would help identify novel neural pathways and lead to new pharmacological or mechanical interventions devised to improve medical treatment.

Pharmacogenetics is a relatively new field dedicated to identifying genetic variation that can predict response to pharmacologic agents. Currently, antiepileptic drugs (AEDs) and other medications are prescribed based on physician experience alone. In the future, genetic testing will identify DNA sequence variation that can accurately predict drug resistance or risk for an adverse side effect. Since 30% or more of all epilepsy patients are either resistant to, or suffer intolerable side effects from current AEDs, the identification of DNA sequence variation that accurately predicts resistance or adverse effects would revolutionize treatment. Prescriptions could be based on scientific tests with acceptable clinical validity and accuracy, and would eliminate much of the 'trial and error' process currently employed.

Background

A combination of linkage and association studies is currently being used to identify the multiple gene variations that underlie complex trait phenotypes, including risk of disease and response to medication.

Genetic Linkage

Genetic linkage studies have been performed for many decades and a seminal paper in this field was published in 1996, describing the advantages and disadvantages of these techniques (see Risch and Merikangas in Further Reading). Genetic linkage analysis is a technique used to identify disease causing genetic 'mutations' by examination of the genomes of related individuals, both affected and unaffected subjects. Linkage techniques can be applied to humans (typically, multiple generations of a single family) and animals. Linkage analysis in inbred strains of mice has been used to identify genes related to epilepsy.

The term 'mutation' is used for a genetic variation that has been proved to cause a disease. Linkage analysis is most effective when it is used to localize mutations that underlie a specific phenotype inherited in a predictable Mendelian fashion. The linkage approach is a global one that examines many DNA markers across the entire genome of all the subjects collected. Typical DNA markers used for linkage analysis include single nucleotide polymorphisms (SNPs) and variable nucleotide repeat elements (VNRE, or microsatellite repeats). Linkage analysis identifies chromosomal regions that harbor mutations by quantifying the form and frequency of specific DNA markers, assigning genotypes, and then calculating differences between those genotypes found in affected family members and those in nonaffected members. DNA markers are tested to determine if they cosegregate with the disease phenotype in affected individuals compared to unaffected; if so, it is concluded that those markers are physically 'linked' to the disease-causing mutation. In the best scenario, the marker tested is the actual disease-causing mutation. However, this best case scenario is generally not the case.

Linkage is a descriptive term to indicate that the causative mutation and DNA marker are inherited together, likely because the two are physically in close proximity on the same chromosome. Linkage equilibrium is a term used to imply that all DNA markers have an equal chance of being segregated during meiotic recombination. We know this 'equality' is not the case, however, because recombination rates between various DNA markers can be experimentally calculated and the rate of recombination has been shown to be dependent on the physical distance that separates the DNA markers of interest on the chromosome. That is, the farther apart two DNA markers are on a chromosome, the more likely it is that they will be separated from each other during meiosis. The term linkage disequilibrium (LD) is used to describe the phenomenon whereby two markers tend to be inherited together because of their close proximity on the chromosome.

To date, all of the confirmed epilepsy-causing gene mutations have been discovered using linkage analysis in large multigeneration families, where specific forms of seizures were found to be inherited in predicable Mendelian patterns. The majority of the identified gene mutations result in alteration of structure and function of proteins related to ion channels and maintenance of ion homeostasis across excitable membranes. These results have led to the conclusion that many types of epilepsy are 'ion channelopathy' diseases. However, there are several examples of epilepsy-causing DNA mutations in nonion channel genes, including mutations in genes related to development and metabolism.

Genetic Association

By contrast, genetic association analysis is performed on DNA samples from either unrelated or related individuals. One common paradigm for this type of analysis is the use of a case control study design. Unrelated patients are grouped into a 'disease' cohort (cases) and the genotypes of specific DNA markers are quantified and compared between these cases and healthy unrelated control subjects. This study design has the advantage that collecting unrelated cases and controls is logistically easier than collecting multiple members of specific pedigrees. However, one potential drawback is that subtle genetic differences between unrelated individuals may lead to an undetected population stratification that could confound results of an association study. This stratification can result, for example, from undetected differences in ancestry in cases and controls. DNA allele frequency varies greatly based on ancestral background, and most studies depend on self reporting of ethnicity. Many of these self reports may be limited in their reliability, and thus undetected differences in allele frequency based on ancestry could lead to false positive results. Numerous researchers have, however, argued that the threat of population stratification as a confounding variable in case control genetic association studies is very minor if a factor at all. The topic remains controversial.

Another type of association study uses relatives of an affected individual as a control. Most often, unaffected parents are used as controls to test for transmission of specific DNA sequences to their affected progeny. This type of association study is know as the Transmission Disequilibrium Test (TDT) and was first introduced by Spielman and colleagues as an alternative to the case control association design (see Further Reading section). The TDT is immune to population stratification confounds because it uses related individuals as controls.

In addition, the TDT can establish linkage in the presence of association, and was originally devised to address situations where a population association was found in the absence of evidence for linkage from traditional family-based study designs. Thus, the TDT can establish linkage if a positive association exists.

Methodology

One excellent source for information on genetic influences on disease traits is the Online Mendelian Inheritance in Man (OMIM) website (http://www.ncbi.nlm.nih.gov/sites/entrez?db = OMIM) maintained by the National Center for Biotechnology Information (NCBI) at the National Library of Medicine (www.ncbi.nlm.nih.gov). The NCBI site contains numerous databases related to human and animal genome and genetic resources used in biomedical research, including DNA, RNA, and protein sequences, information about specific DNA markers and their distribution in the genome, and links to many other genomic and proteomic resources on the internet.

For an association study, DNA markers are typically chosen in high priority candidate genes. High priority candidate genes are those for which there are existing linkage data or other biological evidence to suggest that dysfunction of the gene (and its encoded protein product) could play a role in the etiology of the phenotype under study. For example, genes and proteins related to GABA and glutamate neurotransmitter systems have long been considered excellent candidate genes that may act as epilepsy susceptibility factors based on their role in the biology of neurotransmission of inhibitory and excitatory signaling, respectively. More recently, ion channel genes have been implicated as epilepsy susceptibility factors and have been considered to be high priority candidate genes.

One unresolved question in modeling and designing association studies is whether DNA variations contributing to illness are very rare or very common. Most researchers study markers that are present in at least 5% or more of the population (common variants). The assumption is that rare variations will not be found in large proportions of patients, and therefore these variations would not be useful in generalizing treatment and diagnoses options to the majority of patients. If, however, complex disease traits are caused by rare mutations, then the current methodologies in place will be generally ineffective in identifying these factors.

The statistical interpretation of simple association studies is generally very straight-forward. Most researchers use standard contingency testing such as χ^2 or *t*-tests to compare the form and frequency of DNA variation between cases and controls. In the TDT, a χ^2 statistic is also used to compare the calculated transmission of the suspected disease-linked marker to the alternative form of the marker hypothesized to be unlinked to the disease. Typically, SNPs are used for the TDT; and since they are bi-allelic, only two possible forms of the marker exist to be tested. If a SNP allele is unlinked to disease, then its transmission from a heterozygous parent to an affected child should occur at a transmission rate of 50%, the random probability of transmission for a bi-allelic marker. However, a SNP allele associated and linked with a disease will be transmitted at a rate significantly different from the random distribution of 50%.

The first association studies used limited numbers of DNA markers to study any given candidate gene ranging from one marker (single SNP) to a half dozen or so. The use of multiple markers complicates the statistical analysis in that correction for multiple testing must be considered and factored into any final calculation for measures of significance. In addition, the use of multiple markers introduces the concept of 'haplotypes.' A haplotype refers to multiple linked markers that are physically located on the same sister chromatid of the chromosome pair, and tend to be inherited together based on strong LD. Haplotypes can be easily determined by DNA sequencing especially if DNA from both the patient and their parents is available for study. Since each parent contributes one chromosome of each pair to the progeny, genotyping the parents' DNA provides information on which marker is derived from which parent. If parental DNA is not available, there are computer-based algorithms that can estimate haplotypes in groups of unrelated individuals based on population genotypes. In some cases, haplotype analysis can be more powerful than single marker analysis in identifying the location of a disease-causing mutation or location of a DNA variation that acts as a susceptibility or resistance factor for the phenotype under study. The Ott laboratory at The Rockefeller Institute maintains an extensive database of statistical genetic programs, and is an outstanding resource for those working in (or interested in learning about detailed analyses used for) linkage and association studies (http://linkage.rockefeller.edu/group/).

Technology has progressed to the point where over 500 000 individual SNP markers can be genotyped from a DNA sample from a single individual in a matter of hours. This technology has led to genome-wide association studies (GWAS), where 500 000 or more DNA markers are genotyped and results quantified in hundreds to thousands of cases, and compared to equal (or more) numbers of controls. This type of study is not immune to potential confounding variables. Indeed, performing over 500 000 tests in thousands of individuals introduces a difficult problem in choosing appropriate methods for correction for multiple testing. Quantifying the false discovery rate, to determine potential numbers of false positive or negative results, can also be quite problematic. These studies offer much promise but require intensive

statistical genetic support to 'clean' the large data sets that are generated.

Currently there are no published reports of GWA studies in epilepsy; however, unpublished results were recently obtained by this author in a North American cohort. Similar work is being performed by groups in Europe, Asia, and elsewhere; utility of the GWAS technique will become apparent when analyses of these data sets are published.

Results

In general, although genetic association studies in epilepsy have been performed for over a decade, there has been no gene variation(s) discovered that has a major effect on increasing risk of any of the common forms of epilepsy. Recently, a strong association was discovered that can predict the adverse reaction known as Stevens–Johnson syndrome in some patients of Asian ancestry in response to carbamazepine, a commonly prescribed AED. This association, however, is highly restricted to Han Chinese and Taiwanese patients, and was not found in Japanese or Caucasian patients. Further studies are required before this association is proved valuable for its possible predictive value.

The single most important issue to resolve for genetic association studies in all complex trait disease studies is that of independent replication. Few genetic polymorphisms that have been reported to show association with a complex trait in the initial study have been replicated by an independent group with a separate but similar cohort. One success story is the strong association between the APOE4 allele and common sporadic cases of late onset Alzheimer's disease, initially described by Corder and colleagues (see Further Reading section) and replicated many times since. However, associations of similar strength have not been found for epilepsies, response to AEDs, or most other complex traits.

In the past decade, numerous association studies have been published in an attempt to correlate genetic variation to increased risk of acquiring epilepsy. For example, Sander and colleagues have collected a large and well characterized cohort of patients with common forms of idiopathic generalized epilepsy, and conducted a large number of genetic association studies. This cohort facilitates the ability to investigate novel hypotheses as well as to quickly attempt to replicate the findings of other laboratories. Although some modest associations have been identified while examining novel candidate genes, none of the positive findings has been independently replicated. In addition, attempts to replicate prior claims of positive association by other groups have, in most all cases, led to negative results.

Currently, only one initial positive report of association between a gene variation and epilepsy has been successfully replicated in a separate population. We found a variation in the KCNJ10 gene (that encodes an inwardly rectifying potassium ion channel subunit) to be associated with common forms of human epilepsy, and this result was subsequently replicated in a separate population (Lenzen *et al.*, 2005). The function of this gene in extracellular potassium buffering makes it an ideal epilepsy candidate gene, and offers opportunities to develop pharmacological interventions that target this type of potassium channel to treat common forms of epilepsy. Further work is needed to clarify the role of DNA variation in this region and its possible relation to increasing risk of epilepsy.

The lack of ability to replicate initial positive data has generally led to the conclusion that initial results represent a false positive finding. However, in many cases, the attempts to replicate a study used different methodologies and/or populations. Standards for publication of association studies have been raised substantially in recent years, as the number of investigators performing such work has increased. Many journals have introduced very stringent guidelines to accept such manuscripts, and it is unclear yet if these guidelines will have the desired effect, to reduce the number of false positive findings that are published. However, if the guidelines are too stringent, then many gene variations that *do* associate with illness, but have only a minor contribution, will likely be dismissed – even though they may represent false negatives. Ott has published a suggested set of guidelines that many journals and authors are adapting (see Further Readings) and which address many of the common problems and pitfalls encountered in this field.

Summary and Directions for Future Research

Changes and improvements in the technology to genotype, sequence, and store large numbers of DNA variations is moving at a rapid pace. In addition, our understanding of the structure and function of the genome continues to increase, and research has documented that even DNA variation in nongene coding regions that do not alter primary protein sequence can affect transcription and translation of encoded protein products. These data demonstrate how all DNA variations, including deletions and duplications, must be considered during the course of association studies. Furthermore, research is showing that alteration of DNA and/or its histone protein core, by methylation and other processes, can lead to 'epigenetic' modification of the genome. Such epigenetic factors can be affected by environmental factors and, in turn, can influence the structure and function of DNA that is inherited by progeny without changing the primary DNA sequence. Epigenetic regulation of DNA function would

likely not be discovered by techniques that exploit DNA sequence variation alone.

There are serious challenges facing the field of genetic association in complex traits. Many caveats exist in the design and analysis of association studies. Some of these include heterogeneity of phenotype in cases, population stratification in cases and controls, small numbers of subjects for study, different methods to calculate statistical significance, different methods of correction for multiple testing, different models for gene dose effect, variations in penetrance and modes of transmission, haploype structure and function, control sample collection and use, ethnic variations in DNA structure, epigenetic and environmental factors, and other issues. Many investigators now recognize that collection of tens of thousands of case and control samples may be required to identify many of the contributing genetic factors that exist and influence complex traits. The biggest challenge in the future may well be the development of statistical genetic techniques that can correct all the confounding variables inherent in these studies as they are currently performed.

In conclusion, the search for genetic variation that is linked or associated with complex trait disease will continue far into the future, and perhaps represents one of the best ways to identify new avenues of research into the underlying pathology of the illness under study. The eventual correlation between DNA variation and response to medication (efficacy and tolerability) will revolutionize the way in which drugs are prescribed. Improvements and modifications are continually being made in the design and execution of genetic association studies, and the excitement surrounding their potential impact on disease and pharmacogenetics remains very high.

Genetic Contributions to Brain Structure and Epileptogenesis

M Elizabeth Ross, Weill Medical College of Cornell University, New York, NY, USA

Introduction

The number of mutant genes responsible for brain malformations is rapidly expanding and their associated syndromes often include seizure disorders as part of the mutation-related clinical phenotype. It was once generally accepted that increased cortical excitability accompanies displacement or disorganization of neuronal somata. However, recent advances in understanding the function of molecules encoded by these genes (mutations of which give rise to brain malformations) has significantly altered our view of their roles in epilepsy and indeed in normal behavior. In fact, subtle mutations in brain malformation genes may not produce severe malformations detectable on MR imaging. Nevertheless, loss- or gain-of-function changes in these genes can alter neuronal excitability and so may underlie some idiopathic seizure disorders that are unrelated to a known injury or toxic cause. Thus, the search for genes causing brain malformations in mouse and man is providing an unexpectedly rich source of insight into epilepsy. Some of these recent advances will be discussed concerning research into the function of genes associated with two major types of brain malformation, lissencephaly (smooth brain), and microcephaly (small brain).

Methods

There are several approaches to the identification of the genetic defects underlying brain malformation. They all hinge on the successful characterization of the salient features of a particular malformation – whether in patients or in animal models. In the clinical arena, this detailed phenotyping allows investigators to group like patients to enable physical mapping and cloning of the causative gene. It also makes it possible to compare the structural outcome of genetic manipulations in animal models with the counterpart in human brain, thereby permitting one to take a candidate gene approach to disease gene discovery. Once the responsible gene is identified, comparison of specific mutations with the developmental outcome (establishing genotype–phenotype relationships) provides insight into the important functional domains of the gene product.

Identification of a brain malformation gene in patients can be approached via several routes, which will be dictated by circumstances of the inheritance of the disorder. When malformations appear in families as isolated occurrences, sporadic dominant mutation is a likely mechanism. Cytogenetic investigations of chromosome spreads, including fluorescence in situ hybridization (FISH), may reveal large gene deletions, duplications, and translocations such as were found in Miller Deiker Syndrome (MDS) involving chromosome 17. More recently, smaller mutations and rearrangements have been detected by comparative genome hybridization (CGH) using bacterial artificial chromosome (BAC) probes. Finally, genome arrays are becoming the standard for detection of copy number variants (CNVs) in gene representation that may underlie many sporadic occurrences of brain malformation.

When brain malformation is seen to follow simple Mendelian inheritance – indicating autosomal dominant, autosomal recessive, or X-linked transmission patterns – linkage analysis will often provide the critical interval that must contain the mutant gene. This approach is based on the use of polymorphic microsatellite or single nucleotide polymorphisms (SNPs) that cover the genome at a density that allows the detection of a small portion of the genome that is always inherited with the disease phenotype. Such analyses may be carried out in a single large family, or more often in these conditions, several small families may be grouped (multiplexed) to compare their combined inheritance patterns.

Once a locus is established, the critical interval of the gene containing that mutation is physically studied, by DNA sequencing. Regions to be sequenced may be prioritized based on the nature of the genes known to be present within the critical interval. Patient sequences are compared with normal controls to establish the likely significance of a particular variation. Sometimes a mutation would be predicted to create a premature stop, a nonsense change (i.e., frame shift) that abrogates the protein sequence downstream of the mutation, or a missense mutation that would strikingly alter the size and charge of an amino acid in the coding region. Other more subtle changes could occur in the promoter or enhancer regulatory regions, or in the sequences that direct the splicing of RNA transcribed from the gene. These types of relationships must be investigated in order to decipher the meaning of genetic variation in a locus associated with a genetic disorder.

Brain malformation genes may also be identified through candidate genes, identified either by positional cloning of a naturally occurring mutation associated with brain malformation in an animal model or through recognition of a malformation produced by gene knockout,

most often in mouse models. Examples of such mutations include those found in the reeler mouse, whose human counterpart on chromosome 7q22 was identified because of the marked cerebellar hypoplasia in both the reeler mouse and in patients. Another example of the advantageous use of mouse–human phenotype comparisons was the realization that knockout of the ARX (X-linked aristaless) gene in the mouse displayed remarkable similarity to children with the XLAG syndrome (X-linked lissencephaly with ambiguous genitalia).

Once a gene defect associated with brain malformation is in hand, initial clues to function can be gleaned from comparison with clinical phenotypes. A gene, the mutation of which leads to lissencephaly, is likely to include neuronal migration and other cell motility modalities among its functions. A mutation leading to microcephaly would be expected to impact neural cell proliferation and/or cell survival. Point mutations associated with the phenotype may provide critical clues to the most important functional domains within the encoded protein. Approaches to probing gene function then include manipulation of gene expression levels by RNA interference and overexpression by transfection into cells in culture, or even into tissues in utero (gene transfer made using viral particles or electroporation). Finally, the investigation of the systems-level impact of a gene mutation will be carried out in genetically engineered mouse or rat models.

Background and Results

Lissencephaly Genes and the Neuronal Cytoskeleton

Derived from the two Greek words *Lissos* (smooth) and *encephalos* (brain), lissencephaly is characterized by loss of cortical convolutions (either total absence or widening of gyri called pachygyria) and thickening of the cortical gray matter due to impaired neuronal migration. In classical lissencephaly, the cortical mantle measures a centimeter or more, compared with the usual 4 mm or less, and the normal six layers are replaced with a poorly organized four-layer cortex that includes a cell sparse zone appreciated on MRI. Most of the classical lissencephaly encountered in the clinic can be accounted for by two genes, *LIS1* and doublecortin (*DCX*). More recently, mutations in an alpha tubulin subunit, TUBA1–3, have been found to produce a range of lissencephaly phenotypes in mouse and man.

Lis1

This gene was named as the first lissencephaly gene to be identified from patients with MDS or isolated lissencephaly (ILS). *Lis1* was recognized as encoding a 45 kDa soluble protein with structural similarity to G-protein β-subunits, in which a seven-bladed propeller structure is made from 7-WD40 repeat units. Although it resembles a G-protein subunit, it was soon realized that *Lis1* is a noncatalytic 1b1 subunit of a ubiquitous mammalian protein called platelet-activating acetylhydrolase (PAFAH) and that *Lis1* is evolutionally conserved, bearing striking homology with NUDF (nuclear displacement F) in *Aspergillus*. The NUD family of proteins was functionally defined as causing defects in nuclear migration in fungus, which requires NUD interactions with cytoplasmic dynein in a dynein protein motor complex.

Numerous studies have now linked *LIS1* and function of the dynein protein motor complex. In this role, *Lis1* has been shown to affect neuronal migration, which has often been attributed to its central role in nuclear translocation and coupling of the nucleus to the centrosome. The impact of *Lis1* on dynein also has profound influence on neural progenitor proliferation through their interaction with the kinetochore and mitotic spindles.

The association of *Lis1* with the dynein protein motor complex has become so strong that several investigators have even equated manipulation of *Lis1* or dynein as synonymous with alteration in the other. However, our studies have revealed an additional role for *Lis1* in the regulation of small GTPases of the Rho family to impact the actin-based cytoskeleton. The Rho-GTPases are potent signaling molecules that regulate cytoskeletal dynamics involved in processes that include microtubule growth, pausing (brief halting of growth), and catastrophe (disintegration of microtubules into tubulin monomers), establishment of cell polarity and centrosomal localization, and regulation of actin polymerization as well as capture of microtubule ends to the cortical actin meshwork at the inner plasma membrane Such effects on cytoskeletal dynamics may alter growthcone motility, synaptogenesis, and neuronal excitability.

Given these involvements of *Lis1*, there are several potential ways in which *Lis1*-deficient neurons may generate abnormal discharges and seizures, which have little or nothing to do with the placement of these neurons. The first way in which *Lis1* may impact neuronal physiology is that cells lacking, or expressing defective, *Lis1* may have impaired membrane and protein trafficking through effects on cytoplasmic dynein. Although an impact of *Lis1* on these events has yet to be directly shown, cytoplasmic dynein complex proteins (including dynactin) have been implicated in aspects of endocytosis and in differential protein trafficking contributions to cell polarity. Indeed, evidence points to the ability of *Lis1* to regulate the ATPase activity of dynein, thereby influencing intracellular protein transport.

A second way in which *Lis1* might impact cortical excitability is through aberrant neuronal connectivity stemming not from the misplacement of neuronal cell bodies but from effects on axon outgrowth and actin remodeling events. Electrophysiological evidence supports

synaptic transmission abnormalities in the CA1 region of *Lis1* haploinsufficient mice, and abnormalities of hippocampal pyramidal and granule neuron dendritic arbors have been observed in *Lis1* +/− mice. The impact of *Lis1* on calcium dependent signaling through NMDA-receptor has been shown to occur through modulation of the Rho-family GTPases. Moreover, NMDA receptor and Rho GTPase-dependent mechanisms are known to have a significant regulatory influence on activity-dependent neurite development. The role of *Lis1*, and other neuronal migration genes, in these processes is just beginning to be explored.

Yet a third mechanism likely contributing to epileptogenesis in *Lis1* deficiency is a function of the differential severity of migration defects among neuronal subsets. The long tangential migration of cerebral cortical interneurons from their origins in ventral forebrain was previously shown to result in selective deficits in GABAergic interneurons in *LIS1* deficient human brain. This neuron subtype-specific deficit would presumably reduce not only direct inhibitory inputs to excitatory neurons but would also reduce the GABA content or 'GABA tone' of the extracellular milieu.

DCX

Doublecortin was named for the popular designation of the X-linked syndrome phenotype in affected females, double cortex (aka subcortical band heterotopia, SBH). This band of misplaced neurons collects beneath the relatively normal appearing cortical gray matter as the result of X-inactivation in females. Boys inherit only one X chromosome and so all their neurons use the same *DCX* mutant gene if present. Since female cells possess two X chromosomes (each with its own *DCX* allele or version of the gene), one of them must be inactivated early in embryogensis to avoid excess gene dosage. Selection of which of the two chromosomes gets to be inactivated is a random event. In girls, neurons that inactivate the X chromosome that bears the mutant *DCX* allele use the normal *DCX* gene, and so migrate normally; those neurons that inactivate the X chromosome bearing the normal *DCX* allele must use the mutant copy of the gene and so are impaired in their migration. Thus, the brain of a girl with one *DCX* mutant gene will be 'mosaic' – some neurons will be normal and others will use the mutant form of the protein, creating the displaced band. *DCX* encodes a 40 kDa soluble microtubule-associated protein (MAP) that defines a novel functional class of proteins with microtubule binding domains (*DCX*-like or DCL domains). Within this family is a kinase (doublecortin-like kinase, DCLK) that also interacts with microtubules and phosphorylates *DCX*, among other proteins, including those contributing to the mitotic spindle apparatus. Although *DCX* is expressed primarily in postmitotic neurons, *DCLK* is transcribed in both dividing progenitors and postmitotic neurons. Unlike *Lis1*, which is ubiquitously expressed in most if not all cells, *DCX* is highly selective for neurons of the central and peripheral nervous system. Indeed, *DCX* expression has become a widely accepted marker for young neurons as they emerge from the cell division cycle.

The major mode of *DCX* action is thought to involve regulation of the stability and bundling of microtubules. When there is a mutation, the resulting motility defects include altered nuclear translocation, abnormal branching of the primary neurite, and altered axon extension. *DCX* is a phosphoprotein that is regulated by kinases (including cyclin-dependent kinase 5 (CDK5), Dclk, protein kinase A (PKA), and MARK/Par1) and is dephosphorylated by phosphatases (including spinophillin). This regulation enables *DCX* to finely modulate the motility of neuronal growth cones at the transition point between the microtubule shaft of the axon and the growth cone.

As a classical MAP, *DCX* can impact neuronal function in several ways. When hypophosphorylated, it will bind primarily to microtubules and may influence microtubule dynamics. Hyperphosphorylation of *DCX* shifts the protein from the microtubule to the actin cytoskeletal compartment. *DCX* is also capable of binding to *Lis1*, and may modulate the cytoskeletal effects of that migration protein.

Yeast two hybrid screens have identified the interaction of *DCX* with the mu subunit of clatherin-coated adapter proteins, suggesting a role for *DCX* in protein sorting or vesicle trafficking. This role is supported by observations made in double mutant mice in which both *DCX* and *DCLK* have been inactivated. Such mice display defects in axon outgrowth and in transport of vesicular proteins. A critical demonstration of the important role of *DCX* in neuronal function has been made by the recognition that certain *DCX* mutations in patients can cause mild mental retardation and epilepsy, even though no cortical malformation can be detected (on high resolution MRI) in these patients. Thus, *DCX* mutations need not result in significant neuronal migration abnormalities to impact cortical function in substantive ways.

Other lissencephaly genes and epilepsy

Other forms of lissencephaly include varying degrees of pachygyria because of loss of extracellular signaling molecules. One such example is a mutation that affects reelin (RLN), which gives rise to a form of lissencephaly with severe cerebellar hypoplasia in which the cerebellum of affected patients is nearly absent. *RLN* encodes a large extracellular matrix protein thought to provide guidance, or start/stop cues, to migrating neurons. Mutations in one of the RLN receptor proteins, VLDLR, produce a very similar picture as seen with mutations of the RLN gene – moderately thickened cortex, pachygyria, and significant cerebellar hypoplasia. Genetic interaction evidenced by the cross breeding of mutant mice indicate that RLN signaling is positioned upstream of *Lis1* function. Interestingly,

seizures are not a prominent feature of the clinical presentation of RLN mutations, perhaps because much of the basic neuronal physiology remains intact.

In contrast, lissencephaly because of mutation in the *ARX* gene is associated with severe forms of epilepsy. A transcription factor in the aristiless gene family, *ARX* loss of function leads to profound deficits of GABAergic inhibitory interneurons. These deficits are associated with defects, evident on MRI, in the basal ganglia and even thalamus. During embryogenesis, it is the lateral ganglionic eminence (LGE) that gives rise to caudate/putamen, while the medial ganglionic eminence (MGE) is a major source of interneurons that make tangential migrations to reach the cerebral cortex. The caudal ganglionic eminence (CGE) also contributes interneurons to the cortex and is the embryonic source of much of the thalamus. *ARX* is expressed (used to make ARX protein) in these LGE, MGE, and CGE regions during brain formation, leading to basal ganglia and thalamic abnormalities when *ARX* is mutated. Knockout mice that are deficient in *ARX* reveal marked deficits in interneurons, along with other severe malformation features. Children with *ARX* mutations are prone to infantile spasms, a seizure type that is especially difficult to control. Because of the marked abnormalities in these deep diencephalic structures, *ARX* disorder supports the notion that basal ganglia and especially thalamic structures (including thalamocortical connections) may play a significant role in the pathogenesis of infantile spasms.

A recent addition to the list of lissencephaly-associated genes is the alpha-tubulin (TUBA) subunit. Mutation in the *TUBA1* gene interferes with the efficiency of tubulin dimerization. Sporadic mutations in *TUBA3* produce human lissencephaly; depending on the missense change, this phenotype can appear as severe grade 3 classical lissencephaly with a posterior predominance or a grade 4–5 pachygyria. The *TUBA3* phenotypes include partial agenesis of the corpus callosum and brainstem hypoplasia, all of which point to defects in axonogenesis. Severe epilepsy was described in at least one patient with *TUBA3* mutation.

Genetic defects affecting cytoskeletal regulation and neuritogenesis – and probably synaptogenesis and intracellular protein trafficking – are major underpinnings of seizure disorders associated with cortical neuronal migration defects. Basic studies of mouse models, as well as clinical genotype–phenotype investigations, have revealed important insights into epilepsy pathogenesis associated with these structural abnormalities. Further investigation into the underlying mechanisms is required.

Microcephaly Genes and Deficits in GABAergic Interneurons

Another prevalent category of brain malformation is congenital microcephaly, defined as an occipital–frontal head circumference (OFC) measuring – two standard deviations (SD) below the median for age or smaller. Data from the Center for Disease Control indicate that congenital microcephaly from all causes occurs at a rate of 1.07 per 1000 live births, exceeding the rate of neural tube defects (spina bifida and anencephaly) in the United States. Although undoubtedly dozens of genetic defects are associated with microcephaly, many of the genes now identified are known to impact the cell cycle. For example, microchephaly because of loss of function in the *MCPH1* gene (microcephalin) is associated with neural cells 'hung up' in prophase, impairing passage through M-phase, and thus preventing the split of cells into two daughters. MCPH5 is caused by mutation in the *ASPM* gene – that produces abnormal spindles to interfere with M-phase. And MCPH6 is associated with a mutated centrosomal protein *CENPJ*. All of these phenotypes are relatively mild, in that children display mild mental retardation and a normal lifespan. If seizures do occur with these disorders, they are readily controlled with medication. The most serious consequences of the genetic losses, in this group of relatively highly functioning patients with microcephaly, are in cell proliferation; there appears to be less impact on cortical connectivity and excitability.

Other genes that drive the cell cycle are prime candidates for additional forms of microcephaly. In the mouse, inactivation of cyclin D1 (*Ccnd1*), which acts in G1-phase, produces mild microcephaly and more prominent small stature, with limited life span. Although there are signs of neurological dysfunction (including spasticity) in these animals, the brains are neuroanatomically intact, with no specific cell type deficits. Interestingly, mice deficient in cyclin D1 are relatively resistant to certain epileptogenic drugs like kainate, while they have the same seizure threshold to PTZ as wild type siblings.

In contrast, knockout of another G1-phase cyclin, cyclin D2 (*Ccnd2*), is associated with normal size and body mass but severe microcephaly that is gene dosage dependent; that is, heterozygous nulls have a brain size intermediate between wild type and homozygous null siblings. More important, while the total numbers of all neuronal types is reduced in *cyclin* $D2^{-/-}$ brains, there are selective deficits – of cerebellar granule neurons and cerebellar stellate interneurons in the molecular layer. In the cerebral cortex and hippocampus, there is a selective deficit in parvalbumin-expressing interneurons, but other interneuron cell types are spared, including somatostatin-expressing interneurons that arise from the same (MGE progenitor pool as parvalbuminergic cells. This selective deficit in GABAergic interneurons is sufficient to produce reduced seizure threshold and loss of the larger amplitude miniature postsynaptic currents (mIPSCs). Thus, at least some proliferation deficits may alter the cellular composition of cerebral and hippocampal structures to result in seizures.

Another microcephaly phenotype associated with seizures is the Amish-type lethal microcephaly (MCPHA), due to a defect in a mitochondrial dinucleotide carrier (DNC) protein. Affected children display α-ketoglutaric acidosis and their severe microcephaly is associated with increased cell death in brain, though the precise mechanism leading to reduced brain size has yet to be elucidated. Seizures are presumed at present to result from a metabolic imbalance altering neuronal homeostasis.

Still other forms of microcephaly occur in conjunction with other brain malformation types. For example, bilateral periventricular nodular heterotopia (BPNH) with microcephaly has been linked to the *ARGEF2* gene, which encodes brefeldin-A inhibited guanine exchange factor 2 (BIG2) protein that is required for vesicle trafficking out of the trans-Golgi apparatus. Knockdown of *ARGEF2* inhibits cell proliferation and transport of proteins like E-cadherin and β-catenin to the plasma membrane. Although identification of BIG2 implicates a defect in vesicle trafficking, the mechanism(s) leading to microcephaly and epilepsy in this patient group have yet to be discovered. Nevertheless, the relationship of *Lis1*, and potentially *DCX* as well as ARGEF2/BIG2, with intracellular protein transport suggests that this trafficking has an important role in molecular mechanisms leading to seizure disorders.

Future Directions for Research

The pathogenesis of seizures related to brain malformations is an important frontier that is still in its early stages of investigation. Perhaps the greatest insight yet from these studies is that the mechanisms leading to seizures are not primarily attributable to misplacement of neurons. Rather, epileptogenesis in cortical malformations has more to do with the cellular subtypes comprising the disrupted cytoarchitecture, and the impact of the mutations on the intrinsic physiology of neurons in these altered brains. Important issues arising from these studies include such questions as: How do altered cytoskeletal dynamics impact the cell number, type, and connectivity of neurons – including neurite outgrowth, growth cone motility, synaptogenesis, and synaptic plasticity? What is the role of protein trafficking in neurons and glia in cell function, and what is the impact of impaired protein trafficking on excitability? Detailed knowledge of these events may yield new approaches to seizure management that goes beyond a focus on transmitter/receptor interactions, but impacts events like receptor turnover or subunit composition.

We can expect future fascinating revelations from approaches like conditional knockouts in the mouse to probe the contributions of various brain regions to seizure phenotypes. Conditional knockout models will also yield insight into the timing of when these molecular processes are most critical to the pathogenesis of epilepsy. With such insights, it may then be possible to intervene in the progression of developmental events that contribute to epileptogenesis. For example, modulation of Rho-family GTPase activities during particular temporal windows may promote synaptogenesis, stabilize existing contacts or promote physiological pruning of synaptic contacts to improve seizure control, or promote better cognitive function in the setting of antiepileptic drug administration. Such studies represent a truly new frontier in epilepsy research.

Genetics of Lafora and Juvenile Myoclonic Epilepsies

A V Delgado-Escueta, David Geffen School of Medicine at UCLA and VA Greater Los Angeles Healthcare System, West Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

How do we go about finding the cure(s) for a fatal epilepsy like Lafora progressive myoclonus epilepsy (Lafora epilepsy or Lafora disease), a condition which is rare in the Western world but frequent in the Middle East and South Asia? Likewise, how do we find the cure for a nonfatal but life-long epilepsy like juvenile myoclonic epilepsy (JME), which is common worldwide? To find the cure for these epilepsies, the epilepsy-causing mutations in *Laforin/dual specificity phosphatase* which cause 58% of Lafora disease, and in *Malin E3 ubiquitin ligase* which cause 35% of Lafora disease, were identified. The epilepsy-causing mutations in *myoclonin/EFHC1*, which causes 9% of clinic cases of JME, were also isolated.

These three nonion channel genes cause two similar myoclonic epilepsies when they start during adolescence. Understanding the nature of these gene products has allowed us to clinically separate them at the onset and helped us solve two mysteries of brain biochemistry and clinical epileptology: (1) Why is glycogen absent in neurons in contrast to other cells of the human body? and (2) Why do patients with juvenile myoclonic epilepsy (JME), classified as idiopathic, have areas of brain cortex thicker than normal? The first two genes, *Laforin (dual specificity phosphatase)* and *Malin (E3 ubiquitin ligase)*, working in concert, purge neurons of glycogen and polyglucosan inclusions by polyubiquitination and proteasome-dependent degradation. Thus, there is normally no glycogen in nerve cells. Mutations in *Laforin* or *Malin*, when inherited as a recessive gene, cause insoluble poorly branched glycogen (polyglucosan) to accumulate in nerve cells, cause cell death, produce stimulus-sensitive myoclonias, grand mal and absence seizures, rapid neurologic deterioration and death. The third nonion channel gene, *Myoclonin/EFHC1*, causes chronic and life-long adolescent onset juvenile myoclonic epilepsy. *Myoclonin/EFHC1,* a developmental gene, prunes branches and leaves of dendrites and modulates dendritic R-type voltage-dependent calcium channels (VDCC). Mutations in *Myoclonin/EFHC1*, when inherited as a dominant trait, reduce its pruning functions, cause thicker brain cortex, and at the same time alter dendritic R-type VDCC functions, producing myoclonias and grand mal seizures. Unlike fatal Lafora epilepsy, JME has a good prognosis and responds to antiepileptic drugs that work on VDCC.

Methods

> . . .In linkage analysis the simplest situation is when unequivocal linkage can be demonstrated in a single large pedigree (with lod score >3). Lander and Schork, 1994.

Large (more than 35 members) families, consisting of at least 3 generations that had at least 9 members that were clinically affected with Lafora disease or JME, were used for family genetic studies and linkage analyses. In Lafora disease, homozygosity mapping facilitated location of a chromosome locus. Haplotypes and recombinations, together with positional cloning, then narrowed the size of the chromosome region to 1–2 cM and to kb. Genes in the reduced region were then sequenced, looking for mutations that segregated with affected members of multigeneration families. Functions of *Laforin/dual specificity phosphatase* and *Malin E3 ubiquitin ligase* were studied in a variety of preparations – whole mouse brains, differentiated mouse N2a cells, primary cultured mouse neurons and astrocytes, rabbit skeletal muscles and liver – from wild type mice and Laforin deficient KO mice. To study the functions of *Myoclonin/EFHC1,* primary cultured hippocampal neurons were used for apoptosis experiments, and baby hamster kidney (BHK) cells were used for patch clamps electrophysiological studies.

Background and Results

Laforin and Malin Gene Function in Lafora Disease Explain a Mystery of Brain Biochemistry: Why is Glycogen Absent in Neurons?

Lafora epilepsy is an autosomal recessive fatal epileptic encephalopathy like other progressive myoclonic epilepsies (PME). It is characterized by the triad of stimulus-sensitive resting and action myoclonus, epilepsy, and progressive intellectual, cerebellar and neurological deterioration. A constellation of symptoms separate Lafora disease (LD) from other PMEs, including: greater frequency of visual auras, the rapid course of the illness (with death occurring 10 years after onset of epilepsy), and excessive accumulation of abnormally branched insoluble glycogen (polyglucosan inclusion bodies) in brain, muscles, liver, heart, retina, peripheral nerves, and

skin. Lafora's disease is found in the Mediterranean countries of Southern Europe (Spain, Portugal, Italy, Herzegovina, Croatia, Slovenia, Bosnia, Albania, Greece), Northern Africa (Morocco, Algeria, Tunisia, Libya) and the Middle East (Syria, Israel, Lebanon, Turkey, Cyprus, Egypt). It is also found in Ukraine, Uzbekistan, Kazakstan, Turkmenistan, Azebajian, Armenia, Malaysia, Indonesia, India, Pakistan, and other countries where consanguinity occurs.

Although Gonzalo Rodriguez–Lafora first discovered the periodic acid-Schiff and Alcian blue staining of polyglucosan inclusion bodies in a boy with PME in 1911, the modern story of Lafora disease did not start until 1995 when the first chromosome locus (6q24) for Lafora disease was discovered by Serratosa *et al.* Positional cloning then led to the eventual identification of *Laforin/dual specificity phosphatase* in 1998 and *Malin/E3 ubiquitin ligase* in 2003. About 80–90% of patients with Lafora disease have mutations in EPM2A/*Laforin/dual specificity phosphatase* and EPM2B/*Malin/E3 ubiquitin ligase*. A third locus/gene is yet to be identified. Because the gene function was unknown, the gene was originally called EPM2A. Now we know that it encodes a *dual specificity protein phosphatase*, named *laforin*, that localizes in the rough endoplasmic reticulum. Laforin also contains an N-terminal domain that binds to glycogen and Lafora bodies (see **Figure 1**). The EPM2B or NHLRC1 gene encodes a protein ubiquitin ligase (E3 ubiquitin ligase) called malin that interacts with Laforin in the endoplasmic reticulum (Gentry *et al.*, 2005). Laforin is one of the substrates of malin, meaning malin ubiquitinates laforin. Because laforin and malin are recruited upon proteasomal blockade, both must be involved in protein clearance through the proteasomal system (Mittal *et al.*, 2007). By 2002, two mouse models of Lafora disease were prepared by scientists in Japan and Toronto: one in which the laforin gene was knocked out in the developing embryo and the other in which a mutation of *laforin* was inserted into the developing embryo. With the discoveries of its disease-causing genes and their functions also came explanations for neuronal cell death and associated rapid neurologic deterioration. The EPM2A/*Laforin/dual specificity phosphatase* knockout mice had neuronal degeneration before the formation of lafora bodies and the onset of myoclonic seizures. The transgenic mice line expressing a dominant-negative mutant of *EPM2A/Laforin/dual specificity phosphatase* developed Lafora bodies but not epileptic seizures or early neuronal death. These observations suggest that the formation of Lafora bodies, the onset of epileptic seizures, and cell death are independent phenotypes of disease pathways regulated by *EPM2A/Laforin/dual specificity phosphatase*. Because laforin and malin are both recruited to aggresome when proteosome functions are blocked, cell death in mutations of

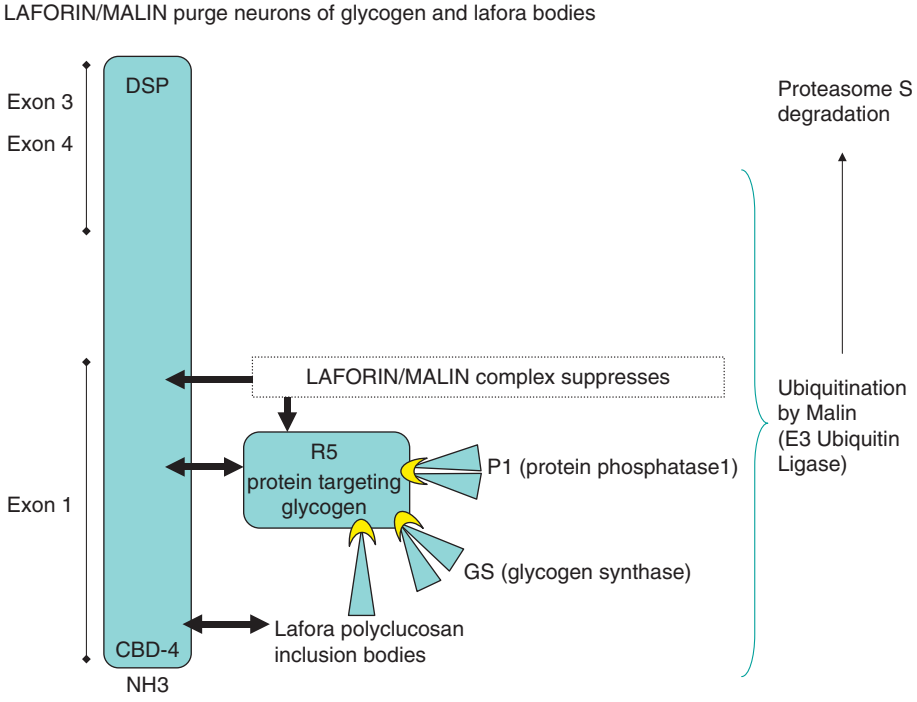

Figure 1 Laforin/malin complex purge neurons of glycogen and lafora bodies. Functional and interacting sites of EPM2A/Laforin with its dual specificity phosphatase (DSP) domain and R5, the protein targeting glycogen (PTG) scaffold in carbohydrate binding domain (CBD-4). Laforin and malin in concert suppress binding/targeting of protein phosphatase and glycogen synthase to R5, thus keeping glycogen synthase in an inactive phosphorylated state. Glycogen in turn inhibits laforin suggesting a feedback system. Malin polyubiquitinates laforin and Lafora bodies and eliminates the 'polyubiquinated laforin-Lafora polyglucosan inclusion and glycogen complex' through proteasome S degradation.

laforin or malin is now considered to be at least partly due to impaired proteolytic processes.

Since the discovery of *laforin* in 1998, six separate laboratories (from California, Indiana, Toronto, Madrid, and Barcelona) had been looking for the biochemical pathways that connect laforin and malin to glycogen and polyglucosan synthesis or degradation. We had hypothesized earlier that decreased *Laforin phosphatase* activities (when the gene was mutated) could lead to decreased dephosphorylation of glycogen synthase, turn glycogen synthase into an overphosphorylated state, and cause the accumulation of excessive amounts of an insoluble form of glycogen – polyglucosans. In this hypothesis of 'secondarily flawed' glycogen synthesis, there is an imbalance between branching enzymes and glycogen synthase activities, with glycogen synthase being favored to go into overphosphorylated drive.

Two earlier observations suggested a link between glycogen metabolism and formation of lafora bodies. The first observation is the G240S mutation in *laforin* which does not affect phosphatase activities or glycogen binding but impairs R5 binding of glycogen synthase. **Figure 1** shows the functional and interacting sites of *EPM2A/Laforin* with its dual specificity phosphatase (DSP) domain in exons 3 and 4 and R5, the protein targeting glycogen (PTG) scaffold in the carbohydrate binding domain (CBD-4) of exon 1. The G240S mutation in exon 1 of *laforin* meant that phosphatase activities can be normal but lafora bodies will still form if R5 binding of glycogen synthase is abnormal. The second observation is the serendipitous observations of Raben *et al.* in the GSL30 transgenic mice. GSL30 transgenic mice are mice that had acid alpha glucosidase knockedout and overexpressed glycogen synthase. Raben *et al.* was trying to replicate the fatal disease phenotype of Pompe disease in the acid alpha glucosidase knockout mice. However, the disease phenotype did not resemble the rapidly deteriorating muscle disease of Pompe disease. Thus, Raben *et al.* overexpressed glycogen synthase in the acid alpha glucosidase knockout mice in an attempt to accelerate the course of the disease. Instead, they were surprised to find accumulation of excessive amounts of poorly branched glycogen that resembled Lafora bodies in skeletal muscle.

Vilchez and colleagues addressed why glycogen is normally absent in neurons, and how poorly branched insoluble glycogen (Lafora inclusion bodies) forms and accumulates in neurons in Lafora disease. Using a neuronal cell model in culture, Vilchez *et al.*, from Guinovart's laboratory in Barcelona, showed that neurons have the enzymatic machinery for synthesizing glycogen. However, this machinery is suppressed by retaining glycogen synthase in the phosphorylated and inactive state. How is this suppression ensured? It appears that laforin and malin cause proteasome-dependent degradation of the receiving or binding protein of laforin called R5 or PTG (protein targeting glycogen in the carbohydrate binding domain of exon 1 of *laforin* (see **Figure 1**)). R5 or PTG (for protein targeting glycogen) is a scaffold adaptor protein that binds and targets glycogen to the glycogen binding site of *laforin* (see **Figure 1**). PTG also normally binds and brings the enzymes involved in glycogen synthesis to *Laforin* which is normally located in the vicinity of the endoplasmic reticulum inside neurons. This function includes bringing protein phosphatase 1 to glycogen synthase, thus activating this enzyme which synthesizes glycogen. PTG also normally brings glycogen synthase to laforin. The laforin–malin complex by degrading R5/PTG in essence block glycogen binding, protein phosphatase 1 activation of glycogen synthase and glycogen synthesis. Overexpression of R5/PTG leads to glycogen deposition in cultured neurons and apoptosis. Thus, the laforin–malin complex ensures a blockade of neuronal glucogen synthesis under normal conditions. In the presence of a mutation in either the laforin or the malin gene, excessive glycogen is deposited in neurons and apoptotic cell death results. In 2008, Worby *et al.* found similar results when they overexpressed PTG, *malin and laforin* in tissue culture cells. The expression of malin or laforin decreased PTG, stimulated glycogen accumulation by 25%, and coexpression of malin and laforin abolished PTG stimulated glycogen accumulation. *Malin* ubiquitinates PTG in a laforin-dependent manner, both in vivo and in vitro, and targets PTG for proteasome-dependent degradation.

The actual experiments proving the 'overphosphorylated glycogen synthase hypothesis' were recently provided in tissue culture and in the *laforin* deficient mice (Epm2a−/−) by experts in glycogen metabolism at laboratories in Indianapolis. Tagliabracci *et al* tested this concept of an overphosphorylated glycogen synthase in the mouse knockout model of Lafora disease (Epm2a−/−). Glycogen isolated from the KO mice had a 40% increase in covalent phosphate content in liver and a fourfold elevation in muscle. Recombinant *laforin* normally releases phosphate in vitro in a time-dependent reaction, with an apparent $K(m)$ for glycogen of 4.5 mg ml^{-1}. These investigators therefore proposed that mutations of laforin disable its carbohydrate/glycogen binding domain and also eliminate its ability to dephosphorylate glycogen. Excessive phosphorylation of glycogen leads to aberrant branching of glycogen, excess glycogen, and Lafora polyglucosan inclusion bodies.

Myoclonin/EFHC1 Gene Function in JME Explains a Contradiction in an Idiopathic Epilepsy: Why do some JME Patients have Areas of Thicker Brain Cortex?

At present, there is no cure for juvenile myoclonic epilepsy, a common and lifelong affliction. JME is the most common form of idiopathic generalized epilepsy and the

most common cause of primary grand mal seizures. JME accounts for 12–30% of all epilepsies in hospitals and clinics, while a house-to-house population survey estimates and undercounts JME at 3% of all epilepsies. The two most common forms or subtypes of JME are classic JME and childhood absence that evolves into JME. In classic JME, awakening myoclonias start when patients reach 13–15 years of age, and grand mal convulsions appear 2 years later. Absence seizures are not present in probands and do not appear as the sole phenotype in affected nonproband family members. When childhood absence evolves to JME, pyknoleptic absences with 3 Hz spike and wave complexes and 4–6 Hz spike or polyspike waves complexes persist into adolescence at which time myoclonias and grand mal convulsions start. Nonproband affected family members can have absence only, grand mal only, or absence and grand mal but they rarely have JME.

Neuropathology of some patients with JME reveals increased number of and diffusely distributed dystopic neurons in gray matter stratum moleculare and subcortical white matter of brains. Quantitative high-resolution voxel-based MRI detects such JME neuropathology as significantly larger, thicker, and increased cerebral cortical gray matter in mesial frontal lobes.

To determine the cause of JME, Suzuki *et al.* identified its disease causing gene, *Myoclonin/EFHC1*, in chromosome 6p12. Mutations accounted for 20% of our JME families. The ancestral origins of these families were from Spain mixed with native American Indians, e.g., Spanish-Amerinds who presently reside in Mexico and Los Angeles, California. Medina *et al.* showed that 9% of consecutive clinic patients with JME, including singletons and sporadic, have M*yoclonin/EFHC1* mutations. Singletons are patients who have no affected siblings but have one parent carrying a mutation. Sporadics are patients who have no affected siblings and have parents who do not have the disease mutation. True sporadic imply a 'de novo' mutation.

To explain displaced neurons in brain gray matter molecular layer on neuropathology, and MRI detected thicker cerebral cortical gray matter in mesial frontal lobes, Suzuki *et al.* transfected mouse hippocampal neurons in cell cultures with wild type *Myoclonin/EFHC1* and characterized neuronal differentiation and neurite outgrowth. Sixteen hours after transfection, GFP–EFHC1 positive neurons showed shorter neurites and fewer branches (in contrast to neurons transfected by pEGFP vector only. Forty-eight hours after transfection, all GFP-EFHC1 positive neurons exhibited signs of neurodegeneration and cell death, including shrinkage of cell body and fragmentation of processes. Control cultures transfected with pEGFP vector showed no features of degeneration. EFHC1 transfected cells were TUNEL positive, indicating apoptosis or programmed cell death, a genetically driven mechanism by which nature prunes cells during development.

To explain susceptibility to seizures in patients with mutations in *Myoclonin/EFHC1*, we looked at its calcium functions, since the myoclonin gene has one calcium binding motif in its EF-Hand component. Our collaborators at the RIKEN Brain Science Institute in Japan patch clamped baby hamster kidney (BHK) cells cotransfected with various types of VDCCs. Significant results were found when *Myoclonin/EFHC1* was cotransfected with R-type VDCC, calcium channels that are mainly in dendrites; *Myoclonin/EFHC1* significantly increased R-type VDCC currents. Mutations from human JME reversed the increased R-type Ca^{2+} currents.

These studies allowed us to hypothesize that *Myoclonin/EFHC1* is involved in pruning neurons and its dendritic tree, and in the enhancement of dendritic R-type VDCC currents. Mutations decrease *Myoclonin/EFHC1* pruning functions and produce the thicker cerebral cortical mantle detected by voxel-based quantitative MRI in JME patients. Mutations also alter calcium homeostasis in postsynaptic dendritic trees mediated by R-type VDCC, thus potentially explaining why JME patients are susceptible to myoclonias and grand mal convulsions when sleep deprived or exposed to alcohol. With our collaborators, we tested these hypotheses in mice and in *Drosophila melanogaster*, and confirmed that *Myoclonin/EFHC1* is a developmental gene involved in neuronal cell division, neuroblast migration and programmed cell death of neurons and its dendrites. We are now examining these same biological functions in the myoclonin deficient KO mice to see if we can link these functions to seizure susceptibility and epileptogenesis.

Present and Future Goals

Genotyping Adolescent Myoclonic Epilepsy Helps Treatment Choice

Genotyping adolescent myoclonic epilepsies will separate Lafora disease from JME. In their early stages, Lafora disease and JME are clinically similar (see **Table 1**). Both Lafora disease and JME start with expression of myoclonic, tonic clonic grand mal, and absence seizures at late childhood or adolescence. The identification of nonsense mutations in Lafora disease is important because nonsense mutations and their premature stop codon can be treated effectively with premature stopcodon readthrough drugs, such as gentamicin. Theoretically, treatment in Lafora disease is best started before neurologic deterioration ensues, before ataxia and dementia set in, before independent daily living activities are lost, and certainly before the need for gastrostomy is realized.

Can early Lafora PME be clinically distinguished from JME? Yes, a clinician experienced in PME can look for subtle differences between these epilepsies, but clinicians

Table 1 Lafora PME and JME are similar at onset of illness

Epilepsies	*Seizures*		*Age (yrs) at onset of neurological deterioration*						
	Age (yrs) at onset of Grand Mal, Myoclonic and Absence	Occipital Seizures	Mild cognitive decline	Mild ataxia	Severe ataxia dementia, preserved daily living activities	Impaired/loss of independent daily living activities	Anorexia, swallowing difficulties, gastrostomy	Respiration Assist; Mutism	Prognosis
Lafora PME									
(a) Laforin-deficient	6–19 yrs (80% at 10–12 yrs)	Yes (in 1/3)	10–14 yrs	10–14 yrs	17–20 yrs	16–20 yrs	18–20 yrs	20–25 yrs	Death in 2–10 yrs
(b) Malin-deficient	7–15 yrs	Yes (in 1/3)	16–27 yrs	16–27 yrs	26–32 yrs	26–32 yrs	26–37 yrs	26–37 yrs	Death in 10–30 yrs
Juvenile Myoclonic Epilepsy (JME)[a] (Herpin-Rabot-Janz type)	8–26 yrs (75% at 12–18 yrs); (Mean age at onset 14 yrs[b])	None	None	None	None	None	None	None	Good

[a]Some cases with myoclonus only.
[b]Usually triggered by sleep deprivation, menses, stress, fatigue, alcohol.

can still mistake one for the other early in their courses, especially when seizures are not stimulus-sensitive, action myoclonus is absent, and there are no occipital seizures. Genotyping will solidify and clarify diagnosis. Genotyping is crucial for early diagnosis in Lafora PME so treatment of nonsense mutations can begin.

Treatment – Curing Lafora Disease

Boosting protein synthesis from <1% to as little as 5% of normal levels reduces severity of disease phenotype.

Premature stopcodon readthrough drugs

Genotyping in Lafora disease will show if deletions, frameshifts, missense or nonsense mutations are present in laforin or malin. If nonsense mutations are present, intravenous gentamicin, a premature stopcodon readthrough drug, is clinically justified for 'compassionate use' in this fatal disorder. PTC 124, a new orally bioavailable nontoxic, small molecule that selectively induces ribosomal readthrough of premature but not terminal codons, and is superior in potency to gentamicin, is not yet commercially available. PTC124 coupled to a fusion protein could penetrate the blood–brain barrier and may be a future treatment.

Because Lafora PME is a lysosomal disease, polyglucosan inclusion bodies accumulate in liver, retina, cardiac muscles, esophageal skeletal muscles, and diaphragm muscles producing anorexia, malaise, visual problems, cardiac arrhythmias, swallowing and breathing difficulties. Boosting protein synthesis of laforin and malin, which function to purge polyglucosan inclusion bodies from cells, should slow the disease and alleviate the peripheral pathologies responsible for anorexia, malaise swallowing and breathing difficulties. High concentrations of intravenous gentamicin can also be expected to cross the blood–brain barrier – because the continuing and frequent seizures cause disruption of the blood–brain barrier, and because endothelium and neuronal cell death break open the blood–brain barrier. Selective and specific readthrough of disease-causing premature termination codons in endothelium and neurons should boost protein synthesis of laforin and malin, which purge the neurons of Lafora inclusion bodies and alleviate the central pathology of Lafora PME. Potential renal and otic toxicities produced by high concentrations of intravenous gentamicin limit their clinical use to invariably fatal diseases like Lafora PME.

Gene replacement therapy is the future

For deletions, frameshifts, missense or nonsense mutations in laforin or malin, gene replacement treatment would be the ideal treatment. Cornford and Hyman have successfully transported laforin across the blood–brain barrier of laforin-deficient KO mice after intravenous administration of an expression plasmid containing laforin packaged in the interior of neutral pegylated immunoliposomes (PIL). The external PIL is conjugated with OX26 monoclonal antibodies against transferrin receptor, which transports the vehicle across the blood–brain barrier. Presently, these investigators are administering PIL packaged with all four exons of laforin, with SV40 promotor, using mice epm2a polyclonal antibodies to confirm passage of epm2a through the blood–brain barrier in exon 4 KO homozygous null mutant mice. So far, laforin has been shown to rescue the pathology of LD in epm2a KO mice when administered in utero and in early postnatal months. Laforin replacement is now being studied in older mice with Lafora disease. In the near future, the same method of delivering epm2a/laforin can be applied to Laforin deficient humans.

Introduction

Broadly defined, a complex genetic trait is one which is present in families, but which is not governed by simple Mendelian inheritance (e.g., autosomal dominant or recessive) whereby the presence or absence of the single genetic variant is the sole determinant of a disease. Although there are several ways in which to violate Gregor Mendel's laws of inheritance, the concept 'complex genetic trait' usually refers to the effects of multiple genetic variants that are coinherited in an individual, and which together with nongenetic, environmental factors, are necessary to effect a biological outcome (**Figure 1**).

Several terms for 'complex genetic trait' have been used somewhat interchangeably in the scientific literature. The term 'polygenic' refers to traits that are determined literally by *many* genetic variants, and 'oligogenic' refers to traits that are determined by *several* genetic variants. The term 'multifactorial trait' is broader, and includes both genetic and nongenetic factors. In animal models, and increasingly in human, one also sees the abbreviation 'QTL' (quantitative trait locus). QTL was classically defined as a trait that is characterized by continuous, metric variation (e.g., height, weight, blood glucose) due to multiple factors. But since many disease-related traits are measured instead qualitatively (i.e., all-or-none traits such as diabetes, cancer, epilepsy, etc.), the term QTL is sometimes used to encompass discrete conditions as well.

How can multiple factors cause an all-or-none disease? The most commonly accepted model is referred to as 'liability-threshold' (**Figure 2**). That is, while disease outcome may be all-or-none, it is presumed that there are multiple factors 'under the hood' – namely, genetic variants and environmental effects which present a liability to the individual. Together, these factors conspire to lower the threshold for disease (or alternatively, to increase susceptibility). Of course, the effect of an individual gene may (if there was a way to measure it) ultimately be quantitative with respect to subsidiary aspects of the disorder. These underlying features, sometimes called sub- or endo-phenotypes, are usually more convenient to measure in metabolic and systemic disorders (e.g., T-cell counts in autoimmune diseases, blood glucose in diabetes, cholesterol in heart disease) than in disorders involving the intact central nervous system. In other words, full-blown disease is often the only endpoint that can be used to measure a trait such as epilepsy.

Finally, adding to the genetic complexity is a phenomenon known as locus heterogeneity – referring to the observation that individuals may have the same disorder but for different genetic reasons. Progress in unraveling the genetic basis of epilepsy is particularly hampered by this phenomenon. A family may indeed carry a single gene defect that underlies the disease, but locus heterogeneity makes finding the defect much more difficult because individual families are usually too small for unambiguous linkage and high resolution genetic mapping.

Introduction

Broadly defined, a complex genetic trait is one which is present in families, but which is not governed by simple Mendelian inheritance (e.g., autosomal dominant or recessive) whereby the presence or absence of the single genetic variant is the sole determinant of a disease. Although there are several ways in which to violate Gregor Mendel's laws of inheritance, the concept 'complex genetic trait' usually refers to the effects of multiple genetic variants that are coinherited in an individual, and which together with nongenetic, environmental factors, are necessary to effect a biological outcome (**Figure 1**).

Several terms for 'complex genetic trait' have been used somewhat interchangeably in the scientific literature. The term 'polygenic' refers to traits that are determined literally by *many* genetic variants, and 'oligogenic' refers to traits that are determined by *several* genetic variants. The term 'multifactorial trait' is broader, and includes both genetic and nongenetic factors. In animal models, and increasingly in human, one also sees the abbreviation 'QTL' (quantitative trait locus). QTL was classically defined as a trait that is characterized by continuous, metric variation (e.g., height, weight, blood glucose) due to multiple factors. But since many disease-related traits are measured instead qualitatively (i.e., all-or-none traits such as diabetes, cancer, epilepsy, etc.), the term QTL is sometimes used to encompass discrete conditions as well.

How can multiple factors cause an all-or-none disease? The most commonly accepted model is referred to as 'liability-threshold' (**Figure 2**). That is, while disease outcome may be all-or-none, it is presumed that there are multiple factors 'under the hood' – namely, genetic variants and environmental effects which present a liability to the individual. Together, these factors conspire to lower the threshold for disease (or alternatively, to increase susceptibility). Of course, the effect of an individual gene may (if there was a way to measure it) ultimately be quantitative with respect to subsidiary aspects of the disorder. These underlying features, sometimes called sub- or endo-phenotypes, are usually more convenient to measure in metabolic and systemic disorders (e.g., T-cell counts in autoimmune diseases, blood glucose in diabetes, cholesterol in heart disease) than in disorders involving the intact central nervous system. In other words, full-blown disease is often the only endpoint that can be used to measure a trait such as epilepsy.

Finally, adding to the genetic complexity is a phenomenon known as locus heterogeneity – referring to the observation that individuals may have the same disorder but for different genetic reasons. Progress in unraveling the genetic basis of epilepsy is particularly hampered by this phenomenon. A family may indeed carry a single gene defect that underlies the disease, but locus heterogeneity makes finding the defect much more difficult because individual families are usually too small for unambiguous linkage and high resolution genetic mapping.

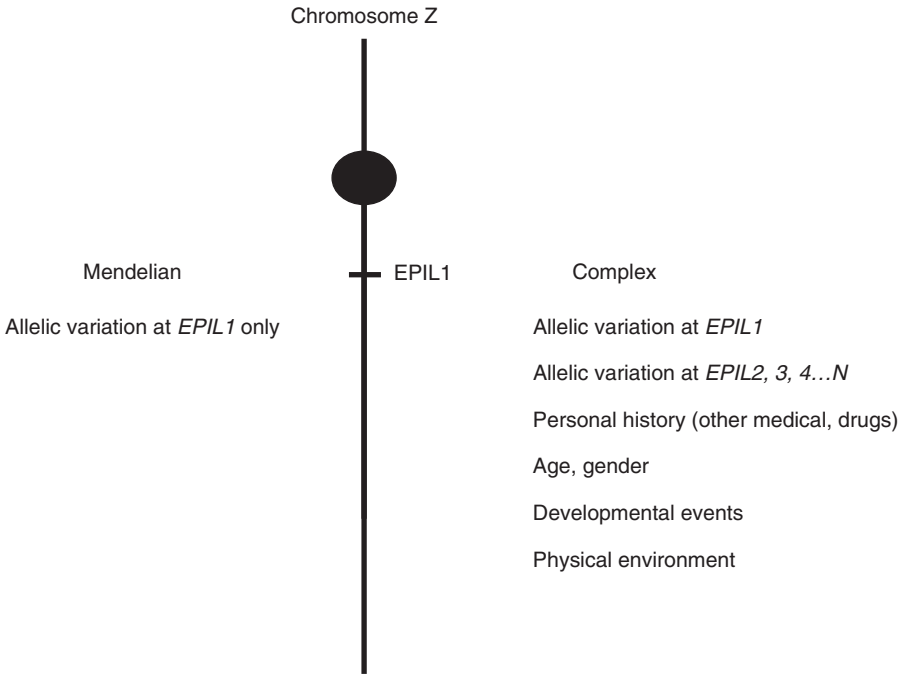

Figure 1 Hypothetical factors influencing clinical manifestation of fictitious epilepsy gene, *EPIL1* Mendelian versus complex trait.

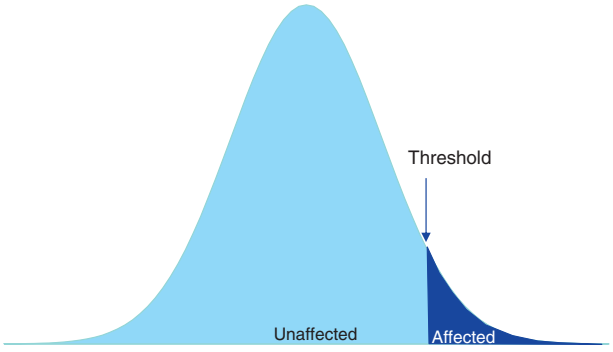

Figure 2 Threshold model for inheritance of discrete complex genetic traits.

The converse, phenotypic heterogeneity, is also a complication in epilepsy. Here, the same genetic variant may result in different outcome for different individuals. Naturally, until the genetic basis of a given individual's disorder is worked out, one cannot know whether phenotypic heterogeneity is due to variable gene expression or to other predisposing factors.

Background

Complex Genetics of Human Epilepsy

The population incidence of epilepsy in developed countries is about 1%. Many epilepsies are generalized, and without obvious physical or organic cause they have been termed idiopathic; other generalized epilepsies that have a suspected cause are termed symptomatic (or cryptogenic). It has long been suspected that idiopathic generalized epilepsies are genetic, since cases tend to cluster in families and do not have other obvious explanations. Indeed, the risk of having a seizure disorder is greater in first-degree relatives of individuals with epilepsy compared with the general population, but the increased risk is modest – only 2–4-fold. Nonetheless, from studies of monozygotic (MZ; genetically identical) versus dizygotic (DZ; fraternal) twins, the evidence for a genetic basis of epilepsy is very strong – for example, with respective casewise concordances of 0.62 (MZ) versus 0.18 (DZ). Furthermore, when considering certain subtypes of epilepsy (e.g., idiopathic generalized, symptomatic generalized, partial), the monozygotic twin concordances are even greater for both idiopathic and symptomatic epilepsies, but even partial epilepsies have a significantly higher concordance in monozygotic twins (MZ = 0.36 vs DZ = 0.05). Together with the observed familial aggregation, these data indicate a strong genetic component for all generalized epilepsies, and further suggest that even partial epilepsies have an appreciable genetic component. However, within most epilepsy families, the mode of inheritance is not straightforward; usually only a few individuals are affected, leaving little power for robust genetic analysis.

Genes for Genetically Complex Epilepsy in Human

Only a very small fraction of families inherit epilepsy in a Mendelian fashion, but almost everything that is known

about the genetic basis of inherited human epilepsy comes from the identification of genes in these few families. To date, approximately 20 genes for human idiopathic epilepsy are suspected or known. Most were identified by linkage analysis and candidate gene testing in pedigrees or small families that had a particular form of Mendelian epilepsy, such as benign neonatal convulsions, febrile seizures, juvenile myoclonic epilepsy, and rare partial epilepsies. Most of the identified genes encode ion channel proteins, others encode genes that likely regulate ion channels, but several encode other types of proteins, some with as-yet unknown function. One way to collect a sufficient number of subjects to confidently detect candidate genes for the more common, genetically complex epilepsies is by undertaking very large-scale genome-wide association studies (GWAS). Indeed, in 2007, GWAS facilitated the identification of genetic factors for several human complex traits, including discrete disorders such as Crohn's disease and diabetes, and quantitative traits such as height. However, it is unclear for epilepsy or other complex genetic disorders whether GWAS will prove to be a panacea or rather merely continue to chip away at the problem by identifying the 'low hanging fruit.' For example, a very good physiological candidate for childhood absence epilepsy is the *CACNA1H* gene, encoding a low-threshold voltage-dependent Ca^{2+} channel – a central player in generating the thalamocortical rhythms that are thought to be involved in absence seizure episodes. Initially, mutations were found in Chinese families. However, a later study examined a larger group of epilepsy patients, and identified a number of *CACNA1H* variants which, when tested in the laboratory, proved to encode functional differences at the protein level. These results suggested that *CACNA1H* variants may contribute to epilepsy more commonly in the population; however, such variants would have been impossible to detect statistically in a typical GWAS approach because they are relatively rare. This 'rare variant-common disease' conundrum does not mean that attempted large-scale GWAS for epilepsy will not be worthwhile, since more common functional variants may well exist. Rather, these results indicate that it is difficult to know how successful the approach will be.

With regard to ion channels as prime candidate genes for common epilepsies, a different approach is represented by the Ion Channel Project at the Baylor College of Medicine. This underlying hypothesis of this study is that common genetically complex epilepsies are largely due to unique (and presumably deleterious) combinations of ion channel variants that exist in the population. The investigators have begun sequencing 250 ion channel genes in several hundred IGE patients and normal controls. Although ion channel variants may not be the whole explanation for genetically complex epilepsy, it is a hypothesis well worth examining, given the role of ion channel defects in Mendelian epilepsies (as well as in animal models). It will be very interesting to learn whether unusual combinations of naturally occurring variants cluster significantly in epilepsy patients.

Methods

Approaches to identifying genetic variants that are associated with complex disease generally fall under the category of 'forward genetics,' which means simply that the molecular identity of the gene is not known ahead of time, and that genetic and genomic methods are used to find it. Typically, to identify genes for simpler genetic traits, one uses the approach of *positional cloning*, whereby the causative gene is identified by virtue of its position on a chromosome. Classically, this process involves 'walking' along the chromosome from a genetic marker on one side of the chromosomal interval associated with a disease, to the other side, characterizing and evaluating molecular variants (e.g., by using gene expression or structure analysis) along the way until one variant is found to be a strong possibility. That variant is then independently tested (e.g., by creating and testing a new allele, or performing a rescue experiment, or both). A variant of *positional cloning* is *positional candidate* – a slightly less systematic approach whereby the chromosomal interval or region is known, and researchers make educated guesses about the gene of interest based on the position or nature of a nearby gene; molecular variants of this 'guess' can then be evaluated.

In principle, finding genes for complex traits can also use positional cloning or candidates. However, the methods are technologically somewhat more challenging because of the ambiguous relationship between genotype and phenotype – that is, the property that defines complex traits as complex. Thus, a study population that is segregating one molecular variant that influences a particular phenotypic trait, is also segregating all the other variants, making it difficult to unambiguously define the genotype–phenotype relationship for a variant. Consequently, it is much harder (and takes quite a bit longer) to achieve a high-resolution genetic map for the trait at hand; in many cases, the best possible chromosomal intervals are still rather large. Because of this difficulty, several genetic and genomic 'add-ons' are often applied to forward genetics of complex traits. These additional features include: (a) treating the genetic mapping population more like an association study rather than as a linkage study (to disambiguate the genotype–phenotype relationship statistically, rather than empirically); (b) combining the genetic analysis (to narrow the position of the gene on the chromosome) with a genomic analysis – for example, to use microarrays or even proteomics tools to find all expression differences between two strains that differ for a trait, and then determine which ones map to the defining

chromosomal interval; and (c) incorporating the role of gene x gene interactions, or epistasis, into the analysis (i.e., when the consequences of inheriting one variant depends very much on whether another variant is coinherited).

Interestingly, in experimental organisms, the same kinds of mapping populations (e.g., backcross, intercross, recombinant inbred, and congenic strains) can be used to map both genetically simple and genetically complex traits. However, the parameters of the study (population size, density of genetic markers used, type and extent of analysis) are much more demanding for genetically complex traits.

Results

Rationale for Modeling Genetically Complex Human Epilepsy in Laboratory Rodents

Rodent genetic models contribute significantly to our understanding of basic mechanisms of human disease in just about every field of research – in autoimmune disorders, cancer, heart disease, and disorders of the central nervous system such as epilepsy. From a molecular perspective, this translation from rodent to human is not surprising, given the very high degree of conservation between human and rodent genomes. There is good reason to think that many core mechanisms are very similar, if not identical, between the two. When clinical manifestations of seizures appear to differ between rodent and human, that difference may reflect (at least in part) our inability to observe the relevant neurological signs at the same level of detail in mice as in patients. Perhaps, with practice, this difficulty may be overcome. However, there may be some aspects of human seizure disorders which mutant rodents might never be able to model; for example, their lifespan may be too short to develop the full spectrum of secondary pathologies of human temporal lobe epilepsy (TLE), even though some rodent models mimic the behavioral, physiological and pharmacological aspects quite well. Nevertheless, enlightening examples of conservation of higher-order function across mammalian orders do exist. For example, given that mice are nocturnal animals and they do not have even a developed frontal lobe, per se, it is not clear that we would predict that the mutation for Autosomal Dominant Nocturnal Frontal Lobe Epilepsy (ADNFLE) (a rare form of partial epilepsy in human) would be functionally conserved between humans and mice. However, the cognate mutant mice seem to model the human disorder reasonably well, as the authors of one study conclude: '. . .these mice cover the spectrum of behavioral and electrographic events seen in the human condition. . .'

This statement epitomizes the general approach to studying animal models of genetically complex epilepsy. They are studied because of obvious parallels with the human condition: the type of seizure, physiological and pharmacological properties – and the complex nature of inheritance. Since until recently it has not been possible to even contemplate mapping and identifying genes for complex traits in humans, rodent systems have been approached with the broader rationale of understanding the 'architecture' of epilepsy as a complex genetic trait. It is likely that the same genes, or at least the same molecular pathways, are affected in humans as in rodents – although this assumption remains to be demonstrated, mainly because so few human epilepsy genes are known.

However, even if we did not know anything about the genetic basis of human epilepsy, from a phenotype search of mouse mutation listings in the The Jackson Laboratory's Mouse Genome Informatics database (from which information about all published mouse mutations can be obtained) one infers that over 400 different genes have the potential to be human epilepsy genes (i.e., by causing spontaneous seizures in mice when mutated) or to lower the seizure threshold. Since most genes have not yet been mutated in mice, and since many that have been mutated represent complete gene knockouts (as opposed to subtle, but functional protein variants), it seems likely that the number of 'epilepsy genes' will be much higher than 400. Certainly, such predictions are consistent with the observed locus heterogeneity in human studies so far.

Beyond locus heterogeneity, however, the inheritance characteristics of rodent models are very likely to predict and validate what we can expect to find in genetically complex epilepsy in human. The remainder of this article considers several examples of what has been learned so far from complex genetic models of epilepsy in mice and rats, drawing from different types of seizure disorders.

Genetically Complex Models for Grand-mal Type Seizures in Mice

Several inbred mouse strains display complex partial seizures with secondary generalizations – grand-mal like episodes that mimic the behavioral and encephalographic features of temporal lobe epilepsy (TLE), a common form of human epilepsy. The strains EL, PL, and SWXL-4 exhibit recurrent seizures beginning at several months of age, following either routine handling (e.g., weekly cage changing) or more systematic, but still gentle physical stress. In 1991, one of the first efforts to map QTLs for any complex trait in mammals was done for epilepsy, by analyzing EL mice that were backcrossed to DBA/2J and ABP, unrelated strains that are relatively resistant to this type of seizure. These studies resulted in three dominant QTLs for seizure frequency (*El1*, Chr 9; *El2*, *Chr 2*; *El3*, *Chr 10*), accounting for a significant fraction of the seizure frequency in the backcross. Although the mapping itself became fairly straightforward with the advent of

genome-scanning technologies, (and many studies followed suit for different disorders and traits), the underlying genetic complexities of epilepsy soon became apparent. First, only one of the three initially mapped loci (*El1*) had an effect in crosses to both resistant strains. Second, in follow-up studies that used an intercross rather than a backcross (these two crosses give different mixtures of parental genotypes for a gene), only one of the three chromosomes showed any association (Chr 9), and further analysis suggested that this association was due to a fourth locus (termed *El4*) residing some distance away from *El1*. Despite this result, however, when the *El1*-, *El2*- and *El3*-containing chromosomal regions were transferred from the EL strain onto ABP (resulting in a congenic strain), two regions (*El1*, *El2*) had large effects on seizure frequency – validating the initial mapping. Last, and strikingly, in crosses between EL and a resistant strain (DDY) that is most closely related to EL, none of the previously mapped QTL had any measurable effect whatsoever! Instead, a new major locus, *El5* (Chr 14) was found, but only in an intercross population, not in a backcross! Together, these data suggest the frustrating conclusion that, despite the persistence of several trait loci in crosses and in congenic strains, none represented a core or essential seizure locus – that is, a locus that defines, or at least is always associated with, the seizure susceptibility of EL mice.

Similar studies involving another inbred mouse strain demonstrated more directly that complex diseases are defined by deleterious combinations of genes from the parents. SWXL-4 mice display seizures similar to EL, but while the precise genealogical origin of the EL strain is not known, SWXL-4 is one of a set of seven. Recombinant Inbred (RI) strains constructed to inherit a deliberate but arbitrary 50:50 mix of the two progenitor strains SWR and C57L. Interestingly, of each progenitor and all six SWXL RI strains, only SWXL-4 exhibited seizures – suggesting that the seizure disorder was a 'synthetic' trait caused by a combination of parental genes. This hypothesis was tested and proved by re-crossing the SWR and C57L, and determining that a fraction of hybrid progeny had high seizure frequency like SWXL-4. Again, however, while QTL associated with seizures were mapped in crosses of SWXL-4 mice, and a new seizure frequency locus (*Szf1*, Chr 7) was confirmed in a congenic strain, *Szf1* was not sufficient to explain why SWXL-4 has a serious seizure disorder. Furthermore, as was the case with at least one locus from EL mouse, *Szf1* itself was determined not to be one gene but to consist of several genes, that happened to be coinherited on the same chromosome and that interacted functionally with each other – another frustrating aspect of resolving some complex trait loci as has been noted in other animal models of complex inheritance.

Additional complexities in these and other models come from gene x environment interactions. Recently, some of the EL genetics were examined in a protocol that was particularly attuned to certain nongenetic variables. The authors were able to replicate and extend some, but not all the seizure loci detected previously; this study demonstrated that both native (e.g., age) and experimental factors (e.g., test conditions) can influence the outcome. Despite the attention to these finer points, the genetic map, and the essential complexity of the models, were not resolved sufficiently to allow breakthroughs at the molecular level – that is, to result in gene discovery.

In summary, these studies of grand-mal like seizures in inbred mouse strains illustrate the typical properties of complex genetic traits. If such mapping results were obtained in a human population and not in the laboratory where they can be relatively easily validated, one might dismiss most of the mapping results as 'false positives.' Instead, however, since many loci were replicable, the results illustrate defining characteristics of complex genetic traits: the impact of, and the ability to define, a susceptibility gene depends heavily on the presence of other genetic variants, and on environmental conditions. It is important to consider this concept in any future efforts to better resolve human complex traits.

Rodents with Genetically Complex Absence, or Petit-mal Seizures

Several strains of laboratory mice and rats display spontaneous absence, or petit-mal seizures, as evidenced by electroencephalographic (**Figure 3**), behavioral, and pharmacological features. As with other animal models of epilepsy, the degree to which these strains mimic the human condition is sometimes questioned. One property of rodent models of absence epilepsy is that frequency of the corresponding electrographic oscillation, known as a spike-wave discharge (SWD), is usually not 3–4 Hz as in human absence epilepsy, but rather 5–9 Hz. This difference is probably due to a species-specific property, perhaps related to the absence of thalamic interneurons in rats and mice which in human may serve to buffer the oscillation. Another difference between rodent and human conditions is that rodent absence episodes do not subside after adolescence; the reason for this difference is not known, but may be viewed as a pragmatic advantage, facilitating laboratory study. In other ways, the models discussed here have all the hallmarks of human absence epilepsy.

Two well studied rat models of genetically complex epilepsy are absence models: the GAERS (Genetic Absence Epilepsy Rat from Strasbourg) and the WAG rat strains. The physiology and pharmacology of GAERS have been studied for many years, while the WAG rat is a more recent subject. Initial genetic analysis has also been done in GAERS and WAG. In crosses between WAG and a nonseizing strain, parameters such as the frequency,

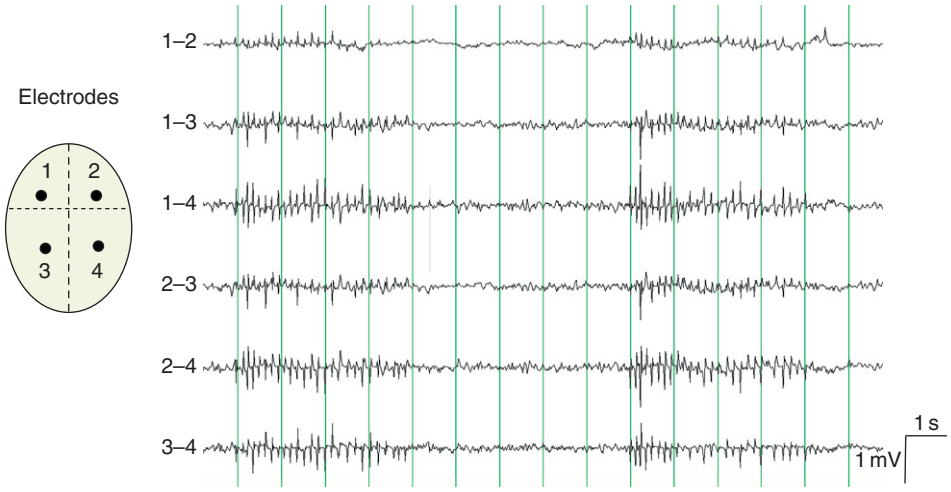

Figure 3 Spike-wave discharges in a mouse model of genetic absence epilepsy.

duration, and amplitude of spike-wave discharges were carefully measured, as well as the qualitative form and shape of the SWD themselves, and QTL analysis was performed. Investigators concluded that absence epilepsy segregates as a complex genetic trait in WAG, with underlying genes mapping to multiple regions of the genome, analogous to the situation with EL mice for convulsive seizures. A similar conclusion was drawn for GAERS, although with different chromosomal locations. While candidate genes reside in the vicinity of these QTLs, the critical intervals are still too large to provide useful hints about which genes encode the underlying variants.

A/J and C3H/HeJ are two inbred mouse strains that display genetically complex absence seizures, possibly representing slightly simpler forms of genetically complex epilepsy. Like GAERS and WAG, these strains do not have any other overt neurological abnormalities. They exhibit a modest incidence of seizure episodes, particularly during slow-wave sleep or in transitions to and from slow-wave sleep. Preliminary analysis in crosses between A/J and the normal strain (C57BL/6J) suggests oligogenic inheritance, with loci on Chromosome 4 contributing to the absence seizure phenotype (although genes have not yet been identified). Significant progress has recently been made in the C3H/HeJ model. Crosses between C3H/HeJ and C57BL/J revealed that a major locus, accounting for about half of the phenotypic variance, mapped to the *Gria4* gene on Chromosome 9, encoding a subunit of the AMPA receptor ion channel. A unique mutation was found in the *Gria4* gene, causing decreased expression of full-length RNA and protein. Further studies utilizing a man-made knockout (null) allele proved that *Gria4* gene defect was responsible for the epilepsy. Interestingly, however, the rate of seizures was much higher in outcrosses than in C3H/HeJ itself, and was not dependent on activity state. This result suggested that several recessive modifier genes together actually dampen the seizure phenotype in the C3H/HeJ inbred strain. In outcrosses between C3H/HeJ and other strains, these modifiers become 'unmasked,' allowing full expressivity of the *Gria4* deficiency; in this latter case, many mice exhibit hundreds of seizure episodes every hour, as opposed to 20–30 episodes per hour in C3H/HeJ itself. The identities of these modifier genes are not yet known.

The A/J and C3H/HeJ represent complex genetic traits that are not hopelessly complex, but not simple either. In the case of A/J, it apparently requires several susceptibility alleles to cause an appreciable frequency of absence seizures, whereas seizures in C3H/HeJ appear to be due to a more Mendelian-like single gene trait, with modifier genes that modify the phenotype.

Genetically Complex, Experimentally-Induced Seizures in Mice

A large body of literature considers the ability of adverse stimuli, including chemicals, electrical shock, and loud noises, to elicit seizures in rodents. In fact, experimentally induced seizures in mice and rats remain the primary basis of screens to evaluate the efficacy of anticonvulsant drugs. While most drug screening efforts utilize only one or two strains, the larger collection of strains that exist reveal a very broad spectrum of seizure response to adverse stimuli, suggesting that there is considerable genetic complexity in mice.

Several efforts have exploited strain diversity in order to study the genetic basis of seizure threshold response to stimuli in mice. The earliest studies in this area considered the susceptibility to audiogenic seizures. In 1946, investigators discovered that the DBA mouse strain is susceptible, and C57BL/6 is resistant, to wild (often lethal) tonic–clonic seizures when exposed to a loud doorbell hung on a galvanized drum. Decades later, extensive

surveys were done using calibrated stimuli to establish the parameters of audiogenic seizure induction in various inbred strains. In the late 1980s and early 1990s, recombinant inbred strains between the susceptible DBA/2J and resistant C57BL/6J progenitor strains were used to map genes that determined sensitivity to audiogenic seizures, resulting in the mapping of several presumptive loci, *asp1* (audiogenic seizure prone-1, Chr 12), *asp2* (Chr 4), and *asp3* (Chr 7). As was the case in EL and SWXL-4 strains, the underlying genes for these loci have not yet been identified, likely due to their complex inheritance.

However, thanks to perseverance by other researchers, there may be light at the end of the tunnel for identifying underlying seizure-susceptibility genes. The same progenitor strains (DBA/2J and C57BL/6J) showed a similar polar response to chemoconvulsants (e.g., pentylenetetrazole (PTZ), the GABA receptor antagonist, and kainic acid) and to electroconvulsive seizures, with DBA/2J being relatively seizure sensitive and C57BL/6J relatively resistant. QTL studies were done in an intercross between these strains; a locus on Chromosome 1 (*Szs1*) was found to be a major determinant of susceptibility, and other significant or suggestive QTLs were ultimately mapped as well (*Szs2*-*Szs13*), some of which have been replicated. Using a congenic strain and an elegant transgenic rescue strategy, investigators narrowed the critical interval for *Szs1* to only six possible genes. A strong candidate was identified in *Kcnj10*, encoding an inward rectifier K^+ ion channel, in which a nonconserved amino acid differs between parental strains. While definitive confirmation is still awaited, the human homologue, *KCNJ10*, has also been shown to harbor a coding variant related to human IGE.

Another example of imminent success comes from studies of mouse strain susceptibility to kainic acid seizure-induced hippocampal cell death. In these studies, the investigators looked beyond clinical phenotype towards possible mechanisms associated with neuronal loss following seizures (as seen in human epilepsies such as TLE). Genetic crosses were characterized between C57BL/6J (relatively resistant) and FVB/N (relatively sensitive) – focusing on cell death as the endpoint – and several QTL were found to contribute to the phenotype, with *Sicd1* (seizure induced cell death-1) on Chromosome 18 having the largest effect. The genetic effect of *Sicd1* was later confirmed using congenic strains, and a strong candidate gene, *Galr1* – encoding a galanin receptor, has emerged.

Although the aforementioned examples have come closest to unequivocal gene identification, numerous other studies have focused on genes causing varying seizure threshold responses in response to other substances. QTL mapping for susceptibility to β-carboline-, cocaine- and pilocarpine-induced seizures, as well as to seizures resulting from alcohol, phenobarbitol, and zolpidem withdrawal, have been carried out. Many of these QTLs were defined in crosses between DBA/2 and C57BL/6 strains; these have been the most popular mouse strains to use over the past decade or two, not only because they are genetically diverse from one another, but also because of the availability of specialized genetic or genomic resources for their study (e.g., RI strain sets, genome sequence, recombinant DNA libraries). However, it should be noted that there are well over 40 inbred mouse strains available to researchers. As mouse strains show wide diversity in seizure threshold paradigms, there are likely many interesting combinations to utilize for genetic studies, to model just about any aspect of seizure disorders or to study the genetics of antiepileptic drug action. Worldwide research community efforts, such as the Mouse Phenome Database, collect and compare phenotypic and genetic information in a large set of mouse strains, thus providing instigation for resource development that supports the study of genetic diversity in mice – which will make it easier to work with more exotic strains in future.

Directions for Future Research

Is Mendelian Epilepsy Really all that Genetically Simple? Studying Human in Mouse

More than 400 mouse mutations cause spontaneous seizures or alter the seizure threshold. Most are single gene, null mutations. One possible interpretation of these findings is that if these genes were mutated in human epilepsy, they would exhibit Mendelian, not genetically complex, inheritance. However, this interpretation is based on a superficial assumption. Most mouse mutations have been studied in mixed hybrids from only two parent strains: 129 (the strain in which most targeted germ-line mutations are created in mice), and C57BL/6 (a popular 'wild-type' strain, often used as a standard genetic background). Fewer studies have examined mutations on either the C57BL/6 or 129 background separately, and fewer still have gone farther afield to explore more strain diversity. Still, those few that have ventured away from C57BL/6 and 129 have noted some very striking differences in seizure incidence, severity or manifestation. For example, mice homozygous for null mutation in *Slc9a1* (encoding a sodium–hydrogen exchanger) were examined on the SJL/J strain (on which the mutation arose), the C57BL/6J strain (onto which it was transferred), and in first (F_1) and second (F_2) generation hybrids between the two parents. Mutants on all four backgrounds exhibit tonic–clonic seizures, but they also exhibit absence seizures that are only obvious in the F_2 hybrids. Another example involves the *Gad65* gene, which encodes one of two glutamate decarboxylase isoforms, the enzyme responsible for synthesizing GABA. Homozygous knockout mice had a much more severe phenotype when the 129-strain based mutation was crossed to the NOD strain background. A third study explored the seizure phenotype

of a gain-of-function transgenic mutation in *Scn2a*, encoding a sodium channel in which human mutations have been associated with Mendelian epilepsy (Generalized Epilepsy with Febrile Seizures Plus, GEFS+). On the SJL strain background, the seizures were very severe and occurred at a younger age than on other backgrounds.

In a final example, a rare variant of childhood absence epilepsy occurred in the gene *GABRG2*, encoding a subunit of a receptor for GABA, the primary inhibitory neurotransmitter in the brain. The same mutation was made in the mouse version of the gene, and 'knock-in' mice were created. Like the ADNFLE mice mentioned earlier, the resultant mice have bona-fide disease, in this case absence seizures (and, despite carrying a mutation that was found in human, have the 5–9 Hz rodent version of SWD). But most interestingly for the GABA story, the severity of disease was very dependent on mouse strain background – with C57BL/6 showing more resistance than DBA/2. This important example illustrates how mouse strain diversity can be exploited directly to gain insight into the regulation of a human mutation. Beginning to identify such genetic modifiers of seizure susceptibility in mouse is a major goal for current research, especially given that several such modifiers have already been found in other mouse models of disease.

The studies discussed here are just the tip of the iceberg, given that most of the genetic diversity in mouse strains is largely untapped. Conceptually, effects of genetic background on the functional expression of single gene mouse mutations will surely mimic the situation in the general human population, where the inheritance of an epilepsy variant is dependent upon the presence of other genes inherited. In fact, genes that cause Mendelian epilepsy in isolated families, which are less genetically diverse than the general population (although not to the extent of a congenic mouse strain or backcross!), may be associated with more genetically complex epilepsy in more typical, genetically heterogeneous families. Although the awaited GWAS and re-sequencing studies in human are welcome, and are bound to yield a measure of success, further understanding (and exploitation) of genetically complex epilepsy in laboratory animals promises to provide a critical understanding of how susceptibility to epilepsy is tweaked by nature. Such insight will certainly be of therapeutic value to human epilepsy.

Role of Genetic Factors in the Etiopathogenesis of Epilepsy-Related Brain Damage

P E Schauwecker, University of Southern California Keck School of Medicine, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy, one of the most common neurological conditions, is a heterogeneous disorder defined by paroxysmal and abnormal discharges of neurons, resulting in recurrent attacks of seizures. Brain damage is caused by persistent and highly repetitive seizures associated with excitotoxic cell death mechanisms. Now it is accepted that epilepsy-associated damage is multifactorial, with genetic and environmental factors interplaying to determine disease onset and progression. Similar to all complex conditions, the genetic component of epilepsy is not limited to a single gene mutation. As a result, the design of genetic studies in complex diseases is challenging. Furthermore, our understanding of the molecular pathways that regulate cell death after seizure activity remain in its infancy – and largely lag behind work in other areas of brain injury. This delay in understanding is due, in part, to the difficulty in delineating changes in gene expression, which are causal for seizure-induced cell death; indeed, any changes detected may simply be secondary to the effects of the seizures themselves. A complementary approach to mechanistic-based studies has been to identify genes that may contribute to seizure-induced cell death through genetic manipulation in animal models of experimental epilepsy. The overarching hypothesis of our research is that a subset of endogenous genes expressed following seizure induction can determine whether or not cells will survive.

Animal modeling of seizure disorders has been instrumental in elucidating the pathophysiological mechanisms underlying epilepsy and in designing more effective therapies for seizure-induced damage. These models allow us to determine the nature of injuries that might contribute to the subsequent development of epilepsy, to observe and intervene in the disease process subsequent to an injury but prior to the onset of spontaneous seizures, and also to study the chronically epileptic brain in exquisite detail, using state-of-the-art physiological, pharmacological, molecular, and anatomical techniques.

To date, numerous studies have examined the neurological effects of seizure-induced cell death, but the elucidation of causal factors mediating susceptibility has proven to be more difficult. A contributing factor is the genetic variability even in genetically-modified animal models. In particular, strain-dependent variation among normal mouse strains has recently been recognized as a major confounding variable, influencing the interpretation of the neurochemical, pharmacological, and behavioral changes in genetically-modified mice. Our research has yielded a genetic differentiation between mouse strains that show no difference in the extent of seizure activity, but exhibit robust differences in susceptibility to seizure-induced excitotoxic cell death. As a result of this analysis, we have produced the *first* model that allows the investigator to test the hypothesis that different molecules are responsible for seizure sensitivity versus seizure-induced cell death susceptibility. The identification of specific genotypes with divergent responses to seizure-induced excitotoxic cell death will facilitate studies into the biological mechanisms underlying neuronal sensitivity. Subsequent identification of these epilepsy susceptibility genes may illuminate new pathways involved in epilepsy and epileptogenesis, and may also aid in the discovery of the common human genetic variation that plays a role in determining an individual's genetic susceptibility to epilepsy.

Background

Excitotoxic Cell Death: A Common Pathologic Mechanism in Neurodegenerative Diseases

It has been suggested that cell death in diverse neurological disorders, such as epilepsy, stroke, Alzheimer's disease, Huntington's disease, and Parkinson's disease, may occur in part from excessive activation of glutamate receptors, resulting in excitotoxic damage. Glutamate, the most abundant excitatory neurotransmitter in the mammalian central nervous system (CNS), plays a major role in synaptic transmission. However, when glutamate receptors are excessively activated, a form of cell death termed 'excitotoxicity' ensues. Excitotoxicity refers to a process of neuronal death initially triggered by elevated levels of excitatory amino acids, resulting in the opening of glutamate receptor-associated ion channels; this action at glutamate receptors causes prolonged depolarization of neurons, the subsequent influx of calcium, and the activation of calcium-dependent enzymatic and nuclear mechanisms of cell death. Although the cellular and molecular mechanisms underlying vulnerability to excitotoxic cell death are unknown, an understanding of the genetic characteristics and molecular mechanisms that trigger excitotoxic cell death may offer therapeutic strategies for neuronal damage and loss that occurs in these disorders.

Strain-Related Differences in Seizure-Induced Excitotoxic Cell Death

Similar to what has been observed for seizure sensitivity, genetic background plays a major role in determining the acute effects of seizures. Previously, we demonstrated that mouse strains show remarkable genetic differences in susceptibility to the neuropathological consequences of seizures in the kainate model of status epilepticus. In particular, the extent of seizure-induced cell death differs markedly between strains of inbred mice; importantly, these differences are not necessarily related to differences in the extent of seizure activity induced by kainate. Given that strains of mice differ markedly in their response to seizure-induced excitotoxic cell death, it is obvious that there must be a genetic basis for these differences that are passed on from one generation to the next. Thus, genetic techniques can be employed to define and understand these differences.

Functional Genetic Approaches to Identification of Candidate Genes Modulating Excitotoxicity

The well-accepted notion that overactivation of glutamate receptors can mediate cell death in several neurological diseases has prompted considerable effort to develop drugs to attenuate or abolish the excitotoxicity. In many biological systems, mutant organisms have proved to be powerful tools for advancing our understanding of the molecular pathways that could be considered as potential therapeutic targets. At present, gene function can be disrupted, attenuated, or enhanced in conditional and reversible fashion using a combination of gene targeting and transgenic approaches. It is becoming increasingly clear that several genes can modulate susceptibility to excitotoxic cell death, and much research has focused on identifying genes that may contribute to the pathogenic sequelae of neuronal damage. Traditionally, these studies can be divided into forward or reverse genetic approaches. Forward genetic approaches (from phenotype to gene) use genetic dissection (e.g., the identification and mapping of specific genes) to isolate mutants that affect a process of interest. In this process, genes are mutated at random. Thus, the resulting changes in the phenotype of a cell or organism are then attributed to the mutated genes, without any prior knowledge of the genes' function. Studies in our laboratory have utilized a forward genetic approach to dissect the genetic influences on differences in seizure-induced cell death between two strains of mice that are divergent for susceptibility to seizure-induced cell death.

Conversely, reverse genetic approaches (from gene to phenotype) involve the disruption of a gene of interest, and have been used extensively to determine the role of a particular gene within a specific pathway. In the mouse, a reverse genetic approach has been utilized extensively to identify the functional relevance of several genes in modulating susceptibility to excitotoxin-induced cell death. Classical reverse genetic approaches have involved the creation of knockout cell lines or organisms to eliminate the function of a gene of interest, or have involved transgenesis studies, in which a particular gene is overexpressed in a cell line or organism. Although the analysis of gene modulation in vivo, using knock-out, knock-in or transgenic mice, remains the gold standard for any target validation project, these approaches can be expensive and time-consuming. Further, gene expression is often poorly controlled (e.g., may be 'supraphysiological'), creating the potential for expression artifacts.

Methods

Experimental Genetic Approach: Identification of Quantitative Trait Loci (QTLs)

Genetic linkage is often used to elucidate the underlying genetic mechanisms for inherited traits and to find chromosomal locations for genes. The experimental dissection of quantitative traits is a multi-stage process, typically involving (1) coarse genome-wide linkage mapping, (2) fine mapping of specific regions, (3) recombination or association mapping to identify candidate genes, and finally (4) positionally cloning and characterizing quantitative trait loci (QTLs). The QTL method can identify chromosomal regions involved in regulating a trait in any animal system for which two key resources are available: genetically divergent strains and a linkage map covering all of the genome.

Linkage mapping of quantitative trait loci in mice begins by choosing parental inbred strains that are genetically variable for the trait of interest. Although not selectively bred for these characteristics, the FVB/N mouse has been found to be genetically predisposed to susceptibility to excitotoxicity, whereas the C57BL/6 mouse has been found to be genetically predisposed to be cell death resistant. As these two strains exhibit maximum differences in susceptibility to seizure-induced excitotoxic cell death, they represent the phenotypic extremes for this trait. There must be a genetic basis for these differences that are passed on from one generation to the next, and thus genetic techniques can be employed to define and understand these differences.

In an attempt to perform a genetic dissection of seizure-induced cell death through a linkage analysis approach, we created mouse hybrid populations from the crossbreeding of seizure-induced cell death susceptible (FVB/N) and seizure-induced cell death resistant (C57BL/6) mice. These two parent strains have different mean values for the trait of susceptibility to seizure-induced cell death. A mapping population was then derived by backcrossing the first generation (F1) progeny

to one or both parents. The intervals defined by ordered pairs of chromosomal markers are searched in increments, and statistical methods are used to test whether a QTL is likely to be present at the location within the interval or not. While the position of the peak statistically significant value gives the most likely position for at QTL, its exact location remains unknown. As a result, the identification of any QTL via coarse genome-wide linkage mapping is only the first step towards the ultimate goal of gene identification. The next step is the production of congenic strains, by which the existence of a QTL may be verified and the implicated chromosomal region be reduced to a size applicable to positional cloning of the causal gene.

Confirmation of the QTL and Fine Mapping

In organisms amenable to genetic manipulation, the effects of an individual QTL can be magnified by constructing strains that are genetically identical except for a defined region surrounding the QTL. A congenic strain is traditionally constructed by the serial backcrossing of a donor strain to a recipient strain. Chromosomal regions are monitored at each backcross for heterozygosity using polymorphic microsatellite markers. These strains constitute a permanent genetic resource from which multiple measurements of the trait phenotype can be obtained in order to increase the accuracy of determining the QTL genotype. The region surrounding the QTL can be a whole chromosome or a small interval (interval-specific congenic strains). After eight to twelve backcrosses, according to Mendelian laws, more than 99% of the genetic background is that of the recipient strain. On completion of the backcrossing, the final step of brother X sister mating fixes the strain so that the desired chromosomal region is homologous for the donor's alleles in one quarter of the offspring.

Once a phenotype has been anchored to a congenic segment, the investigator requires a fine saturated map of the region of interest in order to progressively narrow the area containing the disease-related gene, and thus to generate congenic sublines carrying smaller and smaller pieces of the original QTL. To fine-map this locus, we created congenic mice by introgressing (moving a group of genes from) segments of C57BL/6 (B6) chromosome 18 into the FVB/N (FVB) background, predicting that B6 alleles would further reduce susceptibility to seizure-induced cell death. This procedure has the further advantage of reducing a multifactorial trait into a simple Mendelian trait. Moreover, it allows the final cloning of the gene either by position or by candidate gene analysis.

Identification of Candidate Genes through Recombination Or Association Mapping

While QTL mapping cannot provide direct evidence for which specific genes are involved in a particular trait, mapping experiments can identify the probability that a gene of interest exists at the chromosomal location. Once a plausible candidate gene(s) has been identified in the QTL region, the next crucial step is to identify likely disease gene candidates. The analysis of candidate genes is a key step in strategies for disease gene identification and includes: (1) identifying candidate genes that might have a role in the etiology of the disorder; (2) identifying variants in or near those genes that might cause a change in the protein or its expression; or (3) assessing the association between a particular allele (or set of alleles) of a gene in population and the underlying phenotype; and then using statistical methods to determine whether there is a correlation between those variants and the phenotype. For example, for our study of seizure-induced excitotoxic cell death, we take advantage of previous studies have identified causative genes (in mutant mouse models and in familial human forms of epilepsy) that encode ion channels and neurotransmitter receptors. Once a candidate gene has been chosen, a decision must be made as to which type of polymorphism would be most useful for testing in an association study. Most of the DNA sequence variation in the human genome is in the form of single base pair changes in the DNA, known as single nucleotide polymorphisms (SNPs) based on their natural frequency and presence in both coding and noncoding regions, single nucleotide substitutions are probably the underlying cause of most phenotypic differences among humans.

Recent Results

Quantitative trait loci (QTL) mapping studies designed to localize seizure-induced cell death susceptibility genes in C57BL/6 (seizure-induced cell death resistant) and FVB/N (seizure-induced cell death susceptible) mice have detected a significant effect originating from distal chromosome 18. In order to confirm the presence and refine the position of the chromosome 18 QTL for susceptibility to kainate-induced cell death, reciprocal congenic strains between B6 and FVB mice were created using a DNA marker-assisted backcross breeding strategy, and mice were studied with respect to changes in cell death. A genomic interval delimited by marker D18Mit141 and D18Mit25 was introgressed for 10 generations. Comparison of cell death susceptibility between congenic and control (parental genetic background) mice indicated that genes influencing this trait were captured in nearly all strains. Thus, mice from strains having B6 alleles from chromosome 18 on a FVB genetic background exhibited significantly reduced cell death compared to control littermates (Figure 1) in contrast, congenic mice harboring FVB chromosome 18 alleles on a B6 genetic background exhibited significantly greater cell death compared to control littermates.

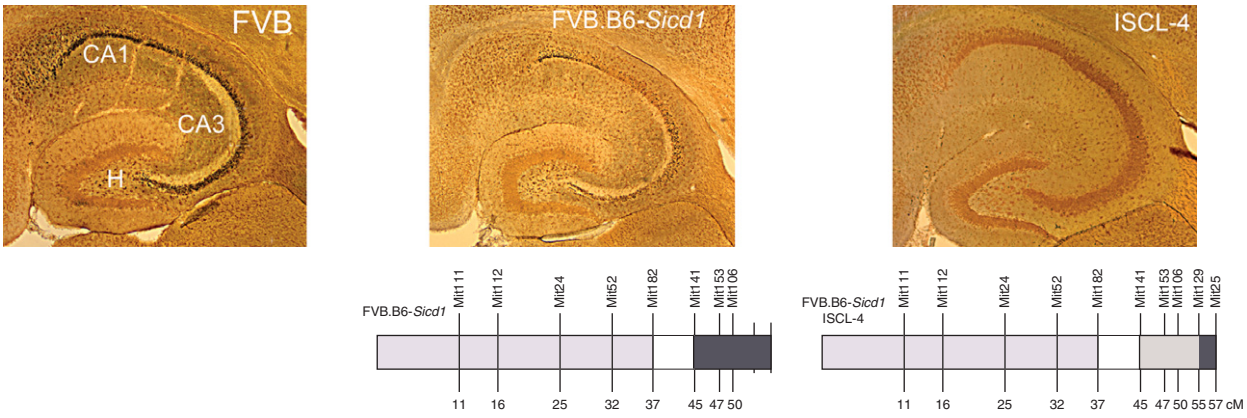

Figure 1 Kainate-induced cell death susceptibility is reduced in the FVB.B6-Sicd1 congenic strain and substantially reduced in interval-specific congenic line-4. Low-magnification Gallyas silver-staining of horizontal sections through the hippocampus in FVB/N (background strain), FVB.B6-Sicd1 congenic mice, and in ISCL-4 congenic mice 7 days following systemic administration of KA. Note that cell death is reduced in area CA3 and CA1 in FVB.B6-Sicd1 congenic mice and that little to no cell death is observed in ISCL-4. Schematic diagrams of chromosome 18 in FVB.B6-*Sicd1* congenic mice and in ISCL-4 congenic mice are shown below the corresponding photomicrograph. Lightly shaded regions reflect genomic contribution from the FVB strain and darkly shaded regions reflect genomic contribution from the B6 strain. Numbers below represent the genetic map position (http://www.informatics.jax.org/) and are given in cM. CA1 and CA3 denote the hippocampal subfields; H, dentate hilus.

As a means of refining this interval, we next created a series of overlapping, congenic, recombinant strains by breaking the QTL interval into subregions. The development of a series of strains termed, interval specific congenic lines (ISCLs) have been used extensively to refine the location of a QTL for identification and confirmation of candidate genes in a variety of other species. Each ISCL is recombinant at a specific sub-interval, thereby reducing the QTL to a much smaller interval than the original congenic strain. We produced four interval-specific congenic strains carrying differing intervals from chromosome 18 of B6 on an FVB-derived susceptible background. All of the ISCLs exhibited reduced cell death associated with the B6 phenotype, as compared with the parental FVB strain. However, the most dramatic reduction, a nearly four-fold reduction in the extent of seizure-induced cell death susceptibility, was expressed in ISCL-4 which carried a reduced B6-derived region of chromosome 18 on an FVB-derived susceptible background. In particular, seizure-induced excitotoxic cell death was significantly reduced in all hippocampal subfields (dentate hilus, area CA3, and area CA1) as compared with the FVB parental strain, the other ISCL strains, and the congenic strain (Figure 1). Consequently, the reduction in cell death may be attributed to the B6 alleles from this introgressed region. Moreover, the ISCL-4 strain further narrows the QTL interval to a small region of murine chromosome 18, and supports the proposition that the protective gene(s) is contained within this smaller interval – i.e., that ISCL-4 contains the putative gene(s) of the QTL for susceptibility to seizure-induced cell death.

As a means to verify that the reduced chromosome 18 locus significantly reduced susceptibility to KA-induced excitotoxic cell death, we took a candidate gene approach to identify the causal susceptibility gene(s) responsible for the effect. The genetic variation underlying this QTL could consist of polymorphisms in either the coding region (thus altering the amino acid sequence of the translated protein) or in the regulatory region (affecting expression of a gene). Among the many candidate genes present in this region, *galanin receptor 1* (*Galr1*) and *myelin basic protein* (*Mbp*) are the most compelling possibilities. Both of these genes have relevance to modulation of neuronal excitability and seizure threshold. To confirm the identity of any putative candidate genes, expression studies can be performed using qRT-PCR, and any gene expression differences observed would presumably be the result of changes in allele frequencies due to selection rather than a response to kainate treatment. We found that B6 mice, as well as the congenic mice carrying the B6-derived resistant allele at the region where *Galr1* is located on the FVB genetic background, showed significantly decreased basal hippocampal *Galr1* expression compared with the susceptible FVB control littermates. We speculate that the downregulation of *Galr1* observed in these mice supports its role as a modulator of neuronal excitotoxic cell death in the hippocampus.

Future Goals: Challenges for the Future

There are several inherent complexities in the investigation of genetic influences on protection against seizure-induced cell death. Firstly, epilepsy is a heterogeneous disorder characterized by variable clinical and pathological presentations. Thus, genetic dissection of such a

complex disease is a difficult task; there are likely to be contributions of several genes, each one exerting a small effect on the final phenotype. By definition, as most epilepsies are likely polygenic diseases, no single marker will ever allow a definitive diagnosis or certain risk prediction. However, it is hoped that specifiable combinations of such markers will be found, and will provide a reasonable basis for diagnosis or prognosis. Results of our work suggest that, although susceptibility to seizure-induced cell death may be affected by more than one locus, a few loci may account for much of the variation present in the trait of susceptibility at any given time.

Secondly, seizure-induced neuronal damage represents an extremely complex pathophysiological cascade of events that includes inflammation, oxidative stress, necrosis and apoptosis, calcium dysregulation, mitochondrial dysfunction, and excitotoxicity. As such, the factors resulting in damage associated with epilepsy are still largely undefined. Hypothesis-driven candidate gene studies are important, but with approximately 25 000 genes in the human genome it is often difficult to predict how variation in any one gene product will affect a particular phenotype. Thus, any attempt to link a gene with a specific pathophysiological occurrence that exerts influence on a specific disease or clinical outcome can be problematic. In the future, it will be of interest to determine the nature of DNA sequence variants, which give rise to alleles of quantitative effect, and eventually understand phenotypic evolution at the level of the individual loci. We have narrowed down the search for molecular variants responsible for quantitative genetic variation in susceptibility to seizure-induced cell death will; this work will provide a basis for further studies to estimate the frequency of these variants in different populations and species. Identified variants can also become key entry points from which to explore the network of genes, proteins, pathways, and systems important in the determination of susceptibility to seizure-induced excitotoxic cell death. Furthermore, as the presence of strong homologies between genes in mice and humans usually guarantee overlapping or even near identical functions, polymorphic genes in mice may also be polymorphic in humans.

Thirdly, the road from locus to gene identification can be difficult and cumbersome. It remains unclear whether the difficulty in moving from quantitative trait locus to quantitative trait gene is the result of complex gene-to-gene interactions (affecting gene expression throughout the genome), or is more reflective of the heterogeneous and complex nature of the epilepsy disorders (e.g., complex pathophysiology, large number of interacting proteins at different stages of the evolution of the disorder, etc.). Thus, future genetic research studies should focus on both 'top-down' approaches (such as genome scans) and 'bottom-up' approaches (such as candidate gene studies) to make sense of what is going on. As our understanding of gene function at present is too limited to let us predict a priori which genes are involved with a particular trait, a combined approach of mouse genetics and transcriptomics, together with studies involving humans patients with diverse epilepsy phenotypes, will yield the fastest progress.

Single Gene Mutations in Inherited and Sporadic Epilepsy

J Kearney, Vanderbilt University, Nashville, TN, USA
M Meisler, University of Michigan, Ann Arbor, MI, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy is a common neurological disorder affecting ~1% of the population. One-third of patients have an underlying physical cause such as trauma or stroke. For the remaining two-thirds of cases, no preexisting condition is recognized and these epilepsies are classified as 'idiopathic.' Genetic factors are thought to play a central role in idiopathic epilepsy. Common types of idiopathic epilepsy are likely to be polygenic, resulting from the combination of mild mutations in several different genes. A small proportion of epilepsies exhibits Mendelian inheritance and is caused by mutation of a single gene.

Background

We will review achievements of the past decade in identifying the molecular basis for many of the monogenic epilepsies. Identification of these genes relied heavily on tools generated by the Human Genome Project, including an abundance of markers for tracing the inheritance of diseases through large family pedigrees, and the complete human genome sequence for identifying positional candidate genes. The genes mutated in rare monogenic epilepsies define pathways that are also likely to play a role in the more common, polygenic epilepsies. Some of the identified epilepsy genes play important roles in neuronal signaling, including voltage-gated ion channels, neurotransmitter receptors, and ion channel-associated proteins (**Table 1**). We will examine the spectrum of single gene mutations and the mechanics leading to a common endpoint, the increased firing of excitatory neurons that underlies epileptic seizures.

Methods

Success in identification of genes responsible for monogenic epilepsies was obtained by classical genetic mapping in large families with inherited epilepsy. Examination of linkage with thousands of microsatellite markers and millions of SNP markers makes it possible to localize the disease gene in a large family to only a few megabases of DNA. Examination of the reference human genome sequence can then provide a list of candidate genes located within the regions of linkage, which can be amplified by PCR and sequenced to identify the pathogenic mutation. After potential disease-causing variants are identified, the effect on protein function must be determined, using functional assays specific for each candidate gene. Introduction of the human variant into the germ line of the mouse can be used to confirm the pathogenic effect. Ion channel mutations have been evaluated in transfected cells and in genetically engineered mice. Spontaneous mouse models have also been important in suggesting new candidate genes for human epilepsy.

Recent Results

Sodium Channel Mutations

Voltage-gated sodium channels are responsible for the initiation and propagation of action potentials in neurons. The sodium channel consists of a pore-forming α subunit and accessory β subunits that modulate activity. The α subunits are large transmembrane proteins (~2000 amino acids) containing four homologous domains, each with six transmembrane segments (**Figure 1**). The four domains surround a central, sodium-permeable pore through which sodium ions flow down their concentration gradient after depolarization of the cell membrane. β subunits contain an extracellular IgG loop, a single transmembrane segment, and a short intracellular C-terminus (**Figure 1**). Association with β subunits influences cell-surface expression and kinetics of the α subunit. There are nine human α-subunit genes and four β-subunit genes, encoding channel proteins that differ in tissue specificity and biophysical properties. Mutations in three of these genes have been associated with epilepsy, the α-subunit genes *SCN1A* and *SCN2A* and the β-subunit gene *SCN1B*.

SCN1B

In 1998, the first sodium channel mutation was identified in an Australian family with generalized epilepsy with febrile seizures plus (GEFS+), a mild, dominantly inherited disorder. This syndrome is characterized by febrile seizures that persist beyond 6 years of age and may progress to afebrile, generalized seizure types. Only three additional mutations of *SCN1B* have been reported since the first report. The effect of the *SCN1B* mutations in functional assays is reduction of sodium channel activity. This partial loss-of-function mechanism is supported by the observation that heterozygotes for a mouse knockout allele of *Scn1b* exhibit spontaneous seizures.

Table 1 Single gene mutations responsible for inherited epilepsy

	Gene	*Chromosome*	*Syndrome*	*OMIM ref*[a]
Voltage-gated ion channels	*SCN1A*	2q24	GEFS+, SMEI	182389
	SCN1B	19q13	GEFS+	600235
	SCN2A	2q24	BFNIS, GEFS+	182390
	KCNQ2	20q13	BFNS	602235
	KCNQ3	8q24	BFNS	602232
	CLCN2	3q27	IGE	600570
Neurotransmitter receptors	*CHRNA4*	20q13	ADNFLE	118504
	CHRNB2	1q21	ADNFLE	118507
	CHRNA2	8p21	ADNFLE	118502
	GABRG2	5q34	GEFS+, FS, CAE	137164
	GABRA1	5q34	JME, CAE	137160
	GABRD	1p36.3	GEFS+	137163
Others	*EFHC1*	6p12	JME	608815
	LGI1	10q24	ADPEAF	604619
	MASS1	5q14	FS	602851

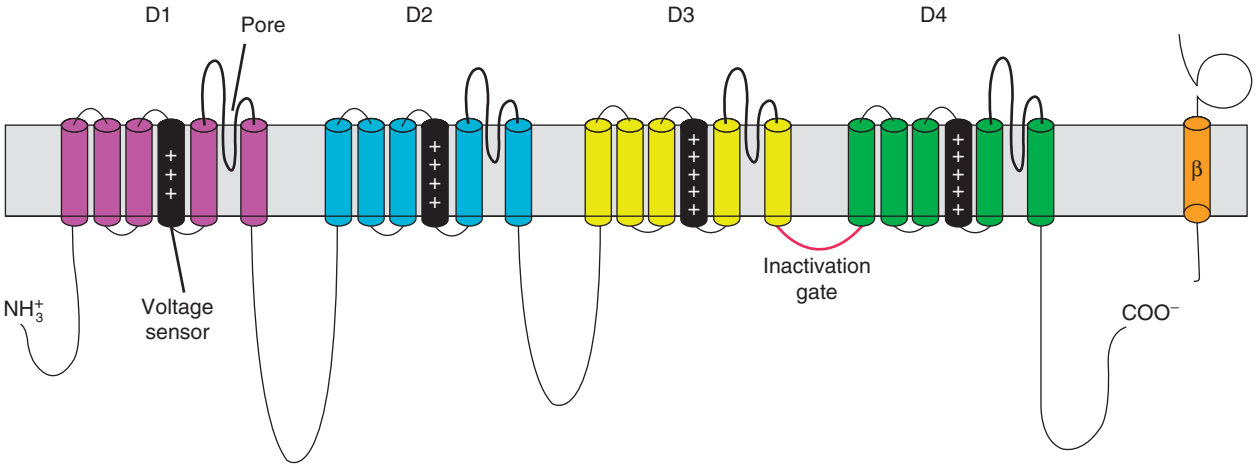

Figure 1 The sodium channel α and β subunits are transmembrane proteins. The four homologous domains of the α subunit are represented in different colors. Important functional domains are labeled.

SCN1A

In 1999, a second GEFS+ locus was mapped to chromosome 2q24 by linkage analysis in two large families. Our laboratory identified heterozygous *SCN1A* missense mutations in both families that change evolutionarily conserved amino acids: T875M in one family and R1648H in the other. Since 1999, 20 mutations of *SCN1A* in GEFS+ families have been reported (**Figure 2(a)**). Functional characterization of GEFS+ mutations in heterologous expression systems has revealed several different gain-of-function effects. The lack of a clear phenotype–genotype correlation may reflect the limitation of nonneuronal expression systems to evaluate mutations in neuronal sodium channel genes. The most reliable data on functional consequences of channel mutation can be obtained from recordings of neurons in mice engineered to carry human mutations.

In 2001, de Jonghe reported the surprising observation of *SCN1A* mutations in patients with a noninherited form of epilepsy, severe myoclonic epilepsy of infancy (SMEI). This infant-onset syndrome is characterized by generalized clonic, tonic–clonic, or hemiclonic seizures. In later life, patients may develop myoclonic, absence, or partial seizures. Poor response to antiepileptic drugs is common. Development is normal prior to onset, but disease progression is often accompanied by decline of psychomotor and mental development. Nearly 250 mutations of *SCN1A* have been identified in SMEI and borderline SMEI (SMEIb), accounting for the disease in ~70% of SMEI patients. SMEI mutations arise de novo in the affected child and are not present in the parents, with the exception of rare cases of parental mosaicism. The large proportion of SMEI patients with de novo mutations of *SCN1A* means that genetic screening of *SCN1A* is an effective diagnostic tool for children with SMEI.

Approximately half of SMEI mutations result in protein truncation due to nonsense, frameshift, or splice site

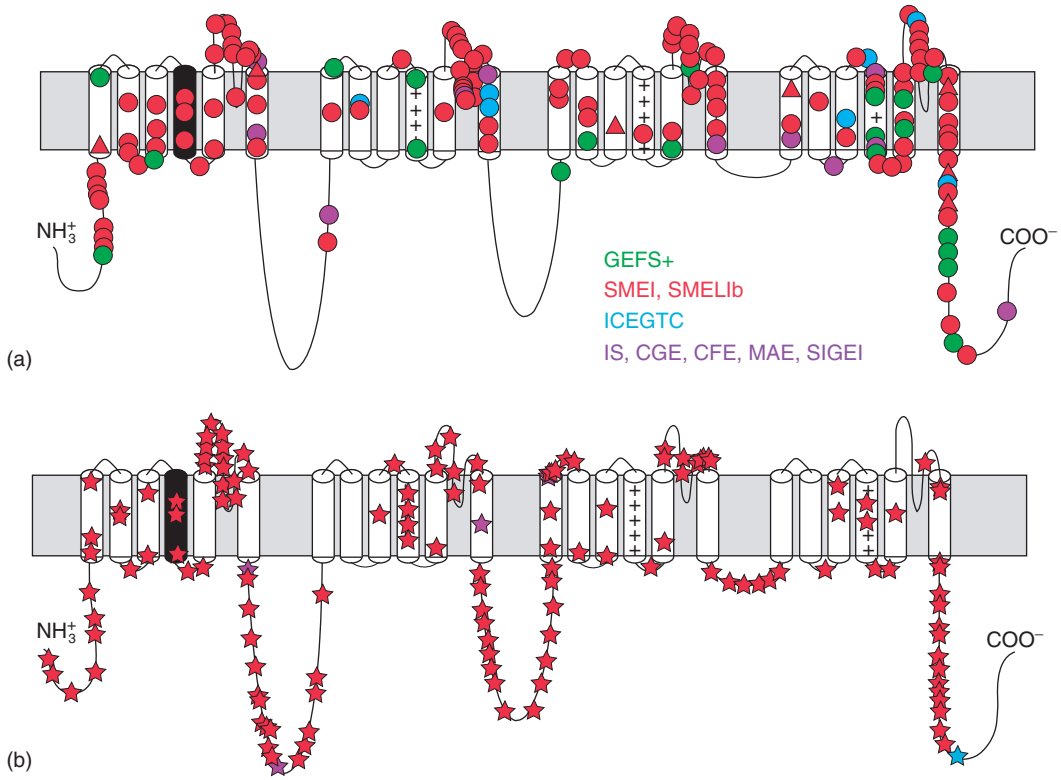

Figure 2 Epilepsy mutations in *SCN1A*. (a) Missense mutations (circles) and small in-frame deletions (triangles). (b) Truncations (stars) resulting from nonsense, splice site, and frameshift mutations. GEFS+, generalized epilepsy with febrile seizures plus; SMEI, severe myoclonic epilepsy of infancy, SMEIb, severe myoclonic epilepsy of infancy borderline; ICEGTC, idiopathic childhood epilepsy with generalized tonic–clonic seizures; IS, infantile spasms; CGE, cryptogenic generalized epilepsy; CFE, cryptogenic focal epilepsy; MAE, myoclonic astatic epilepsy; SIGEI, severe idiopathic generalized epilepsy of infancy.

mutations; these lesions are distributed throughout the protein domains (Figure 2(b)). Missense mutations of *SCN1A* in patients with SMEI are concentrated in the transmembrane segments of the protein, similar to GEFS+ mutations (Figure 2(a)). Deletions of individual exons and of the entire *SCN1A* gene have been reported. The large number of protein truncation alleles suggests that haploinsufficiency of *SCN1A* is responsible for the severe SMEI syndrome. Consistent with this model, mice heterozygous for a null allele of *Scn1a* exhibit spontaneous seizures and reduced lifespan. Recordings of cultured hippocampal neurons from these mice revealed reduced activity in inhibitory interneurons and normal activity in excitatory neurons, suggesting a cell-specific mechanism of reduced inhibitory input underlying seizures. Twenty missense mutations from SMEI patients have been characterized in mammalian expression systems, and 12 of these mutations lacked channel activity, consistent with a loss-of-function basis for this disorder.

A small number of *SCN1A* mutations have been identified in other types of infantile epilepsy, including idiopathic childhood epilepsy with generalized tonic–clonic seizures (ICEGTC), infantile spasms (IS), cryptogenic generalized epilepsy (CGE), cryptogenic focal epilepsy (CFE), myoclonic astatic epilepsy (MAE), and severe idiopathic generalized epilepsy of infancy (SIGEI) (Figure 2).

Vaccine-related encephalopathy and SCN1A

There has been considerable controversy regarding claims that routine vaccination can result in an encephalopathy syndrome that includes seizures and mental decline. Berkovic and colleagues recently tested DNA from patients who had been initially diagnosed with vaccination encephalopathy, due to seizure onset within 72 h of DPT or PT vaccination. Eleven of the 14 individuals tested were found to carry mutations of *SCN1A*. Two of the mutations have previously been seen in patients diagnosed with SMEI. In eight of these cases, parental samples were tested and found to lack the mutation, indicating that these were de novo mutations. The data indicate the fever associated with vaccination may have triggered the first episode of an underlying SMEI-like genetic disorder.

Neuronal specificity of SCN1A mutations

Neuron subtypes vary with regard to the relative level of expression of different ion channel genes. To explain the association of *SCN1A* mutations with hyperexcitability, it has been suggested that inhibitory interneurons might be

particularly dependent on this channel. In support of this hypothesis, recent immunohistochemical studies demonstrated that Nav1.1 is localized to the axon initial segments of parvalbumin-positive inhibitory interneurons in developing neocortex and hippocampus, while it has lower somatodendritic expression in excitatory pyramidal neurons. In *Scn1a* heterozygous null mice, a model for SMEI, inhibitory interneurons isolated from hippocampus displayed reduced current amplitude and reduced generation of action potentials, while excitatory pyramidal neurons did not differ from wild-type mice. In a mouse knockin model of the human SMEI mutation R1407X, Ogiwara *et al.* (2007) showed that parvalbumin-positive inhibitory neurons in neocortical slices displayed pronounced spike amplitude decrement during prolonged spike trains while neighboring pyramidal neurons did not differ from those in wild-type. These data demonstrate the importance of neuronal heterogeneity in determining the clinical manifestation of genetic mutations.

SCN2A

SCN2A is a sodium channel gene closely related to *SCN1A* and located in an adjacent position on chromosome 2q24. Since 2002, missense mutations of *SCN2A* have been identified in one patient with GEFS+ and nine patients with benign familial neonatal-infantile seizures (BFNIS), a syndrome of mild seizures that remit by the first birthday. Functional characterization of BFNIS mutations demonstrated gain-of-function effects that are predicted to increase sodium current and result in neuronal hyperexcitability. One truncation mutation of *SCN2A* was found in a patient with intractable epilepsy and mental decline, similar to SMEI. The mouse model Q54 carries a missense mutation of *Scn2a* that increases neuronal excitability and results in epilepsy. The dramatic loss of hippocampal neurons in the Q54 mouse after the onset of seizures resembles hippocampal sclerosis in patients with mesial temporal lobe epilepsy. The influence of strain background on the severity of seizures in Q54 mice is being used to identify genetic modifiers that could play a role in human epilepsy.

Potassium Channel Mutations

The potassium channels encoded by the genes *KCNQ2* and *KCNQ3* combine to form a heteromultimeric potassium channel responsible for M current. This neuronal current maintains the resting potential of the neuron and limits repetitive firing. Mutations in *KCNQ2* and *KCNQ3* were first reported in 1998 in families with benign familial neonatal seizures (BFNS), a mild, autosomal dominant disorder of generalized seizures during the first few days of life that remit within months. More than 60 mutations of *KCNQ2* have been identified in BFNS families, as well as a few de novo mutations in sporadic cases. Half of *KCNQ2* mutations lead to protein truncation, and exon duplications and deletions have been reported. Only four mutations in *KCNQ3* have been observed. The loss-of-function mutations of *KCNQ2* and *KCNQ3* in BFNS result in reduced M current, increased repetitive firing, and neuronal hyperexcitability.

Acetylcholine Receptors

The nicotinic acetylcholine receptor (nAChR) is a pentameric complex with three α and two β subunits. These presynapatic ligand-gated channels regulate excitatory neurotransmitter release. Mutations in the nAChR subunits *CHRNA4*, *CHRNB2*, and *CHRNA2* have been identified in families with autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). This disorder is characterized by partial seizures originating from the frontal lobe that occur during nonrapid eye movement sleep. Analysis of ADNFLE mutations demonstrated reduction in the calcium dependence of acetylcholine release, leading to excess excitatory signaling.

GABA Receptors

GABA is the primary inhibitory neurotransmitter in the brain. The $GABA_A$ receptors are pentamers typically composed of two α subunits, two β subunits, and one γ, δ, ε, or π subunit. The subunits assemble to form a chloride-selective central pore. Upon binding GABA, the channel opens and the rapid increase in chloride conductance suppresses depolarization, resulting in reduced firing of neurons. Mutations in *GABRG2*, *GABRA1*, and *GABRD* have been reported in GEFS+, juvenile myoclonic epilepsy (JME), and childhood absence epilepsy (CAE). Several mutations result in loss of function of the $GABA_A$ receptor, leading to reduced inhibition and net hyperexcitability.

Chloride Channels

CLCN2 encodes the voltage-gated chloride channel ClC-2, which is expressed in neurons that are postsynaptic to GABAergic inhibitory synapses. Maintenance of a low intracellular chloride concentration by ClC-2 is necessary for the inhibitory response to GABA. Mutations in *CLCN2* have been associated with several idiopathic generalized epilepsy (IGE) subtypes, including JME, CAE, and EGMA (epilepsy with grand mal upon awakening). However, in families with monogenic IGE, there is variable expressivity, suggesting that genetic modifier alleles may influence the clinical phenotype. Functional studies of *CLCN2* mutations indicate that reduced ClC-2 function

leads to hyperexcitability of the cell postsynaptic to GABAergic synapses.

LGI1

LGI1 (leucine-rich, glioma-inactivated 1) is a subunit of the presynaptic voltage-gated potassium channel (Kv1) complex. Mutations in *LGI1* are found in autosomal dominant partial epilepsy with auditory features (ADPEAFs), with auditory simple partial seizures with onset in the second or third decade of life. Loss of function of *LGI1* results in elevated rapid inactivation of the Kv1 channel, prolonged action potentials, and neuronal hyperexcitability.

EFHC1

The EFHC1 protein contains a Ca^{2+}-sensing EF-hand motif and modulates R-type calcium current by interaction with the C-terminus of Ca(v)2.3. Mutations of EFHC1 have been identified in nine families with JME. The mechanism for seizure induction is not clear.

MASS1/VLGR1

MASS1 (monogenic audiogenic seizure-susceptible) was first identified by positional cloning of the mouse *Frings* mutant with audiogenic seizure susceptibility. *MASS1* encodes a calcium-binding seven transmembrane G-protein-coupled receptor, designated VLGR1 (very large G-protein coupled receptor). A nonsense mutation in *MASS1* was found in one family with febrile and afebrile seizures. The relationship to neuronal firing is not clear.

Future Goals

A major goal of future research will be to determine the role of these monogenic disease genes in common varieties of epilepsy. This determination will require large-scale genomic sequencing in patients with sporadic, nonfamilial disease. In a test of large-scale 'medical re-sequencing' in progress at the Baylor Genome Center, exons from 250 channel genes are being sequenced in epilepsy patients and controls. This project previews the type of diagnostic testing that is likely to become available within the next 5 years, replacing single gene analysis with a comprehensive evaluation of the overall channelome in each new patient with a seizure disorder.

The 'channelome,' the total ion channel content of a specific neuron, determines neuronal excitability and firing patterns. From a systems biology perspective, it is becoming apparent that neuronal firing patterns are determined by the sum of genetic variation at all of the ion channels expressed within each neuron subtype. Two recent examples illustrate the interaction between genetic variation affecting different ion channel genes that are expressed in the same cells. In one case, mice were generated that carried two subclinical mutations, one in *Kcnq2* (V182M) and one in *Scn2a* (Q54); the combination resulted in severe, early onset seizures. In another case, seizure severity was *reduced* when a pathogenic mutation in *SCN1A* was combined with heterozygosity for a null allele of *Scn8a*. The differences in the channel content of different types of neurons discussed earlier underlie these examples. Null alleles of *Scn1a* reduce the activity of inhibitory interneurons in the hippocampus, while null alleles of *Scn8a* have a greater effect on the activity of excitatory neurons. Similarly, mutations in the related channel *SCN9A* have different impact in DRG and visceral sensory neurons, due in part to the expression of *SCN10A* in the DRG neurons only. In the future, newly diagnosed patients with seizure disorders will be genotyped for hundreds of candidate genes, and individualized therapies tailored to the overall channelome will become possible.

Introduction

Inbred strains of mice have long been established to provide research scientists with standardized tools for designing and conducting a wide variety of experiments related to human health and disease. The fundamental characteristics of inbred mouse strains not only facilitate studies of biological processes in whole organisms, but also provide a means to understand the complex genetic architecture that contributes to the determination of their anatomy, physiology, and behavior. It is hypothesized that aspects of genetic influence on complex traits and behaviors of mice – as they are mammals – are relevant to those of humans. And despite the obvious limitations inherent in extrapolations from mouse to man, numerous examples of important associations between mice and men have been documented with respect to genetics and behavior.

Background

C57BL/6J and DBA/2J Mice

Of all of the many mouse strains that have been used to study experimental seizure susceptibility, none has been used more extensively than the C57BL/6J (B6) and DBA/2J (D2) inbred strains. B6 is the most common inbred strain of mice used for research (as measured by literature citations) and was used to generate the publicly available sequence of the mouse genome. D2 was the first inbred strain established and remains one of the most important strains of mice utilized for research purposes. Thus, these two inbred mouse strains hold special importance among the larger panel of common mouse strains used in biomedical research.

The robust difference in seizure susceptibility between B6 and D2 mice was first evidenced over 60 years ago. By measuring the propensity of mice to experience a maximal seizure (defined essentially as involving tonic extension of hind limbs) in response to a loud sound, it was shown that D2 mice exhibit a very high degree of susceptibility relative to B6. An electrophysiological correlate of this so-called 'audiogenic' seizure can be demonstrated through measurements of auditory-evoked brainstem potentials, which showed greater neuronal recruitment to acoustic stimuli in higher-order auditory brain centers of D2 mice compared to B6. Initial studies of audiogenic seizures were extended to show that the susceptibility of D2 mice is influenced significantly by age, with animals becoming resistant to audiogenic seizures by the time they are 3–4 weeks old. A confounding factor in testing susceptibility to audiogenic seizures is age-related hearing loss, a strain-specific phenomenon that occurs early in life in D2 mice compared to B6. Importantly, however, while D2 mice acquire resistance to audiogenic seizures with age, they remain more susceptible to most other forms of experimentally induced seizures compared to B6 mice (as well as many other inbred strains). Such experimentally induced seizures include those induced by pentylenetetrazol (PTZ) and electroshock stimulation, as well as other physical methods of seizure induction such as elevated atmospheric pressure. Comparisons of adult B6 and D2 mice with regard to their seizure susceptibility have documented differential strain responses to a wide variety of chemical convulsants, including drugs that diminish GABAergic activity such as bicuculline and PTZ, and drugs that enhance glutamatergic activity such as kainic acid (KA) and NMDA. D2 mice are also more susceptible than B6 to seizures induced by less conventional chemoconvulsants such as beta-carobolines. Taken together, studies of acute seizure susceptibility suggest that there are fundamental differences in the regulation of neuronal excitability between B6 and D2

Introduction

Inbred strains of mice have long been established to provide research scientists with standardized tools for designing and conducting a wide variety of experiments related to human health and disease. The fundamental characteristics of inbred mouse strains not only facilitate studies of biological processes in whole organisms, but also provide a means to understand the complex genetic architecture that contributes to the determination of their anatomy, physiology, and behavior. It is hypothesized that aspects of genetic influence on complex traits and behaviors of mice – as they are mammals – are relevant to those of humans. And despite the obvious limitations inherent in extrapolations from mouse to man, numerous examples of important associations between mice and men have been documented with respect to genetics and behavior.

Background

C57BL/6J and DBA/2J Mice

Of all of the many mouse strains that have been used to study experimental seizure susceptibility, none has been used more extensively than the C57BL/6J (B6) and DBA/2J (D2) inbred strains. B6 is the most common inbred strain of mice used for research (as measured by literature citations) and was used to generate the publicly available sequence of the mouse genome. D2 was the first inbred strain established and remains one of the most important strains of mice utilized for research purposes. Thus, these two inbred mouse strains hold special importance among the larger panel of common mouse strains used in biomedical research.

The robust difference in seizure susceptibility between B6 and D2 mice was first evidenced over 60 years ago. By measuring the propensity of mice to experience a maximal seizure (defined essentially as involving tonic extension of hind limbs) in response to a loud sound, it was shown that D2 mice exhibit a very high degree of susceptibility relative to B6. An electrophysiological correlate of this so-called 'audiogenic' seizure can be demonstrated through measurements of auditory-evoked brainstem potentials, which showed greater neuronal recruitment to acoustic stimuli in higher-order auditory brain centers of D2 mice compared to B6. Initial studies of audiogenic seizures were extended to show that the susceptibility of D2 mice is influenced significantly by age, with animals becoming resistant to audiogenic seizures by the time they are 3–4 weeks old. A confounding factor in testing susceptibility to audiogenic seizures is age-related hearing loss, a strain-specific phenomenon that occurs early in life in D2 mice compared to B6. Importantly, however, while D2 mice acquire resistance to audiogenic seizures with age, they remain more susceptible to most other forms of experimentally induced seizures compared to B6 mice (as well as many other inbred strains). Such experimentally induced seizures include those induced by pentylenetetrazol (PTZ) and electroshock stimulation, as well as other physical methods of seizure induction such as elevated atmospheric pressure. Comparisons of adult B6 and D2 mice with regard to their seizure susceptibility have documented differential strain responses to a wide variety of chemical convulsants, including drugs that diminish GABAergic activity such as bicuculline and PTZ, and drugs that enhance glutamatergic activity such as kainic acid (KA) and NMDA. D2 mice are also more susceptible than B6 to seizures induced by less conventional chemoconvulsants such as beta-carobolines. Taken together, studies of acute seizure susceptibility suggest that there are fundamental differences in the regulation of neuronal excitability between B6 and D2

mice. This hypothesis is supported by behavioral studies that test aspects of neuronal excitability such as acoustic startle responses, which are more readily elicited in D2 mice compared to B6. Interestingly, in contrast to results with other drugs, B6 mice have been reported to be more susceptible than D2 with respect to seizures induced by the administration of cocaine.

Brain Structure and Function

Given the robust difference in susceptibility to experimental seizures that has been documented between B6 and D2 mice, many studies have been based on the hypothesis that insight into mechanisms of seizure susceptibility will be gained by comparing parameters of brain structure and function between the two strains. Thus, over the years, numerous anatomical, physiological, and biochemical studies have been conducted using B6 and D2 mice. These are summarized to indicate their scope and allow an appreciation of the general nature of the differences observed.

Adenosine triphosphatases

One of the first clues to a potential mechanism involved in B6 and D2 seizure susceptibility came from studies of the fundamentally important brain enzyme system, Na-K-ATPase. Early work documented lower brain levels of Na-K-ATPase in both juvenile (21-day-old) and adult (110-day-old) D2 mice compared to same-age B6 mice. Two other related cellular enzyme activities, carbonic anhydrase and HCO_3-ATPase, distinguish juvenile B6 and D2 mice, but are equivalent in older mice, suggesting a potential relevance specifically to changes in audiogenic seizure sensitivity in D2 mice. Strain differences in Na-K-ATPase function are also observed in response to the anticonvulsant drug phenytoin, further supporting a potential relationship of this enzyme to strain differences in neuronal excitability. However, despite some promising leads, a clear mechanistic association between ATPase activities and seizure susceptibility in B6 and D2 mice has not been forthcoming.

Neurotransmitters

Differential function of neurotransmitters may play a role in strain-specific seizure responses and measures of all the major neurotransmitter systems of B6 and D2 mice have been compared at some level. However, the nature of this work has been largely correlative and the cause/effect studies between brain neurochemistry and seizure susceptibility are lacking. Temporal and spatial resolutions of neurochemical analyses have been a major limiting factor as well. Nonetheless, many neurochemical differences have been documented between B6 and D2 mice and it is possible that some of them reflect differences in seizure susceptibility. Such differences, summarized below, may be used ultimately to validate future studies of the mechanism.

Acetylcholine

With respect to cholinergic neurotransmission, significant strain differences have been reported in acetylcholine turnover and cholinergic receptor binding. Also, significantly fewer forebrain cholinergic neurons are present in B6 compared to D2 mice, a finding that has been investigated more in relation to strain differences in learning and in responsiveness to antipsychotic drugs than to seizure susceptibility. Nonetheless, the role of differential cholinergic function in the determination of differential B6 and D2 seizure responses cannot be excluded on the basis of available data.

Glutamate and GABA

Amino acid neurotransmitter function has long been documented to play a role in neuronal excitability and the generation of seizure activity. Studies of glutamatergic systems have revealed profiles of brain kainate and AMPA receptor binding that show several minor but significant differences between adult B6 and D2 mice in the striatum and cortex, with more major strain differences in glutamate receptors being associated with aging. However, despite comprehensive receptor profiling, the involvement of glutamate receptors in differential strain seizure susceptibility is not established. GABAergic systems have also been studied in several ways in B6 and D2 mice and have also been suggested to be involved in strain-specific seizure susceptibility. However, the analysis of GABA receptor binding has yielded conflicting results, with some studies reporting similar measures between the strains and others reporting differences. Minor differences in GABA levels, GABA uptake processes, and GABA turnover have also been reported. Nonetheless, as is the case with glutamate, it has not been firmly established whether any of these differences in parameters of GABAergic function are relevant to strain-specific seizure susceptibility. The prominent role of glutamate and GABA in determining neuronal excitability supports the need for additional investigation of these neurotransmitter systems in B6 and D2 mice.

Monoamines

Extensive comparisons have been made of the three main monoamine neurotransmitters in the central nervous system, serotonin, norepinephrine, and dopamine, between B6 and D2 mice; however, like studies of the other neurotransmitter systems, they have not led to a unifying hypothesis regarding the neurochemical basis of differential seizure susceptibility. The strains have similar serotonergic system profiles, although there is evidence that cortical serotonin receptor density distinguishes them and it is possible that this is related to differences in seizure susceptibility. Noradrenergic systems are also characterized by a few minor but statistically significant differences between strains. However, of all the major neurotransmitters, the system that best distinguishes B6

and D2 strains is the dopamine system. There are many differences between B6 and D2 mice reported for parameters of dopaminergic neurotransmission, including immunohistochemical measures of the dopamine transporter protein, the vesicular monoamine transporter type 2 protein, and tyrosine hydroxylase. Such differences are consistent with reported dopaminergic underactivity throughout the brain in B6 mice relative to D2. Although strain differences in dopaminergic measures have been suggested to influence strain-specific behavior related to drugs of abuse such as cocaine and ethanol, there is as yet no direct evidence for influences on seizure susceptibility.

Cell culture

Insight gained from whole animal studies has been supplemented through the use of in vitro methodologies. In one approach, cultured astrocytes from B6 and D2 mice have been used to examine basic parameters of cell function and have revealed higher sodium and chloride levels in astrocytes derived from B6 mice compared to those derived from D2. In vitro studies using cultured astrocytes also confirm higher Na-K-ATPase activity in B6 compared to D2 mice, but show further that these differences may not be sufficient to produce fundamental differences in cell activity. A novel potential mechanism with respect to seizure susceptibility emerged during the study of polyamine uptake and catabolism to GABA, which when altered, differentially influences the GABA/glutamate ratio, and thus potentially, the balance of excitation and inhibition, in B6 and D2 mice.

Neuroanatomy

Anatomical differences in the brain have also been documented between B6 and D2 mice and it is possible that such factors may be involved in determining differential seizure thresholds. Studies of brain size suggest both gross and microscopic strain differences. Thus, B6 mice have larger brains than D2 mice and they also have thicker layers in the cerebellum. Region-specific differences between B6 and D2 mice have also been documented with regard to anatomical features of the hippocampus and olfactory bulbs. Strain differences in long-term potentiation have been reported and suggested as functional correlates of differences in hippocampal and amygdalar architecture. Functional studies based on the audiogenic seizure phenotype have uncovered strain differences in the amplification of signals at different levels in the auditory pathway. These alterations may be related to morphological changes that occur both peripherally and centrally.

Hippocampus

The special role of the hippocampus in the control of seizure activity has focused considerable attention on this brain region in B6 and D2 mice. Differences in levels of hippocampal signal transduction molecules such as protein kinase C exist between B6 and D2 mice, but they have not been associated directly with differences in seizure susceptibility. Hippocampal slice electrophysiology is generally consistent with relative strain susceptibilities reported in vivo such that application of KA produces bursts of high frequency repetitive spikes in CA1 neurons in slices from juvenile D2 mice, whereas only single spikes are elicited from B6 CA1 neurons. Responses of CA1 neurons in slices from adult B6 and D2 mice are similar upon exposure to KA; however, measures of CA1 responses to a wider variety of chemical stimuli including glutamate, NMDA, and potassium show differences between the strains for both juveniles and adults. Measures of synaptic potentiation reveal that D2 mice have a significantly reduced paired-pulse inhibition of the population spike (a measure of polysynaptic inhibitory feedback) within the dentate gyrus and also show a deficit in the maintenance of potentiation of EPSP and population spikes compared to B6.

Genetic Studies

As can be appreciated from the sections above, considerable research effort has been expended to gain an insight into the neurobiology of differential seizure susceptibility in B6 and D2 mice through direct comparisons of various phenotypic traits. Limited insight has been gained into the biology of seizure mechanisms using this research strategy; however, the correlative nature of such studies does not permit the establishment of cause and effect relationships. Further restrictions imposed by the lack of resolution at both cellular and developmental levels also contribute to the limitations of previous phenotypic studies. Identification of the genetic determinants of a phenotypic trait provides direct insight into the biological mechanisms of trait expression. Unlike studies that are focused on specific transmitters, brain regions, or pathways, genetic studies using B6 and D2 mice offer unbiased opportunities to identify key molecules and systems that specifically define differences in seizure susceptibility.

One of the earliest studies of genetic influences on the difference in seizure susceptibility between B6 and D2 mice was based on a test involving the exposure of animals to environments in which the atmospheric pressure is gradually increased and a generalized seizure is thus elicited. In such a paradigm, susceptibility of 5–10-week-old D2 mice relative to B6 mice was modeled using classical genetic crosses between the strains, and shown to result from the influence of multiple genetic loci, one of which was suggested to have a major effect. Characterization of the model as polygenic prompted a quantitative trait loci (QTL) mapping study, the results of which localized one of the genes involved to a segment of chromosome 17 near the histocompatibility complex. Although the high atmospheric pressure model of seizures

has not been pursued, genetic analysis of other seizure phenotypes in B6 and D2 mice based on QTL mapping has proved to be a valuable means to exploit this animal model in the interest of gaining direct insight into the biology of seizure susceptibility.

Methods

QTL mapping is a method utilized to define the general chromosomal position of genes or genetic variants that influence the magnitude of a measurable trait. Most measurable or quantitative traits are considered complex in that they are determined by the influence of multiple genes that function independently and that also interact with each other and with the environment. Conceptually, mapping genes for complex traits is straightforward, involving correlation between trait values and genotypes at DNA markers spaced evenly at intervals across the genome (in individual organisms from a genetically variable population). However, in practice, many factors influence the likelihood of successful mapping, which is gauged not only by the detection of QTLs but also more importantly by the identification of underlying quantitative trait genes (QTGs). It is noteworthy that while QTLs have been mapped for hundreds of multifactorial traits in mice, only recently have some of these QTLs been resolved at the level of single genes. QTL methods are optimized if initial mapping populations are derived from a pair of inbred strains whose respective trait values are extremely discordant, residing at opposite ends of the phenotypic continuum – such as is the case with seizure susceptibility traits in B6 and D2 mice. This condition increases the likelihood that genes of detectable effect are involved and can be identified using currently available methods. Thus, in this sense, the B6 and D2 strains are an ideal pair for use in QTL mapping studies of seizure susceptibility.

Recent Results

QTL Mapping Studies

Audiogenic seizures

Similar to the high atmospheric pressure seizure phenotype described above, audiogenic seizure susceptibility in B6 and D2 mice has also been characterized as a polygenic trait. The rudimentary nature of mouse genetic maps in use at the time of early QTL studies did not allow comprehensive genome analysis. Thus, initial mapping was based on studies of a panel of BXD RI strains in which the strain distribution pattern at a relatively small number of DNA markers and gene variants (and at several other loci where genotype was inferred from the analysis of other traits unrelated to seizures) was correlated with audiogenic seizure susceptibility. Using this approach, genetic influences on audiogenic seizure susceptibility are shown to arise from chromosomes 4 and 12 (**Table 1**). Interestingly, Ca-ATPase activity, which is inversely correlated with audiogenic seizure susceptibility, is also linked to these loci. As no genes encoding Ca-ATPase subunits are located on either chromosome 4 or 12, the 'audiogenic seizure prone' (Asp) loci may involve an effect on regulation of gene expression from a trans-acting factor. Alternatively, it is possible that regulation of Ca-ATPase activity is an indirect or 'downstream' functional effect of the locus. Full dissection of audiogenic seizure susceptibility in immature B6 and D2 mice awaits completion, and thus, specific causative genetic variation remains to be identified in this seizure model.

Pharmacological studies

Most of the genetic studies in B6 and D2 mice have focused on paradigms involving the use of pharmacological agents to elicit seizures and quantify seizure susceptibility. Two general types of approaches have been utilized as screening tools in this regard. One involves scoring mice for seizure susceptibility following systemic administration of traditional convulsant agents such as KA and PTZ. The other involves scoring mice for susceptibility to withdrawal seizures induced by handling, following systemic administration of central nervous system depressants such as ethanol and barbiturates. A major difference between these pharmacological models and the audiogenic model is that the former involve study of adult mice whereas the latter involves juveniles.

The first full genome scan conducted to map loci for susceptibility to chemoconvulsant seizures utilized a population of B6 × D2 F2 intercross mice and challenged them with a single injection of KA. Two sets of QTLs are revealed by this paradigm. The first set is 'susceptibility' loci – that is, loci that influence whether or not mice will experience a KA-induced seizure – and the second set is 'severity' loci – that is, loci that influence the magnitude of the seizure response in mice that exhibit KA-induced seizures. The strongest locus in the model, which accounts for the greatest amount of the genetic variance, is in the telomeric region of chromosome 1 (**Table 1**). As expected, greater susceptibility is associated with the D2 allele. Susceptibility loci of weaker effect exist on chromosomes 4, 5, 11, 15, and 18 with susceptibility from chromosomes 4 and 11 arising somewhat unexpectedly from B6. Seizure severity loci are harbored on chromosomes 5, 7, and 15 (**Table 1**) with greater severity at the first two of these loci also associated with B6 alleles.

QTLs that influence 'ethanol-withdrawal' seizures in B6 and D2 mice are detectable on chromosomes 1, 4, and 11 by scoring hybrid progeny for seizures induced by handling the mice 2–12 hours following a single high dose of ethanol. This is consistent with QTLs for KA seizure susceptibility in that there is an overlap between confidence intervals for the chromosome 1 and 4 KA and ethanol withdrawal QTLs, and in that the susceptibility

[a]QTLs are included if they meet criteria for genome-wide significance (Lander and Kruglyak, 1995) or if there is a correspondence of suggestive QTLs from multiple studies.
[b]QTL position refers to the position of the most significant single marker analyzed in the original genome scan or the position given to the QTL in the public database at http://www.informatics.jax.org/.
[c]This QTL was mapped in a cross of A/J and D2 inbred strains.

allele on chromosome 1 is D2-derived and that on chromosome 11 is B6-derived. Like the KA QTL, the chromosome 1 QTL effect is robust for ethanol withdrawal seizures and none of the other loci have larger effects. It is possible that KA and ethanol QTLs on the telomeric aspect of chromosome 1 represent the same genetic influence. The chromosome 4 ethanol withdrawal QTL overlaps the chromosome 4 KA QTL; however, it is derived from the D2 strain suggesting a distinct genetic factor and/or mechanism. Contrary to the correspondence observed between the location of the KA and ethanol QTLs on chromosomes 1 and 4, the location of the QTLs on chromosome 11 are somewhat different, being centromere for ethanol withdrawal and telomeric for KA (Table 1). These findings suggest that the chromosome 11 QTLs for KA and ethanol are mediated by independent influences. Other provisional QTLs for handling-induced ethanol withdrawal seizures map to chromosome 2 (Table 1).

Confidence intervals of QTLs that mediate differences between B6 and D2 mice in susceptibility to PTZ-induced seizures overlap with those for KA and ethanol handling-induced (Table 1). Importantly, the strongest genomic influence localizes again to the telomeric region of chromosome 1, corresponding closely with the position of KA and ethanol QTLs. Other significant and suggestive QTLs for PTZ seizures map to chromosomes 1 (centromeric), 3, 4, 5, 6, and 18. Loci on chromosomes 5 and 18 overlap with and show inheritance patterns consistent with those reported in the KA screen (Table 1). The position and inheritance pattern of the chromosome 4 QTL are consistent with the locus detected in the ethanol withdrawal screen (Table 1).

Another withdrawal model utilizes a phenotype based on handling-induced seizure severity quantified following injection of pentobarbital. Applying this model to BXD RI strains, B6 × D2 F2 intercross mice and short-term selection lines permitted mapping of another series of seizure susceptibility QTLs. Like other pharmacological studies, the strongest influence in pentobarbital screens localizes to the telomeric region of chromosome 1 (Table 1) suggesting that it represents the effect of the same genetic variation detected in screens with KA, PTZ, and ethanol. In addition, QTLs for pentobarbital withdrawal seizure susceptibility on chromosomes 2, 4, and 11 overlap with those from paradigms described above. The chromosome 2 QTL intervals (centromeric and telomeric) overlap with QTLs from the ethanol screen, the chromosome 4 QTL interval overlaps with QTLs from the PTZ and ethanol screens, and the chromosome 11 QTL interval overlaps with QTLs from the KA and ethanol screens (Table 1). Thus, there is overall good correspondence between mapping results involving phenotypes based on the susceptibility of B6 and D2 mice to chemically mediated seizures. However, an important caveat, is that the overlap of QTL intervals between studies conducted with different but related paradigms does not guarantee that the influence of the same genetic variation is operative at each such locus, even when the studies utilize the same strains of mice.

Electroshock seizure threshold

Potentially confounding factors in the use of drugs to enhance the excitability of the nervous system and predispose to seizure activity relate to pharmacokinetics. Issues of drug disposition within whole animals may include some that are specific to particular drugs and some that are relevant to multiple drugs. A QTL mapping procedure for seizure susceptibility that circumvents the use of pharmacological agents involves measurement of electrical seizure threshold. Interestingly, QTLs for maximal electroshock seizure threshold (MEST) in B6 and D2 mice map to some of the same regions of the genome as identified in pharmacological studies. Most notably, as in studies that utilize drugs to study seizure susceptibility, a telomeric chromosome 1 locus explains the greatest amount of the variance and represents the prime genetic determinant of the large difference between MEST in B6 and D2 mice. Statistically significant MEST QTLs also exist on chromosomes 2, 5, and 15 in regions that overlap with QTLs detected in the pharmacological screens. With regard to chromosome 15, two significant MEST QTLs exist, one closer to the centromere and the other closer to the telomere. The centromeric locus overlaps closely with a chromosome 15 QTL detected in the KA screen (Table 1). The MEST QTL on chromosome 5 overlaps with chromosome 5 QTLs detected in the KA and PTZ screens; however, the susceptibility allele for the MEST chromosome 5 QTL is contributed by the D2 strain whereas the QTL for susceptibility to KA and PTZ seizures is contributed by B6, suggesting that they reflect the effects of different gene variants and/or mechanisms. Finally, the centromeric chromosome 2 QTL for MEST overlaps roughly with QTLs detected in screens involving ethanol and pentobarbital, as does the telomeric chromosome 2 QTL; however, susceptibility at the latter is contributed by B6 for MEST but by D2 for the depressant drugs (Table 1).

Genetic Studies: QTL Confirmation and Analysis

The polygenic determinism of the seizure paradigms applied to B6 and D2 mice involves QTLs that are shared by virtue of overlapping genetic map positions between all or several of the paradigms, as well as QTLs that appear to be specific for individual paradigms. Regarding shared QTLs, the hypothesis that the same genetic variants influence responsiveness in different kinds of seizure screens allows QTLs to be prioritized for further analysis since genes whose variation influences diverse seizure phenotypes may encode proteins that play a fundamental role in neurotransmission and may be most relevant to the initiation and/or propagation of seizure activity. This perspective

has provided the impetus for creating specialized congenic strains to analyze seizure QTLs in B6 and D2 mice. As described below, significant progress has been made towards identifying the genes and their variation that underlie seizure related QTLs on chromosomes 1 and 4; however, it is apparent that these influences together explain only a portion of the overall difference in seizure susceptibility and that more influences remain to be identified.

Congenic strain studies

Several seizure susceptibility QTLs mapped in the B6 and D2 model have been confirmed by creating and studying strains of mice that are congenic between B6 and D2, that is, strains in which a defined segment of the genome (representing the QTL interval) is transferred from one strain to the other via standard backcrossing and DNA marker-based selection of progeny. QTLs are confirmed when transfer of the genomic segment produces a predictable alteration in the phenotype of the congenic strain. Such predicted phenotypic changes have been documented by using congenic strains to study seizure-related QTL intervals on chromosomes 1, 4, and 5 – regions of the genome that have been shown to harbor B6–D2 seizure-related QTLs in multiple studies employing diverse experimental seizure screens (**Table 1**). The QTL on chromosome 11 has been further dissected and confirmed by haplotype analysis in a hybrid population of D2 and D1 strains of mice; however, direct confirmation of this locus in the B6–D2 model has not been reported.

Chromosome 4 QTL

The chromosome 4 QTL has been confirmed and narrowed to a 1 cM segment of DNA using a series of interval-specific congenic strains assessed with screens for ethanol and pentobarbital withdrawal seizure susceptibility. Analysis of genes within the critical interval has led to the nomination of variation in the promoter sequence of *Mpdz* as the cause of the effect. The *Mpdz* promoter sequence variation is associated with responsiveness to a variety of chemoconvulsants and with mRNA and protein expression across a panel of inbred strains. The product of the *Mpdz* gene belongs to a large family of proteins that have a PDZ domain. The PDZ domain is a common structural domain of 80–90 amino-acids found in the signaling proteins of bacteria, yeast, plants, and animals. PDZ is an acronym combining the first letters of three proteins – postsynaptic density protein (PSD95), *Drosophila* disc large tumor suppressor (DlgA), and zonula occludens-1 protein (zo-1) – which were the first discovered to share the domain. PDZ-domain proteins have diverse cellular functions related to molecular trafficking, anchoring of transmembrane proteins to the cytoskeleton, and maintenance of signaling complexes. It is not yet established how Mpdz variation, or differential expression of the Mpdz protein, influences seizure susceptibility in the B6 and D2 model.

Chromosome 1 QTL

The telomeric chromosome 1 QTL has also been dissected and refined using a series of congenic strains that have overlapping segments of the critical interval. Refinement of the QTL map position helped to identify a non-synonymous SNP in the inward-rectifier potassium channel gene *Kcnj10*, and this led to the nomination of *Kcnj10* as the QTG at the telomeric chromosome 1 locus. *Kcnj10* encodes an inward rectifier potassium channel subunit that is highly expressed in glial cells that are responsible for buffering extracellular potassium in the nervous system during action potential firing. The Thr(B6)262Ser (D2) protein coding substitution occurs in the C-terminal portion of the protein that is critical for determining channel density in the cell membrane as well as the appropriate clustered pattern of distribution. Bacterial artificial chromosome (BAC)-mediated transfer of a construct containing the B6 allelic version of *Kcnj10* (and five other tightly-linked genes) increases MEST and thus can 'rescue' a seizure-susceptible phenotype (defined by low MEST) in a gene-dosage dependent manner. Such evidence provides support for the hypothesis that *Kcnj10* is a seizure-related QTG in the B6 and D2 model with functional consequences determined by the Th262Ser amino acid variation. Another interpretation of these results is that overexpression of *Kcnj10* (or another gene harbored on the BAC) per se is responsible for the observed phenotypic rescue, and this possibility warrants further investigation.

Future Directions – Relevance to Human Epilepsy

Elucidation of the specific genes and their variation that define seizure susceptibility QTLs in B6 and D2 mice is given added importance by the possibility that such factors will provide insight into the biological basis of susceptibility to epilepsy in humans. Unraveling the complex genetic influences in common forms of human epilepsy is a daunting task that, to date, has been undertaken primarily by means of candidate gene association and some linkage studies. On the horizon are whole-genome association studies, large-scale expression and proteomics studies, and studies on the epigenome. All of these approaches are aided by data that help to prioritize candidate genes and specific kinds of variation within them for confirmation and validation.

The characteristics of B6 and D2 mice described in this chapter do not model epilepsy per se but rather reflect susceptibility to acute experimentally induced seizures. Despite this obvious difference, it is hypothesized that human epilepsy also involves alterations of seizure susceptibility in which neurons and their networks, predisposed by a pattern of variation among potentially many genes, exhibit paroxysmal hyperexcitability and mediate specific

seizure events. Translation of findings from the B6 and D2 genetic models to human epilepsy has begun to substantiate this hypothesis. Thus, provisional identification of variation in *Kcnj10* as the causative factor underlying the telomeric chromosome 1 QTL led to studies of this gene in human epilepsy. Association analysis using patients with generalized epilepsy identified the significant influence of a nonsynonymous SNP (predicting Arg271Cys) on *KCNJ10*. Interestingly, the human KCNJ10 variant is only several residues away from the variant in B6 and D2 mice and may have a similar end result on protein function. The significant genetic association results were confirmed in a second study by an independent laboratory using a larger patient population, and thus the KCNJ10 discovery represents one of the only replicated genetic associations in the field of human epilepsy research. This work provides a new inroad for understanding and treating human epilepsy.

Based on such results, it can be argued that genetically complex animal models of seizure susceptibility, as reflected in the B6 and D2 inbred strain model, are useful tools with which to gain insight into common forms of human epilepsy. In fact, such models may offer greater potential utility compared to single gene models that are based on spontaneous or induced mutations, since they may be more 'naturalistic' and may more closely reflect the multifactorial nature of most cases of human epilepsy. Thus, the continued dissection of the B6 and D2 model, as well as models developed using other common strains of mice, will help to further elucidate the combination of multiple gene effects, multiple environmental effects, and their interaction that defines the complex architecture of human epilepsy.

Introduction

Epilepsies are not a single disorder but rather a highly heterogeneous group of neurological conditions that differ in etiology, genetic background, treatment options, prognosis, and recurrence risks. Overall, epilepsies have a lifetime cumulative incidence of 3% in Western populations. One simplified classification would be to differentiate between epilepsies in which seizures are the main or only symptom and those in which seizures are just one symptom among others. The reasons why individuals develop epilepsy, or disorders in which seizures are a frequent feature, are numerous. Examples for mostly nongenetic causes of repetitive seizures are trauma, tumor, and infections (e.g., neurocysticercosis, a tapeworm infection that is a major cause of epilepsy in developing countries worldwide). On the other end of the spectrum are epilepsies that are caused by single gene mutations and are characterized by Mendelian inheritance patterns. Most epilepsies do not belong to either of these groups but are due to a mixture of genetic and nongenetic factors. The genetic factors in the common forms of epilepsies (such as juvenile myoclonic epilepsy, childhood absence epilepsy, juvenile absence epilepsy, and grand mal epilepsy on awakening) most often show only a low penetrance effect with respect to the phenotype. It can be assumed that several susceptibility genes are involved in each patient, and that the interaction among these gene loci is multiplicative rather than additive. Some genes might determine the seizure threshold by influencing neuronal excitability, while other susceptibility genes might be responsible for the age of onset and therefore the seizure subtype. The identification of such genes would be helpful not only for the understanding of epileptogenesis, but also for the development of new prevention and treatment strategies. However, low penetrance genes are notoriously difficult to identify in the genome. To get an idea about the type of genes that are involved in epilepsy, we decided to search first for genes underlying monogenic epilepsies. We made this decision 15 years ago, and the first gene that we discovered under this strategy was the α4-subunit (*CHRNA4*) of the neuronal nicotinic acetylcholine receptor (nAChR) that can cause autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE). As it turned out, this gene – and the gene family to which it belongs – still fascinates researchers from various fields.

Background

ADNFLE: What is the Phenotype?

When patients are telling the story of their nocturnal frontal lobe epilepsy, one repeatedly hears that the diagnosis was only made when, retrospectively, the seizures had already occurred for months, or even years. This situation is mainly explained by the fact that the seizures are mostly occurring at night, and that late childhood to early adulthood is the main age of onset. Sometimes in children, the abnormal nocturnal episodes are recognized for what they are when the individual shares a room with a sibling or parent on vacation; in adults, this recognition may not occur until the individual starts living together with a partner. Even then, it is not uncommon for the seizures to be misdiagnosed as night terrors, somnambulism, or benign nocturnal parasomnias. A correct and early diagnosis is also hampered by the fact that frontal seizures are notoriously difficult to detect on EEG. Interictal EEG abnormalities are rarely seen in ADNFLE, and only some patients show infrequent ictal epileptiform activity in the EEG. The clusters of brief motor seizures occur mostly out of non-REM (rapid eye movement) sleep (typical for dream-poor sleep phases). Patients can have frequent recurring arousals per night, followed by seizure episodes of 2–20-s duration. Some seizure episodes last longer, and in sleep-walking periods, patients might move around, talk unintelligibly, or scream for 3 min or more. Many patients report nonspecific aura phenomena, including epigastrial, sensory, or psychic symptoms that sometimes precede their seizures. Typically, the seizures start with gasps, grunts, or some vocalizations followed by thrashing hyperkinetic activity or tonic stiffening of the limbs, often with superimposed clonic jerking. The consciousness is only infrequently impaired; indeed, patients often report that they have been conscious during the seizure. Seizure frequency can be highly variable even within the same family. In some of the patients, seizures are frequent and tend to cluster, while in others, seizure occurrence is more sporadic; sometimes (for unknown reasons) decade-long periods of spontaneous remission occur before the seizure episodes occur again. Most patients experience a decrease of seizure frequency in later adulthood. Physical examinations and brain imaging results are usually normal. Seizures are often, but not in all patients, readily controlled by antiepileptic drugs, especially carbamazepine.

ADNFLE: Hunting for the First Gene

In the first half of the last decade of the twentieth century, positional cloning of a gene required much more effort than what is required now (i.e., since the sequencing of the human genome has been completed). Once a gene was linked to a certain genomic region, either by linkage studies or through the finding of an unusual structural chromosomal abnormality in a patient, the hunt started for the gene of interest – which was often buried among many mostly unknown genes. This part of the cloning process could take years, in some cases even decades. Thus, we were more than lucky that we had already started to catalogue the genes located in chromosomal region 20q13.3 when Berkovic and colleagues mapped the first gene for ADNFLE to this region in early 1995. This mapping enabled us to join forces, and together, our groups were able to identify a mutation in the *CHRNA4* gene as the underlying cause in the large ADNFLE family that helped to map the disorder to 20q13.3. It quickly became obvious that *CHRNA4* is not the only gene for ADNFLE, but that some of the other subunits of the same receptor can also cause sleep-related epilepsy. Interestingly, several years after the discovery of the first epilepsy gene, a second epilepsy gene was located in close vicinity to *CHRNA4*. This second gene, *KCNQ2*, which codes for a voltage-gated potassium channel, is responsible for another rare monogenic type of epilepsy – benign familial neonatal convulsions (BFNCs). Thus far, nobody has been able to find a convincing functional explanation for this colocalization of two distinct epilepsy genes to the tip of the long arm of chromosome 20.

The Nicotinic Acetylcholine Receptor

Together with glycine, $GABA_A$, and serotonin receptors, the nAChRs are members of the large family of ligand-gated ion channels of which muscle nAChRs are the prototype. Five (identical or different) homologous subunits are assembled and arranged around a central axis, forming a cation-selective ion pore. Each subunit is composed of four transmembrane domains, an extracellular N-terminal domain, and a short intracellular loop between transmembrane domains III and IV. The extracellular domain carries the acetylcholine binding site that, in the assembled receptor, is located at the boundary between subunits, while the four transmembrane domains delineate the axial cation-specific channel or ion pore. The extracellular domain and the four-transmembrane domain-complex are topologically distinct but are coupled allosterically to each other. A chemical signal represented by a local increase of extracellular agonist concentration can be converted by the nAChR into an electrical signal generated by the opening of the ion channel.
