In addition to studying target alterations that could underlie the AED resistance observed in our model, we determined the expression of Pgp in brain capillary endothelial cells that form the blood–brain barrier. Phenobarbital-nonresponders exhibited significantly higher expression of Pgp in piriform cortex and hippocampus than responders, indicating that reduced brain uptake and increased brain efflux of phenobarbitone could be involved in resistance to this drug. For direct proof of this hypothesis, we coadministered the selective

Pgp inhibitor, tariquidar, in phenobarbital-resistant rats, showing that resistance can be counteracted, at least in part, by such treatment.

The variety of changes in phenobarbital-resistant epileptic rats (**Figure 2**) makes it particularly challenging to determine the functional significance of each of these alterations. Nevertheless, consideration of the individual changes could provide clues to the cellular basis of drug-resistant epilepsy and may lead to novel therapeutic strategies.

In conclusion, as suggested by our recent studies in post-SE models of TLE in rats, it is possible to identify rats with drug-refractory spontaneous seizures by prolonged AED administration and continuous EEG/video monitoring of spontaneous recurrent seizures. Such drug-refractory rats seem to be ideal models for pharmacoresistant epilepsy and could be used for evaluating the therapeutic potential of novel compounds for the treatment of epilepsy. Furthermore, as shown by our recent data in phenobarbital-resistant rats, such AED-refractory rats are extremely valuable to study the mechanisms underlying pharmacoresistance.

Future Goals

Drug-resistant epilepsy represents a challenge for both experimental and clinical research to gain new insights and perspectives of its mechanisms in order to improve future rational management approaches. As shown in this article, there are a number of potentially useful chronic animal models of drug-refractory epilepsy which can be used to study mechanisms of drug resistance. Such models should be added to the late preclinical phases of AED development in order to prove at a relatively early stage if a new drug exhibits advantages over standard AEDs in drug-resistant seizure types. There should be a continuing effort to validate existing models and identify new models of different types of refractory epilepsy. It is hoped that further investigation and exploitation of such models may contribute to our understanding of the processes through which epilepsy becomes intractable. Investigation of the basis of drug resistance in epilepsy should offer new rational approaches to treatment, for instance by design of novel AEDs that are not targets for brain-expressed resistance mechanisms. Furthermore, animal models of AED-resistant epilepsy can be used to study prognostic factors of resistance, and to investigate whether resistance can be prevented by pharmacological treatment after a brain insult.

Brain Imaging of P-glycoprotein Function in Drug-Resistant Epilepsy

Introduction

Drug efflux transporters constitutively expressed at the blood-brain barrier (BBB) limit the ability of many drugs to access the brain. The prototypic drug efflux transporter, P-glycoprotein (Pgp), was discovered in 1970s as a transporter involved in multidrug resistance of cancer cells, but was also the first drug efflux transporter detected in endothelial cells of the human BBB. Subsequently, Pgp was located in brain capillary endothelial cells of several species, including humans and other primates, rats, mice, cattle, and pigs, suggesting that Pgps may constitute a general defense mechanism in the mammalian BBB, protecting the brain from being intoxicated by potentially harmful lipophilic compounds from natural sources and other lipophilic xenobiotics that otherwise could penetrate the BBB by simple diffusion without any limitation.

Epilepsy was the first CNS disorder for which drug resistance was associated with enhanced expression of Pgp in the brain. Pathologically elevated expression of Pgp has been found in resected brain tissue of patients with refractory temporal lobe epilepsy (TLE) undergoing epilepsy surgery, as well as in limbic brain regions of mouse and rat models of TLE. In such animal models, increased expression of Pgp was associated with decreased brain concentration of antiepileptic drugs (AEDs) such as phenytoin. These observations have led to the multidrug transporter hypothesis, which proposes that refractory epilepsy may be the consequence of a localized overexpression of transport proteins that prevents AEDs from penetrating the BBB in sufficient concentration and would explain why patients are resistant to multiple AEDs with distinct mechanisms of action.

However, species differences in substrate recognition by Pgp have been reported, and there is as yet no direct evidence that human Pgp transports any AED. Furthermore, whether overexpression of Pgp is exclusive to patients with pharmacoresistant seizure disorders remains to be resolved. Even if differences in Pgp expression between AED-resistant and responsive patients exist, overexpression of Pgp in pharmacoresistant epilepsy patients may be an epiphenomenon related to the frequency of seizures or underlying pathology, without any functional consequences for brain levels and efficacy of AEDs. Noninvasive brain imaging of Pgp function in AED-resistant and responsive epilepsy patients is the only strategy to evaluate whether overexpression of Pgp has any functional consequences that may be relevant for the mechanisms underlying pharmacoresistance in epilepsy.

Background and Methods

Modern brain imaging methods now provide unprecedented opportunities for the in vivo study of CNS function. There are several methods for imaging compounds in the brain, including positron emission tomography (PET), single photon emission computed tomography (SPECT), and magnetic resonance imaging (MRI). PET and SPECT are imaging techniques in which a radionuclide is introduced into a molecule of potential biological relevance and administered to a patient or an experimental animal. Both PET and SPECT imaging are high sensitivity methods in which radioactive-labeled drugs are used for measuring local neuronal activity, in vivo neurochemistry, or in vivo pharmacology. These methods are particularly attractive to clinical researchers, because they can be applied to the living human brain. PET typically makes use of the isotopes carbon 11, nitrogen 13, oxygen 15, or fluorine 18. These isotopes decay by emitting a positron, with radioactive half-lives of 20, 10, 2, and 110 min, respectively. The emitted positron annihilates with an electron and emits two annihilation photons (gamma rays) that can be detected outside the body. Typically, the isotopes are made in a cyclotron and, because of their short half-lives, need to be rapidly incorporated into the molecule of interest immediately prior to administration. In SPECT, isotopes that decay by electron capture and/or γ emission are used, and include both 123-iodine (^{123}I) and the long-lived meta-stable nuclide 99 m-technetium (^{99m}TC).

Both PET and SPECT, together with radiolabeled substrates and inhibitors of Pgp, have been used for quantitative assessment of Pgp function in the BBB. For PET studies on Pgp function, radiotracers based on known Pgp substrates have been developed and characterized in vitro and in vivo in laboratory animals, including [^{11}C]-daunorubicin, [^{11}C]-colchicine, [^{18}F]-paclitaxel, [^{11}C]-carvedilol, [^{11}C]-loperamide, and [^{11}C]-verapamil. [^{11}C]-verapamil is

the best validated of these PET tracers that has already been used in humans. In Pgp-knockout mice, a 10-fold increase in [^{11}C]-verapamil uptake in brain was found compared with the wild-type mice. A similar effect has been described in normal mice by administration of the Pgp inhibitor cyclosporin A (CsA). In humans, a 70% increase of [^{11}C]-verapamil concentrations in brain was determined following CsA infusion as compared with baseline scans, which confirmed that [^{11}C]-verapamil is transported by Pgp at the human BBB. However, none of the radiotracers available now is ideal for PET imaging owing to their low uptake in brain and complex pharmacokinetics, so there is a need to develop novel imaging probes. The same is true for SPECT. The radiotracer most widely used as a transport substrate for Pgp in SPECT studies is [^{99m}Tc]-sestamibi, a cationic radiotracer originally developed for myocardial scintigraphy. Because of its unique role as a Pgp-specific substrate, this compound can be used to examine Pgp functional activity in vitro and in vivo under pathologic conditions. [^{99m}Tc]-sestamibi is widely used to detect in vivo Pgp activity in tumors, and may be useful for monitoring the development of Pgp-mediated multidrug resistance. In rats, inflammation-mediated downregulation of brain *mdr1a* mRNA, the gene encoding Pgp in brain capillary endothelial cells in rodents, is associated with higher accumulation of [^{99m}TC]-sestamibi in the brain, further demonstrating the potential utility of [^{99m}Tc]-sestamibi for noninvasively assessing Pgp function in vivo. However, to a lesser extent, [^{99m}Tc]-sestamibi is also transported by multidrug resistance-associated protein 1 (MRP1), which may form a bias for results obtained with [^{99m}Tc]-sestamibi. Alternative Pgp substrates for SPECT analysis are [^{99m}Tc]-tetrofosmin and a 99mTc(I)-tricarbonyl complex of sestamibi. However, because all these compounds are cationic radiotracers, cellular functions other than Pgp and MRP1 function, most likely cationic ion transporters, may affect their distribution. Furthermore, in contrast to PET, SPECT does not enable quantitative measurements of uptake and efflux kinetics of Pgp substrates and thus has only limited use in studying Pgp function in the BBB.

Recent Results

The use of PET or SPECT to determine Pgp function in patients with refractory epilepsy has started only recently. In seven patients with drug-resistant unilateral TLE, the Pgp substrate R-[^{11}C]verapamil and PET were used to test for differences in Pgp activity between epileptogenic and nonepileptogenic brain regions. Unfortunately, the most interesting epileptogenic brain region, i.e., the hippocampus, could not be analyzed owing to spill-in of radioactivity from the adjacent choroid plexus. However, in five of the seven patients, increased efflux of R-[^{11}C] verapamil was determined in ipsilateral parahippocampal regions, indicating increased Pgp expression in the epileptogenic hemisphere. These pilot data in a small sample size of patients may indicate that regionally enhanced Pgp activity contributes to drug resistance in some patients with TLE.

Differences in Pgp expression in patients with epilepsy may be due to polymorphisms in drug transporter genes. One of these, a single nucleotide polymorphism (SNP) in exon 26 (C3435T) of the *Multidrug Resistance 1* (*MDR1*) gene, is associated with altered expression, functionality, and substrate specificity of the *MDR1* product Pgp. Because the efflux drug transporter Pgp is highly expressed at the BBB, genetic variation in its expression or functionality could directly affect brain uptake and extrusion of AEDs. Indeed, several recent genetic association studies have indicated an association of the 3435CC genotype, which is associated with increased Pgp expression, with AED-resistant epilepsy. However, other studies did not support such an association. In healthy volunteers differing in *MDR1* haplotypes, no difference in the brain distribution of [^{11}C]verapamil could be detected by PET analyses. However, in a recent SPECT study in patients with epilepsy, the 3435CC genotype was associated with reduced brain uptake of [^{99m}TC]-sestamibi.

Of course, the ideal PET or SPECT radiotracer for studies in epilepsy patients would be a radiolabeled AED. About 30 years ago, [^{11}C]-phenobarbital and [^{11}C]-phenytoin were synthesized and the latter radioligand has been used to study in vivo distribution of phenytoin in monkeys and humans. In a study of eight patients with medically resistant partial epilepsy and two patients without epilepsy, [^{11}C]-labeled phenytoin was used to evaluate the brain kinetics of this AED. At steady-state, brain:blood [^{11}C]-concentration ratios were determined for the visual cortex, resulting in an average value of 1.32 (range 1.05–1.66) in epilepsy patients compared to 1.61 (1.34–1.87) in nonepileptic patients. Whether phenytoin steady-state concentration is lower within the epileptic focus was not addressed in this study. Preliminary data indicated that [^{11}C]-phenytoin kinetics within the estimated epileptogenic area were not significantly different when compared with the contralateral homologous brain region in the same epilepsy patients, but additional data with high-resolution PET are needed for such an analysis. Furthermore, as indicated by the study on [^{11}C]-verapamil in epilepsy patients, the uptake and efflux kinetics rather than steady-state levels of Pgp substrates should be examined in epileptogenic brain regions.

Future Goals

In the past few years, methods for assessing the role of Pgp expression in cerebral kinetics of drugs in humans have

become more accessible. By using imaging techniques such as PET or SPECT, a future goal will be the comparison of brain kinetics of Pgp substrates in AED-resistant and-responsive patients with epilepsy. Furthermore, if such studies support a role of Pgp in AED-resistant epilepsy, PET or SPECT may be used to identify AED-resistant patients – with regionally enhanced Pgp activity – who would most likely benefit from coadministration of Pgp inhibitors. Recent studies from our laboratory using AED-resistant epileptic rats with increased Pgp expression in epileptogenic brain regions have shown that AED resistance could be counteracted by coadministration of the selective Pgp inhibitor, tariquidar. Thus, animal models may be useful to develop principles of how to identify and treat individuals in whom Pgp overexpression is involved in pharmacoresistance.

Recent advances in small animal imaging have provided new ways to perform biologic research. These nondestructive, in vivo imaging techniques permit longitudinal studies of the same animals over an extended period. Both SPECT and small animal PET ('microPET') have been extensively used to study brain kinetics of Pgp substrates in mice or rats. We plan to use a high-resolution small animal PET system for studying the potential role of Pgp in AED resistance by two strategies in rats (**Figures 1** and **2**). In the first strategy, a pilocarpine-induced status epilepticus (SE) is used. We have shown recently that such SE is followed within 48 h by a regionally restricted, significant overexpression of Pgp in brain capillary endothelial cells forming the BBB. The overexpression of Pgp in the hippocampus is associated with a significantly reduced brain:plasma ratio of phenytoin. Thus, such rats are ideal models to study whether the regionally restricted increase in Pgp expression and function can be detected by PET using radiolabeled Pgp substrates such as [^{11}C]verapamil or [^{11}C]phenytoin (**Figure 1**).

The second approach, illustrated in **Figure 2**, is much more time- and labor-extensive. In this approach, AED-resistant and responsive epileptic rats are selected by prolonged treatment with phenobarbital. Epilepsy is induced by prolonged electrical stimulation of the basolateral amygdala (BLA), resulting in spontaneous recurrent seizures after about 4–6 weeks following the SE. About 30–40% of the epileptic rats are resistant to both phenobarbital and phenytoin, whereas the remaining rats respond to these AEDs. We have shown recently that AED nonresponders exhibit a significant overexpression of Pgp in brain capillary endothelial cells of the hippocampus, dentate gyrus and parahippocampal areas. Inhibition of Pgp by tariquidar counteracts the AED resistance. We now plan to use small animal PET to study the differences in brain kinetics of Pgp substrates between AED responders and nonresponders. Because

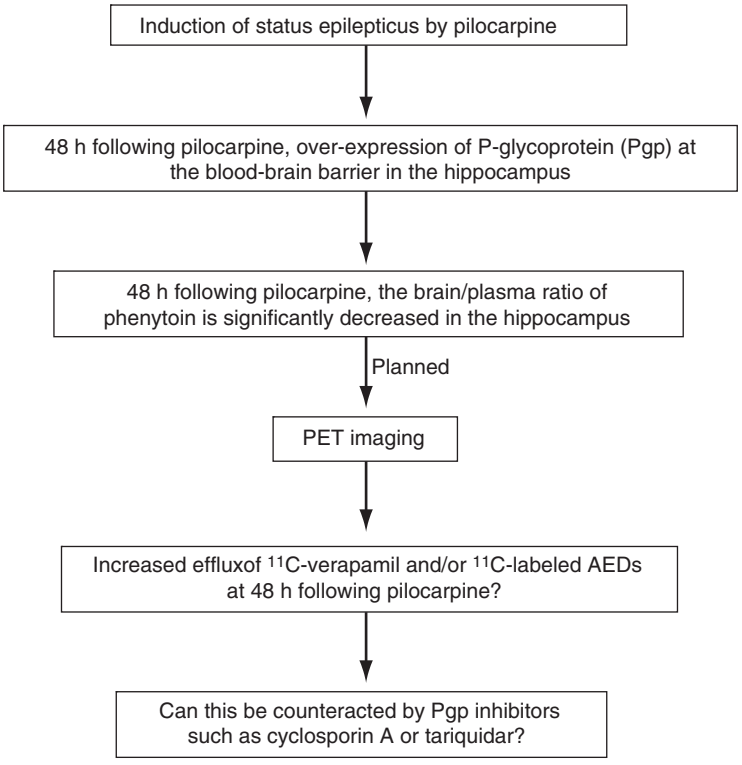

Figure 1 Schematic illustration of a relatively simple experimental approach to obtain rats with regionally restricted overexpression of Pgp in the brain for brain imaging studies with PET or SPECT. We have recently shown by immunohistochemistry that overexpression of Pgp in brain capillary endothelial cells develops within 24–48 h after a pilocarpine-induced status epilepticus.

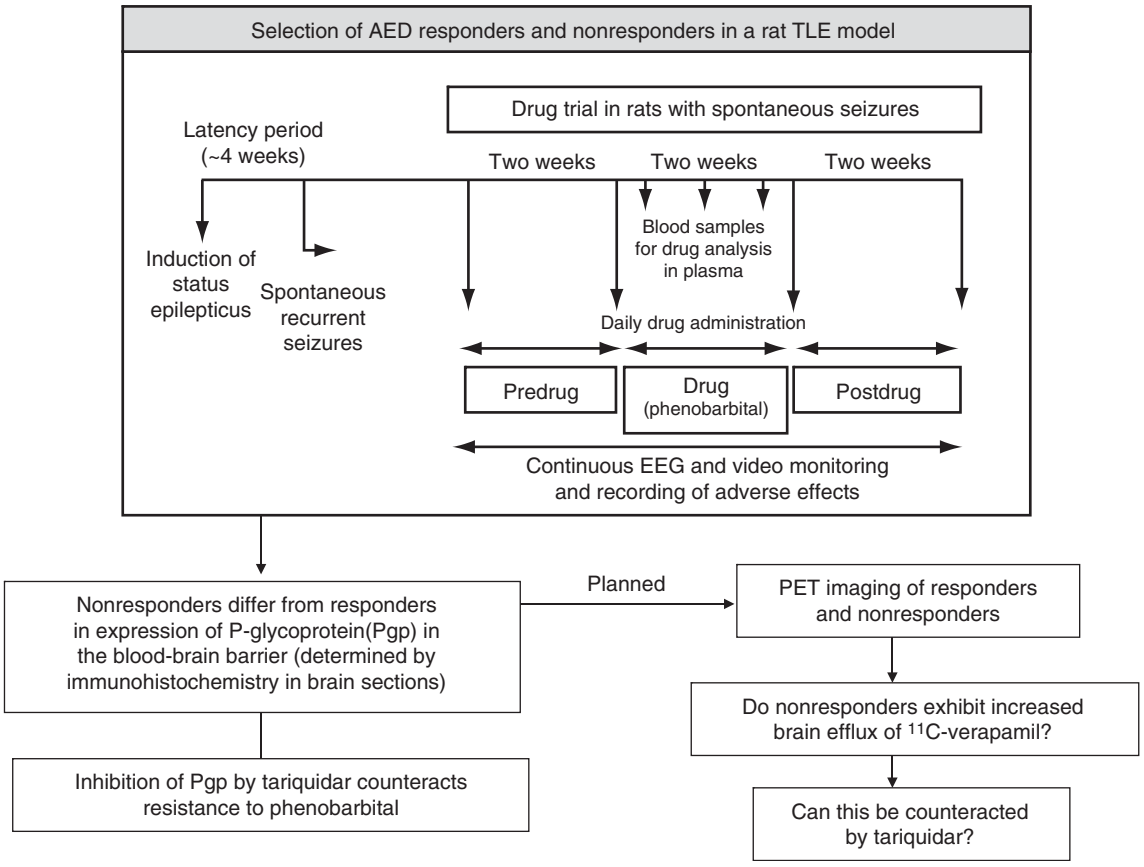

Figure 2 Schematic illustration of a rat model allowing selection of AED responders and nonresponders for brain imaging studies with PET or SPECT. We have recently shown by immunohistochemistry that nonresponders exhibit significantly higher expression of Pgp than responders in brain capillary endothelial cells of hippocampus, dentate gyrus, and piriform cortex. This overexpression of Pgp in epileptogenic brain regions seems to be involved in AED resistance, because inhibition of Pgp by tariquidar counteracts resistance to phenobarbital.

our rat model has strong parallels with human TLE, we hope that the results from these studies will help to develop strategies for evaluating the multidrug transporter hypothesis in patients with refractory TLE.

In conclusion, the recent development of radiolabeled Pgp substrates for human use now allows investigators to directly evaluate the role, if any, of Pgp in medically refractory epilepsy. Furthermore, PET and SPECT are useful to explore the relationship between polymorphisms of *MDR1* and the pharmacokinetics of Pgp substrates within the brain of patients with epilepsy. Information about the transport function of Pgp and the effect of modulating this function may improve the therapeutic treatment of patients with pharmacoresistant epilepsy.

Cellular and Molecular Mechanisms Contributing to Pharmacoresistance in Human Neocortical Tissue

Introduction

A majority of epilepsy patients respond to available anticonvulsant or antiepileptic drugs (AEDs) with an acceptable degree of seizure control. However, a considerable fraction of epilepsy patients – about 30% – do not respond adequately to available drugs. Patients are considered to be 'pharmacoresistant' if they still suffer seizures, even though their compliance has been ascertained and the drugs of choice for a given clinical syndrome have been maintained within the therapeutic range. This phenomenon of pharmacoresistance is a major challenge for pharmaceutical industry, clinicians, and basic researchers alike.

Two hypotheses have emerged to account for an insufficient seizure control – the transporter hypothesis and the target hypothesis. The 'transporter hypothesis' is based on numerous observations that transporter proteins in the endothelium of the blood–brain barrier limit the brain parenchymal concentration of substances by actively extruding a large variety of chemically unrelated drugs, including various AEDs. The observed upregulation of these transporters in both tissues from human epilepsy surgery and in animal models of epilepsy lend support to this concept (which has been the subject of several reviews). The 'target hypothesis' stems from investigations demonstrating a reduced efficacy of drugs in exerting established effects at various channels or receptors in epileptogenic tissues.

Voltage-activated sodium channels are the hallmark of excitable cells, and particularly of neurons. Modulation of sodium currents is the common denominator of various AEDs, including: phenytoin, carbamazepine, lamotrigine, and valproic acid. Molecular changes in these channels have been implicated in both an increased excitability of neurons and a reduced effectiveness of some of the AEDs. For instance, recent evidence suggests that alterations in the β1 subunit of sodium channels may be crucial for both the phenotype of generalized epilepsy with febrile seizures and a reduced responsiveness to modulation by phenytoin. In addition to the fast sodium current, the persistent sodium current also plays a crucial role in hyperexcitability. Mutation of $Na_v1.2$ causes a slowed inactivation and an increased persistent current when expressed in *Xenopus* oocytes. Transgenic mice expressing the mutated channel exhibited focal seizure activity in the hippocampus, generalizing to the neocortex. Since the persistent sodium channel is inhibited by some AEDs – e.g., lamotrigine, further studies may reveal whether an altered modulation of the persistent sodium current contributes to a reduced efficacy of lamotrigine in treating seizures.

Among the voltage-gated potassium channels, the hyperpolarization-activated cation current (I_H) has recently attracted considerable interest partly due to the fact that it represents a novel target for AEDs (lamotrigine, gabapentin). This current has several functions in cortical neurons, including stabilization of membrane potential and modulation of temporal summation of synaptic input. The impact of this current on neuronal excitability has long been underestimated. Judging from the about 100% increase in resting membrane resistance in the presence of the selective I_H antagonist ZD7288, the conductance mediated by I_H channels represents about 50% of the resting conductance of cortical neurons.

Introduction

A majority of epilepsy patients respond to available anticonvulsant or antiepileptic drugs (AEDs) with an acceptable degree of seizure control. However, a considerable fraction of epilepsy patients – about 30% – do not respond adequately to available drugs. Patients are considered to be 'pharmacoresistant' if they still suffer seizures, even though their compliance has been ascertained and the drugs of choice for a given clinical syndrome have been maintained within the therapeutic range. This phenomenon of pharmacoresistance is a major challenge for pharmaceutical industry, clinicians, and basic researchers alike.

Two hypotheses have emerged to account for an insufficient seizure control – the transporter hypothesis and the target hypothesis. The 'transporter hypothesis' is based on numerous observations that transporter proteins in the endothelium of the blood–brain barrier limit the brain parenchymal concentration of substances by actively extruding a large variety of chemically unrelated drugs, including various AEDs. The observed upregulation of these transporters in both tissues from human epilepsy surgery and in animal models of epilepsy lend support to this concept (which has been the subject of several reviews). The 'target hypothesis' stems from investigations demonstrating a reduced efficacy of drugs in exerting established effects at various channels or receptors in epileptogenic tissues.

Voltage-activated sodium channels are the hallmark of excitable cells, and particularly of neurons. Modulation of sodium currents is the common denominator of various AEDs, including: phenytoin, carbamazepine, lamotrigine, and valproic acid. Molecular changes in these channels have been implicated in both an increased excitability of neurons and a reduced effectiveness of some of the AEDs. For instance, recent evidence suggests that alterations in the β1 subunit of sodium channels may be crucial for both the phenotype of generalized epilepsy with febrile seizures and a reduced responsiveness to modulation by phenytoin. In addition to the fast sodium current, the persistent sodium current also plays a crucial role in hyperexcitability. Mutation of $Na_v1.2$ causes a slowed inactivation and an increased persistent current when expressed in *Xenopus* oocytes. Transgenic mice expressing the mutated channel exhibited focal seizure activity in the hippocampus, generalizing to the neocortex. Since the persistent sodium channel is inhibited by some AEDs – e.g., lamotrigine, further studies may reveal whether an altered modulation of the persistent sodium current contributes to a reduced efficacy of lamotrigine in treating seizures.

Among the voltage-gated potassium channels, the hyperpolarization-activated cation current (I_H) has recently attracted considerable interest partly due to the fact that it represents a novel target for AEDs (lamotrigine, gabapentin). This current has several functions in cortical neurons, including stabilization of membrane potential and modulation of temporal summation of synaptic input. The impact of this current on neuronal excitability has long been underestimated. Judging from the about 100% increase in resting membrane resistance in the presence of the selective I_H antagonist ZD7288, the conductance mediated by I_H channels represents about 50% of the resting conductance of cortical neurons.

This marked conductance would tend to shunt potential changes generated by other conductances, in fact blockade of I_H reveals intrinsic burst firing in certain previously regularly firing pyramidal neurons. The properties and pharmacology of I_H are discussed in another article.

Remarkably little is known about the role of glutamatergic receptors in pharmacoresistance. Three types of ionotropic receptors are activated by physiologically released glutamate, and are named according to the most potent agonists: *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazol-propionic acid (AMPA), and kainate. These receptors have been cloned and exhibit fascinating molecular biology. Each receptor consists of a multimer of subunits. The AMPA and NMDA receptors are tetrameric, while kainate receptors are pentameric arrays of subunits. Splice variants of subunits and mRNA editing cause important changes in voltage-dependence and in the relative permeability of the channel for Na^+ and Ca^{2+}. These posttranscriptional modifications, which may be affected to some extent by the cellular activity, not only provide a rich diversity of functional channels, but also put genetic attempts to understand epilepsy into perspective. Several lines of evidence suggest an interaction of AEDs with glutamatergic transmission. Valproate for instance decreases AMPA binding and reduces neuronal responses to iontophoretic application of kainate and quisqualate. Both AMPA and kainate receptor-mediated currents are also decreased to a different extent by topiramate. Interestingly, topiramate reduces the field potentials by only about 10% but the build-up of intracellular Ca^{2+}, induced by four consecutive stimuli, is markedly reduced. Whether this modulation is altered in epileptogenic tissue is unknown.

The NMDA receptors differ from AMPA and kainate receptors in their unique voltage-dependent block by magnesium ions and by a variety of modulatory sites (e.g., the glycine site). Augmentation of NMDA receptor-mediated synaptic transmission by removal of magnesium is a well-established model of acute hyperexcitability in slices from rodents. NMDA receptors have also been implicated in the mediation of the large synaptic responses recorded from human epileptogenic tissue. However, detailed patch-clamp analysis has revealed no correlation between the magnitude of NMDA-receptor mediated currents and the severity of epilepsy in human tissue samples. In any case, a modulation of NMDA receptors as a therapeutic option is probably seriously constrained; direct attenuation may cause adverse effects on learning and memory, and targeting NMDA modulatory sites may cause psychotropic side effects. Few data are available on the possible modulation of NMDA receptors by clinically established AEDs (except for felbamate), let alone an altered efficacy relating to pharmacoresistance.

$GABA_A$ receptors are the target of several drugs in clinical use, and molecular changes of these receptors have been linked to reduced drug efficacy. In previous studies, acute hyperexcitability (in the zero magnesium model) was seen to cause a decrease in the level of mRNA encoding the $GABA_A$-receptor 2-subunit. Moreover, in the pilocarpine model of epilepsy, a decrease in the $GABA_A$-receptor 1-subunit was demonstrated, causing a reduced augmentation of $GABA_A$ responses by zolpidem, a selective agonist for the type 1 benzodiazepine site on $GABA_A$ receptors. Data from human temporal cortical pyramidal neurons when compared with those from adult rat cortical neurons revealed similar findings regarding the dose–response characteristics toward GABA and clonazepam modulation.

We began our investigation by focusing on two modern AEDs, tiagabine and lamotrigine. Tiagabine was chosen for its well-defined action in blocking GABA uptake, while lamotrigine represented potential due to its diverse cellular effects. In our setting, about 25% of patients operated on had received lamotrigine and were not responding adequately. A comparison of the cellular effects of lamotrigine in tissues from nonresponding patients and those in tissues from patients not treated with lamotrigine (potential responders) may, in the long run, reveal differences contributing to pharmacoresistance.

Background

Tiagabine, the derivative of nipecotic acid, a well-known blocker of GABA uptake, is a useful AED in animal models of epilepsy and in focal and complex partial epilepsy in humans. The established effect of tiagabine is the reduction of GABA uptake through blockade of GABA transporter 1 (GAT 1) at low concentrations, whereas other GAT subtypes are only blocked at much higher concentrations. The block of uptake elevates extracellular GABA levels and prolongs the inhibitory action of GABA at $GABA_A$ receptors. Furthermore, it facilitates the recruitment of previously inaccessible $GABA_B$ receptors. This would augment the inhibitory potency of GABA (in addition to a prolongation of $GABA_A$ receptor activation alone). Such an effect, for instance, has been suggested as contributing to an antinociceptive action of tiagabine in vivo. The well-defined action of tiagabine, whereby it selectively augments GABAergic inhibition, initially suggests that it is a potent anticonvulsant in cases where inhibition is impaired by aberrant GABA receptors or insufficient GABA release.

However, several reports have indicated considerable side effects of tiagabine in some patients, particularly the induction of absence status epilepticus (SE). This result corresponds to in vivo experimental results showing that tiagabine augments spike-wave activity in epilepsy-prone rats. In healthy Wistar rats, tiagabine induces hypersynchronous slow EEG activity during wakefulness and enhances delta activity during non-REM sleep. These

effects may be related to an altered negative feedback of GABA on its own release via presynaptic $GABA_B$ receptors. Although single inhibitory postsynaptic potentials (IPSPs) are augmented by tiagabine, subsequent IPSPs may be abnormally attenuated because of prolonged presence of GABA in the extracellular cleft. These tiagabine-mediated changes in the temporal pattern of inhibition during repetitive activation would help to facilitate cortical synchronization and may contribute significantly to the mechanisms of spike-wave activity.

Lamotrigine belongs to the last generation of AEDs. The spectrum of reported effects includes the 'usual suspects': a use-dependent depression of sodium-dependent action potentials (APs), decrease of glutamate release, and increase in GABA release. Especially, given that contrasting effects have been reported, several important questions about lamotrigine mechanisms of action remain unanswered. For instance, decreased GABA release was inferred from experiments on slices from the basolateral amygdala, whereas increased GABA release has been suggested on the basis of studies in the entorhinal cortex. Interestingly, lamotrigine was shown to augment I_H in the hippocampus, and several reports provide a link between reduced I_H and epileptic disorders: decreased I_H in entorhinal cortex neurons following kainate-induced seizures; smaller I_H in a genetically epilepsy-prone rat (WAG/Rij); and absence epilepsy in a knockout mouse for the HCN2 subunit. The augmentation of I_H is not confined to lamotrigine; gabapentin also increases the I_H in hippocampal neurons (albeit through a different mechanism). It remains to be seen whether alterations of I_H-subunit composition render the heteromeric channel less responsive toward either drug. Nevertheless, the 50% reduction of I_H in WAG/Rij animals (compared with nonepileptic rat strains) suggests a considerable change in this potential target of drug therapy.

Methods

The methods for tissue handling and some of the electrophysiological techniques have been described in another article. We additionally employed patch-clamp recordings with infrared video-microscopy. These methods have been described previously. In brief, individual slices were placed in a recording chamber attached to an upright microscope equipped with an infrared video camera and contrast enhancement to visualize individual neurons. Whole-cell recordings were carried out in the voltage-clamp and current-clamp modes to investigate the possible effects of lamotrigine on neuronal firing behavior. In some of the experiments, the standard pipette filling solution also contained biocytin, to allow for subsequent morphological identification of the recorded neuron.

Recent Results

Effects of Tiagabine on Neurons in Human Epileptogenic Tissue

To characterize the cellular effects of tiagabine, we first evaluated the possible actions on neuronal properties. Application of tiagabine (10 μM) induced slight and variable effects on membrane potential. Some neurons depolarized and a considerable number of neurons hyperpolarized; however, on average, membrane potential remained unaltered (control, -72.9 ± 2.8 mV; tiagabine, -74.5 ± 3.4 mV; $p > 0.5$). Neuronal input resistance decreased slightly in some neurons, in others the input resistance increased, and on average input resistance decreased by less than 10%. Firing of APs during constant current injection was reduced in some neurons, but in most neurons, AP firing was essentially unaltered. The lack of consistent effects of tiagabine on membrane potential might be anticipated from the small difference between resting membrane potential and the $GABA_A$ reversal potential usually present in the neocortex and the reduced function of $GABA_B$ receptors. Interestingly, the neuronal input resistance was also only marginally reduced by tiagabine, implying a low steady-state concentration of GABA in the vicinity of the recorded neuron, and thus only marginal increases after the reduction of GABA uptake by tiagabine.

We also evaluated the effects of tiagabine on synaptic potentials. In human epileptogenic cortex, synaptic responses usually consist of a large depolarization without discernible inhibitory component. Unlike bicuculline-induced paroxysmal depolarization shifts (PDSs) in the rodent neocortex, the synaptic responses in the human tissue were devoid of the typical barrage of APs and are therefore referred to as depolarization shifts (DSs). To avoid threshold phenomena, the effects of tiagabine on DSs were evaluated at different stimulus intensities (2–20 V, 2 V increment). At low stimulus intensities, a marked depression of the amplitude (by 75% and 70%, at 6 and 8 V stimulus intensity, respectively) was recorded. At high intensities, the depression was much smaller (20% and 15% at 18 and 20 V, respectively). Consequently, the input–output relation of synaptic responses was considerably altered by tiagabine application, yielding a more shallow increase. To further evaluate the effects of tiagabine, the voltage-dependence of DSs was investigated. To this end, DSs were elicited at various membrane potentials induced by families of current injections (from about -0.5 to $+0.7$ nA, 600 ms). Hyperpolarizations increased the amplitude of DSs in control and in the presence of tiagabine. Depolarizing the neurons did not reveal a clear-cut $IPSP_A$ component, neither in control conditions nor in the presence of tiagabine. The excitability of neurons was apparently unaltered in the brief period between the onset of current injection and stimulation, but the repetitive firing generated at higher current injections after the stimulus was abolished by tiagabine. During this period, AP generation is usually precluded in the healthy

neocortex by the temporally distinct $IPSP_A$ and $IPSP_B$ components. Since $GABA_B$ receptors are impaired in human epileptogenic tissue, this observation suggests an augmented $GABA_A$ shunting effect following the stimulus, despite the lack of a clear $IPSP_A$ component.

To further evaluate this result, we tested the excitability of neurons by brief (300 ms) current injections applied at various intervals (up to 1500 ms) after eliciting a DS. Comparing the firing evoked by current injection with and without preceding synaptic response at different intervals provided an estimate of the time course of possible inhibition, despite the absence of any obvious inhibition (i.e., hyperpolarizing component) in the DS. In control conditions, this paradigm revealed a marked depression in the number of APs (50%) at 100 ms poststimulus. This depression gradually declined; at delays near 500 ms, the firing was the same as without orthodromic stimulation. We then evaluated the effects of tiagabine with this paradigm, and found a marked increase in the magnitude and duration of AP depression. The APs evoked by current pulses with a delay of 100 ms after the synaptic response were depressed by 90%, and at 1 s delay, by about 70%. Application of the $GABA_B$-receptor antagonist CGP55845A in the presence of tiagabine did not change the magnitude and time course of AP depression, indicating that this depression was mediated by $GABA_A$ receptors.

Two DSs evoked with pairs of stimuli (interstimulus intervals, 100 ms to 1.5 s, increment: 100 ms) are virtually constant in human epileptogenic neurons. Bicuculline-induced PDs in the rodent neocortex, however, exhibit a marked transient depression. We considered the possibility that this constancy of DSs during paired stimulation in human tissue – compared with the marked transient depression of bicuculline-induced PDSs in rat cortex – is due to insufficient release of GABA in the human tissue. We therefore evaluated the effects of tiagabine on synaptic responses elicited with paired stimulation of incrementing intervals. The second DSs of the pairs were slightly reduced in amplitude and duration by tiagabine, but a marked time-dependent depression was not observed.

Together, these data indicate that inhibition of neuronal firing through $GABA_A$ receptors can be augmented by tiagabine. The failure to obtain a marked time-dependent depression of DSs during paired-pulse stimulation in either control conditions or in the presence of tiagabine is consistent with the reduced function or density of $GABA_B$ receptors. Therefore, the marked depression of bicuculline-induced PDSs in rat neuocortex underscores the role of presynaptic $GABA_B$ receptors in the maintenance of small synaptic responses and temporal coding of synaptic processing in the healthy neocortex.

The obtained data also have important implications for pharmacoresistence. Tiagabine certainly dampens excitability of neurons in the epileptogenic human cortex by augmenting $GABA_A$ receptor-mediated inhibition; this effect can be inferred from tiagabine's marked depression of AP firing. However, the net effect of augmented $GABA_A$ inhibition may be rather limited, as only half the neurons have an inhibition with a normal ionic gradient, while the other half have a depolarizing $GABA_A$ response (see article, **Cellular and Molecular Mechanisms Contributing to Pharmacoresistance in Human Neocortical Tissue**). Therefore, tiagabine – and probably also direct modulators of $GABA_A$ receptors (e.g., benzodiazepines) – would have little net effect on single $GABA_A$ receptor-mediated events in arrays of neurons. Additionally, the potentially beneficial effect of tiagabine – a reduction in the magnitude and frequency of excess synaptic activity through presynaptic $GABA_B$ receptors – is not possible, despite the increase in ambient GABA due to the reduced function of $GABA_B$ receptors. Together, the lack of 'net effect' on single $GABA_A$ responses (due to heterogeneity of reversal potential across cells) and the reduced $GABA_B$-receptor function would render all possible sites for increased GABA concentration by tiagabine rather ineffective. Moreover, in perifocal tissue, the likely normal $GABA_B$-receptor function would make inhibition more vulnerable to frequency-dependent depression when the availability of GABA is prolonged by tiagabine. This effect might, paradoxically, facilitate recruitment of perifocal tissue and aggravate seizure activity.

Effects of Lamotrigine on Neurons in Human Epileptogenic Tissue

We started investigating the effects of lamotrigine on human neocortical neurons with both sharp microelectrodes and patch-clamp recordings. Depolarizing current injections of incrementing amplitudes elicited, above a given threshold, trains of APs of constant amplitudes (on average about 90 mV). Some neurons exhibited an initial doublet of APs, which may have been due to the presence of a T-current giving rise to an 'extra' AP. Fast-spiking or bursting neurons were only rarely encountered and have not yet been included in the analysis. Application of lamotrigine (100 μM) had no consistent effects on membrane potential and neuronal input resistance. However, it caused a marked and significant reduction in the number of APs during a given current injection with both recording techniques. Also the amplitude progressively declined during a train of APs. These effects were reversible upon washout and are probably related to findings indicating an altered sodium-dependent inactivation in the presence of lamotrigine.

We also evaluated the effects of lamotrigine on synaptic responses with sharp microelectrode recordings. To this end, the same paradigms described elsewhere in this encyclopedia were employed. Input–output curves were slightly altered by lamotrigine, the slope was slightly shallower, and the half-maximal stimulation shifted toward higher stimulus intensities. Also the amplitude progressively declined

during a train of APs. These alterations are probably beneficial, since they shift these parameters of the input–output curve toward those obtained in the healthy rat cortex. The maximal amplitudes obtained were not significantly altered by lamotrigine. In any case, these effects would be compatible with a reduced release of glutamate at low to intermediate stimulus intensities. We also evaluated the synaptic responses at near maximal stimulus intensities, which effectively recruit inhibition in the rat cortex. Families of current injections of incrementing amplitudes, with concommitant stimulation, were used to quantify synaptic responses (see earlier). A small $GABA_B$ receptor-mediated IPSP was revealed with the larger amplitudes of injected current. Application of lamotrigine caused a significant reduction of this component, and estimates of the conductance indicate a decrease by about 60%.

With the patch-clamp method, we specifically investigated the properties of I_H and its modulation by lamotrigine. These data are also presented elsewhere in this encyclopedia. Briefly, application of lamotrigine had no consistent effect on the magnitude and time course of I_H.

Future Goals

The data concerning the effects of tiagabine support our conclusion in another chapter – namely, that $GABA_B$ receptors are greatly reduced in the human epileptogenic neocortex. Although tiagabine augments the availability of GABA (as the decreased firing probability after a stimulus clearly demonstrates), the synaptic responses are only slightly affected. The constant, time-invariant occurrence of DSs in the presence of tiagabine, compared with the marked transient failure of bicuculline-induced PDSs, emphasizes the pivotal role of $GABA_B$ receptors in controlling synaptic processes. Concerning the implications for pharmacoresistance, the augmentation of $GABA_A$ inhibition by tiagabine may augment some tonic inhibition, but would have little net effect on the average GABAergic function in an array of neurons. The augmentation of hyperpolarizing inhibition is likely to be counterbalanced by the augmentation of inhibition in those neurons exhibiting a depolarizing $GABA_A$ response. This very phenomenon would of course also render other drugs ineffective that directly modulate the receptor kinetics.

Future experiments will focus on pharmacologically isolated IPSPs for quantifying synaptic currents to further evaluate the role of GABA uptake during the time-course of inhibition. Using the whole-cell patch-clamp technique will allow us to set the ionic gradient of $GABA_A$ inhibition, thus greatly facilitating the characterization of the pharmacological properties of $GABA_A$ receptors in the human epileptogenic cortex. Ultimately, we would like to establish a correlation between $GABA_A$ receptor function and the clinical history of a given patient (resected tissue sample). The most effective method to achieve this goal would be molecular analysis of the expression pattern of $GABA_A$ receptors and transporters involved in the maintenance of the chloride gradient in human tissue. Immunohistochemical characterization of relevant proteins ($GABA_A$ and $GABA_B$ receptor subunits, together with transporters, e.g., KCl cotransporter and channels, e.g., voltage-activated chloride channels) would provide a more representative view of the cellular alterations of a given tissue compared with the recordings from individual neurons. In addition, for such studies the inevitable lack of controls could be avoided by using postmortem material.

Lamotrigine attenuation of APs in human pyramidal neurons was also identified. For some of the tissues, the lamotrigine levels in blood plasma and tissue had been determined and were within the therapeutic range. Therefore, a reduced parenchym level of lamotrigine (due to multidrug transporters) appears very unlikely, and the effects observed in the slices are probably also present in vivo. Yet, these patients are pharmacoresistant, suggesting that use-dependent depression of APs, common to several AEDs, may not be sufficient to control seizure activity. A more quantitative analysis of the alterations of sodium-current properties by lamotrigine and other AEDs is needed, and should be compared with properties of rat cortical neurons, both under control conditions and in epileptic rats (e.g., after SE). Using procedures for acute isolation of neurons, and perhaps a short-term culture preparation to prolong the use of these unique human tissue samples, would further this goal greatly.

Our data indicate a marked depression of inhibition by lamotrigine, in line with a published observation on amygdala neurons of rats. From the data obtained to date, we tentatively propose that pharmacoresistance to lamotrigine may be due to a combination of the two opposing effects. On the one hand, lamotrigine reduces the excitability of pyramidal cells. On the other hand, lamotrigine appears to reduce inhibition, presumably by a reduction of GABA release. This decrease may be brought about by reduced excitability of GABAergic interneurons. Choosing non-pyramidal cells for patch-clamp recordings would provide evidence of whether lamotrigine affects sodium currents of fast-spiking interneurons. In this context, the synaptic responses of interneurons would be of particular interest. If synaptic activation normally elicits several APs in interneurons, a use-dependent depression of sodium currents may affect the output quite markedly. This phenomenon may also be an issue with other drugs that modulate sodium currents. The resulting depression of GABA release might be useful for reducing focal activity – since GABA has a depolarizing effect in human epileptogenic neurons. However, a depression of GABA release in perifocal tissue would facilitate spread of focal activity and increase the probability of seizure activity.

In conclusion, the triad of deficits we observed in the human epileptogenic cortex – depolarizing $GABA_A$ responses, decreased $GABA_B$-receptor effects, and decreased density of I_H – may combine to render various pharmacological strategies ineffective. The pivotal role of this triad in epilepsy is obvious from observations on knockout mice, where impairment of each mechanism in isolation is sufficient to induce seizures.

Introduction

Drug resistance is a feature of different forms of epilepsy or epileptic syndromes. It is defined as the persistence of unacceptable seizures, in spite of reasonable pharmacotherapy and drug use to the highest tolerable dosage. It affects between 20 and 30% of patients with epilepsy overall. Interestingly, many of the childhood epilepsy syndromes do not respond to clinically employed anticonvulsants. For example, infantile spasms, neonatal seizures, and atonic seizures are frequently pharmacoresistant. Further, Ohtahara syndrome, Dravets syndrome, West syndrome, Rasmussen encephalitis, Lennox Gastaut syndrome, and the migrating focal seizures during infancy are frequently associated with pharmacoresistance. In such conditions, drug resistance may exist from the onset of disease. Interestingly, seizurelike events induced in the intact hippocampus from young rodents are also refractory to antiepileptic drugs, suggesting that immature neuronal circuits do not respond to currently used antiepileptic drugs (AEDs).

In adolescent and adult epilepsy patients, a particularly high incidence of drug resistance is encountered in patients with focal or partial epilepsies. In addition, drug resistance can also be a feature of status epilepticus, where the resistance may evolve over time. Prolonged drug resistant status

In conclusion, the triad of deficits we observed in the human epileptogenic cortex – depolarizing $GABA_A$ responses, decreased $GABA_B$-receptor effects, and decreased density of I_H – may combine to render various pharmacological strategies ineffective. The pivotal role of this triad in epilepsy is obvious from observations on knockout mice, where impairment of each mechanism in isolation is sufficient to induce seizures.

Introduction

Drug resistance is a feature of different forms of epilepsy or epileptic syndromes. It is defined as the persistence of unacceptable seizures, in spite of reasonable pharmacotherapy and drug use to the highest tolerable dosage. It affects between 20 and 30% of patients with epilepsy overall. Interestingly, many of the childhood epilepsy syndromes do not respond to clinically employed anticonvulsants. For example, infantile spasms, neonatal seizures, and atonic seizures are frequently pharmacoresistant. Further, Ohtahara syndrome, Dravets syndrome, West syndrome, Rasmussen encephalitis, Lennox Gastaut syndrome, and the migrating focal seizures during infancy are frequently associated with pharmacoresistance. In such conditions, drug resistance may exist from the onset of disease. Interestingly, seizurelike events induced in the intact hippocampus from young rodents are also refractory to antiepileptic drugs, suggesting that immature neuronal circuits do not respond to currently used antiepileptic drugs (AEDs).

In adolescent and adult epilepsy patients, a particularly high incidence of drug resistance is encountered in patients with focal or partial epilepsies. In addition, drug resistance can also be a feature of status epilepticus, where the resistance may evolve over time. Prolonged drug resistant status

epilepticus is a rare condition, but is extremely dangerous because of its dramatic consequence with respect to cell death and subsequent reorganization of the nervous system. These consequences, in turn, are believed to aggravate the epileptic condition and cause cognitive impairment as well as other malfunction of the CNS.

Pathological mechanisms involved in pharmacoresistance are currently classified into three general categories: disease-related mechanisms, genetics (e.g., polymorphisms in drug transporters), and drug-related mechanisms (e.g., tolerance). Within the category of disease-related mechanisms, two hypotheses have been proposed: The transporter hypothesis postulates that overexpression of multidrug transporters could reduce the concentration of AEDs in the epileptogenic brain regions; this view has been developed in the other article of this volume. The target hypothesis postulates alterations in drug target; this approach is developed in more detail in the following sections.

Background

Models of Drug Resistance

There are no good predictive in vivo animal models for drug resistance. Different types of spontaneous seizures in epileptic dogs, spontaneous seizures in amygdala-kindled rats, and poststatus epileptic seizures after prolonged electrical stimulation of the basolateral amygdala have all been shown to be pharmacoresistant in subgroups of the experimental animals. To rely on these models for drug developments is difficult, since it requires tedious testing of the animals with different agents. Further, pharmacodynamic analysis in animal models (dogs, cats, rodents) may be of questionable relevance given that the metabolism of antiepileptic drugs has often been found to differ from that in humans.

Given such difficulties in intact animal models, attempts have been made to use in vitro seizure models (i.e., brain slices obtained from normal adult animals) to identify pharmacoresistance mechanisms and to develop more effective drugs. In such preparations, seizurelike events comparable to those recorded in vivo can be induced, e.g., by lowering magnesium and calcium, or by elevating potassium concentration. The application of different drugs, such as veratridine and 4-aminopyridine (4-AP) also induces seizurelike events. However, when tested for sensitivity to current antiepileptic drugs, these models, in general, exhibit drug-sensitivity. An exception to these observations has been seen with prolonged treatment with low Mg (and sometimes also with 4-AP); these treatments resulted in a change in activity pattern, from seizurelike events to late recurrent discharges – which were pharmacoresistant. Activity mimicking late recurrent discharges could also be readily induced by the combined application of 4-AP and bicuculline, or by the combined application of low Mg with bicuculline. These results suggest that transition to late recurrent discharges is due to a strong reduction in efficacy of GABAergic synaptic transmission, potentially due to consumption of GABA in the GABA shunt of the tricarboxic acid cycle. This observed reduction in GABAergic synaptic transmission is not likely to be dependent on malfunction of GABA receptors, since the application of muscimol or GABA can reverse late recurrent discharges into drug sensitive seizurelike events and eventually block this activity.

A somewhat different in vitro system has also provided a window onto pharmacoresistance. In organotypic slice cultures (from rats and mice), most (if not all) cell types present in the intact animal are preserved. These preparations maintain physiological connectivity, but can also develop aberrant connectivity similar to that in human hippocampus with hippocampal sclerosis. The induction of epileptiform activity by 4-AP or lowering of extracellular Mg concentration induces electrical activity patterns that are similar to seizures in intact animals. In this in vitro model, we have noted that seizurelike events were typically resistant to AEDs which interfere with cellular excitability (such as carbamazepine, phenytoin, and valproate) or which augment the efficacy of synaptic inhibition (such as benzodiazepines and barbiturates). The activity was also resistant to gabapentin.

Finally, seizurelike events have been induced by elevating potassium concentration in human tissue (hippocampus, neocortex, and subiculum) obtained after surgical interventions. Interestingly, this activity was suppressed by antiepileptic drugs if slices came from patients with no epilepsy or where patients had seizures which were controlled by AEDs. In contrast, in most cases where slices came from patients with drug refractory epilepsy, seizurelike events were found to be insensitive to carbamazepine and valproic acid. These studies suggest that such tissue is suitable for analysis of mechanisms of drug refractoriness.

The Development of Tolerance

Even without the occurrence of chronic seizures or status epilepticus, the development of resistance in the course of treatment is observed for a number of substances, and has been termed 'tolerance.' For instance, tolerance is observed following treatment with GABA-mimetic drugs. In the case of barbiturates, this effect may be related to the induction of liver enzymes. However, the fact that withdrawal seizures can occur when other GABA-mimetic agents are used indicates that the central mechanisms of tolerance development must also be involved. These mechanisms may be part of homeostatic plasticity. Thus, in dissociated neuronal cultures, blocking of $GABA_A$ receptors leads to upregulation of $GABA_A$ receptors, while down regulation of GABA receptors was observed following an increased activation by GABA agonists. Such adaptation of central GABA

receptors may lead to a reduction in the efficacy of inhibitory mechanisms after a long-term use of GABAmimetic drugs and could explain withdrawal seizures after abrupt cessation of delivery of GABA mimetic drugs. Such withdrawal seizures have also been noted in subjects that do not have epilepsy (such as in drug addicts consuming alcohol, barbiturates and/or benzodiazepines). Thus, the development of tolerance may be independent of the presence of chronic epilepsy.

The mechanisms underlying the development of tolerance to benzodiazepines are not well understood, but may involve changes in the GABA receptor subunit composition, changes in GABA synthesis, and also in other neuromodulatory systems. The loss of efficacy has been proposed as the basis for tolerance to vigabatrin. These data collectively suggest that development of resistance/tolerance can occur purely as a consequence of long-term treatment with certain drugs, without effects of the epileptogenic process. Such a scenario is less likely for drugs such as valproic acid (VPA), phenytoin (PHT), and carbamazepine (CBZ), for which tolerance has not been observed in nonepileptic subjects. These agents have been used for a number of indications other than epilepsy, including neuralgias and depressions.

Drug Targets in Chronic Epilepsy

Clearly, the development of tolerance does not seem to be a common feature of long-term application of all anticonvulsant drugs. Thus, it appears likely that epilepsy (seizure)-related preexisting or acquired changes contribute to drug resistance. As indicated earlier, two main concepts have evolved to explain disease-related drug resistance in chronic epilepsy. The target hypothesis suggests that the molecular targets for anticonvulsant drugs may be functionally or genetically altered, and that these modifications subsequently render them insensitive to AEDs. A large number of ion channels and receptors have been identified that are targets for anticonvulsant drugs. Voltage-gated ion channels are involved in the anticonvulsant effects of drugs such as PHT, CBZ, VPA, and lamotrigene (LTG). Transient and persistent sodium channels are sensitive to PHT, CBZ, LTG, VPA; calcium channels are sensitive to ethosuximide (ESM), VPA, PHT, and gabapentin. Recent data now suggest that potassium channels can be potential target for anticonvulsants, such as retigabine and perhaps also for gabapentin.

Another large group of drugs acts to enhance the efficacy of synaptic inhibition. This effect can be achieved by increasing affinity for GABA at the receptors (e.g., by benzodiazepines (BDZ)), by increasing Cl channel mean open time (barbiturates, neurosteroids), by increasing presynaptic GABA release (vigabatrin), and by reducing GABA uptake (tiagabine). There are some drugs which act by not-yet-fully-resolved mechanisms, such as leviracetam and topiramate, which may affect mitochondrial metabolism but also appear to have other molecular targets. It should be noted that the list of targets for established anticonvulsant is also likely incomplete, and may expand as their actions on novel targets are examined. This diversity of drug mechanisms of action presents a conceptual problem: explaining concurrent resistance to multiple anticonvulsant drugs, which is frequently encountered in epilepsy patients, would require the modification of a large number of very different drug targets or drug-targeting mechanisms.

Methods

The study of mechanisms underlying drug resistance requires suitable models. Most, if not all, in vivo models of drug resistance are post hoc models (i.e., drug resistance of the model can be determined only after one studies effects of a drug), and therefore rather tedious to apply to investigations of the underlying mechanisms. In contrast, there are now in vitro models in which drug resistance can be predicted with high reliability. In neonatal whole hippocampal preparations, seizurelike events induced by low magnesium have been shown to be drug-refractory. Organotypic slice cultures, prepared between postnatal days P2 and P12 and tested a week after preparation, also present with drug resistance of seizurelike events induced by 4-AP or by low magnesium This drug resistance persists for months after preparation. In status epilepticus in vitro models, prolonged exposure of entorhinal cortical tissue to low Mg leads to pharmacoresistance; the same holds true when bicuculline and 4-AP are applied in combination. Finally slices from human patients can be prepared and seizurelike events, induced (e.g., by elevation of extracellular potassium concentration); these seizurelike events are drug-sensitive when the tissue comes from patients which had been responding to antiepileptic drugs, but not (in most cases) when the patients have been drug-refractory. As is the case with low Mg-induced activity and combined application of 4-AP with bicuculline, this human drug refractory tissue often shows signs of disinhibition.

Results

Drug Resistance in Chronic Epilepsy: The Transporter Hypothesis

The transporter hypothesis contends that the drug levels necessary to prevent ictogenesis are simply not reached within the CNS parenchyma. There are several mechanisms that could give rise to such a phenomenon. For instance, cleaving enzymes that degrade anticonvulsant drugs might be up-modulated. Alternatively, genetic or functional upregulation of drug transporter molecules

could account for decreased permeation of anticonvulsant drugs into the CNS. The drug transporter hypothesis, however, faces the difficulty that virtually many insults and noxious stimuli (e.g., traumatic brain injury, tumors, malformations, hypertension, stress, or seizures) can be associated with an opening of the blood–brain barrier, potentially allowing access by anticonvulsant drugs.

Several genes have been discovered which encode proteins that function as drug efflux pumps, including MDR1, MDR2, and the MRP family (MRP 1–7). Both MDR1 and some of the MRPs have been shown to be expressed by endothelial cells composing the blood–brain barrier, and a large body of evidence now exists which indicates that drug transporter molecules are upregulated in human epileptic patients as well as in experimental models of epilepsy – and that this upregulation correlates with less efficient seizure control. Additionally, expression of drug transporters in epileptic foci was observed in cell types which do not usually express them, such as astrocytes or dysplastic neurons in foci with neuronal dysplasia. If upregulation of drug transporters in endothelial cells underlies pharmacoresistance, then seizurelike events in brain slices from human epileptic brain should be sensitive to AEDs (since the BBB is by-passed in this preparation). This responsiveness is, however, rarely the case in our series of studies on human slice preparations suggesting that upregulation of drug transporters at the blood–brain barrier is only rarely a case of drug resistance in humans. It is important to note, however, that in human and experimental tissue, ectopic expression of drug transporters (on neuronal membranes) has been demonstrated; such ectopic localization could contribute to drug refractoriness, but only if AEDs act from inside the cells.

Drug Resistance in Chronic Epilepsy: The Target Hypothesis

As mentioned earlier, in brain slices from epilepsy patients, elevation of the extracellular K^+ concentration resulted in the expression of seizurelike events. In tissue from patients who were pharmacoresistant to CBZ, such artificially induced convulsions did not respond to CBZ, even at concentrations as high as 100 μM. In marked contrast, seizure activity in patients who were clinically sensitive to CBZ proved sensitive to CBZ. These results appeared to be independent of the type of mesial temporal lobe epilepsy. Because CBZ, along with other anticonvulsants such as PHT and lamotrigine, targets voltage-gated Na^+ channels, it appeared likely that changes in Na^+ channel properties in these tissues might render them unresponsive to these drugs. All three of the drugs mentioned earlier have several concomitant effects on Na^+ channels: (1) They reduce the maximal amplitude of Na^+ currents; (2) They shift the voltage-dependence of inactivation in a hyperpolarizing direction, thus reducing the number of available Na^+ channels; and (3) These anticonvulsants slow the recovery from inactivation of these channels. This third mechanism may be particularly relevant to the treatment of epilepsy because it causes a preferential reduction of Na^+ channel availability during high frequency discharges. Indeed, subtle reductions in the anticonvulsant drug effects on the voltage-dependent inactivation, and more pronounced changes in the recovery from inactivation, have been described, both in animal models of epilepsy and in human epilepsy tissue. Both in the pilocarpine model of epilepsy and in therapy-resistant patients, CBZ effects on the recovery from inactivation were completely lost. These data suggest CBZ loses a major mechanism of action in chronic epilepsy. These results also suggest that there is a fundamental change in the Na^+ channel molecule, which may be related either to altered subunit composition or to different forms of posttranslational modification.

The main pore-forming component of Na channels is the alpha subunit. Nine different alpha subunits have been identified, termed Na_v 1.1–1.9. Of the nine alpha subunits, Na_v1.1–1.3, 1.5, and 1.6 are expressed in the CNS. Na^+ channels also contain auxiliary β subunits (β_{1-4}) that modulate the biophysical properties of the channel and are important for the subcellular localization and transport of Na^+ channel pore-forming subunits. On the mRNA level, a number of changes in Na^+ channel expression have been described following kainite-induced seizures or in human epileptic material – changes that potentially lead to altered drug responsiveness.

Changes in pharmacological properties of Na^+ channels could also be due to various posttranslational modifications of the channel protein. Evidence that metabolic changes can affect sodium channels is sparse. However, effects of unsaturated fatty acids on Na^+ channels have been described, which might be related to scavenging of radical oxygen species. That ROS production is increased in chronic epileptic tissue, and that mitochondrial functions are chronically altered in human and animal forms of TLE, are well documented. Other posttranslational modifications, like glycosylation or phosphorylation, may also alter the properties of Na^+ channels, but whether they modulate the pharmacoresponsiveness of these channels is unknown.

Apart from alterations in Na^+ channels, the most significant advances in determining the potential relevance of changes in drug targets for the development of drug resistance have been made for $GABA_A$ receptors. Several hypotheses have been offered to explain the development of drug resistance to GABA-mimetic drugs, including changes in GABA receptors, alterations in the efficacy of GABAergic synaptic transmission, and reorganization in GABAergic neuronal networks. On the molecular level, GABA receptors in chronic epileptic tissue undergo highly coordinated subunit changes. In some regions of the hippocampus, such as the dentate gyrus, changes in subunit

composition profoundly affect the sensitivity of the GABA receptor complex to intrinsic modulators as well as possible anticonvulsant drugs. For example, the sensitivity of GABA receptors to zinc in epileptic dentate granule cells is considerably increased, while their sensitivity to the benzodiazepine site agonist, zolpidem, is dramatically decreased. Both of these findings have some important consequences. The block of GABA receptors by zinc, which may be released onto granule neurons by recurrent mossy fibers, may render GABA-mimetic drugs less effective. Additionally, the fact that a benzodiazepine site agonist is less effective in these cells implicates a reduced efficacy also of other substances targeting the benzodiazepine binding site. It remains to be seen whether such changes can also be observed in other mesial temporal subregions. Other alterations have been observed in area CA1 which would also suggest a reduced sensitivity of GABA receptors to some anticonvulsants. Most evidence suggests that neither CA1 nor the DG regions are seizure initiation sites, but rather participate in seizure spread. Hence, it would be important to know whether similar alterations in GABA receptors occur in seizure initiation sites such as the medial entorhinal cortex or area CA3.

Studies of seizure-induced alterations in GABAergic synaptic transmission have focused recently on potential alterations of chloride transport. During ontogenesis, GABA-mediated events induce a strong depolarization which may elicit action potentials in immature neurons. Three mechanisms can be involved in this effect: First, the inward chloride transporter NCC1, which is highly expressed in developing brain, establishes a very depolarizing reversal potential for chloride. Second, upregulation of KCC2 – the transporter that moves chloride ions out of the cell – occurs after birth; in rats, KCC2 gains a major influence on the chloride equilibrium potential only after postnatal day 10. Third, as GABA-activated channels are also permeable to bicarbonate ions, the capability of cells to generate $HCO3^{-}$ introduces a further confounding variable. During development, the neuronal carboanhydrase appears only at postnatal day 14. This enzyme shifts the reversal potential of IPSPs again in a depolarizing direction, and may be responsible for GABA-mediated depolarizations during seizures and in response to repetitive stimulation. The known anticonvulsant effect of some carboanhydrase inhibitors, including topiramate, may therefore depend on preventing a seizure-induced depolarizing shift of reversal potentials for GABA. Interestingly, recent studies in human hippocampal tissue have demonstrated that depolarizing GABA-mediated events are involved in the generation of spontaneous epileptiform bursts in the subiculum. If these events occur also elsewhere in human epileptic tissue, any GABA-mimetic drug would augment the depolarizing effect of GABA. The fact that some epileptic patients profit from treatment with carboanhydrase inhibitors suggests that reduced generation of $HCO3^{-}$ – and thereby maintenance of hyperpolarizing IPSP reversal potentials – may indeed be an important therapeutic strategy. However, to what extent GABA-mediated responses are depolarizing in chronic epileptic tissue remains a matter of dispute even in the human subiculum.

Finally, in chronic epileptic tissue, reorganization also affects interaction between interneurones and principal cells. Three classes of interneurones have been described: those that interact with the soma and axon initial segment, and thus control output of the neuron (soma targeting interneurones); those that interact with apical dendrites and control input to principal cells (dendrite targeting interneurones); and those that interact only with other inhibitory interneurones (IN interneurones). When principal cells die and are therefore reduced in number, as in temporal lobe epilepsies with hippocampal sclerosis, surviving interneurones interact more strongly with other interneurones. Therefore, the normal throughput of information through the hippocampus, via glutamatergic mechanisms, may be replaced by interactions between interneurons; information may now be transferred by disinhibition of interneurons. GABA-mimetic drugs, which augment inhibition, might then augment disinhibition and facilitate seizure generation.

Directions for Future Research

The alterations in chronic temporal lobe epilepsy may be such that typical targets for anticonvulsant drugs are no longer appropriate for a pharmacological intervention. This possibility implies that combinations of current drugs – even with different pharmacological targets – may be unlikely to offer an effective therapeutic alternative. If that is the case, then a search for alternative drug targets would be required. Such targets might include adenosine receptors, cholinergic receptors, receptors for certain peptides with proven anticonvulsant potential, glycine receptors, etc. The fact that human tissue slices present with pharmacoresistant forms of epileptiform seizurelike discharges offers the potential to test newly developed drugs in human tissue from pharmacoresistant patients. This opportunity would increase the potential for discovery of agents which are effective in the treatment of drug resistant seizures.

Introduction

Temporal lobe epilepsy is the most common form of epilepsy in the adult population, afflicting at least 800 000 Americans. Its pathogenesis is, however, poorly understood. Pharmacotherapy usually fails to achieve adequate long-term control of seizure discharge, in part because the available drugs do not target abnormal mechanisms unique to this disorder. Although temporal lobe epilepsy can arise from numerous causes, most cases are believed to develop after a lesion of the brain. Most of, and sometimes all, the detectable pathology is found in the hippocampus. Within the hippocampus, the most consistent region of neuronal loss is the hilus of the

dentate gyrus. Therefore many studies – including our own – have focused on mechanisms by which hilar damage leads to periodic spontaneous seizures.

The consequences of brain injury depend not only on the degeneration of neurons and their axonal projections but also on reactive growth triggered by the injury. Synaptic sites denervated as a result of injury do not remain unoccupied, but become reinnervated by axons that survived the injury. For the most part, axon sprouting and neosynaptogenesis appear to restore normal function, because the normal lamination of afferent fibers is preserved. The lost synapses are replaced mainly by fibers of the same pathway and/or by heterologous fibers that normally project to the same lamina. In some instances, however, axon sprouting creates an aberrant pattern of connections. In animal models of temporal lobe epilepsy, the number of monosynaptic recurrent excitatory synapses increases dramatically in several brain regions, including the dentate gyrus, area CA1 of the hippocampus, and the neocortex. Strengthening of recurrent excitatory circuitry is one mechanism that could synchronize neuronal firing, thus amplifying epileptiform discharge and enhancing seizure propagation.

Our research has focused on the dentate gyrus. Aberrant synaptic reorganization in epileptic brain was first described in the dentate gyrus, and this remains the only form of anatomic plasticity documented to occur in human epilepsy. Reorganization of the dentate gyrus is of particular interest because this region normally imposes a high resistance to the propagation of seizures from the highly-excitable entorhinal cortex to the equally excitable CA3 area of the hippocampus. The principal neurons of the dentate gyrus, the granule cells, are difficult to activate, both individually and as a synchronized population, due to their robust synaptic and tonic GABA inhibition, high resting membrane potential, high K^+ conductance, limited Ca^{2+} conductance, low intrinsic burst capability and virtual absence of monosynaptic recurrent excitation. Thus establishment of novel recurrent excitatory circuitry in this brain region is expected to facilitate seizure propagation by providing a mechanism for synchronizing granule-cell firing. Development of monosynaptic recurrent excitation is not the only mechanism that can synchronize granule-cell firing. However, such circuitry serves as the major substrate for synchronization of pyramidal-cell bursts in area CA3, and it would be expected to play a similar role in other brain regions. The ultimate goal of our studies is to identify properties of the novel circuitry that could serve as targets for therapeutic intervention.

Background

Most of our knowledge about reorganization of the dentate gyrus in epileptic brain comes from studies of animal models, although the essential features have been observed also in human hippocampi that were surgically resected to control medically-intractable seizures. Studies of animal models revealed that dentate granule cells become synaptically interconnected through the growth of recurrent mossy fibers. Mossy-fiber sprouting appears to be initiated largely by the hilar lesion. Neurons of the dentate hilus include excitatory mossy cells and several distinct populations of inhibitory GABA interneurons. Both mossy cells and GABA interneurons degenerate. Recurrent mossy fibers then cross the granule-cell body layer and innervate the proximal portion of the granule-cell apical dendrite (**Figure 1(b)**), the same territory normally occupied by synapses of mossy-cell axons (associational–commissural fibers; **Figure 1(a)**). Indeed the extent of mossy-fiber sprouting detected with the Timm heavy metal stain (**Figure 1(g)** and **1(h)**) is directly, and essentially linearly, related to the loss of mossy cells. This change in granule-cell innervation must have profound consequences for information processing by the hippocampus. Both the recurrent mossy fiber and associational–commissural pathways support forms of recurrent excitation. However, the recurrent mossy-fiber pathway creates a monosynaptic circuit oriented in the transverse plane, whereas the degenerated associational–commissural pathway connected granule cells in the longitudinal plane and on different sides of the brain through a disynaptic circuit.

About 10% of dentate granule cells in rodent epilepsy models have a basal, as well as an apical, dendrite. Granule cells in normal rodent brain are much less likely to have a basal dendrite, and basal dendrites that extend a long distance into the hilus appear unique to epileptic brain. Granule-cell basal dendrites provide an additional target for recurrent mossy-fiber synapses (**Figure 1(c)**). In humans, ~25% of dentate granule cells normally have a basal dendrite. Thus, recurrent excitation of granule cells may be a normal feature of human brain, which is then enhanced by mossy-fiber sprouting during epileptogenesis.

Dentate granule cells are unusual in that they continue to be born and differentiate throughout life. Seizures increase the rate of granule-cell neurogenesis markedly. Some studies suggest that postseizure neurogenesis contributes importantly to the progressive worsening of epilepsy. Most of the newly-born granule cells migrate into the granule-cell body layer and differentiate normally (although some retain a basal dendrite, thus accounting for the increased number of bipolar granule cells). However, a sizable subpopulation of newly-born granule cells migrates aberrantly, and many of these cells are later found throughout the dentate hilus (**Figure 1(d—f)**). Few granule cells are located in the hilus normally. Hilar ectopic granule cells (HEGCs) receive mossy-fiber innervation from other granule cells and also innervate other granule cells (**Figure 1(c)**) in addition to the normal mossy-fiber targets (CA3 pyramidal cells and inhibitory interneurons).

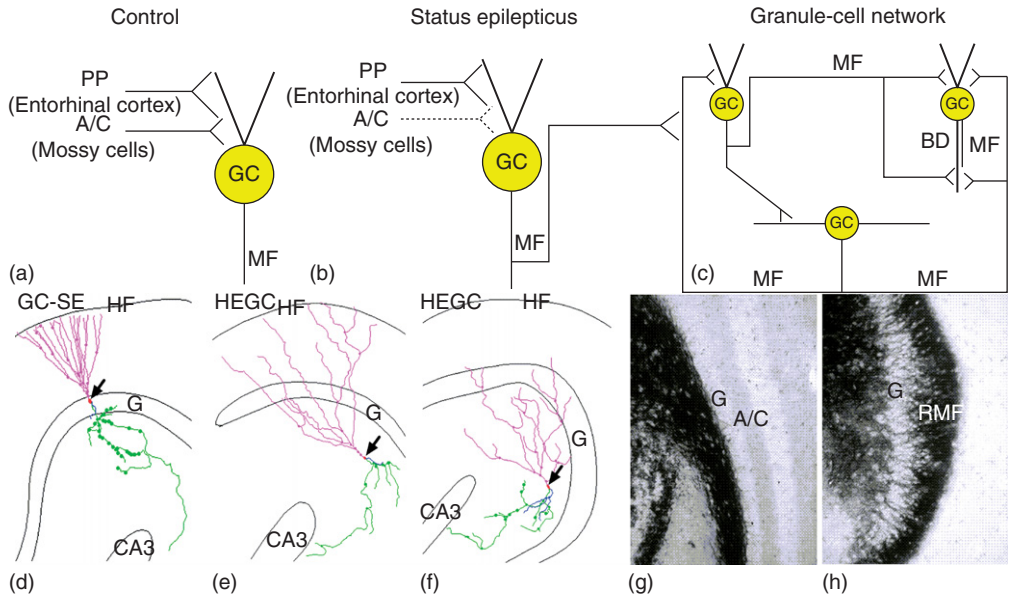

Figure 1 (a) Dentate granule cells (GC) normally receive excitatory innervation from perforant path (PP) and associational–commissural (AC) pathways on the distal and proximal portions of the apical dendrite, respectively. Mossy fibers (MF; granule-cell axons) project into the dentate hilus and area CA3. (b) Status epilepticus kills hilar mossy cells, causing mossy fibers to elaborate recurrent branches that make synapses on the portion of apical dendrite formerly innervated by associational–commissural fibers. (c) The granule-cell network consists of normally-located granule cells, with or without a basal dendrite (BD), and ectopic granule cells. These components are interconnected by mossy fibers. (d–f) Reconstructions of granule cells filled intracellularly with biocytin after whole-cell patch-clamp recording in a hippocampal slice. G, granule-cell body layer; HF, hippocampal fissure. Purple, apical dendrite; red, cell body (indicated by arrow); blue, basal dendrite; green, mossy fiber. (d) After status epilepticus, granule cells (GC-SE) in the cell body layer retain normal cellular morphology, except that a minority have a basal, as well as an apical, dendrite. (e–f) Two HEGCs demonstrating the widespread, but relatively sparsely-branched, dendrites characteristic of these cells. (g–h) Timm-stained dentate gyrus. G, granule-cell body layer. (g) The light staining of the inner molecular layer in controls is characteristic of the associational–commissural (A/C) pathway. (h) Dark staining associated with the recurrent mossy-fiber (RMF) pathway fills the inner molecular layer after status epilepticus. (a–c) Reproduced from Nadler JV (2003) The recurrent mossy fiber pathway of the epileptic brain. *Neurochemical Research* 28: 1649–1658, with permission of Springer Science and Business Media.

Thus normal granule cells, granule cells with a basal dendrite, and HEGCs are synaptically interconnected by recurrent mossy fibers, forming a reverberating network unique to epileptic brain. These anatomical changes are not essential for the development of epilepsy either in humans or in animal models. However, they have been associated with a progressive increase in the frequency and duration of spontaneous seizures.

Methods

Our studies utilize rats that had developed status epilepticus after the administration of the muscarinic receptor agonist pilocarpine. We normally allow status epilepticus to self-terminate without the administration of an anticonvulsant. Animals that experience prolonged (6–8 h) status epilepticus exhibit very extensive and uniform hilar lesions followed by robust recurrent mossy-fiber growth, as observed in many persons with temporal lobe epilepsy. The pilocarpine model also replicates the accumulation of HEGCs observed in those persons. Rats that experience pilocarpine-induced status epilepticus invariably develop unremitting spontaneous seizures after a delay of 1–3 weeks. In these respects, the pilocarpine model produces more consistent outcomes than the alternatives, such as the kainic acid or electrical stimulation models. Finally, pilocarpine-induced status epilepticus kills fewer CA3 pyramidal cells than does kainic acid or electrical stimulation, better replicating the lesion most commonly observed in surgically-resected hippocampi and facilitating the placement of a stimulating electrode in the mossy-fiber bundle of hippocampal slices.

Most of our studies are performed during the chronic epileptic period 10 weeks or longer after status epilepticus. By this time, the granule-cell network appears to be fully mature. Some analyses are also performed 4–6 days after status epilepticus, before the new circuitry can be detected. Hippocampal slices are prepared for electrophysiological studies. Extracellular recording, whole-cell and cell-attached patch-clamp recording, and perforated patch recording are used, as appropriate, to define granule-cell properties, the physiology and pharmacology of mossy-fiber→granule-cell synapses, and the role of the novel circuitry in granule-cell epileptiform activity.

In parallel studies, histological, ultrastructural, immunohistochemical, and immunocytochemical approaches are used to describe and quantitate the cytopathology of the lesion and the anatomical response to the lesion.

Results

Formation of recurrent excitatory circuitry in the dentate gyrus is associated with a reduced threshold for granule-cell synchronization in both humans and animal models. The clearest evidence was obtained in our studies of mossy fiber-evoked granule-cell population bursts. This response can be evoked only in slices with substantial recurrent mossy-fiber growth (**Figure 2(a)**). We have found no experimental conditions under which mossy-fiber stimulation evokes a granule-cell population burst in slices from control animals or in slices prepared from rats that experienced status epilepticus, but had not yet developed a detectable recurrent mossy-fiber pathway.

Although computational models suggest that formation of mossy fiber→granule-cell synapses should reliably enhance synchronized granule-cell bursting, low-frequency stimulation of the mossy fibers evokes population bursts in only 14–25% of hippocampal slices that evidence robust recurrent mossy-fiber growth. Even when the superfusion medium is modified to enhance granule-cell excitability, a population burst may be evoked in only 60–70% of slices. Furthermore, perforant path stimulation may or may not reveal evidence of granule-cell hyperexcitability during the chronic epileptic period, depending on experimental conditions. These observations prompted us to study the factors that regulate excitability in the reorganized dentate gyrus.

Our results revealed that a modest increase in extracellular K^+ concentration, short-term frequency-dependent facilitation (frequencies of 1–2 Hz), corelease of zinc, and feedback activation of presynaptic kainate receptors augment activity in the recurrent mossy-fiber pathway. Activation of presynaptic $GABA_A$ receptors by spillover from nearby GABA synapses and corelease of brain-derived neurotrophic factor (BDNF) from the mossy fibers themselves have been shown to enhance transmission at mossy-fiber synapses on CA3 pyramidal cells and would be expected to enhance recurrent mossy-fiber transmission similarly. Factors that diminish activity in the recurrent mossy-fiber pathway include short-term frequency-dependent depression (frequencies <1 Hz), feedback activation of type II metabotropic glutamate receptors, and neuropeptide Y. Activation of $GABA_B$ receptors by spillover from nearby GABA synapses and activation of presynaptic adenosine A1 receptors and κ opiate receptors by adenosine and dynorphin released from mossy fibers depress synaptic transmission onto CA3 pyramidal cells and would be expected to have similar effects at mossy-fiber synapses on granule cells.

Enhanced GABA inhibition probably accounts for the unexpectedly low excitability of the granule-cell network. Dentate granule cells receive synaptic inhibition from six

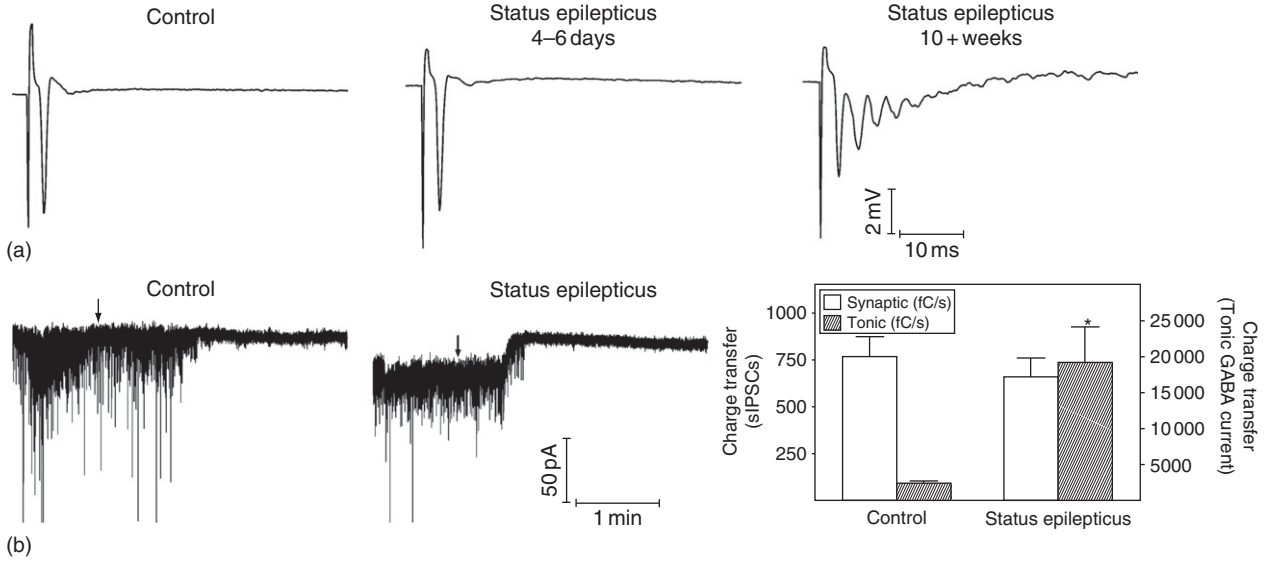

Figure 2 (a) Extracellular recording in the granule-cell body layer reveals evidence of mossy fiber-evoked reverberating excitation only after formation of a substantial recurrent mossy-fiber pathway. Reproduced from Okazaki MM and Nadler JV (2001) Glutamate receptor involvement in dentate granule cell epilepti form activity evoked by Mossy fiber stimulation. *Brain research* 915(1): 58–69, with permission from Elsevier. (b) Whole-cell patch-clamp recording (CsCl-based internal solution, $V_{hold} = -70$ mV) in the presence of glutamate antagonists reveals changes in synaptic and tonic GABA inhibition. The amplitude and charge transfer per second of tonic GABA current increases in dentate granule cells by 10 weeks after status epilepticus and the charge transferred by spontaneous IPSCs per second is only slightly depressed, despite the 70–80% loss of hilar GABA interneurons. Note the differential change in membrane current produced by the addition of the $GABA_A$ receptor antagonist SR95531 (100 μM) to the superfusion medium (arrows). $^*p < 0.05$.

distinct interneuron populations. In addition, dentate granule cells have a tonic GABA current produced by ambient extracellular GABA and released GABA that escapes the synaptic cleft. Prolonged pilocarpine-induced status epilepticus destroys 70–80% of the inhibitory interneurons located in the dentate hilus. As a result, feedback (mossy fiber-evoked) inhibition of granule cells declines substantially and granule-cell excitability increases. Both of these effects reverse with time. Results from our laboratory and others suggest several mechanisms that, in combination, probably explain the recovery of inhibition. Reverberating excitation among granule cells may allow the surviving dentate gyrus interneurons to be driven repeatedly by a mossy-fiber volley rather than just once. The charge transfer per second of spontaneous IPSCs recovers substantially and the magnitude of tonic GABA current increases (**Figure 2(b)**). These effects appear to arise in part from the increased spontaneous firing of surviving interneurons and/or the facilitation of GABA release. Finally, recurrent mossy fibers make some contacts with inhibitory interneurons. Although they account for only 5% of all synapses made by recurrent mossy fibers, their formation might represent a significant percentage increase in the mossy-fiber innervation of those interneurons.

Properties of HEGCs suggest that they could serve as triggers for recruitment of the entire granule-cell population into reverberating excitation – and thus epileptiform activity. We find that most HEGCs possess intrinsic burst capability dependent on retention of the large T-type Ca^{2+} current characteristic of immature granule cells. In addition, both ultrastructural and electrophysiological evidence suggest a much sparser inhibitory innervation than normal granule cells, although their excitatory innervation is of normal size. Hyperexcitable HEGCs may play a role in the initiation of granule-cell population bursting similar to that of the relatively excitable CA2/CA3a pyramidal cells in the initiation of CA3 bursting. In contrast, granule cells that are born after seizures and migrate normally into the granule-cell body layer appear to exhibit reduced excitability compared with granule cells born earlier. Therefore, to the extent that postseizure neurogenesis enhances the frequency and duration of subsequent spontaneous seizures, the newly-born neurons responsible for this are probably the ectopic granule cells.

Future Goals

A central issue is the extent to which the strengthening of recurrent excitation accounts for seizure initiation and/or propagation in the lesional epilepsies. The limited studies of this issue to date have focused mainly on the dentate gyrus and the results have been mixed. Hyperexcitability of dentate granule cells caused by dysfunctional BK-type Ca^{2+}-dependent K^+ channels predisposes to seizures that emanate from the temporal lobe, and at least some spontaneous limbic seizures in animal models involve the dentate gyrus at an early stage. These results support the view that any change that increases granule-cell excitability should have a proepileptogenic effect. However, other seizures appear to propagate directly from the entorhinal cortex to area CA1, bypassing the dentate gyrus. In these instances, the enhancement of recurrent excitation in area CA1 would seem to be of greater importance. In addition, seizure-induced plasticity produces both proepileptogenic and antiepileptogenic effects. Given that homeostatic mechanisms at least partially restore granule-cell excitability toward normal, we still need to define the circumstances under which recurrent excitatory activity overcomes these restraints and synchronizes population bursts.

The mechanism(s) by which dentate gyrus inhibition recovers after the loss of hilar interneurons is also of interest. Studies of CA1 pyramidal cells indicated that both the spontaneous firing of the surviving interneurons and GABA release per impulse increases in pilocarpine-treated rats. Do these changes occur also in dentate gyrus interneurons? If so, what is the underlying mechanism? Which specific interneuron populations respond to the lesion in this manner?

HEGCs have properties that favor a key role in population bursting of granule cells in epileptic brain. However, direct evidence of such a role is needed. Do HEGCs serve as triggers for bursting of the larger granule-cell population or are they primarily followers of such activity? How much do they contribute to the activation of CA3 pyramidal cells? Studies of these issues require, at a minimum, correlating the occurrence and magnitude of population bursts with the number of HEGCs (which can vary among animals by more than an order of magnitude) and the use of agents that act preferentially on HEGCs. It will also be necessary to discriminate the effects of ectopic granule cells from those of newborn granule cells that migrate normally into the cell body layer.

Finally, neuronal loss and axon sprouting create markedly abnormal circuitry in several brain regions, even if the overall level of excitability recovers to normal. An extensive and somewhat controversial literature documents cognitive/behavioral dysfunction in persons with lesional epilepsy. To what extent might reorganization of brain circuitry account for these dysfunctions?

Introduction

Pharmacological therapy for intractable partial-onset epilepsy is aimed to relieve, symptomatically, seizure frequency and severity. Almost 30 000 compounds have been examined using two animal models of acute evoked convulsions, and these tests have provided excellent anticonvulsants; however, to date, these compounds appear to be less effective against other seizure types, and ineffective in altering the progression of epileptogenesis. Advancement in the design and discovery of therapies that alter the development of epileptogenesis has been hindered by our lack of understanding of the fundamental mechanisms of epileptogenic processes – i.e., the pathophysiological process underlying the development of spontaneous seizures. Understanding the mechanisms of epileptogenesis might lead to the discovery of compounds that effectively modify the disease, by altering the natural history of symptomatic partial-onset epilepsy. This article critically summarizes synaptic reorganization in the hippocampal circuitry as a potential mechanism for epileptogenesis. We have focused on the most common, pharmacologically intractable partial-onset epilepsy, mesial temporal lobe epilepsy. Within this context, synaptic reorganization of the hippocampal circuitry progressively enhances limbic hyperexcitability and may also contribute toward pharmacological intractability in partial-onset epilepsy.

Introduction

Pharmacological therapy for intractable partial-onset epilepsy is aimed to relieve, symptomatically, seizure frequency and severity. Almost 30 000 compounds have been examined using two animal models of acute evoked convulsions, and these tests have provided excellent anticonvulsants; however, to date, these compounds appear to be less effective against other seizure types, and ineffective in altering the progression of epileptogenesis. Advancement in the design and discovery of therapies that alter the development of epileptogenesis has been hindered by our lack of understanding of the fundamental mechanisms of epileptogenic processes – i.e., the pathophysiological process underlying the development of spontaneous seizures. Understanding the mechanisms of epileptogenesis might lead to the discovery of compounds that effectively modify the disease, by altering the natural history of symptomatic partial-onset epilepsy. This article critically summarizes synaptic reorganization in the hippocampal circuitry as a potential mechanism for epileptogenesis. We have focused on the most common, pharmacologically intractable partial-onset epilepsy, mesial temporal lobe epilepsy. Within this context, synaptic reorganization of the hippocampal circuitry progressively enhances limbic hyperexcitability and may also contribute toward pharmacological intractability in partial-onset epilepsy.

Background

Mesial temporal lobe epilepsy (MTLE) is the most common epilepsy syndrome with pharmacologically intractable partial-onset seizures. This epileptic syndrome is

associated with acute neurological insults, such as status epilepticus (SE), traumatic brain injury, brain tumors, and stroke; it is highly associated with febrile seizures, particularly complex or prolonged febrile seizures. However, many patients with MTLE have no obvious brain insults, other than, the cumulative effect of repeated brief partial-onset seizures. The natural history of epileptogenesis is clearer in those patients with an acute neurological insult, which provides an initial substrate for a progression to MTLE. After an acute insult, there is typically a latent period (before the onset of spontaneous seizures) that can span several weeks, but often lasting months to years. Severe insults, such as prolonged febrile convulsions and generalized convulsive SE, are associated with a shorter latency to the onset of spontaneous seizures (compared with other less severe insults such as simple febrile seizures). The latent period between the precipitating event and the onset of epilepsy is one of the hallmarks of the pathophysiological process underlying the progression of epileptogenesis in MTLE.

Most patients with intractable MTLE have a seizure onset within the hippocampal formation. After resective surgery to remove the hippocampus, electrophysiological studies of the resected tissue demonstrate evidence of cellular hyperexcitability in the subiculum and the dentate gyrus. Subicular pyramidal neurons and dentate granule cells are hyperexcitable, but only under conditions that impair inhibitory mechanisms. Such studies have also shown a correlation between the degree of granule cell hyperexcitability and the extent of mossy fiber (dentate granule cell axons) synaptic reorganization. This type of morphological plasticity resulting in rewiring of the hippocampal circuitry is a feature of intractable MTLE (and has been shown in many experimental models), suggesting that the spontaneous epileptic seizures might be associated with these pathological alterations. However, causative relationships between the structural and functional phenomena observed in human MTLE cannot be determined, because the available resected tissue reflects only the late stage of human epileptogenesis, many years after the onset of spontaneous seizures.

Numerous neuropathological abnormalities have been described in the epileptic hippocampus from patients with intractable MTLE. Widespread neuronal injury produces a pattern of hippocampal neuronal loss known as mesial hippocampal sclerosis. The neuronal circuitry in the dentate gyrus undergoes synaptic reorganization, primarily involving the mossy fibers. These neuropathological abnormalities might be consequences of repeated seizures or the result of the initial precipitating brain insult that led to repeated seizures. Further, each of these abnormalities might also reflect a potential mechanism that contributes toward the process of epileptogenesis, which ultimately results in pharmacologically intractable MTLE. Understanding the relative contribution of these pathological abnormalities in epileptogenesis has been considerably improved by utilizing experimental models of MTLE, in which the relationship between the morphological plasticity, the pathological abnormalities, and other potential mechanisms can be systematically tested.

Methods and Experimental Approach

Several strategies are used to study the process of epileptogenesis in experimental models of MTLE. One approach utilizes chemoconvulsants to induce a prolonged period of convulsive SE and an acute excitotoxic insult in limbic structures including the hippocampus. This acute treatment gives rise to the later development of spontaneous brief seizures. The experimental chemoconvulsant SE models generally offer a latent period (between initial SE and the onset of spontaneous seizures) of several days to weeks before the onset of partial seizures. Two frequently used acute chemoconvulsants that employ this approach are the kainic acid and pilocarpine. Rats that have experienced several hours of convulsive SE induced with these chemoconvulsants exhibit neuropathological and neurophysiological abnormalities similar to those observed in intractable MTLE. Adult rats that have experienced SE demonstrate prominent neuronal damage and gliosis in hippocampal pyramidal neurons and the hilar polymorphic neurons of the dentate gyrus. After hippocampal neuronal loss, these regions demonstrate morphological reorganization of the neuronal circuits, and associated enhanced excitability. A problem with this approach is the considerable variability and mortality among experimental animals, and the severity of these pathological abnormalities (which mimics only the late stages of intractable human MTLE).

Another strategy utilizes a chronic model of repeated exposure to seizures, using electrical stimulation of limbic pathways (kindling) or chemoconvulsants to produce frequent, short insults that lead only to brief repeated seizures. In general, these chronic models of MTLE exhibit considerably less injury, and a reduced severity of pathological or physiological abnormalities (compared with the models that require an initial episode of SE). Although the chronic 'repeated exposure' models might more appropriately mimic the frequency of seizure in patients with intractable MTLE, they offer less frequent late spontaneous seizures and a less discrete latency period as compared to the kainic acid or pilocarpine model of MTLE.

Sprouting and synaptic reorganization have been investigated primarily in hippocampal pathways; however, neuronal loss has been demonstrated in multiple limbic areas. An advantage of the acute chemoconvulsant models of MTLE is that the time course of progression of the neuropathological and neurophysiological abnormalities can be studied in relation to the development of spontaneous partial-onset seizures. Following an acute excitotoxic insult,

one can study the time course and sequence of development of the different forms of morphological plasticity, as well as other neuropathological abnormalities that occur during the latent period – i.e., before the emergence of cellular hyperexcitability and the onset of spontaneous seizures. During the latent period, there are transitory functional impairments of inhibitory control that recover during the chronic state. Other neuropathological abnormalities and plasticity that appear in the latent period are permanent. It has been hypothesized that these permanent alterations underlie the mechanisms of epileptogenesis of intractable MTLE (**Figure 1**). Synaptic reorganization of the mossy fibers – i.e., sprouting into the inner molecular layer of the dentate gyrus – is the most studied form of circuitry reorganization induced during the latent period. The time course of development of mossy fiber synaptic reorganization correlates temporally with the emergence of cellular hyperexcitability in the dentate granule cells, and precedes the occurrence of spontaneous seizures. Mossy fiber synaptic reorganization has been described as a permanent alteration of the hippocampal circuitry virtually in all models of MTLE and human intractable MTLE.

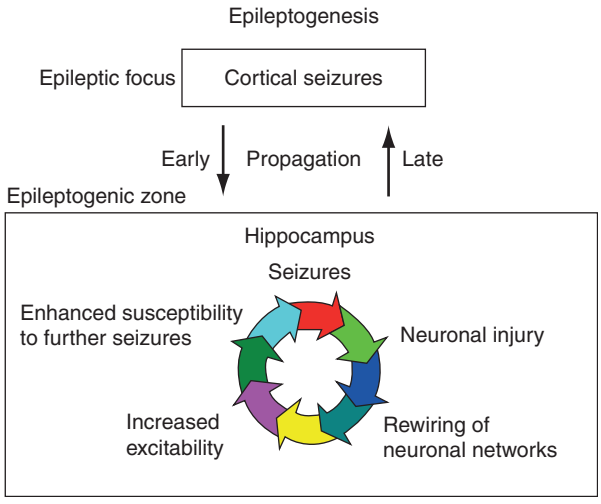

Figure 1 Mechanisms of epileptogenesis. The schematic diagram describes the relationships between pathophysiological phenomena and brain location during epileptogenesis in mesial temporal lobe epilepsy. Partial-onset seizures might initially originate in neocortical areas, but after the establishment of intractability, there is a vicious circle of interrelated pathophysiological phenomena within the hippocampal circuitry that self-sustains intractable seizures with propagation to neocortical structures. Modified from Cavazos JE and Cross DJ (2006) The role of synaptic reorganization in mesial temporal lobe epilepsy. *Epilepsy & Behavior* 8: 483–493.

Recent Results

Mossy Fiber Sprouting

The most commonly documented circuitry reorganization in MTLE is in the mossy fiber pathway of the dentate gyrus. Most studies in experimental models of MTLE have shown sprouting in the mossy fiber pathway into the inner molecular layer of the dentate gyrus (DG) and sprouting of the distal mossy fiber projection to the CA3 region. Synaptic reorganization induced by seizures has been studied extensively in the mossy fiber pathway due to the ease of detecting changes in the laminar pattern of this pathway using Timm histochemistry or Dynorphin-A immunocytochemistry. These changes in laminar pattern have been confirmed in experimental models of MTLE, using techniques that trace the axonal projections of the mossy fibers from individual dentate granule cells.

Timm histochemistry depicts the projection pattern of the mossy fibers in the hippocampus due to the high zinc content of their synaptic terminals. In normal rats and humans, there are few Timm granules in the inner molecular layer of the dentate gyrus. However, after many repeated seizures or SE, a dense band of Timm granules appears in the inner molecular layer of the dentate gyrus (**Figure 2**). Investigations have demonstrated that this

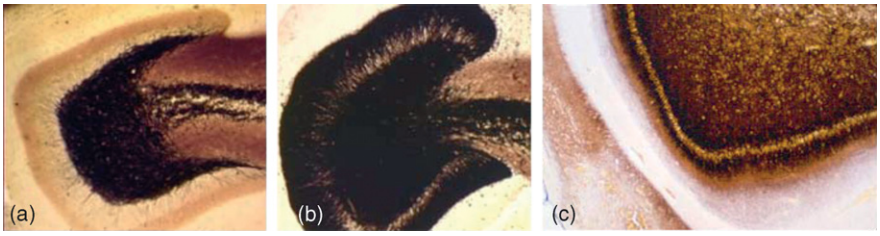

Figure 2 Mossy fiber sprouting. These are three photomicrographs from histological sections of the dentate gyrus (DG) stained with Timm histochemistry. Dark punctate granules depict the projection pattern of mossy fiber terminals that originate from granule cell axons. (a) The DG from a normal rat shows dense staining in the hilus (area within the U-shape of the DG) and in the CA3 region, with an absence of dark punctate granules in the molecular layer of the DG (arrow). (b) The DG from a rat that experienced SE-induced with kainic acid demonstrates prominent staining in the molecular layer. (c) Human DG obtained surgically during a standard anterior temporal lobectomy for the treatment of pharmacologically intractable mesial temporal lobe epilepsy. Note that the molecular layer of the DG has prominent staining, demonstrating mossy fiber sprouting into that region. Modified from Cavazos JE and Cross DJ (2006) The role of synaptic reorganization in mesial temporal lobe epilepsy. *Epilepsy & Behavior* 8: 483–493.

new Timm-positive band is due to the appearance of mossy fiber collaterals, which sprout into the inner molecular layer to form new synaptic contacts with primarily onto spines and dendrites of granule cells but also onto the dendrites of interneurons. Light and ultrastructural examination of Timm-processed tissue has been used to assess the time course of development and permanence of these reorganized axonal projection. In one kindling experiment, adult Sprague–Dawley male rats (250 g) were implanted with electrodes into the perforant path, and the entorhinal projection to the molecular layer of the dentate gyrus was stimulated twice daily to evoke five after-discharges over 3 days. Tissue from these animals was examined histologically (with Timm histochemistry) on days 1, 5, 21, and 90 after the first stimulation. A small degree of mossy fiber sprouting into the inner molecular layer was found as early as day 5, and had a maximum development by day 21 (with no further changes on day 90). In other kindling experiments, mossy fiber sprouting was observed to last as long as 18 months (when the age of the rats was over 21 months), suggesting that this morphological plasticity is permanent circuitry reorganization.

In acute chemoconvulsant models with exposure to SE early in development, there is a relative resistance to neuronal injury and lack of mossy fiber sprouting into the inner molecular layer. There seems to be a developmental age threshold in rats – around postnatal day 21 – after which exposure to SE leads to the pathological abnormalities and mossy fiber plasticity, as observed in adults. However, it should be noted that the lack of mossy fiber sprouting into the inner molecular layer does not imply an absence of circuitry reorganization. For example, SE induced with kainic acid on postnatal day 15 results in mossy fiber sprouting at the distal projection to the CA3 region, as well as, at the distal projection from the CA1 region to the subiculum.

Among the neuropathological alterations strongly associated with MTLE is hilar polymorphic neuronal loss, a possible trigger for mossy fiber synaptic reorganization. In the kainic acid model of MTLE, the acute excitotoxic insult results in neuronal degeneration in the hilus that can be recognized as early as 6 h after the onset of SE. Terminal degeneration in the inner molecular layer can be detected 24 h prior to the development of mossy fiber sprouting.

Experimental manipulations that prevent terminal degeneration from hilar polymorphic neurons also prevent the development of mossy fiber sprouting. Degeneration of axon terminals in other central (and peripheral) neural systems results in sprouting in the absence of seizures, suggesting that denervation per se is a sufficient trigger for sprouting. However, there is evidence that seizures also induce a small degree of neurogenesis of newly formed granule cells, perhaps migrating to ectopic locations and developing aberrant axonal projections.

Mossy fiber sprouting alters the organization of the dentate gyrus circuitry, making available new recurrent excitatory connections within a structure that is considered to be the 'gate' to hippocampus, and which is normally under a high degree of inhibitory control. Normally, there are few recurrent excitatory connections between granule cells. However, in epileptic animals, the sprouted mossy fibers provide direct excitatory feedback to neighboring granule cells (and to some interneurons). In the kainic acid and pilocarpine models, most of the newly formed synaptic terminals in the inner molecular layer are on granule cell spines, primarily creatinga recurrent excitatory collateral circuit. The axons from a sprouted granule cell form ~500 new synaptic contacts with granule cells, and fewer than 25 contacts onto interneurons. The chronic model of repeated kindling of limbic structures has been used to study the early stages of mossy fiber sprouting into the inner molecular layer; these studies suggest that the initial postsynaptic targets of sprouting mossy fibers are dendrites of interneurons. In Timm histochemistry, the light microscopy shows collections of Timm granules aligned in few 'strings' along the granule cell layer and the inner molecular region, presumably in association with interneuron dendrites. As many more kindling seizures are evoked, the pattern spreads along the inner molecular layer until forming a dense band of granules. Thus, it is likely that in its initial stage, mossy fiber sprouting is a homeostatic compensatory mechanism aimed to restore inhibitory control by providing feedback synaptic connections onto inhibitory basket cell interneurons. However, as the repeated seizures continue, the terminal degeneration in the inner molecular layer creates many postsynaptic targets on dendrites, spines, and somata of granule cells, providing a substrate for the formation of recurrent excitatory collaterals onto principal excitatory neurons. Computer models of the epileptic dentate gyrus demonstrate that an increase from 1% to 5% in the number of recurrent excitatory collaterals (i.e., sprouting mossy fibers) is sufficient to explain the degree of cellular hyperexcitability observed in the epileptic dentate gyrus.

Seizure-induced reorganization of the mossy fiber pathway is not limited to the formation of aberrant recurrent collaterals into the inner molecular layer of the dentate gyrus. The mossy fiber pathway also increases its branching within the hilus and expands the granule cell connectivity between the two blades of the dentate gyrus and along the septotemporal axis of the hippocampus. The net effect of this latter connectivity is the involvement of other hippocampal lamella (see below). Recurrent collaterals are also formed (along the septotemporal axis of the hippocampus) in the terminal projection of the mossy fibers to the CA3 region, particularly into the basal dendrites and spines of the CA3 pyramidal neurons in the stratum oriens.

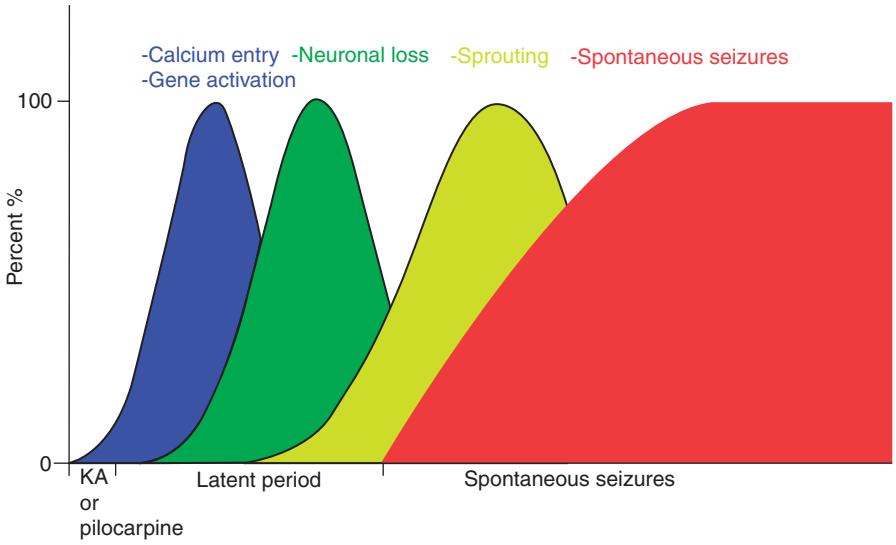

Figure 3 Time course of morphological alterations during the latent period.

To summarize, the latency of the development of morphological plasticity matches the time course of development of spontaneous seizures in acute and chronic experimental models of MTLE (see **Figure 3**). Hilar neuronal loss and terminal degeneration of their projections precede the development of mossy fiber sprouting into the inner molecular layer in acute models of MTLE; there is a direct correlation between the amount of hilar neuronal cell loss, the extent of mossy fiber sprouting into the inner molecular layer, and the degree of granule cell hyperexcitability. However, the physiological consequences of hilar polymorphic neuronal loss and mossy fiber sprouting remain a controversial subject.

Synaptic Reorganization in CA1 and Subiculum

In human MTLE and experimental models, pyramidal neurons of CA1 and subiculum also show persistent cellular hyperexcitability, and extensive neuronal loss is seen in the CA1 pyramidal neurons. Examination of the time course to formation of sprouted CA1 recurrent collaterals in acute models of MTLE suggests that seizure-induced CA1 hyperexcitability might be due to the formation of recurrent excitatory collaterals. Although hyperexcitability in CA1 neurons has been proposed to result from circuitry reorganization, these results were demonstrated in hippocampal slices, in which axonal projections perpendicular to the plane of the slice are severed. Importantly, hippocampal slices preserve the trisynaptic circuitry but do not recapitulate the complexity of the anatomical topography of the CA1 projection to the subiculum and the stratum lacunosum-moleculare of CA1.

A recent study examined the possibility that the distal axonal projections of epileptic CA1 pyramidal neurons reorganize outside of its normal laminar boundaries within the subiculum and CA1 hippocampal region (**Figure 4**). Synaptic reorganization of the CA1 projection to its primary output, the subiculum, might provide a mechanism for the enhanced and persistent cellular

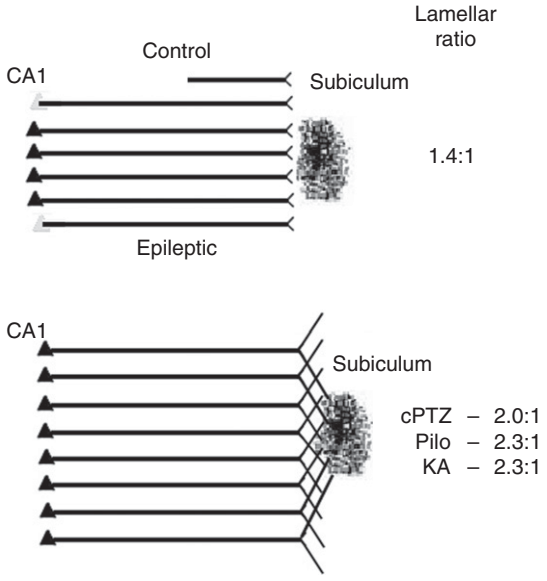

Figure 4 Synaptic reorganization in the CA1 projection to subiculum. There is prominent reorganization of the lamellar projection of the CA1 axonal pathway to the subiculum in several animal models of mesial temporal lobe epilepsy using retrograde tracers. In control rats, the extent of CA1 retrograde labeling from an injection site is limited to a couple of lamellae above and below the injection site in subiculum. In contrast, in epileptic rats, the retrograde labeling extends beyond several CA1 lamellae above and below the normal projection. This is direct evidence that axonal terminals from neurons in those layers extend their axons into the area of injection. Modified from Cavazos JE, Jones SM, and Cross DJ (2004) Sprouting and synaptic reorganization in the subiculum and CA1 region of the hippocampus in acute and chronic models of partial-onset epilepsy. *Neuroscience* 126: 677–688.

hyperexcitability in this region – an observation made in several studies using different techniques. In five animal models of MTLE, neural tracing experiments (using a retrograde labeling technique) showed that the distal branches of axons of CA1 pyramidal neurons extend 42–67% beyond their normal lamellar projection to include lamellae above and below the injection site. This study demonstrated substantial circuit reorganization of the CA1 projection to the subiculum along the septotemporal axis of the hippocampus, a finding that would support increased transverse connectivity among hippocampal lamellae above and below the normal circuitry. This type of circuit reorganization might allow epileptic activity arising in a given hippocampal lamella to recruit and synchronize activity in additional hippocampal lamellae, amplifying the epileptic response and playing a role in the persistent hyperexcitability observed in intractable partial-onset epilepsy (Figure 5).

The mechanisms triggering circuitry reorganization of the CA1 axons projecting to the subiculum are not known. In the acute chemoconvulsant models of MTLE, there is some degree of neuronal degeneration in the subiculum, but it is considerably less than in the CA1 pyramidal layer or in the hilus of the dentate gyrus. As indicated above, neuronal loss is not observed in these acute chemoconvulsant models of MTLE, if the exposure to SE occurs prior to postnatal day 21 in rats. Interestingly, in an experiment inducing SE with kainic acid on postnatal day 15 rats, investigators showed a larger extent of CA1 reorganization than in adult animals – despite the absence of overt neuronal loss in the subiculum or the CA1 pyramidal region. Furthermore, in the immature brain's response to excitotoxic insult, circuit reorganization did not occur in hippocampal pathways proximal to the site of axon origin (i.e., mossy fiber sprouting into the inner molecular layer; sprouting of CA1 axons into the stratum lacunosum-moleculare of CA1) in response to excitotoxicity in the immature brain. In contrast, circuit reorganization of hippocampal pathways distal to the site of axon origin (i.e., mossy fiber projection to CA3; CA1 projection to subiculum) displayed

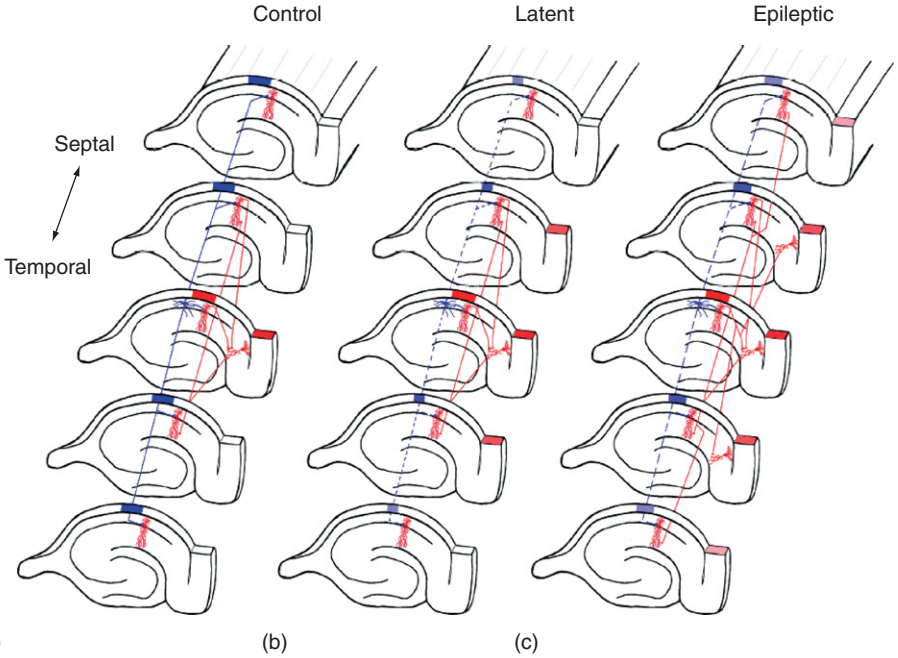

Figure 5 Synaptic reorganization in CA1 projection to the subiculum results in translamellar hyperexcitability in the hippocampal formation. The schematic drawings illustrate normal hippocampal circuitry and abnormal circuitry during the latent state and after development of spontaneous seizures in the kainic acid model of mesial temporal lobe epilepsy. The red neurons and axons are excitatory neurons; the blue neurons are inhibitory interneurons. (a) In the normal hippocampus, activation of the CA1 pyramidal neurons in a lamella results in limited activation of subicular neurons shown also in red, and the CA1 interneurons inhibit CA1 pyramidal neurons from lamellae above and below the activated lamella (shown as a blue block over those lamellae). (b) During the latent state, inhibitory mechanisms are functionally impaired, with slow improvement in the inhibitory tone (perhaps, in part, due to synaptic reorganization of inhibitory pathways). There is a mild degree of disinhibition in lamellae above and below the activated lamella (shown as smaller blue block in those lamellae). Furthermore, mild disinhibition results in a greater degree of activation in subiculum (shown as a greater number of activated subiculum sections). (c) Once spontaneous seizures develop in epilepsy models, there is prominent synaptic reorganization of the CA1 pyramidal axons, making synaptic contacts with additional CA1 pyramidal neurons and subicular neurons in sections (lamellae) above and below their normal projection pattern. The resulting increased recurrent excitatory connectivity between principal neurons in the hippocampus and within hippocampal lamellae results in translamellar sprouting. Modified from Cavazos JE and Cross DJ (2006) The role of synaptic reorganization in mesial temporal lobe epilepsy. *Epilepsy & Behavior* 8: 483–493.

a similar type of reorganization in the immature brain as it is seen in the adult brain in response to excitotoxicity. Therefore, there are significant differences between the immature and the adult brain (when exposed to excitotoxicity and SE) in distribution and extent of hippocampal circuit reorganization. The differences suggest different mechanisms for the development of seizure-induced circuit reorganization in the immature and mature brain.

Future Directions

Neuronal loss induced by excitotoxicity or repeated seizures is widespread in limbic structures. However, synaptic reorganization has been investigated primarily in the mossy fiber pathway (and to a lesser extent in the CA1 projection to the subiculum). It is likely that circuit reorganization occurs in other limbic regions, which need to be systematically studied. The physiological connectivity among these regions also requires further investigation. Such studies should focus on whether the increased connectivity within the epileptic networks (e.g., in the hippocampus) actually provides the basis for increased neuronal synchrony and facilitates the propagation of epileptic discharges beyond the epileptic focus. The mechanisms underlying the formation, development, and permanence of circuit reorganization need further investigation, as they might become targets for disease modification and prevention of intractability for MTLE. Lastly, further analysis of the differences between early life insults and insults during adulthood might provide a window for understanding critical age-dependent mechanisms of plasticity. Circuit reorganization of limbic pathways appears to be a key element in the process of epileptogenesis of MTLE. Finding strategies to prevent, stop, or reverse this process might lead to a cure of MTLE.

Dendritic Abnormalities in Epilepsy

J W Swann and M Nishimura, The Cain Foundation Laboratories, Baylor College of Medicine, Houston, TX, USA

Introduction

Studies of dendritic abnormalities in epilepsy have a long history. Microanatomical studies of human epilepsy were first conducted more than 100 years ago, and described a number of dendritic abnormalities, including a marked decrease in the number or even a complete loss of dendritic spines. In the intervening years, these observations have been reproduced by numerous investigators studying both human tissue and tissue from various animal models of epilepsy. Dendrites and their spines are well known to be major sites of excitatory synaptic transmission. Thus, these results generally suggest that this form of synaptic transmission may be significantly compromised in the epileptic brain. However, such a conclusion raises an important paradox in epilepsy research. How can one explain the presence of epilepsy – a state of chronic neuronal/network hyperexcitability – when many of the synapses that mediate excitatory synaptic transmission are presumably absent? One approach to this paradox is to consider the numerous comorbidities associated with many forms of epilepsy – perhaps most prominently cognitive disabilities. Glutamatergic synapses are thought to be sites of memory consolidation and storage, and well-known synaptic plasticity mechanisms – mediated by NMDA and mGluR receptors at these synapses – are thought to participate in important ways in learning and the formation of memories. A significant decrease in the normal complement of glutamatergic synapses in the hippocampus or neocortex, and an associated loss of these 'memory molecules,' would be expected to compromise the ability of a neuron to store memories. Thus, it is important to understand the cellular and molecular events that produce dendritic abnormalities in the epileptic brain and their functional consequences. Only by combining microanatomical and neurophysiological studies with behavioral analyses in animal models, will we be able to determine if the dendritic changes that are so prominent in the epileptic brain contribute to the learning and memory deficits observed. And perhaps only then may we be able to develop an explanation for 'the epileptic dendrite paradox,' where anatomical biomarkers predict decreased neuronal/network excitability despite the presence of epilepsy.

Background

The majority of the studies of dendrites from human brain have been carried out on tissue removed during surgery to control intractable epilepsy, and thus represents effects of persistent partial and intractable seizures on hippocampal and/or neocortical neurons. In animals, experiments have been done primarily in models of partial seizures, where alumina cream or ferric chloride was injected locally into neocortex to produce an epileptic focus, or pilocarpine or kainate was injected systemically to produce prolonged limbic motor seizures. Thus the results that have been reported so far may not apply to generalized epilepsy and may not be observed, for example, in animal models of absence seizures.

Spine loss is only one of the dendritic abnormalities found in epilepsy. In focal or partial epilepsy, decreases in dendritic arbor complexity have been commonly reported, an abnormality that could result from both a decrease in the number of dendritic branches and decreases in the length of individual dendrite segments. However, in most instances, neuronal reconstructions have not been conducted and thus a quantitative analysis has not been performed. Nonetheless, the reported effects appear to be quite dramatic; thus, in addition to spine loss, decreases in dendritic arbor complexity are thought to occur. This type of change would be expected to result in a further reduction in the number of glutamatergic synapses in affected brain regions.

Another dendritic abnormality seen in epilepsy is varicose or nodular swellings along the length of dendrites. This phenomenon gives dendrites a 'string-of-beads' appearance. Such dendritic beading is easily evoked in culture systems by application of glutamate receptor agonists – such as NMDA or kainate. Thus, dendritic beading is thought to be one hallmark of early excitotoxic injury. However, dendritic beading is readily reversible in neuronal cultures, as long as the concentration of the agonists is kept reasonably low and neuronal cell death does not occur. Recently, dendritic beading has also been demonstrated in response to kainate-induced status epilepticus in the intact animal. Again, beading appeared to be transient; after 30 m of status, dendritic beading was quite evident, but beading disappeared 1–2 h after cessation of the seizures.

The relationship between dendritic beading and spine loss (as well as excitotoxic injury) in epilepsy has been the subject of some discussion. Currently, evidence favors the view that these are independent phenomena, although they can occur simultaneously. This view is based on the observation that the time course of beading and spine loss can differ. Some investigators have observed spine loss preceding beading, but others have reported that it follows the formation of these nodular swellings. In the latter case, spines were observed emanating from swellings, and only later did some of the spines disappear. The mechanisms underlying dendritic beading and spine loss are likely to differ. There is evidence from excitotoxicity studies (as well as from epilepsy investigations) that spine loss can be prevented by pharmacologically inhibiting the activity of the calcium and calmodulin-dependent phosphatase, calcineurin. These and other results implicated increases in intracellular calcium in depolymerization of F-actin, which is a major component of the cytoskeleton of dendritic spines. Other experiments, however, have shown that dendritic beading is not calcium-dependent, instead is most likely mediated by the movement of Na^+ and Cl^- intracellularly – with beading the result of water moving intracellularly to maintain osmolarity. In these experiments, replacing Na^+ or Cl^- with impermeant cations or anions (respectively) prevented bead formation. Overall, experimental results support the notion that dendritic beading is a transient process that occurs when neurons receive intense excitatory synaptic input – such as that occurring during status epilepticus. Once seizure activity ceases, the acute changes (e.g., in Na^+ and Cl^- and water) should rapidly dissipate. However, spine loss could be longer lasting; indeed, in the recent study of kainate-induced status epilepticus, most dendritic beads disappeared within 1–2 h but spine loss persisted for at least 24 h – the maximum length of time for which images were obtained.

In summary, over 100 years have passed since dendritic abnormalities in epilepsy were first described. It is remarkable how little progress has been made in understanding the cellular and molecular events that are responsible for these abnormalities. However, in recent years, important experimental tools have been developed that promise to speed discovery in this area of investigation, and thus help unravel the role dendrites play in epilepsy and its cognitive comorbidities. For example, transgenic mice have been created that express a variety of fluorescent proteins in subpopulations of neurons in the brain. The dendrites of these cells can be easily imaged, not only in fixed tissue but also in live preparations – either in vitro or in vivo. These preparations allow investigators to examine the consequences of seizures (or seizurelike activity) on dendrites in exquisite detail. The following section reviews methods commonly used to study dendrite morphology and function.

Methods – Experimental Approaches to the Study of Dendritic Abnormalities

Most studies of human brain tissue have relied on the Golgi technique. Intracellular injections of biocytin have been performed in tissue removed during epilepsy surgery, and biocytin reconstructions have been generated in a number of animal models. The Golgi-stained sections are relatively easy to prepare but the unpredictability of the staining can be problematic, especially when many neurons are stained. The complexity of dendritic branching, and the intermixing of arbors when many cells are stained, make complete reconstructions challenging – particularly when portions of the dendritic arbor are in adjacent sections. The biocytin technique has advantages over the Golgi method, since one cell is usually filled with the dye, and the neurophysiological properties of that neuron are also available for analysis. However, the requirements of electrophysiological equipment and expertise can be a significant barrier for the use of the biocytin technique in some laboratories.

The discovery of green fluorescence protein (GFP), and the creation of numerous derivatives with their own excitation and emission spectra, have revolutionized the study of the morphology of neurons – and in particular, investigations into how seizures may impact on dendrites. Transfection of cells with GFP can be readily achieved using a variety of techniques, including lipofection, electroporation, viral transduction, and biolistic transfer. The latter procedure uses the so called 'gene gun,' whereby microscopic gold particles coated with a plasmid (in the simplest case, the DNA for GFP itself) are shot into cells. This technique is particularly advantageous for slice culture experiments where the morphology of individual neurons can be studied in detail with confocal or two (or multiphoton) microscopy. Dendrite reconstructions can be carried out once slices are fixed or can be done in living neurons. Time-lapse imaging can be employed in living tissue to study the time-dependent effects of seizurelike activity, induced in a variety of ways (e.g., zero magnesium, high potassium, disinhibition, etc.). More recently the Diolistic techniques have been introduced, in which tungsten microparticles are coated with a variety of lipophilic flurochromes like DiI and DiO. When these particles are shot into the tissue, neurons that come in contact with the particles are filled with the dye and reveal the detailed morphological features of cells. Diolistic methods can also be used in lightly fixed brains, where sections can be shot and the morphology of individual cells, studied.

The creation of an ever growing number of transgenic mice that express GFP (or a derivative) in specified neurons of the CNS has made possible more detailed, cell-specific studies of seizure effects (and pathologies associated with many other brain disorders) on neuronal

morphology. Mice that express fluorescent proteins in subpopulations of GABAergic interneurons, hippocampal and neocortical pyramidal cells, and Purkinje cells (among many others) are now readily available. When these mouse strains are crossed with genetic models of CNS disorders, insight into microanatomical abnormalities can become readily accessible. In addition to genetic models of epilepsy, the acquired epilepsies can also be studied in these transgenic mice. For instance, kainate or pilocarpine status epilepticus can be induced and the effects on neocortical pyramidal cells dendrites, studied. Alterations can be evaluated using advanced imaging techniques and quantitatively assessed by dendrite reconstructions in fixed brain tissue. And as mentioned earlier, acute morphological alterations of dendrites produced by seizures can be described in living mice using multiphoton microscopy.

To evaluate microanatomical changes in dendrites, quantitative analysis is most often required. Historically, camera lucida techniques were used for this purpose – where neurons were drawn on paper with the aid of a drawing tube that was attached to a microscope. Data were quantified by manually counting or measuring features of interest from the paper. This procedure has now been replaced by computer systems where morphological features are entered – most often still by tracing – into computer memory. Computer programs then rapidly quantify morphological features of neurons. More recently, morphological studies have generated stacks of confocal images, which are imported into computer programs; neuronal processes can be traced on the computer monitor, as one follows their course while stepping through a series of images acquired in the z axis. Large data sets are generated relatively rapidly by these methods and numerous graphical and statistical algorithms have been developed to further analyze results.

As in all areas of the neurosciences, anatomical data can only make suggestions about the functional consequences of the observed changes. Neurophysiological recordings from effected neurons – and when possible, from dendrites themselves – will ultimately lead to a clearer understanding of the consequences seizures have on neuronal function and physiological properties of dendrites. Behavioral studies will provide insights into the role dendritic abnormalities play in cognitive deficits. Molecular studies will be required to ultimately understand how seizures produce their effects.

Results – The Impact of Seizures on Developing Dendrites

As mentioned earlier, cognitive deficits – including mental retardation – are comorbidities commonly associated with severe childhood epilepsy. Such comorbidities are particularly problematic in the catastrophic epilepsies of childhood. The frequent seizures that characterize these conditions have often been implicated as contributors to cognitive disabilities. However, since many of these children have a preexisting neuropathology, and are also treated with multidrug anticonvulsant therapies, it has been difficult to establish a clear causal relationship between recurrent seizures and deficits in learning and memory. Studies in a variety of animal models have attempted to address the relationship between early-life seizures and cognition. Results have uniformly shown that brief but recurring seizures in early-life can produce spatial learning deficits. One of the models used for this purpose was the tetanus toxin model, which is characterized by frequent brief seizures during the second to third week of postnatal life in rats. As adults, these animals have marked spatial learning deficits but neuronal cell death is not apparent in the hippocampus. However, consistent with results reviewed earlier, the dendrites of hippocampal pyramidal cells from these animals show a marked loss of dendritic spines and decreases in the number of branch points in basilar dendrites. Biochemical studies of the flurothyl model, another model of early-life seizures, have reported marked decreases in the expression of proteins primarily expressed postsynaptically in dendrites. Similar results have been obtained from slice cultures where $GABA_A$ receptor antagonists have been used to induce epileptiform activity. Additional experiments have shown that these effects in slices were completely suppressed by NMDA receptor antagonists.

The mechanisms underlying these effects on dendrites in developing hippocampus have been the subject of discussion and speculation. It is conceivable that the changes observed in dendrite spine density and branching complexity could be the result of excitotoxicity in dendrites. As described earlier, application of glutamate receptor agonists to neurons in culture produces beading of dendrites and spine loss (although these two effects are likely mediated by different molecular mechanisms). Similar effects have been reported in vivo in adult rodents during status epilepticus. Thus, one possibility is that the dendritic abnormalities observed in vivo and in vitro developmental epilepsy models are the product of dendrotoxicity – a sublethal impact of massive amounts of glutamate released during seizures on dendrites. However, dendritic beading – a surrogate marker for dendrotoxicity – has not been demonstrated in developing neurons subjected to brief/recurring seizures activity. Alternatively, differences in spine density and dendritic arbor complexity, observed between control and neurons that have undergone early-life seizures, might be explained by seizure-induced suppression of dendrite growth. Recent studies from our laboratory support such a hypothesis. Here, recurring epileptiform activity was induced in hippocampal slice cultures prepared from

1 week old YFP-H mice. These mice express yellow fluorescent protein (YFP) in a subset of CA1 pyramidal cells. Figure 1 summarizes results from a set of experiments. Reconstructions of basilar dendrites over a 4 day period (3–7 days in vitro-DIV) showed that during this time, dendrites undergo rapid growth; new branches are added and the length of individual segments increases. However, when slices were treated with the $GABA_A$ receptor antagonist bicuculline (or high potassium) to induce epileptiform discharging, the growth of dendrites observed in sister cultures was markedly suppressed. This result was further shown to be an NMDA receptor-dependent process.

Challenges for the Future

Based on these results, experiments in vivo are needed to verify that recurrent seizures in infant rodents produce similar results. Such a demonstration would open up

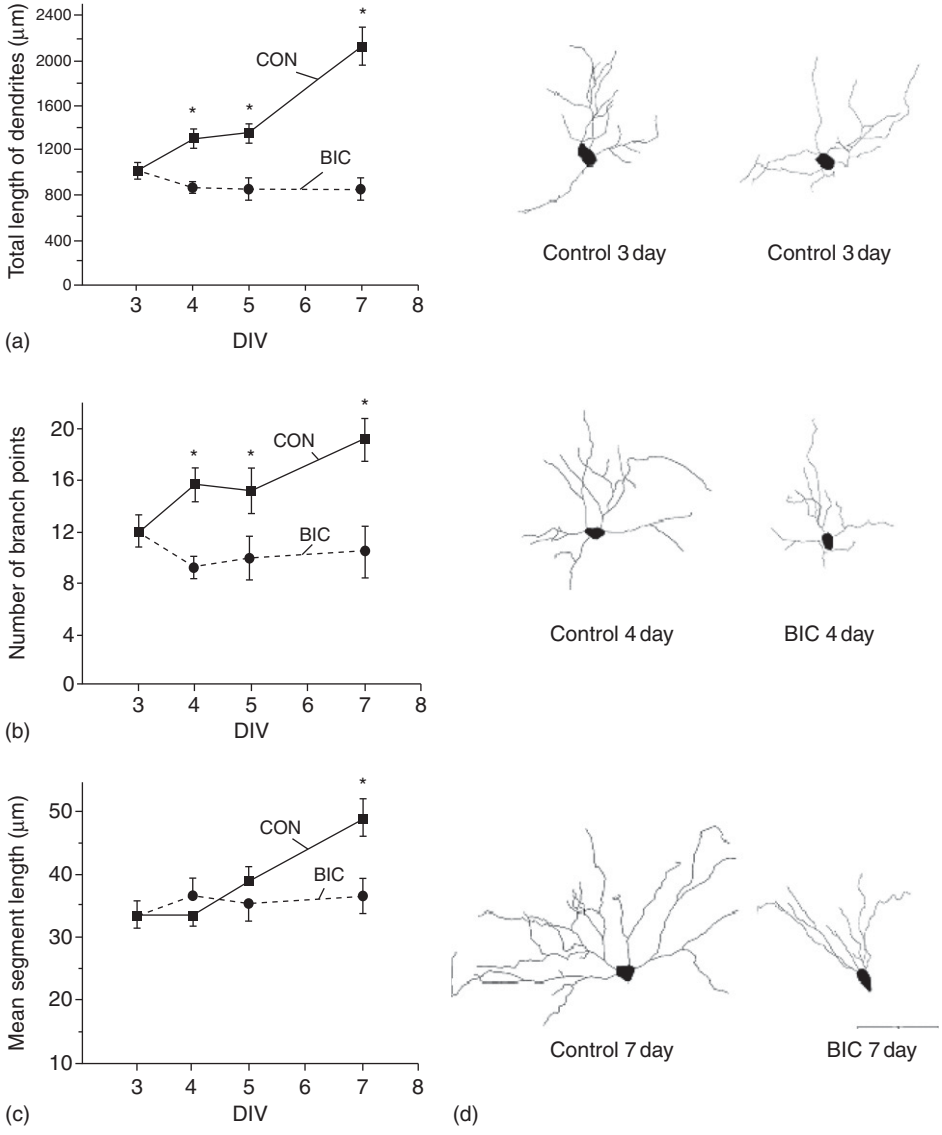

Figure 1 Chronic disinhibition suppresses the growth of CA1 hippocampal pyramidal cell dendrites. (a–c) Between 3 and 7 days in vitro (DIV), the basilar dendrites of CA1 pyramidal cells in control slices gradually increased in: total length, number of branch points and mean segment length. However in bicuculline treated slices, dendrites did not increase in length or branching complexity. (d) Representative Neurolucida reconstructions of dendrites of YFP positive CA1 pyramidal neurons at selected times in vitro. The soma and basilar dendrites of these cells are shown. Reproduced from Nishimura M, Owens J, and Swann JW (2008) Effects of chronic network hyperexcitability on the growth of hippocampal dendrites. *Neurobiology of Diseases* 29: 267–277, with permission from Elsevier.

many new avenues of investigations into the molecular mechanisms that are responsible for growth suppression. Indeed, in recent years a number of important molecular signaling pathways have been identified as important players in normal dendrite growth. Some of these pathways are directly regulated by neuronal activity. Alterations in one or more of these pathways would be a candidate mechanism for seizure-induced dendritic growth suppression. Normally, neuronal activity is thought to promote dendrite growth in early life; based on this hypothesis, one would think that the hyperexcitability of recurring seizures would result in an accelerated growth or even overgrowth of dendrites. However, such accelerated growth is not observed, either clinically or in laboratory studies. Instead, one might speculate that growth suppression (if it really occurs in children with epilepsy) is a compensatory and neuroprotective response of growing/developing neurons to abnormally high levels of neuronal activity.

During development dendrites eventually stop or greatly decrease their rate of growth. 'Stop growing signals' are likely produced to shut off molecular developmental programs mediating dendrite growth. Levels of neuronal activity are likely to be one of a number of environmental and genetic cues integrated by neurons to signal the end of the rapid phase of dendrite growth. If so, it is easy to envision how excessive neuronal activity that characterize seizures could produce a premature induction of a stop growing signal. Such a process could also be viewed as neuroprotective, since decreasing dendrite arbor length and complexity should result in a decrease in the number of excitatory synapses onto pyramidal neurons, which would in turn result in diminished neuronal and network excitability – something that might be advantageous in intractable childhood epilepsy. However, another effect of such neuroprotection would be a decrease in the complement of glutamatergic synapses (and their molecular machines) that are thought to be critical contributors to learning and the storage of memories.

We are at the early stages of understanding the impact seizures have on dendrites in both the mature and immature nervous systems, as well as the contributions these changes make to epileptogenesis and coexisting cognitive and psychiatric difficulties. However, many new experimental tools have become available in just the past five years, and new methods and techniques in molecular biology, genetics, and imaging are being added at impressive rates. Many of these new approaches should be directly applicable to epilepsy research and promise to provide interesting answers to many long-standing questions.

Inositol Lipid Signaling in Synaptic Activity, Neuronal Plasticity and Epileptogenesis

N G Bazan and A E Musto, Louisiana State University Health Sciences Center, New Orleans, LA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Excessive glutamatergic neurotransmission is a major factor underlying the pathophysiology of seizures and of epilepsy. The use of ionotropic glutamate receptor antagonists as potential antiepileptic drugs has shown therapeutic potential in animal models of epilepsy, but this strategy has failed in early clinical trials. Recent studies have suggested that the modulation of metabotropic glutamate receptors (in addition to drug effects at glutamatergic ionotropic receptors) could ameliorate seizures. Specifically, metabotropic glutamate (mGlu) receptor (possibly $mGlu_5$) agonists (as accessed in basolateral amygdala neurons from brain slices of kindled rats) activate the Na^+–Ca^{2+} exchanger, suggesting that the mechanism for removal of the excess intracellular Ca^{2+} occurs during periods of high glutamate release such as seizures. mGluR1 and mGluR5, both linked to phosphoinositide hydrolysis, show perturbations in mRNA expression in hippocampus of amygdala-kindled animals, studied at different time points after the last generalized seizure (stage 5 from Racine's score). Inositol hydrolysis leads to sustained increase in protein kinase C activity following amygdala kindling, suggesting that these agonists trigger inositol lipid hydrolysis, and enhance protein kinase C activity during early stage of epileptogenesis. Given these results, there is an interesting potential for ameliorating seizures with the combination of mGlu receptor ligands with other glutamatergic (and non-glutamatergic) agents.

The exploration of second-messenger signaling, mediated through activation of mGlu receptors, will expand our understanding of the modulation of seizures and epileptogenesis. mGlu receptor activation is correlated with an increase of intracellular diacylglycerol (DAG) because of hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) (**Figure 1**, wild type). The molecular species 1-stearoyl-2-arachidonoyl-*sn*-glycerol comprises 80% of brain PIP_2. Arachidonoyldiacylglycerol (AA-DAG) is a second messenger derived from phosphatidylinositol 4,5-bisphosphate and generated by stimulation of glutamate metabotropic receptors linked to G protein and activation of phospholipase C. AA-DAG signaling is terminated by its phosphorylation to phosphatidic acid, catalyzed by diacylglycerol kinase (DGK). The significance of DGK family in synaptic function has been investigated in mice with targeted disruption of the DGKε gene. $DGK\varepsilon^{-/-}$ mice showed a higher resistance to electroconvulsive shock, with shorter tonic seizures and faster recovery than do $DGK\varepsilon^{+/+}$ mice. The phosphatidylinositol 4,5-bisphosphate-signaling pathway in cerebral cortex was greatly affected by the DGKε gene deletion, leading to lower accumulation of AA-DAG and free AA. Also,

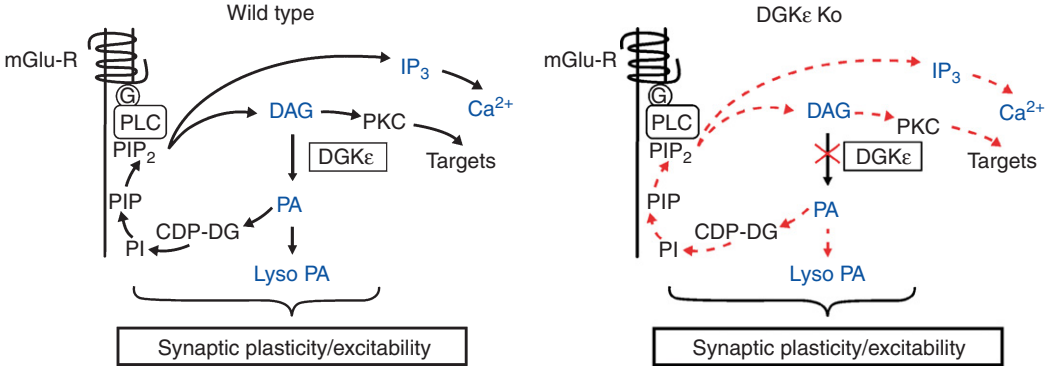

Figure 1 Diagram depicting seizure-induced inositol lipid signaling in wild-type and DGKε deficient mice (DGKε KO). In wild-type mice, metabotropic glutamate receptor interacts with G proteins, which in turn activate PLC, resulting in the hydrolysis of PIP_2 that generates DAG and IP_3. DGKε is a lipid kinase that modulates multiple signaling functions related to epileptogenesis, such as synaptic plasticity and excitability. DGKε catalyze the phosphorylation of DAG to PA. Inositol cycle is interrupted leading to decreased availability of bioactive molecules: DAG, PKC, IP3, CA2, PA and lyso-PA. PI phosphatidylinositol; PIP, phosphatidylinositol 4-phosphate; PIP_2, phosphatidylinositol 4,5 phosphate; PLC, phospholipase C; G, G protein; IP_3, inositol 1,4,5 phosphate; CDP-DG, cytidine diphosphate-diacylglycerol; PA, phosphatidic acid; lyso-PA, lyso-phosphatidic acid.

long-term potentiation (LTP) and kindling epileptogenesis were attenuated in these DGKε$^{-/-}$ mice. On the basis of these studies, we propose that DGKε contributes to modulate neuronal signaling pathways linked to synaptic activity, neuronal plasticity, and epileptogenesis.

Background

Inositol lipid-derived diacylglycerols (DAGs) are generated by the excitatory neurotransmitter glutamate through the activation of phospholipase C (PLC). Activation of metabotropic receptors (mGluRs), coupled to G proteins and PLC, increases DAG concentration because of the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2). A subsequent increase in DAG pool size follows as a result of phospholipase D (PLD)-catalyzed hydrolysis of phosphatidylcholine to phosphatidic acid (PA) and its conversion to DAG. The early and late DAG peaks are temporally dissociated, and their fatty acid composition is different. Inositol phospholipids are enriched in arachidonate at the sn2 position of the glycerol backbone, whereas in phosphatidylcholine this position is occupied mainly by monounsaturated fatty acid chains (i.e., oleic acid, 18:1n-9).

AA-DAG activates protein kinase C (PKC) in vitro and plays second messenger functions in vivo. Moreover, there is evidence that targets of DAG can distinguish between different DAG species. Thus, the distinct fatty acid composition of inositol phospholipids in neuronal cell signaling may be important for the maintenance of cellular functional integrity. Enzymes responsible for inositol lipid synthesis selectively use AA-containing lipids as substrates. DAG kinase ε (DGKε), which selectively phosphorylates AA-DAG to generate PA, is one candidate for this selective function. Eight other mammalian DGKs, with no significant selectivity, have been identified.

Activation of inositide lipid signaling through metabotropic glutamate receptor (mGluR) and PKC is involved in synaptic plasticity, learning, memory, LTP, and long-term depression (LTD). Moreover, alterations of this signaling have been implicated in epilepsy, Alzheimer's disease, and depression. To explore the mechanisms underlying metabotropic glutamate-mediated lipid signaling in epilepsy, the targeted deletion of the DGKε gene was explored as an effective approach to determine whether DGKε contributes to arachidonate enrichment – and to determine the functional consequences of DGKε gene deletion with respect to seizure responses and LTP. The AA-DAG signal generated from mGluR-activated PIP_2-PLC pathway is switched off by DGKε that generates PA. The PA, in turn, is used for the synthesis of phosphatidylinositol and the replenishment of the precursor by phosphorylations to phosphatidylinositol 4-phosphate (PIP) and PIP_2.

Methods

Electroconvulsive Shock (ECS)

Two- to three-month-old wild-type, heterozygous (+/−), and homozygous (−/−) DGKε mice (20–25 g, male/female) were acutely implanted with two platinum electrodes under the scalp (parallel, 1 cm apart) and then stimulated. A single stimulation train of square pulses was delivered at 50 V DC and 0.5-ms pulse duration at 100 Hz; train duration was 200 ms, and train rate was 0.750 per second.

Lipid Analysis

Mice were killed by high-frequency, head-focused, microwave irradiation, their heads were cooled quickly in ice-cold water, and the brains were dissected. Lipids from the right cerebral cortex were extracted with hexane/isopropanol, 3:2 (vol/vol), for the analysis of free fatty acids (FFA) and DAG. Polyphosphoinositides (PPI) were extracted from the left cerebral cortex with acidified chloroform/methanol. Lipid classes by TLC were isolated and their acyl groups were analyzed by gas liquid chromatography.

Electrophysiological Recordings

Hippocampal slices were prepared from DGK-deficient mice (either sex) and age-matched controls. Whole-cell patch–clamp recordings were made with an Axoclamp-2B patch–clamp amplifier in bridge mode. Excitatory postsynaptic potentials (EPSPs) in response to stimulation of the perforant path (at a frequency of 0.05 Hz) were recorded, and the amplitude range of the evoked EPSPs was adjusted to 2–6 mV (<30% threshold for generating an action potential). LTP in the perforant path was induced by high-frequency stimulation (HFS). HFS consists of eight trains, each of eight pulses at 200 Hz, with an intertrain interval of 2 s. LTP was operationally defined as >20% increase above baseline for the amplitude of ESPSs from 26 to 30 min after HFS.

Rapid Kindling Epileptogenesis

Bipolar electrodes were implanted in the right dorsal hippocampus of male DGKε$^{+/+}$ and DGKε$^{-/-}$ mice. Ten days post surgery, kindling was achieved by stimulating six times daily for 4 days with a subconvulsive electrical stimulation protocol (10-s trains, of 50-Hz biphasic pulses, 75–200-μA amplitude) and a 30-min intertrain interval. After 1 week, mice were rekindled. Hippocampal evoked responses immediately after subconvulsive stimulations were recorded and analyzed to characterize epileptogenic events, such as spike, sharp waves, or abnormal amplitude and rhythms.

Histology

The right hippocampus was analyzed by histological and immunocytochemical techniques (Timm staining, NPY, and GFAP immunoreactivity), and using TUNEL staining for DNA fragmentation, following provider protocols.

RNA Isolation and Quality Control

Left and right hippocampal total RNA was isolated using Trizol reagent (Invitrogen Life Sciences, Carlsbad, CA) and RNA quality was screened and quality controlled using RNA LabChips (Caliper Technologies, Mountain View, CA). Each total RNA sample was scanned from 220 to 320 nm using a GeneSpec III spectrophotometer (Hitachi Genetics, Alameda, CA) and the $A_{260/280}$ of total RNA (based on peak area) was typically >1.8. RNA samples were next analyzed for spectral purity and concentration (ng μl^{-1}) using RNA Nano LabChip analysis Chips and a 2100 Bioanalyzer (Caliper Technologies, Mountainview, CA; Agilent Technologies, Palo Alto, CA).

RNA Labeling and DNA-Array Analysis

Total RNA was labeled using the Enzo Bioarray High Yield RNA Transcript Labeling system (Affymetrix, Santa Clara, CA), hybridized to the Test3 and analytical GeneChips, washed, and scanned.

Statistical Analysis

Data are presented as mean ± SEM. Statistical analysis was performed with the unpaired Student's *t* test. One-way ANOVA with Fisher's PLSD post hoc was used for statistical comparison when appropriate. Statistical analysis of the frequency of the behavioral responses to ECS was carried out with the χ^2 test. Differences were considered significant when $P < 0.05$.

Recent Results

DGKε Expression in Mice

Murine DGKε displayed similar selectivity for AA-DAG as human DGKε; thus, the enzymatic selectivity of DGKε seems to be conserved in mammals. This AA-DAG-specific DGK may be significant in terminating signals transduced through AA-DAG generated in the PIP_2 cycle. However, the tissue distribution patterns of murine and human DGKε are different, as demonstrated by Northern blotting; murine DGKε is primarily expressed in brain, but human DGKε is predominantly expressed in testis. This difference may reflect the involvement of murine and human DGKε in different signaling pathways. The cellular distribution of murine DGKε in brain, as seen with in situ hybridization, was similar to that of the mGluR1 in cerebellar Purkinje cells, mitral cells of the olfactory bulb, hippocampal interneurons, and neurons of the thalamus and substantia nigra. G protein-coupled mGluR1 leads to PIP_2 hydrolysis catalyzed by PLC and the subsequent activation of PKCβ.

Downregulation of AA–Inositol Lipid Signaling and Resistance to Seizures

Since ECS and ischemia activate the PLC-mediated release of AA-DAG, and since DGKε terminates AA-DAG signals, we investigated whether deficiency of DGKε (in the mouse knockout) would affect the seizure response to ECS. In fact, male and female DGKε-deficient mice were more resistant to ECS, displaying shorter tonic seizures and faster recovery than do $DGK\varepsilon^{+/+}$ mice. This behavioral response was paralleled by decreased degradation of brain PIP_2 and decreased accumulation of DAG and FFA after ECS (in DGKε-deficient mice compared with wild-type controls). Moreover, DAG returned to basal levels within 1 min after ECS in $DGK\varepsilon^{-/-}$ mice, but a more sustained accumulation was observed in $DGK\varepsilon^{+/+}$ mice (**Figures 2** and **3**).

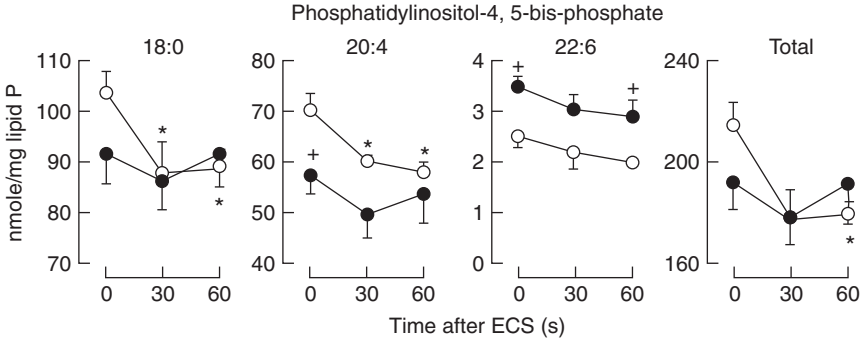

Figure 2 ECS-induced degradation of PIP_2 is decreased in the $DGK\varepsilon^{-/-}$ mice. Mean values ± SEM are shown ($n = 4$–6). Statistically significant differences (Student's *t* test, $P < 0.05$) are indicated: *, with respect to control (0 time); +, $DGK\varepsilon^{-/-}$ mice (●) vs. $DGK\varepsilon^{+/+}$ mice (○). (2001) Diacylglycerol kinase epsilon regulates seizures susceptibility and long term potentiation through inositol lipid signaling. *Proceedings of the National Academy of Sciences USA* 98: 4740–4745, with permission from National Academy of Sciences.

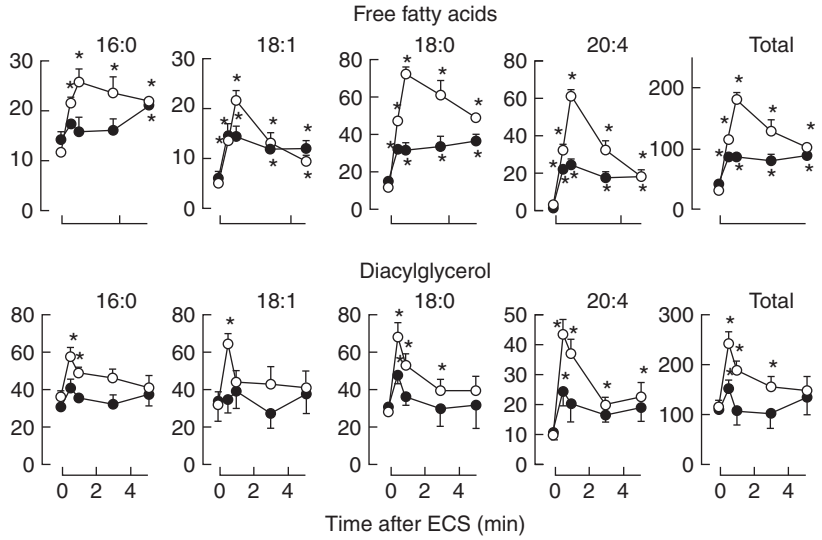

Figure 3 ECS-induced accumulation of FFA and DAG in wild-type (○) and DGKε$^{-/-}$ mice (●). Mean value ± SEM are shown. Basal values (time 0) are the average of 16 samples. Other time points are from 5–8 individual samples. * denotes values significantly different from basal ($P < 0.05$, Student's *t* test). Modified from Rodriguez de Turco EB, Tan W, Tophan MK, *et al*. (2001) Diacylglycerol kinase epsilon regulates seizures susceptibility and long term potentiation through inositol lipid signaling. *Proceedings of the National Academy of Sciences USA* 98: 4740–4745, with permission from National Academy of Sciences.

Although resting levels of PIP and PIP_2 were similar in cerebral cortex from DGKε$^{-/-}$ and DGKε$^{+/+}$ mice, some differences were detected. Neuronal PPI is maintained by de novo synthesis via PA, whereas the DAG–DGKε pathway contributes to their resynthesis after synaptic activity-induced PIP_2 degradation. Activation of the mGluRs regulates the operation of this cycle through PLC. In DGKε$^{-/-}$ mice, only AA-PIP_2 displayed decreased resting levels. Therefore, despite the deficiency in DGKε selective for AA-DAG phosphorylation, other DAG kinase(s) and/or the de novo synthesis pathway may partly compensate to generate AA-PA (that is then channeled to inositol lipids) in DGKε$^{-/-}$ mice. Moreover, DGKε$^{-/-}$ mice did not show enrichment in AA-DAG, and only 31% of the animals displayed higher resting levels of total DAG as compared with DGKε$^{+/+}$ mice. It is likely that the resting AA-DAG pool of the PPI pathway is very small compared with the pool of AA-DAG linked to the turnover of other phospholipids, and therefore changes in this pool may be masked within the total DAG pool.

The ECS-induced 18:0- and AA-DAG accumulation in the cerebral cortex, at 30 s post-ECS, was lower in DGKε$^{-/-}$ mice than in DGKε$^{+/+}$ mice. However, removal of DAG showed similar kinetics in both DGKε$^{-/-}$ and DGKε$^{+/+}$ mice, suggesting that even after stimulation, other DGK(s) may compensate for the DGKε deficiency. The DAG pathway is terminated by DGK through its phosphorylation to PA, and/or by DAG lipases with the generation of FFA. However, the rapid removal of DAG in DGKε$^{-/-}$ mice was not paralleled by a further increase in FFA, supporting the notion that DGKs other than DGKε, rather than DAG lipases, are involved in the efficient removal of DAG after ECS in DGKε$^{-/-}$ mice (**Figure 3**).

Interestingly, DGKε$^{-/-}$ mice displayed very low PIP_2 degradation after ECS, suggesting impairments in mGluR function linked to G proteins and PLC activation. It is possible that to cope with the deficiency of the DGKε, adaptive and/or compensatory changes are developed, including a persistent PKC binding to the membrane in close association with the mGluR–G protein–PLC complex, where AA-DAG accumulates. Because PKC controls the PPI cycle by feedback inhibition of PLC, this sustained translocation would inhibit the PPI–PLC signaling, as reflected in the low ECS-induced AA-DAG release.

In DGKε$^{-/-}$ mice, a significant decrease of 18:0- and AA-PIP (not observed in DGKε$^{+/+}$ mice) took place after ECS. Because stimulation activates degradation and resynthesis of inositol lipids, the levels of PIP and PIP_2 reflect the balance of these two pathways. In DGKε$^{+/+}$ mice, degradation of PIP_2 occurs at a faster rate than its replenishment from PIP by PIP 4-phosphate 5-kinase, while PIP is being replenished through the DAG–PA–phosphatidylinositol pathway. This results in a decrease of PIP_2 and no detectable changes in PIP. In DGKε$^{-/-}$ mice, the decrease observed in PIP may indicate its active phosphorylation to PIP_2 and its slower replenishment from the DAG–DGKε$^{-/-}$ pathway. Because type I PIP 4-phosphate 5-kinase is highly expressed in the brain and greatly stimulated by PA, deficiency of DGKε will likely not force PIP_2 resynthesis. Therefore, other metabolic dysfunctions should be considered in DGKε deficiency, including PIP degradation by PLC and/or its dephosphorylation to phosphatidylinositol.

In DGKε$^{+/+}$ mice, there was also accumulation of 16:0- and 18:1-DAG after ECS, while levels of 16:0- and 18:1-PIP_2 remained unchanged (data not shown). These changes are consistent with degradation of other phospholipids through a PLD pathway that contributes to the sustained accumulation of DAG. In DGKε$^{-/-}$ mice, however, no change in 16:0- and 18:1-DAG was observed. Thus, the disruption of the inositol lipid cycle, and the consequent lack of DAG-stimulated PKC-mediated activation of PLD, may lead to the loss of PLD response to stimulation. These results suggest impairments in multiple signaling pathway response to ECS in DGKε$^{-/-}$ mice that may contribute to the observed faster recovery of DGKε$^{-/-}$ mice from tonic–clonic seizures. The magnitude of free AA and other FFA accumulation after ECS in DGKε$^{-/-}$ mice (compared with DGKε$^{+/+}$ mice) reveal potential alterations in the calcium-dependent $cPLA_2$ pathway. Degradation of 18:0- and AA-DAG generated from PIP_2 after ECS may contribute to the FFA pool. However, the release of AA after ECS, when PIP_2 levels start to recover, implicates the activation of $cPLA_2$ targeting with high selectivity of AA-phospholipids.

NMDA Receptor Activation Leads to Calcium Influx and $cPLA_2$ Activation

The intracellular mobilization of calcium by IP_3 also contributes to sustained activation of $cPLA_2$. The $cPLA_2$ signaling has a profound impact in responses to stimulation because AA by itself, and eicosanoids generated by COX-1–COX-2, are involved in the modulation of synaptic activity. Moreover, $cPLA_2$ generates lyso-PAF, the precursor of PAF, a neuromodulator of LTP that stimulates glutamate release from presynaptic terminals and activates transcription of genes. In cultures of hippocampal neurons from DGKε$^{-/-}$ mice, glutamate stimulation resulted in lower accumulation of intracellular Ca^{2+} compared with cells from DGKε$^{+/+}$ mice (unpublished results). In this context, it is relevant that sustained increase in intracellular Ca^{2+} appears to be required for $cPLA_2$ translocation to the membrane and full enzymatic activity. Decreased activity of $cPLA_2$, and consequently lower release of AA and PAF production in DGKε$^{-/-}$ mice, is also supported by the observation that LTP is attenuated in perforant path–dentate granular cell synapses.

In summary, changes in lipid messengers generated in the brain after one ECS are complex and suggestive of alterations in different signaling pathways (i.e., PLA_2, PLC), related to glutamate receptors activation. Knockout mice with a deficiency in DGKε have helped to explore the roles of metabotropic glutamate receptor–inositol lipid signaling. The lack of the DGKε blocks the availability of several lipid mediators (DAG, PA, lyso-PA) and other signaling molecules (IP3, Ca, PKC) during seizures, which likely are involved in epileptogenesis (**Figure 1**).

HFS-Induced LTP is Reduced in DGKε-Deficient Mice

Synaptic transmission and plasticity were examined in dentate granular cells of DGKε-deficient mice. There were no abnormalities in basic membrane properties, including resting membrane potential, input resistance, and action potential generation in cells in hippocampal slices from enzyme-deficient mice. However, the potentiation of EPSP amplitude by high-frequency stimulation (HFS) was significantly reduced in cells from DGKε$^{-/-}$ mice (potentiation, mean ± SEM, 135 ± 11% of baseline from 26 to 30 min after HFS) when compared with that in the DGKε$^{+/+}$ mice (224 ± 23%). These DGKε$^{-/-}$ mice displayed lower release of AA-DAG induced by ECS, suggestive of lower $cPLA_2$ activity necessary for PAF synthesis. Since PAF enhance neuronal excitability, the attenuation of LTP seen in DGKε$^{-/-}$ mice may be the consequence of diminished PAF synthesis. However, low production of other AA–inositol lipid-derived signaling molecules also may contribute to alterations in synaptic plasticity. Thus, alterations in the AA–inositol lipid cycle take place in limbic structures that display high DGKε expression and may contribute to synaptic dysfunction and pathology.

Diacylglycerol Kinase Epsilon Modulates Kindling Epileptogenesis

In a rapid kindling paradigm, DGKε$^{-/-}$ mice had significantly fewer motor seizure and epileptic events compared with DGKε$^{+/+}$ mice from the second day of stimulation (**Figure 4**). These differences were maintained during rekindling. DGKε$^{-/-}$ mice also exhibited lower-amplitude spike-wave complexes, shorter spreading depression events, and predominant lower-frequency (1–4 Hz) EEG bands throughout stimulation (compared with DGKε$^{+/+}$ mice), as determined by power spectral analysis. Further, DGKε$^{-/-}$ mice displayed no sprouting in the supragranular area or NPY immunoreactivity in the hilus, and had weak astrocyte reactivation in all hippocampal areas. No TUNEL-positive cells were detected in any group of mice.

DGKε modulates kindling epileptogenesis through inositol lipid signaling. Arachidonate-containing diacylglycerol phosphorylation to phosphatidic acid is selectively blocked in DGKε$^{-/-}$ mice. This finding suggests that the shortage of arachidonoyl-moiety inositol lipids, and/or the messengers derived from there, is a key signaling event in plasticity during epileptogenesis.

Diacylglycerol Kinase Epsilon Deficiency Upregulates COX-2

Gene-expression patterns can be effectively displayed by plotting the data as 'volcano plot' (V-plot) representations.

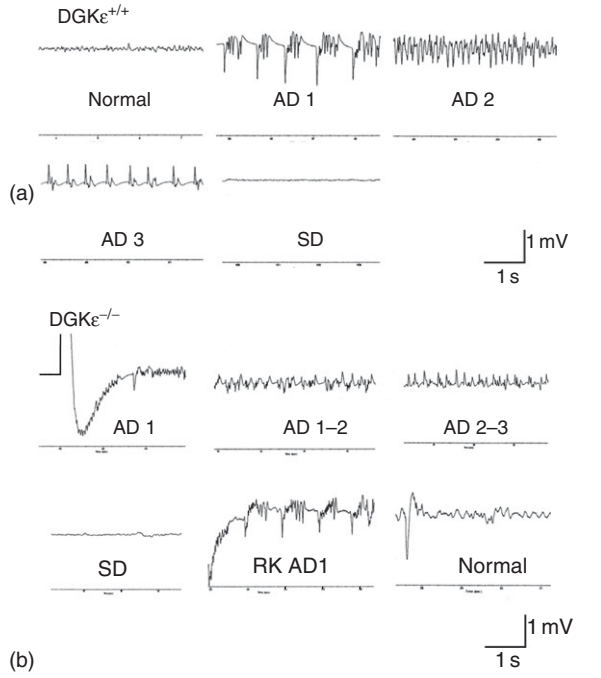

Figure 4 (a) Distinctive EEG patterns of afterdischrage (AD) obtained from DGKε$^{+/+}$ mice during stages 4–5. Repetitive, synchronized bursts of high-amplitude spikes followed by polyspikes-waves were observed immediately after the stimulation (AD1); continuing this pattern, repetitive spikes (AD2) and spike-wave complexes (AD3), with opposite polarization compared with AD1, were observed. A spreading depression was observed at the end of each AD. (b) In contrast, DGKε$^{-/-}$ mice had few spikes and merged AD1–AD2 profiles or merged AD2–AD3 profiles (AD 1–2; AD 2–3), which were observed only sporadically in the rekindling session. The spreading depression was shorter or became a normal EEG after the last spike. Modified from Musto A and Bazan NG (2006) Diacylglycerol kinase epsilon modulates rapid kindling epileptogenesis. *Epilepsia* 47: 267–276, with permission from Blackwell Publishing.

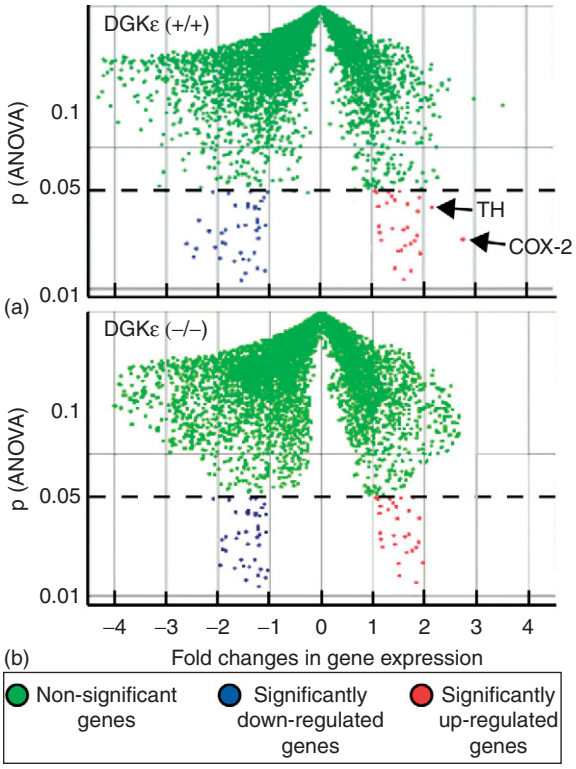

Figure 5 Volcano plots of (a) kindled DGKε$^{+/+}$ vs. control DGKε$^{+/+}$ mice and (b) kindled DGKε$^{-/-}$ vs. control DGKε$^{-/-}$ mice in whole hippocampus. Arrows point to upregulated oxygenase-encoding genes TH and COX-2; for clarity the data of nonsignificant genes in the region $P \leq 0.05$ (dashed horizontal line) and fold-changes ≤ 1.0 are not shown. Modified from Lukiw WJ, Cui JG, Musto AE, Musto BC, and Bazan NG (2005) Epileptogenesis in diacylglycerol kinase epsilon deficiency up-regulates COX-2 and tyrosine hydroxylase in hippocampus. *Biochemical and Biophysical Research Communications* 338: 77–81, with permission from Elsevier.

Using the experimental cut-off of $P \leq 0.05$ and changes greater than or equal to twofold (either up- or down-regulated), we found that changes in only four genes achieved significance in comparing kindling vs. control conditions in DGKε$^{+/+}$ animals; two of these genes encoded the oxygenases COX-2 and tyrosine hydroxylase (TH). Interestingly, animals kindled with electrodes in the right dorsal hippocampus showed higher levels of both COX-2 and TH in the ipsilateral (left) hippocampus, when compared against βTUBIII RNA levels in the same sample; no changes in the levels of the 'housekeeping' genes βTUBIII or COX-1 RNA were noted in either the left or right hippocampus after kindling (**Figure 5**).

Future Goals

Arachidonic acid and AA-DG mediators should be further studied as modulators of synaptic plasticity and seizure susceptibility. Exploration of these signaling pathways, specifically their downstream targets (e.g., protein kinases and phosphatases, transcriptional factors, ion channels, receptors, adhesion proteins) and the organization of pathways at the subcellular level in both neurons and astrocytes, is likely to contribute critical mechanisms relevant to neuronal hyperexcitability.

Damage and death of neurons and astrocytes may occur as consequences of an imbalance of neuronal signaling pathways activated by excessive excitatory and/or deficient inhibitory stimulation. However, if the seizures do not result in cell death, but instead cause functional damage as a consequence of aberrant signaling – e.g., over-stimulation of metabotropic glutamate receptors and subsequent inositol lipid signaling – the resulting processes (even those associated with epileptogenesis) could trigger homeostatic or neuroprotective signaling. The identification of the pathways and targets of inositol lipid signaling could, therefore, contribute to the identification of novel potential therapeutic interventions.

Introduction and Background

Kindling is a robust form of seizure-induced plasticity that refers to the induction of progressive, permanent increased susceptibility to seizures in response to repeated seizures. The phenomenon of kindling was recognized by Graham Goddard during experiments investigating the effects of electrical stimulation of neural pathways on learning paradigms in rats. These experiments unexpectedly revealed that repeated periodic trains of electrical stimulation – evoking seizures – induced progressive permanent increases in susceptibility to additional seizures. He referred to this phenomenon as 'kindling.' Several years later, Bliss and Lomo reported that high frequency trains of tetanic stimulation, applied to the perforant path (PP) in anesthetized rabbits, induced long-lasting increases in synaptic transmission in granule cells of the dentate gyrus – a phenomenon referred to as 'long-term potentiation' or LTP.

Following these pioneering observations, it was subsequently appreciated that *either* tetanic stimulation across of range of frequencies *or* network synchronization during seizures acutely induces long-lasting increases in synaptic transmission. The observation that induction of LTP or kindling increases synaptic efficacy suggests that cellular mechanisms of activity-dependent synaptic modification in response to patterns of coincident synaptic activation (LTP) – widely regarded as a physiological basis for

information storage in synapses, a mechanism underlying memory – are potentially linked to mechanisms of synaptic modification associated with network synchronization and seizures – a feature of epilepsy. The increases in synaptic transmission induced by LTP and kindling are both long-lasting in the case of kindling, these changes are permanent. While the permanent alterations in neural function induced by kindling can be regarded as a form of information storage in neural pathways, the repeated seizures evoked by kindling (unlike LTP) lead to the pathological outcome of permanently increased seizure susceptibility – and eventually progression to spontaneous recurring seizures (i.e., epilepsy). Although the outcomes of kindling and LTP are thus clearly distinct, the fact that both LTP and kindling increase synaptic transmission suggests that activity-dependent modification of synaptic transmission underlying synaptic information storage and memory may contribute to network dysfunction associated with epilepsy. Given this apparent overlap, analysis of these two forms of activity-dependent plasticity is of considerable interest to determine the differential bases for normal plasticity vs. pathological plasticity.

Experimental and Methodological Details: LTP vs. Kindling

Induction Methods (LTP vs. Kindling)

While high frequency trains of stimulation can be used to induce LTP or kindling, there are distinct differences in the specifics of the stimulation paradigms that induce these phenomena of activity-dependent plasticity. LTP can be induced either in vivo or in vitro by application of high-frequency 1 s stimulus trains, typically consisting of pulses of 0.05–0.1 ms in duration delivered at 50–400 Hz. Timing of activation in the theta range (5–12 Hz) is also reported to be effective, and may more closely mimic ongoing neuronal firing and cerebral rhythms. The induction of LTP after application of tetanic stimulation is detected by physiological measurements of synaptic transmission. Using extracellular recording methods as in the original description of Bliss and Lomo, increases in synaptic transmission induced by LTP are indicated by an increase in the slope of the population EPSP or amplitude of the population spike evoked by test pulses of constant intensity (compared to responses evoked by test pulses prior to the tetanic stimulus train). Increases in synaptic transmission may be detected using intracellular recording techniques by assessing the amplitude of the evoked EPSP (or EPSC) recorded in response to stimulation of an afferent with a test pulse of constant intensity.

The increases in synaptic efficacy which are observed after tetanic stimulation trains are time-dependent. Immediately after the tetanic stimulation there is an initial increase (in the population EPSP slope, the amplitude of the population spike, or the intracellular EPSP) which is referred to as post-tetanic or short term potentiation of synaptic transmission. This initial increase in synaptic transmission is followed by lower amplitude but persisting increases (LTP). The latter long-term increases in synaptic efficacy (LTP) require protein synthesis and typically persist for the duration of recording in brain slices, or for hours to days when recorded in vivo, in awake animals. LTP can also be induced in vitro by pairing postsynaptic depolarization with low frequency stimulation of presynaptic afferents, implicating coincident neural activity in the resulting strengthening of synaptic connections, as originally postulated by Hebb in 1949.

In contrast to LTP, kindling is (by definition) an exclusively in vivo phenomenon induced in awake, freely behaving animals by stimulation that typically consists of 1–2 s trains of 1.0 ms biphasic pulses delivered at 10–150 Hz, once or twice daily. The duration of the stimulus pulses used for kindling (1 ms biphasic) are typically longer than the stimulus pulses used to induce LTP (e.g., 0.05–0.1 ms). Stimulation trains of 60 Hz are particularly effective in evoking afterdischarges (ADs), which are required for the progression of kindling. ADs are repeated high amplitude discharges and spikes (recorded by EEG) which outlast the stimulus train and typically propagate beyond the immediate synaptic target of the stimulated pathway. The evoked ADs are accompanied by behavioral seizures which are initially focal, but gradually evolve and progress to secondary generalized tonic–clonic (Class V) seizures. The increased susceptibility to ADs and to evoked Class V seizures, induced by repeated evoked seizures, is permanent.

The key difference in the stimuli that induce LTP vs. kindling is that the tetanic trains that induce LTP do not evoke the sustained ADs that are required for kindling (**Figure 1**). While occasional short ADs may be observed after stimulation trains that induce LTP, these episodes are not sustained and are quite brief. Indeed, when afterdischarge-like phenomena are evoked in the context of LTP experiments, there is often a 'depotentiation' or loss of synaptic enhancement. The observation that LTP can be induced in specific synapses by pairing stimulation of presynaptic afferents with postsynaptic depolarization also emphasizes that LTP can be induced in a limited population of synapses in the absence of propagating ADs.

The stimulation trains that induce LTP or evoke kindled seizures *both* increase synaptic efficacy in the immediate synaptic target of the activated afferent pathway, but the increases in synaptic efficacy induced by stimulation trains evoking LTP are typically confined to those synapses which are directly activated by the stimulus trains. The effects of stimulation that induces kindling, in contrast, propagate significantly to secondary and downstream synapses and circuits – during the initially

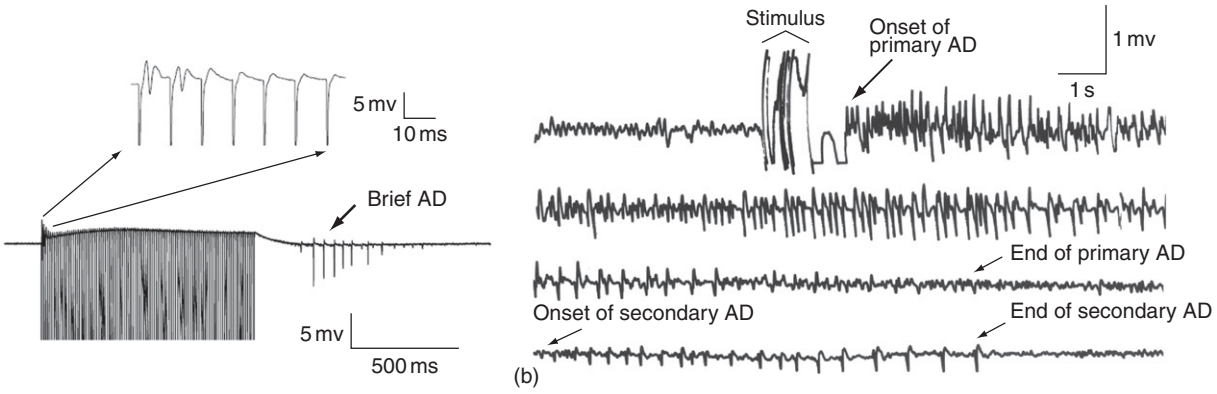

Figure 1 Examples of evoked activity and afterdischarges (ADs) in response to stimulus trains typically inducing LTP (a) or kindling (b). In (a), extracellular recording of the evoked field potential in the dentate gyrus of hippocampal slice from a rat in response to a 1 s 100 Hz train of 0.05 ms pulses delivered to the PP is followed by a brief AD that rapidly decrements within 500 ms. Inset at faster sweep speed demonstrates that the first two pulses evoke population spikes superimposed on the population EPSP. In (b), depth EEG recording in the PP of an awake freely moving rat with an electrode implanted in the region of the angular bundle demonstrates normal baseline activity and a stimulus artifact induced by a 1-s train of 60 Hz biphasic 1.0 ms pulses. The stimulus is followed by continuing artifact and then by a prolonged AD consisting of repetitive rhythmic spikes which continue for ~29 s and by a secondary AD of lower amplitude.

evoked ADs as well as in advanced stages of kindling. The progression of kindled seizures into advanced motor manifestations, such as bilateral tonic–clonic movements with loss of postural tone (Class V seizures) is presumed to represent propagation of long-lasting (permanent) *transynaptic* changes into motor and brainstem circuitry. The rate of progression to Class V seizures is reliably related to the site of stimulation that evokes the seizures, further implicating seizure-induced alterations in specific pathways and activated circuitry as the substrate for the permanent alteration in neural function induced by kindling.

Distinctive Functional Consequences of Increases in Synaptic Plasticity Induced by LTP vs. Kindling

In the original description of kindling, Goddard emphasized the potential importance of kindling as a form of permanent seizure-induced plasticity with relevance to epilepsy. Nevertheless, the gradual induction of incremental but permanent modification of neural function induced by kindling was also initially regarded as an example of information storage in neural pathways, a process that might be potentially relevant to mechanisms of learning and memory formation. In this respect, initial speculative perspectives about kindling included suggestions that long-lasting cellular alterations induced by kindling might also be relevant to memory, as was also postulated for LTP. It is now apparent that kindling induces permanent modification of neuronal and circuit functions spanning molecular to systems levels, and produces a predictable pattern of evolving molecular and cellular alterations that include alterations in transcription and translation, changes in composition and biophysical properties of membrane receptors, alterations in signal transduction pathways, neuronal cell loss in the hippocampus and other limbic structures, and sprouting and reorganization of neuronal circuitry, gliosis, and neurogenesis.

Furthermore, the functional consequences of kindling include not only progressive permanent induction of increased susceptibility to seizures, but also permanent memory disturbances and cognitive dysfunction in behavioral tasks (such as hippocampal-dependent spatial memory, which increases in severity with progression of kindling and in association with seizure-induced neuronal loss in the hippocampus). It is thus clear that kindling is not a model of memory, but rather *causes* memory dysfunction.

Relationships between Synaptic Plasticity (LTP) and Seizure-Induced Plasticity (kindling)

While there are systematic differences in the stimulation paradigms that induce LTP and kindling, and both distinctive immediate effects of the inducing stimulus trains (i.e., induction of sustained ADs) and different long-term effects (induction of a predictable sequence of neuronal and circuit alterations leading to spontaneous seizures), the stimulus trains that induce LTP or ADs that evoke kindled seizures *both* induce long-lasting increases in synaptic transmission. The relationship between synaptic plasticity induced by LTP and kindling has been studied in particular detail in the synapses of the PP projection to granule cells in the dentate gyrus, where the phenomenon of LTP was originally described. In rats undergoing kindling, synaptic potentiation resembling LTP develops in the monosynaptic PP projection to the dentate gyrus in

association with an initial evoked AD. The synaptic potentiation induced by repeated ADs is, in many respects, quite similar to LTP. However, repetitive induction of LTP, with high frequency stimulation trains (64 pulses of 0.1 ms duration at 400 Hz) delivered once daily for 20 days, is not sufficient to produce kindling – but did facilitate subsequent kindling (by ~90%) when stimulation trains that evoke ADs (60 pulses of 1 ms duration at 60 Hz) were applied. These observations indicate that repeated trains of stimulation that induce LTP are not sufficient to induce kindling, thus further highlighting the distinctive differences between these forms of activity-dependent plasticity. Nevertheless, synaptic plasticity (LTP) does have effects on seizure-induced plasticity (kindling), as the rate of kindling is increased after prior induction of LTP in the PP.

Conversely, in the studies cited above, low frequency stimulation with an equivalent number of pulses (64 pulses of 0.1 ms duration at 0.33 Hz) delivered once daily for 20 days reduced the rate of kindling. Low frequency stimulation paradigms are now recognized to induce long-term-depression (LTD), another form of activity-dependent modification of synaptic efficacy. LTD serves, in part, to restrain or prevent activity-driven increases in synaptic efficacy (LTP) from reaching saturating levels, which would preclude a dynamic range of functional synaptic modification. LTD is typically induced by application of low-frequency stimulus pulses at 1 Hz, which reduce the amplitude or slope of EPSPs evoked by test pulses of constant duration and intensity. A typical stimulus paradigm for induction of LTD is 600–900 pulses of 0.5–0.1 ms duration at 1 Hz. LTD may also be induced in vitro by pairing postsynaptic hyperpolarization with low-frequency stimulation of presynaptic afferents. The strength of synaptic connections between neurons which are firing together is increased as a consequence of LTP conversely the strength of synaptic connections between neurons which fire independently decreases as a consequence of LTD.

Recent Results

More recent studies have demonstrated that activity-dependent reduction of synaptic efficacy, by trains of stimulation that induce LTD, reliably reduce rates of kindling. This result further supports the view that activity-dependent synaptic plasticity has potentially important influences on circuit function, including susceptibility to network synchronization, seizure generation, and epilepsy. The rate of kindling of the amygdala is reduced by prior low frequency stimulation of the piriform cortex, and low frequency stimulation of amygdala also reduces behavioral seizure scores when the low frequency stimuli are applied prior to stimulation trains evoking kindled seizures. It is thus clear that activity-dependent synaptic plasticity can modify susceptibility to network synchronization and seizures. These effects have been most clearly demonstrated in terms of chronic seizure susceptibility as represented by kindling, but may also be contributing to the emergence of network synchrony underlying acute susceptibility to seizures evoked by other methods.

Directions for Future Research

The evidence that activity-dependent synaptic plasticity, including LTP and LTD, influences acute seizure generation and chronic epileptogenesis is consistent with the possibility that deep brain stimulation (through implanted electrodes) could be of potential therapeutic benefit for epilepsy. More generally, the demonstration that LTP and LTD can modify network function suggests that the modification of this process (i.e., of activity-dependent plasticity in synapses and circuits) may have potential as a therapeutic target for a novel treatment of epilepsy. Recent studies have provided evidence that activity-dependent plasticity is controlled through mechanisms of synaptic scaling and homeostatic plasticity. The relevance of these emerging phenomena for epilepsy has not been explored, and could possibly provide new therapeutic approaches.

Possible Role of Synaptic Reorganization in Epileptogenesis after Experimental Status Epilepticus

F E Dudek, University of Utah School of Medicine, Salt Lake City, UT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Status epilepticus (SE) can be a devastating medical emergency. It is known in humans that neuronal injury from severe SE is often followed by the development of epilepsy. Research with animal models has shown that regardless of how SE is induced, if it is allowed to proceed for prolonged periods (e.g., >1 h), neuronal death in the hippocampus and elsewhere is followed by the development of spontaneous recurrent seizures (i.e., acquired epilepsy). The goal of this article is to examine some of the key hypotheses, concepts, and controversies relating to how epileptogenesis occurs. In particular, we consider how animal models of SE have been used to examine the hypothetical mechanisms of epileptogenesis, with a focus on synaptic reorganization (the progressive formation of new recurrent excitatory circuits) following SE-induced selective loss of specific, vulnerable, GABAergic interneurons. We propose that these two processes – selective interneuron loss and circuit reorganization – alone may account for some of the critical changes associated with injury-induced epileptogenesis.

Background

Models of Temporal Lobe Epilepsy

One of the primary reasons why a considerable amount of experimental epilepsy research has focused on models of SE is that these models are viewed as a possible approach to reproduce some aspects of temporal lobe epilepsy (TLE), which is arguably the type of epilepsy most refractory to antiepileptic drug (AED) treatment. As is briefly discussed later, another model of TLE involves 'kindling,' but most recent research in this field has centered on either electrically evoked or chemoconvulsant-induced SE. The models involving chemoconvulsants generally rely on either kainic acid (i.e., kainate) or pilocarpine injections. One reason for the interest in these models is that SE leads to injury in the hilus of the dentate gyrus and in the CA3 and CA1 areas of the hippocampus, similar to the pattern of cell loss found in many cases of human TLE. Further, these animal models lead, after a latent period of several days to a week or two, to the development of spontaneous recurrent seizures (i.e., acquired epilepsy). Considerable debate continues on whether such animal models of SE accurately recapitulate the condition in humans.

Definition of Epileptogenesis

The process of epileptogenesis is widely believed to consist of a collection of molecular, cellular, and systems-level changes that ultimately lead to spontaneous recurrent seizures. The process is generally considered to be time-dependent in that chronic epilepsy does not generally occur immediately after the injury, but rather takes time to develop and mature; indeed, the occurrence of spontaneous recurrent seizures in humans can be weeks, months, or even years after the precipitating injury. For our description, in this article, the term 'epileptogenesis' does not include the acute seizures that occur when brain tissue is injured, does not include those alterations in animals or isolated tissue where seizures occur after pharmacological treatments, and also does not include those cases where genetic abnormalities lead to altered seizure susceptibility.

Introduction

Status epilepticus (SE) can be a devastating medical emergency. It is known in humans that neuronal injury from severe SE is often followed by the development of epilepsy. Research with animal models has shown that regardless of how SE is induced, if it is allowed to proceed for prolonged periods (e.g., >1 h), neuronal death in the hippocampus and elsewhere is followed by the development of spontaneous recurrent seizures (i.e., acquired epilepsy). The goal of this article is to examine some of the key hypotheses, concepts, and controversies relating to how epileptogenesis occurs. In particular, we consider how animal models of SE have been used to examine the hypothetical mechanisms of epileptogenesis, with a focus on synaptic reorganization (the progressive formation of new recurrent excitatory circuits) following SE-induced selective loss of specific, vulnerable, GABAergic interneurons. We propose that these two processes – selective interneuron loss and circuit reorganization – alone may account for some of the critical changes associated with injury-induced epileptogenesis.

Background

Models of Temporal Lobe Epilepsy

One of the primary reasons why a considerable amount of experimental epilepsy research has focused on models of SE is that these models are viewed as a possible approach to reproduce some aspects of temporal lobe epilepsy (TLE), which is arguably the type of epilepsy most refractory to antiepileptic drug (AED) treatment. As is briefly discussed later, another model of TLE involves 'kindling,' but most recent research in this field has centered on either electrically evoked or chemoconvulsant-induced SE. The models involving chemoconvulsants generally rely on either kainic acid (i.e., kainate) or pilocarpine injections. One reason for the interest in these models is that SE leads to injury in the hilus of the dentate gyrus and in the CA3 and CA1 areas of the hippocampus, similar to the pattern of cell loss found in many cases of human TLE. Further, these animal models lead, after a latent period of several days to a week or two, to the development of spontaneous recurrent seizures (i.e., acquired epilepsy). Considerable debate continues on whether such animal models of SE accurately recapitulate the condition in humans.

Definition of Epileptogenesis

The process of epileptogenesis is widely believed to consist of a collection of molecular, cellular, and systems-level changes that ultimately lead to spontaneous recurrent seizures. The process is generally considered to be time-dependent in that chronic epilepsy does not generally occur immediately after the injury, but rather takes time to develop and mature; indeed, the occurrence of spontaneous recurrent seizures in humans can be weeks, months, or even years after the precipitating injury. For our description, in this article, the term 'epileptogenesis' does not include the acute seizures that occur when brain tissue is injured, does not include those alterations in animals or isolated tissue where seizures occur after pharmacological treatments, and also does not include those cases where genetic abnormalities lead to altered seizure susceptibility.

This article considers only those instances in which a defined (i.e., time-limited) brain insult leads to demonstrable spontaneous recurrent seizures. Within this context, some investigators have argued that the brain insult need not necessarily cause neuronal death and cell loss. Indeed, many studies of pediatric epilepsy, particularly involving models of hypoxia, febrile seizures, and even SE in the immature brain, argue that epilepsy can develop without neuronal death. Clearly, that view is not consistent with the hypotheses offered in this article; in the view of this author, most of those studies have not adequately documented the lack of neuronal death or the occurrence of spontaneous recurrent seizures, and have therefore not shown that epilepsy develops without neuronal death.

Synaptic Reorganization

Mechanisms of acquired epilepsy, including but not limited to those dependent on experimental induction of SE, may invoke a wide range of mechanisms, including alterations in neurotransmitter receptors (e.g., $GABA_A$ and NMDA receptors) and/or alterations in voltage-dependent currents (e.g., sodium channels and H-current). While those examples of cellular plasticity may well be important, this article focuses exclusively on local circuit alterations, which can be viewed under the broad heading of synaptic reorganization. Many different hypotheses involving local circuits have been proposed. The two key mechanisms that are discussed here are: (1) the loss of GABAergic interneurons, leading to a decrease in GABA-mediated inhibition (Figure 1); and (2) axon sprouting followed by increased recurrent excitation (Figure 2). The first of these mechanisms would be expected to cause an immediate loss of interneurons as a result of SE – but it is important to note that interneurons could also be continuously lost during the process of epileptogenesis. The second mechanism has garnered considerable attention because it is viewed as process that might occur during a latent period, perhaps involving other progressive changes – that is, that axon sprouting and consequent synapse formation is a time-dependent process.

Loss of GABAergic Interneurons

Nearly half a century ago, numerous investigators showed that pharmacological treatments that lead to a blockade of $GABA_A$-mediated inhibition could evoke abnormal epileptiform activity and even frank seizures. Early studies in both in vivo and in vitro preparations showed that penicillin induces epileptiform activity, and later it was determined that this effect results primarily from a block of $GABA_A$ receptors. Several decades ago, investigators showed that some, but not all, GABAergic interneurons are lost in animal models of temporal lobe epilepsy and in human tissue (hippocampus) resected for the treatment of intractable epilepsy. Some researchers emphasized that most of the GABAergic interneurons were, however, still present, and thus challenged the concept that GABAergic inhibition was severely depressed in this tissue. A variety of more recent studies (reviewed later in this article) have provided strong evidence from both histopathological and electrophysiological experiments that selective interneuron populations are lost. Because the change in the total

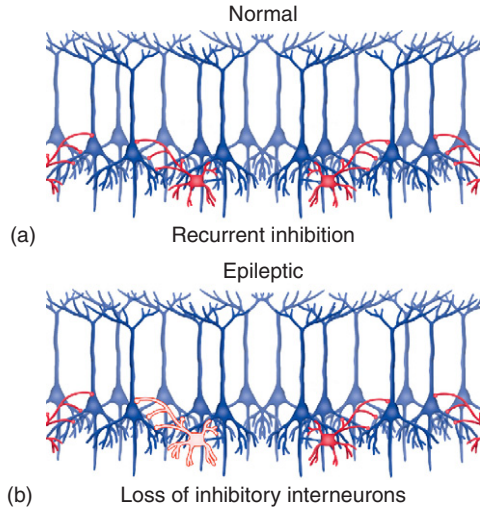

Figure 1 Schematic diagram showing hypothetical loss of interneurons in the hippocampus from a normal (a) and an epileptic brain (b). The two diagrams, which include pyramidal cells and interneuron's, illustrate the hypothesis that the hippocampus from epileptic brain has lost some but not all of the interneurons.

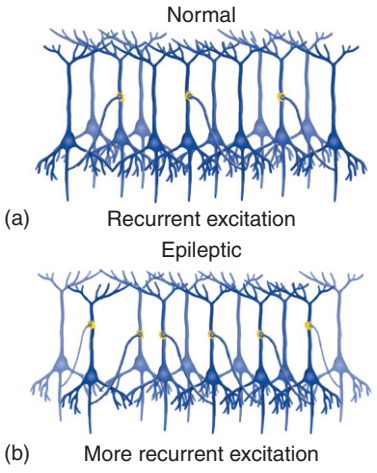

Figure 2 Schematic diagram illustrating the hypothesis of axon sprouting and increased recurrent excitation during epileptogenesis in the hippocampus (e.g., CA1 area). The two diagrams of pyramidal cells compare normal and epileptic brain, and show that although recurrent excitation is present among some pyramidal cells in the normal brain (a), epileptogenesis is associated with increased recurrent excitation (b).

number of interneurons is comparatively small, it can be difficult to demonstrate this loss of interneurons; further, this selective loss leaves intact many inhibitory circuits within relevant cortical networks (Figure 1).

Axon Sprouting and Increased Recurrent Excitation

Roughly 25 years ago, a series of histopathological studies showed that axons of the dentate granule cells (i.e., the mossy fibers) can be labeled with the Timm stain, and that the inner molecular layer of the dentate gyrus shows a robust increase in Timm stain in both tissue resected from humans with intractable TLE and in various animal models (most notably the kainate-treated rat, and later the kindled rat). This histopathological observation led to the hypothesis that dentate granule cells form new recurrent excitatory circuits, and that this reorganization would lead to positive feedback among dentate granule cells. A wide range of studies have confirmed that the mossy fibers synapse on other granule cells in this tissue. Some researchers, however, have suggested that interneurons receive mossy fiber synapses (an unlikely possibility given available quantitative analyses) – and have suggested that mossy fiber sprouting is associated with increased inhibition (a view based on data obtained using indirect techniques, such as paired-pulse stimulation, which is simply not a reliable approach to this question). In contrast, a variety of electrophysiological studies from several laboratories (using antidromic stimulation of the mossy fiber axons, analyses of spontaneous excitatory postsynaptic potentials and currents, focal glutamate microstimulation, and dual intracellular recording) have provided strong evidence that granule cells form new recurrent excitatory synapses with other granule cells.

The discussion regarding axon sprouting and epileptogenesis has been plagued by the view that mossy fiber sprouting in the dentate gyrus is the sole location in the brain where synaptic reorganization would occur following SE. However, numerous studies have now suggested that the CA1 pyramidal cells show similar changes (Figure 2), and other research implicates a similar mechanism after a variety of injuries to the neocortex and elsewhere. Histopathological evidence for the role of axon sprouting and increased recurrent excitation in epileptogenesis has now been supported by electrophysiological studies performed with whole-cell recording under conditions that exclude other possible mechanisms.

Methodological Approaches

Animal Models of SE

Several animal models of SE are available, and each of them has advantages and disadvantages – although the overall results from the models are probably more similar than different. In all cases, it is generally believed that a 'self-sustaining' component of the SE must occur in order to generate neuronal death and subsequent epilepsy. Experimental status epilepticus has been induced with the chemoconvulsants kainate or pilocarpine (with or without pretreatment with lithium). Both of these compounds are generally given as a single intraperitoneal injection, although some studies have used repeated low-dose protocols in an effort to enhance survival and to increase the proportion of animals that experience a sufficiently prolonged period of SE to cause neuronal death and subsequent epileptogenesis. Kainate first received substantial attention because it was shown that kainate injections cause a relatively selective death of neurons in the hilus and in the CA3 area. Similarly, pilocarpine induces SE and is commonly associated with neuronal death in the hilus and in the CA1 area. Both of these chemoconvulsants, however, induce cell death not only in hippocampal fields (hilus, CA3, and CA1) but also in many other areas of the brain. Similarly, electrically evoked SE can be used, and this technique has the potential advantage that one can more easily adjust the input (i.e., the electrical stimulation parameters), and thus one is, in theory, less likely to cause significant mortality. The disadvantage of the electrical stimulation protocol is that one must implant the stimulating electrodes – unless, of course, one wants to undertake chronic electrophysiological recording. If one aims to perform experiments without electrodes implanted in the brain, then the chemoconvulsant approaches may be advantageous, or at least easier. Some researchers argue that the chemoconvulsant itself is a problem for the experiment, although one could argue that electrical stimulation is also abnormal.

All of these techniques lead to SE; some researchers attempt to terminate the SE with injections of a benzodiazepine, such as diazepam.

These studies are meant to provide a general model of TLE, although some cases of TLE are quite different, histopathologically, from the animal models employing SE. In these cases of TLE, there is relatively little neuronal loss or evidence of mossy fiber sprouting, and this observation has fueled a debate about the homogeneity of TLE.

Some studies have used the kindling model, where electrical stimulations that evoke seizures on a daily basis lead to an increased seizure susceptibility or lowered threshold, but without the occurrence of spontaneous seizures. This approach, it has been argued, is advantageous in providing a more controlled experimental situation. However, because the kindling model does not generally involve spontaneous recurrent seizures (the hallmark of chronic epilepsy), it fails to recapitulate a key feature of epilepsy. Thus, there are several important advantages to the use of SE as a model of acquired epilepsy, if not TLE, but there are also disadvantages that need to be accounted for when designing experiments.

Histopathological Techniques

Most research concerning hypothetical changes in synaptic circuitry has involved histopathological studies, and oftentimes these anatomic techniques have been used before electrophysiological experiments. Thus, early studies showed that mesial temporal sclerosis involves profound neuronal death in structures such as the CA1 and CA3 areas of the hippocampus; this cell loss was readily seen with traditional Nissl stains. In addition, this profound neuronal death has been associated with extensive gliosis, which can also be studied (somewhat indirectly) with Nissl stain. Studies of altered GABAergic inhibition, and particularly, the loss of GABAergic interneurons began with immunohistochemical techniques, initially using GAD as a marker of GABAergic interneurons, but more recently involving other markers for specific subclasses of GABAergic interneurons. The studies of axon sprouting and other forms of synaptic reorganization began with use of the Timm stain, which is a marker for heavy metals that are mostly located in the mossy fibers of the dentate granule cells. Other studies in the dentate gyrus, and particularly the CA1 area of the hippocampus, have used intracellular staining with markers such as Neurobiotin; such studies have revealed an increase in axon collaterals months after SE. Thus, several different types of histopathological techniques have all been used to develop and test hypotheses about synaptic reorganization.

Electrophysiological Experiments

Electrophysiological experiments are plagued with the problem that intact animals are essentially required to study spontaneous recurrent seizures, and these only occur when animals are freely behaving (i.e., not anesthetized). Yet, mechanistic studies in an intact animal generally require anesthesia, and are most feasible with in vitro experiments involving single-cell recordings in brain slices. Relatively few studies have been done on the detailed properties of the SE that occur after an induction treatment (outlined earlier) to determine the degree to which the characteristics of SE are responsible for neuronal death and subsequent epileptogenesis. Many experiments have been done in vivo on anesthetized animals after experimental SE. These studies have the important advantage of preserving three-dimensional circuitry through extensive networks – circuitry that is always damaged in a brain slice preparation. Unfortunately, the presence of anesthesia compromises these experiments. These studies also generally involve extracellular recordings of hippocampal field potentials, which can be extremely difficult to interpret in terms of the underlying mechanism. Brain slice experiments have traditionally used tissue in which electrodes are positioned based on gross landmarks, but more recent experiments have used thinner slices and 'visualized patch' techniques (where cell-level landmarks and individual neurons can be seen with infrared illumination and differential interference contrast optics). In order to study cellular mechanisms of the epileptogenic processes, brain slice techniques are essentially required. In vivo techniques are necessary to study the development of epilepsy. What has been problematic is the use of in vivo techniques to study cellular mechanisms.

Recent Results

Loss of Interneurons

A large body of data strongly and directly support the hypothesis that GABAergic inhibition is depressed because of a modest loss of a specific set of GABAergic interneurons (**Figure 1**). These data are derived from several anatomic and physiologic techniques, from a variety of laboratories, and from experiments on both human tissue and in animal models (based primarily, but not exclusively, on SE). The techniques of immunohistochemistry and in situ hybridization have been used to show, in the dentate gyrus and in the hippocampus proper, that specific types of GABAergic interneurons are lost in animals that have been shown to generate spontaneous recurrent seizures after SE. Several studies have used immunohistochemical antibodies against neuropeptides that are coexpressed with GABA as evidence for a selective loss of interneurons. The loss of somatostatin-containing interneurons in the hippocampus is probably the best documented, but parvalbumin-positive interneurons are also often reduced. Even with Nissl staining, one can see that some of the neurons outside of the cell body layers (i.e., cells that are most likely to be GABAergic interneurons) are lost; this observation provides indirect evidence that the reduced number of neurons stained by immunohistochemical techniques is not a result of staining artifact. Because the same, or at least very similar populations of interneurons, appear to be lost in several models, investigators have concluded that some interneurons are much more vulnerable than others. The observation that 'hyperexcitability' is present shortly after SE is explained, in part, from this loss of interneurons – although other mechanisms, (such as redistribution of chloride ions so as to reverse the polarity of GABA-mediated inhibitory potentials) could also contribute to this effect.

Axon Sprouting and Increased Recurrent Excitation

The major experimental observation that led to the generation of the axon sprouting-recurrent excitation hypothesis (i.e., that injury-induced axon sprouting leads

to increased recurrent excitation, which in turn causes seizures) was that Timm staining appeared in the inner molecular layer of the dentate gyrus of epileptic animals after SE (and also in humans with TLE). This pattern of Timm staining is not seen in controls. As this technique is relatively easy, it has been used extensively, and has essentially been equated with axon sprouting and increased recurrent excitation. One important result that has been made not only in animal models of SE but also in the kindling model, is that the amount of Timm stain in the inner molecular layer of the dentate gyrus increases with time after the precipitating insult. This observation is important within the context of these models, inasmuch as one could envision that gradual growth and connectivity would create a latent period after a brain insult, and that this mechanism would generate progressive or time-dependent changes in excitability and epileptogenesis. Early studies examined the functional consequences of this structural change in experiments with GABAergic inhibition left intact – despite the fact that numerous studies (e.g., on the CA3 area, which normally has recurrent excitation) showed that $GABA_A$-receptor-mediated inhibition *masks* the effects of recurrent excitation. Since GABAergic inhibition itself is hypothesized to be changed, in this tissue, one must block GABAergic inhibition (at least partially) in both the experimental and control group to test the hypothesis that there is enhanced excitability due to axon sprouting (**Figure 2**).

Several studies, using antidromic stimulation of the mossy fibers to bypass the major synaptic input from the perforant path, showed that animals that have been subjected to kainate-induced SE (and have been observed for several months to document the development of epilepsy) show burst responses with long and variable latencies. The burst generation mechanism (i.e., with a long and variable latency) to low-intensity stimulation is a hallmark of recurrent excitation, and differentiates it from the results of traditional dendritic excitatory synaptic input. Furthermore, recent experiments using caged glutamate and focal photo-stimulation to active specific granule cells in the dentate gyrus, showed that local excitatory circuits increase with time after kainate-induced SE. When GABAergic inhibition is suppressed, the stimulation of the granule cells anywhere in the cell body layer can evoke a synchronous epileptiform burst throughout the dentate gyrus in slices from kainate-treated rats with chronic epilepsy, but not in controls. More recent studies have also shown, with paired intracellular recordings, that dentate granule cells are synaptically connected when animals have developed epilepsy after pilocarpine treatment. These experiments, and several others, strongly argue that axon sprouting leads to the formation of new recurrent excitatory circuits, which in turn promotes seizures.

It has been reported that pretreatment of rats with cycloheximide (i.e., a protein-synthesis inhibitor) can block mossy fiber sprouting; and furthermore, spontaneous recurrent seizures can still be observed several months after status epilepticus. These results, however, have not been reproduced in two subsequently published studies; in fact, cycloheximide pretreatment had no effect on mossy fiber sprouting. Nonetheless, although mossy fiber sprouting is often seen in a variety of animal models of epilepsy, this mechanism in this structure is almost certainly *not necessary* for epilepsy to occur after injury. Not only synaptic reorganization, including increased recurrent excitation, occurs in other brain areas, but also the spontaneous recurrent seizures that have been observed within a couple weeks after status epilepticus are present before much sprouting has occurred, and may well be the result of a reduction in interneurons.

Other Mechanisms

At least two other possible mechanisms of synaptic reorganization have been invoked to account for epileptogenesis. One of them is the so-called dormant basket cell hypothesis, which states that basket cell interneurons are still present, but that they have lost glutamatergic input (i.e., they are inadequately activated, and their output is therefore diminished). Virtually all the evidence to support this hypothesis comes from paired-pulse recording, which has numerous interpretational problems. Another hypothesis is that GABAergic interneurons sprout axon collaterals, and that this leads to increased GABAergic inhibition. Although this remains possible, studies examining the frequency of mIPSCs shortly after kainate-induced status epileptics versus several months later (when the animals are epileptic) showed that the reduced interneuron input (i.e., mIPSC frequency) to granule cells persisted for several months, when the animals were having spontaneous recurrent seizures, a finding that argues against this hypothesis. Several other possible mechanisms involving reorganization of synaptic circuits could contribute to epileptogenesis – or could reflect compensatory changes that reduce epileptogenesis.

Challenges for the Future

How to Better Analyze Local Synaptic Circuits During Epileptogenesis?

The fundamental problem of testing hypotheses about synaptic reorganization is precisely how to study it. Most experiments have used extracellular electrical stimulation as a means of examining the level of excitation/inhibition in the circuit. This approach is fraught with problems, including the fact that extracellular electrical stimulation will almost certainly activate fibers of passage that may project from areas completely outside of the area of study. Also, electrical stimulation generally activates

action potentials in both directions (i.e., orthodromic and antidromic). Indeed, even the acute isolated slice preparation contains living axons projecting from sites outside of the slice. Extracellular stimulation certainly does not specifically activate those neurons that remain intact in the slice preparation. Many studies also use field-potential recordings, which have relatively little resolution to differentiate cellular mechanisms. In particular, the paired-pulse technique (as a primary tool of extracellular studies) is fraught with a variety of mechanistic problems. Another approach is to study spontaneous or miniature inhibitory and/or excitatory postsynaptic currents (m- and s-IPSCs and EPSCs). The sEPSCs and sIPSCs are difficult to interpret, since these events reflect both action potential-independent transmitter release (i.e., as seen with mPSCs) and action potential-dependent release; changes that cause death of neurons or changes in the activity of neurons necessarily impact the amplitude and frequency of sPSCs. The alternative, to use mIPSCs and mEPSCs as a measure of circuitry integrity (as described earlier), assumes that spontaneous synaptic release is unaltered by SE, and that we can record all mPSCs (while most of them are probably below the resolution of whole-cell recording). The most direct approach is dual recording, but this method is particularly difficult, not so much for the technique itself, but because only a small proportion of individual neurons are directly connected with each other. Given these methodological difficulties with electrophysiological analysis, it is hoped that various imaging techniques will be useful (although to date these methods, too, lack the resolution needed to study the activity of individual neurons).

Experimental Isolation of Local Synaptic Circuits

Another important challenge is differentiating alterations in local synaptic circuits from mechanisms that are intrinsic to individual neurons, which in turn can be divided into two types – voltage-dependent ion channels and transmitter receptors that are on postsynaptic neurons (e.g., $GABA_A$ and NMDA receptors). Nearly any study that aims to identify alterations in local synaptic circuits should account for possible changes in intrinsic properties. Dual recording is the technique most likely to address these possibilities, but even this approach has some interpretational difficulties in separating these two classes of mechanisms.

Can One Prevent Epileptogenesis by Blocking Reorganization of Local Synaptic Circuits

One of the most pressing problems in experimental epilepsy research is how to block the development of epilepsy after a brain injury. If one assumes that epileptogenesis depends on alterations in membrane receptors or ion channels, one can envision that it might be possible to target those receptors and channels selectively, or to prevent their expression after injury. However, if epileptogenesis arises – at least in part – from the death of interneurons (e.g., **Figure 1**), the only approach would be to replace these cells. And indeed, many researchers are starting to use stem cell approaches to reestablish GABAergic interneurons. Although this approach seems worthy of future experimentation, it is unclear how these exogenously introduced interneurons will be engineered to project to the right locations. Similarly, if axon sprouting and the formation of new recurrent excitatory circuits are a critical mechanism (**Figure 2**), then one must devise a way to block this reorganization. Several studies are underway to develop such interventions. Extrapolation of these and other approaches, from the bench to the bedside, is a major goal in our efforts to develop better treatments for humans at risk for acquired epilepsy.

Introduction

The brain is unique among all organs in the body, being composed of many different cell types each with discrete functions. This complexity represents a major challenge for studying events at the molecular level, which are involved in a multifaceted disease process such as epilepsy. The heterogeneity of brain cell types makes it important to focus on analysis of specific brain regions, cell types, and even subcellular fractions. The kindling model of focal epilepsy perturbs neuronal networks that impinge on the hippocampus, among other structures. Although an animal may be kindled even in the absence of a hippocampus, when the hippocampus is involved in the kindling process, there is a well-documented long-term (perhaps permanent) increase in hippocampal excitatory neurosecretory activity. Our underlying hypothesis has been that the associated molecular transformation involves alteration of the synaptic machinery, particularly the proteins underlying the dynamics of vesicle docking and fusion. These alterations are most easily studied in well-characterized systems, such as the hippocampus; however, such alterations may occur at other nodes in neuronal networks involved with kindling, so findings in hippocampus may be generalized to similar processes of plasticity and beyond the hippocampus.

To date, application of proteomic approaches to the study of neurological disorders has focused primarily on neurodegenerative conditions such as Alzheimer's and Parkinson's diseases, where human tissue is readily available. However, the increasing use of surgical resection to treat some epilepsy patients, studies comparing cerebral cortical samples from patients with temporal lobe epilepsy (TLE) and age-matched nonepileptic subjects (suffering trauma, tumor, etc.) has given rise to demonstrations of distinct differences in protein representation in affected tissue, including reduction in levels of Mn-SOD and alterations in levels of a number of housekeeping and cytoskeletal proteins in mesial sclerosis-associated TLE.

Background and Methods

Procedures for Proteomic Analysis of Protein Contents of Brain Tissues

Gel-based procedures

The development of commercially available immobilized pH gradient (IPG) strips formed with covalently attached prefocused ampholines is the primary advance that has revolutionized 2D gel procedures. The reproducibility in electrofocusing separations of proteins afforded by these IPG strips has been essential for comparative 2D gel mapping studies. IPG strips are available in a number of different pH ranges that permit high-resolution separation of different protein subsets. Initial separations are routinely performed using the widest range available, pH 3–10.

Proper sample preparation is critical to achieving high-resolution and reproducible separation in the first dimension IPG separation. Samples must be concentrated to a small volume as well as desalted prior to IPG separation. In our experience, simple precipitation with ice cold acetone in water (8:1) followed by centrifugation has proved to be superior to all other procedures. This procedure removes bulk salts and lipids and concentrates the sample. Precipitated samples are redissolved in a minimum volume of standard 6 M urea/2 M thiourea buffer, and this solution is used to rehydrate the IPG strips of appropriate pH range for specific applications. Isoelectric focusing (IEF) is generally performed using a series of timed voltage ramps, up to a final high voltage for a fixed total of volt-hours. Tracking dyes are routinely included in samples to ensure that focusing is proceeding uniformly. The pH gradient can also be calibrated by inclusion of known IEF standards available from commercial vendors.

Second dimension separations are performed by SDS-PAGE. The IPG strip is removed from the focusing tray and equilibrated in standard SDS-PAGE buffer containing reducing agent. A second equilibration follows in the same buffer but with 1.5% iodoacetamide substituted for the reducing agent in order to irreversibly block cysteinyl groups preventing formation of disulfide bonded dimers. The strip is then transferred to an SDS-PAGE gel, overlaid with 0.5% Agarose in standard SDS-PAGE buffer and separation is performed in an appropriate 2D slab gel apparatus. For most applications, laboratory-cast 10–15% SDS-PAGE gels give excellent reproducibility at low cost. Molecular weight standards are included in a separate lane on every gel. As proof that low molecular weight proteins have been retained, it is essential to keep the tracking dye on the gel.

For high sensitivity detection and quantification, gels are stained with SyproRuby (Molecular Probes) and detection and quantification performed using a fluorescent gel scanner. Other high sensitivity staining methods also can be used depending on the availability of suitable gel scanning apparatus (e.g., Coomassie R250 with infrared scanning). The

data acquired from all methods can be analyzed by any of several software packages that are now available commercially (e.g., PDQuest from Bio-Rad). These procedures are of sufficient sensitivity to detect and quantify proteins in low nanogram quantities and are linear over a broad concentration range (up to micrograms). Spots of interest can be excised subsequently by either eye or using a robotic spot cutter with fluorescence detection. Excised spots are digested with trypsin after reduction and alkylation and the resulting peptides analyzed by mass spectrometry (MS).

A major concern for these types of analyses is the reproducibility of sample application, which makes it extremely difficult to perform absolute quantification on any given gel. For this reason, comparison of intensities for a given spot from one gel to the next is best done by normalizing spot intensities detected to total gel fluorescence (equivalent to total protein), then comparing these relative spot intensities among different gels. Reproducibility of electrophoretic separations and quantification of spot intensities after SyproRuby staining by repetitive analysis of cytosol, particulate, and vesicle fractions prepared from whole rat brain is $\pm 5\%$ in almost all cases across a wide range of spot intensities. The use of total gel fluorescence for normalization of data circumvents the problem of unequal capture of sample during the rehydration of IPG strips. It is also feasible to use a selected group of spots such as actin, tubulin, or other prominent proteins in a sample for normalization. However, it is possible that these proteins are not equally recovered from one sample to the next or may vary because of a given type of treatment.

New methods for comparative protein profiling studies are based on differential labeling of samples for comparison with Cyber dyes with distinct fluorescence excitation wavelengths. Labeled samples are mixed, then coelectrophoresed and analyzed by differential fluorescence scanning densitometry. This methodology can overcome the problem of loading artifacts but suffers from being extremely expensive and from the fact that the proteins modified with different CyDyes do not comigrate precisely with each other or the unmodified protein making it more difficult to excise spots for MS.

For studies of protein phosphorylation, 2D gels are stained first with the phosphoprotein fluorescent stain Pro-Q Diamond (Molecular Probes). After scanning, the gels are destained then restained with SyproRuby and scanned to determine protein content. Pro-Q Diamond is more sensitive then SyproRuby and specific to proteins containing pSer, pThr, and pTyr. For quantitation, it is most accurate to use the absolute values for spot intensities obtained from scans. As shown later in studies of the 14-3-3 family, the ratio of Pro-Q Diamond staining to SyproRuby staining reflects the molar phosphorylation state for each spot in the gel. However, phosphorylation causes a shift in p*I* giving a set of closely migrating spots at approximately equivalent migration rates (MRs; phosphorylation can also alter migration in SDS-PAGE in some cases). Therefore, absolute quantification of the level of phosphorylation of a protein requires identification of all phospho- and dephospho-forms of a given protein on the 2D gel.

Identification of proteins by mass spectrometry

In most instances, the approaches for MS available to an investigator will be dictated by the corresponding facilities at each institution. In general, identification involves fragmenting the intact protein, usually through trypsin digestion as noted earlier, then analysis of the resulting peptides. Mass peptide mapping approaches involve determining the exact masses of as many peptides from the digest as possible, then comparing these masses with in silico generated peptide mass databases for identification. The more exact approach is to determine the amino acid sequences of a number of peptides in the digest by partial fragmentation, and subsequent mass analysis with comparison of the resulting peptide sequences to established databases. It should be noted that most facilities operate on a fee for service basis. Thus, the MS component of proteomic studies must be planned carefully to avoid becoming cost prohibitive.

Important Results to Date

Proteomic Analyses of Alterations of Synaptosomal Protein Complements in Control and Kindled Rat Hippocampi

We have previously reported initial studies to establish 2D gel maps for rat hippocampal synaptosomes and subfractions (synaptosol, plasma membrane, and vesicle fractions) in both the control and fully kindled state. **Figure 1** shows 2D gel analyses of gradient-purified synaptosomes compared with the synaptosol, synaptic vesicle, and particulate (SPM, mitochondria, etc.) fractions isolated by further Percoll gradient centrifugation following isotonic lysis. Although major cytoskeletal proteins such as actin and tubulin are common constituents of synaptosomes and whole cell homogenates, over 100 of the protein spots in the upper left panel appear to be enriched in the synaptosome, compared with whole hippocampus (gel not shown). Furthermore, the 2D gel profiles for the synaptosomal subcompartments are also largely unique from one another. As would be expected, the pattern obtained for the synaptosol most closely resembles that of the intact synaptosome, while the patterns for the vesicle and particulate fractions are distinct.

We have used this 'divide and conquer' approach to identify proteins that are altered in specific synaptosomal compartments. A number of protein spots in the 2D gel of the synaptic vesicle fraction are either increased or decreased in intensity relative to total gel fluorescence, in kindled samples than in controls. The identities of several of these proteins were determined by LC–ESI–MS/MS

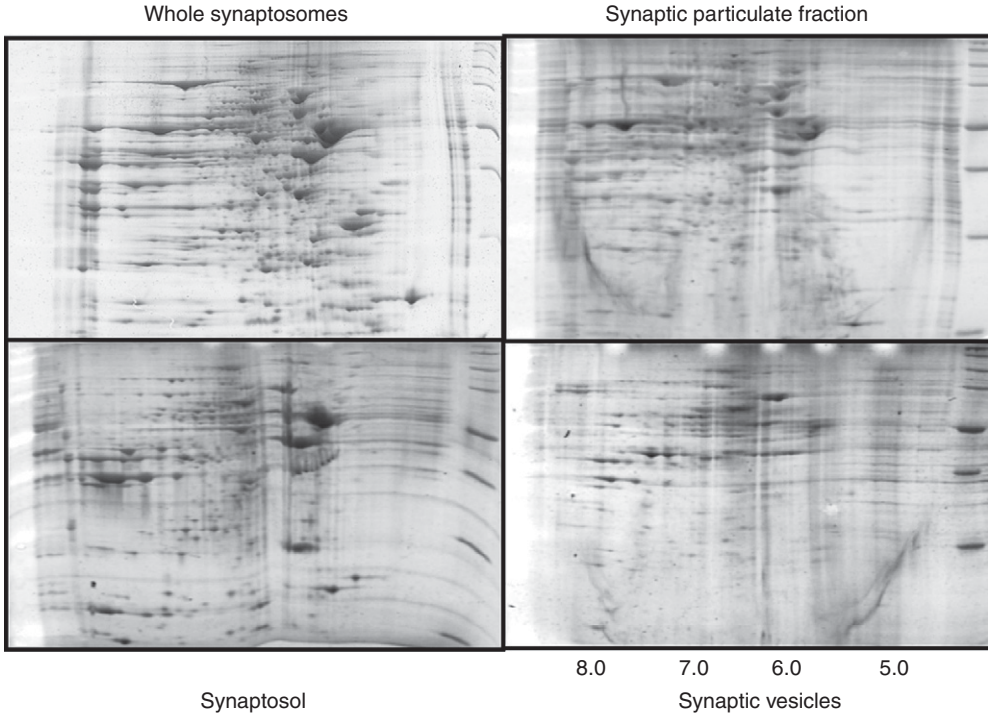

Figure 1 2D gel analysis of synaptosomal proteins. Samples were prepared by density gradient centrifugation and protein precipitates isolated by centrifugation following acetone precipitation. Precipitated proteins were redissolved in 6 M Urea, 2 M thiourea isoelectric focusing buffer and resolved on 11 cm IPG strips followed by 11 cm SDS-PAGE. The resulting gels were stained with SyproRuby and scanned on a Storm phosphorimager.

(liquid chromatography–electrospray ionization mass spectrometry/mass spectrometry), following excision of the spot from the gel and trypsin digestion. The bulk of the proteins appeared to be unchanged 1 month subsequent to stage 5 kindling, including essential proteins such as β-tubulin and the PI3 kinase adaptor protein. However, a major group of proteins around an isoelectric point of 6 increased in concentration in the kindled vesicle sample, including the synaptic vesicle H^+-ATPase required for neurotransmitter uptake.

We previously reported (see Further Reading) that a number of proteins, in the pellet fraction from disrupted kindled synaptosomes, are altered compared with controls – including increases in both α- and β-subunits of the mitochondrial ATP synthase complex, with a corresponding loss of the regulatory d-subunit. A number of proteins in the synaptosol fraction also appear to be altered substantially in kindling but as yet are unidentified. A major limitation of protein profiling studies such as those described earlier is the inherent complexity of proteomes, even of subcellular compartments. An alternative approach described later is to examine specific families of proteins in order to further enhance detection capabilities.

Studies of Synaptosomal 14-3-3 Proteins

Members of the 14-3-3 family of acidic ~30 kDa regulatory proteins exist as homo- and heterodimers that recognize specific phosphorylated Ser/Thr motifs of the type RSXpS/TXP (mode 1) and RXXXpS/TXP (mode 2). They act as both chaperones and regulatory molecules for a host of proteins in the cell, including members of numerous signaling pathways, as recently demonstrated in detail by global proteomic analyses. Among these chaperoned and/or regulated proteins are protein kinase C isoforms and CaM kinase, for which the 14-3-3s serve as inhibitors. Brain is the richest source of 14-3-3 proteins, where all but the σ isoform appear to be expressed. Two 14-3-3 isoforms, β and ζ, can be phosphorylated, at least in brain tissues, apparently inhibiting the formation of dimeric species.

We have examined the 14-3-3 protein complement of rat hippocampal synaptosomes by a combination of 2D gel analysis with both protein and phosphoprotein stains and immunoblotting, coupled with mass peptide mapping studies to identify the isoforms present and to quantify their levels and phosphorylation states, in control versus kindled hippocampus. As shown in **Figure 2**, the most prominent 14-3-3 isoforms present in rat hippocampal synaptosomal preparations are the phospho- and dephospho- forms of the β and ζ isoforms and 14-3-3ε. The amounts of these isoforms and their relative phosphorylation status did not change substantially either 1 month after completion of entorhinal kindling or with simple depolarization (as shown in the included bar graphs). Identification of all isoforms was performed with trypsin digests of the excised spots both by SELDI–TOF

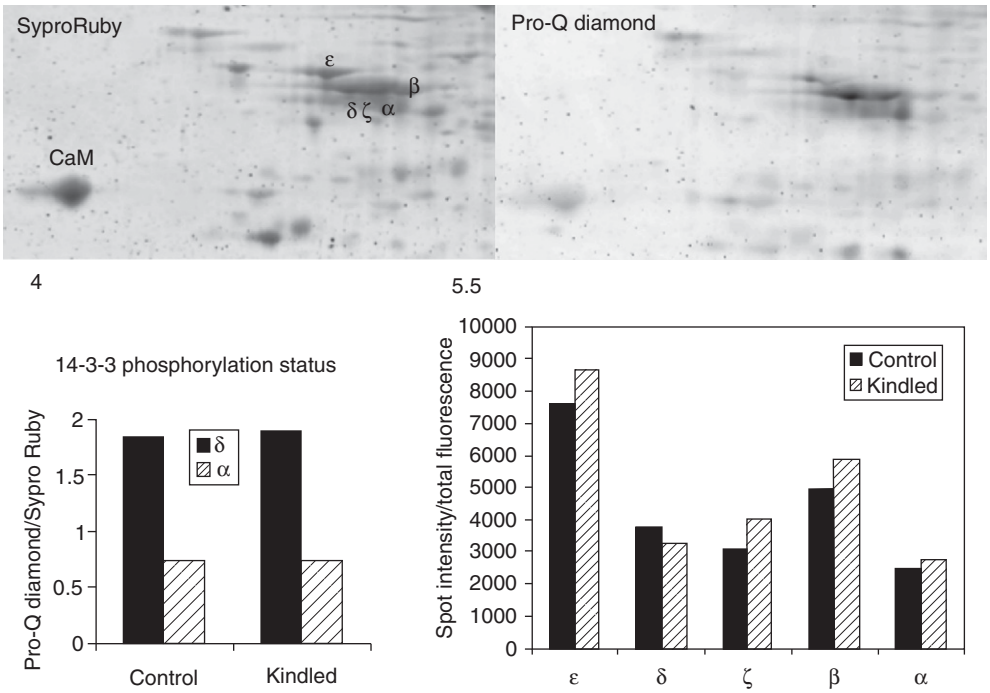

Figure 2 Entorhinal kindling does not alter levels or phosphorylation status of 14-3-3 isoforms in hippocampal synaptosomes. The two upper panels show SyproRuby (left) followed by Pro-Q Diamond staining of a representative of four different 2D gels run with samples of synaptosomes from kindled versus control rat brains. The gel shown was that obtained with an ipsilateral kindled animal. Quantification with a Typhoon phosphorimager showed no significant difference among any sets of samples in the 14-3-3 region of the gel. Average right and left values for Pro-Q Diamond/SyproRuby ratio (left) and for relative spot intensity with SyproRuby (right) are shown in the lower bar graphs.

(surface-enhanced laser desorption ionization –time of flight) mass peptide mapping and LC–MS/MS analysis. Immunoblot analyses of 2D gels (in parallel with the run shown in Figure 2 with a 14-3-3 pan-specific antibody) detected only the spots identified as 14-3-3 isoforms (data not shown). The large SyproRuby staining spot running at a p$I \sim 4.2$ and MR ~ 17 kDa is calmodulin (CaM) which serves as an excellent internal standard for quantification.

Other investigators have reported an apparent decrease of total 14-3-3 levels in cytosol (25%) and microsomal (50%) but not mitochondrial fractions isolated from rat hippocampus 4 h following seizures induced by intraamygdala administration of kainic acid. This change was correlated with a corresponding ipsilateral-specific increase in the proapoptotic factor BAD, suggesting that alterations in 14-3-3 might be triggering neuronal cell death. One may speculate that the differences between these results and our data (reported earlier) reflect the fundamental difference between electrical kindling and kainic acid-induced status epilepticus, and specifically the attendant pathological morphologic changes of the latter. It should also be noted that we have recently reported studies showing a number of kindling-dependent changes in secretory proteins at the synapse that are independent of the site of stimulation but identical for a given kindling stage.

Alterations of the CaM System in Epileptogenesis

The preeminent calcium signaling molecule at the synapse is CaM. One of our major hypotheses has been that the heightened state of excitability leading to spontaneous hypersynchronous neuronal activity (as seen in the epileptic state) must involve alterations in the CaM system. Numerous papers have appeared showing apparent alterations in the primary CaM kinase of the synapse, CaM kinase II, in both chemical and electrical models of epilepsy and in human material from epilepsy surgery. For example, a decrease in hippocampal CaM kinase II at both protein and mRNA levels has been reported with septal kindling and pilocarpine treatment. This change is consistent with the observation that homozygous CaM kinase IIα knockout mice show an enhanced epileptic response and spontaneous seizures. Conversely, increased accumulation of CaM kinase IIβ has been reported in response to PTZ-induced seizures, mediated by a nontranscriptional mechanism. Chronic reduction in CaM kinase II activity is most often correlated with status epilepticus in these models, apparently arising from inhibitory phosphorylation at multiple sites and/or conversion of the enzyme to an insoluble form. Other investigators have reported increased levels of CaM kinase II activity in rat hippocampus after

kainate-induced seizures. Given these disparate results, it is likely that the nature of alterations in CaM kinase II expression and activity depends on multiple variables. Other members of the CaM family have been linked to epileptogenesis, including the death-associated (DAP) kinase and the CaM-activated phosphatase calcineurin. Elevated expression levels of DAP kinase in TLE have been posited to be responsible for the increased neuronal cell death accompanying mesial sclerosis.

Surprisingly, a global analysis of the CaM family during epileptogenesis has not been reported. Indeed, we have only recently begun to apply the tools of proteomics to determining the CaM subproteome at the synapse. This type of analysis is made possible by the ability to isolate CaM binding proteins by calcium-dependent interaction, first described by our laboratory in 1976. **Figure 3** shows the 2D gel profiles for the CaM protein complement isolated from detergent solubilized synaptosomal preparations. This soluble fraction was mixed with an excess amount of biotinylated CaM derivative, prepared with a recombinant CaM containing an inserted Cys residue at position 5 (CaM^{T5C}), and processed as described in the legend of **Figure 3**. Proteins were recovered by acetone precipitation then resolved on standard 2D gels (pH 3–10, IPG/10% SDS-PAGE) subsequently stained with SyproRuby. The numbered spots were excised and subjected to LC–MS/MS to identify the proteins indicated in the figure legend. The complexity of the sample is dramatically reduced compared to the whole synaptosome shown in **Figure 1**. The patterns obtained for the control vs. kindled samples also were quite reproducible. In preliminary analyses, it appears that at least one low molecular weight (41 kDa) spot with an isoelectric point of 5 in the control sample is missing in the profile obtained with the kindled sample. Studies are currently in progress to identify which protein this represents, and to determine the mechanism of its kindling-dependent alteration.

Future Goals

The gel methods outlined earlier remain the primary approach used for initial global quantitative proteomic studies. However, this two-tier procedure is time consuming and cumbersome. A number of procedures have been devised recently which permit direct comparative protein profiling by MS alone. Most of these approaches rely on differential mass tagging of proteolytically digested samples which are then mixed and analyzed by MS. Comparison of the relative peak heights for the differentially tagged peptide peaks is used for quantification. This method has the obvious advantage of the high detection sensitivity of MS, and its ability to identify the protein of interest by subsequent fragmentation sequencing in the same analysis. A recent review of these strategies is given in the recommended readings.

We feel that the isobaric tagging for relative and absolute quantification (iTRAQ) tagging strategy has the most promise for proteomic studies of kindling. The iTRAQ reagents are a multiplexed set of up to eight isobaric reagents for quantitative proteomics analysis. They possess an amine-reactive group that labels the N terminus of all peptides, as well as the side chain of

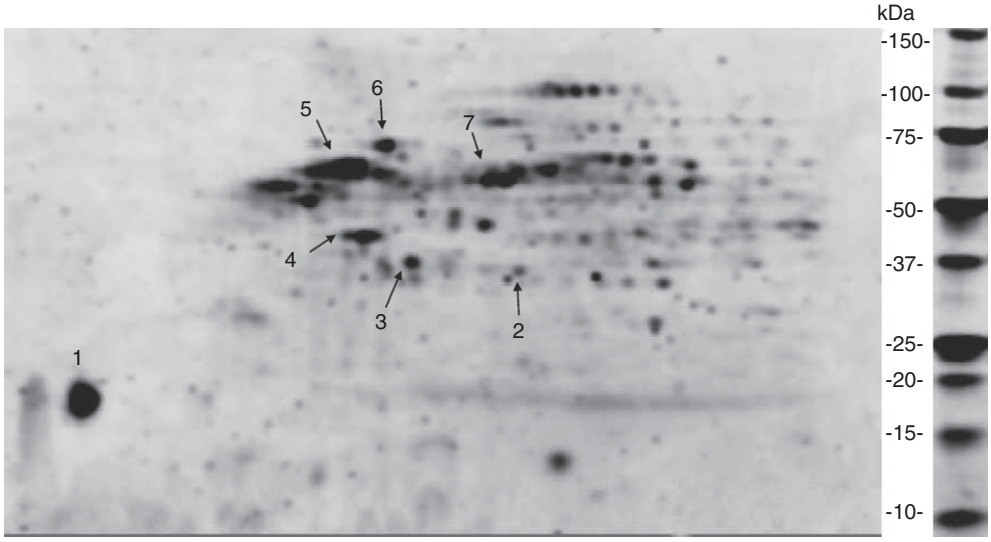

Figure 3 2D gel analysis of CaM binding proteins from hippocampal synaptosomes. Samples of hippocampal synaptosomes were solubilized in 20 mM *N*-ethylmorpholine, 1% TritonX-100, 1 mM $CaCl_2$, pH 7.0, preabsorbed with phenothiazine–Sepharose then mixed with sufficient biotinylated CaM^{T5C} to give 1 mM. After a 10 min incubation, CaM and bound proteins were captured using excess streptavidin magnetobeads, the beads washed with binding buffer then CaM and associated proteins eluted with the same buffer containing 5 mM EGTA in place of Ca^{2+}. Proteins were recovered by acetone precipitation then resolved on standard 2D gels (pH 3–10, IPG/10% SDS-PAGE) subsequently stained with SyproRuby. The numbered spots were excised and subjected to LC–MS/MS as described in Methods to identify the following proteins: (1) calmodulin; (2) annexin 3; (3) G protein β subunit; (4) Actin; (5) CaM kinase II α, β, and γ; (6) Hsp 70/72; (7) dihydropyramidase-related protein 2.

internal lysyl residues. The reagents are isobaric, with a different distribution of isotopes between a reporter and a balance group. Thus, the labeled peptides obtained after modification are identical in MS mode. Upon fragmentation in MS/MS mode, the labeled peptides produce strong, diagnostic, low-mass MS/MS signature ions. Relative areas of these reporter peaks indicate the contribution of each sample to total peptide present, allowing for quantification of up to eight different samples simultaneously. MALDI–TOF/MS (matrix-assisted laser desorbtion ionization–time of flight–mass spectrometry) analysis gives low femtomole to high attomole sensitivity in both MS and MS/MS modes. It should be noted that the iTRAQ approach has been used to demonstrate relatively modest increases in phosphorylation state of CaM kinase II on depolarization of purified rat brain synaptosomes. This demonstration clearly shows the power of the iTRAQ approach in kindling, especially for detecting potential alterations in depolarization dependent protein modifications.

As a final comment, it must be noted that it is essential to confirm any putative kindling-related changes seen with proteomic analyses by traditional quantification methods such as quantitative immunoblotting. We have used this approach quite successfully to study specific members of the secretory protein family. The ultimate goal of these types of studies is to identify changes in the levels of protein at the synapse, reflected by corresponding changes in gene expression, that dictate the state of elevated neuronal activity leading to seizure activity. It is hoped that determining these changes, and the nature of the molecular events and signaling pathways responsible for them, will provide new targets for therapeutic intervention to treat even the most persistent and pernicious seizure conditions in humans.

The Role of Calcium in Mediating Neuronal Plasticity in Epileptogenesis

Introduction

Acquired epilepsy (AE), the development of spontaneous, recurrent seizures following a neurological insult, constitutes approximately half of all cases of epilepsy. The majority of cases of AE are produced by one of the three injuries to the brain: status epilepticus (SE), stroke, and traumatic brain injury (TBI). Although the precipitating events causing these injuries are distinct from one another, it has been shown that each can lead to the development of AE. This process wherein healthy brain tissue is transformed into a hyperexcitable network of

Seizure-Induced Alterations in Motor and Sensory Maps

Introduction

In vertebrate animals, interconnected networks of large numbers of neurons directly generate behavior. Other causal factors like genes, ion channels, and individual neurons and glia influence behavior because they affect the functioning of neuronal networks. Thus, a comprehensive understanding of behavior requires a complete characterization of neuronal systems. This article presents an overview of several studies conducted to study the neocortex of rats and cats following repeated seizures. These studies have examined network properties, and have shown that neuronal networks have greater interconnection and reduced functional specificity as a consequence of repeated focal seizures.

Background

We have chosen the forelimb area of sensorimotor cortex of the rat and the primary auditory (AI) neocortex of the cat to conduct our studies. The rat sensorimotor neocortex is topographically organized, supports seizure activity, is highly plastic (showing synaptic potentiation and depression phenomena), and is important in the execution of skilled reaching behaviors. Cat AI neocortex exhibits a tonotopic organization that is dynamically regulated and continually altered by ongoing experience, even into adulthood. Cat AI neocortex also presents an ideal structure for examining unit firing characteristics following seizure-induced reorganization because the naïve system has previously been described in detail, and a great deal is known about underlying mechanisms.

The presence of a highly ordered somatotopic map of movement representations was intuited by John Hughlings Jackson, on the basis of his observations of the ordered spread of tonic and clonic activity to adjacent muscle groups during a single ictal event. Penfield later confirmed Jackson's notion and provided the classic descriptions of movement representations within the human precentral gyrus. Much of the initial characterization of these motor maps came from surface stimulation experiments conducted on human patients prior to surgery intended to remove an epileptic focus. More recent work has shown that stimulation-evoked movements in some people with epilepsy could be elicited from regions well outside the classic motor strip located along the Rolandic fissure. This finding suggested that the topography of movement representations within the primary motor cortex could reorganize in response to recurrent seizure activity. I have speculated that Penfield's classic depictions of cortical representations, which Philip Servos found to contain an error (the face representation should be inverted), might be due to the fact that they were obtained from tissue exposed to chronic epileptiform activity.

Neurons in primary AI of the cat respond most vigorously to simple sounds (tone pips) of a particular relatively narrow frequency range. A tuning curve provides a three dimensional plot of the firing rate of auditory cortical neurons over a restricted range of stimulus frequencies and intensities. The frequency to which the neurons are maximally responsive is known as the characteristic frequency (CF). Examination of tuning curves provides a useful way of examining the response properties of single cells within larger neural networks.

Methods and Recent Results

Motor Map Alterations

We decided to directly examine whether experimentally induced repeated seizure activity could reorganize the topography of movement representations. Furthermore, we wanted to determine whether there was a correlation between reorganization and synaptic potentiation, whether the reorganization was persistent, and whether it could be driven by seizures from either cortical or limbic sites. We used the rat sensorimotor neocortex, specifically the forelimb area, to answer these questions. The forelimb area is defined as that area of rat sensorimotor neocortex in which intracortical microstimulation (ICMS) elicits movements of the digits, wrist, elbow, or shoulder of the contralateral forelimb. Under ketamine/xylazine anesthesia, an ICMS procedure involves performing a craniotomy over one hemisphere and removing dura. A grid is placed over a digital image of the brain's surface and is used to identify the points where an electrode is lowered to layer V. Brief trains of high-frequency cathodal current are delivered once per second and the intensity of stimulation is raised until a movement is detected or a limit of 60 μA is reached (see **Figure 1** 'Control').

The primary findings of our studies is that rats that had seizures initiated from the corpus callosum, amygdala, or hippocampus exhibited a profound increase in the area of neocortex from which forelimb movements could be elicited relative to control (i.e., nonstimulated) rats

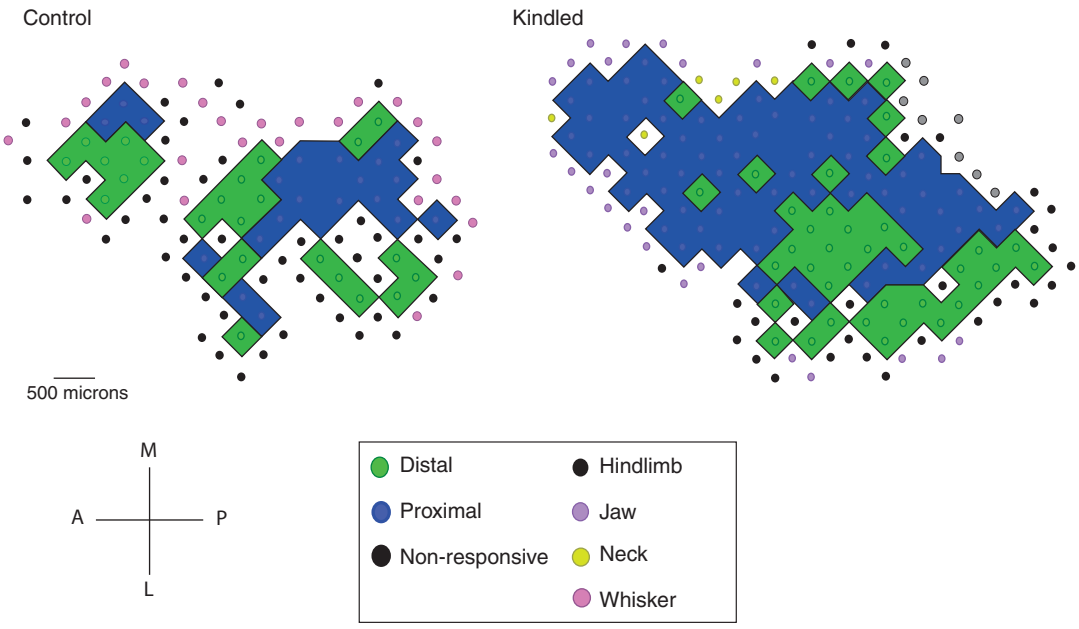

Figure 1 Rat forelimb movement representations. Color-coded representation of the motor map of the rat forelimb areas for a Control and Kindled rat. Each point represents the place where a stimulating microelectrode was lowered 1550 μm into the left hemisphere motor cortex, and stimulation was applied (up to 60 μA) until movement was elicited. Distal is defined as digit or wrist movements while Proximal is defined as elbow or shoulder movements. External map boundaries were always defined as electrode penetrations that failed to elicit movement or nonforelimb area movements (Hindlimb, Jaw, Neck, or Whisker). A–P refers to the direction of the anterior–posterior axis. M–L refers to the direction of the medial–lateral axis.

(see Figure 1 'Kindled'). This change in function facilitates the ability to elicit forelimb movements from regions of neocortex that would not previously produce forelimb movements in response to similar stimulation. At higher ICMS intensities, rats that had seizures also showed a greater number of multiple forelimb muscle responses compared with controls. We have also shown that the size of the maps strongly and positively correlates with both the number of cortical seizures and the degree of cortical synaptic potentiation. Furthermore, seizure-induced motor map expansion is persistent, lasting for at least 5 weeks after the last seizure.

The dramatically expanded forelimb movement representations, in the rats that had seizures, are not a result of alterations in anesthetic levels or ICMS intensity. Because ICMS appears to elicit movement by stimulating a pool of neurons interconnected by horizontal fibers within the neocortex rather than via direct stimulation of corticospinal neurons, enhanced synaptic efficacy may be responsible for the expanded motor representations. We have also shown that high-frequency stimulation-induced synaptic potentiation of horizontal fibers – stimulation that does not result in seizures – results in map expansion. Moreover, low frequency stimulation-induced synaptic depression (of horizontal fibers), that also does not result in seizures, reduces the size of motor maps. Thus, alterations in synaptic efficacy are likely a mechanism underlying functional reorganization within motor cortex.

Although synaptic potentiation phenomena may be necessary for map expansion, a subsequent study detailed below showed that they might not be sufficient. In order to more deeply explore the relationship between epileptogenesis, synaptic efficacy, and the size of motor maps, we used the epileptogenic-prone (FAST) and epileptogenic-resistant (SLOW) rat strains that differ dramatically in their kindling rate. These strains have become a valuable tool for investigating the neurochemical and neurophysiological basis of epilepsy. FAST and SLOW rats received daily repetitive high-frequency stimulation of the corpus callosum in order to induce long-term polysynaptic potentiation. They then underwent high-resolution ICMS in order to assess forelimb motor map size. We observed that high-frequency stimulation induced similar increases in polysynaptic potentiation in both rat strains – and therefore potentiation does not underlie the inherent differences in epileptogenesis between the two strains. Despite the similarities in the magnitude of potentiation, we found that only the FAST potentiated rats showed an increase in the size of their motor maps. SLOW potentiated rats did not manifest an increase in the size of their motor maps compared with SLOW control rats, whereas the FAST potentiated rats had motor maps that were about twice the area of FAST control rats. Thus, our results suggest that although potentiation may be necessary, it is not sufficient to account for map expansion; some other unidentified factor(s) are also involved.

Sensory Map Alterations

We examined the response properties of neurons in AI from cats that had seizures elicited by electrical stimulation through implanted electrodes, cats that were implanted but not stimulated, or nonimplanted controls. Cats were anesthetized with ketamine and the right temporal lobe exposed. In a sound-attenuated room, multiple single units were recorded from layers III/IV across the extent of AI (using one or two 4×2 rectangular electrode arrays) in response to a series of tone pips over a series of frequencies. We observed that the tuning properties of neurons in the primary auditory cortex were altered in the cats that had seizures. In AI of cats, there are normally a high percentage of neurons that express narrow V-shaped tuning curves. In the cats that had seizures, there was a greater tendency for double-tuned single-units (29%) than in the normal controls; the percentage of double tuned neurons in cat AI was only about 8% for the nonimplanted controls and 14% for the sham controls. This change may represent less specification between thalamocortical afferents that provide the normal tuning, and/or the stronger interconnection of cortical horizontal fibers that convey the CF range. Thus, single auditory neurons from cats that had seizures responded vigorously over a broader range of sound frequencies, consistent with the neurons being more strongly interconnected.

Cat auditory cortex normally exhibits a tonotopic organization with a gradual progression from low characteristic frequencies at the posterior ectosylvian sulcus (PES) to high characteristic frequencies towards the anterior ectosylvian sulcus (AES). Substantial changes in the tonotopic maps in AI were observed in all cats that had seizures. The maps from cats that had seizures in AI typically exhibited a lack of a tonotopic gradient, with large portions of AI tuned to the same range of characteristic frequencies (see Figure 2). During spontaneous neural activity, we also observed that neurons recorded from different electrodes within the array show higher intercorrelations in the cats that had seizures. The enhanced spontaneous neural synchrony was not only observed between neurons, but also extended over a greater area of primary auditory cortex. All of these observations can be explained by a greater amount of interconnections mediated by horizontal corticocortical synaptic connections.

We also investigated the effect of seizures on the response properties of neurons in the auditory cortex to periodic stimuli. Temporal coding in the auditory cortex normally manifests itself as the ability to follow the slower amplitude modulations in a complex stimulus, a phenomenon referred to as 'envelope locking.' Envelope locking can be quantified by the ability of neurons to respond to periodic stimuli with varying repetition rates. To examine envelope locking in animals exposed to repeated seizures, we used a relatively simple stimulus: 1 s duration click trains, with click rates ranging from 2 to 64 clicks per second, presented once every 3 s. With this stimulus, we evaluated the capacity of the cortical cells to follow the click periodicity. Neurons from cats that had seizures could not follow the higher-frequency periodic stimuli compared with neurons from control cats.

Mechanisms

Although the neural mechanisms underlying representational plasticity are not fully known, a potential neurochemical mechanism is that preexisting lateral excitatory connections are unmasked by decreased intracortical inhibition. Repeated seizures may induce expansion and reorganization of neocortical representations by altering glutamatergic and GABAergic transmission. A role for

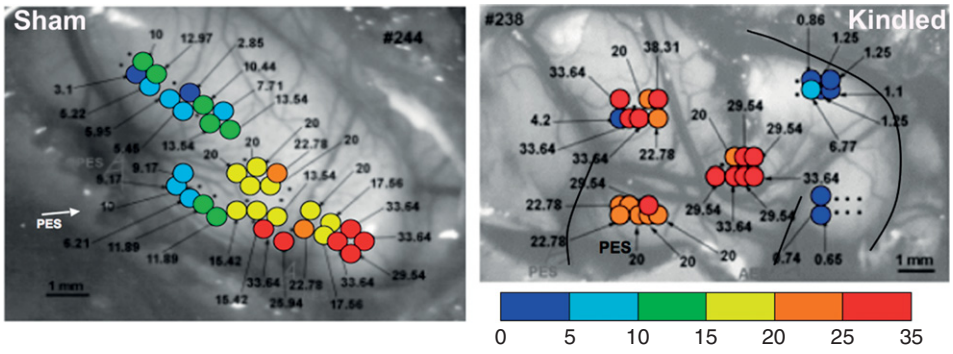

Figure 2 Tonotopic organization of cat primary auditory neocortex. Photographs of the exposed cortical surface depict the map of the characteristic frequency (CF) of each electrode position recorded from the auditory neocortex of Sham and Kindled cat. Indicated are the posterior ectosylvian sulcus (PES) and anterior ectosylvian sulcus (AES). Anterior is toward the right-hand side of each figure. The CFs are color coded according to the color bar shown. Cats normally have a gradual progression from low CFs (down to 2.5 kHz, lower CFs are found in the banks of the PES) near or just beyond the PES to CFs up to 35 kHz near the AES as shown in the Sham. In the example from a Kindled cat, a clear low- to high-frequency gradient is absent and clustering of similar CFs over a large area is found.

enhanced glutamate transmission in the reorganization of maps is suggested by the observation that NMDA antagonists block neocortical motor map plasticity induced by passive limb movements. Repeated seizures have been shown to enhance glutamatergic transmission by enhancing NMDA receptor activation, recruiting previously dormant NMDA receptors, increasing glutamate agonist potency, and increasing presynaptic glutamate release. Kindling has also been associated with a loss of GABAergic inhibition, and GABA antagonists have been shown to facilitate the induction of long-term potentiation in the motor neocortex and to induce expansion of movement representations. Thus, both the relative suppression of GABAergic transmission and enhancement of glutamatergic currents may underlie the reorganized map in rats and cats that have had repeated focal seizures.

Future Directions

The implications of seizure-induced alterations of motor and sensory neocortical organization, at the behavioral level, are altered motor function and sensory perception. Indeed, there are reports of these manifestations in people with epileptic foci in those two areas. Experimentally, we have reported altered skilled motor behavior in rats that have had focal seizures. Our evidence suggests that very strong horizontal synaptic connections within the neocortex likely underlie these neural and neural network properties. We and others have also reported that these connections may be supported by increased numbers of the highly efficacious perforated synapses that have larger synaptic contacts and more abundant NMDA and AMPA channels. A rationally designed treatment may be efficacious if it were to reverse this enhanced horizontal connectivity. Thus, pharmacological agents, and electrical or magnetic stimulation, that reverse glutamate receptor upregulation should be effective. We have recent data that show that low-frequency electrical stimulation can, to some degree, reverse seizure-induced map expansion, possibly by reversing enhanced horizontal connectivity. Another treatment alterative is sensorimotor enrichment or behavioral therapy. Sensory and motor areas are highly plastic, and there is good reason to believe that exposure to broad arrays of sounds, or training on skilled motor tasks, may reverse the seizure-induced pathological reorganization that occurs in auditory neocortex and motor areas respectively.

Seizures are hypersynchronous and hyperexcitatory oscillatory discharges that can occur in the vertebrate central nervous system as the result of a wide variety of intrinsic (i.e., ion channel mutations, neurotransmitter imbalance) and extrinsic (i.e., drugs, infections) factors. Seizures appear to induce a Hebb-like increase in synaptic efficacy: cells that fire together during seizures subsequently 'wire together.' The functional changes summarized here that occur with seizures likely can be accounted for by a corollary to Hebb's rule: cells that are wired together, fire together *and* recruit more cells into the response. Treatments that reverse seizure-induced plastic changes should be effective at restoring sensory and motor map topography and function, and thus reduce the interictal behavioral comorbidities that occur with epilepsy.

Introduction

Epilepsy is one of the most prevalent neurological diseases, affecting about 1% of the population worldwide. In addition to the immediate disabling effects of the seizures themselves, patients with epilepsy frequently suffer from a range of chronic neurological, psychological, and behavioral problems. In particular, epilepsy is often associated with severe cognitive deficits, including mental retardation, learning disabilities, and memory problems, which are often progressive. While the causes of neurocognitive dysfunction in epilepsy are multifactorial and likely involve a complex interaction between biological, environmental, and psychosocial factors, accumulating evidence indicates that seizures themselves may directly cause brain injury and thus contribute to the development and progression of neurocognitive deficits of epilepsy patients.

Seizures can potentially produce brain injury via diverse cellular and molecular mechanisms. The most obvious form of seizure-induced brain injury is neuronal death. Both clinical studies and animal models strongly suggest that neuronal death occurs as a direct result of seizures, at least under some conditions, such as following prolonged seizures (status epilepticus). However, despite the relatively high incidence of neurological and behavioral deficits in epilepsy, many patients with epilepsy have no clear evidence of neuronal death – at least based on neuroimaging, neuropathology, or evaluation of biochemical markers of neuronal injury. Thus, in addition to overt neuronal death, there likely exist more subtle, 'non-lethal' mechanisms of seizure-induced brain injury, affecting neuronal structure and function and accounting for cognitive deficits in epilepsy. Since higher cognitive processes involve highly patterned communication between neurons in complex cortical networks, seizure-induced alterations in the cellular and molecular components of synaptic transmission between neurons could have a profound negative impact on cognition and behavior.

Dendritic spines, tiny protrusions emanating from the dendrites of many neurons, receive the majority of excitatory glutamatergic synaptic inputs to cortical neurons and have been strongly implicated in mechanisms of synaptic plasticity and learning. As such, dendritic spines represent a potential target for pathological modulation by seizures; seizure-related changes in these spines may mediate detrimental effects on neurocognitive function. Indeed, one might logically predict that the synchronous discharging of thousands of neurons in an epileptic focus that occurs repetitively during a seizure, the resulting massive release of glutamate, and the associated intense synaptic activation and depolarization of postsynaptic cells would produce numerous biochemical and structural changes to spines. In fact, numerous studies have provided evidence that dendritic structure is often abnormal following acute seizures or in chronically epileptic brains. Further investigation of seizure-related changes in dendritic spine structure should provide important insights into mechanisms of seizure-induced brain injury and may lead to novel therapeutic approaches for preventing brain injury and associated neurocognitive deficits.

Background

A variety of studies involving both human tissue and animal models suggests that epilepsy does result in alterations in various components of dendritic ultrastructure. However, most of this previous work has used fixed tissue specimens, and thus have several limitations in determining causal relationships and functional implications of these seizure-related dendritic changes. Furthermore, little is known about the specific cellular and molecular mechanisms mediating these effects of seizures on dendritic structure.

Dendritic Spine Changes in Human Epilepsy

Studies of dendritic spines in human epilepsy are essentially limited to pathological analysis of brain tissue, usually obtained during surgical treatment of patients with

Introduction

Epilepsy is one of the most prevalent neurological diseases, affecting about 1% of the population worldwide. In addition to the immediate disabling effects of the seizures themselves, patients with epilepsy frequently suffer from a range of chronic neurological, psychological, and behavioral problems. In particular, epilepsy is often associated with severe cognitive deficits, including mental retardation, learning disabilities, and memory problems, which are often progressive. While the causes of neurocognitive dysfunction in epilepsy are multifactorial and likely involve a complex interaction between biological, environmental, and psychosocial factors, accumulating evidence indicates that seizures themselves may directly cause brain injury and thus contribute to the development and progression of neurocognitive deficits of epilepsy patients.

Seizures can potentially produce brain injury via diverse cellular and molecular mechanisms. The most obvious form of seizure-induced brain injury is neuronal death. Both clinical studies and animal models strongly suggest that neuronal death occurs as a direct result of seizures, at least under some conditions, such as following prolonged seizures (status epilepticus). However, despite the relatively high incidence of neurological and behavioral deficits in epilepsy, many patients with epilepsy have no clear evidence of neuronal death – at least based on neuroimaging, neuropathology, or evaluation of biochemical markers of neuronal injury. Thus, in addition to overt neuronal death, there likely exist more subtle, 'non-lethal' mechanisms of seizure-induced brain injury, affecting neuronal structure and function and accounting for cognitive deficits in epilepsy. Since higher cognitive processes involve highly patterned communication between neurons in complex cortical networks, seizure-induced alterations in the cellular and molecular components of synaptic transmission between neurons could have a profound negative impact on cognition and behavior.

Dendritic spines, tiny protrusions emanating from the dendrites of many neurons, receive the majority of excitatory glutamatergic synaptic inputs to cortical neurons and have been strongly implicated in mechanisms of synaptic plasticity and learning. As such, dendritic spines represent a potential target for pathological modulation by seizures; seizure-related changes in these spines may mediate detrimental effects on neurocognitive function. Indeed, one might logically predict that the synchronous discharging of thousands of neurons in an epileptic focus that occurs repetitively during a seizure, the resulting massive release of glutamate, and the associated intense synaptic activation and depolarization of postsynaptic cells would produce numerous biochemical and structural changes to spines. In fact, numerous studies have provided evidence that dendritic structure is often abnormal following acute seizures or in chronically epileptic brains. Further investigation of seizure-related changes in dendritic spine structure should provide important insights into mechanisms of seizure-induced brain injury and may lead to novel therapeutic approaches for preventing brain injury and associated neurocognitive deficits.

Background

A variety of studies involving both human tissue and animal models suggests that epilepsy does result in alterations in various components of dendritic ultrastructure. However, most of this previous work has used fixed tissue specimens, and thus have several limitations in determining causal relationships and functional implications of these seizure-related dendritic changes. Furthermore, little is known about the specific cellular and molecular mechanisms mediating these effects of seizures on dendritic structure.

Dendritic Spine Changes in Human Epilepsy

Studies of dendritic spines in human epilepsy are essentially limited to pathological analysis of brain tissue, usually obtained during surgical treatment of patients with

intractable epilepsy. Such pathological specimens from the region of the epileptic focus, in neocortex or hippocampus, have revealed various dendritic abnormalities but most commonly show a loss of dendritic spines. A loss of spines has been reported primarily in hippocampal pyramidal neurons and dentate granule cells in patients with temporal lobe epilepsy, and this loss may occur either in isolation or in association with varicose swelling of the dendrites. Similar findings of spine loss and dendritic swelling have been documented in pyramidal neurons of neocortex distant from the primary site of epileptogenesis. Other less common dendritic abnormalities have been described in both neocortical and hippocampal epileptic tissue, including changes in dendritic length, shape, and branching patterns, as well as a focal increase in dendritic spine number.

A loss of dendritic spines, particularly in hippocampus, represents a logical mechanism to explain learning and memory deficits in epilepsy patients. Studies of the physiological properties of neurons in the resected brain tissue from epilepsy patients have identified correlations between loss of dendritic spines and responses to glutamate, suggesting that the spine loss has important effects on synaptic physiology. However, owing to the intrinsic limitations of clinical-pathological studies, it is difficult to directly link spine changes to behavioral or cognitive problems in epilepsy patients, thus making the functional implications and consequences of dendritic spine abnormalities in human epilepsy unclear. Another limitation of human studies is the inherent problem of determining the specific causes, and mechanisms, of the spine changes. Dendritic abnormalities documented in pathological specimens resected from patients with intractable epilepsy could be due to direct effects of seizures, but could also relate to other variables, such as the underlying neurological insult (e.g., an insult originally causing the epilepsy), the use of antiepileptic drugs, or other environmental factors. Thus, well-controlled animal studies may be better suited for determining the importance of different factors and mechanisms in mediating seizure-related spine changes.

Dendritic Spine Changes in Animal Models of Epilepsy

Animal models of epilepsy can complement and extend the clinical studies of dendritic spines by controlling for many of the confounding factors that complicate interpretation of human data and by facilitating more mechanistic investigations. The direct effect of seizures on dendritic spines has been tested in different animal models. Similar to the clinical studies, the most consistent finding following seizures in animal models has been a loss of spines, often associated with varicose swelling of the dendrites. In the rat pilocarpine model of temporal lobe epilepsy, acute seizures result in a marked reduction in spine density in dentate gyrus within 24 h. Dendritic spines in hippocampus are also decreased in rats with chronic epilepsy induced by tetanus toxin, as well as in other hippocampal and neocortical seizure models. In contrast, at least one study has reported a localized increase in dendritic spines in hippocampus following limbic seizures.

Given the controlled nature and timing of the animal studies, these experimental models strongly suggest that seizures themselves can directly lead to dendritic changes. However, because all these previous studies also relied on conventional histological analyses of fixed tissue from different subjects at different time points, it is still difficult to distinguish between a direct, specific effect of seizures and indirect, coincidental or compensatory processes. Furthermore, pathological studies only give isolated 'snapshots' in time and may miss more acute, dynamic changes that may occur on a more rapid time scale. To address these limitations, studies that can visualize the same dendrites serially over time in living tissue should be able to more directly and comprehensively assess the effects of seizures on spines. Remarkably, pioneering time-lapse live imaging studies have revealed that dendritic spines normally possess a great degree of motility and plasticity, on a rapid time scale of seconds, that was not previously anticipated based on fixed-tissue analysis. Thus, while previous fixed tissue experiments assayed spine changes only hours to days after seizures, modern time-lapse imaging techniques can test for very rapid effects of seizures on spines. We and others have recently used multi-photon microscopy to examine the direct, acute effects of seizures on dendritic spines imaged in vivo in several different rodent seizure models. Although the acute effects of seizures on dendritic structure may vary depending on conditions and seizure model, we have documented stereotypical, evolving changes in dendrites over a rapid time scale following seizures. We have also begun to determine the molecular mechanisms mediating this form of dendritic injury, focusing on regulation of the actin cytoskeleton.

Methods

We utilized modern cellular imaging techniques to assess seizure-induced morphological changes on dendrites and dendritic spines in living mice. Compared with conventional histological studies, these newer imaging methods, particularly multiphoton microscopy, allow repetitive, time-lapse imaging of dendritic spines within the living brain in vivo, so that the same dendritic spines can be directly monitored before, during, and after physiological or pathological perturbations over a rapid time scale of seconds to minutes, as well as for longer time periods.

Transgenic mice expressing enhanced green fluorescent protein (GFP) in subpopulations of pyramidal neurons in neocortex and hippocampus (*thy1* promoter, line GFP-M) have been used for all imaging experiments. Under anesthesia, a craniotomy window was produced surgically over frontal neocortex with a coverslip, which was sealed with dental acrylic. In some experiments, a cannula for drug application directly to the cortex, and neighboring EEG wire electrodes, were placed along the craniotomy window. Images of dendrites and dendritic spines of GFP-expressing neocortical pyramidal neurons were obtained through the cranial window with a Zeiss LSM 510 multiphoton microscope. A Coherent Titanium-Sapphire pulsed infrared laser was used to stimulate GFP at 900 nm. Low-magnification images, ~50–100 μm below the neocortical surface, were first obtained to identify regions with GFP-expressing dendrites. At higher magnification (5× digital zoom), Z-stacks of 6–10 images separated by 1 μm steps were taken of dendrites and accompanying spines.

In control experiments, the same dendrites and spines could be identified and followed serially under continuous anesthesia or while intermittently allowing the animal to recover from anesthesia in between images, over hours to days. For seizure experiments, control images of dendrites were taken under anesthesia prior to seizure induction and then the same dendrites were followed serially after seizure induction by various pharmacological agents. By these methods, we have examined the direct effects of two seizure models on dendrites: focal neocortical seizures induced by 4-aminopyridine (4-AP) applied locally to cortex, and secondarily generalized seizure induced by systemic kainate. Seizures were monitored by video-EEG or standard behavioral observation and staging.

We have also used standard histological, immunohistochemical, and molecular biological techniques to investigate the potential molecular mechanisms of seizure-induced dendritic changes. In particular, we have employed the rhodamine-phalloidin labeling method, which selectively assays changes in filamentous actin, to determine the effects of seizures on actin dynamics. In addition, we have utilized Western blotting to assess the effects of seizures on the expression of a variety of cell signaling molecules and actin-binding proteins that can regulate actin dynamics and potentially mediate structural changes in dendritic spines.

Recent Results

Focal 4-Aminopyridine Neocortical Seizures Increase Risk of Dendritic Injury under Limited Conditions

Using a model of neocortical partial seizures, initial studies examined the acute effects of focal seizures induced by 4-AP on dendritic structure of neocortical pyramidal neurons in vivo. The first set of experiments was performed under continuous isoflurane anesthesia. Time-lapse multiphoton imaging of GFP-positive dendrites of neocortical pyramidal neurons was performed through the same cranial window before and for several hours after local administration of ACSF or 25 mM 4-AP to neocortex. In ACSF-injected mice, no seizure activity was detected by EEG and the dendritic spines remained remarkably stable for the several hour period. Local infusion of 4-AP through the cranial window quickly induced repetitive electrographic seizures (without a clinical correlate) lasting several hours under anesthesia, but had no obvious effect on dendrites or spines. Quantitative analysis demonstrated that >95% of dendritic spines remained stable over several hours under both control and seizure conditions, with minimal loss of existing spines or gain of new spines. There was no significant difference between control and seizure conditions in spine turnover.

Since anesthetics have been reported to inhibit dendritic spine motility, we performed a second set of experiments to eliminate the potential protective effect of anesthesia during seizures. Similar methods were used as previously, except that after baseline control images of dendrites were obtained and 4-AP (or ACSF) was injected under isoflurane anesthesia, the mice were allowed to recover from anesthesia and have EEG-confirmed clinical seizures for 30 min in the absence of anesthesia. The mice were then reanesthetized, and using blood vessel landmarks as a reference, the same dendrites were reimaged for several hours to determine the acute effects of the preceding seizures. A dose-dependent response was observed in both clinical seizure severity and dendritic injury. With ACSF injection, no seizures were elicited and no significant spine changes were detected, comparing serial imaging before and for several hours after ACSF injection (**Figure 1(a)**). Lower doses (250 μM) of 4-AP induced stage 1–3 seizures with staring, head bobbing, and mild forearm clonus, but also had minimal effects on dendrites. Higher doses (1–2.5 mM) of 4-AP reliably resulted in stage 4 seizures with rearing and forearm clonus, but no falling or convulsions, and 25 mM 4-AP usually caused generalized convulsive activity (stage 5). After 30 min of stage 4 or 5 seizure activity, secondary dendrites from some animals exhibited acute swelling and beading, with associated loss of spines that was often irreversible over a several hour period (**Figure 1(b)**). However, there is an important caveat: The dendritic injury usually was more pronounced within the original field of imaging, compared with an adjacent (naïve) site outside the initial imaging field. This result suggests a possible synergistic effect of phototoxic damage (from the initial laser exposure) with severe seizures. As dendritic injury was not observed in ACSF-injected mice or

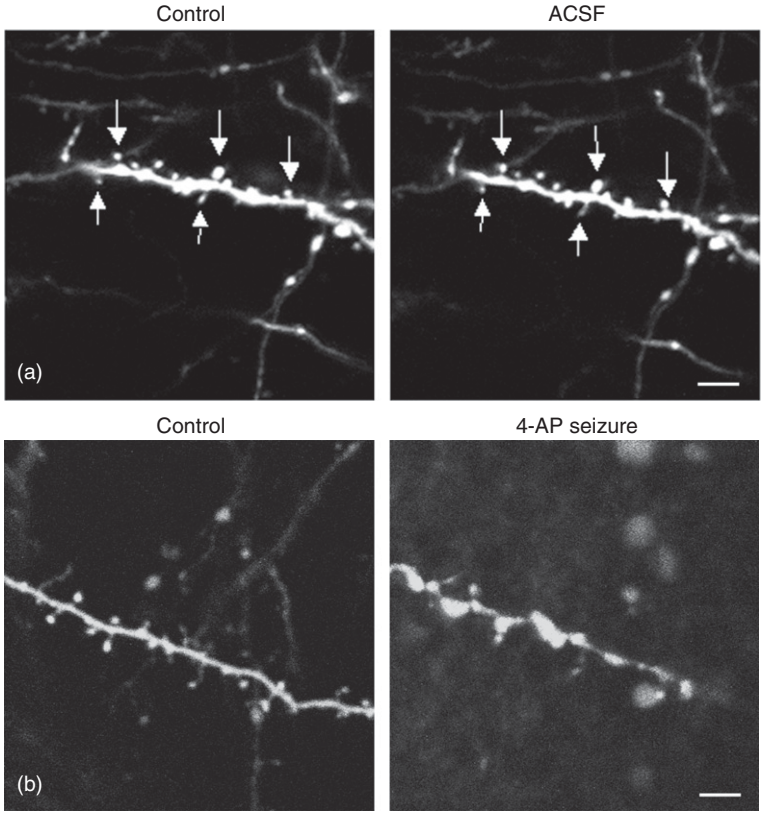

Figure 1 Seizures cause acute dendritic beading and spine loss. (a) Time-lapse in vivo multiphoton imaging of a neocortical dendrite of a control mouse performed serially before and after ACSF injection shows no significant changes in dendritic structure and spine number/position. Arrows mark examples of individual spines, demonstrating the stability of spines over time. (b) 4-AP induced seizures in unanesthetized mice cause acute dendritic beading and loss of spines within one hour of seizure termination. Scale bars = 5 μm for all images. mice with low stage seizures using identical imaging methods, these findings indicate that some neocortical seizures may increase the risk of dendritic injury when combined with other pathological stimuli. Although laser phototoxicity obviously represents an artificial stimulus, other pathophysiological conditions – such as hypoxia, hypoglycemia or hyperthermia – could be associated with seizures and may act synergistically to cause dendritic injury.

Secondary Generalized Kainate Seizures Cause Robust Dendritic Injury

Since the acute effects of focal neocortical 4-AP seizures on dendrites were relatively limited, and appeared to be contingent upon another pathological factor, we have explored other seizure models that may cause more robust dendritic injury. It is possible that seizure models involving other, more generalized, seizure types or utilizing different mechanisms of seizure induction may have stronger effects on dendrites. Thus, we have performed additional experiments in a different seizure model: the systemic kainate model. More severe kainate seizures, which originate in the hippocampus but then secondarily generalize throughout neocortex, may cause more extensive cortical activation than focal 4-AP seizures and involve direct glutamatergic stimulation. After obtaining control images under anesthesia, mice were injected with 30 mg kg^{-1} kainate i.p and allowed to recover from anesthesia. Following 30 min of severe behavioral stage seizures, the mice were reanethesized and the same dendrites were reimaged. Similar to the results with focal 4-AP injection, more severe behavioral stage (stage 4–5) kainate seizures caused an acute dendritic swelling, beading, and loss of spines. However, in contrast to the 4-AP seizures, the dendritic injury was seen equally in naïve regions of neocortex (i.e., areas that had not been previously imaged and so not exposed to potentially toxic effects of the laser), indicating that there was no synergistic effect with laser phototoxicity. Furthermore, the live time-lapse imaging revealed a rapid, dynamic evolution of dendritic abnormalities, with the dendritic beading often resolving within a couple hours, but spine loss persisting for much longer. Thus, these studies demonstrate more definitively that some seizures can cause direct injury

to dendrites, that the injury may evolve over a rapid time scale, and that different seizure types may have different effects.

Acute Seizure-Induced Dendritic Injury May Be Mediated by Calcineurin-Dependent Activation of Cofilin and Depolymerization of F-Actin

In addition to demonstrating acute dendritic injury in different seizure models, we have also started to investigate potential molecular mechanisms and signaling pathways mediating the effects of seizures on dendritic morphology, focusing on the regulation of the actin cytoskeleton of dendrites (**Figure 2**). Actin is a major structural protein that can exist in a monomer form (G-actin) or a polymerized filamentous form (F-actin); it is highly concentrated in dendritic spines, forming complex filamentous networks that provide structural support for dendrites and dendritic spines. Since physiological activity may modulate actin networks to cause changes in dendritic structure and function, we have examined the effect of both focal 4-AP neocortical seizures and systemic kainate seizures on F-actin levels, as assayed by rhodamine-phalloidin labeling. We found that both seizure types led to a significant decrease in F-actin in relevant cortical areas, indicating that seizures induce a depolymerization of actin filaments.

F-actin can be depolymerized by the regulatory actin-binding protein, cofilin. As cofilin is inactivated by phosphorylation, dephosphorylation of cofilin at the Ser3 residue leads to cofilin activation, which can trigger depolymerization of F-actin (**Figure 2**). Thus, we tested whether seizure-induced depolymerization of F-actin is related to a decrease in the phosphorylated form of cofilin (p-cofilin). By Western blot analysis, both 4-AP and kainate seizures had no effect on total actin or cofilin levels, but caused a significant decrease in p-cofilin expression in cortex. These studies indicate that seizures induce a rapid activation of cofilin and corresponding depolymerization of actin filaments in dendrites, which may, at least in part, account for the acute structural effects of seizures on dendrites.

We have also performed preliminary experiments to test the potential role of up-stream, activity-dependent signaling pathways in mediating seizure-induced regulation of the actin networks and dendritic structure. Cofilin and actin dynamics can be regulated by a number of upstream intracellular signaling elements, including a variety of phosphatases and kinases. In particular, the calcium-dependent phosphatase, calcineurin, is activated by seizures and may mediate regulation of cofilin activity by calcium (**Figure 2**). We utilized a calcineurin inhibitor to test whether calcineurin may be involved in the effects of kainate seizures on cofilin activation and dendritic morphology. Pretreatment with the calcineurin inhibitor, FK506, significantly blocked the seizure-induced decrease in p-cofilin in both hippocampus and neocortex. In addition, FK506 at least partially antagonized the effects of kainate seizures on dendritic beading and spine loss observed in the in vivo imaging studies. These results suggest that calcineurin may play a role in mediating the effects of kainate seizures on actin dynamics and spine morphology, and demonstrate that calcineurin inhibitors may have therapeutic potential in limiting seizure-induced dendritic injury.

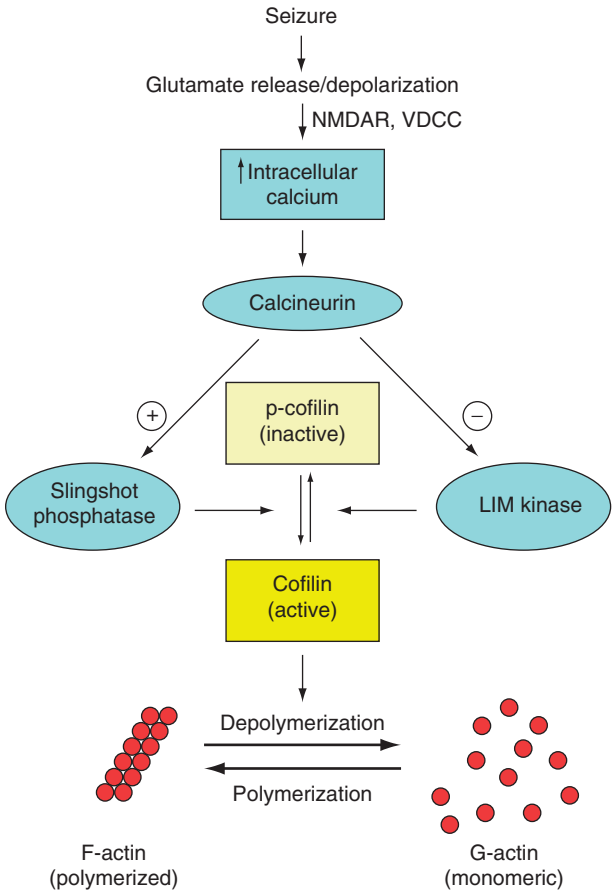

Figure 2 Putative signaling pathways and molecular mechanisms mediating seizure-induced dendritic injury. Seizures cause excessive glutamate receptor activation and neuronal depolarization, resulting in calcium influx into dendrites via NMDA receptors (NMDAR) and voltage-dependent calcium channels (VDCC). Elevated intracellular calcium can trigger a cascade of calcium-dependent enzymes, such as CaM kinase and calcineurin, causing complementary regulation of downstream opposing phosphatases (Slingshot) and kinases (LIM kinase) due to changes in phosphorylation states. Finally, activation (dephosphorylation) of cofilin (or actin depolymerizing factor) causes depolymerization of F-actin, which may lead to break-down of the normal actin cytoskeleton of dendrites.

Future Goals

Live in vivo time-lapse imaging methods have shown that seizures can directly cause dendritic injury and revealed a rapid evolution of acute dendritic changes that could not be detected by previous conventional fixed tissue histological studies. In addition, some of the molecular mechanisms and pathways mediating these seizure-induced changes in dendritic structure have begun to be elucidated. However, much additional work is needed to characterize seizure-induced dendritic injury and determine underlying mechanisms in more detail. First, there is some variability in the properties of dendritic abnormalities observed in different seizures models. Future studies should help determine what network, cellular, or molecular factors are most critical in determining the observed differences in propensity for dendritic injury (e.g., from kainate seizures versus the focal 4-AP model). Similarly, future studies will need to elucidate the potential synergistic roles of seizure-associated systemic factors – such as hypoxia, hypoglycemia, and hyperthermia – in promoting dendritic injury. Second, while previous fixed tissue experiments support the finding of a chronic seizure-induced spine loss, future time-lapse in vivo imaging studies over days to weeks should be performed to extend and verify the long-term time course of the observed acute, evolving dendritic changes. Finally, while work to date strongly implicates the involvement of the actin cytoskeleton, more detailed mechanistic studies are needed to further clarify and delineate the critical molecular pathways and mechanisms mediating seizure-induced dendritic injury. In particular, the role of other regulatory enzymes (e.g., LIM kinase, Slingshot, Rho-GTPases) and actin-binding proteins can be studied.

Of direct clinical relevance, further understanding of the molecular mechanisms mediating seizure-induced spine changes may finally lead to new therapeutic strategies for either treating seizures or preventing neurocognitive deficits in epilepsy. While most drugs for epilepsy have targeted neurotransmitter receptors and ion channels, an innovative therapeutic approach would be to modulate the structural components of synaptic plasticity, such as dendritic spine motility, in an activity-dependent fashion. As suggested by our preliminary data, inhibition of activity-dependent intracellular signaling elements, such as calcineurin, may limit seizure-induced dendritic injury. A more selective stabilization of the dendritic actin cytoskeleton during seizures, by drugs that directly regulate actin polymerization, could potentially help prevent seizure-induced spine changes and reduce associated cognitive deficits. Thus, better insights into the mechanisms of spine modulation by seizures could have significant impact in reducing the long-term negative consequences of epilepsy.

Synaptic Potentiation and Inhibition after Partial Seizures

L S Leung, University of Western Ontario, London, ON, Canada

Introduction

There are two major models of neural plasticity induced by brain stimulation – kindling and long-term potentiation (LTP). The kindling model involves brief but repeated stimulations that evoke electrographic seizures or afterdischarges (ADs), as was first reported by Goddard *et al.* in the late 1960s. Repeated stimulations (kindling) are accompanied by prolongation of the AD duration and increase in severity of the behavioral seizures. Although first proposed as a model of learning and memory, kindling is more appropriately described as a model relevant to epilepsy; indeed, the kindling process of increasing seizure duration and severity may be considered a process of epileptogenesis.

LTP is a long-lasting enhancement of synaptic transmission, first reported by Bliss and Lomo in the early 1970s for the synapse between the medial perforant path (MPP) and the dentate gyrus (DG). LTP is suggested to be a cellular correlate of learning and memory, and many glutamatergic synapses are capable of LTP. The cellular mechanisms and behavioral significance of LTP have been intensively studied. Ca^{2+} influx into the postsynaptic cell is essential to activate various kinases, resulting in long-lasting postsynaptic increase in the number and sensitivity of α-amino-3-hydroxyl-5-methyl-isoxazole-4-proprionate (AMPA) receptors, and/or an increase in presynaptic release of glutamate. Coincidence of pre- and postsynaptic activity is important for a type of LTP (Hebbian LTP) that depends on Ca^{2+} influx through *N*-methyl-D-aspartate (NMDA) receptors. In addition, LTP may be mediated by Ca^{2+} influx through voltage-dependent Ca^{2+} channels or other Ca^{2+}-permeable channels and on Ca^{2+}-induced Ca^{2+} release. Long-term depression (LTD) is the converse of LTP, and it may be induced with low-frequency stimulation that causes a smaller Ca^{2+} influx than that during LTP induction.

Stimulations that evoke LTP, without evoking ADs, contribute little to the kindling process (i.e., to increasing AD duration and seizure severity) (**Table 1**). Further, LTP stimulations do not induce the clear behavioral changes in animals seen with kindling (e.g., changes in emotional and psychiatric symptoms) (**Table 1**). However, short-term neural plasticity (e.g., changes that last for several milliseconds to minutes after stimulation, as induced by posttetanic potentiation or paired-pulse facilitation, may help to augment and propagate a seizure.

The term 'seizure-induced potentiation' (SIP) will be used here to describe the synaptic potentiation that is induced by a seizure or an AD, as distinct from LTP that is induced by stimulation without evoking an AD. Two models of partial epilepsy, kindling and status epilepticus (SE), are considered in this article.

Background

SIP often occurs during the process of kindling. During kindling by stimulation of the MPP, SIP was found after the first AD, but incremental SIP was small with subsequent ADs. However, SIP was not found during kindling of some pathways (e.g., at the lateral entorhinal cortex (EC)-to-DG

Table 1 Summary of phenomena induced by repeated afterdischarges or long-term potentiation in the hippocampus or amygdala

Phenomenon	*ADs*	*LTP*
AD duration	increase	NC
Seizure severity	increase	NC
AD threshold (amygdala)	decrease	NC
Facilitates kindling	sometimes	no
Spontaneous interictal spikes	increase	minimal change
Monosynaptic potentiation	yes	yes
Trans-synaptic hippocampal potentiation	yes	yes, less persistent
CA1 inhibition ($GABA_A$)	decrease	NC/increase
Psychiatric symptoms	increase	NC
Emotional behaviors	increase	NC
Spatial maze performance deficit	sometimes	sometimes
Retention in radial arm maze	decrease	NC

ADs are induced by tetanic stimulation; LTP is elicited without an AD.
ADs, afterdischarges; LTP, long-term potentiation; NC, no change.

synapse). Changes in epileptiform activity, such as increase in AD severity and duration and increase in spontaneous interictal spikes, are reported to have a different pharmacology from LTP or SIP. Blocking NMDA receptors blocks SIP of the MPP–DG synapse; kindling is slowed but not abolished. Similarly, antagonizing NMDA receptors blocks an AD-induced potentiation of basal dendritic synaptic transmission in CA1 (**Figure 1(a)**). However, NMDA receptor blockade does not block the AD-induced interictal spikes in CA1 (**Figure 1(b)**). Many interictal spikes resemble large basal dendritic field excitatory postsynaptic potentials (fEPSPs), with a negative wave at the basal dendrites and a positive wave at the cell body layer and apical dendrites. However, SIP is not essential for the interictal spikes.

Considerable evidence supports an alteration of inhibition after partial seizures. $GABA_A$ receptors in the DG are persistently altered following SE and kindling. After seizures, mini- or evoked $GABA_A$-mediated inhibitory postsynaptic currents (IPSCs) are increased in DG granule cells. These IPSCs, in tissue from animal models or from temporal lobe epilepsy patients, are more sensitive to blockade by Zn^{2+} and insensitive to the benzodiazepam type1-specific agonist zolpidem, possibly because of a relative decrease in α1-subunit expression. GABAergic interneurons may be functionally disconnected from their excitatory inputs ('dormant basket cells'), which may explain functional disinhibition despite preservation of GABAergic neurons. However, specific types of interneurons may be lost, as suggested by the differential loss of inhibition at dendritic and not somatic synapses. Also, not all brain areas show loss of inhibition; indeed, after hippocampal kindling, inhibition is increased in the DG, but decreased in CA1 and CA3.

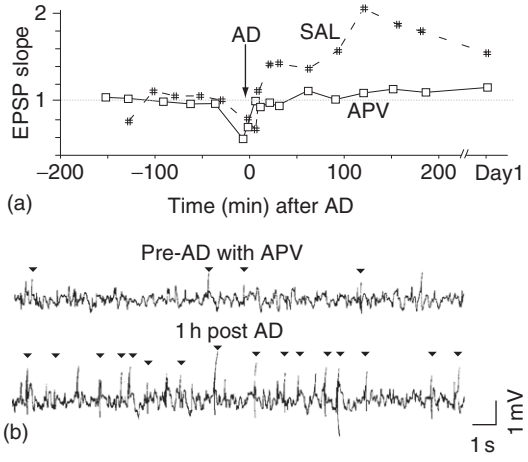

Figure 1 Potentiation of field excitatory postsynaptic potentials (fEPSPs) and interictal spikes in CA1 after an afterdischarge (AD) evoked by tetanization of the basal dendritic CA1 afferents in freely behaving rats. (a) Slope of the basal dendritic fEPS, normalized by the average fEPSP slope before each AD, showed a long-lasting potentiation after an initial depression, when saline (SAL) was infused intracerebroventricularly (i.c.v.); the AD-induced potentiation in the same rat was blocked when NMDA-receptor antagonist APV (D,L-2-amino-5-phosphonovaleric acid) was infused i.c.v., in another experiment several days later. (b) APV, given i.c.v., did not block the increase in frequency of spontaneous interictal spikes (marked by inverted triangles) induced by a hippocampal AD. APV alone did not change the frequency of interictal spikes, unpublished figure from study of Leung (1994). (a) From Leung LS and Shen B (1993) Long-term potentiation in hippocampal CA1: Effects of afterdischarges, NMDA antagonists and anticonvulsants. *Experimental Neurology* 119: 206.

Synaptic plasticity may be altered after partial seizures. The magnitude of LTP in the hippocampus and amygdala is diminished in animals after amygdala kindling and in the human DG near the primary focus of temporal lobe epilepsy. The capacity for synaptic plasticity, or the plasticity of synaptic plasticity, is called 'metaplasticity.' A synapse may show altered synaptic plasticity (LTP or LTD) without manifesting a change in synaptic strength. Synaptic metaplasticity may depend on all the factors that affect synaptic plasticity, including NMDA receptors, Ca^{2+} channels, metabotropic glutamate receptors, inhibition, and kinase function (protein kinase C, protein kinase A or Ca^{2+}/calmodulin kinase). Since partial seizures cause massive pre- and postsynaptic activities that affect the signaling pathways for synaptic plasticity, the effects of partial seizures can be regarded as 'metaplasticity.' An important major rationale for studying the altered capacity for synaptic plasticity after partial seizures is that it may be a mechanism of postictal and interictal cognitive and behavioral deficits.

Methods

We studied changes in glutamatergic and GABAergic transmission after hippocampal kindling. Adult male rats were implanted chronically with indwelling electrodes for stimulation and recording. Electrophysiological criteria were used to guide the recording electrodes to straddle the CA1 or the DG cell layer. Stimulating electrodes were placed in the MPP, and in CA1 to stimulate the basal or apical dendritic afferents to CA1. Freely moving rats were recorded at least 4 days after surgery. Before and after each AD, fEPSPs were recorded in CA1 and the DG following single or paired-pulse stimulation of the MPP, or of the basal and apical dendritic afferents to CA1. ADs during kindling were evoked by high-frequency stimulation in CA1 at hourly intervals, 5 times a day. Results described here followed partial hippocampal kindling, using 10–15 ADs.

In a different approach, in vitro transverse hippocampal slices were prepared at various times (1 day to 6 weeks) after CA1 kindling. fEPSPs were recorded in CA1 and DG. A theta-frequency primed burst (PB) stimulation of CA1 stratum radiatum (SR) was used to induce LTP. One PB consisted of 2 priming pulses at 100 Hz

followed 170 ms later by a train of 8 pulses at 100 Hz; the PBs were repeated 8 times at 10-s intervals. In other experiments, the monosynaptic IPSC in CA1 was evoked in the presence of ionotropic glutamatergic antagonists, following paired-pulse stimulation of the local interneurons in SR (apical dendritic layer).

Hippocampal electrophysiology was also examined in urethane-anesthetized rats at various times after a SE induced by intracerebroventricular (i.c.v.) injection of kainic acid (KA) in adult male rats. Laminar profile of the field potentials in CA1 and DG was recorded simultaneously by a 16-channel silicon probe, or sequentially mapped by a micropipette at 50-μm depth intervals. Current source density was analyzed from the depth distribution of field potentials at one instant of time. A current sink is a macroscopic measure of net inward current, and current source is a measure of net outward current, in a fixed volume. In a cortical structure such as the hippocampus, the time course and location of dendritic excitation are revealed by current source density analysis.

Results

Kindling Results in Potentiation of Multisynaptic Pathways

Robust SIP of the basal dendritic responses occurred during partial hippocampal kindling. The basal dendritic fEPSP in CA1 was increased after the 1st AD, and appeared saturated after the 5th and 10th AD (**Figure 2**). No behavioral convulsion was evoked, but the AD duration increased with the number of ADs evoked, indicating the process of kindling. The MPP-to-DG synapse, which was activated trans-synaptically by commissural (CA3 axon) stimulation, showed a robust and long-lasting potentiation (SIP). SIP of the MPP–DG synapse was shown by the increase of the population spike (extracellular compound action potential) generated in the DG (PS1 and PS2 in **Figure 2(b)**). The increase in the DG population spikes and MPP-evoked multisynaptic response in CA1 (Sch1 and Sch2 in response to LMPP stimulation in **Figure 2(b)**) persisted at least 27 days after kindling. In contrast, SIP at the basal dendritic CA1 synapse typically lasted only ~5 days after kindling. SIP at the apical dendritic CA1 synapse (not shown) may be small but long lasting (>27 days after kindling). The cross temporo-ammonic response (RMPP-evoked responses in **Figure 2(b)**) was minimally altered during and after kindling.

In summary, hippocampal kindling induced SIP in a multisynaptic circuit, 'propagating' to several synapses beyond the directly activated synapse. The persistently potentiated MPP-to-DG synapse was at least two synapses away from the directly activated CA3-to-CA1 synapse (**Figure 2(a)**). During a hippocampal AD, the synchronous firing of principal cells likely recruits neurons several synapses away. The frequency of synchronous firing during an AD is typically 2–15 Hz, which is capable of inducing LTP or recruiting other neurons by frequency potentiation. A temporal lobe AD is known to increase metabolic activity in many areas of the brain, including the thalamus, substantia nigra, and nucleus accumbens.

Excitation, Inhibition, and LTP In Vitro after Kindling

When hippocampal slices from partially kindled rats were recorded in vitro, on one day or 3 weeks after kindling, there was no significant difference in the single-pulse-evoked fEPSP in CA1, CA3, and DG in vitro. However, paired-pulse facilitation of the fEPSP, and in particular of the population spike, was increased in CA1 and CA3, but decreased in the DG in kindled rats than in control rats.

When monosynaptic $GABA_A$-mediated IPSCs were recorded, paired-pulse depression (PPD) of the IPSCs was strong in control rats, but much smaller in kindled rats (**Figure 3(a)**). PPD of the IPSCs is mediated by $GABA_B$ receptors on GABAergic terminals (autoreceptors), and it is blocked by a $GABA_B$ receptor antagonist. This result suggested that kindled rats show a decrease in $GABA_B$ autoreceptor efficacy. The amplitude of the single-pulse IPSC was not significantly different between kindled and control rats, but the decay of the IPSC was faster in neurons from kindled rats than those from control rats (**Figure 3(a)**).

When LTP was induced by theta-frequency PBs in vitro, slices from partially kindled rats showed decreased LTP magnitudes as compared with control rats (**Figure 3(b)**). In the presence of a $GABA_B$ receptor blocker, PB-induced LTP was suppressed in both control and kindled rats. The decrease in efficacy of the $GABA_B$ autoreceptors was suggested to account for the smaller PB LTP in kindled rats than in control rats.

Palizvan *et al.* recently reported another change in LTP associated with kindling. They showed that the mechanism of nonprimed high-frequency LTP is different before and after kindling. LTP in CA1 is normally dependent on NMDA receptors, but it becomes increasingly dependent on voltage-dependent Ca^{2+} channels after pentylenetetrazol-induced kindling.

Multisynaptic Alterations of Entorhinal-Hippocampal Circuit after Kainic Acid SE

Similar to kindling (**Figure 2**), multisynaptic changes were found in the EC–hippocampus circuit (**Figure 4(a)**) in vivo after SE induced by KA. Synaptic excitation was assessed by mapping a depth profile of the field potentials in rats under urethane anesthesia, and current source density analysis was used to reveal the extracellular current sink (inward current) at particular layers of the hippocampus. Increase in single-pulse excitatory response was found for the MPP-to-DG synapse and for the monosynaptic

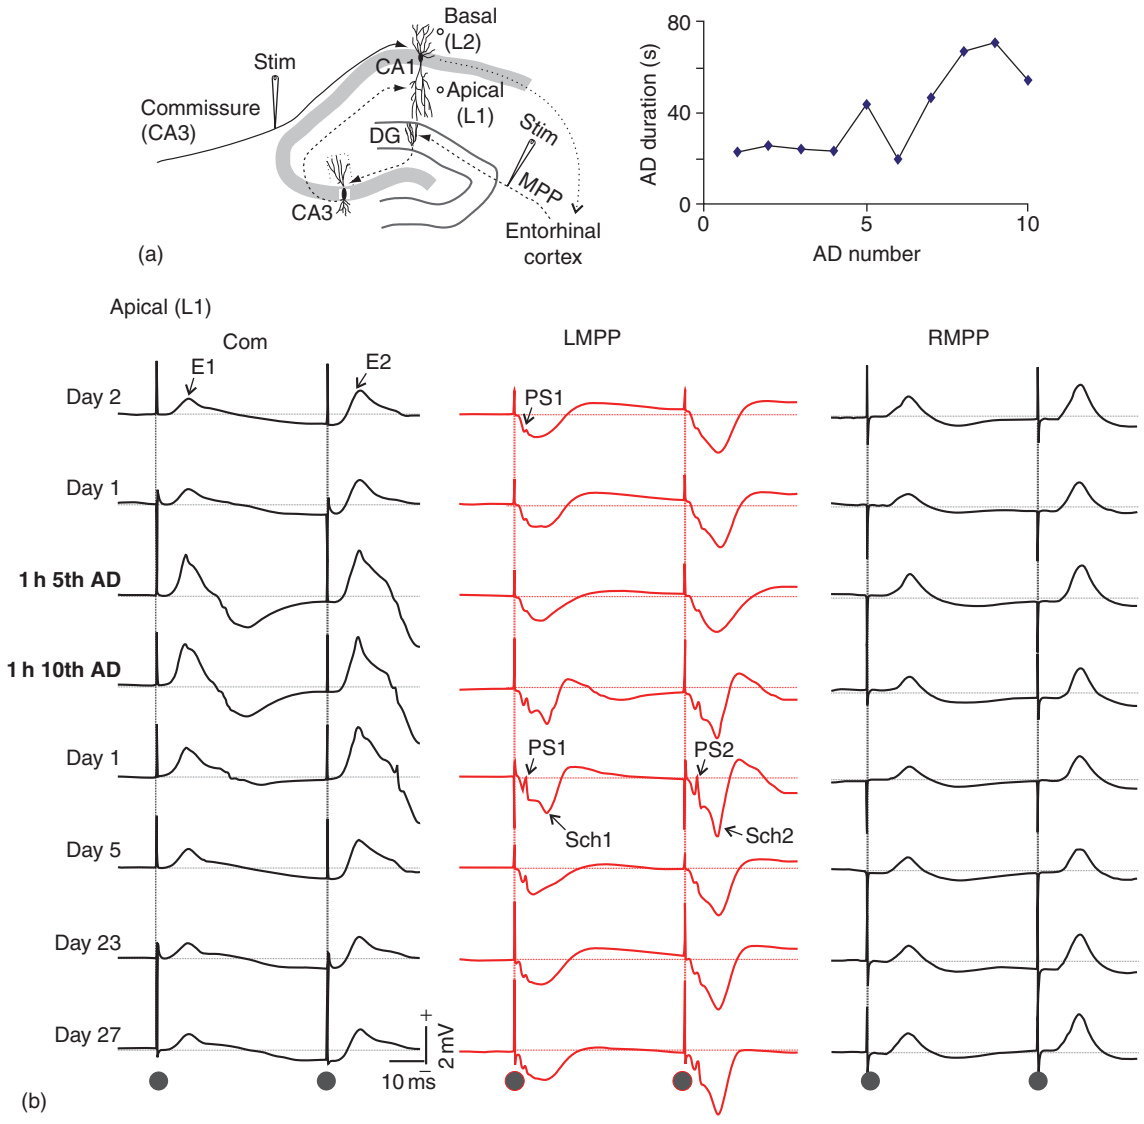

Figure 2 A schematic diagram showing stimulation and recording configuration, and increase in afterdischarge (AD) duration during partial kindling of the right CA1 in a representative rat. fEPSPs were recorded in left CA1 following paired-pulse stimulation of right CA1 (commissural), left and right medial perforant path (MPP) derived from the entorhinal cortex. L1 electrode shows a large increase of fEPSP in left CA1 during and within 5 days after kindling (10 ADs). Population spikes (PS1 and PS2 after 1st and 2nd pulse respectively) and polysynaptic CA1 responses (Sch2 after 2nd LMPP pulse) were enhanced until day 27 after kindling. Cross temporo-ammonic (RMPP) response was largely unchanged. Unpublished data from the study of Leung and Shen (2006).

excitation of MPP at the distal dendrites of CA1. However, single-pulse CA3-to-CA1 transmission was decreased in KA-treated rats than in control rats, likely because of CA3 cell death. In addition, mossy-fiber excitation of the inner molecular layer of the DG in vivo was decreased in KA-treated rats than in control rats, possibly due to increased inhibition in the DG (despite mossy-fiber sprouting).

Robust changes were found for paired-pulse responses in KA-treated rats than in control rats, in both the DG and CA1. Inhibition was measured by the population spike response to paired-pulse stimulation. The population spikes evoked by the 1st and 2nd stimuli of MPP were measured as PS1 and PS2, respectively (**Figure 4(b)**); the PS2/PS1 ratio at 30–100-ms interpulse interval was significantly smaller in KA-treated rats than in control rats. Interestingly, a small i.c.v. dose of $GABA_A$ receptor antagonist bicuculline also *decreased* the PS2/PS1 ratio in control rats (**Figure 4(c)** top trace). The same bicuculline dose given to KA-treated rats induced spike bursts in the DG after MPP or CA3 stimulation (**Figure 4(c)**). Thus, the enhanced inhibition in the DG was 'fragile,' and this fragility may be associated with the alteration of $GABA_A$ receptors after SE.

Paired-pulse inhibition in CA1 was decreased after KA treatment. This change is shown by the increased PS2/PS1 ratio in KA-treated rats than in control rats (**Figure 4(b)**). In addition, an extracellular (population) backpropagating

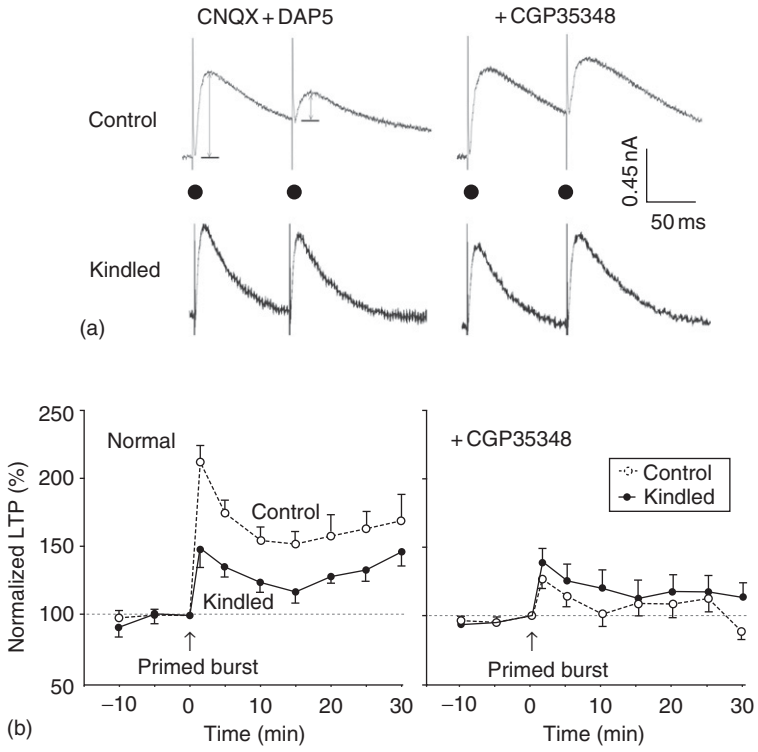

Figure 3 In vitro hippocampal slice recorded one day after partial hippocampal kindling (15 ADs). (a) Monosynaptic IPSCs recorded in CA1 pyramidal cells following paired-pulse local stimulation in the presence of ionotropic glutamate antagonists, without (left) and with (right panel) addition of a $GABA_B$ receptor antagonist CGP35348 (1 mM). A decrease in $GABA_B$ autoreceptor function in the kindled rat was indicated by the decreased paired-pulse depression of the IPSCs. Adapted from Wu C and Leung LS (1997) Partial hippocampal kindling decreases efficacy of presynaptic $GABA_B$ autoreceptors in CA1. *Journal of Neuroscience* 17: 9261–9269. (b) Apical dendritic fEPSPs recorded at the apical dendrites of CA1 showed LTP after theta-frequency primed bursts. LTP was larger in control slices than in kindled slices, but no difference was found when LTP was induced in the presence of CGP35348. Data from Leung LS and Wu C (2003) Kindling suppresses primed-burst-induced long-term potentiation in hippocampal CA1. *Neuroreport* 14: 211–214.

dendritic spike was shown to invade the distal dendrites of CA1 pyramidal cells in KA-treated rats but not in control rats, likely because of a loss of distal dendritic inhibition. In control rats, the CA3-evoked population spike in CA1 propagated to the middle part of SR, similar to the first-pulse evoked spike (* in **Figure 4(d)**). After KA treatment, the population spike evoked by the second-pulse invaded further into the distal dendrites (** in **Figure 4(d)**), and a 'late' spike started from the distal dendritic layers of CA1. The late spike was activated by polysynaptic excitation – CA3 excited the EC that excited CA1. A backpropagating distal dendritic spike in CA1 in SE rats has also been reported in vitro.

Seizure-Induced Potentiation and Behavioral Changes

SIP may change the synaptic strengths of behaviorally related circuits, via trans-synaptic mechanisms, and these synaptic changes may cause postictal and chronic behavioral changes (**Table 1**). One example is that kindling of the hippocampus induces schizophrenia-like behavioral changes, such as hyperactivity, loss of sensorimotor gating, and abnormalities in social interactions. These changes may in part be mediated by the hippocampal projection to the nucleus accumbers and ventral tegmental area. Affective defensive behaviors in cats were attributed to potentiation of excitatory transmission from the amygdala to ventromedial hypothalamus/periaqueductal gray after partial amygdala kindling. Partial hippocampal kindling (repeated ADs) in CA1 induces a deficit in retention of a spatial task, and the duration of retention deficit correlates with the duration of altered synaptic transmission in the hippocampus.

Future Goals

Understanding of the mechanisms of SIP is incomplete. Mechanisms of LTP are unlikely to account for all aspects of SIP. Since seizure or repeated seizures is capable of altering cellular biochemistry and molecular biology of neurons and glialcells in ways beyond LTP, it is expected that SIP will involve multiple receptors and signaling pathways, but these signaling pathways remain to be studied in detail.

Some comparisons between seizure (kindling) and LTP may be inappropriate, because a seizure (and

epileptogenesis) requires many synapses while LTP studies are typically restricted to single synapse. Thus, the absence or blockade of LTP or SIP at a single synapse does not exclude the participation of LTP or SIP at other synapses in distributed and multisynaptic neural circuits. In addition, involvement of NMDA receptor-independent LTP in kindling and epileptogenesis has not been thoroughly tested.

Short-term neural plasticity that lasts several milliseconds or minutes after stimulation may help to augment and propagate neural activity, including epileptiform activity, across synapses. The causes and effects of short-term potentiation after seizures have not been fully addressed. The results reviewed in this article indicate that paired-pulse excitatory and inhibitory responses are changed after kindling and SE, and these changes may increase frequency potentiation during normal and abnormal activity, and perhaps increase seizure susceptibility. Conversely, short-term and LTD may have therapeutic significance since they may suppress seizure generation and propagation, but investigations of how these processes may affect seizure generation are preliminary.

Seizure-induced alteration in synaptic metaplasticity may contribute to cognitive and behavioral deficits, since hippocampal LTP may be a mechanism of spatial navigation and declarative memory. The mechanisms of metaplasticity remain to be studied, and so far, the relation between LTP and behavioral deficits after seizures is tentative and purely correlational. The ability of partial seizures to alter excitatory and inhibitory synapses in multisynaptic circuits suggests that neural network changes may underlie the behavioral deficits and seizure susceptibility that are characteristic of partial epilepsy.

Synaptic Reorganization in the Hippocampal Dentate Gyrus

Introduction

The hippocampus is one of the most plastic neural structures, and that plasticity is thought to be particularly important in epileptogenic processes. A major subject of analysis with respect to hippocampal plasticity is the sprouting of dentate granule cell axon collaterals, primarily to the region of their own dendrites within the dentate gyrus (DG) – the mossy fiber sprouting (MFS) that occurs in both human mesial temporal lobe sclerosis and in

several animal models of temporal lobe epilepsy. It has been proposed that MFS, both in humans and experimental animals, could be responsible for epileptogenesis in temporal lobe epilepsy. The aberrant reorganization of the dentate mossy fiber system has been touted as one of the leading bases for hyperexcitability that underlies hippocampal seizures. It is becoming clear, however, that MFS is only one side of a more involved tale. Regardless of its relevance to epilepsy, the robustness of MFS as a plastic phenomena allows us to investigate issues that might be relevant to synaptic reorganization in general, whether adaptive or not.

Background

In a significant number of patients with temporal lobe epilepsy, several types of studies (imaging, electrophysiological, and psychological) suggest a seizure focus in the hippocampus (in at least one side of the brain). Diagnosis of this localization often leads to surgery, and adequate removal of the structures underlying the irritative focus can cure the epileptic condition. This apparently direct cause-and-effect relationship indicates the need for the investigation of the features present in the resected brain structures that underlie the epilepsy. Early pathologists, studying tissue from autopsies, described a hardening of the mesial portions of the temporal lobe and coined the term 'mesial temporal sclerosis.' The medial temporal lobe consists of the hippocampal region (CA fields, DG, and subicular complex) and the adjacent perirhinal, entorhinal, and parahippocampal cortices. Analysis of this brain area in patients with epilepsy and in animal models of epilepsy, often reveals marked atrophy and cell loss. More importantly, in the late 1980s and early 1990s, several authors described an impressive synaptic plasticity in this region, the MFS.

Connectivity

Mossy fibers are the axons of dentate granule cells in the hippocampal region. In the normal hippocampus, these axons of granule cells elongate within the dentate hilus and stratum lucidum, and innervate hilar cells and CA3 pyramidal cells. In temporal lobe epilepsy, however, mossy fibers 'sprout' out of the dentate hilus, and cross the granular cell layer into the inner molecular layer. These sprouting axon collaterals form new – aberrant – synaptic connections with the dendrites of granule cells in the inner third of the molecular layer or with other cellular elements in the dendritic fields of CA2 and CA1. As a result, some of the granule cells become monosynaptically interconnected. Mossy fibers not only sprout into the molecular layer just above the granular layer (giving rise to supragranular MFS) but also within the CA3 stratum oriens region and into CA2 and CA1, giving rise to MFS onto pyramidal cells. The best studied of these phenomena, in terms of a potential epileptogenic mechanism, is the supragranular MFS.

The organized laminar nature of the inputs that contact normal dentate granule cell dendrites is maintained in the epileptic tissue. Consistent with this generality, mossy fibers sprouted to the DG have a projection field that is restricted to the inner molecular layer. The factors underlying the selectivity of this aberrant projection have been one of the subjects of interest in our laboratory.

Functional Relevance

Investigators first demonstrated that in slices from control rats, antidromic stimulation of the mossy fibers elicited a single population spike in the granular layer of the fascia dentata. They then showed that, in contrast, when slices from kainic acid-treated epileptic rats were similarly tested, antidromic stimulation elicited multiple population spikes. The study showed that abnormal responses to antidromic stimulation correlated with the loss of CA4 (i.e., hilar) neurons and the growth of supragranular mossy fiber collaterals in the same animals. The authors suggested that aberrant supragranular mossy fiber collaterals form a functional recurrent excitatory circuit that could facilitate seizure activity. Futher, loss of hilar neurons was seen as a key, indissociable element of supragranular MFS.

Failed Attempts to Block MFS

Given its position as a likely culprit in temporal lobe epilepsy, a number of experimental strategies were devised to suppress or modulate supragranular MFS, and thus directly assess the role of sprouting in epileptogenesis. Infusion of antibodies against NGF in animals subjected to kainate- or pilocarpine-induced status epilepticus (SE), while effective in modulating the sprouting of cholinergic fibers to the DG inner molecular layer, failed to influence supragranular MFS. In a subsequent series of experiments using knockout mice or the intracerebral infusion of neurotrophic factors, the contribution of tyrosine kinase B (trkB), trkA, and trkC receptors, c-Fos, neurotrophin 3 (NT3), and brain derived neurotrophic factor (BDNF) for MFS were evaluated by several groups. While all of these neurotrophins were found to be relevant (i.e., able to either impair or promote MFS in animal models of epilepsy), none of those experiments was able to completely abolish MFS.

An important source of evidence for the link between supragranular MFS and epilepsy was observed (drawn from both kainate and pilocarpine models) that the more intense the SE and more widespread the cell loss, the greater was the ensuing supragranular MFS and greater the likelihood of spontaneous recurring seizures. In some

of these studies, the authors reported a lack of supragranular MFS; however, this observation should be viewed with caution given that in those experiments the investigators suppressed or greatly attenuated the lesional event (e.g., SE). As expected, animals of a nonepileptic background that do not undergo sufficient hyperexcitability (i.e., SE) and related hilar cell death, will not develop any of the plastic changes associated with epilepsy.

Methods

When we initiated our studies, some of the evidence mentioned earlier was already available. We, as most authors in the field, hypothesized that effective blockade of supragranular MFS would be associated with a substantial reduction in hyperexcitability, and possibly in attenuation or suppression of the subsequent development of spontaneous seizures. To increase the effectiveness of such a blockade, we considered the use of a protein synthesis inhibitor in close association with the induction of SE. Given the profound changes likely to be associated with such a treatment (i.e., in terms of the activation of both transcription and translation), we opted for a broadly acting agent to achieve our goals. We chose cycloheximide. To eliminate the possibility that the obtained results were due to some effects of cycloheximide other than to its well-established actions on transcription and translation, we also tested anisomycin, an antibiotic that is a potent inhibitor of protein synthesis.

The choice of animal model was also based on the already available evidence. The pilocarpine model of SE had the advantage of inducing the most robust supragranular MFS, as well as providing a high frequency of later spontaneous seizures. Disadvantages of the model included the fact that seizures could arise form several different sources, especially given the systemic nature of the administration of pilocarpine and the associated widespread brain damage. To address this problem, we also tested the effects of cycloheximide in the small dose intrahippocampal model of kainic acid. Finally to further broaden the scope of the findings with cycloheximide, we evaluated its ability to affect supragranular MFS in mice subjected to pilocarpine-induced SE.

The main resource used in the evaluation of the effects of cycloheximide and anisomycin (in both pilocarpine- or kainate-induced SE animals) was a histological technique to evaluate the presence of mossy fibers. Timm staining detects the high content of zinc in the mossy fiber terminals, yielding a high contrast picture of the mossy fiber axons and terminals, and thus a reliable way to detect changes in this axonal system. In all of our studies, we used smaller concentration of sodium sulfide (0.1% as opposed to the usual 1%) than typically employed, thus providing a greater specificity for the detection of mossy fibers. Given that Timm staining requires a 'development' process analogous to that used in film photography, the intensity of staining and thus sensitivity of the method can be adjusted as desired. Additional techniques used in our study included observation of behavioral spontaneous seizures, standard behavioral tests of cognitive and emotional function, electroencephalographic (EEG) recordings for the assessment of SE and for the detection of spontaneous seizures, slice electrophysiology for the functional evaluation of the reorganized dentate circuitry, staining for injured cells, evaluation of the mitotic rate of dentate granule cells, and immunohistochemical approaches for the detection of specific neuronal populations.

Results

We initially demonstrated that administration of cycloheximide, in close proximity to the induction of pilocarpine SE, blocked supragranular MFS in rats – but did not prevent the subsequent development of spontaneous seizures or affect their frequency. Those results provided, for the first time, direct evidence against a causal role for supragranular MFS in temporal lobe epileptogenesis. One possible explanation for this dissociation is that seizure generation in the pilocarpine and kainate models of epilepsy could be driven by extrahippocampal sources. Indeed, the relative contributions of thalamus, amygdala, and piriform cortex in the initiation of spontaneous seizures in these models have been indicated in a number of studies.

To address this issue, we next used the small dose intrahippocampal application of kainic acid. Here again, cycloheximide was able to completely block supragranular MFS in most animals, without altering the frequency and intensity of spontaneous ictal and interictal EEG events. We concluded that also in the intrahippocampal small dose kainate model, where spontaneous seizures were more likely to initiate in the injected hippocampus, supragranular MFS is not necessary for the occurrence of ictal events.

Given that most of our analysis in the initial experiments evaluated animals 2 months after the initial precipitating injury, we then sought to investigate how supragranular MFS would be affected by the spontaneous seizures. Some publications on this subject have shown that animals with more frequent seizures have a more intense supragranular MFS, thus suggesting that this form of synaptic reorganization is somehow associated with a greater propensity to seize (even if it does not determine whether or not seizures emerge). Other investigators have argued that the density of supragranular MFS is not associated with the total number of lifetime seizures or the seizure frequency (in experimental or human temporal lobe epilepsy), and many authors no

longer consider MFS as a necessary or sufficient event in temporal lobe epilepsy. However, in the human condition we have no control on the background status of the tissue. And in most experimental studies, SE was required for the emergence of seizures – where there is no question that supragranular MFS is largely the reflection of a preceding SE episode. By producing an experimental condition in which no supragranular MFS was derived from the initial SE episode, we were able to investigate the relative contribution of subsequent spontaneous seizures to this synaptic reorganization. We concluded that supragranular MFS did not show any association with the frequency of spontaneous seizures, and seemed to depend more critically on time after the initial injury. Indeed, under this condition, supragranular MFS eventually developed in all animals, even though at a much slower pace; further, it did not seem to be more robust in animals with greater frequency of recurrent spontaneous seizures.

The description of granule cell dispersion in human tissue from patients with temporal lobe epilepsy gave rise to the suggestion that developmental changes could be at the base of the subsequent epilepsy in those patients. The demonstration, first in the pilocarpine rat model and later in kainate-treated mice, that adult rodents could develop granule cell dispersion indicated that these cytoarchitetonic changes could also be the consequence of the initial precipitating episode of SE. The subsequent demonstration that neurogenesis of dentate granule cells was increased after SE introduced an additional possibility – that hippocampal network plasticity associated with epileptogenesis could arise from aberrant connections formed by newly born dentate granule cells. We, therefore, investigated whether cycloheximide would affect the onset of supragranular MFS by means of blocking granule cell neurogenesis. Much to our surprise, we observed that cell proliferation in the DG is dramatically increased in epileptic animals treated with cycloheximide. Induction of SE in animals injected with pilocarpine alone led to 2–7-fold increases in the mitotic rate of dentate granule cells, as compared to 5–30-fold increases for pilocarpine/cycloheximide-treated animals. We suggested that such increased mitotic rates were associated with a protection by cycloheximide of a vulnerable precursor cell population that would otherwise degenerate after pilocarpine-induced SE. We further suggested that MFS and neurogenesis of granule cells are not necessarily linked to one another. This dissociation is consistent with the finding that irradiation of animals subjected to pilocarpine-induced SE essentially abolished dentate granule cell neurogenesis, but failed to prevent mossy fiber reorganization in the dentate molecular layer.

Whole cell patch-clamp recordings in hippocampal slices had shown that the amplitude and frequency of spontaneous excitatory postsynaptic currents in granule cells increased with time after kainate treatment. This increased excitatory synaptic input was correlated with the intensity of the Timm stain in the inner molecular layer. When inhibition was reduced with bicuculline in slices from kainate-treated animals, flash photolysis of caged glutamate applied in the granule cell layer evoked epileptiform bursts of action potentials (an effect not seen in granule cells from control rats). These data supported the hypothesis that kainate-induced supragranular MFS results in the progressive formation of aberrant excitatory connections between granule cells. To evaluate the changes in the electrophysiological profile that would result from cycloheximide treatment, in vitro electrophysiology (extracellular recordings) was performed 2 months after pilocarpine-induced SE. Evoked potentials in slices from pilocarpine- and pilocarpine/cycloheximide-treated rats displayed small-amplitude polyspiking activity (epileptiform responses) in CA1 and an apparently normal isolated population spike in DG. More importantly, the DG in slices from pilocarpine and pilocarpine/cycloheximide animals did not differ with respect to electrophysiologic abnormalities, even under high K^+ or high K^+/bicuculline. Analysis of the neo-Timm staining, as expected, revealed strong supragranular MFS in pilocarpine-injected rats and significantly less staining in pilocarpine/cycloheximide rats. Thus, occurrence of abnormal stimulus responses, and high K^+- or high K^+/bicuculline-induced epileptiform activities, did not depend on the degree of supragranular MFS.

One long standing question regarding the development of MFS in animal models of SE is whether sprouted mossy fibers would add new synapses to the dendrites in the molecular layer – or whether these sprouting fibers simply substituted for vacated synapses (due to hilar cell degeneration). Indeed most studies on the subject suggested the loss of hilar mossy cells, normally a major hilar target of granule cell mossy fibers, as an important factor in initiating supragranular MFS. Pilocarpine-induced SE in the presence of cycloheximide resulted in a reduced number of injured hilar cells compared to rats not pretreated with cycloheximide. Presumed mossy cells, identified by calcitonin gene related peptide (CGRP) immunohistochemistry, were not significantly reduced in either groups 60 days after SE (given the seeming inconsistency of this finding with a preponderance of evidence indicating a loss of mossy cells SE, we assume that CGRP might constitute a marker of a sub-population of mossy cells.). Whereas controls had a strong band of CGRP-positive fibers (putative mossy cell axons) and no neo-Timm stained fibers in the inner molecular layer, pilocarpine-treated rats had no CGRP fibers and strong neo-Timm staining. Cycloheximide–pilocarpine-treated animals, in contrast, had CGRP and neo-Timm staining similar to controls. We concluded that cycloheximide could protect hilar CGRP-positive cells during SE; by allowing those cells to retain their normal axonal projection, MFS was prevented – a scenario consistent with the 'irritable' mossy cell

hypothesis that relies on the survival of mossy cells for network hyperexcitability. We suggested that cycloheximide prevents SE-induced supragranular MFS by preventing the loss of hilar CGRP-positive cells (putative mossy cells).

The fact that cycloheximide protected hilar cells and further increased cell proliferation in the DG after SE created the setting for a hypothesis that integrates current observations. Investigators have shown that some newly born granule cells develop in abnormal locations within the hilus. These ectopic granule cells demonstrate regular bursts of action potentials that are synchronized with CA3 pyramidal cell burst discharges and the bursts of hilar neurons (including mossy cells). In addition to the formation of ectopic hilar granule cells, several articles characterized the formation of hilar basal dendrites on granule cells in epileptic animals. Both features certainly allow for aberrant synapses in the hilus, either by ectopic or irritable cells or in aberrant basal dendrites, which may account for changes in hyperexcitability – regardless of the presence of supragranular MFS.

Future Directions

We have not yet examined whether cycloheximide affects the development of ectopic dentate granule cells. Such an investigation should include not only the histological characterization of these cells, but also a description of their electrophysiological properties. It is also important to evaluate whether cycloheximide affects the formation of aberrant basal dendrites on granule cells.

Still unresolved are the specific aspects of synaptic reorganization that underlie the epileptogenic process. The global changes that ensue after SE – and our ability to block specific aspects of these changes – will remain a hot topic of investigation. The current emphasis on trkB receptors has, to date, not yet yielded any major insights, but it is clear that neurotrophic factors and their receptors will remain major targets of research in this area.

Detailed investigation of synaptic changes associated with seizure-like plasticity is likely to require the use of organotypic cell culture in addition to studies in intact animals. Some of the differences between rodents and primates, in terms of neuronal connectivity or neuronal response to injury, may require studies in nonhuman primates. Also, greater attention should be devoted to exploring seizure-related plasticity in other portions of the hippocampal region such as the pyramidal CA1 and entorhinal cortex, and thalamus. Finally, research using computational models of the reorganized circuits and ionic channels is also likely to provide important information.

Regardless of its importance to epileptic (or epileptogenic) processes, supragranular MFS will remain an important topic of research, especially given the enormous amount of information that has already been generated and the wealth of knowledge now available about hippocampal connectivity. Rather than being a maladaptive change, this form of 'aberrant' synaptic plasticity may reflect a critical step in the ongoing process of recovery from injury in damaged tissue.

Introduction

The Center for Disease Control (CDC) has estimated that each year 1.5 million people suffer a traumatic brain injury (TBI) in the United States, resulting in almost 100 000 patients per year with long-term disabilities and annual costs to the economy of over $50 billion. TBI and its sequelae have been referred to as an 'invisible epidemic' in which patients suffer devastating life-long cognitive, sensory, emotional, and motor deficits.

Head trauma and brain injury are important factors in epilepsy etiology, contributing about 4% of newly diagnosed cases in the United States. However, the underlying mechanisms remain unknown. The percentage of all victims of a serious head injury that go on to develop posttraumatic epilepsy (PTE) has been estimated at 10–34%, depending on the severity of the injury. One of the strongest predictors of the likelihood of PTE is a penetration of the dura. A unique characteristic of PTE is the variable delay, or latent period, between the trauma itself and the development of seizures – a delay which can last from weeks to years. This latent period is of considerable biological interest. What slow processes are triggered during injury that do not cause seizures until much later? The latent period provides a unique therapeutic opportunity. If we knew what was happening during the latent period, then therapies might be designed that stop this process and prevent a patient at risk from ever becoming epileptic.

The consequences of TBI are as diverse as its causes. Acute aspects of TBI include loss of blood, hemorrhaging, thrombosis, infection, inflammation, intracranial hypertension, and edema. Although these acute complications can often be managed with timely clinical care, long-term consequences, such as PTE, frequently leave TBI victims disabled. To devise effective therapeutic strategies for minimizing the long-term adverse consequences of TBI, we should understand their biological basis.

Background

Fundamental Elements of TBI

Which features of TBI need to be modeled to understand the genesis of PTE? Multiple processes undoubtedly act together to alter the normal balance of synaptic excitation and inhibition and render the brain incapable of functioning normally after injury. Given the overwhelming complexity of the injured brain, it is helpful to consider separately several of the fundamental consequences of lesions that are common to many forms of TBI and are likely to

internal lysyl residues. The reagents are isobaric, with a different distribution of isotopes between a reporter and a balance group. Thus, the labeled peptides obtained after modification are identical in MS mode. Upon fragmentation in MS/MS mode, the labeled peptides produce strong, diagnostic, low-mass MS/MS signature ions. Relative areas of these reporter peaks indicate the contribution of each sample to total peptide present, allowing for quantification of up to eight different samples simultaneously. MALDI–TOF/MS (matrix-assisted laser desorbtion ionization–time of flight–mass spectrometry) analysis gives low femtomole to high attomole sensitivity in both MS and MS/MS modes. It should be noted that the iTRAQ approach has been used to demonstrate relatively modest increases in phosphorylation state of CaM kinase II on depolarization of purified rat brain synaptosomes. This demonstration clearly shows the power of the iTRAQ approach in kindling, especially for detecting potential alterations in depolarization dependent protein modifications.

As a final comment, it must be noted that it is essential to confirm any putative kindling-related changes seen with proteomic analyses by traditional quantification methods such as quantitative immunoblotting. We have used this approach quite successfully to study specific members of the secretory protein family. The ultimate goal of these types of studies is to identify changes in the levels of protein at the synapse, reflected by corresponding changes in gene expression, that dictate the state of elevated neuronal activity leading to seizure activity. It is hoped that determining these changes, and the nature of the molecular events and signaling pathways responsible for them, will provide new targets for therapeutic intervention to treat even the most persistent and pernicious seizure conditions in humans.

The Role of Calcium in Mediating Neuronal Plasticity in Epileptogenesis

Introduction

Acquired epilepsy (AE), the development of spontaneous, recurrent seizures following a neurological insult, constitutes approximately half of all cases of epilepsy. The majority of cases of AE are produced by one of the three injuries to the brain: status epilepticus (SE), stroke, and traumatic brain injury (TBI). Although the precipitating events causing these injuries are distinct from one another, it has been shown that each can lead to the development of AE. This process wherein healthy brain tissue is transformed into a hyperexcitable network of

neurons manifesting spontaneous recurrent epileptiform discharges (SREDs) is called epileptogenesis. Identification of common molecular pathways that lead to development of AE following neuronal injury would lend insight into the pathophysiology of epileptogenesis and provide novel molecular targets that would aid in the development of newer approaches to prevent epilepsy.

Background

Calcium (Ca^{2+}) is not only a divalent charge carrier but is also an important second messenger. Intracellular calcium concentration ($[Ca^{2+}]_i$) is normally maintained at approximately 100 nM by a complex network of intracellular Ca^{2+} regulators and Ca^{2+} efflux pathways. This concentration is significantly lower than the 1–2-mM concentration observed in the extracellular space. This concentration gradient between extracellular and intracellular spaces provides a potent driving force for Ca^{2+} entry into the cell; further, since the intracellular concentration in normally so low, even minute changes in intracellular Ca^{2+} concentration provide a sufficiently large change to trigger downstream signaling. Brief elevations in $[Ca^{2+}]_i$ (**Figure 1**, top arrow) are required for transmitter release at synapses and for gene expression, and represent the normal physiological stimuli that occur for the maintenance of the basic neuronal functions. These transient elevations in $[Ca^{2+}]_i$ are also necessary for the cellular correlates (e.g., long-term potentiation, LTP) of higher brain functions such as learning and memory consolidation.

Elevated $[Ca^{2+}]_i$ and altered Ca^{2+} homeostatic mechanisms have been demonstrated following severe brain injuries such as SE, stroke, and TBI. The severity of injury and the resulting Ca^{2+} influx dictate the fate of neurons (**Figure 1**); this Ca^{2+} influx and injury are mediated largely by elevations in the excitatory neurotransmitter, glutamate. Under normal conditions, glutamate is highly regulated, with extracellular concentrations measured between 1 and 5 μM. The excess glutamate, a hallmark of SE, stroke, and TBI, causes the overstimulation of glutamate receptors, including the *N*-methyl-D-aspartate receptor (NMDA-R) that is coupled to a Ca^{2+} permeable channel (**Figure 2**). Hence, increased levels of glutamate can lead to the excess movement of Ca^{2+} across the cell membrane into the cell. While glutamate acts at several receptors, it appears that the NMDA receptor contributes most significantly to the neuronal pathology and Ca^{2+} changes observed post-injury, confirmed by the ability of NMDA antagonists to decrease the volume of ischemic infarct in whole animal models and offer neuroprotection in cell culture models of excitotoxicity.

Together, the degree of glutamate-stimulation and the subsequent Ca^{2+} influx contribute to the level of injury sustained by the neurons. Severely injured cells exhibit an irreversible Ca^{2+} overload that leads to cell death (**Figure 1**, bottom arrow). In all of the major injuries associated with AE, cell death is often an associated manifestation in the epileptic brain. Since dead neurons do not seize, it is the surviving neurons that contribute to the development of the epileptic phenotype. The surviving neurons – presumably those that are less severely injured – sustain reversible elevations in $[Ca^{2+}]_i$ that are maintained over days or weeks by altered homeostatic mechanisms. These increases mediate changes in synaptic plasticity, gene expression, and neuronal function (**Figure 1**, middle arrow). These neurons become the substrate for epileptogenesis, and also the target for future therapies to prevent AE. The ability to target these intracellular changes and reduce the intracellular Ca^{2+} load may prevent the development of the epileptic phenotype following SE, stroke, and TBI.

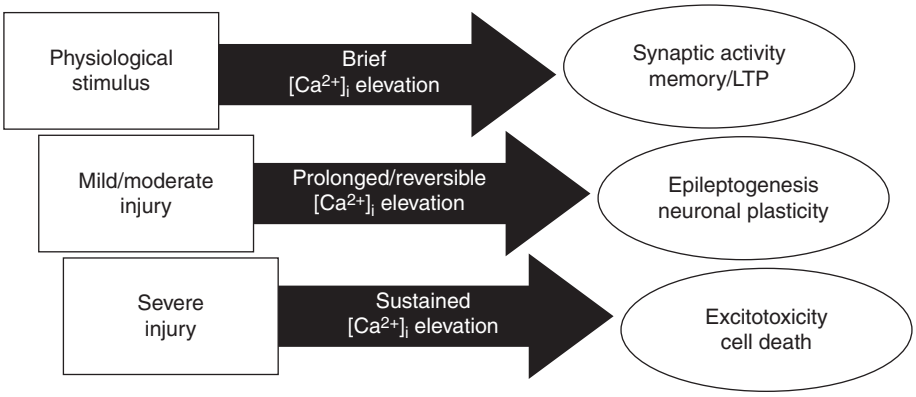

Figure 1 Effect of elevated $[Ca^{2+}]_i$ on neurons. Normal stimuli cause transient elevations in $[Ca^{2+}]_i$ that control synaptic activity and are responsible for learning and memory (top arrow). Mild to moderate injuries may cause prolonged elevations in $[Ca^{2+}]_i$ that are ultimately reversible (middle arrow). Such elevations are not substantial enough to initiate cell death but are able to cause plasticity changes in neurons, leading to epileptogenesis. Finally, severe injury causes sustained, massive increases in $[Ca^{2+}]_i$ that lead to cell death (bottom arrow).

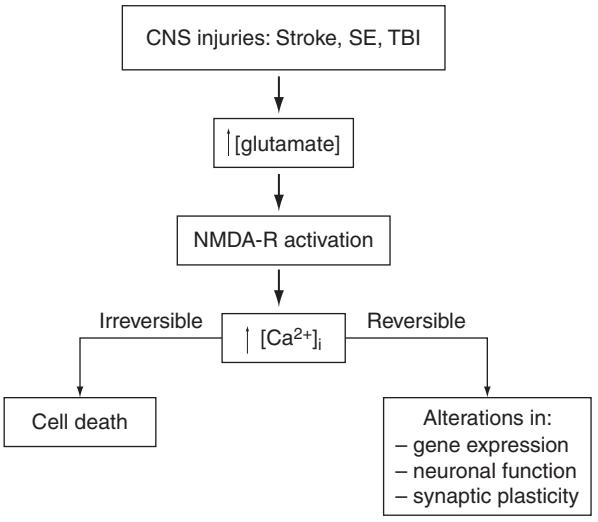

Figure 2 SE, stroke, and TBI cause death or plasticity changes in neurons. CNS injuries such as stroke, SE, and TBI can lead to one of two fates for affected neurons. First, all injuries cause increases in glutamate concentration, which cause the over-stimulation of glutamatergic receptors, including NMDA receptors (NMDA-R). The activation of these receptors trigger an influx of Ca^{2+} across the cell membrane and cause a Ca^{2+} overload. This elevation in $[Ca^{2+}]_i$ can be irreversible and overwhelm cellular processes, resulting in cell death. In contrast, neurons that are less severely injured exhibit a sustained but reversible increase in $[Ca^{2+}]_i$ that leads to alterations in gene expression, neuronal function, and synaptic plasticity through second messenger systems.

Methods

We have utilized several different in vivo and in vitro models to study AE and to characterize Ca^{2+} changes in SE-induced AE. For in vitro studies, hippocampal neurons are treated with a solution containing no added Mg^{2+} (low-Mg^{2+}) for 3 h during which time cells exhibit high frequency spiking analogous to SE. Following the return of Mg^{2+} to the solution (physiological basal recorded solution, pBRS), the networked neurons continue to exhibit synchronous spontaneous recurrent epileptiform discharges (SREDs) for their life in culture. For studies in the intact brain, we use the pilocarpine model. Injection of the cholinergic agonist pilocarpine induces SE in rats and following a latent period, these animals develop recurrent seizures.

To study stroke-induced AE in an in vitro setting, we developed a model in which subexcitotoxic concentrations of glutamate were added to neuronal cultures. This concentration was maintained on the cells for 30–45 min and induced transient depolarizations of the membrane potential and increases in $[Ca^{2+}]_i$, consistent with what is observed in the ischemic penumbra of in vivo models of stroke. SREDs were observed in the surviving neurons 24 h following this treatment. For the in vivo studies, the middle cerebral artery occlusion model was used. We also employed the decapitation ischemia model wherein ischemia was produced in vivo and Ca^{2+} imaging and electrophysiological experiments were then performed on acutely dissociated hippocampal neurons from the ischemia-injured brain slices.

Our in vivo rat model for TBI utilizes a central or lateral fluid percussion injury that leads to hyperexcitability of the hippocampal dentate gyrus and spontaneous recurrent seizures. For in vitro studies of TBI, neurons are cultured on a flexible silastic membrane substrate; cells are mechanically injured by stretching the membrane in a controlled manner. The majority of work using in vitro model has been performed at acute time points; therefore, it remains to be determined whether these models accurately mimic chronic hyperexcitability and epileptiform activity.

Following experimental stroke, SE, or TBI, animals are monitored for the development of AE using video/EEG to detect behavioral and electrographic seizures. Electrodes are implanted following recovery from injury and animals are subjected to a minimum of 4 days of monitoring (at various time points post-injury) to determine the development of epilepsy.

In the whole animal, after determining whether an animal has developed chronic epilepsy, Ca^{2+} dynamics are evaluated in vitro. We acutely isolate neurons by triturating hippocampal slices from the animals of interest, and plate them on poly-L-lysine and Cell-Tak® coated glass bottom chambers for Ca^{2+} imaging or on 35-mm dishes for electrophysiology.

Changes in $[Ca^{2+}]_i$ are evaluated using fluorescent calcium indicators – Fura-2, Fura-ff, and Indo-1. Ratio images are acquired using alternating excitation wavelengths and are corrected for background. Data analyses are performed using standard methods and procedures.

Results

The results of our studies reflect the changes in $[Ca^{2+}]_i$ levels and alterations in Ca^{2+} homeostatic mechanisms, observed acutely and at different times following SE, stroke, or TBI. $[Ca^{2+}]_i$ was assessed at several time points – during injury, during epileptogenesis (i.e., in 'latent' periods), and finally during the chronic phase of AE. Following the injury, neurons were also evaluated for their ability to restore Ca^{2+} homeostasis following a brief excitatory stimulation with glutamate, as altered homeostatic mechanisms may account for dysregulated $[Ca^{2+}]_i$.

In vitro SE Causes Increased $[Ca^{2+}]_i$

To model SE in an in vitro system, cultured hippocampal neurons were treated with low-Mg^{2+} solution for 3 h.

Whole-cell current clamp techniques revealed that the low-Mg^{2+}-treated cells displayed high frequency spiking that exceeded 3 Hz. Clinical SE is characterized by spike frequencies greater than 3 Hz on an EEG; thus, the low-Mg^{2+}-induced high frequency spiking in the hippocampal neurons meets the electrophysiological definition of clinical SE. Control neurons showed only the occasional firing of action potentials (**Figure 3(a)**). During the 3 h in low-Mg^{2+} solution, $[Ca^{2+}]_i$ increased almost sevenfold compared to the levels observed in control neurons (**Figure 3(b)**). Moreover, when the neurons were briefly stimulated with 50 μM glutamate immediately following the restoration of Mg^{2+}, they demonstrated marked alterations in the ability to recover from this excitatory challenge (**Figure 3(c)**). Changes in $[Ca^{2+}]_i$ observed in neurons following treatment with low-Mg^{2+} were evident in pseudocolor images from neurons after in vitro SE. These images from low-Mg^{2+}-treated cells showed increased Fura-2 ratios compared to the control neurons (**Figure 3(d)**). These altered $[Ca^{2+}]_i$ levels observed in neurons following SE lasted for 6–7 h following the restoration of Mg^{2+}, representing the Ca^{2+} plateau following in vitro SE.

In vitro SE Causes AE-like Activity and Prolonged Alterations in $[Ca^{2+}]_i$ and Ca^{2+} Dynamics

To determine whether Ca^{2+} dynamics were altered after the establishment of in vitro epilepsy, cultured hippocampal neurons were observed for electrophysiological activity and changes in fura-2 ratios 24 h post-in vitro SE. Whole-cell current clamp recordings displayed SREDs in low-Mg^{2+}-treated neurons, while the control neurons displayed baseline activity (**Figure 4(a)**). Consistent with clinical epilepsy, in vitro seizure episodes were comprised of paroxysmal

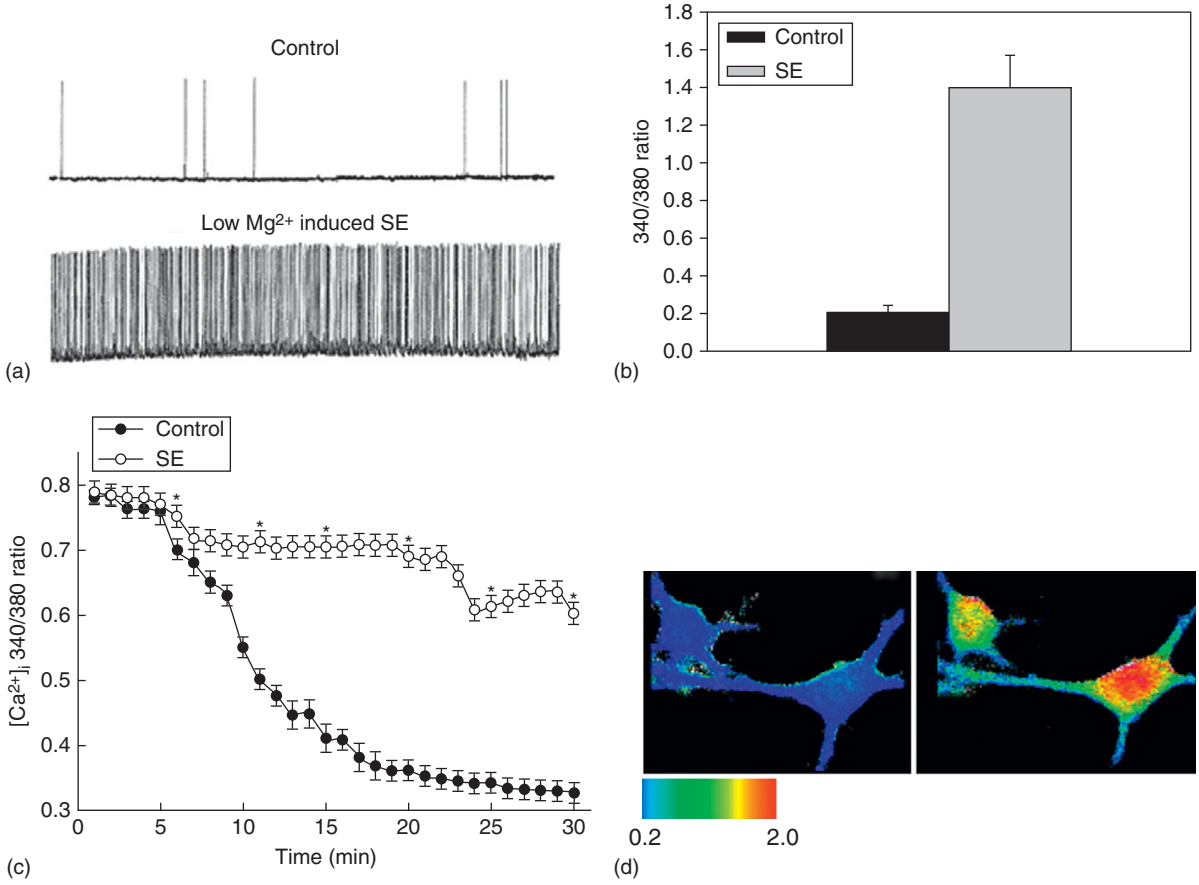

Figure 3 Alterations in $[Ca^{2+}]_i$ and Ca^{2+} homeostasis immediately following 3 h of low-Mg^{2+}-induced in vitro SE. (a) Current–clamp electrophysiological recordings of a representative control neuron and a neuron in low-Mg^{2+}. The control neuron displays occasional action potentials, whereas the neuron in low-Mg^{2+} shows frequent discharges. Resting membrane potential = −62mV; duration of shown trace = 15 min. (b) Bar graph comparing fura-2 340/380 ratios in control neurons versus in vitro SE neurons. The low-Mg^{2+} cells exhibit ratio values of 1.4 ± 0.17 as compared to the control neurons with values of 0.20 ± 0.04. (c) Following glutamate stimulation, elevations in $[Ca^{2+}]_i$ are observed in both control and in vitro SE groups. Control neurons show faster recovery rates than treated neurons. (d) Pseudocolor ratio images of control (left panel) and low-Mg^{2+}-treated (right panel) neurons show increased 340/380 ratio immediately following treatment with low-Mg^{2+}.

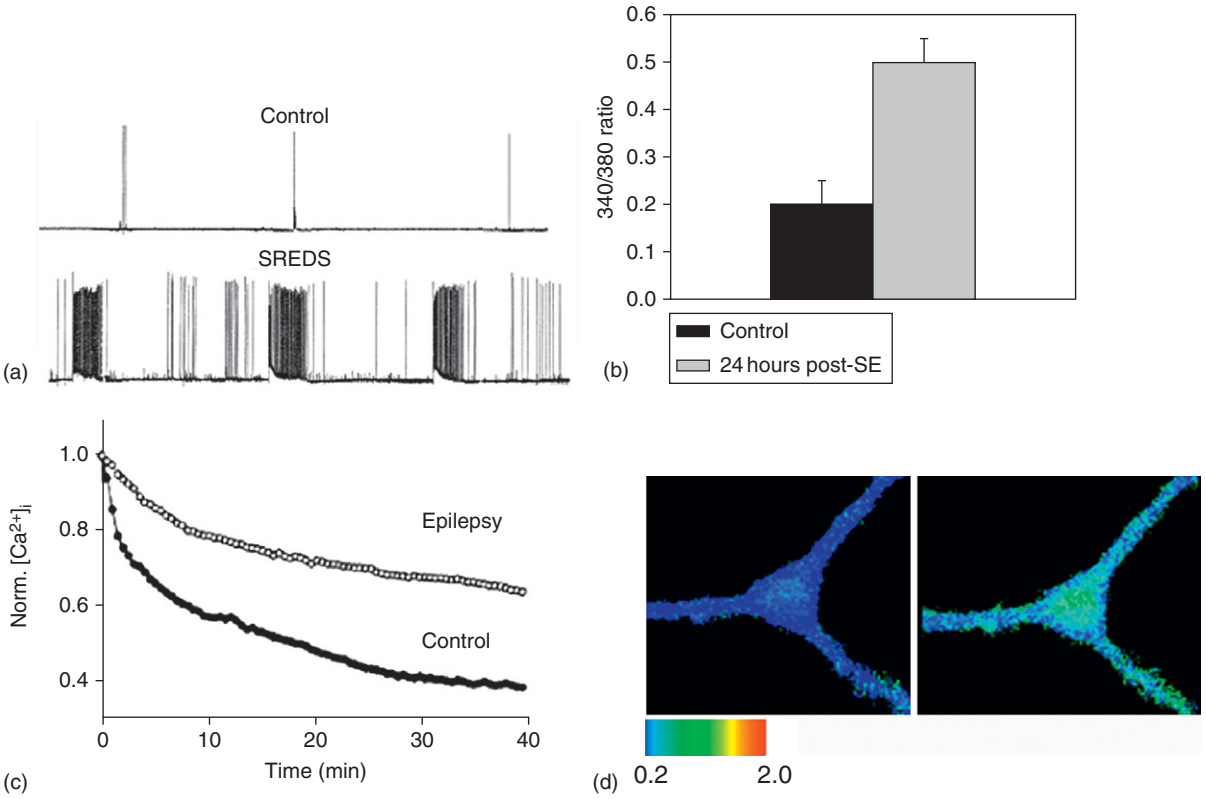

Figure 4 Alterations in $[Ca^{2+}]_i$ and Ca^{2+} homeostasis in neurons expressing spontaneous recurrent epileptiform discharges (SREDs), 24 h post-in vitro SE. (a) Current–clamp technique demonstrate baseline activity in control neurons and SREDs in neurons that were treated in low-Mg^{2+} for 3 h. Resting membrane potential = −61.5 mV; duration of shown trace = 30 min. (b) Compares 340/380 ratio values in neurons, 24 h after either pBRS + $MgCl_2$ or low-Mg^{2+} treatment. Neurons in the low-Mg^{2+}-treated group exhibit mean ratios of 0.5 ± 0.08, significantly higher than the ratio of 0.20 ± 0.05 observed in the control group. (c) Shows recovery of both control and low-Mg^{2+} groups following glutamate stimulation. Peak ratios following the glutamate challenge are normalized to 1.0. SRED neurons show a decreased ability to recover. (d) Pseudocolor ratio images of neurons 24 h after either pBRS + $MgCl_2$ (left panel) or low-Mg^{2+} (right panel) treatment highlight the increases in $[Ca^{2+}]_i$ in epileptic neurons.

depolarization shifts and exhibited similar anticonvulsant sensitivity. Calcium imaging revealed that ratio values for the baseline neuronal $[Ca^{2+}]_i$ levels were elevated 2.5-fold when cells were exposed to the low-Mg^{2+} treatment that caused continuous epileptiform discharges (Figure 4(b)). Moreover, when the neurons were stimulated with 50 µM glutamate, they demonstrated marked alterations in the ability to recover from this excitatory challenge (Figure 4(c)), indicating a diminished ability to buffer the increased Ca^{2+} load when compared to the control (Figure 4(d)).

In vivo SE Causes Increased $[Ca^{2+}]_i$, Altered Ca^{2+} Homeostasis, and a Prolonged-Elevated $[Ca^{2+}]_i$ Plateau

Rats injected with pilocarpine were allowed to seize for 1 h before the termination of seizure activity with diazepam. The electrical activity in the brain was evaluated using electroencephalography, with pilocarpine-treated animals showing activity consistent with clinical SE (Figure 5(a)). Immediately following SE, the rats were sacrificed and hippocampal neurons were acutely isolated. Significant elevations in $[Ca^{2+}]_i$ were observed in hippocampal neurons from the CA1 region following pilocarpine-induced SE, but not in those isolated from vehicle-control animals (Figure 5(b)). When these acutely isolated neurons were stimulated with glutamate (Figure 5(c)), a decrease in the rate of recovery and the ability to restore $[Ca^{2+}]_i$ to baseline levels was evident in the neurons isolated from post-SE animals, whereas control neurons were able to restore the Ca^{2+} load to baseline levels.

We have also demonstrated that the elevated $[Ca^{2+}]_i$ falls slightly over the days and weeks following SE; however, levels never decrease to baseline values observed in controls. This maintenance of a Ca^{2+} 'plateau' following injury contributes to the 'Ca^{2+} hypothesis of epileptogenesis' which suggests that altered Ca^{2+} homeostatic mechanisms and the inability of the cells to maintain normal, resting $[Ca^{2+}]_i$ contribute to the long-term development of AE through Ca^{2+}-triggered second messenger effects.

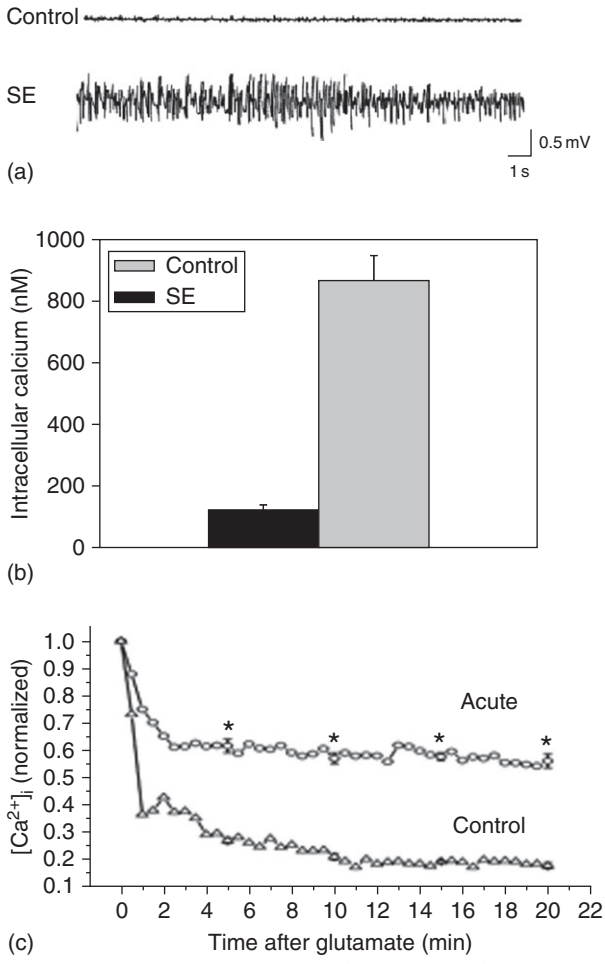

Figure 5 SE causes increased $[Ca^{2+}]_i$, altered Ca^{2+} homeostasis, and a prolonged, elevated $[Ca^{2+}]_i$ plateau in vivo. (a) Representative EEG recording from control (vehicle) rats and rats in SE (pilocarpine-treated). (b) $[Ca^{2+}]_i$ is higher in neurons from animals immediately following SE when compared to animals in the control group – 850 ± 59 and 90 ± 22 nM, respectively. (c) Upon glutamate stimulation, the $[Ca^{2+}]_i$ in control neurons returns to baseline levels within ~10 min but fails to do so in neurons from the SE group.

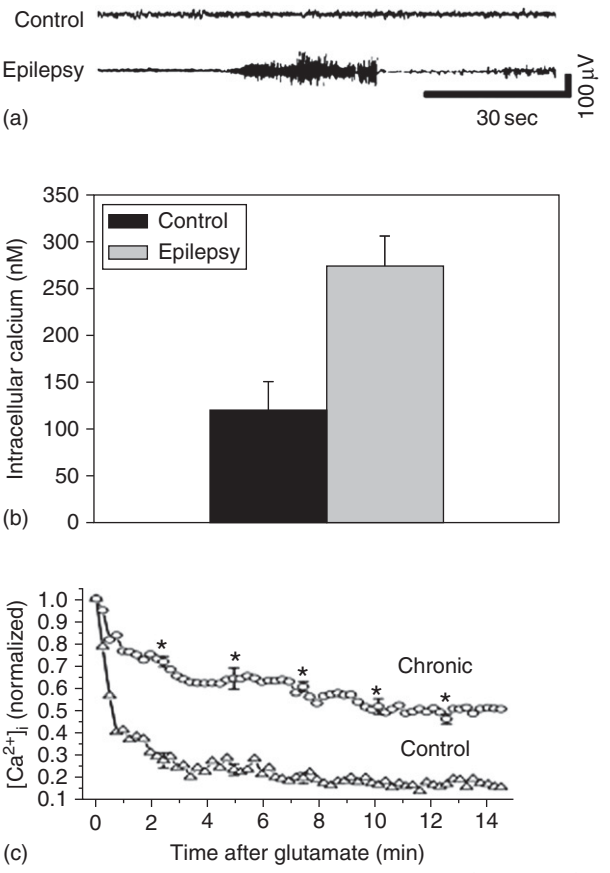

Figure 6 AE is associated with alterations in $[Ca^{2+}]_i$ and Ca^{2+} homeostatic mechanisms 1-year post-in vivo SE. (a) Representative EEG recording from control (vehicle) rats and epileptic rats (following pilocarpine-induced SE). (b) $[Ca^{2+}]_i$ is higher in neurons from epileptic animals (325 ± 35 nM) when compared to those from animals in the control group. (c) Upon glutamate stimulation, the $[Ca^{2+}]_i$ returns to baseline in neurons from the control group, unlike neurons from the epileptic group, which fail to return to baseline.

In vivo SE-Induced AE is Associated with Alterations in $[Ca^{2+}]_i$ and Ca^{2+} Homeostatic Mechanisms

To determine whether these changes were transient or still present during chronic epilepsy, animals were treated with pilocarpine or vehicle (as earlier) and were maintained for one year following SE. Video-EEG monitoring revealed spontaneous, recurrent seizures in the pilocarpine but not vehicle-treated group (Figure 6(a)). Hippocampal neurons isolated from epileptic animals one year post-pilocarpine demonstrated markedly elevated $[Ca^{2+}]_i$ compared to neurons isolated from age-matched animals (Figure 6(b)). The cells were evaluated for the ability to restore baseline Ca^{2+} levels post-glutamate stimulation; similar to our observations in culture models, neurons from epileptic animals demonstrated a decreased ability to buffer a given load of Ca^{2+} at one year post-injury (Figure 6(c)).

Alterations in Ca^{2+} Following Stroke-Induced AE

We used the in vitro glutamate-mediated injury model to mimic ischemic stroke. With this model, we evaluated the development of SREDs. This model results in approximately 10–20% cell death and SREDs in the 80–90% of the neurons that survive the injury. Studies have demonstrated that surviving cultured hippocampal neurons manifested elevated $[Ca^{2+}]_i$ compared to control neurons (Figure 7(a)). Glutamate excitotoxicity thus provides an in vitro model of stroke-induced AE.

In this model, tetrodotoxin (TTX) was used to block epileptiform discharges, to determine whether Ca^{2+} influx was due to the seizurelike activity recorded from these

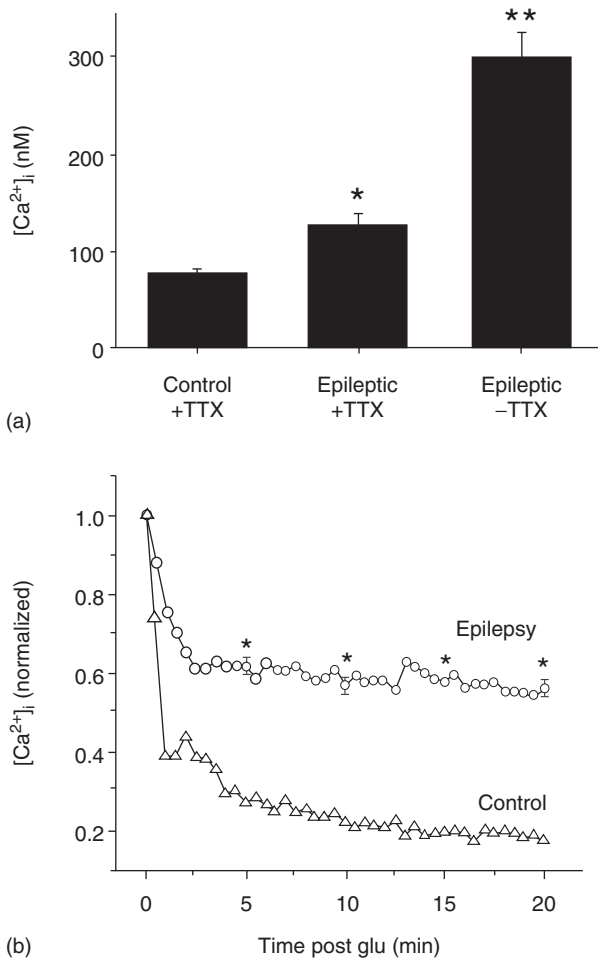

Figure 7 Alterations in $[Ca^{2+}]_i$ and Ca^{2+} homeostatic mechanisms following in vitro stroke. (a) 5 days post-injury with glutamate, chronic elevations in basal $[Ca^{2+}]_i$ were measured. Epileptiform activity contributed in part to these levels; however, blockade of epileptiform activity by 600 nM TTX significantly reduced the long-lasting elevations in basal $[Ca^{2+}]_i$ in epileptic neurons in comparison to epileptic neurons exhibiting SREDs. Basal $[Ca^{2+}]_i$ in epileptic neurons was still significantly elevated compared with control neurons in the presence of TTX. (b) Following glutamate stimulation to assess homeostatic mechanisms, the percent of Ca^{2+} load remaining 20 min post-washout in the epileptic neurons was significantly higher than that observed in control neurons.

neurons. Following treatment with TTX, cells in these cultures still showed elevations in baseline Ca^{2+} (Figure 7(a)). It appears that while a component of the elevated $[Ca^{2+}]_i$ is due to seizure activity, it does not account for the entire Ca^{2+} overload. These observations are similar to those following SE-induced hyperexcitability in vitro. Cultures were also evaluated for their ability to respond to glutamate-stimulated elevations in $[Ca^{2+}]_i$. As demonstrated in the SE model, control neurons restored basal $[Ca^{2+}]_i$ at a higher rate than the SRED-producing neurons following in vitro glutamate exposure (Figure 7(b)). Thus, in culture models of stroke-induced hyperexcitability, we demonstrated that both $[Ca^{2+}]_i$ and Ca^{2+} homeostatic mechanisms are altered following injury for the life of the neurons in culture.

Little work has been done to evaluate changes in Ca^{2+} dynamics employing in vivo models of stroke-induced AE. We have performed both decapitation ischemia and middle cerebral artery occlusion, and have found that both cause acute increases in $[Ca^{2+}]_i$, consistent with what is seen both in models of SE-induced AE and in vitro stroke. Furthermore, preliminary results following middle cerebral artery occlusion show that neuronal Ca^{2+} dynamics are affected by this injury. Whether these alterations in Ca^{2+} dynamics eventually lead to the development of the epileptic phenotype is currently unknown and is being actively investigated.

TBI-Induced Increases in $[Ca^{2+}]_i$ Levels and Ca^{2+} Homeostatic Mechanisms

The TBI model of epilepsy is the least characterized of these models. However, recent studies by Pitkanen's group, in which they carefully examined the experimental conditions and time course of the development of spontaneous recurrent seizures following TBI caused by the fluid percussion in rats, demonstrated (with long-term continuous EEG monitoring) that AE develops in a significant number of rats following TBI. Our laboratory has recently evaluated $[Ca^{2+}]_i$ levels in cells from rats subjected to fluid percussion TBI. We have shown that $[Ca^{2+}]_i$ remains elevated for prolonged periods after the injury in hippocampal neurons from animals post-TBI. More specifically, $[Ca^{2+}]_i$ was elevated at day-1 and week-1, but not month-1, after central fluid percussion injury. These recent observations indicate that the injury produced by TBI initiates the same changes in $[Ca^{2+}]_i$ levels that occur after injury produced by SE or stroke (Figure 8). Further studies are needed to correlate these changes with the development of epileptogenesis.

Alterations in Ca^{2+} homeostatic mechanisms following TBI were evaluated using the standard glutamate-stimulation technique. When challenged with glutamate (50 μM, 4 min), neurons acutely isolated from TBI animals (at 1, 7, and 30 days following injury) demonstrated significant alterations in their ability to recover baseline Ca^{2+} levels. Age-matched control and sham-operated neurons promptly restored elevated $[Ca^{2+}]_i$ following the excitatory stimulus (Figure 8).

Thus, TBI causes long-lasting elevations in hippocampal neuronal $[Ca^{2+}]_i$ levels and alterations in Ca^{2+} homeostasis. These long-lasting changes in $[Ca^{2+}]_i$ levels and Ca^{2+} homeostasis were not the result of dying neurons, as demonstrated through simultaneous assays examining cell death and Ca^{2+} changes. These studies demonstrated that the neurons manifesting elevated $[Ca^{2+}]_i$ levels did not show

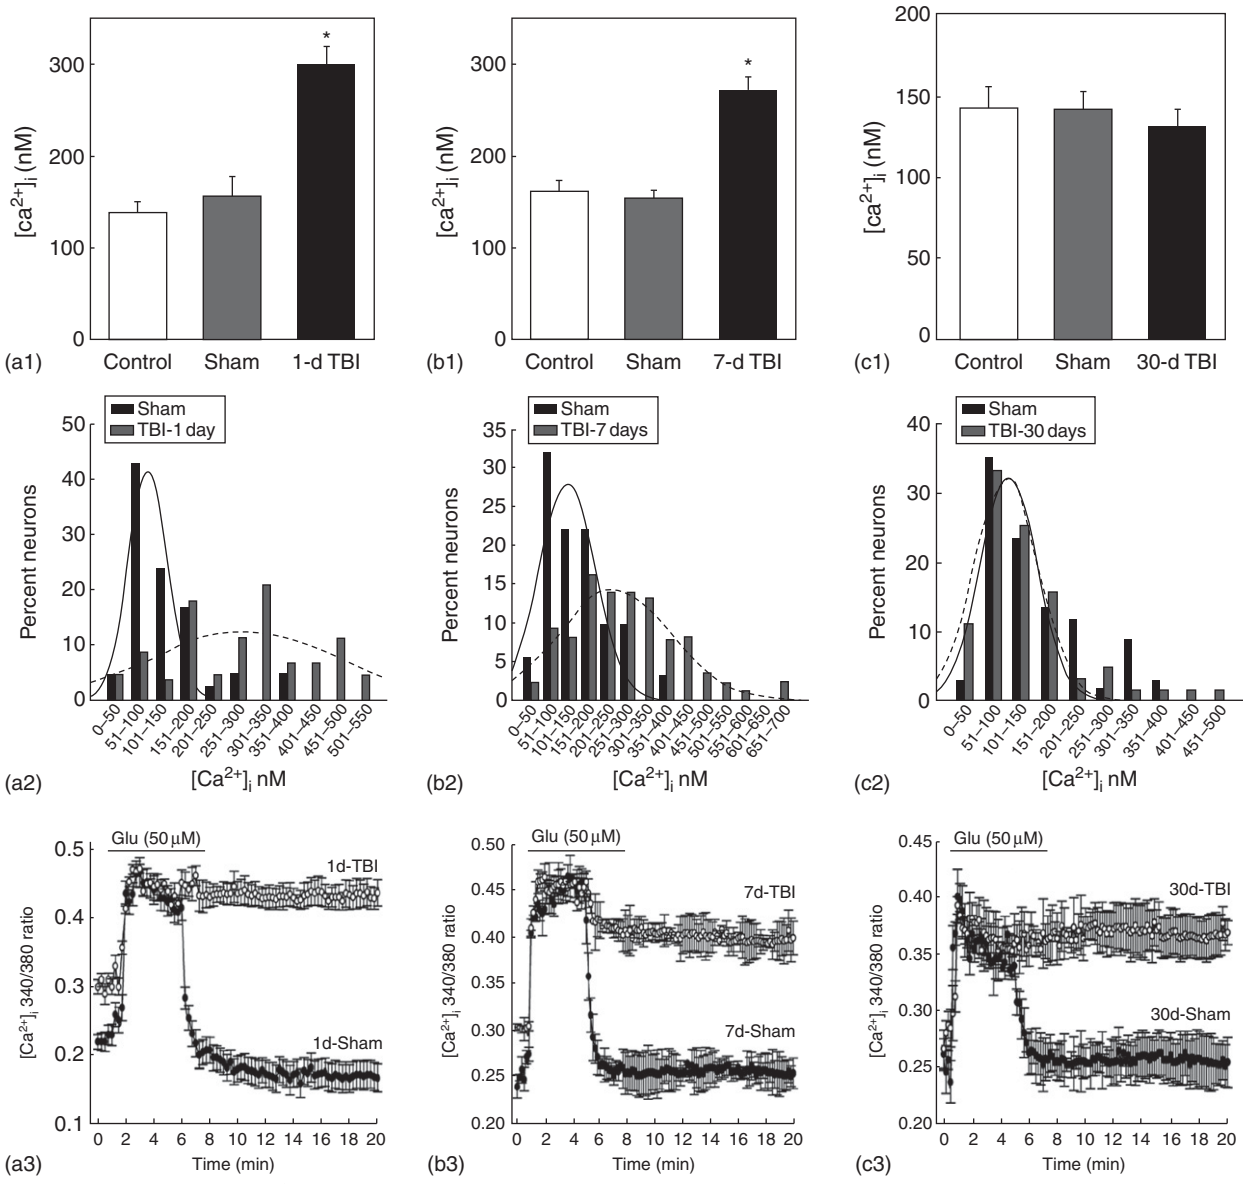

Figure 8 Basal neuronal $[Ca^{2+}]_i$ in TBI injured hippocampal neurons 1,7, and 30 days after moderate central fluid percussion injury. (a1) Acutely isolated CA3 hippocampal neurons 1 day post-injury manifested significant elevations in $[Ca^{2+}]_i$ compared to both age-matched control and sham neurons. (b1) Elevations in basal neuronal $[Ca^{2+}]_i$ persisted 7 days following TBI. Injured neurons manifested significant elevations in $[Ca^{2+}]_i$ compared to both age-matched control and sham neurons. (c1) Basal neuronal $[Ca^{2+}]_i$ normalized 30 days after moderate central fluid percussion injury. Thirty days post-injury, acutely isolated CA3 hippocampal neurons did not manifest significant differences in $[Ca^{2+}]_i$ compared to age-matched control and sham neurons. (Color scheme: white = control, gray = sham and black = TBI).Distribution of $[Ca^{2+}]_i$ levels for sham and TBI hippocampal neurons one, seven and thirty days after moderate central fluid percussion injury. (a2) Sham neurons demonstrated a normal distribution for $[Ca^{2+}]_i$ levels with approximately 88% of neurons exhibiting $[Ca^{2+}]_i$ levels less than 200 nM. In contrast 1-day TBI neurons demonstrated a rightward shift towards higher $[Ca^{2+}]_i$ levels with only 35% neurons exhibiting $[Ca^{2+}]_i$ levels less than 200 nM. (b2) Seven days following TBI, neurons still exhibited a rightward shift towards higher $[Ca^{2+}]_i$ levels compared to sham neurons. (c2) Thirty days following TBI there was no shift towards higher $[Ca^{2+}]_i$ levels. Approximately 75% and 85% of sham and TBI neurons exhibited $[Ca^{2+}]_i$ levels less than 200 nM. The distributions of $[Ca^{2+}]_i$ levels was significantly different at days 1 and 7 post TBI but not at 30 days following TBI.Inability of TBI injured hippocampal neurons to restore basal neuronal $[Ca^{2+}]_i$ following excitatory stimulation. A $[Ca^{2+}]_i$ load was produced by a glutamate exposure (50 μM, 4-min) and the ability to restore preglutamate Ca^{2+} levels was measured using the low affinity Ca^{2+} indicator, Fura-FF. Glutamate stimulation in both sham and TBI dissociated neurons at all the time points following injury produced a Ca^{2+} load as evidenced by sudden increase in Fura-FF ratio. Upon removal of glutamate, sham neurons promptly restored Fura-FF ratio to pre-stimulation levels. However, TBI neurons [a3: 1-day, b3: 7-day, and c3: 30-day] failed to restore Fura-FF ratio to preglutamate levels despite glutamate washout. The ratio remained elevated throughout the experiment indicating a chronic inability of TBI neurons to handle Ca^{2+} loads. All the time points for TBI neurons following the glutamate washout were significantly different compared to sham neurons.

histopathological evidence of apoptosis or acute cell death, indicating that the persistent alteration in Ca^{2+} dynamics is a function of injured but surviving neurons. These long-term alterations in Ca^{2+} dynamics contribute to the pathophysiology of TBI, and may represent a molecular basis for mediating some of the persistent plasticity associated with the chronic disability from TBI, including cognitive disorders and post-traumatic epilepsy.

Future Directions

As diagrammed in Figure 9, stroke, TBI, SE, and other injuries of the central nervous system have the ability to elicit permanent cellular alterations, some of which may result in epilepsy. The period between injury induction and expression of recurrent seizures is called epileptogenesis. It represents a therapeutic window of opportunity wherein the progression of brain tissue from healthy to hyperexcitable can be halted. The development of such therapeutic targets is dependent on our ability to isolate and identify specific changes that allow for such dissimilar injuries to result in one common clinical condition.

The findings that $[Ca^{2+}]_i$ and Ca^{2+} homeostatic mechanisms are significantly altered in both in vitro and in vivo models of AE may prove to be the common thread in the pathogenesis of AE. While we have begun to elucidate which regulatory systems are responsible for both the increased $[Ca^{2+}]_i$ and the decreased ability to buffer this load, it is crucial to further tease out the specific contributions of Ca^{2+} systems. Drugs targeting alterations in Ca^{2+} binding proteins, Ca^{2+}-induced Ca^{2+} release mediated by ryanodine- and IP_3-receptors, sarco-endoplasmic reticulum Ca^{2+}-ATPase, Ca^{2+}/calmodulin-dependent protein kinase II, and myriad Ca^{2+} channels in the plasma membrane may prove to have therapeutic potential. Studies using NMDA antagonists have already demonstrated that blocking the Ca^{2+} overload can be neuroprotective. Clearly, identifying which systems contribute to the changes observed post-injury is necessary for the development of new therapeutic targets. The identification of new targets to prevent the development of epilepsy has tremendous clinical implications. Currently there are no antiepileptogenic drugs to prevent the transformation from a normal to an epileptic phenotype. The development of such a drug, that could be administered shortly after injury to prevent the induction of epilepsy through the buffering of $[Ca^{2+}]_i$ or the restoration of normal, Ca^{2+} homeostasis, may prove to be invaluable.

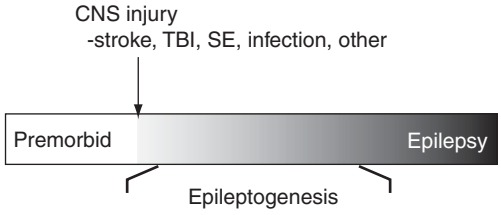

Figure 9 The progression to acquired epilepsy: A possible therapeutic window of opportunity. Injuries to the central nervous system such as stroke, TBI, and SE (down arrow) can elicit permanent changes in neurons, resulting in the development of epilepsy. The period between the inciting injury (down arrow) and the manifestation of recurrent seizures or epilepsy (black) is called epileptogenesis (gray). This gray period may provide a therapeutic window of opportunity wherein the use of pharmacological agents or molecular tools can prevent the transition of healthy brain tissue to a hyperexcitable network manifesting spontaneous recurrent epileptiform discharges.

The Role of Short Term Synaptic Plasticity in Development and Spread of Seizures

Introduction

Factors that contribute to the generation and propagation of seizure activity throughout the brain undoubtedly include the way in which neurons interact with one another at the circuit level. More specifically, the balance between excitatory and inhibitory processes within the circuit can govern the level of local network stability. Indeed, experimental manipulations, both in vivo and in vitro, which disrupt inhibition or enhance excitation, have been shown to generate seizures or seizure-like electrographic activity. Thus, the initiation of seizures from the preictal state may depend on a shift in the relative strengths of synaptic excitation and inhibition in a very small set of neural networks. This shift may come about because of changes in the expression of a variety of voltage-gated and ligand-gated channels in a 'damaged' area of brain and/or because of altered circuits.

Although partial seizures are initiated in areas of the brain that act as epileptic foci, seizure activity can readily spread through regions of relatively normal brain, both locally and at a distance. This propagation of seizure activity through regions of normal brain tissue implies that 'normal' synaptic connections and processes are sufficient to support the spread of seizure activity throughout the brain. It has therefore been hypothesized that short-term, frequency-dependent changes in the degree of inhibition and excitation can contribute substantially to both the initiation of seizures and the spread of seizure-like activity in the brain. We will provide a brief overview of the kinds of short-term synaptic plasticity that have been observed at CNS synapses, and that are thought to play a role in the generation and propagation of seizure activity.

Background

From even the earliest studies of chemical neurotransmission at the neuromuscular junction, it became apparent that the amplitudes of postsynaptic responses are quite labile and depend on the firing frequencies of the presynaptic neuron. Therefore, not only can neurons within a circuit convey information strictly via excitation or inhibition, but short-term modifications in the relative strength of the excitation and/or inhibition can provide information and dictate the overall stability of the network.

Facilitation is a common form of synaptic plasticity that has been identified at synapses with a low probability of release. Facilitation is a quickly occurring and quickly dissipating (in the order of hundreds of milliseconds) increase in the amplitude of a postsynaptic potential (PSP) or current (PSC), in response to presynaptic action potentials that occur at high frequency. The residual calcium hypothesis remains the most widely accepted theory for explaining short-term synaptic facilitation. Following an initial action potential, calcium concentrations near neurotransmitter release sites remain elevated. With the occurrence of subsequent action potentials, this residual calcium contributes to an overall larger calcium signal than that which occurred following the first action potential, causing an enhancement of the probability of release of neurotransmitter and a subsequent increase in the amplitude of the postsynaptic response. The residual calcium hypothesis can also adequately explain other common forms of short-term synaptic enhancement, such as augmentation and posttetanic potentiation (PTP). These forms of synaptic plasticity require bursts of action potentials and can last for several seconds (in the case of augmentation) to several minutes (in the case of PTP).

Another hypothesis to explain at least some forms of facilitation relates to accumulation of extracellular K^+. After each action potential, K^+ is extruded from the cell and may accumulate around cell bodies and axons. Small increases in extracellular K^+ may facilitate action potential generation, which can subsequently be reflected in an apparent increased probability of transmitter release. This mechanism may be particularly important in epileptic processes, where injured tissue may be more susceptible to the influences of extracellular K^+ accumulation and where astrocytes (that normally effectively buffer extracellular K^+) may be altered.

Synaptic depression is another prominent form of short-term plasticity that most often occurs at synapses with a high probability of release. Robust depression of PSP(C)s can be observed following just a single presynaptic action potential and can last for several seconds. Strikingly, such depression has been observed at many inhibitory synapses in the cortex and hippocampus. Based on the fact that even mild disruptions of inhibitory

processes elicit seizures, it is compelling to think that such depression at inhibitory synapses can result in a profound reduction of inhibition in cortical and hippocampal circuits, and thus contribute to both ictogenesis and the spread of seizures once seizures develop. While this feature of many inhibitory synapses has been known for some time, the advent of paired recordings of identified neurons (in brain slice preparations) has shown that many excitatory synapses in the cortex also exhibit depression. In a series of elegant experiments, investigators recorded from monosynaptically connected pairs (either pyramidal cell–pyramidal cell excitatory connections, or fast spiking cell–pyramidal cell inhibitory connections) of neurons in slices of the rat visual cortex. Both excitatory synapses between the recorded pyramidal cells and inhibitory synapses between the fast-spiking interneurons and pyramidal cells showed depression in response to trains of action potentials. Indeed, over the course of long stimulation trains, the EPSCs diminished steadily until the majority of responses consisted of failures of transmission. Although the amplitude of the IPSCs depressed faster than the EPSCs, IPSCs reached a steady-state plateau very rapidly; in contrast to EPSCs, the probability of failures was substantially lower and IPSCs were measurable throughout the train of action potentials. It is hypothesized that such differential depression among recurrent excitatory and inhibitory connections serves to dynamically stabilize cortical networks, which might otherwise be prone to instability and hyperexcitability. It remains to be determined if such a homeostatic property of short-term plasticity is preserved in the epileptic brain.

As is the case for synaptic enhancement, most forms of short-term depression appear to be due primarily to presynaptic mechanisms such as depletion of a readily releasable pool of transmitter vesicles. In addition, other presynaptic mechanisms have also been shown to contribute to short-term synaptic depression. For example, activation of presynaptic receptors that modulate release (such as $GABA_B$ receptors, adenosine receptors, or kainate receptors) can play a role in the activity-induced depression observed at some synapses. Indeed, this mechanism of action appears to complicate the effects of one of the newer anticonvulsant drugs. This drug was designed to inhibit GABA uptake at synapses. Although the drug did work to suppress partial seizures, it also appeared to enhance generalized seizures in some individuals – an effect attributed to the fact that the increased GABA in the synaptic cleft was able to activate presynaptic $GABA_B$ receptors and diminish inhibition at some synapses in the thalamus.

Other postsynaptic mechanisms may also contribute to the types of plasticity observed. For example, at most excitatory synapses, postsynaptic AMPA receptors desensitize rapidly, thus contributing to the depression observed. In the hippocampus, it has been shown that the reversal potential for $GABA_A$ receptor-mediated IPSPs in inhibitory interneurons of the stratum oriens can change rapidly during a train of action potentials elicited at high frequencies. This rapid change in driving force for Cl^- results in a unique form of short-term plasticity at these synapses, as both presynaptic and postsynaptic mechanisms are simultaneously involved.

Methods

To understand short-term synaptic plasticity, our laboratories have primarily used the whole cell patch clamp technique in a number of different preparations, including dissociated cell cultures, organotypic hippocampal slice culture preparations, and acute brain slices containing the entorhinal cortex and hippocampus. These tools have been used to evaluate and determine underlying mechanisms of short-term synaptic plasticity at a number of different types of identified synapses. We use dual patch clamp recording techniques to directly monitor the electrical activity of both the presynaptic and postsynaptic neurons in a synaptically coupled pair of cells. In addition, when finding pairs of synaptically coupled neurons is not possible, we utilize extracellular minimal stimulation techniques to evaluate short-term plasticity. Finally, we have begun to explore plasticity in preparations obtained from animal models of temporal lobe epilepsy. For details concerning the methods employed to prepare, maintain, and record from the different preparations, please consult Further Reading.

Results

Much of our work on short-term plasticity was originally performed in low-density primary cultures of either hippocampus or cortex; Figure 1 illustrates the basic approach. A pair of neurons is patch clamped; action potentials are elicited in the presynaptic cell, and either excitatory or inhibitory postsynaptic currents (EPSCs or IPSCs, respectively) are recorded in the postsynaptic cell

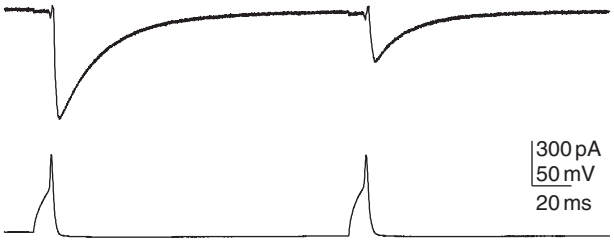

Figure 1 Paired pulse depression is observed between monosynaptically connected neurons in a low-density, dissociated hippocampal culture. Action potentials elicited in the presynaptic cell (lower trace) reliably evoke IPSCs in the postsynaptic cell. Note that the second IPSC is greatly attenuated compared with that of the first.

(depending on the neurotransmitter being released by the presynaptic cell). In these dissociated cell cultures, the predominant excitatory neurotransmitter is glutamate, whereas the predominant inhibitory neurotransmitter is GABA. An advantage of the whole cell patch clamp technique is that the reversal potential for PSCs can be determined by the investigator, and depends on the internal solutions used in the recording pipettes. In these studies, it is critical to determine that the paired cells establish monosynaptic – and not polysynaptic – interactions. Toward that end, we have modified our culture techniques to allow development of neurons at very low density, such that there are only two (or at most, a very few) neurons in a microscopic field. In addition, physiological criteria for monosynaptic connectivity include a constant latency for the PSC, a monotonic rise to peak in the PSC, and the ability of PSCs to occur with fidelity during high-frequency trains of action potentials. These experiments have led to many insights into the basic principles of short-term plasticity, as discussed earlier. In addition, these experiments allow us to ask detailed questions about the presynaptic or postsynaptic location of action of novel compounds that might be effective for decreasing excitability and treating seizures (a topic that is beyond the scope of the present article).

Figure 1 is an example of commonly observed paired pulse depression at a $GABA_A$-mediated inhibitory synapse recorded from pairs of neurons in a low-density primary culture of dissociated hippocampal neurons. Whereas low-frequency stimulation results in stable IPSC amplitudes, action potentials delivered within several hundred milliseconds of each other resulted in substantial postsynaptic IPSC depression. Our work has demonstrated that this depression is primarily due to a depletion of the readily releasable pool of vesicles. Depression at other synapses, in other systems, may be due to activation of G-protein-coupled autoreceptors that are activated as a consequence of neurotransmitter being released following the first action potential.

Our laboratories, and others, have also utilized the organotypic hippocampal slice culture preparation to examine short-term plasticity in a system with considerably more intact circuitry. Figure 2 is an example demonstrating target selective plasticity of CA3 pyramidal cells. When pyramidal cells in this preparation synapse onto other pyramidal cells, no dramatic depression of EPSCs is observed when action potentials occur at high frequency. In contrast, EPSCs recorded in the postsynaptic interneurons (receiving input from CA3 pyramidal cells) exhibited profound depression. Such target selective plasticity is not uncommon throughout the CNS. Therefore, it is critical that as synaptic properties are incorporated into computational models of network activity in physiological and pathological conditions, there must be careful evaluation of individual synapses within the circuit.

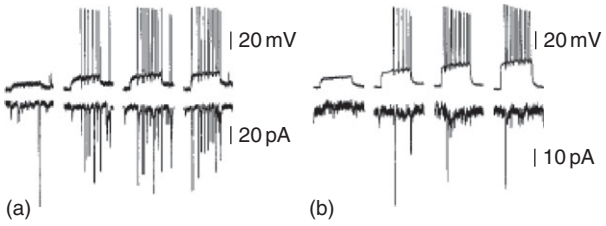

Figure 2 Responses to trains of action potentials (500-ms current injections of increasing amplitudes) in (a) PYR:PYR pair and (b) PYR:INT pair. Note the reliable following and lack of major depression in the PYR:PYR pair, while the PYR:INT pair shows extensive IPSC dropout or decrement during each train, reprinted with permission from Aaron and Dichter, 2001.

An additional complication in assessing short-term plasticity at various synapses is the not uncommon observation that a given synapse may simultaneously exhibit different forms of plasticity. For example, in cerebellar slices, and in cultured hippocampal neurons, repetitive EPSCs depress with high-frequency stimulation, whereas asynchronous release of miniature EPSCs (mEPSCs) dramatically increases over the same time scale. The enhancement of asynchronous release is calcium dependent, as perfusion with a membrane-permeant calcium chelator with slow on-rate kinetics, EGTA-AM, can prevent the facilitation of mEPSCs while having no overt effect of the depression of the evoked EPSC. It is unclear what the barrage of mEPSCs means functionally for the postsynaptic cell; however, it is likely that such asynchronous release of neurotransmitter would contribute greatly to the overall level of excitability of the postsynaptic cell.

Synaptic plasticity that might also be involved in ictogenesis may involve long-term forms. Although we propose that short-term plasticity plays a significant role in the transition from the interictal to ictal state, there is evidence to suggest that other mechanisms of synaptic strengthening, such as long-term potentiation (LTP), may also be involved. This contribution may be especially important during the 'buildup' of activity prior to the actual seizure. Furthermore, low-frequency stimulation of the kind typically used to induce long-term depression (LTD) can dramatically reduce the propensity of brain slices to burst, and continuous sinusoidal electrical stimulation has recently been shown to be an effective mechanism to suppress epileptiform activity in the in vitro rat hippocampal preparation. Therefore, although short-term plasticity might enable seizure initiation and spread, it may follow on the heels of strengthening certain feedforward excitatory pathways by the development of longer lasting forms of potentiation within the circuits.

As suggested earlier, a major technical breakthrough in the study of synaptic transmission in the central nervous system has been the development of methods to simultaneously record from identified, monosynaptically

connected neurons in both culture systems and in brain slices. Experiments in these preparations have yielded a wealth of important findings concerning basic mechanisms of synaptic transmission, and the ability to record from synaptically connected neurons within the context of the neural circuit has proven invaluable in determining a wide variety of 'rules,' which govern synaptic function, at least within the circuitry of the hippocampus and cortex. Furthermore, these types of experiments have begun to unravel important homeostatic mechanisms governing frequency-dependent activity in the mammalian brain. These 'synaptic rules' appear to stabilize intrinsically excitable neural circuits, which might otherwise be predisposed toward uncontrolled activity. Such studies have given rise to important concepts about synaptic regulation, such as synaptic scaling, spike timing-dependent plasticity (STDP), synaptic redistribution, inverse homosynaptic versus heterosynaptic plasticity, and maintenance of constant firing rates by changes in ion channel expression function and expression.

Future Goals

Great strides in our understanding of synaptic activity have been made with our increased ability to record from pairs of identified neurons within the context of neuronal circuitry in brain slices. Furthermore, by combining experimental studies with computational approaches, improving EEG monitoring technologies within different animal models of epilepsy, and enhancing our cellular monitoring/recording techniques, we should be able to assess in much greater detail the neural circuits involved in seizure generation and propagation. Questions concerning the homeostatic strategies of synaptic transmission in pathological conditions should provide an in-depth understanding of the processes underlying seizure initiation and propagation. This mechanistic approach to analyzing the events leading up to seizure generation will no doubt subsequently provide new approaches for the control of seizures.

While the experiments discussed here have been performed in tissue from nonepileptic animals, it is imperative that the field investigates changes in short- and long-term synaptic plasticity in tissue obtained from epileptic animals or in tissue resected from patients with epilepsy. This goal is especially important for analyzing partial seizures that arise from the temporal lobe, the most prevalent and troublesome form of intractable epilepsy seen in adults. In such tissues, brain injury can initiate several potentially epileptogenic reactions: many types of cells die throughout the limbic system, including large populations of inhibitory interneurons; sprouting of remaining axons results in functional changes in neural circuitry, possibly introducing aberrant forms of recurrent excitation, and multiple changes are observed in gene expression (for ion channels, neurotransmitter receptors, and other important regulatory proteins). Understanding changes in the rules governing synaptic plasticity in the various forms of epilepsy should set the stage for innovative therapeutic approaches for the control of seizures, and perhaps even illuminate strategies that might modify the process of epileptogenesis in patients at risk following an insult to the CNS.

Posttraumatic Epilepsy Caused by Fluid Percussion Injury

R D'Ambrosio, University of Washington, Seattle, WA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Western societies are plagued by acquired forms of epilepsy. Among these, posttraumatic epilepsy (PTE) is the most common. Furthermore, PTE often manifests itself as complex partial seizures, which are often resistant to treatment with antiepileptic drugs (AEDs). Therefore, PTE results in a significant social burden and has been the subject of large research efforts in the basic, translational, and clinical realms. The socio-economic value of developing drugs that prevent epilepsy following insult to the central nervous system, or fully control seizures now considered to be pharmacoresistant, would be enormous. However, several obstacles currently hamper the achievement of better treatments:

1. The cellular mechanisms necessary for clinical ictogenesis and epileptogenesis after head injury are still not known. Many different pro-epileptic mechanisms have been proposed to cause (or have a role in) PTE, including loss of inhibition, intrinsic membrane depolarization of hilar neurons, mossy cell hyperexcitability, enhanced excitatory synaptic connection, saturation of synaptic long term potentiation, and impaired K^+ buffering by posttraumatic glia. However, head injury probably results in countless pro-epileptic changes in the brain, and the clinical relevance and the relative importance of any of the investigated mechanisms – in the onset of human PTE or its pharmacoresistance – have yet to be defined; indeed, no direct cause–effect relationship between any of these pro-epileptic changes and the precipitation or maintenance of clinically relevant chronic spontaneous recurrent partial seizures (CSRPSs) has ever been established. Therefore, we currently do not know what the best therapeutic targets might be.
2. Human PTE often manifests with multiple epileptic foci (or epileptogenic zones), which greatly complicates the treatment of the pharmacoresistant patient. Therefore, animal models that faithfully reproduce this level of complexity should be employed to investigate mechanisms and treatments of disease progression that might be relevant to the human condition. Conversely, the hippocampus has been the almost unique center of attention for much of experimental epilepsy research (based on one-focus models). While the hippocampus certainly has a role in human mesial-temporal lobe epilepsy, head injury patients often develop neocortical foci, suffer from progressive temporal cortex pathology, and may not be seizure-free after hippocampectomy. Therefore, understanding the mechanisms by which multiple neocortical and subcortical epileptic foci arise, interact, and progress following head injury is crucial for the development of novel treatments. Animal models that just focus exclusively on hippocampal mechanisms may be greatly limiting our capability to understand clinical epileptogenesis.
3. Current efforts to discover better treatments rely on two sub-optimal approaches.

   The first approach consists of screening substances with animal models of acute seizures or epilepsy that typically involve application of electrical (kindling, electroshock) or exogenous chemical stimuli (pilocarpine, kainate, pentylenetetrazole), which are quite unlike the insults that produce clinical PTE. Further, the mechanisms of epileptogenesis in these models are unclear, and have never been shown to correspond to those responsible for human epileptogenesis. In addition, the lack of temporal definition of chemical insults and the occurrence of acute seizures which commonly appear during the induction of epileptogenesis, make it difficult to distinguish antiepileptic, neuroprotective and antiepileptogenic effects of the agent screened.

   The second approach is to test a substance in clinical trials on patients who suffered injuries that put them at risk for acquiring epilepsy. In the hope that either acute seizure control could prevent a hypothetical seizure-induced kindling-like phenomenon in humans, or that neuroprotection could be equated with antiepileptogenesis – both unproven concepts – several classical AEDs and neuroprotective agents have been studied. In lengthy and expensive clinical trials on posttraumatic patients, these agents have been shown not to be antiepileptogenic in humans. These clinical trials extended over decades and costed tens of millions of dollars. There remain many questions about why these drugs failed to exert antiepileptogenicity – e.g., because of an intrinsic lack of activity or because of the doses and windows in which they were tested. Whatever be the answers to these questions, there is increasing concern that epilepsy models used to screen antiepileptogenic drugs may not optimally target clinically relevant epileptogenic mechanisms, and therefore may be unsuited to find the first clinically effective antiepileptogenics, or even better AEDs.

Overcoming all these obstacles requires the development of improved and clinically relevant animal models of epileptogenesis and pharmacoresistant epilepsy. That is not to say that classic epilepsy models are not useful. Indeed, work on these models has resulted in the identification of several effective AEDs. However, to take the next step in epilepsy research – to control the large fraction of complex partial seizures that are currently pharmacoresistant, or have lower side effects – novel models are needed that probe the neuropathophysiological mechanisms of human epilepsy, and allow for preclinical tests and optimization of clinical trial design.

Background

In an effort to fill the gap, two laboratories have worked independently to develop a novel in vivo model of PTE in the rat in which CSRPS appear after a single clinically relevant insult that mimics concussive closed head injury – the fluid percussion injury (FPI). This model represents a significant departure from previous models of acquired epilepsy because it presents unique similarities to the human post-traumatic epileptic condition (Table 1), and all the features tested thus far satisfy the conditions identified as desirable in an "ideal" animal model for the study of acquired epileptogenesis:

- The initiating insult, a transient compression of the *dura mater* without brain penetration, is mechanically very similar to human cases of concussive closed head injury. The FPI-induced epilepsy is not dependent on the presence of chronic stimuli (the clinical relevance of which is unproven) – which provide the bases for neurotoxicant- and kindling-based models, and/or are of questionable clinical relevance.
- FPI-induced epilepsy presents with: (1) focal seizures, as in human cases of acquired epilepsy, (2) pathology consistent with human epilepsy, (3) a 'seizure-free' latent period between the initiating injury and the onset of the epileptic condition, (4) CSRPSs following this latent period, and (5) temporal progression in seizure frequency and duration. Whether this form of PTE is resistant to classic AEDs (another feature of the ideal animal model of PTE) is currently under investigation. Finally, FPI-induced PTE presents progressive mesial temporal lobe seizures and pathology similar to human mesio-temporal lobe epilepsy. In this regard, FPI-epilepsy is not a *model* of head injury-induced epilepsy – it is real head-injury induced epilepsy in the rat, and it models human PTE to the extent a rat brain may model the human. In FPI, a fluid pressure wave models the blunt impact induced by a solid usually seen in humans. Because of these similarities, we consider FPI-epilepsy to provide the best effort on a "similarity scale" of current models of acquired epilepsy and believe that it is highly likely that the epileptogenic mechanisms recruited by FPI are those involved in human post-traumatic epileptogenesis.

Table 1 Known similarities between FPI-induced PTE in the rat and human PTE

1	The traumatic brain injury model is mechanically very similar to human cases of closed head injury.
2	Chronic spontaneous recurrent seizures appear after a single event of traumatic brain injury.
3	Seizure free latent period between the initiating injury and the onset of the epileptic condition.
4	Seizures are focal, with or without secondary bilateral spread.
5	The ictal behavior is consistent with human complex partial seizures.
6	Neocortical and hippocampal epileptic foci.

Methods

There are different variations of FPI employed in traumatic brain injury research. The most important variants involve the anesthetic employed, the location of the injury, and the size of the craniotomy through which the injury is delivered. In our laboratory we implemented specific variations to render FPI more suitable for epilepsy research. Briefly, our animals are anesthetized with 4% halothane in an anesthesia box and then placed on a heated pad to maintain core temperature at 37 °C. Rats are endotracheally intubated and then they are mechanically ventilated with ~1.5% halothane and 30% oxygen/air mixture. Lidocaine (1%) plus bupivacaine (0.25%) are infiltrated subcutaneously at the proximal ventral region of the tail and midline of the cranial vertex. After the head of the rat is fixed in the stereotaxic frame, the skull is exposed, under aseptic conditions, by a longitudinal incision from occiput to the forehead. A 3-mm burr hole is drilled parasaggitally, taking maximal care not to damage the underlying dura either by compression or heat. A Leur–Lok cannula with an inner diameter of 2.5 mm is secured (with methyl methacrylate) to the skull over the craniotomy. The injury cannula is filled with sterile isotonic saline and connected to the FPI device. The animal is disconnected from the ventilator, and a single pressure pulse (2–4 atm, ~8 ms) is delivered into the closed cranial cavity to induce the injury. In response to this insult, the animal stops breathing for up to 10 s and then either spontaneously recovers, or it is put back on the ventilator. The FPI injury does not penetrate the dura. The animal is weaned from the ventilator and extubated. The wound site is closed with wound clips and gentamycin is applied topically on the wound.

We prefer performing the procedure with volatile anesthetics because rats are known to suffer from respiratory arrest following either FPI or cortical impact, when the pressure shock reaches the pons. If the animals are intubated, then they can be rescued by ventilation. Conversely, with anesthesia by i.p. injection, animals are not ventilated and the injury results in much higher mortality because of respiratory arrest. It should be noted that severe head injury patients would be rescued by intensive care and would enter the pool of patients suffering from PTE. Therefore, volatile anesthetics allow for a more clinically relevant application of the model, and for lower mortality of the animals. Also, we prefer to use a smaller craniotomy (3 mm vs 4.8 mm) because it allows for a defined neocortical focus, limits the diffuse component of the FPI, and therefore, also limits the direct injury to subcortical structures such as hippocampus. This strategy has allowed us to observe a clearly distinguished time course of epileptogenesis in neocortex versus hippocampus after FPI which may have clinical therapeutic relevance.

An important technical issue of FPI-induced epilepsy is worth mentioning here. Drilling a skull craniotomy is a significant surgery that, if not performed with the utmost care and skill, can result in cortical damage and later focal EEG discharges. Cortical damage can result either by compression of the brain during drilling, or by heat produced by friction of the drill bit carving the bone. To reduce the chances of damage we continuously cool the bone during drilling with room-temperature sterile saline. In addition, to prevent brain compression and laceration, we never drill down to the dura. Rather, we carve a crown of bone and lift it up with forceps. Similar precautions must be used when implanting epidural electrodes. We always obtain pathological data at the end of each experiment to verify that animals entering the studies have not suffered from damage induced by electrode implantation or craniotomy – e.g., as indicated by a focus of glial reactivity right under the location of the electrodes. These controls are time consuming and require attention to details. However, omitting them is risky and may explain why some investigators see short focal seizures in their control rats – electrode-induced cortical damage.

Recent Results

FPI-induced epilepsy is a progressive disorder (**Figure 1**). Seizure activity appears within 2 weeks after injury and worsens over time, as reflected in frequency, duration, and behavioral correlates. FPI-induced epilepsy manifests with 3 types of cortical electrical discharges. Grade 1 electrical seizures consist of focal epileptic ECoG events, detected only by peri-lesional electrodes, which do not appear to spread ipsi- or contralaterally (**Figure 1a**). Grade 2 seizures are first detected by the perilesional electrodes, and then spread to the ipsi-and/or contralateral cortex (**Figure 1b**). Grade 3 seizures appear bilateral at their cortical onset, often involving all electrodes simultaneously. The observation that grade 1 and 2 seizures are first detected by the perilesional electrodes, together with the finding of focal neocortical hyperexcitability in vitro, suggests that the neocortex near the site of FPI develops the earliest epileptic focus.

Seizures in the first weeks postinjury are difficult to detect by simple behavioral observation because they are associated with only subtle behavioral output (i.e., are most commonly associated with behavioral arrest). To best assess the behavioral correlates of CRSPSs, we rank (off-line) the concurrent behavior of epileptic ECoG events according to a scale we designed: 0 = no behavioral change (i.e., subclinical to the best of our observational capability); 1 = freeze-like pause in behavior without impaired posture; 2 = freezelike pause in behavior without impaired posture and accompanied by facial automatisms (twitching of vibrissae, sniffing, eye blinking, or jaw automatisms); 3 = head nodding; 4 = body myoclonus; 5 = loss of posture, atonia; 6 = loss of posture followed by motor manifestations (facial automatisms, contralateral limb dystonia); 7 = tonic–clonic convulsion; and 8 = partial statuslike electroclinical syndrome. Typically, 2–3 weeks after FPI, epileptic rats show freezelike pauses in their behavior, with or without facial automatisms, in synchrony with all three grades of epileptic ECoG events. Behavioral correlates of seizures 4–7 months postFPI more commonly include clonus or loss of posture (**Figure 1d**). A partial seizure at this time postinjury typically consists of crawling behavior (at the bottom of the cage) in a stereotyped fashion for few seconds before the onset of bilateral cortical discharge. The fact that the clinical seizure precedes cortical epileptiform activity suggests a subcortical origin for grade 3 seizures.

Another consistent feature of FPI-epilepsy is a time-dependent change in the frequency (**Figure 1e**), severity (**Figure 1f**), and type (**Figure 1g**) of seizures, similar to certain forms of acquired human epilepsy. Furthermore, there is a distinctive time-dependence in the relative proportion of seizure types (**Figure 1e**). We consistently find that 2–3weeks postinjury, grade 1 seizures are by far the most common seizure type, which is in agreement with a neocortical origin of FPI-induced epilepsy at this time-point. However, their proportion progressively decreases over time. Grade 2 seizures are rare at early times after injury, but peak at about 14–15 weeks postinjury. Grade 3 seizures are also rare in the early weeks postinjury, but progressively increase over time, becoming the most common seizure type by 4months postinjury. The worsening in severity of FPI-epilepsy can therefore be appreciated in the increase in seizure frequency, duration, and probability of bilateral spread of seizures over time postinjury.

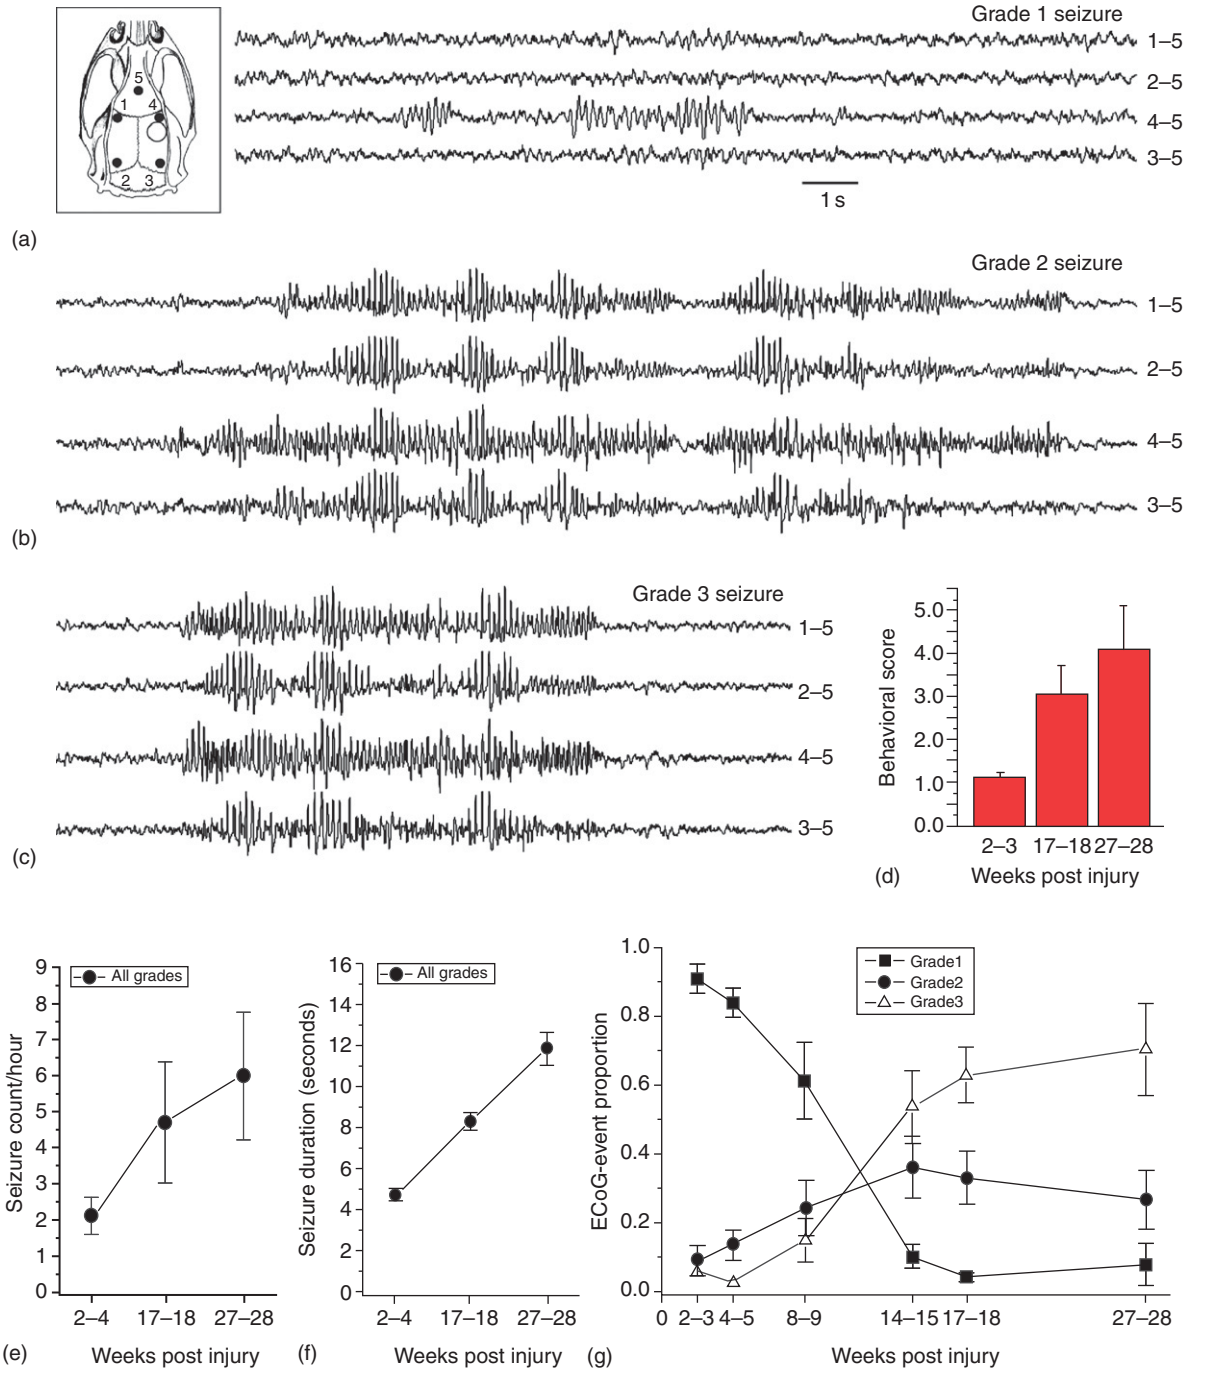

Figure 1 Types and temporal evolution of chronic spontaneous recurrent partial seizures induced by rostral parasaggital FPI. Panels A though C represent continuous ECoG recording in wake animals. (a) Representative grade 1 seizure detected exclusively by the peri-lesion electrode 2 weeks post-FPI. The Inset depicts the locations of the five epidural electrodes (filled circles) and of the injury site (hollow circle) in respect to the rat skull. (b) A representative grade 2 seizure first detected by the peri-lesion electrode and then by multiple channels 27 weeks post-FPI. (c) A representative grade 3 seizure detected simultaneously by multiple channels 15 weeks post-FPI. The numbers next to each ECoG trace indicate the electrodes by which the trace is recorded and its reference. (d) Temporal progression of the behavioral correlate of seizures. See behavioral scale in text. (e) The frequency of FPI-induced seizures is time dependent. (f) Also the duration of FPI-induced seizures increases over time post-injury. (g) 2–3 weeks post-injury, grade 1 seizures are the most common seizure type, but their proportion progressively decreases over time. Conversely, grade 2 and especially grade 3 seizures are rare in the early weeks post-injury, but progressively increased over time becoming the most common seizure type 7 months post-injury. These data show that the probability of seizures spreading bilaterally increases over time and that epilepsy worsen over time post injury. Data are shown as mean ± S.E.M. (d–g) are modified with permission from D'Ambrosio *et al*. (Brain 2005, 128: 174–188).

Future Goals

The Model Needs Optimization and Standardization

The two groups working with this model have reported remarkably similar findings – in particular, the observation of CRSPSs and their progressive worsening over time. However, they also observed significant differences. One group observed progressive neocortical and hippocampal electrical and behavioral partial seizures without tonic–clonic convulsions, while the other observed only hippocampal seizures accompanied by tonic–clonic convulsions. The different electrical and behavioral correlates of PTE reported by the two laboratories probably reflect differences in their experimental approach, including the genetic background of rat colonies, the age of the animal at the time of the injury, the location/extent/degree of injury, and anesthesia employed. Indeed, while one group employed rostral-parasaggital FPI performed through a 3-mm craniotomy on 1-month-old rats, the other employed caudal-parasaggital FPI performed through a 4.8-mm craniotomy on 2.5-month-old rats. These differences require further study and suggest the need for standardization of the model before it can be used confidently as a preclinical investigative tool. However, these differences also greatly enhance the potential value of, and the enthusiasm for, the FPI-induced epilepsy model. Indeed, human PTE is also very heterogeneous, manifesting itself as complex partial seizures with a variety of behavioral and electrical correlates that likely depend on the type, degree, and location of the injury; the age of the patients at the time of injury; and their genetic backgrounds.

Models of FPI-induced epilepsy have only recently been developed, and therefore, we expect that a certain period of time will be needed for protocols to be optimized. For example, in our initial studies we induced FPI by delivering injuries at 3.5–4 atm, which resulted in 33% acute mortality. That was in itself not objectionable, because it compared favorably with the mortality obtained with the pilocarpine protocol used by many laboratories studying epileptogenesis. However, after further tests, we determined that injuring the animals at exactly 3.25 ± 0.1 atm resulted in only 11% acute mortality, and resulted in comparable seizure frequency. Two other variables that need to be studied are the location and degree of injury on the type and severity of FPI-induced epilepsy.

FPI-Epilepsy Should be Adapted to the Mouse

The development of a murine model of genuine CSRPSs would be of tremendous help in epilepsy research. The use of genetically engineered mice would allow the investigation of genetic factors – such as apolipoprotein E epsilon-4 allele, haptoglobin Hp2–2 allele, or IL-1β (511) allele 2 – that predispose the posttraumatic brain to the later development of PTE. In addition, it would allow investigators to further assess the relevance of specific cellular mechanisms of epileptogenesis and seizure progression. For example, recent elegant work has shown that conditional deletion of TrkB, the receptor for brain-derived neurotrophic factor, prevents epileptogenesis in the kindling model. However, it is not known what role TrkB might play in more relevant models of human PTE such as FPI-induced epilepsy.

Reliable Automatic Seizure Detection is Currently Lacking

Another area that requires further development to make the best use of FPI-epilepsy – and of similar models of epilepsy that could be used for drug discovery – is computerized EEG analysis for automatic seizure detection. Animals must be monitored for prolonged periods of time, and the problem of mining for seizures in such large datasets is considerable. This issue has generally not been critical in past studies of epilepsy-related mechanisms in animal models, as investigators have been primarily focused on evaluating drug effects relative to acute and/or behavioral correlates of severe seizures. These effects are easier to identify/measure because they tend to be stereotyped and obvious in a video played at fast-forward speed. However, detection of seizures in the EEG, and especially counting seizures that may have subtle behavioral correlate (i.e., behavioral arrest) is much more difficult. In the absence of software to automate such work, seizures must be found by manual analysis of the ECoG, which is exceedingly time consuming and expensive. In our laboratory, primary manual analysis of 24 h of continuous rat ECoG takes approximately 1.5 h.

Conclusions

The recent discovery that FPI, a relevant model of concussive closed head injury, induces PTE in the rat opens new research horizons in the study of clinically relevant mechanisms of acquired epileptogenesis. FPI is the model of acquired epilepsy that provides the greatest similarity to the human condition. As such, it is the model that offers the greatest opportunity for identifying mechanisms of posttraumatic epileptogenesis that are clinically relevant. We believe that it will be an important aid in the search for new antiepileptic drugs and for the first antiepileptogenic agents as it probes mechanisms of epileptogenesis that are likely to be closely related to epileptogenic mechanisms in humans. However, as always occurs when a new model is first introduced, an extensive characterization of its features is necessary to optimize its use. Furthermore, development of algorithms and software for computerized seizure detection will greatly facilitate the

analysis of data obtained with the FPI-induced epilepsy model, as well as with any other model of CRSPSs.

Introduction

Traumatic brain injury (TBI), according to the World Health Organization, will surpass many diseases as the major cause of death and disability by the year 2020. With an estimated 10 million people affected annually by TBI, the burden of mortality and morbidity that this condition imposes on society makes TBI a serious public health and medical problem. TBI accounts for 20% of symptomatic epilepsy in the general population and 5% of all epilepsy. Posttraumatic epilepsy refers to the occurrence of late seizures (1 week or longer after the injury), and the latency from injury to appearance of epilepsy may be many months or years.

Clinicians involved in the regular care of patients with epilepsy know that posttraumatic epilepsy is an extremely disabling condition. These patients are frequently pharmacoresistant and are often not good surgical candidates. Traditionally, TBI patients have been treated with a prophylactic anticonvulsant – that is, an antiepileptic drug (AED) – with the expectation that treatment will reduce the incidence of posttraumatic epilepsy. The results of trials with AEDs as antiepileptogenic agents have been very disappointing. Nevertheless, the long latency period between the initial insult and the occurrence of chronic spontaneous seizures raises the possibility of designing preventive – that is, antiepileptogenic – therapies for susceptible individuals after serious head trauma.

The challenge of translating discoveries at the cellular and molecular level to an effective antiepileptogenic therapy requires an appropriate animal model. Also, studies on posttraumatic epileptogenesis would greatly benefit from surrogate markers that may serve to denote risk for future epilepsy. Such markers would be useful for the timely identification of key points in the epileptogenic process that would be amenable to intervention. Targets for the prevention of epileptogenesis most likely change as the process proceeds, so that appropriate targets at one

Introduction

Traumatic brain injury (TBI), according to the World Health Organization, will surpass many diseases as the major cause of death and disability by the year 2020. With an estimated 10 million people affected annually by TBI, the burden of mortality and morbidity that this condition imposes on society makes TBI a serious public health and medical problem. TBI accounts for 20% of symptomatic epilepsy in the general population and 5% of all epilepsy. Posttraumatic epilepsy refers to the occurrence of late seizures (1 week or longer after the injury), and the latency from injury to appearance of epilepsy may be many months or years.

Clinicians involved in the regular care of patients with epilepsy know that posttraumatic epilepsy is an extremely disabling condition. These patients are frequently pharmacoresistant and are often not good surgical candidates. Traditionally, TBI patients have been treated with a prophylactic anticonvulsant – that is, an antiepileptic drug (AED) – with the expectation that treatment will reduce the incidence of posttraumatic epilepsy. The results of trials with AEDs as antiepileptogenic agents have been very disappointing. Nevertheless, the long latency period between the initial insult and the occurrence of chronic spontaneous seizures raises the possibility of designing preventive – that is, antiepileptogenic – therapies for susceptible individuals after serious head trauma.

The challenge of translating discoveries at the cellular and molecular level to an effective antiepileptogenic therapy requires an appropriate animal model. Also, studies on posttraumatic epileptogenesis would greatly benefit from surrogate markers that may serve to denote risk for future epilepsy. Such markers would be useful for the timely identification of key points in the epileptogenic process that would be amenable to intervention. Targets for the prevention of epileptogenesis most likely change as the process proceeds, so that appropriate targets at one

point may not be relevant at another. Many other issues need to be addressed, including such questions as: What are the risk factors for eventual development of posttraumatic epilepsy? When are these risk factors sufficiently clear and of high enough predictive value to warrant treatment with potentially deleterious drugs? What are the critical and realistic time points for these risk factors to be detected clinically? The importance of preclinical studies in animal models of PTE, to address these questions, cannot be overestimated. Useful laboratory data must be based, however, on the development and study of clinically relevant animals models – so that anatomic, biochemical, cellular, and molecular components of the posttraumatic epileptogenic process can be understood.

Background

Clinical research to date has defined a clear relationship between the severity of TBI and the development of posttraumatic epilepsy. Severe brain injuries with focal intracranial lesions, skull fractures, or prolonged alteration in consciousness are the most important risk factors for the development of posttraumatic seizures. Other important factors include bilateral contusions, subdural hematoma with surgical evacuation and acute intracerebral hematoma, multiple intracranial procedures, and midline shift (over 5 mm). Focal seizures are the most common type diagnosed. According to human studies, up to 56% of patients with PTE present with temporal lobe epilepsy. Seizures arise from frontal lobes in 36% of patients, while cases of parietal and occipital seizure focus are relatively rare (5% and 3%, respectively).

The multiple pathological consequences of TBI include primary damage from direct shearing, laceration or contusion of brain tissue by bone fragments or foreign bodies, hemorrhage, and diffuse axonal and vascular injury. Also, secondary damage may be caused by hypoxia-ischemia, edema, and breakdown of the blood–brain barrier. Epileptogenesis develops simultaneously with the progress of secondary injury and posttraumatic recovery. From the point of view of developing clinically relevant models, disease heterogeneity presents a real challenge; indeed, simulating all aspects of human TBI with any one single animal model may be an impractical goal. Given the great variation in the nature of TBI, it is not surprising that a number of different models – ranging from mechanical trauma to individual neurons in culture to acceleration–deceleration injury in nonhuman primates – have been developed to study basic mechanisms of head injury. Several animal models have been used to elucidate the structural, chemical, and physiologic changes that are associated with TBI and that may contribute to seizures and epilepsy.

On the basis of our current understanding of the factors that contribute to the development of epilepsy, the following characteristics have been suggested for an ideal animal model: (1) mechanisms consistent with those of human epilepsy, (2) existence of latent period between the initiating insult and expression of behavioral seizures, (3) spontaneous seizures as a final result of the functional and structural reorganization that occurs during the latent period. The remainder of this article reviews the three TBI models in which chronic epilepsy, or permanent hyperexcitability, has been consistently reported after the initiating brain insult (**Table 1**).

Methodology and Summary of Results

Hemorrhage-Iron Deposition (A Model of PTE Caused by Blood–Brain Barrier Damage Associated with TBI and Extravasation of Blood with Iron Deposition)

Hypothesis of action

Head injury with contusion, cortical laceration or intracerebral hematoma formation results in extravasation of

Table 1 Occurrence and characteristics of posttraumatic epilepsy in different animal models as compared to humans

*According to the experiments performed in neocortical slices

blood and breakdown of red blood cells and haemoglobin. Hemolysis and deposition of iron compounds (such as hemosiderin) within brain tissue is a common finding in cortical tissue samples of patients with drug-refractory PTE and a cortical seizure focus. Moreover, according to human imaging studies, the occurrence of PTE is significantly correlated with the evidence of acute intracerebral hematoma, and hemorrhagic contusions with a gliotic wall incompletely surrounding hemosiderin dregs present a risk factor for PTE.

Subpial or amygdalar injection of ferrous/ferric chloride is suggested to mimic the harmful effects of iron after parenchymal hemorrhage. Iron liberated from haemoglobin, and haemoglobin itself, are associated with the generation of reactive oxygen species (ROS) and reactive nitrogen species (RNS). ROS, especially ·OH, induce peroxidation of unsaturated fatty acids that are components of neuronal membranes, and also cause alterations in excitatory and inhibitory neurotransmitters, presumably leading to epileptogenicity.

Cortical iron injection

In a model of PTE developed initially by Willmore and colleagues, a Ø1 mm burr hole was made in the calvarium over the left sensorimotor cortex of a rat (1.5 mm rostral and 3.5 lateral to bregma). A 30-gauge needle attached to a microinjection syringe was inserted into the cortex 1.2 mm below the exposed dura, and 5 µl of aqueous solution containing 100 mM $FeCl_2$ or $FeCl_3$ was injected (over a 5 min period). In cats, 10 µl of aqueous solution of iron salts was injected into the left postcruciate gyrus or left posterior sigmoid gyrus. Cortical electroencephalographic recordings were made daily for 1 week and weekly thereafter for 3 months.

Findings

Isolated spikes appeared in EEG almost immediately after the iron injection, and by 24 h the majority of animals displayed isolated spike- or sharp-wave discharges or sustained bursts of focal spike-wave activity ipsilateral to injection site. Between 48 h and 5 days after injection, 96% of iron-injected animals had frequent and sustained bursts of high amplitude polyspike discharges on the ECoG. Interestingly, 22% of control animals (injected with 0.9% NaCl acidified to pH 1.5 with hydrochloric acid to equal the pH of the solutions of iron salts) also exhibited focal ECoG spike activity during the first 14 days. In iron-injected animals, epileptiform activity originated on the injection side and spread contralaterally. Occasional behavioral convulsions and electrographic seizures were reported at later time-points.

To determine whether this epileptiform activity lasts beyond a 3 months time-point, (i.e., can be considered chronic iron-induced epilepsy), a more extensive ECoG study was performed by Moriwaki and colleagues with the same model. Three-hour long recordings were started immediately after the completion of surgical procedures, and thereafter repeated 3 times a week for 12 months. In the period starting immediately after injection and lasting for the next 30 days, isolated spikes were recorded that increased in frequency. After 30 days, spike-and-wave complexes (200–1000 µV, 7–10 Hz) appeared, and this activity was sustained until the end of experiment in 28–38% of injected animals, accompanied with head nodding and vibrissae tremors. No full-blown electrographic seizures have been reported.

Later the procedure was modified by Ueda, Willmore and colleagues, and amygdalar $FeCl_3$ injections were used to create lymbic-type seizures in rats. Animals were injected in the right amygdaloid body (3.3 mm posterior, 5.0 mm lateral to bregma, and 8.5 mm below the skull surface) with a silica tube connected to the microinjection pump. The silica tube was positioned inside a 22-gauge guide canula, and 1–1.5 µl of 100 mM $FeCl_3$ was injected over a 1.5 min period. Following the injection, EEG recording and behavioral observations were obtained daily for 10 days and then every 5 days for the 30 days of the experiment. Acute injection of $FeCl_3$ into the amygdala caused a gradual increase in spikes over 20 min, followed by normalization of EEG pattern by the end of the 30 min recording. From 7 to 30 days after injection, spontaneous stage 4 (rearing and forelimb clonus, according to Racine) behavioral and electrographic seizures were observed in 92% of animals. Seizures started from the amygdalar regions (basolateral nucleus of the left amygdaloid body) and rapidly propagated to the hippocampal electrodes (**Figure 1(a)**).

Histologic analysis 6 weeks after cortical iron injection revealed a narrow 0.5 mm cavity at the site of injection, extending through all layers of the isocortex, with ferric-cyanate complexes in macrophages within the lesion. Neuronal loss and astrogliosis were observed within the depth of the injection site, and pyramidal neurons in lamina V beneath the injection site stained with iron-cyanate particles. Neurons adjacent to the lesion cavity showed deformity of dendrites, dendritic nodularity and loss of spines. After $FeCl_3$ injection in amygdala, histopathologic changes were reflected by mossy fiber sprouting and cell loss in the hilus and CA1 region of the hippocampus of animals with spontaneous seizures. Aspartic acid, glutamic acid and γ-aminobutyric acid levels were reported to decrease transiently after the injection of ferric chloride in the rat brain. The in vivo antioxidant capability of the dorsal hippocampus was reported to decrease significantly bilaterally in animals with $FeCl_3$-induced seizures. The expression of hippocampal GABA transporter protein GAT-1 and GAT-3 (which remove GABA from the synaptic cleft and terminate the synaptic effect of this neurotransmitter) increased bilaterally at 5–15 days after injection; GAT-1 returned to control levels by 30 days and GAT-3 remained elevated up

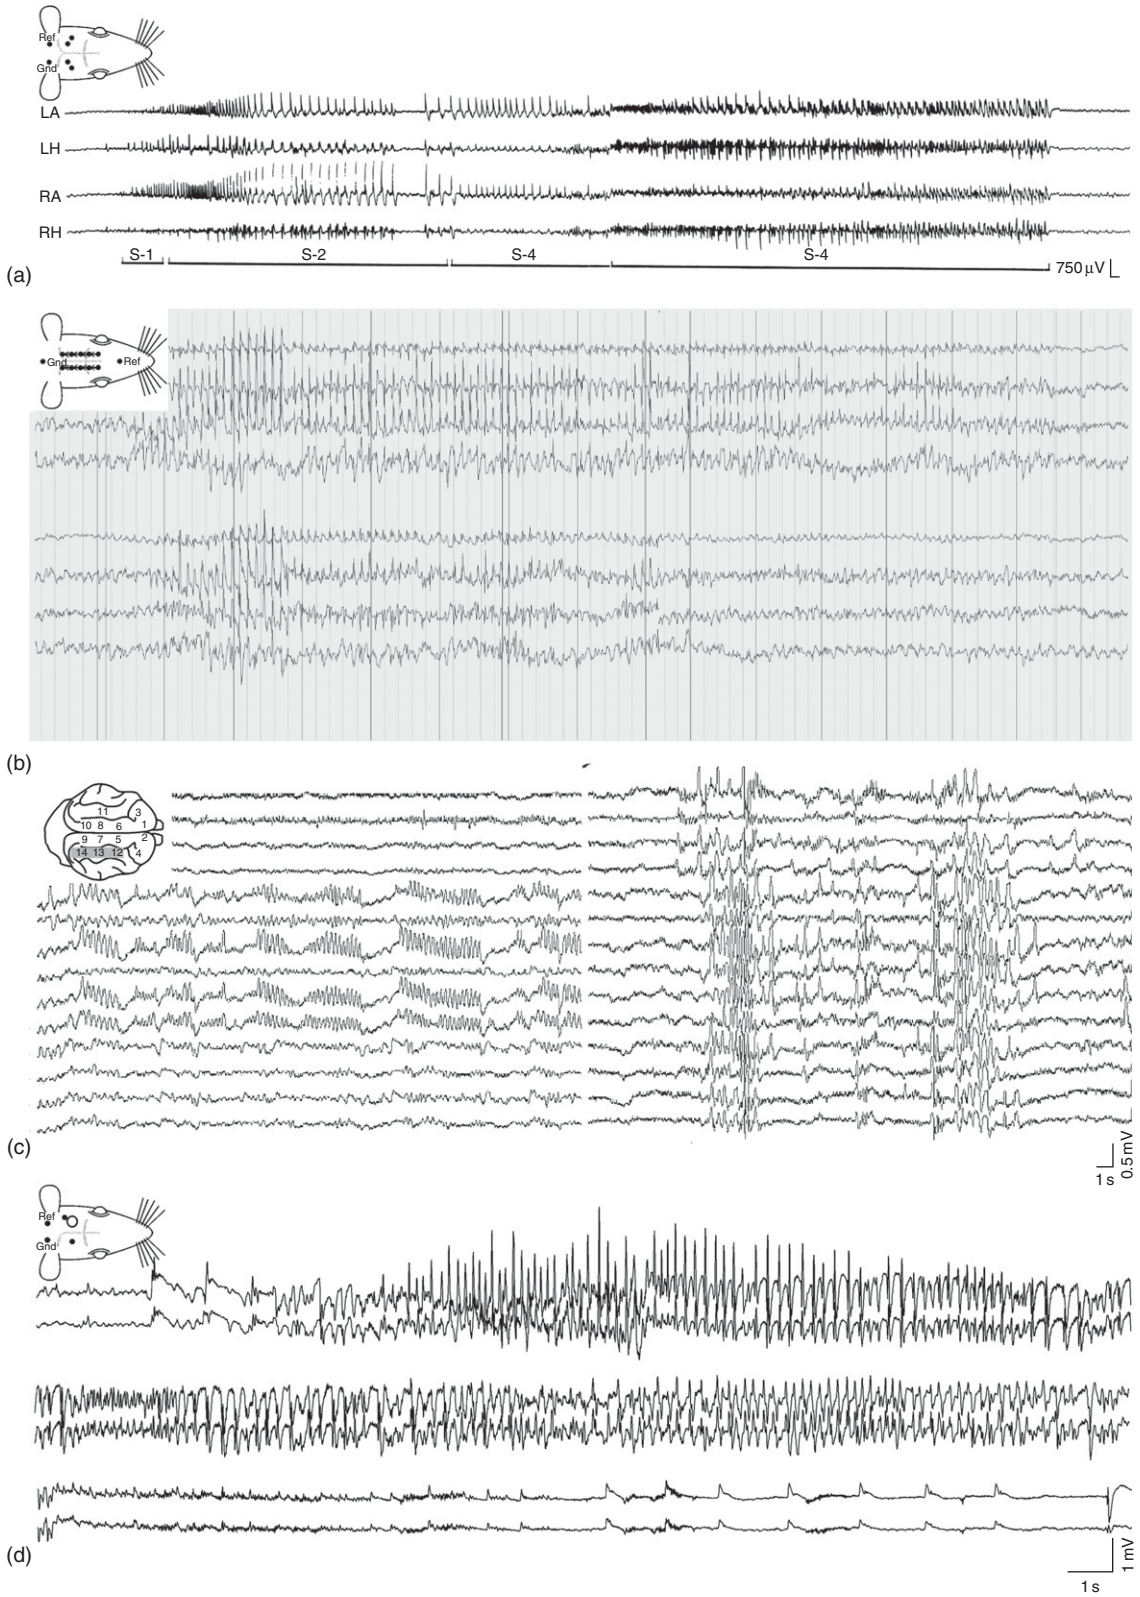

Figure 1 Representative EEG fragments showing ictal episodes in each of the models of post-traumatic epilepsy. (a) Amygdalar ferric chloride injection. Spontaneous electrographic seizure in an 8-week old Sprague–Dawley rat recorded 15 days after the injury. Electrographic ictal event lasted 120 s and was accompanied by a generalized behavioral seizure, progressing from score 1 (S1) to score 4 (S4), according to Racine scale). Recording electrodes bilaterally in the amygdala (LA–RA) and hippocampus (LH–RH). (b) Chronic partial cortical isolation in rat. Seizure in a 4-month old Sprague–Dawley rat recorded ~3 months after surgery. Seizure

to 60 days. The glutamate–aspartate transporter protein GLAST, which limits excitation initiated by synaptic release of glutamate, was upregulated in the hippocampus 5 days after iron injection, but decreased chronically at 15–60 days post-injection, when animals experienced spontaneous seizures. The authors suggested that the failure to remove synaptic glutamate may underlie the process of posttraumatic epileptogenesis. The immunoreactivity of another glutamate transporter, EAAC-1, peaked at day 5 after the iron injection and remained elevated from 15 to 30 days.

Several antiepileptic drugs have been tested over the years (1984–2007) in the iron-injection model. Valproate treatment administered for 14 days after amygdalar iron injection caused the downregulation of the two GABA transporters, GAT-1 and GAT-2, in the hippocampus, as well as a marked increase in the production of GLAST. Similarly, clobazam, levetiracetam, and zonisamide treatment administered for 14 days after iron injection suppressed glutamate neurotransmission by upregulating the levels of glutamate transporter proteins, enhanced GABAergic inhibition by downregulation of GABA transporters, and suppressed spontaneous seizures in a significant number of injected animals. Pretreatment with α-tocopherol in combination with selenium, 90 mg kg^{-1} methylprednisolone and natural antioxidant TJ-960 prevented histopathologic changes caused by iron injection and suppressed epileptiform discharges in EEG.

Caveats

Compared to human PTE, with a latency period lasting from months to years, in iron-injected animals the epileptiform activity developed soon after injection, without a clearly defined latency period. Ictal activity developed in 92–96% of animals, as opposed to a maximum 53% of human subjects with severe head injury. Further, according to clinical imaging studies (GE T2*-weighted MRI) in patients with isolated hemosiderin deposits as the sole MRI finding, occurrence of PTE is very low. EEG monitoring during the extended period of follow-up would be useful to detect and quantify the occurrence of chronic spontaneous seizures beyond the subacute (2 weeks) period.

Cortical Undercut (A Model of PTE Caused by Penetrating Cortical Injury)

Hypothesis of action

Axotomy of cortical outputs of neurons, as well as their cortical and subcortical inputs, disruption of intracortical inhibitory and excitatory circuitry, and neurodegeneration occur as a result of a direct cortical injury produced by a stab wound. These features are proposed to be the anatomic substrates that underlie the development of hyperexcitability in the cortical undercut model.

Data from human cortical slabs isolated at the time of surgery have demonstrated that the deafferented cortical tissue can display paroxysmal high-voltage activity shortly after isolation. A computational model of posttraumatic epileptogenesis in isolated cortical islands concluded that paroxysmal discharges are due to changes in intrinsic properties of pyramidal cells and enhanced NMDA synaptic conductances, without reduced (or even in the face of increased) inhibition.

Partial cortical isolation in rats

The procedure designed by Graber and Prince is currently performed in the rats 1–5 weeks of age. A rectangular (4 × 8 mm) craniectomy is made over one hemisphere with a medial edge ≥1 mm away from the midline, to avoid damage to the superior sagittal sinus. Underlying dura, pial vessels, and cortical surface are kept intact. Almost any cortical region can be chosen for partial isolation, but sensorimotor cortex is most commonly selected one. For this procedure, the bone window is centered over the coronal suture. A 30-gauge needle is bent to 90° at 2–3 mm from the tip; the needle is inserted through the dura and under the pia, so that the bent distal end of the needle is parallel to the pial surface. The needle is then pushed down through all cortical layers (2 mm), rotated 180° and carefully removed through the point of insertion.

Findings

Digital video-EEG recordings show brief (10 s) 10 Hz spike-wave ictal discharges arising from the posterior part of the partially isolated cortex (**Figure 1(b)**), accompanied by freezing, slight rising of the head, followed by head-drop and return to normal exploratory activity.

lasted ~10 s and was accompanied by arrest of movement and eye blinking followed by the head drop at the end of the ictal activity. Generalized motor seizures have not been reported in animals with undercuts, supposedly because most of the connections to other brain areas are limited by the lesion. (c) Cortical undercut in cat. Ictal events recorded over the cortical surface at day 5 and day 45 during the waking state. Recordings in a cat with deafferented left suprasylvian gyrus (depicted as a grey box on the schematic drawing) indicate that paroxysmal activity is present initially in the cortical areas adjacent to the deafferented cortex, and shows a tendency toward generalization at later time-points. Electrographic ictal events were associated with ocular movements at the beginning and end of the discharge. Recording electrodes bilaterally over surpasylvian gyrus, marginal gyrus. (d) Lateral fluid percussion. Spontaneous electrographic seizure recorded in a Sprague–Dawley rat 9 months after the injury. Electrographic ictal activity lasted 49 s and was accompanied by generalized score 4 (modified Racine scale) seizure, i.e., forelimb clonus and rearing. Recording electrodes in the ventral hippocampus ipsilateral to injury and contralateral parietal cortex. The insert in the left upper corner of each panel shows location of the electrodes. Courtesy of Dr. Willmore and Dr. Ueda (a), Dr. Prince (b), Dr. Timofeev (c).

Generalized motor seizures or full-blown electrographic seizures have not been described in this partial cortical isolation model in rats. Electrophysiological characterization of brain slices prepared from the injured region has shown hyperexcitability 10–14 days following the isolation and not earlier. Hyperexcitability lasted up to 122 days. Transcortical rather than undercut lesions seem to be critical for the development of hyperexcitability. The combination of these two lesions, however, produces slices that are more excitable than those with tanscortical lesions alone. Epileptiform potentials arose from layer V. Furthermore, layer V pyramidal neurons displayed increased input resistance and membrane time constants, and appeared to be the source of sprouted axons that were associated with an increased number of excitatory connections. Targets of sprouted axons included both other pyramidal cells in layer V and inhibitory interneurons. Immunocytochemical labeling for parvalbumin and calbindin, (calcium binding proteins present in subgroups of GABAergic neurons), as well as for GABA itself (or neuropeptide Y) has demonstrated an increase in the number of immunoreactive inhibitory interneurons. Layer V pyramidal neurons have shown a decreased capacity to maintain normal Cl^- gradients during intense firing, due to downregulation of KCC2 transporter; this change would decrease the efficacy of GABA inhibition during epileptiform activity. Neurofilament immunoreactivity was highly increased in both pyramidal neurons and interneurons, consistent with substantial reorganization induced by injury; c-fos immunoreactivity also increased, likely indicating early postinjury molecular alterations. Investigators have shown that hyperexcitability could be blocked when tetrodotoxin (TTX), a voltage-dependent sodium channel blocker, was placed subdurally over the lesion immediately following injury in vivo. TTX treatment started at the time of injury (or with a maximum 3-day delay), and lasting for at least 3 days, was effective against the subsequent development of hyperxcitability after the silent period. Treatments of shorter duration were ineffective, indicating the presence of a critical period for development of epileptognesis. Finally, it was shown that uptake of glutamine (immediate precursor of synaptically released glutamate) was increased in the slices from injured cortex compared to control slices, and this difference was caused by increased expression of the system A transporters SNAT1 and SNAT2; these results suggest that glutamine metabolism and system A transport would be potential targets for pharmacological intervention in posttraumatic epilepsy.

Caveats

Further investigations with a long term video-EEG monitoring would help to elucidate whether the development of hyperexcitability in partially isolated cortex is later followed by the occurrence of chronic spontaneous seizures – a hallmark of posttraumatic epilepsy.

Partial cortical deafferentation in cats

In the procedure designed by Steriade, Timofeev, and colleagues, the undercut cortex is produced by large white matter transections below the suprasylvian gyrus (posterior–anterior, 13–15 mm; medio-lateral, 3–4 mm; depth 3–4 mm). A knife is inserted into the posterior part of the suprasylvian gyrus perpendicular to its surface, rotated 90° and advanced rostrally along the gyrus – parallel to its surface – for 13–15 mm, then moved back, rotated 90° and removed (from the same spot at which it entered the cortex). By transecting the white matter below the posterior part of the gyrus, partial cortical deafferentation is created by disruption of thalamocortical projections. Field potential (EEG) recordings were obtained with an array of 7–8 monopolar electrodes located 2.5 mm apart along the whole length of suprasylvian gyrus at a depth of 1.5 mm. Intracellular recordings were obtained from the partially deafferented and relatively intact areas of the suprasylvian gyrus. Importantly, all the recordings were performed under ketamine–xylazine anesthesia (10–15 and 2–3 mg kg^{-1} i.m., respectively), which is thought to best mimic the slow sleep oscillation during natural slow-wave sleep in experimental animals.

Findings

In the acute experimental period (immediately after – to 10 h post injury), the EEG activity in the partially deafferented cortex remained markedly decreased up to 1–2 h. Between 2 and 3 h after the undercut, in 60–75% of animals, EEG recovered to the pattern of 'normal' slow oscillation with absence of spindles at deafferented sites. The remaining 25–40% of animals demonstrated paroxysmal-like activity (high amplitude slow waves, spikes, sharp waves) or clear-cut electrographic seizures (spike-wave and polyspike-wave complexes at 2–3 Hz and fast runs at 10–15 Hz). Electrographic seizures were initiated in the intact postcruciate gyrus and $\sim$ 7 s later appeared in the undercut cortex. Seizures lasted 5–50 s (average 17.0 ± 3.3 s), and such paroxysmal activity could last from 1 to 5 h within an experiment. It was shown that increase in the synchrony toward the end of seizures induced larger neuronal depolarization, which activated Ca^{2+}-dependent K^+ currents and terminated seizures.

In the subchronic experimental period (week 1 to week 5 after the injury), Nita and colleagues showed that more than 90% of injured animals displayed 3–4 Hz spike-wave and polyspike-wave complexes intermingled with fast (10–20 Hz) runs, which were described as similar to the patterns found in patients with severe epileptic encephalopathies. Electrographic seizures re-appeared at the border of intact and undercut cortex; with time, paroxysmal activity involved neighbouring cortical regions, until

finally (at about 4–6 weeks after the undercut) epileptiform discharges were recorded in all electrodes. These investigators concluded that following the undercut, the neocortex displays progressively increased signs of paroxysmal activity, expressed by gradually enhanced amplitudes and synchrony of spike-wave complexes. Interestingly, with barbiturate anesthesia, seizures did not develop – neither in the acute nor in the chronic phase – but enhanced activity (isolated spikes and epileptiform discharges merged with spindles) was observed in areas surrounding the undercut cortex.

Recently, the relation between paroxysmal activity in the deafferented cortex and natural state of vigilance in chronically implanted cats was investigated by the same group. Out of six animals studied, three displayed small localized muscular jerks and abnormal tail wagging during the waking state, and 1 cat had a generalized tonic–clonic seizure. EEG recordings were performed from day 5 to day 120 after the injury. Ictal events on EEG were observed in all recorded animals and consisted of 3–4 Hz spike-wave complexes of 5 s duration (**Figure 1(c)**), occurring intermittently in waking state when they were associated with eye movements. Initially, paroxysmal events were exclusively present over areas around the undercut cortex. During later stages (30–40 days), there was a tendency toward generalization over the whole cortical surface. Ictal events in the waking state were quantified based on 3-min recordings (day 4–day 120). The number of ictal events increased during the first 2 weeks, followed by a 30% decrease between days 20–40, and then a secondary increase that reached a plateau (75% of the initial number) after day 40. The intermittent ictal events observed during the waking state became almost continuous during slow wave sleep, and were completely absent during the REM sleep. These investigators suggested that an increase in intrinsic and synaptic excitability of intact neurons in areas adjacent to the undercut cortex is sufficient for the generation of electrographic paroxysmal activity.

Caveats

A possible major role of ketamine–xylazine anesthesia (which is known to favor the development of seizures) must be considered. Further, slow wave sleep is considered a potent activator of epileptiform discharges, as seen also in humans. Long lasting (days) EEG recordings in control animals maintained under ketamine–xylazine would help to rule out the possibility of spontaneous occurrence of spike-wave/polyspike-wave complexes during slow wave sleep. It is of interest that the electrographic seizures were found only in animals that showed propagation of the slow sleep-like oscillation in control conditions. Latency to seizures (2–3 h following the injury) should also be taken into consideration, as it is much shorter than latency period observed in humans with PTE.

Both the cortical undercut model and partially isolated cortex model produce very focal, limited cortical lesion – as opposed to human penetrating head injury where the damage is usually more diffuse and multifactorial. Cortical stab wounds are relatively rare clinical precursors of PTE.

Fluid Percussion Brain Injury (FPI) (A Model of PTE Induced by Closed Head Injury in Humans)

Hypothesis of action

FPI is the most widely used and investigated model for human closed head injury. As shown in multiple studies, lateral FPI is capable of inducing cortical contusion as well as intracerebral and subdural hematomas in rat brain – the features that are associated with the increased risk of PTE. At the cellular level, lateral FPI causes hippocampal sclerosis and reactive gliosis, and alters neurotrophin and ROS levels in the hippocampus – that is, all neurobiologic processes which are thought to be associated with secondary injury, circuitry reorganization and possibly epileptogenesis. These data suggest that the model of lateral fluid percussion brain injury offers the neuropathophysiological features that reproduce the complex mechanisms of human PTE.

In 1992, Lowenstein and colleagues showed that selective loss of hilar interneurons in the dentate gyrus is associated with abnormal hyperexcitability of the dentate granule cells, as measured by extracellular field potentials in response to paired-pulse stimulation of the perforant path. Later, Coulter and colleagues conducted in vitro electrophysiological studies with combined hippocampal-entorhinal cortical slices from rats with FPI. They demonstrated that slices from injured rats showed greater disinhibition in the dentate gyrus and CA1 subfield of the hippocampus (compared with slices from control rats) and that 86% of the slices generated self-sustaining epileptiform activity after stimulation of Schaffer collaterals (the main afferent input from CA3 to CA1 pyramidal neurons). Toth and colleagues next showed that the number of parvalbumin- and cholecystokinin-positive dentate interneurons, supplying inhibitory innervation of granule cells, was decreased months after FPI. Subsequently, Santhakumar and colleagues showed that hilar interneuron loss was not preferential compared to non-GABAergic hilar cells (i.e., mossy cells) and suggested that the surviving glutamatergic mossy cells play a critical role in the hyperexcitability of the dentate gyrus after TBI. Later, the same investigators discovered a long-term persistent hyperexcitability of CA1 pyramidal cells in response to Schaffer stimulation. However, critical evidence that the model actually can cause development of chronic spontaneous seizures was missing until recently.

Lateral fluid percussion brain injury (Originally designed by McIntosh and colleagues)

In our laboratory, preparation of the animal involves a 5 mm diameter craniectomy over the left parietal cortex with preservation of dura mater. The center of the craniectomy is located half way between bregma and lambda, with the lateral edge of the craniectomy adjacent to the left lateral ridge. A rigid plastic cap, cut from a female Luer–Loc needle hub, is carefully inserted into the hole over the intact dura and sealed to the skull with the Vetbond glue. The 'injury cap' is filled with 0.9% saline to check the quality of the seal and to prevent drying of dura. The injury cap is then cemented onto the skull with dental acrylic. The animal is then ready for the FPI insult. There is a 90 min interval between the anesthesia preceding surgical manipulations and the injury, to allow for the anesthetic (a single i.p. injection of a mixture containing sodium pentobarbital and chloral hydrate) to dissipate. The fluid percussion injury device consists of a plexiglass cylindrical reservoir filled with isotonic saline and bound at one end by a cork-covered plexiglass piston. The other end of reservoir is fitted with a metal housing which terminates with a male Luer–Loc fitting. The animal is connected to this fitting via the injury cap mounted on its head. A metal pendulum is released from a predetermined height and strikes the cork piston. As a result, the fluid pressure pulse propagates through the cylinder and impacts on the intact dura (without penetration), which is considered to recapitulate the effects of closed head injury in humans. The impact has brief (21–23 msec) duration, and the force is adjusted to 2.9–3.2 atm to induce severe lateral fluid percussion brain injury (which is assumed to maximize the likelihood of posttraumatic epilepsy). Pressure pulses are measured extracranially by a transducer mounted on the metal housing. One week after the injury, animals are implanted with a depth hippocampal electrode ipsilateral to injury, and two cortical screw electrodes bilaterally over the parietal cortex.

Findings

Chronic (11 months) continuous video-EEG monitoring demonstrated the occurrence of posttraumatic epilepsy in 43–50% of injured animals during the course of follow-up; this percentage is similar to that in humans with severe TBI. In addition, the absence of PTE in about half the impacted animals allows the investigators to compare animals (epileptic rats with those which fail to develop epilepsy after the traumatic insult) for mechanisms of posttraumatic epileptogenesis. In the PTE animals, the latency period varied from 4 weeks to 11 months, and the number of epileptic animals increased gradually over time. Behavioral seizures also worsened with time in individual animals, from partial to secondarily generalized (mean score 3.3 ± 1.4 according to the Racine scale). The electrographic seizure activity was detected first by the hippocampal electrode located ipsilateral to the injury site, and then spread rapidly to the contralateral cortex. Electrographic seizures were represented by high amplitude rhythmic discharges containing spikes, polyspikes, slow waves and spike-wave complexes, which had a clear onset, temporal evolution in amplitude, and frequency, and were followed by postictal depression (**Figure 1(d)**). Mean seizure duration was 113 ± 46 s, and mean seizure frequency, 0.3 ± 0.2 seizures per day. There was a tendency towards increased seizure frequency in individual animals during the course of follow-up observations. Interictal activity was presented with isolated spikes or spike-wave discharges in the hippocampus ipsilateral to injury.

Animals had bilateral hippocampal damage, but neuronal loss was more substantial ipsilateral to injury, and included hilus, CA1, and CA3. The extent of TBI-induced neuronal loss in the hilus of the dentate gyrus did not correlate with the occurrence of posttraumatic epilepsy. Both injured hippocampus and thalamus showed substantial atrophy and shrinkage compared to the contralateral side. Subicular complex and enthorhinal cortex also underwent neurodegenerative changes. Further, while all experimental animals demonstrated mossy fiber sprouting in the injured (ipsilateral) dentate gyrus, the extent of synaptic reorganization in rats with epilepsy was more pronounced than in those animals with TBI but no epilepsy. In contrast to nonepileptic rats, mossy fiber sprouting in epileptic animals was bilateral. These results suggest that TBI-induced hippocampal injury and synaptic reorganization do not necessarily lead to epilepsy. Long-term MRI studies (T2, volumetry) performed in this model confirmed a progressive cortical and hippocampal pathology lasting over 8 month period, as well as atrophy of thalamus. Diffusion weighted imaging revealed an early (3 h post-injury) diffusion drop in the hippocampus ipsilateral to injury, similar to that previously described in human TBI. This early drop in diffusion, and subsequent increase at 23 days to 3 months post injury, showed significant correlation with increased susceptibility to seizures 1 year after the injury – suggesting that diffusion weighted imaging at early and subchronic time-points after traumatic brain injury can provide a potential surrogate marker for subsequent development of posttraumatic epilepsy.

Caveats

Despite close approximation to the clinical syndrome of human PTE, several methodological features – e.g., lack of uniformity in the precipitating insult, high levels of acute mortality after the injury, slow progression of disease, and low seizure frequency – represent a challenge in seizure monitoring and use of this protocol for the evaluation of efficacy of therapeutic intervention.

PTE in juvenile rats

D'Ambrosio and colleagues recently induced rostral lateral FPI in juvenile male Sprague–Dawley rats at

postnatal day 32–35. The center of the 3-mm diameter burr hole was located 2 mm posterior to bregma and 3 mm lateral to midline. Thus, the lesion was more rostral and medial than the lesion produced by lateral FPI in adult rats. A fluid pressure pulse of 3.75–4 atm was applied.

Findings

Intermittent extended video-electrocorticography (EcoG) with epidural electrodes demonstrated partial seizures originating in the neocortex proximal to the lesion site, with or without secondary generalization. The majority (60%) of animals displayed electrographic epileptiform activity within the first 2 weeks post injury. Nine weeks post injury, epileptiform activity was present in 100% of animals. Ictal EcoG events were categorized into three different grades: grade 1 activity originated from the cortical lesion focus and was limited to it; grade 2 activity originated from the focus, with subsequent spread; grade 3 activity (generalized) started simultaneously in several recording channels. Ictal episodes consisted of 7–10 Hz rhythmical spike-wave discharges of up to 10 s duration, with abrupt onset and end. During ictal discharges, injured animals typically demonstrated behavioral arrest, sometimes followed by facial automatismsms, myoclonus or 'ictal atonia.' Tonic–clonic behavioral seizures or full-blown electrographic seizures have not been reported. In vitro local field potential recordings demonstrated persistent hyperexcitablitiy of the neocortex at the site of and around the lesion, associated with increased glial reactivity. In a 7 months follow-up study, ictal-like episodes originating in the hippocampus were reported, which gradually increased in frequency, suggesting that the ictal focus had moved from the fronto-parietal cortex (at or near the site of injury) to the temporal lobe. Interestingly, at 7–8 months of age, idiopathic seizures were observed in 33% of sham-injured controls that had identical anesthetic and surgical manipulations without the FPI. Cresyl violet and glial fibrillary acidic protein-staining indicated that early pathologic changes were confined to the lesioned cortex and thalamus. Changes included neuronal loss, areas of calcification, and reactive gliosis. In a chronic follow-up study, atrophy of CA1 and CA3 subfields of the hippocampus ipsilateral to injury was also reported.

Caveats

It is unclear whether the etiological factor has led to distinct clinical outcome or not. Further behavioral and electrophysiological studies are required to prove that this model indeed imitates the features of human PTE.

The differences in outcome between the adult and juvenile rats that were exposed to FPI include: (i) latency period (longer in adult animals), (ii) frequency of occurrence of epilepsy (50% in adult rats versus 92% in juvenile rats), (iii) seizure frequency, (iv) appearance of electrographic seizures (wave morphology and duration), and (v) behavioral correlate of electrographic ictal events (generalized seizures versus freezing and facial automatisms). Several methodological factors might explain these differences, including the age of the animals, anesthesia, size of the craniectomy and location of lesion, construction of fluid-percussion injury device, and severity of the applied pressure pulse.

Future Challenges

Despite a considerable amount of research in this area, our understanding of the pathophysiology of trauma-induced seizures and epilepsy is still in its infancy. Continued evaluation is needed to explore and explain subtle and gross differences in epilepsy phenotype across the PTE models, and assess their validity in relation to the human condition.

Animal models are ultimately designed not only to study the mechanisms of a given epileptic syndrome, but also to assist the drug discovery process by testing whether each novel molecule is biologically active and does not have a negative impact on recovery from injury. It is possible that the models best suited to study basic mechanisms of seizures and epilepsy may be different from those models for therapy discovery.

As it was pointed out at the White House-initiated 'Curing Epilepsy: Focus on the future' conference held in 2000, the important characteristics of a desirable model are reproducibility, cost and suitability for the high-throughput screening of large numbers of drugs. Moreover, models should be age-appropriate (for the developing, mature, and aged brain) and offer the possibility to study the contribution of genetic background to epilepsy. Meeting these important requirements remains a major challenge in modeling posttraumatic epilepsy.

Introduction

Traumatic brain injury causes a complex sequence of events, which result in chronic seizures in some patients. This clinical observation has triggered a number of studies in our laboratory focusing on the sequence of reactions and factors that are associated with the development of chronic seizures (i.e., epileptogenesis).

Biochemical injury to neurons may cause a sequence of changes ranging from cellular loss with replacement gliosis, to subtle alterations in neuronal plasma membrane. Membrane changes initiated by biochemical effects of injury may alter densities and distribution of ion channels on neuronal membrane. Alteration of membrane ionotophores could affect Na^+ and Ca^{2+} currents, alter thresholds, and lead to progressive depolarization. Intrinsic cellular bursting also may develop with an increase in extracellular K^+ or reduction of extracellular Ca^{2+}. The mechanism or critical physiological changes causing posttraumatic epileptogenesis remains unknown. However, several processes may provide useful candidate areas for investigation. For example, trauma may cause mechanical shearing of fiber tracts with loss of inhibitory interneurons following anterograde transsynaptic neuronal degeneration. Trauma-induced release of aspartate or glutamate, with attendant activation of NMDA receptors, elaboration of nerve growth factor or enhancement of reactive gliosis, may also occur. In addition, trauma and associated hemorrhage may alter endogenous antiepileptic systems.

Our laboratory approach to this issue of posttraumatic epilepsy developed indirectly from experiments designed to understand the basis for seizure generation seen in animal models in which metallic cobalt was embedded into isocortex. Applying cobalt in aqueous solution to cortex caused epileptiform discharges, and we reasoned that cations of cobalt (in solution in the neuropil) caused physiological changes that altered neuronal calcium homeostasis. Since cobalt is in the transition region of the periodic table, we began to evaluate other elements in that group, including aqueous iron. We found that ferrous and ferric cations in aqueous solution also caused acute and focal epileptiform discharges. This finding was particularly intriguing given the fact that iron is liberated into the neuropil following an intracerbral hemorrhage when red blood cells hemolize. Intracerebral hemorrhage is a common feature of traumatic brain injury – and such injuries lead to epileptogenesis.

During transport in plasma, iron is sequestered in carrier proteins, thus preventing the generation of free radicals. Neural tissue does not possess a mechanism for sequestration of iron. As hemoglobin breaks down, heme compounds and blood products admix with brain lipids and neural tissue. Red blood cell contents pose hazards to neural tissue because autoxidation of iron in biological

Introduction

The Center for Disease Control (CDC) has estimated that each year 1.5 million people suffer a traumatic brain injury (TBI) in the United States, resulting in almost 100 000 patients per year with long-term disabilities and annual costs to the economy of over $50 billion. TBI and its sequelae have been referred to as an 'invisible epidemic' in which patients suffer devastating life-long cognitive, sensory, emotional, and motor deficits.

Head trauma and brain injury are important factors in epilepsy etiology, contributing about 4% of newly diagnosed cases in the United States. However, the underlying mechanisms remain unknown. The percentage of all victims of a serious head injury that go on to develop posttraumatic epilepsy (PTE) has been estimated at 10–34%, depending on the severity of the injury. One of the strongest predictors of the likelihood of PTE is a penetration of the dura. A unique characteristic of PTE is the variable delay, or latent period, between the trauma itself and the development of seizures – a delay which can last from weeks to years. This latent period is of considerable biological interest. What slow processes are triggered during injury that do not cause seizures until much later? The latent period provides a unique therapeutic opportunity. If we knew what was happening during the latent period, then therapies might be designed that stop this process and prevent a patient at risk from ever becoming epileptic.

The consequences of TBI are as diverse as its causes. Acute aspects of TBI include loss of blood, hemorrhaging, thrombosis, infection, inflammation, intracranial hypertension, and edema. Although these acute complications can often be managed with timely clinical care, long-term consequences, such as PTE, frequently leave TBI victims disabled. To devise effective therapeutic strategies for minimizing the long-term adverse consequences of TBI, we should understand their biological basis.

Background

Fundamental Elements of TBI

Which features of TBI need to be modeled to understand the genesis of PTE? Multiple processes undoubtedly act together to alter the normal balance of synaptic excitation and inhibition and render the brain incapable of functioning normally after injury. Given the overwhelming complexity of the injured brain, it is helpful to consider separately several of the fundamental consequences of lesions that are common to many forms of TBI and are likely to

strongly alter the affected cell populations' activity, such as axonal injury or neuronal deafferentation.

Cell death and glial scarring

TBI is initially characterized by diffuse or focal neuronal and glial cell death, owing to physical damage as a result of trauma and by release of excessive excitatory neurotransmitter such as glutamate. This physical insult is then followed by an intense inflammatory response, owing to breakdown of the blood brain barrier, microglial activation, and reactive astrogliosis. Secondary neuronal damage is often produced by delayed apoptotic cell death (>24 h post-injury). Finally, reactive astrocytes form a glial scar that may spatially restrict the injury, but may also impede healing.

There is a strong correlation between PTE and loss of brain volume after head injury in humans, notably bilaterally reduced hippocampal volume. Neuronal loss in the hilus of the dentate gyrus is the most consistent neuropathologic feature within the hippocampal formation, and its severity is correlated with the neuronal loss in CA1 and CA3 areas. Extensive cortical and subcortical neuronal loss occurs in several well-studied animal models as well, such as cortical weight-drop and fluid percussion injuries (see later text). The extent of the damage is proportional to the depth of the cortical deformation, and may include the hippocampus and thalamus in addition to the directly affected neocortical area. In the controlled cortical impact (CCI) model, diffuse damage in the ipsilateral hippocampus (including the loss of CA3 and CA1 pyramidal neurons) and dentate gyrus has been described, and is related to the depth of the impact. Degeneration in these models occurs between 6 and 72 h after injury.

Selective loss of neurons following several forms of hippocampal pathology is associated with the development of abnormalities in physiology. The loss of GABAergic interneurons and glutamatergic mossy cells in the hilus of the dentate gyrus is well known in injury models, and the vulnerability of specific subpopulations of hilar interneurons (including somatostatin- and parvalbumin-containing neurons) has been established. Little is known, however, about the loss of subpopulations of GABAergic neurons in areas CA3 and CA1 after TBI.

Mechanical and pathologic damage to the adult CNS induces an injury response known as 'reactive gliosis' (or glial scarring) at the site of the lesion. Formation of the glial scar is thought to be important for recovering the tensile strength of the tissue in addition to protecting the remaining parts of the brain. Glial scar tissue is composed primarily of hypertrophic astrocytes, microglia, and oligodendrocyte progenitor cells, and includes clotted blood and deposition of extracellular matrix molecules. Different cell types arrive and participate at different times following injury in the glial scar formation. Macrophages and microglia are the first cell types to be found at the site of injury. Oligodendrocyte precursors from surrounding tissue are then recruited, and finally, large numbers of astrocytes migrate into the site of injury and eventually fill in the vacant space. Dynamic changes in macrophages and microglia-mediating reactive astrogliosis occur 24–48 h after head injury in human TBI and in experimental TBI models.

Although many studies suggest that the glial scar inhibits axonal regeneration, recent data have shown that reactive astrocytes can also release molecules that promote axonal regeneration and that the microglia/macrophage response may support axonal sprouting by producing and releasing growth factors.

Axonal injury

Traumatic axonal injury is a common sequela of TBI. In many head injuries there is irreparable damage to axons, either through the direct physical trauma of a penetrating head wound or indirectly because of the shearing and stretching of axons that occurs when the brain experiences rapid acceleration and deceleration. These injuries may not be fatal to the cell whose axon is injured, but the axon itself may be irreversibly damaged and may ultimately degenerate.

Traumatic axonal injury involves a progressive and transient disruption of the axonal membrane allowing for unregulated calcium influx. Excess intracellular calcium can induce a metabolic cascade involving calpain activation, mitochondrial swelling with cytochrome *c* release, and caspase activation, leading to perturbed axonal transport and axonal disruption over time. In addition, axonal injury initiates a variety of changes in axotomized cells, including changes in the expression of ligand-gated or intrinsic voltage-gated ion channels.

Denervation

Head injuries can also result in a complete or partial loss of the normal inputs to large populations of neurons as the result of degeneration of severed and injured axons, combined with direct and secondarily triggered (excitotoxicity, apoptosis) death of populations of cells that are presynaptic to a given region. Decreased synaptic densities are commonly observed in many forms of brain injury, indicative of denervation.

There is abundant experimental evidence that these kinds of injury-induced changes in afferent activity may alter the excitability of the affected neuronal population. After deafferentation, many types of cells respond to the loss of normal excitatory drive by increasing their excitability by various means. In cell culture systems, cells respond to a global decrease in their average action potential discharge rate by compensating homeostatically in a manner that will restore their normal discharge rate. Turrigiano and colleagues have established that the expression of synaptic glutamate receptors in cortical cells is

up-regulated in response to lowered activity levels, unlike the denervation supersensitivity displayed by denervated muscle. The expression of intrinsic voltage-gated ion channels can also be affected by altered activity levels. There is evidence that changes in the level of neurotrophins may be the signal that triggers these homeostatic responses. Exogenously applied neurotrophins can compensate for decreased activity and prevent homeostatic responses under some conditions.

Models of PTE

Diffuse Brain Injury

Three models of TBI enjoy widespread use, although they have only found limited application to the study of PTE. It is also noteworthy that all three models induce severe changes in blood flow, breakdown of the blood brain barrier, edema, and traumatic axonal injury. While realistic models of human TBI, these factors complicate the study of the biological basis of PTE.

Fluid percussion injury (FPI) is the most commonly used model to study TBI. FPI is induced with a rapid injection of saline onto the intact skull. The pressure administered is equivalent to a sudden impact received by a human skull, resulting in similar physiological effects in animals and humans. FPI produces a very realistic and reproducible diffuse, closed skull injury and results in well established neurobehavioral and cognitive deficits.

Controlled cortical impact (CCI) involves a pneumatic piston that delivers a blow directly to the pial surface of the brain at a surgically placed opening in the skull. CCI results in injury to the cerebral cortex and underlying subcortical areas. This CCI device provides an accurate, reproducible injury, and reproduces many characteristics of human TBI, particularly focal cortical contusions.

Weight drop injury has some similarities to the CCI model. In this model a weight of several hundred grams falls freely for as far as one meter onto the closed skull to produce mild TBI. Alternatively, a weight of a few tens of grams falls a few tens of centimeters directly against the cortex (after craniotomy) to produce a more severe injury.

Acute seizures, occurring immediately during injury, have been reported in the CCI model. In addition, hippocampal hyperexcitability has been revealed after stimulation or proconvulsant drug exposure. It is important to note, however, that epilepsy – that is, spontaneous recurring seizures – has only been demonstrated after severe FPI and weight-drop injuries in rats. These injuries are associated with significant neural degeneration.

Undercut Cortex

One of the first experimental demonstrations of chronic epileptogenesis associated with brain injury was described 50 years ago, and involved aberrant excitability in regions of chronically isolated cat and monkey neocortex. The aberrant excitability was produced by undercutting the cortex so as to leave the pial blood vessels intact. Much like human PTE, hyperexcitability was only observed with a delay of weeks after the lesion. Once established, the epileptiform discharge in the isolated cortical areas remained for more than one year. More recently, this model has been thoroughly characterized by Prince and colleagues in rodents, particularly through detailed electrophysiological studies in ex vivo brain slices. Their finding that the hyperexcitability persists after removal of the tissue from the injured animals provides strong evidence for a persistent reorganization of excitatory and inhibitory neural circuits as a consequence of the injury. These studies have found evidence of alterations in intrinsic neuronal excitability, GABAergic inhibition, and glutamatergic excitation, as well as reactive axonal sprouting.

Schaffer Collateral Transection

We have modeled a penetrating TBI by transecting the Schaffer collateral pathway in hippocampal slice cultures. Lesions of Schaffer collateral axons of CA3 pyramidal cells were made using a razor blade shard after the cultures had been allowed to develop in vitro for >14 days (**Figure 1(a)**). Lesioned cultures are hyperexcitable (see later text). We are also developing a model of acute brain injury with dural penetration by transecting the Schaffer collateral pathway in rats in vivo. Preliminary results demonstrate a delayed increase in excitability, apparent in depth recordings and maintained in ex vivo brain slices, and the occurrence of behavioral seizures in these animals. Although the hippocampus is rarely involved in human PTE, this type of lesion is simpler to study than comparable injuries in the neocortex, (such as that produced by undercutting) because of the regular cellular organization of the hippocampus. Indeed, its organization allows the presynaptic (i.e., axonal injury) and postsynaptic (i.e., denervation) consequences of injury to be studied in spatially isolated cell populations (CA3 and CA1, respectively), without the complications present in other models of brain injury (e.g. cell death, interruption of blood supply, edema).

Methods

Slice Culture Preparation and Schaffer Collateral Transection

We have performed Schaffer collateral transections in hippocampal slice cultures from rat and mouse. Hippocampal slice cultures were prepared using the roller tube method. In brief, the hippocampi were dissected from neonatal pups (postnatal days 1–8), 400 μm-thick slices were cut on a tissue chopper, and the slices were attached

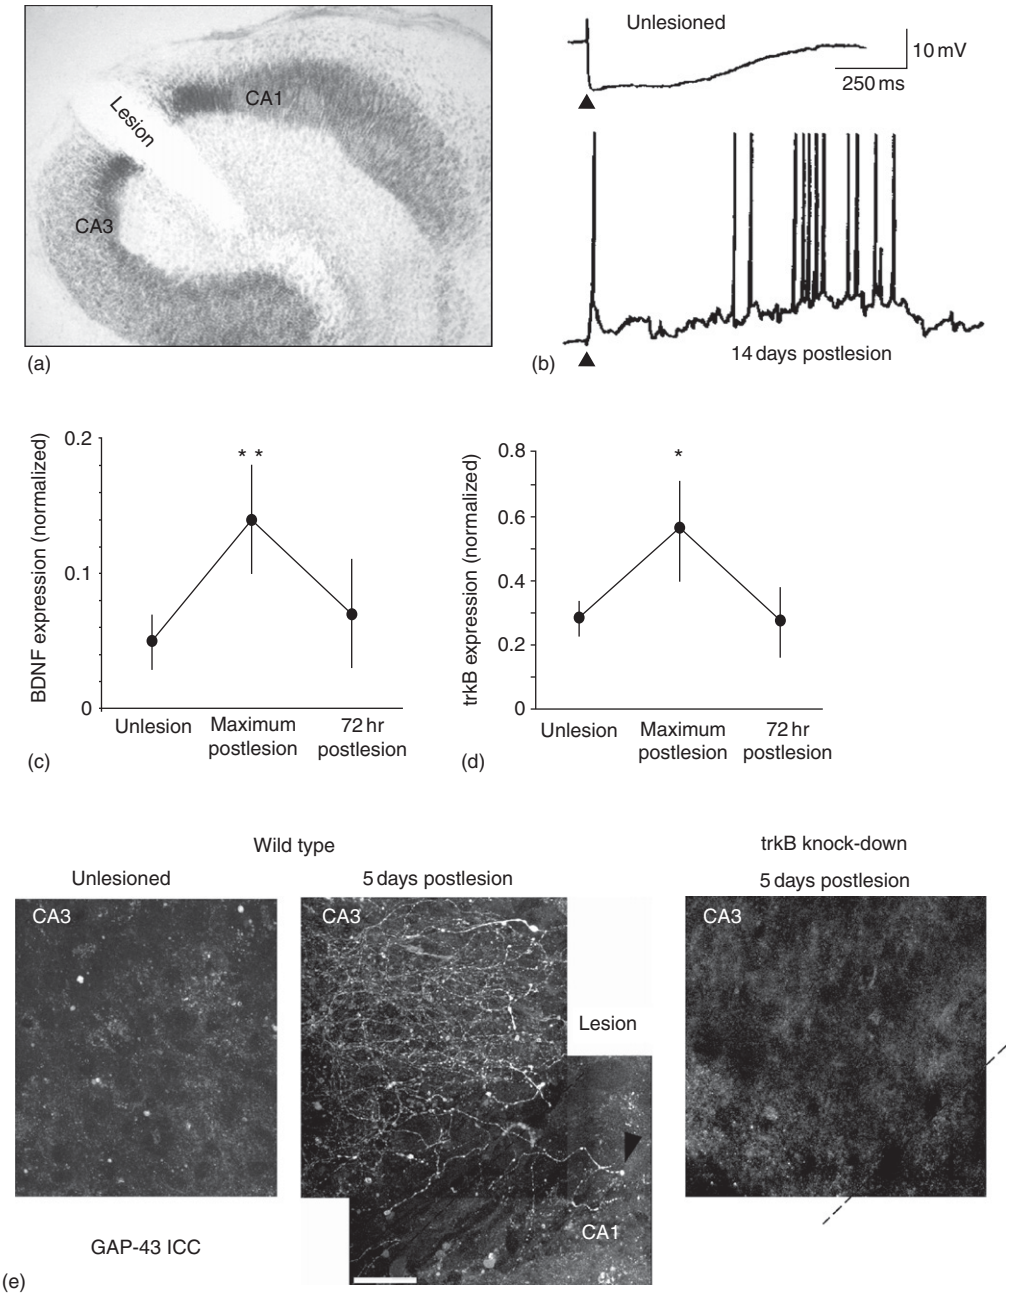

Figure 1 Reactive axonal sprouting and neurotrophin signaling after axonal injury. (a) Image of a Nissl stained hippocampal slice culture taken 14 days after making a transection of the Schaffer collateral pathway. Such lesions allow the consequences of axonal injury to be studied relatively selectively in area CA3 and the effects of chronic partial denervation to be studied in area CA1. (b) Membrane potential responses of CA3 pyramidal cells elicited after stimulation within area CA3 of an unlesioned control hippocampal slice culture (upper trace) and a culture in which the Schaffer collateral pathway had been transected 14 days earlier (lower trace). A normal EPSP–IPSP sequence was elicited in the control culture, whereas abnormal afterdischarge was elicited in the lesioned culture. (c) The expression of BDNF is increased transiently in area CA3 24–48 h after Schaffer collateral transection in hippocampal slice cultures, as determined with an Elisa assay. (d) The expression of the BDNF receptor trkB is also increased in area CA3 24–48 h after Schaffer collateral transection in hippocampal slice cultures, as determined with quantitative immunoblotting. (e) Single confocal images of rat hippocampal slice cultures stained with an antibody against the growth-associated protein, GAP-43 – a marker of growing axons. No immunoreactive fibers are seen in the unlesioned rat hippocampal slice culture (left), but many labeled fibers, some of which are tipped by growth cones (arrowhead), are seen crossing from area CA3 to area CA1 in the culture lesioned 5 days earlier (middle). Scale bar = 25 μm. In contrast, few or no immunoreactive fibers are seen when lesions are made in mouse hippocampal slice cultures in which the level of trkB expression has been genetically reduced (right). Adapted from McKinney RA, Debanne D, Gähwiler BH, and Thompson SM (1997) Lesion-induced axonal sprouting and hyperexcitability in the hippocampus in vitro: Implications for the genesis of posttraumatic epilepsy. *Nature Medicine* 3: 990–996, and Dinocourt C, Gallagher SE, and Thompson SM (2006) Injury-induced axonal sprouting in the hippocampus is initiated by activation of trkB receptors. *European Journal of Neuroscience* 24: 1857–1866.

to glass coverslips in a film of clotted chicken plasma-fibrin solution. The coverslips were then placed in sealed test tubes containing a semi-synthetic medium. The tubes were placed in a roller drum in an incubator. Cultures were allowed to develop for 14 days in vitro to allow for dendritic and synaptic maturation. At this age, cultures were removed and placed in a solution containing glutamate receptor antagonists under sterile conditions. A razor blade shard was drawn from the approximate position of the hippocampal fissure to the outer edge of the culture at the border between areas CA1 and CA3 in order to sever the projections from area CA3 to area CA1. Cultures are then returned to their test tubes and maintained for days or weeks after the lesions. This type of injury produces little neuronal degeneration, except within the immediate vicinity of the lesion, and thus represents a relatively selective form of axonal injury.

Immunocytochemistry

Tissue was fixed in 4% paraformaldehyde in phosphate-buffered saline overnight, then rinsed. After overnight preincubation in a blocking solution containing 0.4% Triton X-100, bovine serum albumin, and goat serum, cultures were incubated for 24 h in a solution containing an anti-GAP-43 monoclonal antiserum (10E8/E7, diluted 1:10). Biotinylated secondary antibodies and fluorescently labeled avidin were used for visualization of GAP-43-immunoreactive processes. TrkB expression levels were assessed with immunoblotting using a polyclonal anti-trkB antibody from Upstate Biotechnology (Lake Placid, NY). Brain derived neurotrophic factor (BDNF) levels were assessed with a Promega ELISA kit (Madison, WI).

Electrophysiology and Glutamate Photolysis

Conventional whole-cell voltage- and current-clamp techniques were used to record from CA1 and CA3 cells in the hippocampal cultures. In some experiments, we used photolysis of caged glutamate to study the responses of distal dendrites. In brief, UV light from an argon ion laser was directed into a quartz multimode fiber (10–25 μm in diameter). The proximal end of the fiber was then positioned in a focal plane conjugate with the target dendrite via a pair of relay lenses. The light is then directed into the back of the objective via a dichroic mirror that allows for simultaneous imaging with conventional wide field illumination, in order to visualize the target dendrite or monitor changed in intracellular calcium concentration microfluorometrically. Caged glutamate (*N*-NCM-glutamate, synthesized by our collaborator Dr. Joseph Kao) was applied at 500 μM and a brief pulse of the UV light (1–32 ms, spot size = 1–10 μm) was used for uncaging.

Recent Results – Mechanisms of PTE

Disinhibition

Epilepsy is widely recognized to result from an imbalance between excitatory and inhibitory synaptic processes. Certainly acute blockade of GABAergic inhibitory synapses is the most powerful and simple means of inducing epileptiform discharge in tissue from many brain regions. Nevertheless, the evidence of persistent disinhibition in various chronic epilepsy models, including those induced by TBI, is surprisingly weak. Some older work demonstrated loss of inhibitory synapses after chronic neocortical isolation or neonatal hypoxia. These studies gave rise to the notion that GABAergic interneurons might be selectively vulnerable to injury (compared to excitatory pyramidal cells), thus resulting in an imbalance between inhibition and excitation. More recent studies have failed to corroborate these findings, however. The evidence favors preservation of GABAergic interneuron number (as detected immunocytochemically) in the undercut cortex model, although there are modest reductions in the hippocampus after FPI in most (but not all) studies. The evidence is better for more subtle defects in GABAergic inhibition. Chronic decreases in the frequency of spontaneous inhibitory synaptic responses have been reported after TBI in various models, typically attributed to reductions in the number of inhibitory synapses, as well as impairment of Cl^- extrusion and Cl^- transporter expression. Such changes would weaken inhibition during periods of elevated activity. The difficulty in identifying alterations in GABAergic inhibition after TBI, especially compared to the more obvious alterations in intrinsic and synaptic excitation (described below), suggests that disinhibition may make only a minor contribution to the genesis of PTE.

Reactive Sprouting After Axonal Injury

An important clue as to the nature of lasting changes underlying the genesis of PTE was the discovery that axonal reorganization can occur in the adult brain in response to neuronal injury. This process has been studied almost exclusively for the mossy fiber axons of dentate granule cells because of the ease and specificity with which they are labeled using the Timm stain for heavy metals (zinc being found at high concentrations in mossy fibers). Dentate granule cells display abnormal mossy fiber collaterals within the dendritic regions of the dentate gyrus in hippocampi removed from epileptic patients, but not in matched non-epileptic patients. This mossy fiber termination pattern, called supragranular sprouting, led to the initial suggestion that axonal sprouting after injury might be an important contributing factor to the genesis of PTE. In experimental PTE produced by cortical weight-drop,

mossy fiber sprouting appears 1 or 2 weeks after the injury and persists for many months afterwards. Physiological studies indicate that newly sprouted mossy fiber collaterals form excitatory synapses with dentate granule cells, and that the net effect of these new synapses is to increase the excitability of the tissue. Thus, the slow time course of this mossy fiber regrowth may account for the delayed development of PTE.

It is now clear that axonal sprouting is not limited to granule cells. Axonal sprouting by pyramidal cells has also been observed after brain injuries and may be more widespread than is currently appreciated. Tissue from hyperexcitable areas of undercut neocortex (see previous text) display evidence of axonal sprouting by pyramidal cells near the lesion. There is also evidence for upregulation of GAP-43 and other growth-associated proteins in the cortex after some forms of TBI. Using biocytin filling of the axons of single pyramidal cells, GAP-43 immunocytochemistry, and mice in which some CA3 pyramidal cells express GFP constitutively, we have provided evidence that CA3 pyramidal cells also sprout new axon collaterals after Schaffer collateral transection in hippocampal slice cultures. After injury-induced axonal sprouting, the probability that any two CA3 pyramidal cells in the vicinity of the lesion are connected by an excitatory synapse is increased by about 50%, providing a lasting injury-induced morphological substrate for the spread of excitation through the population of CA3 cells. We also observed that lesioned cultures are hyperexcitable (**Figure 1(b)**) and have an increased sensitivity to proconvulsive conditions. The strong correlation between the number of sprouted axons and the degree of excess excitation supports the hypothesis that injury-induced axonal sprouting contributes to the generation of PTE. In order to test this hypothesis, however, it is necessary to stop the reactive axonal growth.

What Factors Trigger Axonal Sprouting After Injury?

Neurotrophic factors (NTs) were first discovered because they promote neurite outgrowth during development. They are now known to exert this action in the adult CNS as well. The hippocampus displays the highest level of neurotrophin mRNA in the brain, particularly for BDNF. In the hippocampal formation, BDNF mRNA is particularly prominent in CA1 and CA3 pyramidal cells. Responsiveness to NTs is conferred by expression of the high affinity neurotrophin receptor tyrosine kinases, trkA, trkB, and trkC. trkB receptors are highly expressed in hippocampal pyramidal cells, and bind BDNF and NT-4/5 with high affinity. Binding of NTs to their receptors causes them to homodimerize and autophosphorylate tyrosine residues in their cytoplasmic domain. In the hippocampus, resting levels of phosphorylation are very low, indicating low levels of constitutive activation of these receptors.

Expression of BDNF and other NTs is up-regulated in several models of experimental epilepsy, and increases during induction of kindled seizures and after kainic acid-induced seizures. These observations led to the hypothesis that enhanced NT expression contributes to the lasting changes underlying epilepsy. Indeed, axonal sprouting and increased excitability are induced by exogenous trkB ligands in hippocampal slice cultures. NTs are thus prime candidates to trigger axonal sprouting after neural injury.

We have performed a first test the hypothesis that TBI promotes axonal sprouting by CA3 pyramidal cells by causing upregulation of NT signaling via the trkB receptor. Consistent with the hypothesis, an ELISA assay detected a threefold increase in BDNF levels in area CA3 within 24–48 h after Schaffer collateral transection and recovery by 72 h postlesion (**Figure 1(c)**). Immunoblotting also revealed that trkB expression in area CA3 increases two to threefold after transection (**Figure 1(d)**). In slice cultures from transgenic mice ($trkB^{fBZ/fBZ}$) in which trkB expression is reduced to about 20% of control levels, the percentage of cultures displaying GAP-43-immunoreactive axons after Schaffer collateral transection was significantly reduced to only 23%, as compared to the >70% of lesioned cultures from wild-type mice that display sprouted axons (**Figure 1(e)**). Similarly, immunoblot analysis indicated that the lesion-induced upregulation of GAP-43 was decreased in the $trkB^{fBZ/fBZ}$ cultures to only 44% of the level seen in wild-type cultures. These are the first results demonstrating that injury-induced NT signaling promotes axonal sprouting in the CNS. We now have an experimental approach with which to test the hypothesis that injury-induced axonal sprouting contributes to the hyperexcitability seen after lesions. We are performing these experiments using newly created mice with pharmacologically-sensitive trkB receptors.

Homeostatic Plasticity After Denervation

The discovery of the 'paroxysmal depolarizing shift' as the intracellular correlate of interictal EEG spikes led to considerable debate between proponents of the 'giant synaptic potential' and 'epileptic neuron' hypotheses. The giant synaptic potential hypothesis holds that synchronous, all-or-none interictal events result from the summation of large numbers of synchronized excitatory glutamatergic synaptic inputs. The epileptic neuron hypothesis holds that depolarization shifts are generated by intrinsic depolarizing conductances in pyramidal cells that are then synchronized by modest synaptic excitation. The intrinsic propensity to produce long duration, large amplitude bursting responses may normally reside in a

subset of cells or may be displayed by a subset of pathologically 'epileptic' cells. In the case of disinhibited hippocampal slices, it is now clear that both hypotheses are partially correct: epileptiform discharge results from synchronous synaptic excitation and recruitment of several intrinsic depolarizing conductances, particularly dendritic voltage-dependent Ca^{2+} conductances. How well this conclusion applies to other forms of epilepsy remains unclear.

While much of the current focus is on changes in synaptic circuitry and function as the cause of epilepsy, changes in intrinsic postsynaptic excitability or receptor expression are now receiving increased attention. There are several examples of injury-induced hyperexcitability in which amplification of intrinsic excitability has been implicated. First, *denervation supersensitivity* to acetylcholine was first described for denervated muscle in 1949. Denervation supersensitivity has since been attributed to the increased expression of receptors, both at extrajunctional and junctional sites. A similar phenomenon also occurs in neurons. Decreasing postsynaptic activity in cultured cortical neurons (as produced with tetrodotoxin-TTX) results in increased postsynaptic glutamate receptor expression. Second, cells also increase their *intrinsic excitability* following manipulations that decrease action potential discharge. Inactivation of cortical cell cultures with TTX, for example, leads to a selective down-regulation of voltage-dependent K^+ currents. The effects of TTX on the expression of both glutamate receptors and intrinsic conductances have been attributed to decreases in the activation of postsynaptic trkB receptors by endogenously-released BDNF. Recent studies have suggested that dendritic currents, in particular A-type K^+ currents and hyperpolarization activated cation currents, may have persistently altered function in some chronic epilepsy models. Persistent increases in the propensity for repetitive firing and enhanced glutamatergic excitation are also reported in experimental TBI.

We have obtained considerable evidence that Schaffer collateral transection induces an increase in the excitability of CA1 cell dendrites as the result of the deafferentation and decrease in neuronal discharge. Using whole-cell current-clamp recording from CA1 cells in slice cultures 7–10 days after Schaffer collateral transection, we observed that a single stimulus delivered in *str. radiatum* within area CA1 elicited synaptic responses that were identical in lesioned and unlesioned slices. In contrast, synaptic responses were significantly prolonged in lesioned slices compared to controls when short strains of high frequency stimulation were delivered. A similar pattern emerged when distal apical dendrites were stimulated with photolysis of caged glutamate. Weak photostimulation elicited responses that were statistically indistinguishable in their amplitude and kinetics in lesioned and unlesioned cultures, whereas strong stimulation elicited so-called 'plateau potentials' in denervated cells that were significantly increased in duration compared to normally innervated cells (**Figure 2(a)** and **2(b)**). The lack of change in the amplitude and kinetics of the small responses suggested that a change in the expression of postsynaptic glutamate receptors or dendritic electrotonic properties were not causing the hyperexcitability. We concluded, instead, that an increase in intrinsic excitability was responsible. But what channels are affected?

Plateau potentials represent all-or-none responses of single dendritic branches and are mediated by the activation of voltage-dependent Ca^{2+} channels in the stimulated dendrite. Plateau potentials are most easily evoked with the prolonged depolarization produced by NMDA receptor activation. We have discovered that SK-type Ca^{2+}-activated K^+ channels are primarily responsible for the repolarization of the plateau potential. Several specific SK channel blockers (such as apamin, **Figure 2(c)**), high concentrations of tetraetylammonium (TEA), and intracellular dialysis of the Ca^{2+} chelator 1,2-bis(o-aminophenoxy)ethane-N, N,-N′,N′-tetracefic acid (BAPTA) all double the duration of the plateau potential.

Because acute block of SK-channels prolongs plateau potentials in control cells to a duration comparable to that occurring after chronic deafferentation, we examined SK channel function in denervated dendrites. We found that apamin, TEA, and intracellular BAPTA all failed to produce a significant prolongation of plateau potentials in denervated cells. In addition, the SK2 channel-mediated medium-duration afterhyperpolarization, recorded from the soma in response to trains of directly evoked action potentials, was significantly reduced in denervated CA1 cells. We concluded that plateau potentials in denervated dendrites are prolonged, compared to control cells, because the normal SK channel-mediated repolarization process is dysregulated. Finally, we observed no changes in SK2 mRNA in denervated CA1 cells (using quantitative RT-PCR) or in SK protein levels (using Western blotting). We thus concluded that the SK-channels are present, but not functioning normally, after chronic denervation.

Why does plateau potential prolongation promote hyperexcitability within the affected cell population? We found that plateau potentials in distal dendrites were almost always ineffective in triggering action potentials. In contrast, acute prolongation of plateau potentials in control cells with apamin (**Figure 2(e)**) or chronic prolongation of plateau potentials by deafferentation (**Figure 2(f)**) substantially increased the probability that a plateau potential would trigger fast action potential discharge. We thus demonstrated that an increase in intrinsic excitability, in particular a change in the function of dendritic Ca^{2+}-activated K^+ channels, is a primary cause of hyperexcitability in denervated CA1 cells in hippocampal slice cultures. In preliminary experiments,

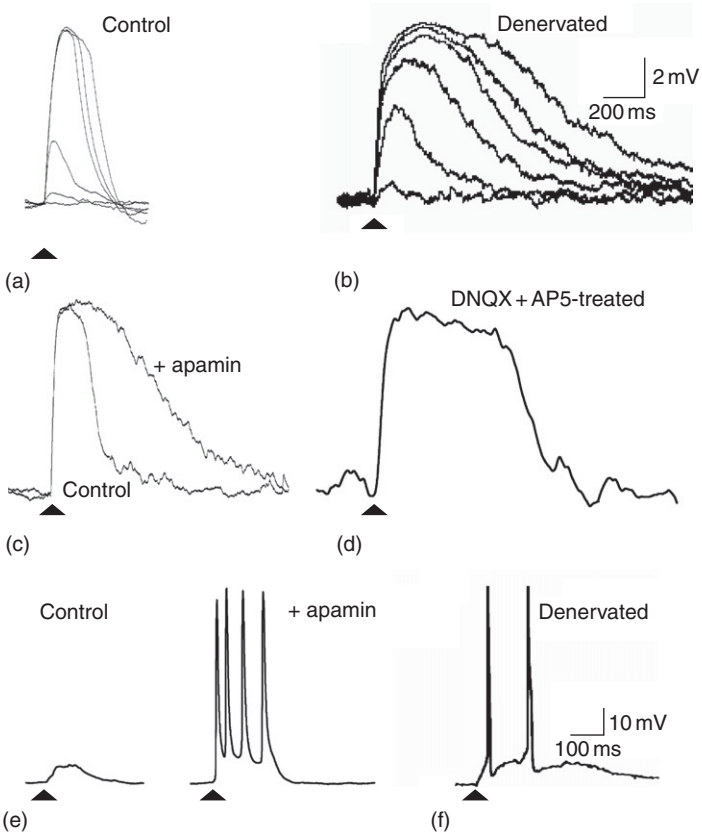

Figure 2 Changes in intrinsic dendritic excitability after chronic partial denervation. Traces represent membrane potential responses of CA1 pyramidal cells to photolysis of caged glutamate at a single distal apical dendrite at the time indicated by the solid triangle. All responses in a–d were recorded in the presence of TTX to block fast action potentials. (a) A series of photostimuli of increasing intensity elicited either graded, small EPSP-like responses or all-or-none plateau potentials. On average, plateau potentials are 10 mV in amplitude, as recorded with whole-cell pipettes from the soma, and have a duration of 100–200 ms. (b) Identical photostimulation in a CA1 cell recorded 7 days after partial denervation produced by transecting the Schaffer collateral inputs to the cell. Note that the amplitude is not different from the amplitude in control cells, but that repolarization is slowed and the duration of the plateau potential is threefold longer. Note also that the amplitude and time course of the small events are not different after denervation. Scale bar applies for panels a–d. (c) Block of SK-type Ca^{2+}-activated K^+ channels with apamin slows repolarization of plateau potentials and increases their duration in normally enervated cells. (d) The effects of partial denervation on plateau potential duration are mimicked by treatment of cultures for 7 days with the glutamate receptor antagonists, DNQX and AP5. (e) In the absence of TTX, plateau potentials elicited with dendritic photostimulation are not usually accompanied by fast action potentials. Application of apamin, however, greatly facilitates action potential discharge in response to dendritic stimulation. (f) In contrast to normally enervated cells, photostimulation of distal dendrites in denervated cells almost always elicits fast action potentials. Scale bar applies for panels e–f. Adapted from Cai X, Liang CW, Muralidharan S, Kao JPY, Tang CM, and Thompson S-M (2004) Unique roles of SK and Kv4.2 potassium channels in dendritic integration. *Neuron* 44: 351–364, and Cai X, Wei D-S, Gallagher SE, *et al*. (2007) Hyperexcitability of distal dendrites in hippocampal pyramidal cells following chronic partial deafferentation. *Journal of Neuroscience* 27: 59–68.

we have seen evidence that a similar process occurs in area CA1 of ex vivo hippocampal slices taken from animals with Schaffer collateral transections made in vivo.

The increase in intrinsic excitability after partial deafferentation represents a response of the cells to a decrease in postsynaptic activity levels. We found that treatment of slice cultures with a combination of the AMPA and NMDA receptor antagonists, DNQX and AP5, for 7 days caused an increase in the duration of plateau potentials elicited with glutamate photolysis that was even larger than that resulting from Schaffer collateral transection (**Figure 2(d)**). Because excitatory afferents were intact in these cultures, we could record miniature excitatory postsynaptic currents (mEPSCs) from CA1 cells after washout of the chronically applied DNQX + AP5, to assay the expression of postsynaptic glutamate receptors. We found that there were no statistically significant differences in mEPSC amplitude in cultures exposed to DNQX + AP5 for 7 days compared to untreated control cultures. In addition, there was no statistically significant change in the amplitude or kinetics of small glutamate responses, subthreshold for activation of plateau potentials, as in the denervated cells. We thus concluded that

an increase in glutamate sensitivity is not required for the prolongation of plateau potentials following deafferentation.

In conclusion, a decrease in neuronal discharge in cells that have been chronically denervated will react homeostatically to increase their excitability. We suggest that this increase in intrinsic excitability and reactive axonal sprouting act synergistically to cause hyperexcitability and PTE after TBI.

Challenges for the Future – Implications for Treatment and Therapy

PTE represents one of the few forms of epilepsy in which a true 'cure' can be imagined. Because of the long latent period between the time of the injury and the onset of clinical seizures, there is a relatively wide window of opportunity to interrupt the injury-induced processes underlying the generation of the epilepsy. In theory, a well-directed therapeutic approach could prevent patients at risk after TBI from ever developing PTE. This goal continues to drive research into the causes of PTE. Many important questions with regard to the genesis of epilepsy after TBI remain to be answered. Does axonal sprouting cause injury-induced hyperexcitability? Is the excitability of the postsynaptic targets of these newly sprouted axons increased after injury? Can evidence of these processes be seen in tissue from injured human brains?

The changes in neural function that occur after TBI, such as axonal sprouting, disinhibition, or altered intrinsic excitability, are likely to represent the brain's natural homeostatic mechanisms for healing itself. They also reflect the biological principle that recovery from injury often means reverting to a more immature state, perhaps produced by the re-expression of a constellation of genes normally active early in development. Both axonal growth and homeostatic regulation of synaptic and intrinsic excitability are prominent features of the young, growing brain. We suspect that these normally 'sensible' homeostatic responses to injury result in unfortunate, 'maladaptive' functional consequences that cause several of the neurological complications of TBI.

No question is more important than identifying better therapeutic approaches for the treatment of PTE. At least 30–40% of all patients with epilepsy are partially or totally resistant to currently available anticonvulsant medications, and an even greater percentage suffers from the negative side-effects of the drugs. Treatment of PTE is particularly problematic, perhaps because of the hard-wiring of the rearrangements that occur after the injury during the latent period. A major challenge for epilepsy researchers is to use our increasing knowledge of the cellular biology underlying epileptogenesis to offer better anticonvulsant therapies. It is to be hoped that the data gathered from the study of in vitro models of PTE will lead to the development of novel, well targeted therapeutic interventions that significantly improve on today's medications.

Introduction

Traumatic brain injury causes a complex sequence of events, which result in chronic seizures in some patients. This clinical observation has triggered a number of studies in our laboratory focusing on the sequence of reactions and factors that are associated with the development of chronic seizures (i.e., epileptogenesis).

Biochemical injury to neurons may cause a sequence of changes ranging from cellular loss with replacement gliosis, to subtle alterations in neuronal plasma membrane. Membrane changes initiated by biochemical effects of injury may alter densities and distribution of ion channels on neuronal membrane. Alteration of membrane ionotophores could affect Na^+ and Ca^{2+} currents, alter thresholds, and lead to progressive depolarization. Intrinsic cellular bursting also may develop with an increase in extracellular K^+ or reduction of extracellular Ca^{2+}. The mechanism or critical physiological changes causing posttraumatic epileptogenesis remains unknown. However, several processes may provide useful candidate areas for investigation. For example, trauma may cause mechanical shearing of fiber tracts with loss of inhibitory interneurons following anterograde transsynaptic neuronal degeneration. Trauma-induced release of aspartate or glutamate, with attendant activation of NMDA receptors, elaboration of nerve growth factor or enhancement of reactive gliosis, may also occur. In addition, trauma and associated hemorrhage may alter endogenous antiepileptic systems.

Our laboratory approach to this issue of posttraumatic epilepsy developed indirectly from experiments designed to understand the basis for seizure generation seen in animal models in which metallic cobalt was embedded into isocortex. Applying cobalt in aqueous solution to cortex caused epileptiform discharges, and we reasoned that cations of cobalt (in solution in the neuropil) caused physiological changes that altered neuronal calcium homeostasis. Since cobalt is in the transition region of the periodic table, we began to evaluate other elements in that group, including aqueous iron. We found that ferrous and ferric cations in aqueous solution also caused acute and focal epileptiform discharges. This finding was particularly intriguing given the fact that iron is liberated into the neuropil following an intracerbral hemorrhage when red blood cells hemolize. Intracerebral hemorrhage is a common feature of traumatic brain injury – and such injuries lead to epileptogenesis.

During transport in plasma, iron is sequestered in carrier proteins, thus preventing the generation of free radicals. Neural tissue does not possess a mechanism for sequestration of iron. As hemoglobin breaks down, heme compounds and blood products admix with brain lipids and neural tissue. Red blood cell contents pose hazards to neural tissue because autoxidation of iron in biological

fluid initiates a series of one-electron transfer reactions that yield free radical intermediates, with formation of superoxide radicals and production of lipid peroxidation. Indeed, evaluating data from patients subjected to traumatic brain injury, several investigators have noted that risk factors for epileptogenesis are determined not only on trauma 'dose' (i.e., severity), but also the presence of cortical contusion and intracerebral hematoma. Although shear injury and injury associated with patterns of pressure waves and cavitation were obviously important, we wondered particularly about how hemorrhage might be associated with epileptogenesis.

Background

Effects of Iron on Brain Tissue

Addition of iron salts or heme compounds to solutions containing polyunsaturated fatty acids (PUFA) or to suspensions of subcellular organelles results in the formation of highly reactive free radical oxidants, including perferryl ions, superoxide radicals singlet oxygen, and hydroxyl radicals. Although free radical species may form by iron-catalyzed Haber–Weiss reactions, these oxidants are also actively generated by iron in biologically chelated forms in heme or with ADP. Free radicals react with methylene groups adjacent to double bonds of PUFA and lipids within cellular membranes, causing hydrogen abstraction and subsequent propagation of peroxidation reactions. This nonenzymatic initiation and propagation of lipid peroxidation causes disruption of membranes of subcellular organelles, degrades deoxyribose and amino acids, and yields diene conjugates and fluorescent chromophores. Inorganic iron salts, hematin, and hemoproteins will stimulate peroxidation of lipids of microsomes and mitochondria, as well as change cellular thiodisulfide function. Alkyl hydroxyl and peroxyl species of fatty acids propagate until a termination reaction occurs with a membrane constituent capable of electron donation without formation of a free radical. Such constituents include tocopherol, cholesterol, proteins or the sulfhydryl group of glutathione. Histopathologic alterations following injection of aqueous iron into neural tissue can be prevented by pretreatment of animals with α-tocopherol and selenium, further supporting the contention that peroxidative reactions are of importance in trauma-induced brain injury responses.

Sustained membrane changes that are associated with generation of epileptiform discharges may result from free radical injury to neuronal nuclear or mitochondrial DNA. Cellular responses to generation of free radical oxidants following decompartmentalization of hemoglobin or iron containing heme compounds may depend upon the induction of protective mechanisms. Differentiation of susceptibility to develop epilepsy after a given trauma dose may be related to the ability of repair response induction following initiation of lipid peroxidation. For example, different strains of *Escherichia coli* may be differentiated based on their responses to peroxide, suggesting critical genetic factors that determine protection. Induction of enzymes to repair DNA damage induced by Fenton-derived free radicals appears to be critical for cellular survival.

The specific genetic factors that protect against, or cause vulnerability to, the development of posttraumatic epilepsy remain unknown. However, a possible genetic predisposition has been observed with the detection of decreased levels of serum haptoglobin in familial epilepsy. Haptoglobins are acute phase glycoproteins in the α-1-globulin fraction of serum; they form stable complexes with hemoglobin. Since antioxidants such as superoxide dismutase and peroxidases are not found in high concentration in extracellular fluid, control of oxidation in neural tissue must depend upon binding of reactive metals to carrier proteins, including transferrin, lactoferrin, ceruloplasmin, and haptoglobins. Since one mechanism of protection against induction of oxidant stress is sequestration of free hemoglobin with haptoglobins, an understanding of impairments in the synthesis of these glycoproteins may provide insight into an inherent susceptibility to development of epilepsy after head trauma.

Initial Studies on Iron-Induced Epileptogenesis

Our original methods to produce chronic seizures in rats at first involved injection of 100 mmol $FeCl_2$ (a concentration that is equiosmotic with CSF) into isocortex. Over the following 30 days, animals develop focal seizures and epileptiform discharges. In a colony of injected rats observed for over 1 year, 34% showed persistence of seizure. Subsequently, we have focused our studies on hippocampus in response to amygdala injections, taking advantage of the large literature on hippocampus within the context of amygdalar kindling. Targeting the amygdalar nuclear complex allowed observation of clear endpoints from resultant rodent behavioral changes, as predicted from kindling experiments.

Using this model, we began a series of experiments to elucidate the mechanisms of iron- and hemoglobin-induced epileptigenesis. Triggs *et al.* developed a microfluorescence method for detection and measurement of lipid peroxidation that results when iron cations are mixed with lipid. Although initial experiments used iron in aqueous solution, we demonstrated that not only iron in aqueous solution, but also blood products containing the iron moiety, would initiate lipid peroxidation. Subsequently, we found that pretreatment with α-tocopherol and selenium not only prevented epileptogenesis but completely inhibited the formation of a region of encephalomalacia with gliosis at the iron injection site. That striking observation was replicated by another laboratory,

using cat spinal cord injections. The tocopherol acetate pretreatment experiments led to an evaluation of the alcohol form of tocopherol as a treatment strategy.

Methods

Sprague-Dawley rats, weighing 200–280 g, were used for our studies (with approval from the appropriate animal use committees). Surgical procedures are performed with the animals anesthetized with pentobarbital sodium (37.5 mg kg^{-1}, i.p.). Animals were prepared for behavior and/or electrophysiological assessment. Control animals were injected with saline (0.9%), with pH adjusted to equal the acidity of the iron salts solution (pH of either ferrous or ferric chloride solutions were not adjusted, since pH manipulations will cause complex formation and cations to precipitate from solution).

Animal implantation involves stereotaxic placement of a 22-gauge guide cannula (lumen occluded with a stylet) just above the left amygdala. A bare-tipped insulated wire is affixed to the lip of the guide cannula orifice. The cannula is cemented to the skull with dental acrylic. After positioning the guide cannula, we remove the stylet and replace it with a fused silica tube that is attached to a microinjection pump (CMA Type 100); the tube is positioned in the left amygdala. Animals are then injected with 1.5 µl of 100 mmol $FeCl_3$ over 1.5 min, or with an equal volume of 0.9% NaCl (pH adjusted to 2.2, as for the ferric chloride solution). The cannula is removed at the end of the injection and the animals are allowed to recover. During injection, and for the following 30 min, all of our animals undergo continuous EEG recording (Grass Model 79). In addition, we used video recording (2 h, in a dimly lit room, on selected days between 8 and 10 a.m.) to monitor seizure behavior. Seizures are scored by the criteria of Racine; experimenters are blind to the nature of the injectate. Chronic recording from freely moving animals are carried out using teflon-coated stainless steel electrodes (<0.25 mm bare tips), positioned into the basolateral nucleus of the right amygdaloid body and into both dorsal hippocampi. Stereotaxic coordinates for amygdala are: 3.3 mm posterior from bregma, 5.0 mm lateral, and 8.5 mm below the surface of the skull; coordinates for the dorsal hippocampus are: 3.3 mm posterior from bregma, 1.5 mm lateral, and 3.4 mm below the surface of the skull. Stainless steel screws are placed in the occipital bone to provide reference and ground contacts. All electrodes are attached to wires with pin adapters and then affixed to the skull with dental acrylic. After 5 days of recovery from the surgery, the stylet is removed from the guide cannula and is replaced with an injection cannula consisting of a 24-gauge guide wire, the tip of which is a 0.5 mm length of fused silica (0.075 mm ID, 0.15 mm OD). These freely moving animals are injected with an aqueous solution (1.5 µl) of 100 mmol ferric chloride ($FeCl_3$, pH 2.2) at a rate of 1 µl min^{-1} using the microinfusion pump. Following injection, EEG recording and behavioral observations can be obtained daily for the duration of the experiment.

Animals prepared for neurochemical assessment or for molecular biological experiments are injected with $FeCl_3$, as described earlier, but chronic recording electrodes are not placed within the depths of the brain. Seizure behaviors are recorded for each animal during scheduled observations.

Results

Seizure Behavior and EEG

Acute injection of $FeCl_3$ into rat amygdala causes a gradual increase in spike discharges over 20 min, followed by quiescence of EEG patterns by the end of 30 min of recording. Animals injected with acidified saline have occasional isolated spike discharges. Of animals injected with $FeCl_3$ into the left amygdaloid body, up to 92% develop spontaneous seizures (stage 4 or 5) by the fifth day after injection. None of the acidified saline injected control rats have either sustained EEG discharges or behavioral seizures.

We have prepared parallel groups of animals with either EEG recording capabilities or with no intracranial electrodes – to allow for neurochemical experiments using microdialysis or molecular biological experiments. Among those animals prepared for chronic recording, all of those injected with $FeCl_3$ in our initial experiment developed spontaneous behavioral seizures and epileptiform discharges recorded from the depth electrodes. Epileptiform patterns are recorded from the ipsilateral amygdaloid body within 5–10 min after injection of $FeCl_3$. Over the following days, mainly epileptiform discharges are recorded from the ipsilateral $FeCl_3$-injected amygdala. During the following 3 days, focal spike discharges are much more frequent in the ipsilateral amygdala. However, by 5–7 days post-injection, isolated spikes can be recorded from both hippocampi and the contralateral amygdala. At 7 days after injection, we begin to record spontaneous rearing and limb clonus seizure (Racine stage 4–5) with rhythmic epileptiform discharges. Both the electrographic patterns and the behavioral seizures are observed until we terminate our experiments at 30 days post-injection. Saline-injected animals remain without spontaneous seizures or epileptiform abnormalities on the EEG recordings.

Histopathology

Timm staining of the hippocampus, as seen at 30 days following ipsilateral amygdala injection of $FeCl_3$, shows mossy fiber sprouting. In addition, with Berlin blue combined with H&E staining reveals cell loss in the ipsilateral and contralateral hippocampi (CA1 and 4 regions and the dentate hilus).

Genetic and Molecular Changes

Given that repetitive microinjection of glutamate into the amygdala causes seizure behaviors, we examined the regulation of neurotransmitter transporters by measuring mRNA and proteins responsible for glutamate and GABA removal. We extracted crude synaptic membrane fractions from hippocampal tissue and used immunoblotting and quantitative densitometry to measure the regulation of the high-affinity glutamate transporters GLAST, GLT-1, and EAAC-1. By 30 days following iron injection into the amygdala, the production of glial glutamate transporter GLAST is downregulated in both hippocampi. We hypothesize that the lost ability of brain to remove synaptic glutamate is fundamental to the process of posttraumatic epilepsy as modeled in these animals. Of interest, GABA transporters, particularly GAT3, are upregulated in a pattern that suggests compensatory responses within the inhibitory system.

Challenges for the Future

Within the context of this model, it is important to investigate the molecular basis of epileptogenesis, and the effects of drugs that might interfere with this process. Further, we continue to evaluate the impact of antiepileptic drugs on our model. Indeed, while epileptogenesis is correlated with the downregulation of GLAST and upregulation of EAAC-1, administration of valproate caused an increase in the quantity of GLAST protein measured in the hippocampus. Further, valproate treatment decreased GLT-1 in both control and experimental animals in both hippocampi, suggesting a unique mechanism of action. Specifically, valproate appears to affect the removal of glutamate by upregulating GLAST and decreasing GABA transport (which could result in increased tissue concentrations of GABA). Zonisamide administration increased the quantity of EAAC-1 protein in hippocampus and cortex, and downregulated the GABA transporters GAT-1, thus also increasing tissue and synaptic concentrations of GABA.

Fundamentals of neurochemical injury may offer clues for intervention in posttraumatic epileptogenesis. Hydroxyl radicals, superoxide radicals, and peroxides generated in biological systems – by oxidative chemistry or by actions of heme-containing compounds liberated within lipid systems – are quenched by the actions of enzymes such as catalase, peroxidase, and superoxide dismutase. Glutathione peroxidase, using glutathione as a cosubstrate and selenium as a metallic cofactor, reduces intracellular formation of hydrogen peroxide and free radicals. Oxidative stress increases activity of glutathione reductase, glucose-6-phosphate dehydrogenase, and glutathione peroxidase. Selenium, a metallic cofactor of glutathione peroxidase, also seems to act synergistically with α-tocopherol in preventing peroxidation of structural membrane components. These neurochemical sequences suggest that treatments designed to block free radical generation or quench the cascade of lipid peroxidation might lead to ways to prevent the development of epilepsy following trauma. α-Tocopherol prevents peroxidative injury of sulfhydryl groups of glycolipids and glycoproteins, apparently augmenting the antioxidant effects of enzyme systems such as glutathione peroxidase. Tocopherol also prevents peroxidation of unsaturated fatty acids and lipids by reaction of phenolic hydroxyl groups with propagating lipid radicals that were initiated by oxidative carbonyl hydrogen abstraction. Further, the phytyl side chain of tocopherol may intercalate within the acyl chains of polyunsaturated phospholipids, causing lipid membrane stabilization and reduction in membrane permeability. Tocopherol may also act as a free radical scavenger and singlet oxygen quenching agent. A novel nonglucocorticoid 21-aminosteroid with properties of inhibiting iron-dependent lipid peroxidation has been shown to have a protective effect on concussive injury to mice. Superoxide radicals induce cellular and vasogenic edema. Initiation of focal edema by cold-induced injury to the cerebral cortex of rodents causes increased levels of superoxide radicals. Administration of liposome-entrapped copper–zinc superoxide dismutase interferes with the development of cold-induced edema, suggesting that superoxide dismutase interruption of oxygen–free radical induced fatty acid injury may have potential for interruption of trauma-induced brain injury.

We continue to use amygdala injection of minute quantities of aqueous iron to initiate epileptogenesis, and then challenge that process with drugs and compounds. We believe this model provides a neurochemical and molecular framework for the study of epileptogenesis.

Introduction

Temporal lobe epilepsy (TLE) patients have a high incidence of schizophrenia-like symptoms. These symptoms may be present at all times between seizures (interictally) or only after seizure (postictal). I3n some patients, schizophrenic symptoms disappear following convulsive seizures. However, in other TLE patients, a single seizure, or more commonly, a cluster of seizures may result in psychiatric symptoms and occasionally in postictal psychosis that lasts for days.

The mechanisms of how seizures induce or suppress psychiatric symptoms are not well understood. A temporal lobe seizure may have time-dependent effects, on both local and remote structures in the brain. Seizures are known to alter synaptic transmission, either transiently or persistently. Excitatory synaptic transmission may be increased by frequency potentiation or other short-term potentation mechanisms, during or immediately after the seizure. Postictal potentiation, similar to long-term potentiation, may be long lasting. Inhibitory GABAergic transmission may be temporarily lost during and after a seizure, and permanently altered in epileptic patients. Seizures may also alter signaling pathways and gene function, and thus alter behaviors through gene expression.

Excessive mesolimbic dopamine activity, especially in the nucleus accumbens (NAC), has been proposed as the major cause of schizophrenia. Schizophrenia is a mental

These symptoms may be present at all times between seizures (interictally) or only after seizure (postictal). I3n some patients, schizophrenic symptoms disappear following convulsive seizures. However, in other TLE patients, a single seizure, or more commonly, a cluster of seizures may result in psychiatric symptoms and occasionally in postictal psychosis that lasts for days.

The mechanisms of how seizures induce or suppress psychiatric symptoms are not well understood. A temporal lobe seizure may have time-dependent effects, on both local and remote structures in the brain. Seizures are known to alter synaptic transmission, either transiently or persistently. Excitatory synaptic transmission may be increased by frequency potentiation or other short-term potentation mechanisms, during or immediately after the seizure. Postictal potentiation, similar to long-term potentiation, may be long lasting. Inhibitory GABAergic transmission may be temporarily lost during and after a seizure, and permanently altered in epileptic patients. Seizures may also alter signaling pathways and gene function, and thus alter behaviors through gene expression.

Excessive mesolimbic dopamine activity, especially in the nucleus accumbens (NAC), has been proposed as the major cause of schizophrenia. Schizophrenia is a mental

illness characterized by impoverished affect, nonsensical association, autistic behavior, ambivalence, delusions, and hallucinations. Psychotic symptoms can be relieved by a dopamine receptor antagonist. Some drugs that enhance dopamine function, e.g., amphetamine, induce schizophrenia-like symptoms in normal humans. Schizophrenia is also increasingly regarded as a disorder of an integrated system. Alteration of structure and function of the temporal lobe, particularly of the entorhinal cortex and hippocampus, may contribute to schizophrenia.

Many temporal lobe structures, including the hippocampus (CA1 and subiculum), entorhinal cortex, and amygdala, project excitatory glutamatergic afferents to the NAC, also known as the ventral striatum (Figure 1(c)). The NAC also receives glutamatergic afferents from the medial prefrontal cortex and dopaminergic afferents from the ventral tegmental area. The NAC has been suggested to be an interface between the limbic system and the motor system, and plays a critical role in reward and addictive behaviors.

Enhanced or disrupted synchrony of gamma waves of 30–100 Hz has been reported in the neocortical electrical activity of schizophrenic patients. In animals, increased gamma waves were reported in the hippocampus or NAC during schizophrenia-like behaviors induced by psychotomimetic drugs such as ketamine or phencyclidine. Electrophysiological studies of hippocampal gamma waves indicate that they are generated by purely GABAergic

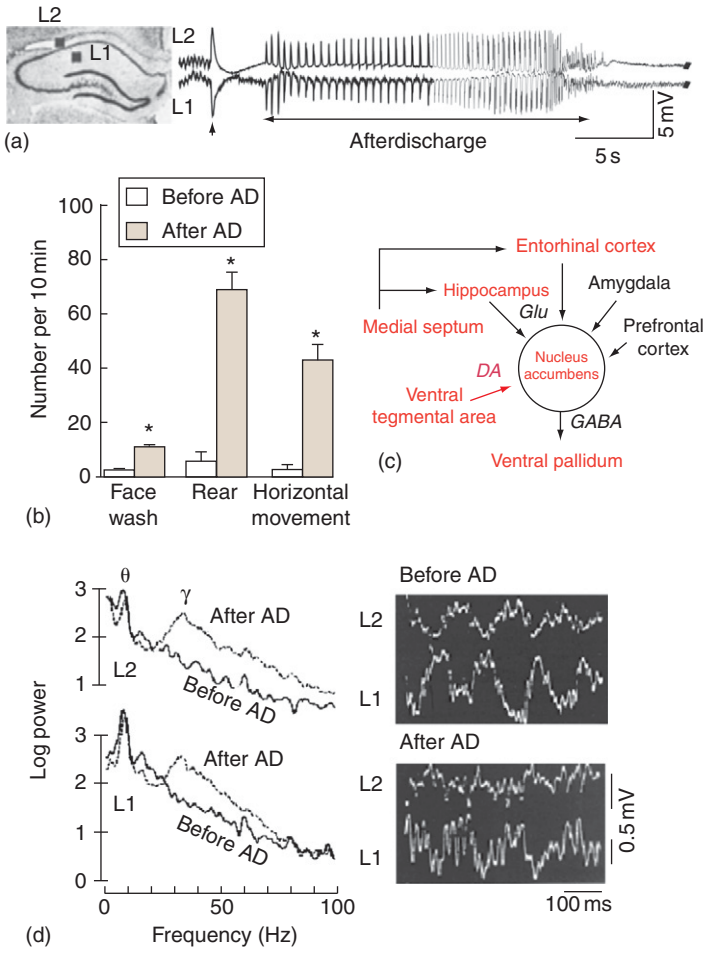

Figure 1 (a) A hippocampal afterdischarge (AD) of 21-s duration was recorded at electrodes L2 and L1 across the CA1 cell layer, evoked by a brief high-frequency stimulation (arrow) of the contralateral CA1 stratum radiatum. (b) Number of occurrence of face washes and vertical (rearings) and horizontal locomotion significantly increased in the 10 min after the AD, as compared with the 10 min before the AD. Adapted from Ma J, Brudzynski SM, and Leung LWS (1996) Involvement of the nucleus accumbens-ventral pallidal pathway in postictal behavior induced by a hippocampal after discharge in rats. *Brain Research* 739: 26–35. (c) Proposed neural circuit that mediates postictal behavioral hyperactivity, via dopamine release in the nucleus accumbens. Amygdala or prefrontal cortical AD did not induce postictal behavioral hyperactivity independent of the hippocampus. (d) Logarithmic power spectra of hippocampal EEG show enhanced gamma (γ, 30–100 Hz) but not theta (θ, 6–8-Hz peak) rhythm at the electrodes L2 and L1 (at stratum oriens and stratum radiatum of CA1, respectively) during the time of behavioral hyperactivity, 7 min after the AD. interactions among inhibitory interneurons, or by recurrent inhibitory interactions between excitatory pyramidal cells and inhibitory interneurons.

Background

Kindling of temporal lobe structures, notably the amygdala and the hippocampus, is a model of TLE. Kindling is the process of repeated and spaced stimulation of a brain structure, with the intention of evoking an afterdischarge (AD) with each stimulus. In classic studies, kindling of the amygdala increases the duration of the evoked AD and the severity of the accompanying behavioral convulsions. Full kindling is defined as attaining the stage of generalized convulsive seizures (stage 5 seizure of Racine). Chronic interictal behavioral changes are observed in the animals after amygdala kindling, in particular, after full kindling. Alteration of emotional behaviors, labeled as aggressive or defensive, has been reported in response to an animal intruder or to capture by a researcher. Kindled animals also show persistent changes in anxiety behaviors on an elevated maze, and deficient spatial behaviors in radial arm maze and water maze.

Dopamine hyperfunction after kindling has been indicated by several measures. Systemic injection of amphetamine (which releases dopamine) or a dopamine agonist may induce higher locomotor response in amygdala-kindled animals, as compared with non-kindled control animals. Changes in dopamine receptor sensitivity, dopamine release, and dopamine binding have also been found in chronic TLE models.

Postictal behavioral depression may also occur after a temporal lobe seizure, typically after a prolonged seizure accompanied by generalized convulsions. Behavioral depression after an amygdala AD (in a fully kindled animal) involves the release of endogenous opiates, which may decrease dopaminergic function in the NAC.

This article will focus on the postictal effects of a single AD in the hippocampus of rats, and on psychiatric symptoms in the partially hippocampally-kindled rats. Partial kindling refers to the repeated elicitation of ADs or electrographic seizures that are not accompanied by convulsive behaviors (i.e., Racine seizure stage 0 or 1).

Methods

We studied the changes in EEG and in synaptic transmission in the limbic system after hippocampal kindling. For studies in behaving rats, the rats were chronically implanted with indwelling electrodes for stimulation and recording. Guide cannulae were targeted at specific brain areas, including the hippocampus, medial septum, ventral pallidum, ventral subiculum, and NAC for infusion of drugs. Drugs included *N*-methyl-D-aspartate (NMDA) for excitation of glutamate receptors in the hippocampus, D_1 and D_2 receptor antagonists in the NAC, and $GABA_A$ receptor agonist muscimol for local inactivation of various structures. Electrically induced ADs were evoked by high-frequency stimulation (1-s train duration, 100–200-Hz frequency, stimulus intensity of 50–800 μA, 0.1–0.5-ms square pulse duration) in the dorsal and ventral hippocampus, ventral subiculum, amygdala, or medial prefrontal cortex of adult male Long Evans rats. For kindling, ADs were induced at intervals of not more than once every hour and 5 times a day. Partial hippocampal kindling reported here used 1, 10, or 21 ADs delivered to dorsal hippocampal CA1 area, without evoking behavioral convulsions.

Locomotor activity was quantified by analysis of the videotaped behaviors or by interruption of infrared beams in a $69 \times 69 \times 49\ cm^3$ high Plexiglas chamber. Locomotor activity was measured before and after injection of drugs. Sensorimotor gating deficits are found in schizophrenic patients, and sensorimotor gating is commonly tested by prepulse inhibition (PPI) of a startle reflex response. PPI was measured in rats by inhibition of an acoustic startle response, with a low-intensity noise serving as a prepulse (20-ms duration burst of noise of 73, 75, or 80 dB) presented 100 ms before a startle pulse of 120 dB. Percent inhibition of the startle response, averaged across the three prepulse intensities, provide a measure of PPI (see later). Muscimol (0.25 μg in 0.6 μl of saline) or saline (0.6 μl) was infused into the medial septum 15 min before evoking a hippocampal AD, and the rat was tested for PPI at 5–20 min after an AD.

Results

A Single Hippocampal AD Induces Behavioral Hyperactivity and PPI Deficit

In naive rats that were handled and implanted with chronically indwelling electrodes, but not otherwise experimentally manipulated, a long AD (>15-s duration) was evoked from the dorsal hippocampal CA1 area by a high-frequency stimulation (**Figure 1(a)**). The AD was followed by an increase in behavioral activity that included face washes, and most robustly, horizontal and vertical movements (**Figure 1(b)**). The behavioral hyperactivity lasted about 15 min after the AD.

PPI of the acoustic startle response showed a decrease when tested 5–20 min after a dorsal hippocampal AD, as compared with baseline in the same animal (pre-AD) or to control animals not given an AD (**Figure 2(b)**). There was no effect on the acoustic startle response itself (**Figure 2(a)**). Similarly, a PPI deficit was also found immediately after evoking an amygdala AD in a fully kindled rat. However, Howland *et al.* recently reported that PPI was not significantly altered immediately or two

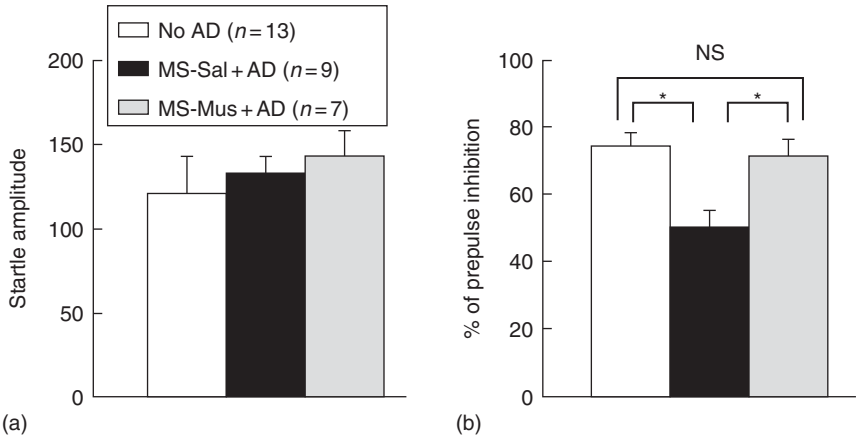

Figure 2 A hippocampal AD suppressed prepulse inhibition (PPI) of the acoustic startle (b) but not the startle itself (a). Muscimol infusion into the medial septum (MS-Mus) 15 min before the AD normalized the PPI, as compared with saline infusion into the medial septum (MS-Sal); * $p < 0.01$. Adapted from Ma J, Shen B, Rajakumar N, Leung LS (2004) The medial septum mediates impairment of prepulse inhibition of acoustic startle induced by a hippocampal seizure or phencyclidine. *Behavioral Brain Research* 155: 153–166.

days after a stage-5 AD evoked in the ventral hippocampus or the perirhinal cortex. For unknown reasons, it appears that a convulsive AD in the ventral hippocampus or perirhinal cortex, in contrast to an AD in the dorsal hippocampus or the fully kindled amygdala, may not induce significant functional disruption of structures involved in PPI, such as the NAC.

Structures and Pathways that Mediate Postictal Behavioral Alterations

Putative structures that are involved in postictal behaviors were identified by local infusion of drugs. Behavioral hyperactivity after a hippocampal AD was suppressed by infusion of a D_2 receptor antagonist sulpiride, or haloperidol, but not a D_1 receptor antagonist SCH 23390, into the NAC. This result suggests that hippocampal AD increased dopamine release and D_2 receptor activation. Inactivation of the ventral pallidum by local muscimol infusion also suppressed postictal hyperactivity (postictal PPI loss was not tested). Muscimol infusion into the medial septum suppressed both postictal hyperactivity and postictal PPI deficit. The medial septum projects cholinergic, GABAergic, and glutamatergic afferents to the hippocampus and modulates hippocampal excitability and EEG.

By recording electrical activity using chronically implanted electrodes, we showed that behavioral hyperactivity induced by infusion of NMDA into the ventral subiculum required the occurrence of a local AD. Little hyperactivity was induced by electrical or chemical stimulations in the ventral subiculum that did not evoke an AD. In addition, ADs evoked by electrical stimulation of the ventral subiculum had to last longer than 10 s in order to elicit behavioral hyperactivity. The number of horizontal movements was found to correlate with the duration of the AD evoked by ventral subiculum stimulation. Stimulation of other limbic structures gave different results: Stimulation of the ventral tegmental area typically induced stereotypic head movements, such as sniffing and forward locomotion, without evoking an AD. A nonconvulsive AD in the amygdala did not consistently change locomotor activity early in the kindling process, while a convulsive stage 5 amygdala AD in fully kindled animals was accompanied by a decrease in locomotor activity. Prefrontal cortical ADs only induced behavioral hyperactivity when the AD induced high-frequency gamma oscillations (of >70 Hz) in the NAC.

Partial seizures arising from the temporal or frontal lobe in patients are commonly associated with ictal or postictal automatic behaviors called automatisms. Postictal behavioral hyperactivity induced by a hippocampal AD in rats is a type of automatism, and it depends on dopaminergic D_2 receptor activation in the NAC. It is thus suggested that some postictal automatisms in TLE patients may be mediated by the NAC via a dopamine D_2 receptor mechanism.

Hippocampal Gamma Waves Are Associated with Postictal Behavioral Alterations

The power of gamma waves in the hippocampus was enhanced tenfold (one log unit) during the postictal behavioral hyperactivity induced by a hippocampal AD (**Figure 1(d)**). The period of enhanced hippocampal gamma waves lasted about 15 min after a hippocampal AD, generally similar to the duration of enhanced behavioral activity. However, the high gamma-wave activity did not abate during a brief period of behavioral immobility. Inactivation of the medial septum with muscimol (either before or immediately after a hippocampal AD) did not affect the AD duration, but it suppressed the AD-induced increase in both hippocampal gamma waves and

locomotor behaviors. The muscarinic cholinergic antagonist, scopolamine, partially suppressed the AD-induced increase in both gamma waves and locomotor behaviors. However, lesion of the cholinergic septohippocampal neurons in the medial septum by specific cholinotoxin 192IgG-conjugated saporin did not block the postictal increase in gamma waves or behavioral hyperactivity. Hippocampal disinhibition by both cholinergic and GABAergic septohippocampal afferents may be required for postictal gamma wave increase in the hippocampus.

Chronic Psychiatric Symptoms after Partial Hippocampal Kindling

Changes in behaviors were found after partial hippocampal kindling, as compared with nonkindled rats. Three behaviors – (1) increase in climbing episodes, (2) increase in locomotion after 1 mg kg^{-1} i.p. methamphetamine, and (3) decrease in PPI (**Figure 3**) – may be associated with an increase in dopamine functions in the NAC. Twenty-one hippocampal ADs, but not 10 hippocampal ADs, were needed to induce the latter behavioral changes. Similarly, kainic acid-treated rats (that experienced status epilepticus) showed increased behavioral hyperactivity with amphetamine challenge.

Kalynchuk *et al.* reported altered defensive and social behaviors in rats after 99 ADs in the amygdala, while Adamec showed that emotional behaviors in cats were induced by partial kindling (12 ADs) of the ventral hippocampus. A deficit of PPI was not found during the interictal state of amygdala-kindled rats, pentylenetetrazol-kindled rats, or in rats induced with kainic acid status epilepticus.

Future Goals

The ability of a single hippocampal AD to induce psychiatric symptoms such as locomotor hyperactivity and loss of PPI suggests that seizure activity in the limbic system alone can induce psychiatric symptoms. Locomotor hyperactivity is shown to be dependent on dopamine release in the NAC. Dopamine function appears to be sensitized and then suppressed during the process of kindling, but the mechanisms of sensitization and suppression are not fully studied.

The conditions (seizure origin, spread, and stage) whereby an AD can induce behavioral hyperactivity and PPI remain to be determined. Our data suggest that a bilaterally prolonged limbic AD has the ability to drive behavior by activation of the NAC. In the case of ADs evoked by stimulation of hippocampal CA3/CA1 or ventral subiculum on one side, the hippocampal AD spread bilaterally via the strong connection through the ventral hippocampal commissure. The AD was also prolonged, most likely because of the intrinsic physiology and/or the functional connections of the rat's hippocampus. Despite a direct connection to the NAC, the amygdala and the prefrontal cortex may not generate an AD of sufficient duration or sufficient bilateral synchrony to induce postictal psychiatric symptoms. Alternatively, a generalized AD in the amygdala or prefrontal cortex may mediate postictal behavioral depression by releasing opiates in the NAC. In humans, bilateral hippocampal ADs are relatively rare because of a small ventral hippocampal commissure.

Hippocampal gamma waves induced by a hippocampal AD do not have a moment-to-moment relation to the behavioral hyperactivity. However, periods of enhanced hippocampal gamma waves correlate with periods of behavioral hyperactivity, and medial septal inactivation reduces both gamma waves and behavioral hyperactivity. It is known that generation of hippocampal gamma waves depends on local inhibitory interneurons, but further studies are needed to address the alteration of hippocampal interneuronal interactions that correlate with schizophrenia-like behaviors. Procedures or drugs that modulate the inhibitory circuits in the hippocampus,

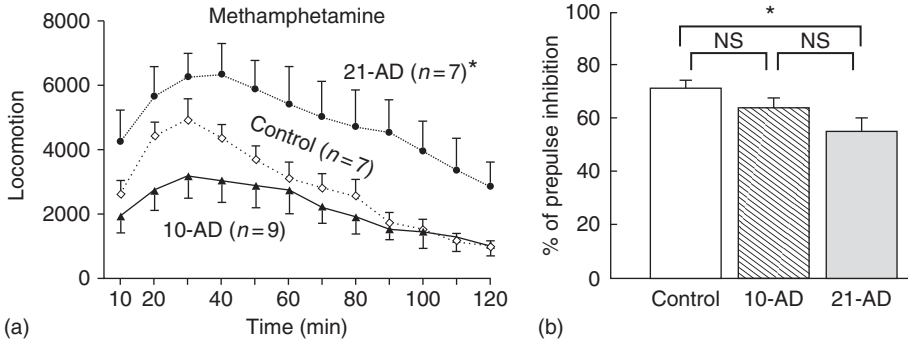

Figure 3 Methamphetamine-induced behavioral hyperactivity and decrease in PPI were found after partial hippocampal kindling with 21 ADs, but not with 10 ADs. Locomotion was measured by interruption of infrared beams counted in 10-min bins. Methamphetamine (1 mg/kg i.p.) induced increased locomotion in 21-AD group as compared with control or 10-AD group. A significant loss of PPI of the acoustic startle was found in the 21-AD group ($N = 6$), but not in the 10-AD group ($N = 9$), as compared with control group ($N = 11$) tested 3 days after the last AD. Interictal Anxiety in Temporal Lobe Epilepsy

L E Kalynchuk and N M Fournier, University of Saskatchewan, Saskatoon, SK, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy is a common and serious neurological disorder affecting almost 1% of the world's population. Most people with epilepsy lead normal lives; however, a significant proportion experience severe interictal (i.e., in between seizures) disturbances in cognition and behavior. Consistent with this observation, clinical studies have repeatedly shown that the rate of anxiety, depression, and psychosis is overrepresented in epileptic populations. These behavioral disturbances are especially high among patients with partial seizures that result from epileptiform discharges within mesial temporal limbic structures – a condition called temporal lobe or limbic epilepsy. Although seizures are the primary problem in epilepsy patients, the continuous and protracted presentation of these behavioral disturbances can profoundly affect their quality of life. However, these problems often go unrecognized and even when identified, they are frequently under-treated.

Considering the high prevalence of temporal lobe epilepsy (TLE) among adult seizure disorders, characterizing the nature and etiology of interictal anxiety is a worthwhile objective. However, studying interictal anxiety clinically has been difficult because of the heterogeneity in seizure-related factors among patient populations. The use of animal models of epilepsy has helped expand our understanding of how changes in cognitive and emotional behaviors relate to seizure-induced changes in neurobiology.

Background

Clinical Manifestations of Anxiety in TLE

Given the well-known role of the limbic system in regulating complex aspects of emotional behavior, it is not surprising that the major types of behavioral changes associated with TLE encompass areas of mood, personality,

such as inactivation of the medial septum by a GABAergic agonist, may provide therapeutic treatment of psychiatric symptoms in TLE patients.

Interictal Anxiety in Temporal Lobe Epilepsy

L E Kalynchuk and N M Fournier, University of Saskatchewan, Saskatoon, SK, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy is a common and serious neurological disorder affecting almost 1% of the world's population. Most people with epilepsy lead normal lives; however, a significant proportion experience severe interictal (i.e., in between seizures) disturbances in cognition and behavior. Consistent with this observation, clinical studies have repeatedly shown that the rate of anxiety, depression, and psychosis is overrepresented in epileptic populations. These behavioral disturbances are especially high among patients with partial seizures that result from epileptiform discharges within mesial temporal limbic structures – a condition called temporal lobe or limbic epilepsy. Although seizures are the primary problem in epilepsy patients, the continuous and protracted presentation of these behavioral disturbances can profoundly affect their quality of life. However, these problems often go unrecognized and even when identified, they are frequently under-treated.

Considering the high prevalence of temporal lobe epilepsy (TLE) among adult seizure disorders, characterizing the nature and etiology of interictal anxiety is a worthwhile objective. However, studying interictal anxiety clinically has been difficult because of the heterogeneity in seizure-related factors among patient populations. The use of animal models of epilepsy has helped expand our understanding of how changes in cognitive and emotional behaviors relate to seizure-induced changes in neurobiology.

Background

Clinical Manifestations of Anxiety in TLE

Given the well-known role of the limbic system in regulating complex aspects of emotional behavior, it is not surprising that the major types of behavioral changes associated with TLE encompass areas of mood, personality,

and thought. These emotional disturbances can range from mild fear to pathological levels of anxiety and depression, and may include episodes of psychosis. Although these symptoms may develop concomitant to seizure activity (in prodromal, ictal, or post-ictal periods), they are more commonly present during chronic interictal periods. Higher rates of emotional disturbances are observed in people with TLE than those afflicted with other types of seizure disorders. Estimates have suggested that the prevalence of emotional disturbances among TLE patients may be as high as 50% during the interictal phase.

Anxiety is one of the most common interictal behavioral disturbances reported in patients with TLE. Several studies have estimated that the prevalence of interictal anxiety in TLE patients is between 14% and 25%, and in some settings it is as high as 65%. However, relative to other psychiatric-epileptic dyads (such as depression and psychosis), the relationship between anxiety and epilepsy has been less thoroughly investigated. This is surprising considering the frequent comorbidity of anxiety with other psychiatric conditions (such as depression) and the considerable focus that current psychiatric research has placed on understanding the pathophysiology of anxiety. Clinical observations suggest that seizure-related factors such as age of onset, duration of epilepsy, antiepileptic treatment, seizure severity, and lateralization of seizure spread can be important predictors for the development of interictal anxiety in patients with TLE. In addition, several questionnaire studies have tried to examine the relative contribution of anxiety in reducing health-related quality of life measures in people with epilepsy. In one study, interictal anxiety was the most significant predictor for reduced quality of life in epileptic patients, explaining 27% of the variance in these measures compared with 12% for depression and 3% for seizure frequency.

Preclinical Research on Interictal Anxiety

The neurobiological study of interictal anxiety in human epileptic patients has been slowed by the diversity in seizure-related factors among patients and potential psychosocial influences that may affect their lives. Determining how seizures alter brain function interictally to produce lasting changes in emotionality has been difficult. The development of animal models of epilepsy has helped in this regard by removing many of the inherent problems associated with human clinical research and allowing for controlled investigations of the pathophysiology of interictal anxiety. The kindling model of TLE has been one of the most valuable methods for studying the neural mechanisms associated with interictal anxiety and emotionality. The remaining sections of this chapter will focus on the kindling model. We encourage the reader to consult the 'Further Reading' section for additional discussion on interictal behavioral disturbances found in other animal models of epilepsy.

Kindling as an experimental tool for measuring interictal anxiety

Kindling refers to the process whereby repeated application of initially subconvulsant focal electrical stimulations to subcortical or cortical regions results in long lasting, if not permanent, increases in seizure susceptibility. Although kindling has been commonly used to study epileptogenesis, several features of kindling have made it an attractive model for understanding the pathogenesis of interictal behavioral disturbances. For instance, because the site of stimulation is under the control of the experimenter, inducing epileptic seizures from different brain sites can allow for the investigation of neuroanatomical structures that might be important in mediating interictal anxiety. In addition, because the time-window between consecutive seizures can also be controlled and manipulated by the experimenter, the potential influence of ictal and post-ictal effects on the interpretation of behavioral data is minimized. Finally, because the behavioral and electrographic evolution of seizures during kindling is progressive, this model also offers the possibility of evaluating the behavioral consequences of seizures at different stages in the development of epilepsy.

Effects of kindling on interictal anxiety

Kindling can enhance fear and defensive responses in rodents and felines. From a clinical perspective, studying interictal changes in fear and defensive behavior is important because these animal behaviors model many aspects of human anxiety (**Table 1**).

Table 1 Common behavioral and clinical correlates of fear and defensiveness in kindled rats and in humans suffering from clinical anxiety disorders (generalized anxiety disorder)

Animal	*Fear/anxiety*	*Defensive*
Kindled rats	Increased startle response, increased freezing to novel situations, changes in heart rate, hypoalgesia, increased defection and urination in response to stress, autonomic dysregulation (such as sweating, piloerection, etc.), and hyperlocomotion	Fighting, biting, escape (flight or jumping) and avoidance (passive, active, and/or defensive burying)
Humans (w/GAD)	Exaggerated startle response, experiences of worry (and apprehension), inability to inhibit behavior, cardiovascular changes, autonomic dysregulation, diarrhea and increased urination	Irritability, outbursts of anger, and persistent avoidance of the aversive stimulus

Adamec was the first to systematically document the effect of kindling on interictal fear and anxiety-like behavior. In his seminal studies, partial kindling (i.e., kindling that produces afterdischarges but no generalized motor convulsions) of the amygdala or ventral hippocampus in cats resulted in long-lasting changes in emotional behavior that appeared to be independent of motor seizures or interictal spiking for their maintenance. He found that partially kindled cats displayed elevated defensive responses (such as defensive posturing, piloerection, ear retraction, and vocalizations) when exposed to rats, mice, or recorded vocal threats from conspecifics. These effects were lasting and could still be evoked 4 months after the last afterdischarge.

Many of these findings were soon replicated in the rat. Pinel and his colleagues demonstrated that increased interictal defensiveness (i.e., resistance to being captured, Table 2) followed protracted kindling of the amygdala but not the caudate nucleus. Similar changes in defensiveness in the rat were also reported by Post using a pharmacological kindling model of repeated lidocaine injections. Subsequent work by Caldecott-Hazard and her colleagues further showed increases in locomotor activity during exposure to a novel environment 21 days after bilateral amygdala kindling. Of particular interest was the fact that these investigators also reported a global reduction in deoxyglucose metabolism in the forebrain after kindling. This finding may be of clinical relevance because similar reductions in glucose metabolism are often seen in limbic regions of TLE patients who report high levels of anxiety and emotional disturbances.

It is well known that stress can precipitate the development of affective illnesses such as anxiety and depression. Several studies have revealed that kindling can exacerbate the effects of stress. Most notable are the studies of Henke and Sullivan, who reported that amygdala kindling potentiated the formation of stress-induced stomach ulcers. Furthermore, Weiss and her colleagues showed that administration of the stress hormone corticotrophin-releasing hormone (CRH) elicited defensive fighting in rats that had been previously kindled. These results suggest that repeatedly evoked seizures can lead to the subsequent dysregulation of stress circuitry and may contribute to the appearance of interictal behavioral disturbances.

Short-term kindling protocols – in which animals receive daily electrical stimulations until three to five consecutive generalized motor convulsions are elicited (i.e., 15 and 30 stimulations in the case of amygdaloid stimulations) – have been used to examine interictal changes in emotionality. Using this protocol, several researchers have shown that short-term kindling decreases open-arm exploration on an elevated plus maze, increases passive (e.g., freezing) and active defensive responses (e.g., flight and fighting) to both threatening and nonthreatening stimuli, increases withdrawal from social interactions, and increases fear-potentiated startle. The changes in interictal behavior associated with kindling appear to be highly specific and involve increases in fear and/or anxiety-like behavior. Despite the high concordance of depression in patients with TLE, we (and others) have found that kindled rats do not show differences – compared to non-kindled controls – on measures of depression such as sucrose preference (a measure of anhedonia) or forced swimming (a measure of helplessness).

Table 2 The 7-point scale for resistance to capture

0 = Easy to pick up
1 = Vocalizes or runs away from hand
2 = Shies away from hand and vocalizes
3 = Runs away from hand
4 = Runs away from hand and vocalizes
5 = Bites or attempts to bite
6 = Launches a defensive jump attack

Methods

We have developed an animal model of interictal emotionality in which rats receive 99 electrical stimulations of the amygdala. It was our contention that if interictal emotionality involves the development of hyperexcitable fear circuits, then this process would be far from complete after just a few consecutive generalized convulsions. Long-term amygdala kindling would produce changes in interictal emotionality that may not be apparent with partial kindling, and these changes would be more robust than the ones produced by short-term kindling. As a result, long-term kindling offered a unique advantage in that it would provide a robust and reliable method for studying changes in interictal behavior after seizures. An additional point of importance was that delivering 99 electrical stimulations ensured that our animals would be well kindled, but not so well kindled that they would begin exhibiting spontaneous convulsions, which would seriously confound the interpretability of behavioral testing. Early work by Pinel and colleagues showed that spontaneous seizures do not occur unless rats receive at least 200 amygdala stimulations. Indeed, we have never observed a spontaneous seizure in a rat subjected to 99 kindling stimulations.

Our general methods are as follows. Rats are brought into our animal facility from a commercial supplier. They are given a few days to acclimatize to the facility, and then they are subjected to stereotaxic surgery. During the surgery, a bipolar stimulating electrode is implanted into the structure of interest in the left side. This is usually the basolateral amygdala, but we have also studied the effect of kindling the central nucleus of the amygdala, hippocampus, caudate nucleus, claustrum, perirhinal cortex, and bed nucleus of the stria terminalis. Rats are given several days to recover from the surgery prior to the onset of kindling. During kindling, rats receive three stimulations per day, 5 days per week, with a minimum

of 2 h between consecutive stimulations. Each stimulation consists of a 1 s, 60 Hz train of square-wave pulses, and each pulse has a biphasic amplitude that is well above threshold to elicit an afterdischarge (e.g., 800 μA peak-to-peak for amygdala stimulation). We always include a separate group of control rats that receive sham stimulations, in which the stimulating electrode is implanted and subsequently attached to the stimulation apparatus – but no current is passed. Our primary measure of seizure severity is the convulsion class elicited by each stimulation. We use the following extension of the Racine scale: class 0 convulsions comprise an arrest in behavioral mobility; class 1 convulsions comprise orofacial automatisms; class 2 convulsions comprise orofacial automatisms and repetitive head nodding; class 3 convulsions comprise unilateral forelimb clonus and mastication with salivation; class 4 convulsions comprise generalized convulsions with rearing and forelimb clonus; class 5 convulsions comprise rearing with rapid bilateral forelimb clonus followed by a loss of equilibrium; class 6 convulsions comprise bouts of multiple class 5 convulsions; class 7 convulsions comprise running fits and jumping; class 8 convulsions comprise any of the preceding symptoms with intermittent periods of tonus.

We generally conduct our behavioral testing beginning one day after the final kindling stimulation, but in some cases we have delayed the behavioral testing for one week or one month. We have used a number of different behavioral tests to assess changes in anxiety and depression-like behavior, including the open field, resistance to capture from the open field (see **Table 2**), elevated plus maze, social interaction, acoustic startle, forced swim, and sucrose preference tests. Rats receive no more than one behavioral test per day. After the completion of behavioral testing, rats are sacrificed and brains are processed to analyze changes in gene and protein expression using several different molecular techniques.

Recent Results

Long-Term Amygdala Kindling and Interictal Anxiety

We consistently see increased fear and anxiety-like behavior in rats subjected to long-term kindling. For example, when placed into an unfamiliar open field, long-term amygdala-kindled rats show a short initial period of immobility or freezing that is followed by a longer period of explosive ambulation and escape-related behaviors (**Figure 1**). At the end of testing, these rats display extreme resistance to being captured and engage in several active defensive responses such as fleeing, biting, and defensive jump attacks. These fear responses are exaggerations of normal species-specific displays of fear (e.g., freezing, fleeing, and fighting) to unfamiliar environments and potentially threatening stimuli. Such liability in emotional responses towards novel and mildly anxiety-provoking stimuli is consistent with the idea that repeated seizures lead to sensitization in neural pathways related to fear and escape-related behavior. Two additional lines of evidence also support this idea. First, we found a monotonic relationship between the number of kindled stimulations (i.e., 99 > 50 > 30 > 20 stimulations) and the magnitude of fear behavior produced by amygdala kindling. Second, we found that elevations in resistance to capture were dependent on the novelty and unfamiliarity of the testing environment; i.e., kindled rats

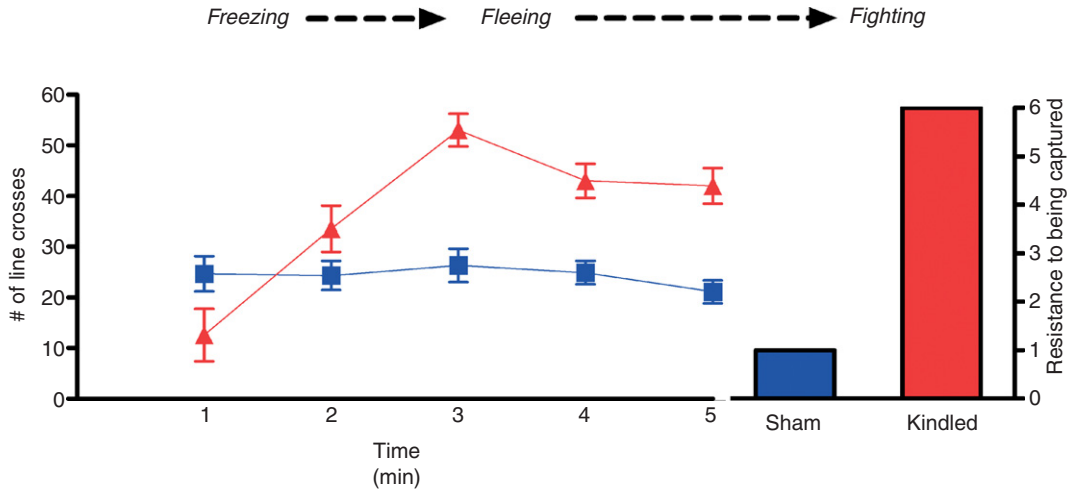

Figure 1 An example of the behavioral profile of kindled rats exposed to an unfamiliar environment. When placed in an unfamiliar open field, kindled rats first engage in a period of freezing, followed by enhanced exploration and darting from one end of the open field to another. After five minutes of this exploration, kindled rats display extreme resistance to capture from the open field, characterized by fleeing, vocalizations, attempts to bite, and defensive jump attacks (see text and **Table 2** for further discussion). These findings suggest that long-term kindling of brain structures related to emotionality, such as the amygdala, can lead to profound changes in interictal responses to mildly anxiogenic events.

displayed little resistance to capture from their home cages or from an already familiar open field.

The behavioral outcome of repeated seizures also appears to be highly dependent on the brain area that is stimulated. Our analyses revealed the following pattern of fear behavior after long-term kindling: basolateral amygdala = central amygdala > bed nucleus of the stria terminalis > perirhinal cortex = ventral hippocampus > claustrum = caudate = sham. These findings show that kindling of amygdaloid nuclei and related structures results in the greatest increases in fear behavior, whereas kindling of hippocampal and parahippocampal regions produces only intermediate increases in fear. Of importance is the fact that kindling non-limbic structures, such as the caudate and claustrum, does not increase interictal fear. Although these non-limbic structures are known to be involved in the spread of seizures, the fact that kindling them does not increase interictal fear suggests that it is not generalized seizure activity per se that is important for the development of interictal disturbances. Instead, it appears that the location of seizure initiating activity and/or potential seizure-inducing modifications is most critical.

An important question is how long the changes in interictal behavior last once the kindling stimulations have been terminated. The persistence of interictal emotional behavior is extremely important in forming hypotheses about the neural mechanisms that mediate sensitized fear and anxiety-like responses. For example, if interictal anxiety declines quickly once the seizures have stopped, then the anxiety might be simply an epiphenomenon (or by-product) of seizure activity. Alternatively, if interictal anxiety persists for long periods of time, then it is reasonable to speculate that potentially permanent modifications in emotional neural circuits may accompany chronic seizures. We have found that long-term amygdala kindling produces the greatest increases in fear behavior one day or one week after the final seizure, but kindled rats tested two months after the final seizure remain significantly more fearful than sham-stimulated controls. It should be noted that the biological outcome of a 30 to 60-day period in a rat is probably not functionally equivalent to a 30 to 60-day period in a human; a 30 to 60-day period in an adult rat would be functionally equivalent to a period of roughly 2–5 years in an adult human. Thus, the persistent elevations in interictal anxiety and emotionality for such a considerable period of time would certainly fit even the most conservative criteria of a clinical anxiety disorder.

Possible Mechanisms Underlying Interictal Anxiety

Electrophysiological studies

The lasting nature of interictal anxiety produced by kindling suggests that seizures modify the functional and perhaps physical relationships among sets of neurons. The neurocircuitry involved in fear and defensive behavior in the rat has been well characterized. The hippocampus and nuclei of the amygdala play important roles because of their direct and indirect innervation of the ventral medial hypothalamus (VMH) and midbrain periaqueductal grey (PAG) matter – two brain structures important in defensive behavior. Early studies by Adamec and his colleagues revealed that the threshold response to elicit defense reactions from VMH and/or PAG stimulation in the cat was significantly lower after partial amygdala kindling. Later, Adamec's group showed that partial kindling potentiated efferent transmission from the amygdala to the PAG. Indeed, amygdala-kindling-induced potentiation of neurons of the PAG and VMH could contribute to increased efficacy in transmission between these structures. Adamec's group went on to show that bilateral low frequency stimulation of the amygdala could selectively depotentiate the changes in efferent transmission to the PAG and VMH that occurred after partial kindling. Interestingly, potentiation of the right amygdala connection with the PAG caused defensive behaviors to return to pre-kindling levels. These findings may be of clinical relevance as epileptogenic foci lateralized to one particular side of the brain are associated with different psychiatric symptoms (e.g., depression is correlated with left hemispheric foci).

Receptor binding studies

In a series of receptor binding studies, we found that measures of interictal anxiety correlated with changes in a number of receptor subtypes localized primarily in the hippocampus. The pattern of results was clear: inhibitory receptor binding (e.g., for $GABA_A$, benzodiazepine, and $5\text{-}HT_{1A}$ receptors) was significantly increased within the dentate gyrus after kindling, whereas excitatory receptor binding (e.g., for NMDA and AMPA receptors) was significantly decreased in this region (**Figure 2**). Surprisingly, no significant changes in receptor binding were detected in the amygdala. We also found decreased *c-fos* immunoreactivity (a molecular marker of cellular activation) in the dentate gyrus and CA1 after kindled rats were exposed to fear-provoking stimuli. These findings led us to speculate that the hippocampus of kindled rats might be in a state of hyper-inhibition, which resulted in a type of functional lesion and ultimately, in dysfunction.

There is further support for the idea that hippocampal dysfunction might play a role in interictal anxiety. Several studies, most notably the work of Gallagher and colleagues, have shown that human TLE patients express increased levels of the stress hormone adrenocorticotrophic hormone (ACTH) between seizures. Surgical resection of the epileptogenic focus appears to normalize ACTH levels. In addition, several researchers have noted that limbic seizures increase the release of glucocorticoids (cortisol in man; corticosterone in rat). We have found that long-term amygdala kindling decreases glucocorticoid

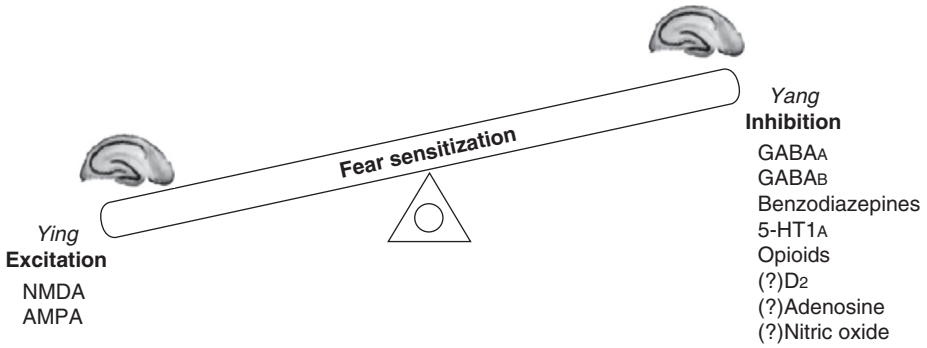

Figure 2 Hypothetical model for explaining increased fear sensitization and interictal behavioral pathologies after long-term kindling. (?) denotes possible changes in receptor subtype or neurotransmitters.

receptor (GR) mRNA expression in the dentate gyrus and hippocampal CA1 region. It is very likely that high levels of circulating glucocorticoids after kindled seizures lead to an eventual downregulation in GR expression in the hippocampus. These changes in GR expression may have important functional consequences for the development of interictal anxiety. First, alterations in the transcription of genes controlled by the GR promoter could lead to downstream effects on different genes and their protein products, some of which may be involved in anxiety. Second, because hippocampal GRs are instrumental in terminating the stress response, a downregulation of GR receptors could result in consistently elevated levels of circulating corticosterone or cortisol. Finally, high levels of glucocorticoids are known to induce dendritic remodeling of pyramidal neurons of amygdala and hippocampus, which may play a role in enhancing epileptiform activity.

Does increased inhibition play a role in maintaining the interictal state?

An important question is whether the increase in hippocampal inhibition after kindling plays a functional role in the pathogenesis of interictal anxiety. Considering the prominent role of the hippocampus in the processing of contextual information and in mediating some aspects of anxiety and fear behavior, increased inhibition in hippocampal circuits after kindling might explain the elevated anxiety and fear that occurs in response to novel environmental stimuli. The dentate gyrus is known to regulate hippocampal excitability and serves as a major gateway through which excitation from the entorhinal cortex enters the hippocampus. Some investigators have speculated that the development of inhibitory processes and other seizure suppressing mechanisms after epileptic seizures reflects a homeostatic response that serves to maintain the interictal state. Interestingly, kindling potentiates feedback and feedforward inhibition in the dentate gyrus, and there is some evidence that inhibitory mechanisms in CA1 might also be compromised in the chronically epileptic brain. Gutierrez and colleagues found that after seizures, dentate granule cells begin to synthesize and release the inhibitory neurotransmitter GABA from normally excitatory mossy fiber terminals. When taken together with the results from our receptor binding studies, these findings suggest that increased inhibition after kindling might reflect an endogenous compensatory response to reduce the likelihood of subsequent seizures. Viewed in this way, interictal anxiety could be a by-product of the brain's attempt to limit the future occurrence of seizures.

Neurogenesis and interictal anxiety

The discovery that seizures can increase neurogenesis in the adult hippocampus has become the focus of much experimental research. Although most of this work has focused on how aberrant neurogenesis might contribute to epileptogenesis, an interesting question is whether the birth of new neurons after seizures also plays a role in the emergence of interictal behavioral disturbances. Our preliminary work has revealed that hippocampal neurogenesis is substantially increased following short-term amygdala kindling to about 30 stimulations, but that it declines from there as more kindling stimulations are delivered. By the 99th kindling stimulation, the rate of cell proliferation is back to baseline levels (**Figure 3**). Given the observation that newly born neurons require 2 weeks to 1 month to fully integrate into preexisting adult hippocampal circuits, newly generated cells born after the 30th kindling stimulation would have time to differentiate, migrate, and functionally integrate themselves by the time the 99th kindling stimulation is delivered (~4 weeks after the 30th kindled stimulation). We believe that these newborn cells may play a role in the emergence of interictal anxiety after long-term kindling.

Some exciting recent findings from Katherine Jakubs of Olle Lindvall's laboratory in Sweden suggest that at least some of the new neurons born after epileptic seizures might serve to maintain network homeostasis after seizures. Jakubs and colleagues found that new neurons produced under seizure conditions received increased inhibitory and reduced excitatory synaptic input. The reduced excitability of these new neurons suggested to

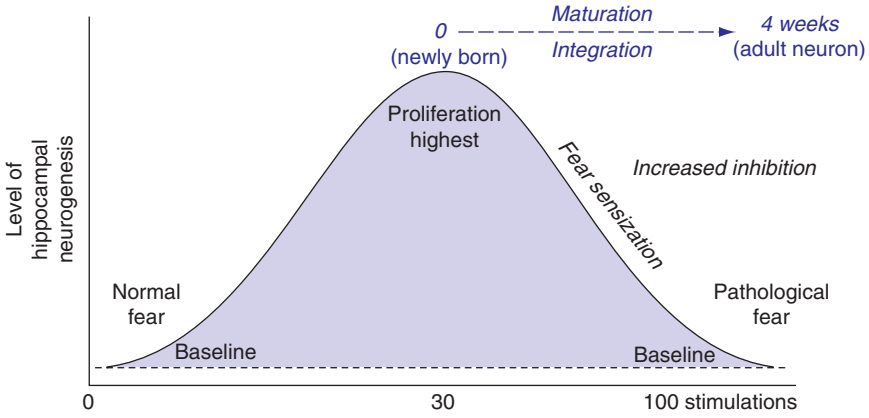

Figure 3 Time course of seizure-induced neurogenesis and interictal behavioral pathology.

them that at least some aspects of seizure-induced neurogenesis might serve to compensate for the increased excitatory activity associated with epilepsy. It is possible that increased inhibition within the dentate gyrus exacerbates kindling-induced emotional behavior during the interictal period. An intriguing idea is that the increased inhibitory drive on newly generated dentate neurons might play a role in this process. This hypothesis is consistent with the possibility suggested above, that some of the compensatory changes in inhibitory activity that serve to maintain a seizure-free state have the secondary consequence of increasing the development of behavioral disturbances.

Future Directions

Effect of Gene Expression on Interictal Anxiety

There has been much interest in examining how seizures lead to changes in gene expression. Despite the extensive use of microarray and proteomic technologies to examine changes in the expression of genes and gene products (proteins) associated with different types of epilepsy disorders, there has been no systematic study to date investigating which gene changes might relate to the development of affective psychopathology in epilepsy. Rats that have been selectively bred to be more or less susceptible to enhanced amygdala excitability and the effects of kindling (e.g., FAST and SLOW kindled rats) display altered levels of anxiety and fear in response to novel environments. These findings suggest that an important topic of future research should be directed at how specific genetic factors influence both seizure susceptibility and the development of behavioral disorders associated with epilepsy.

Effect of Increasing Hippocampal Activity on Interictal Anxiety?

If increased inhibition in the hippocampus leads to the development of interictal anxiety in individuals with TLE, then procedures that are known to increase hippocampal activity and adaptive plasticity might help reduce fearful behavior in kindled rats. We tested this hypothesis recently using procedures such as training on a Morris water maze spatial cognition task or housing in a complex (spatially enriched) environment. Importantly, these two procedures are known to activate and elicit synaptic changes within the hippocampal formation. In both cases, kindled rats exposed to these procedures were much less fearful than kindled rats that were not exposed to the procedures. Although the mechanism(s) responsible for the beneficial effects of hippocampal activation on interictal anxiety is unknown, one intriguing possibility is that these procedures may work by altering the course of hippocampal neurogenesis. We have hypothesized that new cells, born under conditions of continuing seizure activity, may be predisposed to take on abnormal inhibitory characteristics – partly in an attempt to reduce the probability of future seizure activity. However, new cells born under conditions of enrichment or learning may be predisposed to take on normal excitatory characteristics – which could re-set normal emotional responding to aversive stimuli. This idea is speculative, but it does provide a framework for future research aimed at understanding the particular features of adaptive plasticity that ameliorate seizure-induced changes in behavior.

Discovery of More Effective Anticonvulsant Treatments

Most anticonvulsant interventions are administered with the primary aim of preventing the complications of unprovoked seizures by reducing their frequency and/or their severity. However, several clinical studies have revealed that treatment with certain antiepileptic drugs can aggravate interictal anxiety in some patients. These disruptions in normal behavior can have profound effects on the quality of life for the patient, which can overshadow the beneficial effect of the drug on seizure occurrence.

If inhibitory systems are enhanced during chronic epilepsy, then it is possible that certain anticonvulsant drugs, whose mode of action is to potentiate inhibitory transmission and suppress ictogenic events, may exacerbate behavioral disturbances during interictal periods. There has been very limited study of this issue using experimental models of epilepsy. What is known is that administration of the anticonvulsants carbamazepine and valproate can exacerbate interictal defensiveness in spontaneously epileptic cats, whereas treatment with flumazenil (a benzodiazepine antagonist) can decrease interictal defensiveness in partially kindled rats. Further study in this area may help identify pharmacological as well as potential non-pharmacological interventions that simultaneously provide effective seizure relief and decrease the interictal behavioral comorbidities associated with epilepsy.

Conclusions

The study of epilepsy and its psychiatric comorbidites provides an excellent opportunity to explore the relationship between pathological brain activity and behavior. By determining how seizures impact the structural and function organization of the brain, we hope to gain a better understanding of the neural mechanisms that underlie the development of interictal anxiety. The information gained from these studies may help in the development of more effective treatments that can reduce the impact of these disturbances.

Introduction

Although the behavioral problems associated with epilepsy are greater than would be expected on the basis of the existence of a chronic illness alone, there is debate in the field about just how common the problems are. The notion that epileptic seizures themselves can produce a persistent disruption of normal neuronal function, and result in the appearance of interictal behavioral disorders, has a long history. However, this view is still not

completely accepted and is even fervently dismissed by some. Recent studies have concluded that behavioral comorbidities with epilepsy are the rule rather than the exception. But are these behavioral disturbances due to the same altered neural functioning that gives rise to seizures? Are they a consequence of seizures themselves? Or are they due some other unrelated factors? With electrical kindling, we can assess the long-term behavioral consequences of seizures without confounding factors (e.g., heterogeneity of the population, seizure locus and frequency, undetected ictal events, anticonvulsant medications, social stigma) that make such assessments in patients so difficult. For instance, the focus and frequency of seizures, as well as the influence of anticonvulsant medications on behavior, can easily be controlled. Further, the influence of social stigma can be ruled out in kindling studies, which thus can generate neurobiological explanations for interictal behavioral disturbances. This article focuses on the major behavioral consequences of kindling and speaks to the behavioral disturbances in adults with focal (partial) epilepsy. We discuss issues related to the site and hemisphere of stimulation, the time course of changes, and whether kindling produces a functional lesion.

Background

Psychology and neuroscience have a long history of determining the contribution of a specific area of the brain to the generation of behavior. When a behavior is abolished, reduced, or even enhanced following creation of a lesion, this result is interpreted as evidence that the lesioned area was, at least in part, involved in the generation or regulation of that behavior. Although kindling is not associated with a gross lesion, we argue below that it does result in lasting changes in the behaviors or functions subserved by kindled circuits. Furthermore, behavioral capacity or functions can be increased or decreased, depending on whether the circuits are enhanced (perhaps due to potentiation of excitatory transmission) or suppressed (perhaps due to potentiation of inhibitory influences). In either case a functional lesion is created, meaning that normal behavior is disrupted by the seizures.

Emotional Disturbances

It appears that some people with temporal lobe epilepsy do differ from both healthy people and those with chronic non-neurological disorders in their behavioral traits. This difference is suggested by results from several early reports – e.g., by Waxman and Geschwind in 1975, who characterized an interictal behavioral syndrome that they believed was associated with temporal lobe seizures, and by the systematic 1977 Bear–Fedio Inventory – and by more recent studies using modern psychiatric diagnoses. The behavioral differences are primarily in emotional behaviors such as fear, anxiety, and depression, although there is no consensus on the exact nature of the emotional differences. The relation between seizures and depression is particularly intriguing, as depression can precede, and is a risk factor for, epilepsy. Interestingly, electroconvulsive therapy is an effective treatment for some people with chronic depression.

Using kindling in cats, Adamec first showed that kindling produces changes in predation and defensiveness, both measures of interictal emotionality. Domestic cats normally vary in their tendency to be either aggressive (killers) by displaying efficient mouse predation and little fear of humans, or to be defensive (nonkillers) by displaying stereotypic fear responses to rats, humans, and conspecific threat vocalizations. Partial kindling of the amygdala of killer cats converts them to nonkillers and increases their defensive behavior. After partial kindling of the ventral hippocampus, a region that facilitates attack behavior, speed of killing increases and defensiveness decreases in killer cats. These behavioral changes last for several weeks in some cats, and as long as the animals are maintained (4 months) in other cats.

There are a number of interesting correlates of the emotional behavior. Compared to defensive cats, killer cats have higher thresholds for after discharge (AD) in the basolateral amygdala, a region that tonically inhibits attack. The behavioral change after hippocampal kindling is associated with potentiation of the field excitatory postsynaptic potential (f EPSP) in the dentate gyrus. Furthermore, the potentials evoked in the medial hypothalamus by stimulation of the basomedial amygdala are greater in defensive cats than in aggressive cats, whereas potentials evoked in the ventral hippocampus are greater in aggressive cats than in defensive cats.

These findings suggest that baseline differences in behaviors, such as aggressiveness and defensiveness or fearfulness, are associated with preexisting differences in excitability of limbic structures. Furthermore, the changes in interictal behaviors after kindling are associated with lasting changes in the efficacy of synaptic transmission between the structures. Thus, endogenous differences in excitability interact with seizures to determine the behavioral outcome, with aggressive and defensive cats responding differently to partial hippocampal kindling. Adamec has also provided evidence that some of the interictal behavioral changes are related specifically to kindling-induced potentiation (KIP) of amygdaloid circuits in the right hemisphere.

Emotional behavior is also altered in a variety of tasks that measure anxiety and fear following amygdaloid kindling in rats. Kindling of the amygdala exaggerates conditioned fear-potentiated startle responses, increases immobility in a social interaction test, increases defensive fighting induced by corticotrophin releasing factor, and increases stress-induced stomach ulcers. Amygdaloid

kindling also decreases exploratory behavior and decreases the latency to killing mice in rats that are spontaneous mouse-killers. The alterations in interictal emotional behavior produced by amygdaloid kindling appear to be specifically related to changes in fear or anxiety-like behavior, rather than to a general change in motoric activity.

Anxiety-like behavior, measured in the elevated plus maze, is also affected by kindling in rats. In the elevated plus maze, anxiety in rats is characterized by a preference for the closed arms of the maze, avoidance of the open arms, and risk assessment (a behavior in which the rat stretches toward an open arm but keeps its hind quarters anchored in a closed arm) – all of which can be increased after amygdaloid kindling. Amygdaloid-kindled rats will even leap from the plus maze, presumably as an escape response. However, the situation is complicated by the fact that some studies have reported decreased anxiety, or anxiolytic effects, after kindling. Adamec relates this discrepancy to the hemisphere stimulated and the exact placement of the electrode. That is, he finds that anxiolytic effects are generally observed with kindling of the left amygdala, whereas anxiogenic effects are associated with kindling of specific nuclei in the right amygdala, including the ventral and anterior basolateral nuclei. In contrast, Hannesson and Corcoran have found that anxiogenic effects are produced by amygdaloid kindling, regardless of hemisphere stimulated or exact placement of the electrode. Controversies aside, there is general agreement that increased anxiety does not occur with kindling of all sites. For example, kindling of hippocampal field CA1 fails to increase anxiety-like behavior.

Learning and Memory

Over the last several decades, a number of studies have demonstrated specific declines in memory function in people with unilateral temporal lobe epilepsy, although there is some inconsistency in the literature surrounding the deficits associated with nondominant temporal lobe dysfunction. Generally, left temporal lobe epilepsy is associated with deficits in verbal learning and recall, and right temporal lobe epilepsy is associated with spatial and configural deficits. One problem with interpretation is the relatively unknown contribution of the damage or sclerosis seen in these populations versus the neural network reorganization due to the seizures themselves. Kindling provides insight into these issues.

We now have extensive knowledge about the effects of kindling on learning and memory. When considering the results, it is useful to distinguish between paradigms involving emotional conditioning, such as avoidance conditioning or conditioned emotional response, and more cognitively demanding paradigms, such as spatial learning or object recognition memory, as well as the retrograde and anterograde effects of kindling in the various paradigms. Other important variables are the site and extent of kindling, and the interval between kindling and behavioral testing.

Effects on Emotional Conditioning

Retrograde amnesia is the loss of information that had already been learned. Kindled seizures produce retrograde amnesia for aversively motivated tasks learned immediately before the seizure. As McIntyre showed in the earliest work on behavioral consequences of kindling, acquisition of a conditioned emotional response, which involves association of a neutral tone with the aversive consequences of shock, is disrupted when a generalized amygdaloid seizure (but not a focal seizure kindled from anterior neocortex) is triggered 6 s after each conditioning trial. Partial anterior neocortical seizures do not produce retrograde amnesia for passive avoidance, but neocortical seizures that include a generalized limbic-type component do. The amnestic effects of amygdaloid seizures involve the adrenal glands (the effects are abolished by adrenalectomy), as are the state-dependent (dissociative) effects of amygdaloid seizures. Thus, the amnestic effects of kindled seizures may in part be due to the seizures' ability to produce dissociation of memory. The dependence of both the amnestic and the dissociative effects of kindled seizures on the adrenal glands suggests that seizures trigger the release of adrenal hormones (adrenaline, adrenal steroids), which are responsible for both dissociation and the consequent amnesia.

In contrast to retrograde amnesia, anterograde amnesia is a deficit in the ability to form new memories. Significant and long-lasting anterograde effects of amygdaloid kindling are also evident in a variety of paradigms, including conditioned emotional response, passive avoidance, and conditioned taste aversion, in which rats readily learn to avoid a flavor paired with an internal state of malaise. In some of these tasks, disruptive effects have been documented as long as 55 days after kindling. Lesions of the amygdala also produce anterograde effects in the same behavioral tasks, suggesting that kindling the amygdala produces a functional lesion. The kindled amygdala may generate aberrant activity that interferes with subsequent learning; alternatively, kindling modifies plastic synapses in the amygdala and thereby 'uses up' the amygdala's capacity to be further involved in learning. In theory, kindling-induced changes in emotional conditioning could be secondary to nonspecific sensorimotor deficits. However, this possibility is likely not the case, given the selectivity of the effects on specific tasks. For example, amygdaloid kindling disrupts retention of brightness discrimination, but fails to affect acquisition of brightness discrimination or active avoidance.

Effects on Cognitive Learning

Kindling of partial or generalized seizures with stimulation of sites in the hippocampal formation disrupts

retention of spatial learning in the water maze, a form of retrograde amnesia. Deficits are produced by kindling of other sites such as the olfactory bulb or amygdala only when a large number of seizures (e.g., >100) are triggered, which we define as extended kindling. The retrograde effects of hippocampal kindling could be due either to disruption of consolidation or to a failure of retrieval, perhaps related to the state-dependent effects of kindling. They probably are not due to gross sensorimotor deficits, however, because kindled rats can readily escape to a visible platform that protrudes above the water, demonstrating that sensorimotor capacity and motivation to escape remain intact.

Skilled Performance

The ability of people with epilepsy to learn and perform a new motor task has received very limited experimental assessment, and the use of anticonvulsant medications has potentially confounded any interpretation. In a study from Lassonde's laboratory, a specific neuropsychological profile was obtained for children with frontal lobe epilepsy that distinguished them from children with temporal lobe epilepsy and generalized absence epilepsy on several measures that were purported to assess frontal lobe functions. It was shown that children with frontal lobe epilepsy exhibit many characteristics that are commonly associated with frontal lobe dysfunction in adult patients. More specifically, they show impairments in motor coordination, response generation, impulse control, and planning ability. Motor deficits are more marked for tasks involving bimanual coordination and asymmetrical movements, thus confirming the crucial role of the frontal lobes in interhemispheric integration of complex motor programs. In a conceptually related work, the hypothesis that kindling in the sensorimotor region results in a functional lesion in adult rats acquiring a new motor task has been experimentally tested.

Methods

Electrical Kindling

The electrical kindling technique involves the implantation of chronic electrodes targeted at specific brain regions, and the regular (usually daily) elicitation of self-sustaining afterdischarges and seizures by the application of 1 or 2 s of electrical stimulation. Interictal behavioral changes have been well modeled using the electrical kindling technique, with kindled animals showing persistently altered anxiety-like and aggression-related behaviors, changes in spatial memory abilities, and alterations of skilled motor performance – depending on the kindling location and number of seizures. Kindling has an advantage over models that result in spontaneous seizures, because unanticipated seizures can potentially interfere with interictal behavioral assessments.

Behavioral Testing

Spatial learning

The primary cognitive task studied with kindling is spatial learning, in either the water maze or the radial arm maze. The standard water maze involves placing a rat in a large circular swimming pool with milky water hiding a submerged platform. Rats are highly aquatic animals and very good swimmers, but they do try to escape from the cold water and prefer standing on the submerged platform to swimming. The inner walls of the pool are undifferentiated by intra-maze cues, and in order to escape from the water the rat must therefore learn the location of the platform based on extra-maze cues. In the radial arm maze, each arm of the maze is baited with food; the rats must visit each arm once, retrieve the food, and then go to the unvisited arms until all the food has been retrieved (and, ideally, no arms have been revisited). Arms are also distinguished by their position relative to extra-maze cues.

Resistance to capture

The rat's resistance to being picked up was scored on a 7-point scale, with lower values indicating no or low emotional response and higher values indicating more emotionality, such as the rat launching a jump attack at the experimenter's hand. After 100 kindling or sham stimulations of the amygdala, the experimenters measured the rats' resistance to capture, as follows: One day after the final stimulation, each rat was placed in an unfamiliar open field for a few minutes and then forcefully picked up from above by an experimenter who was wearing a large leather glove.

Nictitating membrane conditioning

This paradigm involves establishing conditioned closing of the nictitating membrane (a translucent secondary lid that covers the rabbit's eye) in response to a previously neutral tone, and then establishing a discrimination between a relevant stimulus (CS+) and an irrelevant control stimulus (CS−). After the response has been conditioned to the CS+, a reversal contingency is imposed, in which the rabbit must learn to respond to the CS− and withhold responding to the CS+.

Skilled forelimb behavior

The assessment of skilled forelimb behavior involves training a rat to reach through a narrow slit, and grasp and consume a small food pellet. The rat is normally trained on this task for 10 minutes a day, and it requires about 2 weeks of training before the rat reaches asymptotic levels of performance. The task generates not only an

end point of success (# of successful reaches/# of attempts × 100) but also allows for the determination of *how* the rat reaches with kinematic analysis. Kinematic analysis involves a frame-by-frame analysis of the high-speed recording of the behavior. The reaching behavior is broken down into 10 discrete subcomponents. If each movement appears normal, it is given a score of 0; if it is ambiguous, it is given a score of 0.5; if it is impaired but recognizable, it is given a score of 1; if it is absent or completely unrecognizable, it is given a score of 2.

Recent Results

Emotional Disturbances

To further explore kindling-induced alterations in emotionality, Kalynchuk and colleagues developed a new test of emotionality in rats called 'resistance-to-capture' (see Methods section). As predicted, the kindled rats had substantially higher resistance to capture scores than did the sham-stimulated rats. But the question of whether kindling increases defensiveness or aggressiveness in rats had yet to be addressed. This question was tested in a resident-intruder paradigm. The resident-intruder paradigm was originally developed so that sequences of aggressive and defensive behaviors that commonly occur in the interaction between resident and intruder rats can be differentiated. Kindled or sham-stimulated rat were tested as an intruder with naive resident rats. The kindled rats displayed more active defensive behaviors, such as defensive upright postures and defensive attacks, and fewer aggressive behaviors, such as lateral displays and biting, than did the sham-stimulated rats. Thus the results of this experiment suggest that kindling-induced emotional behavior is primarily defensive in nature. Kalynchuk has shown that increased defensiveness occurs only when the rats are tested in a novel environment (not in a familiar environment), an effect that may be related to the conditioned anticipatory responses to kindling that are environment-specific. Furthermore, she showed that increased defensiveness is specific to kindling of limbic sites. It is most dramatic after amygdaloid kindling, significantly less robust after hippocampal kindling, and marginal after caudate kindling. The increased defensiveness is correlated with increased binding at the benzodiazepine receptor and at a receptor for serotonin in the dentate gyrus, pointing to GABA and serotonin as possible molecular participants in the effect.

The fact that kindling-induced emotionality is defensive rather than aggressive in nature has important implications for people with temporal lobe epilepsy. For decades, it has been assumed, despite the lack of documentation in well-controlled studies, that people with epilepsy are prone to outbursts of aggression. The few appropriate studies that have attempted to document a relation between temporal lobe epilepsy and aggression have been largely unsuccessful. The finding that enhanced emotionality is fundamentally defensive may therefore help to change the common assumption that people with temporal lobe epilepsy are particularly aggressive. Furthermore, the finding that enhanced emotionality is revealed in unfamiliar situations may be useful to people with temporal lobe epilepsy.

Learning and Memory

A hint of the complexity of the neural changes underlying the effects of kindling on even simple learning is found in a research by Robinson and colleagues, indicating that perforant path kindling has a bidirectional effect on conditioning of the nictitating membrane response in rabbits. Kindling facilitates acquisition of the nictitating membrane response but impairs reversal learning. Because the enhanced acquisition resembles the effects of induction of LTP in the perforant path, and the impaired reversal resembles the effects of hippocampal lesions, perforant path kindling produces both enhanced hippocampal processing, and at the same time a functional lesion of the hippocampal formation. Enhancement of conditioned responding in fear-potentiated startle also occurs after partial kindling with amygdaloid stimulation, indicating that enhancement of processing can occur with kindling of several different sites.

By manipulating the conditions of the spatial task, it is possible to distinguish between working memory, a short-term memory store containing information that changes between trials, and reference memory, a long-term memory store containing information that is constant within and between trials. Hippocampal kindling can be shown to disrupt both working and reference memory in the radial arm maze, although the impairment in reference memory appears to be greater. In the water maze, on the other hand, both working and reference memory are impaired by hippocampal kindling, but the impairment in working memory appears to be greater. Hannesson has argued that the critical variable to be considered in explaining these discrepant results may be the overall memory load, rather than the dimension of working or reference memory. In other words, greater demands may be placed on memory in the 'working memory' version of the water task – for example, because it involves retention of multiple platform locations across days. This hypothesis has not yet been tested experimentally.

Kindling of generalized seizures with hippocampal stimulation also impairs acquisition of spatial information, evidence of an anterograde amnesic effect. Prior hippocampal kindling disrupts spatial learning or short-term spatial memory, but not long-term spatial memory, as evidenced by a disruption in a 1-day acquisition paradigm in the water maze but unimpaired retention (after the

kindled rats learn the maze) at 7 and 28 days. In contrast, Hannesson and Corcoran have shown that kindling of generalized seizures with stimulation of the perirhinal cortex fails to affect spatial cognition, but it does (as expected) impair acquisition of an object discrimination task in a modified water maze. Thus, there is considerable anatomical and task-related specificity of the effects of kindling on behavior.

Skilled Performance

Henry and Teskey asked the following questions: Does the kindling of seizures in adult rats impair their ability to perform a new task? When the rats do learn the task, do they perform it in the same manner as nonkindled control rats? The rat sensorimotor neocortex is a ripe target for examining both questions. Within the sensorimotor neocortex there are movement representations, better known as motor maps, that when stimulated result in the elicitation of movements in discrete muscle groups. When these areas are ablated, rats show a reduction in their ability to perform with the affected body musculature. For instance, when a region of sensorimotor neocortex known as the caudal forelimb area is removed, rats show both a lower success level on skilled tasks with the impaired forelimb and an alteration in the expression of the reaching behaviors. Thus, performing a skilled task using the forelimb is dependent on the integrity of the neocortical caudal forelimb area. Henry and Teskey kindled with stimulation of the midline corpus callosum at the level of the caudal forelimb area, and then examined skilled reaching (using the single pellet task, in which rats are required to repeatedly reach through an open vertical slit in a Plexiglas chamber for a single food pellet). Nonkindled rats performed the task as expected. Kindled rats made just as many attempts, but their success at retrieving the food pellets attained asymptotic levels significantly below the success level achieved by nonkindled rats. A detailed kinematic analysis of the reaching behavior made from the videotaped record showed that kindled rats employ an altered strategy for reaching. Normally, rats bring their elbow to midline before extending the forelimb through the vertical slit. However, the kindled rats do not perform this subcomponent of the behavior, and the elbow remains well to the side of the open vertical slit. Thus the kindled rats make more of a 'swipe' at the side of the pellet, rather than trapping the pellet from above as do nonkindled rats. A frequent consequence of the swiping motion is that the rats miss the pellet altogether, resulting in lower success at obtaining the pellet. The kindled rats that do successfully grasp the pellet often drop it as they bring it to their mouths. Instead of placing the palm of its hand so that it faces its mouth, the kindled rat only turn the wrist so that the palm is facing upward at approximately a 135° angle (as opposed to the 180° angle seen in the nonkindled rats). The food pellet thus slips off of the hand as the rat raises it to its mouth. To determine whether the altered motor performance and reduced reaching success in kindled rats generalized to other tasks, Henry also required rats to walk across a horizontal ladder that was missing some randomly removed rungs. Kindled rats make more forelimb faults than do control rats on this task as well.

On the single pellet and ladder walking tasks, therefore, kindled rats behave as if they have a reorganized caudal forelimb area of their sensorimotor neocortex, and indeed we have observed increased numbers of highly efficacious (perforated) synapses in the same region following kindling. Whether the impairment is strictly sensory, motor, or both has not yet been determined. What is clear is that repeated seizures elicited from this region can result in a long-term alteration in motor performance. These intriguing results lead to a novel prediction: People with adult onset epilepsy with foci in their sensory and motor neocortices will show impaired and altered performance when learning new motor skills. Apart from anecdotal evidence of clumsiness, there are few systematic studies that have experimentally investigated the way in which people with epileptic foci in sensory and motor areas perform behaviors requiring skill.

Conclusions and Future Directions

Some of these behavioral effects suggest that function in the stimulated region is enhanced by kindling, whereas other effects on behavior resemble a lesion. Possibly various output pathways from or to target sites of the stimulated area are differentially susceptible to failure or enhancement after kindling. In a general sense, the data suggest that kindling can affect neural circuits or cell assemblies involved in normal behavioral and psychological processes. Furthermore, susceptibility of limbic sites to epileptiform activity is affected by the subject's general behavioral predispositions. This result is precisely what would be expected if kindling represents a pathological distortion of the mechanisms of neural plasticity that participate in the regulation of conventional behavior. In a real sense, epilepsy and susceptibility to kindling are the price the nervous system pays for learning and memory.

An additional and perhaps surprising implication of the findings is that the behavioral effects of kindling are specific to the area stimulated. That is, kindling of virtually identical generalized seizures from different sites – for example, the amygdala and field CA1 of hippocampus – has radically different effects on behavior: Amygdaloid kindling increases anxiety-like behavior but fails to affect spatial cognition, whereas hippocampal kindling disrupts spatial cognition but fails to affect anxiety-like behavior. Thus, the functional effects of kindling are due to local alterations in the area stimulated

rather than to the more widespread consequences of seizures per se. The regional specificity evident in kindling of partial seizures (partial kindling) or a few generalized seizures (full kindling) is lost, however, when a large number of generalized seizures are triggered from various sites – as seen in the extended kindling model. The behavioral consequences of extended kindling can therefore be attributed to the anatomically distributed effects of multiple seizures rather than to local alterations in the area stimulated. The mechanisms of local alterations, as well as the more diffuse changes following multiple generalized seizures remain largely unexplored.

Central neural networks are the most proximate generators of behavior, and therefore a comprehensive understanding of the functional neurobiology of neural networks and their regulation should lead to insights into the generation and execution of behavior. Future experiments exploring interictal behavioral alterations should be performed using a variety of animal epilepsy models. Furthermore, understanding mechanistic differences between fully generalized, secondarily generalized, and focal seizure expression on behavior will aid both our understanding of seizure-induced pathological changes and how to mitigate or reverse their effects. Moreover, how sensory systems change following seizures remains almost completely unexplored and should be investigated more thoroughly.

Introduction

Epilepsy and Depression Comorbidity

The link between epilepsy and depression was first described by Hippocrates, who noted that a relatively high frequency of epileptic patients experienced 'melancholia,' and that melancholics were prone to develop epilepsy. Since this noteworthy observation, a preponderance of the epilepsy and depression literature reveals that the comorbidity is bidirectional. Epileptic patients are at high risk for depression, and patients with major depression have a higher frequency of epilepsy than the general population. As evidenced by the abundance of published reviews over the past few years, the association between these two

rather than to the more widespread consequences of seizures per se. The regional specificity evident in kindling of partial seizures (partial kindling) or a few generalized seizures (full kindling) is lost, however, when a large number of generalized seizures are triggered from various sites – as seen in the extended kindling model. The behavioral consequences of extended kindling can therefore be attributed to the anatomically distributed effects of multiple seizures rather than to local alterations in the area stimulated. The mechanisms of local alterations, as well as the more diffuse changes following multiple generalized seizures remain largely unexplored.

Central neural networks are the most proximate generators of behavior, and therefore a comprehensive understanding of the functional neurobiology of neural networks and their regulation should lead to insights into the generation and execution of behavior. Future experiments exploring interictal behavioral alterations should be performed using a variety of animal epilepsy models. Furthermore, understanding mechanistic differences between fully generalized, secondarily generalized, and focal seizure expression on behavior will aid both our understanding of seizure-induced pathological changes and how to mitigate or reverse their effects. Moreover, how sensory systems change following seizures remains almost completely unexplored and should be investigated more thoroughly.

Introduction

Epilepsy and Depression Comorbidity

The link between epilepsy and depression was first described by Hippocrates, who noted that a relatively high frequency of epileptic patients experienced 'melancholia,' and that melancholics were prone to develop epilepsy. Since this noteworthy observation, a preponderance of the epilepsy and depression literature reveals that the comorbidity is bidirectional. Epileptic patients are at high risk for depression, and patients with major depression have a higher frequency of epilepsy than the general population. As evidenced by the abundance of published reviews over the past few years, the association between these two

diseases, and the challenges encountered in attempting to treat them simultaneously, have recently become topics of great interest. There is some debate about the magnitude of the risk factors for epilepsy and depression comorbidity because of variance in study design and diagnostic criteria. However, most estimates place the risk for epileptic patients developing depression, and for depressed patients developing epilepsy, at four to fivefold higher than the general population. Nearly all reviews caution that depression is severely underdiagnosed and undertreated in the epileptic population. Raising awareness among clinicians of this link, and developing experimental models and therapies by researchers, are critical for the future of treating comorbid individuals.

Many theories have been put forth to explain the comorbidity between epilepsy and depression, including arguments based on neurobiology, genetics, social environment, and drug treatment side effects. It is likely that all these factors contribute to the connection to some extent. Why is the link between these two diseases underrecognized and undertreated clinically? One reason could be that despite the numerous hypotheses concerning the basis for the comorbidity, none have been empirically tested or convincingly demonstrated. Although epidemiological data support comorbidity between epilepsy and depression, other types of experimental data – and particularly the identification of a common underlying mechanism – would substantially reinforce general acceptance of this phenomenon. Because many studies that would be definitive are unethical to perform in humans, animal models appear to be the best experimental alternative to study the biological basis of epilepsy and depression comorbidity. To date, very few animal models designed to test these hypotheses have been described.

Background

Norepinephrine: A Molecular Link between Epilepsy and Depression?

Epilepsy and depression are very complicated neurological disorders, and it is generally accepted that no one single neurotransmitter is responsible for the manifestations of either epilepsy or depression. Of all the candidates that may represent a molecular link between epilepsy and depression, a particularly strong case can be made for norepinephrine (NE) because of the overwhelming evidence of its ability to modulate both seizure susceptibility and mood, as first proposed by Jobe and colleagues.

NE is one of the three most widely recognized neurotransmitters (serotonin [5-HT] and dopamine [DA] being the others) in the etiology and treatment of depression. The evidence for the involvement of NE in depression comes from both human and animal studies, and can be summarized as follows: (1) NE reuptake inhibitors and monoamine oxidase inhibitors (MAOIs) that increase NE levels are among the most widely used and efficacious antidepressant drugs available. (2) Depletion of NE via neurotoxins or dietary restriction leads to recurrence of symptoms of depression in patients in remission. (3) Postmortem studies reveal multiple alterations in the noradrenergic system of depressed individuals, including changes in NE biosynthetic enzymes, the NE transporter (NET), and NE receptors. (4) Reduced NE levels have been detected in the cerebrospinal fluid of depressed individuals. (5) NE dysfunction contributes to aberrant behaviors in animals that in some ways resemble depressive symptoms. (6) NE is critical for the efficacy of antidepressant drugs in some behavioral tests in rodents. (7) Chronic treatment of rats with antidepressant drugs changes the firing properties of locus coeruleus (LC) neurons, the major noradrenergic nucleus in the brain. Therefore, the etiology of depression involves a reduced function of the noradrenergic system, and treatment involves increasing extracellular NE levels. It should be noted, however, that there is also strong evidence for the roles of DA and 5-HT in depression and its treatment, indicating that depression likely involves changes in multiple neurotransmitter systems.

Despite the particular focus of modern epilepsy research on amino acid neurotransmitters (i.e., GABA, glutamate) and ion channels, NE is a very potent endogenous anticonvulsant neurotransmitter in the brain. It is important to note that the function of NE in epilepsy appears to be of a modulatory nature, since a loss of NE function does not result in spontaneous seizures. Therefore, the evidence demonstrating a relationship between NE and epilepsy is not as overwhelming as that between NE and depression. The strongest evidence supporting an involvement of NE in epilepsy is the following: (1) A reduction in central NE levels, induced either by neurotoxins or genetic manipulation, increases susceptibility of animals to a large variety of convulsant agents. (2) Stimulation of LC neurons, and the subsequent release of NE at their terminals, reduces susceptibility of animals to convulsant agents. (3) LC noradrenergic neurons are activated when a seizure occurs. (4) NE is required for the efficacy of some antiepileptic therapies. (5) Noradrenergic receptor agonists can suppress seizures. A common link between epilepsy and depression, therefore, may be reduced noradrenergic function.

Animal Models of Epilepsy and Depression Comorbidity

Perhaps the best-characterized model of reduced noradrenergic function contributing to the comorbidity of epilepsy and depression is the genetically epilepsy-prone rat (GEPR). These rats were selectively bred for susceptibility to audiogenic seizures, but they have also been

reported to display behavioral responses related to depression, such as increased immobility in the forced swim test (FST), and decreased saccharin consumption that is possibly indicative of anhedonia. Importantly for the subject of this article, noradrenergic dysfunction appears to be at least partially responsible for the seizure phenotype of these rats, and antidepressant drugs that block the NET and increase extracellular NE prevent seizures in GEPRs. Thus, a noradrenergic deficit in NE may underlie both the susceptibility to seizures and depression-like behaviors in this model. A critical test of this hypothesis would be to determine whether drugs that augment NE signaling could attenuate the depressive-like behaviors as well as the seizure susceptibility.

Methods

Rat Model of Depression-like Phenotypes

We have recently developed a new animal model of epilepsy and depression comorbidity. With the idea of expanding upon the available rodent models of depression, Weiss and colleagues selectively bred normal Sprague-Dawley rats for several phenotypes relevant to human depression. These lines include: Swim-Lo active (SwLo), with low motor activity in a Porsolt forced swim test (FST); Swim-Hi active (SwHi), with high motor activity in the FST; Swim-test susceptible (SUS), which are highly susceptible to having their swim-test behavior disrupted by mild stress; Swim-test resistant (RES), which are highly resistant to having their swim-test behavior disrupted by mild stress; Monitor Hyperactive (HYPER), which experience long-lasting hyperactivity following stress; and Monitor Resistant (MON RES), which are resistant to changes in activity following stress. Randomly bred (nonselected; NS) rats served as controls. To determine whether genetic susceptibility to depression-like phenotypes also influences limbic seizure susceptibility, adult rats of each of the six selectively bred lines, and NS controls, were tested for maximal seizure severity after administration of kainic acid ($10\,mg\,kg^{-1}$, then $5\,mg\,kg^{-1}\,h^{-1}$ until tonic–clonic seizure).

Dopamine β-hydroxylase Knockout (*Dbh*$^{-}$<?tfqs-$^{/-}$<?tfqs-) Mouse

The previously described models used genetically susceptible animals, and we wondered whether an environmentally-induced depressive-like state could also enhance seizure susceptibility. Specifically, we tested whether mice subjected to a chronic mild stress (CMS) paradigm would be more susceptible to kainic acid-induced seizures. The CMS paradigm uses a random series of multiple daily unpredictable mild stressors (e.g., forced swim, food or water deprivation, physical restraint, exposure to white noise, reversed light/dark cycle, etc) to elicit a depressive state. At the same time, we investigated further the possibility that a reduction in NE may be a potential link between epilepsy and depression by utilizing a mouse model of NE deficiency, the dopamine β-hydroxylase knockout ($Dbh^{-/-}$) mouse. DBH converts Dopamine to NE in noradrenergic cells; thus, $Dbh^{-/-}$ mice completely lack NE. We have previously shown that $Dbh^{-/-}$ mice are hypersensitive to many seizure-inducing agents. We predicted that $Dbh^{-/-}$ mice might be particularly prone to changes in seizure susceptibility following CMS exposure. Adult male $Dbh^{-/-}$ and control ($Dbh^{+/-}$) mice that have normal NE content were exposed to 5 weeks of CMS. Following 5 weeks of CMS, the mice were assessed for seizure severity following KA administration. Mice were injected with KA ($20\,mg\,kg^{-1}$, i.p.) and observed for one hour. During this hour, seizure behavior was scored using a modified version of the Racine scale: 1 = staring, 2 = heading nodding, 3 = forelimb clonus, 4 = rearing and falling, 5 = generalized clonic–tonic (CT) seizure, 6 = death.

Recent Results

Seizure-Related Mortality in Rats Bred for Depression-like Phenotypes

The strains selected for susceptibility to depression-like phenotypes (SwLo, SUS, and HYPER) had significantly higher mortality following kainic acid seizures than the strains selected for resistance to depression-like phenotypes (SwHi, RES, and MON RES) (**Figure 1(a)**). Non-selected control rats fell roughly in between the seizure susceptible and seizure resistant strains. The dose of kainic acid required to produce a CT seizure was equivalent between each pair of strains, except for the SUS rats, for which the dose was slightly but significantly increased (**Figure 1(b)**). However, the higher CT threshold dose probably cannot account for the increased mortality of the SUS rats, because dose and mortality were not significantly correlated across all lines. For example, some NS control rats that received a cumulative dose of $20\,mg\,kg^{-1}$ survived, while others that received $15\,mg\,kg^{-1}$ or even as little as $10\,mg\,kg^{-1}$, died; similar patterns were also observed among the other strains. The kainic acid seizure-induced mortality phenotype was evident across multiple generations of these rat lines, indicating that the depression and seizure mortality phenotypes are co-inherited and may be controlled by the same genes. In addition, the seizure mortality phenotype is unlikely to derive from a brain-wide change in excitability, as there were minimal strain differences in susceptibility to flurothyl, which induces generalized seizures that are likely cortical in origin (**Figure 2**). These results demonstrate that rats selectively bred for susceptibility or resistance

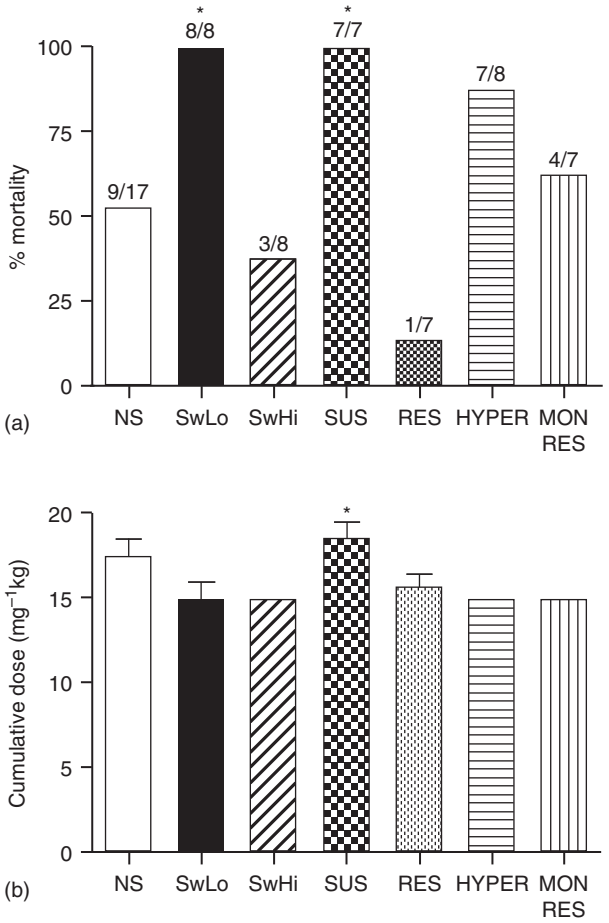

Figure 1 Kainic acid-induced seizure mortality. Kainic acid was administered to rats at a dose of 10 mg kg^{-1}, followed by 5 mg kg^{-1} booster injections until a clonic–tonic (CT) seizure was produced. Shown is (a) mortality, with the number of animals that died over the total tested above each bar, and (b) the cumulative kainic acid dose (mean ± SEM) required to produce a CT seizure. *$P < 0.05$ for the depression-susceptible line compared to its depression-resistant counterpart (SwLo vs. SwHi, SUS vs. RES, HYPER vs. MON RES, respectively). Reproduced from Tabb KD, Boss-Williams KA, Weiss JM, and Weinshenker D (2007) Rats bred for susceptibility to depression-like phenotypes have higher kainic acid-induced seizure mortality than their depression-resistant counterparts. *Epilepsy Research* 74: 140–146, with permission from Elsevier.

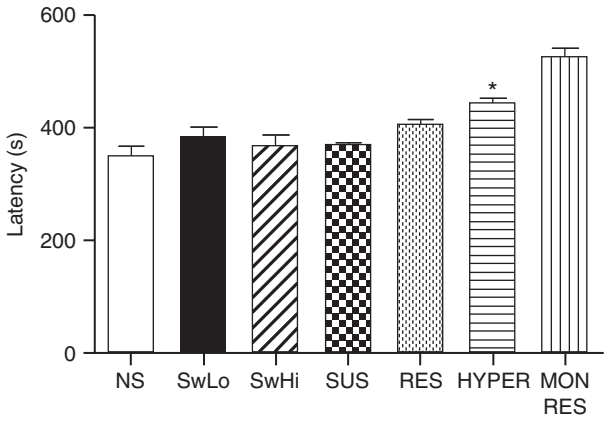

Figure 2 Flurothyl-induced seizure susceptibility. Flurothyl was administered to rats at a rate of 20 µl min^{-1}, and latency to CT seizure was observed. Shown is latency to CT seizure (mean ± SEM) for each line. $N = 6$–16 per group. *$P < 0.05$ for the depression-susceptible line compared to its depression-resistant counterpart (SwLo vs. SwHi, SUS vs. RES, HYPER vs. MON RES, respectively). Reproduced from Tabb KD, Boss-Williams KA, Weiss JM, and Weinshenker D (2007) Rats bred for susceptibility to depression-like phenotypes have higher kainic acid-induced seizure mortality than their depression-resistant counterparts. *Epilepsy Research* 74: 140–146, with permission from Elsevier.

to depression-like phenotypes are also susceptible or resistant, respectively, to kainic acid-induced seizure mortality. Consistent with this result, and perhaps more directly related to the issue of linking depression with seizure susceptibility, we recently completed a pilot study and found that SwLo rats have a shorter latency to CT seizure following administration of the muscarinic convulsant agent pilocarpine than SwHi rats (unpublished data).

Our model possesses two other salient features that are particularly relevant to the topic at hand. First, genetic load is a critical component of both epilepsy and depression, and a family history of depression is itself a risk factor for developing epilepsy. The selective breeding approach embodies a strong genetic component, because we used rats selectively bred for more than 30 generations for susceptibility or resistance to behaviors associated with human depression. Of particular note, all three lines bred for depression-relevant behavioral phenotypes were also susceptible to kainic acid-induced seizure mortality (compared to their counterparts that are resistant to these phenotypes), which suggests the lines may share genetic changes that contribute to the phenotypes. Furthermore, both the depression-like and seizure-related mortality phenotypes were stable over multiple generations, indicating co-heritability. Second, the incidence of major depression is particularly high in patients with temporal lobe epilepsy (TLE), ranging from ~20% to 70%. We found that our rat lines differed in response to kainic acid and pilocarpine, which are commonly used to model TLE, but not to any seizure phenotype related to flurothyl, which produces generalized seizures.

Strikingly similar to the GEPR strains, the SwLo and SUS rats have lower NE levels than their SwHi and RES counterparts, particularly in the hippocampus, and the depression-related phenotypes of both SwLo and SUS rats can be reversed by treatment with noradrenergic antidepressant drugs. The low NE levels in SwLo and SUS rats suggested to us that the reduction of NE in the depression-sensitive lines might underlie both the swim

test and kainic acid phenotypes, and provide a potential mechanistic link between epilepsy and depression. However, initial attempts to attenuate kainic acid-induced seizure mortality in the depression-sensitive lines with these antidepressant drugs have been unsuccessful (unpublished data). Further experiments will be required to fully test this hypothesis.

CMS in Dopamine β-hydroxylase Knockout Mice

As shown in Figure 3, two-way ANOVA revealed that KA-induced seizure severity was generally higher in $Dbh^{-/-}$ mice (main effect of genotype; F [1,41] = 6.7, $P = 0.01$), as we have previously shown. However, CMS did not increase seizure severity in mice of either genotype. Thus, the 'depression' induced by CMS in normal or NE-deficient mice does not appear to render them more seizure-sensitive, at least using the KA model. However, some caveats should be noted. While the mice were exposed to a CMS paradigm previously shown to elicit depressive-like behaviors, we did not conduct such measures in these experiments. Thus, it is possible that our CMS conditions were not severe enough to result in a depressive state and an increase in seizure susceptibility. In addition, KA-induced seizure severity is already quite high in unstressed $Dbh^{-/-}$ mice, so there may have been a 'ceiling effect.' Modified studies of this kind may provide further insight.

Treatments for Epilepsy and Depression Comorbidity

Many cases of depression are successfully treated with pharmacotherapy (antidepressants such as 5-HT and/or NE reuptake inhibitors). Similarly, many individuals with epilepsy are successfully treated with anticonvulsants (e.g., valproic acid, phenytoin, lamotrigine, or gabapentin). However, it is unclear how best to treat individuals suffering from both diseases simultaneously. This issue is particularly important and complex because some antidepressant drugs (e.g., bupropion) are reported to increase seizure risk, and some anticonvulsant drugs (e.g., phenobarbital) can precipitate depressive episodes.

Both NE and 5-HT have antidepressant as well as anticonvulsant properties, and it has been suggested that increasing the signaling within these neurotransmitter pathways could be useful for the treatment of comorbid individuals. We set out to test this idea by administering antidepressant drugs to mice, either acutely (single i.p. injection) or chronically (3 weeks via osmotic minipump) and assessing susceptibility to seizures induced by flurothyl. Importantly, our chronic administration paradigm was as therapeutically relevant as possible, taking into account both the delay between the start of administration and the antidepressant effect, and doses that produce serum drug levels comparable to those seen clinically. Surprisingly, we found that many of the antidepressant drugs tested had a bidirectional effect on flurothyl seizures; i.e., they were both proconvulsant (reduced the latency to seizure) and anticonvulsant (reduced seizure severity). This was particularly true of the selective NE reuptake inhibitors, and was confirmed using NET knockout mice. Interestingly, the dual 5-HT–NE reuptake inhibitor, venlafaxine, was the exception; it had no proconvulsant effect on seizure latency while retaining some of the anticonvulsant effect on seizure severity.

Our results suggest that, contrary to our hypothesis, pure NE reuptake inhibitor antidepressant drugs may not be the best choice for treating individuals with concurrent epilepsy and depression. One caveat to our experiments is that we tested these drugs only on flurothyl-induced seizures, which model generalized epilepsy. Given the prevalence of depression in TLE patients and the results with our selectively bred rats, it will be important to repeat these experiments using a limbic seizure model such as kainic acid.

What are some good candidates for epilepsy and depression pharmacotherapy? Our results in mice indicate that venlafaxine warrants further investigation. Other serotonergic drugs may also be of value. Although this article focuses on NE, there is growing evidence that changes in 5-HT could contribute to epilepsy and depression comorbidity. The involvement of 5-HT in depression is well established, and mice lacking the 5-HT2C receptor or the 5-HT7 receptor have increased seizure sensitivity. Furthermore, early life KA-induced seizures in rats lead to increased depressive-like behavior in adulthood, and evidence suggests an involvement of the 5-HT5B receptor in this process. Finally, it was recently shown that 5-HT1A receptor abundance in the brain is reduced

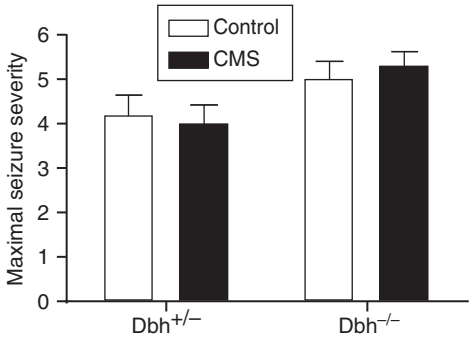

Figure 3 Effects of chronic mild stress on kainic acid-induced seizures in $Dbh^{+/-}$ and $Dbh^{-/-}$ mice. Following 5 weeks of CMS, mice were injected with kainic acid (20 mg kg^{-1}, i.p.). Shown is maximal seizure severity (1 = staring, 2 = heading nodding, 3 = forelimb clonus, 4 = rearing and falling, 5 = generalized CT seizure, 6 = death). $N = 10$–14 per group.

in TLE patients, and this reduction was significantly more pronounced in TLE patients with comorbid major depression.

The anticonvulsant drug lamotrigine has shown some promise in early trials to treat this comorbidity. In addition to its known therapeutic effect on seizures, it also appears to improve mood in epileptic individuals with depression. In initial studies, there was no correlation between improvement on mood and seizure frequency, suggesting that the effects of lamotrigine on depressive symptoms were not a secondary consequence of its anticonvulsant activity. Other intriguing possibilities include nondrug therapies such as the ketogenic diet and vagus nerve stimulation. Both of these treatments were originally developed for treating epilepsy, and later found to have a positive effect on mood. Interestingly, both the ketogenic diet and vagus nerve stimulation increase extracellular NE in the hippocampus and require NE for their anticonvulsant efficacy in animals, while lamotrigine inhibits monoamine reuptake in vitro. It remains to be seen whether the mood-enhancing properties of lamotrigine treatment also involves NE.

Conclusions and Directions for Future Research

Despite the prevalence of depression in epilepsy and the mounting interest in the subject, the neurobiological mechanisms underlying the comorbidity remain unknown. NE and other monoamines remain the best candidates for a common mechanism, although the relationship tying epilepsy and depression appears to be complicated. The role of NE and 5-HT in depression is very well documented, but detailed studies of potential changes in these transmitter systems in epileptic and comorbid individuals are needed. Further investigation of animal models, such as the GEPR rats and the Weiss selectively-bred lines, may yield clues that could evolve into new therapies for treating individuals suffering from both diseases. Treatments aimed at these neurotransmitters should be carefully considered.

Introduction

The fruitful concept of a disturbed balance of synaptic excitation and inhibition underlying epileptiform activity, as opposed to alterations in intrinsic neuronal mechanisms, tacitly implies a view of synaptic processes and the voltage-dependent channels of a given neuron as distinct independent entities. Undoubtedly, either an increase of excitatory glutamatergic transmission or decrease of inhibitory GABAergic transmission has profound effects on the activity of arrays of interconnected neurons. Likewise, increases of neuronal conductances promoting depolarizations (Na^+, Ca^{2+}) or decreases of conductances opposing depolarizations (K^+) can decisively alter neuronal responses to a given input. The resulting increase of the neuron's output, in turn, increases excitatory activity of networks of neurons. Accordingly, the role of altered function of sodium or potassium channels in hyperexcitability – i.e., alterations of intrinsic neuronal mechanisms – has been discussed in several reviews.

The presence of inhibitory interneurons, however, complicates the simple extrapolation of a given alteration of a certain channel to neuronal activity in a network of neurons. A given change, for instance a functional decrease of a certain potassium channel, would have different effects on the activity at the network level depending on which type of neuron (excitatory pyramidal neuron or inhibitory interneuron) is affected. The chances that both types of neurons are affected by a given channel mutation are very small. Studies of the hippocampus, for example, have provided evidence indicating that subpopulations of neurons are endowed with molecularly distinct complements of channel subtypes (which in turn determine the discharge properties of different neuronal populations).

In the neocortex, three main types of neurons can be distinguished on the basis of firing behavior: regularly firing neurons, fast spiking neurons, and intrinsic bursting neurons. The different firing patterns may depend, to some extent, on the different morphologies of these neurons, but probably reflect different channel properties governed by the expression pattern of molecularly distinct channels. However, little is known about the molecular basis of these different firing patterns in the neocortex.

Regularly firing neurons typically generate, on injections of sufficiently large currents, a train of action potentials (APs). At low to intermediate current injections, the interspike intervals are typically about 200 ms and those intervals decrease progressively with further depolarization. These neurons have been morphologically characterized and mainly consist of pyramidal neurons. Synaptic stimulation elicits, in these neurons, a typical sequence of an excitatory postsynaptic potential (EPSP) followed by two inhibitory components. Typically, at high-stimulus intensities the EPSP reaches threshold for eliciting a single AP. Apparently regularly firing neurons often exhibit an initial deviation from regularity, at certain current injection amplitudes, the interval between the first two APs is much shorter than the intervals between subsequent APs, probably due to the presence of a transient low threshold Ca^{2+} current (T-current), which gives rise to an extra AP at short latency after the first one.

Fast spiking neurons have been shown to fire in high-frequency trains of APs, with regular interspike intervals on the order of 10 ms. This firing pattern is, for instance, obtained from aspiny stellate neurons – i.e., GABAergic interneurons. Understanding the basic function of GABAergic interneurons is complicated by the diversity

of morphologically distinct interneuron types, each of which has distinct targets on the soma and basal and apical dendrites of pyramidal neurons. In our experimental condition, such neurons are rarely encountered with sharp microelectrodes, thus precluding a detailed analysis.

Intrinsic bursting neurons generate, on moderate depolarizing current injections, a stereotype response consisting of a burst of APs superimposed on a slow depolarizing component followed usually by solitary APs. In these neurons, small excitatory synaptic responses can recruit a very similar burst response in a voltage-dependent manner. The bursting neurons are pyramidal-shaped, with a rich arborization of axon collaterals. This fact, together with the powerful amplification provided by the burst mechanism, is thought to facilitate synchronization of large arrays of follower cells. The currents underlying this intrinsic bursting behavior are in contention. Originally, the bursting of cortical neurons was attributed to the presence of a T-current. However, the persistence of the slow component with depolarization, which should inactivate T-currents, and the enhancement of bursting during reduction of extracellular Ca^{2+} concentration or antagonism of Ca^{2+} currents suggest the involvement of other mechanisms. A tetrodotoxin (TTX)-resistant sodium current had been proposed to generate the slow component of bursting neurons. Other studies have provided evidence indicating TTX-sensitive sodium currents to underlie bursting. Interestingly, the voltage- and time-dependent recovery from inactivation of bursts differs markedly from the T-current. The inactivation time constant is near 100 ms, which would therefore facilitate synchronization of large arrays of neurons up to about 10 Hz. Most investigators agree that these data suggest a key role of bursting neurons in synchronization of larger arrays of neurons, and therefore their critical role in epileptic discharge. The observation that extracellular Ca^{2+} concentration decreases before interictal-like activity emerges (in penicillin foci of rat cortex in vivo) would be consistent with the view that Ca^{2+}-dependent mechanisms limit the excitability of bursting neurons. Also, the reduction of the spectral power in the α-range by carbamazepine suggests that a sodium current (capable of synchronizing arrays of neurons) is attenuated by this drug.

It is important to point out, that the three categories of neurons mentioned earlier are an oversimplification. Nevertheless, intrinsic neuronal properties (governed by neuron-specific sets of voltage-dependent conductances) are modulated by various transmitters, and the effects of transmitters are in turn modulated by voltage-dependent conductances. These various mutual interactions between synaptic transmission and intrinsic properties are further complicated by the diversity of channels expressed in subtypes of neurons and by their subcellular distribution.

The classical interaction between synaptic potentials and intrinsic mechanisms is in the depolarization of the neuronal membrane by excitatory synaptic potentials – which eventually triggers the generation of APs. In the neocortex, synaptic potentials of regular firing neurons are considerably augmented in the subthreshold range (the time integral is about fourfold increased) by both a persistent sodium current and a T-current. Obviously, this modulation represents a voltage-dependent activation of intrinsic currents, but it also can be regarded as a modulation of the synaptic potential by intrinsic currents. The presence of hyperpolarization-activated cation current (I_H) and inwardly rectifying potassium currents (K_{ir}) attenuates synaptic potentials arriving in the soma. These modulations of synaptic potentials by intrinsic currents are complemented by a modulation of intrinsic currents by neurotransmitters. Depending on the channel being modulated and level considered, both decreases and increases of excitability occur. The modulation of Ca^{2+} currents by, e.g. GABA, would tend to decrease excitability in synaptic terminals, and the resulting depression of GABA release would increase excitability of the network. In contrast, activation of muscarinic receptors increases neuronal excitability, brought about by a reduction of the M-current (mediated by the family of KCNQ (K_V7) channels), which normally provides a conductance increase during depolarizations that attenuates the excitability. These few examples illustrate that intrinsic neuronal properties modulate synaptic input as well as being subject to a modulation by neurotransmitters.

To delineate the mechanisms contributing to excess activity in the human epileptogenic cortex, it is important to consider the various facets affecting the excitability of different types of neurons – and their interplay.

Background

Molecular Biology of Sodium Channels

Voltage-gated sodium channels are ubiquitously expressed in excitable cells such as neurons and muscle cells. Functional sodium channels of central neurons consist typically of an α subunit forming the pore and an auxiliary β subunit. A single α subunit contains four homologous domains, each consisting of six transmembranal helices. The sodium channels have various modulatory sites for phosphorylation by the protein kinases A and C (PKA, PKC) and binding sites for toxins (e.g., TTX). Sodium channels have been cloned, revealing a family of nine members, which have been termed $Na_V(1.1–1.9)$. The channels made of $Na_V1.1$, $Na_V1.2$, and $Na_V1.3$ subunits are widely expressed in the central nervous system. The possible combination of $Na_V1.1$ and $Na_V1.2$ with four types of β subunits, and $Na_V1.3$ combining only with $\beta1$ or $\beta3$, yields a rich diversity of functionally distinct sodium channels. Although present throughout the brain, the $Na_V1.1$ and $Na_V1.2$ subunit are not homogeneously distributed. Interestingly, the cardiac

sodium channel $Na_V1.5$ subunit has been detected in limbic areas of the rat brain. Similar to the $Na_V1.8$ and $Na_V1.9$ subunits, the $Na_V1.5$ subunit is fairly insensitive to TTX.

Sodium Currents and Epilepsy

About 10 mutations of sodium channels are known and some of them cause augmentation of the current, e.g., by a slowed inactivation. Mutation of $Na_v1.2$ for instance causes a slowed inactivation and an increased persistent current when expressed in *Xenopus* oocytes. This increase of persistent sodium current would augment the duration of depolarization produced by these currents, facilitating the generation of higher frequencies of APs via the fast transient sodium currents. Transgenic mice expressing this mutated channel exhibit focal seizure activity in the hippocampus, generalizing to the cortex. Recent evidence suggests that mutations in the β1 subunit of sodium channels may be crucial for the phenotype of generalized epilepsy with febrile seizures, and also play an important role in reduced channel responsiveness to the modulation by the anticonvulsant phenytoin.

As pointed out in a recent review, a mutation of a sodium channel subunit $Na_V1.1$ causes a decreased probability for channel activity in the inherited epilepsy, generalized epilepsy with febrile seizures plus (GEFS+). This effect is, at first glance, counterintuitive. It is due, however, to the dominance of this channel in interneurons; the reduced excitability of interneurons would tend to decrease the synaptic release of GABA. This effect illustrates how difficult it is to predict the functional consequences of a given channel mutation on the excitability of arrays of neurons, without detailed knowledge concerning the population of neurons affected.

Potassium Channels

Potassium channels are unquestionably the most numerous and diverse ion channels in mammals. To date, 70 different gene loci have been identified encoding potassium channels. The majority of potassium channels (40 genes) are members of the family of voltage-gated channels. The extraordinary complexity of potassium channels is obvious not only from the number of genes encoding them, but also from their structural diversity containing 2, 4, 6, or 7 transmembrane domains. Even the family of closely related K_V1–6 and K_V8,9 subunits exhibits an astounding variability. Each gene encodes a single subunit, and functional channels are homomeric or heterotetrameric assemblies of various subunits. Furthermore, functional channels are associated with modulatory subunits and accessory proteins. Finally, these channel subunit proteins are subject to posttranslational modifications. This potential for a huge stoichiometric variability of channels composed of K_v1–6 subunits presents an important safety factor for the control of neuronal excitability, despite possible adverse mutations. This speculation is based on the assumption that most moderately adverse mutations would impair a heteromeric assembly of channels only by a fraction compared with a monomeric assembly (if the function is some kind of 'average' of the subunits' function). With heteromeric assembly, a complete loss of a given subunit would perhaps be less devastating, since in a heteromeric channel, a missing subunit might be replaced by another subunit. Thus, the effect of the mutation would likely be much smaller than would be the case if the mutation resulted in a loss of a complete set of monomeric channels.

A detailed discussion of potassium channels is beyond the scope and space of this article. Therefore, I just briefly mention one example from another family of K_v channels, with a clear relevance to epilepsy. The mutations underlying benign familial neonatal convulsions (BFNCs) were mapped to chromosome 20 and 8, and demonstrated to encode the KCNQ2 and KCNQ3 ($K_V7.2$, $K_V7.3$) channels. Estimates suggest that the mutations associated with BFNCs reduce the total current through $K_V7.2/3$ channels by about 30%. The question of whether other types of epilepsy are also related to impaired M-currents remain unanswered.

A compelling line of evidence indicates that $K_V7.2/3$ channels are the substrate of the M-current, which tends to decrease excitability. Activation of muscarinic receptors reduces the M-current via G-proteins (Gq/11) thus sufficient activation of muscarinic receptors reveals the maximel excitability governed by the other conductances. Interestingly, the muscarinic receptors have been associated with cognitive functions, perhaps by a modulation of M-currents.

Among the voltage-gated channels, the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels mediating the I_H have recently attracted considerable interest. The HCN-channels belong to the superfamily of channels containing six transmembranal helices. Functional channels are homo- or heterotetramers of subunits encoded by four genes (HCN1–HCN4) and allow the flow of both K^+ as well as Na^+ ions to a different degree. The stoichiometric composition of the channels determines the activation kinetics, voltage dependence and their sensitivity to cyclic nucleotides (e.g., cAMP).

In cortical neurons, I_H has several functions, including a stabilization of membrane potential and modulation of temporal summation of synaptic input. The impact of this current on neuronal excitability has long been underestimated. Judging from the ~100% increase in resting membrane resistance in the presence of the established channel antagonist ZD7288, the conductance mediated by I_H channels represents about 50% of the resting conductance of cortical neurons. Interestingly, such a blockade also reveals intrinsic burst firing in previously apparently

regular firing pyramidal neurons. The role of I_H in epileptic disorders is currently the focus of a considerable debate. Some authors suggest that increased I_H contributes to hyperexcitability. Evidence from three laboratories, however, strongly suggests that I_H function is decreased in epileptic disorders. In the kainate model of epilepsy, a decrease of I_H was observed in entorhinal cortex neurons. In a genetically epilepsy-prone rat (WAG/Rij), I_H is also greatly reduced in the neocortex, associated with a decreased expression of HCN1 subunits. The augmented temporal summation, brought about by a reduced I_H, may account for the rapid spread of focal activity in the WAG/Rij rats. In addition, HCN2 subunit knock-out mice exhibit seizure activity.

Methods

The methods for tissue handling, slice preparation, and intracellular recordings with sharp microelectrodes have been described previously and are discussed elsewhere. In brief, human tissue was collected in the operating theatre and transferred to the laboratory. The tissue was cut into slices (nominal thickness, 400 μm), which were stored in beakers containing artificial cerebrospinal fluid (ACSF) equilibrated with carbogen. Individual slices were transferred to submerged-type recording chambers. Intracellular recordings were carried out with sharp microelectrodes (about 100 MΩ, containing 1 M K-acetate plus 1 mM KCl, pH 7.2) connected to a current-clamp amplifier (SEC10L, npi, Tamm, Germany). The signals were fed to a PC-based acquisition system (Digidata 1200, p-clamp 9, Axon Instruments).

Some slices were mounted in a submerged-type chamber attached to an upright microscope (Axioskop FS, Zeiss, Oberkochen, Germany) equipped with an IR camera (Hamamatsu, Herrsching, Germany). Patch-clamp recordings were carried out on visually identified pyramidal-shaped neurons using a conventional patch-clamp amplifier (EPC9, HEKA, Lambrecht, Germany). Electrodes suitable for patch clamping were made on a puller (DMZ Universal Puller, Zeitz, Munich, Germany). Neuron recordings were accepted if membrane potential exceeded −60 mV and AP amplitude 70 mV. For voltage-clamp recordings, series resistance was below 20 MΩ. Hyperpolarizing command steps (10 mV increments, down to −140 mV) were applied from a holding potential of −60 mV to elicit hyperpolarization-activated inward currents (I_H and K_{ir}). To quantify the magnitude and kinetics of I_H, we employed a modification of the established back-extrapolation method, whereby a triple exponential function is fitted to the current trace to yield estimates of the K_{ir} and the two I_H components. Direct measurement of the I_H amplitude is not possible because the onset of the I_H is contaminated by the concurrent instantaneous K_{ir} component and the capacitive transient. Standard leak subtraction protocols cannot be used either, because leak subtraction requires an ohmic behavior, which is not the case with K_{ir} and I_H present.

Recent Results

KCNQ Channels in Human Neocortical Neurons

As mentioned in the Introduction, pyramidal neurons of the cortex usually exhibit a regular firing behavior. The phasic firing pattern, typically associated with the presence of M-currents, is rare. Nevertheless, we evaluated a possible involvement of KCNQ channels in the altered excitability of the resected human epileptogenic tissues. To this end, we began characterizing the effects of the unselective muscarinic agonist, carbachol. Neuronal excitability was tested with a family of current injections, typically from −0.5 to 1 nA. The number of APs were counted and plotted versus the injected current magnitude. At current levels above threshold for initiating AP discharge, the number of APs increased fairly linearly with increases in current amplitude (equivalent to the steep part of *F–I* curves), and then deviated from linearity with a reduced increase of the number of APs with further increases of current. The initial part of this curve was approximated by a linear fit, yielding two parameters: the slope of the curve relating APs versus injected current (firing–current relation); and the extrapolated intercept of the curve – i.e., the current that is just below threshold (rheobase). Human cortical neurons had markedly lower rheobase values than did rat cortical neurons, despite comparable resting membrane potentials; that is, human neurons require less current injection to reach threshold. This approach revealed, moreover, a slightly steeper slope in human neurons (human, 36 APs per nA; rat, 26 APs per nA; 600 ms pulses); that is, the human neurons responded with more APs to a given current injections. This difference in slope between rat and human cortical neurons might be due to the attenuation of M-current. Application of carbachol (10 μM) increased the slope in both rat and human neurons. However, the slope of the firing–current relation increased in rat neurons by about 90% (to: 49 APs per nA), but in human neurons it increased by only about 10% (to 44 APs per nA). Thus, the average values obtained from human and rat cortical neurons in the presence of carbachol were indistinguishable. Although these data are from a small sample of neurons (human, $n = 10$; rat, $n = 5$), they indicate that the initial difference in slopes may relate to differences in the M-current. Co-application of pirenzepine (a presumed M_1-type receptor antagonist) prevented these changes in slope, indicating the involvement of M_1-type receptors. We therefore assume a deficit in M-current-mediated control of excitability in human neurons from epileptogenic cortex. Further data are

necessary, including data from nonepileptogenic tumor resections.

Considering possible links between cholinergic transmission (particular muscarinic receptors) and cognitive functions, the increased neuronal firing in response to the same input when carbachol is present may reflect an important feature of normal cortical neurons. The enhanced firing induced by carbachol represents an increased gain of neuronal coding. In addition, the higher frequency of APs would facilitate temporal summation of follower cells. The observed reduction in muscarinic modulation in human epileptogenic neocortex, therefore, may not only contribute to hyperexcitability but also to cognititve deficits in cases of severe epilepsy.

Hyperpolarization-Activated Inward Currents of Human Cortical Neurons

Our original observations, from a small number of tissue samples, indicated a relatively small component of I_H in human neurons from epileptogenic cortex. We further investigated the biophysical properties of I_H in human cortical neurons to resolve possible changes in epileptogenic tissues. Hyperpolarizations elicited three distinct current components: an almost instantaneous current and two slow components with different kinetics. Pharmacological manipulations revealed that the instantaneous current was greatly reduced by the application of the Ba^{2+} ions, known to antagonize K_{ir}-type currents. Application of ZD7288, an accepted antagonist of I_H, greatly reduced the two slower components. The amplitude of the fast I_H component was, on average, smaller than those seen in rat cortical neurons and the kinetics much slower (time constant (at -140mV) in human neurons: 43.6 ms, in rat neurons 17.0 ms). Comparison of the current amplitudes per se is questionable when the neurons are of different sizes. Therefore, the currents were normalized with the membrane capacitance as an index of the neuronal surface area. Even after such normalization, the resulting current densities of human cortical neurons were significantly smaller than those of rat neurons (human, $-2.6\,\mathrm{pA\,pF^{-1}}$; rat, $-6.9\,\mathrm{pA\,pF^{-1}}$). This slower kinetics and smaller I_H density in neurons from human epileptogenic tissue is similar to our observations on tissue from epilepsy-prone WAG/Rij animals.

To establish a possible relation between the smaller I_H and epilepsy is difficult, given the lack of adequate human control tissue and the arguable comparison with rat neurons. Nevertheless, we tried to correlate the magnitude of I_H with the duration and severity of epilepsy in the human patients from whom tissue had been excised. To this end, we averaged the I_H densities from each tissue sample (based on measures from 3 to 11 neurons per sample, with an average of about 5 neurons). The average current densities revealed no significant correlation with the duration of epilepsy. Interestingly, the majority of data points suggested a decrease of I_H with increasing duration of epilepsy, but two clusters of data (one at short duration and small currents, and one cluster at long duration with large currents) prevented a significant correlation. Regarding the severity of epilepsy, we first used as a simple index the number of grand mal (GM) seizures the patients suffered. This index revealed a clear dichotomy; about half of the patients had a relatively small number of GMs annually, the other half had numerous GMs monthly. Comparing the I_H densities of these two groups revealed a significant difference in the I_H densities. The average neuronal I_H density was smaller in tissues from patients suffering many GMs than in tissues from patients suffering few GMs.

Some of the tissues investigated were from patients receiving the antiepileptic drug (AED) lamotrigine. Since lamotrigine has been proposed to augment I_H, we evaluated the effects of lamotrigine on I_H of human neurons. In our experiments, lamotrigine had no consistent effect on I_H. We considered the possibility that the lack of effect of lamotrigine may relate to the pharmacoresistance of these patients. To investigate this point, we applied lamotrigine under identical conditions to rat neocortical neurons. Interestingly, lamotrigine failed to exert consistent effects on the I_H elicited in rat neocortical neurons.

Future Goals

The data discussed indicate an increased slope of the AP firing–current relation, as well as a lower rheobase value for APs of human neurons from epileptogenic tissue. Obviously, an increased firing of pyramidal neurons for a given input may contribute to cortical hyperexcitability. The depression of M-currents by carbachol results in an increased slope, consistent with current views about muscarinic modulation. Interestingly the effect of carbachol on the slope was much smaller in human neurons than in rat neurons; in the presence of carbachol, the *F–I* slopes are not significantly different. Considering the established view, a depression of M-currents by muscarinic receptors via G-proteins, the smaller response to carbachol of human neurons may be due to a decreased density of receptors or channels. In this context, we plan to further identify the receptor (presumably M_1) involved in this muscarinic action, as well as the associated channel. Evaluation of the effects of the AED retigabine (an activator of K_V7 channels) and linopirdine (a blocker of K_v7 channels) on the firing behavior is planned. Quantification of the M-current with patch-clamp recordings, and assessing the effects of retigabine and linopirdine under these recording conditions, might reveal whether the M-current is reduced. This approach would also allow to characterize

the muscarinic modulation of morphologically identified neurons. In the long run, these cellular data might be correlated with cognitive functions of the patients.

One of the physiological roles of I_H is the modulation of temporal summation of EPSPs. In parallel experiments, the temporal summation of synaptic responses should be further evaluated in the human cortex. The attenuated I_H should cause an enhanced temporal summation at a given synaptic frequency; further, because of the frequency dependence of temporal summation, reduced I_H should also increase the temporal summation at lower frequencies. Together with a voltage-dependent recruitment of, for example T-current, the altered temporal summation would facilitate cortical synchrony at lower frequencies and hence the probability for precipitation of seizures.

Our data indicate a surprising absence of lamotrigine effects on somatically recorded I_H, which may be due to altered stoichiometry of the heteromultimer channel (containing fewer HCN1 subunits) than in normal rat tissue. However, this absence of effect was also seen in rat cortical neurons, suggesting that the reported augmentation of I_H by altered voltage dependence may be a peculiarity of hippocampal neurons (the subject of earlier investigations) or is not accessible with somatic recordings. To examine these possibilities, we will first test whether the effects of lamotrigine obtained with dendritic recordings can also be obtained with somatic recordings in hippocampal neurons. If in these cells the somatic recordings fail to reveal effects of lamotrigine (seen at more distal dendritic sites), the more demanding dendritic recordings must be attempted in human cortical neurons. This task will be challenging, since the visualization of neurons – let alone dendrites – is difficult in human tissues. The clarification of this mechanism is important. If I_H is indeed small in epileptogenic human cortical tissue, then drugs augmenting this residual I_H would be very useful, considering the impact of I_H on the stability of membrane potential and temporal summation of synaptic potentials. Whether a pharmacological enhancement can compensate for the ~70% smaller current density existing in human cortical neurons remains to be seen.

The biophysical and pharmacological properties of transient and persistent sodium currents have not been investigated so far in human epileptic cortex. The patch-clamp technique with infrared videomicroscopy would also allow voltage-clamp experiments characterizing the properties of transient and persistent sodium currents of morphologically identified neurons and their modulation by relevant drugs. The inherent problems associated with voltage-clamp recordings from neurons in situ (e.g., space-clamp, access of drugs) could be alleviated by using acutely isolated neurons. Obviously, this approach could also yield data for other channels (e.g., Ca^{2+}) with intra- and extracellular symmetrical Cs^+ solution, plus a cocktail of appropriate drugs (TTX, TEA, 4-AP).

In the future, we would like to address the cause of different intrinsic neuronal properties (e.g., expression pattern of Na^+ channels in fast spiking interneurons versus regular firing pyramidal neurons with single-cell RT-PCR) and consequences (e.g., input–output relation of each type of neuron with paired recordings) complemented by immunohistochemistry of individually labelled neurons.

In conclusion, the data presented here demonstrate that various electrophysiologically accessible parameters can be quantitatively evaluated in human cortical neurons. The stable recordings (up to hours) from slices in our experimental setting allow for a detailed analysis of the effects of various drugs on membrane currents. Currently, we prefer to take a given neuron through a series of drugs in various combinations (to progressively eliminate distinct components) rather than to compare populations of neurons under various conditions. This approach allows us, with a certain degree of confidence, to extrapolate from a pharmacologically well-defined measurement to the role of a given parameter in the physiological situation – when the impact is obscured by interacting channels and transmitters. Although the slices are viable for up to 20 h and sometimes even longer, only a limited number of neurons are obtained (up to 12 with patch-clamp technique and up to 8 with sharp electrodes, partly due to the different duration of protocols used with the two recording techniques). Perhaps with acute isolation and short-term culture approaches, the yield from all measurements could be increased – so that for each key parameter (e.g., I_H density), a reliable number of neurons are assessed for statistical evaluation. If the number of recorded neurons from a given patient is sufficiently large, and the drug effects on pivotal parameters are determined, we could provide a rational basis for prescribing this patient with a distinct combination of drugs. This rationale approach to drug prescription might not only alleviate the sufferings of the individual patient (especially in the cases were surgical outcome is suboptimal), but might also help to predict the outcome of drug combinations in other patients.

Acknowledgements

I am indebted to R. Fleischmann and Dr. S. Gigout, who did some of the carbachol experiments, and to S. Wierschke, who allowed the inclusion of some of his data on I_H from his PhD work. I am most grateful to Dr. T.-N. Lehmann for providing the human tissues and to Prof. H.-J. Meencke and his team at the Epilepsiezentrum Berlin–Brandenburg for their care for the patients and their interest in my work.

Introduction

CA1 pyramidal cells (PCs) provide a major output of the hippocampus proper. They integrate information arriving directly from the entorhinal cortex via the temporoammonic pathway, and indirectly via the polysynaptic dentate gyrus–CA3–CA1 loop. Both pathways terminate in a spatially segregated manner onto CA1 PC apical dendrites. The temporoammonic pathway targets the distal dendrites in the stratum lacunosum moleculare, while CA3 PC axons terminate within the stratum radiatum. These inputs are integrated in the somatodendritic compartment and converted to an output consisting of action potentials propagating along the CA1 axons, a process controlled by the intrinsic membrane properties of CA1 neurons. We will first consider the mechanisms determining input–output properties of normal CA1 PCs. We will then address how the properties of CA1 PCs change in acute and chronic epilepsy models, and how they might contribute to increased excitability.

Introduction

CA1 pyramidal cells (PCs) provide a major output of the hippocampus proper. They integrate information arriving directly from the entorhinal cortex via the temporoammonic pathway, and indirectly via the polysynaptic dentate gyrus–CA3–CA1 loop. Both pathways terminate in a spatially segregated manner onto CA1 PC apical dendrites. The temporoammonic pathway targets the distal dendrites in the stratum lacunosum moleculare, while CA3 PC axons terminate within the stratum radiatum. These inputs are integrated in the somatodendritic compartment and converted to an output consisting of action potentials propagating along the CA1 axons, a process controlled by the intrinsic membrane properties of CA1 neurons. We will first consider the mechanisms determining input–output properties of normal CA1 PCs. We will then address how the properties of CA1 PCs change in acute and chronic epilepsy models, and how they might contribute to increased excitability.

Background – Control of Intrinsic Excitability in Hippocampal Pyramidal Cells

In a physiological extracellular milieu, CA1 PCs in the normal rodent brain display characteristic, relatively

uniform intrinsic firing properties. As a threshold response to brief current injections, the vast majority of CA1 PCs generate a single action potential, or spike (see **Figure 1(a)**, panel b). When current injection is prolonged, CA1 PCs respond with a series of independent spikes (**Figure 1(a)**, panel a). This type of discharge behavior has been classified as regular firing and sets CA1 PCs apart from neurons that respond to a threshold depolarization with a high-frequency burst of spikes as a minimal response. The latter category of neurons has been termed 'intrinsically bursting.' Bursting neurons are rarely encountered in the normal CA1 region under physiological conditions, but appear under pathological circumstances (**Figure 1(b)**, panels a and b). In other brain regions, however, bursting neurons are prevalent under normal conditions (e.g., in the subiculum or certain thalamic nuclei).

What are the mechanisms that control whether a neuron discharges in a regular or a burst-firing mode? In many types of central and peripheral neurons, the rapid repolarization of the somatic spike is incomplete, and the spike is followed by a slow afterdepolarization (ADP) lasting tens or hundreds of milliseconds. The size of this graded afterpotential is a major factor in determining the firing mode of many neurons. If sufficiently large, the spike ADP redepolarizes the neuron to action potential threshold, thus generating one or more additional action potentials. Thus, the size of the spike ADP is a critical determinant of neuronal discharge behavior.

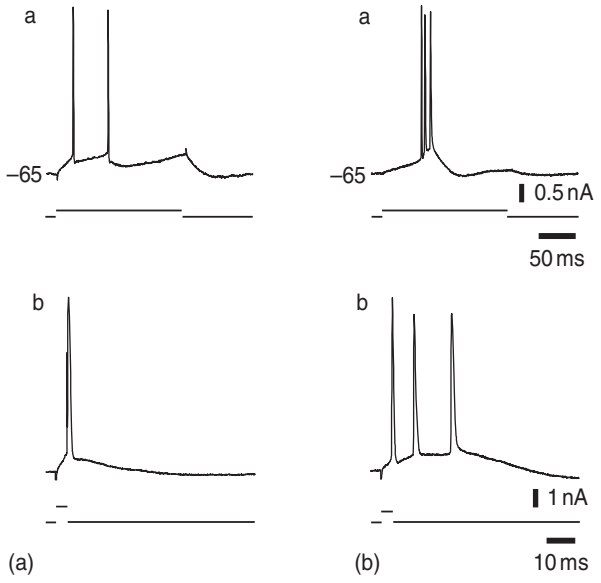

Figure 1 Regular firing and intrinsically bursting CA1 neurons. (a) Representative example of a regular firing CA1 neuron in a normal rat recorded with a sharp microelectrode. Upper traces represent voltage recordings; lower traces represent current injection steps. Responses of CA1 neurons to brief (4 ms, panel b) and long (180 ms, panel a) current injection steps are depicted. (b) Representative example of a bursting neuron in the CA1 region in a pilocarpine-treated rat. This neuron bursts to threshold brief (panel b) and long (panel a) stimulation. Bursting neurons are exceedingly rare in the normal hippocampal CA1 region.

Adult hippocampal CA1 PCs display a conspicuously active somatic spike ADP, but it does not reach spike threshold in most cells. Spike ADPs are composed of a passive and an active component. The passive component is brief, declines exponentially, and reflects passive recharging of the membrane capacitor. This passive ADP component may be augmented in size and duration by a slow inward current (active component) that activates during, or immediately after, the spike. The ion channels responsible for this active spike after-current vary across different types of neurons, and include voltage-gated Ca^{2+} and Na^{+} channels, as well as Ca^{2+}-activated nonspecific cationic channels. In adult CA1 pyramidal neurons, a major component driving spike ADPs is the persistent Na^{+} current (I_{NaP}), a low-threshold, noninactivating Na^{+} current. Patch-clamp studies in CA1 neurons have revealed that I_{NaP} is active within the voltage range of the spike ADP, and that this current gives rise to substantial sustained Na^{+} spike after-currents. Compounds that potently block I_{NaP} also block spike ADPs and associated bursting. In comparison, Ca^{2+} spike after-currents are much smaller in CA1 PCs, and suppressing them has no noticeable effect on spike ADPs.

The size of the spike ADP is not only determined by the magnitude of inward currents, but also depends on the density ratio of the inward spike after-current and opposing outward currents, such as the M-type K^{+} current (I_M). M-currents are noninactivating K^{+} currents that are active in the subthreshold voltage range. Among other cellular functions, they oppose the depolarizing drive furnished by I_{NaP} that causes spike ADPs in adult CA1 PCs. Recordings from CA1 neurons have revealed that I_M activates during the spike ADP. Selectively blocking I_M converts regular-firing CA1 PCs to a burst-firing mode. This result shows that I_{NaP} and I_M constitute two opposing low-threshold currents that in concert govern the magnitude of active spike ADPs.

Because somatic voltage-gated Ca^{2+} currents are mostly high voltage-activated subtypes that deactivate quickly after the spike, they produce only small spike after-currents in adult CA1 PCs. Unexpectedly, blocking them reduces the spike ADPs. The reason for this phenomenon is that Ca^{2+} influx during the spike causes intracellular inhibition of I_M, thereby shifting the balance between I_{NaP} and I_M in favor of the former current, leading to spike ADP facilitation.

Several lines of evidence suggest that both I_{NaP} and I_M originate in proximal axo-somatic compartments of CA1 PCs. First, channel subunits that give rise to I_M (K_v7 subunits), as well as subunits that contribute to I_{NaP} (i.e., $Na_v1.6$) are known to be aggregated at the axon initial segment of CA1 PCs. Second, focal applications of blockers of I_{NaP} or of I_M to the somatic region of CA1 PCs

suppress or augment the spike ADPs, respectively; whereas their focal application to the distal apical dendrites does not affect these afterpotentials. Finally, physically separating apical dendrites from the cell soma (with a fine cut) does not affect spike ADPs of CA1 neurons. Thus, the spike ADP in adult CA1 PCs, under normal conditions, is generated by the interplay of two low-threshold, persistent conductances at or near the soma of the neuron.

Available evidence suggests that under certain conditions dendritic ion channels also play a role in determining the firing mode of adult CA1 PCs. The apical dendrites of these neurons contain high densities of A-type K^+ currents (I_A) and T-type Ca^{2+} currents that are active within the action potential subthreshold range and are activated when action potentials back-propagate into the dendritic tree. Under normal conditions, dendritic excitability is limited by I_A. However, when dendritic I_A is blocked pharmacologically, the invading spike triggers a regenerative slow Ca^{2+} spike in the apical dendrites that spreads to the soma in much the same way as the dendritic excitatory postsynaptic potentials (EPSPs) excite the soma. This causes the somatic ADP to enlarge and escalate to a high-frequency spike burst. Thus, in normal conditions, apical dendrites of adult CA1 PCs harbor a Ca^{2+}-driven burst mechanism that is controlled by I_A (much the same way as the somatic I_{NaP}-driven mechanism is controlled by I_M). Intriguingly, the dendritic mechanism is unleashed in developing CA1 PCs at postnatal days 10–25, causing them to transitionally manifest a Ca^{2+}-driven bursting phenotype that is not ordinarily operative in adult neurons.

Methods

To address the physiological properties of CA1 neurons, electrophysiological techniques have been widely used. Such techniques include sharp microelectrode recordings (in which neurons are impaled) or patch-clamp recordings. Such recordings allow us to determine the resting electrophysiological properties of CA1 PCs (such as the membrane potential and passive electrical properties), and the properties of individual action potentials and their repetitive discharge behavior. In addition, these techniques also allow investigators to record the responses of CA1 neurons to the activation of excitatory and inhibitory synapses. These techniques have been used to glean information on the intrinsic and synaptic properties of CA1 neurons under control (i.e., 'normal') conditions and in chronically epileptic tissue. In CA1 pyramidal cells, patch-clamp recordings can be obtained from the main apical dendrite; such recordings have yielded useful information about dendritic processing and the underlying dendritic voltage gated channels, and their changes in chronic epilepsy.

Results

Plasticity of Intrinsic Excitability in Acute Models of Epilepsy

In vitro or in vivo, epileptiform activity can be induced by changing the ionic composition of the extracellular fluid in various ways. Such models have proved useful for studying the mechanisms underlying the development of synchronized population activity in normal brain. Epileptiform activity can be readily induced by lowering extracellular Ca^{2+} concentration ($[Ca^{2+}]_o$), raising extracellular K^+ concentration ($[K^+]_o$), increasing extracellular pH, or decreasing extracellular osmolarity. In addition, blocking K^+ currents with various blockers, including 4-aminopyridine (a blocker of A-type K^+ currents) causes epileptiform activity in vitro. Though all these manipulations differ in their effects on synaptic activity, they all induce intrinsic bursting in CA1 neurons. Examples for the effects of lowering $[Ca^{2+}]_o$ and raising $[K^+]_o$ are shown in **Figure 2(a)** and **2(b)**, respectively. Cumulatively, these data suggest that the epileptogenicity of hippocampal tissue correlates very well with the propensity of CA1 principal neurons to fire in burst mode.

How these diverse changes in the composition of the extracellular milieu cause the conversion of CA1 PCs to a bursting mode has been addressed in a few instances. Intrinsic bursting induced by lowered $[Ca^{2+}]_o$ is inhibited by blockers of I_{NaP}, indicating that this conductance supplies part of the depolarizing drive for the burst discharge, and suggesting that I_{NaP} may be augmented when $[Ca^{2+}]_o$ is decreased. Indeed, the activation curve of I_{NaP} was potently shifted in a hyperpolarizing direction by lowering $[Ca^{2+}]_o$ from 2 to 1.4 mM. Given such results, it is important to determine how the different voltage-dependent conductances that shape CA1 PC firing behavior are modified by altering the ionic composition of the extracellular milieu. Seizure activity results in large changes in extracellular K^+, Ca^{2+}, osmolarity, or pH, that may feed back onto the intrinsic properties of hippocampal neurons.

Plasticity of Intrinsic Excitability in Chronic Models of Epileptogenesis

In experimental rodent models of temporal lobe epilepsy (TLE), where seizures originate in the hippocampus or related temporal lobe structures, pronounced changes in intrinsic properties of CA1 PCs are also observed. These changes are, in most cases, caused by altered expression or modulation of ion channels that affects the magnitude of the corresponding currents and associated discharge behavior. In the widely used pilocarpine model of TLE, in which epilepsy develops following a single episode of status epilepticus (SE) induced by this convulsant, changes in intrinsic properties of CA1 neurons have been examined in detail. As explained earlier, most CA1

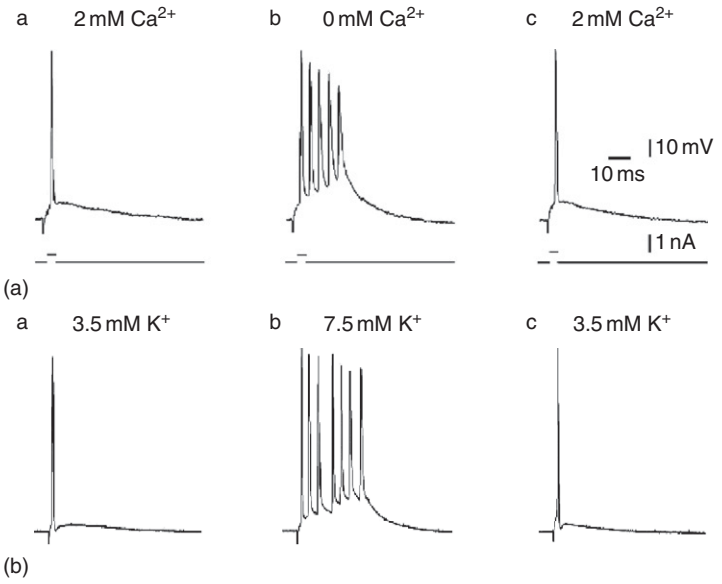

Figure 2 Changes in firing behavior in acute in vitro models of seizures. (a) Removing Ca^{2+} from the extracellular solution causes a conversion of a regular-firing CA1 neuron (panel a) to a bursting mode (panel b). This effect is reversible (panel c). (b) A similar phenomenon is observed following elevation of the extracellular K^+ concentration (panels a–c). Reproduced from Yaari Y and Beck H (2002) 'Epileptic neurons' in temporal lobe epilepsy. *Brain Pathology* 12: 234–239, with permission.

PCs in the normal adult brain are regular firing neurons. Following SE, however, about half of these neurons convert to a low-threshold bursting mode, in which their response to a threshold depolarizing stimulus is a burst of 3–8 spikes. A similar, but less pronounced change has been observed in the kindling model of epilepsy. Further analyses in the pilocarpine model have revealed that this novel bursting behavior is due to the up-regulation of a Ni^{2+}-sensitive T-type Ca^{2+} current. Interestingly, blocking T-type Ca^{2+} channels or Na^+ currents by focal drug application to the dendrites, blocks aberrant bursting, while applying blockers of T-type channels to the soma does not. This differential effect indicates that T-type Ca^{2+} currents in dendrites, presumably activated by back-propagation of action potentials, cause a dendritic Ca^{2+} spike that, in turn, propagates to the soma, eliciting further spikes (the same mechanism invoked following in normal CA1 PCs by blocking dendritic A-type currents; see the earlier sections). Interestingly, down-regulation of dendritic I_A has also been observed in CA1 PCs following SE and likely contributes to the de novo emergence of the dendritic Ca^{2+}-driven burst mechanism.

In addition to altered bursting behavior, a number of other intrinsic membrane properties are potentially altered in epilepsy. For instance, induction of early life seizures with flurothyl in rats markedly reduces spike frequency adaptation and the afterhyperpolarizing potential recorded in adult CA1 PCs. Thus, neonatal seizures also lead to persistent changes in intrinsic membrane properties of CA1 pyramidal neurons. Like the increase in intrinsic bursting behavior, these alterations reflect an increase in neuronal excitability.

How Changes in Intrinsic Excitability Contribute to Epileptogenesis

How relevant are changes in properties of CA1 neurons for the development of chronic epilepsy? Modeling studies from Traub and Wong were the first to suggest that neurons generating spontaneous bursts of action potentials may be critically important in entraining additional neurons into a synchronized population discharge. If this is true, then discharges originating in intrinsically bursting neurons would be expected to precede epileptiform activity. Indeed, in both acute and chronic models of TLE, spontaneously active intrinsic bursters were shown to be the forerunners in the generation of epileptic discharges (**Figure 3(b)**). In contrast, regular firing neurons always discharged in synchrony with the ensuing population discharge (**Figure 3(a)**). Likewise, in neocortical slices treated with blockers of inhibitory transmission, threshold stimulation of afferent fibers evoked long-latency epileptiform bursts, which originated in the cortical layers containing intrinsically bursting pyramidal cells. In the hippocampus, burst discharges of intrinsically bursting neurons are likely to recruit additional neurons in the CA1 region via recurrent excitatory connections. Such recurrent synapses between CA1 PCs are sparse in normal rats, but enhanced in chronically epileptic animals; local sprouting of axon collaterals leads to the formation of novel excitatory synapses between surviving CA1 pyramidal cells that significantly strengthen recurrent feedback excitation. The efficacy of local excitatory feedback is also controlled by GABAergic inhibition. In normal rats, even the sparse connectivity between CA1

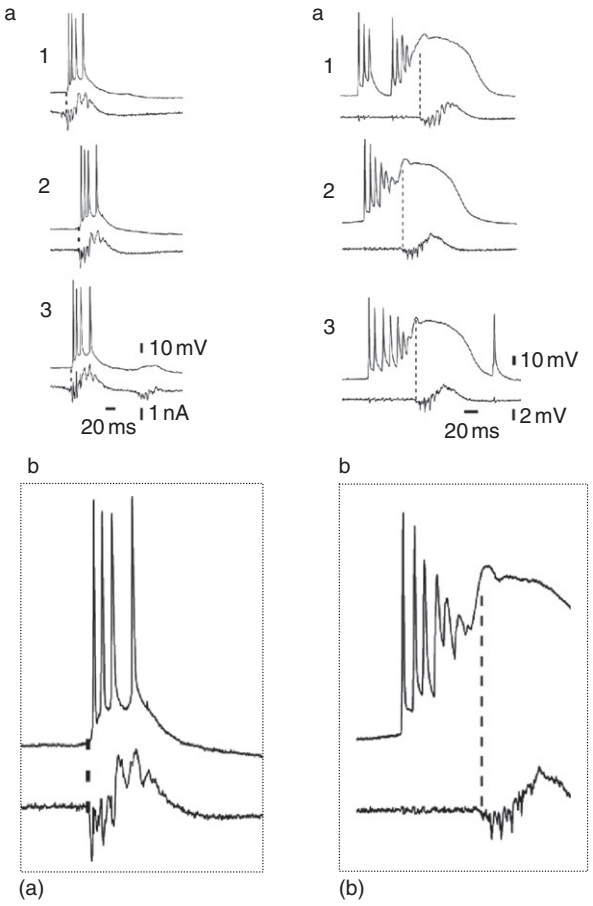

Figure 3 Intrinsically bursting neurons precede population discharges in epileptic tissue. (a) A regular firing neuron in the CA1 region recorded with a sharp microelectrode (upper traces in panel a) obtained simultaneously with a field recording of an epileptiform population discharge (lower traces in panel a). Three different instances of an epileptiform population discharge are shown (1–3, enlarged in panel b). The discharge of the nonbursting CA1 neuron always occurs together with the population discharge. (b) Analogous recording with a bursting neuron that was capable of spontaneous burst discharges. The bursting CA1 neuron invariably discharges previous to the population discharge (panel a, enlarged in panel b), suggesting that spontaneously bursting CA1 neurons may entrain other CA1 neurons into the population discharge. Reproduced from Sanabria ERG, Su H, and Yaari Y (2001) Initiation of network bursts by Ca^{2+}-dependent intrinsic bursting in the rat pilocarpine model of temporal lobe epilepsy. *Journal of Physiology* 205–216, with permission.

neurons can become functionally relevant if $GABA_A$ergic inhibition is blocked, leading to the spread of excitation within the CA1 region. In chronic epilepsy, there is a deficit in some forms of inhibition in CA1. Both enhancement of recurrent excitation and loss of inhibition are likely to provide pathways for the spread of intrinsic bursting within the neural aggregate, thus facilitating the generation of epileptiform events. Clearly, intrinsic and synaptic features in the chronically epileptic hippocampus conspire to produce epileptiform activity in the CA1 region.

Are there other consequences to the conversion of CA1 neurons to an intrinsically bursting mode? A number of studies suggest that the bursting mode affects plasticity at synaptic connections onto these neurons. For instance, synaptically evoked bursts of action potentials, but not solitary spikes, enable *N*-methyl-D-aspartate (NMDA) receptor-dependent long-term potentiation (LTP) of EPSPs in CA1 pyramidal cells. Presumably, the burst discharge is more effective than a single spike in removing the Mg^{2+} block from postsynaptic NMDA receptor-channels, which is a prerequisite for the induction of LTP. In addition to promoting LTP of excitatory synaptic transmission, it is tempting to speculate that intrinsically bursting neurons in epileptic tissue may be more liable to exhibit sprouting of axon collaterals, because this process also depends on NMDA receptor activation. Thus, intrinsic bursting may interact with various plasticity mechanisms, which conspire to cause the progression of the epileptic condition in TLE.

Apart from contributing to the increased propensity to generate burst discharges, changes in dendritic ion channels also affect processing of EPSPs generated at dendritic sites. Several types of dendritically enriched channels, such as A-type K^+ channels, T-type Ca^{2+} channels, and h-channels, are active in the subthreshold range and can therefore be activated by EPSPs that are subthreshold for spike initiation. The activation of all the three channel types can have substantial effects on the propagation of EPSPs from distal dendritic sites to the soma. In addition, dendritic channels affect the back-propagation of action potentials into the dendritic tree. I_A in particular causes attenuation of back-propagating action potentials. A reduction in I_A in chronic experimental epilepsy has been shown to cause a reduced attenuation of action potential amplitude at dendritic sites.

Future Directions

Intrinsic plasticity is a complex process that has often been cited to help explain phenomena observed in experimental epilepsies. Such plasticity can profoundly alter the firing behavior of CA1 PCs. The expression of intrinsic plasticity relies on an altered magnitude of dendritic and somatic voltage-gated ion channels. Even though some progress has been made, extensive further studies will require to dissect the underlying cellular and molecular mechanisms. Several intriguing questions remain to be addressed. First, changes of dendritic conductances dramatically affect synaptic integration. Due to the difficulty of recording from small dendrites, however, our knowledge of the active properties of dendrites is restricted to the main apical dendrite of CA1 neurons. Whether the properties of oblique or basal dendrites are altered in the epilepsies is unknown. Second, it would be important to learn more about the cellular cascades that are important in mediating intrinsic plasticity. A precise

identification of transcriptional and translational pathways underlying the regulation of specific ion channels by activity will be an intriguing area of research in the coming years. Finally, it will be important to use novel techniques that allow investigators to record activity from many neurons simultaneously, to determine the impact of a subpopulation of intrinsically hyperexcitable neurons on the greater CA1 network.

Membrane Properties and Synaptic Circuitry of CA3 Pyramidal Neurons that Promote Epileptiform Neuronal Synchronization

Y Z Pan and P Rutecki, University of Wisconsin School of Medicine, Madison, WI, USA

Introduction

The CA3 region of the hippocampus is composed of pyramidal neurons and a myriad of interneurons that are inhibitory and synapse on pyramidal neurons (as well as on each other). The classic inhibitory neuron is the basket cell, which has numerous synaptic contacts on the cell bodies of CA3 pyramidal neurons and mediates somatic inhibition. Other interneurons synapse on dendrites of pyramidal neurons to produce dendritic inhibition. The CA3 pyramidal neurons receive excitatory synaptic input from dentate granule neurons via the mossy fiber synapse as well as perforant pathway input from the entorhinal cortex to the most apical dendrites. In addition, there are recurrent excitatory connections among the CA3 pyramidal neurons (autoassociational). The CA3 neurons project to the CA1 region via the Schaffer collateral pathways to complete the classic trisynaptic pathway of the hippocampal formation (perforant pathway to dentate granule neurons, dentate granule neurons to CA3, CA3 to CA1 neurons). Recent evidence also demonstrates some CA3 pyramidal neuron axons projecting back to dentate granule neurons. The CA3 pyramidal neurons send axons out of the ipsilateral hippocampus via the alveus and fimbria of the fornix; these axons project to the septal nuclei bilaterally and to the contralateral hippocampus. Inputs from the contralateral CA3 region

and septal nuclei (primarily ipsilateral) also enter the hippocampus through the alveus and fimbria.

The hippocampus is important for memory, and the dentate gyrus/CA3 connections have been shown to produce pattern separation for similar stimuli or inputs, as opposed to pattern completion associated with the CA1 region. Thus dentate/CA3 activity will be selective for the exact orientation or features of a memory cue, whereas the CA1 neurons will not respond so selectively (and a similar pattern of activity will occur for recall of similar objects). The autoassociative (recurrent excitatory) connections among excitatory neurons are hypothesized to produce episodic and one-trial learning. These association pathways also provide a synaptic substrate for abnormal recurrent excitation that favors synchronization and seizures.

Background

CA3 pyramidal neurons were among the first mammalian CNS neurons from which intracellular recordings were made. Kandel and Spencer made recordings from CA3 neurons of the cat; neurons were impaled with intracellular electrodes that were introduced via an intraventricular approach, through the alveus. Neurons were identified as CA3 pyramidal neurons if they demonstrated an antidromic response to fornix stimulation (neurons that were not activated by antidromic stimulation were considered as unidentified). These early studies demonstrated that a burst of action potentials could be generated in identified CA3 neurons by either synaptic activation delivered by subiculum stimulation (presumed to be perforant pathway stimulation) or following depolarizing current injection. Furthermore, these investigators showed inhibitory postsynaptic potentials could be produced by weak fornix stimulation. The burst of action potentials and the spike afterdepolarizations that Kandel and Spencer described were hypothesized to be mechanisms of maintaining an excitatory state. Later work determined this pattern of burst firing and spike after depolarizations were generated (at least in part) by calcium currents.

The CA3 region of the hippocampus appears to be the pacemaker region for spontaneously occurring synchronous epileptiform activity in the hippocampal slice. When convulsants are added to the bathing media of hippocampal slices, the CA3 region is most likely to generate spontaneous epileptiform activity and to drive activity in the CA1 region via the Schaffer collateral pathway. The underlying basis for CA3's susceptibility to epileptiform activity appears to be related to the burst-firing properties of the CA3 pyramidal cells, and to the recurrent excitatory connections among these CA3 neurons. Subtle alterations that promote excitatory synaptic transmission, decrease inhibitory synaptic transmission, or alter the firing properties of CA3 neurons allow for the emergence of network-driven activity that underlies epileptiform discharges. Because the CA3 region displays spontaneously occurring synchronous in vitro activity that resembles interictal and ictal in vivo activity, experiments can be carried out to define variables that favor or suppress epileptiform discharges. Furthermore, the in vitro slice preparation allows investigators to obtain intra- and extracellular recordings, and to thus evaluate changes in membrane or synaptic properties that can be correlated with network-based epileptiform events (see **Figure 1**).

Methods

Most intracellular recordings in the hippocampus are now made from slice preparations (including organotypic hippocampal slice cultures). In general, hippocampal slices are prepared by sectioning the hippocampus using a tissue chopper or vibratome. The slices may be prepared in the transverse, longitudinal, or horizontal planes, depending on what circuitry the investigator wants to preserve and study. The hippocampus from newborn animals may be used to produce organotypic slice cultures that preserve many features of hippocampal anatomy, including synaptic connections from granule to CA3 neurons and CA3 to CA1 neurons.

Using such slice preparations, maintained in a recording chamber, both intracellular and extracellular

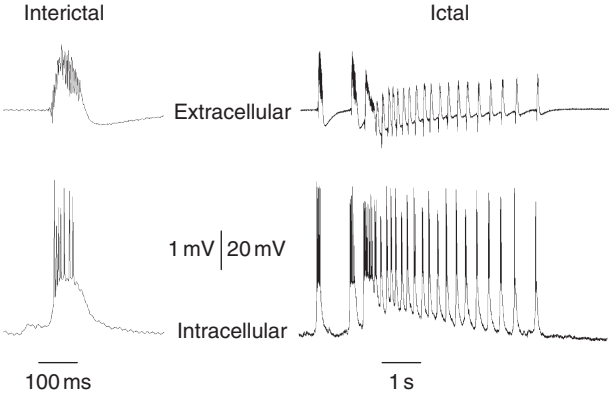

Figure 1 Intra- and extracellular recordings of spontaneously occurring epileptiform activity from the CA3 region of the hippocampal slice. This slice had been exposed to the group I metabotropic glutamate receptor agonist dihyroxyphenlyglycine (DHPG) and the activity continued after the agonist had been removed. The traces on the left show an interictal discharge that is analogous to the interictal spike that is recorded in the EEG. The interictal discharges are relatively brief compared to the discharge depicted in the right side of the figure that is more prolonged and resembles a seizure or ictal discharge. Intracellular recordings from a CA3 pyramidal neuron ($V_m = -64$ mV).

recordings can be obtained by introducing the appropriate type of electrode into the region (or cell type) of interest. Extracellular recordings are often obtained to determine if there is synchronous activity associated with an intracellular signal. Stimulation of various pathways within the slice preparation (often with bipolar electrodes) can be used to induce either antidromic or synaptically mediated activity in the cell of interest. Sharp electrodes were initially used to study intracellular activity in 'current clamp' mode. Whole-cell voltage-clamp recordings can also be made, using either blind techniques (i.e., not directly visualizing neurons but identifying the cell body layer), or a microscope with infrared diffusion interference contrast (IR-DIC) to visualize neurons directly. Data presented in article are drawn primarily from studies of acute slices from young rats (10–40 days old). The younger animals are particularly useful for IR-DIC guided recordings.

Results

Membrane Properties of CA3 Pyramidal Cells

Burst firing

First noted in in vivo studies, some CA3 pyramidal cells tend to fire in brief bursts of 2–3 action potentials when depolarized to threshold, either by current injection or synaptic input. This burst firing property defines pyramidal neuron activity in unit recordings and differentiates these neurons from interneurons, which fire at more sustained higher frequencies. Granule neurons do not burst under normal conditions and CA1 neurons are less likely to show intrinsic burst activity compared to CA3 neurons. Approximately 20% of CA3 pyramidal neurons demonstrate burst firing patterns when depolarized by current injection. Using intracellular recordings, investigators have attempted to elucidate the underlying bases of this burst pattern of discharge. This burst discharge property appears to be dependent on the activation of calcium channels, some of which are activated near rest (i.e., T-type calcium channels). The burst activity is also influenced by higher threshold channels (L, N, or R-type) that are also present in CA3 pyramidal neurons. The dendritic location of calcium channels allows them to amplify synaptic input, and to enhance synaptic activity as a consequence of back-firing action potentials from the soma. When action potentials are generated in the soma, they can back-propagate and activate high threshold calcium channels not originally activated by lower voltage synaptic depolarization. Such a back-propagation may be important for strengthening synapses active during a back propagating potential.

Some investigators have hypothesized that intrinsic bursting neurons are necessary for epileptiform activity. Intrinsic bursting will enhance the probability of synchronization by synaptic mechanisms in a network with recurrent excitatory synaptic connections. Burst firing with appropriate timing between spikes enhances temporal summation of EPSPs, and will increase the likelihood of action potential generation in the postsynaptic neuron. Furthermore, if the postsynaptic neuron itself has burst-generating properties, multiple action potentials may be generated that will lead to enhanced synaptic transmission onto other synaptically connected neurons. Interestingly, in epileptiform bursting induced by elevated extracellular potassium, intrinsic bursting may be less common and the network is driven more by an enhanced frequency or EPSPs.

Afterhyperpolarization

The burst firing of CA3 neurons is terminated and modulated by a number of potassium conductances activated by depolarization and the burst activity. These conductances include voltage dependent channels like the delayed rectifier and M-channel, and calcium-activated potassium channels. There are three calcium-activated potassium conductances that are activated by action potential firing that cause an afterhyperpolarization (AHP) following the burst. The first is the fast AHP (fAHP) which is activated by single action potential generation and controls the spike duration. This fAHP is mediated by channels that have a large conductance (so-called BK channels). These channels appear to be located near calcium channels that are involved in action potential generation. The second AHP, termed the medium AHP, is mediated by calcium activation of the small conductance (SK) class of channels that are sensitive to apamin, a toxin in bee venom. The longest duration AHP is the so-called slow AHP (sAHP) that is mediated by a calcium-dependent potassium conductance and lasts for seconds. The sAHP activates slowly, appears to be activated by higher levels of calcium influx, and is perhaps associated with calcium diffusion into the dendrite.

Some of these channels are negatively modulated by neurotransmitters that enhance epileptiform activity (e.g., muscarinic, beta noradrenergic, and metabotropic glutamate receptors, **Figure 2**, see below). Reduction of the medium and slow AHPs are associated with a faster spontaneous interictal discharge rate and favor more prolonged ictal discharges Finally, it should be noted that the M-current may also contribute to repolarization and an AHP that lasts for 2–300 ms. The M-current is activated by voltages just above the resting potential and controls spike rates when neurons are depolarized. The channels that are responsible for this current are closed when muscarinic receptors are activated and phospholipase C is produced.

Spike frequency modulation

The frequency of action potential generation is greatly influenced by a number of channels that are activated by

depolarization and calcium entry. As in many cortical pyramidal neurons, the frequency of spiking in CA3 pyramidal cells decreases during a prolonged depolarizing current pulse (adaptation) because of channels that repolarize the membrane potential. Under normal conditions, some neurons fire only a short burst of action potentials; the AHP repolarizes the membrane potential and prevents the cell from generating continuous spike. When neuromodulators exert their effects to reduce the various forms of the AHP (see below), the action potentials may be generated at a higher frequency for a more prolonged period. More sustained firing favors higher frequency of interictal discharges and longer lasting network activity, presumably by increasing the likelihood of excitatory recurrent synaptic transmission.

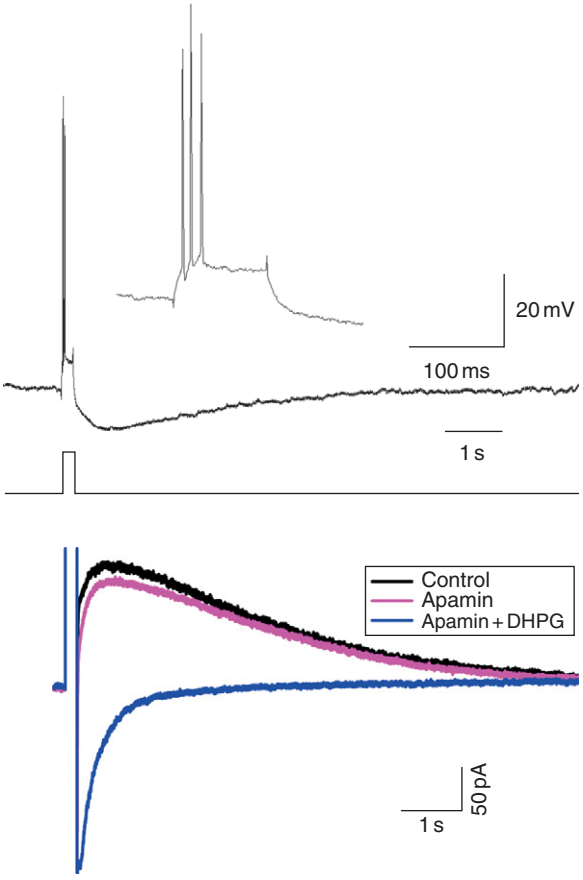

Figure 2 Sharp electrode recording from a CA3 pyramidal neuron ($V_m = -60$ mV) showing a burst of action potentials evoked by an intracellular depolarizing current pulse (top traces). Note that there is a burst of action potentials that accommodate and stop firing by the end of the current pulse that is followed by a long lasting after hyperpolarization (slow AHP). The bottom traces recorded using whole-cell voltage-clamo techniques show AHP currents evoked by a depolarizing voltage step from -50 to $+70$ mV recorded in the presence of TTX, TEA, and bicuculline. A long-lasting outward current develops after the pulse (I_{sahp}). Addition of -50 nM apamin to block the medium AHP produces a slight reduction in the amplitude of the earlier outward current. The group I mGluR agonist DHPG totally eliminates the slow AHP and also produces an inward tail current that probably results from a cationic current activated by the voltage step. These effects greatly enhance excitability and result in the development of spontaneously occurring activity depicted in Figure 1.

Synaptic Circuitry and Synchronization: Recurrent and Feedforward Circuitry

The hippocampus in general, and the CA3 region in particular, have extensive local synaptic circuitry that favors synchronization (Figure 3); this synchronization may be manifested in pathological activity – i.e., epileptiform activity. The basis for this synchrony is the rich recurrent circuitry that includes both recurrent (or feedback) inhibition and recurrent excitatory synaptic connections (autoassociational). Strong afferent excitatory input to CA3 pyramidal cells is mediated by the mossy fiber synapse, the specialized synaptic terminal of the dentate granule cell axons onto the CA3 dendrites. This complex synapse is close to the CA3 pyramidal neuron soma (on proximal dendrites) and provides a powerful drive that is subject to relatively little dendritic filtering or inhibition (compared to more remote associational/commissural synapses or perforant path input to the most distal apical dendrites). The mossy fibers also contact many inhibitory interneurons (many more inputs to

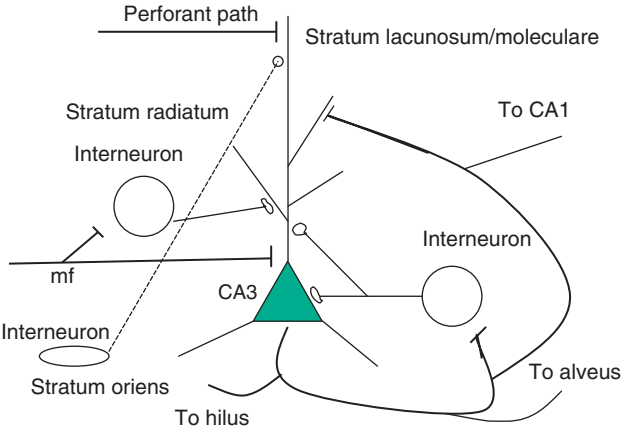

Figure 3 Schematic of the local circuitry of the CA3 region. Input from dentate granule neurons are carried by the mossy fibers (mf) which synapse on interneurons to activate feed forward inhibition and pyramidal neurons. The pyramidal neurons also receive input in the distal apical dendrites from the entorhinal cortex via the perforant pathway. In addition commissural and local associational inputs from other CA3 neurons activate interneurons as well as pyramidal neurons. The local excitatory synaptic connections promote interictal and ictal epileptiform activity. Other interneurons help regulate local circuits including the stratum alveus oriens interneuron that sends it axons to the distal apical dendrites (dotted line).

interneurons than to pyramidal neurons) and mediate feedforward inhibition (see Figure 3).

In addition, strong feedback inhibition onto CA3 pyramidal cells is mediated primarily by CA3 axon collaterals – which activate local interneurons, particularly basket cells. The basket cell provides a dense terminal plexus around the CA3 pyramidal cell soma, and produces a powerful inhibition through $GABA_A$ receptor activation. These somatic synapses are well positioned to prevent action potential generation. Although the somatic inhibition may not produce much change in membrane potential (the resting membrane potential of the CA3 pyramidal neurons is close to the reversal potential of the $GABA_A$-mediated IPSP), it does create a large shunt that will prevent the cell from being depolarized by other (e.g., EPSP) currents.

Blocking inhibition using a $GABA_A$ receptor antagonists (e.g., bicuculline, penicillin, and picrotoxin) produces spontaneously occurring epileptiform activity in the CA3 region that is mediated by a large excitatory postsynaptic potential generated by recurrent excitatory synaptic circuitry. Unlike the burst activity due to the activation of calcium and sodium channels (that can be turned off by hyperpolarizing the membrane potential), the epileptiform burst activity is not reduced by hyperpolarization and is actually increased in amplitude – consistent with an underlying excitatory synaptic potential. Furthermore, the epileptiform burst is accompanied by an extracellular potential that represents synchronous activity of many neurons. The recurrent excitatory synaptic potentials are more likely to synchronize when they are not inhibited by GABAergic synaptic input.

The excitatory recurrent circuitry is mediated by axon collaterals of CA3 pyramidal cells. The CA3 axon provides the major input to CA1 (the Schaffer collateral pathway), collaterals that ramify within the ipsilateral CA3, and collaterals directed to the contralateral hippocampus as well as to the septal nuclei blaterally. The transmitter that is released at the recurrent collateral synapses within CA3 is glutamate. Release of glutamate at these synapses activates AMPA/KA and NMDA receptors. Interestingly, NMDA-antagonists do not suppress epileptiform activity in the CA3 region, whereas low concentrations of AMPA receptor blockers do. In the slice preparation, one can easily see the consequences of the excitatory connections among CA3 neurons; cells are recruited by, and drive activity in other CA3 pyramidal cells when convulsant drugs (e.g., $GABA_A$ blockers, potassium channel blockers, increased extracellular potassium concentration) are added to the medium. The synchronous activity produced by these manipulations appears to be mediated by the AMPA/KA component of recurrent collateral synaptic transmission. The synchronous activity generated within the CA3 region drives synchronous discharges in the CA1 region via the Schaffer collateral pathway.

Modulation of Membrane Properties by Neurotransmitters

A number of neurotranmsitters activate or modulate ion channels through second messengers, and have a metabotropic rather than an ionotropic effect. Metabtropic receptors are not directly coupled to ion channels but are coupled to second messengers that then cause secondary effects (e.g., closing a potassium channel or activating calcium release from intracellular stores). The receptor for these modulating neurotransmitters is often coupled to G-proteins that then cause an effect mediated through a second messenger (either the G-protein itself or another second messenger, such as cAMP).

Cholinergic (muscarinic) modulation

Systemic injection of pilocarpine, a muscarinic agonist, produces status epilepticus, neuronal loss, and eventually spontaneously occurring limbic seizures. Pilocarpine-treated animals have been widely used as a model of temporal lobe epilepsy. The muscarinic receptors in the CA3 region are linked to second messenger systems that activate phospholipase C (PLC) and depolarize the membrane by decreasing the M-current (a potassium current activated near rest), decrease the slow AHP that controls neuronal firing, and causes calcium release from intracellular stores by inositol triphospate (IP3). IP3 is produced by PLC activation and binds to a receptor on the surface of intracellular calcium stores that cause release of calcium. When applied to hippocampal slices, pilocarpine produces synchronous CA3 firing that can last for seconds and mimics seizures in the intact animal.

Adrenergic (alpha and beta) modulation

Norepinephrine (NE) receptors in the hippocampus include the beta and alpha (1 and 2) receptors. NE action at the beta 1 receptor causes a decrease in the slow AHP by activation of cyclic AMP. Presumably, cAMP leads to phosphorylation of either the calcium-activated potassium channel or other effectors of this conductance, and thus reduces the activation of the conductance by calcium. This effect is associated with an increase in the rate of interictal discharges produced by disinhibition or elevations of potassium in the hippocampal slice. The beta receptor also enhances calcium currents carried by L-type channels. Overall, the actions of norepinephrine on noradrenergic beta receptors are proconvulsant.

The alpha-2 adrenergic receptor appears to activate anticonvulsant mechanisms that suppress epileptiform activity (as seen when $GABA_A$ blockade is induced in hippocampal slices). Alpha-1 adrenergic activation increases the rate of spontaneously occurring IPSPs in CA3 pyramidal neurons, an effect that appears to be due to a depolarization of interneurons. Alpha-1 activation also

appears to depress excitatory synaptic transmission by presynaptic mechanisms.

GABAergic ($GABA_B$) modulation

Besides activating $GABA_A$ receptors, GABA also binds to a G-protein coupled receptor termed $GABA_B$. This receptor activates a potassium channel via a G protein and produces a slow IPSP postsynaptically as well as inhibiting transmitter release (both glutamate and GABA) from presynaptic terminals by reducing calcium influx. Baclofen is an agonist at these $GABA_B$ receptors, and usually suppresses epileptiform activity in the CA3 region. In some cases, however, baclofen may lead to longer lasting discharges and can favor ictal-like activity. The reasons for this excitatory effect are not totally clear, but could relate to a reduction in GABA release from inhibitory interneurons. Baclofen may also reduce the amount of glutamate released with each CA3 pyramidal cell action potential, and may enhance prolonged synchronization by limiting transmitter release so that successive action potentials result in less transmitter release. One theory is that the epileptiform burst in CA3 neurons leads to depletion of releasable stores of transmitter, and the time needed to replenish these stores accounts for the period between interictal bursts. When glutamate release is not dampened by this $GABA_B$-mediated effect, only brief synchronous interictal activity occurs – perhaps because maximal glutamate release then leads rapidly to depletion of releasable vesicles in the terminal.

Glutmatergic (metabotropic) modulation

Under conditions of elevated glutamate release, as occurs during seizures, metabotropic glutamate receptors (mGluRs) are activated. This diverse group of receptors includes receptors subtypes located postsynaptically (group I mGluRs, mGluR1 and 5) in a perisynaptic location, as well as presynaptically (group II {mGluR2 and 3} and III mGluRs {mGluR 4, 5 6, 7, and 8}). Group I mGluRs activate second messenger cascades that include phospholipase C and, subsequently, diacylglycerol and inositol triphospate (IP3). IP3 activation results in calcium release from intracellular stores, and may contribute to excitotoxicity. Group I mGluRs also decrease a number of potassium conductances (thus increasing neuronal excitability) and also activate a cation channel that can mediate a slow EPSP. Group I mGluR activation results in seizures in animals, and in epileptiform activity in slices that persists following removal of the agonist.

Group II and III mGluRs appear to be anticonvulsant in action by inhibiting glutamate release presynaptically through calcium channel inhibition. mGluR2 receptors are located at mossy fiber presynaptic terminals, and agonists of mGluRs can be used to block mossy fiber EPSPs in CA3 pyramidal neurons.

Peptide Modulation of CA3 Excitability

A number of peptides play roles in controlling the excitability of the CA3 region and impact the tendency for CA3 pyramidal neurons to synchronize. Neuropeptide Y (NPY) is contained in interneurons, and these terminals increase in number in humans and animals with seizures. NPY has strong presynaptic actions that decrease excitatory transmitter release and suppresses interictal epileptiform activity in the CA3 region. Galanin is another neuropeptide that inhibits epileptiform activity in the hippocampus. Terminals from the medial septum contain galanin and activation of galanin receptors have anticonvulsant effects in vivo.

Dynorphin is a neuropeptide located in mossy fiber terminals, and release of dynorphin leads to activation of kappa opiod receptors. Dynorphin decreases excitatory glutamate synaptic transmission, enhances the M current, and has anticonvulsant properties. Activation of mu opiod receptors inhibits the release of GABA from interneurons resulting in disinhibition and epileptiform activity.

Somatostatin, another neuropeptide localized to interneuron axon buttons, appears to have antiepileptic effects. Somatostatin has been shown to enhance the M-current and reduce the frequency and duration of epileptiform discharges in the CA3 region of the hippocampal slice. Somatostatin also appears to inhibit recurrent excitatory connections.

Summary – Directions for Future Research

The network epileptiform activity that can be produced in the CA3 region of the hippocampus has proved to be a model of epileptiform activity in general. The organization of the recurrent excitatory synaptic connections of CA3 neurons and the firing properties of the CA3 neurons give rise to a system in which to study perturbations that favor epileptiform activity and seizure occurrence. Our understanding of pro- and antiepileptic properties of neurotransmitters and modulators has been improving through study of CA3 epileptiform activity and its modification.

Future studies will continue to define pharmacological manipulations that alter network synchronization in the CA3 region. Furthermore, other recording techniques – including multielectrode monitoring and optical imaging with voltage- or calcium-sensitive dyes –will provide insights into how a small network is capable of generating spontaneously occurring epileptiform activity. The CA3 region also should provide a useful model to study ways to modulate epileptiform activity and seizures by various electrical stimulation protocols. The ability to create prolonged epileptiform activity should help explain key mechanisms for the transition from interictal to ictal

patterns. These experimental approaches should lead to better therapies for temporal lobe epilepsy and epilepsy in general.

Introduction

The hippocampus is a component of the temporal/limbic network, which is thought to play an important role in temporal lobe epilepsy (TLE). The evidence supporting this view includes imaging, surgical, and experimental data. For example, positron emission tomography (PET) studies have demonstrated that the degree of hypometabolism in the temporal lobe correlates with the severity of hippocampal pathology. Further, removal of the hippocampus (with some adjacent parts of the anterior medial temporal lobe) successfully controls seizures in patients with medically intractable TLE. Finally, a large series of studies on experimental models of epilepsy implicate the hippocampus as an epileptogenic zone.

The molecular anatomy of hippocampi removed from the brains of patients with medically intractable TLE has provided important insights. These studies reveal two broad types of organization in these TLE-associated hippocampi. A majority of these hippocampi involved in mesial temporal lobe epilepsy (MTLE) show a pattern of extensive (>50%) neuronal loss across all regions of the hippocampus, including area CA3, along with an increase in the population of astrocytes. These changes

are accompanied by a distinctive reorganization of the neural circuits involving the surviving neurons. This pathological appearance is described as 'hippocampal sclerosis.' Several lines of evidence suggest that these sclerotic hippocampi are epileptogenic. Other surgically removed hippocampi do not show such extensive neuronal loss, gliosis, or reorganization, and are often described as nonsclerotic hippocampi. The latter closely resemble hippocampi from neurologically normal subjects, and are often considered to be nonepileptogenic. The cause of the epileptogenicity in patients with nonsclerotic hippocampi is sometimes a mass lesion (tumor or arteriovenous malformation) outside the hippocampus (mass associated temporal lobe epilepsy – MaTLE). In other cases, the cause remains of yet unknown etiology (paradoxical temporal lobe epilepsy – PTLE). In this article, an 'epileptogenic' (or 'epileptic') hippocampus is considered to be one having sclerosis.

The hippocampus, which is anatomically connected to many other brain regions within and outside the temporal lobe, is structurally complex. It is composed of two major components, the dentate gyrus and the hippocampus proper – the latter also referred to as Ammon's horn or *cornu Ammonis* (CA regions). The Ammon's horn region is divided into four subregions – area CA4 or the hilus, areas CA3, CA2, and CA1. Each of these regions has a distinctive organization, with defined afferents and efferents, and may make varying contributions to the epileptogenicity of the hippocampus. Area CA3 has been implicated in the synchronization of neuronal activity during the emergence of epileptiform activity in the hippocampus in animal models of epilepsy, although evidence for this role of CA3 in the epileptic human hippocampus is not available. The behavior of neurons in area CA3 of the hippocampus in the epileptic brain is determined, at least in part, by the circuitry of this region, including the neurotransmitters and their receptors within these circuits. Species differences in the distribution of receptors and receptor subtypes in CA3 have been reported. This article will review the receptor systems within area CA3, and particularly those localized on the CA3 pyramidal cells in the human brain. We will review the differences in the distribution of these receptors in the human epileptic brain as compared to nonepileptic control hippocampi.

Background

Pyramidal neurons are the principal neuron type in CA3, as in all areas of Ammon's horn. In contrast to CA1 pyramidal neurons, the CA3 pyramidal neurons in the primate often exhibit two apical dendrites arising directly from the triangular cell body, as well as several basal dendrites. A characteristic feature of the CA3 pyramidal neuron is the occurrence of a large number of large spines, or excrescences, on the proximal parts of the dendrites; in the primate, these excrescences are found not only on the apical dendritic shafts but also on the proximal part of the basal dendrites. These proximal spines are complex, having many branches emerging from a single dendritic origin. Distal dendritic segments show smaller and thinner spines. These pyramidal cells receive synaptic inputs from a variety of sources, but the most characteristic of these afferents is the input from the dentate granule cell axon, called the mossy fibers, which form complex synaptic connections with the proximal dendritic excrescences. In the rat hippocampus single mossy fiber boutons contact spines from only one parent dendrite of a CA3 pyramidal cell, and it is estimated that a single bouton can make up to 37 or more synaptic contacts with branched spines from a single CA3 dendrite. Each mossy fiber bouton contains thousands of small (~40 nm) clear vesicles (containing glutamate) and many large dense core vesicles (containing peptides). In addition to mossy fiber inputs, CA3 pyramidal neurons also receive synaptic inputs from the septal region and commissural fibers (that synapse on the apical dendrites in the area of the stratum radiatum), and from perforant path fibers (that synapse in the stratum moleculare).

Associated with the pyramidal neurons in area CA3 are several types of interneurons, some of which also receive mossy fiber inputs; the interneuron-associated mossy fiber boutons are smaller than those associated with the pyramidal neurons. Pyramidal inhibitory basket cells, whose axons innervate pyramidal principal cells are located immediately beneath the CA3 pyramidal cell layer. Another population of interneurons has somata within the stratum lucidum. All these interneurons receive mossy fiber inputs. While some of these interneurons in the stratum lucidum are spiny and contain glutamate, others are aspiny, and provide a GABAergic input to CA3 pyramidal cells.

Synaptic inputs into CA3 pyramidal neurons involve a variety of neurotransmitters. The major transmitter in the mossy fiber terminals is the excitatory neurotransmitter, glutamate. In addition, these mossy fiber terminals contain several peptides, including dynorphin, enkephalin, cholecystokinin (CCK), neuropeptide Y (NPY), and neurokinin-B. Many of the GABAergic interneurons in CA3 colocalize peptides (such as NPY and somatostatin) and are thought to release these peptides within the CA3 network; such colocalization is readily seen in interneurons in the stratum oriens. Given the variety of neurotransmitters that appear to be released at synapses onto CA3 pyramidal neurons, it seems clear that they must possess a broad range of neurotransmitter receptors and receptor subtypes. The localization of these receptors is reviewed later in the following sections.

Methods

Several approaches have been adopted to study the distribution of receptors and receptor subtypes in area CA3. At present, the method of choice is immunohistochemical localization of receptors using primary antibodies specific to a receptor or receptor subtype. Both light and electron microscopic analysis of tissue labeled with these antibodies can provide both the cellular and subcellular localization of the receptor molecules. In situ hybridization analysis for the localization of receptor-specific mRNA is also used to localize the cellular distribution of receptors. However, mRNA localization provides information only about the cell type (i.e., cell body) and does not yield information on the actual subcellular and membrane localization of the receptor proteins. In earlier studies, when specific antibodies were not easily produced or readily available, receptor localization and distribution was done using radioactively labeled molecules that were selective agonists or antagonists for the receptor site. The binding of these molecules to receptor sites was visualized by autoradiographic techniques. More recently, gene expression analysis in specific cell types has been used to compare the *levels* of receptor expression in specific cell types (such as the CA3 pyramidal neurons).

Results

Glutamate Receptors

The principal neurotransmitter of the afferents to CA3 from outside the region, including the mossy fiber terminals, is glutamate. Glutamate can act on several classes of receptors broadly divided into those that are directly linked to ion channels (ionotropic receptors) or those linked to ion channels via a second messenger system (metabotrophic receptors). Of the ionotropic receptors for glutamate, mossy fiber synapses have few *N*-methyl-d-aspartate (NMDA)-type receptors. The most abundant receptor at this mossy fiber synapse is α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid-sensitive (AMPA) receptors. These are mostly located postsynaptically on the pyramidal neuron. Immunohistochemical localization of AMPA-type receptor subunits reveals that in the normal hippocampus, the GluR1 subunit proteins are diffusely expressed on dendrites of neurons; in contrast, the GluR2/3 subunit proteins are strongly expressed on the soma and proximal dendrites of pyramidal neurons, and clumps of punctate GluR2/3 immunoreactivity appear around smaller interneurons. Expression profile analysis performed on individual CA3 and CA1 pyramidal neurons, using a novel single cell RNA amplification methodology along with cDNA array analysis, shows that CA3 pyramidal neurons have significantly higher expression levels of AMPA receptor subunits GluR1 and GluR2 compared with CA1 pyramidal neurons. In the epileptogenic hippocampus of human TLE patients, while immunoreactivity is decreased due to neuronal loss, there is an increased expression of GluR1 on the dendritic excrescences on the proximal dendrites of CA3 pyramidal neurons that survive (**Figure 1**). Electron microscopic examination confirms that this increased GluR1 immunoreactivity in CA3 is postsynaptic and localized on the dendritic excrescences. Mossy fiber terminals make contact with these more intensely immunoreactive dendritic excrescences, suggesting that glutamatergic synapses on surviving CA3 pyramidal cells in the epileptogenic hippocampus probably have more robust responses to glutamate released by mossy fibers at the CA3 synapse.

The kainate family of glutamate receptors is made up of five subunit proteins – GluR5-7 and KA1-2. High-affinity receptor binding studies show that the KA receptors are localized in the mossy fiber pathway and appear to be located on the mossy fiber presynaptic terminal. Both sclerotic and nonsclerotic hippocampi from TLE patients have decreased GluR6 subunit mRNA hybridization densities per CA3 pyramid (as seen in in situ hybridization studies) compared with neurologically normal hippocampi (from autopsy tissue), while only the sclerotic hippocampi have decreased KA1 subunit.

The disposition of the metabotropic glutamate receptors in CA3 has also been studied. In the normal hippocampus, of the group 1 receptors, mGluR1b subunits are localized on the somata and proximal dendrites of pyramidal neurons; weak immunoreactivity for mGluR5 is reported in the CA3 molecular layer. Group 2 receptors mGluR2/3 are expressed in the stratum lucidum as distinct granular staining. Of the group 3 metabotropic receptors, mGluR4a is found consistently in the stratum lucidum, probably on mossy fibers, while mGluR8 is expressed on pyramidal neurons. In general, mGluR subtype expression in CA3 does not show any special pattern of reorganization in the epileptic brain; mGluR5 and mGluR8 subtypes are found on surviving CA3 pyramidal neurons at about the same density per neuron as in controls.

GABA Receptors

Area CA3 also has several GABA receptor subtypes. There are two major classes of GABA receptors – $GABA_A$ and $GABA_B$. Fast inhibitory action of GABA is mediated by the $GABA_A$ receptors. These receptors are composed from several subunits derived from multiple gene families (α1–α6, β1–β3, γ1–γ3, δ, ε π, θ), which are assembled as pentameric structures. The preferred pentameric structures in the hippocampus consist of two α-, two β-, and one γ- or δ-subunit. The localization of

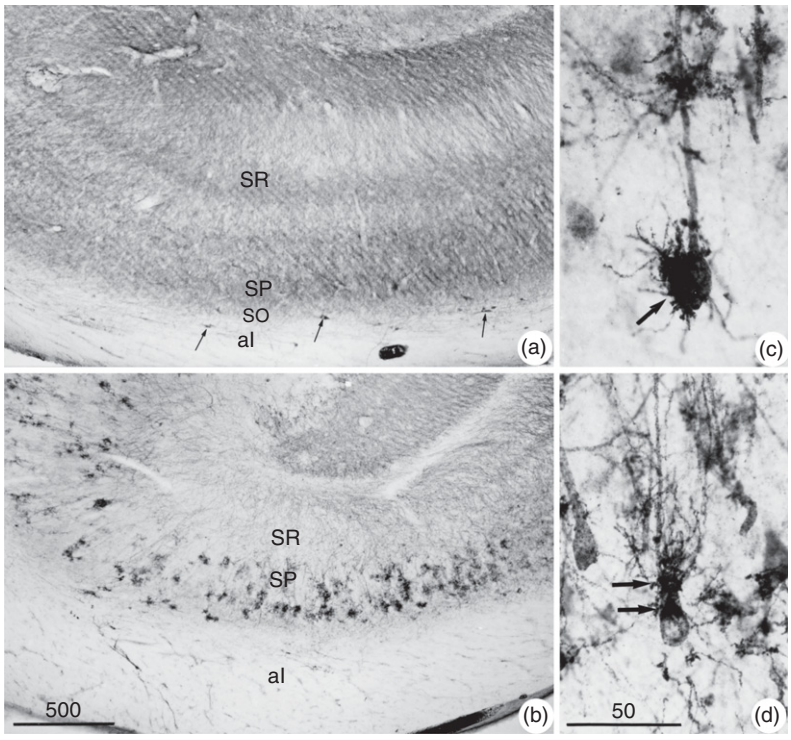

Figure 1 Photomicrographs from area CA3 showing GluR1-like immunoreactivity. (a) A portion of CA3 from a MaTLE (nonsclerotic) hippocampus showing a pattern of diffuse staining. Note the bands of darker staining that correspond to the stratum pyramidale (SP), a region of the stratum radiatum (SR) and the stratum lucidum. In the stratum oriens (SO) can be seen immunoreactive cell bodies (arrows). (b) Area CA3 from a sclerotic patient (MTLE) showing punctate clumps of staining on the cell body and proximal dendrites of neurons. (c) and (d) show individual neurons from area CA3 of MTLE, illustrating the pattern of punctate staining on these neurons. Al, alveus. Bar = 500 μm for (a) and (b), and 50 μm for (c) and (d). Adapted from de Lanerolle NC, Eid T, von Campe G, Kovacs I, Spencer DD, and Brines M (1998) Glutamate receptor subunits GluR1 and GluR2/3 distribution shows reorganization in the human epileptogenic hippocampus. *European Journal of Neuroscience* 10: 1687–1703.

some of these subunits – α1, α2, α3, β2, 3, and γ2 – has been studied in both the normal and epileptic human hippocampus. In both normal autopsy and nonsclerotic surgically removed hippocampi, there is abundant α2-subunit immunoreactivity in area CA3; immunoreactivity is most intense in the pyramidal layer, with lesser intensity in stratum lucidum and stratum radiatum. In sclerotic hippocampi, the intensity of expression of the α2-subunits parallels the degree of neuronal loss in CA3, showing no upregulation on surviving neurons. There is very little expression of the α3-subunit in CA3. Likewise, there is no α1-subunit staining on pyramidal cell bodies or dendrites. Most of the α1-subunit immunoreactivity in CA3 is in interneurons. In the pyramidal layer, these interneurons consist of various classes, including large multipolar cells with dendrites oriented perpendicular to the pyramidal cell layer, medium-sized oviform cells with dendrites that extend into the stratum radiatum, and small round interneurons. Alpha1-subunit expressing neurons with round to oval cell bodies and fine dendrites are seen in the stratum lucidum. In sclerotic hippocampi, there is a marked and significant loss of α1-subunit expressing interneurons in the CA3 pyramidal layer and stratum lucidum, whereas those in the stratum lacunosum-moleculare are preserved.

The $GABA_A$ beta subunits β1 shows comparable expression levels in CA3 of autopsy and sclerotic hippocampi, while increased expression is observed in nonsclerotic surgically removed hippocampi. The β2-subunit is expressed on pyramidal neurons and their processes in area CA3 of normal hippocampi; in sclerotic hippocampi, expression of this subunit is significantly stronger than in autopsy specimens, but similar to nonsclerotic specimens, thus suggesting that its expression may be related to a general effect of seizure activity. β3-Subunit expression is weak in CA3. The subunit γ2 shows diffuse but comparatively stronger expression than the β-subunits in the pyramidal layer of CA3. Expression levels are decreased in sclerotic hippocampus, parallel with neuronal loss. It is difficult, on the basis of published studies on $GABA_A$ β- and γ-subunit expression, to establish any distinctive pattern of change in expression of these subunits in CA3 pyramidal neurons that may be related to the causation or maintenance of seizures.

The $GABA_B$ receptors are metabotropic receptors, which generate long-lasting inhibitory postsynaptic potentials. Two $GABA_B$ receptors, $GABA_{B1}$ and $GABA_{B2}$, have

been identified; the functional receptors are dimeric, formed by isoforms of these two subunits. As presently understood, while both subunits are required for a functional membrane receptor, the $GABA_{B1}$ seems to provide the binding domain whereas the $GABA_{B2}$ is responsible for second messenger processing. Localization of $GABA_B$ receptors by receptor autoradiography with the receptor antagonist [^{3}H]-CGP62349 showed that while the overall binding density was decreased in CA3 of the sclerotic hippocampus compared with controls, $GABA_B$ expression per remaining neuron was increased, suggesting an upregulation of receptors in the epileptic focus. However, another study, which used a different ligand ([^{3}H]-CG54626A), while corroborating the decrease in binding in CA3 in sclerotic hippocampus failed to find an increase in binding when binding densities were adjusted per remaining neuron. Localization of mRNA expression of two $GABA_{B1}$ receptor isoforms ($GABA_{B1a}$ and $GABA_{B1b}$) and $GABA_{B2}$ subunit by in situ hybridization shows that expression levels for $GABA_{B1b}$ were decreased before correction for surviving neuron numbers, but not when per neuron levels are determined. However, $GABA_{B2}$ expression was increased per surviving neuron in area CA3 of the sclerotic hippocampus.

Other Receptors

There have been few published systematic studies on the localization of receptors for other neurotransmitters released by mossy fibers on their targets in area CA3. Whereas dynorphin is a prominent neurotransmitter in this system (being colocalized with glutamate in mossy fiber terminals projecting to area CA3), the expression of the κ1-opiate receptor (the presumed receptor for dynorphin) is only very weakly expressed in this area (though more pronounced in CA1 where there is no dynorphin detected immunohistochemically). The Y2 receptor for neuropeptide Y (NPY), examined by receptor autoradiography, is reported to be upregulated in the stratum radiatum of CA3 in sclerotic hippocampi but not in nonsclerotic hippocampi removed during epilepsy surgery. Y1 receptor levels have not been determined.

In summary, our present state of knowledge regarding the localization of receptor subunits in area CA3 of the epileptogenic (sclerotic) hippocampus in humans suggests that surviving pyramidal cells in these hippocampi show but a few significant receptor subunit changes. Primary among these is the AMPA glutamate receptor subunit GluR1, whose postsynaptic expression at proximal dendrite thorny excrescences is strongly upregulated at synapses with mossy fiber terminals. This change suggests the possibility of increased excitatory drive onto these neurons. There is also somewhat equivocal evidence for the upregulation of $GABA_B$ receptors, particularly the $GABA_{B2}$ subunit (with the $GABA_{B1}$ levels remaining the same per neuron), suggesting the possibility of increased slow but prolonged inhibition of these CA3 cells – although these effects will depend on the precise pre- or postsynaptic localization of these $GABA_B$ receptors. The net functional outcome of enhanced receptor expression for excitatory and inhibitory inputs to CA3 pyramidal cells needs to be elucidated. In addition, there are changes in the expression of presumptive presynaptic receptors on mossy fiber terminals; a decrease in the KA1 subunit on mossy fiber terminals would presumably facilitate glutamate release, whereas an increase in NPY receptor subtype Y2 would tend to inhibit glutamate release. These changes add a further level of complexity to understanding the overall level of excitability of CA3 pyramidal cells, and the underlying mechanisms, in the epileptic brain.

Challenges for the Future

A big challenge in understanding the role area CA3 plays in the human epileptic hippocampus involves identifying the time course of the changes in distribution and localization of receptors, and their subunits, in the transformation of a normal hippocampus into an epileptogenic one. Human hippocampi available for analysis are usually from patients who have many years of seizure disorder before coming to surgery. In many of these hippocampi, there is already considerable neuronal loss – and in some, very few neurons persist. It is difficult to imagine that in such specimens, surviving CA3 pyramidal cells play a significant direct role in the overall epileptic activity of the hippocampal seizure focus. The careful study of hippocampi when removed for seizure control from children with a shorter history of epilepsy may provide important information on pathogenesis. Furthermore, our knowledge of the organization of area CA3, even in the nonsclerotic human hippocampus, remains fragmentary. Knowledge of the exact subcellular localization of receptor subtypes, as may be elucidated from careful ultrastructural analysis of the synaptic organization of this region, is presently lacking and would be valuable in interpreting electrophysiological data obtainable from in vivo and slice electrophysiology of this region. Such electrophysiological studies carried out on the CA3 region in human surgical material are quite sparse at present. As a nodal point in the spread of excitability through the hippocampus, understanding receptor localization and other changes in area CA3 during pathogenesis of epilepsy remains important for a proper understanding of the role of the hippocampus in the epileptic brain. Since the neurochemical organization of the human hippocampus is considerably different from that of the commonly studied experimental models in the rat, elucidation of these details present a considerable challenge.

Introduction

Epileptic seizures are manifestations of epilepsy, a common dynamical disorder second only to stroke among neurological disorders. Of the world's ~50 million people with epilepsy, about one-third have seizures that are not controlled by antiepileptic drugs (AEDs). One of the most disabling aspects of epilepsy is the seemingly unpredictable nature of seizures. If seizures cannot be controlled, the patient experiences major limitations in family, social, educational, and vocational activities. In addition, status epilepticus (SE), a life-threatening condition in which seizure activity occurs continuously, is often successfully treated only with extreme intervention. Until recently, the general belief in the medical community was that epileptic seizures could not be anticipated. Seizures were assumed to be abrupt transitions that occurred randomly over time. However, theories based on reports from clinical practice and scientific intuition, such as the 'reservoir theory' postulated by Lennox, have pointed to the possibility of seizure predictability. Various feelings of auras (patients' reports of sensations of an upcoming seizure) are common in medical literature.

The ability to predict epileptic seizures significantly before their occurrence (onset) may lead to novel diagnostic tools and treatments for epilepsy. Electromagnetic stimulation and/or administration of antiepileptic drugs during the preictal period may disrupt the observed dynamical entrainment of normal brain sites with the epileptogenic focus, and thus lead to a significant reduction of epileptic seizures. Evaluation of antiepileptic drugs and protocols, within the context of a patient's seizure susceptibility period and/or preictal period – as detected by seizure prediction algorithms – may lead to the design of new, more effective drugs with fewer side effects.

Background

The 1980s saw the emergence of new signal processing methodologies, based on the mathematical theory of nonlinear dynamics, for the study of the spontaneous formation of organized spatial, temporal or spatiotemporal patterns in physical, chemical, and biological systems. These methodologies quantify the complexity and randomness of the signal from the perspective of dynamical invariants (e.g., dimensionality of the attractor through correlation dimension, or entropy rate through Kolmogorov entropy), and represent a drastic departure from the signal processing techniques based on the linear model (e.g., Fourier analysis).

The dynamical hypothesis changed some long-held beliefs about seizures. Iasemidis, Sackellares, and colleagues reported the first evidence that the transition to epileptic seizures may be consistent with a deterministic process, and that the ictal electroencephalogram (EEG) can be better modeled as an output of a nonlinear system rather than a linear system. The existence of long-term preictal periods (order of minutes) was initially shown using nonlinear dynamical analysis of EEG from subdural arrays over the temporal lobe, and later from scalp and depth EEG; this demonstration raised the feasibility of developing seizure prediction algorithms by monitoring the temporal evolution of the short-term Lyapunov exponents (STL_{max}), measures of the chaos and instability of a system. The possibility of focus localization and seizure detection with these techniques was also reported.

Our group has described a progressive preictal increase of spatiotemporal entrainment (dynamical synchronization) between the critical sites of the brain as a precursor to epileptic seizures. The algorithm used in this demonstration was based on the entrainment (statistical convergence) of STL_{max} among critical electrode sites that are selected adaptively over time. This observation has been successfully implemented in the prospective prediction of epileptic seizures. Global optimization techniques were applied for selecting the critical groups of electrode sites. We have reported an average anticipation time of about 71.7 minutes prior to a predicted seizure, prediction of 80% to 90% of seizures (sensitivity), and a false prediction rate of 0.12 false warnings per hour. A by-product of this analysis was the finding that the majority of seizures (81%)

in patients with temporal lobe epilepsy (TLE) irreversibly reset (disentrain) the observed preictal dynamical entrainment postictally. This finding, combined with the observed nonresetting of brain dynamics during the preictal period, implies that seizures occur when there is a need to reset the brain's dynamics. Recent reports claim that what characterizes the preictal period is disentrainment rather than entrainment of brain dynamics. However, we have found that this 'reverse' concept of preictal disentrainment is either nonexistent or not consistent across seizures in the same patient, and/or across patients.

Employing neuronal population models that are capable of exhibiting seizurelike behavior, we have shown that entrainment (disentrainment) of the populations' STL_{max}, with increased (decreased) coupling between populations, resembles the observed preictal dynamical entrainment and postictal disentrainment of the STL_{max} at critical sites in the epileptic brain. In agreement with burst phenomena in adaptive systems, 'seizures' in these models occur if the existing (internal to the models) feedback loops are pathological so that they lack the ability to compensate soon enough for excessive increases in network coupling. This situation eventually leads to seizurelike transitions. Motivated by these findings, we postulated the existence of an internal pathological feedback action in the epileptic brain; subsequently, using a control-oriented approach, we developed a functional model for an external seizure controller. During periods of abnormally high synchrony (entrainment), the developed control scheme provides appropriate 'desynchronizing feedback' to maintain 'normal' synchronization levels between neural populations (homeostasis of dynamics). We have called this feedback control view of epileptic seizures 'feedback decoupling'; the developed seizure control strategies, were then validated on coupled chaotic oscillator models and biologically plausible neurophysiologic models.

Methods

The brain is inherently a nonlinear system. Therefore, it makes sense to move one step forward from linear methods of analysis (methods like Fourier transform and linear models), that can accurately analyze and characterize only linear systems, to methods that can analyze and correctly characterize linear and nonlinear systems. This move has progressively produced surprisingly refreshing results for epilepsy. Under certain conditions, through the method of delays, sampling of a single variable of a nonlinear system over time could determine all state variables of the system that are related to it. In the case of the EEG, this method can be used to reconstruct a multidimensional state space of the brain's electrical activity at a corresponding brain site. A dimension of 7 has typically been used to reconstruct the state space from EEG in epilepsy. This selection of dimension for the states (vectors) in the state space, together with a corresponding time delay of 20 msec between their components, has been justified in the literature.

Among the important measures of the dynamics of a linear or nonlinear system are the Lyapunov exponents that measure the average information flow (bits/sec) a system produces along local eigendirections through its movement in its state space. Positive Lyapunov exponents denote generation of information while negative exponents denote destruction of information. A chaotic nonlinear system possesses at least one positive Lyapunov exponent, and it is because of this feature that its behavior looks random, even though as a system it is deterministic. Methods for calculating these measures of dynamics from experimental data have been published. The estimation of the largest Lyapunov exponent from a chaotic system has been shown to be more reliable and reproducible than the estimation of the remaining exponents, especially when the actual value of the dimension of the state space is not known and changes over time. The brain, being nonstationary, is never in a steady state in the strictly dynamical sense, at any location. We have shown that, in the case of a nonstationary system with transients like epileptic spikes, using the short-term maximum Lyapunov exponent (STL_{max}) is a more accurate characterization of the average information flow than the one using the regular maximum Lyapunov exponent. STL_{max} is estimated from sequential EEG segments of 10 sec duration per recording site to create a set of STL_{max} profiles over time for all recording sites. Over the past 20 years, analyzing scalp, subdural, and depth EEG from patients with TLE and frontal epilepsy, we have shown that the STL_{max} profiles at brain sites systematically converge to similar values tens of minutes before a seizure. We have called these brain sites 'critical sites.' The seizure focus sites were found to be included in these sets of critical sites more consistently and more frequently than other sites; thus, a by-product of this methodology appears to be the localization of the epileptogenic zone. We have called this phenomenon *dynamical entrainment*, because measures of *dynamics* (like STL_{max}) appear to converge *progressively* over time and then typically stay entrained until the seizure's electrographic onset. We have also shown that this finding is very specific to seizures versus other interictal time points, and as such it has had wide implications – for example, the development of the first real-time online prospective seizure prediction algorithms. In short, the epileptic brain appears to be entrained by the focal sites, and therefore starts malfunctioning due to a loss of relative independence of processing information at normal brain sites, long before a seizure develops.

A statistical measure of entrainment between two brain sites i and j, with respect to a measure of their dynamics (e.g., STL_{max}), has been developed in the past. Specifically,

the T_{ij} between measures at electrode sites i and j and at time t is defined as

$$T_{ij}(t) = \frac{\hat{D}_{ij}(t)}{\left[\frac{\hat{\sigma}_{ij}(t)}{\sqrt{m}}\right]},$$

where $\hat{D}_{ij}(t)$ and $\hat{\sigma}_{ij}(t)$ denote the sample mean and standard deviation respectively of all the m differences $D_{ij}(t)$ between the STL_{max} values (one STL_{max} value is produced per 10 sec EEG segment) at electrodes i and j, within a moving window $w(t) = [t,\ t\text{-}m^*10\ \text{sec}]$. If the true mean $\mu_{ij}(t)$ of the differences $D_{ij}(t)$ is equal to zero, and $\hat{\sigma}_{ij}(t)$ are independent and normally distributed, $T_{ij}(t)$ is asymptotically distributed as the t-distribution with *(m-1)* degrees of freedom. We have shown that these independence and normality conditions are satisfied in EEG. Therefore, we define disentrainment (dynamical desynchronization) between electrode sites i and j when $\mu_{ij}(t)$ is significantly different from zero at a significance level α. The desynchronization condition between the electrode sites i and j, as detected by the paired t-test, is $T_{ij}(t) > t_{\alpha/2,m-1} = T_{th}$, where $t_{\alpha/2,m-1}$ is the $100\cdot(1\text{-}\alpha/2)\%$ critical value of the t-distribution with *m-1* degrees of freedom. If $T_{ij}(t) \leq t_{\alpha/2,m-1}$ (which means that we do not have satisfactory statistical evidence at the α level that the differences of values of a measure between electrode sites i and j within the time window w(t) are not zero), we consider that sites i and j are dynamically synchronized with each other (with respect to the utilized measure of synchronization) at time t. Using $\alpha = 0.01$ and $m = 60$, that is using a window $w(t)$ of 10 min in duration, the threshold $T_{th} = 2.66$. It is noteworthy that similar STL_{max} values at two electrode sites (and therefore low values of the T-index) do not necessarily mean that these sites even interact. However, when there is a progressive convergence (synchronization) over time of the measures at these sites, the probability that they are unrelated diminishes.

This is exactly what occurs before seizures, and it is illustrated in **Figure 1**. In this Figure, we plot the *average* T-index over time – before, during, and after a seizure of temporal lobe origin. Each average T-index value is estimated per moving 10 min window $w(t)$ and over selected pairs of sites. In particular, the average T-index shown in **Figure 1** (black line) is the average of all T_{ij} of selected pairs of sites (i, j) within $w(t)$ over time t. The selected pairs of sites are the ones that were significantly entrained (i.e., $T_{ij} \leq 2.66$) within a preictal window of 10 min in duration, positioned immediately before the seizure's electrographic onset. We observe significantly low values of T-index (i.e., convergence of the STL_{max} profiles of critical sites) long (90 min) before this seizure's onset. Moreover, the trend towards low values of T-index started 120 min before the seizure's onset; within the next 30 min, the critical pairs of sites became progressively

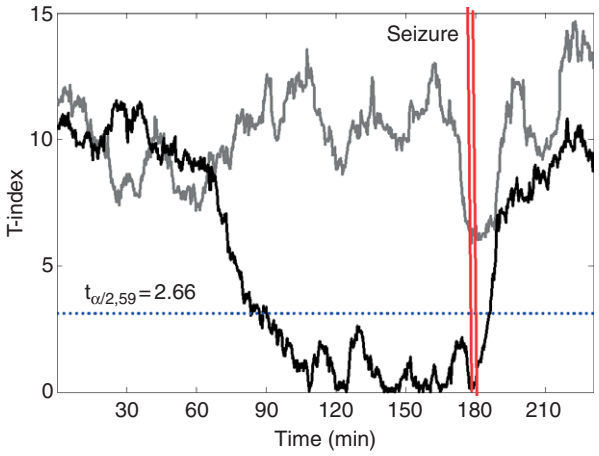

Figure 1 Dynamical resetting at seizures. Black line: Long-term, progressive dynamical entrainment preictally, and short-term disentrainment postictally, of all pairs of sites entrained 10 min prior to a seizure of temporal lobe origin (seizure occurs between the two vertical red lines). These critical pairs of sites get entrained ($T_{ij} \leq 2.66$) approximately 90 min before the seizure. Grey line: No trends indicative of neither the upcoming seizure nor resetting can be observed when pairs of maximally disentrained ($T_{ij} \geq 6.00$) sites are selected within 10 min prior to the seizure. The dynamical analysis was performed on subdural and depth EEG recordings from a patient with TLE admitted at the epilepsy monitoring unit (EMU).

entrained and stayed entrained thereafter, until the seizure's onset. The seizure lasted for 2.5 min (between the two vertical red lines in this Figure). After the seizure's onset, we observe a trend towards disentrainment of the preictally entrained pairs of sites (T-index moves rapidly towards higher values above T_{th}). Within 10 min postictally, disentrainment is established. We have called this reversal of dynamics *brain resetting*. While Morman and colleagues have proposed that preictal desynchronization may be a better precursor to seizures than preictal synchronization, this hypothesis does not seem to be valid. For example, the grey line in **Figure 1** is the counterpart of the black line; that is, it is generated from monitoring preictal desynchronization rather than preictal synchronization. In the preictal desynchronization scheme, maximally desynchronized ($T_{ij} \geq 6.00$) pairs of sites were analogously selected from the 10 min preictal window immediately before a seizure onset. No long-term preictal (or postictal) trends over time are observed in this scheme (see grey line), therefore it is ineffective for seizure prediction. We have shown in the past that the observed dynamical resetting is specific to seizures at the $\alpha = 0.05$ statistical significance level. This observation may reflect a passive mechanism (e.g., high electrical activity during a seizure might deplete critical neurotransmitters and thus deactivate critical neuroreceptors in the entrained neuronal network). An alternative explanation is that the release of neuropeptides in the brain, caused by seizure activity, may contribute to the temporary repair of a pathological feedback that allowed

the dynamical entrainment to occur in the first place, and then last for long time intervals.

These results demonstrate that seizures are not abrupt transitions in and out of an abnormal ictal state; instead they follow a dynamical transition that evolves over minutes to hours. During this preictal dynamical transition, multiple regions of the brain progressively approach a similar dynamical state. These observations are in agreement with observations in systems of coupled neural population models with internal (i.e., part of the overall system) pathological feedback. We have shown that by increasing the interpopulation coupling and detuning their internal feedback mechanism, these systems move from spatiotemporal chaotic states into spatially synchronized, quasiperiodic, 'seizurelike' states. These transitions are also characterized by spatial convergence of the maximum Lyapunov exponents of the individual populations. Such results directly address the process of ictogenesis and appear to support the hypotheses that: a) seizures may result from the inability of internal feedback mechanisms to provide timely compensation for/regulation of coupling between brain sites, and b) seizure control can be achieved by feedback decoupling of the 'pathological' sites via externally provided appropriate stimuli. Such stimuli are functions of both the EEG and the coupling of the respective brain sites. We have called such a closed-loop control scheme 'feedback decoupling.' The block diagram in **Figure 2** shows the basic elements of our hypothetical scheme of how a 'normal' brain works: a) brain in spatiotemporal chaos, b) stimulus enters the system, and changes the spatial coupling between two or more brain sites, c) spatial coupling produces spatial correlations, possibly storing the information about the stimulus and/or initiating action, d) spatial correlations also activate an internal compensating feedback mechanism, e) compensation removes (or assimilates) the developed spatial correlations by the stimulus, f) the system returns to spatiotemporal chaos. In the 'normal brain,' the correlations in the network must lie within a 'normal' range and be able to vary quickly in response to a stimulus – which implies that the internal feedback path should be well-tuned and be able to track changes of the coupling reasonably closely. Accordingly, we propose that the pathologic epileptic brain has pathologic (poorly tuned) internal feedback paths. Such pathology exhibits large errors in the estimates of the coupling, and can cause local destabilization and bursting of the network (seizures). Thus, the observed long-term dynamical entrainment prior to seizures can be interpreted as an indicator of pathology in the internal feedback of the network. This rationale can, of course, easily be applied to 'reflex' epilepsies too.

Recent Results

Given the phenomenon of resetting of brain dynamics associated with a seizure as described earlier, one would predict that status epilepticus (SE) is associated with the failure of seizures to reset the brain. That is what we have actually observed in EEG records analyzed from patients in the emergency room (ER), the intensive care unit (ICU) or the epilepsy monitoring unit (EMU). **Figure 3** illustrates this point in a 75 year old patient brought to ER after he was found unresponsive at home with his right arm twitching and his head deviated to his right. When the patient arrived, he was having rhythmic contractions in his right thigh adductor muscles, followed soon after by tonic–clonic movements on his right side accompanied by right gaze deviation and nystagmus. An EEG confirmed the diagnosis of status epilepticus. The etiology of the patient's seizures was noted as encephalomalacia in the left frontal cortex likely due to a prior stroke. The EEG

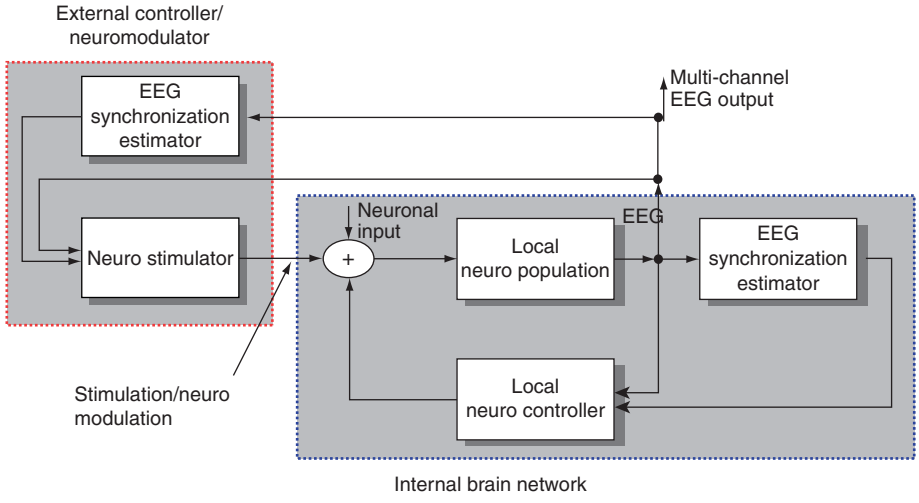

Figure 2 The concept of feedback decoupling for the control of epileptic seizures.

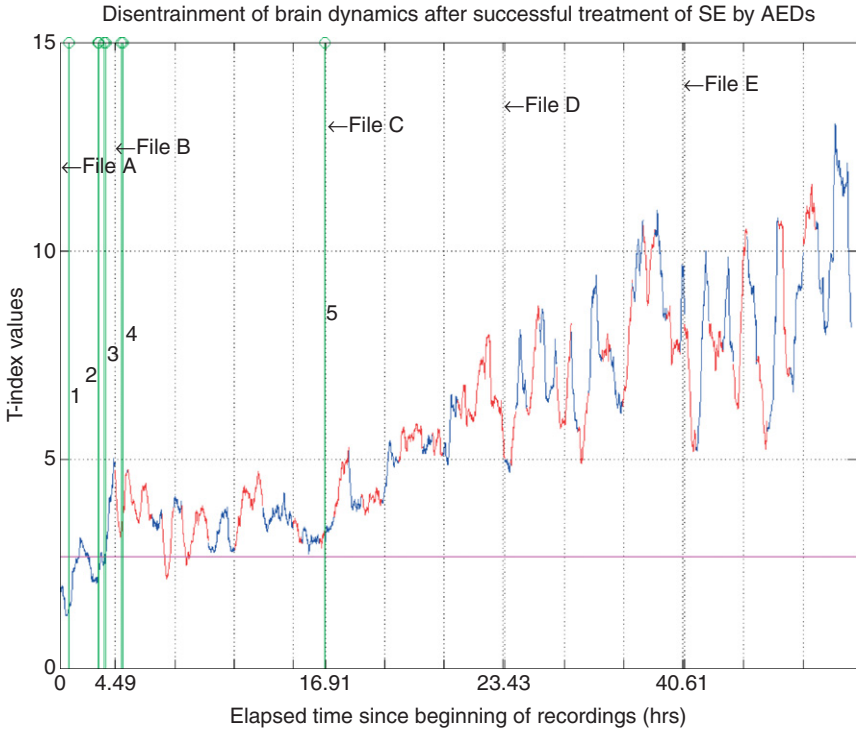

Figure 3 Long-term resetting of the brain dynamics in a patient with status epilepticus via successful administration of AEDs. The effectiveness of AEDs on the patient's recovery is correlated well with the exhibited trends of the T-index of the critical pairs of brain sites. The critical pairs for the analysis were selected 10 min before the beginning of the treatment of the patient with the first AED (a scalp EEG dynamical analysis). The vertical green lines 1 through 5 denote the times of AED administration (see below). The File vertical lines A through E mark the beginning of the five available EEG segments (of total duration of 13.51 hours) for the dynamical analysis (the existing gaps in time between the Files are not shown – the results from the dynamical analysis of the files are concatenated in time – Files A through E were of 1.10, 3.54, 3.03, 3.03 and 2.81 hours in duration respectively). The dynamical analysis shows that the patient was safe (high T-index values above $T_{th} = 2.66$) and stable (high T-index values for a long time) approximately 20 hours following admission to the emergency room. The patient was initially treated with 2 mg of Ativan IV followed by 20 mg/kg of phenytoin equivalence IV and a second fosphenytoin bolus of 5 mg/kg. Line 1 marks the completion of fosphenytoin infusion. Approximately half an hour after the beginning of the EEG recording, the patient was transferred to the ICU. The patient did not respond to the fosphenytoin so he was intubated and placed on a Propofol drip. Soon after, the EEG showed a burst suppression pattern. Line 2 marks the administration of Fentanyl and Etomidate. Line 3 marks when 50 mg of Propofol was administered and the beginning of a 30 mcg/kg/min propofol infusion. Line 4 marks a fosphenytoin 350 mg infusion and propofol administration at 50 mcg/kg/min. An additional dose of 1000 mg of levetiracetam IV was administered along with a propofol drip. Finally, line 5 marks where propofol is running at 35 mcg/kg/min. In the last EEG recording available to us (File E), the patient remained off from propofol.

was recorded using scalp electrodes at a sampling rate of 200 Hz. The patient recovered with AED treatment. The correspondence of the T-index values to the changing medical condition of the patient over time (see **Figure 3** legend) is remarkable, as is the correspondence of the effect (success or failure) of the different AEDs administered to the T-index; high T-index values were observed for successful resetting by an AED, and low values were observed when the influence of the AED was temporary (and therefore unsuccessful). The long-term recovery trend in the T-index over days indicates that this measure could be used for the detection of a patient's seizure susceptibility; that is, this measure could identify periods when a patient might be more vulnerable to seizures.

While seizures can currently be anticipated with relatively good sensitivity and specificity, the question is whether we can effectively intervene to change the pathological brain dynamics (long-term entrainment) in a timely manner and prevent a seizure from occurring. Towards this end, we first showed that impulsive electrical stimulation can temporally disentrain the dynamics of a rat's epileptic brain (larger T-index values post- than prestimulus). Second, we utilized our adaptive seizure prediction algorithm in the feedback external branch of a closed-loop electrical stimulation scheme for seizure control. In the baseline mode (no stimulation, just spontaneous occurrence of seizures), the sensitivity and specificity of the seizure prediction algorithm were tested on epileptic rats with chronic epilepsy, and very similar values to the ones we have reported from patients with focal epilepsy were found. In the control mode, the seizure prediction program was used to analyze the recorded EEG from the rat's brain (continuous real-time estimation of STL_{max} and T-index every 10 sec), issuing seizure

warnings and triggering the stimulator to stimulate the brain at each warning.

In this study, the lithium-pilocarpine (LP) model of acute SE in rats was chosen as the animal model for chronic epilepsy due to the similarities it exhibits with human TLE. Male Sprague–Dawley rats were used for the study. Three to four weeks after PI-induced SE, rats were implanted with a six-microwire monopolar electrode array targeted to four cortical and two hippocampal locations; two Teflon-coated tungsten bipolar twisted stimulating electrodes were implanted in the centromedial thalamic nucleus. A stimulator/seizure prediction program was developed in-house to control an A-M Systems Model 2300 stimulator unit (Calsborg, WA). At a seizure warning, a train of square pulses of amplitude 600 μA, pulse-width 100 μsec, and frequency 130 Hz was administered across the centromedial thalamic electrodes. The train of pulses was 1 min in duration and was delivered in a charge balanced bipolar cathodic fashion.

Some results from this experiment are shown in Figure 4. The seizure rate reduced sharply within 1 day following the onset of the closed-loop control scheme described earlier. The rat became seizure-free during the third and fourth days, but seizures slowly started to reappear thereafter. As can be observed in this Figure, the seizurefree state was attained only when resetting by the externally provided stimulus was achieved. Subsequent open-loop periodic stimulation (that is, without the parallel running of the seizure prediction software) in the same rat, over 10 days with the same stimulus parameters, and rate of stimulation equal to the mean rate of stimulation by the closed-loop control scheme, did not reduce the rat's seizure rate at all. This result implies that the timing of stimulation is critical for seizure control (keeping the same rate of stimulation is not enough). There are two very important observations from this study. First, the T-index values are inversely proportional to the seizure rate, denoting that entrained dynamics increase the probability of seizure occurrence (and thus increase the seizure rate), whereas disentrained dynamics do not (and thus decrease the seizure rate). This point is in agreement with our previous results and concepts. Second, in the portion of the record in which seizure control was not achieved (days 5 to 11), the electrical stimulation protocol we utilized failed to stop the recurrence of seizures – as in SE with unsuccessful AED administration. We suggest that this

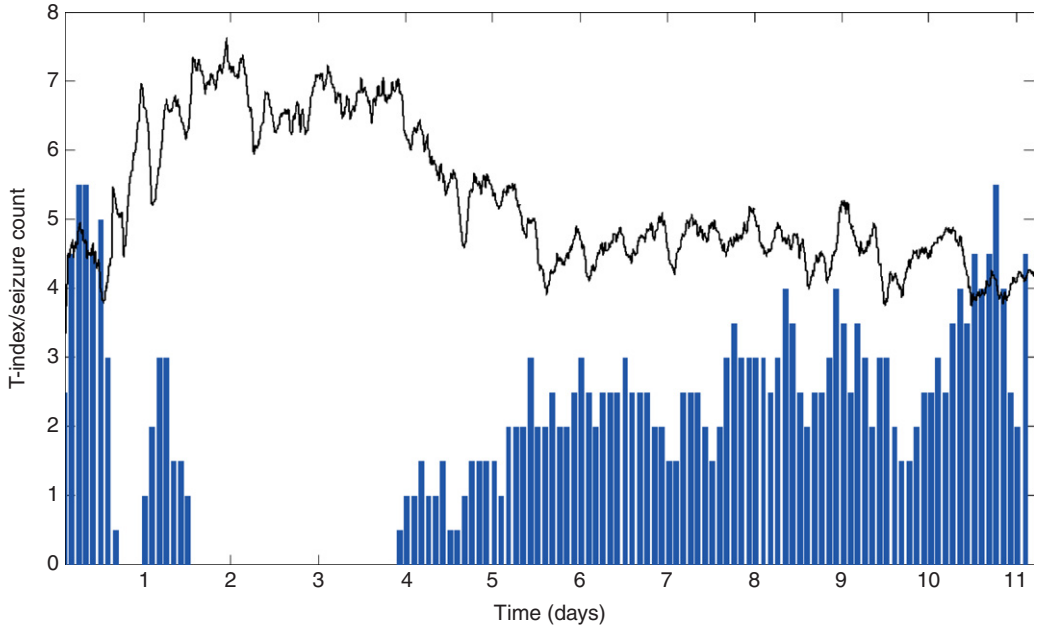

Figure 4 Real-time closed-loop control of seizures in an epileptic rat: On-line seizure prediction algorithm in conjunction with short electrical stimulation delivered to the thalamus when warnings were issued by the seizure prediction algorithm. The T-index profile of critical sites selected from baseline (black line) and the number of seizures exhibited per 2 hour of recording (blue bars) are plotted together (time resolution of the calculations for the T-index curve is 10 min, and for the rate of seizures is 2 hours). In accordance with our hypotheses, it is observed that successful control of seizures (e.g., almost no seizures in days 3 and 4) corresponds to high T-index values, that is, to brain's dynamical disentrainment. Respectively, low values of T-index (high level of entrainment) correspond to failure of seizure control and occurrence of seizures. All EEG data in this study were recorded on a Beehive Millenium® LTM EEG machine (Grass-Telefactor Inc., West Warwick, RI). The EEG machine included two 32-channel preamplifiers with front end digital sampling at 800-Hz which was multiplexed to a PAN-Isocoder unit that down-sampled and saved the data digitally at 200-Hz. Recorded EEG data were bandpass filtered from 0.3—70-Hz (including a 60 Hz notch filter) and written to a network hard disc in 1-min file segments. All recordings were done in a referential montage.

second observation calls for a new type of stimulation that should be incorporated into a more advanced and successful closed-loop control. One such candidate scheme can be the feedback decoupling scheme for seizure control we have proposed. Its application to biologically plausible simulation models with 'seizures' has generated results that can explain the successes and failures of both the open and closed-loop control schemes presented above. In addition, it was shown that the feedback decoupling scheme outperformed both these experimental control schemes presented above with respect to the control of 'seizures' in those models.

Future Goals

In summary, from our group's past and ongoing research on the dynamics of epilepsy, the following three central concepts about epileptic seizures have emerged. First, we have shown that seizures are manifestations of the recruitment of brain sites in an abnormal hypersynchronization. The onset of such recruitment occurs long before the onset of a seizure (on the order of minutes with respect to seizure prediction, on the order of hours and days with respect to seizure susceptibility), and progressively culminates in a seizure. Second, time-irreversible resetting of the observed preictal dynamical recruitment occurs postictally (via a hysteretic loop). Preictal and postictal periods could be mathematically (statistically) defined and detected from dynamical analysis of the EEG. Partial or no resetting of the preictal entrainment of the epileptic brain after a seizure may affect the route to the subsequent seizure (an example of such a situation is the existence of status epilepticus). The partial resetting may also explain the observed nonstationary nature of the seizure occurrences. Third, through control-oriented modeling, a feedback control view of epileptic seizures has been postulated, wherein epileptic seizures are hypothesized to be a result of the inability of the internal feedback/regulatory mechanisms of the brain to track excessive synchronization changes between the epileptogenic focus and other brain areas prior to a seizure.

All these concepts are interrelated, and constitute the basis for the development of seizure prediction algorithms, epileptogenic focus localization algorithms, and first generation closed-loop control algorithms. These concepts may provide the key ingredients for the development of robust brain pacemakers for the treatment of epilepsy in the near future. In addition, these concepts can be used for the evaluation of the efficacy of existing antiepileptic drugs, as well as for the design of novel drugs that would target the resetting of the pathological dynamics of the epileptic brain. Finally, as shown in a case of SE, the developed measures and methodology could be used as monitoring tools incorporated in medical devices for the evaluation of seizure susceptibility.

Introduction

Seizures, defined as a pathological increase in neuronal synchronization, are not just the characteristic symptoms of epilepsy, but can also have direct effects on the brain. In particular, prolonged seizures can produce neuronal damage and trigger cascades of biochemical events that can have long-term effects. These seizure events activate second messengers, transcription factors and gene expression, plastic phenomena (such as mossy fiber sprouting), neurogenesis, and altered neurotransmission – all of which may underlie consequent sensory-motor, developmental, and behavioral and cognitive deficits. Seizure-induced gene expression is of particular importance, since production of new proteins (or proteins at altered levels) provides the means for long-lasting alterations in brain functions. Analysis of alterations in gene expression can single out particular molecular mechanisms involved in such long lasting, potentially harmful, effects of seizures.

Background

Regulation of Gene Expression

In this article we focus on seizure-induced gene expression. While approaching this subject, one should be aware that the regulation of gene expression is a very complex phenomenon. By definition, regulation of gene expression refers to the control of the amount and timing of appearance of functional gene products, that is, RNAs and proteins. The process includes transcription as well as posttranslational modification of protein, which can be modulated at any step via any number of mechanisms.

The first level of regulation of gene expression relies on modification of DNA. Chemical modification refers to methylation of CpG islands by methyltransferase, a common way for silencing a gene. Structural modifications of DNA arise from phosphorylation or methylation of histones; histone acetylation is of special importance for regulation of transcription, since histone deacetyltransferases enable the dissociation of DNA from the histones and therefore allow transcription to proceed.

Progression of transcription and the efficiency of RNA synthesis depend on several components of the RNA polymerase machinery, including several regulatory proteins that bind to regulatory sites, usually located near the promoter. The regulatory proteins can be categorized according to their function as: (1) specificity factors that alter specificity of RNA polymerase for given promoter and repressors that bind to noncoding DNA sequences in the vicinity of the promoter and impede RNA polymerase's progress along the DNA strand; (2) basal factors which position RNA polymerase at the start of transcription, and activators that enhance RNA polymerase interaction at a given promoter either by interaction with RNA polymerase subunits or changing the structure of the DNA; and (3) enhancers that lead to changes in the three-dimensional structure of DNA and bring specific promoters into the vicinity of the initiation complex.

When RNA is synthesized, it undergoes further modifications which influence its stability, and therefore determine the yield of translation into protein. Capping protects mRNA from 5′exonuclease, splicing removes introns – noncoding regions – from RNA and allows translation into proper protein, and addition of poly(A) tail increases mRNA's stability by slowing down 3′exonuclease action.

Autonomic Consequences of Seizures, Including Sudden Unexpected Death in Epilepsy

Introduction – Seizures Cause Autonomic Disturbances

Seizure-induced autonomic dysfunction could cause serious clinical consequences, yet may occur only transiently and escape detection. Signs of autonomic nervous system dysfunction are common in epileptic patients, but are often overshadowed clinically by more apparent motor and cognitive effects of seizures. Small focal (i.e., simple partial) seizures may produce flushing, sweating, and piloerection, while complex partial seizures can produce a broader spectrum of autonomic signs, including changes in heart rate and rhythm (often bradycardia; complete AV block has been reported), blood pressure (usually hypertension), and increased or decreased gastrointestinal motility (usually vomiting) and secretion. Complex partial seizures may also induce relative hypoxia, though the mechanism of this change is not understood. Generalized tonic-clonic seizures may be associated with severe increases in blood pressure and changes in heart rate and conduction, such as complete nodal block. In a subgroup of epileptic individuals, however, seizures may trigger more ominous cardiovascular derangements such as marked bradycardia or asystole. At autopsy, pulmonary edema is the most common finding. Although still poorly understood, the causes of sudden unexpected death in epilepsy (SUDEP) are strongly suspected to involve cardiovascular and/or respiratory dysfunction provoked by seizures spreading into the autonomic nervous system.

Mortality among epileptic individuals is 2–3 times greater than among their nonepileptic counterparts. Among individuals with epilepsy, SUDEP is the single most common cause of death, accounting for as much as 10–15% of mortality in this group and exceeding the mortality attributable to status epilepticus. Estimates of the annual incidence of SUDEP among individuals with epilepsy range from 1 in 1000 to 1 in 500. The average age for SUDEP is 28–35 years, and men in their third or fourth decade have the highest annual risk of SUDEP, as high as 1 in 200. SUDEP occurs in different seizure types, and does not show a consistent predilection for localization-related or primary generalized epilepsy. Further, SUDEP is not restricted to individuals with the most severe seizures. SUDEP incidence, however, is highest in individuals with medically refractory seizures and lowest in individuals with well-controlled seizures. The relative

risk of SUDEP in individuals with two or more seizures per year has been reported to be 20 times greater than the risk in epileptic individuals who are seizure-free, and the increase in risk surpasses 50-fold when the number of seizures in a year is more than 50.

Most studies of the autonomic consequences of seizures have focused on cardiovascular consequences, primarily because these changes are seen as the most significant clinically, but also because considerable information can be extracted from analyses of the ECG. Several analyses of the R-R interval (RRI) – the period of time separating successive heartbeats – reveals RRI fluctuations at the respiratory frequencies that are parasympathetically-mediated, and RRI fluctuations at higher frequencies that are mediated by the combined effects of sympathetic and parasympathetic inputs to the heart. A smaller number of studies monitor other parameters, e.g., blood pressure monitoring by tonometry. Using continuous monitoring of various types, autonomic disturbances have been reported during both ictal and interictal periods. Patients with complex partial seizures had large fluctuations in heart rate during interictal periods that were not seen in controls, and acute deterioration of seizure control was accompanied by increased parasympathetic activity (including bradycardia) before seizure onset. Additionally, some of the dynamic complexity of the autonomic consequences, including baroreceptor reflex function, has been explored. Temporal lobe seizures are frequently associated with bradycardia, but the development of tachycardia during temporal lobe seizures can be proportional to the spread of seizure activity to other cortical areas. Complex-partial seizures were found to be associated with a pattern of parasympathetic activity that fell rapidly about 30 s before seizure onset, and sympathetic activity that continued to rise and peaked at seizure onset.

Although it is clear that the autonomic impact of seizures is broad and complex, it is also clear that clinical studies alone cannot entirely assess the connection between seizures and autonomic dysfunction. Clinical investigations are limited because some phenomena of interest are too infrequent for practical prospective studies, and there are limits to the invasiveness of autonomic monitoring that can be performed with human patients.

Background

Animal Studies of Autonomic Nervous System Dysfunction During Seizures

Animal models offer the advantage of invasive monitoring, but come with the disadvantage of perhaps involving seizure activity unlike that in human epilepsy patients. This disadvantage has been addressed principally by the development of various animal models. Seizures have been caused in different animal species (from rodents to primates) by different means (such as electrical stimulation or chemical convulsants) in different parts of the brain under different conditions (anesthetized or awake).

Seizure induction mechanisms fall into two broad categories: drugs or techniques that enhance excitatory synaptic transmission, and drugs or techniques that reduce inhibitory synaptic transmission. High frequency trains of electrical stimulus pulses can elicit a seizure if the stimuli are large enough in amplitude and given for a sufficient period. Kindling is a technique whereby trains of relatively low amplitude electrical stimuli are repeatedly applied to a region of the brain. Initial stimulation episodes may have no detectable effect, but after repeated presentations of stimuli, each presentation triggers increasingly severe seizures. Chemical convulsants are generally agonists (or modulators) for the glutamate receptor or antagonists (or modulators) of the GABA receptor. Kainic acid is an example of a convulsant that is a glutamate receptor agonist. After a single systemic dose, seizures recur for hours, and a chronic condition can develop after weeks, during which seizures occur spontaneously. Kainic acid-induced seizures appear to begin in the limbic cortices and have led investigators to consider this approach as a model for temporal lobe epilepsy.

Most invasive monitoring is performed in acute anesthetized animal experiments. Some anesthetics permit seizure activity and some abolish seizures. Pentobarbital is a potent anticonvulsant. The combination of ketamine and xylazine permits seizure activity, including motor convulsions. Urethane is interesting as an anesthetic because it permits limbic seizure activity, but not neocortical seizure activity. The hemispherectomized rat is used for acute studies without anesthesia. The entire cortex is removed under short acting anesthesia, and the anesthesia is stopped. In the absence of neo- and limbic cortex, sensory perception and motor activity, including motor convulsions, are abolished. Each animal model offers access advantages for autonomic nervous system studies that can be impossible to obtain when studying patients. Some examples of autonomic consequences of seizures are given here, and more details appear in the listed readings.

Amygdala-kindled seizures in rats were found to activate both sympathetic and parasympathetic systems and produced ictal hypertension and bradycardia that could each be blocked pharmacologically. Left insular cortex stimulation in rats produced an increasing degree of heart block and resultant ventricular escape rhythms that eventually resulted in asystole. In our own rat model, left-sided limbic seizure activity was associated with a more pronounced vagus nerve activity increase and associated blood pressure decrease.

Systemic pentylenetetrazol seizures in cats were shown to be associated with cardiac sympathetic and parasympathetic activity that was intermittently synchronized with interictal spike activity ('lockstep' phenomenon). Unstable

lockstep periods, when interictal spikes and synchronized autonomic activity occurred at irregular intervals, were associated with large fluctuations in blood pressure.

Focal penicillin-G application to the hypothalamus, in hemispherectomized, unanesthetized rats, produced bradyarrhythmias and a small decline in systolic blood pressure. Creating an additional penicillin focus at the mesencephalic level increased paroxysmal activity, and produced severe conduction anomalies (including AV block). Coactivation of hypothalamic and mesencephalic centers by focal injection of penicillin often resulted in death in rats.

Hypoventilation during status epilepticus, in a sheep model of SUDEP, correlated strongly with seizure-induced death; the incidence of benign cardiac arrhythmias, catecholamine levels, seizure type and seizure duration did not differ between animals that died and animals that lived. Mice that exhibit audiogenic seizures frequently display respiratory arrest that can be fatal – and can be prevented by increasing the quantity of oxygen in the environment.

Pathways for Spread of Seizures to the Autonomic Nervous System (ANS)

Neocortex and limbic cortices are heavily connected with structures that constitute the ANS, or with regions that project into autonomic structures. The central nucleus of the amygdala and bed nucleus of the stria terminalis are major inputs to hypothalamic, pontine and medullary structures that control preganglionic autonomic neurons of both the sympathetic and parasympathetic branches of the autonomic nervous system. They are positioned to relay cortical activity into the ANS. Neocortex and limbic cortices, especially subiculum, also have direct projections to hypothalamus. Autonomic pathways are integrated in the hypothalamus and influence all visceral systems, including cardiovascular, genitourinary, endocrine, and digestive, as well as peripheral involuntary muscles such as pilomotor and pupillary sphincters.

Projections of hypothalamic, including pontine and medullary neurons to preganglionic parasympathetic and sympathetic neurons controlling cardiac and respiratory function, have been studied anatomically and physiologically. Hypothalamic cells project onto medullary structures (ventrolateral medulla and periaqueductal gray) that project directly to sympathetic preganglionic cell bodies located in the intermediolateral horn of the spinal cord. Activity of hypothalamic and medullary neurons correlates with sympathetic nerve activity. Some hypothalamic cells themselves project directly into the spinal cord.

For the parasympathetic system, central nuclei of the amygdala and hypothalamus (PVN and SON) project directly into the dorsal motor nucleus of the vagus and the nucleus ambiguus, the sites of parasympathetic preganglionic cell bodies. Furthermore, the sympathetic and parasympathetic paths can influence each other. For example, efferents of the nucleus ambiguus and dorsal nucleus of the vagus (preganglionic parasympathetic neurons) project to the nucleus of the solitary tract which has a relayed projection to intermediolateral horn (sympathetic preganglionic neurons).

It is not surprising, then, that thalamic/hypothalamic discharges elicited by penicillin-G application would be associated with bursts of activity in vagus nerve recordings. We also found bursts of activity in vagus nerve recordings during the slow spiking period at the end of the limbic seizure, although the total amount of vagus nerve activity at these times was much less than we found earlier in each seizure episode. Interestingly, while the types of seizures in these two animal models are quite different, a pathway from hypothalamic areas through the medulla and into the periphery is common, and can account for similarities in vagus nerve discharge.

Methods – Our Acute Rat Model

Our rat model for acute studies of autonomic consequences replicates many features of autonomic disturbances seen in epilepsy patients, and offers some unique advantages. Using kainic acid as the convulsant drug on a background of urethane anesthesia, we produce a prolonged period of recurring limbic seizures that do not significantly involve the neocortex. As a result, animals can be kept in a stereotaxic frame without paralytic agents. The lack of motor convulsions permits stable recordings from the brain, spinal cord, and peripheral nerve, as well as accurate, invasive monitoring of systemic parameters such as blood pressure. We have also developed a simple method for reversibly suppressing seizures in one or both hemispheres repeatedly. The preparation is described briefly here, and more details are given in the readings.

We use male Sprague-Dawley albino rats for most experiments. Six to 8 week old animals (200–350 g) are commonly used. Animals are anesthetized with urethane ($1.5\ g\ kg^{-1}$ ip), fitted with an endotracheal tube, and maintained at 37 °C. Blood pressure is monitored with an intra-arterial line (polyethylene tubing, 0.5 mm id, 0.8 mm od, inserted into the femoral artery) and pressure transducer. An increase in mean arterial pressure, systolic or diastolic pressure (with no increase in pulse pressure) indicates an increase in sympathetic vasoconstrictor tone. Likewise, a decrease in blood pressure reflects a decrease in sympathetic tone. Increases in pulse pressure reflect increased cardiac stroke volume, which occurs physiologically through two mechanisms: At slow heart rates, stroke volume increases through increased diastolic filling time. At increased heart rates, increased stroke volume reflects increased cardiac emptying from increased cardiac contractility produced by

increased sympathetic input to the cardiac muscle and increased circulating catecholamines.

ECG is recorded with parasternal electrodes. Heart rate will increase in response to increased sympathetic and/or decreased parasympathetic outflow to the heart. Decreases in rate are mediated by decreased sympathetic and/or increased parasympathetic outflow. Heart rate changes can occur as a direct response to descending inputs to sympathetic or parasympathetic preganglionic neurons, or changes can be reflexively driven by baroreceptor activity. The presence of abnormally shaped QRS complexes indicates ectopic beats (i.e., patterns of contraction not following the typical conduction pathways). Rates are calculated from the number of beats per unit time and rhythm is assessed by looking at P waves and associated QRS complexes for variations in beat-to-beat intervals and atrial-ventricular coupling. Successive R-R intervals will increase if the heart is under predominant parasympathetic control. Successive R-R interval decreases indicate relative sympathetic nervous system control of the heart. An added benefit of using anesthetized animals is that transthoracic echocardiography can be used to study the mechanical properties of the heart during seizures. The force of contraction, filling and emptying properties, and chamber sizes, are some of the measurements that can be readily made in an echocardiographic study. Ultrasound probes are now quite good for small animal imaging studies, even at the high heart rates seen in mice or rats.

For peripheral nerve recordings, we use a linear array electrode that consists of 4 platinum/iridium wires embedded in a small epoxy trough. Wires pierce large nerves as they lay in the trough. Smaller nerves (e.g., renal nerve) are 'woven' between electrodes. Excellent multi-unit recordings, occasional single unit recordings, and even simultaneous stimulation and recording are possible with this electrode. Vagus or cervical sympathetic electrodes are placed through a ventral neck incision. Renal sympathetic nerve electrodes are placed through a retroperitoneal incision near the kidney. The renal sympathetic nerve contains postganglionic sympathetic fibers to the renal vascular supply. Splanchnic nerve exposure is also through a flank incision on the left side. Greater splanchnic nerve recordings give access to sympathetic preganglionic fibers. Cardiac sympathetic nerves coming off the stellate ganglion are exposed under the second rib through a parasternal incision.

Baroreceptor reflex function is conveniently assessed by recording peripheral autonomic nerve and systemic parameter variations to bolus injections of a vasodilator (e.g., sodium nitroprusside – 0.1 mg i.a.) or a vasoconstrictor (e.g., phenylephrine – 0.25 mg i.a.).

By using a stereotaxic frame, multiple electrodes can be implanted for recording seizure activity from limbic cortical structures. These electrodes are placed using stereotaxic coordinates through craniotomy holes. Depending on the experiment, we use dorsal and/or ventral hippocampal electrode placements. Electrodes are generally 75 μm teflon-insulated stainless steel wires (tip impedances ~100 kΩ). Typical stereotaxic coordinates for EEG electrodes are 5.2 mm anterior to lambda, 3 mm lateral to midline, 2–3 mm below skull surface (dorsal CA1); and 2.7 mm anterior to lambda, 5 mm lateral to midline, 7 mm below skull surface (ventral CA1, ventral subiculum).

Seizures are induced with systemic kainic acid (10–12 mg/kg). A single dose of kainic acid causes a period of recurring seizures that lasts more than 4 h. We found that unilateral common carotid artery occlusion will suppress seizure activity ipsilaterally, and our setup allows for brief occlusion episodes to be repeated and alternated. Our carotid occluder is built from a 0.5 ml syringe, the needle of which is removed and a narrow notch is cut near the top of the syringe. The barrel is shortened and the plunger is removed, but the rubber top of the plunger is left inside the barrel. The short barrel is closed by fusing it to the top of a second syringe, leaving the needle to connect to a length of PE tubing. Air movements in the PE tubing (by a remote syringe) cause the rubber plunger tip to press against the top of the syringe, compressing the artery.

Recent Results

Findings Using Our Model

Kainic-acid-induced seizures were associated with massive increases in parasympathetic (vagus nerves) and sympathetic (cervical sympathetic ganglion, renal sympathetic nerve, splanchnic nerve, cardiac sympathetic nerve) activity. Peripheral nerve activity increases during seizures were much greater than increases that were induced by administration of nitroprusside or phenylephrine, which produced mean arterial pressure changes of >50 mm Hg. Increases in c-fos expression have been found in both sympathetic and parasympathetic medullary regions (as well as hypothalamic areas). Baroreceptor reflex function was impaired during seizures: Changes in nerve activity induced by blood pressure increases or decreases were smaller or absent during tests made with phenylephrine or nitroprusside in the seizure state compared with pre-seizure conditions. In echocardiographic studies, striking acute cardiac dilatation accompanied a profound bradyarrhythmia. Finally, a significant fraction of the animals die during seizures, and the mechanism of death was defined – through ECG, BP, and echocardiographic measures – to be profound mechanical dysfunction coupled with sinus bradycardia and AV nodal block, leading to hypoperfusion of the brain and finally hypoperfusion of the heart itself.

Our preparation has an advantage in that the consequences of severe limbic cortical seizures can be studied in animals that breathe spontaneously. This is a critical

feature for observing and manipulating respiratory activity. We have been able to define the additive roles of seizure-induced autonomic activity and respiratory dysfunction in this seizure model. We have proposed that the massive parasympathetic and sympathetic outflow that occur during a seizure can be compounded by respiratory distress (driving both ANS divisions in the same direction) to impair mechanical function and slow the heart sufficiently to hypoperfuse the brain. The time scale for seizures to impact the heart is seconds, and the development of cardiac dilatation with bradyarrhythmia and eventual death occurs on a time scale of minutes. We suggest that this sequence of events is the most common mechanism for sudden death in epilepsy.

Both Divisions of the ANS are Overactive

The notion that autonomic dysfunction arises from differences in activity of the two hemispheres pre-dates suggestions that asymmetric seizure activity may contribute to sudden death in epileptic patients. The 'brain-laterality hypothesis' was proposed to account for cases of sudden cardiac death, wherein patients died during extreme stress. The brain-laterality hypothesis suggested that emotional arousal could trigger ventricular fibrillation and sudden death by inducing a net lateralized imbalance of activity in some brain areas, leading to uncompensated sympathetic outflow to the heart. Hemispheric inactivation studies have supported this idea.

Differences in activity in the two hemispheres have also been proposed as a contributor or cause for autonomic disturbances – including death – in seizure patients. Controlled lateralized differences in activity are difficult to find (or cause) in studies of seizure activity because seizures can spread rapidly in the brain, and most examples of death during or after a seizure involve generalized seizure activity. A different kind of asymmetry involves differential activation of dorsal and ventral portions of the limbic cortices. Part of this notion comes from data that ventral hippocampal areas (in rodent) have a greater tendency to generate seizure activity than dorsal areas. The connectivity of hippocampal formation with brain regions having autonomic impact – e.g., insular cortex – is also heaviest from ventral areas.

Other studies in people and animals suggest that the extent of the cortical involvement, not lateralization of seizure activity, is important for significant heart rate changes. The study by Epstein and colleagues describes predominantly heart rate increases in patients, but also mentions patients that deviated from the majority, showing heart rate slowing and sinus pauses. Ictal bradycardia was found to most often occur in patients with temporal lobe seizures when the seizure activity was bilateral. In kindling animal models, however, arrhythmias were often seen early in the kindling progression (e.g., stage 2 seizures), when seizure spread is limited; however, none of these arrhythmias were fatal.

Although we have seen differences in ANS activity depending on the hemisphere exhibiting seizure activity, our nerve recordings and c-fos data indicate that both divisions of the ANS are strongly activated during kainic acid-induced limbic seizure activity in rats. Further, our data indicate that death results from massive combined ANS overactivity, with the overall result being a parasympathetic-dominated cardiovascular state. In our opinion, cardiovascular complications depend on the degree and duration of increased autonomic activity, and therefore likely depend on the extent and duration of the seizure.

Death is Mainly a Parasympathetic Phenomenon that Resembles Asphyxia

Death in our animal model does not resemble most of cases of sudden cardiac death. Although the literature spans some three decades, there is almost universal agreement that 80–85% of cases of sudden cardiac death are due to ventricular arrhythmias. Sudden death from fatal arrhythmia is most commonly a ventricular tachyarrhythmia. In some patients, a ventricular tachyarrhythmia is triggered by an acute myocardial ischemic event, and in other patients, a ventricular tachyarrhythmia is related to an anatomical substrate (e.g., scarring from a previous myocardial infarct). Prevention is aimed at preventing the heart disease that can precipitate cardiac events, and treatment is mainly defibrillation. There are fewer treatment options, other than a pacemaker, for the bradyarrhythmias.

It is interesting that the picture we find during seizures resembles the picture found during asphyxiation. In fact, the respiratory distress during a seizure is a form of asphyxiation, and works pathophysiologically in the same direction as the seizures to drive the sympathetic and parasympathetic divisions simultaneously. Respiratory distress causes an increase in vagal activity because of the increase in arterial carbon dioxide, and it increases sympathetic activity (and blood pressure), which also favors an increase in vagal outflow via any functional baroreceptor activity. The combination clearly can be rapidly lethal. Some intense bursts of parasympathetic activity are likely to be large enough to make nodal blockade the initial or predominant first event. In the absence of sustained seizure activity or respiratory distress, a transient arrhythmia may be all that occurs.

In light of these data, one obvious question is whether seizures alone are enough to cause death. In our acute experiments and kindling studies in freely-moving rats, seizures sometimes cause serious arrhythmias, but each episode is usually transient, and therefore not life-threatening. We have not seen evidence for apneic periods caused by seizures in our urethane-anesthetized animals or in animals that have motor convulsions (animals

anesthetized with ketamine/xylazine or unanesthetized animals). The very sudden death that has been described in some mice makes us wonder whether complete respiratory arrest – in addition to or leading to cardiac arrest – is possible. More severe autonomic disturbances might result when seizures occur on the background of a damaged brain, rather than the background of a normal brain. Another possibility is that episodes of arrhythmia predispose to more serious arrhythmias.

Another question that remains unanswered is whether the massive sympathetic outflow that occurs in parallel with the vagal outflow is somehow protective, if it makes matters worse, or if it is irrelevant. Koizumi and others have suggested that there are times when parallel ('non-reciprocal') activation of the sympathetic and parasympathetic outflow to the heart occurs physiologically, e.g., in response to decreased arterial oxygen (in the presence of constant arterial carbon dioxide). They found a similar parallel activation during hypothalamic stimulation, and co-activation actually enhances cardiac output. In rat and rabbit models of asphyxiation, epinephrine and vasopressin have been used with some success to improve resuscitation. These findings suggest that the sympathetic outflow may be a physiological attempt to promote survival of the organism. However, a background of sympathetic activity can enhance cardiac responses to parasympathetic innervation, either directly or via complex activity within the intrinsic cardiac plexus. Such a synergy could enhance the chronotropic and dromotropic actions of the parasympathetic neuronal transmitter, acetylcholine. Favoring this view of harmful consequence of parallel activation is the fact that we never saw ventricular escape beats, even when heart rates fell to what were lethal levels. Finally, strong coactivation of parasympathetics and sympathetics contributes to the impairment of the baroreceptor reflex. Baroreceptor reflex function was shown to be impaired in patients with temporal lobe epilepsy that were refractory to drug treatment. The interaction of sympathetic and parasympathetic innervation at the heart is complex and this question will not be easily settled.

Future Directions

The ultimate goal of our research is to construct a complete picture of the ANS activity during seizures. The afferent pathways used by different types of seizures need to be fully defined. The long-term consequences of seizures should be studied, including (a) the lasting effects on ANS activity (not during the seizure itself) of multiple seizures, in chronically altered brains; (b) the mechanisms by which changes in the network that generates seizures (e.g., as regions sustain damage or by conversion of previously less active areas) impact the ANS; and (c) the possibility that a newly epileptogenic region is more disruptive for ANS function. These questions must be pursued with a combined approach that involves acute and chronic experimentation in animals as well as corollary studies in patients.

Animal studies will not only be essential for defining the pathophysiology of autonomic consequences in people, but also serve a role in identifying the most significant variables that can and should be monitored in patients. Some of these variables may be critical for identifying a specific immediate risk (e.g., an arrhythmia that will have the potential to be life-threatening); other ANS parameters may even aid in seizure detection. Other approaches, such as functional studies of cardiac function with echocardiography, may be more suitable for defining broader periods of risk, or significant changes in risk during the life of a seizure patient.

In the case of many novel seizure-induced genes, it is still a challenge to define the consequences of altered expression because of the lack of information about the function of protein products. Even if we know the localization of transcription, in many cases the only other available information is gene sequence. The information available about the function of a gene (or gene product) in other tissues or cell lines cannot always be easily translated to the brain. Therefore, much basic research is needed before we understand the net effect of global alterations of gene expression in the brain, or even attempt to determine if a given alteration in gene expression is beneficial of harmful.

Seizure Initiation and Termination

J L Stringer, Baylor College of Medicine, Houston, TX, USA

Introduction

A seizure is defined as an episode of excessive, synchronized neuronal activity associated with disturbance of sensation, loss of consciousness, convulsive movements, or combinations of these clinical signs. The precise combination is thought to reflect the brain regions that are synchronized in the discharge. Ever since electrical activity has been recorded in the brain, there has been reference to 'spontaneous' activity, the most marked form of which is seizure activity. Normally, brain activity does not appear to be highly synchronized. However, during a seizure, there is abnormal synchronization of brain circuits. Importantly, however, the occurrence of a seizure does not mean that the brain is abnormal. For example, seizures can be triggered in 'normal' brain by metabolic abnormalities such as hyponatremia and hypoglycemia, or by infection or inflammation. Every brain has a capacity to express a seizure.

The brain produces a variety of transient oscillations – synchronized activity in populations of neurons – that do not initiate seizures. This observation can be viewed in two ways. One is that there is a specific type of 'trigger' necessary to initiate a seizure. This trigger – such as an electrical shock – may itself produce excessive synchronization or may lower some threshold for seizure initiation. Alternatively, one could view the brain as having mechanisms that control the degree of synchronization; if these limiting factors fail, a seizure may begin. An example of such a process would be loss of inhibitory function in the cortex. Interestingly, if both excitation and inhibition are blocked, neurons tend to fire at a higher rate and in a more rhythmic pattern compared with activity during baseline conditions. This finding supports the idea that there are intrinsic mechanisms that determine neuronal excitability in brain networks, and that these intrinsic mechanisms could limit seizure initiation. Certainly, an active input (a trigger) could interact with loss of an

intrinsic brake to result in the excessive synchronization that characterizes a seizure discharge. The discharge provides an increase in excitation that when coupled with other mechanisms, such as strong recurrent synaptic connections, may allow spread of the activity from a single cell to a few cells, and then from the few cells to a larger population.

Epilepsy is generally defined as chronic, recurrent seizures. The mechanisms behind the recurrent seizures are presumably similar to those behind seizures in normal brain, except that the 'trigger' is now present in the brain. Alternatively, or in addition, there is a loss of the intrinsic mechanism that controls/limits synchronization. Yet, despite all of the possible changes in an epileptic brain, the seizures remain episodic. They still start and stop. The changes underlying the epileptic state may make it more likely that the neurons will synchronize to initiate a seizure, but do not explain why the seizure actually starts. Why should it start a one particular moment? Why not 5 or 73 min later? We still have an incomplete understanding of the details of initiation of seizures. Further, a seizure (once started) can vary from a few seconds in duration to tens of minutes. Why the seizure stops is largely unknown. Seizures are followed by a refractory period, both absolute and relative, during which another seizure cannot be elicited. When considering possible mechanisms of seizure onset and termination, the presence of a refractory period needs to be taken into account.

Background

Specific mechanisms have been proposed to contribute to the onset of single seizures. These mechanisms can be distinguished from the more chronic changes that underlie the epileptic condition. The mechanisms proposed for seizure onset can be roughly divided into network mechanisms (which include changes in synaptic connections and in neurotransmitter systems), and cellular/molecular mechanisms. Hormones and other factors are also likely triggers for seizure onset, but will not be discussed here.

The network mechanism that has received much support over the years is a 'fading' of inhibition due to increased neuronal activity. Inhibitory systems in the brain normally function to control neuronal activity and reduce the likelihood of excessive synchronization. Thus, a loss of inhibition would be predicted to increase the chance that a seizure might begin. In support of this idea, GABA antagonists can cause seizures in experimental animals. In addition, in epileptic animals, reduced recurrent inhibition has been found to contribute to neuronal hyperexcitability and hypersynchrony. However, in brain slices, if nothing else is done, complete (or near complete) blockade of GABA receptors is needed to achieve synchronized burst firing in the hippocampus. This observation suggests that, most likely, more than one mechanism underlies seizure onset. Indeed, even in these animal models of reduced inhibition, the seizures are episodic – they start and stop. Reduced inhibition would not be predicted to contribute to seizure termination.

Increases in excitation, either intrinsic excitability or synaptically-mediated excitability, could contribute to seizure initiation. Seizures depend on circadian rhythms as well as minute fluctuations of ionic concentrations, such as increases in extracellular potassium and decreases in calcium, both of which increase excitability. Since astrocytes are thought to play a major role in the regulation of the extracellular environment, an increase in excitability due to changes in the ion concentrations could be due to glial dysfunction. Consistent with this idea, gliosis and/or reactive astrocytes are frequently found in epileptic tissue, and other investigators have described various abnormalities in the normal function of these astrocytes. Other ways in which an increase in excitation might contribute to seizure initiation include an acute increase in glutamate release, a transient inhibition of glutamate transporters on glial cells, or a transient increase in neuronal firing, which could result in recruitment of surrounding neurons and, ultimately, in excessive synchronization.

Changes in the characteristics of a number of ion channels could increase intrinsic excitability, which could in turn contribute to seizure initiation. For example, the presence of a small persistent sodium current has been proposed (based on computer modeling) to be necessary for the generation of spontaneous activity in the CA1 region of hippocampal slices exposed to zero-calcium perfusing solutions. The sodium current is necessary for the generation of an after-depolarizing potential, and prolongs the neuronal firing in an individual neuron. A number of modifications in ion channels (channelopathies) have been described in inherited epilepsies. It is possible that a change in expression of genes that encode the same (or different) ion channels could account for other types of epilepsy that do not now appear to be inherited. However, it seems unlikely that a change in channel function that makes it more likely that a neuron will fire an action potential can be the sole mechanism behind seizure initiation. Seizures require multiple neurons to fire synchronously.

Most seizures begin in a small group of neurons and then spread. One theory has been proposed that irregular action potential discharge, which may or may not be synchronized across a small population of neurons, progresses into rhythmic synchronized discharges. These low-frequency discharges, often expressed as interictal activity, then 'fuse' into larger aggregates. This process can then spread locally and/or to synaptically-connected brain regions. Recurrent excitatory connections, such as in the CA3 region of the hippocampus, provide a

mechanism for synchronizing neuronal activity when only one, or a few, neurons fire. Noteworthy, however, in an animal model of temporal lobe epilepsy, an increase in recurrent excitation in the temporal lobe was not found to contribute to neuronal excitability. If a population of neurons in a brain region begins firing spontaneously, then the probability that 2 or 3 neurons might fire simultaneously is dependent on the frequency of firing. Once a small group of neurons begins to fire simultaneously, then these cells will be more likely to fire together again – and to recruit local or synaptically-connected neurons into the discharge. The presence of interictal activity is also proposed to lead to the formation of new, or abnormal, excitatory connections, promoting further changes in the brain. However, the idea that interictal activity actually begins the process of synchronization is debated. Indeed, interictal activity could reduce the likelihood of synchronization. The relative anatomy and physiology of the brain region in which the interictal activity is present probably determines the outcome.

Our understanding of the mechanisms underlying seizure termination is minimal. One of the earliest theories was that the intense neuronal activity depleted the stores of readily available ATP. Essentially, the theory suggests that running out of energy results in loss of the ion gradients across the membrane, making it impossible to generate action potentials. Such a condition would effectively end the synchronous discharge, and would account for the refractory period seen after a seizure. Short of a complete loss of ATP, there is also the possibility that the ion gradients are lost, or sufficiently reduced, that action potential firing is limited until the gradients can be restored. For this theory to hold true, action potential discharge during seizures would need to be frequent enough that the ion gradients cannot be regenerated. A less extreme hypothesis is that there is inactivation of ion channels underlying action potentials, resulting in blockade of action potential generation – and explaining the refractory period. Other theories for seizure termination include the proposals that the elevated extracellular potassium produced by the seizure activity causes a depolarizing block of neuronal activity, and that the sodium/potassium ATPase activity is enhanced by the seizure. Inactivation of sodium channels by the neuronal activity would also be predicted to terminate action potential firing. It has also been suggested that pacemaker failure is responsible for termination of ictal events in the cortex.

Before and during seizures there is an increase in the concentration of glutamate in the extracellular space. Such an increase could result in desensitization of the glutamate receptors. If the receptors were no longer sensitive to stimulation by glutamate, then neuronal excitability would be reduced. Cyclothiazide, a compound that inhibits desensitization of ionotropic glutamate receptors, has been shown to increase the frequency and prolong epileptiform discharges induced in rat hippocampal slices with low magnesium. This observation suggests that receptor desensitization could contribute to seizure termination. However, in the absence of synaptic transmission, epileptiform activity is also periodic, suggesting that receptor desensitization is not the only mechanism.

In the CA3 region of the hippocampus, the recurrent collateral synaptic connections are postulated to underlie the epileptiform activity that can be easily initiated by reduction of inhibition. Investigation of the burst discharge in this region has shown that exhaustion of the releasable pool of glutamate is a mechanism behind the termination of the individual bursts. When extracellular calcium is replaced with strontium, there is a reduction in the rate of glutamate release and prolongation of the bursts in disinhibited CA3. Replenishment of this pool would account for the interval between the short bursts of action potentials that characterize this epileptiform activity. Another possible mechanism that could contribute to termination of a burst of action potentials is a short-term depression of synaptic function induced by the electrical activity in the burst.

Methods

The major approach to the study of initiation and termination of seizure activity has been electrophysiological – to record from individual neurons and from populations of neurons in specific brain regions. This approach can be combined with pharmacological or genetic manipulation of excitability. Because of the ease of precise localization and identification of cell type in vitro, this type of experiment is typically carried out in acute brain slice preparations.

Epileptiform activity can be produced in hippocampal slices by a variety of methods. Short (<1 s) bursts are readily produced by raising extracellular potassium concentrations, lowering extracellular calcium or magnesium, adding blockers of GABAergic transmission, adding drugs that increases excitability, or a combination of these manipulations. Prolonged epileptiform activity (>5 s), which more closely mimics seizures in vivo, can be produced in vitro in the absence of synaptic transmission in both CA1 and the dentate gyrus. The discharges can be quite long, and consist (at the extracellular level) of a negative shift of the DC potential upon which population spikes are superimposed (indicating synchronous neuronal activity). The bursts recur at fairly regular intervals, suggesting the presence of some type of pacemaker activity. Epileptiform activity can be induced in cortical areas using many of the same manipulations.

There are some limitations of the currently available in vitro models for the study of seizure initiation and termination. In the intact brain, synaptic transmission is rarely, if ever, completely blocked. Therefore, the mechanisms that underlie onset and termination of the prolonged bursts in the absence of synaptic transmission may or may not be the mechanisms behind seizures in vivo. Similarly, the short bursts seen in in vitro models are more characteristic of interictal spikes than of seizures in vivo, leaving open the question of what allows, or stimulates, the more prolonged discharges in vivo. It is also possible that isolation of tissue from the whole brain alters the mechanisms that work to initiate and provide early synchronization of epileptiform activity. Mechanisms behind termination of synchronized activity are also probably different in the presence and absence of synaptic transmission.

Recent Results

Mechanisms of seizure initiation under various conditions have been studied, but relatively few studies have addressed seizure termination. In particular, it is unclear how seizures are terminated in the absence of synaptic activity, where there is no loss of excitatory drive or augmentation of inhibitory inputs. We studied dynamic activity-dependent changes of intracellular pH in the dentate gyrus, in the absence of synaptic transmission, in acute hippocampal slices, using a fluorescent pH indicator. Slices were incubated in 40 μM SNARF-1 AM for 3 h. SNARF-1 is taken up into cells, where it is hydrolyzed by an endogenous esterase. Recurrent epileptiform activity was initiated by perfusing the slices with 0 mM-added calcium and 8 mM potassium solution. After 20–30 min in this solution, prolonged epileptiform activity (20–40 s discharges) recurs at regular intervals in the dentate gyrus. The epileptiform activity consists of a negative shift of the DC potential, with superimposed population spikes. Each burst of epileptiform activity was found to be associated with intracellular acidification, while between seizures the intracellular pH recovered (Figure 1). The average magnitude of the change in intracellular pH was 0.025 pH units; this average includes intracellular pH changes in nonbursting cells. These pH changes begin early in the discharge, suggesting that a particular level of intracellular pH during the prolonged epileptiform activity is associated with termination of the activity. This hypothesis was tested with antidromic stimulation during the recovery period. Early in the recovery period, stimulation could not initiate a prolonged burst. When the stimulation was applied in the middle of the recovery period, it could evoke a burst, but the duration of this burst was shorter than the regularly recurring bursts. This experiment

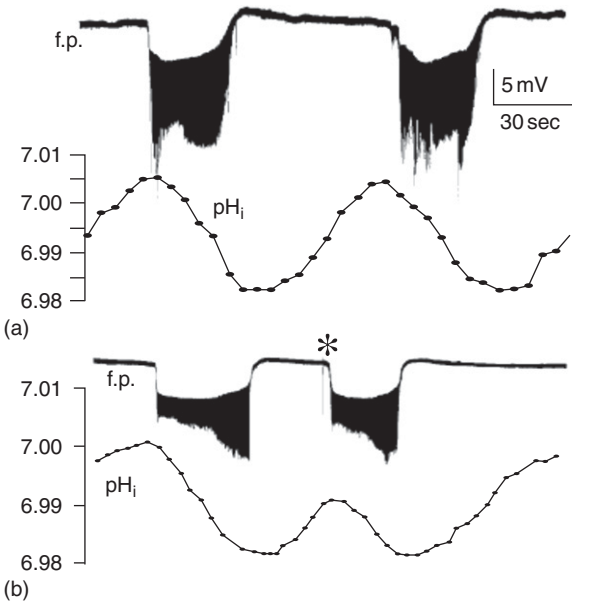

Figure 1 Changes in intracellular pH correlate with duration of prolonged field bursts in the dentate gyrus of hippocampal slices. Cells were loaded with SNARF 1-AM and then the slices were perfused with 0-added calcium and 8 mM potassium. Recurrent epileptiform field bursts were accompanied by intracellular acidification, which gradually recovered between the bursts (a). If an antidromic stimulation was administered between the spontaneous bursts (*), the subsequent field burst was shorter than the previous spontaneous one. The duration correlated with the degree of recovery of the intracellular pH.

demonstrated that the duration of the burst correlated with the degree of recovery of the intracellular pH. A recovery of the intracellular pH to at least ~50% of the baseline was required before the antidromic stimulation could initiate a prolonged burst.

To further explore this relationship, a variety of conditions were tested. Experimental conditions that shortened the epileptiform discharge correlated with more rapid intracellular acidification, and experimental manipulation of intracellular pH altered the duration of the seizure discharge; acidification resulting in early termination of the epileptiform activity. Altogether, these data show a direct relationship between the level of intracellular acidification and the duration of the seizure-like discharge, suggesting that an intracellular pH-dependent process can terminate nonsynaptic neuronal synchronization. Many cellular processes are dependent on pH, but it is not known which process terminates the seizure-like activity in this model.

When considering possible mechanisms of seizure termination, these data demonstrate that neuronal excitability is not reduced at the end of a prolonged discharge. Immediately after termination of the bursting, an antidromic stimulation can elicit a population spike whose amplitude is not reduced when compared with control conditions. Thus, loss of ATP, enhanced sodium pump activity, inactivation of sodium channels or depolarizing

blockade are unlikely to be involved in terminating the burst discharge activity in this model. There is clearly no decrease in neuronal excitability and, since there is no synaptic transmission in this model, there is no change in synaptic function, which would explain burst termination. It would appear that the intracellular acidification inhibits cellular processes that are necessary for continued neuronal firing or bursting.

As suggested earlier, this model of epileptiform activity, in the absence of synaptic transmission, does not accurately model seizures in vivo. However, there are some significant similarities which make this correlation between intracellular pH and seizure termination quite compelling. First, the dentate gyrus provides a gating function in the transmission of seizure activity into and through the hippocampal circuits. The dentate gyrus appears to have a high seizure threshold and to be resistant to the initiation of seizure activity. However, once the seizure activity in the dentate gyrus has begun, all parts of the hippocampal circuit discharge as one. Early in the synchronization of the activity in the dentate gyrus, there is no alkalinization of the extracellular space suggesting that the seizure onset does not involve synaptic activity. In addition, maneuvers that increase or facilitate nonsynaptic mechanisms of synchronization increase the likelihood that discharges will begin in the dentate gyrus. Finally, the only way to mimic the prolonged discharges in an in vitro system is to block synaptic transmission. Together, these observations suggest that nonsynaptic mechanisms are likely to be critical in the initiation and termination of epileptic discharges in the dentate gyrus, a structure that is thought to 'gate' the spread of seizure activity throughout the hippocampal circuit.

Future Goals

If intracellular acidification in the dentate gyrus represents a critical mechanism in control of seizure activity, in at least one brain region important in seizure spread, then determining the source of the acidification – and the cellular processes that are influenced or modulated by the acidification – will be important steps in understanding seizure control. Augmentation of the process, or processes, underlying seizure termination might help control seizures. In addition, understanding how changes in pH affect neuronal function would contribute to our insight into cellular control of neuronal excitability.

One thing that is not clear, and will need to be investigated, is whether the mechanisms that allow initiation and those that terminate synchronized neuronal activity are the same in normal and epileptic brains. Further, it will be important to investigate whether the mechanisms that underlie seizure initiation are the same in all brains with epilepsy – no matter what the type of epilepsy. One would guess that the mechanisms are, in fact, quite diverse. There could also be multiple mechanisms involved in seizure termination. Finally, one must ask whether we can therapeutically reduce the likelihood of seizure onset and augment the mechanisms underlying seizure termination. One could argue (based on what we do know about their mechanisms of action) that the currently available antiepileptic drugs reduce the likelihood of seizure onset. However, whether they (or other drugs) augment termination mechanisms is unknown.

Seizure Prediction

K Lehnertz, University of Bonn, Bonn, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epilepsy affects ~1% of the population worldwide. Two-thirds of affected individuals achieve effective seizure control from anticonvulsive medication, and another 8–10% could benefit from resective surgery. Thus, in about 25% of individuals with epilepsy, seizures cannot be controlled by any available therapy. In most individuals with epilepsy, seizures appear to occur unpredictably, with no discernible pattern; in other patients, seizures appear to be entrained to biological rhythms. Only few individuals can identify periods when seizures are likely to occur, and even these patients can rarely specify an exact time when a seizure will happen. From Lennox's 'reservoir' theory, several seizure-facilitating factors are known, but these factors are rather nonspecific and highly variable; they depend on individual habits, susceptibility, and daily routine. Research in experimental models of focal epilepsy has identified a variety of potential ictogenic (seizure-generating) mechanisms. However, it is still a matter of debate how these mechanisms give rise to seizures, and to date they have not been useful in constructing a seizure prediction algorithm.

Epileptic seizures are commonly believed to begin abruptly, just a few seconds before their clinical manifestations. The motivation for research into the predictability of seizures is thus straightforward. A question of particular interest is whether characteristic features that reliably herald an impending seizure can be extracted from continuous electroencephalographic (EEG) recordings. In recent years, a number of new analytic techniques have been developed that appear to be capable of predicting seizures from EEG recordings. Studies on seizure prediction have advanced from preliminary descriptions of preseizure (preictal) phenomena and proof-of-principle studies, to studies on continuous multiday recordings. Nevertheless, it is still a matter of debate whether seizures are predictable by prospective algorithms. Given the potential impact of seizure prediction methods to expand knowledge of seizure-generating mechanisms, and to move treatment concepts from preventive strategies toward an EEG-triggered 'on-demand' therapy, it is important to understand potential influencing factors, to improve seizure prediction performance, and to develop reliable methods ready for clinical deployment.

Background

If epilepsies are considered as dynamic diseases of brain systems, then one could postulate two primary scenarios of how a seizure could evolve. Initiation of seizures in primary generalized epilepsy could be caused by a sudden and abrupt transition, in which case the seizure would not be preceded by detectable dynamic changes in the EEG. In focal epilepsies, the transition could be a gradual change (or a cascade of changes) in EEG dynamics, which could in theory be detected. A large number of studies have provided clinical and physiological support for the idea that at least certain types of focal seizures are predictable.

Non-EEG-Based Evidence for a Preictal Period

According to Lennox, seizure facilitation can be defined as the input of sensory, metabolic, emotional, or other yet unknown factors that '...fill up some reservoir until it overflows,' which in turn results in a seizure. Factors known to potentiate seizures, particularly in sensory-evoked and reflex epilepsies, include the following: state of consciousness, sleep deprivation, anxiety, disturbances of electrolytes and acid–base balance, sensory stimulation, and exposure to certain drugs. Studies based on questionnaires or seizure dairies have revealed that individual patients can identify periods when seizures are most likely to occur. These periods are characterized by vague sensations, called clinical prodromes, which include mood changes, irritability, sleep problems, nausea, and headache. There are also physiological studies in small numbers of patients who support the existence of a preictal period. In these studies, an increase in blood flow and in cerebral oxygen availability in the epileptic temporal lobe, or changes in brain perfusion, was observed in the minutes to hours prior to seizure onset. Preictal changes in the R–R interval on the electrocardiogram may also have predictive value in some types of epilepsy.

EEG-Based Evidence for a Preictal State – Early Approaches

A large number of studies on the level of neuron networks suggest that focal seizures are initiated by abnormally discharging neurons that recruit and entrain neighboring

neurons into a critical mass. This phenomenon might be mediated by an increasing synchronization of neuronal activity that is accompanied by a loss of inhibition, or by other seizure-facilitating processes. The concept of a critical mass, however, might be misleading, since it implies an increasing number of neurons that are entrained into an abnormal firing pattern. Such a mass phenomenon would be easily accessible to conventional EEG analysis, which, to date, has failed to detect it. Early investigations of the relationship of interictal spike occurrence to seizure onset revealed a decrease (or even total cessation) of spikes before seizures, but a reexamination in a larger sample did not confirm this phenomenon. Moreover, findings obtained from applying linear analysis techniques, such as pattern recognition, analytic procedures of spectral data, or autoregressive (AR) modeling of EEG data indicated that EEG changes characteristic of preictal states may be detectable, at most, a few seconds before the actual seizure onset.

With the availability of so-called nonlinear analysis techniques, a number of laboratories have continued to face the challenge of developing algorithms to detect unknown patterns associated with seizure generation, and have shown characteristic changes minutes to hours prior to seizure onset on the intracranially-recorded EEG. Nonlinear time series analysis techniques involve univariate measures, such as Lyapunov exponents, dimensions, entropies, or correlation densities (see Methods). Additional methods developed to define preictal states include the following: extraction of neurophysiologic features from the EEG associated with epileptiform activity (e.g., bursts, slowing, chirps, and changes in signal energy), recurrent neural networks, simulated neuronal cell models, and techniques developed in catastrophe theory or in the field of self-organized criticality. In addition, some laboratories have focused on bivariate or, more generally, multivariate measures that are based on analysis concepts for synchronization phenomena in nonlinear dynamical systems. These analysis techniques permit the assessment of synchronous activity from multiple sites and include nonlinear interdependence, measures for phase synchronization and cross-correlation, difference of the largest Lyapunov exponents of two or more channels, nonlinear causality, as well as classification approaches based on a fusion of multiple EEG features from multiple sites.

Results obtained from preliminary descriptions of preictal phenomena, and from early proof-of-principle studies, indicated that seizures are not random events, but rather are related to ongoing dynamical processes that may begin minutes to hours to days beforehand. They also indicated that the seizure-initiating process might better be visualized as a process in which an increasing number of critical interactions between neurons in a focal region, and connected units in an abnormal functional network, unfold over time. The different prediction horizons were thought to reflect different aspects of ictogenesis as captured by the different approaches, but also indicated that none of these techniques appears to depict the process fully. Since the observed patterns appeared to be patient-specific, it was conjectured that different approaches may be required to predict seizures with clinically useful accuracy in different individuals or in different epilepsy syndromes. No method, however, convincingly demonstrated unequivocal seizure prediction in blinded, prospective, randomized clinical trials, and with appropriate statistical validation.

EEG-Based Evidence for a Preictal State – Recent Approaches

In 2000, the International Seizure Prediction Group (ISPG) was established with the specific goal of moving the field of seizure prediction forward from proof-of-principle experiments into validated, well-understood methods that could be applied to both basic science and clinical applications. With the wide acceptance of digital electroencephalography, the maturation of methods for recording the EEG from intracranial electrodes, and the availability of powerful computers, members of the ISPG began to store and to analyze complete, long-duration, multichannel EEG datasets acquired during presurgical monitoring from a large number of patients implanted with intracranial electrodes. This approach helped to avoid a potential bias resulting from analyses of highly selected EEG data that was restricted with regard to seizure type, patient state, recording sites, signal to noise ratio, duration of recordings, artifacts, etc. Moreover, since many past studies merely concentrated on sensitivity issues (i.e., ignoring the specificity of preictal changes), techniques were developed that allow one to evaluate the performance of seizure prediction algorithms. These techniques go beyond the mere estimation of sensitivity and specificity (using, e.g., receiver-operating characteristics (ROC)) and include analytical, stochastic, and surrogate-based approaches. With these approaches, it is only recently that some laboratories reevaluated the performance of seizure prediction algorithms previously considered suitable for prediction and showed that many of them (including correlation dimension, Lyapunov exponents, and signal energy) do not perform better than a random predictor. Parenthetically, some of these techniques – particularly nonlinear algorithms – do provide an improved characterization of the spatial distribution of the epileptic process during the interictal period. Evidence has accumulated, however, that particularly seizure prediction algorithms that are based on a quantification of relations between recording sites appear to perform significantly better than random prediction, even if rigorous statistical validation is applied.

Evidence for Preictal Alterations from Studies in Animal Models of Epilepsy

Although there is a considerable bulk of literature on animal models of epilepsy, the phase of transition to the seizure state has not yet been fully explored. Some earlier studies indicated that discernible preictal patterns can be detected, at least in some experimental models of epilepsy, but these studies must be regarded as proof-of-principle studies since most lack a sound statistical validation. In addition, a number of these studies have focused on acute seizure models, whose behavior is not clearly analogous to spontaneous seizures in humans. More recently, alterations in interictal activity were shown to precede the transition to ictal-like activity in a hippocampal–entorhinal brain slice preparation exposed to high extracellular potassium and to low magnesium concentrations. Preictal changes were characterized by alterations in the origin and spread of CA3 epileptiform discharges and by a prominent spectral power increase in the 200–400-Hz frequency range. Similar oscillations were also observed in microelectrode studies in vivo in the hippocampus of kainate-treated rats and in depth EEG recordings from patients with mesial temporal lobe epilepsy. These so-called 'fast ripples' have been hypothesized to identify microscopic regions important to seizure generation, and may reflect pathological hypersynchronous population spikes of bursting pyramidal cells. Fast ripples are also seen during the latent period (i.e., between the occurrence of an initial epileptogenic insult and the onset of recurrent spontaneous seizures) in rat models of chronic epilepsy, and may thus be a possible marker of alterations in interictal activity preceding the transition to ictal activity.

Methods

Methods employed in seizure prediction have been developed to identify unknown patterns on the EEG associated with seizure generation. Many methods are mathematically complex and not easily accessible to those outside of the world of physicists, mathematicians, and engineers. Some of them may be more difficult to relate to the neurophysiology of epilepsy than are others. Many techniques place great demands on the recorded EEG with respect to the precision of the data, the absence of noise, and stationarity. In practice, however, none of these requirements can be exactly fulfilled. Moreover, numerous studies have identified factors related to the EEG recording system that might all have a strong influence on the findings obtained from applying the different methods. Finally, potential pitfalls specific to the individual algorithms have to be taken into account. Thus, although a number of toolboxes are already available, analysis techniques must be painstakingly applied, and the results obtained should be interpreted with great care.

Major Methodological Steps

In a retrospective seizure prediction study, three major methodological steps are involved (see **Figure 1**). The first step consists of preprocessing the EEG. This typically consists of artifact detection and removal, filtering, and normalization – depending on which methods are used in the second step, which consists of scanning the EEG for predictive features. This scanning permits reduction of large amounts of EEG data to a small number of parameters (important for downstream processing), and may consist of an automated detection of epileptiform patterns, such as spikes or slowing. In the majority of studies, however, a certain measure, which is thought to characterize specific aspects of the ictogenic process, is calculated from the EEG using a moving-window technique. The length of the time window is chosen so that there is a reasonable trade-off between approximate stationarity of the EEG signal and sufficient number of data points to characterize the EEG dynamics. The resulting temporal evolution of the measure (measure profile) is then scanned for prominent characteristics that can be related to the actual seizure times. These features might be drops or peaks (e.g., quantified as threshold crossings) or any other distinct pattern in the measure profile, and can be detected automatically with pattern recognition methods or with a variety of novel classifiers, such as probabilistic artificial neural networks. In a third step, the measure's capability to distinguish the preictal state from the interictal interval is evaluated with test statistics quantifying the occurrence of these features relative to the seizure times, which results in some kind of performance value. A high performance value is assumed to reflect the existence of a preictal state and the capability of the applied measure to detect it.

EEG Analysis Techniques and Characterizing Measures

Analysis techniques currently in use to calculate a characterizing measure from continuous EEG recordings can be divided into two main categories: linear and nonlinear. Depending upon whether EEG data from one, two, or more recording sites are analyzed independently, or for possible interactions, these techniques can further be divided into univariate, bivariate, and multivariate approaches. A more detailed description of the physical and mathematical concepts underlying these techniques, along with their implementation details for EEG analysis, can be found in a number of textbooks and review articles.

Linear methods comprise analysis techniques in the time domain such as evaluation of amplitude, interval or period distributions, or estimation of auto- and cross-correlation functions, as well as analysis in the frequency domain (using the fast Fourier transform, the wavelet transform, or other time–frequency transformations) such as power spectral

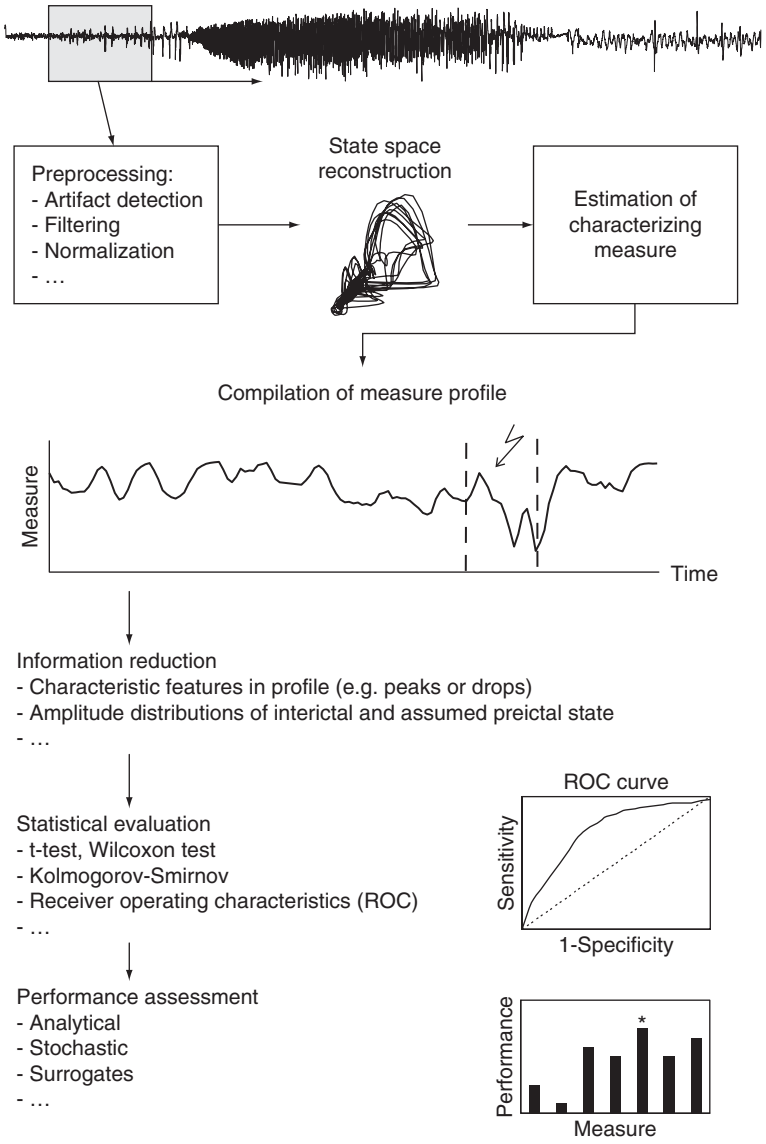

Figure 1 Flow chart of the major methodological steps involved in retrospective seizure prediction studies. The chart is shown for a univariate measure but can be extended easily for bivariate and multivariate measures. An EEG recording is partitioned into segments of a given duration (typically tens of seconds). EEG data of a given segment is preprocessed (if necessary) and the dynamics is reconstructed in state space in case of a nonlinear EEG analysis approach. A characterizing measure is estimated for this segment, and analysis steps are repeated for the next segment, after moving forward in time. The resulting measure profile (i.e., time-dependent changes of a characterizing measure) is then scanned for prominent characteristics that can be related to the actual seizure times. Separability of preictal and interictal characteristics is evaluated with statistical methods to yield estimates for sensitivity and specificity. In case of a multichannel recording, all steps are repeated for each channel (univariate approach) or combinations of channels (bi- or multivariate approaches). It is advisable to assess and to validate the prediction performance, particularly with respect to possible clinical applications.

estimates, cross-spectral functions, or linear coherence. AR and AR moving average (ARMA) models provide an alternative way to estimate properties of the power spectrum.

Nonlinear analysis techniques were originally developed within the physical–mathematical theory of nonlinear dynamics (colloquially termed 'chaos theory') and aim at an improved characterization of the complicated, apparently irregular behavior of complex nonlinear dynamical systems such as the brain. They provide a methodologically different approach to EEG analysis, which in general is based on the reconstruction of the dynamics in a so-called 'state space' – e.g., via the so-called method of delays (time-delay embedding). The Cartesian state space is spanned by all state variables (i.e., the number of degrees of freedom) of a dynamical system, and the system dynamics generates a trajectory through this space. Properties of the trajectory in state space can then quantitatively be characterized by nonlinear measures. It should be noted that the embedding

of an EEG time series in state space is regarded as a crucial point in nonlinear EEG analysis. An improper state space reconstruction is a common source of errors and can lead to a mischaracterization of the dynamics.

A number of univariate and bivariate nonlinear measures are now available, and their ability to detect predictive features in the EEG has already been evaluated in a number of studies. Univariate nonlinear measures comprise an effective correlation dimension, correlation density, entropy-related measures, or Lyapunov exponents, which allow one to draw inferences about the number of degrees of freedom (or complexity), the amount of order or disorder, or about the degree of chaoticity or predictability in a single EEG time series. Other measures provide an estimate of the amount of nonstationarity or allow one to discriminate between deterministic and stochastic dynamics. Bivariate nonlinear measures such as similarity index, phase synchronization, nonlinear interdependency, and other measures for generalized synchronization allow one to estimate dynamical interactions between two EEG time series. Some of these approaches can provide information about the direction of interdependence.

Assessing the Performance of a Seizure Prediction Algorithm

Usually, algorithm performance requires optimizing numerous computational parameter choices and sometimes the choice of an estimation algorithm. These choices often rely on a posteriori knowledge, which interposes significant risk of in-sample overtraining, resulting in seemingly good results just by chance. To avoid the potential for fitting results to the data and to enable independently reproducible results, application of control tests and independent validation is essential. The currently available statistical methods for assessing the performance of seizure prediction techniques comprise analytical, stochastic, and surrogate-based approaches. The analytical approach makes use of the so-called seizure prediction characteristic and compares the sensitivity of a method under investigation with the performance of an unspecific, naïve (random or periodic) predictor. The stochastic approach incorporates an underlying stochastic model for seizure generation and allows for modeling of a so-called permissive preictal state that is able to return to a baseline state without giving rise to a seizure. Surrogate-based approaches test the null hypothesis of the nonexistence of a preictal state, do not assume specific models for the development of a preictal state, and can be applied to any type of analysis, algorithmic or statistical. Seizure time surrogates are artificial seizure onset times generated by randomly shuffling the original interseizure intervals. With surrogate seizure onset times, the EEG data are subjected to the same analysis algorithms and prediction statistics that were used for the original onset times, including any in-sample optimization carried out in the process. Measure profile surrogates are derived from a constrained randomization of the time profile of a characterizing measure with seizure onset times kept fixed. With these approaches, the null hypothesis can only be rejected if the performance of the algorithm for the original data is better than the performance for a number of independent realizations of the surrogates, indicating that a given algorithm can detect a preictal state with a performance above chance level. It is important to keep in mind, however, that the fact that the null hypothesis cannot be rejected does not prove its correctness, since there may be alternative explanations for this result.

Recent Results

Despite the proof-of-principle evidence for the existence of a preictal state, many previous studies provided an overoptimistic view on the performance of prediction algorithms. More recent studies showed that findings obtained by applying highly optimized algorithms to small, selected data sets could not be reproduced on unselected, more extended EEG recordings that are more closely related to the challenge of predicting seizures prospectively from the continuous EEG. The overt initial enthusiasm has now given way to careful introspection. There is now a focus on meticulous data acquisition, annotation, study design and rigorous statistical design of prediction studies, and validation of results. Seizure prediction is now defined as reliably identifying periods of time in which there is increased probability of seizure onset.

The state-of-the-art of the field does not allow us to definitely answer the question of whether seizures can be predicted using prospective algorithms – despite the availability of intracranial, continuous, multiday, multichannel EEG recordings, a multitude of refined EEG analysis techniques, and the more rigorous methodological design in recent studies using statistical methods for performance assessment. Although a few studies have used prediction algorithms in a quasi-prospective manner, these studies have not included a statistical validation or have not allowed conclusions based on statistical validity.

From a number of retrospective studies that included rigorous statistical validation, strong evidence has accumulated that particularly measures quantifying relations between recording sites appear to perform significantly better than do random prediction. These measures allowed identification of a state of increased seizure likelihood lasting up to several hours, but seizures could not be predicted with exact timing. Whether this accuracy is sufficient for a prospective clinical application will need to be decided on an individual basis. Interestingly, some studies reported that recording sites carrying relevant information were not in close vicinity to the epileptic focus, but could be located in remote or even contralateral

brain structures. This finding supports the notion of an epileptic network whose interactions extend over large regions of the brain rather than the concept of a localized and well-defined epileptic focus.

Future Goals

A major challenge in working on seizure prediction is to establish convincing evidence for the existence of a preictal state in prospective studies. In addition, seizure prediction studies must offer an appropriate model for its characteristics in human epilepsy (both in adults and children), and take into account the heterogeneity of the disease. This approach may help to single out candidate epilepsies or candidate seizure types, for which prediction-based intervention techniques can be considered as an alternative therapy option. One should keep in mind, however, that such studies require large, high-quality, meticulously collected and annotated data archives that are well-characterized and represent the heterogeneity of patterns and patients found in human epilepsy.

To gain deeper insights into mechanisms underlying ictogenesis, future studies should address the following questions: What is the period of time over which seizures are generated? What components of the epileptic network are necessary for clinical events to occur? What is the role of high-frequency oscillations in ictogenesis? How are precursors distributed temporally and spatially in brain? What are effective intervention strategies for modulating this process? Together with an improved understanding of the interictal period and all of its confounding variables, answers to these questions might help to refine already existing approaches in order to increase predictive performance, to develop new analysis concepts and measures, and to guide basic science investigations to specific mechanisms. Such studies, however, have to be designed with great care, and with an acute awareness that as we delve deeper into seizure generation, we may be confronted with other, yet unforeseen problems. Along these lines, there is a great need for new analysis methods, using multivariate techniques, to analyze data streams from multiple sensory sites simultaneously, and even to sample at multiple temporal and spatial scales (from single neurons to ensembles, from local to global networks), and to investigate the physiological substrate for larger-scale quantitative observations. In this context, more work on spontaneously seizing animal models of epilepsy will allow access to deep brain structures and other locations in the epileptic network that cannot be explored in human studies because of safety concerns.

Finally, another issue of potential importance is to improve neurocomputational modeling of the dynamics of neuronal networks underlying the transition to seizures. Models currently available are mostly used to investigate epileptic phenomena at different levels of complexity within specific situations. They share, however, the common feature of providing insight into mechanisms involved in the generation of epileptic activity either at a microscopic or a macroscopic level. Research along this line may help to integrate the plethora of experimental data available, to improve analysis concepts and measures, and to test various hypotheses concerning preictal brain dynamics and its relation to endogenous and exogenous control parameters.

It is clear that these investigations require interdisciplinary research and collaborations.

Seizure Termination and the Postseizure Refractory Period

R F Berman, University of California Davis, Davis, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Seizures are typically self-limiting, synchronous electrical discharges of neurons within circuits or systems of the brain. A great deal is known about the epidemiology, pathophysiology, and the treatment of seizures and seizure disorders. However, much less is known about the cellular mechanisms that stop seizures once they begin (Lado and Moshe, 2008), or that may underlie the postseizure refractory period when the brain shows increased resistance to subsequent seizures. Indeed, most seizures stop on their own, with typical durations in the range of tens of seconds. **Figure 1** shows an example of a brief, self-limiting seizure episode recorded from a rat hippocampus 30 s after an i.v. injection of 0.5 $mgkg^{-1}$ bicuculline, a $GABA_A$ receptor antagonist. The initial burst of seizure activity lasted approximately 50 s, followed after a delay by a lower frequency secondary afterdischarge, and then a period of postictal EEG flattening when the hippocampus is typically partially refractory to further seizures activity.

The self-limiting nature of most seizures can also be seen in clinical epilepsy. Video-EEG monitoring of five major seizures types in hospitalized patients shows an average duration of 18.5 s for tonic seizures, 28 s for simple partial seizures, 66 s for primary generalized tonic–clonic seizures, 78 s for complex partial seizures, and 130 s for secondarily generalized tonic–clonic seizures (Jenssen *et al.*, 2006). Prolonged life-threatening catastrophic seizures can occur as in *status epilepticus*, reflecting a failure of normal seizure-terminating mechanisms. The fact that most seizures are self-limiting suggests the operation of some cellular mechanism, or mechanisms, to terminate ictal activity. The purpose of this review is to summarize some of what is known about why seizures stop once started. Research on the cellular mechanisms that contribute to the termination of the ongoing seizure activity is important, because such information may provide new insights into the mechanisms of seizures (and the patterning of seizures over time), as well as indicate new strategies for developing effective therapeutics agents for seizure control.

Background – Problems in Studying How Seizures Stop

While the question of why seizures stop is clear, it is less evident how to answer this question experimentally. This deceptively simple question about why seizures stop is unavoidably tied to questions about why seizures occur. That is, part of the difficulty lies in the fact that seizures can be caused by one (or more) of several brain mechanisms (e.g., channelopathies, mis-wiring of brain circuits, abnormal metabolism, neurochemical disturbances, etc.). Further, there are many different types of seizures, each associated with different, and sometimes overlapping, cellular mechanisms. There are also technical difficulties in determining which neural mechanisms stop seizures that are independent of those mechanisms initiating and maintaining seizures. This challenge arises because seizure-sustaining and seizure-ending cellular mechanisms can occur together during the development and the progression of seizures.

A second type of problem is that models of epilepsy typically model only specific aspects of epilepsy, or are specific to a subtype of epilepsy. For example, the application of penicillin to the cortex has been used to model a localized cortical seizure focus, while intraperitoneal injections of γ-hydroxybutyrate (GHB) are commonly

Introduction

Seizures are typically self-limiting, synchronous electrical discharges of neurons within circuits or systems of the brain. A great deal is known about the epidemiology, pathophysiology, and the treatment of seizures and seizure disorders. However, much less is known about the cellular mechanisms that stop seizures once they begin (Lado and Moshe, 2008), or that may underlie the postseizure refractory period when the brain shows increased resistance to subsequent seizures. Indeed, most seizures stop on their own, with typical durations in the range of tens of seconds. **Figure 1** shows an example of a brief, self-limiting seizure episode recorded from a rat hippocampus 30 s after an i.v. injection of 0.5 $mgkg^{-1}$ bicuculline, a $GABA_A$ receptor antagonist. The initial burst of seizure activity lasted approximately 50 s, followed after a delay by a lower frequency secondary afterdischarge, and then a period of postictal EEG flattening when the hippocampus is typically partially refractory to further seizures activity.

The self-limiting nature of most seizures can also be seen in clinical epilepsy. Video-EEG monitoring of five major seizures types in hospitalized patients shows an average duration of 18.5 s for tonic seizures, 28 s for simple partial seizures, 66 s for primary generalized tonic–clonic seizures, 78 s for complex partial seizures, and 130 s for secondarily generalized tonic–clonic seizures (Jenssen *et al.*, 2006). Prolonged life-threatening catastrophic seizures can occur as in *status epilepticus*, reflecting a failure of normal seizure-terminating mechanisms. The fact that most seizures are self-limiting suggests the operation of some cellular mechanism, or mechanisms, to terminate ictal activity. The purpose of this review is to summarize some of what is known about why seizures stop once started. Research on the cellular mechanisms that contribute to the termination of the ongoing seizure activity is important, because such information may provide new insights into the mechanisms of seizures (and the patterning of seizures over time), as well as indicate new strategies for developing effective therapeutics agents for seizure control.

Background – Problems in Studying How Seizures Stop

While the question of why seizures stop is clear, it is less evident how to answer this question experimentally. This deceptively simple question about why seizures stop is unavoidably tied to questions about why seizures occur. That is, part of the difficulty lies in the fact that seizures can be caused by one (or more) of several brain mechanisms (e.g., channelopathies, mis-wiring of brain circuits, abnormal metabolism, neurochemical disturbances, etc.). Further, there are many different types of seizures, each associated with different, and sometimes overlapping, cellular mechanisms. There are also technical difficulties in determining which neural mechanisms stop seizures that are independent of those mechanisms initiating and maintaining seizures. This challenge arises because seizure-sustaining and seizure-ending cellular mechanisms can occur together during the development and the progression of seizures.

A second type of problem is that models of epilepsy typically model only specific aspects of epilepsy, or are specific to a subtype of epilepsy. For example, the application of penicillin to the cortex has been used to model a localized cortical seizure focus, while intraperitoneal injections of γ-hydroxybutyrate (GHB) are commonly

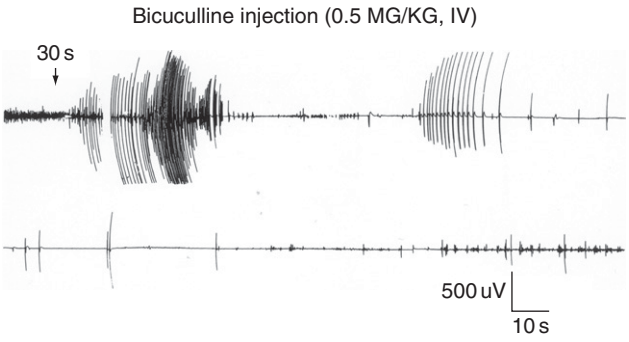

Figure 1 Seizures recorded from the hippocampus induced by 0.5 mg kg^{-1} i.v. bicuculline injection. Seizures began approximately 30 s after injection, resulted in a primary afterdischarge, and a secondary discharge followed by a period of postictal EEG flattening where the EEG was isoelectric. Reproduced from Berman *et al*. (2000).

used to produce spike and wave discharges (SWD) that model absence seizures. Answers about why seizures stop in one model may not apply to other models or types of epilepsy. For example, in vitro models, including low Mg^{2+}, low Ca^{2+}, or elevated K^+ in brain slices, are particularly well suited to discover the cellular mechanisms underlying seizures (and by extension, epilepsy), but results from such studies may not readily generalize to clinical seizures/epilepsy. In vivo animal models, including those developed in nonhuman primate, cat, and rodent, while more realistically modeling clinical epilepsy, still require assumptions that may not be valid when generalizing results to clinical epilepsy. Finally, research carried out directly in human epileptic patients poses its own set of difficulties, including ethical concerns associated with human experimentation, difficulties in controlling the onset and patterning of seizure in a clinical research setting, and obvious difficulties in obtaining tissue for cellular and molecular studies.

Even when such challenges are overcome, the fact that seizures can result in global disturbances in brain activity and metabolism makes it particularly difficult to isolate specific mechanisms central to seizure termination. For example, measurements of specific changes in brain levels of neurotransmitters (e.g., GABA) or neuromodulators (e.g., adenosine) that may be important for stopping seizures can easily be masked or overshadowed by global, and often massive, changes in brain chemistry or metabolism that are involved in triggering and maintaining the seizure activity itself. As an additional example, in vivo microdialysis and ion selective microelectrodes can measure neurochemical and ionic events during either the triggering or stopping of seizures, but are limited to measuring extracellular molecules and ions. As a result, these techniques cannot directly measure intracellular processes that may be particularly relevant to understanding why seizures stop.

Methods

Several in vitro and in vivo models of epilepsy are used to try to understand why seizure stops. Studies of epileptiform spiking in neurons are often carried out in vitro in 400–500 μm thick brain slices cut from the hippocampus or cortex and maintained in culture for hours, or sometimes days. A particularly elegant preparation is the organotypic slice preparation which can be maintained in culture for several weeks. Such slices retain synaptic circuitry capable of supporting seizure activity. Importantly, seizures can be evoked in such brain slices by electrical stimulation of specific fiber pathways (e.g., perforant path axons; Schaffer collateral axons), pharmacological blockade of inhibitory circuitry (e.g., GABA receptor antagonists such as bicuculline), increasing (e.g., K^+) or decreasing (Ca^{2+}, Mg^{2+}) extracellular ion concentrations in the bathing media surrounding the slice, or by activating excitatory circuitry with specific agonists (e.g., glutamatergic agents such as kainic acid). In vivo methods for producing seizures in animal models include the use of chemical convulsants (e.g., fluorothyl; pentylenetetrazol, kainic acid), electrical stimulation (e.g., electroconvulsive shock, electrical kindling, etc.), and the generation of an epileptic focus using focal injections of alumina gel or penicillin into the cortex.

While typically used to study the genesis of seizures, these models are also used to understand why seizures stop, as well as to describe the endogenous anticonvulsant mechanisms in the brain. The research strategy in these model systems is to evoke seizure activity and study the electrophysiological and molecular events that occur in the tissue over the course of seizure activity, concentrating on those events that occur coincident with the cessation of electrographic seizure activity. For example, limbic seizures can be gradually induced by daily electrical stimulation of the amygdala, in a process known as kindling. Implanted microdialysis probes can then be used to sample the chemical environment (i.e., ions, neurotransmitters, neuromodulators) in brain regions showing kindled seizure activity, before, during, and after a seizure episode. Such studies have already provided strong evidence for an endogenous anticonvulsant activity of adenosine as described later in this article.

An alternate approach is to modify some aspects of synaptic circuitry (such as receptor density, second messenger signaling systems, neurotransmitter levels or gene expression) to see how this modification changes the threshold for producing a seizure, or the duration or severity of the seizure. In animal models, this approach often involves the use of genetically altered mice (e.g., receptor knockout or knock-in mice), in which a specific change, sometimes in a specific brain region, can be studied for its effect on seizures. In contrast, studies in humans rely

mainly on relatively noninvasive procedures such as EEG recordings, and MRI and PET imaging procedures to try to understand the electrical, chemical, and metabolic changes that occur in the brain during and after seizures.

Recent Findings

Cellular Mechanisms

Mechanisms that terminate the ongoing seizure activity have been described at the cellular level, and involve changes in sodium, potassium, and calcium channel activity. Specifically, sustained excitatory input during seizures can generate large (20–40 mV) and prolonged (50–200 ms) depolarization of neurons and trigger trains of action potentials. This pattern of prolonged depolarization and high frequency firing of neurons has been called the paroxysmal depolarizing shift (PDS), and epileptiform cortical EEG activity appears to reflect this underlying cellular depolarization. Large and sustained depolarization during seizures also activates calcium- and sodium-dependent potassium channels resulting in substantial potassium efflux into the extracellular space. Extracellular $[K^+]_0$, normally around 3 mM, rises during a PDS to 5–7 mM, and during prolonged seizure activity to as high as 10–12 mM. This large increase in $[K^+]_0$ initially contributes to further membrane depolarization and increased firing. However, prolonged depolarization and the rise in extracellular potassium can cause depolarization blockade, resulting in the cessation of firing, at least in part, through the inactivation of sodium channels. In a recent computer simulation of model neurons, repetitive firing of action potentials did not result in seizure activity, and ion shifts were relatively minor (Kager *et al.*, 2007). However, when the simulated Na^+/K^+ pump current or the glial membrane conductance were depressed, potassium accumulated in the extracellular space and produced regenerative seizurelike electrical discharges. Such studies emphasize the importance of nonsynaptic (i.e., ionic) mechanisms for seizure generation. Decreased extracellular calcium levels during seizures may also play a role in stopping seizures. Measurements with ion-selective electrodes, in brain slices or in vivo, also show a large decrease in extracellular Ca^{2+} beginning with the onset of the seizure discharge, indicating calcium influx into neurons at the seizure focus. Such a decrease in extracellular calcium could limit calcium-dependent release of excitatory neurotransmitters (e.g., glutamate) and contribute to the stopping of seizure activity.

In one of the few studies directly examining the cellular mechanisms underlying the termination of epileptic afterdischarges in the hippocampus (see **Figure 2**), investigators observed that afterdischarges produced in the hippocampus by electrical stimulation of the perforant path or commissural fibers were followed by a slowly spreading (0.1–0.2 mm s^{-1}) negative DC potential that began in the distal apical dendrites of CA1 pyramidal cells (e.g., around the hippocampal fissure) and slowly spread to the pyramidal cell layer.

A similar slowly spreading DC potential occurred with the termination of the afterdischarge in the dentate gyrus/CA3 region, after which the EEG became isoelectric (i.e., postictal EEG depression). The authors suggested that stimulation-induced epileptiform afterdischarges were terminated by a

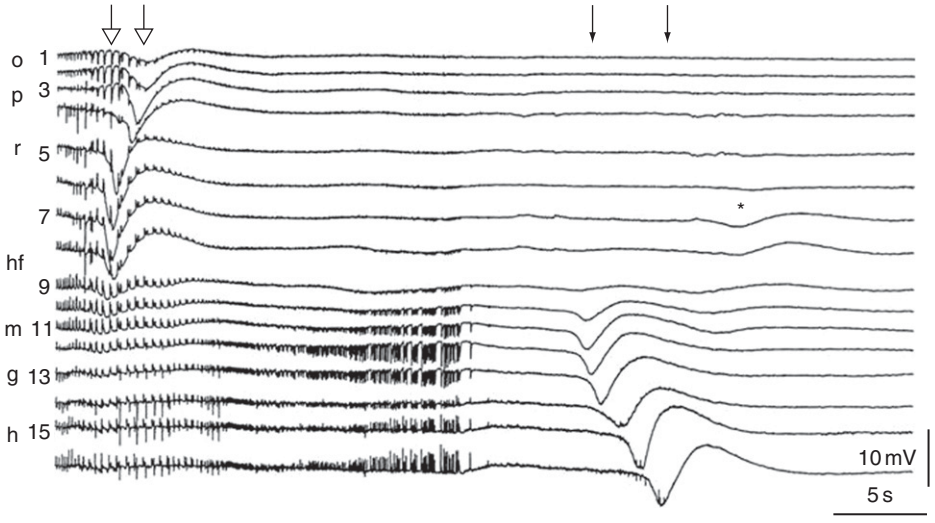

Figure 2 Extracellular recordings of a propagating epileptiform afterdischarge in the CA1-dentate gyrus in the awake rat. Multielectrode recording shows the large DC potential that began in the apical cell layer near the hippocampal fissure (electrode 8) and spreading to the CA1 pyramidal cell layer (electrode 3) at 0.28 mm s^{-1} (open arrows) and later into in the dentate gyrus (filled arrows) at 0.12 mm s^{-1}. Reproduced from Bragin A, Penttonen M, and Buzsaki G (1997) Termination of epileptic afterdischarge in the hippocampus. *Journal of Neuroscience* 17(7): 2567–2579, with permission from Society for Neuroscience.

depolarization blockade of principle cells, followed by a pervasive spreading depression of neuronal activity.

In summary, prolonged and intense seizures can generate large changes in ion homeostasis, including up to a three- to fourfold increase in extracellular potassium with a subsequent depolarization blockade of neuronal firing and termination of epileptiform activity.

Energy Metabolism and Seizure Termination

Altered energy metabolism can also influence the duration of seizures. The cerebral metabolic rate is higher during seizures than during virtually any other state of brain activity, as reflected in a large increase in oxygen uptake, glucose uptake, glucose metabolism, and elevated ATP levels. Increased cerebral blood flow and vasodilation also occur during seizures. In rodents a single electroconvulsive seizure can elevate glucose metabolism for up to 1 h throughout the postictal period.

In general, if arterial blood pressure, arterial oxygenation, and blood glucose concentrations are maintained, enhanced metabolism during seizures can be sustained in excess of one hour.

In contrast, prolonged seizures, as in *status epilepticus*, produce a dramatic fall in energy stores in the brain, depleting levels of brain glucose, glycogen, phosphocreatine and ATP, and decreasing intracellular pH. This finding has contributed to the radical hypothesis that seizures may actually be an adaptive response of the brain to energy failure, particularly failure of microchondrial respiration, with seizures producing vasodilation, increased cerebral blood flow, and greater glucose availability. According to this hypothesis, when energy balance is restored, seizure activity stops. Indeed, hypoglycemia can cause seizures in humans and animals and can potentiate flurothyl-induced generalized seizures, indicating that low systemic levels of glucose are proconvulsive. Interestingly, [^{18}F]fluorodeoxyglucose imaging during the interictal period in humans shows hypometabolism in brain regions showing EEG seizure activity. Such hypometabolism may be a hallmark of an epileptic focus, although neuronal loss due to seizures may also contribute to reduced regional brain metabolism.

Extracellular adenosine triphosphate (ATP) levels are also elevated during intense seizure activity, and elevated ATP levels have been suggested to activate the inwardly rectifying K_{ATP} channel Kir6.2, hyperpolarizing neurons in the substantia nigra pars reticulata (SNr). The SNr has been suggested to serve as a gateway for the propagation of cortical seizure activity, with decreased firing of SNr GABAergic neurons associated with a decreased spread of seizure activity. Because the SNr has been argued to function as a central gating system for the propagation of seizures, its inactivation by Kir6.2 channel activity could represent a mechanism for protection against the development and the spread of generalized seizures.

GABAergic Inhibition

γ-Aminobutyric acid (GABA) is one of the major rapidly acting inhibitory transmitters in the nervous system, and the loss of GABAergic inhibition has been argued to underlie many types of epilepsy. Therefore, the activation of GABA-mediated inhibition may also play a role in the stopping of seizures. GABA mediates the inhibitory activity through opening GABAergic Cl^- ($GABA_A$) or K^+ ($GABA_B$) ion channels, producing hyperpolarization of target neurons. Extracellular levels of GABA rise with the seizure onset in rodents and in human epilepsy, and feed-back and feed-forward inhibition through GABAergic circuitry has been hypothesized to create a powerful inhibitory zone that serves as a barrier to the seizure activity and the seizure spread. In general, such synaptic modulation via the GABAergic system is thought to provide tonic inhibition in the brain, providing a barrier to the pathological excitatory activity that occurs during a seizure.

The focus on GABA is also based on the fact that the enhancement of GABAergic inhibition in the brain is the primary molecular mechanism of action of many, if not most, antiepileptic medications, including the benzodiazepines and barbiturates. Other anticonvulsants, such as γ-vinyl GABA (vigabatrin) and tiagabine potentiate GABA-mediated inhibition of neuronal activity by inhibiting GABA-transminase or GABA uptake, respectively. Conversely, proconvulsant drugs such as picrotoxin, pentylenetetrazol, and *t*-buryl bicyclophosphorothionate (TBPS) decrease the mean $GABA_A$ channel open time and reduce the inhibitory activity.

Changes in pH and Seizure Termination

Neuronal activity elicits substantial changes in intracellular and extracellular pH, and it has been proposed that changes in intracellular pH (pH_i) may have a role in terminating seizures. Paroxysmal epileptiform afterdischarges evoked in rat dentate gyrus cause acidification (0.07–1.5 pH units) in the interstitial fluid of the dentate. The acidification has been attributed to the production of CO_2 and other acid metabolites such as lactate. Extracellular acidification, produced experimentally by increasing CO_2 levels or directly acidifying the bath media to pH 6.7 in the in vitro 0-Mg^{2+} model of epilepsy in hippocampal brain slices, increases the interval and decreases the maximal amplitude of seizurelike events, and lowers the rate of seizure propagation. Intracellular acidification also occurs during the paroxysmal activity evoked in hippocampal slices by incubation in 0 Ca^{2+} and high K^+; acidification occurs with each spontaneous field burst, with the lowest pH_i levels seen at the end of each burst and recovering to resting values over

approximately 20 min. Importantly, when pH_i decreases below a certain value, the paroxysmal burst stops, and the neurons are refractory to further burst activity until pH_i recovers by approximately 50%. Thus, intracellular acidification may contribute to the cessation of epileptiform discharges.

Because many cellular processes are pH-sensitive, intracellular acidification may be an important mechanism preventing neuronal activity from reaching levels that may threaten normal brain. The mechanisms underlying pH effects on epileptiform field bursts are unclear, but could involve proton sensitivity of the NMDA channel via an intrinsic proton sensor. When extracellular pH decreases, such as can occur during the epileptiform activity, NMDA receptors are inhibited and this could inhibit glutamate-associated seizure activity. Gap junction coupling has also been shown to be sensitive to pH_i with closure occurring at a low pH. Therefore, intracellular acidification following seizure activity could reduce gap junction coupling and prevent the development of astrocytic calcium waves that may contribute to the initial spread of seizure activity, thus facilitating seizure termination.

Adenosine

Several lines of evidence indicate that adenosine is important for terminating the ongoing seizure activity (Boison, 2005). Adenosine release has been shown to occur during seizures; adenosine agonists suppress seizures and raise seizure thresholds; and adenosine antagonists are proconvulsant. These actions are not surprising in view of the powerful inhibitory effect that adenosine has on synaptic activity and neurotransmitter release. The proposed mechanism for seizure termination by adenosine involves increased adenosine synthesis from ATP that is coupled to the dramatically increased metabolic demand generated by the seizure activity. Adenosine is synthesized by the hydrolysis of nucleotides (ATP, ADP, AMP) by several endo- and ectonucleotidases. Efflux of adenosine into the extracellular space, through a bidirectional transporter, allows adenosine to interact with cell-surface receptors (i.e., A_1, A_{2A}, A_{2B}, and A_3) to modulate the synaptic activity. Adenosine acts both presynaptically to inhibit the release of excitatory and inhibitory neurotransmitters (including glutamate, acetylcholine, norepinephrine, and GABA) and postsynaptically by hyperpolarizing neurons through an increase in potassium conductance.

As indicated earlier, extracellular levels of adenosine have been shown to increase during seizures in animal models of epilepsy and in human epileptic tissue. Specifically, in vivo microdialysis studies show substantial increases in the hippocampus of rats undergoing pharmacological seizures produced by kainate, bicuculline or pentylenetetrazol. Brief seizures produced by bicuculline can produce increases of up to twofold, while more severe and prolonged seizures produced by pentylenetetrazol can generate 4–5-fold increases. The anticonvulsant activity associated with the adenosine receptor activation appears to be primarily mediated via activation of the A1 receptor subtype. The increase in extracellular adenosine could therefore contribute to the termination of the ongoing seizure activity.

Systemic treatment with adenosine receptor agonists, or direct injection of adenosine agonists into a seizure focus, has been shown to block seizure activity, and to prolong postictal EEG flattening seen during the postseizure refractory period in the kindling model of epilepsy. **Figure 3** shows a typical epileptiform afterdischarge recorded from an amygdala-kindled rat pretreated with saline (a), an adenosine receptor antagonist, adenosine 5′-ethylcarboxamide (NECA) (b), or caffeine, an adenosine receptor antagonist (c). Compared to saline, NECA reduced the seizure duration and prolonged the period of postictal EEG flattening, while caffeine prolonged the seizure and eliminated the postictal EEG flattening.

The combination of *N*6-cyclohexyladenosine, an adenosine A1 agonist, with major antiepileptic drugs (e.g., diazepam, sodium valproate, diphenylhydantoin, phenobarbital, carbamazepine, etc.) shows an enhanced anticonvulsant

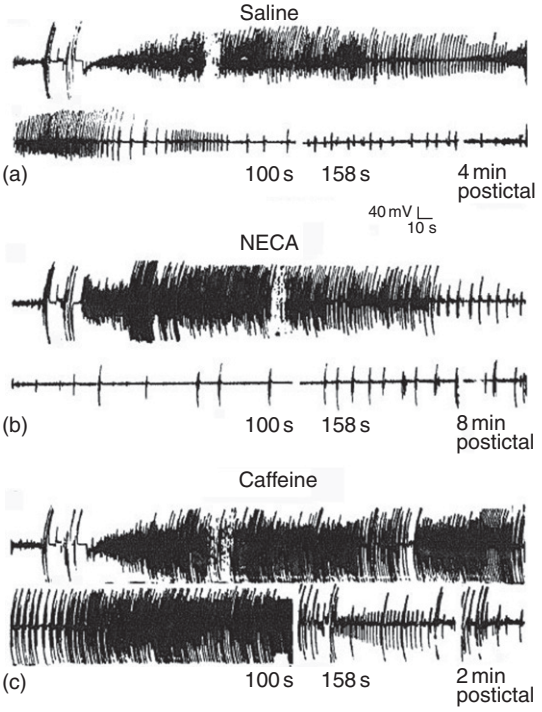

Figure 3 Prolonged epileptiform discharges recorded from the amygdala of an amygdala-kindled rat. (a) Preseizure treatment with saline, (b) 0.032 mg kg^{-1} NECA, or (c) 10 mg kg^{-1} caffeine. Compared to saline treatment, NECA shortened the seizure duration and prolonged the period of postictal EEG flattening. Caffeine prolonged the seizure and eliminated the posticatal EEG flattening. Reproduced from Whitcomb *et al.* (1990).

activity in mice against seizures produced by electroconvulsive shock or pentylenetetrazol. Adenosine reduces seizure activity in the rat hippocampus in the in vitro 0-Mg^{2+} model of epilepsy, and similar effects have been observed in slices of human epileptogenic cortex. Finally, inhibitors of adenosine kinase, which increase brain adenosine levels, are also anticonvulsant.

These studies are consistent with the hypothesis that adenosine release during a seizure can initiate a powerful adenosine-mediated inhibition of neuronal firing that would be expected to terminate seizures and render the brain refractory to further seizures, as long as adenosine levels remain elevated.

Neuropeptides as Endogenous Anticonvulsants

Several neuropeptides, including neuropeptide Y (NPY) and somatostatin (SS) have been shown to have anticonvulsive properties and could play significant roles in the termination of seizure activity. NPY is a 36 amino-acid neuropeptide that is preferentially expressed in GABAergic interneurons and is widely distributed in the mammalian nervous system. Recent findings indicate an important role for NPY in inhibiting the seizure activity. Specifically, mice lacking the NPY gene develop spontaneous seizures and show heightened susceptibility to evoked seizures. Administration of exogenous NPY suppresses seizures produced by a variety of chemical convulsants, suppresses absence seizures in genetically seizure-prone rats, and reduces epileptiform activity in hippocampal and cortical brain slices. The potent anticonvulsant effects of NPY are thought to be due to the activation of presynaptic Y_2 receptors which reduces calcium influx into presynaptic terminals and thereby inhibits glutamatergic synaptic transmission. A possible endogenous anticonvulsant role for NPY is also supported by the findings that it is released following the seizure activity, that the expression of NPY is increased after electrically or chemically induced seizures, and that overexpression of NPY reduces seizure susceptibility in rats. In a rat model of febrile seizures, the most common seizure type in infants and young children, a single prolonged (~24 min) febrile seizure increases the expression of NPY. This observation has led to the hypothesis that the enhanced NPY activity following a febrile seizure inhibits further seizure activity, resulting in the 'single seizure per febrile seizure' phenomenon seen in most children with febrile seizures. In brain tissue specimens from patients with severe drug-resistant mesial temporal lobe epilepsy, abundant sprouting of NPY fibers occurs in the hippocampus along with upregulation of Y_2 receptor, possibly representing an endogenous homeostatic anticonvulsant mechanism. Considered together, these findings suggest that the release of NPY may contribute to the termination of the seizure activity.

Somatostatin (SS) is a tetradecapeptide that was first identified as the anterior pituitary factor that inhibited growth hormone. Since that discovery, SS has been found in several brain regions, including the hippocampus, amygdale, and neocortex, where it is frequently found colocalized with GABA (in GABAergic neurons). Evidence for the fact that SS plays a prominent role in epilepsy includes demonstration of its release during seizures, modulation of SS gene expression and transcription by seizures, and a powerful inhibitory influence on neuronal firing, including anticonvulsant activity. The initial link between SS and epilepsy came from studies showing a loss of SS-containing neurons in the hilus of the dentate gyrus after seizures, and this loss is considered a common characteristic of an epileptic hippocampus. SS inhibits epileptiform activity in in vivo and in vitro hippocampal brain slices. Direct injection into the cerebral ventricles, hippocampus, or amygdala of rats reduces the severity and duration of seizures, and injection into the hippocampus of an antibody directed against SS accelerates the development of hippocampal kindled seizures. In the in vitro hippocampal brain slice preparation, SS inhibits epileptiform bursting in the 0-Mg^{2+} seizure model. The inhibitory effects appear to be mediated via hyperpolarization of neurons through an increase in two types of postsynaptic K^+ currents: a voltage-sensitive current and a voltage-insensitive potassium leak current. Finally, seizures cause a large and prolonged enhancement of SS mRNA expression in models of epilepsy such as kindling. As with NPY, the release of SS during seizures and its powerful inhibitory influence on neuronal activity suggest that SS could be involved in reducing discharge during seizures and thus contributing to seizure cessation.

Endocannabinoids and Seizures

Cannabis extracts have been used for centuries to treat epilepsy, and it is now known that these effects are due to the activity of a family of compounds known as cannabinoids in the extracts. Recent research suggests that endocannabinoids produced in the brain may have anticonvulsant and neuroprotective activity against excitotoxic seizures. Endocannabinoids (EC) are endogenous small lipid molecules, structurally related to the eicosanoids. The two major EC's are arachidonyl-ethanolamide (anandamide) and 2-arachidonyl glycerol (2-AG). They are synthesized by enzymatic activity in neurons and are released postsynaptically in an activity-dependent manner to retrogradely activate presynaptic G-protein coupled receptors. The principal cannabinoid receptor subtype in the nervous system is CB1R, which is localized on or near synaptic terminals. CB1R receptors are widely distributed throughout the brain, and the activation of the CB1R receptor inhibits the release of glutamate and

GABA by blocking presynaptic N-type voltage-gated Ca^{2+} channels. A clear role for EC and their receptors in seizure disorders has not yet been firmly established, but cannabinoid compounds such as Δ^9-tetrahydrocannabinol and WIN 55,212-2 (that activate CB1 receptors) have potent anticonvulsant properties against seizures produced by maximal electroshock in rats. The endogenous ligands anandamide and 2-AG also attenuate low-Mg^{2+} epileptiform activity in the rat in vitro hippocampal slice preparation. The enhancement of endogenous EC activity can be achieved by inhibition fatty acid amid hydrolase (FAAH), the primary mediator of hydrolysis of endocannabinoids. The inhibition of EC hydrolysis, using the FAAH inhibitor AM374, significantly reduces seizure severity as well as cellular markers of neuronal and synaptic damage in kainic-induced seizures in rats. Additional evidence for a neuroprotective function of endocannabinoids comes from studies of human postmortem hippocampal tissue from epileptic patients. The level of mRNA for the CB1 cannabinoid receptor in epileptic tissue, measured by RT-PCR, is reduced by up to 60% compared to control tissue, and the ratio of CB1-positive to CB1-negative axon terminals is reduced in glutamatergic axon terminals, but not in GABAergic terminals. These findings, while not proving that endocannabinoids are involved in seizure termination, do indicate that the endocannabinoid system can modulate seizure activity.

Summary and Directions for Future Research

Our current understanding of why seizures stop is incomplete, and the search for unifying principles continues in this area of research. It is probable that no single mechanism will be found capable of fully explaining the self-limiting nature of most seizures. Multiple inhibitory mechanisms appear to be engaged during seizures, and modulation of seizure activity occurs at several levels, from individual neurons to networks of neurons to more global regulation across brain regions. In spite of such challenges, the self-limiting nature of most seizures has been linked to several mechanisms, including depolarization blockade, pH changes, metabolic state, and the inhibitory actions of neurotransmitters (GABA) and several neuromodulators (e.g., neuropeptide Y, somatostatin, endocannabinoids, etc.). At the single cell level, it is likely that major shifts in ionic equilibria for K^+ and Ca^{2+} trigger nonsynaptic membrane events leading to depolarization blockade and inhibition of neuronal firing. At the synaptic level, several endogenous substances have been clearly implicated in limiting seizure activity. The best evidence to date may revolve around adenosine. Adenosine synthesis and release are linked to enhanced metabolic activity such as occurs during seizures; the powerful pre- and postsynaptic inhibitory actions of adenosine in the CNS are consistent with an endogenous seizure terminating anticonvulsant role. The neuropeptides NPY and somatostatin are also released during seizures and inhibit neuronal activity, albeit by quite different molecular mechanisms. Finally, the endocannabinoids, which are also thought to presynaptically block neurotransmitter release, have received a great deal of recent attention as endogenous anticonvulsants.

Future research should be directed to better isolate and define the critical events that occur at the time seizures stop, with the goal of identifying those events that are necessary and sufficient for the termination of seizures. If depolarization blockade and spreading depression play a central role in stopping seizures, as indicated by current research, then it will be necessary to better understand the cellular mechanisms underlying these phenomena. An important role for glia in regulation of brain excitability is also becoming clear, and their involvement in seizures, and stopping of seizures, should also become a focus of future research. Newer technologies will be needed that can measure, in real-time, changes in putative endogenous anticonvulsants during seizures activity, so that chemical events in the brain can be mapped directly on to the electrophysiological indices of seizure activity and seizure termination. Finally, it will be necessary to develop new pharmacological tools to study some of the more recently discovered substances that appear to have endogenous anticonvulsant activity.

Brain Mechanisms Linking Epilepsy to Sleep

G K Kostopoulos, University of Patras, Patras, Greece

Introduction

Even before proclaiming epilepsy independent of any malevolent deity, the Hippocratic school had already demystified sleep (God Hypnos in Greek mythology). The physicians of antiquity used sleep in their medical practice in various ways, and the relationship between sleep and epilepsy was recognized. Extensive clinical observations in the nineteenth century distinguished a large percentage of seizures (>20%) that occurred only at night (nocturnal), and a particular vulnerability to the occurrence of other types of epilepsy at awakening and sleep onset (i.e., transition times). Advances were made with the advent of electroencephalography (EEG) in the 1930s and with the widespread availability of polysomnography in the following decades, which led to the seminal series of studies that associated 'awakening seizures' to idiopathic generalized epilepsy (IGE) with tonic–clonic seizures. More recently, video-polysomnography and presurgical EEG monitoring have expanded and confirmed these associations, establishing the statistical likelihood of specific types of epilepsy to express their signs during particular sleep stages.

Aggravation of seizures by sleep would sound perhaps incompatible with the old ideas of sleep being a state of brain inhibition and restoration. Today, we know that sleep contains periods of intense neuronal activity, and that even when thalamic gates are closed to the outside world, intracortical dialogue is maintained. We distinguish three states of existence: awake, rapid eye movement sleep (REMS), and non-REM sleep (NREMS). Typically, as one goes to sleep, the low-voltage fast EEG pattern of wakefulness gradually gives way to slower frequencies, as NREMS goes from stage 1 (decrease in alpha) to stage 2 (spindles, K-complexes) to stage 3 and 4 (increasing amplitude and regularity of delta rhythm – see **Figure 1**(**a**)); stages 3–4 are therefore referred to as 'slow-wave sleep.' This pattern of change is the NREMS descending phase, which is followed by a more abrupt ascending phase (from stage 4 to stage 1) and an episode of REMS. Besides the characteristic saccadic eye movements, REMS is characterized by a high level of brain activity, the presence of low-voltage fast EEG activity (desynchronized EEG), the suppression of muscle tone, vivid dreaming, and the highest awakening threshold (therefore, 'paradoxical sleep'). In contrast, during NREMS, brain activity is reduced in most brain areas and thinking is usually nonvisual and ruminative. As displayed in the hypnogram in **Figure 1**(**b**), every night's sleep progresses through several such ~90-min-long NREMS–REMS cycles, with NREMS predominating in

Seizure-Induced Gene Expression

K Lukasiuk, The Nencki Institute of Experimental Biology, Warsaw, Poland

Introduction

Seizures, defined as a pathological increase in neuronal synchronization, are not just the characteristic symptoms of epilepsy, but can also have direct effects on the brain. In particular, prolonged seizures can produce neuronal damage and trigger cascades of biochemical events that can have long-term effects. These seizure events activate second messengers, transcription factors and gene expression, plastic phenomena (such as mossy fiber sprouting), neurogenesis, and altered neurotransmission – all of which may underlie consequent sensory-motor, developmental, and behavioral and cognitive deficits. Seizure-induced gene expression is of particular importance, since production of new proteins (or proteins at altered levels) provides the means for long-lasting alterations in brain functions. Analysis of alterations in gene expression can single out particular molecular mechanisms involved in such long lasting, potentially harmful, effects of seizures.

Background

Regulation of Gene Expression

In this article we focus on seizure-induced gene expression. While approaching this subject, one should be aware that the regulation of gene expression is a very complex phenomenon. By definition, regulation of gene expression refers to the control of the amount and timing of appearance of functional gene products, that is, RNAs and proteins. The process includes transcription as well as posttranslational modification of protein, which can be modulated at any step via any number of mechanisms.

The first level of regulation of gene expression relies on modification of DNA. Chemical modification refers to methylation of CpG islands by methyltransferase, a common way for silencing a gene. Structural modifications of DNA arise from phosphorylation or methylation of histones; histone acetylation is of special importance for regulation of transcription, since histone deacetyltransferases enable the dissociation of DNA from the histones and therefore allow transcription to proceed.

Progression of transcription and the efficiency of RNA synthesis depend on several components of the RNA polymerase machinery, including several regulatory proteins that bind to regulatory sites, usually located near the promoter. The regulatory proteins can be categorized according to their function as: (1) specificity factors that alter specificity of RNA polymerase for given promoter and repressors that bind to noncoding DNA sequences in the vicinity of the promoter and impede RNA polymerase's progress along the DNA strand; (2) basal factors which position RNA polymerase at the start of transcription, and activators that enhance RNA polymerase interaction at a given promoter either by interaction with RNA polymerase subunits or changing the structure of the DNA; and (3) enhancers that lead to changes in the three-dimensional structure of DNA and bring specific promoters into the vicinity of the initiation complex.

When RNA is synthesized, it undergoes further modifications which influence its stability, and therefore determine the yield of translation into protein. Capping protects mRNA from 5′exonuclease, splicing removes introns – noncoding regions – from RNA and allows translation into proper protein, and addition of poly(A) tail increases mRNA's stability by slowing down 3′exonuclease action.

All these regulatory mechanisms determine which genes are transcribed and at what efficiency. The number of mRNA copies of a given gene determines the translation into the protein and protein content in the cell. Additionally, translation and protein stability and trafficking are tightly regulated. The ultimate outcome is the tight control of the cell's structure and metabolism at a given moment in time.

It is, therefore, reasonable to ask whether gene transcription in the brain is regulated by seizures. Are there any regulatory mechanisms triggered by seizures? Studies have now shown that seizures can influence the transcriptional events on several levels. On the level of DNA modification, seizures regulate histone acetylation and phosphorylation on several promoters. There are also data showing that seizures affect the transcriptional machinery by activation of transcription factors, including transcription factors linked to maintenance of CpG islands like SP-1 or transcription factor complexes that provide means of tight control of transcription AP-1, cAMP response element-binding protein (CREB), the activating transcription factor-4 (ATF4), DREAM (downstream response element antagonistic modulator), NF-kappa-B, Nurr1, and others.

The fact that transcriptional events can be regulated by seizures leads us to the next question: What are the target genes which expression is regulated? We address this question in the coming sections, following a brief description of the methods used to study regulation of gene expression.

Methods

Methods Used for Studies of Activation of Gene Expression

Quantitative analysis of the mRNA content of selected genes of interest

One way of approaching the transcriptional activity of genes of interest is simply to evaluate the amount of its mRNA in the tissue. Through the years a number of methods have been mastered to achieve this goal. One of the oldest methods is Northern blot. For this application, RNA is isolated from the sample and then is separated by size, using gel electrophoresis. The RNA is transferred to a membrane which is then exposed to a radiolabeled, gene-specific probe. If the mRNA of interest is in the sample, the probe will specifically hybridize to the mRNA and produce a signal at the predicted size on the autoradiogram.

In situ hybridization provides a means of determining the pattern of mRNA expression at the cellular level. For in situ hybridization, fixed tissue sections with preserved cellular anatomy are used. The tissue sections are mounted on slides and prepared in a way that allows the labeled, gene-specific probe to have access to the cellular compartments and to hybridize with the mRNA present in the section. Radioactively labeled probe is then detected with X-ray film. To obtain cellular details, the slides can be coated with photographic emulsion; following development, the signal will be seen as silver grains (black dots) over the area containing the mRNA of interest. If fluorescently labeled probes are used, the results of hybridization are analyzed using standard fluorescent microscopy techniques.

Another powerful technique for quantifying the mRNA content is reverse transcription polymerase chain reaction (RT-PCR). The principle of this method rests on the propagation of mRNA species of interest from the minute quantities found in the starting material. For gene expression analysis, the first step is synthesis of cDNA on the basis of mRNA extracted from the studied tissue, using the enzyme called reverse transcriptase. This cDNA serves then to amplify cDNA representing the gene of interest; the procedure involves the application of a thermosTable DNA polymerase and gene-specific oligonucleotide primers which hybridize to cDNA of interest and allow the enzyme to attach to and synthesize DNA. The PCR reaction is cycled trough a series of temperature changes which provide the conditions for repeated cycles of: separation of DNA strands (e.g., at 94 °C), primer annealing (usually at 42–65 °C), and synthesis (at 72 °C). PCR results in very efficient amplification of DNA and is successfully used for evaluation of the level of mRNA expression, especially if real-time PCR is used, which allows quantification of amplification product in each reaction cycle.

Global analysis of gene expression

During the last decade, we have witnessed the rapid development of methods for the analysis of the whole transcriptome. Such methods do not require preselection of a gene of interest, and thus provide a means for unbiased analysis of global gene expression – which may result in detection of expression level alterations of previously unknown genes.

Historically, one of the first approaches to study a large fraction of the transcriptome was Differential Display. It is a RT-PCR-based method, used to identify differentially expressed genes. In differential display, mRNAs from the specimen are first reverse transcribed and then amplified using nonspecific primers. The array of bands obtained from a series of such amplifications is separated on a sequencing gel, and compared with analogous arrays from different samples. Any bands unique to a particular sample represent differentially expressed genes. The bands can be purified from the gel and sequenced.

SAGE (serial analysis of gene expression) and MPSS (massively parallel signature sequencing) are methods that involve creation of large number of short cDNA tags

(produced on the basis of studied mRNA), their subsequent sequencing, counting, and assigning to corresponding genes using bioinformatics tools. The frequency of a specific tag is related to the abundance of the corresponding mRNA in the cell, and this information allows for a comparison of mRNA expression of both known and novel genes in different samples. No a priori knowledge of the transcript sequence or mRNA abundance is required.

DNA microarrays are increasingly popular in studies of gene expression. They enable evaluation of the expression levels of thousands of genes at the same time, and thereby provide global insight into transcriptional events taking place in a studied phenomenon. The principle of DNA microarray technology is the hybridization of labeled cDNA synthesized on the basis of mRNA derived from the tissue of interest, to a microarray consisting of a large number of gene probes placed with high density on a solid surface. The strength of the hybridization signal associated with a particular gene probe reflects the abundance of the respective mRNA in the sample. There are currently two main types of microarrays: spotted microarrays and Affymetrix Gene Chips. In the case of spotted microarrays, the probe is usually spotted on a surface and is hybridized with fluorescently labeled cDNA. It is possible to perform simultaneous hybridization with cDNA from two different conditions (for example control vs. treated), with each condition labeled with a different fluorochrome. Detection of transcript using GeneChips, produced by Affymetrix (Affymetrix, Inc., Santa Clara, CA), relays on perfect match versus mismatch oligonucleotide probe pairs; several probes for each gene increase the specificity and reproducibility of the quantitative results. Microarray experiments require specialized bioinformatic tools for analysis of raw hybridization data as well as for extracting biological meaning from such data. Tools that suggest assignment of experimental data to known cellular and molecular pathways are readily available, and new possibilities for in-depth analyses are constantly emerging.

Promoter activity assays

An alternative method to study regulation of transcription is evaluating the transcriptional activity of the promoter of a gene of interest (instead of quantifying its mRNA level). This approach is usually carried out by introducing into the cells under study a plasmid or viral vector containing the reference gene under control of a promoter of interest. The reference gene usually codes for fluorescent protein (luciferase or green fluorescent protein), so that it can be easily measured by fluorescence or luminescence counter. The activity of the promoter is directly related to the amount of the detected reference protein. In this way the influence of a stimulus (e.g., a seizure) on transcriptional activity of a selected promoter can be assayed.

Animal Models of Seizures

The prerequisite for undertaking any experimental study on seizure-induced gene expression is identification of a proper animal model. Although human tissue coming from resections or autopsy is widely used in epilepsy research, it is of limited use in search for seizure-induced events. The molecular state of the tissue is heavily influenced by disease history and medication, which would be indistinguishable from the effects of seizures alone in such tissues.

Selection of the animal model depends on the specific questions being asked, and a wide range of characterized models is available (see Pitkänen and coworkers, 2006 in Further Reading). In some models, seizures can be evoked in otherwise normal animals by application of proconvulsant. Many such convulsive substances have been tested; the most frequently used are $GABA_A$ receptor blockers (pentylenetetrazol, bicuculine, picrotoxin, penicillin), excitatory amino acid receptor activators (kainic acidquisqualic acid, NMDA), acetylocholine-related substances (pilocarpine), strychnine, flurothyl, topical application of metals, and many others. Another way of inducing seizures in normal, nondiseased brain is electrical stimulation of the whole brain (electroshock) or defined brain structures (hippocampus, amygdala). Depending on the specific protocol and method of seizure induction, one can produce short seizures, or status epilepticus (which has much more pronounced consequences for the brain).

Seizures can also be studied in experimental animals that generate seizures spontaneously – that is, that are 'epileptic.' There are a number of rat (e.g., GAERS and WAG/Rij) and mouse (e.g., EL, tottering, staggerer, weaver) models that are genetically prone to develop seizures. A number of genetically modified mice have also been created that express an epileptic (i.e., spontaneous seizure) phenotype. Epilepsy can also be induced experimentally – by chemically – or by electrically induced status epilepticus, stroke, traumatic brain injury, or extensive kindling. Such animals become epileptic with time and express spontaneous seizures.

Some of these models have been successfully used to study seizure-induced gene expression.

Recent Results

The expression of a large variety of genes has been studied in response to seizure activity. Most of the data come from studies using status epilepticus as the seizure model, and only a few studies have monitored gene expression after single induced or spontaneous seizures. Selected papers describing changes in gene expression following brief, chemically or electrically induced seizures or kindling are summarized in **Table 1**. Recently, reviews of status epilepticus-induced gene expression as well as of

global analyses of gene expression have been published (see Further Reading section). In the coming sections, we summarize some of the genes that are most studied.

Transcription Factors

Seizures not only influence the activity of preexisting transcription factor proteins but also act by inducing their mRNA transcription. A number of seizure-induced transcription factors are immediate early genes. By definition, induction of immediate-early genes (IEGs) mRNA expression is rapid and does not depend on protein synthesis. Kindling, electroconvulsive seizures and chemoconvulsants have all been shown to markedly induce the expression of transcription factor mRNAs in the hippocampus and/or cerebral cortex. Among the best studied are components of AP-1 transcription factor (c-fos, c-jun, c-myc, jun-B, fra-1), krox-20, erg-1, erg-2, erg-3, Nurr 1 or CREM/ICER. Genes coding for transcription factors, following translation, can regulate the expression of other sets of genes. Targets genes for some transcription factors have been identified. For example, ATF4 and CREB regulate the expression of $GABA_BR1a$ and $GABA_BR1b$ isoforms of $GABA_B$ receptors, thus influencing neuronal excitability. The DREAM transcription factor regulates genes related to neuronal plasticity such as c-fos and preprodynorphin. The AP-1 transcription factor has been shown to regulate the expression of nerve growth factor (NGF), proenkephalin, and prodynorphin. Changes in the expression of such transcription factors can have long-lasting and pronounced consequences.

Neurotransmitter Receptors, Transporters and Ion Channels

Alterations in the expression of proteins related to the ligand and voltage-gated ion channels would influence the electrophysiological properties of neurons and glia, and therefore represent obvious candidates for studies of network excitability. Many changes in the expression of mRNAs coding for neurotransmitter receptors and ion channels have been described. For example, changes in mRNA expression for selected $GABA_A$ receptor (ligand-gated chloride channels that mediate fast inhibitory synaptic transmission) subunits have been reported following kainic acid, pilocarpine, or electrically induced status epilepticus as well as following kindling-induced seizures. Changes in the expression of mRNAs encoding metabotropic $GABA_B$ receptors occur following chemically or electrically induced status epilepticus or kindling. Expression of genes coding for the glutamate receptors, the major excitatory receptors in the brain, has been extensively described. Seizures induce alteration in the expression of several glutamate-gated ion channels, including NMDA, AMPA, and kainate receptor subunits, as well as metabotropic mGLUR5 and mGLUR1 glutamate receptors. Finally, expression of genes coding for sodium channels, calcium channels, hyperpolarization-activated cyclic nucleotide-gated cation channels, and glutamate transporters can be regulated by seizures. All alterations in the gene expression of neurotransmitter receptors and ion channels will lead to changes in the quantity or subunit composition of receptors and channels, at the synapse or

on other parts of cell membranes, and thus, influence synaptic function. Alteration in neurotransmitter transporter will modify neurotransmitter metabolism and the availability of neurotransmitter for synaptic transmission. Thus, such seizure-induced changes can have pronounced effects on neuronal excitability, and these changes can lead to functional abnormalities.

Neuromodulators

In addition to channels and receptors, many other factors – such as neurotrophins or growth factors – can affect neuronal excitability. Since neurotrophins can influence neuronal network excitability, their expression following seizures has been extensively studied. For example, seizures can induce neuropeptide Y (NPY) expression, which in turn can have a significant role in suppression of seizure activity. Seizures can also regulate the expression of BDNF (increase or decrease), NGF or NT-3, as well as neurotrophin receptors. Seizures have also strong potential for regulating expression of neuropeptides like dynorphin, somatostatin or prohormone convertase. All these changes in expression levels can contribute to seizures-induced plastic changes in the neuronal circuits.

Defense Proteins

Upregulation of the expression of genes coding for immune and defense proteins has been described repeatedly, mainly following status epilepticus. The proteins most often identified include interleukin-1 and-6 (IL-1, Il-6), tumor necrosis factor (TNF-a), leukemia inhibiting factor (LIF), and numerous heat shock proteins (Hsp) or heat shock cognate proteins (Hsc). These expression changes may be caused by status epilepticus-induced neurodegeneration, may reflect cell death, or may reflect the cell's attempt to switch on tissue repair mechanisms. Some of the immune proteins, like IL-6, have been shown to have a direct influence on neuronal excitability.

Structural Proteins

Seizures can influence the expression of number of genes which, by different means, can influence structural features of neurons, including structure of the synapse. A few of the many such genes include homer-1 (which is induced as an immediate early gene and codes for a scaffold protein that anchors metabotropic glutamate receptors to the cytoskeleton and regulates pyramidal neuron excitability) and immediate early gene Arc (an activity-regulated cytoskeletal-associated gene; Arc mRNA is targeted to recently activated synapses and locally translated into protein). Seizures also regulate cytoskeletal protein like α-tubulin or GFAP; vesicle proteins like chromogranin, secretogranin or clathrin; structural synaptic proteins like dystrophin; or extracellular proteins like tenascin or extracellular metaloproteinases and their inhibitors.

Insight from Global Analysis of Gene Expression Studies

Recent technologic developments allow the analysis of gene expression at the level of nearly the whole transcriptome, an approach that provides an unbiased insight into molecular events that occur in the brain following seizures or status epilepticus. Data coming from such experiments have shed new light on molecular phenomena and metabolic pathways involved in determining the effect of seizures on brain function. Studies using animal models (of both seizures and status epilepticus) have confirmed previous results about the effects of seizures on the expression of genes coding for neurotrophic factors, growth factors, ion channels and receptors, a number of plasticity-related genes, and other genes mentioned earlier. In addition, several new groups of genes have been identified, including those involved in angiogenesis, cell cycle and proliferation, protein synthesis, and chemokine signaling. Advanced bioinformatics tools have been used for data mining in order to group these genes into meaningful functional classes, and have been useful for highlighting the most prominent metabolic pathways.

Future Goals

The work of several laboratories over few past decades has uncovered a large number of genes that are induced in the brain by seizures or status epilepticus. These genes belong to a variety of functional classes, and can have effects on many aspects of cell metabolism/function. Despite this knowledge, we still lack a unifying theory about the role of seizure-induced gene expression in the brain. Especially now, in this "genomic era," we are faced with many new genes with unknown roles in the brain. Before we can understand the outcome of changed expression of the whole assembly of genes, we have to address several questions for each gene. Given the phenotypic cell diversity in the brain, the expression of a given gene of interest in neuron versus microglia versus astroglia versus endothelium can have quite a different outcome from the point of view of brain function. Further, neurons and glia display great diversity, and can be divided into a large number of subclasses. In addition to cellular localization of the transcription, one should consider localization within the brain (e.g., hippocampus, cortex) or localization within brain structures (e.g., cortical layer, hippocampal division).

In the case of many novel seizure-induced genes, it is still a challenge to define the consequences of altered expression because of the lack of information about the function of protein products. Even if we know the localization of transcription, in many cases the only other available information is gene sequence. The information available about the function of a gene (or gene product) in other tissues or cell lines cannot always be easily translated to the brain. Therefore, much basic research is needed before we understand the net effect of global alterations of gene expression in the brain, or even attempt to determine if a given alteration in gene expression is beneficial of harmful.

Seizure Initiation and Termination

J L Stringer, Baylor College of Medicine, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

A seizure is defined as an episode of excessive, synchronized neuronal activity associated with disturbance of sensation, loss of consciousness, convulsive movements, or combinations of these clinical signs. The precise combination is thought to reflect the brain regions that are synchronized in the discharge. Ever since electrical activity has been recorded in the brain, there has been reference to 'spontaneous' activity, the most marked form of which is seizure activity. Normally, brain activity does not appear to be highly synchronized. However, during a seizure, there is abnormal synchronization of brain circuits. Importantly, however, the occurrence of a seizure does not mean that the brain is abnormal. For example, seizures can be triggered in 'normal' brain by metabolic abnormalities such as hyponatremia and hypoglycemia, or by infection or inflammation. Every brain has a capacity to express a seizure.

The brain produces a variety of transient oscillations – synchronized activity in populations of neurons – that do not initiate seizures. This observation can be viewed in two ways. One is that there is a specific type of 'trigger' necessary to initiate a seizure. This trigger – such as an electrical shock – may itself produce excessive synchronization or may lower some threshold for seizure initiation. Alternatively, one could view the brain as having mechanisms that control the degree of synchronization; if these limiting factors fail, a seizure may begin. An example of such a process would be loss of inhibitory function in the cortex. Interestingly, if both excitation and inhibition are blocked, neurons tend to fire at a higher rate and in a more rhythmic pattern compared with activity during baseline conditions. This finding supports the idea that there are intrinsic mechanisms that determine neuronal excitability in brain networks, and that these intrinsic mechanisms could limit seizure initiation. Certainly, an active input (a trigger) could interact with loss of an

Introduction

Even before proclaiming epilepsy independent of any malevolent deity, the Hippocratic school had already demystified sleep (God Hypnos in Greek mythology). The physicians of antiquity used sleep in their medical practice in various ways, and the relationship between sleep and epilepsy was recognized. Extensive clinical observations in the nineteenth century distinguished a large percentage of seizures (>20%) that occurred only at night (nocturnal), and a particular vulnerability to the occurrence of other types of epilepsy at awakening and sleep onset (i.e., transition times). Advances were made with the advent of electroencephalography (EEG) in the 1930s and with the widespread availability of polysomnography in the following decades, which led to the seminal series of studies that associated 'awakening seizures' to idiopathic generalized epilepsy (IGE) with tonic–clonic seizures. More recently, video-polysomnography and presurgical EEG monitoring have expanded and confirmed these associations, establishing the statistical likelihood of specific types of epilepsy to express their signs during particular sleep stages.

Aggravation of seizures by sleep would sound perhaps incompatible with the old ideas of sleep being a state of brain inhibition and restoration. Today, we know that sleep contains periods of intense neuronal activity, and that even when thalamic gates are closed to the outside world, intracortical dialogue is maintained. We distinguish three states of existence: awake, rapid eye movement sleep (REMS), and non-REM sleep (NREMS). Typically, as one goes to sleep, the low-voltage fast EEG pattern of wakefulness gradually gives way to slower frequencies, as NREMS goes from stage 1 (decrease in alpha) to stage 2 (spindles, K-complexes) to stage 3 and 4 (increasing amplitude and regularity of delta rhythm – see **Figure 1(a)**); stages 3–4 are therefore referred to as 'slow-wave sleep.' This pattern of change is the NREMS descending phase, which is followed by a more abrupt ascending phase (from stage 4 to stage 1) and an episode of REMS. Besides the characteristic saccadic eye movements, REMS is characterized by a high level of brain activity, the presence of low-voltage fast EEG activity (desynchronized EEG), the suppression of muscle tone, vivid dreaming, and the highest awakening threshold (therefore, 'paradoxical sleep'). In contrast, during NREMS, brain activity is reduced in most brain areas and thinking is usually nonvisual and ruminative. As displayed in the hypnogram in **Figure 1(b)**, every night's sleep progresses through several such ~90-min-long NREMS–REMS cycles, with NREMS predominating in

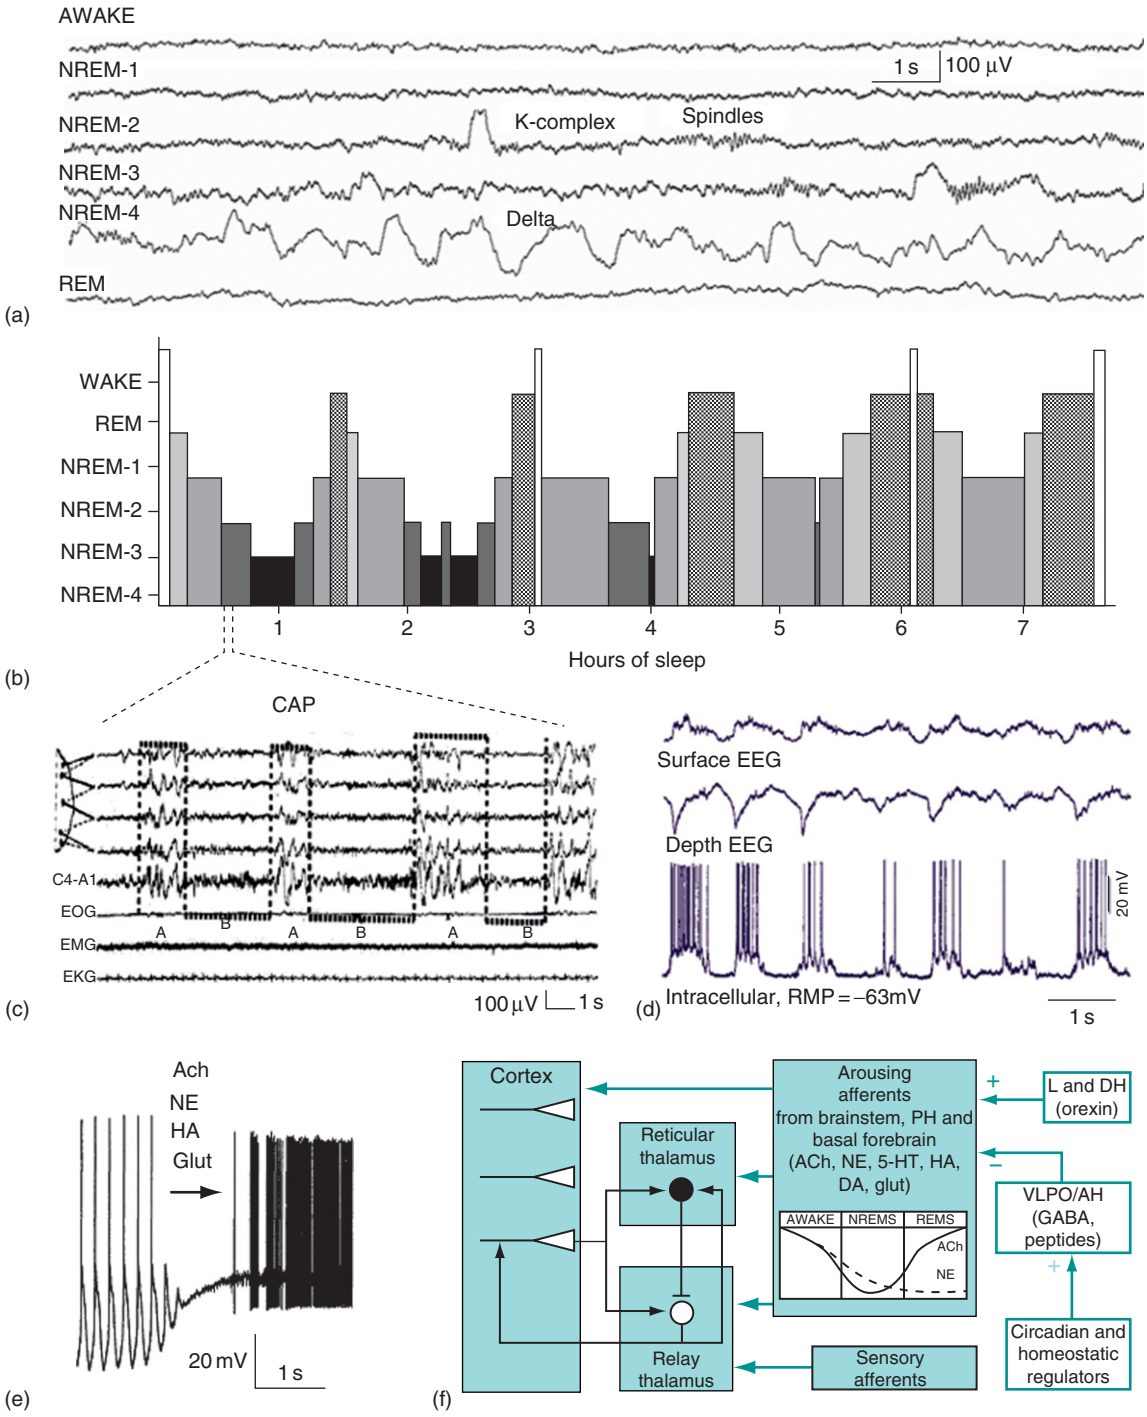

Figure 1 Mechanisms underlying EEG characteristics of sleep. (a) Characteristic EEG traces (all from CZ) from a human sleep. Note that compared with the wake condition the EEG of successive stages of non-REM sleep (NREMS-1 to NREMS-4) is characterized by an increase in power and decrease in frequency. Stage NREM-2 contains large negative or negative–positive waves called K-complexes, and spindles (a rhythm at 13–15 Hz). (b) Hypnogram of a night's sleep showing the time spent in each sleep stage. (c) During stages NREM-2–3 a CAP is observed, which clusters most of the prominent and globally synchronous EEG characteristics, like K-complexes and spindles, in periods ''A'' lasting a few seconds and alternating with rather quiet periods ''B''. Upper four traces bipolar parasaggital derivations from front to back. Next, monopolar recording of a central lead (C4), electrooculogram, electromyogram, and electrocardiogram. (d) experimental recordings from a sleeping cat brain. Note that EEG positive waves reflect negative field potentials in deeper lying cortical layers concomitant to depolarizing periods in a pyramidal neuron. The latter are termed 'up phases' and alternate with 'down phases' exhibiting hyperpolarization/disfacilitation. (e) Thalamic relay neurons appear to switch between two states of firing. In the hyperpolarized condition (left) the neurons tend to slowly oscillate and burst, while in the depolarized one (right) they tend to fire tonically and randomly. The first condition characterizes NREMS and precludes response to sensory input, while the second

the evening cycles (~75/15 min) and REMS increasing in the morning cycles (~60/30 min). NREMS in the morning cycles do not reach stage 4 (delta waves), and the longest part of a night's sleep is the stage 2 NREMS.

Although the importance of sleep is not questioned, and sleep deprivation (SD) can be life threatening, the exact role of sleep is still debated. It now appears that a crucial function of sleep is synaptic plasticity and homeostasis, and thus memory consolidation.

The link between sleep and epilepsy is reciprocal. Seizures have serious impact on sleep, and epileptic patients often have sleep deficits (even when seizure free). Antiepileptic drugs have highly variable effects on sleep organization, and antiepileptic chronic vagal nerve stimulation has been reported to improve alertness and sleep microarchitecture. Therapy for sleep disorders will undoubtedly benefit from a better understanding of the effect of seizures themselves, and of antiepileptic drugs, on sleep architecture. This article, however, will deal only with effects of sleep on epilepsy.

Understanding many types of epilepsy depends on understanding the mechanisms of sleep or SD, which influence them. This task is difficult and demands a systematic approach. One must examine how each of the physiological brain functions putatively involved in epileptogenesis (neuronal excitability and communication, synaptic plasticity and its homeostasis, network properties related to synchronization and/or rhythmicity, and the ability of the entire brain (and body) to express the particular seizure) is affected by the procession of sleep stages and their particular features. We are still far from hard answers, but clues from the clinical picture abound. After reviewing the clinical problem and the basic sleep mechanisms, this article will examine the recent advances showing how these mechanisms may affect epilepsy manifestations.

Background

The Clinical Problem and Questions from the Bedside

Nocturnal epilepsies are either idiopathic or hereditary and have variable course. Among types of partial epilepsy, seizures of frontal lobe epilepsy (nocturnal FLE) typically arise during NREMS – most often in stage 2 – and never during REMS. This is also the case with benign Rolandic epilepsy of childhood. In contrast, temporal lobe epilepsies (TLEs) do not show clear day–night preference. Patients with seizures arising from occipital or parietal lobes have rare sleep-onset seizures. Benign but not uncommon seizures, like those of Panayiotopoulos syndrome, tend also to occur during sleep. Seizures often present in children's sleep as continuous spike and wave discharges (SWD), or poly-SWD (as in Lennox–Gastaut syndrome), indicate predominantly nocturnal types of epilepsy. Of the epilepsies associated with awakening, most common are juvenile myoclonic epilepsy, absence seizures, and epilepsy with grand mal seizures on awakening. Typical absences appear particularly prone to present during drowsiness and transitions between sleep and arousal states. Awakening epilepsies are usually idiopathic or hereditary, with onset in childhood and usually a benign course. Epilepsies with random appearance (during the wake–sleep cycle) are more likely of symptomatic etiology, variable age onset, and relatively worse prognosis.

Although TLE patients have mostly daytime seizures, their EEG interictal epileptiform discharges (IEDs) are more often (and from more extensive neocortical areas) seen in NREMS stages 3 & 4 than in awake or REMS. In contrast, at NREMS 3 & 4, hippocampal spikes are suppressed and reach relative maximum in NREMS 2. This discordance between cortex and hippocampus suggests crucial differences in spike synchronization mechanisms between these two regions. Currently, we do not know which, if any, of the mechanisms involved in IEDs underlie sleep and/or epilepsy. What is apparent is that ictal and interictal events of a given seizure type may have different relationships to sleep.

IEDs increase after SD, a condition known to exacerbate most (perhaps all) seizure types, but more markedly IGE than partial epilepsies. Questions have arisen about whether the SD effect is due to the SD itself, to the fact that more sleep time is recorded after SD, or even to mechanisms underlying some stress associated with SD.

Obviously, questions from the bedside abound. Furthermore, some of them present intriguing paradoxes, warning

characterizes the wake and REMS states. Several synaptic transmitters may mediate this switch from the oscillatory non-responsive state to the tonic one (acetylcholine, norepinephrine, histamine, glutamate). (f) Simplified diagram of mechanisms underlying sleep initiation and maintenance focusing on the thalamocortical circuit pacing cortical rhythms. Filled and open neuronal somata denote inhibitory and excitatory neurons respectively. Among the subcortical modulatory influences, promoting the tonic rather than the oscillatory state of TC, the availability of acetylcholine in thalamocortical circuits synapses is high in both awake and REMS, while that of norepinephrine only in the awake condition. These arousing circuits are promoted (+) or inhibited (−) by other circuits indicated by their anatomical origin and neurotransmitter used (in parenthesis). AH, L&DH, PH respectively anterior, lateral and dorsal, and posterior hypothalamus; VLPO, ventrolateral preoptic nucleus; Ach, acetylcholine; DA, dopamine; HA, histamine; NE, norepinephrine; 5-HT, 5′-hydroxy-tryptamine; GABA, γ-amino-butyric acid; glut, glutamate. against attempts for simple explanations of an enormously complex, multifaceted, and dynamic relationship. From these observations, three fundamental questions arise: (a) What neurobiological differences make some partial epilepsies mostly nocturnal (i.e., NFLE) and some mostly diurnal (i.e., of occipital localization)?; (b) why does NREMS promote, and REMS antagonize epilepsy – i.e., what is peculiar about sleep stages with respect to epileptogenicity?; and (c) what is the neurobiological background of drowsiness and arousal state transitions that promote IGE seizure occurrence? In the following section, we will examine some of the fundamental mechanisms that differentiate neuronal behavior in the different wake–sleep states.

Sleep Mechanisms

During NREMS, there is an infra-slow oscillation (<0.02 Hz, 'cyclic alternating pattern,' CAP, **Figure 1(c)**) during which the synchronous EEG as well as motor and autonomic events appear to cluster together, thus creating successions of eventful phases 'A' and more quiet phases 'B'. Phases 'A' – and especially K-complexes – are considered sleep-promoting responses to endogenous or exogenous arousal stimuli.

A slow rhythm (<1 Hz) is nested within phase 'A,' which presents in individual neurons as sequences of hyperpolarizations ('down state' due to disfacilitation) followed by depolarizations ('up state,' when all activity patterns occur) (see **Figure 1(d)**). The transition from the down state to the up state is increasingly synchronized over wide brain areas as NREMS deepens (NREM 2 to NREM 4, **Figure 1(a)**), and often leads to large waves such as K-complexes or delta waves (**Figure 1(d)**). It is during the depolarizing 'up state' that spindles and higher-frequency rhythms like gamma may appear. Although the infra-slow and slow rhythms appear to be paced by cortical circuits, the pacemaker for the higher-frequency events is considered to be thalamic: thalamocortical (TC) neurons fire rhythmically in bursts when first hyperpolarized (**Figure 1(e)**), and impose this rhythm to cortical neurons responsible for generating EEG waves (**Figure 1(d)**). These neuronal events underlie the fundamental distinction between two states: a state of hypepolarized and bursting TC neurons that are not capable of accurately advancing sensory input to the cortex – which characterizes NREMS; and a state of depolarized TC neurons with tonic firing, with accurate response transmission properties – which characterizes the wake state (conscious processing of environmental input) and (in a different way) REMS (processing of 'internal' brain information).

The mechanisms responsible for the above two states of the TC circuits, which determine the wake–sleep cycle, are increasingly understood. Essential is the role of neurons of the reticular nucleus of thalamus, which are excited by both TC and cortical neurons, and which inhibit TCs as well as each other (**Figure 1(f)**). These neurons, like the TC neurons, have intrinsic currents promoting an escape from inhibition resulting in strong depolarization and burst discharge. The TC and cortical bursting reactivates reticular neurons, and their inhibitory feedback onto TC neurons maintains the rhythm at a frequency determined by the duration of the inhibitory periods imposed on the TC neurons.

Whether this thalamo-corticothalamic rhythmical reverberation will take place is determined by several subcortical inputs. The depolarized state of TC neurons, and therefore arousal, is initiated and maintained by a network of cholinergic neurons in the basal forebrain, histaminergic neurons in posterior hypothalamus, and glutamatergic neurons in the intralaminar thalamic nuclei. These TC neurons, as well as cortical neurons, are further modulated by brainstem afferents releasing norepinephrine (NE), serotonin (5-HT), and acetylcholine (ACh). Depolarization takes TC neurons from their inherent rhythmical bursting mode characteristic of NREM sleep to a tonic firing mode (**Figure 1(e)**), which is the mode compatible with their sensory transmission role and is mandatory for the awake state.

As we fall asleep, both cholinergic and aminergic neurons decrease their firing (**Figure 1(f)**), and so TC neurons return to their bursting mode. Initially, mutual excitation between TC and corticothalamic neurons elaborate the widely synchronous rhythm of spindles (NREMS stage 2). As TC neuron hyperpolarization becomes deeper, the even more synchronous and slower rhythm of delta waves appears (NREMS stage 4). To the extent that these rhythms persist, cortex cannot receive any information from the body or the external environment.

What, however, turns off the cholinergic and aminergic systems that support wakefulness? This role is attributed to active sleep mechanisms located in the ventrolateral preoptic (VLPO)/anterior hypothalamus (**Figure 1(f)**), and implemented through GABA and several peptide factors (including cytokines, growth hormone releasing hormone, and prolactin). Their inhibitory action on brainstem cholinergic and monoaminergic circuits is believed to be initiated by several influences, which constitute a circadian and a homeostatic regulator. The circadian circuit is controlled by pacemaker neurons in the suprachiasmatic nucleus, entrained to the day mainly by light. The homeostatic regulator increases its hypnogenic pressure as waking is extended; prolonged waking activates inducible nitric oxide synthase in the basal forebrain, which (through energy depletion) causes release of adenosine. Adenosine's hypnogenic action appears to be due to an inhibition of cholinergic neurons in basal forebrain and disinhibition of VLPO neurons. In sleep, metabolism is

slower and adenosine is cleared faster than it is produced. Interestingly, caffeine is a specific antagonist of adenosine receptors.

Apart from the waking condition, cholinergic neurons fire strongly also during REMS (**Figure 1(f)**) – and so in contrast to NREMS, TC are not allowed to oscillate and the sensory gate of the thalamus is open during REMS. However, the processing of environmental information is inhibited at higher or lower levels. Therefore, the TC circuits analyze only endogenous stimuli, to produce a dream content that has no time line or coherence due to inactivation of frontolateral cortex areas of working memory. Also, this content is highly emotional because of activation of limbic areas in REMS, and is not remembered because of lack of aminergic modulation. For REMS initiation, two types of 'switches' between REMS-on and REMS-off pontine circuits have been proposed, alternatively involving cholinergic/noradrenergic and GABAergic neurons. These regulate the activation of two glutamatergic projections to basal forebrain and ventromedial medulla, which respectively initiate the EEG features (desynchronization) and muscle paralysis characterizing REMS.

Methods

Electrophysiology has historically been the common thread in sleep and epilepsy research, supported by synaptic chemistry and pharmacology. Molecular biology has recently made some tremendous advances in both sleep and epilepsy research, but not yet so much on their interaction; computational modeling is increasingly used to theoretically explore this interaction. Electrophysiological experiments have provided clues from the level of whole brain EEG, to that of local field potentials, to the single cell membrane potential (**Figure 1(a), 1(d),** and **1(e)**). However, compared with the very long history of valid clinical observations, the experimental approaches to the mechanisms underlying sleep effects on epilepsy have been late and few. One inherent limitation has been the difficulty of applying reductionistic approaches (e.g., intracellular recordings, **Figure 1(d)** and **1(e)**), while carrying out long-term monitoring of a phenomenon as generalized in the brain – and as integrative of the whole body physiology – as sleep. The difficulty of combining good models of sleep and of epilepsy is further illustrated by the fact that most of the currently employed experimental models of epilepsy (e.g., genetic models, kindling) are in rodents, which unlike humans are nocturnal species. Most of the progress on cellular mechanisms has come from experiments in the cat (**Figure 1(d)**), which are increasingly uncommon. Polygraphic (EEG, EOG, EMG, ECG, etc.) and video recording in humans, leading to the construction of hypnograms (**Figure 1(a)–1(c)**) on which seizures time-course is noted, is currently the leading methodology, occasionally complemented with invasive recordings in epileptic patients. The recent ability to noninvasively image in 3D the metabolism (fMRI, PET) and electrophysiology (MEG) of the brain of sleeping epileptic patients raises new hopes for further insight.

Recent Advances on Brain Mechanisms Linking Sleep to Epilepsy

Several interesting advances have been made at the interface of basic mechanistic and clinical inquiry. We will examine them first in sequence of level of integration. Then we will examine the effects on epilepsy of sleep-related synchronous neuronal oscillations of infra-slow, slow, and fast frequency.

Genes, Channels, and Receptors

Strong genetic factors associated with awakening and nocturnal seizures have been increasingly substantiated. The well-known genetic predisposition of childhood absence epilepsy may result from a single nucleotide polymorphism in one of the low-voltage-activated calcium T-channel genes. Currents through these channels are instrumental for bursting in TC and cortical neurons (**Figure 1(e)**), and are therefore critical in the elaboration of normal sleep rhythms like sleep spindles, as well as of SWD of absences. The autosomal dominant nocturnal frontal lobe epilepsy (NFLE) is proposed to be partly due to mutations in the gene coding for the ligand-gated nicotinic receptors of acetylcholine, a major participant in arousing mechanisms (**Figure 1(f)**).

Neurotransmitters, Modulators, and Hormones

Unexceptionally, all neurotransmitter systems (from fast acting amino acids to amines and many neuroactive peptides) have experimentally suggested important roles in both sleep and epilepsy. For example, the cholinergic, serotonergic, and histaminergic components of arousing systems have antiepileptic actions in several seizure models, while the norepinephrine system is changed in kindling and absence models.

The neuromodulator, adenosine, has been proposed both as an endogenous hypnogen (the homeostatic regulator – see **Figure 1(f)**) and an endogenous antiepileptic agent. The two effects are most likely independent, since adenosine's hypnogenic effect appears to be exerted locally (in posterior hypothalamus) but its antiepileptic effect is generalized. Under normal conditions, there is a tonic effect of $[\text{adenosine}]_o$ (suggested by the observation that caffeine is excitatory), which is kept in check by an active uptake of adenosine (uptake blockers increase $[\text{adenosine}]_o$ and depress neurons); the baseline level of

adenosine is in a range of 25–250 nmol, which is anticonvulsant. During epileptic seizures, $[adenosine]_o$ rises rapidly to micromolar levels, a 6–31-fold increase sufficient to terminate ongoing seizure activity. Application of adenosine uptake antagonists can completely block epileptiform discharges in human cortex slices. Furthermore, adenosine receptor density appears to increase after seizures, and remains increased for prolonged periods (in contrast to the more transient GABA receptor changes). Finally, adenosine is neuroprotective, antagonizing excititoxic cell damage. It therefore makes sense to look for antiepileptic medications, based on facilitating this endogenous antiepileptic system, which appears to be rather specifically turned on with seizures. The restriction of adenosine's hypnogenic role to hypothalamus makes the sleep-related side effects of such medication less likely to be problematic. Melatonin, a hormone of the pineal gland, is released at night and affects the sleep–wake cycle. It also has antiepileptic effects in several experimental models in vivo and in vitro, but its levels and therapeutic potential in humans remain undetermined. The hypothalamic peptide, *orexin* (or hypocretin) has a crucial role in waking (**Figure 1(f)**). Its intraventricular application causes behavioral seizures, and its levels increase during experimental epileptogenesis. In slices, it modulates the balance of GABAergic and glumatergic neurotransmission in a way that suggests that endogenous orexin may play an epileptogenic role. The endogenous hypnogen, *delta sleep-inducing peptide*, potentiates GABA and blocks NMDA effects, and has demonstrated antiepileptic action. Finally, pituitary–adrenal secretory activity has been implicated in nocturnal epileptogenesis; this activity, and inhibitory control over cortical stimulus processing, is lower in the early part of sleep.

Regional Brain Energy Consumption and Epilepsy

In most brain regions, relatively lower blood flow and metabolism (as well as neuronal hyperpolarization) are characteristic of inactivation periods in NREMS (especially in association with K-complexes and delta waves). Could energy shortages affect neuronal responsiveness to endogenous epileptogenic activations? At a single cell level, significantly reduced blood flow may affect clearance of extracellular $[K^+]_o$ as well as extracellular space volume. Given that high $[K^+]_o$ and small extracellular space can result from neuronal bursting, and in turn tend to increase excitability through depolarization and ephaptic transmission (respectively), brain metabolism does indeed appear to be an important factor in controlling epileptogenicity. To be sure, not all brain areas change their metabolic activities in the same way during different sleep stages. It may be significant, however, that thalamus appears to be hypoperfused during NREMS, but activated during the phasic periods of REMS. Most relevant to partial epilepsy, normal human amygdala, hippocampal, and parahippocampal metabolic activity increases in REMS and decreases in NREMS, while metabolic activity in lateral prefrontal and temporal cortex decrease during both REMS and NREMS. Cases of unilateral temporal lobe epilepsy have been associated with interictal hypoperfusion in the frontal lobe.

Epileptogenic Sleep-Related Infra-Slow Modulations of Excitability

The appearance of generalized epilepsy with 3-Hz SWD seems to depend on the relationship between two long-term processes, with respective periods of 90–100 min and 24 h, and their interactive modulation. In this relationship, the onset of sleep and onset of arousal are strong boundary conditions; SWDs are promoted by transitional states (between wake and NREMS and between NREMS and REMS), and are inhibited by REMS and alertness. Negative DC shifts have been observed during transitions from wake to sleep. Assuming they have a neuronal origin, such negative DC shifts are usually thought to reflect concomitant periods of mild but widespread depolarization of pyramidal cell apical dendrites and associated increased pyramidal neuron excitability, which have been shown to be a requirement for SWD.

Although the 90-min cycle determines the NREMS–REMS recurrence during a night, the CAP (**Figure 1(c)**) modulates gross cortical excitability during NREMS, with a periodicity of about 20–40 s (~0.02 Hz) organizing EEG and autonomic arousal events in its phase 'A.' Phase A of CAP triggers and modulates the distribution of epileptic events and IEDs of either focal or generalized nature (**Figure 2**). It is noteworthy that IEDs are also correlated to the slow oscillation in stage 2 NREMS, when there are yet no delta waves. Similar observations of very slowly oscillating network excitability were found in hippocampus of rats strains highly susceptible to epilepsy. The phase-locking of epileptic events to the infra-slow cortical oscillation provides a putative mechanism for the as yet enigmatic aggravation of epileptic activity during sleep. The 3-Hz SWD of IGE are proposed to occur during 'phasic arousals without awakening' – i.e., CAP phase A. It remains unclear whether the epilepsy-promoting mechanism is related to the increased neuronal excitability (or to the synchronization) caused by some global event (neuronal, glial, or vascular) associated with the particular phase of CAP.

Epileptogenic Sleep-Related Slow Oscillations

NREMS is characterized by a slow (<1 Hz) oscillation between depolarizing ('up state') and hyperpolarizing ('down state') phases in individual cortical neurons (**Figure 1(d)**).

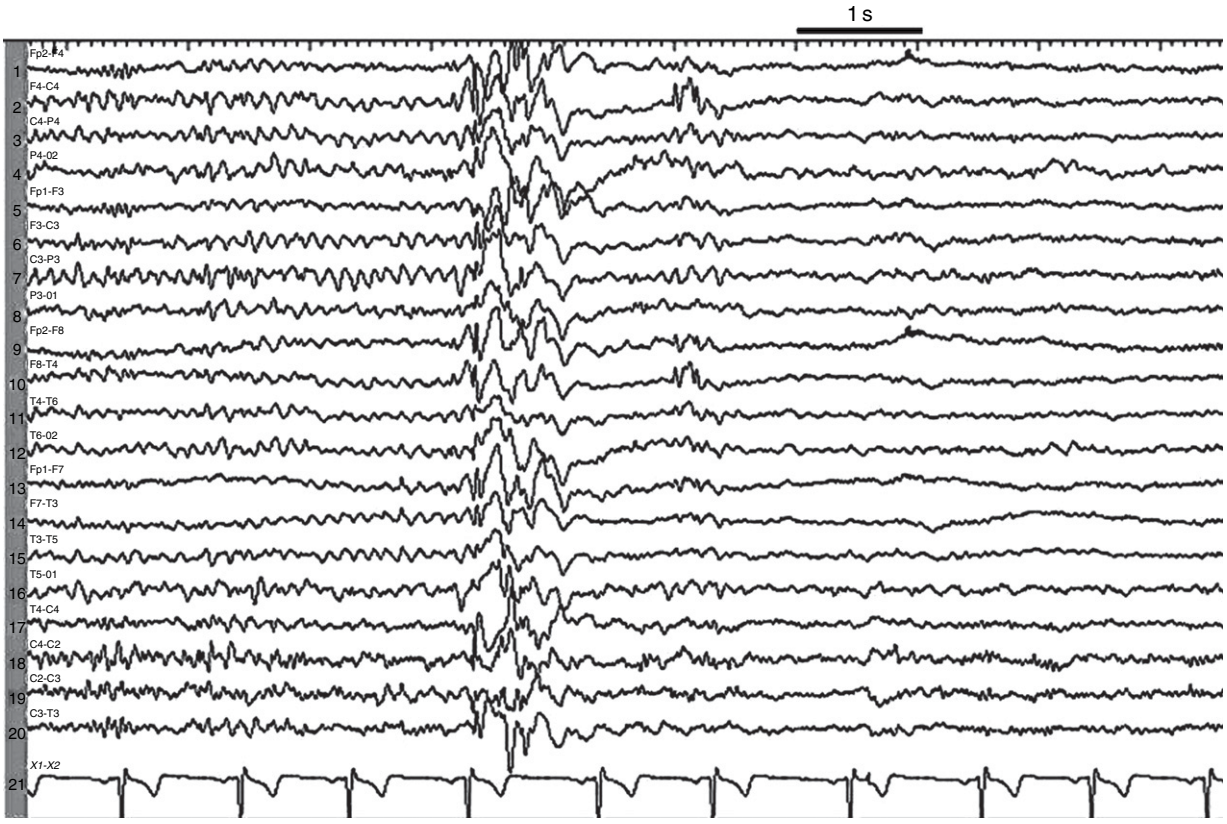

Figure 2 EEG of a 26-year-old man with IGE (JME). Myoclonic seizures on awakening since age 20 years, two GTCS at 25 and 26 years following volleys of myoclonic jerks on awakening. Generalized polyspike-wave discharge during stage 2 of slow sleep separating a phase A from B of a CAP. A second abortive generalized discharge occurs one second later (within phase B). Data courtesy of Dr. Michael Koutroumanides, Department of Clinical Neurophysiology and Epilepsies at Guy's & St. Thomas' NHS Foundation Trust, London, UK.

This neuronal effect is reflected in similar frequency EEG oscillations – to the extent that this rhythm becomes synchronized in large populations of neurons. Under conditions of high synchronization, the EEG corresponding to the 'up states' includes high power representation of almost the entire spectrum of frequencies, as well as stage-specific EEG waves, like K-complexes and spindles. At the single cell level, the 'up states' are periods of increased excitability (although specific cell types in particular brain areas, during particular phases of NREMS, may not participate in this 'increased excitability'). Can this bistability contribute to epileptogenesis during NREMS? And if so, how?

Sleep stages have been shown to influence human single neuron activity in seizure-generating areas. Most illustrative of the epileptogenic potential of NREMS is the demonstrated change of firing properties of cortical neurons, a change which in NREMS challenges the boundaries between the four categories of cortical neurons described from in vitro studies (regular spiking, fast spiking, fast rhythmic bursting, and intrinsically bursting neurons). NREMS favors the appearance of neuronal bursting (**Figure 1(d)** and **1(e)**). Sensory responses appear stronger in 'down states' than in 'up states.' However, of particular importance to nocturnal epileptogenesis may be the transition to the 'up state,' which is facilitated by TC bursting. The slow oscillation has been shown to constitute a nonstationarity of the sensory evoked potentials, which reach a maximum during the negative-to-positive slope of K-complexes and delta waves at the transition from 'down' to 'up' state.

No less relevant to epileptogenesis is the fact that the hyperpolarizations of the 'down state' periods do not reflect synaptic inhibition but rather disfacilitation (paucity of excitatory inputs) and summation of Ca^{2+}- and Na^{+}-dependent outward K^{+} current. There is an increased membrane resistance, maximal at the end of the down state, which may (a) favor distal synaptic input over proximal input (reducing the larger current loss of distal inputs through their longer cellular paths), and so nonspecific over specific TC input, and longer-over shorter-range corticocortical input; (b) favor, nondiscriminately, any input that will be large enough to overcome this hyperpolarization. Both these biases would presumably favor generalization and spread of epileptiform activity.

The mechanisms underlying disfacilitation are not known, but they may include adenosine-mediated depression of presynaptic release, since the adenosine levels maximize before sleep onset and increase further to micromolar levels during epileptic activation.

The characteristic K-complex of stage 2 NREMS (**Figure 1(a)**) is considered a solitary forerunner of delta rhythm waves, representing a transition from a stable low firing rate of cortical activity to an unstable high firing rate. Epileptic discharges – both generalized and focal – tend to cluster around K-complexes. But does this clustering constitute evidence of an influence of K-complex-related mechanism on epileptogenic activity? Similar clustering has been reported around delta waves. Thus, the clustering may simply reflect a general increase of excitability during the activated phase 'A' of CAP (explained earlier) rather than K-complex-specific mechanisms. Within the framework of such a generalization, one must be specific about the particular aspects and the types of epilepsy in question. Lighter stages of NREMS seem to best promote seizures, while deeper stages of NREMS seem to best activate IED. In patients with primary generalized epilepsy, the occurrence of spikes, polyspikes, and SWD is enhanced during the stage 2 of NREMS in conjunction with K-complexes, which is termed 'dyshormia' by Niedermeyer. The latter is defined as faulty or deviant arousal, during which the epileptic K-complex is found localized mid-anterior-frontally rather than at the vertex. This shift suggests an involvement of the supplementary motor area – which has been shown by MEG to be exceptionally active in sleep.

SWD of absence seizures have been hypothesized to emerge from the same TC mechanisms (**Figure 1(e)** and **1(f)**) that elaborate sleep spindles, under conditions of hypersynchronous cortical hyperexcitability. It is worth noting that in the experiments supporting this hypothesis, which demonstrated the development of SWD as transformation of spindles after i.m. penicillin in the awake restrained cat, SWD were not associated with paroxysmal depolarization shifts (PDSs) or other signs of abnormal neuronal discharges; SWD were associated with rhythmical hypersynchronous EPSP–IPSP sequences. The same is true for absence discharge in the rodent. Experiments studying local SWD produced by cortical deafferentation or topical application of large doses of convulsants, in animals sleeping or under excitatory anesthetics, have yielded insights at the membrane/neuronal/circuit level into the putative mechanisms relating sleep to epilepsy with SWD. However, some of these findings (i.e., PDSs reported during spikes of SWD) may model SWD associated with the particular animal model rather than SWD characterizing absence seizures of IGE. SWDs are best characterized, in behaviorally validated models, by neuronal discharges that are very synchronous but not abnormal; most importantly they are nonconvulsive.

In any event, spindles representing a series of depolarizations of lower (type I) or higher (type II) firing capacity (riding on top of a DC negativity) constitute a state of relatively higher cortical excitability, consistent with the correlation of IED with spindle activity – a correlation reported to be even higher than the correlation with slow-wave activity and with longer spindle duration just prior to NFLE seizures. Spindles have been associated with processes of neuronal plasticity and memory consolidation. Sleep mechanisms, similar to those involved in learning, may be employed during both epileptogenesis (establishing new connections) and the expression of seizures (spread of excitability over paths 'facilitated' by the discharges of previous seizures). A recently advanced hypothesis suggests that spontaneous brain activity – especially the bursting activity during the 'up state' of NREMS – may not only serve synaptic homeostasis, but also promote epilepsy.

It may be concluded that the slow (<1 Hz) oscillation of NREMS, and in particular spindles, K-complexes and delta waves, share some features that may contribute to the aggravation of epileptic phenomena. These effects may be related to the dynamic bistability of neuronal membrane potentials and neuronal readiness for bursting and widespread synchronization.

Epileptogenic fast oscillations during sleep

Along with IEDs, epileptic patients show fast oscillations (fast ripples, FRs, 200–500 Hz), whose current generators may more accurately locate epileptic foci than IEDs. FRs, as well as ripples (80–200 Hz), are more frequent during NREMS than during awake and REMS states. Although ripples are considered excitatory, and they are stronger in the 'up state' of NREMS than in awake or REMS, only spontaneous FR – and not ripples – are considered epileptogenic; the two appear to have different generators. FRs are considered to reflect synchronized population spikes within an interconnected network composed primarily of pyramidal cells. Facilitators of this synchronization may be the succession of up and down states of NREMS, which decrease temporal variability between neuronal discharges. As a useful contrast, FRs accompanying sensory evoked potentials in healthy humans are specifically depressed during NREMS.

Conclusions and Challenges

Sleep is recognized as a major precipitator of epileptic activity, but the intervening mechanisms remain enigmatic. Several sleep factors, mechanisms, or conditions that aggravate seizures (in NREM) are found:

- increased number of intrinsically bursting neurons;

- depolarization during the 'up state';
- disfacilitation and increased membrane resistance at the end of the 'down state';
- 'A' phase of CAP and its constituents, such as K-complexes;
- fast ripples;
- synaptic plasticity and associated homeostasis;
- ephaptic transmission and other mechanisms promoting synchronization;
- local blood flow not meeting the metabolic demand related to neuronal bursting.

Relatively few sleep mechanisms that 'antagonize' epilepsy have been recognized:

- hyperpolarization of motoneurons (sleep paralysis in REMS);
- desynchronization and effective inhibition (in REMS);
- enhanced release of neuromodulators like hypnogenic adenosine (at sleep starting time).

Although the findings described above mostly indicate correlations rather than causal relationships, they have opened new ways of understanding the apparently opposing roles of REMS and NREMS stages in epilepsy. However, the fundamental questions are still with us. Why are some epilepsies (i.e., NFLE) promoted by sleep (NREMS) and others (i.e., IGE) by drowsiness? What exactly is neurobiologically peculiar about drowsiness? Do some IEDs – e.g., those of TLE – spread more effectively during NREM simply because the ongoing activity of the brain is more synchronized? Why, then, does NREM not facilitate the spread of all types of IEDs? Typically, investigations aimed at answering these questions raise more questions than they answer, and paradoxes still abound. For example, deep NREMS is shown by transcranial magnetic stimulation studies to be a more excitable state compared with light NREMS; however, both evoked potentials and IEDs are stronger in the latter. The excitability of the entorhino-hippocampal circuits is higher in NREMS than in awake and REMS. Why, then, does NREMS aggravate preferentially FLE and not MTLE?

New directions of research are certainly needed, and relevant new ideas have emerged. Some of them are rather radical – e.g., that epilepsy may be affected not by sleep per se but by factors (endocrine, temperature) simply covarying in time with sleep. Other directions focus on reexamining some of our older assumptions and generalizations. For example, awakening (and to a lesser extent nocturnal) epilepsies are usually of hereditary or idiopathic etiology, whereas diffuse epilepsies are generally symptomatic. Does this difference imply that the links between sleep and epilepsy are mostly constitutional, and so possibly attributable to a single mechanism underlying both sleep and epilepsy, rather than to a causal interaction between the respective mechanisms? What is long overdue is a study of the effect of sleep on epileptogenesis rather than on the expression of seizures. Of particular interest is a study of the development of intractable seizures, whose relationship to sleep is still elusive.

In the earlier paragraphs, I have suggested that research should move from studying the effects of different sleep stages on epilepsy to examining the effects of interactions between brain rhythms. This change of emphasis would involve a shift from a focus on the degree of synchronization (high in NREMS, low in REMS) towards a focus on the role of phase relationships between nested oscillations in the EEG, and on the levels of various global neuromodulators. Understanding the processes of membrane and circuit bistability characterizing specific moments of the sleep–wake cycle, and of neuronal plasticity during sleep, may prove to have important implications for understanding the mechanisms underlying sleep effects on epilepsy.

Epileptic Components of NREM and Antiepileptogenic Components of REM Sleep

Introduction

The two main sleep states, non-rapid-eye-movement (NREM) sleep and rapid-eye-movement (REM) sleep, have different physiological components and contrasting effects on generalized ictal and interictal discharges (IIDs). Epileptiform discharges are likely to propagate during NREM sleep – i.e., during periods of synchronized electroencephalographic (EEG) background activity, during transients such as k-complexes and sleep spindles, and during transitional 'drowsy' EEG arousal periods. In contrast, REM sleep, with its asynchronous cellular discharge patterns and skeletal motor paralysis, is resistant to propagation of epileptic EEG potentials and to clinical motor accompaniment even though focal IID may persist at this time. The contrasting effects of NREM and REM on IIDs and clinically evident seizures are, to some extent, nonspecific with respect to epileptic syndrome (as defined by seizure type, etiology, and clinical course). Among the clinical syndromes in which epileptiform activity occurs prominently during sleep are childhood disorders with Continuous Spike-and-Wave activity during Slow-sleep (CSWS), such as Landau–Kleffner syndrome (LKS), Electrical Status Epilepticus during Sleep (ESES), and to a lesser degree West syndrome.

Increased severity of the epileptic syndrome, which reaches a peak in symptomatic generalized epilepsies such as West syndrome, is more likely to be associated with dispersion of ictal and IID events across the sleep-wake cycle, dissociation of physiological sleep components, medical refractoriness, and poor prognosis. However, there can be severe neurobehavioral consequences of uncontrolled seizures in sleep without overt neuropathy, especially in childhood. The cognitive, perceptual, and emotional consequences typically outlast the seizure disorder, and may be avoided with effective early intervention. Understanding the mechanisms responsible for these consequences should help to direct the development of early interventions and should have implications for developmental brain–behavior interactions.

The clinical observations raise three questions which this manuscript addresses: (1) Which components of NREM account for the propagation of ictal (seizure) and IIDs? (2) Which components of REM sleep suppress them? (3) How might the physiological mechanisms of seizure-prone sleep states overlap with those underlying other neurological consequences of LKS and ESES, including some autistic behaviors?

Background and Methods

To address these questions, many laboratories have established animal models that parallel the different clinical syndromes with respect to the timing of EEG and motor seizure manifestations. For example, systemic penicillin

Introduction

The two main sleep states, non-rapid-eye-movement (NREM) sleep and rapid-eye-movement (REM) sleep, have different physiological components and contrasting effects on generalized ictal and interictal discharges (IIDs). Epileptiform discharges are likely to propagate during NREM sleep – i.e., during periods of synchronized electroencephalographic (EEG) background activity, during transients such as k-complexes and sleep spindles, and during transitional 'drowsy' EEG arousal periods. In contrast, REM sleep, with its asynchronous cellular discharge patterns and skeletal motor paralysis, is resistant to propagation of epileptic EEG potentials and to clinical motor accompaniment even though focal IID may persist at this time. The contrasting effects of NREM and REM on IIDs and clinically evident seizures are, to some extent, nonspecific with respect to epileptic syndrome (as defined by seizure type, etiology, and clinical course). Among the clinical syndromes in which epileptiform activity occurs prominently during sleep are childhood disorders with Continuous Spike-and-Wave activity during Slow-sleep (CSWS), such as Landau–Kleffner syndrome (LKS), Electrical Status Epilepticus during Sleep (ESES), and to a lesser degree West syndrome.

Increased severity of the epileptic syndrome, which reaches a peak in symptomatic generalized epilepsies such as West syndrome, is more likely to be associated with dispersion of ictal and IID events across the sleep-wake cycle, dissociation of physiological sleep components, medical refractoriness, and poor prognosis. However, there can be severe neurobehavioral consequences of uncontrolled seizures in sleep without overt neuropathy, especially in childhood. The cognitive, perceptual, and emotional consequences typically outlast the seizure disorder, and may be avoided with effective early intervention. Understanding the mechanisms responsible for these consequences should help to direct the development of early interventions and should have implications for developmental brain–behavior interactions.

The clinical observations raise three questions which this manuscript addresses: (1) Which components of NREM account for the propagation of ictal (seizure) and IIDs? (2) Which components of REM sleep suppress them? (3) How might the physiological mechanisms of seizure-prone sleep states overlap with those underlying other neurological consequences of LKS and ESES, including some autistic behaviors?

Background and Methods

To address these questions, many laboratories have established animal models that parallel the different clinical syndromes with respect to the timing of EEG and motor seizure manifestations. For example, systemic penicillin

and electroconvulsive shock (ECS) provide models of idiopathic primary generalized epilepsy (PGE), and amygdala kindling is a model of the localization-related seizure disorder, temporal lobe epilepsy (TLE). Our studies employed cats studied at different ages, ranging from preadolescence to adulthood. The sleep-waking state distribution of seizures was quantified before and after several manipulations, as detailed later.

Subjects

Experiments employed cats ranging in age from 2.5 months to over 12 months of age. This time frame roughly corresponds in humans to about 3–4 years of age through adulthood. There are several reasons for selecting cats as subjects: (1) The mechanisms for nearly all the sleep components studied here were initially described in cats, and certain 'dissociative' manipulations, such as the lesion creating REM sleep without atonia, were developed in cats; (2) The brain size of cats, even at the youngest age studied, is large enough and the calvarium strong enough to perform chronic studies of seizure activity at multiple brain sites using a cranial implant that remains stable to adulthood; (3) Brain development is slow enough in cats to capture sleep and seizure development throughout the developmental course in the same animals, thus permitting longitudinal and cross-sectional studies of age effects. These opportunities are either limited or unavailable in rodents.

Animal Models

Feline penicillin epilepsy: Injection of large dosages of penicillin (300 000–400 000 IU/kg, i.m.) into cats induces seizure manifestations of idiopathic PGE, particularly juvenile myoclonic epilepsy (JME). The effect is unique to cats in that it can not be duplicated in any other species. JME is the most common form of convulsive epilepsy on awakening in humans. Spike-wave and multi-spike-wave complexes with myoclonic jerks occur contemporaneously with sleep EEG transients such as sleep spindles and k-complexes during slow-wave-sleep (SWS) (feline term for human NREM sleep) and decline during stable REM sleep. Nearly all generalized tonic-clonic convulsions (GTCs) occur during drowsiness after awakening. Feline penicillin epilepsy is an acute model; all effects subside with metabolism of the penicillin, and multiple trials can be conducted in the same animals without concern for residual effects of penicillin on sleep or epilepsy.

Electroconvulsive shock (ECS): High voltage electrical shock, applied through a thalamic lateral geniculate nuleus (LGN) electrode (paired to a reference electrode in the skull) induces a primary generalized epilepsy with tonic-clonic convulsions that occur predominantly in SWS but not in REM. ECS is generally thought of as an acute rather than a chronic seizure model, can be done in any species, and is often performed through corneal electrodes using a variety of amperages depending upon the species and age. At a high enough current, stimulation any nucleus or brain structure will induce ECS. In rat pups <4 days old, we have used 100 mA interaurally. In cats, we established thresholds aimed at obtaining the lowest possible amperage to achieve a generalized tonic-clonic convulsion (GTC) in each sleep or waking state before and after the REM sleep dissociative manipulation (see results).

Amygdala kindling: Amygdala kindling provides a model of the localization-related seizure disorder, TLE. TLE is one of the most common forms of convulsive sleep epilepsies in humans. As in humans, the spread of EEG seizure discharge from one site to another, called seizure discharge propagation, and spontaneous GTCs occur most often in SWS and in the transition into REM. Focal discharge persists and is highly localized in REM unless the cat wakes up. Also as in humans, several subconvulsive seizure types may be evoked or occur spontaneously at different times in the sleep-wake cycle.

Repetitive electrical stimulation of amygdala (once per workday, between 1 and 3 mA, for 4–37 days) in 2.5–6.5 month old kittens creates a unique spontaneous convulsive sleep epilepsy that can persist to adulthood. The younger the animal, the higher the current needed for initial afterdischarge (AD), the faster they kindle, (defined as the number of ADs required to achieve the first stimulus induced GTC), and the more likely they are to develop spontaneous seizures shortly after initial kindling. [Adults very rarely develop spontaneous seizures as a result of this kindling paradigm, and when they do, it usually results from multiple evoked convulsions after initial kindling.] The objective of our work in amygdale-kindled kittens has been to study the basis for onset of spontaneous seizures, their timing in the sleep-wake cycle, and their developmental course. We also wanted to determine whether sleep disorders and other behavioral correlates of epilepsy resemble age-related findings in human TLE.

All three of these epilepsy models resemble human counterparts in that generalized seizures occur during NREM sleep or transitional arousal periods. These seizure-prone states are characterized by background EEG synchronization, often with phasic events which include sleep EEG transients such as sleep spindles, k-complexes and ponto-geniculo-occipital (PGO) waves, and may involve state or stage shifts. In contrast, EEG seizure discharge generalization is reduced during states characterized by tonic EEG desynchronization, such as alert waking and particularly REM sleep. REM sleep is the most antiepileptic state in the sleep-wake cycle for generalized EEG and motor seizure activity, even though phasic events and localized EEG discharge persist in REM.

Results

We have performed experimental manipulations of discrete physiological characteristics or components (described below) in these epilepsy models, and recently described continuous electrographic seizures in SWS. This electrical seizure activity and the neurobehavioral consequences of sleep-related seizures may provide insights into to seizure phenomena in human ESES and LKS.

Seizure Initiation Associated with Activation of Transient Epileptiform Events

Phasic events of sleep are thought to reflect aborted arousals related to brainstem processing of intrinsic stimulation and can be provoked by extrinsic stimulation such as a loud sound. We have hypothesized that epileptogenesis is associated with abnormal (epileptiform) phasic events, which may sometimes simply disrupt sleep by awakening the animal but at other times precipitate seizures. **Figure 1** shows that exogenous stimulation, in this case photic stimulation (PS) ($20\ s^{-1}$), can not only evoke epileptiform phasic events during SWS, but can also precipitate GTCs in spontaneously epileptic kindled kittens.

The most vulnerable periods for extrinsic stimulus-evoked GTCs are those in which spontaneous seizures most frequently occur, notably in SWS and the transition into REM. The least vulnerable time for evoked seizure activity is REM sleep. Spontaneous phasic activity and highly localized multifocal EEG seizure discharge persist during REM and may be evoked by photic stimulation, but there is no clinical accompaniment. These findings suggest that phasic activity can provoke epileptiform discharges in any sleep state, but that the extent of epileptic EEG discharge spread and the clinical motor accompaniment depend upon tonic EEG and motor sleep components.

Dissociating the Tonic (Sustained) Components of REM and NREM Sleep

The roles of two tonic sleep components (synchronous vs. asynchronous background EEG and presence vs. absence of tone) were evaluated before and after the experimental manipulations depicted in **Figure 2**. The top tracing (1) shows normal REM sleep with tonic EEG

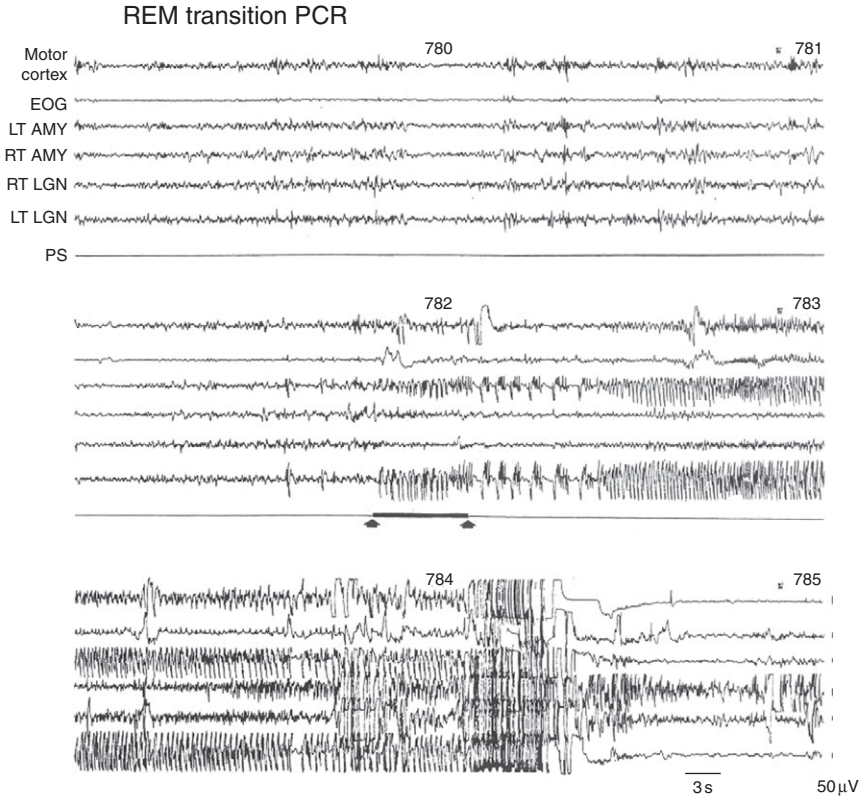

Figure 1 Continuous polygraphic recording showing a REM transition photoconvulsive response (PCR) elicited by $20\ s^{-1}$ PS. Arrows indicate PS onset and offset. PS initially evoked epileptiform PGO spikes in kindled amygdala and ipsilateral LGN. Epileptiform k-complexes in the kindled amygdala and ipsilateral LGN outlasted PS and were followed by EEG seizure discharge propagation with clinical accompaniment. Paper speed is 10 mm. AMY, amygdala; LGN, lateral geniculate nucleus of thalamus; EOG, electrooculogram; EMG, electromyogram. Adapted from Shouse *et al*. (1995) Paroxysmal arousals in amygdala-kindled kittens: microarousals, could they be subclinical seizures? *Epilepsia* 36: 290–300.

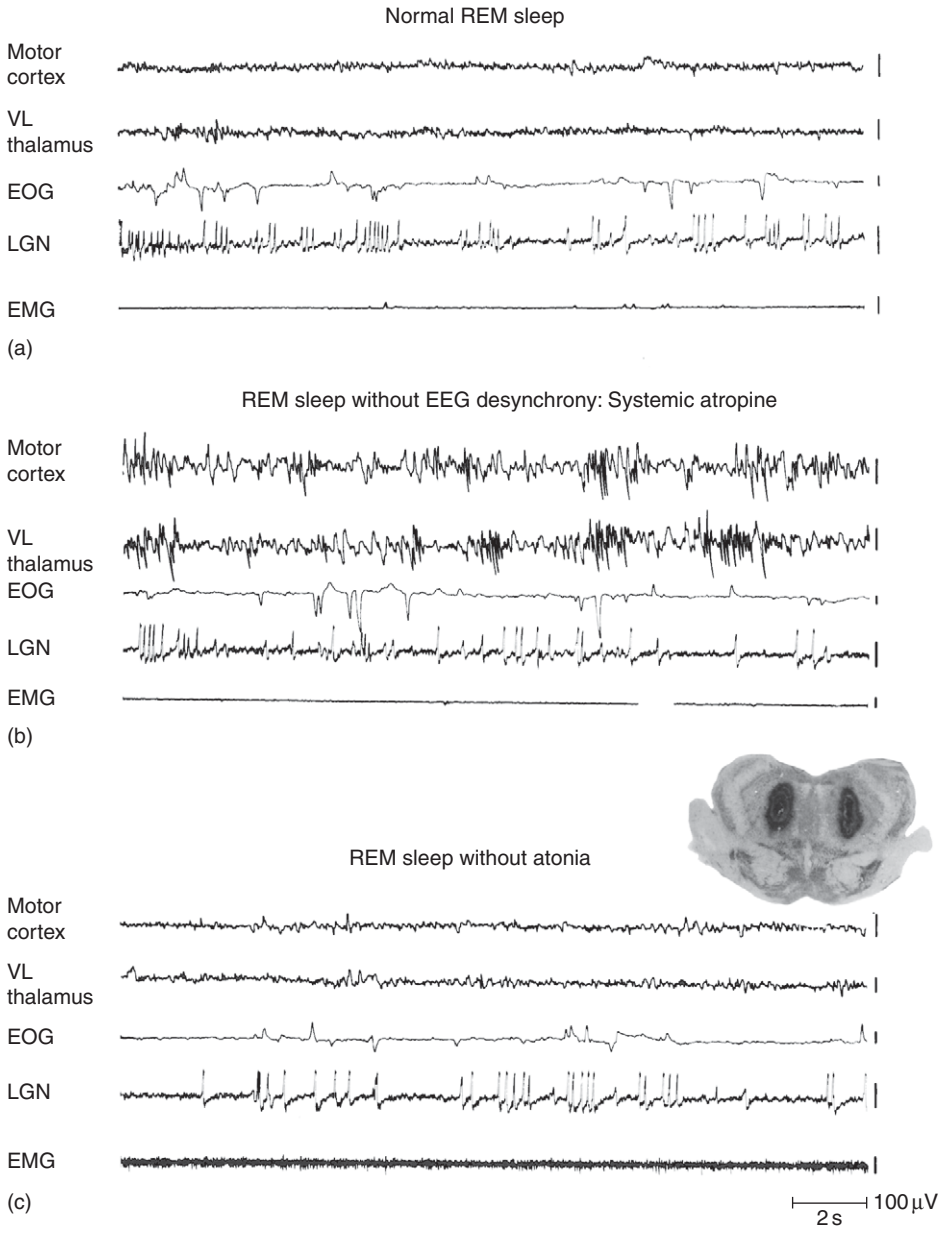

Figure 2 REM sleep before (a) and after experimental techniques designed to selectively alter either EEG synchronization or atonia. (b) Systemic atropine induces REM sleep without EEG desynchronization. (c) A bilateral medial-lateral pontine lesion induces REM sleep without atonia. Abbreviations as in **Figure 2** except for ventral lateral (VL) nucleus of thalamus. Adapted from Shouse *et al*. (1989) Mechanisms of seizure suppression during REM sleep in cats. *Brain Research* 505: 271–282.

desynchronization (motor cortex and ventral lateral thalamus channels), rapid eye movements (EOG channel), PGO waves (lateral geniculate nucleus or LGN channel), and atonia (EMG channel). The middle tracing (2) shows a model of REM sleep without EEG desynchronization induced by systemic administration of atropine. The anticholinergic agent presumably acts by blocking activity in the pedunculopontine tegmentum and nucleus basalis, which are thought to be the critical generators of EEG desynchronization in waking and REM. The result of this treatment is a pervasive NREM-like EEG with sleep spindles. The other phasic and tonic components of REM are also intact, including rapid eye movements, PGO waves, and atonia (note electrical silence in EMG channel). The third tracing (3) shows REM sleep without atonia, created by lesions of the medial-lateral pontine tegmentum. This lesion is thought to destroy cholinoceptive and glutaminergic cells that silence lower motor neurons and create sleep paralysis during REM sleep. REM sleep components are intact except the cat has tone (EMG channel).

Figure 3 illustrates the effect of these dissociative sleep manipulations on penicillin epilepsy. The top tracing

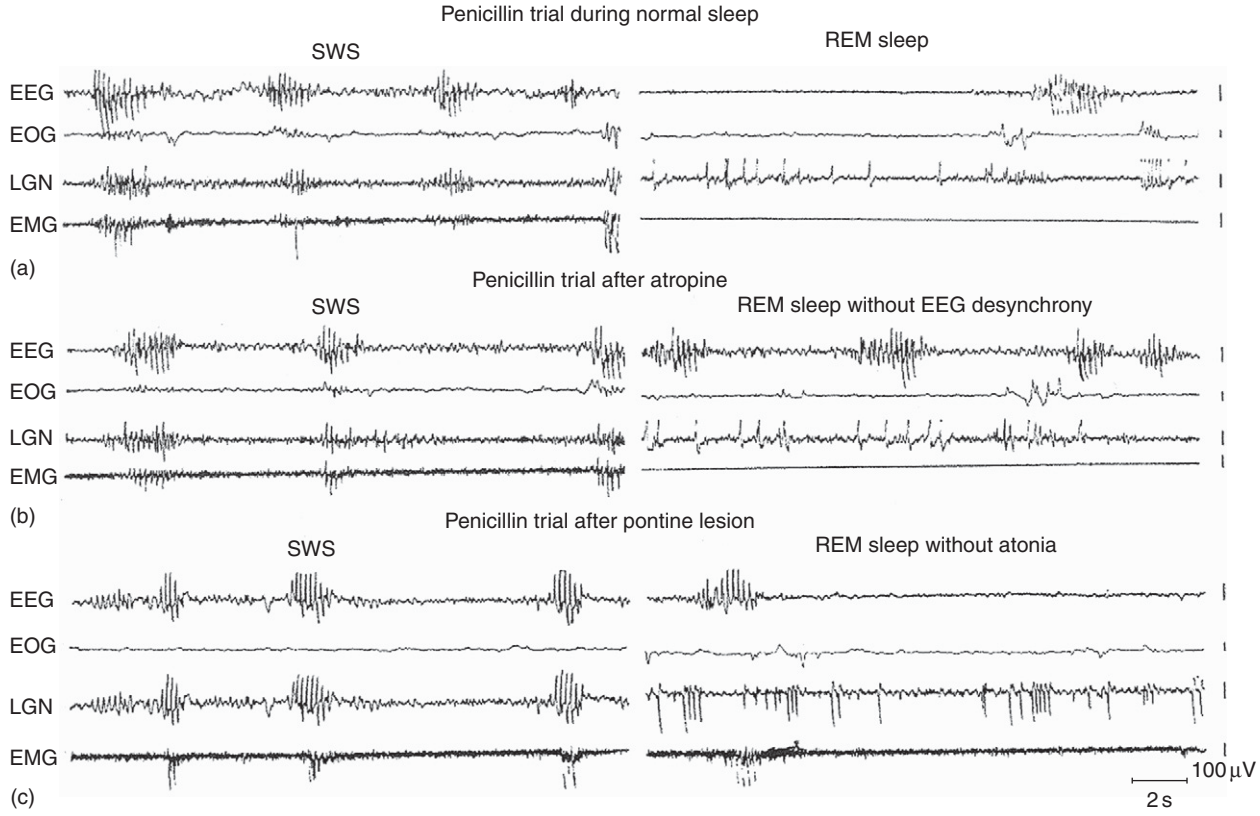

Figure 3 Penicillin epilepsy during SWS (left) and REM sleep (right) before (a) and after dissociation techniques. (b) Atropine creates a SWS-like EEG synchrony in REM and selectively increases incidence of EEG seizure susceptibility in REM without clinical motor accompaniment. (c) Pontine lesions which cause REM sleep without atonia selectively increase clinical motor accompaniment. Abbreviations as in **Figure 2**; the top channel is a motor cortex EEG. Adapted From Shouse *et al*. (1989) Mechanisms of seizure suppression during REM sleep in cats. *Brain Research* 505: 271–282.

Table 1 Parallels and dissimilarities of age-related amygdala kindling in kittens to electrical status epilepticus (eses) and/or Landau–Kleffner syndrome (LKS)

	Parallels	*Dissimilarities*
Age dependency	Critical period for onset	GTCs can last to adulthood in kittens
Spontaneous seizure-related symptomatology	Seizure types (GTCs, partial motor, atypical absence, complex-partial); IID types and cortical 'foci'; Foci change over time	ESES, not CSWS in kittens; Clinical seizures start first kittens and ESES versus LKS and ASD; Fronto-central foci in ESES versus Centro-temporal foci in LKS and kittens
Sleep patterns	NREM onset seizures; ↑ IIDs and spread in NREM and ↓↓ IIDs and spread in REM	Occasional ESES symptoms in kittens; Sleep deficits in kittens
Developmental/ neurobehavioral deficits	↑ Sensitivity and IIDs to sound; Agnosia; Social isolation; Mood change, Stereotypies, Hyperactive, atonic/dystonic aggressive/placid	Type/extent of residual deficits depend on early onset, site and duration of CSWS in humans versus GTCs in kittens
Prognosis and AED response	Good for seizures; ESES self-limited; Residual neuro-behavioral symptoms; Clonidine good for autistic symptoms	Same AEDs untested
Encephalopathy; pathophysiology	Localization-related with subtle/minor cell loss/pathology at foci	?

GTCs, generalized tonic-clonic convulsions; ↑, increased; ↓, decreased; CSWS, continuous spike-and-wave during slow sleep; ASD, autistic spectrum disorders.

(a) shows spike-and-wave complexes riding upon sleep spindles in SWS and accompanied by myoclonic twitching (note related discharge in EMG channel). During REM sleep, spike-and-wave activity is rare and occurs without clinical motor accompaniment. The middle tracing (b) shows that atropine does not affect the rate of EEG and motor seizure activity in SWS. However, the REM sleep cortical EEG is synchronized, and EEG seizure discharge

rate cannot be distinguished from SWS (shown) or waking (not shown). Unlike waking and SWS, there is still no clinical motor accompaniment in REM sleep, presumably because lower motor neuron inhibition remains intact. The bottom tracing (c) shows seizure activity during REM sleep without atonia. Spike-wave activity is as infrequent as during normal REM, but, when a spike-and-wave complex does occur, there is clinical motor accompaniment, presumably because the animal can now move. Similar results were obtained after these dissociative sleep manipulations in 26 cats undergoing penicillin epilepsy ($n = 10$), ECS ($n = 10$) or amygdala kindling ($n = 6$).

Amygdala Kindled Kittens ESES and Landau–Kleffner Syndrome

Recent 24 h video recordings of group housed kittens $\leq$5 months old, during the initial stages of kindling, revealed a far more extensive and complex clinical picture than is seen after kindling older pre-adolescent and adult cats. These young animals display several similarities to ESES and LKS (and occasionally to ASD), as summarized in Table 1.

Amygdala-kindled kittens, like ESES/LKS patients at ~4–7 years of age, display a critical, age-dependent period for development of multiple foci (including, but not limited to, fronto-central and centro-temporal areas), and multiple seizure types (partial, atonic, atypical absence, tonic-clonic, subclinical). IIDs generalize during SWS or NREM sleep, when most clinically evident seizures occur. Sleep disorders common to both the animal model and to the human syndromes include delayed sleep onset, increased wakefulness after sleep onset, and abbreviated sleep time (mostly in children with autistic symptoms). Common behavioral correlates include increased sensitivity to sensory stimuli, extreme fluctuations in temperament (docile or depressed to aggressive) and social isolation. Other behavioral characteristics shown by some kindled kittens better resemble Kluver-Bucy syndrome, notably visual agnosia, hypersexuality and docility. Anti-epileptic drugs can arrest the incidence and progression of seizures and the associated behavioral complications. Unlike human TLE with hippocampal sclerosis, the seizures and their sequelae tend to remit spontaneously (by or during adolescence), although residual language and behavioral symptoms usually persist. Histological changes are nominal in ESES and LKS, and minimal gliosis and cell loss are also a feature of kindled kittens, except for those animals that remain symptomatic to adulthood due to uncontrolled seizures and/or continued evoked seizure trials.

The findings in kindled kittens and LKS suggest an age-dependent pathophysiological process rather than a static or progressive course more often associated with structural anomalies. Kindling is believed to have 'trans-synaptic' effects, in that cells distal to the kindled focus undergo transient or permanent changes in membrane properties, synaptic reorganization, and transmitter release as well as variable degrees of cell loss. These changes are hypothesized to explain the extra-focal alterations in seizure susceptibility, as well as the many other behavioral sequelae of kindling which range from sleep disorders to changes in agonist/antagonist social behaviors. These trans-synaptic effects seen in adults are not always detected in the young.

Some of the concepts currently discussed to explain age-related differences in kindled TLE without hippocampal sclerosis in young rodents may be helpful in explaining the clinical course of amygdala kindling in kittens and perhaps ESES/LKS as well. Young rats (7–14 days old) kindle much more rapidly than adults, and the electrical seizures are far more likely to become multifocal. Different limbic sites kindle with equal speed in young rats, whereas adults usually exhibit preferential kindling sites (e.g., piriform cortex kindles faster than amygdala). Immature rats also do not display the 24 h seizure-resistant or refractory period that occurs between evoked seizure trials in adults,

Table 2 Spontaneous seizure parameters after once daily amygdala microinfusion of either the α-2 agonist idazoxan or the α-2 antagonist clonidine

Type of drug infused	*No. and percent of animals per group with Spontaneous Seizures*	*Spontaneous seizure types, no. of animals with each and mean GTC duration (s) ± S.E.M.*	*Mean No. and duration ± S.E.M. and range (min/max) of post-kindling GTCs to onset of spontaneous GTCs or to end of protocol*
Idazoxan ($n = 7$)	7 (100%)	Focal or generalized slow spike-and-wave with staring ($n = 2$) Generalized subcortical fast trains with staring ($n = 1$) GTC ($n = 7$)[a]; 66.7 ± 3.8 s (53–74.5)	5.86 ± 0.3[a] (5–7); 65.8 ± 3 s (60.3–71.6)
Clonidine ($n = 7$)	0 (0%)	0 (0%)	24.71 ± 0.9 (20–26); 67.85 ± 5 s (54.5–93.0)

[a]Simple *F*-test (df = 1,12), $p < 0.01$ from clonidine.

Number (No.) of spontaneously epileptic animals, spontaneous seizure types, and evoked seizures were noted prior to the onset of spontaneous seizures or to the end of the protocol. Adapted from Shouse *et al.* (2007) The α-2 adrenoreceptor agonist clonidine suppresses evoked and spontaneous seizures, whereas the α-2 adrenoreceptor antagonist idazoxan promotes seizures in amygdala kindled kittens. *Brain Research* 1137(1): 58–68.

nor do they exhibit 'kindling antagonism' in which alternating once daily stimulations between two anatomical sites blocks seizure development at one of the sites. Also unlike adults, immature rats are resistant to structural damage resulting from multiple seizures and/or other cerebral insults, do not exhibit synaptic reorganization of mossy fibers, and do not display increased inhibitory transmission in dentate granule cells.

Moshe and others have concluded that inadequate inhibitory mechanisms, potentially involving GABAergic and noradrenergic transmitter systems, may be responsible for increased vulnerability to multifocal epilepsy in the young. Early in development, GABA has excitatory (depolarizing) rather than inhibitory (hyperpolarizing) effects on neurons and thus might enhance rather than discourage seizures and other disruptive behaviors. Norepinephrine (NE) has well-established inhibitory effects on seizure activity in adults and may not be fully operational in immature brains. For example, NE secretion is believed responsible for establishing and maintaining both the interictal refractory periods and the inter-site 'kindling antagonism' seen in mature animals. Increased NE secretion is also considered critical to selective sensory processing during wakefulness, which is deficient in ESES and LKS. Alpha-2 adrenoceptor agonists (e.g., clonidine) can effectively suppress seizures in kittens (**Table 2**) as well as several behavioral symptoms of autism. It remains unclear how the development of neural networks affects or is affected by seizures (and other behavioral anomalies), but maturation clearly alters the dynamics. Early detection and intervention may halt or attenuate the progression of symptoms.

Future Goals

We propose two major goals for future research. First, there is an important need for establishing better models of continuous spike-wave during slow sleep (CSWS), the EEG seizure signature of ESES and LKS. One approach to this goal is to examine the effects of kindling cortical sites involved in the clinical syndromes. We have seen ESES in amygdala-kindled kittens, but not continuous spike-wave activity per se. Second, we believe that it is critical to develop a more sophisticated behavioral inventory, to help determine the efficacies of new antiepileptic drugs, and to assess whether early intervention in the electrical component of seizure disorders can prevent the neurological/clinical sequelae.

Seizure Initiation: The Transition from Sleep-Related Oscillations to Epileptiform Discharge

F Amzica, Université de Montréal, Montréal, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

This article is devoted to examining the potential initiating mechanisms of seizures, with particular emphasis on the transition from sleep-related oscillations to seizure activity. Toward this goal, we consider the example of nocturnal seizures, which develop almost exclusively from slow sleep oscillations, and then extend our analysis to other spike-wave (SW) paroxysms. Although the contribution of glial cells during epileptic events has been previously acknowledged, few studies have addressed the interaction between neurons and glia. Here, we consider the contribution of glial cells to the triggering of the seizures, to the oscillatory process associated with this initiation process, and to the generalization/propagation of the paroxysms through the brain. Special emphasis is on the modulation of the neuronal activity by the ionic concentrations of the extracellular space.

SW seizures occur predominantly during resting sleep, as has been reported in children with absence epilepsy and in the Lennox–Gastaut syndrome. The vast majority of seizures occurring during sleep are dominated, in their electrographic aspect, by recurrent SW complexes. The electroencephalographic (EEG) SW complexes recur with a frequency of about 2–4 Hz; the precise frequency is determined by various pathologic, structural, and intrinsic factors. In this article we consider the cellular mechanisms generating SW complexes regardless of the etiology of the related seizures; we believe that, in spite of the clinical variety of epileptic seizures displaying this EEG feature, the underlying cellular mechanisms of SW complexes are similar across seizure types.

Background

Physiological Sleep Slow-Wave Oscillations

A continuous range of slow waves and oscillations, generally <15 Hz and of relatively high amplitude, dominates the electrographic pattern of sleep. Current studies of the cellular substrates of these rhythms have indicated that most of the sleep oscillations are generated within the corticothalamic network, under the control of ascending modulatory projections from the brainstem core and basal forebrain (see Steriade in Further Reading).

Although sleep oscillations emerge in the cortex as coalesced events, two rhythms with distinct mechanisms and generated in various substructures of the corticothalamic network can be distinguished: spindles (7–14 Hz) and delta (<4 Hz) waves. The latter frequency band contains several phenomena with distinct generating mechanisms. Among them, a remarkable oscillation, termed 'slow' (less than but close to 1 Hz), assumes a particular role in combining other sleep rhythms and in constituting the germ for paroxysmal development during nocturnal seizures.

Neuronal Mechanisms of the Slow Oscillation

In spite of its ubiquitous presence during sleep, the slow (<1 Hz) oscillation was only recently described. The main rhythm is within the frequency range of 0.5–0.9 Hz, although slower and slightly higher frequencies are not uncommon as a function of the sleep stage, with a clear tendency toward acceleration as sleep deepens. The first description of this slow oscillation came from anesthetized cats and was made at the intracellular level, and subsequent studies described slow oscillations under various anesthetics and during natural sleep in chronically implanted cats as well as in the sleep of humans. One cycle of the slow oscillation consists of an excitatory phase and an inhibitory phase (**Figure 1**). During the excitatory phase, neurons rapidly depolarize to reach a plateau level that is crowned by occasional action potentials; the depolarization lasts for 0.5–1 s and is generated by EPSPs, IPSPs, and intrinsic currents (mostly NMDA and Na^+ persistent).

An important issue concerning the slow oscillation remains the understanding of cellular and/or ionic mechanisms responsible for the switching between the depolarizing and the hyperpolarizing phase. It is not yet understood why the cortical network oscillates, or what elements are responsible for setting the pace of this oscillation. Investigators have demonstrated that the end of the depolarizing phase is accompanied by a progressive disfacilitation during which the excitatory drive within cortical networks diminishes; they have postulated that the progressive diminution of network activity would promote a gradual disconnection between neurons – resulting in cell hyperpolarization. An active inhibition eliciting the hyperpolarizing phase of the slow oscillation

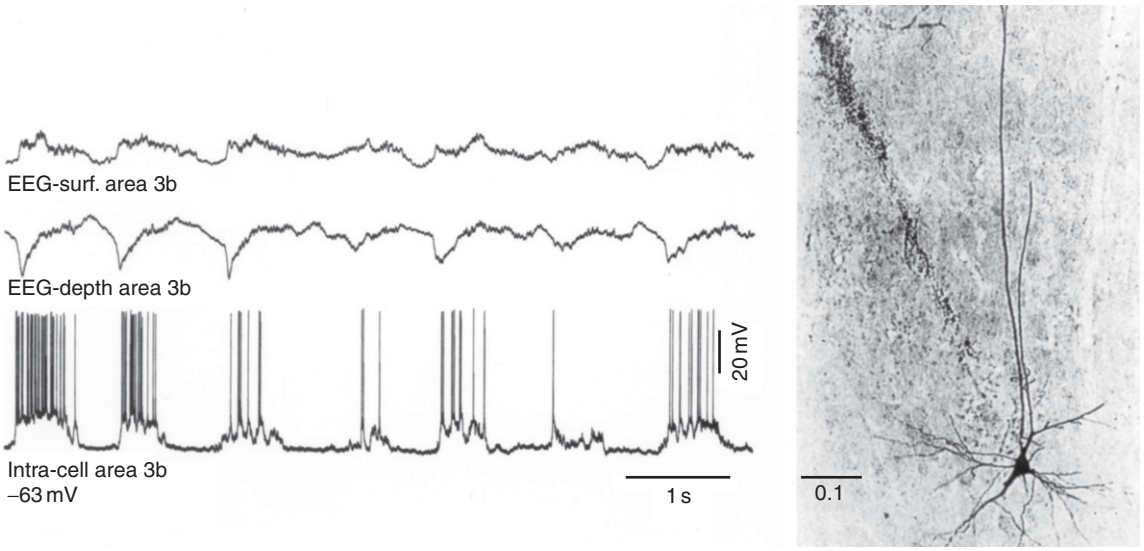

Figure 1 Pyramidal cell from the somatosensory cortex (area 3b) during the slow oscillation. The left panel shows an intracellular recording and simultaneously recorded EEG in the vicinity (~1 mm) of the cell. The EEG was recorded by means of coaxial electrodes located on the surface and at a depth of ~0.6 mm. In this and following figures, polarity of EEG and evoked field potentials is as for intracellular recordings (positivity up). The cell oscillated at 0.9 Hz with depolarizing phases corresponding to depth-EEG negative (surface-positive) potentials. The right panel shows the corresponding cell stained with Neurobiotin (calibration bar in mm). Modified from Contreras D and Steriade M (1995) Cellular basis of EEG slow rhythms: A study of dynamic corticothalamic relationships. *Journal of Neuroscience* 15: 604–622, with permission from the Society for Neuroscience.

has been ruled out. The disfacilitation hypothesis is supported by measurements of the extracellular calcium concentration, showing that the depolarizing phase of the slow oscillation is associated with a progressive diminution of the extracellular calcium (probably due to postsynaptic uptake of calcium), with the effect of a parallel reduction of synaptic efficacy. Another synergistic mechanism involves spatial buffering of potassium by glial cells (see the later sections).

Several lines of evidence support the idea that the slow oscillation is generated within cortical networks. First, the slow oscillation survives in the cortex after extensive thalamic lesions and in preparations with high brainstem transections. Second, the slow oscillation is absent from the thalamus of decorticated animals, while it is expressed by thalamic reticular and thalamocortical cells in intact animals. Third, the slow oscillation has been replicated in vitro, in cortical slices. The mechanisms underlying this oscillatory behavior are partly elucidated at the neuronal level. Studies have shown that slow oscillations are expressed within various cortical areas and by virtually all neuronal types, and they display wide-range and short-range cortical synchronization. There is a large current sink in cortical layer III during the depolarizing phase, and the coherence of the rhythm is impaired after inactivation of synaptic activity or after cortical transections, indicating that intracortical linkages are instrumental to the propagation of the slow oscillation.

The slow oscillation assumes an operational role in its relation with other brain activities during sleep. Its cortical coherence ensures periodic and synchronous inputs to subcortical structures, mainly to the thalamus, where it simultaneously triggers spindle sequences. Once a spindle is generated in the thalamus, it is transmitted to the cortex, thus having a direct impact on the EEG. In this way, the slow oscillation is reflected in the gross brain activity of the sleeping brain. The slow oscillation is expressed in the local cortical field potentials that reflect the membrane currents generated by neurons (and possibly glial cells). Since the depolarizing phase of the slow oscillation reflects the excitation of all cortical neurons, the corresponding extracellular field potential consists of a negative deflection. The shape of this negative potential is similar to that of the K-complex, an EEG wave described many decades ago. The fact that the depolarizing (excitatory) phase of the slow oscillation is conveyed by corticothalamic axons to the thalamus also explains the periodic triggering of spindle sequences in the thalamus and, at the EEG level, the association between K-complexes and spindles. Spindles are triggered in the thalamus mostly during the early stages of slow wave sleep.

Glial Mechanisms of the Slow Oscillation

More insight into the cellular mechanisms responsible for the pacing of slow oscillations, and the switch between depolarizing and hyperpolarizing phases, has come from experiments examining the possible dialog between neurons and glial cells – and particularly exploring the possibility that glia may not only passively reflect, but directly

influence, the state of neuronal networks. Dual simultaneous intracellular recordings from neurons and adjacent glial cells were performed during sleeplike EEG patterns produced by ketamine–xylazine anesthesia. The behavior of simultaneously recorded neurons and glia is illustrated in Figure 2. During spontaneously occurring slow oscillations, the onset of the glial depolarization did, in the vast majority of the cases, follow the onset of the neuronal depolarization, with an average time lag of about 90 ms – considerably longer than the lag seen between pairs of neurons (around 10 ms). Presumably, this glial depolarization reflects, with virtually no delay, the potassium uptake into glia. As potassium is also continuously recaptured by neurons through Na^+/K^+-ATP pumps, the actual onset of the glial depolarization may thus mark the moment at which the increase of extracellular potassium concentration exceeds the capacity of the neuronal pumps. This behavior suggests that glial cells are essential for maintaining extracellular potassium within controlled values.

Toward the end of the depolarizing phase, the glial membrane begins to repolarize before the membranes of neurons (Figure 2). This observation excludes two mechanisms that could have been responsible for the onset of the hyperpolarizing phase of the slow oscillation: an active GABA inhibition at the end of the depolarization and a slow calcium-dependent potassium current. In the first case, the release of GABA would depolarize glial cells either through direct action on $GABA_A$ receptors or indirectly through the potassium output resulting from the neuronal activation of $GABA_B$ receptors. The alternative implication of calcium-dependent potassium currents

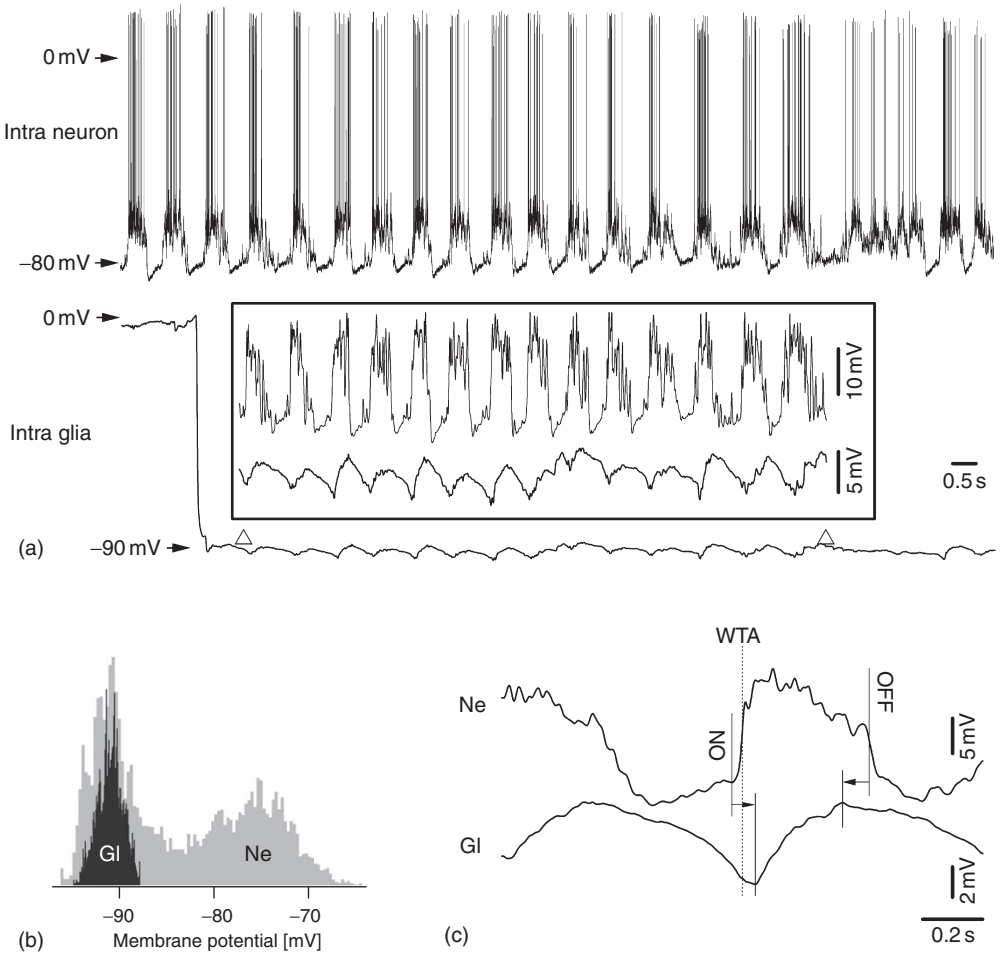

Figure 2 Simultaneous recording of a neuron-glia pair in the cortex of the cat during slow oscillatory patterns. (a) Relationship between neuronal and glial depolarizations on the one hand, and between neuronal hyperpolarization and glial repolarizations, on the other hand (note enlargement within the box). The glial impalement occurred during this period of the recording and is depicted as a brisk drop of the potential from the extracellular (0 mV) to the intracellular (−90 mV) level. (b) Histogram of membrane potential variations in the neuron (in gray) and glial cell (in black). (c) Typical time relationship between the onset and offset moments of the two phases of a slow oscillatory cycle. Note that the onset of the depolarizing phase starts in the neuron, but that the end of this period is anticipated in the glia. Modified from Amzica F and Massimini M (2002) Glial and neuronal interactions during slow wave and paroxysmal activities in the neocortex. *Cerebral Cortex* 12(10): 1101–1113, with permission from Oxford University Press.

should be discarded because the extracellular potassium starts to drop before the onset of the neuronal hyperpolarizing phase.

In addition, the glial membrane potential returns to control value at the end of each of the recurring oscillatory cycles, which has led us to postulate that glial cells might control the pace of the oscillation through changes in the concentration of the extracellular potassium. The overall synchronization of the slow oscillation in the cortex appears to be assisted by glial cells, which are imbedded in a gap junction-based network, through the phenomenon of spatial buffering. Spatial buffering evens local increases of extracellular potassium by transferring it from the extracellular milieu into local glial cells, then through gap junctions and along the potassium concentration gradient to more distant sites with lower concentrations of potassium, where it is again released into the extracellular space. This pathway is preferred to the direct one through the extracellular space, because the tortuosity of the extracellular space makes diffusion difficult. During slow oscillations, the relationship between intracellular glial potentials and extracellular potassium shows little accumulation of potassium in the extracellular space (<1.1 mM per cycle), so there is a minimal imbalance between the extra- and intracellular potassium concentrations. Given that, under physiological conditions such as sleep, glial cells normally deal with low amounts of potassium – but have a high uptake capacity – it is likely that, during the slow oscillation, spatial buffering generally occurs at a relatively local spatial scale.

The local spatial buffering during slow oscillations might play two roles: (i) it contributes to the steady depolarization of neurons during the depolarizing phase of the slow oscillation in a Nernst-related manner and (ii) it modulates the neuronal excitability. The latter mechanism could favor the synaptic interaction within cortical networks at the onset of the depolarizing phase of the slow oscillation, but it could equally induce a gradual disfacilitation as the extracellular potassium concentration reaches higher values toward the top of the glial depolarization. The amplitude of the potassium variations during the slow sleep oscillation reaches 1–2 mM above resting level at its peak; when added to the physiological values of resting concentration (~3 mM), this increased extracellular potassium may assist cortical neurons in oscillating between hyper- and hypoexcitability. This hypothesis was confirmed after testing the excitability of the neurons during the various phases of the slow oscillation cycle with cortical electric stimuli. Neuronal excitability is maximal toward the beginning of the depolarizing cycle and almost zero toward the end of the depolarizing phase of the slow oscillation; it then increases during the hyperpolarizing phase, in phase opposition with the extracellular potassium concentration.

Methods

The results illustrated in this paper were obtained in experiments performed on cats maintained under ketamine–xylazine anesthesia (10–15 and 2–3 mg kg^{-1}, respectively, i.m.). This anesthesia produces the best EEG sleeplike pattern of available anesthetics. Intracellular recordings from both cortical neurons and glia were obtained under stable recording conditions that included muscular paralysis (accompanied by artificial ventilation), hip suspension, drainage of *cisterna magna*, and bilateral pneumothorax; the calvarium was filled with a solution of 4% agar. The animal was kept within stable physiological parameters: body temperature between 37 and 38 °C, heart rate 90–110 beats min^{-1}, end-tidal CO_2 between 3.5% and 3.8%. The intracellular recording electrodes were made of glass capillaries filled with a 3 M potassium acetate solution (resistance, 25–45 MΩ). Field potentials were recorded by means of tungsten microelectrodes (3–8 MΩ resistance) inserted at different depths into various cortical areas. Epileptic seizurelike activity occurred spontaneously, directly from the sleeplike patterns. Extracellular ionic concentrations were measured with micropipettes filled with potassium or calcium ionophores.

Results – Transition from Sleep to Seizures

To understand the mechanisms underlying the occurrence of nocturnal SW seizures, one must consider the precipitating factors acting before and throughout the paroxysmal episode, and the (minimal) critical structures involved in the genesis of SW discharges. The occurrence of seizures may rely on a multitude of factors, ranging from genetic malformations of K^+ channels to imbalances of ionic concentrations or abnormal recruitment of cellular aggregates. In most cases, it is likely that seizures result from a combination of factors.

Consistent with this view, it is noteworthy that nocturnal seizures occur during a state in which coherent oscillations are already present. During the slow sleep oscillation, the neuronal membrane potential varies between hyperpolarized and depolarized values. The hyperpolarization of the neuronal membrane often deinactivates some excitatory currents of the low threshold type, which in turn will have a greater impact on the synchronization of the network. It has been proposed that the slow oscillation acts as a precursor of nocturnal seizures of the Lennox–Gastaut type (**Figure 3**). The slowly oscillating pattern accelerates during a transition period, evolving toward an oscillation at around 1.5–2 Hz; the amplitude of the phasic depolarizing segments increases, while their duration diminishes. Thus, the

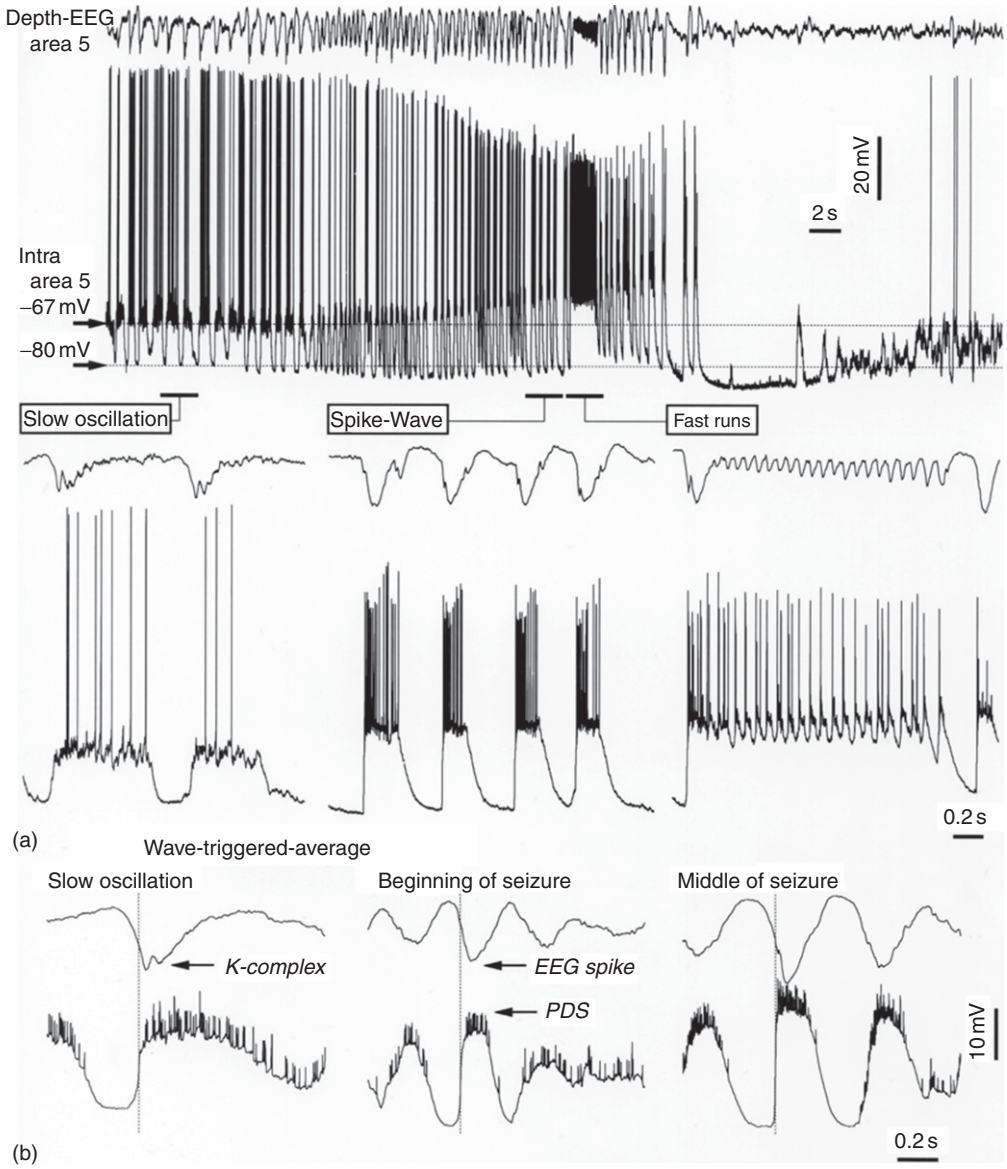

Figure 3 Spontaneously occurring seizure, developing without discontinuity from slow sleep-like oscillations. Intracellular recording from regular-spiking area 5 neuron together with depth-EEG from the vicinity in area 5. (a) Smooth transition from slow oscillation to complex seizure consisting of SW complexes at ~2 Hz and fast runs at ~15 Hz. The seizure lasted for ~25 s. Epochs of slow oscillation preceding the seizure, SW complexes, and fast runs are indicated and expanded below. Note postictal depression (hyperpolarization) in the intracellularly recorded neuron (~6 s), associated with suppression of EEG slow oscillation (compare to left part of trace). (b) Wave-triggered-average during the slow oscillation, at the beginning of seizure and during the middle part of seizure. The averaged activity was triggered by the steepest part of the depolarizing component in cortical neuron (dotted lines), during the three epochs. The depth-negative field component of the slow oscillation (associated with cell's depolarization) is a K-complex. During the seizure, the depolarizing component reaches the level of a paroxysmal depolarizing shift (PDS), associated with an EEG spike. Modified from Steriade M, Amzica F, Neckelmann D, and Timofeev I (1998) Spike-wave complexes and fast components of cortically generated seizures. II. Extra- and intracellular patterns. *Journal of Neurophysiology* 80: 1456–1479, with permission from The American Physiological Society.

normal depolarizing events of the slow oscillation are transformed into paroxysmal depolarizing shifts (PDSs), and K-complexes (at the EEG level) evolve into EEG paroxysmal 'spikes.'

The smooth transition from the physiological to the pathological pattern suggests that the slow and the paroxysmal oscillations have common mechanisms. The PDS is a giant EPSP that also contains IPSPs. Occasionally, the PDSs and their EEG counterparts, the 'spikes,' are superimposed by faster oscillations (at about 10–15 Hz) that produce corresponding indentations on the EEG 'spike,' leading to a polyspike pattern (**Figure 3**). This pattern of discharge is a typical signature for those EEG events occurring in the Lennox–Gastaut syndrome, and their

frequency (1.5–2 Hz) appears to be a resonating phenomenon within the cortical network. This conclusion resulted from a series of experiments where the cortical network was stimulated with trains of electrical shocks at various frequencies; in these experiments, responses to stimulation were maximal (in amplitude and reliability) at a stimulation rate of about 2 Hz.

The wave component of the SW complex is not due to active inhibition because, as demonstrated with multiple intracellular recordings, virtually all neurons (local inhibitory interneurons included) are silent during this phase of the oscillation. In addition, the firing rate tends to diminish toward the end of the PDS due to the inactivation of action potentials. The activity of local-circuit inhibitory cells tends to weaken toward the end of the PDS, and undergoes the general disfacilitation affecting all neurons belonging to the cortical network. The somatic input resistance is lowest at the beginning of the PDS, and continues to increase up to the next PDS, assuming its largest value during the hyperpolarization. This observation would not be consistent with the possibility that GABAergic currents induce the arrest of firing. The disfacilitation could be promoted, as in the case of the slow oscillation, by reduced synaptic efficacy consequent upon the depletion of extracellular calcium ions. Such reduced synaptic efficacy is consistent with the relative refractoriness of cortically elicited PDSs.

Among the ions with a significant impact on the neuronal excitability, potassium fluctuations have been investigated in depth. These studies have shown that the more synchronized the network, and the higher the amplitude of its oscillations, the more potassium is expelled into the extracellular space during action potentials and other currents. During SW seizures, the extracellular potassium concentration increases from resting values (3–3.5 mM) to pathological levels of 9–12 mM. An increase in the extracellular potassium has proved to favor initiation of SW seizures. As indicated above, the extracellular potassium is regulated by glial cells uptake followed by spatial buffering through gap junctions connecting the glial syncytium. While this latter phenomenon 'evens out' the extracellular potassium, it may also contribute to the general depolarization of the neuronal membrane potentials by positively shifting the Nernst equilibrium potential.

The synchronization of neuronal activity, the striking feature of sleep slow activities, creates a favorable environment for seizure genesis because synchronous activities generate local increases of extracellular potassium. The more synchronous the activities, the more potassium will be released. The spatial buffering performed by glial cells will transport the excess of potassium to more distant locations, setting the neurons of those remote sites in a hyperexcitable state. In addition, those distant neurons will receive synaptic bombardment from the neurons involved in generation of the synchronous discharge, thus contributing to the propagation of the oscillations. The protective mechanism against this spread of excitability seems to rely on the ability of glial cells to regulate potassium through uptake; impaired glial uptake of K^+ has been shown to cause epileptiform activity in the hippocampus. Circumscribed foci of epileptic activity can be generated at locations with impaired glial functionality, with spread of this hyperexcitability to remote sites through the same process of spatial buffering.

Besides the steady, very slow variations of potassium, which are reflected by similar changes in the membrane potentials of glial cells, the rhythmic ictal discharges are also accompanied by variations of the extracellular potassium concentration and corresponding phasic potentials in glial cells (**Figure 4**), indicating that the potassium uptake and spatial buffering also undergoes oscillatory influences at the frequency of the intraseizure oscillations (1.5–2 Hz). Further, at this frequency, an additional glial-dependent modulation may occur.

The implication of glial cells in the genesis of SW seizures may also be viewed in the light of recent studies that have expanded our understanding of neuron–glia communication pathways. On the one hand, glial cells are now known to be capable of neurotransmitter release, particularly glutamate, which is released from astrocytes via a calcium-dependent vesicular release mechanism. In agreement with the evolution of the neuronal excitability within each cycle of a SW discharge, the depolarization of glial cells subsequent to potassium uptake may provoke calcium-dependent neurotransmitter release. On the other hand, glial membranes possess receptors for a variety of transmitters, among which are those involved in behavioral state control, such as glutamate (non-NMDA), $GABA_A$, acetylcholine, and norepinephrine. Glutamate, the ubiquitous transmitter in the central nervous system, depolarizes glia through receptors similar to those on neurons and triggers slow calcium-dependent oscillations (as seen in brain slices containing cortical and hippocampal astrocytes). Calcium waves may travel through gap junctions between astrocytes and may unidirectionally cross glia–neuron gap junctions. Such waves may be crucial for the spread of activities from an epileptic focus, a possibility that is especially important since it has been repeatedly shown that during SW seizures the extracellular calcium is depleted at a level that is incompatible with synaptic transmission.

The participation of glial cells during SW seizures has several consequences. First, in vivo intracellular measurements have shown a persistent increase of glial membrane capacitance, developing in parallel with the progression of the seizure. In contrast, the capacitance of neurons did show stable values. This specific behavior of glia is directly proportional to the strength of the seizure and inversely proportional to the distance of the recorded glial cell from the presumed seizure focus. The glial capacitance

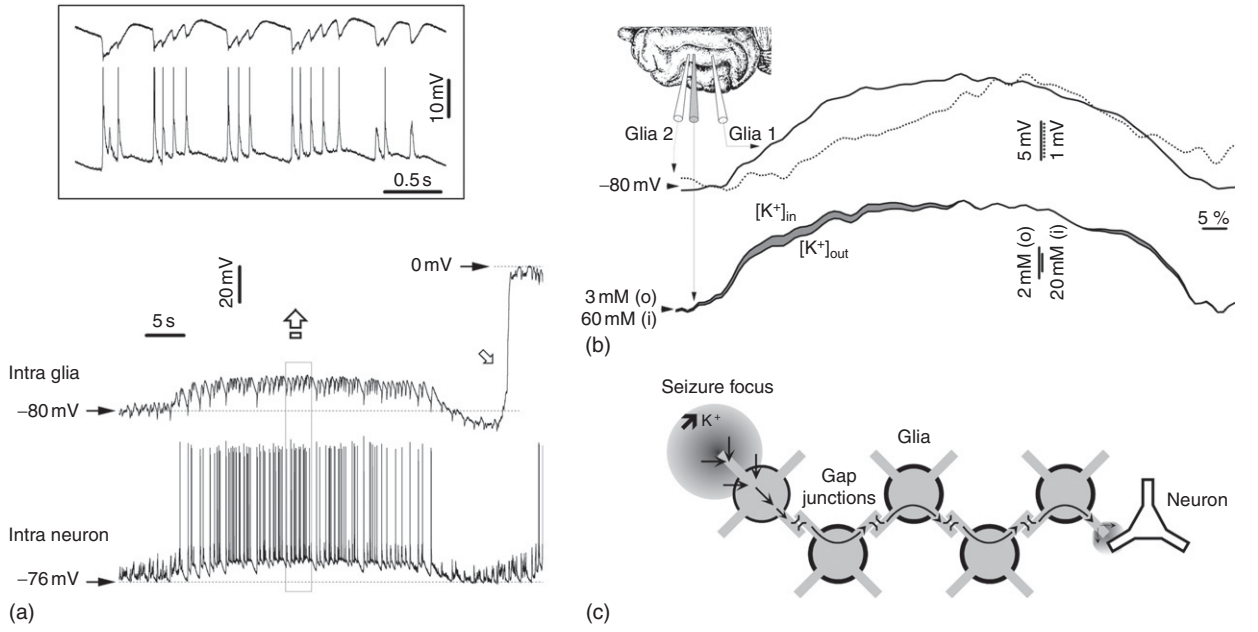

Figure 4 (a) Neuron-glia interaction during SW seizures. Continuous recording containing a double neuron-glia impalement in cortical association area 7. The two electrodes are separated by <1 mm. At the end of the period depicted the microelectrode recording the glial cell was withdrawn from the cell (*oblique open arrowhead*) to show the polarization of the glial membrane. The epochs within the square is expanded above. (b) Propagation of K^+ waves during SW seizures. Dual intraglial recording together with the extracellular potassium concentration $[K^+]_{out}$. The disposition of the recording electrodes in the suprasylvian gyrus is shown in the *inset*. The traces represent the average of 20 normalized seizure envelopes. The *upper* superimposition contains the intracellular seizures in the pair of glial cells expanded at their maximum amplitude (see different voltage calibrations – continuous line for cell 1 and dotted line for cell 2, also corresponding to the envelope traces). From the higher amplitude of the signal, it may be inferred that *cell 1* was closer to the presumed seizure focus. The *lower* panel displays the intra- and extracellular K^+ concentrations superimposed and expanded at their maximum amplitude. The $[K^+]_{in}$ was calculated from the Nernst equilibrium potential in relation with the $[K^+]_{out}$ and the intracellular trace that was recorded closely to the K^+ microelectrode (2). Toward the beginning of the seizure, the estimated $[K^+]_{in}$ rose faster than the $[K^+]_{out}$ (*gray area* between the two traces). (c) Schematic functioning of the spatial buffering during SW seizures. Important increases in the $[K^+]_{out}$ may not be buffered at short distances, in which case the internalized K^+ may travel through the glial syncytium and is externalized at a location with lower $[K^+]_{out}$ values, where it would modulate the activity of nearby neurons. Panel (a) is modified from Amzica F and Steriade M (2000) Neuronal and glial membrane potentials during sleep and paroxysmal oscillations in the neocortex. *The Journal of Neuroscience* 20: 6648–6665; panels (b) and (c) are modified from Amzica F, Massimini M, and Manfridi A (2002) Spatial buffering during slow and paroxysmal sleep oscillations in cortical networks of glial cells in vivo. *Journal of Neuroscience* 22: 1042–1053, with permission from the Society for Neuroscience.

modifications may be attributed to swelling and/or to the modulation of gap junction conductances. The latter process may be due to the fact that the steady glial depolarization observed during SW seizures would induce intracellular alkalinization, which results in increased permeability of gap junctions. The swelling of glial cells during SW seizures could result from the net uptake of K^+ to raise the intracellular osmotic pressure, and is consistent with previous reports about the shrinkage of the extracellular space during periods of increased extracellular potassium. As a direct consequence, glial swelling and shrinkage of the extracellular space would facilitate intercellular ephaptic transmission. We have recently measured such phenomena, reflected as negative intraglial potentials that develop during SW seizures. Ephaptic transmission may become an important factor in the propagation of SW seizures, especially in association with impaired action potential generation due to the high amplitude of the PDSs, and with sustained depletion of extracellular calcium concentration that directly affects synaptic transmission.

It appears, therefore, that the tight homeostasis of the extracellular potassium plays a pivotal role in keeping the normal brain oscillations from evolving into paroxysmal events. Glial cells normally fulfill this function. However, once the potassium regulation is compromised, these same cells may participate in the propagation/generalization of interictal activities. Several studies have drawn the attention to the fact that glial dysfunction is intimately associated with the genesis of epileptic behavior. Among other factors, the opening of the blood–brain barrier and the ensuing extravasation of blood proteins entrain a cascade of events that begin with astrocytic activation, down-regulation of inward-rectifying potassium (Kir 4.1) channels in astrocytes, and impaired interstitial potassium buffering – ultimately leading to the genesis of epileptogenic foci.

Conclusion and Directions for Future Research

Such mechanisms are probably at work, regardless of the vigilance state of the epileptic patient. However, it is clear that the presence of an already widely synchronized state – such as sleep – requires a lesser dysfunction of the buffering properties of glia in order to initiate a seizure. This widespread synchrony during sleep may explain why SW paroxysms are so much more common during sleep than during alert/desynchronized states.

Several aspects still require clarification: We still do not know many of the factors that precipitate the transition from a quiet slow-wave sleep state into an epileptic episode. It is conceivable that all normal sleepers develop some form of epileptiform sleep discharge, without really becoming epileptic. Those suffering from an epileptic syndrome might simply be those whose paroxysmal discharge 'overflows' into clinical symptoms. We also do not know whether the generalization of epileptic seizures might, despite its often devastating expression, have beneficial effects, in that this generalization distributes over large cerebral territories the pressure that would otherwise harm more severely local neurons (at the point of seizure origin). Our understanding of the involvement of the blood–brain barrier in the genesis and spread of seizures is still minimal; it would be interesting to know to what extent blood flow maintains protection or harms the parenchyma – i.e., what the consequence of an open blood–brain barrier is.

Introduction

γ-Amino butyric acid (GABA) is the principal inhibitory neurotransmitter in the mammalian brain. It acts through two classes of receptors: the $GABA_A$ receptors that are ligand-operated ion channels, and the G-protein-coupled metabotropic $GABA_B$ receptors. GABAergic neurons are ubiquitously distributed and encompass a fundamental role in processing and integration of all brain functions. A great number of differently assembled $GABA_A$ receptors that are differentially distributed throughout the brain have been observed. It has been suggested that dysfunction of the GABAergic system may have a crucial role in the propagation of acute seizures and in the manifestation of epilepsy syndromes. Indeed, blockade of the fast inhibitory $GABA_A$ receptors by bicuculline, pentylenetetrazole, or picrotoxin causes severe motor seizures in experimental animals, and mutant mice lacking the synthetic enzyme for GABA production (glutamate decarboxylase – GAD) or expressing mutations of certain $GABA_A$ receptor subunits are prone to spontaneous epileptic seizures.

$GABA_A$ receptors are central to GABAergic transmission. Their roles are seen not only at the synaptic level, but also in volume transmission, synchronization of neurons, and generation of network oscillations. The multiple molecular forms in which $GABA_A$ receptors are assembled in the membrane (discussed in the following sections) indicate highly diverse physiological properties of these receptors. There is growing evidence that mutations in certain $GABA_A$ receptor subunits can lead to altered brain functions, including epilepsies. Further, it has been proposed that an initial severe seizure event (status epilepticus) may alter the expression profile of individual $GABA_A$ receptor subunits, causing different assembly and thus altered function of $GABA_A$ receptors in certain brain areas. These changes could influence (support or inhibit) epileptogenesis. Acute or recurrent seizures may also influence the sensitivity of $GABA_A$ receptors to anticonvulsant drugs (such as barbiturates or benzodiazepines) known to act through the $GABA_A$ receptor.

Changes in the expression of individual $GABA_A$ receptor subunits in subfields of the hippocampus may reflect altered receptor function in this brain area – a region thought to be involved often in epileptogenesis or drug resistance. The cellular sites at which such changes take place may be critical for their roles in these processes.

Background

The $GABA_A$ receptor is a member of a superfamily of ligand-gated ion channels that also includes the nicotinic

acetylcholine receptor, the 5-hydroxytryptamine type 3 receptor, and the glycine receptor. $GABA_A$ receptors are composed of five subunits forming a chloride channel. So far, a total of six α, four β, three γ, one δ, one ε, one π, one θ, and three ρ subunits of $GABA_A$ receptors have been identified in the mammalian nervous system. This subunit heterogeneity is further increased by alternative exon splicing of the premRNA, which generates two forms of the γ2 subunit (γ2S and γ2L), from one gene, that are differently distributed in the brain. Splice variants have also been detected for other subunits, and subunit homologues have been identified in nonmammalian species.

The majority of native $GABA_A$ receptors, however, appear to be composed of two α, two β, and one γ subunit. A δ subunit, or less frequently, an ε or π subunit, can replace the γ subunit in the $GABA_A$ receptor, whereas the θ subunit may be able to replace a β subunit. A given $GABA_A$ receptor complex may consist of various α and β subunits; for example, a functioning receptor may contain two α1 subunits, two β2 and one γ2; or one α1, one α2, two β2 and one γ2 subunit; or any pair of existing α subunits. Also, the β subunits within a given $GABA_A$ receptor may originate from the same or from different genes. The most abundant subunits in the rodent brain are α1 to α5, β1 to β3, γ2, and δ.

The binding site of GABA to the $GABA_A$ receptor is located at the interface of an α and a β subunit. Binding of benzodiazepines occurs at the interface of an α and a γ subunit. Benzodiazepines bind with high affinity to receptors containing α1, and with somewhat lower affinity to those containing an α2, α3, or an α5 subunit (but not to α4 or α6 containing receptors), and only the γ2 (no other γ subunit or δ) subunit can mediate the benzodiazepine-induced increase in affinity to GABA. Barbiturates exert their action after binding at the chloride channel pore, and seem to bind also to α4, α6, and/or δ subunit containing receptors. $GABA_A$ receptors containing only α and β subunits have been described in hippocampal pyramidal cells. They do not respond to benzodiazepines but are highly sensitive to Zn^{2+} ions.

The subunit composition of $GABA_A$ receptors also critically determines their physiological and pharmacological functions. GABA exerts its action by opening a chloride channel. Benzodiazepines and barbiturates can increase the affinity for GABA, thus increasing the frequency or duration of channel opening, respectively. The direction of the chloride flux is dependent on the chloride gradient at the cell membrane. In the mature brain, the chloride transporters (such as the potassium-dependent chloride transporter KCC2) extrude chloride from the cell, allowing in an *inward* chloride flux and a hyperpolarization after channel opening. In the immature brain, the expression level of KCC2 is low; instead, a sodium–potassium-dependent cotransporter NKCC1 is expressed that transports chloride into the neuron. The resulting high intracellular chloride concentration drives an outward chloride flux and depolarization of the cell upon stimulation of $GABA_A$ receptors. Altered chloride transporter expression or function has been associated with genetic forms of epilepsy. It has also been proposed that expression of KCC2 may be altered in certain neurons and lead to impaired inhibition.

In the adult mammalian CNS, synaptic transmission through GABA synapses is characterized by fast and precisely timed inhibitory activity in the form of inhibitory postsynaptic currents that mediate phasic inhibition. A second form of inhibitory transmission, resulting from GABA diffusion out of the synaptic cleft and activating $GABA_A$ receptors located outside the synapse, has been characterized recently and is referred to as tonic inhibition. Tonic conductance has been found in a large variety of principal neurons and interneurons, including those found in the cerebellum, cortex, hippocampus, thalamus, and spinal cord. Depending on the brain region, certain subunits such as α4, α5, and δ preferentially constitute such extrasynaptic receptors and mediate tonic inhibition.

Methods

Using histochemical methods, we investigated changes in the expression of $GABA_A$ receptor subunits after systemic application of kainic acid (KA; 10 mg kg^{-1}, i.p.) in rats. In this model, an initial status epilepticus leads, after a 'latent phase,' to epilepsy characterized by recurrent spontaneous seizure activity. In order to differentiate changes during the acute KA-induced status epilepticus from changes during epileptogenesis (i.e., during the latent phase) and in chronic epilepsy, we investigated $GABA_A$ receptor subunit expression at 24 h, 8 days, and 1–3 months after the initial kainate-induced status epilepticus. Expression was studied at the mRNA and protein level using in situ hybridization and immunohistochemistry, respectively. For in situ hybridization, we used 20 μm thick cryotome-cut sections from snap frozen brains. We incubated them with synthetic oligo-DNA probes labeled by reaction with ^{35}S-dATP in presence of terminal deoxynucleotidyl transferase. For immunohistochemistry, we used 40 μm thick sections from 4% paraformaldehyde fixed brains and processed them by the indirect peroxidase method. Antibodies specific for individual $GABA_A$ receptor subunits were supplied by Prof. Werner Sieghart, Brain Research Center, Medical University Vienna. For semiquantitative evaluation of changes in the expression of individual subunits, we performed densitometry on film autoradiographs and on immunolabeled brain sections.

Studies in human brain tissue were done in collaboration with Prof. Thomas Czech, Department of Neurosurgery, Medical University of Vienna, who supplied us with specimens collected from TLE patients during routine surgery (after approval of the Institutional board of the

Medical University of Vienna). The specimens were either snap-frozen or immersion fixed in 4% paraformaldehyde. For in situ hybridization, the method described earlier was used, applying probes complementary to the respective human RNA sequences. For immunohistochemistry in the human specimens, we performed the slightly more sensitive avidin–biotin method (ABC-kit by Boehringer, Ingelheim, Germany) after treating the sections with target retrieval solution; the same antibodies used for investigating rat brains were also applied for the human tissue.

Results

Studies in Animal Models of Epilepsy

In the studies using the KA rat model of temporal lobe epilepsy (TLE), we observed marked losses in $GABA_A$ receptors that were obviously related to neuronal cell losses (mainly in sectors CA1 and CA3 of the Ammon's horn, hilar interneurons, and the subiculum). This result is consistent with losses in $GABA_A$ receptor binding sites in the whole hippocampus. These prominent neurodegeneration-related changes suggest marked alterations in $GABA_A$ mediated transmission. In addition, there were also significant changes in $GABA_A$ receptor subunit expression in the molecular layer of the dentate gyrus – a structure that remains relatively intact in this animal model. Most conspicuous in this region was a rapid decrease in subunit δ (Figure 1). Indeed, downregulation of subunit δ was a consistent observation in most animal models, including the kindling model, recurrent seizures induced by electrical stimulation, and the mouse model of pilocarpine-induced status epilepticus and epileptogenesis. Interestingly, expression of the α4 subunit (a frequent partner of the δ subunit in the $GABA_A$ receptor complex) is not reduced but increased in the KA model of the rat (Figure 1) and in the pilocarpine model of the mouse. We also observed a clear-cut reduction in the expression of subunit α5 in the dentate gyrus, as well as in the Ammon's horn – although these latter changes were obscured by the severe neurodegeneration in this area after kainate-induced status epilepticus. Houser *et al.* reported less severe damage of the pyramidal cell layer in the mouse pilocarpine model, and were able to demonstrate a reduction in the expression of subunit α5. They also discussed the possibility that these observed decreases in δ subunit expression (and possibly in α5 subunit expression) are associated with reduced tonic inhibition in the epileptic mice.

In contrast to receptors containing the δ subunit, receptors containing the γ2 subunit are primarily associated with synaptic or phasic inhibition. In addition, the γ2 subunit mediates the sensitivity of the receptor to benzodiazepines, and the γ2 subunit is importantly involved in the targeting of the $GABA_A$ receptor complex to the cell membrane. In our initial experiments, we observed a marked and rapid – but transient – reduction in γ2 mRNA levels in the dentate gyrus (6 h) after kainate injection. In the pyramidal layer, a persistent reduction (presumably related to cell damage) was seen. Using immunohistochemistry, we observed conspicuous labeling for subunit γ2-immunoreactivity of dendrites of pyramidal cells and interneurons, lasting up to 1 month. We interpreted these data as a

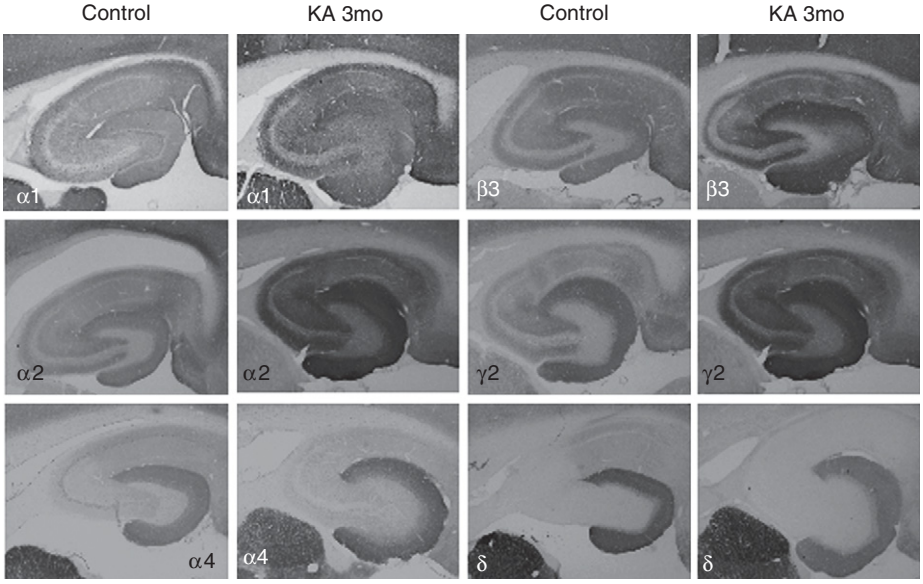

Figure 1 Changes in immunoreactivites of $GABA_A$ receptor subunits in rats with spontaneous seizures, 3 months after status epilepticus induced by injection of kainic acid. Note the decrease in δ subunit immunoreactivity, contrasted by increases in subunits α2, α4, β3, and γ2. Apparent increase in subunit α1 immunoreactivity in the epileptic rats is mainly present in interneurons.

reflection of overexpression of this subunit. Such an increase in γ2-immunoreactivity can also be seen in the dentate molecular layer up to 4 months after KA injection (Figure 1).

Recent studies by Kapur *et al.* and Wasterlain *et al.*, have demonstrated rapid internalization of γ2 subunit protein following status epilepticus. Using immunofluorescence, they demonstrated as early as 1 h after seizure induction, a translocation of subunit γ2-immunoreactivity from the cell membrane to the cytoplasm of the respective neurons. Functionally, this translocation may have considerable consequences. First, it may result in receptors devoid of γ2 subunit. Such receptors (if active at all in vivo) would have strongly altered physiological and pharmacological functions. As mentioned earlier, receptors consisting only of α and β subunits have high sensitivity to the ion Zn^{2+} that can be released from mossy fibers; this sensitivity to mossy fiber-released zinc could result in impaired GABA-mediated inhibition. Receptors lacking the γ2 subunit are also resistant to treatment with benzodiazepines. And, since the γ2 subunit is important for anchoring the $GABA_A$ receptor complex in the cell membrane, internalization of the subunit γ2 may also limit the survival of the whole receptor in the cell membrane. This translocation phenomenon does not affect all $GABA_A$ receptors and/or is not permanent, since even 3 month after kainate-induced status epilepticus we observed high levels of γ2-immunoreactivty in granule cells and pyramidal cells (Figure 1). Consistent with these findings, Houser *et al.* also observed an increase in γ2-immunoreactivty in the chronic phase after pilocarpine-induced status epilepticus in the mouse.

In the normal molecular layer of the dentate gyrus of the rat, the α2 subunit is thought to be the most prevalent. The α1 subunit appears to be preferentially expressed in interneurons of the hippocampus. Expression levels of subunit α4 appear to be low in the rat hippocampus (compared with the thalamus for example), but more abundant in the dentate molecular layer than in the strata oriens and radiatum of the hippocampus proper. In contrast to the human hippocampus, there is no α3 subunit expressed in rat dentate granule cells, and little in interneurons. Subunit α5 is more extensively expressed in pyramidal cells than in granule cells of the rat. Again, this pattern is somewhat different from the expression pattern in humans, where equally high levels of subunit can be seen in dendrites of granule cells and pyramidal cells. Expression patterns of individual $GABA_A$ receptor subunits are also slightly different in the mouse.

As noted earlier, subunits α4 and α5 are presumably related to tonic inhibition. The subunit α4, expressed only slightly in normal brain, is slightly upregulated and subunit α5 downregulated in the dentate gyrus, notable at the later intervals after kainate injection. At this time, in situ hybridization and immunohistochemistry also show increased expression of subunits α1 and α2 in rats treated with KA or after electrically induced status epilepticus.

All three β subunits are expressed in principal cell layers of the rat hippocampus. Expression of subunit β3 appears to be the strongest, that of β1 weakest. Subunit β2 is even more abundant in hippocampal interneurons (coexistent with subunit α1 and γ2, less with δ). In most TLE models, notably in the KA model, there is some upregulation of all three β subunits (notably of β2 and β3).

Taken together, these data indicate increased expression of $GABA_A$ receptors in the dentate gyrus following kainate-induced status epilepticus; however, there is a clear shift from receptors associated with tonic inhibition to receptors associated with phasic inhibition. Increased concentrations of $GABA_A$ receptors in the dentate hilus were reported more than 20 years ago (using ligands for either GABA or benzodiazepine-binding sites) – even in the face of neurodegeneration related receptor losses in Ammon's horn). Why subunits related to phasic inhibition are preferentially lost remains to be determined. One possibility is that GABA produced at high concentrations in granule cells may be released extrasynaptically onto granule cell dendrites, and may then contribute to downregulation of extrasynaptic receptors.

Studies in the Human TLE Hippocampus

There are only a few studies on the expression of $GABA_A$ receptor subunits in specimens removed by surgery in TLE patients. Difficulties experienced in such studies include the availability of valid antibodies (specifically detecting the human subunits) and difficulties in comparing fresh (surgically removed) tissue with post mortem control tissue (in which mRNA and proteins may be degraded to varying extents). The first extensive study was published by Loup *et al.*, who showed upregulation of subunits α1, α2, β2/3, and γ2 subunits in granule cells and granule cell dendrites, downregulation of these subunits in the subgranular zone, and loss of α1 subunit immunoreactivity in interneurons of the hippocampus proper. Using in situ hybridization and immunohistochemistry, we also observed increases in all three β subunits, notably β1 and β3, in the molecular layer, the hippocampus proper and subiculum. In the subiculum (which is highly preserved in human TLE), we observed increases in subunits α3 and γ2, but losses in subunits α1, α3, and γ2 in Ammon's horn (Figure 2).

Taken together, these data indicate that in human TLE there are marked changes in the expression and assembly of $GABA_A$ receptors, suggesting remodeling of GABAergic transmission. Subfields of the hippocampus that are less vulnerable to seizure-induced neurodegeneration, such as the subiculum and dentate granule cell layer, display upregulation of various subunits, indicating

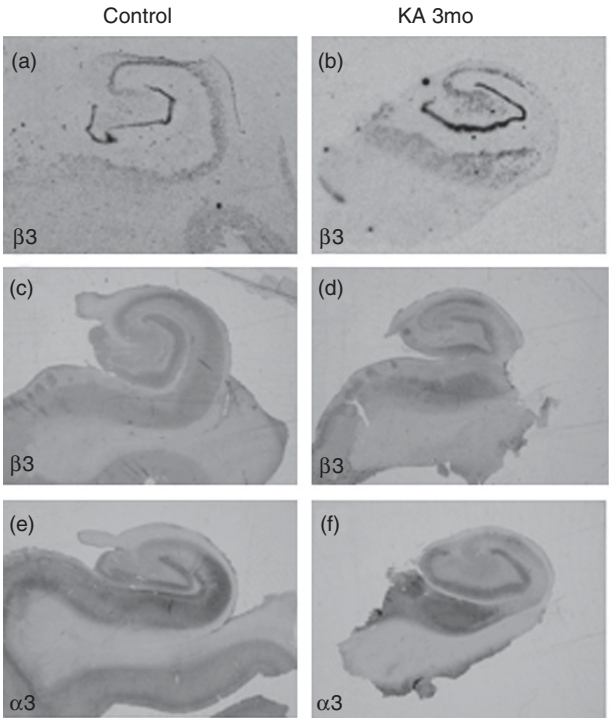

Figure 2 Changes in immunoreactivites of $GABA_A$ receptor subunits in TLE patients. Note the increased expression of subunit β3 mRNA (b vs. a) and immunoreactivity (d vs. c) in the dentate molecular layer and in the subiculum and the increase in α3 immunoreactivity in the subiculum (f vs. e).

facilitation of GABAergic transmission. Striking and difficult to explain is the especially pronounced expression of β subunits – which could result in imbalanced assembly of $GABA_A$ receptors (such as receptors containing three β and two α and no γ subunit, or three β, one α and one γ2 or δ subunit). Studies with recombinant receptors indicate that they would not bind GABA with high affinity or capacity – and if they lacked γ2, they may not be affected by benzodiazepines but would be sensitive to Zn^{2+}. Due to the difficult comparison with postmortem controls, we have so far been unable to obtain evidence for downregulation of subunits δ or α5 in the human tissue, which would (in analogy to the rat) be indicative of reduced extrasynaptic tonic inhibition in the epileptic brain. Appropriate human controls are essential since, as mentioned earlier, the distribution (and thus the function) of certain $GABA_A$ receptor subunits is different in the human hippocampus compared to that in the rat.

Future Goals

It will be crucial to continue work in the human brain, since the physiological properties of single $GABA_A$ receptor may vary much depending on the circuitry in which they are integrated and less critically on their actual subunit composition. Detailed knowledge about the pathology of altered receptor expression will be important for developing appropriate drugs targeting individual $GABA_A$ receptor subtypes (e.g., acting through the benzodiazepine binding site). A limitation of our studies is that although we have learned something about changes in the $GABA_A$ receptor subunit distribution, we have yet to determine the details about changes in actual receptor composition. We are currently performing neurochemical studies, using subtractive purification methods in microdissected hippocampal subfields from KA rats, to approach this question.

Introduction

Milestone progress in large-scale genetic characterization, such as the completion of the Human Genome Project, has opened free online access to virtually all genetic data about the human organism. The transcriptional regulation and interaction of genes raises the challenging issue of functional genomics – and the identification of potential drug targets in human diseases. Not surprisingly, the high-throughput analysis of biological systems by the use of genome-wide expression profiling has also become a fundamental key technology in epilepsy research. Different kinds of array designs have been developed, including DNA microarrays and RNA oligonucleotide microarrays. In addition, recent advances have opened new avenues for establishing protein or antibody microarrays, thus bridging the gap toward post-translational approaches – i.e., proteomics.

Functional genomics deals with the presumption that physiological and pathogenic conditions are caused by, and cause, specific transcriptional alterations. To carry out such studies, access to living tissue without RNA degradation is pivotal. And is frequently a limiting step in the experimental setup of functional genomics studies. This issue is of special importance in the study of many brain disorders, such as epilepsy. For obvious reasons, the availability of human brain tissue is restricted to autopsy samples or specimens obtained by neurosurgical treatment strategies (in pharmacoresistant focal epilepsies). Alternatively, animal models provide useful tools to elucidate those processes that occur before chronic seizure activity appears – i.e., in the period termed 'epileptogenesis.' The present article will offer an overview of the main trends in microarray technologies and their application in epilepsy research. Pros and cons will be highlighted by focusing on studies in temporal lobe epilepsy (TLE), a major cause of focal epilepsies in children and young adults.

The Microarray Experiment

Expression profiling based on microarrays has evolved as a valuable approach to determine transcript patterns in anatomically heterogeneous structures such as the brain, and to monitor genomic responses in complex diseases. A growing number of customized cDNA microarrays and oligonucleotide arrays, also designated as 'chips,' has dramatically accelerated the throughput of gene expression analyses. The core idea of large-scale 'chip' approaches is a 'nonhypothesis'-driven attempt to find gene transcripts that otherwise would not have been expected to play a physiological or pathogenic role. Frequent strategies for chip analysis include comparisons between identified cell populations, brain regions, or groups of neuropathologically characterized individuals.

The present article will offer an overview of the main trends in microarray technologies and their application in epilepsy research. Pros and cons will be highlighted by focusing on studies in temporal lobe epilepsy (TLE), a major cause of focal epilepsies in children and young adults.

The Microarray Experiment

Expression profiling based on microarrays has evolved as a valuable approach to determine transcript patterns in anatomically heterogeneous structures such as the brain, and to monitor genomic responses in complex diseases. A growing number of customized cDNA microarrays and oligonucleotide arrays, also designated as 'chips,' has dramatically accelerated the throughput of gene expression analyses. The core idea of large-scale 'chip' approaches is a 'nonhypothesis'-driven attempt to find gene transcripts that otherwise would not have been expected to play a physiological or pathogenic role. Frequent strategies for chip analysis include comparisons between identified cell populations, brain regions, or groups of neuropathologically characterized individuals.

Background

Expression Profiling in Temporal Lobe Epilepsy

Epilepsies are among the most frequent CNS disorders, affecting ~1.5% of the population worldwide. In TLE, the seizure origin typically involves the hippocampal formation, a structure located in the mesial temporal lobe. Many TLE patients develop pharmacoresistance (i.e., seizures can not be controlled by antiepileptic drugs), and therefore have to undergo surgical treatment strategies.

Hippocampal biopsies obtained during surgery from pharmacoresistant patients reveal two major neuropathological entities. The most frequent finding, in approximately two-third of the patients, is Ammon's horn sclerosis (AHS). Histopathologically, AHS hippocampi exhibit substantial neuronal cell loss in the areas CA1, CA3 and CA4, whereas the CA2 subfield and dentate gyrus granule cells (DG) appear less vulnerable to seizure-induced neurodegeneration. Those areas strongly affected by neuronal cell loss also exhibit pronounced fibrillary astrogliosis and, thereby, sclerosis. Further alterations in AHS hippocampi include dispersion and focal bilamination of the dentate granule cell layer, persistence of Cajal–Retzius-like interneurons, and mossy fiber sprouting. In approximately one-third of pharmacoresistant patients, TLE is associated with focal lesions in the temporal lobe. These lesions include highly differentiated malformations as well as benign glial and glioneuronal neoplasms, such as oligodendrogliomas, pilocytic astrocytomas, pleomorphic xanthoastrocytomas (PXA), gangliogliomas, dysembryoplastic neuroepithelial tumors (DNTs) – referred to as long-term epilepsy associated tumors (LEAT). Within this broad spectrum, two major groups – represented by gangliogliomas and focal cortical dysplasias – are of major interest because of their rather frequent occurrence in the subpopulation of lesion-associated TLE.

Microarray Technology

Different expression array technologies have been developed. While cDNA nylon arrays rely on radioactively labeled probes and semiquantitative phosphorimaging analysis, large-scale oligonucleotide and glass microscope slide DNA arrays are hybridized with fluorescent probes and analyzed by specific detection systems. In the following paragraphs, we will focus on a commercial oligonucleotide microarray procedure (based on the Affymetrix platform) that has been successfully used in our laboratory. For example, modern gene chips for rat RNA provide comprehensive coverage of the transcribed rat genome on a single array with 30 000 transcripts and variants from over 28 000 well-substantiated rat genes. Microarray solutions are supplemented by protocols and reagents for straight-forwarded sample cryopreservation, mRNA isolation, probe labeling, hybridization, high-resolution scanning, and data mining procedures.

Methods

Overview

The Affymetrix microarrays combine more than a million oligonucleotide probes on each 'chip.' The principle of the procedure is to load the chip with the whole transcriptome of a tissue- or cell-type sample. Biotin-labeled RNA fragments are hybridized to the probe array and stained with streptavidin phycoerythrin conjugates. The signal intensity fluorescent images produced during chip hybridizations are read using the scanning systems and digitalized into a cell file (cel) data format using GeneChip operating software of the manufacturer. The signal intensity is proportional to the bound target at each location on the probe array. To obtain biotin-labeled RNA fragments, preparatory procedures on RNA samples include the isolation and cleanup of total-RNA, the reverse transcription (RT) of the mRNA into cDNA, and then in vitro transcription into cRNA using biotin-conjugated nucleotides that can be targeted by the streptavidin phycoerythrin conjugate after hybridization. The cRNA is fragmented before hybridization, as each transcript is represented by several probes on the chip. Hybridization to the probes is designed to either match or mismatch. The signal proportions of matching and mismatching probes are then used to calculate if, and to what extent, a transcript may be present or not.

Experimental Setup

Microarray technology is not a simple genetic 'cash cow.' As in almost any scientific experiment, the careful selection of appropriate samples and controls (or matched pairs of samples) is required for valid and reliable findings. The statistical menace of false-positive findings within a plethora of transcriptional data is one of the biggest obstacles in applications of this technology. To diminish the false-positive discovery rate as much as possible, the a priori inclusion of sufficient replicates is mandatory.

For obvious reasons, access to living brain tissue is frequently restricted. But even if access is possible, there are additional challenges. Relevant transcriptional alterations in distinct cell types may be obscured because of tissue heterogeneity within the sample. Other sources of heterogeneity are inevitable, including (in humans) interindividual genetic background. Another limitation, especially of human surgical specimens, is the strong mRNA degradation effects because of local hypoxic

periods or mechanical stress during tissue resection. Nonetheless, microarray analyses have been successfully established in human brain (e.g., hippocampal) specimens.

Data Mining

Microarray technology allows the experimenter to profile gene expression of thousands of genes at the same time. However, the number of relevant candidate genes that can be further characterized in subsequent validation studies is rather small. This discrepancy between large-scale analysis and the need to focus on distinct candidates makes it necessary to 'filter' the genes of interest. As already indicated earlier, the statistical menace of false-positive findings within a plethora of transcriptional data is a major obstacle. For example, when dealing with 10 000 transcripts and using a *t*-test between two groups with a cut-off of $p < 0.05$, about 500 genes would be expected to pass this filter just by chance. The false-positive discovery rate can be diminished by increasing the stringency of the filter – i.e., applying lower cut-off values. However, this strategy increases the rate of discarded false-negative genes. This higher discard rate can be unfortunate, since even somewhat less reliable genes – i.e., those low abundant transcripts, or high abundant genes with minor but stable expression alterations – may be of scientific interest (exert relevant biological effects).

To find the discriminating genes between two or more conditions, a sequential filtering of the data can be performed. For example, genes of interest can be required to meet the following criteria: (1) perfect match/mismatch ratio to be called present or marginally present, calculated by the analysis software tool based on probe hybridization signals the should match (i.e., perfect match (PM)) and those that should not match (i.e., mismatch probes (MM)); (2) valuable abundance (higher than the median gene expression) in at least one of two conditions; (3) a fold-change of at least two; and (4) interindividual homogeneity measured, e.g., by a two-sided *t*-test with a cut-off of $p < 0.05$ and multiple-testing correction.

Chip to chip variability of signal intensity because of sample processing variability must be adjusted by various normalization strategies. Per gene normalization can be performed with control replicates as reference samples. However, one must keep in mind that mathematical normalization strategies cannot compensate for intrinsic biological variability between individual specimens, a factor in virtually all expression profiling studies. Introduction of certain reference or housekeeping genes enables the investigator to carry out a systematic comparison between different sets of experiments, including complex estimations such as cluster analysis. However, the identification of reliable housekeeping genes may considerably change with experimental paradigms and always needs careful attention.

Complex, sporadic brain disorders such as TLE represent a major challenge for functional genomics, since a variety of molecular pathways and genes are involved and differentially regulated during the long medical history of the disease. Large-scale expression arrays have proven to be efficient tools for monitoring gene expression and open new avenues for the identification of pathogenesis-related molecules and mechanisms of different diseases. Nonetheless, it will be an important future challenge to carry out such analyses in homogeneous patient samples, standardized for distinct pathogenetic aspects (e.g., type of seizures), onset of the disease, and resistance to specific modes of pharmacotherapy.

Validation of Expression Data

The study of gene expression using microarray technology has gained considerable acceptance in the research community. However, gene expression data based on chips must be independently quantified. The most common method is quantitative real-time reverse transcription polymerase chain reaction (RT-PCR), a method that enables the investigation of mRNA levels even from single cells. Furthermore, it allows absolute or relative quantitation of a target transcript. For relative mRNA quantitation, a suitable reference gene is essential as an internal control. Ideally, it should show a constant and high level of expression, independent of experimental conditions. After normalization of the target signals to the reference signal, comparisons between different tissue types, across various developmental stages, and between control and disease tissue can be performed. In our laboratory, validation of the microarray-based gene expression profiling is performed by a quantitative real-time RT-PCR (TaqMan®) assay using the SYBR Green PCR detection system in a three-step RT-PCR amplification cycle. Duplicate reactions are carried out for each gene. The SYBR Green fluorescence signal is measured in each PCR cycle. The comparison of transcription levels is finally calculated by the ΔΔCt-method.

Recent Results

Microarray Analyses in Human Specimens

Hippocampal biopsy specimens from patients with pharmacoresistant TLE have been used for functional genomics. However, these samples only reflect the chronic stage of the disease; this situation may explain why such studies are rarely compared with expression analyses in animal models. When dealing with human specimens, the first issue is to obtain a sufficient yield of mRNA – a potential problem since there is a need for high amounts of starting material. Complex tissue composition (such as is the case for the brain), with expression alterations in only one cell type, may obscure biologically relevant

differences. Laser capture microdissection can be used to obtain pure cell populations, but aggravates the difficulty of obtaining sufficient mRNA amounts. Nonetheless, by introducing amplification steps into the sample preparation protocols, it may be possible to obtain sufficient mRNA for microarray procedures. Use of snap-frozen tissue sections, labeled with standard histochemical stains, is recommended for RNA extraction. This strategy has been further refined and applied to studies using laser microdissection of tissue from immunohistochemically labeled cells after RT of mRNA into cDNA (because DNA is more resistant against degradation during immunohistochemistry than is mRNA). Additional applications, using DNA isolated from microdissected tissue, include analysis of loss of heterozygosity (LOH) or screening for somatic mutations or mosaicisms in distinct cell types. Certainly, tissue heterogeneity on the cellular level must be taken into account in expression studies, but the difficulty may be solved using a two-step approach, with cell-type specific analyses after initial microarray experiments.

Another problem is the need for appropriate control CNS tissue for expression analysis in TLE. For obvious reasons, appropriate age-matched nonepileptic control specimens – e.g., resected hippocampi without any histopathological abnormalities – are virtually impossible to obtain. Cases of nonepileptic tumor patients with resection of a noninfiltrating tumor mass in the close vicinity of the hippocampus rarely occur, so are not feasible for systematic experimental design with large case numbers.

We have used a two-step strategy to study gene expression in complex human CNS disease by combining a cDNA-array-based expression profiling procedure with subsequent real-time quantitative RT-PCR analysis of gene expression levels in histologically specified and laser-microdissected cells. In this setting, epileptic human hippocampi were compared with control biopsy samples from nonepileptic tumor patients, and alternatively compared with hippocampi from epilepsy patients without histopathological alterations of the hippocampal formation but perihippocampal focal lesions. We found about 3.55% of all represented genes to be dysregulated, with the highest signal increase in AHS for ataxin-3. Real-time RT-PCR validation experiments confirmed initial microarray results of an upregulation of ataxin-3 and GFAP, and a reduction in calmodulin expression in AHS hippocampal slices. RNA in situ hybridization approaches confirmed the cellular expression pattern of ataxin-3 and correlated well with the results of the quantitative RT-PCR experiments. Ataxin-3 in situ hybridization showed hybridization signals in DG and hippocampal pyramidal neurons, but not in glial cells. These data indicate that hippocampal biopsy specimens of pharmacoresistant TLE patients are suitable for large-scale expression analyses.

Arion and colleagues performed a microarray study of anterolateral temporal cortical specimens of patients with chronic TLE to compare 'spiking' (abnormal) and 'nonspiking' (normal) brain areas. Gene expression profiling revealed a downregulation of multiple GABA system-related genes as well as an upregulation of oligodendrocyte and lipid metabolism transcripts in the spiking samples. Expression level alterations were also found in transcripts related to signaling transduction systems such as the classical MAPK cascade, suggesting that spiking behavior is substantially correlated with distinct transcriptional fingerprints.

In another cDNA microarray experiment, entorhinal cortex was subjected to expression profiling and compared with corresponding lateral temporal neocortex of the same individuals as control tissue. To discard expression alterations due to physiological differences between brain areas, the experimenters required that the initially found genes lacked regional differences in nonepileptic autopsy samples. Six transcipts fulfilled this criterion: serotonin receptor HTR2A, neuropeptide Y receptor type 1, the FHL2 protein associated with the KCNE1 potassium channel subunit and with presenilin-2, and three immune system-related proteins (C3, HLA-DR-gamma, and CD99). The authors suggested that local dysregulation of the neurotransmission and complement systems in the EC is a frequent event in human MTLE.

Animal Models of TLE

An important aspect of TLE pathogenesis is that the disease usually develops in children or young adults. The process of epilepsy development has been termed 'epileptogenesis,' and the underlying process is suggested in the dictum 'seizures beget seizures.' Underlying pathophysiological as well as pathomorphological mechanisms – i.e., cellular hyperexcitability and axonal fiber sprouting – are likely to reflect distinct alterations in gene expression. However, in the latent period of epileptogenesis, human specimens are not available for functional genome analysis. In this time window, molecular mechanisms of epileptogenesis can only be elucidated using animal models of TLE. The complexity of histopathological alterations in the affected structure of the mesial temporal lobe, the hippocampus, suggests expression alterations in various genetic and molecular signaling pathways specifically involved in key aspects of human epileptogenesis, particularly those expression changes related to synaptic and axonal reorganization resulting in hyperexcitability. There is growing interest in the question of whether onset of recurrent chronic epileptic seizures may be prevented by pharmacological treatment during the latent stage of epileptogenesis. Pathogenic or course-modifying gene expression patterns may provide candidate structures for the design of innovative therapeutic targets.

Currently used TLE animal models can be separated into two major groups: induction of status epilepticus (SE)

by application of an excitotoxic compound (kainic acid, pilocarpine) followed by development of a spontaneous epilepsy condition; and electrically stimulated chronic recurrent seizures referred to as kindling-induced TLE. In the kainic acid and pilocarpine models, segmental neuronal cell loss and astrogliosis of hippocampi intriguingly reflect human AHS. Further, neuropathological findings in lesion-associated TLE are consistent with hippocampi of animals exhibiting chronic seizures after subconvulsive electrical kindling of the amygdala or tractus perforans.

Beside electrical and excitotoxic compound elicitation of SE, other models without induction of SE have also been investigated. One such model focuses on mimicking prolonged febrile seizures in young children. Since many patients with AHS have a history of prolonged febrile seizures during early childhood, an etiological role for these seizures in the development of TLE has been suggested. Although neuronal damage induced by febrile seizures is rather mild, recent findings support an impact of experimental prolonged febrile seizures on structural and molecular changes resulting in hippocampal hyperexcitability, including reduced seizure threshold to convulsive agents.

A common important feature of all experimental TLE models is the possibility to monitor expression dynamics from the 'beginning' of epileptogenesis (i.e., from the time of the epileptogenic insult). In a recent study, we have used oligonucleotide microarrays to carry out expression profiling in vulnerable hippocampal CA1 neurons versus resistant DG at distinct stages of epileptogenesis in the pilocarpine TLE model. An episode of SE, induced by application of pilocarpine to rats, results in chronic TLE after a seizure-free latency interval. We showed that on day 3 following SE, mechanisms of cellular stress and injury as well as inflammatory responses predominated, followed by alterations of the associated transcription factors. The latter changes were consistent with cytoskeletal changes and synaptic reorganization processes seen at 14 days after SE. Finally, the stage of chronic recurrent seizure activity was characterized particularly by expression changes of genes involved in neurotransmission.

The observation of shared features of nervous system development and epileptogenesis has led Elliott and colleagues to hypothesize common molecular mechanisms in both states. And indeed, DNA microarray analysis in the dentate gyrus identified similar patterns of regulation during development and epileptogenesis. Common spatial and temporal gene expression patterns were found (i.e., several genes were either up- or downregulated during both processes). Functionally, many genes were implicated in cell morphology and axon outgrowth or cellular proliferation and fate determination. The relatively high density of plasticity-related genes supported the concept that nervous system development and epileptogenesis may share common mechanisms. Another study focused on expression changes after kainic acid stimulation (activation of non-*N*-methyl-D-aspartate (NMDA) glutamate receptors) resulting in seizures, neurodegeneration, and remodeling processes. The gene profile revealed 36 novel genes that mainly have roles in transcription, and to a lesser extent have roles in cell death, extracellular matrix remodeling, cell cycle progression, neuroprotection, angiogenesis, and synaptic signaling.

Based on the observation that kainate acid-induced SE in immature rats causes neither cell death nor recurrent spontaneous seizures, another microarray analysis was performed to elucidate the mechanisms of these distinct responses with respect to transcriptional changes in neuropeptides following SE. Intriguingly, neuropeptides were differentially regulated by seizures in both immature (P15) and mature (P30) hippocampi. However, the changes were more pronounced at P30 compared with the changes at P15, not only for neuropeptides with convulsive properties but also for those with neuroprotective properties. The authors suggested that distinct neuropeptides might play a neuroprotective role in immature rats by preventing neuronal loss after seizure in adults.

Pitkänen and colleagues have analyzed epileptogenesis-related expression profiles in hippocampal and temporal lobe specimens after electrically induced TLE. Many of the differentially expressed genes were associated with signal transduction, synaptic and axonal plasticity, and cellular metabolism. Recently, first evidence has been found for specific gene expression signatures in response to pharmacotreatment in experimental TLE. Levetiracetam (LEV) treatment was shown to induce substantial effects on gene expression. Several novel genes, as well as many epilepsy-related genes, such as neuropeptide Y, thyrotropin-releasing hormone (TRH), and glial fibrillary acidic protein (GFAP), were identified from the gene chip experiments and confirmed to be upregulated by kindling and partially normalized by LEV treatment. Moreover, some expression changes correlated with the kindled phenotype. Such studies are promising steps towards a better comprehension of the genetic background of susceptibility for pharmacotreatment and pharmacoresistance.

Comparison of Experimental and Human Data

The studies described earlier have addressed transcriptional alterations based on large-scale microarray analyses in different animal models of TLE, with different emphases on distinct spatial or temporal alterations. While the animal models allow for better technical processing and the possibility of analyzing epileptogenesis, it is unclear whether these model findings can be transferred to human conditions. To address this question, comparisons of genomic responses between human and experimental TLE were carried out, with a focus on relationships involving 3409 rat genes and 4126 human

genes. Correlation coefficients of the corresponding genes were in the range of 0.4, but rose to 0.6 when the interspecies comparison concentrated on the expression ratios between DG and CA1 regions of each species. The highest congruency was detected between the chronic epileptic stage in experimental epilepsy and chronic human AHS. In contrast, markedly less codifferentiated gene ratios were observed between human AHS and samples from rats at acute or intermediate stages after SE. Remarkable similarity in gene expression profiles were associated with key cellular functions, such as cell–matrix interaction, neuronal growth, and signaling. Thus, corresponding microarray experiments suggest that changes observed in experimental TLE show a valuable overlap with findings in human disease. Nonetheless, further studies are needed to address the question of whether these genes contribute to the pathogenesis of human TLE.

Future Directions

Recent expression profiling studies in hippocampi of pharmacoresistant TLE patients have yielded results that reflect significant variability between individual specimens. It will be important to carry out such analyses in homogeneous patient samples, standardized for distinct pathogenic factors – e.g., type of seizures, onset of the disease, and resistance to specific modes of pharmacotherapy. Highly structured dynamic expression databases have been developed to cope with the wealth of expression profiling data. These platforms support the integration of expression and clinical data, as well as the automatic exchange and comparison of data from different groups. An additional challenge will be the correlation of RNA expression and proteomics data. Future efforts will need to focus on functional relevance beyond transcription profiling. Novel molecular biological tools, such as small interference RNA technology, may allow the development of high-throughput strategies to functionally validate gene expression profiles.

Genetic Determinants of Temporal Lobe Epilepsy

P A Schwartzkroin and H Jurgen Wenzel, University of California, Davis, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Temporal lobe epilepsy (TLE) is one of the most common, and poorly controlled, forms of seizure disorder. It has been extensively characterized – clinically, electrophysiologically, and histopathologically. Indeed, most of our animal models of chronic seizure disorders have been developed to mimic TLE. At both the clinical and basic research levels, a strong underlying assumption has been that TLE is the result of some brain insult that is eventually manifest in a

characteristic neuropathologic profile. For example, investigators have focused on the epileptogenic nature of traumatic brain injury (TBI), with a particular interest in subsequent TLE. This assumption of TLE as an 'acquired' epilepsy currently appears to be under critical scrutiny. For example, there is a serious debate about the role of early (infant and childhood) complex febrile seizures – or prolonged status epilepticus – in initiating the epileptogenic events that later result in TLE.

The histopathologic features generally associated with TLE include hippocampal cell loss, particularly among CA1 pyramidal cells and/or CA3 and hilar neurons (mesial temporal sclerosis), selective loss of subtypes of GABAergic interneurons, and mossy fiber sprouting. The electrophysiological features may be somewhat varied, but 'by definition' of a partial epilepsy syndrome, these features include seizure initiation in a distinct brain region (the temporal lobe – and usually mesial temporal lobe structures) and secondary spread to the rest of the brain. Behaviorally, the seizures often involve alteration in consciousness and behavioral automatisms. However, it is becoming increasingly clear that the phenomenology covered by this TLE umbrella is quite varied – and both clinicians and researchers are beginning to consider the idea that 'TLE' may in fact reflect a number of distinct disorders, with different underlying etiologies, pathologies, and electrophysiological and behavioral characteristics. For example, a significant number of TLE hippocampi – resected because the seizures were refractory to conventional treatments – show little neuropathologic abnormality.

The possibility that TLE may cover a number of different disorders raises the possibility (likelihood) that distinct therapeutic approaches may be appropriate in different cases. It is, therefore, important to understand the origins and process of these 'syndromes.' Given the growing awareness of genetic determinants of many seizure syndromes, and the knowledge that genetic variation can give rise to different levels of seizure sensitivity, it is worthwhile exploring the possibility that at least some forms of TLE involve important genetic predisposition factors. Identification of these factors may facilitate diagnosis and treatment.

Background

Genetic Determinants of Seizure-sensitivity and of Epilepsy in Animal Models

A large number of studies have now identified genes, the absence or overexpression of which modify excitability. The manipulated genes include those that code for such disparate substances as channel and receptor subunits, modulatory peptides such as NPY and galanin, and ion and neurotransmitter transporters. In addition, experimental observations have led to the identification of a number genes, the mutations of which give rise to human epilepsies. In most cases, these human 'epilepsy genes' are not completely penetrant – that is, their mutations are quite variable in producing an epileptic phenotype. In this respect, then, they too are 'modulatory' of brain excitability. In animals studies (particularly in mice), spontaneous gene mutations have been described that produce epileptic genotypes, and in some cases these genes have human homologs. Interestingly – and perhaps predictably given the widespread expression of these critical genes – most of these epileptic mice display generalized epileptic phenotypes, reminiscent of absence-like epilepsies in human patients.

At a more subtle level, a number of laboratories have determined – in both rats and mice – the importance of background strain for seizure susceptibility (i.e., sensitivity to epileptogenic agents), seizure intensity, seizure-related brain pathologies, and other morbidities (including seizure-related mortality). It is, therefore, quite clear that genetic influences – both subtle and obvious – can be involved in manifestations of seizure and can influence seizure sensitivity.

Genetic Associations with TLE

Given that the same genome is present in all cells of the brain, it seems intuitively attractive that genetic features would have a generalized effect on brain excitability. This expectation has been confirmed by the identification of human and mouse 'epilepsy genes' associated with generalized seizure phenomenology. However, it is also clear that different genes have regionally – and cell type-specific – distinct expression patterns. Thus, there is a reasonable basis for expecting that mutation/dysfunction in some genes might give rise to local changes in excitability and focal epilepsies – a defining feature of TLE. Recent studies of TLE have even identified a particular gene – LGI1 (leucine-rich, glioma-inactivated 1 gene) – mutations of which appear to give rise to an autosomal dominant partial epilepsy in humans (lateral TLE with auditory features). In separate studies, the LGI1 gene product was shown to associate with the Kv1.1 potassium channel α subunit, a particularly interesting finding given that Kv1.1 dysfunctional mutation – in both mouse and man – has sometimes been associated with a seizure phenotype. At least in mouse, the 'epilepsy' seen in Kv1.1 knockout mice has many of the characteristics of TLE, as commonly described in both animal models of TLE (e.g., pilocarine and kainate injections, amygdala kindling, etc.) and in tissue from TLE patients.

A different kind of genetic disorder is associated with abnormalities of brain development, and gives rise to dysplastic lesions closely associated with epileptic disorders. Depending on the location of the dysplasia, these genetic abnormalities may give rise to a TLE-like

syndrome. For example, one of the common histopathological features seen in tissue from TLE patients is granule cell dispersion in the dentate region of the hippocampus. This disorganzational feature – initially believed to be a product of seizure activity per se – is now known to be a product of aberrant brain developmental patterns. Granule cell dispersion is reproduced by several genetic mutations, the best-studied of which is probably the mutation/deletion of the reelin (RELN) gene. The reeler mouse – a spontaneous mutant with a dysfunctional RELN gene – has been known for many years; a human homolog has been identified in a rare epileptic syndrome (autosomal dominant lissencepahly with cerebellar hypoplasia). In mice, the p35 mutation also produces granule cell dispersion, along with an epileptic phenotype which has features of limbic epilepsy (i.e., TLE). While many areas of the brain appear somewhat disorganized in the p35 (and RELN) knockout, the seizure phenotype again appears to be localization-specific and TLE-like. Disorganization of the hippocampal dentate region, with reorganization of afferent and intrinsic connections, has been hypothesized as the basis for this temporal lobe-specific epilepsy manifestation.

Methods

In our laboratory, we have taken advantage of available 'knockout' mice to study models in which a gene mutation/deletion gives rise to what appears to be a limbic-like seizure disorder. In behavioral observations of these mice – the Kv1.1 and p35 knockouts – spontaneous seizures can be described according to the Racine scale for rating amygdala-kindled limbic seizures. Video-EEG monitoring has been used to relate clinical/behavioral phenomena with electrical abnormalities (ictal episodes as well as interictal abnormalities).

It is noteworthy that even in inbred mice, this gene deletion does not appear to produce an 'equivalent' seizure phenotype in 100% of the animals; seizure onset timing, frequency, and severity can differ considerably from animal to animal. Therefore, in addition to monitoring spontaneous seizures, we have tested animals for seizure threshold, primarily using flurothyl to provoke seizure activity. Animals can be compared with age-matched, normal background strain controls.

Animals have also been sacrificed to generate slices of hippocampus for in vitro studies of cellular electrophysiological characteristics, as well as for histopathological features. In hippocampal slices, extracellular and intracellular recording techniques are used to study the normal and reorganizational characteristics of hippocampus, in an attempt to determine what features give rise to the epileptic abnormality. In parallel, histological and immunocytochemical approaches – for gliosis, cell degeneration, changes in intracellular structure, and mossy fiber sprouting – have been employed to relate structural features to electrophysiological dysfunction.

Recent Results

The Kv1.1 knockout mouse has a spontaneous seizure phenotype that varies across homozygous −/− mice (Figure 1). Seizure activity appears developmentally within the second postnatal week, a time that corresponds approximately to the period in which Kv1.1 should begin to appear in hippocampal and cortical neurons. Knockout mice are unusually 'jumpy' and sensitive to external stimuli. In adult knockout mice, seizures often take the form of initial immobility, with subsequent facial automatisms (whisker twitching, licking, etc.) and Straub tail. In some cases, these initial stages progress to forelimb clonus and then generalized tonic–clonic motor seizures. This progression is similar to the 'clinical' stages described initially by Racine for limbic kindled seizures, and used widely to describe limbic (i.e., temporal lobe) epilepsy in animal models (e.g., pilocarpine, kainate). At the EEG level, tonic–clonic seizure activity is consistently related to obvious ictal activity in cortical recordings; immobility/freezing is also associated with ongoing EEG abnormality.

Seizure threshold testing has confirmed that with exogenous seizure-inducing stimuli, these knockout mice are more seizure-prone than $Kv1.1^{+/+}$ littermate controls. Interestingly, while the Kv1.1 heterozygous mouse does not display spontaneous seizures or EEG abnormalities, it does show a seizure threshold that is intermediate between the wildtype and knockout mouse.

Histopathological examination of Kv1.1 animals that have a history of seizure episodes reveals neuropathology that mimics the changes normally associated with human TLE – widespread gliosis, cell loss particularly in the hilus of hippocampus, and mossy fiber sprouting. Critically, however, these TLE-like abnormalities are not seen in young animals (i.e., at a time before the mice have begun to exhibit seizures). Interestingly, however, reactive gliosis is seen at early timepoints, particularly in those regions that should have (but do not in the knockout) high expression of Kv1.1 – suggesting a clinically subthreshold, localization specific discharge within the hippocampal dentate and CA3 regions. Electrophysiological data from $Kv1.1^{-/-}$ hippocampal slices have shown that this tissue is seizure-sensitive, and that the major cellular abnormality involves axonal conduction (and perhaps synaptic release).

These results are consistent with histological and electron microscopic data that indicate a normal Kv1.1 localization that is particularly high in the axons of hippocampus (perforant input from entorhinal cortex, mossy fiber projections from granule cells to CA3, and CA3 axon collaterals). The Kv1.1-containing channels are heteromers

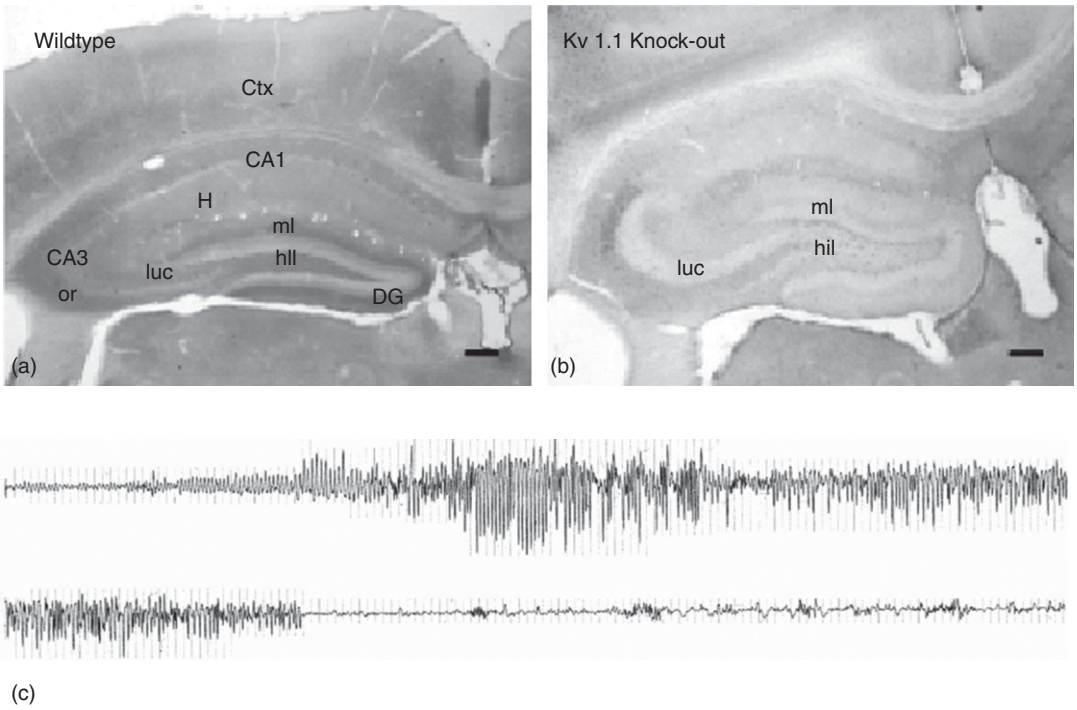

Figure 1 (a) Immunocytochemistry for the Kv1.1 α subunit in wildtype mouse hippocampus. Note particularly high density in the dentate molecular layer (ml), hilus (hil), and CA3 oriens (or) and lucidum (luc). (b) In the knockout mouse, Kv1.1 immunoreactivity is absent. (c) Spontaneous seizure episode recorded from the skull surface (1 s calibration bar).

that generally involve another Kv1 channel subtype (e.g., Kv1.2 and/or Kv1.4) and beta subunits, with Kv1.1-containing channels specifically localized to the extraparanodal region of axons and some terminals. At least in hippocampus, Kv1.1 is not found in the membranes of principal cell somata, but is found in somata of subtypes of interneurons. Immunocytochemistry has confirmed that in Kv1.1 knockouts, the Kv1.1 subunit is completely absent; possible compensatory changes in other subunits are subtle.

It appears that the loss of Kv1.1 from hippocampal axons is sufficient to give rise to seizure activity in these animals. In these locations, in combination with Kv1.4 subunits, the Kv1.1 subunit normally contributes to a channel that mediates 'A-current.' In the knockout, this fast, easily inactivated potassium current is lost, and action potentials become broader (with the danger that long depolarization of axon membrane will trigger aberrant repetitive action potential discharge and/or mediate the release of abnormal amounts of neurotransmitter). Compensatory changes in related Kv1 subunits do not appear to 'normalize' this dysfunction – although such changes may help account for the fact that seizure expression is so variable across knockout animals. Typical TLE-like histopathology does occur in these animals, but not until after they have experienced multiple and/or prolonged seizures. Thus, it appears that these structural changes are a result – not a cause – of the seizures.

In p35 knockouts, the seizure phenomenology – the typical Racine scale description of seizure activity – is similar to that described for the Kv1.1 knockout. However, the relationship between the aberrant structure and the seizure activity is quite different. In these animals, granule cell dispersion, as well as abnormalities in GABAergic interneuron subpopulations, is seen even in immature animals well before seizures can be observed or recorded. In this animal, therefore, the genetic determinant of tissue hyperexcitability is expressed not through a direct modulation of cellular electrical properties, but rather as a consequence of the abnormal structural features (or structural reorganization) that result from abnormal brain development. For example, both in vitro and in vivo studies have shown characteristic mossy fiber reorganization associated with hyperexcitability in tissue from p35 knockouts. Granule cells are monosynaptically connected to each other via excitatory axon collaterals which make contacts not only on the dendritic sites in the inner molecular layer of the dentate, but also on the basal dendrites and displaced granule cell somata in the hilus. This positive feedback from one granule cell to another appears sufficient to trigger hyperexcitable discharge within the hippocampus.

Future Goals

A major challenge in working on localization-specific epilepsies in mouse models is to establish a clear and convincing description of the site of seizure initiation

(and, if possible, the pathways of spread). Since the brain is so small and seizure activity spreads so quickly, it is difficult to establish an initiation site – and requires implantation of microelectrodes into multiple suspect regions. While current data suggest a temporal lobe (limbic) seizure phenotype, we have still not established the temporal lobe – and hippocampus in particular – as the site of origin of seizure activity. Thus, a firm determination of seizure type as 'partial' and 'temporal lobe' must still be established for both Kv1.1 and p35 knockouts.

In trying to elucidate the mechanisms underlying the seizure activity in these mutant animals, it is clearly not enough to identify the aberrant gene or gene product. Understanding the bases of epileptiform activities requires research ranging from the level of molecules to the intact brain. Of key interest, in both the models discussed in this article, is an understanding of how the Kv1.1 alpha subunit protein and the p35 protein normally interact with related gene products. For example, it is clear that appropriate subcellular targeting and channel function for Kv1.1 is determined in large measure by other associated Kv1 subunits. The nature of this interaction in the normal brain, and the changes in subunit interaction (compensatory?) in the knockout brain should be explored. Similarly, it is clear that p35/cdk5 and reelin interact in normal brain to provide guidance for neuronal migration. While the pathways are apparently independent, they appear to interact to produce granule cell dispersion.

The electrophysiological bases for epileptic activity in these models remain incompletely characterized. Our past studies have identified a set of potential epileptogenic mechanisms in hippocampal tissue, but this description needs to be expanded. One obvious area of neglect is the role played by inhibitory (GABAergic) systems in these epileptic tissues, and the possible aberrant features of interneuron populations in these knockouts. Another issue of potential importance is the likelihood that extra-hippocampal regions also express hyperexcitable properties – a possibility still to be explored.

Finally, in order to relate the observations in animal models to the features of human epileptic disorders, it is important to identify common variables – molecular, histological, electrophysiological – in tissue from human epileptic brain. If, as hypothesized, the salient epileptogenic underpinnings of these genetic mutations are preferentially localized to temporal lobe, then evidence for their involvement in epileptiform activities should be obtainable from human epileptic temporal lobe resected for medically intractable epilepsy.

Morphological Abnormalities Associated with Genetic Epilepsies

Introduction

In recent years, numerous gene mutations associated with human epilepsy have been identified; these mutations, together with information obtained from spontaneous mutations and targeted deletion of genes in mice, have provided insights into genetic links to seizure disorders. Many of these genes appear to be related to altered functional excitability (e.g., mutations in channel- and receptor-related genes). Other genes are associated with molecules critical to normal brain development, and mutations in such genes cause severe structural abnormalities. In both types of genes, mutations are frequently associated with not only characteristic anatomical neuropathologies but also developmental disabilities and seizures/epilepsy. Moreover, in mutations of both types of genes, it is often unclear how the altered/deleted gene product causes a seizure phenotype.

Within this context of genetically-determined epilepsies, there is a growing need to understand the relationship between aberrant brain structure and functional abnormalities. In particular, it is important to understand what structural abnormalities lead to epilepsy, and why. Also critical, particularly from the perspective of developing more effective treatments, is the question of how/if functional abnormalities (e.g., channelopathies) give rise to structural abnormalities – and whether that outcome has further consequences for epileptogenicity.

One approach to investigate these issues is the use of animal models. Many such models have been studied, particularly in mice and rats, in which abnormal brain structures have been induced by experimental manipulations (e.g., freeze, undercut, γ-irradiation). Alternatively, in animal models one can attempt to mimic specific gene mutations found to cause epilepsy in the human brain. Among the most commonly studied of these mutations are those that affect voltage-gated channels or that cause various forms of cortical dysplasia. Two such models – the $p35^{-/-}$ (knockout) mouse and the $Kv1.1^{-/-}$ mouse – provide useful illustrations of how structure and function may interact and contribute to epileptogenicity. In the $p35^{-/-}$ mouse, a genetically-induced aberrant cortical structure is primarily – and presumably—the causal factor leading to spontaneous seizures/epilepsy in these animals. In contrast, deletion of the *Kcna1* gene causes hyperexcitability and epilepsy, initially in the absence of any obvious neuropathology; however, neuropathological features do develop as a consequence of repeated seizure activity, and may exacerbate (or at least contribute to the maintenance of) seizure activity.

Background

$p35^{-/-}$ Mouse

The *p35* gene plays a key role in brain development. In wildtype mice, the p35 protein participates in the signaling pathway involved in corticogenesis. It acts as a neuron-specific activator of cyclin-dependent kinase 5 (Cdk5), which in turn regulates neocortical lamination. The brains of mice lacking p35 or Cdk5 show aberrant cortical lamination patterns, including callosal axonal guidance defects. During corticogenesis, the signals that guide the normal 'inside-out' lamination pattern are disrupted (i.e., later born waves of migrating neurons fail to move past pre-existing neurons), thus resulting in a dysplastic neocortex. In addition to the neocortical lamination defects, there are also dysplastic changes in the hippocampus, involving particularly displaced pyramidal neurons and dentate granule cells. The dysplasia also involves disorganized dendritic and axonal arbors and aberrant connectivity among neurons. As these $p35^{-/-}$animals mature, they also exhibit abnormal functional properties, including spontaneous limbic-like seizures. The patterns of pathology – both seizures and dysplasia features – are somewhat different from animal to animal, and the severity depends (at least to some extent) on the genetic background of the mouse.

Recent studies of the pathways involved in neuronal migration have suggested close relationships/interactions between the p35/Cdk5 signaling and other signaling systems that regulate neocortical lamination. Of particular interest for our studies, the reelin pathway has been shown to play a key role in neuronal migration both for neocortical development and for dentate granule cell layering in hippocampus. In the mutant 'reeler' mouse, reelin deficiency leads to aberrant migration patterns similar to those seen in the $p35^{-/-}$ mouse. Although previous studies revealed no seizure phenotype in reeler, recent studies have shown these mice to be seizure-prone. Further, 4 investigations show changes in reelin expression in epileptic hippocampi from patients with temporal lobe epilepsy (TLE) and in experimentally-induced epileptic animals. These studies suggest that in the epileptic hippocampus, abnormalities in either the p35/Cdk5 or

reelin signaling pathways may contribute to granule cell pathologies (e.g., cell dispersion – see below), and subsequently to the aberrant circuitry that underlies seizure activity in TLE.

Kv1.1$^{-/-}$ Mouse

The Kv1.1$^{-/-}$ mouse is one of dozens of single gene mutation models that are collectively referred to as examples of 'channelopathies.' They are particularly interesting as models, since many of the single gene mutation epilepsies in human appear to be channelopathies. The Kv1.1$^{-/-}$ mouse (deletion of the Kv1.1α subunit) is somewhat different from most of the other single gene mutation mice, inasmuch as it exhibits a tonic-clonic seizure phenotype, with features similar to those of temporal lobe epilepsy. In contrast, many of the other mouse channelopathy models present with an absence-like seizure phenotype. The Kv1.1$^{-/-}$ mouse also exhibits enhanced seizure propensity (i.e., lower thresholds to seizure inducing agents) as well as a gene 'dose' effect (Kv1.1+/− mice are more seizure-prone than wildtype). Potassium channels play an important role in hyperpolarizing neuronal membranes, so it is perhaps not surprising that loss of the Kv1.1α subunit results in brain hyperexcitability. What is surprising is the fact that Kv1.1-containing channels are heteromers, containing four primary subunits and auxiliary subunits (in addition to Kv1.1, Kv1.2, and Kv1.4α subunits, Kvβ1 and/or Kvβ2 auxiliary subunits, also participate in these channels). When Kv1.1 homotetramers are studied in expression systems, the channel mediates a delayed rectifier current. However, when Kv1.1 combines with, e.g., Kv1.4 – as it almost always does in the intact brain – the resultant channel has different properties. The current mediated by such channels is a transient A-current. Mutations of the human homolog of Kv1.1 – Kcna1 – have been seen at the clinical level, and at least in some cases are associated with an epilepsy phenotype.

Methods

Animals

For studying structural abnormalities and their relationships to genetic epilepsies, we used mice, in which deletion of a known gene is associated with spontaneous seizure development. In particular, both the animals described earlier (p35$^{-/-}$ and Kv1.1$^{-/-}$ mice) exhibit a limbic, TLE-like seizure phenotype, and both show hippocampal neuropathological features (see later). Wildtype animals – of the same genetic background as the mutated mouse – are used for control observations and comparisons.

Seizure Behaviors and Electroencephalographic (EEG) Monitoring

To characterize functional abnormalities (e.g., changes in seizure susceptibility) related to structural abnormalities and/or gene loss, animals are tested for seizure threshold using the volatile convulsant flurothyl to provoke seizure activity. Latencies to onset of myoclonic jerks and to generalized tonic-clonic seizures are recorded and used as a measure of seizure susceptibility. Video/EEG monitoring is used to record simultaneously both clinical behaviors and underlying electrical phenomena (i.e., electroencephalographic (EEG) activity). Animals are implanted with surface and depth (hippocampal) electrodes, and EEG recordings are made at different times of development to obtain data regarding interictal and ictal episodes in freely-moving animals.

Histological and Immunocytochemical (ICC) Methods

Anatomical features of hippocampus – from normal (age-matched) brains (controls), brains from $^{-/-}$ animals exhibiting little seizure activity, and brains from $^{-/-}$ epileptic mice – are described using various histological procedures for visualization of neurons and glial cells. Quantitative assessments of neuronal cell loss, reactive astrogliosis, and neuronal degeneration of neuronal cell bodies and synaptic terminals are based on Nissl staining, GFAP immunocytochemistry, and silver degeneration procedures. Immunocytochemical techniques are used to determine and compare normal and pathological distribution patterns of chemically-different neuron populations (e.g., interneurons). Reorganization of axonal connections (i.e., mossy fiber sprouting) is visualized using Timm staining. Specific protein localization (e.g., for Kv channel subunits) is determined via immunocytochemical methods, using subunit-specific antibodies.

Electron Microscopy and EM-ICC

Electron microscopic techniques – combined with ICC – are employed to provide ultrastructural details of immunocytochemical localization of Kv channel subunits (e.g., Kv1.1 and Kv1.4 subunits) to various neuronal compartments, cell types, and/or axonal projections, as well as to detect potential compensatory changes in expression levels of other subunits in knock-out mice. Electron microscopy provides a strong anatomical assessment of synaptic connectivity, and a basis for understanding changes in synaptic connectivity (i.e., synaptic reorganization) associated with dysplasia and/or seizure activity. Three-dimensional reconstruction of single cells

(e.g., labeled with an electron-dense marker) from epileptic animals provides insight into reorganization of axons and dendrites.

Hippocampal Slices – Electrophysiology and Single Cell Labeling

Extra- and intracellular recording has been carried out in hippocampal slices – prepared from epileptic and control animals – to study cellular electrophysiological characteristics of neurons in normal and reorganized neuronal circuits. These functional data, in combination with the anatomical observations, allow us to hypothesize about what structural/functional features give rise to the epileptic abnormality. In single cell studies, electrophysiologically-identified neurons are intracellularly labeled (with biocytin), and processed for light- and electron microscopy to assess structural features (including dendritic and axonal arbors) of cells of known function/dysfunction.

Recent Results

Clinical Features (Behavioral and EEG)

p35$^{-/-}$ mice

Deletion of the *p35* gene causes disruption of cortical migration and hippocampal dysplasia in all $^{-/-}$ animals, as well as spontaneous behavioral and electrographic seizures in a subpopulation of the p35$^{-/-}$ mice. Spontaneous (tonic-clonic) behavioral seizures were observed in 25% of the animals as early as 2 months postnatal. Spontaneous epileptiform activity was electrographically verified in 75% of the animals (ages 3–5 months). Most of the recorded spontaneous seizures were strong, generalized tonic-clonic episodes that appeared to occur simultaneously in cortex and hippocampus. Flurothyl seizure testing revealed a significantly greater seizure susceptibility of p35$^{-/-}$ mice as compared to age-matched controls. Since the characteristic neuropathological feature of these animals is seen soon after birth (see below), the fact that spontaneous seizure activity was not observed until 'adolescence' suggests that the genetically-determined structural abnormality precedes (and is a cause of?) hyperexcitability. That is, the seizure-related activity is not a direct expression of the gene mutation (e.g., as mediated through an abnormal cellular discharge properties), but rather a secondary consequence of the structural/developmental abnormalities.

Kv1.1$^{-/-}$ mice

The Kv1.1$^{-/-}$ mouse exhibits spontaneous seizures early in development – typically starting during the third postnatal week. The onset of seizure activity corresponds to the time period - in wildtype mice - of rapid increase in Kv1.1 protein expression in axons of hippocampal and neocortical neurons. Thus, in the Kv1.1$^{-/-}$ animal, seizures appear to correspond with the absence of normal Kv1.1 expression. Early seizure behavior consists of such features as twitching of vibrissae, forelimb paddling, and periods of immobility; as the animal matures, seizures exhibit a more 'typical' phenotype with forelimb clonus and generalized tonic-clonic motor seizures. Generalized tonic-clonic seizures appear 4–5 weeks postnatal; they start with tonic arching and tail extension, followed by forelimb clonus (or rearing and forelimb clonus), and then generalized synchronous forelimb and hindlimb clonus. These seizures are often followed by a period of post-ictal depression. This seizure sequence has the characteristics of typical limbic seizures as observed in experimental animal models of TLE (e.g., kainate, pilocarpine), suggesting a critical role of hippocampus and related structures. Seizure-associated EEG recording confirms that these behaviorally-obvious seizure behaviors are always accompanied by an ictal EEG pattern. Typical EEG recordings of a generalized tonic-clonic seizure event show characteristic changes over time: there is usually an initial pre-seizure interictal spike-like event, followed by an abrupt voltage depression, then a period during which low-voltage fast activity progresses into high-amplitude spiking. At seizure cessation, there is an abrupt loss of high voltage spiking and EEG flattening, corresponding to post-ictal depression. Interestingly, ictal EEG patterns are sometimes observed in the absence of obvious behavioral changes.

Kv1.1$^{-/-}$ mice, along with Kv1.1$^{+/-}$ animals and wildtype controls (Kv1.1$^{+/+}$), have also been tested for seizure susceptibility (using flurothyl) at different ages. This seizure threshold testing confirmed that immature/juvenile Kv1.1$^{-/-}$ mice (at P15) have significantly shorter latencies to flurothyl-induced seizures as compared to wildtype and Kv1.1 heterozygous littermates. The heterozygous mice have latencies between Kv1.1$^{-/-}$ mice and wildtype animals. Electrophysiological data from Kv1.1$^{-/-}$ hippocampal slices have shown that this tissue is seizure-sensitive, and the major cellular abnormality involves axonal conduction (and perhaps synaptic release).

Neuropathology and Epilepsy

p35$^{-/-}$ mice

The deletion of the *p35* gene results in disrupted cortical development in which the neocortex is inverted, and additional abnormalities are exhibited in the hippocampus, including heterotopic pyramidal neurons in the CA1 and CA3 subfields and dispersion of dentate granule cells into the hilus and molecular layer (**Figure 1(a–c)**). The dispersed dentate granule cells exhibit aberrant dendritic orientation (e.g., misoriented dendrites, basal dendrites) (**Figure 1(e)**). Perhaps most importantly, aberrant granule cell axons – i.e., mossy fibers – 'sprout' into the regions

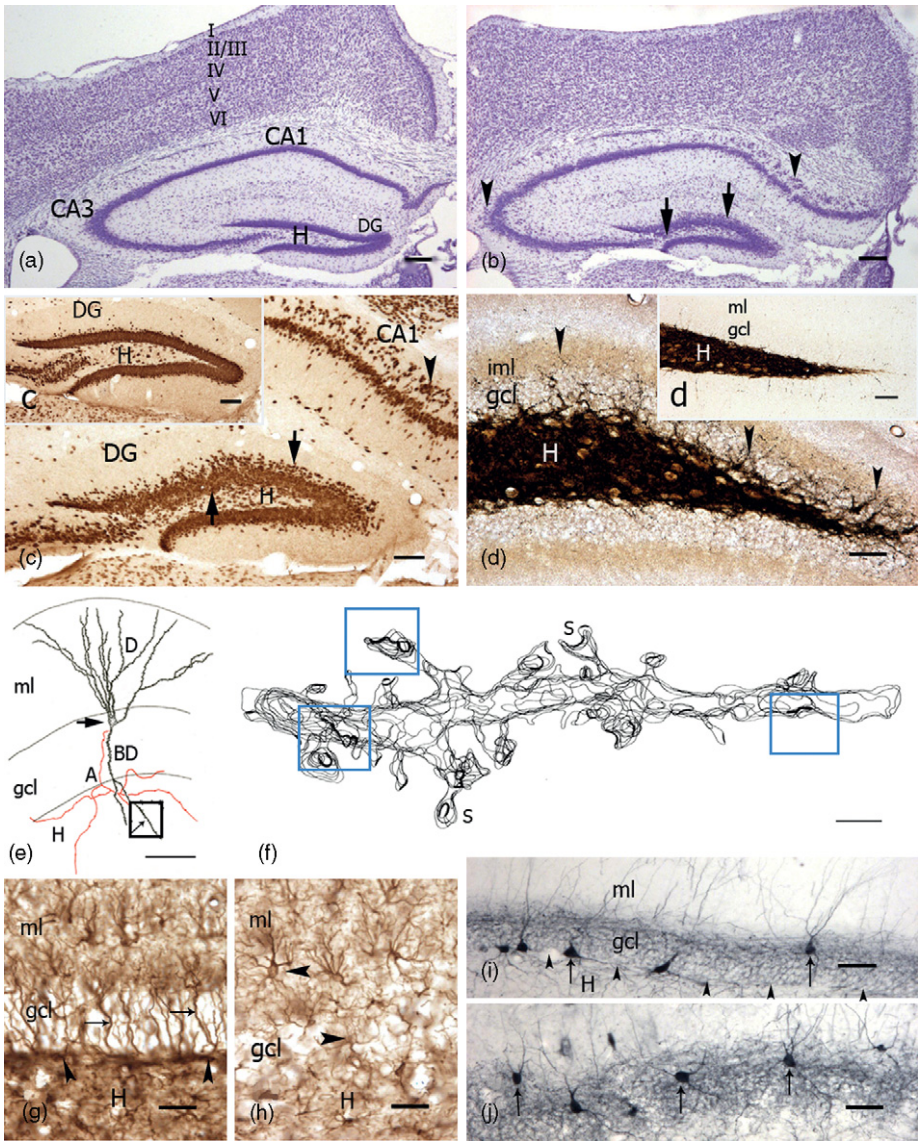

Figure 1 p35 gene deletion is associated with structural abnormalities. (a, b) Transverse sections through neocortex and hippocampus from a p35 wildtype (a) and a p35$^{-/-}$ mouse (b) (cresyl violet). The normal cortical lamination patterns in panel a contrast with the disorganized neocortex and the cell dispersion in hippocampus (b) (arrows show granule cells, arrowheads show pyramidal cells of CA1 and CA3). I–VI – neocortical layers; CA1, CA3 – hippocampal pyramidal cell subfields; DG – dentate gyrus; H – hilus. Scale bars: 200 μm. (c) NeuN-immunocytochemistry in transverse hippocampal sections reveals a normal lamination pattern in the wildtype dentate gyrus (inset c), and aberrant dispersion of CA1 pyramidal cells (arrowhead) and dentate granule cells (arrows) in the p35$^{-/-}$ mouse. Scale bars: 50 μm. (d) Timm histochemistry for zinc in mossy fiber boutons shows the normal staining pattern in the hilus of a wildtype mouse (inset d), and extensive mossy fiber sprouting into the granule cell layer (gcl) and inner molecular layer (iml) (arrowheads) in the p35 knockout mouse. Scale bars: 50 μm. (e) Camera-lucida drawing of a single biocytin-filled granule cell (arrow) from a p35 knockout mouse showing abnormal dendrites (D) emerging from the apical and hilar granule cell pole, and forming basal dendrites (BD). Scale bar: 100 μm. (f) Two-dimensional reconstruction of a representative basal dendritic segment (boxed area in panel e) based on serial section electron micrographs, showing numerous dendritic spines (s) (i.e., postsynaptic synaptic sites); spine synapses with mossy fiber boutons are indicated by blue boxes. Scale bar: 1 μm. (g, h) GFAP-immunostaining of the dentate gyrus from a wildtype mouse (g) presents the typical pattern of radial astroglial cells – located at the granule cell/hilar border (arrowheads) – and their radial fibers (arrows) ascending perpendicularly through the granule cell layer (gcl). In the p35$^{-/-}$ mouse (h), this pattern is absent; astrocytes (arrowheads) and their processes are diffusely distributed. Scale bars: 25 μm. (i, j) Immunocytochemistry for parvalbumin illustrates abnormal migration of interneurons into the dentate of the p35$^{-/-}$ mouse (j) as compared to the wildtype mouse (i). In the normal dentate gyrus (i), parvalbumin-positive neurons (arrows) are mainly located at the granule cell-hilar border (indicated by arrowheads); in the p35$^{-/-}$ dentate gyrus, the borders are disrupted and interneurons (arrows) are diffusely distributed across the layers. Scale bars: 50 μm.

now occupied by aberrant granule cell dendrites (i.e., the molecular layer and the hilus) (**Figure 1(d)**). These abnormal granule cell features in $p35^{-/-}$ mice are also associated with developmental abnormalities of the astroglia. Radial glia are prominent structural features lining the border of the granule cell layer and the hilus, and normally provide guidance for the migrating granule cells. However, in the dentate gyrus of $p35^{-/-}$ animals, these radially-oriented glial cells are absent (**Figure 1(g)** and **1(h)**) (although astrocytes are present and the glial processes run through the granule cell layer in an irregularly oriented pattern).

Studies have suggested that the $p35^{-/-}$ abnormality in neuronal positioning is linked to dysfunction or loss of reelin-containing Cajal Retzius cells, and/or to the absence of radial astroglial cells. Histological investigations of the dentate gyrus of $p35^{-/-}$ mice, using immunocytochemistry and electron microscopic techniques, also show abnormal positioning of dentate interneurons and aberrant projections of their axons (**Figure 1(i)** and **1(j)**).

In $p35^{-/-}$ animals, aberrant mossy fiber collaterals form synaptic contacts with the apical and basal dendrites of misplaced granule cells (**Figure 1(f)**) – both neighbors and, in some cases, their own dendrites (autapses). The morphological results are reflected in the physiological data; hyperexcitability of dentate granule cell responses to stimulation has been demonstrated in vitro. The data are consistent with the hypothesis that formation of recurrent excitatory circuits in the dentate gyrus provides a basis for hippocampal hyperexcitability, and may be primarily responsible for epileptogenesis.

It is significant that this pattern of dysplasia and synaptic reorganization in the dentate gyrus has been found as a consequence of experimentally-induced seizure activity in animal models of TLE, as well as in hippocampi of patients with mesial TLE. It should be emphasized that granule cell dispersion in $p35^{-/-}$ mice is a characteristic aberrant *developmental* feature of the dentate, a result of a migration disorder. Indeed, this granule cell dispersion and related changes in circuitry appear relatively early in postnatal development; by postnatal day 5, granule cell dispersion is evident, as are abnormalities in interneuron structure. That is, while the structural features of the $p35^{-/-}$ mouse resemble some of the pathologies frequently seen in animal models of TLE and epileptic hippocampi from patients with TLE and mesial Ammon's horn sclerosis, these features of $p35^{-/-}$ mice are seen well before seizure onset- and therefore may contribute to (cause) the development of the seizure phenotype.

Mutations in the p35 have not been linked to epilepsy in human. However, there are associations between the Cdk5 signaling pathway (of which p35 is a part) and several genes involved in cortical malformations and epilepsy (e.g., DCX, Lis-1). Further, gene mutations characterized in other mouse models – e.g., the reelin-, Lis-1-, doublecortin mutants – are associated with disruption of normal cortical development. The reelin mutation, in particular, has recently been associated with a rare developmental seizure-related disorder in humans.

Kv1.1 knockout

Kcna1 deletion is associated with characteristic neuropathology and epilepsy. However, in Kv1.1 knock-out mice, the development of these neuropathological alterations is dependent on seizure occurrence and severity. Characteristic neuropathological features, e.g., neuronal cell loss, astrogliosis, and mossy fiber sprouting – normally associated with human MTLE – are consistently seen in animals with documented status epilepticus (**Figure 2**).

These animals exhibit severe neuronal cell loss in pyramidal cell layers of hippocampal CA1 and CA3 subfields, and extensive axonal terminal degeneration across the hippocampal layers (**Figure 2(a–e)**). In the dentate gyrus, cell loss is most apparent in the population of mossy cells and among interneurons. The selective loss of vulnerable neuron populations after prolonged/intense seizures – especially in CA3 and hilus – is the basis for the sprouting hypothesis (**Figure 2(g)** and **2(h)**). Prolonged generalized seizures are always followed by extensive astrogliosis throughout the hippocampus, as well as in other brain regions (e.g., neocortex, thalamus) (**Figure 2(f)**). In contrast to this pattern of neuropathology, $Kv1.1^{-/-}$ mice that experience less severe seizure activity also show limited structural abnormalities (i.e., little or no cell loss, regionally-restricted gliosis, and low levels of mossy fiber sprouting). Thus, even in older $Kv1.1^{-/-}$ mice (>12 months of age), little pathology is evident if the animal has not experienced severe seizure episodes. Interestingly, immature $Kv1.1^{-/-}$ mice show an up-regulation of GFAP expression (in astrocytes) which is relatively restricted to the dentate gyrus and the hippocampal CA3 subfield – precisely those regions of hippocampus in which Kv1.1 is normally expressed at high levels.

Morphological studies on Kv1.1α subunit expression – using ICC and EM techniques – have shown a pattern of specific localization in the mouse brain, not only with respect to brain region, but also with respect to subcellular compartments. Potassium channels containing the Kv1.1α subunit are localized to the juxta-paranodal region of myelinated axons and to fine unmyelinated axons (such as mossy fibers). In normal animals, prominent Kv1.1-immunoreactivity (indicative of Kv1.1α subunit localization) has been found in axons of the major excitatory pathways of the hippocampus (**Figure 2(i)** and **2(j)**). There is little protein expression in somata of hippocampal principal cells; however, somata of subpopulations of hippocampal interneurons stain intensely for Kv1.1α subunit protein. Recent studies on functional consequences of the mouse *Kcna1* deletion have shown that there is

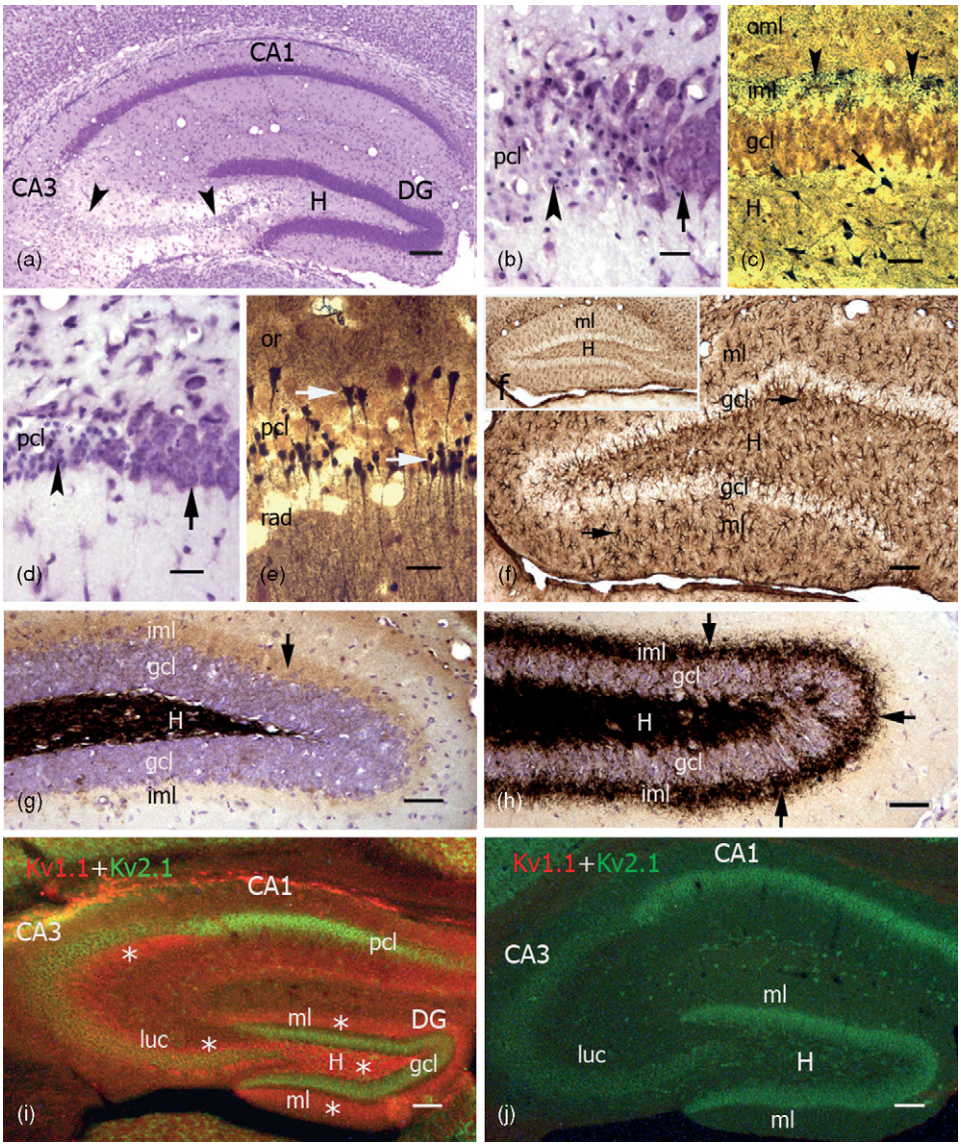

Figure 2 Chronic seizures in the Kv1.1$^{-/-}$ mouse are associated with severe pathology. (a) Transverse section of a Kv1.1$^{-/-}$ mouse shows extensive loss in the CA3 pyramidal cell region (arrowheads) following status epilepticus (cresyl violet). CA1, CA3 – hippocampal subfields; DG – dentate gyrus; H – hilus. Scale bar: 200 μm. (b) Higher magnification of the CA3 pyramidal cell layer (pcl) in A illustrates preserved pyramidal neurons (arrow) and an area with extensive cell damage/loss (arrowhead) (cresyl violet). Scale bar: 25 μm. (c) Higher magnification of the dentate gyrus, showing degenerated neurons (black cells; arrow) within the hilus (H) and terminal degeneration within the inner (iml) and outer (oml) molecular layers (Fink-Heimer silver degeneration staining). Arrowheads in the iml indicate terminal degeneration reflecting damage/death of hilar mossy cells. gcl – granule cell layer. Scale bar: 25 μm. (d) Higher magnification of the CA1 pyramidal cell layer (pcl) showing an area of normal pyramidal neurons (arrow) and an area with damaged (pyknotic) neurons (arrowhead) (cresyl violet). Scale bar: 25 μm. (e) Fink-Heimer staining in the CA1 pyramidal cell layer (pcl), showing degenerated CA1 neurons (black cells; white arrows) and extensive terminal degeneration in strata oriens (or) and radiatum (rad). Scale bar: 25 μm. (f) GFAP immunocytochemistry of the dentate gyrus from a wildtype mouse (inset f) illustrates normal astrocytic cell staining patterns in hilus (H) and molecular layer (ml). In the Kv1.1$^{-/-}$ mouse (f), high levels of GFAP immunoreactivity are present in the hilus (h) and molecular layer (ml), indicating reactive astrogliosis (arrows) following chronic seizures. Scale bar: 100 μm. (g, h) Timm histochemistry for zinc in mossy fiber boutons shows normal staining pattern in the dentate hilus (H) of a wildtype mouse (g) and no/or little staining in the granule cell layer (gcl) and inner molecular layer (iml) (arrow). In the Kv1.1$^{-/-}$ mouse, there is extensive mossy fiber sprouting into the granule cell layer (gcl) and inner molecular layer (iml) (arrows) following chronic seizures and/or status epilepticus. Scale bars: 50 μm. (i, j) Double immunofluorescence of potassium channel subunits (red: Kv1.1; green: Kv2.1) in transverse sections of the hippocampus from wildtype (i) and Kv1.1$^{-/-}$ (j) mice. In the wildtype hippocampus, Kv1.1 is highly expressed (*; red staining) in hilus (H), dentate middle molecular layer (ml) and stratum lucidum (luc), reflecting its localization to entorhinal pathway axons and granule cell axons (i.e., mossy fibers). Kv2.1 immunoreactivity (green) is localized to somatic and proximal dendritic membranes of principal neurons (pcl, gcl) and interneurons. Note the complete absence of Kv1.1 immunofluorescence (red) in the knockout hippocampus in panel j, and preservation of Kv2.1 staining (green) in principal neurons and interneurons. Scale bars: 200 μm.

virtually no compensatory changes in other related subunit (e.g., Kv1.2 and Kv1.4) expression.

Voltage-gated potassium channels are critical regulators of neuronal excitability. In the hippocampus of Kv1.1$^{-/-}$ mice, the A-type potassium current in axons and terminals is lost, leading to broader (more slowly repolarizing) action potentials and the propensity for repetitive discharge and enhanced transmitter release. The resulting hyperexcitability is expressed directly as seizure activity, before any neuropathological features develop. Thus, the Kv1.1$^{-/-}$ mouse reflects a loss of function mutation that results in a TLE-like seizure phenotype, with secondary neuropathological abnormalities. In this case it is the genetic disorder, not structural disorganization, that is the direct cause of the epilepsy.

Future Goals

The animal models of epilepsy discussed here provide investigators with an opportunity to study the structure–function relationships associated with epileptogenesis. In particular, they mimic seizure and structural abnormalities known to be associated with genetic mutations, and provide a context for exploring the causal factors that lead to the epileptic phenotype. The p35$^{-/-}$ and the Kv1.1$^{-/-}$ mice exhibit similar seizure phenotypes, and both animal models are associated with neuropathologies commonly seen in temporal lobe epilepsy – i.e., hippocampal cell loss, granule cell dispersion, mossy fiber reorganization, and gliosis. Current data support the view that the seizure phenotype is primary in the Kv1.1$^{-/-}$ mouse, and the neuropathology develops secondarily to the seizures. In contrast, in the p35$^{-/-}$ mouse, the structural abnormalities appear as the direct result of genetic mutation, and the seizures evolve as a product of reorganization of circuitry due to the aberrant structure. Given this contrast, these models provide an opportunity to investigate a number of interesting and potentially important questions:

1. Although, the current data suggest a temporal lobe (limbic-like) seizure phenotype for both models, the site of origin of seizure generation/initiation must be determined. Neuropathological features are found not only in hippocampus, but also in other brain regions. Further, the genetic mutation itself is common to all cells – and thus could support a 'generalized' seizure type. Thus, these models provide a means of gaining further insight into the presumed 'partial' nature of some idiopathic epilepsies.
2. Gene expression is invariably a developmental process. Absence of a gene normally involved in brain developmental patterning will lead to a developmental abnormality. In p35$^{-/-}$ mice, the early observation of the structural consequences of gene deletion can be examined alongside the maturational expression of the seizure phenotype – thus allowing the investigator to study the relationships between structural alterations and seizures (e.g., which structural changes are most closely linked – causally related to? – seizure activity). More generally, this mouse presents as a model in which to test for functional consequence of early seizures associated with a developmental malformation.
3. Similarly, the Kv1.1$^{-/-}$ mouse shows seizure-dependent pathogenesis, providing a means for exploring the feedback consequences of seizure-associated neuropathology on further seizure propensity and intensity.
4. Recent studies have focused on the interaction of p35 protein with other signaling proteins in normal neuronal migration patterns. The p35$^{-/-}$ mouse offers an opportunity to study such interactions, particularly with reelin and the role of radial glia, in the pathogenesis and developmental basis of seizure disorders such as TLE.
5. A major goal in working with animal models of epilepsy is to elucidate the underlying mechanisms of seizure activity, ranging from the molecular/cellular level to the complex structural organization of neuronal circuits. In the Kv1.1$^{-/-}$ mouse, the precise mechanism by which Kv1.1α subunit deletion gives rise to tonic-clonic seizure activity is not fully understood. Recent studies have yielded insight into the normal structure and function of Kv1.1-containing channels, and the importance of Kv1.1 interactions with related subunits (e.g., Kv1.4) and other gene products (e.g., LGI1). The functional nature of these interacting molecules in the absence of Kv1.1 may provide insight into the molecular basis of the seizure phenotype.
6. Finally, both models provide intriguing windows for exploring the potential for early intervention for preventing epileptogenesis. For example, interference with aberrant circuit organization (i.e., sprouting) in the p35$^{-/-}$ mouse may provide a basis for preventing seizure development. Alternatively, gene replacement therapy can be examined in the Kv1.1$^{-/-}$ mouse as a means of treating epilepsies associated with loss-of-function gene mutations.

Introduction

Glutamate is the main excitatory neurotransmitter of the central nervous system. It is synthesized by neurons and stored in synaptic vesicles localized in axonal terminals. An action potential arriving at the terminal triggers a cascade of events leading to the fusion of the vesicle with the membrane and the release of glutamate into the extracellular space, where its concentration increases from few nanomoles to 1 mM. In less than 1 ms, glutamate binds to specific receptors (AMPA, kainate, or NMDA receptors) located on either the postsynaptic or

presynaptic neuron (and also on astrocytes). These receptors are coupled to ionic channels that are permeable to Na^+ and K^+, and in case of NMDA receptors also to Ca^{2+}. Activation of these glutamate receptors leads to depolarization, and in some case, the genesis of action potentials in a postsynaptic cell. In addition to their action on these ionotropic receptors, glutamate also binds to receptors coupled to G protein (metabotropic receptors). Activation of the latter receptors modulates different ionic channels via second messengers.

Through the activation of these receptors, glutamate plays a major role in many aspects of brain function, including cognition, learning, and memory. During development, glutamate also contributes to cell migration, cell differentiation, and synapse formation and elimination. However, glutamate may have deleterious actions; it is intrinsically involved in many neurodegenerative diseases (e.g., amyotrophic lateral sclerosis, Alzheimers disease) and in epilepsies. The influence of glutamate function in the brain (physiological or pathological) is determined by the spatiotemporal distribution of its concentration in the extracellular space – which will influence the amplitude, the duration, and the number of receptors activated by the transmitter. The intensity of receptor activation, and the area covered by glutamate in the extracellular space, is strongly regulated by the cell surface GluTs. The main action of these proteins is to rapidly uptake and remove glutamate from the extracellular space. GluTs are important elements of regulation of the neuronal network activity, and transporter dysfunction can be the cause of severe neurological disorders. In this article, we examine the main properties of GluTs and discuss the role of these proteins during development, particularly in view of recent findings showing that inhibition of these transporters in the immature brain produces seizures with a 'suppression burst' EEG pattern.

Background

Glutamate Transporter Subtypes

The uptake of glutamate from the extracellular space is performed by cell-surface GluTs that are localized on both neuronal and glial cells. Five subtypes of GluTs have been identified and cloned. They show a high degree of conservation across species. In human brain they are called excitatory amino acids transporters (EAAT1–5). In rodent, the nomenclature is somewhat different: GLAST (glutamate-aspartate transporter) is the human analogue of EAAT1 and is located on astrocytes; GLT1 (glutamate transporter 1) is the human analogue of EAAT2 and also located on astrocytes; EAAC1 (for excitatory amino acid 1) is the analogue of EAAT3 and located on neurons (synaptic terminals, dendritic spines, and somas). These transporters are expressed in the neocortex, the hippocampus, the cerebellum, the retina, and the basal ganglia. EAAT4 and EAAT5 are also located on neurons but specifically expressed on the cerebellar Purkinje cells and in bipolar and photoreceptors cells of retina, respectively.

Functions of GluTs

GluTs play a major role in maintaining glutamate homeostasis in the brain. By transporting glutamate from the extracellular to the intracellular space, they contribute to many functions: (1) maintenance of nM concentration of glutamate in the extracellular space, in order to prevent neurotoxic effect of the transmitter; (2) reduction of glutamate receptors desensitization; (3) synthesis of GABA. With regard to GABA synthesis, GluTs are present on GABAergic terminals, and take up glutamate that is converted into GABA by glutamic acid decarboxylase (GAD); (4) limiting diffusion of glutamate out of active synapses (spill-over) and subsequent activation of glutamate receptors located at extrasynaptic sites and/or at neighbouring synapses. In this way, GluTs help maintain specificity of information transfer from cell to cell; (5) detoxification of NH_4^+/NH_3 in astrocytes, where glutamate is converted into glutamine by glutamine synthetase in the presence of NH_3. This often-overlooked reaction is fundamental to cell health, since hyperammonemia can lead to brain damage and neurological disorders. Glutamate present in the cytosol is also transported into mitochondria by mitochondrial glutamate/H^+ symporters (glutamate carriers GC1 and GC2) or exchange with aspartate (by the aspartate/glutamate carriers, AGC1 and AGC2). AGCs are present only in neurons, while GCs are present in both neurons and astrocytes. In the mitochondria, glutamate is converted by glutamate dehydrogenase into α-ketoglutyrate and NH_3. α-Ketoglutyrate to provide ATP for the cells via the tricarboxylic acid cycle. The glutamate dehydrogenase reaction in the mitochondria is the major source of NH_3, which in astrocytes will be used for the formation of glutamine. Therefore, GluTs function is important for the metabolism of glutamate.

Mechanism of Uptake

The transport of glutamate is an electrogenic process that is accompanied by an increase of positive charges in the cells. Thus, glutamate transport is coupled to the cotransport of three Na^+, one H^+, and counter-transport of one K^+. Na^+ is necessary for the binding of glutamate on the transporter, and K^+ is necessary for transport. In addition, the transporters facilitate anion (Cl^-) flux across the membrane. This flux, which is stimulated by the binding

of glutamate and/or Na^+ to the transporter, follows strictly its own transmembrane electrochemical potential gradient. The amplitude of the chloride conductance varies between different transporters subtypes; the glutamate-elicited current in EAAT5 and EAAT4 is carried largely by chloride ions, in contrast to the small chloride conductance associated with GLAST, GLT1, and EAAC1. Glutamate-induced anion conductance may prevent the depolarizing action of glutamate transport by neutralizing the transported positive charge. It has also recently been shown that the anion current associated with the transport of glutamate by EAAT5 (located at the presynaptic terminal of the rod bipolar cell of the retina) hyperpolarizes the axon and inhibits synaptic transmission between these cells and the AII amacrine cells.

The affinity of glutamate for the transporters is high ($EC_{50} = 4$–$30\,\mu M$) and close to the affinity of glutamate for NMDA receptors or glutamate metabotropic receptors. Moreover, kinetics studies indicate that transporters bind glutamate as rapidly as AMPA receptors (~ 1 ms), allowing a signification pool of transporters to be engaged during glutamatergic synaptic transmission.

In the cortex, 80–90% of the transport is performed by astrocytes, which often ensheath synapses. In contrast to neurons, astrocytes possess many features that are optimized for efficient uptake, including high expression of transporters compared to neurons. In addition astrocytes have a very hyperpolarized resting membrane potential (~ -90 to -100 mV), increasing the gradient concentration of Na^+ and K^+ that drives transport of glutamate into the cells. They have also a low input resistance and do not fire action potentials, thus reducing the likelihood of large depolarizations and allowing the maintenance of the gradient of concentrations of Na^+ and K^+. Moreover, the astrocytic cytosolic concentration of glutamate is low because the transmitter is either converted into glutamine or transported into the mitochondria by symporters. In contrast to astrocytes, neurons can be more easily depolarized because of an higher input resistance (hundreds megaohms), their ability to generate action potentials, and the presence of large numbers of synapses (which give rise to ongoing synaptic events). In addition, the intracellular concentration of glutamate is much higher in glutamatergic neurons than in astrocytes because glutamate is not converted into glutamine or GABA.

Factors Affecting the Function of GluTs

Several factors have been shown to regulate the function of GluTs. This regulation may directly affect the synthesis and expression of the transporters at different levels: DNA transcription, RNA splicing, and turnover and trafficking of transporters from the endoplasmic reticulum to the membrane. The capacity of glutamate uptake may also be indirectly reduced when the gradient of Na^+, K^+, or H^+ is not maintained (e.g., during an hypoxic–ischemic episode when pH and intracellular ATP levels fall), or when glutamate accumulates in the cytosol.

GluTs and Epilepsy

Several studies performed in patients suffering from mesial temporal lobe epilepsy have shown that extracellular glutamate concentration rises at or before seizure onset, especially in the hemisphere where the seizures originate. Similar results have been obtained in chronic seizure animal models (e.g., kindled seizures, genetically epilepsy prone rats). These data have led to the hypothesis that the elevated extracellular concentration of glutamate is related to alterations of GluTs expression and function. Several studies have subsequently been performed in order to test this possibility, both in human temporal lobe epilepsy and animal models. These studies have given rise to some contradictory results. For example, studies of distribution of EAAT1 and EAAT2 in resected human sclerotic hippocampi (compared to non-sclerotic hippocampi) show a reduction of EAAT2, a slight or no reduction of EAAT1, or no change in these transporters. An increase or no change in EAAT3 mRNA (or protein) has also been described in hippocampal surgical specimens from patients with temporal lobe epilepsy. Similarly, there is no clear change in mRNA and protein expression of transporters in animal models of temporal lobe epilepsy (induced by kindling or by neurotoxins such as kainate or pilocarpine). An increase, a decrease, or no change of neuronal (EAAC1) and glial (GLT-1, GLAST) glutamate transporter expression has been reported. These contradictory results can probably be explained by rapid postmortem proteolysis of GluTs. Another approach to this issue, based on the deletion of the transporter genes (knockout mice) or the inactivation of the proteins (antisense treatments) has also been used in order to establish a link between an alteration of glutamate uptake and the generation of seizures. These experiments have also given rise to conflicting results; seizures were seen in the experimental animal groups in some studies but not in others. For example, the GLT-1 KO mice display spontaneous recurrent seizures and are more susceptible to pentylenetetrazol – sensitivities that have been attributed to an elevation of extracellular glutamate concentration. However, chronic administration of antisense nucleotide of GLT1 or GLAST in adult rats produced elevated extracellular levels of glutamate (associated with excitotoxicity) but no seizures. Similar results were seen with nucleotide antisense for the neuronal EAAC1 transporter; while antisense treatment resulted in epileptic seizures (hypothesized to be a consequence of decrease in GABA synthesis); the EAAC1 KO mice did not develop seizures. The reasons for these discrepancies are unclear.

GluTs Function is Essential for Normal Brain Development

A recent study has provided convincing evidence that glial glutamate transporter function is essential for normal brain development. In that study, deletion of both GLAST and GLT-1 genes in mice reduced cell proliferation and radial neuronal migration (leading to a disturbed laminar organization of the cortex). In addition, neuronal differentiation appears to be strongly affected in these mice. This cortical malformation seen in these animals involved, in part, the activation of both AMPA and NMDA receptors, since the $GLAST^{-/-}/GLT1^{-/-}$ phenotype was partially rescued by injection of ionotropic glutamate receptor antagonists. These results indicate that glutamate may act as a neurotransmitter at a very early stage of development, even before synapse formation; these actions of glutamate must be tightly controlled – by GLAST and GLT1 – for normal brain development. In keeping with this view are the following observations: (1) Immunoreactivity for glutamate in the maturing cortex is found in the neuroepithelium during neurogenesis, and later on is present in the intermediate zone (zone of migration), subplate, the cortical plate, and the marginal zone; (2) Functional glutamate receptors are expressed by neuronal precursor cells and neurons, in several structures, at a very early stage of development; (3) Glutamate is released before synapse formation by growing axons and growth cones; (4) GluTs are functional during the perinatal period and contribute to the clearance of glutamate; and (5) In the absence of efficient transport, glutamate diffuses through the extracellular space and activates distant cells in paracrine manner. All these factors suggested that GluTs play an important role in normal brain development, controlling the maturing cortical network activity when synaptogenesis is just getting started. Recent studies support this hypothesis and show that this control is fundamental, as it prevents the generation of seizures.

Methods

For in vitro experiments, we have used whole cell patch-clamp recordings of pyramidal cells and interneurons, together with field recordings, from neocortical (frontal, temporal, occipital) or hippocampal slices of Wistar rats (from embryonic E20 to postnatal day 7). For in vivo studies, we have employed video/EEG monitoring in freely moving rat pups. For the latter experiments, the animal was placed in a stereotaxic frame, and 1 µl of TBOA (5 mM per litre) or saline solution was injected in the left lateral ventricle (ICV injection) with a needle via a peristaltic pump. Two 1 mm-long tungsten electrodes fixed to a copper plug (100 µm diameter) were stereotaxically implanted at the surface of the somatosensory cortex. A reference electrode was implanted in the cerebellum. Two EEG signals were recorded, representing the potential between the reference and the recording electrodes. Signals were amplified (×1000), filtered at 0.16–97 Hz pass, acquired at 256 Hz using a time constant of 0.3 s and analyzed using Coherence 3NT program (Deltamed, France).

Results

GluTs During Development

Most of the studies concerning the function of GluTs and their role in neurologic disorders have been performed in adult brain. In contrast, there are few data available on their function in the developing brain, even though glutamate is known to play important roles in neuronal development. GluTs are expressed early in development, in fetal stages, in both human and rodent brain, suggesting that they may play important roles for brain maturation. Immunohistochemical and immunoblot analysis of EAAT1–4 performed between the seventeenth and twenty-fourth week of gestation in human brain showed that EAAT2 is the most prominent glutamate transporter subtype, highly expressed in cortex, basal ganglia, hippocampus, cerebellum, and thalamus. EAAT2 is rare in cells in the proliferatives zones, but is expressed in the intermediate zone and in the cortical plate. EAAT1 immunoreactivity is found in cortex, basal ganglia, and in the hippocampus, and is present in the proliferatives zones (ventricular and subventricular zones) on radial glial cells, and in the intermediate zone on the radial glial fibers. EAAT1 is also present on astrocytes localized within the cortical plate. EAAT1 and EAAT2 are found in the CA1 field and dentate gyrus of fetal hippocampus, and EAAT3 has been localized in cortex, basal ganglia, thalamus, hippocampus, and the cerebellum. EAAT3 distributes within the subplate and the cortical plate, on pyramidal cells and on the Cajal–Retzius cells of the marginal zone. EAAT4 is present in the cortex, hippocampus, and cerebellum. In rodent, the developmental expression of these four transporters has been found to be generally similar to the human pattern.

GluTs Control Early Network Activity: Their Inhibition Results in Slow Network Oscillations In Vitro

During the perinatal period, when synaptogenesis is just getting started, the ongoing cortical activity is composed of fast synaptic events mediated mostly by GABA (which is excitatory during this period of life) and – to a lesser extent – by glutamate. This cortical activity is often composed of recurrent network driven events of few hundred

milliseconds duration, called giant depolarizing potentials (GDPs). This pattern, observed in wide range of developing structures, reflects a high degree of synchrony in immature neurons in spite of the small number of functional synapses, and is thought to participate in activity-dependent growth and synapse formation. GDPs have been extensively studied in the hippocampus, where they appear to be initiated by a glutamatergic drive, and are mediated mostly by GABA receptors (in the neocortex they are mediated by glutamate receptors). This pattern of activity is developmentally regulated and disappears around the second postnatal week in rats and mice.

Two recent studies demonstrate that GluTs exert a powerful control of the activity of the maturing cortical neurons (neocortex and hippocampus). Using, DL-TBOA, a nontransportable inhibitor of neuronal and glial GluTs, investigators showed that a deficit of glutamate uptake rapidly transforms the ongoing activity into recurrent depolarization of several seconds duration associated with bursts of action potentials (Figure 1). This pattern of activity, referred to as slow network oscillations (SNOs), is generated during the first two postnatal weeks of life (but not thereafter), and is observed in both interneurons and pyramidal cells throughout the neocortex and hippocampus. SNOs display similar features in the two structures and are mediated by both NMDA and $GABA_A$ receptors, but require the activation of NMDA receptors for their generation; thus, SNOs are fully blocked by NMDA receptors antagonists. To summarize published and unpublished observations, the generation of SNOs proceeds as follows: (1) SNOs are initiated by the leakage of glutamate from glial cells. This leakage, unmasked when GluTs are not efficient, give rise to a sustained increase of [glutamate] in the extracellular space; (2) This sustained elevation of [glutamate] tonically activates NMDA and metabotropic glutamate receptors and depolarizes some glutamatergic neurons that display intrinsic recurrent bursting activity; (3) These burst discharging neurons periodically release glutamate into the extracellular space; this glutamate spreads out from synaptic clefts, leading to the activation of extrasynaptic NMDA receptors on both interneurons and pyramidal cells. The periodic diffusion of glutamate in the extracellular space thus leads to the coactivation of large population of cells within the cortical network, enabling these cells to generate bursts (of action potentials) that last for several seconds. From these studies, investigators concluded that GDPs and SNOs are initiated by the same glutamatergic drive, but that a deficiency in the transport of glutamate enlarges the range of action of this drive in the network, due to the diffusion of the glutamate released and extrasynaptic activation of NMDA receptors. This 'spill-over' engages large populations of neurons in rhythmic activities, including cells in which GDPs are ordinarily absent.

GluTs Prevent the Generation of Seizures in Rat Pups in vivo. Inhibition of GluTs Leads to a 'Suppression Burst Pattern' in the EEG and Partial Seizures

The consequence of dysfunction of glutamate transport on electrographic patterns has recently been investigated with video-EEG monitoring in freely moving postnatal

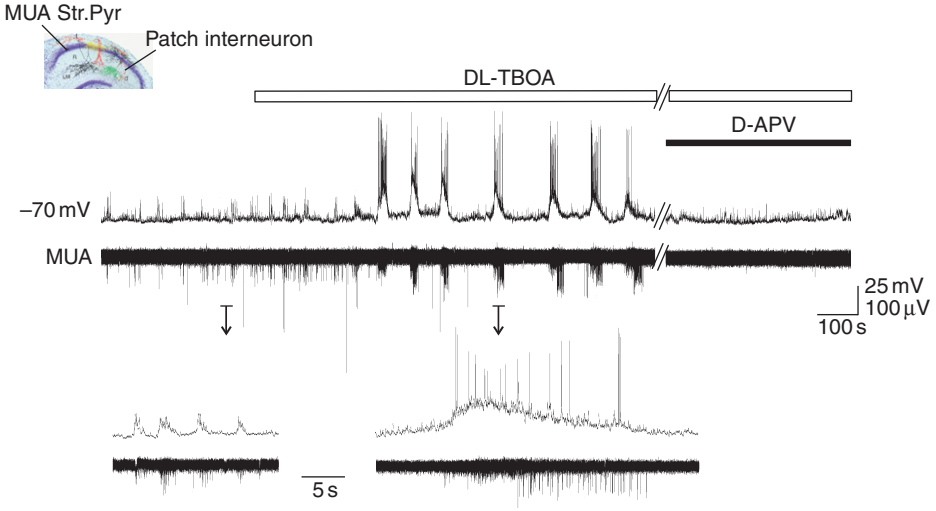

Figure 1 Inhibition of glutamate transporters generates slow network oscillations. Patch-clamp recording of an interneuron from P0 recorded in the stratum radiatum of the hippocampus (upper trace) in current-clamp mode and combined with the extracellular recording of multiple unit activity (MUA) with a pipette located in the stratum pyramidale (Str. Pyr., lower trace). The activity of the CA1 region is composed by GDPs and associated with MUA in the stratum pyramidale (showed at an expanded time scale below the two traces). Bath application of DL-TBOA (100 µM) generates SNOs. This pattern is blocked by D-APV (80 µM), an antagonist of NMDA receptor. The trace is shown 5 min after the application of APV. GDPs recovered 15 min after the washout of the drugs.

day (P)5-P7 rats after intracerebroventricular (ICV) injection of DL-TBOA (a glutamate transporter inhibitor) (see **Figure 2**). In control animals (untreated pups or ICV injection of vehicle), the EEG was composed of bilateral spindle burst (slow delta waves superimposed with faster alpha oscillations). The inhibition of GluTs in rat pups treated with TBOA imposes a singular pattern of activity, composed of recurrent bilateral paroxysmal bursts (a few seconds duration) that alternate with silent periods (also a few seconds in duration). The paroxysmal bursts were sometimes associated with erratic myoclonias. Moreover, partial seizures could also be recorded, as long lasting rhythmic delta–theta oscillatory activities in one hemisphere that were occasionally associated with behavioral manifestation (crawling, tonic posture of one or two limbs, freezing like posture, hypermotor activity). Intraperitoneal injection of NMDA receptor antagonists blocked myoclonias, the 'partial' seizures, and the paroxysmal EEG pattern. These clinical manifestations were not observed after ICV injection of other convulsive agents such as pilocarpine or kainate (which produced a status epilepticus) or after febrile seizures. Therefore, they appear to be related specifically to a deficiency of glutamate transport.

This clinical presentation is observed in some severe forms of early onset epilepsy, such as the early myoclonic encephalopathy with 'suppression burst' pattern. The EEG pattern consists only of complex bursts of spikes and sharp waves, and slow waves lasting 1–5 s, alternating with flat periods of 3–10 s during which there is practically no activity. The paroxysmal bursts can occur either synchronously or independently in the two hemispheres. Partial seizures are also observed in these children. Although the clinical relevance of the study in rat pups to this severe epileptic disorder requires further investigation, the observations do suggest that a deficient transport of glutamate may be a potential cause for early onset epilepsy, particularly those associated with a suppression-burst pattern EEG.

To date the etiology of early epileptic encephalopathy with suppression burst remains elusive. In 50% of patients, cortical malformations are observed with MRI; in others, genetic factors and/or inborn errors of metabolism (leading to a metabolic acidosis, to nonketotic hyperglycinemia, or to a defect of pyridox(am)ine– phosphate–oxydase activity) are thought to play a prominent role. Recently, a mutation in the gene encoding the mitochondrial glutamate/H(+) symporter GC1(*SLC25A22*) has been reported in patients with a suppression burst pattern EEG. The mutation of GC1 has been shown to impair mitochondrial glutamate import, suggesting that a defect of glutamate metabolism may play a major role in this pathology. One might speculate that this GC1 mutation also results in an alteration of glutamate uptake and transport by cell-surface GluTs. Theoretically, a link between the mitochondrial and cell-surface transporters could exist, since cell-surface GluTs are powered by transmembrane gradients of Na^+, K^+, H^+, and substrate, and an abnormal pool of glutamate (that may occur in the GC1 mutated cells) in addition to a rise of intracellular Na^+ concentration may prevent or reduce the uptake of the transmitter from the extracellular to the intracellular space – thus mimicking the action of TBOA.

Conclusions and Future Directions

It is widely accepted that the maturing brain is highly excitable as compared to the adult brain. In human, the

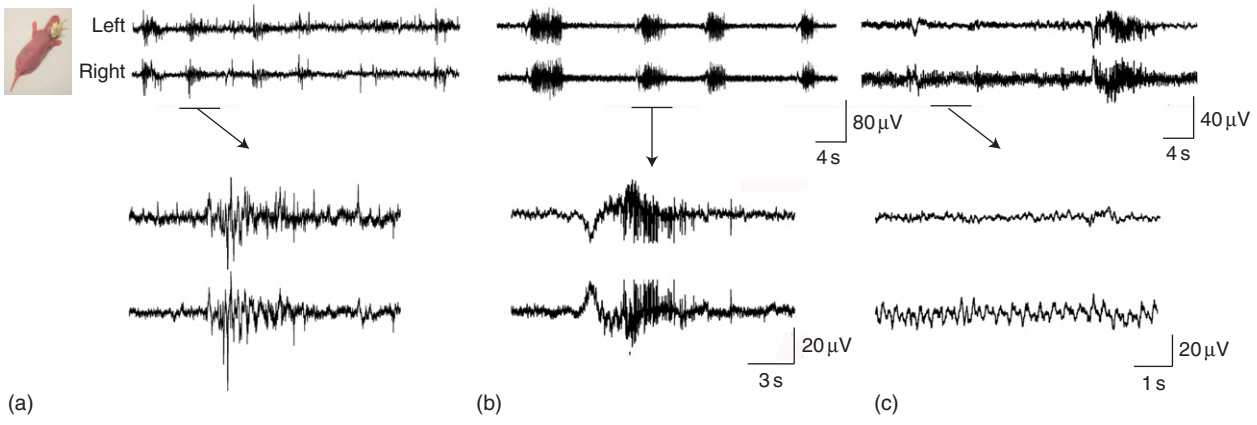

Figure 2 Suppression burst pattern and partial seizures are generated after inhibition of glutamate transporters in rat pups. EEG recording of a freely moving P5 old rat after ICV injection of saline solution (a) or DL-TBOA (b,c). Recording electrodes were placed in the frontal cortex of each hemisphere and the reference electrode was placed in the cerebellum. In the control rat, the EEG is composed of spindle burst (see Khazipov *et al*., 2004). In the TBOA treated rat, the EEG is composed by slow deflections followed by burst of spikes. These paroxysmal bursts occur in recurrent manner and alternate with silent period. (c) Example of partial seizures. Note the presence of slow oscillations only in one hemisphere. This activity was associated with freezing like posture.

incidence of seizures is significantly higher during the first year of life than during adulthood. In rodent, the susceptibility to convulsive agents is higher in the maturing than in adult brain. Studies performed on the brains of developing rodents suggest that several factors may contribute to this preferential hyperexcitability, including excitatory GABA action, high input resistance of cortical cells, and the presence of synchronized network driven events. All these features may be important for the normal development of the brain, but may also favor the generation of seizures. The early expression and function of GluTs are thus fundamental as they appear to tightly control glutamate at these early stages (before synapses are prominent), enabling the correct construction of cortical networks. At later stages of development, when functional synapses are established, these transporters are key to the prevention of paroxysmal activity.

Based on in vitro studies, it has suggested that GluTs reduce the impact of putative glutamatergic 'generators' of rhythmic activity on the network. By preventing or reducing the spread of glutamate released into the extracellular space, GluTs would act to limit the coactivation of neurons and would limit the number of cells that participate in network-driven activity. This control allows the brain to generate a physiological pattern of activity, and prevents specifically, the generation of a suppression burst EEG pattern. This control by GluTs raises the possibility that transporter dysfunction could be a cause of this highly pathological electrical activity in human brain. In this context, it will be important to determine if these transporters are inactivated by direct mutation, or if the metabolic disorders reported in patients suffering from early myoclonic encephalopathy (as a final consequence of their disorder) dysfunction of astrocytes and of GluTs. Finally, our ability to generate in vitro (in cortical slices) recurrent paroxysmal activity that shares similarities with the electrographic pattern in intact brain offers the investigator a rare opportunity to study, in a small circuit, the mechanism leading to the genesis of these recurrent paroxysmal activities. Such studies will lead to a better understanding of the pathophysiological basis of the suppression burst pattern.

GABA Transporters: Regulation of Tonic Inhibition

C B Ransom and G B Richerson, Yale University School of Medicine, New Haven, CT, USA

Introduction

$GABA_A$ receptors are located in the specialized neuronal membrane at synaptic connections, where they respond to GABA released from presynaptic cells (Ca^{2+}-dependent vesicle fusion) by the opening of a Cl^- permeable ion channel. This process underlies fast synaptic, or phasic, inhibition in the brain. $GABA_A$ receptors are also located in the extrasynaptic membrane, where there are no specialized structures for the rapid delivery of GABA to $GABA_A$ receptors, such as exists at synapses. Over the past decade, a great deal has been learned about these extrasynaptic $GABA_A$ receptors. Extrasynaptic $GABA_A$ receptors are molecularly, pharmacologically, and biophysically distinct from those at synapses, and are ideally suited to respond to the low concentrations of ambient [GABA] found in the extracellular space of the brain. The action of ambient [GABA] on these extrasynaptic receptors mediates a tonic conductance, or current, that has been termed 'tonic inhibition.' Tonic inhibition is present in many neurons throughout the brain, including the cerebellum, cortex, and hippocampus.

There are several potential sources of ambient [GABA] responsible for the tonic activation of extrasynaptic receptors, including escape of GABA from synapses after vesicular release, GABA release from nonselective anion channels in glia, and reversal of GABA transporters on neurons and glia. Even when GABA transporters are not working in the reverse direction, theoretical considerations and experimental evidence support an important role for GABA transporters in regulating the ambient [GABA] concentrations that act on extrasynaptic receptors to cause tonic inhibition. This role of GABA transporters is the focus of our discussion.

The expression and function of GABA transporters and the tonic GABA currents they regulate are altered in some epilepsy syndromes and contribute to the actions of many antiepileptic drugs. The continuous inhibitory charge movements and reductions of input resistance produced by tonic inhibition, have significant effects on cellular and network excitability. Indeed, genetic deletion of $GABA_A$ receptor subunits that mediate tonic inhibition in pyramidal neurons of hippocampus results in spontaneous epileptiform discharges. Understanding the physiologic actions of GABA transporters is, therefore, highly relevant to our understanding and treatment of epilepsy and seizures.

Background

GABA Transporter Subtypes

In mammalian brain, there are four cloned isoforms of GABA transporters: GAT-1, GAT-2, GAT-3, and BGT-1 (betaine/GABA transporter). These isoforms have distinguishing pharmacology (see below) and unique cellular localizations. GAT-1 is the primary GABA transporter in the neurons throughout the brain, but is found in glia as well. The expression of GAT-1 is highest in axons and presynaptic terminals. The work of Quick and colleagues has shown that surface expression of GAT-1 can be rapidly regulated by extracellular GABA, and that GAT-1 containing vesicles are mobilized to presynaptic membranes during synaptic events. These findings suggest a dynamic role for GAT-1 in the removal of synaptically released GABA. GAT-3 is primarily expressed in glia. Glial GABA transporters encounter synaptically released GABA when it escapes the synaptic cleft, and contribute to its removal before it diffuses further. GAT-2 expression is most prominent in leptomeningeal cells and ependymal cells, but GAT-2 immunoreactivity has also been identified in the processes of neurons and glia. BGT-1 expression is found in several brain regions, primarily in astrocytes, and in tissues outside the central nervous system including liver and kidney. There exists significant variation in BGT-1 expression patterns across species. We must note that the nomenclature of GABA transporters differs between mice and other species, and this difference can complicate the review of the literature; in mice, GABA transporters are named GAT1-4, and GAT-2 is the same molecule as BGT-1. GAT-2 and GAT-3 in rats and humans are equivalent to GAT-3 and GAT-4 in mice, respectively. In this review we will use the rat (and human) terminology.

Antagonists of GABA transporter function have been indispensable to evaluate the roles of GABA transporters in phasic and tonic inhibition. Commonly used research tools to inhibit GABA transporters include nipecotic acid, SKF-89976a, NO-711, SNAP-5114, and the clinically used anticonvulsant tiagabine. The drugs SKF-89976a, NO-711, and tiagabine are all selective inhibitors of GAT-1. SNAP-5114 inhibits GAT-2 and GAT-3. Nipecotic acid, a structural analog of GABA, blocks the uptake by GAT-1, GAT-2, and GAT-3, but unlike the other agents, it also induces the release of GABA through a process termed 'heteroexchange.' β-alanine is a transportable

substrate for GABA transporters and therefore functions as a competitive antagonist of GAT function. The pharmacology of GABA transporters is discussed more thoroughly elsewhere in this volume.

Biophysical Properties of GABA Transporters and Dynamic Equilibrium

GABA transporters belong to the superfamily of Na^+- and Cl^--dependent co-transporters that harness the potential energy stored in the steep transmembrane sodium gradient (established by the Na^+/K^+-ATPase) to move the substrate from extracellular to intracellular compartments. This secondary active transport process allows a substrate, in this case GABA, to move against its concentration gradient. GABA transporters translocate two Na^+ ions, one Cl^- ion, and one electroneutral, zwitterionic (a zwitterion is a molecule with two or more dissimilarly charged atoms but no net charge) GABA molecule every thermodynamic reaction cycle (see **Figure 1**). Thus, one net charge is transferred to the intracellular compartment during an uptake cycle by the electrogenic GABA transporter. The translocation of GABA, however, may also occur in the reverse direction leading to the release of GABA into the extracellular space. GABA transporters do not function like vacuum cleaners, relentlessly taking up GABA to drive $[GABA]_o$ to zero; instead, they exist in a state of dynamic equilibrium. The direction and magnitude of GABA transport is a direct and predicted consequence of the prevailing thermodynamic conditions,

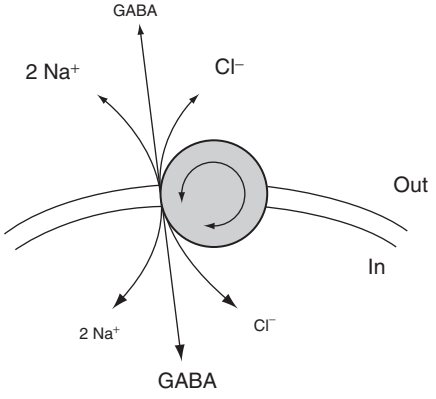

Figure 1 Schematic of GABA transporter. During each transport cycle two sodium ions, one chloride ion, and one GABA molecule undergo coupled translocation. Note that transport can occur in both the forward or reverse direction. The GABA transporters GAT-1, GAT-2, and GAT-3 share this stoichiometry. The betaine/GABA transporter BGT-1 differs in that it translocates three sodium ions per transport cycle. Reproduced from Richerson GB and Wu Y (2003) Dynamic equilibrium of neurotransmitter transporters: Not just for reuptake anymore. *Journal of Neurophysiology* 90: 1363–1374, with permission from American Physiological Society.

determined by membrane potential and the intracellular and extracellular concentrations of Na^+, Cl^-, and GABA. Quantification of the driving force for GABA transport with varying substrate concentrations and membrane potentials is a useful and essential exercise to understand GABA transporter behavior.

The driving force for transmembrane solute movement mediated by transporters and ion channels is a function of the electrochemical potential ($\Delta\mu$) for a given solute, the electrochemical potential being the sum of the electrical potential ($\Delta\psi$) and chemical potential (ΔG). If we were to consider a single molecular or ionic species X, this force is described by the following equation:

$$\Delta\mu_x = \Delta\Psi_x + \Delta G_x = z_x \times F \times E_m + RT \ln \frac{[X]_{in}}{[X]_{out}} \quad [1]$$

where z_x is the valence, F the Faraday's constant, E_m the membrane potential, R the universal gas constant, and T the absolute temperature. When this equation is solved for equilibrium conditions, when $\Delta\mu_x = 0$, it becomes the Nernst equation and describes the equilibrium membrane potential for a given set of intracellular and extracellular solute concentrations. For a GABA transporter such as GAT-1, however, because the translocation of two Na^+ ions, one Cl^- ion, and one GABA molecule are usually linked, the electrochemical potential for this reaction as a whole is described as follows:

$$\Delta\mu_{GAT-1} = 2 \times (\Delta\Psi_{Na} + \Delta G_{Na}) + 1 \times (\Delta\Psi_{Cl} + \Delta G_{Cl}) + 1 \times (\Delta G_{GABA}) \quad [2]$$

Under equilibrium conditions, when $\Delta\mu_{GAT\text{-}1} = 0$ and there is no net force for GABA movement, this equation reduces to:

$$E_m = -\frac{RT}{(2Z_{Na}Z_{Cl})F} \ln \left[\frac{[GABA]_{in}}{[GABA]_{out}} \left(\frac{[Na^+]_{in}}{[Na^+]_{out}} \right)^2 \frac{[Cl^-]_{in}}{[Cl^-]_{out}} \right] \quad [3]$$

This equation defines the reversal potential for GABA transporters, the membrane potential at which GABA movement will change from influx to efflux. The validity of this equation has been experimentally verified. Solving this equation using realistic concentrations of intracellular and extracellular substrate for neurons under normal conditions, we find that the equilibrium potential for GABA transport is −62 mV, close to the resting potential for many neurons (see **Figure 2**). Thus, under control conditions with a membrane potential of −62 mV, there is no net movement of GABA. However, control conditions in neurons are dynamic, and small membrane hyperpolarizations will lead to GABA influx and a subsequent reduction of $[GABA]_o$ towards a new equilibrium value, while small depolarizations produce GABA efflux and a rise in $[GABA]_o$ towards a new equilibrium value.

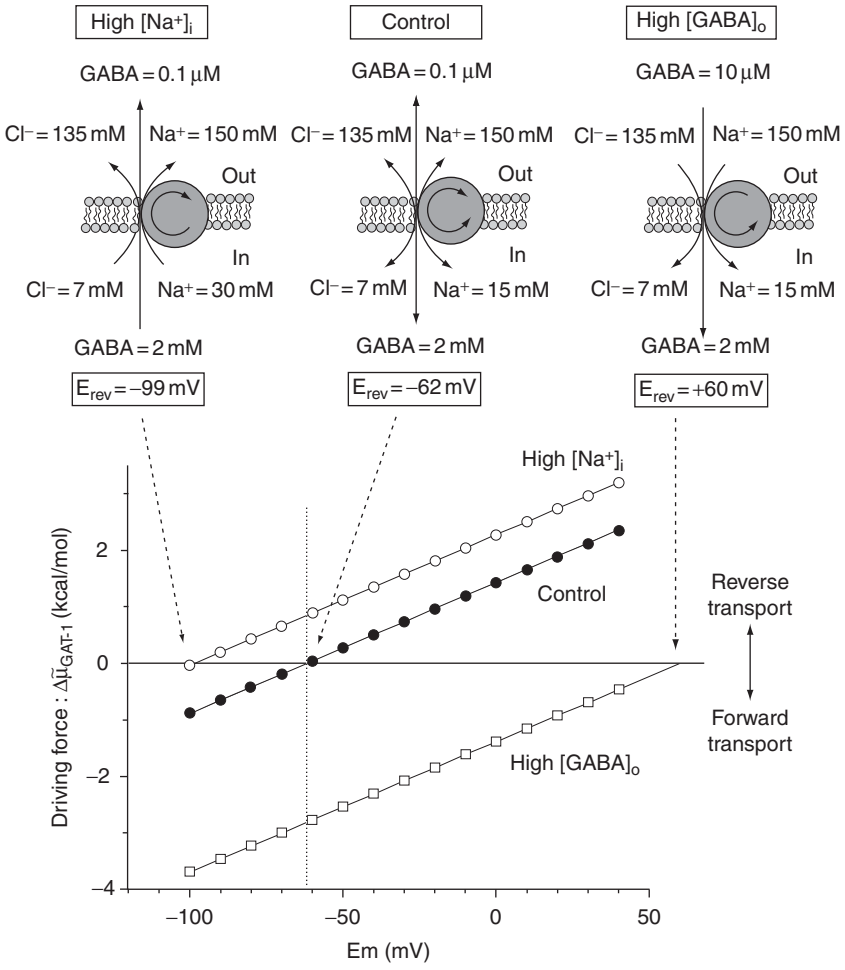

Figure 2 Thermodynamic conditions determined by transmembrane concentration gradients for substrate and membrane potential control the direction and magnitude of GABA transport by GAT-1. The sum of electrochemical potentials for all the transported solutes, μ_{GAT}, represents the driving force for GABA transport. Based on eqn. [2] in the text, this driving force is plotted for three different conditions illustrated at the top of the figure. Under control conditions the calculated reversal potential, the membrane potential at which transport changes direction from influx (forward transport) to efflux (reverse transport), is −62 mV. This is close to the typical resting membrane potential of many neurons indicating that GABA transporter reversal under physiologic conditions will occur in response to small depolarizations. If $[Na^+]_i$ becomes elevated the reversal potential will become more negative and a driving force for reverse transport of GABA will occur at typical resting potentials. In the 'high $[Na^+]_i$' situation this is illustrated as an increase from 15 to 30 mM, in the range of $[Na^+]_i$ changes that occur in hippocampal neurons in response to spontaneous action potentials. Elevations in $[GABA]_o$ will produce positive shifts in the reversal potential and a driving force for forward transport and GABA uptake at normal resting potentials. With $[GABA]_o$ of 10 μM the reversal potential for GABA transport is +60 mV so GAT-1 will always work in the forward direction at membrane potentials that would typically exist in neurons. GABA transporters will dynamically adjust their rate and direction of transport towards new equilibrium values in response to the changes in membrane potential and substrate concentrations accompanying action potentials and synaptic events. Calculations made for 35°C.

Alternatively, increases in intracellular sodium, such as that occurring in neurons during bursts of action potentials or during glutamatergic synaptic transmission, cause the reversal potential for GABA transport to shift towards more negative values, favoring GABA efflux at typical resting membrane potentials. The 'High $[Na^+]_i$' situation illustrated in **Figure 2** shows that an increase in $[Na^+]_i$ from 15 to 30 mM will shift the reversal potential to −99 mV. Changes in the intracellular chloride concentration would have similar, but smaller, effects as those of sodium concentration changes, because only a single Cl^- ion is transported during GABA uptake. In the presence of high $[GABA]_o$, the reversal potential for transport will become more positive – favoring uptake. In the example given in **Figure 2**, $[GABA]_o$ of 10 μM results in a reversal potential of +60 mV. During GABAergic synaptic transmission, when $[GABA]_o$ may transiently reach as high as 1 mM, the reversal potential for GABA transport would be +184 mV. Thus, after synaptic release of GABA there would be a large driving force for reuptake.

These calculations are made for static equilibrium conditions, but the brain does not work as a static system. In reality, GABA transporters of neurons and glia are dynamically adjusting the rate and direction of GABA transport towards new equilibrium values in the face of constant changes in membrane potential and substrate concentrations (resulting from vesicular release of GABA, action potentials, and synaptic potentials). For example, spontaneous action potentials and synaptic transmission can increase intracellular sodium in the soma of hippocampal neurons by as much as 19 mM for durations of several minutes; the rises in intracellular sodium occurring in restricted compartments, such as dendritic spines, may be much larger. This dynamic equilibrium of GABA transporters allows effective uptake of synaptically released GABA to terminate synaptic events and to reclaim GABA. It also permits transporter reversal under physiologic conditions. Biochemical and electrophysiological experiments have demonstrated nonvesicular release of GABA in response to a variety of stimuli (see **Figure 3**). This GABA release is nonvesicular because it can occur after blocking vesicular release of neurotransmitter (e.g., with tetanus toxin or zero Ca^{2+} solution), and is sensitive to GABA transporter inhibitors. GABA transporter reversal is predicted to be augmented under pathologic conditions such as ischemia or seizures, when there is collapse of sodium gradients due to energy failure and widespread depolarization related to high-frequency action potential firing and excessive extracellular potassium accumulation.

Methods

Approaches employed to obtain results on GABA transporters and tonic inhibition described in this review include electrophysiology, biochemical assays, immunohistochemical techniques, as well as the use of transgenic animals.

Electrophysiology

Voltage-clamp experiments to record membrane currents from neurons utilize whole-cell patch-clamp recordings with relatively low resistance microelectrodes (3–5 MΩ) to establish a high-resistance seal (10^9 Ω) between the electrode and plasma membrane. The 'patch' of membrane contained within the electrode tip is then ruptured to allow electrical and physical access to the cell, thus providing control of the composition of both the intracellular and extracellular solutions during the experiment. This methodology has been applied to neurons in tissue culture, neurons in acute brain slices, and cloned $GABA_A$ receptor proteins heterologously expressed in mammalian cell lines. Tonic inhibition is defined as the change in holding current produced by application of $GABA_A$ receptor antagonists (e.g., bicuculline or gabazine). Measurement of tonic inhibition under different conditions allows us to evaluate the contribution of various mechanisms to ambient [GABA] concentrations; these mechanisms (and conditions used to inhibit them) include synaptic release (zero extracellular Ca^{2+}/EGTA) and GABA transport [SKF-86671 (GAT-1) and SNAP-5114 (GAT 2/3)]. Alterations of intracellular concentrations of Na^+ and GABA occur during patch clamp recordings and in response to the influence GABA transporter function; therefore, inclusion of varying concentrations of Na^+ or GABA in pipette solutions, or recording from non-dialyzed cells with perforated-patch clamp methods, is used to overcome this artificial effect of whole-cell recordings on intracellular constituents. GABA transporters are electrogenic, so there are membrane currents associated with their activity that can be detected with voltage-clamp methods.

Biochemical Assays

Measurements of GABA uptake and release may be made with biochemical methods. Exposure of cells to radiolabeled [H^3]-GABA for set periods of time, and then washing cells in ice-cold solution (to remove excess isotope and to attenuate/stop release processes), allows the investigator to quantify GABA uptake by counting emission from the radioisotope. GABA concentrations may also be measured in samples of extracellular fluid with high-performance liquid chromatography. Determination of uptake and GABA concentrations with these methods allows pharmacologic characterization of uptake and release mechanisms. In addition, performing these experiments with zero extracellular calcium, or on cells treated with concanamycin (a H^+-ATPase inhibitor that prevents the pH-dependent packaging of neurotransmitter into synaptic vesicles), provides a means of distinguishing nonvesicular (transporter-mediated) from vesicular release mechanisms.

Results – Regulation of Tonic Inhibition by GABA Transporters

Extrasynaptic $GABA_A$ Receptors and Tonic Inhibition

Spontaneous tonic currents sensitive to $GABA_A$ receptor antagonists exist in cerebellar granule cells (CGCs), dentate gyrus granule cells (DGGCs), and pyramidal cells of hippocampus and cortex. These observations have generated considerable effort from many laboratories to identify and characterize the receptors responsible for this novel form of inhibition. Studies in the cerebellum have

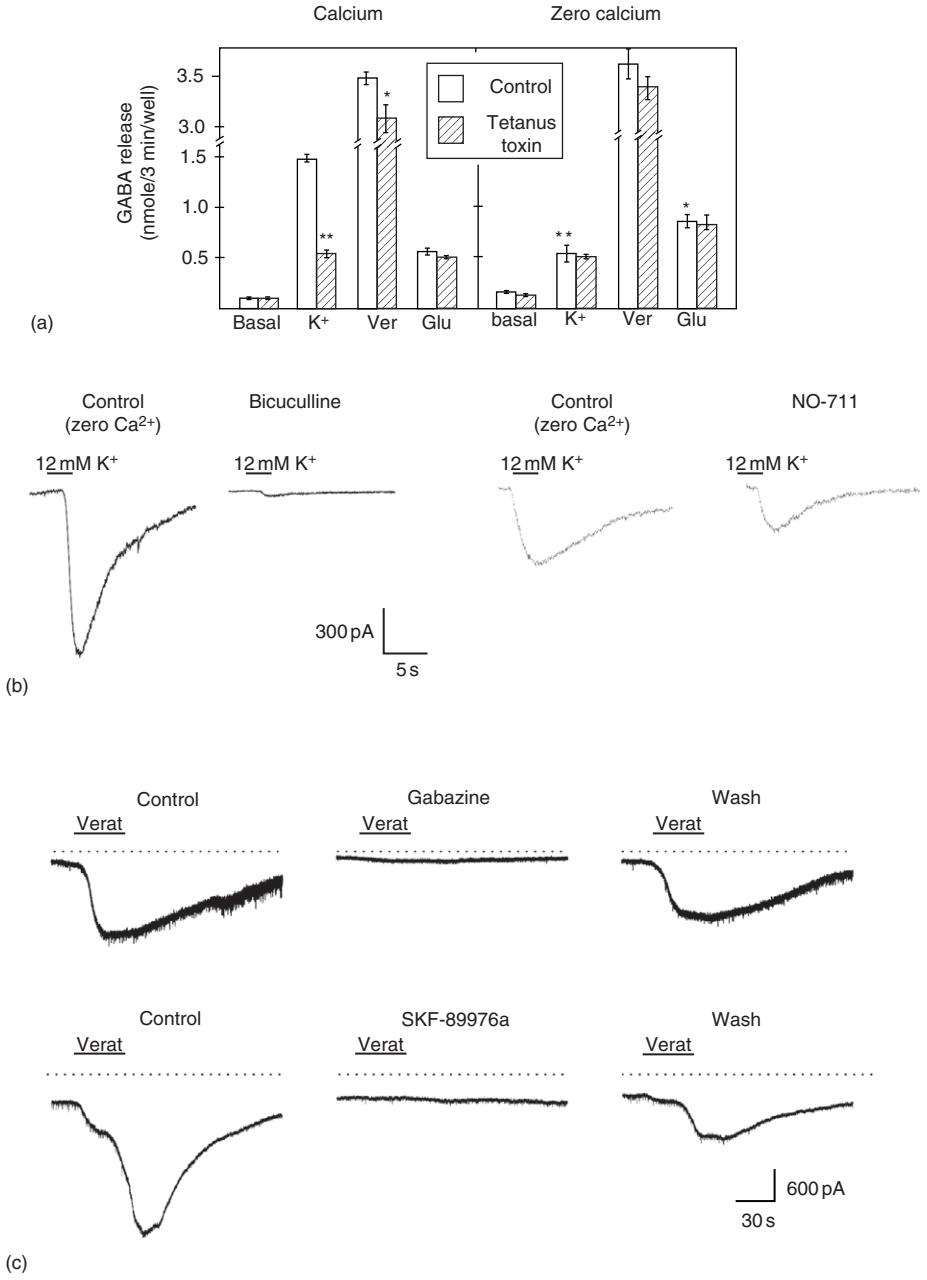

Figure 3 GABA transporter reversal. (a) Biochemical detection of nonvesicular GABA release. With or without extracellular calcium, and/or in the presence of tetanus toxin (maneuvers known to block vesicular release), GABA release from mouse neurons occurred in response to depolarization with 55 mM K^+, the sodium channel opener veratridine (ver), and glutamate. Reproduced from Pin JP and Bockaert J (1989) Two distinct mechanisms, differentially affected by excitatory amino acids, trigger GABA release from fetal mouse striatal neurons in primary culture. *Journal of Neuroscience* 9: 648–656, with permission from Society for Neuroscience. (b) Electrophysiological detection of nonvesicular GABA release in response to depolarization. During patch clamp recordings from hippocampal neurons in the absence of extracellular calcium, application of 12 mM K^+ evoked currents that were completely blocked by bicuculline and partially blocked by the GAT-1 inhibitor NO-711. Transporters other than GAT-1 or other mechanisms may be contributing to the nonvesicular release of GABA seen here in response to elevated K^+. The membrane potential (V_m) was −60 mV and E_{Cl} = 0 mV so $GABA_A$ receptor activation produced inward currents. Reproduced from Gaspary HL, Wang W, and Richerson GB (1998) Carrier-mediated GABA release activates GABA receptors on hippocampal neurons. *Journal of Neurophysiology* 80: 270–281, with permission from American Physiological Society. (c) GABA transporter reversal in response to elevations of intracellular Na^+. Acute application of the sodium channel opener veratridine induced gabazine- and SKF-89976a-sensitive currents in hippocampal neurons. Horizontal bars in panels (b) and (c) indicate period of drug application. These experiments were performed in zero Ca^{2+} solutions. V_m = −60 mV, E_{Cl} = 0 mV. Reproduced from Wu Y, Wang W, and Richerson GB (2006) The transmembrane sodium gradient influences ambient GABA concentration by altering the equilibrium of GABA transporters. *Journal of Neurophysiology* 96: 2425–2436, with permission from American Physiological Society.

been instrumental in advancing our understanding of extrasynaptic receptors that mediate tonic inhibition. Evidence for differential sorting of $GABA_A$ receptor subtypes to synaptic and extrasynaptic membranes came from biophysical studies that identified a uniform single channel conductance of 28 pS for synaptic receptors, in contrast to extrasynaptic receptors which displayed multiple conductance levels. Studies of recombinant $GABA_A$ receptor subunit combinations believed to exist in the cerebellum found specific subunit combinations ideally suited to continuously respond to low levels of ambient [GABA] and mediate tonic inhibition. For example, receptors containing α6 and δ subunits have high affinity for GABA, responding to $[GABA]_o$ as low as 30 nM with EC_{50} values of 0.2–0.4 μM; further, they display little desensitization in the continued presence of agonist. Tonic currents in granule cells and interneurons of the dentate gyrus are also mediated by extrasynaptic receptors containing δ subunits. The δ subunits are of particular interest as these confer unique pharmacology to the receptors mediating tonic currents in some areas of the brain. For example, δ subunits are the target of socially relevant concentrations of alcohol. Low concentrations of ethanol (10–30 mM) potentiate tonic currents in DGGCs and CGCs, and are modulated by neurosteroids. As expected, due to their high affinity for GABA, extrasynaptic receptors and tonic inhibition are blocked by concentrations of the competitive antagonist gabazine that are much higher than needed to completely inhibit phasic inhibition. Additionally, extrasynaptic receptors containing α6 subunits in cerebellum are distinguished by insensitivity to the benzodiazepine diazepam, and to inhibition by furosemide. The main extrasynaptic receptor in CGCs responsible for tonic inhibition is believed to have an α6β3δ subunit composition. Tonic inhibition is present in hippocampal pyramidal cells of areas CA1 and CA3, but is mediated by extrasynaptic receptors with a different subunit combination than that seen in CGCs or DGGCs (not including the δ subunit). The tonic current in these pyramidal cells is insensitive to modulation by low concentrations of alcohol or neurosteroids, and is reduced or absent in mice lacking the α5 subunit.

Tonic inhibition significantly impacts neural processing and behavior. In fact, the total charge transfer due to tonic inhibition is at least threefold larger than that produced by exocytotic release of GABA in response to high frequency stimulation. The firing rate and gain of neurons is modified by tonic inhibition in vitro and in vivo. Modulation of extrasynaptic receptors by neurosteroids has been implicated in catamenial epilepsy and pubertal anxiety. The neurobiological and behavioral effects of socially relevant concentrations of ethanol are due to potentiation of tonic currents mediated by δ subunit-containing extrasynaptic receptors in cerebellum and other areas of the brain. All of these actions of tonic inhibition are ultimately dependent on the ambient [GABA].

Ambient [GABA]

Tonic inhibition is the result of a finite concentration of GABA being present in the extracellular space. Some $GABA_A$ receptors can spontaneously open in the absence of an agonist, but these events occur with a low frequency and are not believed to contribute significantly to tonic inhibition normally recorded in neurons. The primary mechanism of GABA release into the extracellular space is calcium-dependent exocytosis at presynaptic terminals in response to action potentials. The GABA released in this way is meant to rapidly and transiently act on adjacent postsynaptic receptors, causing phasic inhibition. GABA transporters on presynaptic neurons (i.e., GAT-1) and glia (GAT-3) limit the diffusion of GABA away from the synaptic cleft. However, the control of GABA diffusion provided by this system is incomplete, allowing spillover of GABA from synapses where it acts on extrasynaptic receptors to cause tonic inhibition (see the following section). The levels of phasic and tonic inhibition have been experimentally correlated in area CA1 of hippocampus, confirming a contribution of vesicular release of GABA to ambient [GABA] levels. However, tonic inhibition in the cerebellum and hippocampus persists in the presence of TTX to block action potentials and following the blockade of synaptic vesicle release by removal of extracellular calcium, synaptobrevin cleavage with tetanus toxin, or concanamycin inhibition of the vesicular H^+-ATPase that normally establishes the proton gradient responsible for loading neurotransmitter into synaptic vesicles (see Figure 4(a)). In the developing cerebellum, the level of tonic inhibition in young animals is regulated by action potential and calcium-dependent vesicular release, but not in adult animals where nonvesicular release of GABA dictates ambient [GABA]. Nonvesicular release of GABA (and other amino acids) through nonselective anion channels of glia can occur in response to cell swelling or Ca^{2+} waves. Additionally, GABA can be liberated into the extracellular space by reverse operation of GABA transporters of glia and neurons. This latter means of nonvesicular release can occur under physiological conditions, but will be increased during pathologic states such as seizures (when extracellular sodium can decrease by 10–15 mM with concomitant rises in intracellular sodium). The pivotal role of GABA transporters in determining ambient [GABA], and therefore tonic inhibition, is complex and will be discussed in the following section.

GABA Transporters and Tonic Inhibition

In the traditional model of phasic GABAergic inhibition, the time course of an inhibitory postsynaptic potential is determined by the kinetics of $GABA_A$ receptors and removal of GABA from the synaptic cleft. This removal is due to diffusion and uptake by GABA transporters on

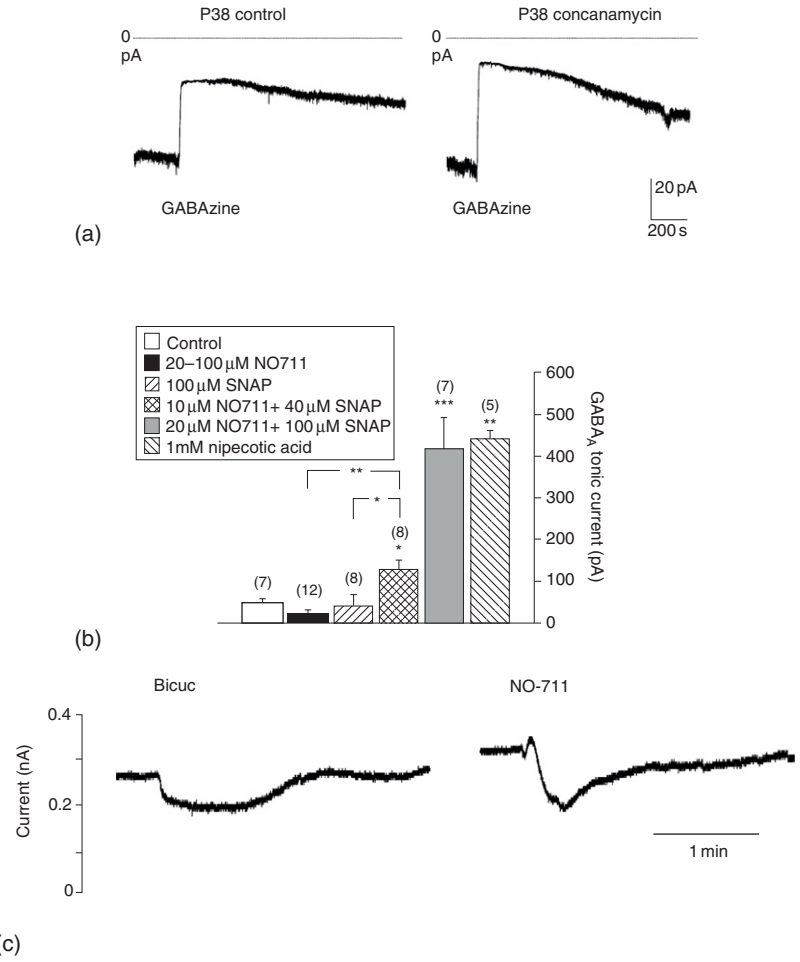

Figure 4 The effects of blocking vesicular GABA release or GABA transporters on tonic inhibition. (a) Patch clamp recordings of cerebellar granule cells from postnatal day 38 rats. Tonic currents recorded at −60 mV in cerebellar granule cells were blocked by gabazine and the amplitude of the gabazine-sensitive tonic GABA current was unaltered following inhibition of vesicular release of neurotransmitter with the vesicular H^+-ATPase antagonist concanamycin. Reproduced from Rossi DJ, Hammann M, and Attwell D (2003) Multiple modes of gabaergic inhibition or rat cerebellar granule cells. *Journal of Physiology* 548: 97–110, with permission from Wiley-Blackwell Publishing. (b) Summary of the effects of GABA transporter antagonism on tonic inhibition in rat neocortex. Tonic currents were not significantly affected by GAT-1 antagonism with NO-711 or GAT-2/3 antagonism with SNAP-5114 in isolation. Inhibition of GAT-1 and GAT-2/3 simultaneously resulted in large increases in tonic current amplitude. Reproduced from Keros S and Hablitz JJ (2005) Subtype-specific GABA transporter antagonists synergistically modulate phasic and tonic GABAA conductances in rat neocortex. *Journal of Neurophysiology* 94: 2073–2085, with permission from American Physiological Society. (c) Gramicidin-perforated patch recording from hippocampal neurons with zero extracellular Ca^{2+}. During these recordings using the perforated-patch configuration, GAT-1 inhibition with NO-711 reduced tonic inhibition, indicating that GABA transporters were working in reverse under these conditions. In these perforated-patch recordings intracellular contents are undisturbed and intracellular Cl^- concentration is low so tonic currents are outward. Reproduced from Wu Y, Wang W, and Richerson GB (2006) The transmembrane sodium gradient influences ambient GABA concentration by altering the equilibrium of GABA transporters. *Journal of Neurophysiology* 96: 2425–2436, with permission from American Physiological Society.

the presynaptic neuron (which must reclaim GABA molecules for repackaging into synaptic vesicles) and perisynaptic membranes (both neurons and glia). This model has fostered the view of GABA transporters as vacuum cleaners that continually operate in the forward direction to bring $[GABA]_o$ close to zero. This model also leads to the conclusion that tonic inhibition is due to GABA molecules that are released at synapses and 'escape' the action of transporters and are thus 'freed' to act on extrasynaptic receptors. The experimental work of many laboratories, demonstrating increased tonic currents after pharmacologic inhibition or genetic deletion of GABA transporters, has strengthened the view that GABA transporters normally serve to limit GABA spillover to extrasynaptic sites and reduce tonic inhibition. The concerted action of presumed neuronal/synaptic GAT-1 and glial/perisynaptic GAT-3 in the control of tonic currents was strikingly demonstrated in neocortex, where inhibition of both types

of transporters was necessary to increase tonic inhibition (see **Figure 4(b)**). However, the persistence of tonic currents in multiple brain regions following blockade of vesicular GABA release compellingly demonstrates that vesicular release of GABA, although an important source of GABA in the extracellular space, is not the sole source of ambient [GABA].

What are the nonvesicular sources of GABA? Astrocytes may release significant quantities of GABA; studies in embryonic hippocampal neurons found that neuronal co-culture with astrocytes, or their treatment with astrocyte-conditioned media, could produce $GABA_A$ receptor currents that were not significantly different from those evoked with 3 μM exogenous GABA. The mechanism for GABA release from glia is not firmly established but it is calcium-independent and may occur through nonselective anion channels, reverse transport, or hemichannels (unpaired gap-junction connexin proteins that may function like an ion channel). GABA release by neuronal transporters is predicted (by eqn. [3]) to occur readily in response to depolarization or intracellular sodium rises that occur under physiologic conditions. Although GABA transporters are often found to limit ambient [GABA] and tonic inhibition, under some conditions – such as during gramicidin-perforated patch recordings, when intracellular contents of cells are undisturbed – blockade of GABA transporters can reduce tonic inhibition (see **Figure 4(c)**). In this situation, reversal of transport contributes to ambient [GABA].

Based on the theoretical considerations discussed above, a more accurate view of the control of ambient [GABA] and tonic inhibition is that GABA transporters set a lower limit for ambient [GABA] governed by the prevailing thermodynamic conditions. Equation [3] can be rearranged to solve for equilibrium values of ambient [GABA], and the solutions to this equation with four different intracellular GABA concentrations is plotted as a function of membrane potential in **Figure 5** (using realistic, experimentally determined values for ion concentrations, as indicated in the figure). These curves demonstrate that the equilibrium value for ambient [GABA], the ambient [GABA] that GABA transporters will dictate even in the absence of vesicular release, is in the range that will activate high-affinity, extrasynaptic $GABA_A$ receptors. Intracellular [GABA] in hippocampal neurons is not known precisely, but values ranging from 1 to 6 mM have been reported for mammalian neurons. If we consider intracellular [GABA] of 2 mM as an average value, ambient [GABA] would range between 0.1 and 0.2 μM for membrane potentials of −60 to −40 mV, respectively. These values are in excellent agreement with results from experiments on tonic inhibition in CGCs, where ambient [GABA] was estimated to range between 90 and 250 nM. Elevation of intracellular GABA, such as occurs following GABA transaminase inhibition with the anticonvulsant vigabatrin, alters the equilibrium of GABA transporters, causing an increase in ambient [GABA] and tonic inhibition.

Summary and Future Directions

Tonic inhibition is a novel form of GABAergic signaling mediated by extrasynaptic $GABA_A$ receptors with distinct

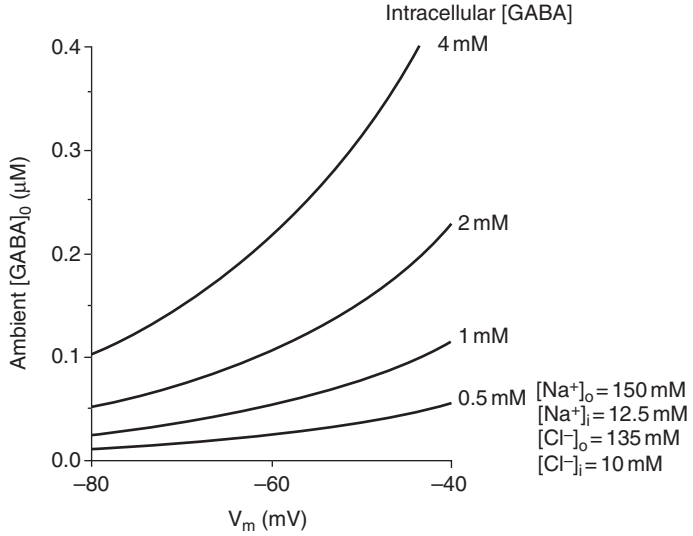

Figure 5 Equilibrium values of ambient [GABA] for GAT-1 as a function of membrane potential. Substrate concentrations are indicated in the figure. Solid lines are drawn for four different values of intracellular [GABA] according to eqn. [3] in text, rearranged for $[GABA]_o$. At −60 mV with $[GABA]_i$ of 2 mM (a low average of published values for $[GABA]_i$ in neurons), GABA transporters at equilibrium would attempt to clamp ambient $[GABA]_o$ at 0.1 μM. This equilibrium value is well within the range needed to tonically activate high-affinity, extrasynaptic $GABA_A$ receptors and consistent with experimental estimates of ambient [GABA].

biophysical and pharmacological properties. Extrasynaptic $GABA_A$ receptors have high affinity and are capable of responding to the low ambient extracellular GABA concentrations in brain extracellular space, on the order of 10^{-7} M. Under physiologic conditions at typical resting membrane potentials, GABA transporters exist near equilibrium and rapidly adjust their rate to take up synaptically released GABA and limit 'spillover' of GABA released at synapses. However, they will also export GABA in response to small depolarizations or changes in ion concentrations. Most importantly, GABA transporter thermodynamics render them incapable of lowering ambient [GABA] below the level needed to activate extrasynaptic receptors and cause tonic inhibition, even in the absence of continued synaptic, vesicular release of transmitter.

As many as 30–40% of patients with epilepsy continue to have seizures despite best medical therapy. The continued expansion of our knowledge of the mechanisms contributing to hyperexcitability – including GABA transporter expression, function, and the regulation of tonic inhibition – has the potential to improve this statistic. GABA transporters remain a promising target in the field of drug discovery for treatment of seizures. Additionally, drugs designed to potentiate tonic inhibition, such as the neurosteroid ganaxolone, have proven effective in several animal models of epilepsy and are currently undergoing phase II trials in humans.

Introduction

Physiological Roles of the GABA Transporters

The canonical role of GABA transporters (GATs) is to remove GABA from the synapse following phasic neurotransmitter release, terminating GABAergic neurotransmission. GABAergic transmission is usually inhibitory, because $GABA_A$ and $GABA_B$ receptors activate Cl^- and K^+ channels, respectively (although some young neurons have a high intracellular Cl^- concentration, producing a depolarized Cl^- equilibrium potential and therefore leading to excitatory GABAergic postsynaptic events). Additionally, GATs perpetually maintain the ambient extracellular concentration ($[GABA]_o$) at a nonzero concentration, which dictates the amplitude of tonic GABAergic currents via activation of extrasynaptic GABA receptors. Even after vigorous synaptic activity, $[GABA]_o$ is much less than the intracellular GABA concentration ($[GABA]_i$) in the presynaptic boutons and surrounding glia. To move the neurotransmitter against this concentration gradient, an electrogenic process cotransports GABA with Na^+ and Cl^- down the combined electrochemical gradient of the cotransported ions.

GATs are attractive targets in the treatment of epilepsy, because inhibiting GABA uptake – through either pharmacological or genetic intervention – prolongs neurotransmitter lifetime and increases ambient $[GABA]_o$ to decrease excitability. Importantly, GATs are equally able to transport substrate in either the forward (into the cell) or reverse (out of the cell) direction. Reverse GABA transport is a physiological process that occurs under depolarizing conditions. Consequently, inhibitory interneuron activation can stimulate both quantal GABA release from synaptic vesicles and nonvesicular GABA release via reverse GABA transport. During periods of high-frequency stimulation, synaptic vesicle stores may become depleted but the transporter-mediated GABA release continues. Furthermore, surrounding astroglia can become depolarized and release GABA through reverse transport. Therefore, during a seizure, reverse transport could have an important neuroprotective function.

This article serves as a brief introduction to the several GAT isoforms expressed in the brain, and reviews how their differential tissue distribution, their structure, and their physiological and pharmacological modulation can control neuronal excitability.

Background

Classification and Differential CNS Expression of GABA Transporters

The GATs are part of the neurotransmitter sodium symporter (NSS) transporter family, which includes transporters for the neurotransmitters dopamine, serotonin (5HT), norepinephrine, and glycine. The NSS transporters are also known as the solute carrier 6 (SLC6) family of membrane proteins. Our laboratory helped to clone the first SLC6 transporter, rat GAT-1 (SLC6A1); 21 human SLC6 transporter genes were subsequently identified, including three other GABA transporters: GAT-2 (SLC6A13), GAT-3 (SLC6A11), and the betaine/GABA transporter, BGT-1 (SLC6A12). GAT-2, GAT-3, and BGT-1, respectively, show 51%, 50%, and 48% amino-acid identity with GAT-1, conservation occurring primarily in their predicted transmembrane spanning regions (**Figure 1**). The 'GAT' nomenclature of the GABA transporters is not the same across species (**Table 1**). The SLC6 gene nomenclature offers a standardized taxonomy, but because this volume focuses on human epilepsy, we prefer to use the more descriptive human/rat classification of the transporter proteins.

Differential CNS distribution of GAT isoforms

Expression of GAT-1 and GAT-3 is restricted to the brain, whereas BGT-1 and GAT-2 are found in peripheral tissues and in the CNS. GAT-1 is the predominant GABA transporter in the CNS; it is localized primarily on axons and presynaptic boutons of GABAergic inhibitory neurons but is also expressed in astrocytes.

Our laboratory generated knockin mice expressing GAT-1 transporters fused to green fluorescent protein (GFP). These mice allow direct visualization and quantification of GAT-1 expression in situ, strongly complementing earlier immunohistochemical and radiolabeling studies. The cerebellar pinceaux exhibit impressively high GAT-1 density, containing almost 8 million GAT-1 molecules per pinceau. The Bergman glia in the molecular layer and the axons and boutons of Golgi cells in the glomeruli of the granule-cell layer account for the more diffuse GAT-1–GFP expression elsewhere in the cerebellum. In the hippocampus, GAT-1 is localized to the axons and synaptic boutons of basket and chandelier cells in strata oriens and pyramidale. A bouton in stratum oriens expresses 79% of the GAT-1 volume density observed in a cerebellar

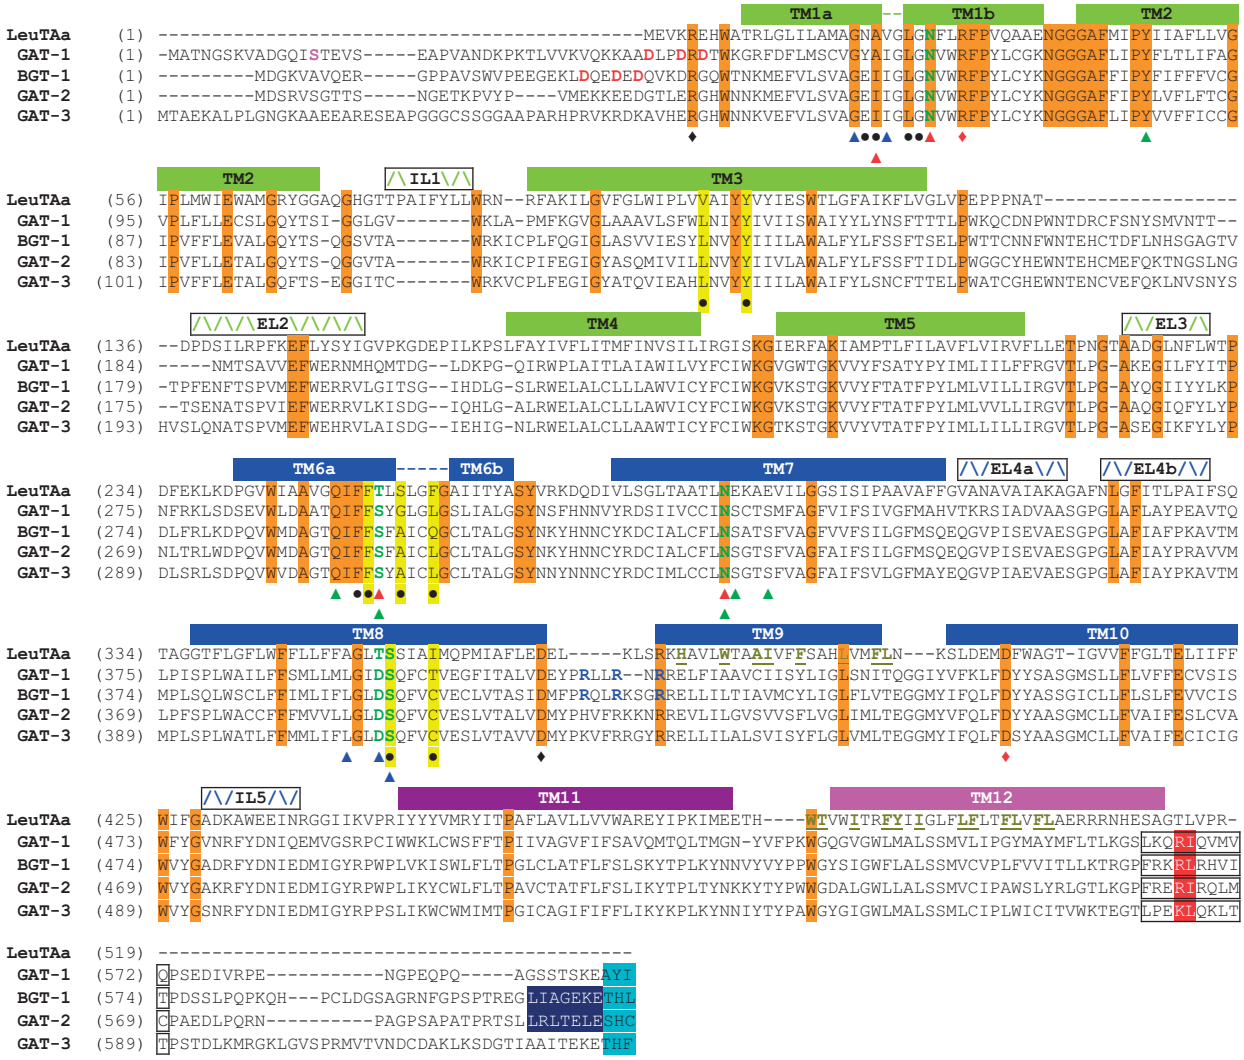

Figure 1 Alignment, secondary structure, and regulatory elements in GABA transporters. A sequence alignment of the four known GABA transporter isoforms with the $LeuT_{Aa}$ bacterial leucine transporter to highlight regions of sequence similarity (presumably leading to structural similarity). Identical residues are highlighted in orange. Transmembrane helices are labeled above the sequences; helices in green (TM 1–5) have pseudo-two-fold symmetry with helices in blue (TM 6–10). TM11 and TM12, which are not part of this symmetry, are colored purple and magenta, respectively. Helical regions in intracellular loops (IL) and extracellular loops (EL) are identified by boxed slashes above the sequences. The red and blue triangles below the sequences highlight residues involved in coordinating ions Na1 and Na2, respectively, and those residues whose side chains interact with the Na^+ ions are shown as green letters. Residues that coordinate the Cl^- ion are marked by green triangles below the alignment. The filled black circles specify the residues involved in binding the leucine substrate in $LeuT_{Aa}$, and residues whose side chains interact with the leucine are shaded yellow. The red and black diamonds indicate the charged pairs at the extracellular and cytoplasmic entrances, respectively. The residues that form the $LeuT_{Aa}$ dimer interface in TM9 and TM12 are shown as underlined brown letters. N-terminal residues involved in syntaxin 1A binding are shown as bold red letters, while IL4 arginines, their interaction partners in the absence of syntaxin 1A, are shown as bold blue letters. The C-terminal sequence implicated in constitutive and PKC-regulated endocytosis is boxed. The R/K-I/L COPII-interacting residues are highlighted in red. Distal C-terminal sequences that mediate somatodendritic (basolateral) sorting are highlighted in dark blue. PDZ-interacting motifs are colored cyan.

pinceau. The relative fluorescence intensity of GAT-1–GFP in the neuropil of hippocampal pyramidal and dentate gyrus cell layers is ~50% of that seen in cerebellar pinceaux but no clear axon or bouton labeling is observed because of high fluorescence in surrounding astrocytes. In human hippocampus, the termini of GAT-1-expressing axon terminals cluster with high density around the dentate

Table 1 Cross-species nomenclature of cloned GABA transporters with official gene symbols

Species	*Nomenclature*			
Human/rat	GAT-1	BGT-1	GAT-2	GAT-3
Mouse	GAT1	GAT2	GAT3	GAT4
Gene name	SLC6A1	SLC6A12	SLC6A13	SLC6A11

gyrus granule-cell somata. GAT-1 expresses at low levels in the cerebellar white matter, striatum and most thalamic nuclei, the latter tissue restricting GAT-1 expression to the astrocytes. Higher expression occurs in the GABAergic thalamic reticular nucleus. In neocortex, GAT-1 immunostaining is associated exclusively with punctate structures resembling axon terminals around the perikarya, and especially in cartridges surrounding the proximal portions of the apical dendrites of pyramidal cells. Cartridges are comprised, at least in part, by the terminals of cortical chandelier and basket cells.

Weak GAT-2 expression is detected in the neurons and astrocytes in cerebral cortex, cerebellum, brainstem, and hippocampus. The greatest GAT-2 expression occurs in the leptomeninges, ependyma, and choroid plexus. Similar to GAT-1 and GAT-3, distal astrocytic processes express GAT-2. However, only GAT-2 is expressed in astrocytic cell bodies and proximal processes. Neuronal GAT-2 expression occurs in axon terminals, mainly in deep layers of rat cerebral cortex, but in areas distant form the synaptic cleft. Weak GAT-2 expression is also detected in the cytoplasm of dendrites from rat cortical neurons. It is unclear if these transporters are ever present at the dendrite surface. Thus, the subcellular distribution of GAT-2 suggests that its primary function is modulating the ambient $[GABA]_o$ rather than terminating GABAergic neurotransmission at the synapse.

The physiological role of GAT-3 is probably similar to GAT-2, as it is exclusively expressed in distal astrocytic processes. GAT-3 is present in the hindbrain, midbrain, olfactory bulb, subfornical organ, hypothalamus, thalamus, and brainstem. Within the basal ganglia, GAT-3 expression is high in globus pallidus, subthalamic nucleus, and substantia nigra but low in the caudate nucleus and putamen. In the neocortex, punctate GAT-3 labeling of distal astrocytic processes forms a continuous sheet around the somata of both pyramidal and nonpyramidal neurons in all layers.

BGT-1 was first identified in kidney, where it accumulates the osmolyte betaine in the hypertonic environment of the renal medulla. It is also expressed in the CNS, although its distribution does not closely correlate with GABAergic pathways despite having a higher substrate affinity for GABA than betaine. Astrocytic cultures from rat brain express BGT-1; monkey BGT-1 expression has been reported in the somata and dendrites of excitatory pyramidal neurons in cerebral cortex and in the CA fields of the hippocampus.

Temporal lobe epilepsy (TLE) has strong ties to GABA transport. Although some GABAergic interneurons are preserved in sclerotic hippocampal tissue from TLE patients, there is a marked reduction in the typical punctate GAT-1 immunoreactivity around the cell bodies of pyramidal cells in the CA regions and granule cells of the dentate gyrus. This pattern reflects reduced GABAergic innervation of these cell types, predisposing them to hyperexcitability. Furthermore, TLE is also characterized by a decrease in glutamate-induced GABA transport reversal. This change is important since seizures are marked by elevated glutamate concentrations, and reduced GAT-1 reversal under this condition would lessen the contribution of reverse GABA transport on seizure inhibition. Regional increases in excitability may be further compounded by general increases in extrasynaptic GAT-3, which could lead to greater GABA removal from the extracellular space, thus reducing GABAergic tone and promoting hyperexcitablity.

Methods

In the Background section, we described research arising from GAT-1–GFP knockin mice that we generated in our laboratory. We have also generated a strain of GAT-1 knockout mice (available from the Mutant Mouse Regional Resource Centers; the knockin mice are generated from this strain by crossing to a strain expressing cre recombinase). More recently we have been studying the oligomerization and trafficking of GAT-1 by generating fusion proteins of the transporter with cyan and yellow fluorescent proteins (CFPs and YFPs, respectively). Besides being fluorescent, these fusions were engineered to be identical to wild-type GAT-1 in all their quantifiable functional properties. Fluorescent GAT-1 fusions were expressed in the neuroblastoma 2a (N2a) cell line, which because of its neuronal origin, possesses much of the necessary cellular machinery to process and traffic GAT-1 correctly. We assessed the lateral mobility and membrane confinement of a fluorescent GAT-1 by fluorescence recovery after photobleaching (FRAP) using an inverted laser scanning confocal microscope. GAT-1 FRAP experiments were performed by photobleaching regions of interest (ROIs) in both the cell footprints and perimeters. We have investigated tethering of GAT-1 to the cytoskeleton by depolymerizing actin with 5 μM of latrunculin B or microtubules with 10 μM of nocodazole and by analysis of the GAT-1 mobile fraction. The mobile fraction was calculated by normalizing the magnitude of fluorescence recovery normalized to the total possible fluorescence intensity.

Förster resonance energy transfer (FRET) was employed to study oligomerization of GAT-1 and also its other intermolecular interactions. If a quantifiable energy transfer was detected between coexpressed proteins tagged with CFP and YFP, it would reflect an intimate intermolecular interaction between the two proteins (<10 nm separation). We employed a spectral laser scanning confocal microscope that has an array of photodetectors that simultaneously yield a full fluorescence emission spectrum at each pixel, allowing the experimenter to deconvolve the individual CFP and YFP spectra without

excessive photobleaching. FRET efficiency was calculated by assessing the magnitude of CFP dequenching during incremental YFP photobleaching.

Recent Results

Structure, Function, and Regulation of GABA Transporters

Insights from recent crystal structures

When GAT-1 was first cloned in 1990, its primary sequence predicted that the transporter possessed 12 transmembrane (TM) spanning segments topologically oriented in the plasma membrane with the carboxy (C−) and amino (N−) termini residing in the cytoplasm. Functional characterization determined that GABA transport was dependent on the cotransport of two Na^+ ions and one Cl^-. In 2005, Gouaux's laboratory reported the crystal structure of a functional leucine transporter, $LeuT_{Aa}$, a homolog of the mammalian NSS transporters (20–25% sequence identity) isolated from the bacteria *Aquifex aeolicus*. The $LeuT_{Aa}$ crystal structure provides a model on which all future structure–function research on NSS transporters can be based. Importantly, features were revealed that could not have been predicted from 15 years of previous experimental data. TMs 1–5 and TMs 6–10 form a structural repeat arranged around a pseudo-two-fold axis in the plane of the membrane (**Figure 2(a)** and **2(b)**). TM1 and TM6 run antiparallel to each other at the core of the protomer, and the center of their helices unwind in the middle of the plasma membrane (**Figure 2(a)**). The exposed main-chain carbonyl oxygen and nitrogen atoms afford hydrogen bonding partners that form most of the contacts with the bound substrate (**Figure 2(c)**). The unwinding of

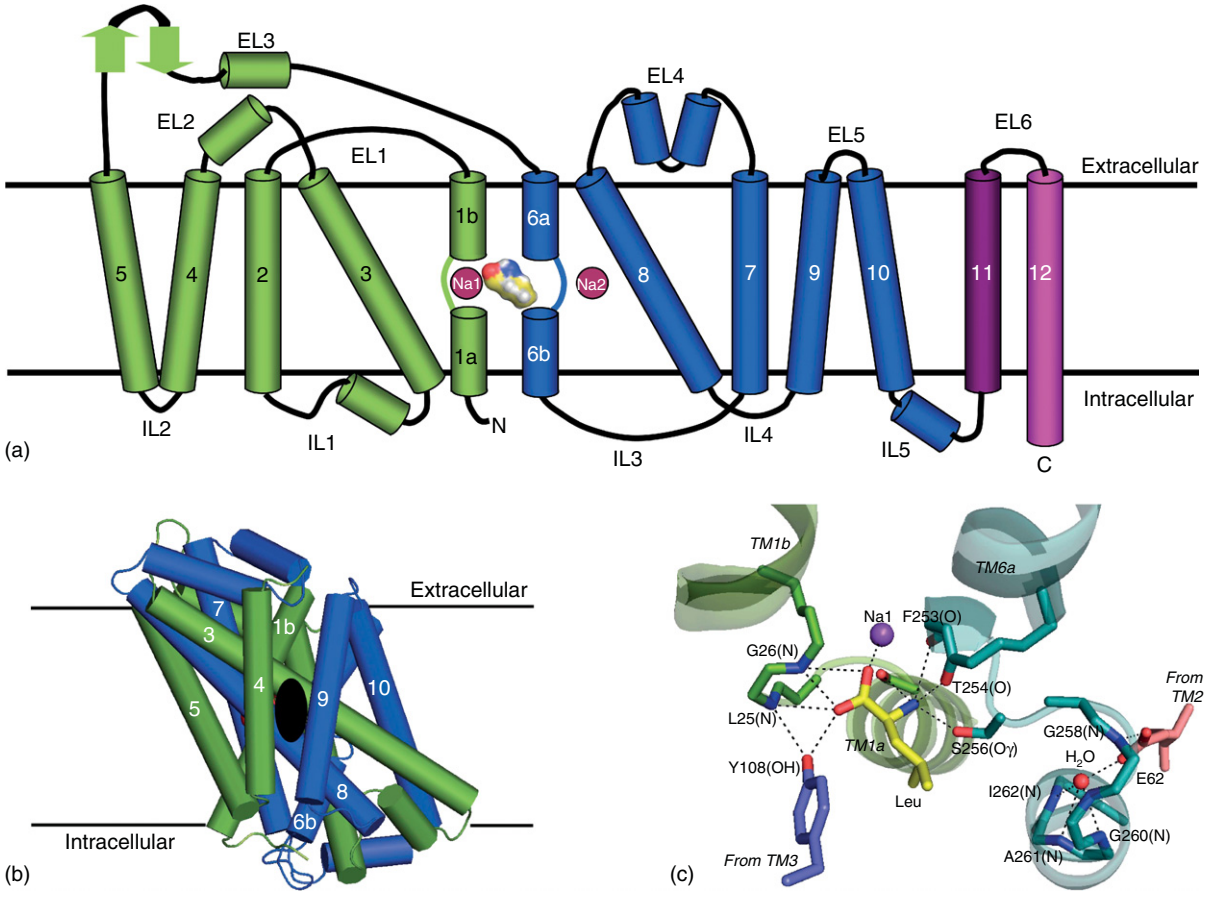

Figure 2 Topology, folded structure, and substrate-binding site in the $LeuT_{Aa}$ bacterial homolog of the mammalian GABA transporters. Panel (a) shows the membrane topology of the SLC6 transporters as exemplified by $LeuT_{Aa}$. Leucine substrate is shown coordinated in the center of the unwound regions of TM1 and TM6; the two Na^+ ions are shown as purple circles. IL, intracellular loop; EL, extracellular loop. Green arrows highlight region of β-sheet structure; the α-helical TM domains are labeled 1–12 and colored according to their pseudo-two-fold symmetrical arrangement in the membrane, which is displayed in panel (b). The black ellipse in panel (b) marks the rotation axis for this symmetry. Panel (c) depicts the hydrogen bonds and ionic interactions that coordinate the substrate (leucine) and the Na^+ ion in the transporter-binding site, which makes direct contact with the leucine. Ion spheres are 25% actual size in order to display all the interactions. Image was generated from the 2A65 PDB $LeuT_{Aa}$ crystal structure using PyMOL v0.99 (DeLano Scientfic, San Francisco, CA).

TM1 and TM6 further stabilizes the substrate. The negative α-helical dipole moments of TM1a and TM6a are placed adjacent to the amino group of the leucine, and the positive moment of TM1b is located next to its carboxy group. The two Na^+ ions cotransported with substrate stabilize the unwound helices at the transporter core for high-affinity substrate binding. Na1 makes direct contact with the carboxyl group of the substrate, (**Figures 2(c) and 3(a)**) which at limiting substrate concentrations could determine the apparent Na^+ affinity of substrate transport. Residues from TM3, TM7, and TM8 form the remainder of the dehydrated substrate/Na^+-binding core. The selectivity for Na^+ as the cotransporting ion arises simply because the pockets are too small to accommodate larger cations such as K^+ (**Figure 3(a) and 3(b)**). $LeuT_{Aa}$ does not require Cl^- cotransport to function, but a Cl^- ion functions as the trigger of the conformational changes that allow substrate to permeate to the cytoplasm in mammalian NSS transporters. The Cl^- is proposed to bind within 5 Å of Na1; the proximity allows the Cl^- to strongly couple with Na1 and stabilize the substrate-binding site. Cl^- is coordinated by the residues that align with GAT-1 Tyr86, Ser295, Asn327, and Ser331 (**Figure 3(c)**). One laboratory also reports the involvement of Gln291. Asn327 is conserved in almost all known NSS members. Ser331 is conserved in all mammalian Cl^--dependent NSSs. Replacing Ser331 or Asn327 (or their aligning residues) in GAT-1, GAT-3, SERT, or DAT (the dopamine transporter), with a carboxylic residue, makes substrate transport independent of Cl^-. Reciprocal mutations in the Cl^--independent $LeuT_{Aa}$ make leucine transport Cl^--dependent. Thus, all NSS transporters require a negative charge (from cotransported Cl^- or an acidic side chain) to be supplied in this pocket during substrate transport.

In the general 'alternating access transport' scheme, a transporter has a cavity that is alternately available for substrate/ion permeation from the extracellular or intracellular side of the membrane; substrate and cotransported ions must all be bound together before translocation across the membrane occurs. Access to the cavity is controlled by intracellular and extracellular 'gates,' which open and close with conformational changes in the transporter. The $LeuT_{Aa}$ structure captures the protein in an intermediate substrate occluded state, in which both these gates are closed. The closed extracellular gate is formed by a water-mediated salt bridge between Arg30 and Asp404, and beneath that, the large hydrophobic side chains on Tyr108 and Phe253. The occluded structure and sulphydryl accessibility studies on mammalian NSS suggest that the extracellular gate opens via movements in TMs 1, 3, 6, and 10 moving Arg30 and Asp404 apart, coupled to a major rearrangement of extracellular loop 4 (ECL4) whose V-shaped tip forms a lid that dips into the extracellular cavity when the gate is closed. The closed cytoplasmic gate is more complicated, comprising 20 Å of packed protein between the substrate and the cytoplasmic face of the protein. Part of this is formed by the backbones of TM1a, TM6b, and TM8 below the substrate-binding site, an Arg5–Asp369 charge pair, an Arg5–Ser267 H-bond, and an Arg5–Tyr268 cation–π interaction at the cytoplasmic face. Trp8 inserts between the backbones of TM1 and TM6b and anchors the N-terminus,

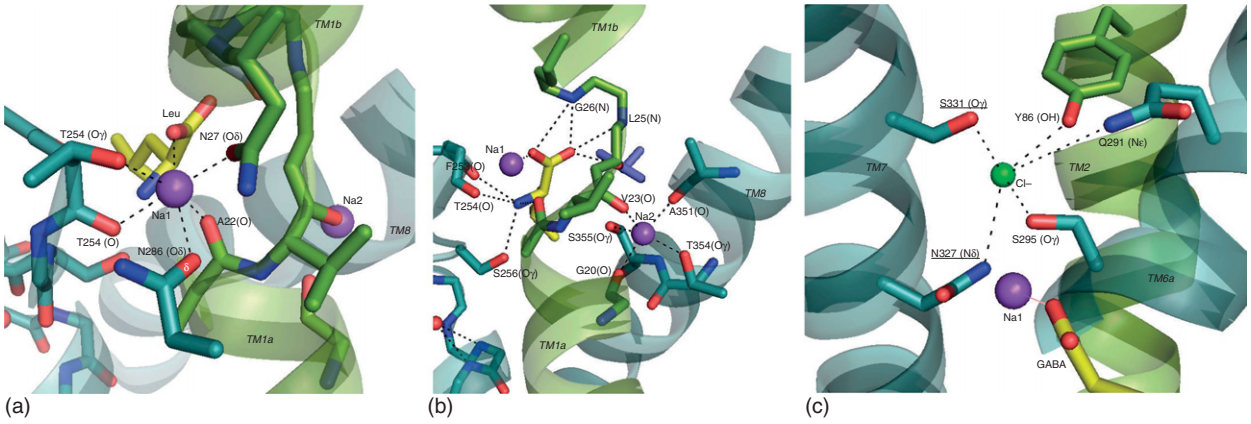

Figure 3 Residues that coordinate the binding of the cotransported Na^+ and Cl^- ions in NSS transporters. (a) Na1 in $LeuT_{Aa}$ coordinated by residues from TM1a, TM1b, TM6a, and TM7 together with the bound leucine are shown. The location of Na2 is shown in the background. (b) TM1a and TM8 residues from $LeuT_{Aa}$ that coordinate Na2 are shown, with the location of Na1 and leucine in the background. (c) Residues from TM2, TM6a, and TM7 that coordinate Cl^- in the GAT-1 transporter. Residue numbering is for GAT-1 in this panel. Underlined residues are almost completely conserved in all NSS transporters. In all panels, ion spheres are 25% actual size in order to display all the interactions. We include the interaction between Gln291 and the Cl^- ion reported by Zomot *et al*., which is not present in the homology models of Forrest *et al*. Panels (a) and (b) were generated using PyMOL v0.99 from the 2A65 PDB $LeuT_{Aa}$ crystal structure. Panel (c) was generated using PyMOL v0.99 from a homology model of GAT-1 based on $LeuT_{Aa}$ kindly provided to the authors for the purpose of this review by Dr. L.R. Forrest and Dr. B. Honig (Howard Hughes Medical Institute, Center for Computational Biology and Bioinformatics, and Department of Biochemistry and Molecular Biophysics, Columbia University, NY).

including Arg5. These residues are conserved throughout the NSS family, and mutation of the aligning amino acids in mammalian NSS transporters impairs transport.

Experiments on SERT have begun to define the pathway through which the substrate diffuses from the transporter core to the cytoplasm. When cysteine residues are substituted at positions that correspond to $LeuT_{Aa}$ residues Gly190, Ile191, Phe194, Ile197, Ala198, and Thr201 in the cytoplasmic half of TM5, the cysteines become extremely reactive to sulphydryl reagents in the presence of 5HT. This indicates that these residues, which are buried in the $LeuT_{Aa}$ occluded structure, become available in a substrate-bound state. They are protected from MTSEA reaction in the presence of cocaine, which traps the SERT in the extracellular-facing conformation.

Trafficking – Modulating transporter number at the plasma membrane

The number of GATs at the plasma membrane shapes neurotransmission and controls excitability. Quantifying the fluorescence intensity in presynaptic boutons and axons in the cerebellum and hippocampus of GAT-1–GFP knockin mice determined that the membrane density of GAT-1 molecules ranges from 800 to 1300 μm^{-2}. Of this value, 61–63% of these molecules are inserted in the plasma membrane, and the remainder are just below the membrane in cytoplasmic vesicles (see later). However, the interplay of constitutive and functional regulatory elements controls the density of transporter at the cell surface at any given point in time.

Constitutive transporter trafficking

Several laboratories, including our own, have measured FRET between transporters fused with CFP and YFP to demonstrate the constitutive oligomerization of transporter protomers. Although single transporter protomers are transport-competent, mutations that prevent oligomerization eliminate FRET, and the fluorescently tagged transporter proteins are retained in intracellular compartments. $LeuT_{Aa}$ crystallized as a dimer, with TM9 and TM12 probably providing the assembly interface. However, this structure likely represents only a low-order oligomerization state for these transporters, as evidence exists for the further oligomerization of transporter dimers. FRET between YFP-tagged Sec24D, a fluorescently tagged component of the COPII vesicle coat, and a CFP-tagged GAT-1 demonstrates that after oligomerization export from the endoplasmic reticulum (ER) occurs via COPII-coated vesicles. Sec24D interacts with a conserved motif (R/L-I/L consensus sequence) in the C-terminal of all NSS transporters. Transporters lacking this proximal C-terminal motif are retained in the ER and exert a dominant negative effect when coexpressed with wild-type protein. Additionally, the ER retention of oligomerization-deficient mutants in which the Sec24D interaction is preserved demonstrates that COPII vesicle-coat interaction is necessary but not sufficient for ER export.

GAT-1 transporters are delivered to the plasma membrane via a population of vesicles, ~50 nm in diameter, which are distinct from the neurotransmitter-containing vesicles. This distinction probably allows regulated transporter expression independent of neurotransmitter release. These vesicles insert their cargo into the plasma membrane under control of the exocyst. The three most C-terminal residues of GAT-1 conform to a consensus sequence for a type II PDZ-interacting motif (**Figure 1**; PDZ, postsynaptic density 95/discs large/zona occludens 1). This sequence mediates transporter interaction with the exocyst by association with PDZ-domain-containing proteins and stabilizes the transporter in this location once inserted. Importantly, NSS transporters are primarily located intracellularly unless they interact with a PDZ-domain-containing protein at their distal C-terminus. For example, a truncated GAT-1 lacking the PDZ-interacting epitope exhibits impaired plasma membrane expression in vitro. Similarly, GAT-1–GFP knockin mice, which express the same amount of total GAT-1 protein as wild-type mice, exhibit a three-fold decrease in cell surface-expressed transporter, because the GFP disrupts the endogenous PDZ-interacting epitope (-AYI). Interestingly, the GAT-1–GFP mice do not phenocopy GAT-1 knockout mice, which have a constant 25–32-Hz tremor in their limbs and tail and display ataxia and anxiety. Thus, there appears to remain a default exocyst-independent pathway through which sufficient GAT-1–GFP can be delivered to the cell surface to maintain wild-type-equivalent GABAergic tone.

Live-cell imaging of GAT-1 molecules reveals that plasma membrane GAT-1 is tethered to the actin cytoskeleton via a multicomponent protein assembly that is mediated by the GAT-1 PDZ-interacting epitope, a PDZ protein, and ezrin. Through FRAP, we recently established that GAT-1 exhibits 30% greater lateral mobility in the plasma membrane when the PDZ-interacting domain is disrupted. Furthermore, FRET determined that the efficiency of the interaction between GAT-1 and ezrin was significantly reduced on depolymerization of the actin cytoskelton. Therefore, interaction with PDZ proteins mediates transporter anchoring in the membrane.

A candidate PDZ-domain-containing scaffold protein that mediates these properties is the membrane-associated guanylate kinase (MAGUK) PALS1 (protein associated with LIN-7, subtype 1). The PALS1–GAT-1 interaction is dependent on the C-terminal-AYI residues, and its coexpression with GAT-1 promotes increased transporter surface expression, presumably by stabilizing the residence of membrane-inserted GAT-1. Neuronal expression of PALS1 and GAT-1 does not perfectly overlap, and it follows that both molecules almost certainly interact with other partners in some cell types and in some

subcellular compartments. The interaction of GAT-1 with PDZ-domain-containing MAGUKs may play a cell-specific and compartment-specific role in regulating transporter availability, location, and stability.

GAT-2, GAT-3, and BGT-1 possess PDZ-type-I-like interacting motifs at their C-termini (Figure 1). GAT-2 and BGT-1 interact with PDZ proteins, including $G_{\alpha i}$-interacting protein COOH terminus (GIPC) and LIN-7, respectively, to stabilize their presence in the plasma membrane. Deletion of these motifs results in redistribution of transporter to intracellular regions but does not perturb the sorting of GAT-2 or BGT-1 to the appropriate cellular compartments. GAT-2 and BGT-1 sort to the basolateral surface when expressed in Madin-Darby canine kidney II (MDCK) cells, a well-established expression system to study polarized sorting of proteins into cellular compartments. The seven amino acids immediately proximal to the PDZ-interacting motifs in GAT-2 and BGT-1 comprise a motif unique to these particular transporters that dictates their delivery to the basolateral surface of MDCK cells (Figure 1). In general, basolateral sorting in epithelial cells corresponds to somatodendric sorting in neurons, while apical sorting, which is observed for GAT-1 and GAT-3, corresponds to axonal (and consequently presynaptic) sorting – although not all proteins fit this paradigm. Truncation of the entire GAT-1 C-terminus does not perturb its apical sorting, but removing the three C-terminal residues from GAT-3 is sufficient to result in mixed apical and basolateral sorting. The THF terminal amino acids of GAT-3 resemble, but do not rigidly conform to, a Type-I PDZ-interacting motif (X-S/T-X-V/L) and reportedly bind the PDZ-domain protein CAP70. For GAT-3 at least, the PDZ interaction may therefore play an important role in both axonal sorting in neurons and stabilizing its expression in the plasma membrane.

Constitutive endocytosis of NSS transporters from the plasma membrane is controlled in large part by the nonpolar residues within the nonclassical endocytic motifs present in their proximal C-termini (consensus sequence L(X)ERLAY(X)IT, Figure 1). Regulated endocytosis and exocytosis occur through pathways distinct from the constitutive processes.

Regulated transporter trafficking

One-third of the total cellular GAT-1 resides in a pool that acutely recycles between the plasma membrane and cytoplasm. In the basal state, one-third of this pool (11% of total GAT-1) resides in the plasma membrane. However, protein kinase and phosphatase activity serves to modulate the transporter cytoplasmic/plasma membrane distribution equilibrium through multiple and distinct pathways. The motif in the proximal C-terminus responsible for constitutive internalization is also implicated in protein kinase C (PKC)-induced transporter endocytosis. PKC-mediated endocytosis is absolutely dependent on the L(X)ERL portion of the L(X)ERLAY(X)IT region, and is located immediately downstream from a conserved putative serine/threonine phosphoacceptor residue. Stimulation of PKC promotes a relative decrease in surface transporter levels, attenuating transporter recycling and redistributing transporter to the endosomal compartments. Stimulating tyrosine kinase activity has the opposite effect. When high neuronal activity elicits large amounts of quantal GABA release, the cell may benefit from redistributing transporters from the intracellular pool to the plasma membrane in a rapid homeostatic response to maintain the local [GABA] close to equilibrium $[GABA]_o$. As substrate permeates the transporter, conformational changes present tyrosines at the cytoplasmic ends of TM2 or TM7 for modification. The phosphorylated side chains signal for reduced transporter internalization, resulting in substrate-induced transporter up-regulation. Analogously, direct inhibition of tyrosine kinases results in rapid attenuation of uptake by GAT-1. NSS transporters therefore exist in mutually exclusive PKC or tyrosine kinase phosphorylated states, and the relative abundance of each of these states dictates the proportion of the recycling transporter pool that is present at the plasma membrane. Nonetheless, direct transporter phosphorylation is often insufficient to drive redistribution. PKC-mediated regulation is still reported even after removal of all consensus phosphorylation sites in the transporter. Protein phosphatases (PPs) also regulate transporter function; in general, PP1 and PP2A inhibition down-regulates transporter activity. Elevated $[Ca^{2+}]_i$ is also reported to decrease GAT-mediated uptake via calmodulin- and calpain-sensitive pathways.

The SNARE complex protein syntaxin 1A is present in the distinct vesicle population that delivers GAT-1 to the cell surface; its coexpression with GAT-1 results in increased transporter numbers on the plasma membrane. A paradoxical feature of this interaction is that syntaxin 1A also serves as negative regulator of the transporter's intrinsic properties. Syntaxin 1A binds to three negatively charged aspartates in the GAT-1 N-terminus (Figure 1), but a cluster of four arginines in GAT-1 IL4 competes with syntaxin 1A at this binding site. Syntaxin 1A interaction with GAT-1 N-terminus releases IL4, which inhibits GABA transport. However, chronic exposure to substrate relieves this inhibition by causing dissociation of syntaxin 1A from the transporter, freeing the N-terminus to sequester IL4. The GAT-1–syntaxin 1A-interaction probably forms only part of a multimeric protein complex that modulates transporter function. PKC-mediated phosphorylation of syntaxin 1A-binding partners (e.g., Munc 18) inhibits their interaction with the SNARE proteins and promotes the syntaxin 1A-mediated effects on GAT-1, while SNAP-25, another SNARE protein, both potentiates syntaxin 1A-mediated inhibition of substrate transport and promotes GAT-1 surface expression. GAT-2 and GAT-3 are not modulated by syntaxin 1A, and FRET indicates

that no direct interaction occurs between syntaxin 1A and these transporters, presumably because their N-termini lack the necessary triplet of aspartate residues present in the N-terminus of GAT-1 and other NSS family members (Figure 1).

Pharmacology – Modulation of the GAT by antiepileptics

GATs are an attractive target in anticonvulsive therapy, because their inhibition leads to activity-dependent prolongation of GABA signals in otherwise hypo-GABAergic synapses. Although many GAT inhibitors possess antiepileptic properties in animal models, tiagabine is the only FDA-approved second-generation antiepileptic drug that selectively inhibits a GABA transporter, GAT-1. Tiagabine-mediated GAT-1 inhibition enhances GABAergic inhibition by prolonging phasic GABA currents. The drug also blocks reverse transport, and so it potentially has proconvulsive properties. Cognitive side-effects of tiagabine are minimal in comparison to first-generation antiepileptics such as valproate, which cause general psychomotor slowing. Nonetheless, the major side-effect of tiagabine is tremor, which can be accompanied by ataxia, dizziness, asthenia, sedation, and nonspecific nervousness. Genetic knockout of GAT-1 produces mice with increased $GABA_A$ receptor-mediated tonic conductance in both cerebellar granule and Purkinje cells, and a slower decay of spontaneous inhibitory postsynaptic currents in cerebellar granule cells. These results point to increased extracellular $[GABA]_o$ due to the lack GAT-1-mediated clearance. Importantly, these mice also partially phenocopy several of the clinical side effects of tiagabine, particularly tremor, indicating the side-effects are inherent to a clinical strategy that specifically targets GAT-1 rather than to nonselective actions on other targets.

Gabapentin and vigabatrin, other antiepileptics in clinical use, do not act directly on GATs, but still influence their function. They indirectly enhance reverse GABA transport during high-frequency stimulation, which could be neuroprotective during seizure.

Although primarily localized on astrocytes and in extrasynaptic regions, BGT-1 is emerging as an attractive antiepileptic target. EF1502 is an equipotent, noncompetitive GAT-1/BGT-1 inhibitor. It has a broad-spectrum anticonvulsant profile in animal models of generalized and partial epilepsy, exhibits a superior tolerability profile in comparison to tiagabine, and displays a synergistic rather than additive anticonvulsant interaction when co-administered with tiagabine. The efficacy of EF1502 is likely explained by its inhibition of extrasynaptic BGT-1, increasing GABA-induced tonic conductance. Similarly, co-administration of NO711 (a selective GAT-1 inhibitor) and SNAP-5114 (a GAT-2/-3 inhibitor) in rat neocortex increased GABAergic tone, but application of either drug alone was insufficient to effect tonic currents. Administration of non-GAT-1 transporter inhibitors alone show enhanced efficacy in the generalized epilepsy models but reduced efficacy on partial seizures when compared with tiagabine. To date there is no known compound that specifically targets BGT-1, GAT-2, or GAT-3.

Future Directions and Challenges

Up to 30% of patients diagnosed with epilepsy exhibit resistance to the available antiepileptic drugs. Among those patients who do respond to treatment with the available medications, seizures are often not completely controlled and many experience one or more undesirable side-effects (e.g., tremor or sedation). The development of new compounds or refinement of existing drugs to create GAT antagonists selective for each isoform remains an attractive option for enhancing GABAergic transmission. Administration of such compounds alone or in combination could form the basis of new treatment paradigms for controlling epilepsy or other CNS GABAergic disorders in a regional or cell type-specific manner. The crystal structure of $LeuT_{Aa}$ has greatly enhanced our understanding of how the NSS transporters' molecular structure relates to their function. The recently reported co-crystal structures of $LeuT_{Aa}$ with tricyclic antidepressant (TCA) drugs now indicates that $LeuT_{Aa}$ may also serve as a pharmacological model for NSS transporters. Both studies determined that TCAs bind in a vestibule in the extracellular face of the transporter, 11 Å 'above' (toward the extracellular face) the substrate and Na^+ ions. Functional studies determined that TCAs can bind $LeuT_{Aa}$ in the absence or presence of substrate and that leucine dissociation was dramatically inhibited by clomipramine. Therefore, it would appear that TCAs noncompetitively inhibit $LeuT_{Aa}$, stabilizing the transporter in a conformation with its extracellular gate closed. However, functional studies in mammalian monoamine transporters suggest that TCAs bind a site deeper in the protomer, inhibiting transport competitively. Despite these functional differences for TCA transporter inhibition between $LeuT_{Aa}$ and the monoamine transporters, the identification of a noncompetitive binding site in the bacterial SLC6 homolog is an exciting development. EF1502, the noncompetitive GAT-1/BGT-1 inhibitor, might bind in the analogous vestibule in GAT-1 or BGT-1. Homology models of GAT-1 or BGT-1 based on the $LeuT_{Aa}$ structure could be used in docking studies of EF1502 and similar compounds to determine whether this is possible. Any significant findings could then be substantiated through functional studies on GAT subtypes carrying pertinent mutations. Tiagabine is a competitive GAT-1-specific inhibitor when in the presence of GABA but is not a substrate. Nipecotic acid, tiagabine's parent compound, is both a potent GAT inhibitor and

substrate. At this time we cannot predict whether tiagabine uses the newly discovered extracellular vestibule when binding GAT-1, but the starting point of any tiagabine docking study is apparent: The substrate-binding site, with the nipecotic-acid moiety of tiagabine coordinated in the place of GABA.

To date, there is no reported evidence of any antiepileptic drug binding $LeuT_{Aa}$. However, if functionally viable, $LeuT_{Aa}$/GAT chimeras could be generated and expressed in *Escherishia coli* for use in the screening of libraries of known antiepileptic drugs or novel compounds for GAT isoform selectivity. In analogous studies to the TCA/$LeuT_{Aa}$-binding investigations, drugs that bind $LeuT_{Aa}$ or the hypothetical $LeuT_{Aa}$/GAT chimeras could be co-crystallized with the bacterially expressed transporters to determine which residues confer drug selectivity between the four GAT isoforms.

Finally, our recent finding of a role for ezrin in the tethering of GAT-1 to the actin cytoskeleton may also imply an important function for this interaction in the pathophysiology of epilepsy. Ezrin is expressed in CNS neurons and is upregulated in the hippocampus of patients with mesial TLE. Likewise, in the lithium-pilocarpine-treated rat model of TLE, ezrin up-regulation occurs within 48 h of seizure induction. Epilepsies associated with malformations of cortical development such as focal cortical dysplasia (FCD_{IIb} and FCD_{IIa}) and gangliogliomas are also marked by neuronal ezrin accumulation. Although the role of ezrin up-regulation in seizure progression has not been formally identified, recent evidence points to the role of ezrin as a downstream target in the phosphoinositide 3-kinase (PI3K) pathway. Further investigation is therefore required to establish if the recently identified interactions between GAT-1, ezrin, and actin are adversely affected by aberrant PI3K signaling in epilepsy-associated malformations.

Glutamate Transporters in Epilepsy

S Underhill and S Amara, University of Pittsburgh, Pittsburgh, PA, USA

Introduction

Much evidence exists to support the idea that epilepsy is mediated by an imbalance of GABA and glutamate in the brain. Both the overstimulation of excitatory synapses by an abundance of extracellular glutamate, and the understimulation of inhibitory synapses by reduction of extracellular GABA, can contribute to the pathological events resulting in seizures and cellular injury. The clearance and metabolism of these two neurotransmitters are intricately coupled, and thus drugs modulating these processes provide potential therapeutic avenues for the treatment of epilepsy.

Synaptic transmission in the brain is generally described in three steps: stimulated release, receptor stimulation, and clearance of the neurotransmitter. This third step is particularly important for shaping neuronal responses. Extracellular concentrations of neurotransmitters are regulated by either enzymes that degrade the transmitter into an inactive form or by transporters that carry the neurotransmitters from the extracellular space into neurons and glia. In the human brain, the extracellular levels of both glutamate and GABA are controlled by neurotransmitter transporters.

Background

Glutamate Transporters

Excitatory amino acid transporters, or EAATs, serve as the major mechanism for limiting the action of the excitatory amino acid glutamate in the central nervous system. In humans there are five different isoforms of EAATs. The expression of each of these transporters is independently regulated and unique to different cell types. EAAT1 (GLAST) is found primarily in astrocytes of the cerebellum, while EAAT2 (GLT-1) is found predominantly in astrocytes throughout the brain, as well as on the presynaptic terminals of glutamatergic neurons. EAAT3 (EAAC1) and EAAT4 are found in the postsynaptic membranes of neurons, while EAAT5 is expressed selectively in photoreceptors and bipolar cells within the retina. Other families of neurotransmitter transporters, such as those for the biogenic amines (dopamine, serotonin and norepinephrine) have single isoforms, which are restricted to neurons that release the cognate neurotransmitters, thus enabling reuptake and repackaging for further cycles of release. In contrast, glutamate transporters are widely distributed, with multiple subtypes expressed both pre and postsynaptically with respect to the glutamatergic neuron, in nonglutamatergic neurons, and on glial cells. In fact, most glutamate is cleared from the extracellular space by the astrocytic carriers.

Many studies have examined the relative impact of each glutamate transporter isoform on glutamate homeostasis, neural function, neurodegeneration, and behavior. Mouse strains with gene deletions in EAATs 1, 2, 3, and 4 have been generated, and while EAAT1, 3, and 4 knockout animals do not exhibit any remarkable neurological developmental profiles, EAAT2 knockout animals exhibit spontaneous and often lethal seizures. One report has suggested that changes in EAAT2 can compensate for reduced glutamate clearance observed when both EAAT1 and EAAT3 genes have been disrupted. EAAT1/EAAT2 double knockout animals are embryonically lethal, underscoring the critical requirement for glial uptake in the maintenance of glutamate homeostasis.

Although the impact of both EAAT1 and EAAT3 on brain physiology was not immediately apparent in knockout animals, more sophisticated analyses have revealed a profound role for these two transporters. As EAAT3 knockout animals age, they begin to exhibit behavioral deficiencies, brain atrophy, decreased glutathione content, and related disability to cope with oxidative injury. The neuronal carrier is an important means of cysteine transport, and reduced levels of this substrate for glutathione synthesis most likely contributes to cell death via oxidative stress.

Recently, it was reported that EAAT1 knockout animals show decreased expression of the GABA transporter, GAT1. A decrease in GABA uptake could increase GABAergic tone and attenuate the epileptic tendency in these animals, as observed with GAT inhibitors in clinical use. This compensatory decrease in GAT1 also could provide an explanation for why EAAT1 knockout mice are not obviously seizure prone, in contrast to EAAT2 knockout animals. The relationship between glutamate and GABA, particularly in the epileptic brain, makes this observation particularly intriguing.

Glutamate Metabolism

Astrocytes recycle glutamate via the glutamate-glutamine cycle (Figure 1). During this process, glial cells take up glutamate, convert it into glutamine using the enzyme,

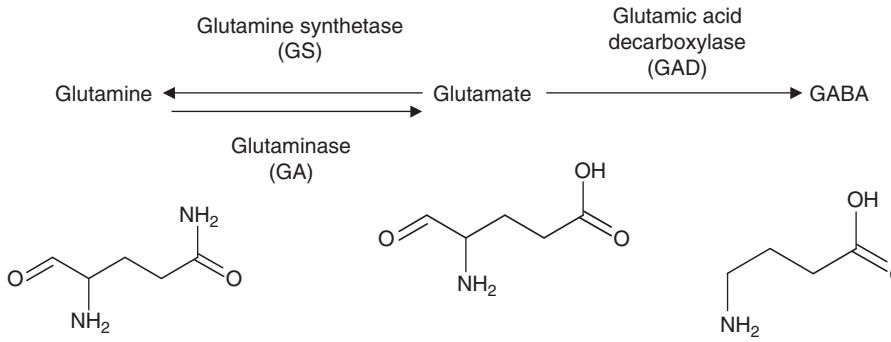

Figure 1 Glutamate and GABA are metabolically coupled. Glutamate can be transported out of the extracellular space into either astrocytes or neurons. In astrocytes, glutamate is converted into glutamine by glutamine synthetase (GS), released into the extracellular space, taken up by neurons and converted back into glutamate by phosphate activated glutaminase (GA). In neurons, glutamate can serve as a source of GABA by conversion via glutamic acid decarboxylase (GAD).

glutamine synthetase (GS), and then release glutamine into the extracellular space through other types of membrane transporters (Figure 2). Neurons take up glutamine and use glutaminase (GA) to resynthesize glutamate and package it into vesicles for synaptic release. A reduction of GS and/or an elevation of GA would lead to an overall increase in extracellular glutamate; indeed, in clinical studies, alterations in GS and GA expression have been linked to several types of epilepsy. However, it remains unclear whether these changes in enzyme levels are the root cause of the pathology or an effect of reduced EAAT activity.

Postsynaptic neurons that express EAAT3 and EAAT4 are often GABAergic. The glutamate that is transported into these cells is converted into GABA by glutamic acid decarboxylase (GAD) and used for inhibitory GABA neurotransmission. Studies inhibiting EAAT activity by a variety of methods have measured a decrease in GABA content and GABAergic activity. This observation reflects the significance of glutamate transport for GABAergic neurotransmission and the content of GABA in the neurotransmitter pool.

Interestingly, GABA is transported from the extracellular space into GABAergic neurons and into astrocytes. Neurons repackage GABA for synaptic release while astrocytes metabolize GABA and effectively remove it from the neurotransmitter pool. Recent investigations of GABA transporter inhibitors as a treatment for epilepsy have shown that inhibition of astrocytic GABA transporters is anti-convulsant, presumably because it preserves GABA in the neurotransmitter pool; however, inhibition of neuronal GABA transporters can be pro-convulsive due to the decrease in inhibitory GABA neurotransmission.

The metabolic pathways for neurotransmitter synthesis and degradation provide a number of potential avenues for therapeutic intervention in the treatment of epilepsy. Several current antiepileptic drugs target GABA transporters, GABA receptors, and glutamate receptors. However, these drugs do not always provide successful treatment, and alternative approaches involving the modulation of glutamate clearance may prove to have utility for limiting the hyperexcitability associated with seizures.

One potential therapeutic strategy directed at glutamate clearance would be to develop drugs that increase the activity of astrocytic and neuronal EAATs, thus reducing the accumulation of extracellular glutamate and limiting its excitatory actions. In addition, increasing the activity of EAATs located on GABAergic neurons could have the beneficial effect of enhancing GABA synthesis and increasing the pool available for release. However, the EAAT isoform, as well as its cellular location and relative abundance, will ultimately determine the therapeutic impact of enhancing EAAT activity.

Another potential means of targeting EAATs for the development of anticonvulsant medications could be through the design of subtype-selective EAAT inhibitors. Although at first this approach might seem counterintuitive, EAAT3 is positioned to regulate the amount of neurotransmitter available to activate metabotropic glutamate receptors (mGluRs). Blockade of EAAT3 would elevate local glutamate concentrations, increase the activation of mGluRs, and trigger mGluR-dependent mechanisms that reduce glutamate release and/or downregulate synaptic glutamate receptors. The neuronal carrier, EAAT3, displays a subcellular distribution that overlaps considerably with mGluRs and thus the selective inhibition of EAAT3 could provide a means of potentiating the homeostatic actions of mGluRs and reducing excitatory tone at nearby synapses.

Currents Associated with EAATs

Glutamate transporters use the sodium gradient to transport glutamate against its concentration gradient – extracellular glutamate concentrations are generally lower than intracellular levels. One cycle of the transporter brings in two or three sodium ions and an hydroxyl ion while glutamate and one potassium ion are expelled as the carrier returns to the outward facing configuration

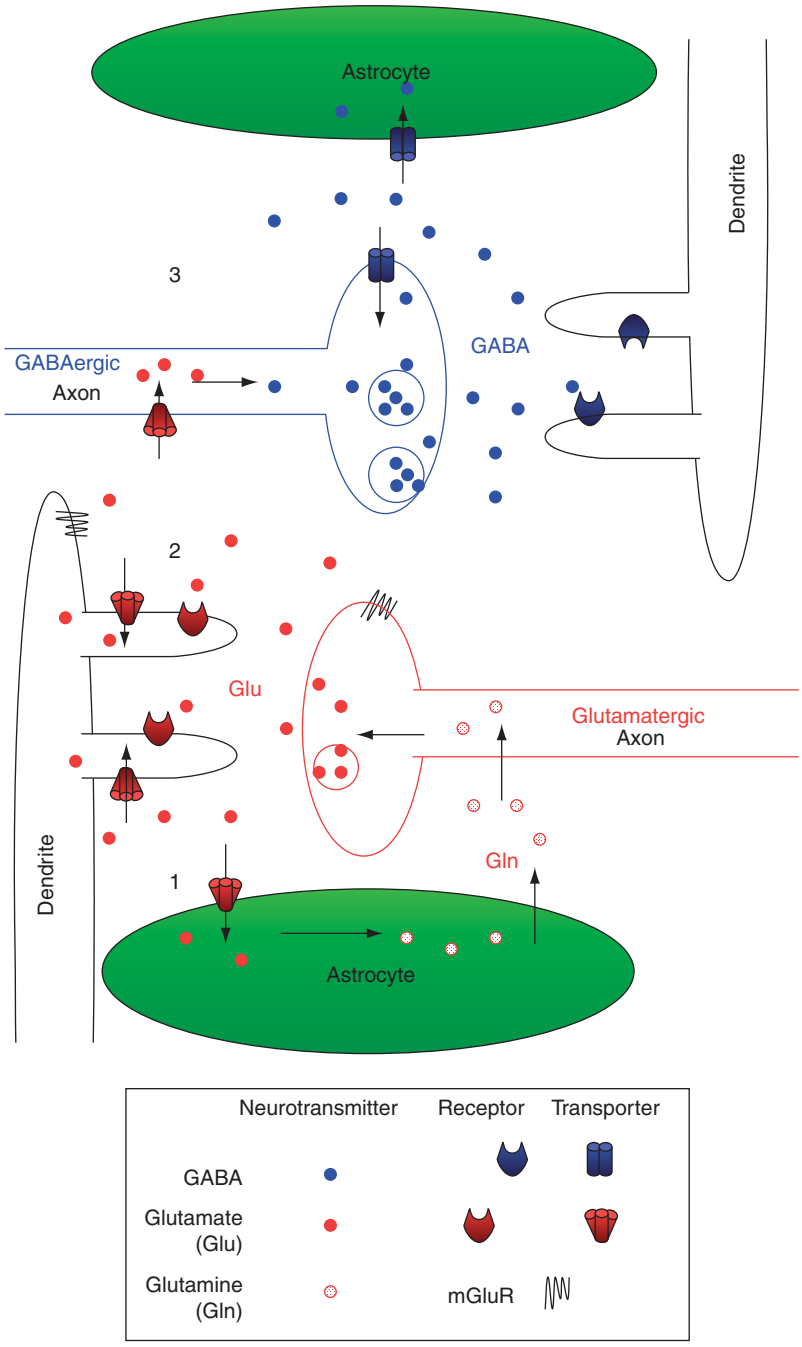

Figure 2 Cellular locations of EAATs and metabolic actions. 1. Glutamate release from the presynaptic terminal activates synaptic glutamate receptors. Synaptically-released glutamate is removed by EAATs located on neurons and astrocytes. Once inside the astrocyte, glutamate is converted into glutamine, which is transported out and taken up by neurons and converted back into glutamate to re-enter the cycle of neurotransmission. 2. Glutamate also diffuses away from sites of release to activate mGluRs. Postsynaptic EAATs can regulate the amount of glutamate available to activate mGluRs. Some of the extracellular glutamate is taken up by neighboring GABAergic neurons where GAD converts glutamate into GABA and enters the GABAergic neurotransmitter pool. 3. GABA is removed from the neurotransmitter pool by GATs on astrocytes or maintained in the neuronal pool by presynaptic GATs.

(Figure 3). Because the substrates and co-substrate carry a net charge, this exchange is electrogenic and a current is generated across the membrane. In fact, monitoring membrane currents is often used to monitor glutamate transporter activity in recombinant systems.

The dependence of glutamate transporters on ion gradients also suggests increased vulnerability of this system when membranes are pathologically hyperpolarized or depolarized. For example, during anoxia, neurons undergo a prolonged state of depolarization, ('anoxic

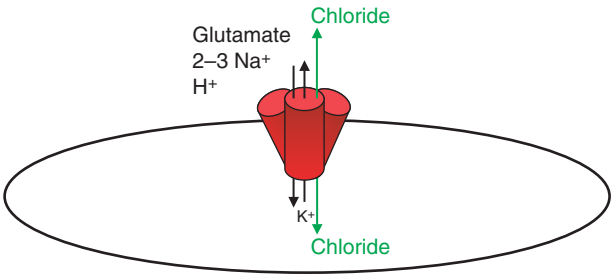

Figure 3 Transport kinetics of EAATs. Under normal, physiological conditions EAATs transport glutamate into cells, against a concentration gradient, by the co-transport of sodium. Hydrogen ions are also brought into the cell and potassium is effluxed. A separate glutamate and sodium gated chloride conductance has also been found, the direction of which is dictated by intracellular and extracellular chloride concentrations.

depolarization'). Depletion of energy stores and the resulting run-down of the sodium pump can lead to a significant reduction in the transmembrane sodium gradient. During this time, glutamate transporters are less functional and may, in fact, transport in reverse. After an ischemic event, extracellular glutamate levels are greatly elevated, in part to EAAT disregulation. The subsequent elevated extracellular glutamate leads to overstimulation of excitatory neurons and glial cells and subsequent cell death. This process is known as excitotoxicity.

In addition to clearing glutamate, some subtypes of glutamate transporter also possess an uncoupled chloride that is activated by substrates and sodium. This secondary role of EAATs as ligand-gated ion channels can complicate the analysis of substrate currents. It has been shown recently for EAAT5 in the retina that these transporter-mediated currents act to hyperpolarize neurons and can directly regulate neurotransmitter release from bipolar cells.

Methods

Initial characterizations of glutamate transport activities in the central nervous system were performed by measuring uptake of radio-labeled substrates in a variety of preparations, including brain slices, synaptosomes (a brain homogenate enriched in pinched off nerve terminals) and primary neuronal and/or glial cultures. To gain a clearer understanding of the energetics and ion requirements of transport, studies were also undertaken in more simplified preparations such as proteoliposomes, in which partially-purified transporter proteins are reconstituted into lipid membrane vesicles. Following the molecular cloning of the various members of the EAAT family, studies of EAATs were extended to include additional molecular and cell-based assays, in which cloned transporter isoforms could be expressed, mutated, and studied in different cellular environments. Two approaches-the measurement of radio-labeled substrate flux and electrophysiological analyses of transport currents-have been used as primary assays of transporter function, regulation, pharmacology, and structure.

The kinetics of uptake can be determined for members of the EAAT family using radio-labeled amino acids. In these assays, a transporter substrate, most commonly tritiated glutamate, is applied to the extracellular side of the cell (or membrane vesicle), and transport is allowed to proceed. Next, the radio-label is washed off, and the incorporated radioactivity is determined. Transport by the EAATs can be described by standard enzyme kinetic equations (Michaelis-Menten), and thus these assays can be used to establish the time-, concentration- and ion-dependence of the process. In addition, the effects of drugs and inhibitors on transport activity can be examined using this approach. In recombinant expression systems, point mutations and other modifications in transporter structure can be made in order to determine the contribution of the primary amino acid sequence to function.

Uptake kinetics can change in two major parameters – apparent affinity or maximum velocity. Changes in apparent affinity can reflect an alteration in the binding sites for substrates or ions within the transporter, whereas changes in maximum velocity usually reflect either a change in the catalytic rate of the carrier (turnover number) or a change in expression on the plasma membrane. Changes in carrier abundance at the cell surface can be assessed with an assay in which surface carriers are covalently modified with a biotin-containing reagent that is added to the external medium. Briefly, a biotin molecule conjugated to a reactive chemical moiety (succinimide) is applied to the outside of the cells where it reacts with exposed lysines. The cells are then harvested and the proteins are isolated by affinity chromatography on avidin-conjugated agarose beads. Western blot analysis of the proteins eluted from the agarose provides a quantitative profile of the membrane expression of the protein of interest. These techniques have been used to demonstrate both increases and decreases in EAAT membrane expression.

Two-electrode voltage clamp recording of currents in *Xenopus laevis* oocytes has been used to measure currents associated with electrogenic transport by the EAATs. Synthetic RNA transcripts of EAATs are injected into the oocyte cytoplasm where the transporter proteins are synthesized and trafficked to the plasma membrane. Once the EAATs appear on the cell surface, substrate-activated currents can be measured electrophysiologically. This approach has enabled investigators to examine the stoichiometry, external ion requirements, and voltage-dependence of the transport process. In addition, because uptake assays can also be done in single oocytes, our group and others have been able to correlate influx of radio-labeled substrates (such as L-glutamate and D-aspartate)

with inward currents, to assess the net charge flux per molecule of substrate.

These methods have provided valuable insights into EAAT function and regulation. Together with approaches from other fields, such as genetic knockdown (RNAi), targeted gene disruption (knockout mice), protein biochemistry, and structural biology (X-ray crystallography), many aspects of the structure and regulation of glutamate transporter function and structure have recently been clarified.

Recent Results

Exciting new studies of EAATs have revealed several distinct structural and regulatory properties of these proteins. A better understanding of the protein's structure and ligand binding is beginning to emerge; the unique features of the protein may indicate directions for devising targeted pharmacological interventions. Unique targeting and trafficking profiles for EAATs, and the potential to manipulate the membrane expression of these transporters, suggest another approach to increasing or decreasing EAAT activity in the human brain.

Pharmacology and Protein Structure

Since the cloning of the EAATs in the 1990s, a variety of useful pharmacological tools have been developed to aid in the characterization of the structure and function of glutamate transporters. Some of these compounds show selectivity for different transporter subtypes and have been used to help establish which transporters are involved in various clinical models of brain injury and disease. A particularly well-studied compound, dihydrokainate (DHK), is a derivative of kainate and exhibits relative selectivity for EAAT2 (**Figure 4**). TBOA blocks all glutamate transporters with comparable potency, but a recently reported derivative, TFB-TBOA, shows selectivity for EAATs 1 and 2. Another recently described compound, NBI 59159, selectively blocks EAAT3. These tools are useful in characterizing the structures of the various EAATs, in experimentally elucidating the contributions of the different isoforms to glutamate homeostasis in the healthy and the injured brain, and in providing avenues for clinical intervention.

Another pharmacological approach to studying glutamate transporters was recently illustrated by a compound isolated from the venom of a spider (*Parawixia bistriata*) that preys on insects. Because insects use glutamate as the neurotransmitter at their neuromuscular junctions, spider venoms often contain components that target glutamatergic systems. Previous studies of the venom from the Joro spider, *Nephila clavata*, have yielded an important antagonist for the study of glutamate receptors. Recent analyses of fractionated *Parawixia bistriata* venom revealed components that altered the activities of glutamate and GABA transporters. This work showed that a component of *Parawixia bistriata* venom, referred to as Parawixin1, appears to act directly and selectively to stimulate glutamate uptake

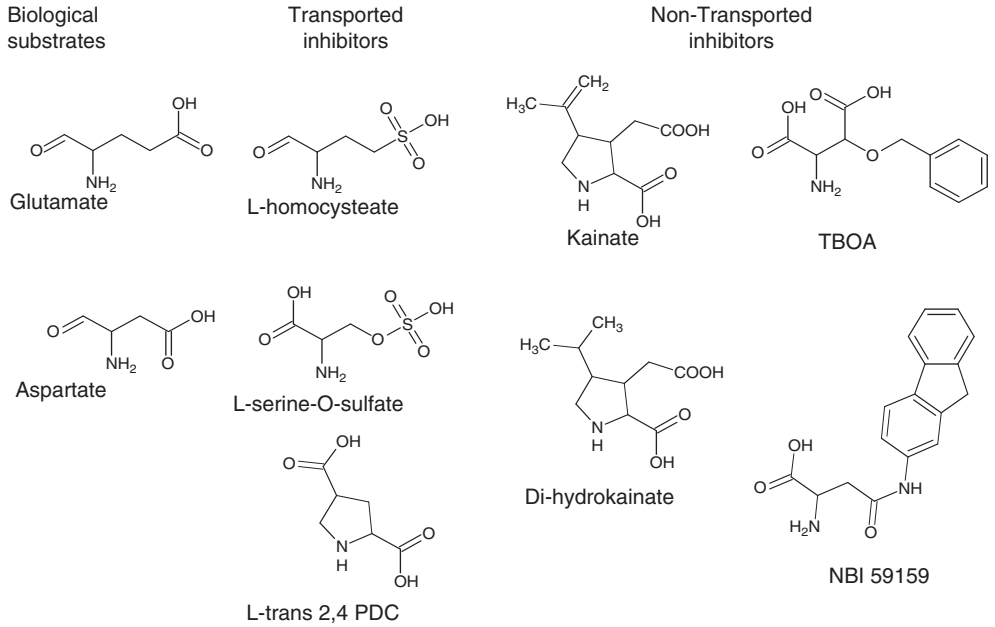

Figure 4 Structure of glutamate transporter inhibitors. Both glutamate and aspartate are substrates for EAATs (left). Transported inhibitors (central column) share some structural similarities. Non-transported inhibitors (right column) are somewhat bulkier and can, as seen with modifications of kainate yielding di-hydrokainate, demonstrate EAAT subtype specificity.

by EAAT2, the major CNS carrier. Studies using EAAT2-enriched proteoliposomes demonstrated that Parawixin1 does not alter the rate of glutamate influx or efflux, but instead facilitates the major rate-limiting step in the transport cycle, the reorientation of the empty carrier to the extracellular surface. An allosteric transport modulator that acts by this mechanism not only provides a research tool for characterization of conformational movements during the reorientation steps in the cycle, but also would have potential utility as a neuroprotective glutamatergic modulatory drug in pathological states characterized by an excess release of glutamate. Consistent with this potential action, Parawixin1 was found to prevent neuronal cell death in a transient ischemia reperfusion model of retinal excitotoxicity. Interestingly, a second component of *Parawixia bistriata* venom, fraction PbTx2, is a GABA transport inhibitor that has an anti-epileptic action.

High throughput screens of chemical libraries have also been a means to identify new modulators of EAAT activity. Recently, a screen of FDA approved reagents found an increase in EAAT2 expression stimulated by beta-lactam antibiotics. Phase 3 clinical trials investigating the potential use of this antibiotic in conditions of long-term glutamate disregulation, such as ALS, are underway.

Understanding the structure of EAATs is another important approach in the development of agonists and antagonists of transport activity. Cloning of the EAATs provided an amino acid sequence that was used to predict membrane topology (**Figure 5**). It appeared that the transporter had 8–12 transmembrane (TM) domains. Topology studies indicate that both the N- and C-termini are on the inside of the cell, and that the transporter is comprised of 8 TM domains with 2 hairpin loops (HP). Functional studies with various mutations have demonstrated that HP1, HP2, TM7 and TM8 are essential for substrate and sodium binding.

Advances in crystallography have yielded important data regarding EAAT structure. A prokaryotic transporter, GLT_{Ph}, has recently been crystallized and illuminates many important new structural features. These studies reveal a trimeric configuration of the transporter, with three subunits associating to form a bowl-like structure. It appears that glutamate can enter into this bowl, essentially moving the substrate half-way across the cell membrane, before any of the transport cycle begins. This crystallized structure also indicates the relative location of the TMs and the HPs. However, data regarding the intracellular N- and C-termini is absent from this model, and other approaches are being used to address their roles in transporter function. These structural features suggest new avenues for agonist and antagonist sites of interaction.

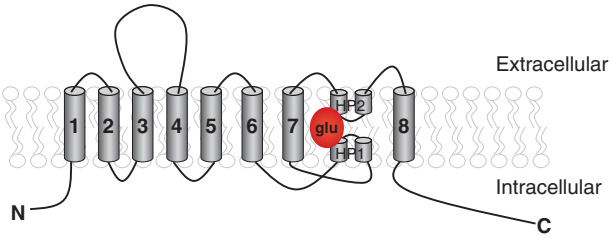

Figure 5 2-dimensional structure of EAATs. EAATs are comprised of 8 transmembrane domains, interspersed with two hairpin loops. Both the N- and C-termini are inside the cell, potentially acting as interactors with other proteins. A large extracellular loop between TMs 3 and 4 appears to by glycosylated, the function of which is unclear.

Cellular Trafficking of Transporters

Membrane trafficking is an important means of regulating transporter function. There are a variety of mechanisms that control the insertion and removal of membrane proteins at the cell surface as a means of increasing or decreasing their activity. For example, an elegant mechanism has been proposed for the regulation of GABA transport in which the accumulation of intracellular GABA through GAT activity triggers a cascade of events that increase GAT surface expression, effectively increasing transporter activity in response to increased synaptic activity.

One robust observation regarding transporter regulation involves stimulation of the protein kinase C (PKC) pathway. EAATs 1 and 2, like the monoamine transporters, are internalized by endocytosis in response to PKC stimulation. However, EAAT3 appears to be regulated differently. Rather than being expressed predominantly at the cell surface, EAAT3 is often found in vesicles just beneath the cell membrane. In response to a PKC stimulus, the transporter is recruited from the intracellular compartment to the cell membrane, increasing glutamate transport activity. The differences in the behavior of the various EAAT isoforms and their cellular locations provide interesting avenues of research.

The cellular mechanisms that govern the insertion and internalization of transporters in neurons and glial cells have not been established. Although many studies support the involvement of kinases and phoshatases in the regulation of transporter trafficking, it remains unclear whether direct phosphorylation of the transporter serves to trigger transporter recruitment or internalization. Several years ago, a number of glutamate transporter associated proteins (GTRAPs) were identified through a yeast-two hybrid screen. GTRAP41 and GTRAP48 interact with, and increase the activity of, EAAT4 through a mechanism involving an increase in the cell surface levels of the transporter. Another of these putative regulatory molecules, GTRAP3-18, interacts with and reduces the activity of EAAT3 by lowering substrate affinity. The LIM-domain containing protein, Ajuba, was identified as an EAAT2 interacting protein; however, as with many of the glutamate transporter-interacting proteins identified

to date, the physiological role of the protein in regulating transporter function remains to be determined.

In addition to having distinct protein binding partners and a variety of mechanisms for regulation, glutamate transporter subtypes display different patterns of subcellular distribution. There is a growing body of knowledge addressing polarized sorting, targeting, clustering and anchoring domains that dictate the localization of carriers to specific regions of the cell. While the EAATs exhibit substantial homology, unique domains in EAAT3 have been shown to be important for its polarized sorting in neurons and kidney epithelial cells, the two major cell types where it is expressed endogenously. For example, in neurons, EAAT3 targets to dendrites and is distributed perisynaptically; in the kidney, EAAT3 is found almost exclusively on the apical membrane of the cell. Using gene constructs to resolve the sequences required for polarized sorting in neurons and kidney epithelial cells, we demonstrated a unique sequence within the C-terminus of EAAT3 that is required for both targeting to apical membranes of epithelial cells and to dendrites in neurons. This sequence was not, however, required for clustering of the carrier in the postsynaptic membrane, suggesting that multiple signals are required to specify targeting and anchoring of the carriers. Targeting to specific subcellular domains can also be facilitated by lipid raft dynamics, short cytoplasmic motifs, glycosyl-phosphatidylinositol (GPI) linkage and/or glycosylation.

Recent studies suggest that EAAT2 localization may be facilitated by targeting to lipid rafts. Lipid rafts are specialized domains of the membrane that are rich in cholesterol and sphingolipids. EAAT2 was shown to be different from other glutamate carriers in its localization within a detergent-resistant lipid microdomain, suggesting that the protein may contain sequences that preferentially target it to raft-like structures. In fact, depletion of cholesterol from primary cortical cultures leads to a decrease in glutamate transport, which is paralleled by a decrease in EAAT2 clustering and membrane expression. It is unclear which domain in the EAAT2 structure dictates lipid raft targeting; however, this distinct targeting profile may explain why EAAT1 and EAAT2 appear in different subcellular compartments in astrocytes and are subject to differential regulation.

Conclusions and Directions for the Future

Epilepsy is characterized by an imbalance of extracellular glutamate and GABA. Neurotransmitter transporters are responsible for maintaining appropriate levels of neurotransmitters in the extracellular space and pose an avenue of potential therapeutic intervention. Inhibition of GABA transport has been used widely in managing epilepsy; however, such treatment does not address all kinds of epilepsies. Modifications of the glutamate system may prove to be another useful avenue of intervention or a complementary treatment to GABA modulation.

Work in our laboratory addresses the structure, function, and trafficking of EAATs. We have been interested in using our current understanding of the transport mechanism and its relationship to EAAT structure to enable the design of agents to modulate glutamate transport in pathological conditions. Increases in extracellular glutamate prior to or at seizure onset have been described, and glutamate has also been implicated in the initiation, spread, and maintenance of seizure activity. Thus, the development and design of compounds that enhance glutamate uptake is an attractive therapeutic strategy, both for epilepsy as well as for neurodegenerative diseases linked to excess glutamate. With this goal in mind, we have investigated the mechanism of action of spider-venom derived compound, Parawixin1, which enhances glutamate clearance by the major glial carrier, EAAT2. This mechanism for enhancing the rate limiting step in the glutamate transport cycle provides 'proof of principle' for the identification of small molecule drugs which increase uptake by similar allosteric mechanisms, and which may prove beneficial in clinical settings.

EAAT activity may also be increased by modifications in membrane expression. Current understanding suggests that changes in the carrier's localization are mediated by phosphatase and kinase activation. These enzymes effect either the transporter directly or a unique binding partner. Identifying and understanding all of the components of the intracellular cascades that contribute to targeting and trafficking pathways will likely lead to other methods for modifying EAAT activity and for developing therapeutic tools to treat epilepsy.

Future challenges include a better understanding of all these features of EAATs, as well as a larger understanding of the overall regulation of glutamate in the human brain. Screens for small molecules may identify compounds that manipulate trafficking, chloride currents, transport efficiency, or even modify GAD or GS. New advances in gene therapy present other tools for examining glutamate homeostasis. Genetic regulation of EAATs is also being explored with investigations of upstream regulators of the transporters.

Introduction

The movement of ions through membrane channels is generally thought to be limited by the open probability of the channel through which the ions flow. However, this is not so true for chloride-permeable channels. Although the concentration of chloride in the extracellular space is about 120 mM, the intracellular concentration is only 2–20 mM, depending on the cell type. The rest of the anions inside the cell are negatively charged amino acids such as glutamate and aspartate, either free in the cytoplasm or more commonly as components of proteins. Changing the chloride concentration by just a few millimoles will alter the reversal potential for chloride to be positive or negative to the resting membrane potential of a neuron. In other words, small alterations in chloride concentration will change the direction of chloride flow through channels that open when the cell is at rest. Changing the direction of ion flow changes the effect of channel opening from hyperpolarization of the membrane to depolarization of the membrane.

GABA, the principal inhibitory neurotransmitter in the mature brain, operates an ion channel that is selectively permeable to ions, particularly chloride. Some of

Introduction

The movement of ions through membrane channels is generally thought to be limited by the open probability of the channel through which the ions flow. However, this is not so true for chloride-permeable channels. Although the concentration of chloride in the extracellular space is about 120 mM, the intracellular concentration is only 2–20 mM, depending on the cell type. The rest of the anions inside the cell are negatively charged amino acids such as glutamate and aspartate, either free in the cytoplasm or more commonly as components of proteins. Changing the chloride concentration by just a few millimoles will alter the reversal potential for chloride to be positive or negative to the resting membrane potential of a neuron. In other words, small alterations in chloride concentration will change the direction of chloride flow through channels that open when the cell is at rest. Changing the direction of ion flow changes the effect of channel opening from hyperpolarization of the membrane to depolarization of the membrane.

GABA, the principal inhibitory neurotransmitter in the mature brain, operates an ion channel that is selectively permeable to ions, particularly chloride. Some of

the most effective anticonvulsants such as the benzodiazepines and barbiturates work by increasing the open probability of the $GABA_A$ receptor-operated channel. The efficacy of these anticonvulsants is thus predicated on the gradient for chloride flux. Understanding how this transmembrane chloride gradient is maintained, and the physiological and pathological conditions under which it is reversed, are thus of direct import to epilepsy research.

Background

The neuronal $GABA_A$ receptor is selectively permeable to anions, particularly chloride. The driving force for chloride movement through the $GABA_A$ channel is quite precarious, and can be redirected to drive chloride either into or out of the neuron when GABA binds to the $GABA_A$ receptor. The direction of chloride flow determines whether the opening of $GABA_A$ receptor-operated channels results in the net accumulation or loss of negative charge. When negative charge is accumulated, the net result of $GABA_A$ receptor activation is hyperpolarization of the membrane and inhibition of neuronal firing. When intracellular negative charge is reduced as a consequence of chloride efflux, the net result of $GABA_A$ receptor activation is membrane depolarization, which may excite the neuron by virtue of initiating action potentials or activating voltage-gated calcium channels. Thus, the ion transporters that determine the driving force and direction for GABA-gated chloride flow are important determinants of the function of GABAergic synapses. It follows, then, that chloride transport also determines the effects of anticonvulsants – such as the benzodiazepines and barbiturates – that act by increasing the open probability of GABA-gated chloride channels.

Chloride transporters do not directly utilize ATP to provide the energy to move chloride across its electrochemical gradient. Rather, 'upstream' chloride transport (i.e., movement of chloride against its electrochemical gradient) is energized by coupling the chloride transport to the 'downstream' movement of a cation such as sodium or potassium. KCC2 is a chloride transporter expressed only in neurons that couples the transport of chloride and potassium out of the neuron. Although KCC2 is freely reversible, the transmembrane potassium gradient is maintained by NaK-ATPase such that potassium efflux is strongly favored, so KCC2 is normally a chloride exporter. NKCC1 is a chloride-importing transporter that couples the influx of chloride and potassium to the influx of sodium down its electrochemical gradient. The potassium-chloride and sodium-potassium-chloride transporters are electrically neutral. In other words, an equal number of cations and anions are transported across the membrane in a given direction. Electronuetral transporters are not affected by the membrane potential, nor do they affect the membrane potential or the membrane resistance.

Membrane ion transport must be plastic; that is, it must change to accommodate differing physiological conditions. For example, the cellular response to increases and reductions in intracellular volume is critical to the survival of the cell. NKCC1 is generally activated by decreases in intracellular volume. The electroneutral import of sodium chloride and potassium chloride by this transporter results in osmotically driven increases of intracellular water that act to restore cell volume. KCC2 provides the opposite function, exporting potassium chloride to reduce cell salt in order to drive an osmotic reduction in cell water and volume. These transporters are subject to a variety of regulations, most of which remain poorly understood in neurons. As one example, it is important that both transporters not operate at the same time. Each transporter is capable of moving sufficient ions to alter the intracellular concentration of chloride at a rate of mM/liter/second. If both NKCC1 and KCC2 were active at the same time, they would move similar quantities of sodium and potassium, which would need to be replaced at the same rate by NaK-ATPase. The consequence would be a catastrophic reduction in the ATP concentration over the course of only a few seconds. One mechanism to prevent this scenario is oppositely directed activation sequences. Specifically, NKCC1 is activated by phosphorylation while KCC2 is activated by dephosphorylation.

Immature neurons maintain high intracellular chloride concentrations through the action of NKCC1. In these neurons, GABA is excitatory because opening anion-selective channels results in efflux of negatively charged chloride ions. Perhaps as a consequence, anticonvulsants such as the barbiturates are not very effective treatments of neonatal seizures. NKCC1 is selectively blocked by nanomolar concentrations of the diuretic bumetanide. The block of NKCC1 leaves no active transport in immature neurons, because KCC2 is not expressed in neurons until later in the development. However, even when chloride is passively distributed across the membrane (so that the chloride reversal potential = resting membrane potential), opening chloride channels is inhibitory because of the increase in membrane conductance that effectively shorts out or shunts excitatory currents. Thus, bumetanide has been proposed as an adjunct to the treatment of neonatal seizures with barbiturates or benzodiazepines.

In mature neurons, the intracellular chloride concentration is maintained at low levels by the action of KCC2. Opening chloride-permeable $GABA_A$ receptor-activated channels results in chloride influx and hyperpolarization of the membrane. However, KCC2-mediated chloride transport does not always keep up with GABA-mediated chloride flux. In mature neurons, this 'mismatch' results in depolarizing shifts of the chloride reversal potential during periods of intense activation of $GABA_A$ receptors.

The $GABA_A$ channel is also slightly permeable to bicarbonate, which has a reversal potential near 0 mV at physiological pH. Under some circumstances, bicarbonate efflux through the GABA channel can dominate chloride flux (when KCC2 transport fails to keep up with GABA-gated chloride flux). When this occurs, the net anion flux is outward, resulting in GABA-mediated depolarization of the membrane. Bicarbonate flux can be reduced by inhibiting carbonic anhydrase, the enzyme that catalyzes the hydration of CO_2 to bicarbonate and the dehydration of bicarbonate to CO_2. This action may comprise the anticonvulsant action of the diuretic acetazolamide.

The transport of chloride can change not only physiologically, as occurs during normal development, but also under pathological conditions such as human and experimental epilepsy. The maximal transport rate has been demonstrated to be decreased in two different experimental epilepsy models. This decrease may occur as a consequence of reductions in KCC2 expression due to BDNF activation of TrkB receptors; other potential mechanisms have not been evaluated, such as dephosphorylation-mediated reduction in the activity of KCC2 or an alteration in membrane trafficking. In human temporal lobe removed during surgery for intractable epilepsy, GABA has been demonstrated to be excitatory in some neurons in the subiculum, and corresponding reductions in the expression of KCC2 and increases in expression of NKCC1 have been demonstrated in this brain region. The reduced transport capacity of KCC2 makes it more likely that KCC2 activity can be overwhelmed during periods of intense GABAA receptor activation, while the expression of NKCC1 implies that any level of $GABA_A$ receptor activity may result in membrane depolarization.

One way to sort out the changes in chloride transport occurring during epilepsy is to evaluate the kinetics of chloride transport. The techniques for this approach are described in the following sections.

Methods

In comparison with other cell types, neurons are uniquely equipped for studies of chloride transport because of the $GABA_A$ receptor-operated chloride channel. The $GABA_A$ channel can be activated whenever needed and for as long as is needed by application of ligand. The $GABA_A$ channel can be used to either load the neuron with chloride or deplete the neuron's chloride. Further, the channel can be used to assay the concentration of chloride inside the neuron by testing the reversal potential of the currents flowing through the channel. The ability to alter the concentration of intracellular chloride and assay the changes in chloride concentration provide the tools necessary for experiments in which the neuronal chloride concentration is perturbed and then monitored as the transporters work to drive the chloride concentration back to the steady state. The time course of the chloride concentration changes after the perturbation can be used to derive important kinetic data regarding the active transporter, including the maximum velocity of transport, the affinity of the transporter for chloride, and the driving force for transport.

There are several technical aspects of these kinetic studies that are worth emphasis. The methods used to activate $GABA_A$ receptors can influence the results of the experiment. In brain slice preparations, GABA is subject to rapid uptake, and so does not diffuse far from the point of application. Using agonists that are not subject to reuptake, such as muscimol or isoguvacine, will result in diffusion across the preparation, with the activation of many distant GABA receptors. In kinetic experiments, the volume into which the GABA-gated chloride currents flow is an important variable and using GABA limits the region of activation. If the chloride currents flow into or out of small intracellular volumes, the change in chloride concentration will be proportionately larger than if the currents flow into or out of a larger intracellular volume. Since the change in chloride concentration is what drives the change in transport rate, and is what is monitored by the change in GABA reversal potential, regions with many GABA receptors per unit volume (such as the dendrites) are more easily studied than areas with fewer GABA receptors per unit volume (such as large somata) with these techniques.

When GABA receptors are activated over limited regions of the neuron, the diffusion of chloride to or from other regions of the neuron will act in concert with the active chloride transport to restore the chloride concentration to equilibrium. One way to address the impact of diffusion is to estimate the geometry of the activated region (based on DIC microscopy) and then estimate the rate of diffusion. The diffusion coefficient for intracellular chloride has been published, so these calculations are quite feasible. A more accurate means of separating the effects of diffusion from active transport is to repeat the experiment with active transport blocked. This protocol leaves only diffusion to restore the chloride concentration. The rate of restoration of chloride concentration after transport is blocked can be subtracted from the rate before the block of transport to derive the rate of transport. This approach is particularly useful for NKCC1, which can be selectively blocked by bumetanide. KCC2 and KCC3 cannot be selectively blocked, although in normal adult neurons there is a minimal NKCC1 expression, so a nonselective transport inhibitor such as furosemide can be used.

Gramicidin-perforated patch electrodes that are selectively permeable to cations are commonly assumed to be the best means to study chloride transport. Neurons

expressing NKCC1 are very sensitive to the intracellular sodium concentration, as this concentration determines the free energy available for the import of potassium and chloride against their concentration gradients. Gramicidin electrodes alter the intracellular sodium by virtue of diffusion of sodium into or out of the electrode solution, and because many physiologists leave sodium out of the electrode solution, the resulting intracellular sodium concentration may be artificially low. This situation would result in an excessively large driving force for NKCC1 and a correspondingly high intracellular chloride concentration. Neurons that only express KCC2 are less vulnerable to this effect, because the intracellular potassium concentration is already high in these neurons, and small errors due to diffusion of electrode solution via gramicidin ionophores will not significantly change the driving force for potassium efflux.

Results

Several labs have examined the relaxation of intracellular chloride concentrations after loading or depletion. There is general agreement that this relaxation is a first-order process. Characterizing the relaxation by a rate constant provides some insight into the process, but does not separate the various aspects of transport that contribute to the rate. These contributions include the transporter's affinity for chloride, maximum transport rate, and the driving force for forward or reverse transport. We found that transport by NKCC1 was as reversible as transport by KCC2, suggesting that both transporters are likely to be limited by the driving force or free energy available at the steady-state intracellular chloride concentration. Although Michaelis–Menten kinetics are frequently used to describe membrane ion transport, in the case of neuronal chloride the Michaelis–Menten equation fails to capture the effects of the amount of free energy available to drive transport. This point is important because the action of the transporter changes the chloride concentration and thus the free energy available for transport – while the Michaelis–Menten equation assumes that the available free energy is constant.

We measured the time course of NKCC1 transport after correcting for diffusion by subtracting the rate of chloride relaxation in the presence of bumetanide from the relaxation rate in the absence of chloride. In analogy to Ohm's law, the time course of chloride relaxation was described by an equation containing a conductance term (the transport availability described by the Michaelis–Menten equation) and a term describing the driving force in terms of the total free energy for the transported species, sodium, potassium and chloride. This equation fits the data well despite the fact that the only free variables were the maximum velocity of transport and the steady-state chloride concentration. The affinity of the transporter for chloride was not a useful parameter because the extracellular chloride concentration was high and constant.

These experiments demonstrated that in immature/developing hippocampal neurons, NKCC1-mediated inward chloride transport is limited primarily by the driving force available, so that the resting chloride concentration defines the point at which the free energy for both forward and backward transport is zero. NKCC1-mediated transport was limited by the maximum velocity of transport only at very high rates of GABA-gated chloride flux. The determination of resting chloride concentration by the free energy available for transport has an important implication: changing the concentrations of potassium or sodium, the cations that are cotransported with chloride will change the free energy and thus the steady-state chloride concentration. This relationship led to a surprising finding: changes in NaK-ATPase activity, induced by a series of action potentials, led to changes in the steady state concentration of chloride, presumably by altering the intracellular sodium concentration and thus the free energy available for chloride import. Sodium diffusion into a low-sodium electrode solution in gramicidin-perforated patch recordings will induce similar increases in intracellular chloride, as previously discussed.

Experiments that explore changes in chloride transport in epilepsy are more difficult because it is not easy to compare results across animals and conditions. For example, suppose the density of $GABA_A$ receptors is changed in epileptic animals so that there are fewer $GABA_A$ receptors per unit of membrane area. Under these conditions, a reasonable experimental control – such as ascertaining that the GABA currents used to load neurons with chloride are the same size in control and epileptic animals – may actually distort the results. That is, to elicit the same current, a larger area of membrane will need to be exposed to GABA in the animals with lower densities of GABA receptors; this 'compensation' will lead to smaller changes in chloride, which may be interpreted as better maximum chloride transport, as well as a more significant diffusion component to the relaxation back to steady state. To offset this problem, the volume into which the evoked chloride currents flow can be estimated in each experiment by dividing the total loading chloride flux by the change in neuronal chloride concentration.

The effects of action potential trains on chloride transport, as noted earlier, would certainly suggest that seizure activity may lead to increases in inwardly directed neuronal chloride transport and corresponding increases in neuronal chloride concentration. Increases in neuronal NKCC1, in epileptic tissue, have been demonstrated at both RNA and protein levels, and increases in neuronal chloride have also been reported. It is interesting that this

increase is not at all uniform across neurons in a region. The chloride reversal potential is quite heterogeneous, suggesting that each neuron's transport may be uniquely impacted by the processes that lead to epilepsy.

Future Directions

A great deal of progress has been made in the last decade regarding the physiology of neuronal chloride transport. Characterization of the kinetics of chloride transport has been performed in normal animals, and similarly detailed studies are beginning to be undertaken in epileptic animals. The heterogeneity of chloride transport in epileptic animals will be a challenge, because of the increased number of neurons that will need to be evaluated. Chloride transport studies require 30 min or so of very stable recordings; perforated patch recordings are frequently required. These conditions make electrophysiological analyses of chloride transport particularly labor-intensive, and thus it will be difficult to study the requisite number of neurons in epileptic animals. The development of genetic dual-wavelength chloride-sensitive dyes, such as Clomeleon, may make these studies much easier to undertake. Voltage clamp recordings have the advantage of manipulation of the membrane potential, which greatly facilitates chloride loading and depletion. However, as long as chloride is not passively distributed, it is possible to alter the neuronal chloride concentration by the activation of GABA receptors. The advantages of chloride dyes will rest on the increased number of neurons that can be studied, the ease with which chloride changes can be recorded, and the possibility of assessing anatomical distribution of the chloride changes.

Clinically, pharmacological manipulation of chloride transport is about to undergo clinical trial, as bumetanide is tested as an adjunct to phenobarbital for neonatal seizures. Bumetanide is very lipid soluble, but data regarding its permeability across the blood–brain barrier is limited. Pilot trials of diuretic therapy for intractable temporal lobe epilepsy have been reported in abstract form, with some excellent successes mixed with predictable side effects related to diuresis. Development of strategies to limit the block of NKCC1 to the brain may therefore be particularly useful.

Introduction – Intracellular [Cl$^-$] Homeostasis

Chloride is one of the most abundant free anions in animal cells, and it clearly has important roles in cell physiology. Since $[Cl^-]_i$ is an important determinant of the Cl^- electrochemical gradient across the plasma membrane, it helps dictate the electrical consequences of anion channel function, and thereby plays a significant role in various cell functions, including cell volume regulation, transepithelial salt transport, and synaptic signaling (depolarizing and hyperpolarizing responses). In addition, $[Cl^-]_i$ is a powerful allosteric regulator of many different proteins, including regulatory proteins and transport proteins. These facts belie the outdated view that $[Cl^-]_i$ is not actively regulated and is distributed at equilibrium across the plasma membrane. It is now well established that Cl^- is actively maintained away from its equilibrium distribution, and is subject to tight regulatory control in virtually all animal cells. Two notable exceptions are skeletal muscle cells and vertebrate red blood cells, both of which have remarkably high Cl^- permeability owing to the constitutive activity of either a high conductance Cl^- channel or a robust anion exchanger.

Like other intracellular ions, steady-state $[Cl^-]_i$ is determined by the relative contributions of active 'pumps' and passive 'leaks.' Most animal cells maintain steady-state $[Cl^-]_i$ above electrochemical equilibrium ($[Cl^-]_i > 30$ mM), implying the presence of a dominant transport pathway that actively *accumulates* Cl^- inside cells. A key exception to this generality is the mature neuron that exhibits hyperpolarizing synaptic inhibition mediated by ligand-gated anion channels. In these neurons, $[Cl^-]_i$ must be below electrochemical equilibrium (i.e., $[Cl^-]_I \sim 5–7$ mM) in order for Cl^- influx to carry hyperpolarizing current; these cells therefore require the presence of a dominant transport pathway that actively *extrudes* Cl^- from the neuron. Thus, depending on the cell type, $[Cl^-]_i$ can be maintained either above or below electrochemical equilibrium by dominant active Cl^- accumulation or extrusion mechanisms, respectively. To date, the most important Cl^- 'pumps' identified are the secondary active cation chloride cotransporters (CCCs), including Na-K-Cl cotransport (NKCC), Na-Cl cotransport (NCC), and K-Cl cotransport (KCC). Through the operation of the CCCs, energy stored in the Cl^- electrochemical gradient can be used by dissipative 'leak' pathways to perform useful electrical and chemical work, such as Cl^- secretion in epithelial cells by cystic fibrosis transmembrane regulator (CFTR) and Cl^--dependent neuronal signaling by $GABA_A$ and glycine receptors ($GARA_AR$ and GlyR).

Background – Developmental and Trauma-Induced Changes in Neuronal [Cl$^-$] Homeostasis

In mature central neurons, GABA and glycine are inhibitory neurotransmitters that mediate fast hyperpolarizing inhibition through activation of anion-permeant $GABA_A$ and glycine receptor/channel complexes, respectively. In immature neurons, however, $GABA_A$/glycine receptor-mediated responses are typically depolarizing, leading to transient increases in intracellular $[Ca^{2+}]$ and often excitation. Such depolarizing $GABA_A$/glycine receptor-mediated responses in immature neurons may provide a critical trophic signal during neuronal development, possibly controlling neuronal proliferation, migration, and targeting. The depolarizing $GABA_A$/glycine receptor-mediated responses are typically replaced by hyperpolarizing responses as neurons mature. The timing of this polarity switch depends on the degree of neuronal maturation, and hence will vary between brain regions and between animal models (e.g., precocious vs. altritial young).

The commonly observed developmental polarity shift (depolarizing to hyperpolarizing) in $GABA_A$/glycine receptor-mediated responses is due to an alteration in neuronal $[Cl^-]$ resulting from a differential expression/activity of CCCs, specifically the NKCC1 and the neuronal K-Cl cotransporter, KCC2. NKCC1 is present in immature neurons where it mediates robust neuronal Cl^- accumulation, leading to elevated $[Cl^-]_i$ and depolarizing $GABA_A$/glycine receptor-mediated responses. In contrast, as most neurons mature, they begin to express KCC2 and reduce NKCC1 expression. Under normal physiological conditions, KCC2 is a Cl^- extrusion pathway, and it plays a critical role in maintenance of low $[Cl^-]$ and hence hyperpolarizing $GABA_A$/glycine receptor-mediated responses of mature neurons.

Remarkably, depolarizing $GABA_A$/glycine receptor-mediated responses are observed not only in immature

neurons, but also in mature neurons shortly after a traumatic insult (e.g., concussion, epileptic seizures, hypoxia/ischemia). Such trauma-induced depolarizing $GABA_A$/glycine receptor-mediated responses in mature neurons are due to a positive shift in Cl^- reversal potential, indicating that there is an alteration in Cl^- transport capacity and accumulation of neuronal $[Cl^-]$. A number of recent studies have examined the expression of the CCCs following various types of trauma, including seizures. Each of these studies observed a marked reduction in expression of KCC2 protein following trauma that was invariably coupled with the appearance of depolarizing and often excitatory $GABA_A$R-mediated responses. Trauma-induced loss of KCC2 protein expression in mature neurons involves both cessation of KCC2 gene expression and degradation of KCC2 protein. A BDNF/TrkB receptor-mediated signaling mechanism has been directly linked to the downregulation of hippocampal KCC2 mRNA and protein after sustained interictal-like activity. In addition to the downregulation of KCC2 gene expression, we have begun to examine the cellular mechanisms responsible for the degradation of KCC2 protein following trauma.

Methods

In our studies, we have made use of two different trauma models, an in vivo whole animal model (i.e., focal cerebral ischemia) and an in vitro cultured model (i.e., glutamate exposure of cultured cerebellar granule cells). Focal ischemia was induced in rats using the middle cerebral artery occlusion (MCAO) technique. Male Sprague-Dawley rats (250–300 g) were anesthetized with ketamine (20 mg per 100 g intraperitoneally) and xylazine (0.1 mg per 100 g intraperitoneally). The left common carotid artery was dissected out. The superior thyroid artery and the occipetal artery were coagulated. The internal carotid artery was dissected out carefully from the vagus nerve, and the pterygopaletine artery was ligated. After ligating the external carotid artery and clamping the common and internal carotid artery, an incision was made in the external carotid artery to insert a suture (3.0 Dermalon-20 mm) with a blunt end. The suture was advanced until the blunt end stopped, which indicated the starting point of the middle cerebral artery (MCA). The clamps were removed and MCA remained occluded for 1 h. The suture was withdrawn from the MCA, and the brain was immediately perfused with 4% paraformaldehyde (pH 7.4) in PBS via the asceding aorta. The brain was dissected, post-fixed for 2 h, and coronal sections (100 μm) were cut for immunohistochemistry.

Cerebellar granule cells (CGC) were obtained in primary culture from 7-day-old rats (Sprague-Dawley) and plated at a density of $\sim 5 \times 10^6$ cells cm^{-2} on dishes coated with poly-D-lysine. CGCs were grown in modified Eagles' minimum essential medium containing 10% fetal bovine serum, 25 mM KCl, 30 mM glucose, 7 μM para-aminobenzoic acid, and 100 mU l^{-1} insulin. Glial cell proliferation was inhibited by the addition of 20 μM cytosine arabinofuranoside 24 h after plating. For in vitro trauma experiments, conditioned growth media was removed and saved, and the CGCs were washed twice in Mg^{2+}-free Locke's solution (154 mM NaCl, 5.6 mM KCl, 3.6 mM $NaHCO_3$, 2.3 mM $CaCl_2$, 5.6 mM glucose, 5 mM HEPES). CGCs were then brought up in Mg^{2+}-free Locke's solution containing glutamate at 30 μM or 100 μM. After 30 min incubation in a humidified incubator (5% CO_2; 37°C), glutamate-containing solution was removed, and CGCs were washed three times in Locke's solution. After this initial washing, CGCs were returned to their conditioned media in a humidified incubator (5%CO_2; 37 °C). CGCs were sampled at various time points following glutamate exposure (1–24 h) by lysing cells in sample buffer.

We used standard immunological techniques to detect changes in NKCC1 and KCC2 protein expression at specific times points following MCAO or glutamate exposure. Western blotting and immunohistochemical protocols have been previously published from our laboratory. For Western blots, whole cell lysates were separated on 7.5% SDS-PAGE tricine gels, electroblotted to PVDF membranes, and NKCC1 (~150-kDa) and KCC2 (~140-kDa) proteins were quantified using chemiluminescence and phosphorimaging. The antibodies we employed included rabbit anti-KCC2 antibodies and a mouse monoclonal anti-NKCC antibody.

Results

Focal ischemia in rat brains was induced by a one hour occlusion of the middle cerebral artery (MCAO). In this preparation, only those arteries supplying blood flow to the right hemisphere were occluded. The left hemisphere remained unaffected, thus providing an internal control for the focal ischemic insult. To determine those brain regions impacted by the focal ischemic insult, brain sections (2 mm thick) were stained with 2% 2,3,5,-triphenyltetrazolium chloride monohydrate (TTC). Those areas exhibiting injury following one hour MCAO remained unstained by TTC and included the right frontal, parietal, piriform, and perirhinal cortices and striatum (**Figure 1(a)**). Significantly, KCC2 immunoreactivity was markedly reduced in those areas where infarction occurred (**Figure 1(b)**). In contrast, we observed little change in NKCC1 immunoreactivity in control and ischemic regions (data not shown). In sham-operated animals, no significant change was observed for KCC2 immunoreactivity (**Figure 1(c)**). These data indicated that there is a selective and rapid reduction in KCC2 protein following in vivo ischemic injury.

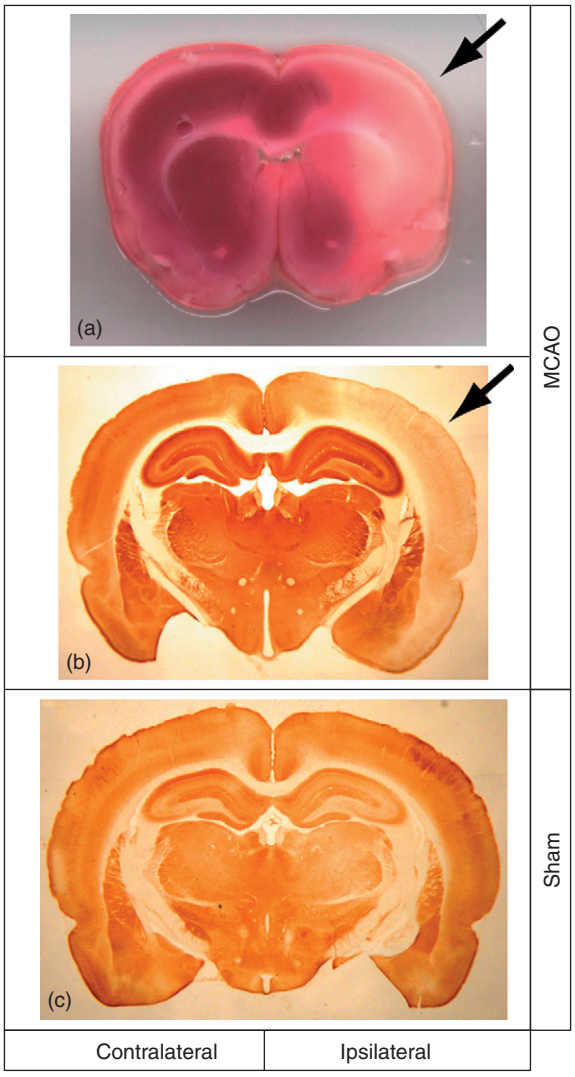

Figure 1 Infarct volume (a) after 1 h MCAO and KCC2 immunohistochemical staining after 1 h MCAO (b) or sham operation (c). Arrows in a and b point to ipsilateral side (right hemisphere) of cerebral cortex where there was significant cerebral injury (a) and loss of KCC2 immunoreactivity (b) after 1 h MCAO. Infarct volume was identified with 2,3,5-triphehyltetrazolium chloride (TTC) on 2 mm thick coronal sections and KCC2 immunoreactivity was visualized with diaminobenzedine on coronal sections (100 μm). Data are representative of 4 (MCAO), 3 (sham), or 2 (TTC) experiments.

To investigate the cellular mechanisms responsible for this rapid reduction in KCC2 protein expression following injury, we established an in vitro trauma model, using cultured cerebellar granule cells (CGCs) exposed to glutamate. We have previously shown that these neurons robustly express KCC2 in the adult rat brain. Furthermore, GCGs are easily obtained in large numbers at high purity (>90%) in primary culture. GCGs express increasing levels of both NKCC1 and KCC2 protein when grown in primary culture. NKCC1 immunoreactivity reached 70% of its maximum by the end of the first week in culture, i.e., 7 days in vitro (DIV). In contrast, KCC2 immunoreactivity appeared much more slowly in culture – not starting until the end of the first week of culturing and reaching a peak at 12 DIV. In order to ensure maximum expression of the cation chloride cotransporters, we used GCGs between 14 and 18 DIV in subsequent glutamate exposure experiments. Cultured GCGs were exposed to glutamate (30 μM or 100 μM) for 30 min and then subsequently washed free of glutamate and incubated in glutamate-free media. As shown in Figure 2, GCGs exhibited a rapid reduction in KCC2 protein expression when exposed to glutamate. Thirty minutes after exposure to each concentration of glutamate, there was a significant loss of KCC2 immunoreactivity; only ~50% of the control KCC2 protein level remained after 100 μM glutamate exposure. We interpret this loss of KCC2 immunoreactivity to be the result of protein degradation. Three hours after 100 μM glutamate exposure, KCC2 protein expression reached 40% of control levels, and this level was maintained for up to 24 h. As with the results for focal ischemic injury, the loss of KCC2 protein following in vitro trauma was selective; we never observed a significant change in NKCC1 protein levels in GCGs at any of the time points (up to 24 h) following cell exposure to 100 μM glutamate. Furthermore, cell viability experiments (trypan blue exclusion) demonstrated that greater than 80% of cells survived 30min exposure to 100 μM glutamate (data not shown). These data indicated that glutamate exposure of cultured CGCs represents a useful in vitro trauma model in which to study the cellular mechanisms responsible for trauma-induced KCC2 protein degradation.

Previous studies have shown that increased levels of intracellular [Ca^{2+}] play an important role in glutamate excitotoxicity. To assess the potential role of extracellular Ca^{2+} influx through *N*-methyl-D-aspartate receptors, we monitored KCC2 levels 3 h after 100 μM glutamate exposure in the presence of either the NMDA receptor antagonist, MK-801 or the Ca^{2+} chelator, EGTA. As shown in Figure 3(a), KCC2 degradation was completely abolished by these two agents, indicating that Ca^{2+} influx via NMDA receptors is likely involved in trauma-induced KCC2 degradation. Further support for the role of extracellular Ca^{2+} influx in trauma-induced KCC2 degradation was obtained from experiments using A23187, a divalent cationophore. Application of this cationophore was able to mimic the glutamate-induced degradation of KCC2 protein (Figure 3(a)). Removal of extracellular Ca^{2+} with EGTA as well as incubation in Ca^{2+} free medium completely prevented the degradation of KCC2 induced by A23187 treatment (Figure 3(a)), confirming that elevated intracellular [Ca^{2+}] is likely a key component in triggering a series of events leading to the loss of KCC2 protein in CGCs exposed to glutamate.

To examine in more detail the mechanisms responsible for trauma-induced KCC2 protein loss, we used inhibitors

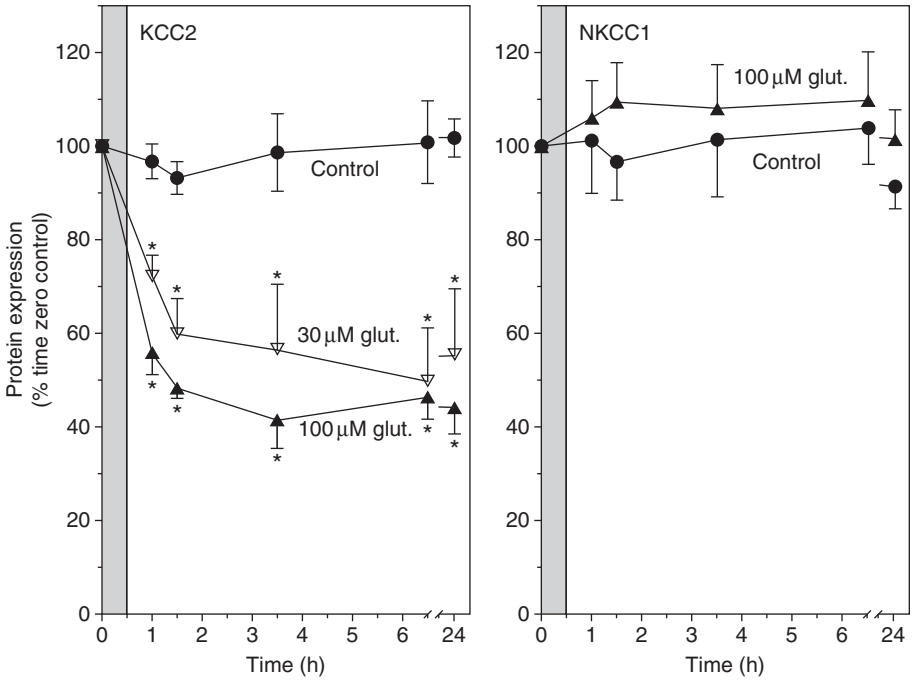

Figure 2 Protein expression of KCC2 and NKCC1 in CGCs after glutamate exposure. GCGs were exposed to glutamate (30 μM and 100 μM) for 30 min after which glutamate was removed and CGCs sampled at various time points (30 min–24 h after glutamate exposure). KCC2 and NKCC1 protein expression in whole cell lysates were quantified by Western blotting and phosphorimaging. Data are mean ± SEM of 4 experiments. *Significance from control value ($p < 0.05$; *t*-test).

of the various cellular pathways of protein degradation. These degradation pathways include lysosomes and proteosomes as well as cytosolic proteases. Neither methylamine nor NH_4Cl, agents, which increase both cytosolic and lysosomal pH, were effective in preventing trauma-induced KCC2 degradation (**Figure 3(b)**), indicating that the cellular mechanism did not likely involve an acidic hydrolase. In contrast, leupeptin prevented the degradation of KCC2 after glutamate exposure (**Figure 3(b)**), suggesting that a cysteine protease(s) was involved. The serine protease inhibitors, PMSF and aprotinin, were unable to rescue KCC2 from trauma-induced degradation. Furthermore, lactacystin was ineffective at preventing KCC2 degradation after glutamate exposure, excluding the possible involvement of the proteosome in the degradation process (**Figure 3(b)**).

Based on the above data, we reasoned that the protease(s) responsible for KCC2 degradation following glutamate exposure was likely a calcium-dependent cysteine protease with optimal activity at neutral pH. One potential candidate that fits these characteristics is the protease, calpain. Significantly, both calpain inhibitor I and calpeptin, which are relatively specific inhibitors of calpain, were able to prevent KCC2 degradation caused by both glutamate exposure (**Figure 3(b)**) and A23187 treatment (data not shown). These results strongly support the involvement of calpain in the process of KCC2 degradation in these conditions.

We examined the possibility of calpain activation in CGCs following 100 μM glutamate exposure by monitoring α-spectrin breakdown products. Non-erythroid α-spectrin (280-kD; α-fodrin) is a well established cellular substrate of caplain. Calpain cleaves two sites of α-spectrin in a sequential manner. The first site is cleaved rapidly once calpain is activated, producing a 150-kD breakdown product, whereas prolonged activation of calpain cleaves the 150-kD fragment to a 145-kD fragment. The appearance of a 150- and 145-kDa doublet of α-spectrin is an excellent indicator of calpain activation. Indeed, we observed a significant increase in the levels of the 150- and 145-kDa doublet of α-spectrin in CGCs exposed to 100 μM glutamate (data not shown). These data confirmed that calpain is activated in our in vitro trauma model and provide further support for the hypothesis that calpain was responsible for KCC2 degradation following glutamate exposure of CGCs. In order to test directly the ability of calpain to proteolyze KCC2, we performed an in vitro cell-free experiment where purified μ-calpain and m-calpain were added to rat cerebellar membranes in the presence of calcium. These two calpain isoforms are classified by their different activation profiles, with μ-calpain being activated in vitro at μM concentrations and m-calpain by mM concentrations. As shown in **Figure 4**, both μ-calpain and m-calpain degraded KCC2 with appropriate activation profiles, demonstrating that KCC2 is indeed an in vitro substrate for calpain.

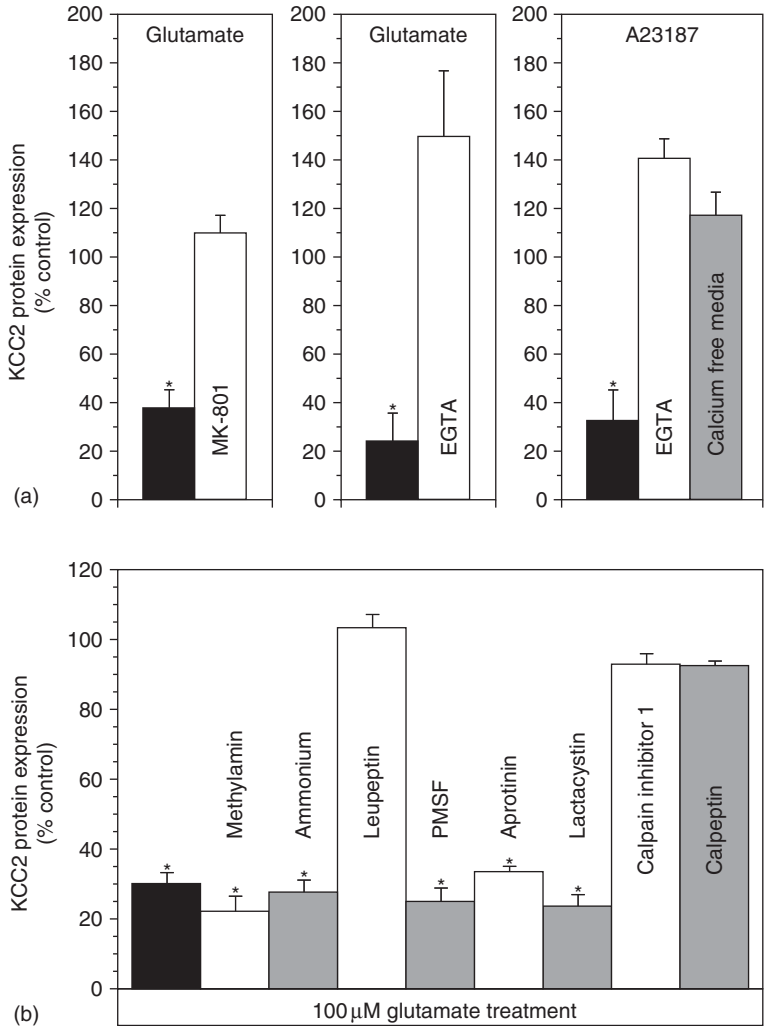

Figure 3 Calcium (a) and protease (b) dependence of KCC2 degradation in CGCs. (a) KCC2 protein expression in whole cell lysates was quantified from Western blots following 2h treatment with 10 μM A23187 or 2–3 h following 30 min exposure to100 μM glutamate. (b) KCC2 protein expression in whole cell lysates was quantified from Western blots 2–3 h after 100 μM glutamate exposure with or without protease inhibitor treatment. Reagents in b were preincubated 30 min prior to glutamate exposure and present in medium throughout incubation time. The concentrations of reagents used: 1 mM methylamine, 10 mM NH_4Cl, 100 μg per ml leupeptin, 1 mM PMSF, 1 μg perμl aprotinin, 10 μM lactacystin, 75 μM calpain inhibitor 1, and 40 μM calpeptin. Data are mean ± SEM of 3–4 experiments. *Significance from time zero control value ($p < 0.05$; *t*-test).

Future Goals

KCC2 clearly plays an essential role in mature neurons through its operation as a major regulator of intracellular Cl^-. Under normal physiological conditions, KCC2 uses the favorable K^+ chemical gradient to extrude Cl^- from the neuron, and thereby helps maintain low intracellular $[Cl^-]$ required for fast hyperpolarizing inhibition mediated by $GABA_A$/glycine receptors. It is important to recognize certain characteristics of this unique transporter, including its robust constitutive activity, its reversible transport capability, and the cell volume changes that will accompany its net ion movement. These are important considerations in epilepsy research, since high neuronal activity as occurs with seizures can result in elevated extracellular $[K^+]$, leading to KCC2-mediated net Cl^- influx (due to reversal of the thermodynamic driving force for KCC2) along with osmotically obliged water (i.e., cell swelling) – both of which have the potential to aggravate seizures.

An important challenge for future research is to understand the factors regulating KCC2 activity. It is now apparent that the operation of KCC2 is controlled through complex regulatory pathways at the level of both the KCC2 protein (i.e., post-translational) and gene (i.e., transcriptional). Recent work indicates that KCC2 activity is controlled through changes in phosphorylation state of the KCC2 protein. Such changes in KCC2 phosphorylation have the potential to modulate the unitary translocation rate of KCC2 and/or the surface KCC2 protein expression (i.e., membrane trafficking). With regards to modulation of gene expression, brain-derived neurotrophic factor (BDNF) appears to differentially

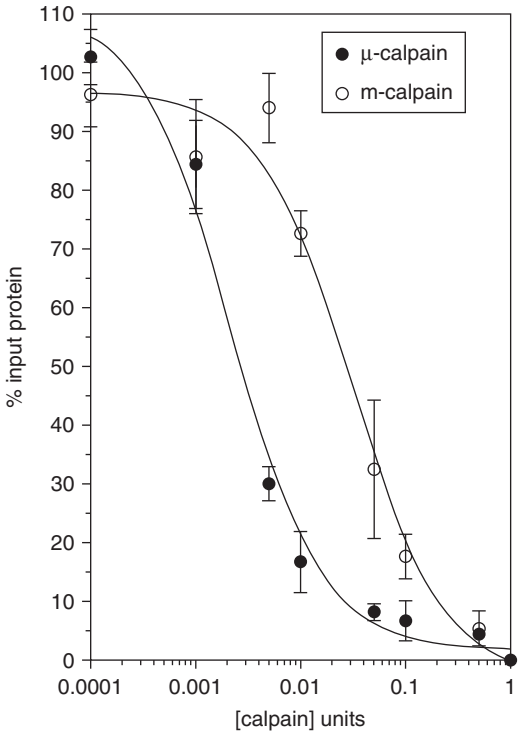

Figure 4 In vitro μ- and m-calpain proteolysis of KCC2 in crude membranes prepared from rat cerebellum. Immunoreactivity of 140-kDa KCC2 was quantified from Western blots and phosphorimaging. Data are mean ± SEM from three experiments.

regulate KCC2 gene transcription, depending upon whether it is acting on developing neurons or mature neurons subjected to traumatic insults. In developing neurons, BDNF acts a trophic factor, leading to upregulation of KCC2 gene expression. In contrast, in mature neurons, BDNF controls the trauma-induced downregulation of KCC2 gene expression. How BDNF can provide such diverse signals for KCC2 gene expression appears to lie in the multiple downstream signaling cascades controlled by the BDNF/TrkB receptor. An essential part in the down-regulation of KCC2 activity following trauma in mature neurons is protein degradation. We have shown that KCC2 is rapidly degraded after trauma via the Ca^{2+}-depended neutral protease, calpain. Thus, once KCC2 gene expression ceases after trauma, KCC2 protein loss can be rapid.

In additon to determining the cellular mechanisms responsible for reduced KCC2 expression/activity in injured neurons, it is equally important to understand the reasons for such a dramatic alteration in neuronal Cl^- homeostasis. The appearance of depolarizing and often excitatory $GABA_A$-receptor mediated responses in mature neurons (after trauma) might at first appear to be detrimental and contribute to the general pathology of the traumatic event. However, one must consider the strong possibility this change is an adaptive response that provides neurons greater flexibility in recovering from the insult by providing a necessary signal for neuronal sprouting and retargeting. After all, depolarizing $GABA_A$-receptor-mediated responses are present and necessary in immature neurons for proper growth and synapse formation during development. Furthermore, the re-emergence of molecular and cellular developmental events following trauma are well documented.

Control of Seizure Activity with Electrical Stimulation

D M Durand, Case Western Reserve University, Cleveland, OH, USA

Introduction

Epilepsy is a disorder of the nervous system that has severe consequences for patients and generates a significant social burden. About 3 million people have been diagnosed with epilepsy in the United States and the cost to the society is about $12.5 billion per year. More must be done to enhance the therapeutic treatment of these patients. Although antiepileptic drugs are effective at controlling seizures in most patients, a significant portion of the clinical population is not adequately managed. In these patients, neuroablative surgery can treat epilepsies refractory to conventional pharmacotherapy. However, epileptic foci resection does not guarantee seizure reduction and is not appropriate for generalized epilepsies. Therefore, novel therapeutic approaches, such as electrical stimulation, have been developed for the treatment of epilepsy.

Electrical stimulation has traditionally been used in the nervous system to excite axons and neurons for the purpose of studying basic mechanisms or to replace a function lost following injury. Electrical fields and currents applied to the nervous system generally cause excitation and generate synchronized activity. A more difficult problem is to generate inhibition and/or desynchronization using electrical techniques. Over the past two decades, researchers and clinicians have developed novel methods to treat epilepsy using electrical fields. Electrical stimulation protocols have been designed to directly suppress neuronal firing or to interfere with the synchronization of a population of neurons. Such techniques are extremely valuable in patients suffering from conditions where the neurons and axons fire abnormally, such as in epilepsy and spasticity.

Although several studies have shown that electrical stimulation of the brain can reduce clinical symptoms in patients with epilepsy, the mechanisms of action are still unknown. Despite the lack of clearly identified mechanisms, clinical implementation of electrical stimulation therapies is possible. Recent technological development has led to the formation of several new companies that are investigating the possibility of open-loop and/or closed-loop feedback to decrease the seizure frequency in patients. Electrodes are placed in the epileptic focus of the patient, and stimulation is applied when seizures are detected. Although some reduction of seizure occurrence rate has been achieved with this new technology, therapeutic efficacy of the stimulation paradigm has not yet been established.

The purpose of this article is to review the various methods by which electrical stimulation can be used to suppress abnormal neuronal activity. The focus of the article is on the frequency-dependant suppression of neural activity for seizure control. Some methods use DC subthreshold currents to inhibit action potential initiation, whereas others suppress neural activity with suprathreshold currents at low (1–5 Hz) or high (100–300 Hz) frequencies. These methods may engage different

mechanisms; however, in all cases, the imposed electric fields interact with neural tissue and can modify the excitability of the neural tissue or the synchronized behavior of the network.

Background

Fundamentals of Electrical Stimulation

Electric fields generated by electrodes in volume conductors

Neurons in the CNS are surrounded by an extracellular medium with a relatively low resistivity (80–300 Ω cm). Modeling the current flow around the electrodes is crucial to understanding the effects of electrical fields on excitable tissue. The current density, voltage, and electrical field distributions can be obtained from the quasistatic formulation of the Maxwell equations (since the stimulus frequencies used are usually under 10 kHz). From these equations, it is possible to derive the expression for the voltage generated by several monopolar electrodes in a homogeneous volume conductor with conductivity σ. Assuming n electrodes generating a current I_i located at a distance r_i from the recording point, the voltage is given by

$$\phi = \frac{1}{4\pi\sigma}\sum_{n}\frac{I_i}{r_i} \qquad [1]$$

The voltage difference across a distance Δx generated by large field electrodes producing a uniform field is given by $\Delta V = I \times R \times \Delta x / D$ where I is the current injected, R the resistance between the electrodes, and D is the distance between the electrodes. Voltages generated in nonhomogeneous media can also be calculated using numerical approximations such as boundary element or finite element methods.

Electric fields and excitable tissue

When neurons are placed inside a volume conductor, the current lines generated by external sources will pass through their cell membranes, thereby generating depolarization when current flows outward and hyperpolarization when current flows inward across the membrane. For both uniform and localized fields, positive (anode near soma) stimulation will induce hyperpolarization of the soma. The substhreshold transmembrane voltage generated by the external currents can be calculated using the passive cable equation [2]. (Nonlinear ionic channel conductances can be added in parallel with the membrane resistance and capacitance.) A compartment of length Δx can be modeled at rest by a capacitance C_m in parallel with a series combination of a battery (E_r) representing the resting potential and a resistance R_m simulating the combined resistance at rest of all the membrane channels. Applying Kirchoff's law at each compartment, one obtains the following inhomogeneous cable equation:

$$\lambda^2\frac{\Delta^2 V_m}{\Delta x^2} - \tau\frac{dV_m}{dt} - V_m = -\lambda^2\frac{\Delta^2 Ve}{\Delta x^2} \qquad [2]$$

The space constant of the membrane depends only on the geometric and electric properties of the membrane.

$$\lambda = \frac{1}{2}\sqrt{\frac{R_m^s d}{R_a^s}} \qquad [3]$$

where R_m^s is the specific membrane resistance, R_m^a the axoplasmic specific resistance, and d the diameter of the axon. τ_m is the time constant of the membrane and is given by

$$\tau_m = R_m C_m \qquad [4]$$

The term on the right side of eqn. [2] is called the driving function and is the product of the square of the space constant with the second spatial derivative of the extracellular voltage. Equation [2] predicts that the transmembrane voltage induced in an axon by an external field is proportional to the second-order spatial derivative of the extracellular voltage. Shorter structures such as dendrites are sensitive to the first spatial derivative of the extracellular electric field.

Methods and Recent Results

Direct Current Membrane Polarization

Externally applied currents or fields have been shown to influence excitability in many neuronal systems, such as turtle cerebellum and mammalian Purkinje cells, hippocampal dentate granule cells, and pyramidal and cortical neurons. These studies used uniform fields applied with large field electrodes placed on the surface of the cortex for in vivo experiments, or across the tissue for in vitro studies. These studies have shown that DC electrical fields (with amplitudes similar to those generated endogenously) can produce either excitation or inhibition of neuronal activity, depending on the location, the polarity, and the orientation of the applied field with respect to the dendritic tree. For example, a cathode located near the basal dendrites of hippocampal CA1 neurons produces depolarization of the dendrites and cell body, thereby generating excitation. However, an anode in the same location produces hyperpolarization in that region and can inhibit electrical activity. In addition, the cable equation clearly shows that the transmembrane voltage depends on the extracellular voltages generated along the membrane and is sensitive *only* to longitudinal fields. Therefore, as confirmed by experiments, the orientation of cell bodies with respect to the electric field affects the longitudinal field amplitude, and thus the efficacy of the applied field. Moreover, a cell structure located perpendicular to the induced field lines would not be affected by stimulation.

In vitro studies of direct current effects

The effect of exogenous uniform DC electric fields on epileptiform activity has been tested in several models epilepsy, including the high potassium and low calcium in vitro models. These studies have shown that anodic electric fields (applied with large electrodes) as low as $5\,\text{mV}\,\text{mm}^{-1}$ can completely suppress interictal bursting. Reversal of the field polarity (cathodic stimulation) enhanced the activity as indicated by the number of bursts per minute. The mechanism for activity suppression and enhancement involves membrane polarization, as described earlier, and does not require synaptic transmission. Similar results were obtained in other in vitro models, such as low calcium and picrotoxin (see Figure 1).

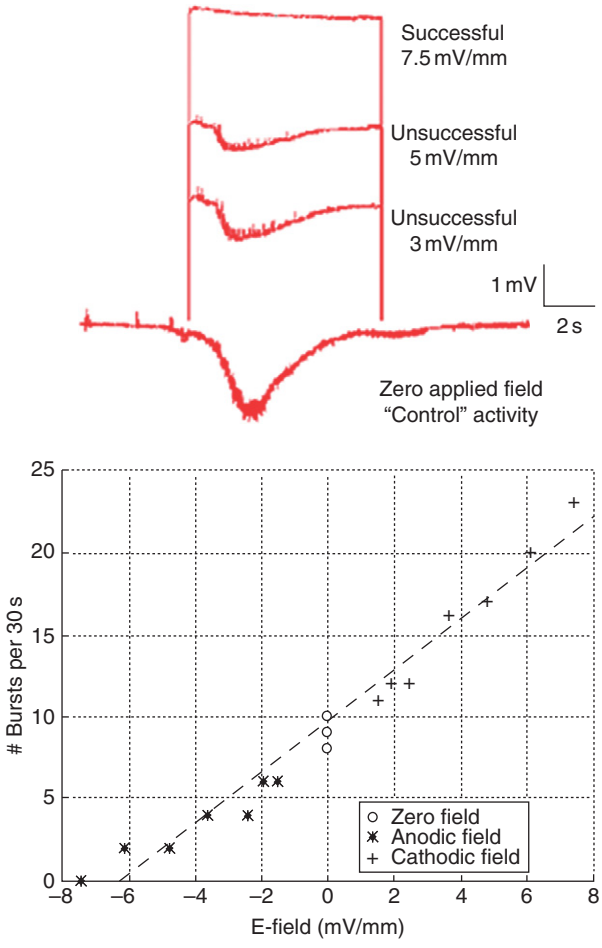

Figure 1 DC current applied to the CA2 region of the hippocampus using large field electrode. The electric is uniform parallel to the dendritic axis of the dendrites. Cathodic current can suppress spontaneous epileptiform activity induced by low-calcium solutions while anodic fields can enhance these events. Modified from Ghai *et al*. (2000).

Effect of low-level DC current in animal models in vivo

Membrane polarization with applied fields at very low frequency and amplitude has been applied in vivo to control seizure activity produced by the tetanus toxin in rats. Small current amplitudes were observed to modulate the seizure activity with an electrode placed centrally in the hippocampus. Low-level DC currents have also been tested in vivo on the kindling model of epilepsy. Currents as low as 5–15 μA applied $15\,\text{min}\,\text{day}^{-1}$ for 14 days to amygdala-kindled animals significantly increased seizure threshold. DC currents are known to generate tissue damage through nonreversible chemical reactions that take place at the electrode surface.

Noninvasive direct current stimulation

Weak direct currents applied noninvasively across the head, using large electrode and employing low voltages, have also been shown to modulate the excitability of cortical neurons in both humans and animals. Currents as low as 100 μA applied for long periods of time (30–60 min) can elevate the threshold of seizures in freely moving rats without any neural damage. Similarly, in patients with epilepsy, 1 mA cathodic current applied for 20 min was shown to decrease seizure frequency. Although the mechanisms for these effects are not known, they are thought to be related to membrane hyperpolarization, as described earlier. Moreover, the target neurons for these effects are unknown. In human patients, the current is applied to the brain through saline-soaked sponges to avoid potential damage caused by DC stimulation. Bipolar stimulation can also avoid the electrochemical damage generated at the interface between the neural tissue and the electrodes, and has been effective to suppress seizures at both low and high frequencies.

Low-Frequency Electrical Stimulation for Seizure Suppression

Effect of LFS on neural excitability in animal models

Low-frequency electrical stimulation has been used successfully to suppress seizure activity in both in vivo and in vitro models of epilepsy. The stimulation is applied using narrow a pulse width and at supra-threshold amplitudes. In vitro studies in the hippocampus have shown that stimulation of the Schaffer collaterals and mossy fibers at frequencies around 1.0 Hz suppress seizure activity and after-discharge duration in rats. Although there are many studies that demonstrate the ability of LFS to suppress seizure activity in various animal models, the mechanisms are still unknown. Effects of stimulation such as increased inhibition and long-term synaptic depression (LTD) have been proposed to explain the decrease excitability.

Effect of LFS on neural excitability human patients

In patients with epilepsy, low-frequency electrical stimulation (at 0.5 Hz, biphasic square waves, 2–4 mA) delivered to different ictal onset zones each day in 30 min intervals, was able to reduce seizure frequency. In addition, stimulation of the caudate nucleus at 4–8 Hz, in 57 patients suffering from intractable epilepsy, also reduced the seizure frequency. The mechanisms for the effects of the caudate stimulation were attributed to the possible activation of inhibitory responses in the network. Although, activation of the ictal zones in patients with intractable epilepsy can decrease seizure frequency, one of the possible side effects of the stimulation is induction of seizures even at these low frequencies.

Noninvasive LFS with transcranial stimulation

LFS can be applied noninvasively through the skull using transcranial magnetic stimulation. Magnetic coils placed on the head of patients are energized with large-amplitude but brief current pulses. The current pulses induce brief electric fields in the neural tissue according to Faraday's law of induction. When applied at frequencies (0.5–5 Hz) similar to those known to generate long-term depression of synaptic transmission (LTD), stimulation can lower the excitability of the cortex. Trains of LFS are applied to coils placed over the vertex for several consecutives days. However, when applied to patients with intractable epilepsy, the results and efficacy of this method to suppress seizures remains controversial. Some studies reported a significant decrease in the frequency of seizures, and but others reported only mild and nonlasting effects. Induction of seizure activity is evident at frequencies greater that 10 Hz. However, at even higher stimulus frequencies, suppression of activity is again observed.

HFS for Seizure Suppression

HFS of the CNS

Deep brain stimulation (DBS) uses HFS applied at frequencies between 100 and 300 Hz, and is an effective treatment for movement disorders such as Parkinson's disease. HFS produces the same effect on clinical symptoms as resection of neural tissue. Therefore, one possible explanation is that electrical stimulation produces a depolarization blockade of neurons within the target neural structures. Yet, recordings obtained downstream from the stimulation electrodes show excitation at or near the stimulus frequency. Therefore, another potential mechanism is a disruption of the neural firing pattern responsible for the disorder's symptoms.

Current DBS paradigms have not been consistently effective for relieving symptoms in patients with epilepsy. Pilot studies show that HFS provides limited therapeutic control of intractable epileptic seizures. Yet, it remains unclear how HFS affects seizure propagation within hippocampal and limbic neural networks. The way in which HFS affects cell bodies, afferent and efferent axons, and axons of passage is likely to be different from mechanisms engaged by LFS; elucidation of those mechanisms remains an important goal. Current research indicates that the nucleus stimulated, its location within the brain, and its neuronal composition are important factors in determining these effects. Our own studies using an in vitro hippocampal preparation show that both local and global application of HFS suppresses cellular synaptic and nonsynaptic epileptiform activities. Although computer simulation studies and in vivo studies confirm that HFS induces suppression of cell bodies, they provide contradictory data on whether HFS excites or inhibits the axons of projection neurons and afferent inputs. Recent experiments have shown that HFS suppresses not only cellular activity but also axonal conduction in vitro. The subthalamic nucleus (STN), basal ganglia, and hippocampus all have important axonal projections vital to the maintenance of seizure (and tremor) loops within limbic and cognitive circuitry. Therefore, HFS modulation of axonal activity would significantly impact the behavior of downstream nuclei and seizure propagation.

The mechanisms of HFS are also unknown. Some evidence shows that voltage-gated ion channels in neurons are impaired by HFS. A more recent report suggests that HFS applied to the subcortical white matter generates a depression of excitatory synaptic currents, while HFS applied in the neocortex produced both synaptic depression and reduced neuronal excitability. The literature also indicates that HFS enhances glutamate release, but does not adversely affect electrogenic pumps, so that glutamate and potassium clearance are preserved during HFS. Our own results show that extracellular potassium concentration is clearly increased during HFS. Measurements showed a correlation between extracellular potassium ($[K+]_o$) accumulation and suppression of synaptic and nonsynaptic epileptiform activity, resulting in depolarization blockade. Moreover, the suppression effects of the HFS can be generated in the presence of synaptic blockers using either sinusoidal or square pulse stimulus waveform trains. These results suggest that the mechanisms involve nonsynaptic phenomena such as depolarization block (see **Figure 2**) or desynchronization. This block may be limited to some localized areas since excitation of other nuclei around the electrodes has been observed and could contribute to the therapeutic effects by disrupting the abnormal neural activity.

DBS electrodes for the control of epilepsy have been located in structures similar to those used for Parkinson's disease. The STN was first used as a target for stimulation, and the results of these initial studies showed that the frequency of seizures was significantly decreased. In the thalamus, stimulation of the centromedian nucleus has

Figure 2 Transmembrane recording obtained by subtracting the extracellular voltage from the intracellular voltage from a CA1 neurons during sinusoidal stimulation at 50 Hz. The signal has been filtered with a 10 Hz low pass filter to eliminate the stimulation artifact. Note that cell fires at the onset of the stimulation and remains depolarized during the stimulus without firing. Note also that the filter significantly reduced the amplitude of the actions potentials normally around 80 mV. Modified from Bikson *et al*. (2001).

been shown to be effective in tonic–clonic seizures but not complex–partial epilepsy. More recently, other structures such as the anterior thalamus, substantial nigra pars reticulata, hippocampus, and cortex have also been targeted. Although DBS for epilepsy appears to be safe, and can decrease the number of seizures in patients with intractable epilepsy, the optimum location and stimulation parameters for such stimulation still need to be determined.

HFS of the peripheral nervous system (vagus nerve stimulation)

HFS of the peripheral nervous system can also affect seizure frequency. In particular, high-frequency vagal nerve stimulation (VNS) can inhibit seizures in canines and interfere with CNS excitability. Subsequent studies showed this paradigm to be effective in other animals, including rats and monkeys. Animal studies have shown that while high-frequency (>70 Hz) VNS can generate EEG desynchronization, low-frequency (20–50 Hz) stimulation induced EEG synchronization.

There are now close to 10 000 patients per year implanted with high-frequency VNS systems for the treatment of epilepsy. The VN stimulator received FDA approval in July 1997. Because of the pattern of vagus nerve innervation of the heart, the vagus nerve can only be stimulated unilaterally (i.e., the left side only). Typically, the treatment routine consists of adjusting the current amplitude to tolerance (0.25–4 mA in 0.25 mA steps), using a 30 Hz frequency, 0.5 ms pulse width, for 30 s ON time and 5 min OFF time. The stimulation can be manually triggered by placing an external magnet over the patient's chest. In multicenter, randomized, double-blind studies, patients receiving high-intensity VNS (30 Hz, 0.25–4 mA, 0.5 ms pulse width, 30 s ON time and 5 min OFF time) experienced a ~30% reduction in seizure frequency. In contrast, patients receiving low-intensity stimulation (1 Hz, 0.13 ms pulse width, 30 s ON time and 180 min OFF time) experienced a ~10% reduction. Stimulation of the trigeminal nerve can also produce significant reductions in the number of seizures when the frequency of stimulation is greater than 50 Hz and with current amplitudes between 3 and 11 mA.

Although VNS is currently the only commercially available electrical stimulation modality for seizure control in patients with epilepsy, the mechanisms underlying the VNS effect have not been elucidated. However, VNS is known to alter the vagal afferent activity and the neuronal firing patterns in the reticular activation and noradrenergic systems, leading to an increase in the seizure threshold of cortical tissue. The effectiveness of this method of stimulation is limited.

Future Work

Several electrical stimulation protocols can either suppress or interfere with abnormal neuronal activity. This suppression has been demonstrated in several animal models of epilepsy and in humans. Unlike surgical resection, the effect of electrical stimulation is generally reversible. Unlike drugs, electrical stimulation can be applied to specific regions of the brain and the 'dosage' of stimulation can be varied easily and instantaneously. By simply changing stimulation parameters, clinicians could potentially screen different protocols. However, there are serious problems to be overcome before these techniques can be implemented routinely. The mechanisms involved in all these stimulation methods are unknown, and unanticipated side effects could potentially induce, rather than suppress, seizures. However, electrical stimulation is potentially a powerful tool to control seizures. Novel approaches in neural imaging, modeling, and electrode design should allow researchers to unravel unknown mechanisms and design more effective stimulation methods to control abnormal activity in the brain.

© 2009 Elsevier Ltd. All rights reserved.

Introduction

It has been estimated that seizures are uncontrolled in as many as 30% of the patients with epilepsy. Clearly, there is a profound need for new therapies that control seizures but are also safe. Deep brain electrical stimulation (DBS) has the potential to be an effective new therapy for epilepsy. Early clinical reports suggested the efficacy of DBS, but these studies were poorly controlled or limited to individual case reports where the results were mixed and difficult to interpret. As a consequence, research in this area remained dormant for a number of years. However, the successful use of DBS for the treatment of movement disorders, and the application of vagus nerve stimulation (VNS) for epilepsy have led to a renewed research effort to develop electrical stimulation as a therapy for epilepsy.

Before electrical stimulation can become an accepted treatment for epilepsy, the fundamental questions of where and how to stimulate need to be answered. Two general approaches have been taken: (1) stimulus activation of seizure-gating networks or (2) direct stimulation of an identified seizure focus. Parameters such as stimulus frequency, intensity, duration, and waveform may all be critical as to whether a given stimulus will successfully interfere with seizure activity. While the majority of studies have tested the efficacy of high-frequency stimulation (HFS) (similar to protocols used to treat movement disorders), a number of recent reports – based on in vivo experimental seizure models and in vitro preparations – have determined that low-frequency stimulation (LFS) can also interfere with or prevent seizure activity. Once safe and effective stimulation paradigms are identified, the goal will be to combine that therapy with seizure detection technology, in an implantable device that will be capable of delivering stimulation therapy at the optimal time to prevent or disrupt a seizure. This approach will allow for therapy to be customized to the specific needs of a given patient.

Background

Clinical Studies

With all studies in this area, the results are highly dependent on where and how the stimulation was delivered, as well as on the nature of the patient population included in

However, the successful use of DBS for the treatment of movement disorders, and the application of vagus nerve stimulation (VNS) for epilepsy have led to a renewed research effort to develop electrical stimulation as a therapy for epilepsy.

Before electrical stimulation can become an accepted treatment for epilepsy, the fundamental questions of where and how to stimulate need to be answered. Two general approaches have been taken: (1) stimulus activation of seizure-gating networks or (2) direct stimulation of an identified seizure focus. Parameters such as stimulus frequency, intensity, duration, and waveform may all be critical as to whether a given stimulus will successfully interfere with seizure activity. While the majority of studies have tested the efficacy of high-frequency stimulation (HFS) (similar to protocols used to treat movement disorders), a number of recent reports – based on in vivo experimental seizure models and in vitro preparations – have determined that low-frequency stimulation (LFS) can also interfere with or prevent seizure activity. Once safe and effective stimulation paradigms are identified, the goal will be to combine that therapy with seizure detection technology, in an implantable device that will be capable of delivering stimulation therapy at the optimal time to prevent or disrupt a seizure. This approach will allow for therapy to be customized to the specific needs of a given patient.

Background

Clinical Studies

With all studies in this area, the results are highly dependent on where and how the stimulation was delivered, as well as on the nature of the patient population included in

the study. Interpretation is also complicated by the fact that most of the studies are not controlled or limited to case reports. As a consequence, the results from clinical studies are mixed and often conflicting. Acute clinical experiments that demonstrated that direct cortical stimulation caused a flattening of the EEG – accompanied by a decrease in spontaneous epileptiform discharges – were encouraging. However, the results from studies that examined cerebellar stimulation were inconsistent. Some early studies reported that cerebellar stimulation had no effect on seizure frequency in patients with intractable epilepsy, while a recent limited trial reported that cerebellar stimulation induced a decrease in the frequency of motor seizures. The first controlled clinical trial, in 1992, found that centromedian thalamic stimulation failed to decrease seizure activity. More recently, investigators reported that brief bursts of direct cortical stimulation were found to terminate afterdischarges induced during the process of cortical mapping. High-frequency stimulation of the anterior thalamus, hippocampus, and motor cortex has also been reported to significantly decrease seizure frequency in a limited number of patients. However, it is difficult to know the true significance of these results since very few double-blinded controlled studies have been performed.

To date most clinical studies have used an 'open-looped' stimulation protocol in which stimulation is delivered on a fixed schedule independent of the patient's physiological state. The efficacy of these stimulation paradigms may improve if delivered using closed-looped stimulation – i.e., stimulation that is delivered in direct response to the detection of abnormal epileptiform activity. Combining the appropriate stimulation therapy with seizure detection technology will allow for this approach.

Animal Studies – Activation of Seizure-Gating Networks

Animals studies have identified several brain areas that, when stimulated, appear to activate seizure-gating networks that raise seizure threshold or interfere with seizure propagation. These structures include the basal ganglia, cerebellum, anterior thalamus, subthalamic nucleus, mamillary bodies, locus coeruleus, substantia nigra, and most recently the hypothalamus. Although the mechanism underlying these effects is unclear, the anticonvulsant effect of stimulation of the striatum, subthalamic nucleus, and substantia nigra appears to be mediated through disinhibition of deep layers of the superior colliculus (SC). Activation of the SC has been shown to suppress seizures induced by electroconvulsive shock and spontaneous absence seizures in the GAERS rat. It has been hypothesized that suppression of seizure-induced hind limb extension is likely mediated through projections from the SC to brainstem, while suppression of cortical seizure activity may be mediated through ascending projections to the parafascicular and centromedian nuclei, which have connections with the cortex.

The anticonvulsant action of another seizure-gating network may depend on the activation of ascending noradrenergic pathways. Direct stimulation of the locus coeruleus has been shown to decrease seizure activity in a number of experimental models, whereas locus coeruleus lesions are proconvulsant, and depletion of norepinephrine can accelerate kindling. While the majority of these studies used high-frequency pulsatile stimulation, similar to the paradigms used successfully in clinical treatments for movement disorders, several recent studies have reported efficacy using low-frequency stimulation delivered to structures distant from the seizure focus.

Animal Studies – Direct Stimulation of the Seizure Focus

The effect of direct stimulation of a seizure focus has been examined primarily in the kindling seizure model. Electrical stimulation delivered directly at the kindling focus has been shown to raise afterdischarge threshold, delay kindling acquisition, decrease afterdischarge (AD) duration, and decrease the incidence of seizures in response to the kindling stimulus. However, the efficacy of different stimulation paradigms appears to be dependent on whether the therapeutic stimulation is delivered before, during, or after the seizure.

In Vitro Studies

Several laboratories have demonstrated that field stimulation and direct stimulation can decrease the incidence of epileptiform activity in several different slice preparations. Low- and high-frequency pulsatile stimulation have been shown to decrease epileptiform burst activity induced by 4-AP, bicuculline, ferric chloride, and low magnesium in neocortical, hippocampal, amygdala-perirhinal, and hippocampal-entorhinal slices. Low-frequency stimulation has also been shown to prevent the transition from interictal to ictal activity in several of these preparations.

Vagus and Trigeminal Nerve Stimulation

Currently, vagus nerve stimulation (VNS) is the only approved therapy for the treatment of epilepsy that uses electrical stimulation. Continuous stimulation of the left vagus nerve provides effective seizure control in a small population of patients. The efficacy of VNS has been estimated to be equivalent to that of a new antiepileptic drug, but not as effective as surgical resection. The mechanism by which this therapy works is unknown. It has been hypothesized that VNS eventually activates the locus

coeruleus, which has widely distributed noradrenergic projections that could raise seizure threshold and decrease the likelihood of a seizure. There are some drawbacks to this therapy. It is impossible to predict which patients will benefit from this therapy before surgery and stimulation effects are directly assessed. In addition, besides the potential complications of surgery, patients have complained of hoarseness, voice changes, and dyspnea. A second surgery may be required to remove the device if it proves to be ineffective. Given the relatively small population of patients who benefit from this therapy, it does not obviate the need for new therapies.

The success obtained with VNS has led to an examination of other peripheral nerves as targets for stimulation. The trigeminal nerve has received attention because the trigeminal nucleus receives projections from the locus coeruleus (and, as indicated earlier, it has been postulated that the anticonvulsant effect of VNS is mediated through activation of the locus coeruleus). Unlike VNS, the trigeminal nerve can be stimulated through cutaneous electrodes and is therefore a noninvasive procedure. In one experiment, trigeminal nerve stimulation decreased PTZ-induced seizure activity in the rat. In a preliminary clinical trial, two patients reported a decrease in the number of complex partial seizures after trigeminal nerve stimulation.

Selection of Stimulation Parameters – HFS versus LFS

Stimulation frequency appears to be a key parameter in the activation of seizure-gating networks. Many of the studies that report a decrease in seizure activity after stimulation of the basal ganglia and thalamic nuclei used HFS. HFS (100 Hz) of the anterior thalamus of the rat raised the threshold for PTZ-induced clonic seizures, but 8-Hz stimulation was proconvulsant. HFS of the solitary nucleus, a site distant from the kindling focus, interfered with kindling acquisition. These results suggest that HFS may be effective at activating seizure-gating networks. It has been suggested that HFS induces a functional lesion at the stimulation site due to depolarization block or preferential activation of inhibitory neurons. Inhibition of the stimulated structure leads to activation of other structures within the seizure-gating network through disinhibition. Activation of these normally inhibited structures leads to a net increase in the inhibitory output from the network. It is interesting that direct stimulation of the locus coeruleus at frequencies of 20–50 Hz effectively suppressed penicillin-induced epileptiform activity. In this case, the nucleus was likely activated and not suppressed by the stimulation.

LFS using pulsatile or sinusoidal waveforms may be more effective when delivered directly at the seizure focus. LFS is effective when delivered at the kindling focus and in in vitro slice preparations. It has been suggested that LFS may have a greater potential clinically since the effects of the stimulation last well beyond the duration of the stimulation. This hypothesis is supported by the observations that LFS induced an increase in kindled afterdischarge threshold that lasted for days, and that LFS induced a decrease in bicuculline-induced epileptiform discharges in the hippocampal slice that continued after stimulation was discontinued. LFS mimics the frequency of interictal spikes. It has been hypothesized that the interictal spike may be inhibitory, and that an increase in interictal activity may decrease the likelihood of an ictal event. LFS delivered to CA3 of the hippocampal–entorhinal slice decreased the number of ictal events induced by 4AP and zero magnesium. Recently, LFS has been reported to decrease interictal and ictal events in patients with epilepsy. The mechanism underlying the anticonvulsant effect of LFS is unknown. The term 'quenching' has been used to describe the decrease in kindled seizures after LFS – an effect that later proved to be due to long-term exposure to direct current. Low-frequency pulsatile stimulation is similar to stimulations used to induce long-term depression (LTD) or depotentiation, and investigators have speculated that an LTD-like mechanism underlies its efficacy.

Methods

Our laboratory has focused on identifying stimulation paradigms that either alter epileptogenesis or are anticonvulsant. To address these possibilities, we tested the effect of low-frequency sine wave stimulation (LFSWS) on kindling acquisition and in fully kindled animals. The kindling seizure model was selected for these experiments because it offered several advantages over other models. Briefly, kindling is characterized by the repeated spaced presentation of an initially subconvulsive stimulus that, over time, causes a permanent change in brain function that eventually results in the same initially subconvulsive stimulus consistently inducing a limbic seizure. The severity of kindled seizures can be quantified both behaviorally and electrographically. Changes in afterdischarge (AD) threshold, AD duration, behavioral seizure score, and the number of stimulations required for the animal to become fully kindled can be used to assess changes in the epileptogenic process. Once an animal has exhibited three consecutive stage 5 (Racine scale) seizures, it is considered fully kindled. Changes in seizure incidence, behavioral seizure score, seizure threshold, and AD duration can then be used to measure antiepileptic efficacy in fully kindled animals. In addition, knowing when the seizure will occur (it is a triggered event) affords the investigator a great deal of control when testing a potential therapy.

Effect of Preemptive LFSWS on Kindling Acquisition

Initial experiments examined the effect of preemptive LFSWS (1 Hz) on kindling acquisition in the amygdala of the rat. Earlier studies that examined the effect of LFSWS in kindling reported positive effects, but were difficult to interpret and therefore largely ignored. To carefully characterize the effect of LFSWS, experimental Sprague-Dawley rats received LFSWS (1 Hz, 50 μA, 30 s) immediately before each kindling stimulus (60 Hz, 1-ms pulse duration, 400 μA for 1 s). Control animals received only the kindling stimulus. A total of 20 stimulations were delivered to each group.

Effect of Preemptive LFSWS in Fully Kindled Animals

In these experiments, a LFSWS stimulus (1 Hz, 50 μA, 30 s) was delivered immediately before the kindling stimulus (60 Hz, 1-ms pulse duration, 400 μA for 1 s) in rats that had been fully kindled in the amygdala or the hippocampus. The effect of the stimulation on behavioral seizure score, seizure incidence, and AD duration was measured for each animal.

The effect of preemptive low-frequency pulsatile stimulation (biphasic square wave) was also tested in animals fully kindled in the hippocampus. A LTD-like stimulus (1 Hz, 1-ms pulse duration, 50 μA) was delivered for 15 min before the kindling stimulus.

At the conclusion of each experiment, the brains from each animal were processed for histological assessment of electrode location and damage at the stimulation site. Brains were sectioned on a vibratome and the sections Nissl-stained.

Recent Results

Effect of Preemptive LFSWS on Kindling Acquisition

Basolateral amygdala kindling usually requires 9–12 stimulations for the rat to become fully kindled. The acquisition phase is characterized by an increase in AD duration and electrographic complexity accompanied by an increase in behavioral seizure score. During kindling acquisition in control animals, the kindling stimulus rarely fails to elicit an AD. The presentation of preemptive LFSWS immediately before the kindling stimulus significantly decreased AD duration and behavior seizure score during the kindling process (Figure 1). More significantly, preemptive LFSWS profoundly decreased the incidence of AD by 30% in response to the kindling stimulus (Figure 2, $p < 0.0001$, Fisher exact test).

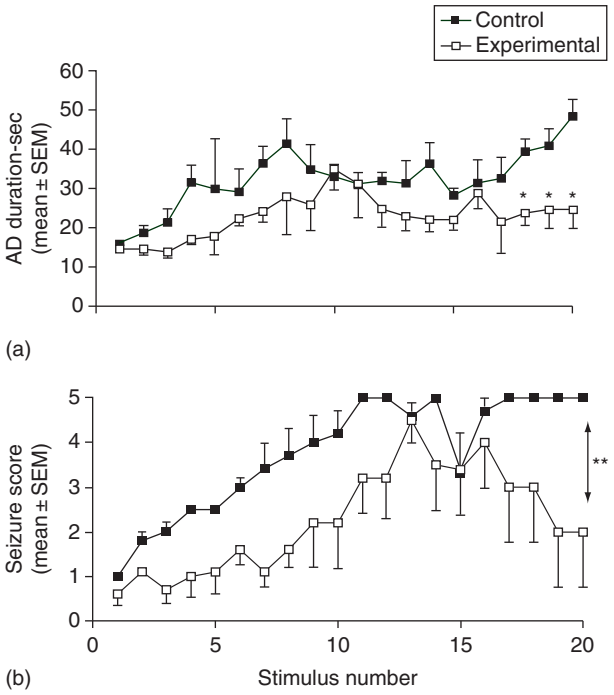

Figure 1 Effect of preemptive LFSWS on kindling acquisition. (a) LFSWS significantly decreased AD duration ($p < 0.01$) and (b) behavioral seizure score ($p < 0.001$). Reproduced from Goodman *et al.* (2005) Preemptive low-frequency stimulation decreases the incidence of amygdala-kindled seizures. *Epilepsia* 46: 1–7, with permission from Epilepsia.

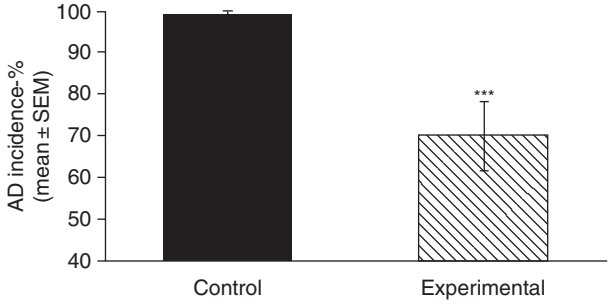

Figure 2 Preemptive LFSWS significantly decreased the incidence of AD by 30% during kindling acquisition ($p < 0.0001$). Reproduced from Goodman *et al.* (2005) Preemptive low-frequency stimulation decreases the incidence of amygdala-kindled seizures. *Epilepsia* 46: 1–7, with permission from Epilepsia.

Effect of Preemptive LFSWS and in Fully Kindled Animals

The effect of preemptive LFSWS was examined in animals fully kindled in the amygdala or hippocampus. Baseline seizure frequency was determined for both groups of animals. In the absence of LFSWS, the incidence of stage 5 seizures was 98–100% in response to the

kindling stimulus. When LFSWS was delivered immediately before the kindling stimulus, the incidence of stage 5 kindled seizures was significantly decreased by 58% in the amygdala (Figure 3, $p < 0.0001$) and by 30% in the hippocampus ($p < 0.0001$, data not shown). Interestingly, when these animals failed to have a stage 5 seizure, there was a complete failure to exhibit an AD or behavioral seizures with lower scores. No change was observed in the incidence of stage 5 seizures in rats fully kindled in the hippocampus when the same experiment was performed using preemptive low-frequency pulsatile stimulation (1 Hz, 1-ms pulse duration, 50 μA, for 15 min). A histological assessment of the stimulation site revealed no evidence of damage that could explain the decrease in seizure incidence in animals exposed to LFSWS.

It is unclear why in this study LFSWS decreased the incidence of kindled seizures while low-frequency pulsatile stimulation had no effect. Other studies have reported positive effects after low-frequency pulsatile stimulation in kindling and in slice preparations. The ineffectiveness of low-frequency pulsatile stimulation in this study may be due to the specific stimulation parameters used. It has recently been reported that LFSWS induced a significant increase in AD threshold that lasted for several days. An elevation in seizure threshold would explain the decrease in seizure incidence observed after LFSWS.

The majority of clinical and basic studies that have assessed the efficacy of electrical stimulation as a therapy for epilepsy have used pulsatile stimulation. Short duration biphasic pulses are charge balanced and less likely to cause damage. But several studies in the 1980s reported decreases in kindling with LFSWS. LFSWS is continuous, with no interpulse interval, so that current is delivered over the entire second of stimulation. The schematic in Figure 4 illustrates that the relative amount of total current per second delivered with LFSWS stimulation is significantly greater than would be delivered with low-frequency 1-ms pulsatile stimulation. This difference raises the possibility that LFSWS may be effective in patients who do not respond to pulsatile stimulation.

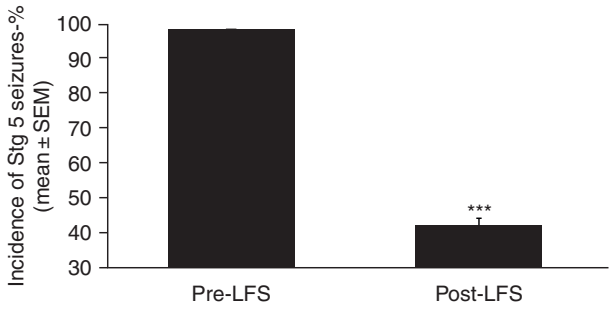

Figure 3 Preemptive LFSWS significantly decreased the incidence of stage 5 kindled seizures from 98% to 42% in rats fully kindled in the amygdala ($p < 0.0001$). Reproduced from Goodman *et al.* (2005) Preemptive low-frequency stimulation decreases the incidence of amygdala-kindled seizures. *Epilepsia* 46: 1–7, with permission from Epilepsia.

Future Goals

Experimentally, it will be important to determine if stimulation paradigms that successfully decrease kindled seizure activity are also effective in models that produce spontaneous focal seizures. The tetanus toxin model appears to be well suited for this assessment. Tetanus toxin injected into the motor cortex or hippocampus induces spontaneous random seizure activity (similar to that observed in human partial epilepsy) with no evidence of damage. It will also be important to further characterize brain regions that, when stimulated, can activate seizure-gating networks.

The ultimate goal of this research is to combine safe and effective stimulation paradigms with early seizure detection in an implantable stimulator, so that it is possible to intervene and prevent seizures from occurring – or limit their duration and severity. An intelligent implantable stimulator can be programmed to detect abnormal epileptiform activity specific to the individual patient, and then to deliver the appropriate therapeutic stimulus.

Introduction

Laboratory data and clinical trials have shown that electrical brain stimulation applied to either the central or peripheral nervous system (CNS or PNS) has the potential to reduce seizure frequency in patients with epilepsy. Current standard options for reducing seizure activity include pharmacological intervention, vagal nerve stimulation (VNS), and/or surgical resection. These treatments all have potential drawbacks – e.g., unwanted side effects, risk of infection, potential cognitive impairments, suboptimal efficacy, or drug resistance. In fact, antiepileptic drugs (AEDs) fail to achieve adequate seizure reduction in about 30% of epilepsy patients. For a variety of reasons, not all patients with drug-resistant epilepsy can be considered as candidates for resective surgery. Therefore, the development of novel electrical brain stimulation protocols for suppressing seizure frequency has important ramifications for improving treatment management in specific patients suffering from seizure disorders.

To this end, electrical stimulation of CNS brain structures – either directly involved in epileptic activity (e.g., hippocampus, neocortex), connected via white-matter tracts (e.g., corpus callosum) to epileptogenic regions, or deep-brain structures (e.g., subthalamic nucleus (STN), caudate nucleus) that modulate the activity of cortical structures – has been attempted with some success. Electrical stimulation may, in many cases, have several benefits, including 'reversibility.' In addition, electrical stimulation typically involves no brain tissue removal or destruction. The electrical parameters of the stimulator may be adjusted so as to achieve the best clinical outcome for seizure suppression, and the parameters of stimulation can be individualized for each patient's specific condition.

However, many important questions about electrical stimulation approaches for seizure control still exist. For example, what are the most effective target sites or the optimal electrical parameters? It is also discomforting – but intriguing from a scientific view – that we do not adequately understand the mechanisms responsible for the suppression of epileptic activity achieved by electrical stimulation. Several theories about the mechanisms of action have been put forward, particularly for VNS and deep-brain stimulation (DBS), but none have been thoroughly tested or substantiated. Indeed, that some electrical stimulation protocols have anticonvulsant action on nervous system function is somewhat paradoxical, since

Introduction

Laboratory data and clinical trials have shown that electrical brain stimulation applied to either the central or peripheral nervous system (CNS or PNS) has the potential to reduce seizure frequency in patients with epilepsy. Current standard options for reducing seizure activity include pharmacological intervention, vagal nerve stimulation (VNS), and/or surgical resection. These treatments all have potential drawbacks – e.g., unwanted side effects, risk of infection, potential cognitive impairments, suboptimal efficacy, or drug resistance. In fact, antiepileptic drugs (AEDs) fail to achieve adequate seizure reduction in about 30% of epilepsy patients. For a variety of reasons, not all patients with drug-resistant epilepsy can be considered as candidates for resective surgery. Therefore, the development of novel electrical brain stimulation protocols for suppressing seizure frequency has important ramifications for improving treatment management in specific patients suffering from seizure disorders.

To this end, electrical stimulation of CNS brain structures – either directly involved in epileptic activity (e.g., hippocampus, neocortex), connected via white-matter tracts (e.g., corpus callosum) to epileptogenic regions, or deep-brain structures (e.g., subthalamic nucleus (STN), caudate nucleus) that modulate the activity of cortical structures – has been attempted with some success. Electrical stimulation may, in many cases, have several benefits, including 'reversibility.' In addition, electrical stimulation typically involves no brain tissue removal or destruction. The electrical parameters of the stimulator may be adjusted so as to achieve the best clinical outcome for seizure suppression, and the parameters of stimulation can be individualized for each patient's specific condition.

However, many important questions about electrical stimulation approaches for seizure control still exist. For example, what are the most effective target sites or the optimal electrical parameters? It is also discomforting – but intriguing from a scientific view – that we do not adequately understand the mechanisms responsible for the suppression of epileptic activity achieved by electrical stimulation. Several theories about the mechanisms of action have been put forward, particularly for VNS and deep-brain stimulation (DBS), but none have been thoroughly tested or substantiated. Indeed, that some electrical stimulation protocols have anticonvulsant action on nervous system function is somewhat paradoxical, since

electrical stimulation of nervous tissue has historically been used to excite neurons. Thus, this phenomenon of seizure control remains to be fully explained.

Background

Targets and Frequencies

Electrical stimulation of the nervous system has a long history. The ancient Greeks used electric rays (suborder Torpedinoidei) for applying controlled electrical shocks to those suffering from medical conditions such as headache. In modern times, DBS in human patients with movement disorders has been markedly successful (typically using stimulation protocols with frequencies near ~130 Hz). These protocols have been effective at suppressing neuronal firing and improving symptoms associated with Parkinson's disease, such as tremor, rigor, and bradykinesia. Targets for such procedures include the thalamus, striatum, and the STN.

The use of electrical stimulation for treating epilepsy has included PNS, and more recently, CNS targets. In the PNS, both vagal nerve and trigeminal nerve stimulation have been assessed. VNS has been used for a number of years for seizure control in epilepsy, but only with mixed success. VNS shows benefit, but is not highly efficacious since it only helps about 40–50% of those patients treated. Using the VNS in humans, Olejniczak found previously that a 30-Hz frequency reduced interictal epileptiform activity. A review of the stimulation frequencies used in VNS shows that those above 50 Hz caused major damage to the nerve, and so the U.S. Federal Drug Administration (FDA) has approved frequencies only between 20 and 30 Hz for clinical use. Trigeminal nerve stimulation has been attempted in the PNS of rats, where a decrease in seizure activity has been reported.

In the CNS, stimulation targets have included the cerebellum, hippocampus, the neocortex, and deep-brain structures such as the caudate nucleus, posterior hypothalamus, thalamic nuclei, and the STN. More recently, the substantia nigra pars reticulata (SNr), a popular target for stimulation in Parkinson's disease, has been postulated to be an important player in the pathophysiology of epilepsy. These targets can be divided into two broad categories based on whether the stimulation is directly applied to the epileptic zone or whether the stimulation activates nerve fibers 'upstream' of the epileptic zone. It is not yet clear which method is optimal for clinical applications.

One approach to this issue has been to stimulate an endogenous network that modulates cortical neuronal excitability. The SNr is part of such an endogenous system, inhibiting epileptic seizures through γ-aminobutyric acid (GABAergic) projections to the superior colliculus. The SNr, via this inhibitory output, maintains a constant inhibition of the dorsal midbrain region in the deep layers of the superior colliculus. In this network, tonic glutamatergic input from the STN maintains SNr firing at a high rate. Reduced output of the SNr GABAergic neurons results in loss of inhibitory control over both convulsive and nonconvulsive generalized epileptic seizures. High-frequency stimulation of the STN or SNr has been found to reduce seizure frequency, suggesting that the SNr may be part of a major desynchronizing system that influences the regulation of seizures.

Direct focal stimulation of the hippocampus in human epileptic patients has also successfully decreased seizure activity in patients with intractable temporal lobe seizures. For example, in a preliminary study by Velasco *et al.*, electrical stimulation (130 Hz) was applied prior to a planned anterior temporal lobectomy. Subacute stimulation (i.e., for 2–3 weeks) abolished clinical seizures and significantly decreased the number of interictal spikes at the focus after 5–6 days of stimulation. Moreover, microscopy of the stimulated tissue revealed no obvious histopathological differences between stimulated vs. non-stimulated tissue. Additionally, chronic stimulation (i.e., for 3–4 months) produced a sustained, long-lasting anti-epileptic effect, with no apparent change on short-term memory.

In vitro animal model studies using hippocampal slice preparations have demonstrated that direct stimulation can disrupt experimentally induced epileptiform activity. These in vitro preparations are advantageous, since they allow an examination of potential mechanisms of action under well-controlled conditions, and are manipulated easily. Using this preparation, we have shown that both high- and low-frequency protocols have suppressive effects on seizure-like activity. However, the pattern of effect is quite different in each case (see later). Additional studies on hippocampal slices conducted independently by Durand, Schiff, and others have shown that the application of electric fields also has a suppressive effect; both brief, low-frequency stimuli and direct current high-frequency stimuli suppressed epileptiform activity in these slice studies.

Experiments have also shown that protocols using 1–5-Hz stimulation, similar to those used for studies of long-term depression (LTD), reduce kindling in rats and cats. In kindling studies of this kind, stimulation frequencies of 40–100 Hz are used to elicit the kindling phenomenon. A stimulation of 60 Hz is commonly applied (for 1–2 s) over a period of days to stimulate structures such as the amygdala, which results in the generation of generalized convulsions. Low-frequency stimuli, applied either before or after kindling has begun (to targets such as the amygdala or hippocampus), attenuate the kindled seizure activity. Low-frequency stimulation (1 Hz) in hippocampal–entorhinal rat slices has also been shown to block ictal activity in a 4AP convulsant model of

epilepsy. Inhibitory effects were induced by 1-Hz stimulation in both the subiculum and the entorhinal cortex. Since stimulation patterns used in these studies for suppressing seizure activity are similar to those used for the induction of LTD, mechanisms responsible for LTD (or 'depotentiation') may play a role in the suppression of seizure-like activity.

Mechanism(s)

In general, electrical stimulation – i.e., applied voltage in a local neural network – artificially depolarizes or hyperpolarizes neurons (i.e., modulates membrane potentials). Electrical stimulation can also initiate action potentials, which may propagate orthodromically or antidromically (or even both ways) along the axon. Depending on the intensity of the applied voltage, electrical stimulation can block the propagation of action potentials, thus providing a potential treatment modality for disorders such as epilepsy. However, it is still not clear how electrical stimulation modulates seizure activity. It is likely that there are several mechanisms at work, including perhaps those specific to target site or frequency of stimulation. At the current time, there are two general hypotheses that have been put forth. The first hypothesis, known as 'stimulation-blockade' or 'depolarization-blockade,' posits that electrical stimulation induces alterations in the activation of currents through voltage-gated channels that are in close proximity to the stimulating electrode. According to this hypothesis, electrical stimulation causes a nonspecific suppression of nerve-cell activity via constant membrane depolarization, which in turn inactivates voltage-gated sodium channels that are responsible for the depolarizing phase of the action potential. The second hypothesis, labeled 'synaptic inhibition,' suggests that stimulation effects on seizure activity are mediated indirectly, regulating neuronal output in cells in close proximity to the stimulating electrode, which in turn inhibit excitability at distant sites. In support of this hypothesis, proponents point out the large numbers of GABAergic terminals in structures such as the thalamus and the basal ganglia – i.e., targets for DBS; activation of these axon terminals by high-frequency protocols may inhibit activity in postsynaptic neurons by the summation of inhibitory postsynaptic potentials (IPSPs). The time course of GABAergic IPSPs match well with the optimal summation that occurs at frequencies where DBS is most effective.

With regard to the PNS, several interesting observations have been made, but the precise mechanisms of action of VNS remain unknown. The antiepileptic effects of VNS were initially linked to noradrenaline increases, especially given that locus coeruleus was found to mediate some of the effects of VNS in attenuating seizures; however, more recent data suggest that this explanation is not entirely satisfactory. VNS also appears to change brain function by direct afferent action. Additionally, VNS has been shown to reduce the firing rate of hippocampal neurons in laboratory animals.

Methodological Considerations and Recent Results

Novel electrical stimulation methods include open loop, semiclosed loop, and closed loop protocols. 'Open loop' stimulation is characterized by stimulation that is independent of brain activity; typically, the protocol has a timed on and a timed off period. 'Semiclosed' and 'closed loop' stimulation incorporate feedback from the nervous system of the patient (or experimental animal). In semiclosed protocols, however, the recorded physiological information is only used to switch stimulation on and off rather than to generate a dynamic-state-related stimulation protocol.

Unfortunately, most electrical stimulation protocols have not been evaluated clinically in controlled double-blind clinical trials. The absence of such trials may make efficacy difficult to evaluate, since in some cases patients can sense when stimulation is being induced.

To test the efficacy of DBS on ictal onset in a kindling model of epilepsy (in rat), Wyckhuys *et al.* evaluated the effect of high-frequency stimulation (130 Hz), using a protocol similar to that used by Velasco *et al.* in epileptic patients. These investigators used the 'alternate day rapid kindling' model of temporal lobe epilepsy (TLE), and placed their stimulation electrode in hippocampus (since this structure is often thought to be a seizure focus in human TLE). Electrical stimulation in the hippocampus of epileptic rats was found to modulate the characteristics of evoked afterdischarges in a way that reflects a reduction in excitability of the target region. The beneficial effects of 130-Hz stimulation on evoked afterdischarges were demonstrated to outlast the stimulation for at least 1 week.

Our laboratory compared both high- and low-frequency electrical stimulation protocols (in the same preparation) to determine which protocol was more effective at reducing epileptiform activity. In these hippocampal slice studies, we used convulsant agents such as bicuculline, or bathing medium deficient in magnesium, to generate seizure-like activity. In these paradigms, the epileptiform activity observed in brain slices is similar to the interictal spike discharge seen in EEG recordings of epilepsy patients.

We found that during high-frequency 100-Hz stimulation (for as little as 10 min), an immediate inhibition of extracellular field potential epileptiform discharges was observed (**Figure 1**). The effect was seen within just a few hundred milliseconds of the stimulation onset. In contrast, 1-Hz stimulation demonstrated only a gradual suppression of the complex epileptiform field potential, requiring

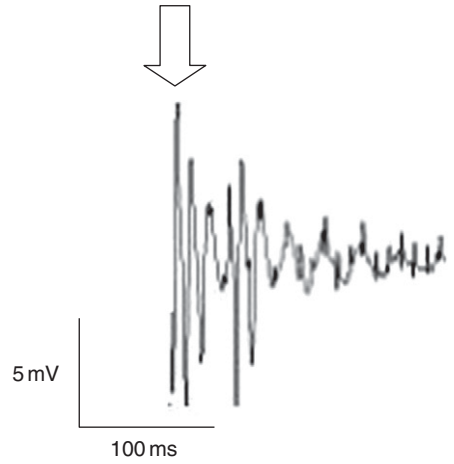

Figure 1 Multiple spiking discharges observed during the application of 100-Hz stimulation in the CA1 rat hippocampal brain slice. The arrow indicates the onset of stimulation. Notice that the extracellular field potential response is greatly reduced in amplitude within just 200–300 ms of the stimulation onset.

30 min for complete suppression. Interestingly, however, once the 1-Hz stimulation was turned off, the beneficial suppression continued for at least 20 min. This longer-term effect was not seen with high-frequency (100 Hz) stimulation, where multiple spiking responses rebounded immediately back to their original amplitudes when the stimulator was turned off. This long-lasting effect of the low-frequency protocol is similar to what has been seen in studies involving LTD.

At the clinical level, Velasco *et al.* recently reported a follow-up study to evaluate the safety and efficacy of electrical stimulation (130 Hz) of the hippocampus, and to assess the impact of stimulation on memory, in patients with refractory mesial TLE. Five of the nine patients had normal MRIs, and stimulation led to seizure reduction of more than 95%. The remaining four patients had hippocampal sclerosis, and stimulation led to seizure reduction of 50–70%. The authors concluded that electrical stimulation provided improved seizure outcome (without memory alteration), particularly in patients with nonlesional TLE. Another clinical study, by Boon *et al.*, prospectively evaluated the effectiveness of long-term DBS in patients with medial TLE. Patients underwent long-term stimulation of medial temporal lobe. After mean follow-up of 31 months, 5 of 10 patients in the DBS group had a seizure-frequency reduction of more than 50%, thus showing efficacy for long-term DBS in medial temporal lobe structures.

Future Goals

Currently, 17 medical centers in the United States are participating in the SANTE (Stimulation of the Anterior Nucleus of the Thalamus for Epilepsy) Trial, using DBS to determine whether bilateral stimulation of the anterior nucleus of the thalamus can effectively and safely reduce seizure frequency in patients with epilepsy. Recent results by Wyckhuys and Velasco (mentioned earlier) and the prospect of new clinical trials using electrical stimulation for seizure control in human studies are encouraging.

Future clinical trials, involving double-blind design, however, will be essential for validating stimulation therapies. The study of electrical stimulation in epileptic patients has unique design problems, particularly the need to make the patient oblivious to differences in the trial (since patients can often detect the stimulation). Other problems include the choice of stimulation parameters and the methods for handling unavoidable variation in seizure rates among patients (i.e., how to evaluate effects when starting from different baselines).

Furthermore, the best targets to stimulate, and the mechanisms underlying stimulation effects, are still unknown. A broad range of novel and existing stimulus protocols still need to be thoroughly tested in potential targets.

Future studies will also likely focus on 'state estimation' of the condition of seizure-prone areas as well as 'state transition.' Progress on prediction and detection systems, which will work hand-in-hand with novel prevention or treatment modalities, will be critical, and the stimulation protocols that could be incorporated into treatments that are based on seizure prediction will be essential for future implementation.

In summary, electrical stimulation is a promising treatment option for a subgroup of patients with intractable epilepsy who are not candidates for surgery. Measures of efficacy, optimal targets, electrical stimulation parameters, and types of devices, as well as patient selection criteria, still need to be characterized.

Epilepsy and Gene Therapy: Resculpturing Synaptic Transmission with Neuropeptides

M Kokaia and A T Sørensen, University of Lund, Lund, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neuropeptide Y (NPY) is widely expressed in mammalian brain and has been shown to be involved in various functions, such as regulation of blood pressure, circadian rhythms, feeding behavior, anxiety, memory, and cognition. NPY is often colocalized with classical neurotransmitters in neurons, and is predominantly released during high frequency neuronal activity. The effects of NPY are mediated via a number of G-protein-coupled receptor subtypes, including Y1, Y2, Y4, Y5, and Y6 identified so far. The Y1, Y2, and Y5 receptors are expressed throughout the hippocampus, particularly in the mossy fibers and Schaffer collaterals, in the molecular layer of the dentate gyrus, and in granule cells.

Increasing data indicate that NPY might be involved in adaptation mechanisms and/or pathophysiology underlying epileptogenesis. NPY has been shown to exert anticonvulsant action in vivo, when either overexpressed in transgenic rats or injected intraventricularly in different seizure models. In hippocampal slices, NPY has been shown to inhibit epileptiform activity induced by bicuculline, picrotoxin, or zero Mg^{2+} perfusion. In cortical slices, we showed similar inhibitory effects of NPY in the zero Mg^{2+} model. The seizure-suppressant effects of NPY in the hippocampus seem to be mediated mostly via Y2 receptors, but some involvement of Y5 receptors has also been reported. We have shown previously, using NPY receptor Y2/Y5 double KO mice, that activation of both Y2 and Y5 receptors suppress hippocampal seizures in vitro, while activation of Y5 receptors in extrahippocampal regions suppresses generalized seizures in vivo. More recently, hippocampal NPY gene therapy has been shown to effectively suppress seizures in various animal models of epilepsy. To further assess the clinical applicability of such approach, we have investigated how synaptic transmission and plasticity in synapses of the hippocampus is modulated by viral vector-mediated NPY overexpression.

Background

Application of exogenous NPY to cortical and hippocampal slices of the normal brain has been shown to modulate inhibitory and excitatory synaptic transmission, respectively. The most well known action of NPY in the central nervous system is inhibition of excitatory synaptic transmission in the hippocampus. This effect is most likely achieved by decreasing glutamate release via suppressing presynaptic voltage-dependent Ca^{2+}-channels.

Introduction

Neuropeptide Y (NPY) is widely expressed in mammalian brain and has been shown to be involved in various functions, such as regulation of blood pressure, circadian rhythms, feeding behavior, anxiety, memory, and cognition. NPY is often colocalized with classical neurotransmitters in neurons, and is predominantly released during high frequency neuronal activity. The effects of NPY are mediated via a number of G-protein-coupled receptor subtypes, including Y1, Y2, Y4, Y5, and Y6 identified so far. The Y1, Y2, and Y5 receptors are expressed throughout the hippocampus, particularly in the mossy fibers and Schaffer collaterals, in the molecular layer of the dentate gyrus, and in granule cells.

Increasing data indicate that NPY might be involved in adaptation mechanisms and/or pathophysiology underlying epileptogenesis. NPY has been shown to exert anticonvulsant action in vivo, when either overexpressed in transgenic rats or injected intraventricularly in different seizure models. In hippocampal slices, NPY has been shown to inhibit epileptiform activity induced by bicuculline, picrotoxin, or zero Mg^{2+} perfusion. In cortical slices, we showed similar inhibitory effects of NPY in the zero Mg^{2+} model. The seizure-suppressant effects of NPY in the hippocampus seem to be mediated mostly via Y2 receptors, but some involvement of Y5 receptors has also been reported. We have shown previously, using NPY receptor Y2/Y5 double KO mice, that activation of both Y2 and Y5 receptors suppress hippocampal seizures in vitro, while activation of Y5 receptors in extrahippocampal regions suppresses generalized seizures in vivo. More recently, hippocampal NPY gene therapy has been shown to effectively suppress seizures in various animal models of epilepsy. To further assess the clinical applicability of such approach, we have investigated how synaptic transmission and plasticity in synapses of the hippocampus is modulated by viral vector-mediated NPY overexpression.

Background

Application of exogenous NPY to cortical and hippocampal slices of the normal brain has been shown to modulate inhibitory and excitatory synaptic transmission, respectively. The most well known action of NPY in the central nervous system is inhibition of excitatory synaptic transmission in the hippocampus. This effect is most likely achieved by decreasing glutamate release via suppressing presynaptic voltage-dependent Ca^{2+}-channels.

Methods

In our studies, the serotype 1/2 rAAV vector, carrying the NPY gene under the control of the NSE promoter, is injected stereotactically into the hippocampus of rats. Recombinant adeno-associated viral (rAAV)–NPY vector is produced using standard procedures and is obtained via collaboration with Dr. Matthew During from Cornell University, New York, USA. Injection is performed as follows: Animals are anaesthetized and placed in stereotaxic frame, a hole is drilled in the skull according to predetermined coordinates, and glass pipette filled with viral vector solution is inserted into the brain through the hole; injection of 1 µl solution is performed over the course of a few minutes, and the pipette is left in place for another few minutes to prevent backflow of the viral vector into the pipette tract. The vector construct used in our experiments gives a neuron-specific widespread expression of NPY in the hippocampus. Electrophysiological experiments are performed with both field and whole-cell recordings in brain slices prepared three to seven weeks after viral vector delivery. Vibratome-cut slices are maintained in artificial cerebrospinal fluid (aCSF) bubbled with a gas mixture of 95% O_2 and 5% CO_2, and continuously perfused with gassed aCSF in the recording chamber. Field recordings are made with a pipette filled with aCSF, while whole-cell recordings are made with patch-clamp pipettes filled with solutions specifically designed for certain experimental requirements, having pipette tip resistances of 4–6 MΩ. Field or whole-cell potentials or currents are amplified with patch-clamp amplifier (HEKA elektronik, Germany), and the recordings are saved on the computer for later off-line analysis performed with IgorPro and FITMASTER software using appropriate statistical tests. Detailed method description could be found elsewhere (see Further Reading).

Recent Results

Our studies demonstrate that injection of rAAV–NPY vector into the hippocampus of naïve animals leads to high levels of transgene NPY expression, as estimated by increased immunoreactivity in transduced areas of hippocampus. Further, such injections alter excitatory synaptic transmission, predominantly during high frequency neuronal activity (high frequency stimulation – HFS). This effect seems to be due to the release of transgene NPY from neurons, which acts on presynaptic Y2 receptors and suppresses glutamate release. These effects are demonstrated on **Figure 1(a)**, where relative depression of consecutive EPSPs, generated in Schaffer collateral-CA1 cell synapses during the later phase of HFS, is more pronounced in slices from rAAV–empty vector-treated animals

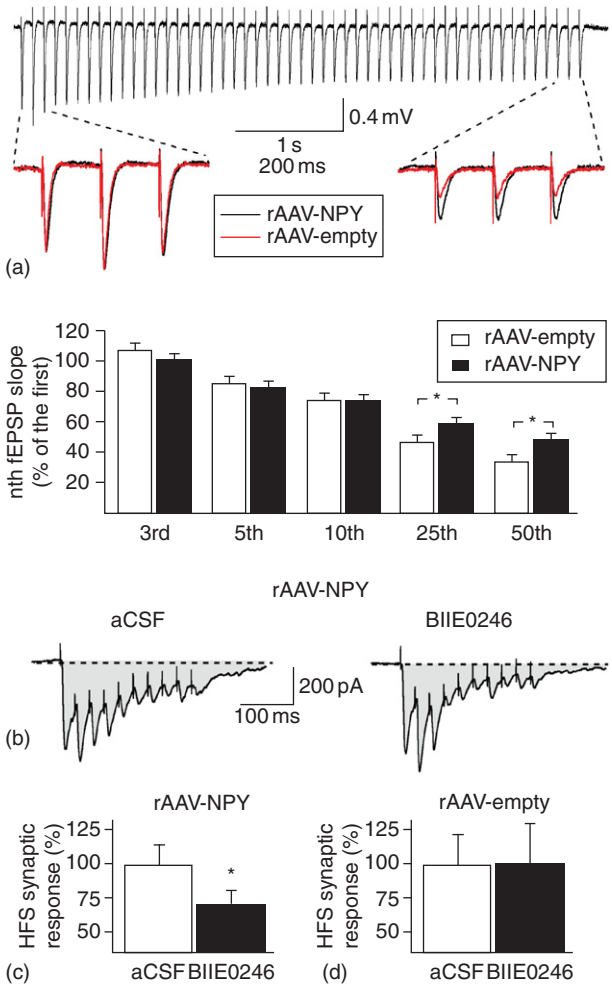

Figure 1 Transgene NPY is released during high frequency stimulation (HFS). (a) Representative trace from a rAAV–NPY treated slices showing a 10 Hz HFS-evoked field EPSPs (fEPSPs) recorded in stratum radiatum of CA1 with AP-5 (NMDA receptor blocker) present in the perfusion medium. Insets: superimposed traces showing more pronounced depression of only last three fEPSPs in rAAV–empty relative to rAAV–NPY treated slices. Average bar plot showing initial slopes of the consecutive fEPSPs (3rd, 5th, 10th, 25th, 50th) expressed as relative percent of the first evoked fEPSP in rAAV–NPY and rAAV–empty treated slices (*$p < 0.05$, *t*-test). (b) Whole-cell patch-clamp recording from a proximal subicular neuron in rAAV–NPY treated slice showing HFS-induced (25 Hz) depression of consecutive EPSCs. Application of Y2 receptor antagonist, BIIE0246, significantly increased EPSC depression in this cell. (c) Average HFS-induced EPSC depression expressed as an integral of the whole response divided by the integral of the first EPSC before (aCSF) and after (BIIE0246) BIIE0246 application. Note the significant decrease of the averaged responses (increased depression) after BIIE0246 application. Such decrease was not observed in rAAV–empty (d) treated slices (*$p < 0.01$, paired *t*-test).

as compared to those treated with rAAV–NPY. In line with this observation, application of the selective Y2 receptor antagonist, BIIE0246, in rAAV–NPY vector treated slices leads to more pronounced depression of consecutive EPSCs induced in subicular neurons by HFS of alveus (**Figure 1(b)**

and 1(c)). BIIE0246 application had no effect on rAAV–empty treated slices (**Figure 1(d)**). These data suggest that transgene NPY is released during HFS, which decreases glutamate release. This initial decrease in glutamate release, in turn, leads to slower depletion of the releasable vesicular pool of glutamate, reflected as less pronounced depression of synaptic responses during HFS.

The fact that transgene NPY is released during HFS is further confirmed by our experiments using two independent pathway stimuli (**Figure 2(a)**). The test pulse-induced EPSC was decreased when HFS stimulation was delivered to another afferent pathway of rAAV–NPY treated animals (**Figure 2(b)** and **2(d)**). This effect was not seen after BIIE0246 application (**Figure 2(c)** and **2(d)**), or in rAAV–empty vector-treated animals (**Figure 2(e)**). Taken together, these data strongly suggest that transgene NPY is indeed released by HFS, and inhibits glutamate release even in neighboring, nonactivated excitatory synapses. Such 'volume transmission' generated by transgene NPY could be a mechanism for reducing/precluding recruitment of nonactivated synapses (and eventually neurons) during high frequency activity. Such an effect would suppress spread of seizures in the hippocampus.

Worryingly, certain types of neuronal high frequency activity in the hippocampus occur not only during seizures, but also during induction of long-term potentiation (LTP), a process related to learning and memory. In rAAV–NPY vector treated animals, we found that LTP in both Schaffer collateral-CA1 (**Figures 3(a)** and **3(b)**) and CA1-subicular cell synapses (**Figure 3(c)**) seems to be attenuated. These findings could raise some concerns about possible interference by transgene NPY in learning and memory process if used in patients with epilepsy. However, behavioral studies indicate that such deficits in learning and memory induced by rAAV–NPY treatment could be transient, and that the animals still learn hippocampal-related tasks – although with some delay. Moreover, our preliminary data suggest that in animals that have been kindled, LTP in Schaffer collateral-CA1 cell synapses is slightly attenuated. The LTP in these 'epileptic' animals does not seem to worsen by injections of rAAV–NPY vector into the hippocampus.

We are currently investigating whether and how NPY affects inhibitory circuits of the hippocampus, and study the possible contribution of NPY-induced alterations of the inhibitory circuitry in the seizure-suppressant action

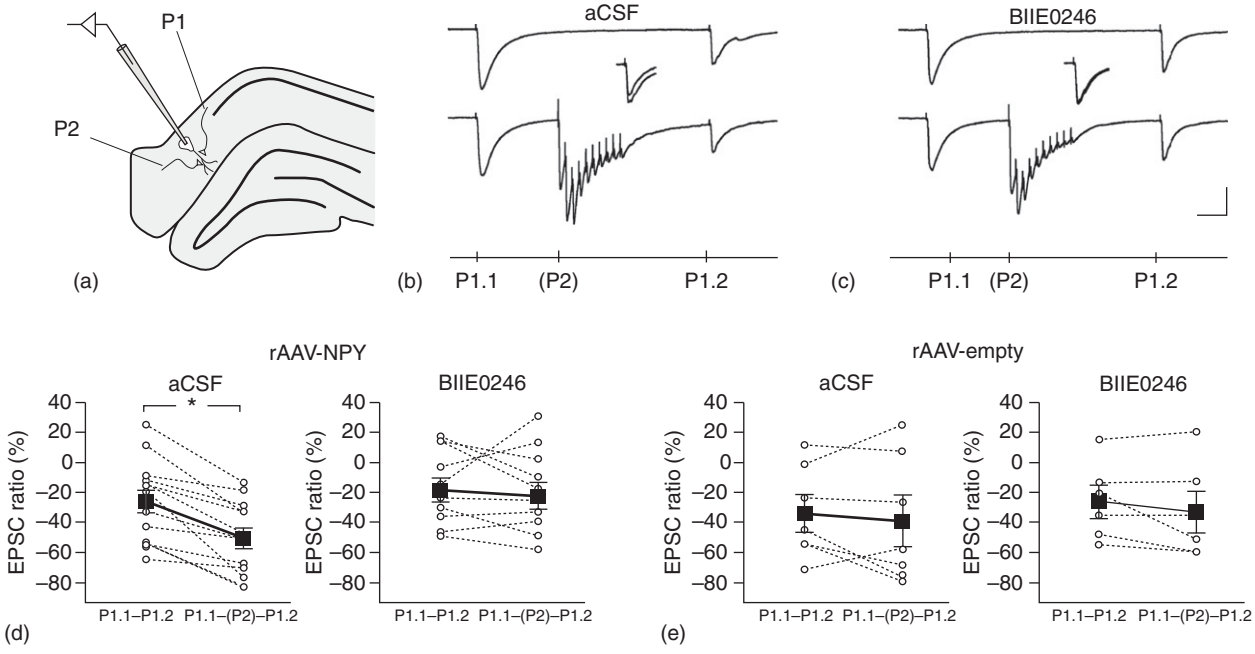

Figure 2 HFS-induced release of transgene NPY suppresses glutamate release in neighboring synapses as a volume transmitter. (a) Schematic illustration of the recording setup, showing the patch electrode in contact with a pyramidal neuron in proximal subiculum, and two stimulation electrodes placed on each side, to activate two independent afferent pathways (P1 and P2) impinging onto the same recorded cell. (b) Representative traces showing EPSCs evoked by paired stimulation of the P1 pathway (top trace, P1.1–P1.2), or P1 pathway with intermediate HFS train stimulation of P2 pathway (lower trace, P1.1–(P2)–P1.2) in a rAAV–NPY treated slice. Time points of stimulation for P1 and P2 are shown on bottom line. Note the reduction of EPSC amplitude evoked by P1.2 stimulation after HFS of P2 (inset). (c) Similar traces as shown in (b), but after BIIE0246 application. Note that EPSCs evoked by P1.2 stimulations are of similar amplitude (inset). Scale bar is 100 ms and 100 pA, for both (b) and (c). (d) EPSC amplitude ratios (P1.2–P1.1)/P1.1 of paired EPSCs are plotted for each recorded cell before and after BIIE0246 application in rAAV–NPY treated animals. Dotted lines and open circles show EPSC ratio changes in individual cells. Thick line and filled squares show the mean ± SEM values from all cells (*$p < 0.05$, paired *t*-test). (e) Similar as in D, but for rAAV–empty treated rats.

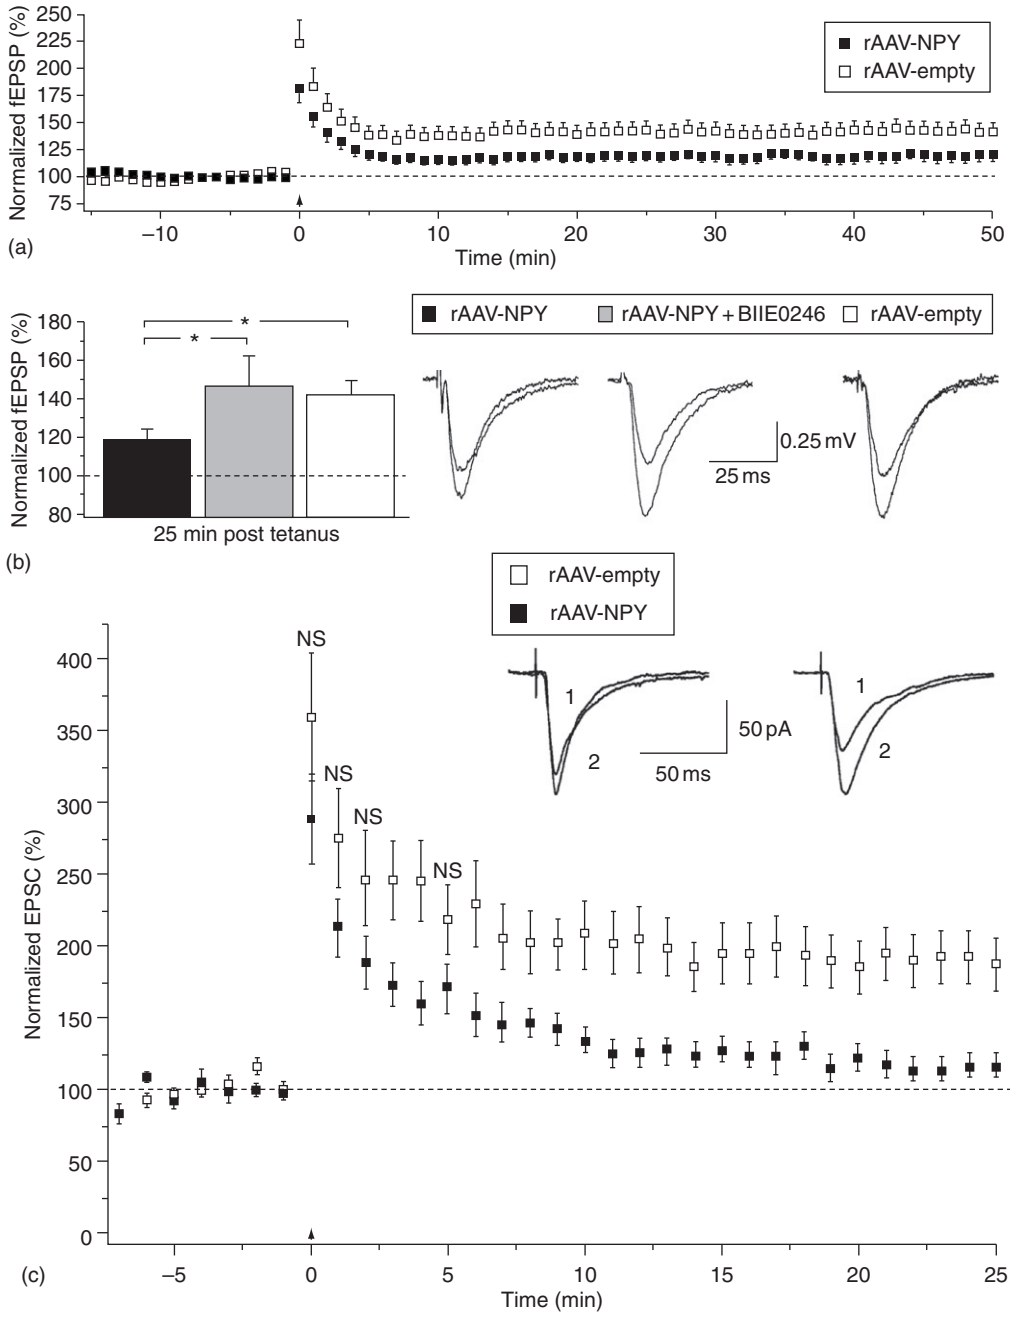

Figure 3 LTP is attenuated by transgene NPY in Schaffer collateral-CA1 and CA1-subicular cell synapses. (a) LTP of fEPSPs in Schaffer collateral-CA1 synapses in rAAV–NPY and rAAV–empty treated slices. LTP is induced by tetanic stimulation (100 Hz, 1 s), marked by arrow at 0 min. Initial slopes of EPSPs are normalized to the average baseline values (−15 to 0 min) and plotted against time. (b) Bar graph showing average values of fEPSP LTP in percent to baseline at 25 min post-tetanus with respective fEPSP traces on the right. Application of Y2 receptor antagonist, BIIE0246, to slices from rAAV–NPY treated animals reversed the attenuation of LTP to similar levels as recorded in rAAV–empty treated slices (*$p < 0.05$, *t*-test). (c) LTP in subicular-CA1 synapses, as recorded by whole-cell patch-clamp from proximal pyramidal cells, is significantly attenuated ($p < 0.05$, *t*-test) at most time points after tetanic stimulation in rAAV–NPY as compared to rAAV–empty treated slices (NS, nonsignificant). *Inset*: Representative EPSCs recorded in subicular cells during baseline (1), and 10 min post tetanus (2), in rAAV–NPY and rAAV–empty treated slices.

of transgene NPY. Our preliminary data indicate that exogenous application of NPY decreases inhibitory drive (as measured by mIPSC frequency) on a basket cell subpopulation of the GABAergic inhibitory interneurons; this influence could possibly contribute to the antiepileptic effect of NPY by disinhibiting inhibitory GABAergic interneurons, and thus increasing inhibitory drive onto the principal cells.

Future Goals

In the future, we will explore whether NPY receptor overexpression using rAAV vectors is possible, and if such treatment alone – or in combination with NPY overexpression – would exert stronger antiepileptic and/or antiepileptogenic effect in the hippocampus. We will also adopt encapsulated cell biodelivery (ECB) technology to deliver gene products via genetically modified and encapsulated cell line transplants into the brain (in this case NPY, or another endogenous antiepileptic neuropeptide, galanin), to evaluate the seizure-controlling capabilities of such approach. The ECB devices provide some additional safety aspects for tentative clinical applications, as they could be easily removed from the brain in case of any adverse effects.

Focal Cooling as a Potential Treatment for Neocortical Epilepsies

S M Rothman, University of Minnesota Medical School – MMC 486, Minneapolis, MN 55455-0374, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Scope of the Problem

The end of the twentieth century witnessedremarkable advances in the understanding and treatment of many of the epilepsies. The scientific speculation that some genetic epilepsies were caused by mutations in ion and voltage-gated channels was validated by a series of landmark genetic discoveries. New anticonvulsants, several with highly favorable therapeutic indices, were introduced. Sensitive magnetic resonance and positron-emitting based imaging tests that revealed the focal etiology of many complicated, symptomatic epilepsies emerged and evolved rapidly. Finally, the once radical therapeutic option of surgical resection for both lesional and nonlesional epilepsies became much more accepted as a mainstream therapeutic option for medically refractory patients.

Despite this progress, many patients with epilepsy have been left behind. The focal cortical epilepsies have remained especially problematic. Accounting for up to half of patients with poorly controlled seizures, focal and multifocal seizures arising from the neocortex have proven extremely refractory to both conventional anticonvulsant therapy and the newer surgical approaches. Even with guidance from modern neuroimaging techniques that allow functional anatomic correlation of seizure onset with surface rendering of the neocortex, the surgical treatment of cortical seizures is successful in about 50–60% of cases only. There are at

Future Goals

In the future, we will explore whether NPY receptor overexpression using rAAV vectors is possible, and if such treatment alone – or in combination with NPY overexpression – would exert stronger antiepileptic and/or antiepileptogenic effect in the hippocampus. We will also adopt encapsulated cell biodelivery (ECB) technology to deliver gene products via genetically modified and encapsulated cell line transplants into the brain (in this case NPY, or another endogenous antiepileptic neuropeptide, galanin), to evaluate the seizure-controlling capabilities of such approach. The ECB devices provide some additional safety aspects for tentative clinical applications, as they could be easily removed from the brain in case of any adverse effects.

Focal Cooling as a Potential Treatment for Neocortical Epilepsies

S M Rothman, University of Minnesota Medical School – MMC 486, Minneapolis, MN 55455-0374, USA

Introduction

Scope of the Problem

The end of the twentieth century witnessedremarkable advances in the understanding and treatment of many of the epilepsies. The scientific speculation that some genetic epilepsies were caused by mutations in ion and voltage-gated channels was validated by a series of landmark genetic discoveries. New anticonvulsants, several with highly favorable therapeutic indices, were introduced. Sensitive magnetic resonance and positron-emitting based imaging tests that revealed the focal etiology of many complicated, symptomatic epilepsies emerged and evolved rapidly. Finally, the once radical therapeutic option of surgical resection for both lesional and nonlesional epilepsies became much more accepted as a mainstream therapeutic option for medically refractory patients.

Despite this progress, many patients with epilepsy have been left behind. The focal cortical epilepsies have remained especially problematic. Accounting for up to half of patients with poorly controlled seizures, focal and multifocal seizures arising from the neocortex have proven extremely refractory to both conventional anticonvulsant therapy and the newer surgical approaches. Even with guidance from modern neuroimaging techniques that allow functional anatomic correlation of seizure onset with surface rendering of the neocortex, the surgical treatment of cortical seizures is successful in about 50–60% of cases only. There are at

least three reasons why surgical management of neocortical epilepsy is so difficult. First, conventional neurophysiological techniques frequently have a difficult time localizing the site of a patient's seizures. Second, identification of the specific neurological function(s) residing in the seizure onset zone, essential for an accurate prediction of adverse effects of resection, can be very difficult. Third, in many instances, the expectation that resection will leave a permanent neurological deficit precludes surgery altogether.

Alternatives to Permanent Resection for Neocortical Epilepsy

A variety of invasive but nondestructive strategies have recently been employed or proposed to reduce the frequency and severity of neocortical seizures. For the past 15 years, vagal nerve stimulation (VNS) has been used for selected children and adults with refractory epilepsy. Although a variety of clinical studies have validated its efficacy, the overall reduction in seizure frequency with VNS approximates 50%. This certainly represents an improvement in seizure control, but for many patients the improvement in quality of life is not substantial. There is some experimental evidence that trigeminal nerve stimulation might provide better seizure control, but as yet there have been no human studies of this modality. Transcranial magnetic stimulation for epilepsy has been described in several publications. The initial reports were optimistic, but subsequent controlled prospective trials have not shown significant reduction in seizure frequency. There are also brain slice studies indicating that the direct application of a constant or DC electrical field can diminish neuronal excitability and experimental seizure discharges.

Although DC fields have not yet been tried clinically, there is limited experience with several variations of intermittent electrical stimulation for human epilepsy. At least five publications have identified subsets of patients who benefited from intermittent hippocampal or thalamic stimulation. These results are still too premature to allow definite conclusions. The most sophisticated intervention is a totally implantable, closed-loop feedback system for seizure detection and cortical stimulation to terminate focal seizures. Using the same electrodes for both recording and stimulation, in conjunction with a custom-designed seizure detection algorithm, this device has been able to abruptly terminate seizures by delivering a 100 Hz burst of pulses lasting about a tenth of a second. At this time, the reliability of this device is being determined in prospective clinical trails at several North American epilepsy centers.

Background

Another appealing, nondestructive strategy for terminating and possibly preventing focal seizures is the application of focal cooling. There is an extensive literature that documents that cooling reduces synaptic transmission in the mammalian brain, and it should be possible to use new engineering technology to deliver very focal cooling. The first descriptions of the central neurological effects of focal cooling come from articles written by Stefani and Deganello at the end of the nineteenth century. A decade later, the German physiologist Trendelenburg began a systematic study of local hypothermia, investigating its effects on both brainstem autonomic reflexes and the neocortex. While lacking any cellular insights, all three investigators concluded that cooling reduced neurological function at the system level. Throughout the rest of the twentieth century, physiologists continued to use local cooling to investigate cortical and subcortical localization of specific brain functions. Information about the neurobiological effects of cooling advanced over the last fifty years. Using intracellular recording at the frog neuromuscular junction, Katz and Miledi showed that cooling reduced end plate potentials, likely by diminishing the probability of acetylcholine release from presynaptic terminals. More recent experiments in mammalian tissue culture and brain slices have shown that cooling alters excitatory transmission by both pre- and postsynaptic mechanisms. Cooling can augment the magnitude of neuronal action potentials and inhibits the sodium–potassium ATPase. Although the initial ATPase inhibition and concomitant cell depolarization may elicit transient hyperexcitability, cooling eventually reduces neuronal excitability. Our own recent observations indicate that hypothermia rapidly reduces transmitter release from presynaptic vesicles and suggest that this may be a dominant effect of rapid cooling on central neuronal excitability.

The potential clinical utility of cooling for neurological disease has been discussed for half a century. Fay began an extensive investigation of brain cooling in 1938. He suggested that either systemic hypothermia or local cooling of the brain with cooled fluid circulating through a sealed metal capsule might be an efficacious treatment for head trauma and intractable pain. He also thought reducing brain temperature might inhibit tumor growth and tried intracranial cooling for inoperable gliomas. More recent controlled studies have reported benefits of cooling patients after acute head trauma or asphyxia. Interestingly, the temperature reduction in these recent clinical reports is generally no more than 4 °C, which would not be expected to have a very large effect on synaptic transmission. This temperature change is also a much smaller drop than the cooling required to terminate experimental seizures.

Physicians have been aware of a causal relationship between elevated temperature and seizures since Hippocrates. Moreover, numerous *in vitro* and *in vivo* experimental epilepsy studies have consistently demonstrated

that cooling diminishes paroxysmal bursting and can reduce or stop seizure activity. There are encouraging clinical reports suggesting the utility of brain cooling for human seizures as well. A quarter century ago, two separate clinical investigations documented the efficacy of cooling in the therapy of a limited number of patients with acute, prolonged seizures or chronic, recurrent seizures. The initial paper showed that externally cooling (31–36 °C) six patients with refractory status epilepticus stopped seizures in five. The second paper described 25 patients, ranging in age from 8 to 46, who had frequent major motor seizures poorly controlled on chronic anticonvulsant therapy. While under general anesthesia, they were placed in an enclosed chamber and chilled to 29 °C with cold air. At that point, bilateral frontal burr holes were opened and the subarachnoid space or ventricles were irrigated with iced saline, which reduced cortical surface temperature below 24 °C in 21 of the patients. A total volume of 500–20 000 cc of saline was infused into the patients who were slowly recovered from anesthesia. Of the 15 patients followed for 1 year, 11 showed a marked reduction in seizure frequency, including 4 who had been seizure free. These long term favorable outcomes suggest that transient cooling can exert a sustained effect, whose mechanism remains to be determined.

Two more recent descriptions of direct cooling of human brain during operative neurosurgical mapping have confirmed that acutely lowering cortical temperature will terminate paroxysmal discharges. In these cases, focal spikes abruptly stopped when iced saline was applied to the neocortex in the operating room. Both sets of studies have encouraged the development of more convenient methods of brain cooling for epilepsy.

Methods and Recent Results

The inconvenience of cooling with circulating cold water or conventional refrigeration devices has precluded the application of cooling for the chronic therapy of epilepsy. However, improvements in thermoelectric devices and the necessary supporting technology make it essential to reevaluate cooling as a viable therapy for some forms of epilepsy. Thermoelectric devices exploit Peltier's observation in 1834 that a temperature gradient develops at the junction between two dissimilar conductors when an electric current is applied across them. The discovery in the 1920s that synthetic semiconductors were superior to metals as thermoelectric elements hastened progress in this field. The development of modern semiconductors, typically alloys of bismuth, tellurium, selenium, and antimony, has made possible the fabrication of small, light thermoelectric modules or Peltier devices. In these modules, pairs of N- and P-type semiconductors are connected electrically in series and thermally in parallel, between two ceramic plates, to form a wafer (**Figure 1a**). When current is passed, one of the plates cools almost instantly and the other heats, depending on direction of current flow. Thermoelectric devices are capable of generating temperature differentials of 70 °C, but for these differentials to result in cooling, heat must be efficiently removed from the hot side. For most of our work, we have attached the hot side of the device to a copper rod, which removes heat and acts as a convenient holder for a manipulator. These devices can be fabricated in mm dimensions.

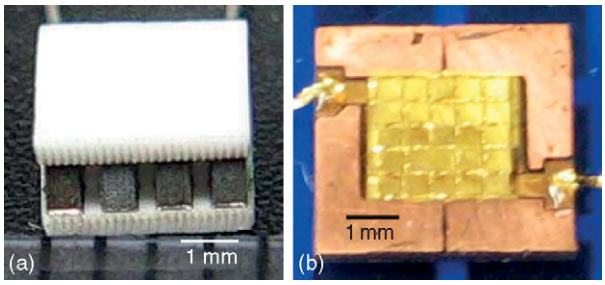

Figure 1 Photographs of thermoelectric or Peltier devices. (a) Commercially available Peltier device showing the individual semiconductors connecting the two ceramic wafers. (b) Thin film Peltier device (Nextreme) composed of 25 smaller units within a 6 mm^2 surface. These devices can be fabricated to a thickness of less than 0.2 mm.

In 1999, we became aware of the attractive features of commercially available thermoelectric devices and began experiments to determine whether they could terminate acute seizures. Initially, we induced seizures in rat hippocampal brain slices by perfusing them with 4-aminopyridine (4-AP), a blocker of voltage-gated potassium channels and a well-established convulsant. We positioned the slices on the surface of a thermoelectric device that had been machined into a plexiglass chamber. In this configuration, we were able to rapidly cool the slices at the onset of electrographic seizures. We found that cooling to 20 °C quickly terminated this paroxysmal activity and also reversibly inhibited evoked field potentials.

These positive *in vitro* results encouraged us to attempt to suppress ictal activity *in vivo*. We found that we could reliably induce focal seizures in halothane-anesthetized rats with 4-AP solution. The 4-AP was inserted 0.5 mm below the pial surface of the motor cortex using a micropipette. The animals developed recurrent focal seizures within 20 min, and continued to have electrographic seizures for approximately 2 h. Untreated seizures lasted between 60 and 80 s. When we allowed a thermoelectric device to directly contact the neocortex immediately above the injection site, and activated cooling to 20 °C at seizure onset, seizure duration was reduced to approximately 7 s (**Figure 2**).

This rapid effect is due to the local cooling, because the thermoelectric device did not influence seizure duration if it was not in direct contact with the cortical surface.

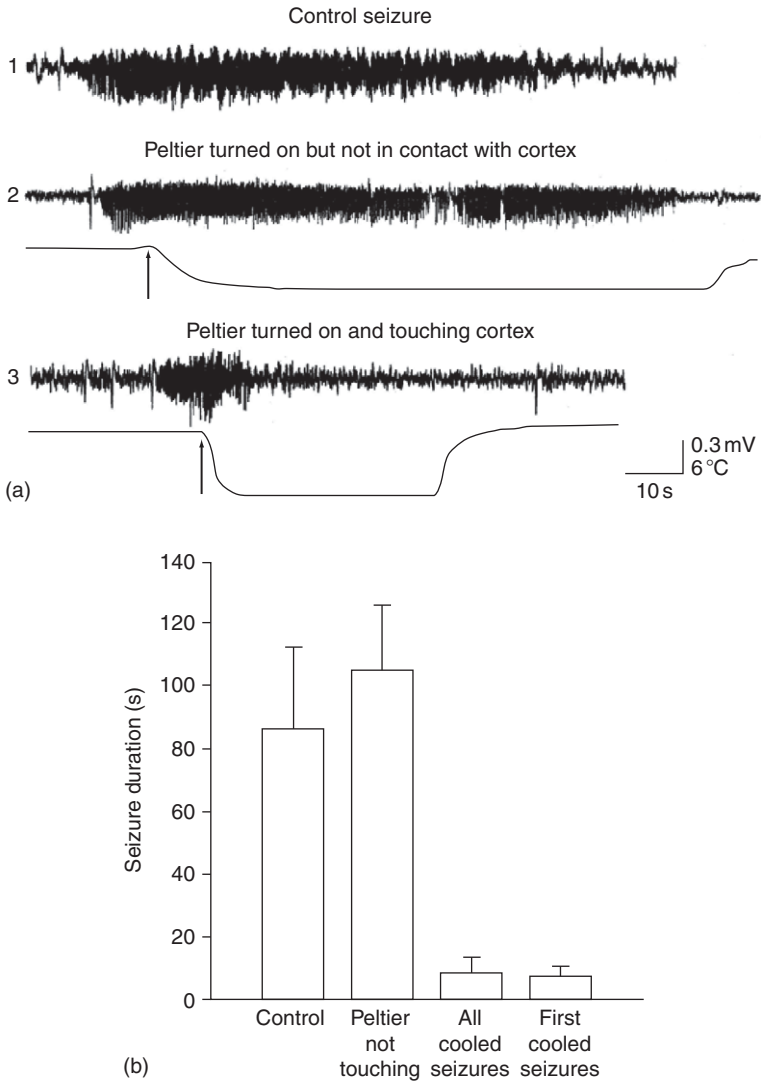

Figure 2 (a) Examples of 4-AP-induced neocortical seizures. (a1) Control seizure lasting 90 s. (a2) Activating the Peltier device did not alter the course of a 110 s seizure when the device was not in direct contact with the cortical surface. (a3) Direct cortical cooling by the Peltier device 8 s after seizure onset terminated the seizure within 9 s. The temperature reductions in a2 and a3 differ because the Peltier surface was cooled from room temperature (about 25 °C) to 20 °C in a2 and from brain surface temperature (about 34 °C) to 20 °C in a3. (b) Cortical cooling significantly reduces the duration of seizures. Cooling shortens the duration of the entire group of cooled seizures as well as the first cooled seizure in each animal. Activation of the Peltier had no effect on seizure duration when the device did not directly contact the cortex. Cooled seizure durations were significantly different from both control groups ($p < 0.001$). This figure was modified and reproduced from Yang X-F and Rothman SM (2001) Focal cooling rapidly terminates experimental neocortical seizures. *Annals of Neurology* 49: 721–726.

In this preparation, there was a progressive decrease in seizure duration below 26 °C, but no difference between 22 and 20 °C. We have not yet tried temperatures below 20 °C. We may even be overestimating the degree of cooling required for seizure termination. Another group has reported that paroxysmal discharges in a slice model of epilepsy were eliminated by rapid temperature reductions of only 1 °C (**Figure 3**).

We went on to develop a frequency-based seizure detection algorithm for the 4-AP seizures, which allowed us to use a closed-loop system to abort seizures. To minimize false positives, we set a relatively high threshold before cooling was activated. In these circumstances, our closed-loop system was as effective in terminating seizures as manual activation. Had we decided to accept more false positives, we could have initiated more rapid cooling and further reduced seizure duration.

Additional experiments have revealed other attractive aspects of cooling for focal seizures. Using a small thermocouple inserted into a 30 g needle, we mapped the cortex below our thermoelectric device and showed that cooling extends only about 4 mm below the surface. Thus, its effect should be localized to just a small region of neocortex below the pia. Recent work has explored the

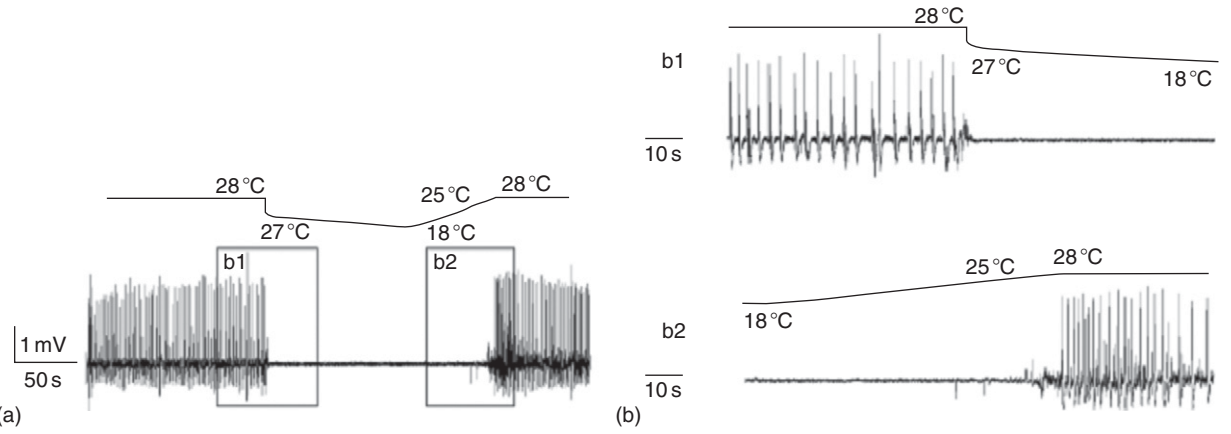

Figure 3 Seizures in hippocampal slice stop after rapid 1 C temperature reduction. (a) Slice seizure induced by 4-AP is characterized by repetitive field potentials, which disappear immediately after rapid reduction in perfusate temperature from 28 C to 27 C. (b) Faster time scale recording of seizure onset and offset. Boxes b1 and b2 in (a) correspond to traces b1 and b2. Although temperature was reduced to 18 C, the seizures disappeared at 27 C. This figure was modified and reproduced from Motamedi GK, *et al*. (2006) Termination of epileptiform activity by cooling in rat hippocampal slice epilepsy models. *Epilepsy Research* 70: 200–210.

possibility of brain damage induced by local cooling. Thus far, we have not seen any evidence that cooling as low as 5 °C for 2 h produces neuronal loss or activates apoptotic pathways. While there is minimal gliosis close to the region of cortical contact with the Peltier, it is similar to the response provoked by any foreign body and cannot be attributed to cooling. Interestingly, when brain slices obtained from transgenic mice expressing the Green Fluorescent Protein were cooled to 5 °C, there was transient, but completely reversible blebbing of dendrite shafts and loss of spines. This is probably an effect of ion pump inhibition, because other investigators have made similar observations after treating brain slices with Na^+/K^+ ATPase inhibitors. We have also failed to observe any neuronal loss in cat neocortex, after 7–10 months of intermittent cooling during neurophysiological localization experiments. These results make us optimistic that the effect of cooling will be exquisitely focal and well tolerated.

A series of more recent experiments demonstrated that cooling is capable of reducing the severity and length of other types of focal seizures. Both the grade and afterdischarge duration of kindled rat hippocampal seizures were reduced by cooling to between 23 and 26 °C with cold saline flowing through thin copper tubing positioned next to dorsal hippocampus. A limited set of observations on a monkey have verified that our thermoelectric device is capable of inhibiting function in the primate neocortex. When our thermoelectric device was placed in direct contact with the pia on the surface of the hand region of the precentral gyrus, there was a consistent, reversible impairment in skilled finger movements associated with a reduction in surface temperature. This indicates that the small thermoelectric devices have sufficient power to cool primate cortex. Of note, even with cooling to 10 °C, the impairment was not instantaneous and did not completely paralyze hand movements.

To move ahead with the design of a fully implantable cooling device for human focal epilepsy, we have begun to address the problem of heat dissipation from the hot side of thermoelectric devices. While a copper rod has worked well for experiments in anesthetized or immobilized animals, a more compact device will be required to transfer heat from a clinical device. There is an extensive literature describing heat pipes, which are hollow, evacuated, wicked tubes that rapidly equilibrate temperature by allowing a liquid to alternately evaporate and recondense under reduced atmospheric pressure. Our engineering colleagues have designed a thin, bendable, laminar heat pipe composed of outer layers of copper foil and an inner layer of sintered copper columns sandwiched between two layers of sintered copper. The charging fluid, water, flows between the copper columns. The mechanical properties of this heat pipe indicate that it should be capable of diffusing sufficient heat from a thermoelectric device in contact with the cortex to maintain a cold side temperature of 20 °C without heating adjacent brain above 38 °C. We envision positioning a similar heat pipe between the hot side of a thermoelectric device and dura, skull, or scalp, so that heat can be efficiently transferred to one of these highly vascular compartments.

Future Plans

At this point there seems to be little reason to pursue further animal work on cooling for focal seizures. The existing data already shows a robust effect of cooling in rodent models and there are no primate focal epilepsy models that have been validated for therapeutic testing.

The most critical question at this time is the degree of cooling required to terminate or prevent human focal seizures, and rodents are unlikely to inform us about this question. There is no rodent model of chronic focal epilepsy that reliably reproduces the human condition; the 4-AP model, which we have used in our studies, is much more severe than even the most refractory human epilepsy. The rats typically have 60–80 s seizures every 2–3 min, which would be unrealistic for almost all human epilepsies. Human seizures would be expected to be much less frequent. It seems likely, therefore, that rodent focal seizures will require a much larger temperature reduction than human seizures. This information is critical because the required degree of cooling will govern the current required to power the thermoelectric device. Moreover, the degree of cooling will determine the amount of heat that has to be dissipated through the heat pipe to the vasculature.

We believe that the most efficient way to sort this out will entail fabricating a cooling device that utilizes cold saline rather than a thermoelectric device. The device would combine a conventional silastic grid used for invasive monitoring and a bladder through which cold saline flows. This device would allow focal cooling of an epileptic focus in appropriate patients during monitoring, prior to surgical resection. It would permit us to determine the degree of cooling required to stop seizures without having to cope with heat dissipation. Once the cooling parameters have been better defined, it will be possible to rationally design an implantable device using thermoelectric technology.

We have recently been encouraged by improvement in the design of thermoelectric devices. It is now possible to use thin film technology developed for the microelectronics industry (Nextreme; **Figure 1b**) to fabricate cooling devices that are less than 200 μm thick and have up to ten times the heat pumping capability of conventional devices. These will be ideal for medical devices.

There are several clear obstacles and objections that need to be addressed before focal cooling can be used to treat human epilepsy. First, the convolutions of the human brain keep approximately two-thirds of the neocortex buried in sulci and inaccessible to surface cooling. However, it should still be possible to cool portions of the substantial area of exposed cortex that are responsible for seizure generation. In addition, cooling the lip of cortical sulci may block the spread of seizures arising within the sulci, a suspected mechanism of wider seizure generalization. It should even be feasible to connect thin, flexible heat pipes to thermoelectric devices to cool structures deeper in the brain. Second, cooling may be as disruptive to normal brain function as some seizures. We are optimistic that there may be a temperature range that separates seizure control from disruption of normal cortical function. The results of Bakken and colleagues that cooling below 10 °C over eloquent cortex did not produce a complete anomia or nonfluent aphasia support this hope.

Third, while we are concerned that the current requirements for present commercial thermoelectric devices exceed an ampere, the short-duty cycle may allow these devices to operate for long periods without recharge or replacement. Moreover, improvements in battery life and thin film thermoelectric design should make it possible to generate more efficient devices soon. Fourth, while there is presently no fully validated closed-loop device for seizure control, several seizure detection and prediction algorithms appear promising. Variations of these algorithms are currently undergoing trials in devices using either an external or implanted detection system linked to electrical stimulation. There is nothing about these systems that would preclude replacing stimulation with cooling as the efferent arm of the device.

Full implementation of cooling as a clinical therapy will still require further applied research. However, given the steady neurobiological progress over the last 5 years and the continuous progress in many phases of mechanical and electrical engineering, it would be surprising if some investigational application of cooling for epilepsy management was not available by the end of the decade.

Gene Therapy in Epilepsy

M J During and V Riban, The Ohio State University, Columbus, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The application of gene therapy has expanded tremendously in the last two decades. Since the first clinical study almost 20 years ago, gene therapy has been successfully used in very diverse fields, including genetic diseases, metabolic disorders, and more recently neurological diseases. Theoretically, gene therapy can be applied to any disease for which the cascade of pathophysiological events has been identified. Indeed, gene therapy has proved beneficial in simple genetic as well as complex acquired disorders, as this approach enables either overexpression or knockdown (using interfering RNA) of genes within a pathological network. However, some technical constraints remain, and new gene therapy vectors with better efficiency and specificity have been developed to overcome these limitations and widen the field of application. The outcomes of recent clinical trials are very promising and suggest that gene therapy could be beneficially applied for several neurological disorders.

There is a significant unmet need for new therapeutic approaches in epilepsy. About one-third of epileptic patients suffer from pharmacoresistant seizures – despite the development of new antiepileptic drugs. For many of these patients, particularly those with temporal lobe epilepsy, surgical resection is often the only effective therapeutic alternative. Moreover, antiepileptic drugs do not prevent the progression of the disease, and seizure management is often synonymous with lifelong pharmacological treatment, with side-effects that can be debilitating and the risk of increasing refractoriness over time. Some exciting preclinical studies, using experimental animal seizure and epilepsy models, and human data from early stage trials for other neurological disorders, suggest that gene therapy is now ready for translation to the epilepsy clinic.

Background

The majority of epilepsies are complex acquired disorders with both genetic and environmental contributions. Although initial forays into gene therapy targeted simple genetic disorders – for example cystic fibrosis and hemophilia – the early disappointing results suggested that genetic disorders are not necessarily the ideal indications. For the majority of genetic disorders, mutations are found throughout the body, and typically it is not a single cell population or tissue that needs correction in order to reverse the disease phenotype. Moreover, the efficient transduction of both multiple cell types and/or organs is problematic; further, systemic gene therapies, particularly those involving viral vectors, have often elicited significant immune responses, thus limiting the efficacy of the approach.

Introduction

The application of gene therapy has expanded tremendously in the last two decades. Since the first clinical study almost 20 years ago, gene therapy has been successfully used in very diverse fields, including genetic diseases, metabolic disorders, and more recently neurological diseases. Theoretically, gene therapy can be applied to any disease for which the cascade of pathophysiological events has been identified. Indeed, gene therapy has proved beneficial in simple genetic as well as complex acquired disorders, as this approach enables either overexpression or knockdown (using interfering RNA) of genes within a pathological network. However, some technical constraints remain, and new gene therapy vectors with better efficiency and specificity have been developed to overcome these limitations and widen the field of application. The outcomes of recent clinical trials are very promising and suggest that gene therapy could be beneficially applied for several neurological disorders.

There is a significant unmet need for new therapeutic approaches in epilepsy. About one-third of epileptic patients suffer from pharmacoresistant seizures – despite the development of new antiepileptic drugs. For many of these patients, particularly those with temporal lobe epilepsy, surgical resection is often the only effective therapeutic alternative. Moreover, antiepileptic drugs do not prevent the progression of the disease, and seizure management is often synonymous with lifelong pharmacological treatment, with side-effects that can be debilitating and the risk of increasing refractoriness over time. Some exciting preclinical studies, using experimental animal seizure and epilepsy models, and human data from early stage trials for other neurological disorders, suggest that gene therapy is now ready for translation to the epilepsy clinic.

Background

The majority of epilepsies are complex acquired disorders with both genetic and environmental contributions. Although initial forays into gene therapy targeted simple genetic disorders – for example cystic fibrosis and hemophilia – the early disappointing results suggested that genetic disorders are not necessarily the ideal indications. For the majority of genetic disorders, mutations are found throughout the body, and typically it is not a single cell population or tissue that needs correction in order to reverse the disease phenotype. Moreover, the efficient transduction of both multiple cell types and/or organs is problematic; further, systemic gene therapies, particularly those involving viral vectors, have often elicited significant immune responses, thus limiting the efficacy of the approach.

In the field of seizure disorders, an increasing number of causative genetic mutations have been identified in familial epilepsies, with the majority resulting from polymorphisms in ion channels. However, pure monogenic epilepsies are relatively rare. Further, it is often not clear which cells (within the CNS) harboring the mutation(s) are most critical in inducing the epilepsy phenotype. The situation is further complicated by compensatory mechanisms that cloud the link between a genetic mutation and the hyperexcitability phenotype. Finally, it is very difficult to design an effective gene therapy intervention for a disease that involves a large area of the brain, simply because of the technical limitations of achieving widespread gene transfer. For these reasons, genetic forms of epilepsy are amongst the most challenging and have not been the initial target for development of gene therapy-based treatments.

Focal epilepsies, and in particular temporal lobe epilepsy, are more ideal candidates for gene therapy. The pathophysiology of temporal lobe epilepsy has been well studied in animal models, as well as in the analysis of surgically resected tissue, and several candidate genes show promise as potential therapeutic targets. Furthermore, the epileptogenic area can be well defined by imaging and physiological recording techniques. Gene therapy allows specific targeting of the epileptogenic region, thus sparing the surrounding healthy tissue and minimizing side effects that often go hand in hand with small molecule antiepileptic drug treatment.

Methods – Gene Delivery to the CNS

Delivery of nucleic acids to the brain is a technical challenge because of the presence of the blood–brain barrier, which limits access to the CNS of peripherally administered drugs or biological agents. Intranasal administration of DNA, using different vectors, has been attempted; however, the resulting level of brain transgene expression obtained with this technique is very limited. Furthermore, any systemic delivery method is not appropriate for therapies in which transduction of only a focal region of the brain is required, since current vectors typically are not able to target selected subpopulations of cells when delivered systemically.

An invasive approach, specifically local injection via stereotactic surgery, is a far more efficient method to deliver a therapeutic gene to a specific area of the brain. Moreover, with the current generation vectors, a relatively low number of virions (vector particles) can be injected and typically do not induce an immune or toxic or inflammatory response. In addition, very high levels of transgene expression in the vicinity of the injection can be achieved by this route. To date, this approach is by far the most commonly used method of gene delivery to the brain, and the only approach used in current neurological gene therapy clinical trials. A major advantage of direct in vivo gene transfer to the brain is the limited immune response induced after intraparenchymal delivery. The CNS is largely devoid of antigen presenting cells, with only a very limited lymphatic system present. However, invasive surgery induces a breach of the blood–brain barrier and the potential penetration of large molecules and even cells, including activated lymphocytes. Therefore, the notion that the brain is immunologically privileged has been somewhat reevaluated; while the immune response observed in the brain is generally less robust or functionally important than in other peripheral organs, it remains an important factor in the choice and design of the technique for gene transfer. Other essential factors to be considered are the efficiency of gene delivery, the level and stability of transgene expression, and the ability to regulate transgene expression. Different techniques have been used to express a gene in a specific region of the brain, including cells transplantation in an ex vivo approach (fetal cells, immortalized cells, fibroblasts), nonviral vector delivery (e.g., liposomes and polymers), and viral vectors. Of the latter, the most commonly used in the CNS include herpes simplex virus, lentivirus, adenovirus, and adeno-associated virus (AAV).

Nonviral, lipid, and/or polymer-based systems of gene delivery are the simplest technique for gene delivery. Their main advantages are their high loading capacity, low immunogenicity, and their ability to transfect nondividing cells. However, gene expression is inefficient and transient, and these systems are not yet sufficiently developed for effective clinical translation in neurology. Similarly, nonviral delivery of naked DNA is not currently feasible because of the low efficiency of transfection and the high level of immune response.

The two main techniques used for gene therapy in clinical applications are ex vivo gene transfer involving transplantation of the transduced cells and direct in vivo cellular transduction by viral vectors. Cell transplantation approaches currently emphasize the use of stem cells, typically embryonic stem cells (ES) or adult stem cells. Their main advantage is the high compatibility of the transplant with the host. Additionally, ES cells are pluripotent and can differentiate into either glia or different neuronal phenotypes. In vitro, these cells can be transfected to express a protein of interest. However, controversy over the use of human ES cells (which requires destruction of the embryo), has limited their use in the clinic. The development of porcine fetal tissue as xenograft material has been proposed to overcome the limitation of stem cells availability. Xenotransplants have been made in patients with neurodegenerative diseases. Studies suggest that the graft may survive and even successfully develop synaptic contacts with host cells, but the use of this approach is still limited because it carries additional risk of infection due to animal pathogens – and the

probability that the graft will be rejected is increased compared to allogeneic grafts.

Viral vectors are currently the most promising tools to directly introduce a gene into the brain, with the current emphasis on herpes simplex virus (HSV), adenovirus, lentivirus, and AAV vectors. Retroviruses are not applicable for the adult brain and differentiated neuronal cells because they require the cell to undergo mitosis for integration and expression. Furthermore, the use of retroviruses in gene therapy has raised safety issues due to the possibility of insertional mutagenesis. HSV, AAV, and lentiviruses (typically HIV, EIAV (equine infectious anemia virus), or FIV (feline immunodeficiency virus)) transduce both dividing and nondividing cells, and are therefore suitable vectors for gene therapy of neurological disorders. Each of these vector systems has distinct advantages and limitations for CNS applications and potential clinical translation. These advantages and limitations have been extensively reviewed elsewhere (see Further Reading).

Our lab has focused on the use of recombinant AAV vectors (rAAV) due to the lack of induction of a cellular immune response and the high level of transgene expression that can now be routinely achieved. AAV is a nonpathogenic single stranded DNA virus that belongs to the parvovirus family. In the absence of a helper virus that provides the genes necessary for its replication, AAV infects the cell; following transport and uncoating, the genome remains stable (as an episome) essentially for the life of that cell. In this form, AAV is nondeleterious for the host cell and gene expression can persist stably (**Figure 1**).

Recombinant AAV (rAAV) are obtained by insertion of a transgene cassette between the inverted terminal repeats sequences (ITR). Further development of the vector is still needed, including improvement of expression cassettes, which have a packaging limit of approximately 4.7 kb, and the characterization of cell-specific promoters to express in a restricted subset of cells. A large number of AAV serotypes have now been isolated from humans and nonhuman primates, and many of those that have been characterized so far display differing tropism for various neuronal types and brain areas. The rAAV vectors that have been characterized to date have strong neuronal tropism, and are therefore not optimal for gene therapy of disorders requiring transduction of glial cells. High throughput functional screening was developed for more recently isolated serotypes, which have been tested for their tissue tropism and gene transfer potency. Several serotypes are raising interest. Amongst them, AAV9 displays a broad tropism and shows a higher transfection efficiency than the other serotypes in the different tissues tested, making it an interesting vector for systemic disorders. AAV2 was the first vector used and remains the vector of choice for most neurological indications. This serotype displays a very good neuronal tropism, negligible diffusion, and no local or diffuse toxicity. AAV1 also has strong neuronal tropism and no toxicity, with the advantage of a higher transduction efficiency. In our hands, these two serotypes (AAV1 and AAV2) remain the most appropriate vectors for current and future therapeutic applications.

Results

Experimental Studies

Experimental animal models of epilepsy have been used to assess several alternative gene therapy approaches.

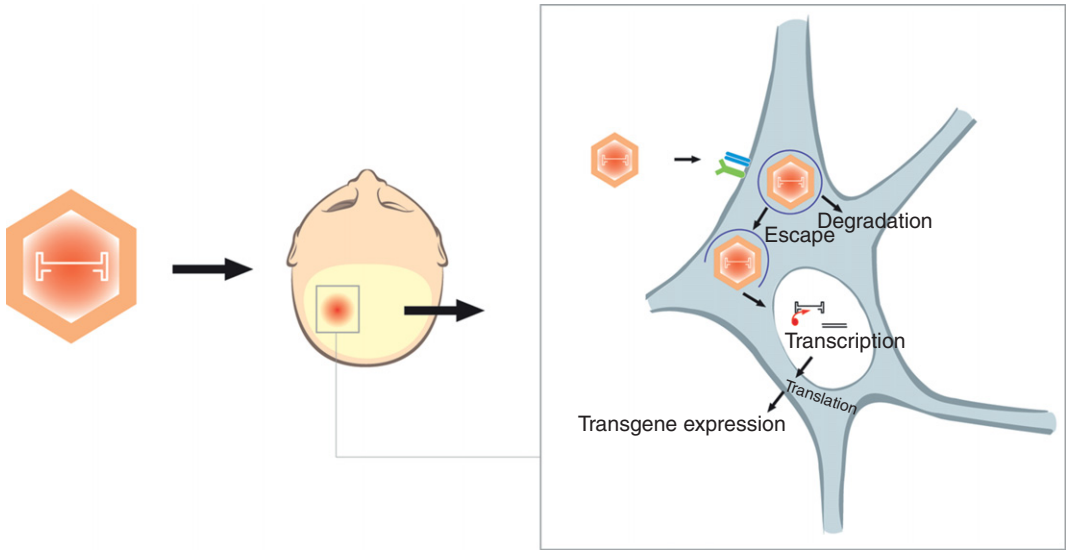

Figure 1 Schematic illustration of rAAV transduction into the host cell in gene therapy. rAAV binds to heparan sulphate proteoglycans (with integrins or fibroblast growth factor as coreceptors), and is endocytosed. A portion of rAAV escapes the endosomal compartment and translocates to the nucleus. Second strand synthesis in the nucleus provides a stable double strand DNA template for transcription and leads to the expression of the transgene.

Genetic strategies to enhance GABA-mediated inhibition has been an early strategy, based on pharmacologically validated data showing that an increase in GABAergic neurotransmission in the epileptogenic area increases the threshold for excessive neuronal excitability, hence decreasing seizure occurrence. Different techniques of in vitro or in vivo transfection of glutamic acid decarboxylase (GAD, the rate limiting enzyme that catalyzes the synthesis of GABA), have been used to increase GABA levels in the tissue of interest. Transplantation of fetal GABAergic neurons into the *substantia nigra* (SN), a structure involved in the propagation of seizures, induces transient decrease in seizure severity in the kindling model. Similarly, transplantation of engineered mouse cortical neurons and glia expressing GAD65 into the SN or piriform cortex shows an anticonvulsant effect. Viral vector-based approaches have also been used to directly express GAD in cultured rat hippocampal neurons. The different techniques used in these studies were able to induce the expression of exogenous GAD in the target cells and thereby increase GABA production and release. However, the expression obtained with ex vivo transduction and subsequent cell transplantation was only transient in some studies. In addition, the effects observed were largely the consequence of a local increase of GABA levels from the transplanted cells – which therefore appear to act simply as biological GABA pumps. A complementary approach has been to express GABA(A) receptor subunits, specifically the alpha1 subunit; this study showed therapeutic efficacy in a rat pilocarpine model. However, the effect of a strategy that targets cell populations non-specifically are difficult to predict. Indeed, in the hippocampus, the hyperexcitability occurring in epilepsy is likely due (at least in part) to the reorganization of neuronal circuits – including the loss of a specific population of interneurons and feedback inhibition. Conversely, some interneurons are preserved under these epileptic conditions, and are believed to underlie network synchrony. Transduction (and auto-inhibition) of these two different systems could have dramatically opposite effects on epileptic seizures. This complexity emphasizes the importance of both promoter choice and vector tropism. More importantly, these considerations emphasize that for conditions like epilepsy, vectors may need to be engineered to transduce a specific cell population.

Over the past decade, the modulatory roles of neuropeptide Y (NPY) and galanin, as well as the action of adenosine, have been well established. The observation that epileptic seizures induce the release of these neuropeptides and nucleoside led to the hypothesis that they play an important role in arresting epileptic activity. Experimental studies further confirmed their anticonvulsant and neuroprotective roles, and suggested that these neuropeptides and adenosine, and their receptors, constitute an endogenous system to control epileptic activity. These systems thus appear a promising target for the development of new therapeutics – and in particular may be excellent targets for gene therapy.

Several experimental studies showed that galanin is released during epileptic seizures and has an inhibitory effect on neuronal activity through presynaptic inhibition of glutamatergic transmission, as well as a strong neuroprotective effect. Administration of galanin or nonpeptide ligands for the galanin receptor also induces a robust anticonvulsant effect in animal models of limbic seizures. In a study from our laboratory (see Further Reading), a recombinant adeno-associated viral (AAV) vector, constitutively overexpressing galanin, was injected into the rat hippocampus. Kainic acid-induced seizure activity was significantly decreased, confirming the antiepileptic effect of galanin in vivo. Interestingly, administration of rAAV-galanin resulted not only in long lasting expression of galanin, but also in the transport of the neuropeptide along the axonal arborization. rAAV-galanin has also been demonstrated to suppress acute seizures activity induced by electrical stimulation in rats and had a neuroprotective effect on hilar cells.

The inhibitory neuromodulator adenosine has also raised interest as an endogenous anticonvulsant. Decreased adenosine levels have been observed in different models of epileptogenesis and epileptic activity. Interestingly, adenosine has also been shown to restrict the site of epileptogenesis. An experimental approach using an ex vivo gene therapy based on transplantation of cells engineered to release adenosine, has shown that secreted adenosine protects from seizures in the kindling model.

In several animal models of epilepsy, seizure-induced increases of NPY mRNA and protein have been observed in the dentate gyrus of the hippocampus, suggesting a modulatory role of the neuropeptide on neuronal excitability. This role was confirmed by in vitro data showing that application of NPY to hippocampal slices reduces glutamatergic synaptic excitation; in vivo studies have also shown a strong anticonvulsant effect of NPY mediated by the Y2 and Y5 receptors. In addition, NPY knockout mice develop spontaneous epileptic seizures, confirming the importance of NPY in controlling neuronal excitability. In human tissue from temporal lobe resection, NPY-mediated neurotransmission is altered by seizures, and the modulatory role of NPY on epileptic activity has also been validated on hippocampal slices. The effect of chronic overexpression of NPY in the hippocampus, mediated by gene therapy was examined in the kainic acid model in rats. rAAV-mediated gene transfer of NPY (injections into the hippocampus) delayed seizure onset and dramatically decreased the occurrence of epileptic seizures. Moreover, in a progressive spontaneous seizure model, the AAV-NPY vector was able to significantly reduce the number of seizures and stop progression, suggesting a potential anti-epileptogenic effect.

Recent Results in Clinical Trials and Future Developments

Clinical experience with gene therapy to date has largely been for rapidly fatal disorders. These studies, for the most part, have not surprisingly shown only limited efficacy, although the tide is shifting and increasingly gene therapy trials are showing significant benefit. Notably, in contrast to its reputation as a high risk intervention, gene therapy has had minimal adverse events compared to other breakthrough technologies, and appears safer than alternative surgical approaches. Published data on neurological gene therapy trials is limited, but appears promising, particularly in Parkinson's disease.

There has been only one clinical genetic intervention study for epilepsy. In this first ex vivo gene therapy trial for epilepsy, surgeons implanted a xenograft of GABA expressing cells in a patient candidate for temporal lobe resection. This procedure failed to show an antiepileptic effect. Several issues arise from the use of transplants in neurological diseases. In addition to the limited availability of some cells and tissues (e.g., embryonic stem cells), the survival of the graft is variable. Experimental results in animal models also tend to show a limited survival time of cell transplants in the epileptic brain. Moreover, transformed cells have oncogenic potential, and large tumors can result. Furthermore, the temporal lobe is a highly heterogeneous structure, organized into complex layers. The type of synaptic connections that a graft would develop in this multisynaptic circuit is unknown. In addition, the transplanted cells would be subject to recurrent hyperexcitability in the epileptogenic area, which may affect the survival of these cells. Data obtained from experimental animal studies suggest that a direct in vivo viral vector approach is a more feasible strategy for clinical trials. As indicated above, the most established vector system for in vivo gene transfer in mammalian brain is that of AAV. Indeed, gene transfer into cells in human hippocampal slices (obtained from temporal lobectomy cases), using an AAV vector, showed an efficient level of cell transduction in epileptic tissue.

The most comprehensive in vivo gene therapy trial for neurological disease to date involved Parkinsonian subjects (see our 2007 *Lancet* study in Further Reading). The infusion of AAV vectors expressing GAD65 and GAD67 in the subthalamic nucleus induced a significant and persistent improvement in motor symptoms. None of the patients developed any immune response against AAV or the transgene GAD, and no adverse events relating to the gene therapy was observed. In addition, biodistribution studies have shown that the transgene expression is limited to the structure injected, with negligible spread into the surrounded structures. A second study has also recently been published (see 2008 *Lancet Neurology* paper in Further Reading) in which the authors again used AAV, but a different transgene, the growth factor neurturin, delivered to the putamen and caudate. This study showed also safety and tolerability, with significant improvements in clinical outcome.

In contrast to neurodegenerative disorders in which attempts to replace or regenerate lost cell populations have been a common theme, in epilepsy the emphasis has been to disrupt the abnormal epileptic activity and restore normal inhibition. The most established approach, and the most consistent experimental data, have been obtained through modulation of endogenous inhibitory peptidergic signaling (i.e., with galanin and NPY), as well as using the nucleoside, adenosine. These strategies are most likely translate to clinical trial in the near future. Indeed, we submitted an AAV-NPY based clinical trial to the Recombinant DNA Advisory Committee of the USA (www4.od.nih.gov/oba/RAC/meetings/Sept2004/RACagenda092304.pdf) and have subsequently filed an IND to the US FDA for a Phase I trial.

Conclusions and Future Directions

In conclusion, the experimental and clinical data obtained from other neurological diseases have shown the feasibility of gene therapy for epilepsy. Subjects who are good candidates for temporal lobectomy are an ideal population, since the gene transfer would occur in the brain region which has been planned for resection, providing a built-in rescue procedure if the gene therapy was ineffective or associated with significant adverse events. The relatively low risk associated with gene therapy, and the promising preclinical data on both NPY and galanin gene transfer in experimental animal models, suggest that temporal lobe epilepsy is an ideal context for clinical testing.

Gene therapy for neurological diseases is still at an early stage. It will require more safety data as well as technical advances to consider gene therapy as a therapy for a larger population of epileptic patients. Viral vectors are undergoing further developments to restrict gene transduction to a cell subpopulation and allow a better control of gene expression. Cell type-specific promoters, conditional expression with inducible promoters, and insertion of a larger expression cassette, are all features of these vectors now under development. The diffusion of the vector (in particular through retrograde transport) is also an important factor to take in account.

In the NPY clinical trial, the approach is that of potentiating an endogenous system of seizure modulation. This approach is worth further analysis and development, inasmuch as it may induce less compensatory effects, and be more efficient than trying to compensate for a loss of a specific neuronal population, in particular, in a sclerotic hippocampus that has encountered multiple plasticity phenomena and reorganization.

The goal of gene therapy for epilepsy is to obtain not only a sustained anticonvulsant effect, but also an antiepileptogenic effect that will block the progression of the disease, maintain focalization of the epileptic zone, and/or stop secondary generalization.

Gene therapy offers a variety of tools to target the disease at different levels, from expression of inhibitory neuropeptides or neuromodulators to antiapoptotic genes, to neurotrophins and receptors channels. With such a comprehensive approach, there is a strong likelihood of achieving a robust therapeutic effect. To conclude, experimental and clinical data suggest that gene therapy is likely to have a significant impact on epilepsy management in the coming decade.

Introduction

Although a large number of anticonvulsant drugs are available to treat those with epilepsy, a significant proportion of patients with epilepsy are refractory to treatment. In addition, a significant number of patients suffer from side effects from the drugs used to treat their seizures. Thus, there is a continued need to develop more effective and safer drugs for the treatment of epilepsy.

Plants have provided an important source of medicine. In fact, the availability of plant products, such as quinine for the treatment of malaria, has played an important role in the history of mankind. There are a number of traditional systems of medicine, such as traditional Chinese medicine, Ayurveda (Indian), Tibetan medicine, unani-tibb (Greco-Arabic), and Kampo (Japanese), that have long histories of effective use of herbal preparations. In addition, various native peoples, in the Americas and elsewhere, have a history of using plant material to effectively treat symptoms of disease. Although these traditional medicines are considered to have efficacy, the scientific basis of that efficacy is not understood. As science evolved and the field of medicine emerged, investigations into herbal remedies attempted to demonstrate efficacy in controlled trials and to identify the active components. As more work has been done with these traditional medicines, it has become apparent that there are a number of active ingredients in plants. A number of prescription medications currently in use in the United States are isolated from plants or derived from plant components. In fact, plants are the basis of at least 30% of the drugs available today. However, the use of herbal extracts is not generally accepted by Western medicine.

Our understanding of herbal products has been limited by the fact that there are often multiple active ingredients in one species of plant. Some of the components may have beneficial effects and some may be toxic. There has rarely been standardization of the preparation of extracts

Introduction

Although a large number of anticonvulsant drugs are available to treat those with epilepsy, a significant proportion of patients with epilepsy are refractory to treatment. In addition, a significant number of patients suffer from side effects from the drugs used to treat their seizures. Thus, there is a continued need to develop more effective and safer drugs for the treatment of epilepsy.

Plants have provided an important source of medicine. In fact, the availability of plant products, such as quinine for the treatment of malaria, has played an important role in the history of mankind. There are a number of traditional systems of medicine, such as traditional Chinese medicine, Ayurveda (Indian), Tibetan medicine, unani-tibb (Greco-Arabic), and Kampo (Japanese), that have long histories of effective use of herbal preparations. In addition, various native peoples, in the Americas and elsewhere, have a history of using plant material to effectively treat symptoms of disease. Although these traditional medicines are considered to have efficacy, the scientific basis of that efficacy is not understood. As science evolved and the field of medicine emerged, investigations into herbal remedies attempted to demonstrate efficacy in controlled trials and to identify the active components. As more work has been done with these traditional medicines, it has become apparent that there are a number of active ingredients in plants. A number of prescription medications currently in use in the United States are isolated from plants or derived from plant components. In fact, plants are the basis of at least 30% of the drugs available today. However, the use of herbal extracts is not generally accepted by Western medicine.

Our understanding of herbal products has been limited by the fact that there are often multiple active ingredients in one species of plant. Some of the components may have beneficial effects and some may be toxic. There has rarely been standardization of the preparation of extracts

from these plants. In addition, the concentrations of the active components in these plants may vary, depending on the growing conditions (including weather and soil type) and which part of the plant is used (roots compared with leaves and stems or seeds or berries) to prepare the extract. Finally, clinical or animal studies to demonstrate effectiveness have not always utilized the same preparation. Thus, herbal products have struggled to gain acceptance in modern medical practice.

In 2004, the Food and Drug Administration (FDA) in the United States developed specific guidelines for the development of botanical products. These guidelines take into account the fact that there is often a long history of human use of a particular plant. For legally available products with no known safety issues, there is a reduced requirement for preclinical safety data and reduced documentation of the chemistry, manufacturing, and controls needed to support an Investigational New Drug (IND) application for initial clinical studies. In fact, the FDA does not require identification of all of the constituents in a botanical product for an IND application. There is, however, a requirement for controls that will ensure the identity, purity, quality, potency, and consistency of the botanical product.

For the purposes of the FDA guidelines, a botanical product is a labeled product that contains vegetable matter as ingredients. There are specific definitions for whether a botanical product is considered a food, a dietary supplement, and/or a drug. A botanical product is considered a drug if it is intended for use in diagnosing, mitigating, treating, curing, or preventing disease – as it would be if it were marketed as an anticonvulsant or antiepileptic agent. As a drug, it is subject to different regulations than if the botanical product were to be considered a dietary supplement.

Background

Over 50 plants, or plant products, have been reported to have anticonvulsant activity. Most of these products have been reported to have efficacy in in vivo animal models, but a few have been shown to have activity only in in vitro systems/models. Of these products, about one-third has been analyzed to determine the active components. The structure of the active component has been determined in 80% of those plants in which the active compound has been isolated. As can be seen in **Figure 1**, a wide variety of these structures have activity in the central nervous system, from fairly simple compounds to steroidal saponins to quite complex compounds. Thus, more than a single class of compounds produced in plants has activity, and research on the activity of these compounds needs to be comprehensive.

To date, none of the currently available anticonvulsant drugs was derived from a plant product or derived from a traditional medical system. Huperzine A, a cholinesterase inhibitor used in traditional Chinese medicine for dementia, is moving towards clinical trials as an anticonvulsant.

Methods

Any of the currently available models of seizures or epilepsy could be used to test the efficacy of herbal products. However, if one wants to evaluate the antiepileptic effects of a plant product that is used in traditional medicine somewhere in the world, then one would like it to be effective in an in vivo model. Although an in vitro model (such as induced epileptiform activity in a hippocampal slice) might be a faster way to screen a large number of extracts or isolated components, these preparations have significant limitations with respect to interpreting the in vitro effects. If an extract or herbal product has activity in an in vivo model, then it must be able to cross the blood–brain barrier (not the case for an in vitro model); if an active metabolite is important for the activity of the product/extract, then it may only have efficacy in the whole animal. An in vivo model will not distinguish between an effect on seizure spread or focal seizure initiation, but drugs acting on either will have antiepileptic efficacy.

Within the in vivo models of seizures and epilepsy, one could use either an acute or chronic model of seizures. A chronic model of spontaneous seizures most closely mimics the clinical situation, but requires long-term monitoring. In contrast, an acute model has the advantage that the seizures will occur at a predetermined time, as elicited with electrical stimulation or with chemical convulsants. Normally, with electrical stimulation, the animal receives a stimulus train to determine the seizure threshold and then a suprathreshold stimulation is used to repeatedly elicit seizures for drug testing. With chemical convulsants (pilocarpine, kainic acid, etc.), the seizure onset is more gradual and it is possible to determine whether a drug alters the early processes involved in seizure initiation. Using electrical stimulation or infusion of pentylenetetrazol, it is possible to test the effect of drugs on the seizure threshold.

The National Institutes of Health (NIH) has an anticonvulsant screening program that was designed to encourage and facilitate the discovery of new therapeutic agents for the treatment of seizure disorders. Evaluation of a submitted compound begins with a comparison of the compound's structure with stru ctures of other compounds in the NIH database (over 21 000 compounds). Compounds are then screened in a variety of accepted animal models of seizures. Herbal products can be submitted to this program for testing in these animal models. The program will test compounds that consist of complex mixtures of constituents, as well as isolated/purified

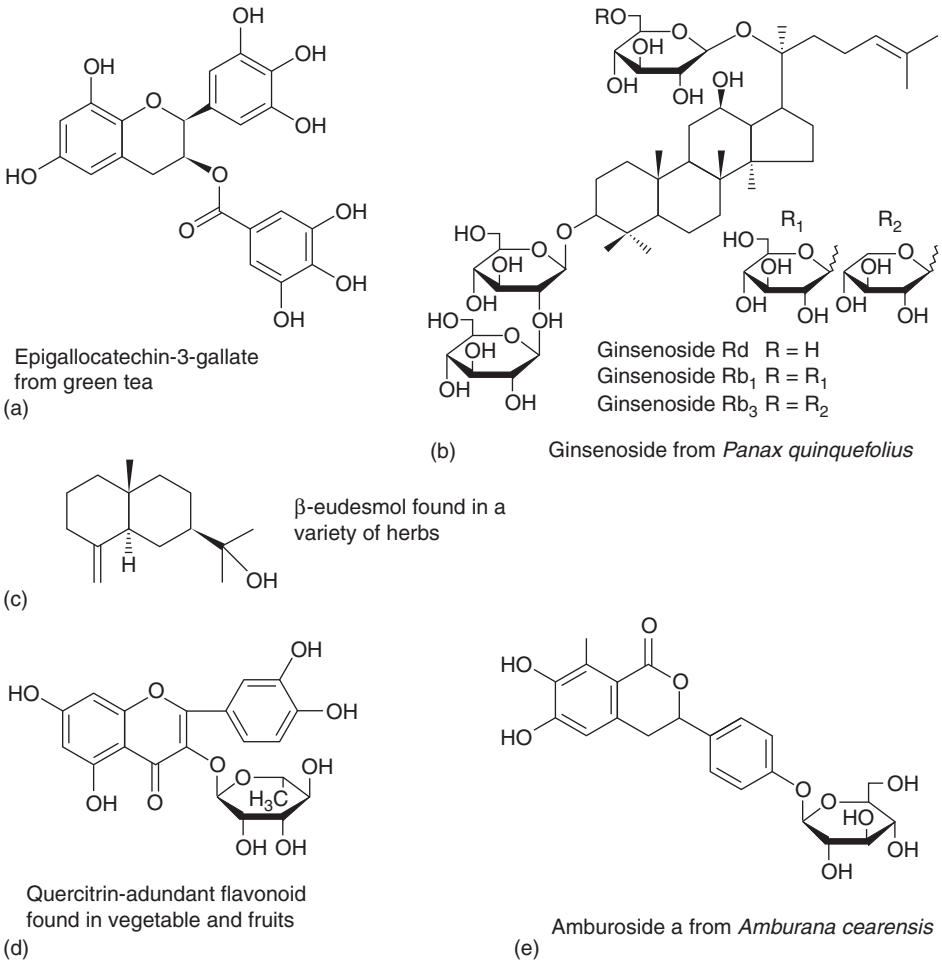

Figure 1 (a) The structure of EGCG, a polyphenol found in Green Tea. EGCG has been shown to have anxiolytic activity, antioxidant activity and an interaction with $GABA_A$ receptors. (b) The structure of three of the active components (ginsenosides) in ginseng that have been shown to have anticonvulsant activity. (c) A sesquiterpenol found in a variety of Chinese herbs. β-Eudesmol has been shown to reduce convulsions induced in mice. (d) The structure of the glycoside form of quercetin, a flavonoid from vegetables and fruits that has been shown to have antioxidant properties. (e) The structure of a compound isolated from the trunk-bark of *Amburana cearensis*, a tree common to the Brazilian northeastern savannah, which has been shown to have neuroprotective activity.

constituents. The results are returned to the investigator and the investigator can make a decision about whether to proceed further with drug development.

Recent Results

One herbal product that has been reported to have anticonvulsant activity is ginseng. The results from animal testing of ginseng will be used here as an example of the process involved in testing an herbal product. There are seven major species of ginseng, but the three most commonly used in traditional medicines are *Panax ginseng* (Asian), *P. quinquefolius* (American), and *P. japonicus* (Japanese). In traditional Chinese medicine, Asian ginseng is used for shock, syncope, shortness of breath, and weak pulse; American ginseng is used for mild depression, chronic stress, age-related memory loss, and cloudy thinking. Native Americans have used American ginseng as a bitter tonic and for nervous afflictions. The biological activity in ginseng is thought to be due to the presence of saponins (**Figure 1**) called ginsenosides. Numerous pharmacological effects have been attributed to ginsenosides, both in the central nervous system and peripherally. Few clinical trials have been carried out for any species of ginseng.

Over 28 ginsenosides have been isolated from all major species of ginseng. These ginsenosides have been divided into two groups, based on structure: the panaxadiols (Rb_1, Rb_2, Rb_3, Rc, Rd, Rg_3, Rh_2, and Rh_3) and the panaxatriols (Re, Rf, Rg_1, Rg_2, and Rh_1). Although the root is most commonly used, the leaves and stems of the ginseng plant also contain ginsenosides. According to traditional Chinese medicine, Asian ginseng nourishes the *yin* and *qi* and

is energetically 'hot,' while American ginseng is believed to be 'cooler.' Interestingly, American ginseng generally contains a lower Rg_1/Rb_1 ratio than does Asian ginseng, and this difference is thought to be the basis of the difference in the 'hotter' and 'cooler' nature of the two species. That ginseng may have anticonvulsant activity was suggested in 2002. It was reported that the kainic acid-induced seizures in rats were shorter when the animals were pretreated with a mixture of ginsenosides from Asian ginseng. In addition, some of the ginsenosides have been reported to have neuroprotective activity.

Although knowledge about a product's mechanism of action in the central nervous system is not needed to develop a drug for clinical use, understanding the action would enhance development of related drugs. However, relatively little is known about how the ginsenosides might work as either neuroprotective or anticonvulsant agents. Ginsenosides are amphiphilic in nature and have the ability to intercalate into the plasma membrane, leading to changes in membrane fluidity. This property could alter the function of the membrane itself and also alter the function of receptors and other proteins within that membrane. There is also some evidence of direct interactions of ginsenosides with membrane bound steroid receptors. However, the most accepted theory is that at least some of the ginsenosides have antioxidant activity and the ability to scavenge free radicals. How an antioxidant would be anticonvulsant is not known. There could also be actions of the ginsenosides that have not yet been discovered.

For the initial study of the anticonvulsant properties of ginseng, both American and Asian ginseng varieties were considered. However, the relatively higher concentration of the panaxadiols (Rb_1 and relatives) in American ginseng suggested that this species might contain more of the anticonvulsant compound(s). An analysis determined that an extract from the root of Asian or American ginsengs contained 30.2% ginsenosides; extract from the leaves and stems contained 85% ginsenosides. These preparations were tested in animals given either pilocarpine (300 mg kg^{-1} i.p., preceded by methylscopolamine 1 mg kg^{-1} subcutaneous) or pentylenetetrazol (50 mg kg^{-1} i.p.). When status epilepticus was induced with pilocarpine, administration of these extracts actually increased mortality; it appeared that the root extract (30% ginsenosides) was more toxic than the extract prepared from the leaves and stems (85% ginsenosides). This observation suggested that some of the non-ginsenosides in the root extract are toxic. The study also led to the recommendation that persons with epilepsy should not take any of the available ginseng products available as food supplements in the United States, since they are all prepared from ginseng root.

Although the results with the extract from the leaves and stems were somewhat variable, it appeared that there might be some anticonvulsant activity in this preparation. These results, plus some data in the literature suggesting a neuroprotective action of the panaxadiols, led to the hypothesis that the panaxadiols (Rb_1 and relatives) might contain the anticonvulsant activity. Therefore, a partial purification of ginseng, to concentrate the Rb ginsenosides, was carried out using leaves/stems from American ginseng. The product of this partial purification, called the Rb extract, was then compared with the root preparation and leaves/stems preparation (also from American ginseng). Doses of the whole root and leaves/stems preparations were calculated to provide equivalent doses of the ginsenosides in the Rb extract. The Rb extract had a dose-dependent anticonvulsant effect – increasing the latency to the seizures, decreasing the seizure score, and shortening the seizure duration. In addition, it reduced weight loss and subsequent neuronal damage after pilocarpine, and reduced mortality after pentylenetetrazol. In contrast, the root extract worsened seizures (as indicated by the decrease in latency to seizure onset and mortality), while the extract from the leaves and stems had relatively little effect (did not worsen seizures, but also did not reduce their severity). The Rb extract was also tested for effectiveness against kainic acid-induced seizures. The extract significantly increased the latency to seizures and decreased the seizure score in a dose-dependent fashion. These results suggest that some ginsenosides are anticonvulsant, but that other components of the whole extract from roots or leaves/stems are either proconvulsant or contain components that neutralize the anticonvulsant activity (**Table 1**).

The obvious next step was to determine which of the components in the Rb extract has anticonvulsant activity. The Rb extract contains 24.8% Rb_1, 46.4% Rb_3, and 13.1% Rd. The anticonvulsant activity of these individual ginsenosides was tested in the same animal models and using the same measured parameters. Doses of individual ginsenosides were calculated to provide an equivalent dose to the 20 mg kg^{-1} of the Rb extract. Using purified ginsenosides, a mixture was also prepared that matched the relative concentrations of the ginsenosides in the Rb extract. This mixture was used to determine that these three ginsenosides are the active components in the Rb extract. Pretreatment with Rb_1, Rb_3, Rd, or the mixture significantly increased the latency to the first wet dog shake induced by kainic acid. All the ginseng products appeared to reduce the seizure score after administration of kainic acid and pilocarpine, but this decrease did not reach statistical significance. Only the mixture of purified ginsenosides and the Rb fraction significantly reduced the seizure score. The same trend held for the seizures induced by pentylenetetrazol; the purified ginsenosides caused a modest increase in the latency to the seizures (which did not reach statistical significance). Only the mixture and the Rb extract produced a significant increase in the latency and duration of the seizure activity.

Table 1 Activity of various preparation from American ginseng

	Pilocarpine		*PTZ*		*Kainic acid*	
	Latency	*Severity*	*Latency*	*Duration*	*Latency*	*Severity*
Root	–	–	–	–	n.t.	n.t.
Leaves/stems	–	+	+	+	n.t.	n.t.
Rb extract	++	++	++	++	++	++
Rb_1	–	+	–	+	++	+
Rb_3	–	+	+	+	++	+
Rd	–	+	+	+	++	+

– = no effect; + = suggestion of anticonvulsant activity, but not statistically significant; ++ = statistically significant anticonvulsant effect; n.t. = not tested.

These data suggest that the individual ginsenosides have some anticonvulsant activity, but since a dose–response curve was not done with each of the individual ginsenosides, it is not known whether a single ginsenoside has equivalent efficacy to the Rb extract. The mixture of ginsenosides suggests that the activity of the individual ginsenosides is additive – producing an effective product.

The Rb extract was also submitted to the NIH anticonvulsant screening program for testing. It was tested in three animal models of seizures – subcutaneous pentylenetetrazol (50 mg kg^{-1}), 6 Hz stimulation at two stimulus amplitudes, and kindling. The Rb extract was not considered effective in these models. However, the animals were only evaluated for the presence or absence of seizures; no delay in seizure onset or changes in seizure severity were specifically measured.

Because of the long history of safe use of ginseng in humans, a preparation of root extract would need little additional safety data before a clinical trial could be started. However, the data suggest that the root extract might actually be harmful. The animal studies show that ginseng is a mixture of active compounds, include one group with anticonvulsant activity and one group that appears unsafe when the animal has seizures. When a partial purification is done to remove the potentially harmful components and concentrate the anticonvulsant components, the anticonvulsant potential looks quite promising. Either a defined extract, such as the Rb extract, or purified individual ginsenosides could be developed for clinical testing as anticonvulsant medication. However, because there is no history of use of these specific preparations in humans, for FDA approval they are considered new drugs. In this instance, a complete battery of preclinical data would need to be collected and submitted for review – making the development of such compounds, even for preliminary testing, quite time-consuming and expensive.

Future Goals

Given the number of plants that have been shown to have some anticonvulsant activity in either animal experiments or in humans, it is highly likely that useful medications for the treatment of epilepsy could be developed from herbal products. Successful development of new drugs from plant products will require careful consideration of the needs for animal testing, including plans for future development and clinical testing. The most efficient route is to demonstrate activity with an existing botanical product with clear evidence of safety with human use. However, even in this instance there is a need to determine the component(s) in the botanical product that has anticonvulsant activity. This determination would allow for standardization of the product with respect to its clinical utility, and would result in greater acceptance of such a product for use by patients with epilepsy and by the physicians who care for them.

The identification of a single (or multiple) component with anticonvulsant activity from a botanical product would be useful from a number of standpoints. If, as in the case of ginseng, the whole extract is less effective (or possibly harmful) than the partially-purified compound, identification of the active ingredients would direct the partial purification or concentration of the active components while simultaneously removing the harmful ingredients. Alternatively, the active ingredient could be purified and developed as a single agent. Finally, the structure of the active component could be used as a lead compound for the development of a new class of anticonvulsant compounds through the development of structural analogs – a strategy that might be more efficacious than tedious purification processes.

Studies of botanical products, particularly those most likely to be ingested by patients with epilepsy, must also provide evidence of safety for patient use. It is possible that some readily available herbal products, such as ginseng root extract, are potentially harmful in patients with epilepsy. These products may lower the seizure threshold or have interactions with medication to either increase the side effects or reduce the effectiveness of that medication. Changes in pharmacokinetics due to addition of an herbal product, and changes in efficacy or changes in seizure threshold, would need to be systematically examined.

While providing evidence of the mechanism by which a botanical product produces its anticonvulsant effect is not necessary for clinical trials (or for obtaining a patent on a compound), investigations into the underlying mechanism of a candidate substance could further our understanding of epilepsy. In neurology and psychiatry, much of our current understanding of disease is based on laboratory studies of drugs that are clinically effective. Investigations into the effects of novel anticonvulsants could provide important insights into the mechanisms of seizure onset and termination in the brain, and/or to understanding the abnormalities present in the epileptic brain.

Introduction

Despite unprecedented growth in the number of FDA-approved epilepsy therapies, seizures in approximately 25% of patients with epilepsy remain refractory to pharmacological treatment. Only a small fraction of these patients qualify for, and have access to, therapeutic brain surgery. Further, worldwide most people with epilepsy have no access to modern treatments. Therefore, there continues to be a pressing need for new and effective treatments for epilepsy, especially for those that are accessible and affordable to patients everywhere.

Herbal medicines, a subgroup of natural products, have provided several small molecules used to understand biological processes as well as the pharmaceutical agents that treat human disease. Herbal medicines display remarkable specificity and potency. Structural characteristics of natural products have been used to develop modern synthetic compound libraries. Over half of the best selling prescription drugs contain natural product derivatives.

In Asian countries, herbal medicines have an extensive history and continue to be used widely. For example, in China, there are at least 2500 hospitals devoted to Traditional Chinese Medicine (TCM), and the majority of patients treated at these hospitals receive herbal medicines. In addition, 95% of general (western style) hospitals in China have TCM departments. In China at least 13 000 farms specialize in the production of TCM herbal medicines, and more than 800 TCM pharmaceutical factories were found to produce an annual output of 400 000 tons of 500 kinds of herbal medicines.

In the Republic of Korea (South Korea), 151 hospitals and 8734 clinics of Korean Medicine have been devoted to providing medical care in the tradition of Korean Medicine. Most patients in those hospitals and clinics receive herbal medicines as the primary form of

Introduction

Despite unprecedented growth in the number of FDA-approved epilepsy therapies, seizures in approximately 25% of patients with epilepsy remain refractory to pharmacological treatment. Only a small fraction of these patients qualify for, and have access to, therapeutic brain surgery. Further, worldwide most people with epilepsy have no access to modern treatments. Therefore, there continues to be a pressing need for new and effective treatments for epilepsy, especially for those that are accessible and affordable to patients everywhere.

Herbal medicines, a subgroup of natural products, have provided several small molecules used to understand biological processes as well as the pharmaceutical agents that treat human disease. Herbal medicines display remarkable specificity and potency. Structural characteristics of natural products have been used to develop modern synthetic compound libraries. Over half of the best selling prescription drugs contain natural product derivatives.

In Asian countries, herbal medicines have an extensive history and continue to be used widely. For example, in China, there are at least 2500 hospitals devoted to Traditional Chinese Medicine (TCM), and the majority of patients treated at these hospitals receive herbal medicines. In addition, 95% of general (western style) hospitals in China have TCM departments. In China at least 13 000 farms specialize in the production of TCM herbal medicines, and more than 800 TCM pharmaceutical factories were found to produce an annual output of 400 000 tons of 500 kinds of herbal medicines.

In the Republic of Korea (South Korea), 151 hospitals and 8734 clinics of Korean Medicine have been devoted to providing medical care in the tradition of Korean Medicine. Most patients in those hospitals and clinics receive herbal medicines as the primary form of

treatment. Herb farms constitute one of the main agricultural industries of the country. Approximately 100 species are farmed, and nearly 300 species are collected from the wild and marketed. Similarly, Taiwan, Africa, and South America have rich traditions in herbal medicines.

People with epilepsy have used diverse therapies for thousands of years. Some of these therapies persist even today, especially where access to medical care is poor. Indeed, antiepileptic drugs (AEDs) and epilepsy surgery are relatively new in the history of epilepsy treatment. For example, bromides were introduced in 1857, phenobarbital in 1912, and epilepsy surgery in the 1940s.

Despite a lack of convincing evidence of efficacy and safety, surveys suggest that up to one-third of patients with epilepsy in the United States and the United Kingdom take herbs and/or dietary supplements, and that the majority of these patients do not discuss this intake with their physicians. Most of these patients do not take alternative medicines for seizure control, but rather for general health maintenance or for other symptoms – for example, valerian for difficulty sleeping, St. John's wort for depression, and *ginkgo biloba* for memory disturbance. Thus, the alternative medicines taken by a patient with epilepsy may be a clue to that patient's side effects from their anticonvulsants or comorbid disorders.

Although botanicals have historically been an important source of therapeutic compounds in general, they have been relatively understudied as epilepsy therapies. Therefore, our research has focused on botanicals as potential anticonvulsants. The overarching goal of our research program at Harvard Medical School is to (1) develop a pipeline of herbal medicine extracts and their constituent compounds that have promising activity in animal epilepsy models and relevant in vitro assays, (2) conduct the necessary preclinical studies to proceed with early-stage clinical studies, (3) perform these clinical studies, and then (4) partner to develop the compounds as FDA-approved therapies for epilepsy.

Background

Over the centuries, many Asian as well as African and South American herbal medicines have traditionally been used to treat convulsive diseases. A partial list includes the followings:

Gastrodia elata;

Uncaria rhynchophylla;

Menispermum dauricum;

Shitei-To, a mixture of extracts from three medicinal herbs – *Shitei* (Kaki Calyx; calyx of *Diospyros kaki* L. f.), *Shokyo* (Zingiberis Rhizoma; rhizome of *Zingiber officinale* Roscoe) and *Choji* (Caryophylli flos; flowerbud of *Syzygium aromaticum* [L.]);

a mixture of radish and pepper;

Qingyangshen;

Kanbaku-taiso-to, a mixture of three herbal drugs – *Glycyrrhizae Radix*, *Tritici Semen* and *Zizyphi Fructus*;

Paeoniae Radix; and

Zheng Tai Instant Powder (a complex prescription of traditional Chinese medicine indicated for grand mal epilepsy).

Published reports suggest that several of these herbs may be neuroprotective, while others show efficacy in animal models of epilepsy and hippocampal slice models.

Published clinical studies have reported on over 135 different herbs used singly or in 80 different combination formulas for the treatment of seizures. The ten most frequently used herbs in published reports are:

Pinella ternate (Ban Xia),

Arisaemi japonicum (Tian Nan Xing),

Acorus calamus (Shi Chang Pu),

Gastrodia elata (Tian Ma),

Buthus martensii (Quan Xie),

Poria cocos (Fu Ling),

Bombyx bartryticatus (Jiang Qiang),

Citrus reticulate (Chen Pi),

Uncaria rhynchophylla (Gou Teng),

Glycyrrhiza glaba (Gan Cao), and

Salivae miltiorrhizae (Dan Shen).

Most of these studies are observational, including case reports.

Despite the large number of pre-clinical and clinical publications, scientific studies of herbal medicines, including those with potential use in epilepsy, have been limited by inconsistent descriptions of herbal extraction methods, lack of characterization and further in vitro and in vivo testing of the active constituent compounds, and poorly described clinical study designs and patient populations.

Methodological Approaches

Our botanical epilepsy research program has systematically addressed these limitations and begun to develop a pipeline of compounds isolated from herbal medicine extracts that have promising activity in animal epilepsy models and relevant in vitro assays, conduct the necessary pre-clinical studies to proceed with early-stage clinical studies, perform these clinical studies, and then partner to develop and commercialize the compounds as FDA-approved drugs for epilepsy.

Our group, which includes collaborators in India, the Middle East, and the Far East, has now identified and tested nearly 30 herbal medicine extracts and pure, extract-derived compounds isolated from Chinese, Japanese, and Indian herbal medicines in animal models of epilepsy. We have also carried out vitro assays to characterize membrane currents mediated by AMPA, NMDA,

and $GABA_A$ receptors; and voltage-dependent sodium, potassium, and calcium ion channels. The specific methods and processes involved are further detailed in the upcoming sections.

Identification of Botanicals

Botanicals are selected based on careful consideration of many factors, such as knowledge and previous experience of the investigators, promising results from preliminary work by the investigators, published results of in vivo or in vitro studies from other laboratories, electronic database searches, published clinical recommendations of senior herbal and epilepsy experts in China and Korea, review of original (traditional) textbook references, and previous clinical studies.

Compound Isolation

Herbal extracts, and compounds derived from those extracts, are obtained using standard methods, and the purity of the compounds is assessed by thin layer chromatography or high pressure liquid chromatography. Molecular structure and weights are determined using various well-validated techniques. Sufficient quantities of extracts and compounds are produced for all the in vitro and in vivo studies, and samples are saved for future reference.

In Vitro Assays

Compounds and their parent extracts are analyzed using in vitro assays that focus on currents mediated by AMPA, NMDA, and $GABA_A$ receptors, and voltage-dependent sodium, potassium, and calcium ion channels. Techniques used include (1) whole-cell patch-clamp recording of ligand- and voltage-gated currents in cultured rodent cortical and hippocampal neurons, (2) whole-cell patch-clamp recording of recombinant NMDA receptors in human embryonic kidney (HEK293) cells, (3) characterization of NMDAR-mediated excitotoxicity in primary neuronal cultures from mouse cortex, and (4) determination of NMDA-induced nitric oxide (NO) production in cultured primary neurons from mouse hippocampus.

Epilepsy Animal Models

In parallel to the in vitro experiments, compounds as well as their parent extracts are tested in the screening epilepsy animal models of the NINDS Anticonvulsant Screening Program (ASP), including maximal electroshock seizure (MES) and subcutaneous pentylenetetrazol (sc PTZ) tests following oral and intraperitoneal (i.p.) administration; compounds are also examined in the levetiracetam-sensitive 6-Hz psychomotor seizure test following i.p. administration. Extracts are tested, in addition to the pure compounds, because they may contain active compounds that were too low in concentration to be isolated. When quantities allow, extracts and compounds are also evaluated for their ability to prevent the development of kindling.

In addition to these efficacy studies, effects on motor behavior are assessed by their propensity for causing behavioral impairment. For mice, behavioral impairment is determined by the rotarod test; behavioral impairment in rats is estimated from a battery of behavioral assessments including gait, stance, placing response, and muscle tone. The dose producing behavioral impairment in 50% of the population (i.e., TD_{50}) is calculated, and where possible, the protective index (TD_{50}/ED_{50}) is then calculated. In rats, minimal motor impairment (MMI) is determined by overt evidence of ataxia, abnormal gait, and stance.

Collectively, the results from these studies provide a reasonable estimate of a candidate substance's anticonvulsant profile and form the basis for selecting lead substances for further preclinical and subsequent clinical evaluation.

Results to Date

Of the nearly 30 extracts and compounds isolated from those extracts that have been procured or isolated and have undergone partial or complete in vivo and in vitro testing, nearly three-quarters of the materials show efficacy in one or more animal models. A common underlying mechanism of action of these materials appears to be protection against NMDA- and glutamate-mediated neuronal death, including Huperzine A, our lead compound. This finding is encouraging because glutamate-mediated hyperexcitability is believed to underlie the seizures and the neuronal degeneration that is often associated with chronic epilepsy, especially mesial temporal lobe epilepsy involving the hippocampus. Ionotropic glutamate receptor antagonists have been viewed as an important class of compounds for new epilepsy therapies, both to inhibit seizures and to block glutamate-mediated neuronal degeneration. However, previous NMDA receptor antagonists developed for epilepsy have been associated with histopathological and neurochemical changes in the brains of adult rats, and cognitive and behavioral side effects, including psychosis, in adult humans, thereby limiting their clinical usefulness.

Huperzine A

The first compound studied by our group was Huperzine A, a sesquiterpene Lycopodium alkaloid isolated from Chinese club moss (*Huperzia serrata*), also known as the Chinese

folk medicine *Qian Ceng Ta* (Figure 1). Huperzine A is also found in related plants, such as *Phlegmariurus carinatus*.

(-)-Huperzine A was first isolated from *Huperzia serrata* in 1986, and the average content of Huperzine A by weight is 0.011%. Its chemical nomenclature is [5*R*-(5a,9b,11*E*)]-5-amino-11-ethlidene-5,6,9,10-tetrahydro-7-methyl-5,9-methanocycloocta [*b*] pyridin-2(1*H*)-one. The CAS No. for Huperzine A is 120786-18-7; its molecular formula is $C_{15}H_{18}N_2O$ and molecular weight 242.32. Huperzine A is stable when stored at room temperature.

Huperzine A has been shown to be neuroprotective in several models, likely by acting as a non-competitive antagonist of NMDA receptors at one of the polyamine binding sites at or near the PCP and MK-801 ligand sites, but without the psychotomimetic side-effects of PCP or MK-801. Pretreatment of primary neuronal cells with Huperzine A reduced glutamate-induced toxicity. Pretreatment of cultured rat primary cortical neurons with 1 μM Huperzine A significantly attenuated apoptosis induced by serum deprivation, possibly by effects on intrinsic caspase-3 pathways. Two-week oral Huperzine A (0.1 mg kg^{-1} twice daily) following transient global ischemia in gerbils reduced memory impairment and neuronal degeneration in the CA1 region compared to sham controls, and partially restored hippocampal choline acetyltransferase activity. Similarly, Huperzine A (0.01–0.1 mg kg^{-1}, i.m.) improved spatial working memory in aged monkeys and young adult monkeys with scopolamine-induced cognitive impairment.

Huperzine A is a potent, highly specific and reversible inhibitor of acetylcholinesterase, with comparable potency to physostigmine, galantamine, donepezil, and tacrine. It produces dose-dependent increases of norepinephrine and dopamine in rat cortex when administered i.p. or locally through a microdialysis probe, and has many other actions, including the ability to protect cells against hydrogen peroxide, beta-amyloid protein (or peptide), and staurosporine-induced cytotoxicity and apoptosis. These protective effects are related to its ability to attenuate oxidative stress, regulate the expression of apoptotic proteins Bcl-2, Bax, P53, and caspase-3, protect mitochondria, upregulate nerve growth factor and its receptors, and interfere with amyloid precursor protein metabolism.

Huperzine A has been administered to healthy volunteers and patients in numerous trials, many in China, demonstrating acceptable safety and tolerability as well as efficacy in Alzheimer's disease, benign senescent forgetfulness, vascular dementia, and myasthenia gravis. It has traditionally been used in China for the treatment of swelling, fever and inflammation, blood disorders and schizophrenia, and is approved and used in China for the treatment of Alzheimer's disease. Huperzine A was classified as a dietary supplement by the FDA in 1997. As a nutriceutical, it is available in health food stores or via the internet, labeled as a memory aid, and is being studied in a multi-center NIH-sponsored trial for Alzheimer's disease at dosages up to 400 μg BID. There are no available published data of efficacy or tolerability in patients with epilepsy in the medical literature.

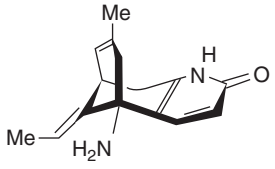

Figure 1 Huperzine A.

Huperzine A was selected for study in animal models of epilepsy based on its known neuroprotective properties. Under the auspices of the ASP, Huperzine A (ADD 357133) was found to be potently active against s.c. PTZ-induced seizures and less so against maximal electroshock-induced seizures following oral administration to Swiss-Webster mice, with peak anticonvulsant activity at one hour. At doses of 1, 2, and 4 mg kg^{-1}, a maximum of 62.5% protection was observed. Impairment on the rotarod test was observed in 75 and 100% of mice tested at doses of 2 and 4 mg kg^{-1}, respectively. The TD_{50} was 0.83 mg kg^{-1}.

In further work using the 6-Hz model, ED_{50} values for i.p. Huperzine A were 0.28, 0.34 and 0.78 mg kg^{-1} for 22, 32, and 44 mA, respectively, suggesting marked potency as well as a possible advantage over phenytoin, carbamazepine, lamotrigine and topiramate, each of which display limited efficacy in this model at doses devoid of behavioral toxicity (Table 1). The less than 2-fold ratio of dosages effective across the range of stimulation currents suggests a further possible advantage of Huperzine A over other drugs that are active in this model, such as levetiracetam.

We have also studied Huperzine A with the mouse formalin pain model. One mg/kg i.p. produced complete inhibition of pain behavior in all treated animals at all time points, and 0.5 mg kg^{-1} i.p. (60% of the TD_{50}) produced near complete inhibition. Both sets of results demonstrated statistically significant differences from controls ($P < 0.01$), and suggest potential efficacy in somatic (e.g., inflammatory, traumatic) as well as neuropathic pain syndromes.

Table 1 ED_{50} (mg/kg, i.p.) for AEDs in the 6-Hz model (data courtesy of H. Steve White, PhD)

AED	*22 mA*	*32 mA*	*44 mA*
Phenytoin	9.4	>60	>60
Lamotrigine	4.4	>60	>60
Levetiracetam	4.6	19.4	1089
Valproic acid	41.5	126	310
Huperzine A	0.28 (0.16–0.48)*	0.34 (0.28–0.40)*	0.78 (0.56–1.01)*

ED_{50} – dose at which seizures are blocked in half of the treated animals; i.p. – intraperitoneal; *– 95% confidence interval.

Challenges for the Future

The study of herbal medicines and botanicals for the identification of possible new epilepsy therapies, using a plant to bench to clinic strategy that is inspired by centuries-old tradition and that utilizes modern methods, appears very promising. This approach, and others underway around the world, may also yield neuroprotective agents. Theoretically, such agents could protect against the onset of epilepsy, against seizure worsening, or against progressive behavioral changes (e.g., memory loss). Further, some of the herbal medicines and their derived compounds that are active in the animal models of epilepsy may be found to have novel neuronal mechanisms of action that could lead to the development of additional pharmacological interventions for epilepsy.

Huperzine A may represent a new class of anticonvulsant compounds with a novel combination of mechanisms of action. Plans are now underway to conduct a proof-of-principle assessment of the compound's safety and tolerability and to study early-stage pharmacokinetics of Huperzine A (up to 800 $\mu g\,day^{-1}$ (0.8 $mg\,day^{-1}$)) as add-on, open-label therapy in patients with medically-refractory partial seizures, with or without other seizure types. A secondary aim is to provide preliminary data on the efficacy of Huperzine A and its effects on mood and memory function in this cohort of patients.

The pre-clinical study of herbal medicines poses several challenges. Chief among these are developing the best and most cost-effective methods for (1) identification, authentication, extraction and fractionation of botanical materials to study, (2) characterization of the active compounds, (3) isolation of sufficient quantities of active compounds for pre-clinical and clinical studies, and (4) establishing analytic methods for assessing purity of compounds and serum concentrations.

Introduction

Despite the advances during the decade of the brain, there is still no effective treatment for Alzheimer's disease, Parkinson's disease, ALS, Huntington's disease (HD), and many monogenic diseases such as Rett's syndrome, fragile x syndrome, Canavan's disease, Tay-Sachs disease, and the mucopolysaccharidoses including Lafora's disease. In all the cases, the mutated gene is known and cloned. However, copies of the potentially life-saving genes sit dormant in research laboratories because of the problems in expressing an exogenous gene in the brain. There is a perception that delivery across the BBB is an insurmountable problem.

In recent years, attempts to cure monogenic diseases using viral vector delivery methods – and particularly using adeno-associated virus (AAV) vectors – have been widely heralded. However, the tragedies associated with gene therapy have been widely publicized, damping enthusiasm for this approach. The first person publicly identified as having died in a clinical trial for gene therapy was injected with an adenovirus-vectored gene therapeutic and died four days later, apparently having suffered a massive immune response triggered by the use of the viral vector used to transport the gene into his cells. Adeno-associated virus vectors were assumed to provide an increased safety margin, but another patient died recently during a clinical trial using AAV-gene therapy to treat inflammatory rheumatoid arthritis. Her death halted the clinical trial and further heightened the concerns surrounding viral vector-mediated gene therapy.

Demyelination is a problem associated with viral vectors. And unpredictable responses have also been seen in other viral-vector studies. For example, a gene-therapy trial for severe combined immune deficiency (SCID) caused leukemia in three children. This incident underscores the value of laboratory testing. For example, in animal model studies of mucopolysaccharidosis, an adeno-associated virus (AAV) vector was used to deliver the GUSB gene to knockout mice and 33% of these treated mice were found to have developed hepatocellular carcinoma. This finding raised safety concerns over the clinical use of AAV vectors. The cessation of gene-therapy trials using retroviral vectors, and the apparent failure of cystatin B-HIV-TAT viral protein as a potential new therapy for Unverricht–Lundborg epilepsy emphasize a need to develop alternative delivery methods.

Ideally, gene therapy should use a nonviral carrier formulation that can be administered intravenously for ease of clinical use. The method should be available for multiple administrations and should provide widespread expression throughout the brain. The gene being replaced should be targeted to the brain and shielded during its transit to the brain from the ubiquitous exonucleases and endonucleases present in blood circulation. The nonviral vector should protect the replacement gene from immune recognition, and prevent uptake by the reticuloendothelial system. Finally the carrier vector must transport the replacement gene through the blood–brain barrier (BBB) capillaries and must then be released to the cells of the neuropil without untoward side effects. Development of such a method is the topic of this article. We describe the effectiveness of pegylated immunoliposomes (PILs) in delivering an exogenous gene to the brain.

Background

Inherited forms of epilepsy have been recognized for years, and recently the specific loci and genes involved in many epilepsy syndromes have been identified. Causative mutations have been found for several single-gene conditions, and this information has guided the identification of candidate genes for multifactorial epilepsy disorders. Monogenic epilepsies would also naturally be the model of choice for initial studies of gene therapy because of their simplicity, even though multifactorial epilepsies are more common.

Lafora's Progressive Myoclonic Epilepsy as a Candidate for Gene Therapy

In 1911 Gonzalo Lafora first described a fatal progressive myoclonus epilepsy with periodic acid Schiff (PAS+) stain intracellular inclusion bodies in an adolescent boy.

Lafora's disease was later shown to be a generalized metabolic disorder involving glycogen and mucopolysaccharides. It is now recognized as an autosomal recessive, adolescent onset, progressive and fatal generalized polyglucosan storage disorder with predominant central nervous system manifestations. Eighty percent of patients die by 18 years of age, and afflicted family members rarely live beyond 30 years. Although rare in the USA, the gene for Lafora's disease has been enriched in segments of society in Southern Europe (Italy, France, Spain), Northern Africa, India, Pakistan, and the Middle East. It is also seen in sectors of the population in the Appalachian Mountains and in villages of Quebec, Canada, where cultural practices lead to a high rate of consanguinity.

Delgado-Escueta and colleagues, in their studies of the 6q24 locus of Lafora's disease, have refined the map position, constructed a physical map of 6q24, isolated genes, and defined the mutations. They also isolated the full-length mouse cDNA clones as well as mouse genomic clones of laforin (i.e., epm2a) and mapped it to mouse chromosome 10, the syntenic region of human 6q24. Consequently, because the gene locus of this disease has been fully characterized and its clinical (and pathological) characteristics faithfully reproduced in the knockout mouse model, gene therapy approaches for Lafora's disease can be rigorously tested in this mouse model prior to adapting laboratory methods to the clinical situation.

Gene Therapy in Lafora's Disease may Forecast the Treatment of Other Single-Gene Disorders

There are many inherited diseases of the CNS which are candidates for treatment by gene therapy. Lysosomal storage disorders encompass about 50 metabolic diseases that include neuronal ceroid lipofucinoses, mucopolysaccharidoses (MPS), mucolipidoses IV, sphingolipidoses, sphingomyelinoses (Niemann–Pick disease), gangliosidoses (e.g., Tay-Sachs and similar diseases), glycoproteinoses, and other monogenic inborn errors of metabolism that collectively affect about 1 in 5000 live births. In each of these diseases, there is a deficient activity of enzymes responsible for catabolizing substrates in the lumen of lysosomes. All these deficiencies lead to a characteristic pathological accumulation and intracellular storage of the substrate. The accumulation of undigested metabolites in lysosomes leads to multisystemic dysfunction, including progressive neurologic deterioration, mental retardation, hepatosplenomegaly, blindness, and early death. Even though all of these diseases are inherited as single-gene defects, the development of new therapies has been slowed because tissue delivery of the (single) primary enzyme or protein defect is difficult, but bone marrow transplants and gene therapy offer promise.

The Rationale for Immunoliposome-Based Brain Delivery

Most drugs cross the BBB as a result of their lipid solubility profile; however, permeability is a function of molecular size, and their molecular mass must be <400–600 Da to cross the BBB. Exceptions to this rule (e.g., cyclosporine (1203 Da), vinblastine (814 Da), and vincristine (825 Da)) also include drugs which cross via transporter-mediated mechanisms, such as fluoro-deoxyglucose, vigabratin, and dihydroxy phenylalanine (L-DOPA). Gene therapeutics are invariably large molecules, which do not cross the intact BBB. This difficulty in efficient delivery and expression of therapeutic DNA inhibits the potential of gene therapy. Possible methods for delivery of genes to the human brain include capillary disruption, invasive craniotomy, cationic-liposome DNA complexes, or viral vectors. Each technique has significant limitations, and the efficiency of viral vectors for delivering genes across the BBB has yet to be shown. Intracerebral implants require craniotomy and deliver therapeutic agents to only a localized region. The efficiency of osmotic disruption of the brain capillaries is unproven; further, like those treatments requiring craniotomy, the method is unsuitable for multiple treatments. Gene delivery whereby DNA is complexed with cationic liposomes has also been tested, but these formulations aggregate in saline solutions. Consequently, when administered i.v., the aggregation results in selective gene expression in the lung, with no expression in the brain. Demyelination is a problem associated with viral vectors, and the safe use of even modified human viruses requires further development.

Gene therapy would ideally use a nonviral formulation; would be intravenously given for ease of clinical use and multiple administrations; and would provide widespread expression throughout the brain. Recent work indicates that this therapeutic approach is possible when pegylated immunoliposomes are used to target the gene to the brain. The liposome capsule shields the therapeutic DNA from the ubiquitous exonucleases and endonucleases present in the circulation. Polyethylene glycol strands attached to the liposome (pegylation) allow the liposome to escape immune recognition, and prevent uptake by the reticuloendothelial system. Monoclonal antibody (MAb) to the transferrin receptor permits the liposome to undergo receptor-mediated transport through the BBB capillaries and the cells of the neuropil. The liposome capsule undergoes lipolytic degradation to release its contents, without untoward side effects.

Studies on Pegylated Immunoliposome Delivery to Brain

The attachment of immunoreactive moieties to liposomes, and the formation of immunoliposomes designed

to target specific tissues, have been known for two decades. However the cellular barrier formed by closely situated brain endothelial cells was assumed to exclude liposomes, even small (50–80 nm) unilamellar vesicles. The most dramatic new advance in BBB transit methodology has been the demonstration that immunoliposomes (antibody-directed liposomes) can be used for brain delivery of drugs and other neuropharmaceuticals (such as those based on antisense nucleic acid targeting). Investigators showed that this approach for the delivery of ^{3}H-daunomycin in pegylated immunoliposomes (PILs) increased brain drug delivery by 4 orders of magnitude. Subsequent studies showed that i.v.-administered PILs bound to the luminal and abluminal rat (or pig) brain capillary membranes, undergo endocytosis, and release more than 90% of the liposome cargo within CNS or glioma cells.

A related approach utilizes the fact that proliferation of high grade astrocytomas is associated with overexpression of the epidermal growth factor receptor (EGFR). In a ground-breaking study, Pardridge and colleagues applied their 'nonviral' PIL-targeted gene delivery system to suppress EGFR in an experimental human brain tumor model (Figure 1). These investigators had demonstrated that PILs were able to deliver an exogenous gene (β-galactosidase) uniformly into the rat brain, where its expression could be imaged. In applying this method to tumor therapy, the targeted gene delivery system used an 'artificial virus' with the EGFR antisense gene inserted into a nonviral expression plasmid, packed within an 85 nm PIL.

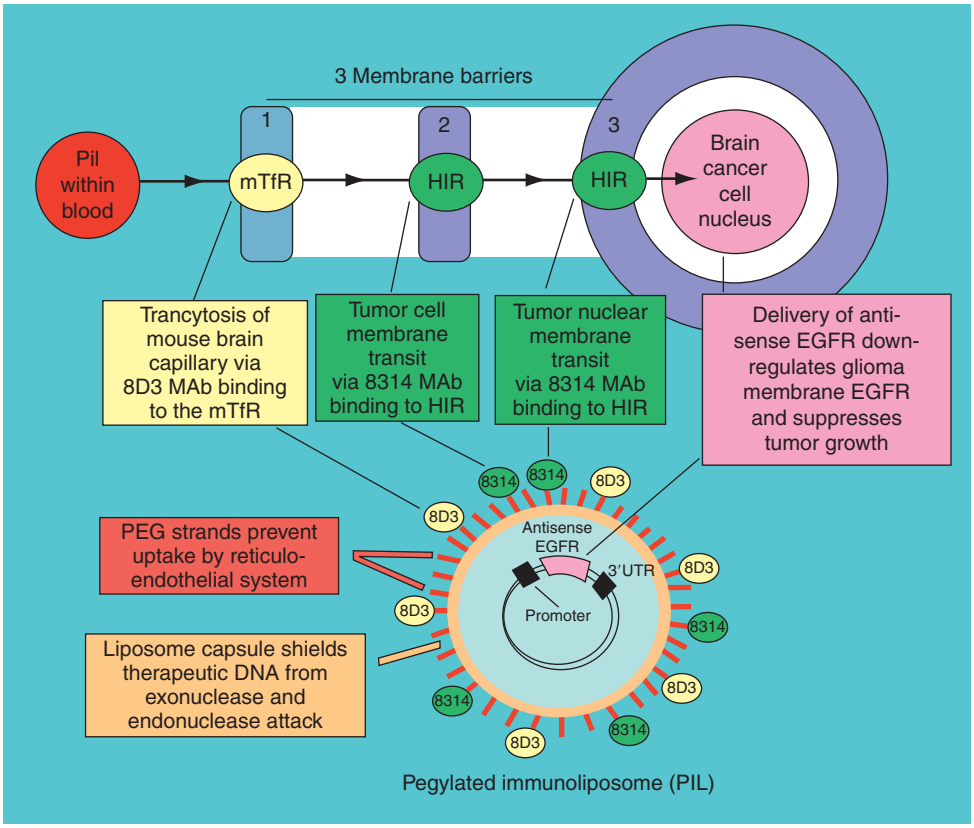

Figure 1 CNS gene therapy in brain cancer using an 'artificial virus' pegylated immunoliposome (PIL) delivery system (from Cornford and Cornford, 2002). Lower panel: Encapsulation of the therapeutic EGFR antisense plasmid DNA within a 'nanocontainer' liposome, prevents degradation of the therapeutic DNA by the ubiquitous endonucleases present in vivo. Strands of polyethylene glycol (PEG^{2000}) extend from the surface of the pegylated liposome, and the targeting MAb (about 35–50 MAb molecules per individual liposome) is attached to the tip of about 2% of these PEG strands. 'Peglyation' of the liposome prevents uptake of the PIL by cells lining the reticuloendothelial system (RES). The expression plasmid encoding the EGFR antisense gene is encapsulated within the interior of the PIL for brain delivery. Upper panel: In order to reach the nuclear compartment of the glioma cell, the intravenously administered PIL must traverse three biological barriers. (1) The BBB at the tumor microvasculature, (2) the tumor cell plasma membrane (TCM), and (3) the nuclear membrane of the tumor cell. The first barrier, the luminal and abluminal membranes of the BBB, is traversed by the 8D3 MAb to the transferrin receptor (TfR), which is abundant on the brain capillary. The second barrier, the human TCM, is traversed by the murine 8314 MAb to the human insulin receptor (HIR), and the HIR MAb also traverses the third barrier, the tumor cell nuclear membrane. Delivery of the antisense EGFR oligonucleotide to glioma nuclei down-regulates epidermal growth factor receptors and suppressed tumor growth. This work also predicts that gene delivery across sequential biological barriers (i.e., placenta and fetal BBB) in utero is feasible with PIL methods.

The surface of the PIL was supplied with two different peptidomimetic MAbs for transport across the multiple biological membranes separating the blood from the cancer cell nucleus. The 8D3 MAb to mouse transferrin receptor facilitated transport of the PIL across the murine BBB. The second barrier, the human glioma cell membrane, was traversed by the murine 8314 MAb to the human insulin receptor (HIR). The HIR MAb also traversed the tumor cell nuclear membrane, due to the usual intracellular trafficking of insulin to the nucleus, and this characteristic makes insulin-receptor targeting useful in widespread PIL delivery of genes to the primate brain.

Mice bearing intracranial U87 human gliomas were treated with this expression plasmid encoding antisense mRNA against the EGFR. The life-span of the mice treated once weekly (for 4 weeks, with i.v. EGFR antisense gene therapy) increased 100% relative to controls. Small brain tumors were seen in surviving mice (which had received gene therapy), while massive tumor growth was confirmed (postmortem) in the control mice. The unusual success of this animal model study, and its successful subsequent application to gene delivery in primates, provide hope that the human counterpart will soon be forthcoming. The work also suggests that the replacement of the missing or mutated genes within the CNS can be achieved using the PIL technology. Enhanced gene expression is seen with HIR-targeted PILs, and insulin-receptor based PILs efficiently deliver genes to the primate brain.

More recently, the same molecular 'Trojan horse' methods have been used in conjunction with RNA interference (RNAi) gene therapy using the EGFR (instead of antisense mRNA) as the liposomal cargo. Short hairpin RNA encoding nucleotides 2529–2557 of the human EGFR was encapsulated within immunoliposomes and administered to SCID mice bearing U87 glioma implants. The feasibility of this RNAi approach was evaluated by showing that it was possible to achieve a 90% knockdown of brain tumor-specific gene expression with a single intravenous injection in adult rats or mice with intracranial brain cancer. The survival of mice with intracranial human brain cancer was extended by nearly 90% with weekly intravenous injections of PILs carrying this plasmid DNA It has been proposed that RNAi-based gene therapy can be coupled with gene therapy that replaces or restores mutated tumor-suppressor genes, to build a polygenic approach to the gene therapy of brain cancer.

Experimental Parkinsonism has also been successfully treated using PIL-delivered gene therapy. In these studies, the unilateral intracranial administration of 6-hydroxydopamine was used to cause a loss of dopamine hydroxylase in the striatum, and apomorphine injections result in a contralateral rotation behavior of these rats. Three days after Transferrin-receptor targeted PILs were employed to deliver a tyrosine hydroxlase (TH) expression plasmid, investigators measured the normalized TH enzyme activity, along with a 70% reduction in rotational behavior. The pharmacological effect was both time- and dose-dependent. In contrast, this reversal of rotational behavior has not been seen in studies when the lesioned rat is treated with TH genes which are targeted with a viral vector; effective treatment may require transduction of a significant volume of the striatum with the TH gene, which may not be possible with a single intrastriatal injection of a viral vector. These investigations (which compare two alternate methods of gene delivery) seem to support the conclusion that in treating CNS disorders, PIL-delivered gene therapy appears to be more effective than therapy based on viral vectors.

In summary, the liposome functions as a biological nanocantainer (sometimes called an 'artificial virus') and shields its cargo from nuclease attack. The 8D3 monoclonal antibody allows the immunoliposome to function as a molecular Trojan horse, and deliver the desired gene product across the mouse BBB via receptor-mediated transcytosis. If immunoliposome nonviral delivery methods can treat the disease in animal models (see **Figure 1**), an immunoliposome-based cure for diseases such as Lafora's epilepsy may be developed for widespread clinical use.

Methodological Approaches and Results to Date

How is CNS Gene Delivery Accomplished? Preparation of Pegylated Immunoliposomes

When the expression of the exogenous luciferase gene is studied, the commercially available PGL3 luciferase vector (Promega; Madison, WI) may be used to provide a source of plasmid nucleic acid. The same vector may be modified and a PGL3-laforin plasmid is prepared to study gene replacement in Lafora null mutant knockout mice. EcoR1 can be used to cut the luciferase cDNA from the PGL3 plasmid at the 5″ flanking end, between the SV40 promoter and the 3′UTR. The PGL3-laforin expression plasmid is then formed by annealing Laforin cDNA in place of the luciferase cDNA.

Immunoliposomes are synthesized in a series of stepwise reactions beginning with plasmid nucleic acid preparation. The expression of plasmid may be driven by the broadly expressed simian virus 40 (SV-40) promoter, or alternatively by the brain-specific promoter taken from the 5′ flanking sequence of the human glial fibrillary acidic protein (GFAP) gene. The rationale driving this decision is that the transgene is expressed in both brain and peripheral tissues when the SV-40 promoter is used, whereas its expression is confined to the brain when under the influence of the brain-specific GFAP promoter. Thus, the SV-40 promoter, used in combination with

transferrin-receptor targeting, will deliver and express the gene construct to brain and to tissues such as the liver, spleen, and muscle in situations where the EPM2a gene is to be restored in Lafora knockout mice. (In these animals, peripheral tissues as well as the brain are affected, and also contain Lafora inclusion bodies.) In contrast, if the treatment situation requires expression of the gene only in CNS tissues (as might be the case for studies of hereditary childhood absence epilepsy), a GFAP promoter would be the logical choice because this promoter has been shown to selectively drive brain specific expression.

The lipids are mixed to form pegylated liposomes, mixed with plasmid DNA, and then extruded to make liposomes of specific size dimensions. Excess external nucleic acids are removed enzymatically. Finally the monoclonal antibody, which targets the finished product to a brain capillary receptor, is added to the PEG-strands and the immunoliposomes are purified by gel filtration chromatography for systemic intravenous administration.

Receptor-mediated transcytosis of the PIL and its cargo is dependent upon the selectivity and affinity of the targeting monoclonal antibody for the mouse transferrin receptor. If the 8D3 MAb proves to be unsuited, or proves to be an inefficient means of delivering (pPGL3-luciferase or pGL3-laforin) DNA in the knockout mouse, alternative methods may be considered. The RI7–217 MAb is another rat monoclonal antibody which undergoes receptor mediated transcytosis via the mouse transferrin receptor, and its brain uptake is comparable to that of the 8D3 MAb. The 8D3 MAb is the vector of first choice simply because it affords better delivery to renal and hepatic tissues, and slightly better delivery to the brain.

Milligram quantities of the peptidomimetic 8D3 MAb which is used as the (TfR) targeting ligand are required. This 8D3 hybridoma cell line grows efficiently in the peritoneal cavity of nude mice. Nude mice generate ascitic fluid containing high specific activity MAb. The MAb must be thiolated in order for it to be attached to the liposome. Using Traut's reagent, it can be attached to the tips of the polyethylene glycol strands, converting the liposome to an immunoliposome. Gel filtration chromatography is then used to separate the PILs from unreacted material, and the eluted PILs are then concentrated and filter-sterilized prior to injection.

Immunoliposomes are injected intravenously, and the cargo is delivered into the CNS. Studies suggest that the gene therapeutic is delivered to an episomal location within the cells, so there is no concern over insertional mutagenesis. In rodent models, the effect of the gene therapeutic persists for about 2 weeks. While multiple injections would be necessary over an extended treatment period, the advantage is that untoward effects due to overexpression of the administered gene can be controlled by simply ceasing to treat for the desired period.

Electron Microscopic Confirmation of Laforin-PIL Preparations

The electron microscopic appearance of an immunostained PIL is shown in the inset of Figure 2. A small volume of the PIL preparation was deposited directly onto a formvar-coated grid, and dehydrated. The presence of immunoreactive IgG attached to the PEG strands was confirmed by staining the grids with goat antirodent 20 nm gold particles. Here we counted 7 ± 7 ($X \pm$ SD; $n = 24$) gold particles per PIL, a measure not inconsistent with a density of 31 MAb/liposome estimated from PIL-isotope incorporation. Other studies have shown that large 20-nm gold particles underestimate epitope density by at least 50%, compared to analyses utilizing either 5- or 10-nm gold particles. Furthermore, because 50% of the epitopes are situated under the liposome, and not exposed to the MAb, there is a further 50% underestimation of MAb density. Thus, the observation of seven 20-nm gold particles per liposome would represent ~28 MAb per PIL.

This illustration also compares the dimensions of this receptor-mediated drug delivery system with that of the biological barrier to the CNS. The PIL (depicted in the inset) is 70–100 nm in diameter, and its path of transcytosis through the capillary endothelial cell varies from

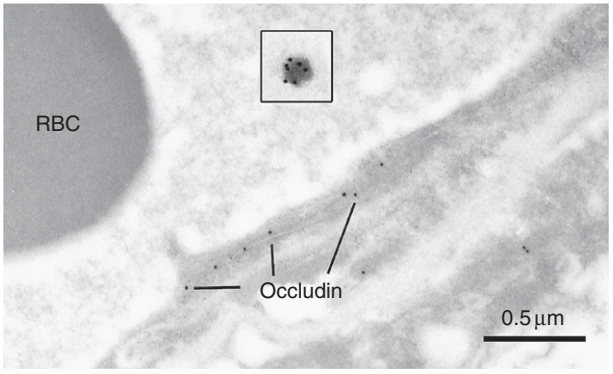

Figure 2 Comparative illustration of normal rodent brain capillary, and a pegylated immunoliposome (PIL) containing DNA from the Laforin plasmid. Tight-junctional proteins, such as occludin, are highly expressed at endothelial cell junctions in the cortical BBB, preventing the blood-to-brain passage via interendothelial clefts. The PIL utilizes receptor-mediated transport to undergo a transcellular passage from blood to brain. The inset depicts a pegylated immunoliposome, illustrated at the same magnification as the capillary profile. 10 nm gold particles are tagged to the polyclonal rabbit antiserum to occludin (Zymed Laboratories Inc, San Francisco, CA). Occludin-immuno-reactive epitopes are expressed intermittently along the length of the interendothelial junction, and no reactivity is apparent at any other blood–brain barrier domain. A targeting antibody (e.g., rat antiserum to the mouse BBB transferrin receptor, TfR; or in control immunoliposomes, normal IgG) is bound to the tips of the polyethylene glycol strands covering the immunoliposome, and is identified with a primary antibody followed by a gold-conjugated secondary antibody (e.g., goat anti-mouse 20 nm gold particles; Ted Pella Inc., Redding, CA).

200 to 450 nm. A typical CNS drug MW is 357 Da (smaller than a 1 nm gold particle). **Figure 2** compares the relative sizes of a 10 nm-gold labeled occludin epitope to that of the PIL nanocontainer; this illustration emphasizes the huge increment in BBB large molecule drug delivery that can be achieved with molecular Trojan horse technology.

Fusion Proteins

If a large molecule biopharmaceutical does not have to be protected within a liposomal container, it is now possible to reengineer the drug as a fusion protein. These IgG fusion proteins are new chemical entities that are dual- or triple-function molecules. They enter the brain by binding to an endogenous BBB receptor, and induce the desired pharmacologic effect in brain following passage across the BBB. A recent review (see Pardridge in Further Reading section) details how one end of the engineered molecule recognizes a receptor (such as the human insulin receptor) to permit BBB transit. The other end of the molecule may be a recombinant neurotrophin, or a therapeutic enzyme, or a single chain Fv antibody; in each separate situation, the alternate end is able to produce a unique therapeutic effect within the CNS. This type of therapeutic would be useful in treating a single gene defect where enzyme replacement therapy is effective, but (because of the ubiquitous endo- and exonucleases) not suited to delivering a gene therapeutic via intravenous injection.

Challenges for the Future use of the Trojan Horse Liposome Method

Even though more than 80 million individuals in the United States have some disorder of the brain, and more than 98% of all new drugs do not cross the BBB, less than 1% of the drug companies in the world today have a BBB drug-targeting program. There is currently a critical need for new neurotherapeutics designed for the treatment of neurological diseases. Despite the advances during the decade of the brain, there is still no effective treatment for Alzheimer's disease, Parkinson's disease, ALS, Huntington's disease (HD), or many other neurodegenerative conditions. For example, the gene for HD was identified a decade ago, yet an approved new therapy has not yet emerged. Antisense or RNAi therapy designed to selectively block the CAG repeats in the huntingtin transcript is theoretically possible, but developing this strategy was not pursued because the large molecule drugs do not cross the BBB.

There are numerous single-gene defect diseases that have devastating effects on the children of adult carriers, such as Rett's syndrome, fragile x syndrome, Canavan's disease, Tay-Sachs disease, and the mucopolysaccharidoses including Lafora's disease. In all the cases, the mutated gene is known and cloned. However, gene-based therapies have not been developed in most cases, because of problems in expressing an exogenous gene throughout the brain. There is a perception that delivery across the BBB is an insurmountable problem – or new treatments for CNS disorders are discussed within a context that fails to mention the problem of BBB transit However, neonatal and childhood onset diseases may be treated with brain-target gene-based therapies; available information suggests that pharmaceuticals such as molecular Trojan horses – which successfully undergo BBB transit – can also bind to endogenous receptor mediated transporters, and may be able to ferry gene products in the placental barrier, delivering selected nucleic acid to replace a deleted or mutated gene into the fetal brain.

There is now a real opportunity to translate recent advances in gene localization of inherited epilepsies and BBB gene delivery into the development of a new therapy. Available information suggests that Lafora's disease is candidate for gene therapy. Given the adverse events seen in studies employing viral vectors, the development of alternative methodologies for brain gene delivery has to become a high priority. Furthermore, we believe that continued and increasing support for gene therapeutic studies involving the administration of receptor-specific Trojan horse liposomes can produce results which will translate into therapies for a variety of genetically based disorders. The power and promise of this method have been shown in a variety of animal models of CNS diseases, where gene delivery has been achieved, and amelioration of the disease is apparent.

New Research on Biofeedback for Seizure Control

Y Nagai, University of Essex, Colchester, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Over the last three decades, the behavioral treatment of epilepsy using different kinds of biofeedback has become increasingly considered; for the most part, results from such trials have been encouraging. In biofeedback, the subject is provided with on-line visual or auditory feedback based on a covert physiological signal, such as heart rate, skin conductivity, or brain wave pattern. This protocol can enable a subject to learn to control – actively – the physiological signal. A number of biofeedback signaling approaches have been suggested for the management of epilepsy, including different electroencephalographic (EEG) frequencies, EEG cortical potentials, and peripheral physiological responses such as respiration.

The galvanic skin response (GSR) is an accessible and sensitive index of centrally generated autonomic activity. It reflects changes in peripheral physiology through the sympathetic nervous system. Skin conductance increases with enhanced arousal level. The peripheral GSR activity is centrally regulated by a matrix of brain regions which are involved in interoceptive representations and homeostatic control. The manipulation of peripheral arousal using biofeedback has direct and indirect consequences upon central brain states. In contrast to other technically demanding biofeedback protocols for seizure control, such as EEG or respiratory control, GSR biofeedback training represents an accessible and easy-to-implement behavioral procedure.

Background

Slow Cortical Potential: Indicator of Cortical Excitation

Among biofeedback treatments, EEG-biofeedback using slow cortical potentials (SCPs –negative DC shifts recorded using surface EEG) has been shown to produce the most successful reduction of seizures in patients with drug resistant epilepsy. In healthy subjects, SCPs index specific cognitive processes, including alertness, attention, information processing, motor anticipation, and response preparation. However, in epilepsy, spontaneous SCPs are viewed as pathological signatures, related to interictal states and reduced seizure threshold. In an experimental model of epilepsy, chemical generation of an ictal focus elicits a corresponding cortical negative potential (SCP), and in patients with epilepsy, negative DC shifts on EEG are often observed clinically in anticipation of, and during, epileptic seizures. In both cases, increased cortical negative potentials reflect an overexcitability of neural pathways, predisposing to seizure generation. A mechanistic explanation argues that SCPs are related to depolarization of apical dendrites in cortical pyramidal cells, reflecting cortical excitation. Pharmacological treatment of seizures is frequently associated with a reduction in SCPs. Correspondingly, decreasing negative potential shifts through biofeedback may, therefore, attenuate cortical excitation to successfully reduce seizure frequency.

A slow cortical potential can be recorded during a simple behavioral procedure – the forewarned reaction time task. The subject is presented with a warning stimulus that indicates that, after a fixed interval, he/she should make a rapid motor response to a second (imperative) stimulus. In the time period between the warning and imperative stimulus, there is a slow negative shift in the EEG, the contingent negative variation (CNV) signal. The CNV has two components: An early wave appears immediately after the warning stimulus and reflects a cholinergically mediated orienting response. The later wave is related more closely to motor preparation and anticipation of the imperative stimulus, and reflects dopaminergic activity.

Introduction

Over the last three decades, the behavioral treatment of epilepsy using different kinds of biofeedback has become increasingly considered; for the most part, results from such trials have been encouraging. In biofeedback, the subject is provided with on-line visual or auditory feedback based on a covert physiological signal, such as heart rate, skin conductivity, or brain wave pattern. This protocol can enable a subject to learn to control – actively – the physiological signal. A number of biofeedback signaling approaches have been suggested for the management of epilepsy, including different electroencephalographic (EEG) frequencies, EEG cortical potentials, and peripheral physiological responses such as respiration.

The galvanic skin response (GSR) is an accessible and sensitive index of centrally generated autonomic activity. It reflects changes in peripheral physiology through the sympathetic nervous system. Skin conductance increases with enhanced arousal level. The peripheral GSR activity is centrally regulated by a matrix of brain regions which are involved in interoceptive representations and homeostatic control. The manipulation of peripheral arousal using biofeedback has direct and indirect consequences upon central brain states. In contrast to other technically demanding biofeedback protocols for seizure control, such as EEG or respiratory control, GSR biofeedback training represents an accessible and easy-to-implement behavioral procedure.

Background

Slow Cortical Potential: Indicator of Cortical Excitation

Among biofeedback treatments, EEG-biofeedback using slow cortical potentials (SCPs –negative DC shifts recorded using surface EEG) has been shown to produce the most successful reduction of seizures in patients with drug resistant epilepsy. In healthy subjects, SCPs index specific cognitive processes, including alertness, attention, information processing, motor anticipation, and response preparation. However, in epilepsy, spontaneous SCPs are viewed as pathological signatures, related to interictal states and reduced seizure threshold. In an experimental model of epilepsy, chemical generation of an ictal focus elicits a corresponding cortical negative potential (SCP), and in patients with epilepsy, negative DC shifts on EEG are often observed clinically in anticipation of, and during, epileptic seizures. In both cases, increased cortical negative potentials reflect an overexcitability of neural pathways, predisposing to seizure generation. A mechanistic explanation argues that SCPs are related to depolarization of apical dendrites in cortical pyramidal cells, reflecting cortical excitation. Pharmacological treatment of seizures is frequently associated with a reduction in SCPs. Correspondingly, decreasing negative potential shifts through biofeedback may, therefore, attenuate cortical excitation to successfully reduce seizure frequency.

A slow cortical potential can be recorded during a simple behavioral procedure – the forewarned reaction time task. The subject is presented with a warning stimulus that indicates that, after a fixed interval, he/she should make a rapid motor response to a second (imperative) stimulus. In the time period between the warning and imperative stimulus, there is a slow negative shift in the EEG, the contingent negative variation (CNV) signal. The CNV has two components: An early wave appears immediately after the warning stimulus and reflects a cholinergically mediated orienting response. The later wave is related more closely to motor preparation and anticipation of the imperative stimulus, and reflects dopaminergic activity.

Relationship Between Central and Peripheral Arousals

The relationship between peripheral and central arousals was investigated using the GSR and SCP/CNV as physiological parameters of interest. The CNV was measured at different physiological states during GSR biofeedback-induced aroused and relaxed conditions; GSR biofeedback was used to increase or decrease the subject's arousal level. It was found that there was an inverse relationship between GSR and CNV amplitudes – increases in peripheral sympathetic activity were associated with reductions in this EEG index of cortical neural excitation. That is, an increase in peripheral GSR activity was associated with less cortical excitation (**Figure 1**).

Neural Mechanisms Related to Central and Peripheral Arousals

A recent fMRI study identified brain areas involved in generation of the CNV in healthy subjects. Activity in thalamus and within limbic cortices, and motor and supplementary motor cortices (SMA) was correlated with CNV amplitude. CNV activity in some of these areas (cingulate cortex, SMA, and insula) was also correlated with peripheral GSR change. The results were consistent with the theory that amplitude of the CNV is regulated by a specific thalamocortical circuit, with a higher CNV amplitude related to increased information flow between thalamus and cortex. Together with the observation from the EEG study, these data indicate that modulation of peripheral GSR may influence thalomocorical circuits, and thereby change the epileptic seizure threshold. In the EEG studies, the reduction in CNV amplitude associated with GSR arousal was attributed to the regulation of sensory input to the cortex via the thalamic reticular nucleus (RN). Convergent evidence from animal studies

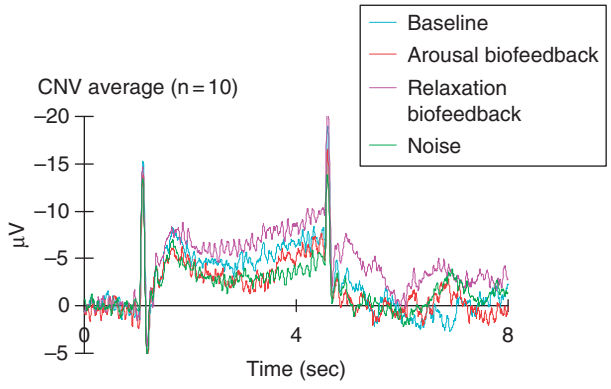

Figure 1 CNV amplitude during different physiological states. CNV amplitude increased with relaxation biofeedback. Arousal biofeedback and noise have a similar effect on CNV and reduced amplitude.

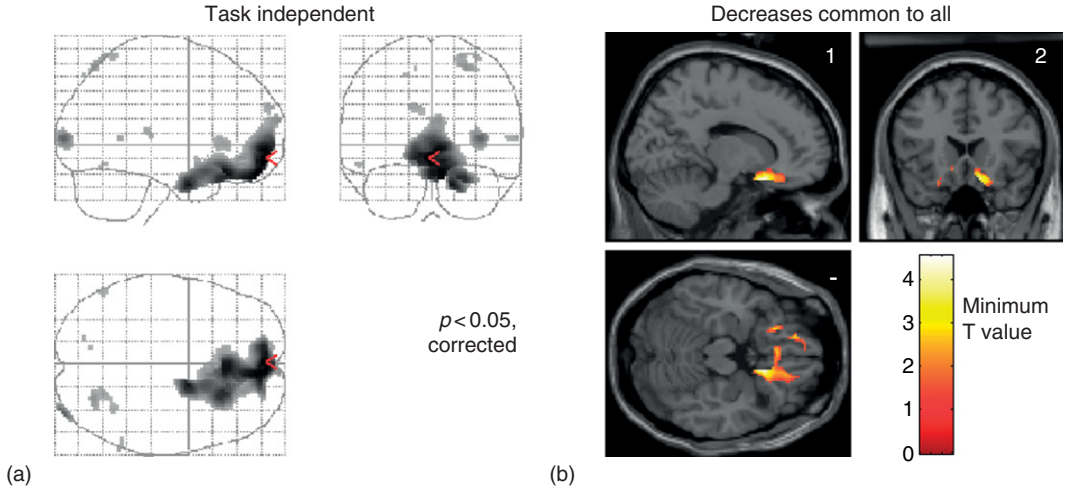
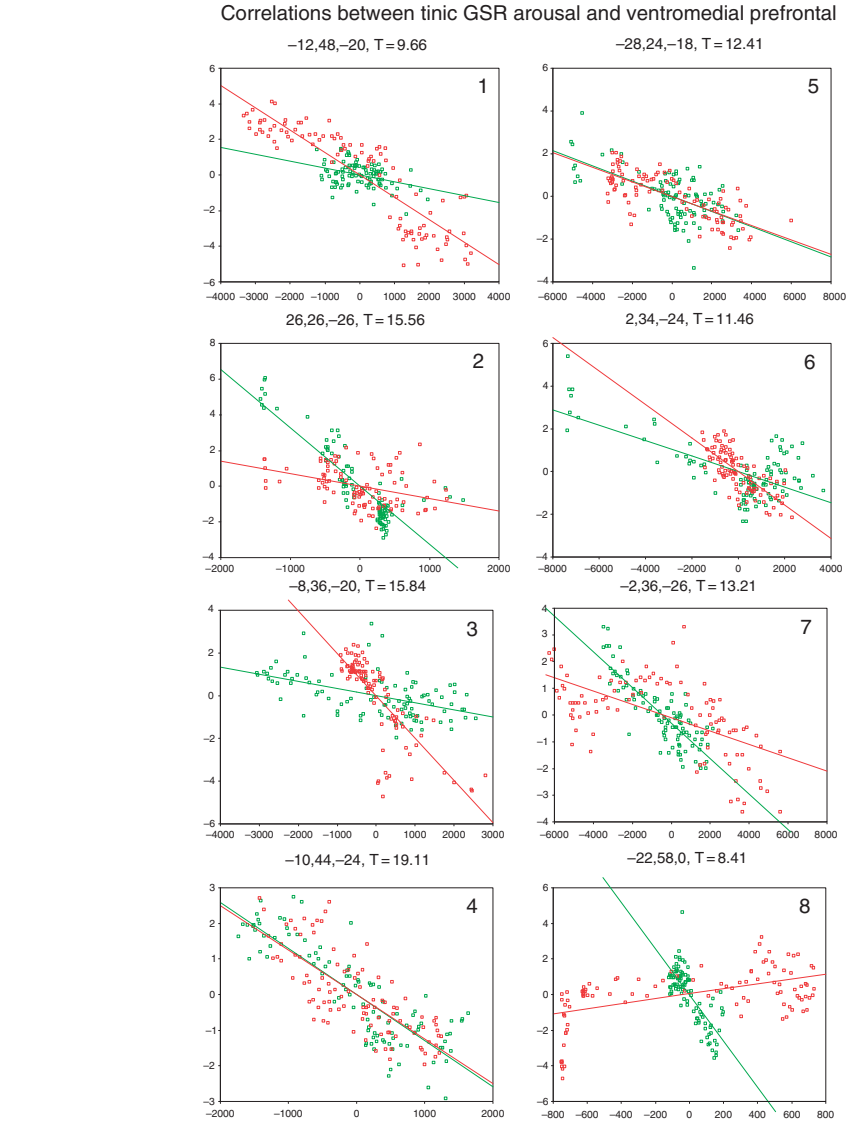
indicate that RN neurons, which are GABAergic (inhibitory), regulate sensory information in thalamocortical neural circuits, and therefore probably modulate seizure threshold by altering excitatory input to the cortex.



In other studies using fMRI, investigators identified brain structures involved in the regulation of peripheral GSR activity (**Figure 2**). There was a clear negative correlation between the level of sympathetic tone (GSR level) and activity within subgenual cingulate, and orbitofrontal and ventromedial prefrontal cortices. These brain regions are typically more active when individuals are in a restful and disengaged state, and are deactivated with attention and arousal. For therapeutic purposes, GSR biofeedback is given to patients to increase arousal level, and thus should enhance deactivation of these "default-state" brain regions.



In summary, the peripheral state of arousal measured with the GSR was found to be inversely related to cortical arousal measured with the slow cortical potential (SCP) using a contingent negative variation (CNV) paradigm. This observation suggests that increased sympathetic arousal attenuates cortical excitability. We, therefore, hypothesized that training patients to increase GSR arousal through biofeedback training will lead to improved seizure control (**Figure 3**).

Methods

We conducted a preliminary, randomized, controlled study with 18 patients with drug resistant epilepsy. Patients were randomly assigned to either the active biofeedback group or the noncontingent biofeedback (control) group. Measurement of GSR and the implementation of biofeedback were undertaken using a biofeedback system (the Inner Tuner: Professional, Ultrasis Plc., London). Biofeedback took the form of the same computer-generated graphics in both control and biofeedback conditions, presented visually on a computer monitor in front of the patient at eye level. In the biofeedback active group, a reduction in the participant's skin resistance (i.e., GSR arousal) resulted in a series of animations (progressing from a picture of a fish, to a mermaid, to a woman, to an angel, and to a star – with rightward movement through the sequence) when the participant's GSR changed in the intended direction (**Figure 4**). Should the patients' GSR reverse its resistance, the display would return to an earlier animation form. Thus, in the biofeedback session, the subject watched the 'evolution' of the graphics as GSR sympathetic activity increased (skin resistance decreased).

In the control (sham biofeedback) group, patients were shown a video of the same computer-generated animation as was used in the active biofeedback condition. In the control group, the patients also tried to alter their GSR level using the sequence of video events on the computer

screen. However, in contrast to the active treatment condition, in each sham control condition, the patient unknowingly watched a video animation which was prerecorded. The progress of the animation change was gradually increased, session by session, so that the patients in the control group would also have the impression of progress in each session. However, the animation changes were unrelated to the patient's own GSR change, as the GSR monitor was not connected to the computer generated animation.

The study was composed of three phases: a three month baseline period, a one-month treatment period in which the respective groups of patients were given either active biofeedback treatment or sham control biofeedback, and a 3-month follow-up period. In all phases, patients were asked to keep a careful record of their number of seizures (Table 1).

During the treatment phase, participants attended a total of 12 sessions (3 sessions per week). Each session lasted thirty minutes, during which patients assigned to the active treatment group received true biofeedback, and patients assigned to the control group received sham biofeedback. They were not informed as to whether they were given sham or contingent GSR biofeedback, but were all instructed to actively attend to and change the animation on the computer screen by increasing their level of alertness. After the completion of the treatment, each patient was asked to continue to keep careful seizure records for another three months and to practice the skill they learned in biofeedback session at home, without the biofeedback machines, preferably on a daily basis. They were also asked to use this same skill as a countermeasure when they were aware that a seizure was about to start.

The primary outcome measure of this study was the change in seizure frequency after a month of GSR biofeedback treatment, as a proportion of baseline seizure frequency. The secondary outcome measure was an increase in percentage GSR reduction over each treatment session which, in the biofeedback active group, provided an index of behavioral learning of GSR biofeedback skills over the 12 treatment sessions.

We hypothesized that the therapeutic effect of GSR biofeedback treatment would be physiologically based, and not merely a placebo effect of the behavioral intervention. We also predicted a significant reduction

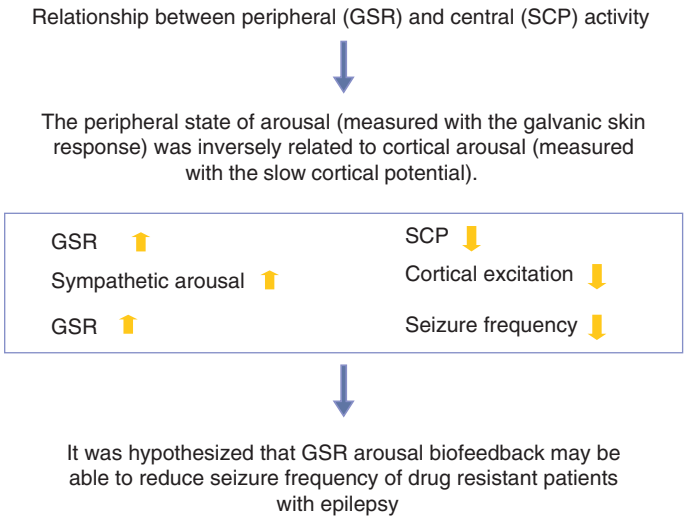

Figure 3 The figure illustrates the summary of background for the GSR biofeedback treatment for epilepsy.

Figure 2 Regional brain activity associated with decreases in skin conductance level. (a) Regional brain activity related to task-independent decreases in skin conductance level (SCL). Decreases in SCL were associated with increased activity in ventromedial prefrontal cortexVMPFC and OFC. A conjunction analysis was used to identify regional activity negatively correlating with across both biofeedback relaxation and arousal tasks ($p < 0.05$, corrected). (b) Regional brain activity associated with decreases in tonic skin conductance level common across all subjects (conjunction analysis associated with decreases in skin conductance), presented on a normalized template brain scan at ($p < 0.05$, corrected) for whole brain. The color scale represents the minimum *t*-value shared by all eight subjects contributing to the conjunction analysis. The common brain activity was found in ventromedial prefrontal VMPFC and orbitofrontal cortex OFC. (c) Plots of individual subjects data showing correlations between skin conductance and ventromedial and orbitofrontal BOLD activity during biofeedback relaxation (green dots) and arousal tasks (red dots). Data are plotted for the peak voxels of activity identified in first-level individual subject analyses. Pearson correlations showed significant negative correlation between adjusted orbitofrontal VMPFC and OFC BOLD responses and task-independent skin conductance SCL activity in the eight subjects.

Table 1 Experimental condition

Before treatment	*Treatment*	*After treatment*
3 month, recording baseline seizure frequencies	1 month GSR biofeedback treatment 30 min session, 3 times/week for 4 weeks biofeedback and control	3 month, recording posttreatment seizure frequency + countermeasures

in seizure frequency after a month of treatment in the active biofeedback group – in contrast to no significant benefit observed in the control group.

Recent Results

Changes in Seizure Frequency

Patients who experienced the active GSR biofeedback intervention experienced a significant reduction in seizure frequency (anecdotally, also seizure intensity) that was not experienced by the control patients who received sham biofeedback ($p = 0.017$). In the biofeedback active group patients, a month of GSR biofeedback training was associated with a significant decrease in seizure frequency ($p = 0.01$). Out of 10 patients in the biofeedback group, six patients showed more than a 50% seizure reduction compared to their seizure frequency before the treatment. The mean percentage change of seizure frequency was −49.26% (SD = ±41.64, median = −56.4%) for the biofeedback group. One patient became seizure free. In contrast, there was no significant reduction seen in the control patients who received sham biofeedback training (mean percentage reduction of seizure +24.59% (SD = ±45.64, median = +9.53%)).

The change in the seizure frequency of six individuals showing a good response to treatment (response rate >50%) over 28 weeks (pretreatment for 12 weeks, treatment for 4 weeks, and posttreatment for 12 weeks) is shown in Figure 5. The response rate is calculated as the percentage of patients who showed more than a 50% reduction in their seizure frequency compared to their pretreatment frequency.

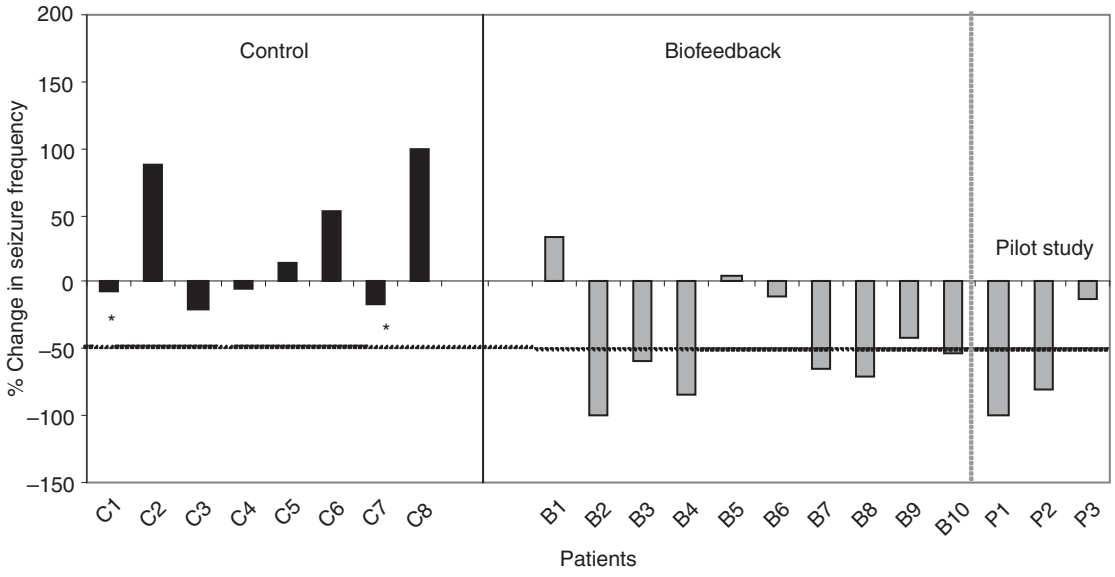

Figure 5 Percentage seizure frequency change after GSR biofeedback treatment in control and biofeedback groups. * Shows patients who dropped out in the middle of the training.

The following graph shows individual data of patients who received active biofeedback treatment (Figure 6).

Relationship Between Seizure Reduction and GSR Change

Patients in both the biofeedback active and control groups were given the same instructions to attend to the visual feedback display and try to influence the animation by increasing their alertness level. As a result, both groups of patients were able to change their GSR (by demonstrating an increase in sympathetic arousal). In fact, change in GSR reached significant levels both in the control and in biofeedback groups: biofeedback group ($p = 0.001$) and control group ($p = 0.028$). The mean percentage change in GSR was greater in the biofeedback group (mean% $\pm$ SD $= 42.58 \pm 30.16$) compared to the control group (mean% $\pm$ SD $= 25.27 \pm 26.9$).

The main difference between the patient groups was therefore the extent to which they learned to control GSR level through biofeedback, indicated by the degree of improvement of patients in GSR biofeedback performance. This control was broadly indexed by the average percentage GSR change over last three sessions compared to the first three treatment sessions. Patients in the active biofeedback group showed a significant improvement in performance of GSR biofeedback ($p = 0.007$), whereas patients in the control group demonstrated no significant improvement in GSR control with time (group difference $p = 0.004$). This observation is interesting as it means that developing the ability to modulate GSR arousal state through biofeedback training is the crucial predictive factor for seizure reduction. This relationship was further reflected in a significant correlation between reduction in seizure frequency and the degree of patients' improvement in GSR biofeedback performance, in both the biofeedback and control groups ($\rho = 0.736$, $p = 0.001$) (see Figure 7). Across individuals, the correlation between the magnitude of GSR reduction and seizure frequency did not reach significance, reinforcing the notion that the learning and implementation of the biofeedback technique were a greater therapeutic factor in reducing epileptic seizures than perhaps the overall change in GSR arousal itself.

In summary, the efficacy of GSR biofeedback compares extremely favorably with other treatments of refractory epilepsy where a 21–47% response rate is reported for new anti-epileptic drugs, and a 27% response rate is reported for vagus nerve stimulation. GSR biofeedback training has potential as a potent adjunctive nonpharmacologic means of reducing seizure-frequency in drug resistant epilepsy without obvious side-effects.

Future Goals

Finally, there are a number of important limitations to generalizing the findings of this initial patient study. First, the high demands of the study protocol made it difficult to recruit a large sample size. In addition, only one investigator was available to undertake the biofeedback/control sessions, and thus was not blind to the interventions being used for each patient. The patient group was not homogenous in terms of seizure types, and the study did not actively monitor the patients' compliance with their anti-epileptic drugs (e.g., using blood serum samples taken at regular

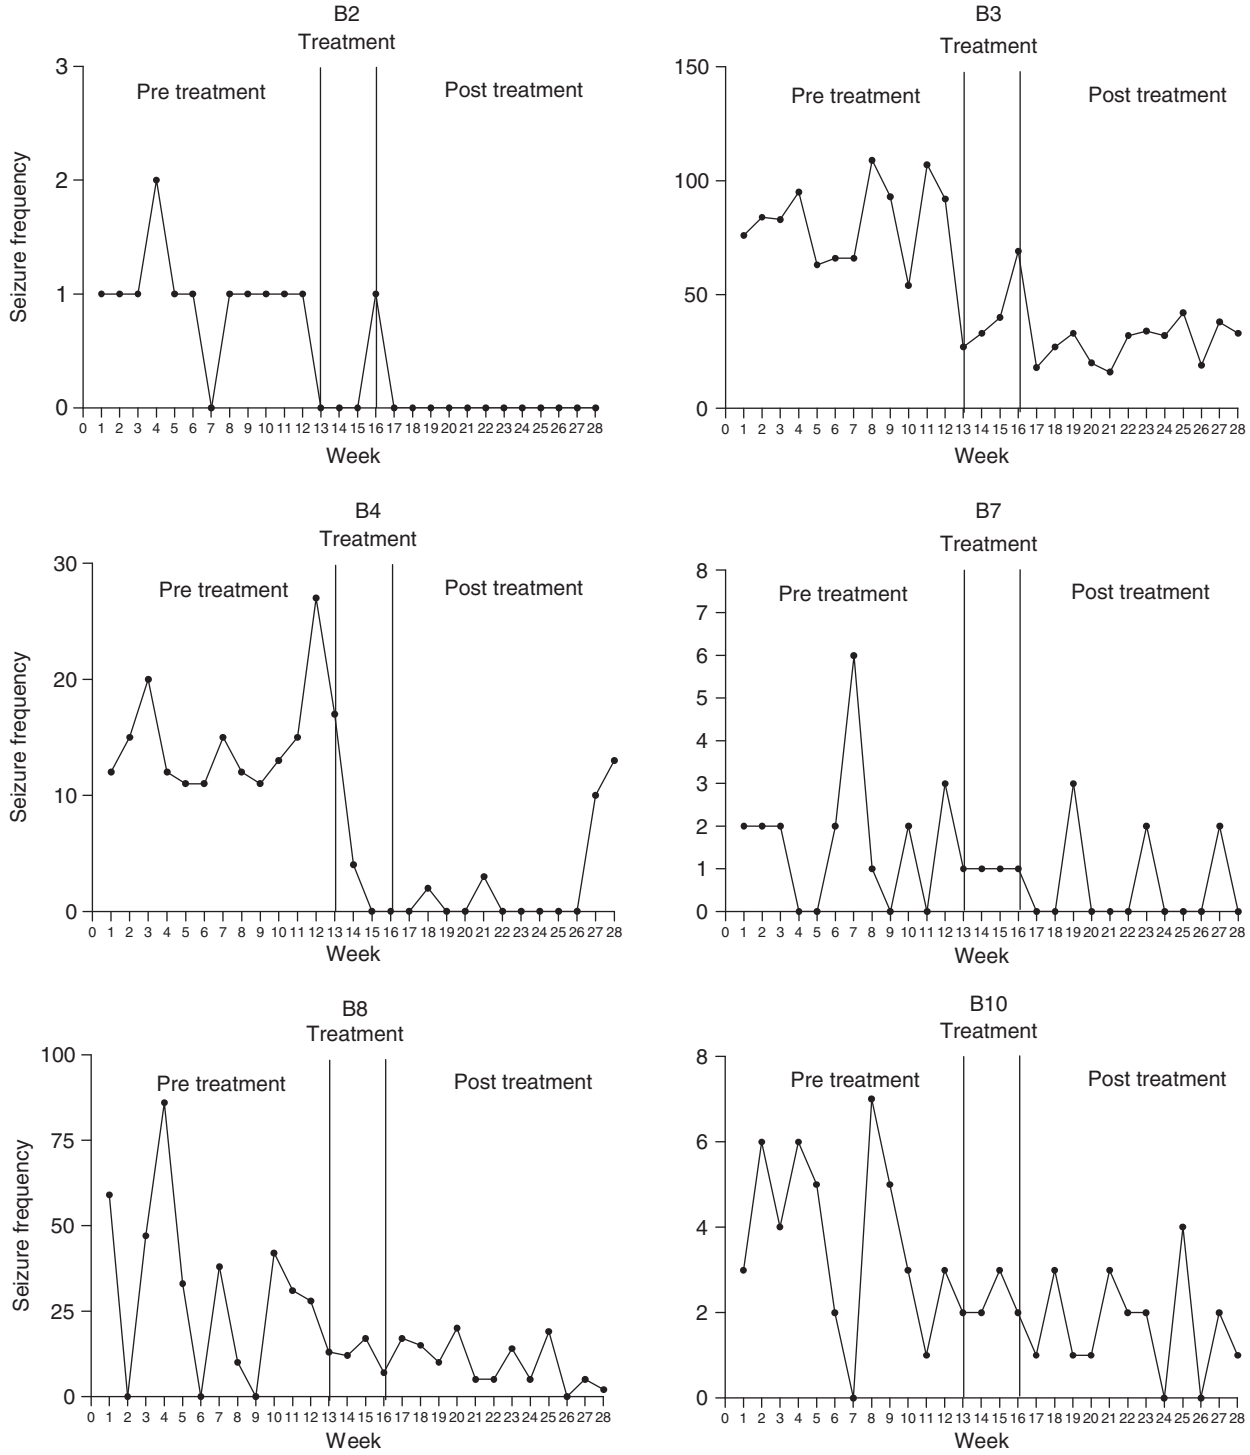

Figure 6 The figure illustrates the changes in individual seizure frequency change in patients over 28 weeks covering the period of GSR biofeedback treatment. The figure shows data only from those patients who showed a response rate >50%. The vertical axis indicates the actual number of patients' seizures.

intervals); this measure would have ensured that differences in compliance between the two groups did not account for the findings. While these limitations mean that caution is needed in data interpretation, the current study provides the basis for wider investigations applying this type of biofeedback to achieve significant seizure reduction. Certainly, the robustness of the findings, even in this small clinical group, is encouraging. Further work is needed to explore the effects of

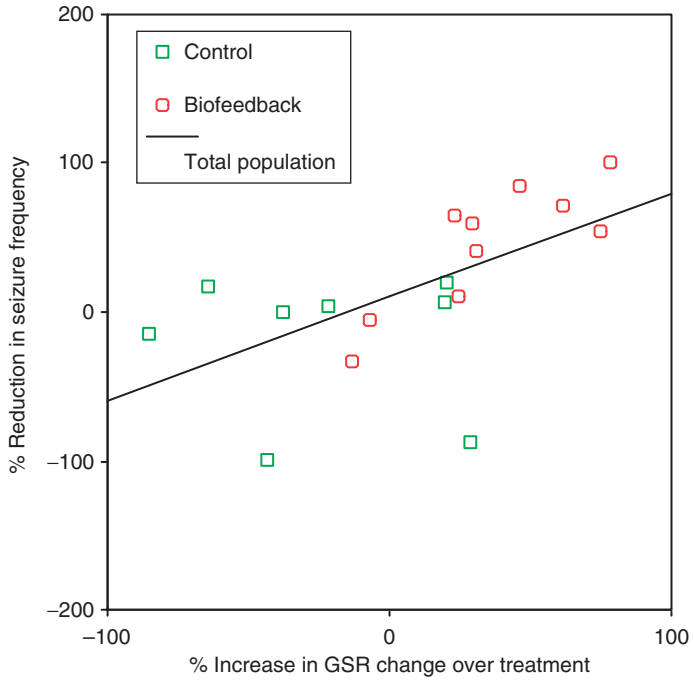

Figure 7 Correlation between seizure frequency change and performance improvement in GSR biofeedback.

biofeedback in a larger group of patients with refractory epilepsy, and in patients suffering from different seizure types, so that the therapy may be better targeted to those who are most likely to benefit. Our group continues to pursue a comprehensive understanding of the neural mechanisms, as revealed in EEG and fMRI analysis, through which GSR biofeedback reduces epileptic seizures.

Viral Vector Approaches for Antiepileptic Gene Therapy

T J McCown, UNC School of Medicine, Chapel Hill, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The Rationale for Epilepsy Gene Therapy

Epilepsy afflicts about 2.5 million people in the United States, and now, anti-epileptic medication effectively controls seizures in about 70% of this population. For the remaining 30%, however, medications do not adequately control the seizures. In these intractable cases, surgical resection provides a final treatment option, but only if a circumscribed site of seizure genesis can be defined and does not impinge upon brain sites associated with critical functions, such as speech. With the emergence of gene therapy techniques, viral vector gene transfer and expression offers – in theory – an attractive, alternative treatment option for focal epilepsies. By definition, focal epilepsy arises from a circumscribed site of seizure genesis, so the localized nature of in vivo viral vector transduction should prove sufficient to influence excitability in those brain areas critical to the initiation of seizure activity. In addition, adeno-associated virus (AAV) vectors and lentivirus vectors exhibit a dominant neuronal tropism in vivo. Because it is generally believed that the excessive synchronous discharge by large populations of neurons arises from a decrease in inhibitory function, an increase in excitatory function, or both, the neuronal tropism of these viral vectors provides an opportunity to directly influence neuronal excitability. Certainly, the ability to transduce neurons provides a wide range of potential therapeutic targets.

Background

The Untoward Consequences of Variable In Vivo Tropism

Excitatory and inhibitory neurotransmitter receptors, as well as various ion channels regulate the excitability of neurons, providing what appear to be ideal targets for anti-epileptic gene therapy. However, our first attempts to regulate excitability using viral vector gene transfer uncovered an important liability inherent to in vivo viral vector gene transfer and expression. N-methyl-D-aspartic acid (NMDA) receptors influence seizure sensitivity, and a fully functional receptor requires the NMDA receptor 1 (NMDAR1) protein. Therefore, we reasoned that if one impaired expression of the NMDAR1 subunit protein, seizure sensitivity would be significantly reduced. Indeed using recombinant AAV vectors, we did find that transfer and expression of a 729 base pair NMDAR1 antisense reduced NMDA receptor function in vitro and significantly reduced NMDAR1 protein in vivo. Furthermore, using a CMV promoter to drive gene expression, in vivo transduction significantly attenuated focal seizure sensitivity. However, when expression of the same NMDAR1 antisense construct was driven by a tetracycline-regulated minimal CMV promoter, the seizure sensitivity actually increased, such that the animals were more seizure sensitive. The observation that NMDA receptor mediated excitation drives endogenous GABA inhibition provided a tenable explanation for these diametrically opposed results. In the case of the CMV promoter, primary seizure output neurons likely comprised the preponderance of transduced cells; thus, removal of NMDA receptor excitation blunted the seizure sensitivity. However, in the case of the regulated minimal CMV promoter, the preponderance of gene expression probably occurred in inhibitory GABA interneurons, so removal of the endogenous excitatory drive to these inhibitory interneurons increase seizure sensitivity. The likelihood of such an occurrence was validated when equal amounts of each AAV vector were administered together. Some neurons supported expression from both promoters, but significant numbers of transduced neurons exhibited transduction from only one or the other of the promoters. This difference could not be attributed to a virus-specific tropism, because all of the vectors were recombinant AAV type 2 viruses. Thus, a slight change in only the promoter evoked a substantial shift in the final outcome of the gene expression. These surprising findings markedly emphasize how differential vector or promoter tropism might markedly alter the ultimate therapeutic outcome. Certainly, a promoter's tropism could easily differ between experimental animals and humans. Likewise, it is possible that the tropism inherent to specific viral vectors may differ between experimental animals and humans. Thus, without some detailed knowledge of the transduction pattern in humans, any manipulation of neurotransmitter receptor proteins or ion channels could easily lead to heightened seizure sensitivity instead of the desired reduction of seizure sensitivity. Given the paucity of knowledge regarding viral vector tropism in the human CNS, such a therapeutic liability poses an unacceptable clinical risk.

The Focus upon Neuroactive Peptides

Neuroactive peptides provided another potential therapeutic target, particularly since several neuropeptides have been shown to exert anti-seizure activity in several

animal models. Numerous studies have shown that local infusion of the endogenous neuropeptides, galanin or neuropeptide Y (NPY), significantly suppresses seizure activity. Therefore, we reasoned that if one could express and constitutively secrete a neuroactive peptide, then as long as the appropriate receptor was present in the area of transduction, differential promoter or vector tropism would not influence the outcome. In general laminar proteins are constitutively secreted from a wide range of cells. In the case of the laminar protein, fibronectin, a secretory signal sequence traffics the fibronectin into a constitutive secretory pathway. Therefore, we constructed an AAV vector in which the coding sequence for the active galanin peptide was preceded by the secretory signal sequence of the laminar protein, fibronectin. Thus, the active peptide should be secreted from the transduced cell in a nonregulated fashion. Because it had already been shown that focal infusion of galanin significantly attenuated local seizure activity, the primary question was whether this approach could secrete enough vector-derived galanin to influence local seizure activity. Indeed, our studies demonstrated that the fibronection secretion signal sequence did cause constitutive secretion of the gene product from the transduced cells in vitro, and upon transduction in vivo, exerted significant attenuation of focal seizure sensitivity and blockade of seizure-induced cell damage. Furthermore, our studies demonstrated that effective seizure suppression could be obtained regardless of the promoter. Thus, as predicted, constitutive secretion of a neuroactive peptide circumvented the liability of differential promoter tropism. Because intractable mesial temporal lobe epilepsy presents the most likely gene therapy application, we subsequently showed that following AAV transduction, enough vector-derived galanin was secreted in the piriform cortex to essentially block both behavioral and electrographic seizures produced by systemic kainic acid administration. Clearly, this novel gene therapy approach proved quite effective in attenuating seizure activity in vivo.

Although these studies with galanin provided a proof-of-principle, we wished to explore how this approach might generalize to other neuropeptides, as well as receptor-specific neuropeptide fragments. Vezzani's laboratory previously showed that AAV mediated expression of preproNPY significantly attenuated seizure activity, but this effect was only robust when extensive, high levels of gene expression were obtained. Furthermore, such an approach assumes that the transduced cell is capable of processing the preproNPY and appropriately trafficking the NPY, such that vector-derived NPY is released upon neuronal stimulation. When we utilized the constitutive secretion construct with NPY, like galanin, transduction of the piriform cortex markedly attenuated kainic acid-induced seizures. In addition, expression and constitutive secretion of the NPY 2 receptor-specific fragment, NPY (13–36), also significantly attenuated kainic acid-induced seizures. Thus, these findings show that the constitutive secretion approach also can be used with receptor-specific neuropeptide fragments. Although other anti-seizure gene therapy approaches have been reported, at present the results with galanin and NPY provide the most promising gene therapy approach for the treatment of epilepsy. Several issues, however, remain to be addressed to optimize the chances for a successful clinical trial.

The Potential Impact of Pre-Existing Immunity and Seizure Pathology on Anti-Seizure Gene Therapy

Although neuropeptide gene therapy appears effective in animal seizure models, two major issues remain: pre-existing AAV immunity and pre-existing seizure pathology. Approximately 80% of the human population tests positive for antibodies to wild type AAV serotype 2 (AAV2) capsid proteins, and in 30–70%, antibodies are present that neutralize the AAV2 capsid. Although the blood-brain barrier normally prevents peripheral immune responses from gaining access to the CNS, site infusion of a vector would likely disrupt the blood-brain barrier, at least locally. Furthermore, it has been established that seizures can cause transient leakiness in the blood-brain barrier. If indeed the antibodies to AAV2 gain access to the CNS, then vector efficacy could be seriously compromised. For example, Mandel's laboratory has shown that when rats are immunized with AAV2, high levels of inactivating antibodies are found in the circulation, and subsequent infusion of AAV2 vectors into the striatum do not support expression of the vector-derived gene product. One means to avoid such an inactivation would be to use a different AAV serotype, and indeed the administration of a recombinant AAV serotype 5 (AAV5) vector circumvented this antibody inactivation. Given the range of different AAV serotypes, numerous options exist to avoid pre-existing immunity to AAV 2 – though one must insure that the tropism of the alternate serotype proves adequate for the particular gene therapy application.

A second issue involves seizure-induced neuropathology. In most studies, viral vector transduction precedes the seizure manipulation, a temporal sequence made necessary by the lag time between viral vector infusion and subsequent gene expression. In marked contrast, any clinical trial will involve viral vector treatment in brain tissue that has experienced chronic seizure activity. We have partially addressed this issue by showing that AAV mediated expression and constitutive secretion can still attenuate seizure sensitivity in animals that had been previously kindled to class V seizure activity. Electrical kindling, however, does not produce the degenerative neuropathology typically observed in chronic temporal lobe epileptics. Thus, it is crucial to demonstrate the

efficacy of viral vector transduction and gene expression in chronically seizure-exposed tissue.

To achieve immune evasion and optimal transduction of pathological brain tissue, studies must focus upon properties of the AAV vector, in particular properties conferred by the capsid proteins. As seen with the immunity studies, different AAV serotypes can evade immunity to AAV2 capsids, and to date, eleven different serotypes (AAV1 through AAV11) and over one hundred variants have been isolated from human and nonprimate tissue samples. A permutation in this serotype approach involves rational mutagenesis of the capsid proteins. By introducing specific point mutations in certain AAV capsid proteins, the tropism can be significantly altered. An example involves removing or introducing the ability to bind heparin. In the present context, though, the success of rational manipulation of the AAV capsid depends upon prior knowledge pertaining to the phenotypic traits of the capsid and/or structural information derived from previous crystallography studies. Unfortunately, we presently do not have *a priori* knowledge of the properties necessary to evade immune responses or optimally transduce neuropathological brain tissue. One means to circumvent this weakness is through the combination of DNA shuffling and directed evolution, where phenotypic traits can be selected in the total absence of any *a priori* knowledge.

Methodological Considerations

Vector Optimization Using DNA Shuffling and Directed Evolution

The rapidly developing fields of DNA shuffling and directed evolution provide an excellent means to select mutant AAV vectors that exhibit a range of specific properties. For example, Schaffer's laboratory recently introduced random changes in a single AAV2 capsid protein using error prone PCR and then selected those mutants that exhibited specific properties. By combining error prone PCR with directed evolution, they were able to identify unique AAV2 variants that exhibited marked reduction in heparin binding or evaded AAV2 immunity in vivo. These studies provided the proof-of-principle that directed evolution could be successfully applied to AAV.

Another means to introduce substantial diversity into AAV capsid proteins utilizes the rapidly advancing technique of DNA shuffling. Through this method, enormous diversity can be generated across a wide range of different AAV capsid proteins. Essentially, libraries of hybrid genes can be generated by random fragmentation of a pool of related genes, followed by reassembly of the fragments in a self-priming polymerase reaction. When this technique is combined with directed evolution, both single and multigene traits can be evolved rapidly even though they might require many mutations to achieve the improved phenotypes. As mentioned previously, we have no *a priori* knowledge of those properties that would optimize transduction of chronic seizure-exposed tissue. Thus, any attempt at rational mutagenesis would proceed in the absence of a guiding rationale. In contrast, DNA shuffling combined with directed evolution allows selection of those mutants that actually fulfill the desired phenotypic properties. We currently are pursuing this approach in order to identify the optimal AAV vector for anti-seizure gene therapy.

Recent Results

Recently, Samulski's laboratory has developed a combinatorial strategy involving DNA shuffling of AAV serotype capsid sequences to generate a library of AAV mutants,

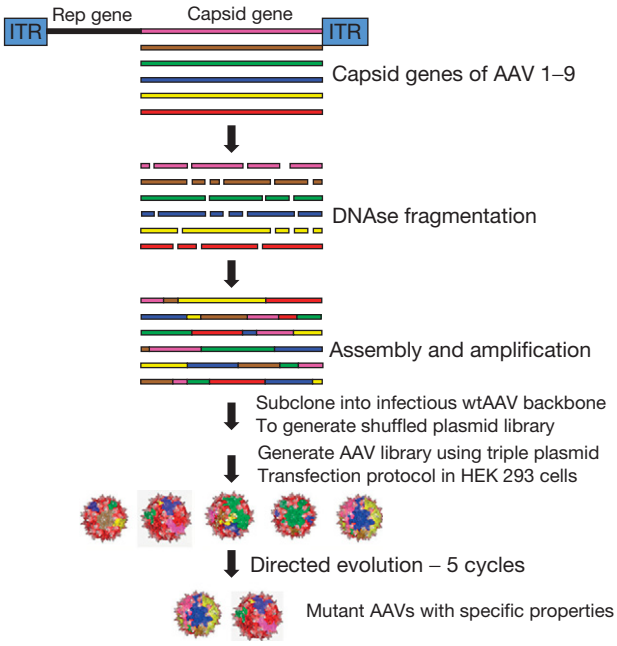

Figure 1 A flow chart illustrating the DNA shuffling/directed evolution procedure. Initially, the capsid protein sequences from AAV serotypes 1–9 are partially digested with DNAse creating fragments ranging in size from 400 to 1200 base pairs. The fragments are then assembled through a two stage PCR procedure and subsequently subcloned into an infectious wild type AAV backbone. The resulting plasmid library is packaged as virus using the standard triple plasmid protocol, and then the target tissue is infected with this AAV library. For in vitro applications, the infectious mutants are rescued by coinfection with adenovirus, but for in vivo applications, rescue is accomplished by PCR amplification, because wild type adenovirus is toxic and would only rescue those mutants in adenoviral permissive cells. This selection process is repeated for five cycles, leading to the identification of those mutants that most effectively infect the target tissue. Thus, by combining DNA shuffling and directed evolution, one can develop mutant AAVs that exhibit highly selective properties. (ITR-AAV inverted terminal repeats).

which provides the starting materials for directed evolution of cell type/receptor-specific AAV variants. With limited DNase digestion, followed by extraction of 400–1200 bp fragments, capsid regions of AAV serotypes 1–9 were successfully shuffled (see **Figure 1**). Then a mixture of fragments was subjected to PCR with Taq DNA polymerase, first without primers and then using a long template PCR system with forward and reverse primers. The purified PCR products were cloned into a wild type AAV2 plasmid backbone to generate a plasmid library with chimeric AAV capsid genes. Subsequently, a mutant AAV library was generated using established plasmid transfection protocols. The initial in vitro studies focused upon the CS1 cell line, derived from chinese hamster melanoma. The cells were infected with the mutant AAV library and then wild type adenovirus was added so as to rescue and replicate those AAV mutants that infected the cells. By repeating this process five times, an AAV mutant was identified that proved very efficient for CS-1 cell transduction. Sequence analysis and alignment with parental serotype sequences revealed a chimeric capsid subunit protein (VP1) derived from AAV1, AAV8, AAV2, and AAV9, so this mutant was termed AAV-1829. Obviously, this DNA shuffling, directed evolution technique proved capable of producing a unique AAV serotype.

When the tropism was explored in the rat CNS, quite surprising results emerged particularly in comparison with the established transduction patterns of the parental AAV serotypes (Li, Samulski and McCown, unpublished results). A recombinant AAV-1829 vector was produced in which a CMV promoter drives expression of the green

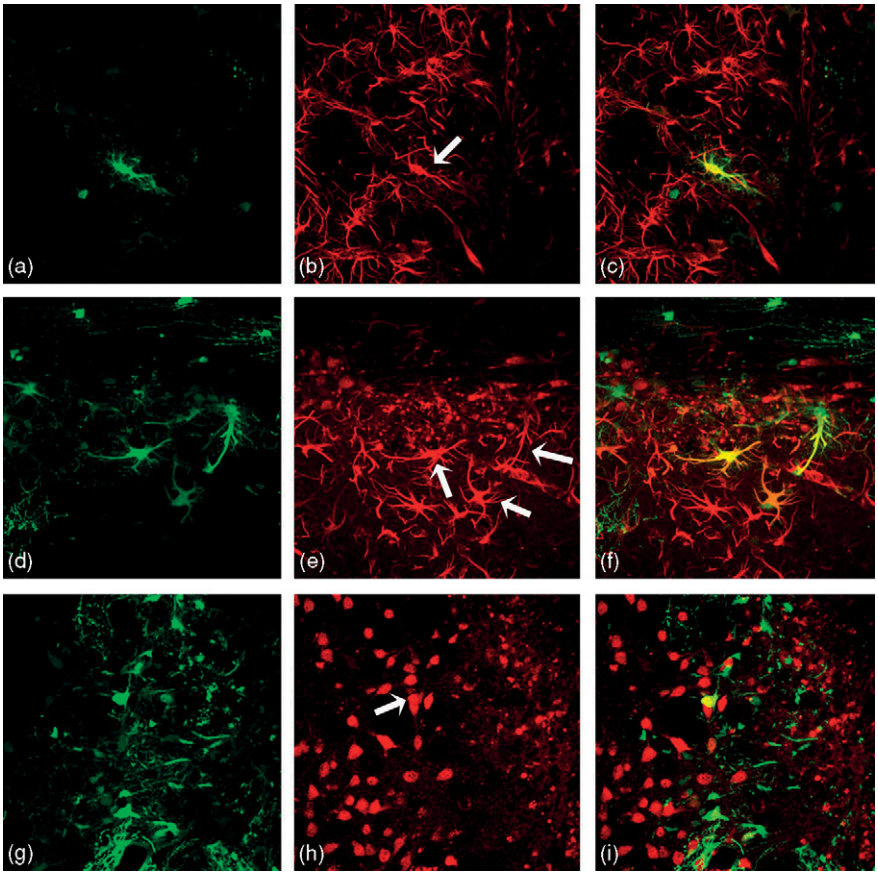

Figure 2 The CNS tropism of the mutant AAV vector, AAV-1829. Rats received a 2 μl infusion of AAV-1829-GFP vectors into the striatum, and 7 days later the brains were processed for immunohistochemistry. When immunohistochemistry was conducted for glial fibrillary acidic protein (GFAP), confocal microscopy identified numerous GFP positive cells that colocalized with GFAP-like immunoreactivity. Panel a shows a 2 μm slice through a GFP positive cell that also proved positive for GFAP-like immunoreactivity (panel b, arrow). Panel c shows the merge of a and b. More surprisingly, numerous GFP positive cells exhibited colocalization with nestin-like immunoreactivity, a marker of neuronally fated progenitor cells, reactive astrocytes or type I astrocytes. Panel d shows a 2 μm slice through GFP positive cells that also proved positive for nestin-like immunoreactivity (panel e, arrows). Panel f shows the merge of a and b. Finally, Panels g–I show the colocaliztion of a GFP positive cell with NeuN-like immunoreactivity, a marker for neurons. However, the number of GFP positive neurons were quite small in comparison with the total number of GFP positive cells. Thus, in direct contrast to the predominant neuronal tropism of AAV serotypes 1, 2, 8, or 9, AAV1829 exhibited a nonneuronal tropism in vivo. These findings demonstrate the ability of DNA shuffling/directed evolution to generate novel AAV mutants.

fluorescent protein (GFP) marker gene. One week after infusion of this AAV-1829-GFP vector into the rat striatum, the level of transduction was low and not particularly neurotrophic. However, many of the GFP positive cells colocalized with GFAP, a marker for astrocytes (**Figure 2 (a–c)**). More surprisingly, a large number of the GFP positive cells exhibited colocalization with nestin, indicative of either neuronally fated progenitor cells, reactive astrocytes, or type I astrocytes (**Figure 2(d–f)**). There were some GFP positive cells that colocalized with the neuronal marker, NeuN (**Figure 2(h–g)**), but these cells were in the clear minority of AAV-1829 transduced cells. These in vivo findings indicate that the DNA shuffling and directed evolution technique allowed the selection of a mutant AAV that exhibited a markedly altered the CNS tropism. Furthermore, the altered pattern of tropism appears quite unique in comparison with the CNS tropism of the parental AAV serotypes from which AAV-1829 was derived. Thus, this approach will allow future research to identify unique AAV mutants that fulfill specific properties within the CNS, such as optimal transduction of seizure-induced pathological tissue and evasion of AAV2 neutralizing antibodies.

Future Directions and Conclusions

Viral vector gene therapy provides a promising alternative therapy for intractable focal epilepsies. Our studies have established a novel gene therapy platform that not only has proven quite effective against seizure activity, but also circumvents several therapeutic liabilities. The expression and constitutive secretion of galanin, NPY, or NPY (13–36) markedly suppresses limbic seizure activity. However, further advances are necessary to optimize this therapy. To this end, we are using the techniques of DNA shuffling and directed evolution to identify optimal AAV vectors for anti-seizure gene therapy.

Introduction

After rigorous, lengthy, and expensive preclinical testing, identification of appropriate drug formulations, and the development of a reliable manufacturing process, a fledgling antiepileptic drug (AED) is finally ready for clinical testing. Its further journey toward the marketplace will follow a well-circumscribed path, which is largely dictated by the demands of regulatory authorities, such as the Food & Drug Administration (FDA) in the United States and the European Medicines Agency (EMEA). For the most part, clinical trials are performed out of necessity; they may provide important information about efficacy and tolerability, but are predominantly focused on obtaining a license for the sponsor (pharmaceutical company). Regulatory trials are performed in series – from Phase I to Phase III – with little or no overlap, and with the results of one study informing the design of the next. A minimum number of trials is required to achieve regulatory approval but additional studies are often requested, particularly to clarify unexpected results. Such studies can add substantially to the duration of the development program, which currently costs in the region of $800 million for each new AED. Getting the development program right the first time is, therefore, extremely important to the sponsor. Phase IV studies and monotherapy trials are typically undertaken after the initial license (usually as adjunctive treatment for refractory localization-related epilepsy) has been obtained.

Basic Principles

There are a number of issues that need to be considered at the outset of all clinical development programs. The most significant are discussed in detail below.

Sample Size

One of the first considerations is sample size calculation or power. Bigger is invariably better. It would be unethical to conduct a trial with insufficient numbers of patients to demonstrate a statistically significant drug effect. However, it would be similarly unethical to expose large numbers of patients to an experimental treatment that is unlikely ever to reach the marketplace. In any power calculation, the investigator must first select the primary outcome measure and then estimate the size of the treatment effect. A power of 90% is typically employed in regulatory studies, with the cut-off for statistical significance usually set at $p < 0.01$. Where the required recruitment levels are regarded as unrealistic, it may be necessary to engage more investigators, to reduce the number of planned comparisons, or – if all else fails – to relax the statistical stringency.

Inclusion/Exclusion Criteria

Phase II and Phase III studies have strict inclusion/exclusion criteria. These criteria are selected to minimize unnecessary variability and potentially confounding factors in the study population, and to reduce the likelihood of adverse events being unfairly ascribed to treatment. Typical inclusion criteria for Phase III trials include: age between 16 and 65 years, uncontrolled partial seizures with or without secondary generalization, minimum of 4 seizures per calendar month with no seizure-free months, and ability to provide informed consent. Exclusion criteria are usually wide-ranging – for example, more than two or three concomitant AEDs, history of alcohol or drug abuse, psychiatric illness, pregnancy or possibility of pregnancy, single method of contraception (females only), nonepileptic attack disorder, previous status epilepticus, abnormal liver function tests, abnormal

electrocardiogram, progressive neurological disorder, etc. Strict inclusion and exclusion criteria create an artificial environment in which the efficacy and tolerability of a new AED is assessed in a cohort of patients that does not always accurately reflect the epilepsy population for which the drug will be licensed. So-called special populations, such as the elderly and females of child-bearing potential, are often excluded from regulatory trials. Individuals with infrequent seizures or concomitant comorbidities are similarly under-represented. Regulatory approval for use of the drug in children and for idiopathic generalized epilepsies requires additional, dedicated trials that are typically performed after initial marketing.

Randomization

Random allocation of participants to individual treatment groups is an important part of most clinical studies, regulatory or otherwise; the process minimizes bias and increases the probability that observed differences can be ascribed to treatment. In open-label studies, randomization eliminates any temptation to assign a specific treatment to a specific patient. In its simplest form, effective randomization can be achieved by coin-tossing (heads or tails), rolling dice (odd or even), assigning patients according to sequential order of enrolment, or using pre-sealed envelopes containing study group assignments. Automated telephone randomization is increasingly common, particularly in double-blind, placebo-controlled regulatory studies, and often employs a system of random permuted blocks, with stratification as necessary.

Blinding

Preconceptions or prior knowledge regarding efficacy and/or tolerability necessitate blinding of trial participants and/or investigators to minimize bias. Single-blind studies are those in which the patient is unaware of the treatment – whether drug or placebo – whereas the doctor has full knowledge. There is a significant risk of physician bias, and so single-blind studies are rare in the epilepsy field. Most regulatory trials are double-blind, so neither the participant nor investigator knows what treatment has been assigned. Double-blind studies allow objective assessment of treatment and accommodate the placebo-effect, but can be problematic when serious adverse events arise. On rare occasions, the blind may be broken to determine whether a life-threatening adverse event was likely to be treatment-related.

Control

Choice of an appropriate control is important in the design of clinical trials and can influence the outcome and the validity of the resulting observations. In studies employing a historical control, all patients receive the active treatment and pharmacological effects are compared to a baseline period. This is a common approach in open-label Phase IV studies and has the advantage that patients act as their own control. Placebo control is the gold standard for regulatory studies and is preferred for all Phase II and Phase III trials in epilepsy; patients are randomized to add-on treatment with either study drug or an inert tablet (placebo). A dose control design dispenses with the placebo arm and instead compares multiple doses of an individual drug in discrete groups of patients. Active control studies are typically reserved for monotherapy trials in newly diagnosed patients, where the study drug is compared head-to-head with an established agent.

Dose Selection

Selecting appropriate drug doses and titration rates in clinical trials is fundamental to their success or failure. Doses known to be effective in preclinical studies will inform the design of Phase I trials, which in turn inform Phase II, and then Phase III investigations. Thus, dose selection is refined throughout the development program. Interestingly, many modern AEDs are used clinically at doses and titration rates that are lower and slower, respectively, than were originally employed in pivotal trials. High doses achieved via fast titration rates tend to be more efficient in providing persuasive efficacy data for regulatory authorities.

Clinical Pharmacokinetics

Preliminary information regarding the pharmacokinetics of new compounds can be derived from preclinical studies and is often utilized in designing the Phase I program. Pharmacokinetic analysis continues through all stages of clinical development, with protocols being refined to accommodate new data regarding elimination half-life, time to peak concentration, food effects, presence of active metabolites, and routes of elimination. Short half-life drugs may need to be administered several times daily in order to maintain steady-state serum concentrations, whereas long half-life agents will require less frequent dosing. Once- or twice-daily dosing is preferred for all AEDs. Drugs that require more frequent administration may be associated with compliance issues and peak-concentration related side effects. Developing an extended-release formulation should be considered early with such molecules in order to optimize tolerability and ease of use. Separate pharmacokinetic studies in children are usually requested if a license for the drug is subsequently sought in this patient population.

Drug Interactions

Another important pharmacological consideration in clinical drug development is the potential for drug–drug interactions. These interactions can be a substantial impediment to the successful outcome of add-on trials unless

completely understood from the outset. Trials that include patients established on enzyme-inducing AEDs (particularly phenobarbital, phenytoin or carbamazepine) may underreport efficacy due to enhanced metabolism and lower serum concentrations of the study drug. In contrast, those performed in patients concomitantly treated with enzyme inhibitors (such as sodium valproate) may overreport side effects due to reduced metabolism and higher serum concentrations of the new AED. Most development programs include specific Phase II interaction studies so that potential problems are identified at an early stage. A detailed pharmacokinetic and metabolic profile is a statutory requirement for regulatory approval.

Analysis

Data generated from regulatory clinical trials are analyzed by the study sponsor. There are two principal approaches: intention-to-treat and per-protocol analysis. Intention-to-treat is the conservative approach preferred by regulators. It expresses efficacy and tolerability as a percentage of all randomized patients, or more often, of all patients who took at least one drug dose. Protocol violators are regarded as having not responded to the drug. In contrast, per-protocol analysis focuses on patients who reach a recognized end-point. For example, if ten patients start a clinical trial and six return for their first follow-up visit, four of whom are seizure-free, an intention-to-treat analysis will report a seizure-free rate of 40% (4 of 10), whereas the per-protocol figure will be 67% (4 of 6). Thus, per-protocol analyses tend to provide more favorable data and, arguably, provide a more realistic and clinically relevant view of the efficacy and tolerability of a new AED.

Trial Designs

There are two principal designs that can be employed in Phase II and Phase III trials in epilepsy; cross-over and parallel-group. Parallel-group trials are more commonly employed, predominantly because they permit the evaluation of multiple doses versus placebo in a single investigation and allow amalgamation of results from similarly designed protocols.

Cross-Over Studies

Cross-over studies (Figure 1) recruit a cohort of epilepsy patients, who are followed-up for a baseline period of approximately 8 weeks prior to randomization. Participants are generally randomized in 1:1 ratio to active drug or placebo, with titration over the subsequent 2–6 weeks. There then follows an evaluation period (usually 8–12 weeks), after which patients are tapered off their initial treatment. After a washout period of around 2–4 weeks, they are titrated onto the alternative treatment (active drug or placebo). There is then a second evaluation period, before the participants are either withdrawn from the study or given the opportunity to enter a long-term extension phase. The advantages of the cross-over design are that each subject acts as his or her own control, and that a smaller number of patients are required in comparison to parallel-group studies. The disadvantages are numerous. Cross-over studies are often of longer duration than parallel-group studies. There may be difficulty in incorporating multiple dosage arms and in dealing with drop-outs; patients who only complete the first evaluation phase contribute little to the analysis. There is also potential for unblinding, when the effects of the

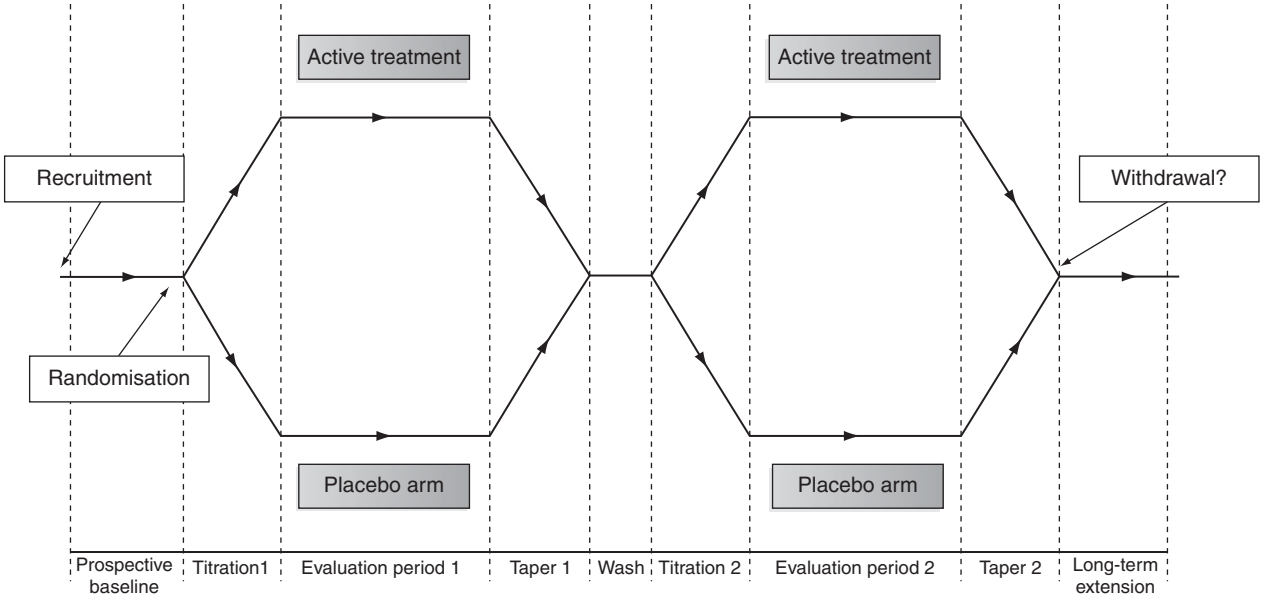

Figure 1 Schematic of simple cross-over design trial.

active drug are more obvious to the participants than those of placebo, and for carry-over effects between evaluation phases, particularly for drugs with long elimination half-lives.

Parallel-Group Studies

Parallel-group studies (**Figure 2**) recruit a cohort of patients who are followed-up for a baseline period of usually 8–12 weeks prior to randomization. These studies permit the inclusion of multiple active drug arms (allowing the assessment of multiple doses) in comparison with a single placebo arm (**Figure 3**). Titration is performed over approximately 2–6 weeks, depending on the pharmacokinetic and pharmacodynamic characteristics of the trial drug. The titration period is followed by a relatively short evaluation period (8–16 weeks), after which patients are tapered off their allotted medication and either withdrawn from the study or entered into a long-term extension phase. The advantages of parallel-group

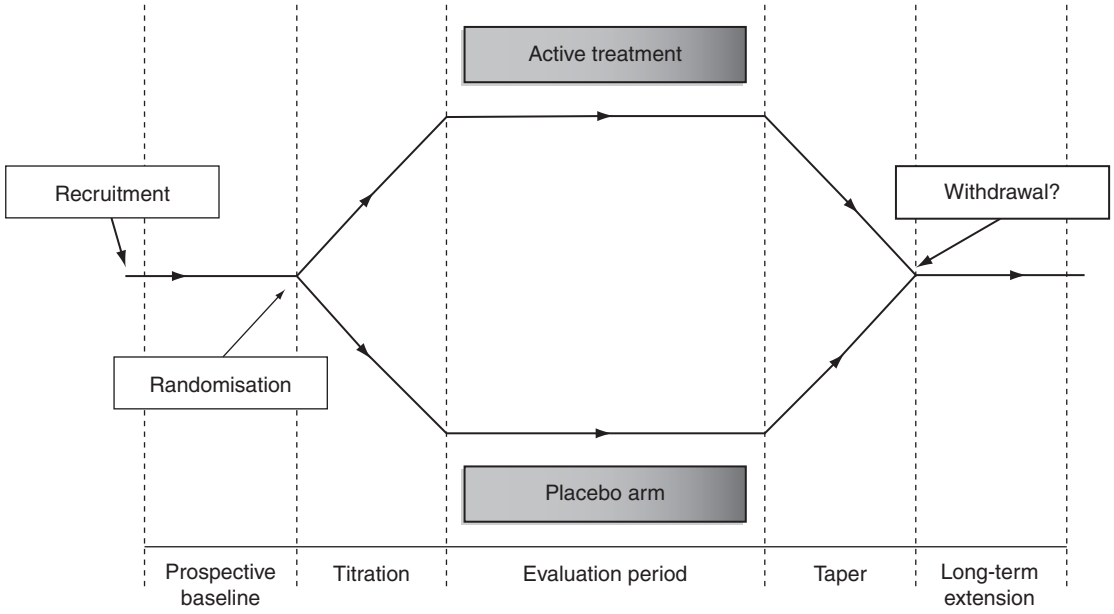

Figure 2 Schematic of simple parallel-group design trial.

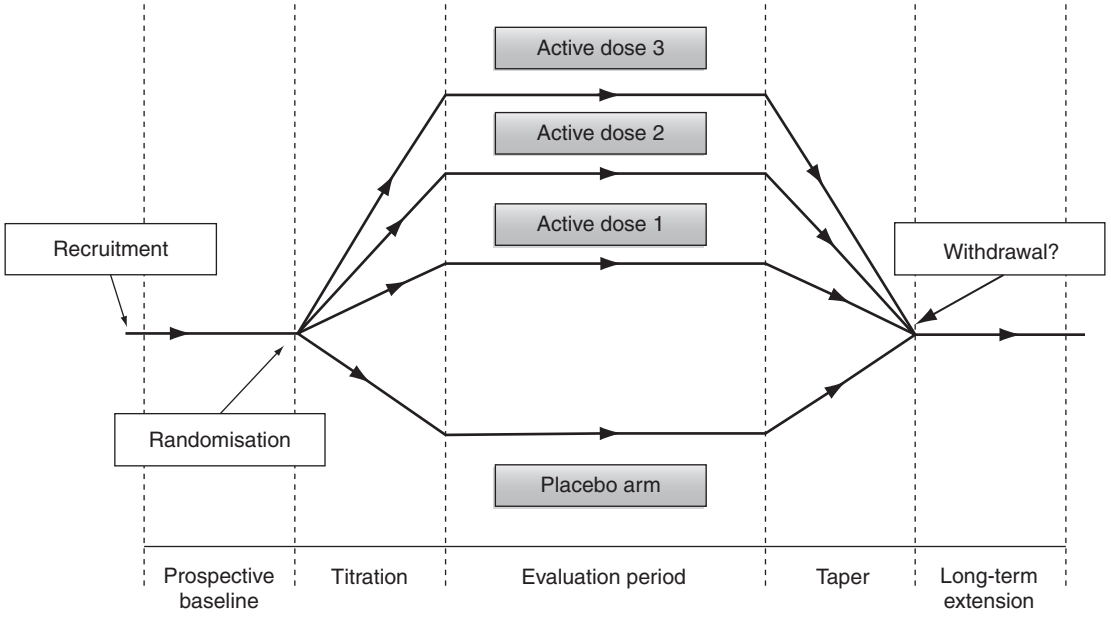

Figure 3 Schematic of multiple dose parallel-group design trial.

studies include relatively short duration, straightforward blinding, and the ability to incorporate multiple dosage arms. On the downside, these trials require a large number of participants and place an emphasis on equitable randomization.

Long-Term Extension Studies

Long-term extension studies follow Phase II and Phase III trials and allow patients to continue treatment with the study medication over a longer period, often several years. Participants who experienced genuine (or perceived) benefit from inclusion in the trial may opt to enter the long-term extension phase and will be tapered/titrated (depending on whether they were receiving active drug or placebo in the evaluation phase) to a predetermined dose of the active drug. This dose is then administered on an open-label basis, with dosage adjustments allowed according to clinical need. Those who failed to benefit from the trial are tapered off their allotted treatment (active drug or placebo) and either withdrawn from the study or given the opportunity to enter the long-term extension phase, on the basis that prior lack of efficacy may have been the result of receiving placebo in the double-blind evaluation period. Long-term extension studies provide the sponsor with valuable safety data which might not be readily apparent from the short evaluation period employed in most Phase II and Phase III studies. They also satisfy the demands of regulatory authorities who require efficacy and safety data on several hundred patients, with multiple years of drug exposure, when considering approval for marketing.

Phase I Trials

Phase I trials represent the first human exposure to any potential new AED and are largely performed in small groups of healthy volunteers. Some Phase I trials recruit a handful of individuals with refractory epilepsy, as patients will often have a different sensitivity to side effects than volunteers. Phase I trials are typically randomized, single- or double-blind, and placebo-controlled. They are predominantly concerned with tolerability and safety, the principal objectives being to establish the likely effective dose range, the maximum tolerated dose, and the pharmacokinetic profile (including early indications of pharmacokinetic interactions). They are often performed in dedicated clinical trial units where volunteers can be observed closely during early drug exposure.

Phase I trials can be subdivided into Phase Ia and Phase Ib. Phase Ia studies involve the single administration of multiple drug doses in a placebo-controlled, dose-escalation design in order to explore the limit of tolerability. Care is taken to avoid the simultaneous exposure of multiple volunteers to a high dose of any novel compound. Phase Ib studies are informed by the results of Phase Ia and typically involve daily drug administration over several weeks. The results of Phase I studies play a significant role in the design of subsequent trials, particularly in terms of dose selection and dosing interval. Where Phase I results deviate from expectation, there may be a requirement to reconsider the dose range (particularly where adverse effects occur at the lowest dose or where they are absent at the highest dose), a need to reformulate the drug (if significant peak concentration toxicity occurs), or even an obligation to abandon development altogether (where significant and insurmountable concerns about the bioavailability, pharmacokinetics or safety profile become apparent).

Phase II Trials

Phase II trials are randomized, double-blind, placebo-controlled, and represent the first use of the new compound in significant numbers of people with refractory epilepsy. The objectives are to establish tolerability and relative safety, to explore the pharmacokinetic profile in epilepsy patients, and to exclude any significant drug–drug interactions. Phase II trials can also provide preliminary evidence of efficacy – and while not often powered to do so reliably, this evidence may be sufficient for the sponsor to make a decision on whether to proceed further with clinical development. Phase II trials can be subdivided into Phase IIa and Phase IIb; the former is essentially a pilot study involving a limited number (~50) of participants, whereas the latter will often recruit several hundred epilepsy patients. This subdivision allows for protocol amendment and optimization.

Phase II trials typically take the form of multicentre, add-on studies, employing a cross-over (rarely) or parallel-group (usually) design with a long-term extension phase. These trials involve recruitment of adults with refractory localization-related epilepsies, experiencing four or more seizures per month, and taking one, two, or occasionally three other AEDs. Phase II studies in epilepsy are far removed from clinical practice. They employ fixed doses and fast titration rates, which allows for little interindividual flexibility and increases the likelihood of withdrawal due to poor tolerability. The short evaluation period does not provide any clinically meaningful information on efficacy and safety.

Phase III Trials

Phase III trials are scaled-up versions of those performed in Phase II, tailored according to the results of previous investigations and powered to confirm efficacy. They are known

as pivotal studies. A minimum of two such studies with broad geographical representation are required for regulatory approval. Each Phase III trial typically recruits around 1000 patients and is routinely performed as a multicentre, randomized, double-blind, placebo-controlled, add-on study in adults with refractory partial seizures, with or without secondary generalization. The principal objective is to demonstrate that the study medication is significantly more efficacious than placebo in reducing seizure frequency. Phase III trials also provide important information regarding tolerability in this setting and allow further investigation of safety, pharmacokinetics, and drug interactions.

Phase III studies generally have a multiple dosing parallel-group design, with a single placebo arm and two or three active treatment arms (which permit investigation of different doses and/or dosing intervals) and a long-term extension phase (**Figure 3**). The advantages of this design include the ability to demonstrate a dose–response relationship and the ability to identify the optimum effective dosage range. Problems include the fixed titration period (which invariably results in a greater number of drop-outs at the highest dose), the need for a large number of patients, and the dependence on good dose selection. Like Phase II trials, pivotal studies are an artificial paradigm; they recruit a highly selected patient population (often with severely refractory epilepsy), employ fixed doses and fast titration rates, and usually only provide evidence of efficacy for partial seizures with or without secondary generalization.

Submission and Approval

After completion of successful Phase III pivotal trials, the sponsor will prepare a detailed new drug application (NDA) for submission to regulatory authorities. This application includes information obtained at all stages of the drug development program, from basic physicochemical properties through preclinical testing, investigation of toxicology, details of manufacturing, and finally the results of all clinical trials, from Phase Ia to Phase III. There is an obligation to include all data (positive and negative) and to make results of individual laboratory studies and case record forms available for scrutiny. Sponsors are encouraged to seek publication of all Phase II and Phase III data in peer-reviewed journals, irrespective of the results, and investigators are required, by law, to retain individual patient records for a 15-year period. Scrutiny of the NDA and any additional material requested by the regulators can take upwards of 12 months.

Should the compound be approved for marketing, what has been learned by whom at each stage of the process? Preclinical studies suggest to the sponsor that the drug is likely to have efficacy and that there is a reasonable separation between effective and toxic doses. Phase I trials convince the sponsor that the new chemical entity is suitable for development as a potential AED. Phase II trials convince the sponsor that the drug is well-tolerated and that it may be effective clinically. Phase III trials convince the regulators that the drug is effective and relatively safe.

As far as prescribing physicians are concerned, once a new AED has been approved, they can be sure that it is better than nothing at all (i.e., better than placebo) in the treatment of refractory focal epilepsies, that it has good tolerability when used over short-periods at doses not exceeding those employed in the trial program, and that there were no significant safety concerns in the 1500–3000 patients exposed to date. Missing information at the time of approval includes: evidence of efficacy for specific epilepsy syndromes; efficacy in infants, children, the elderly and in patients with infrequent seizures; efficacy as monotherapy; comparative efficacy and tolerability versus established agents; optimum target doses and titration rates; the incidence of rare and occasionally life-threatening side effects (c.f. felbamate); and the full spectrum of clinically relevant drug–drug interactions. Much of this missing information will be accumulated subsequently through Phase IV studies and with clinical experience.

Phase IV Studies

Phase IV studies are typically performed in the postmarketing period, once the new drug has received its license as adjunctive therapy for partial seizures with or without secondary generalization in adults. They focus on issues that are not addressed during regulatory trials, such as efficacy for specific syndromes and special populations. Their design is highly variable; they are not constrained by any regulatory requirement and so can range from clinical audit to randomized head-to-head comparisons. There is little use of blinding or placebo-control in Phase IV because efficacy has already been established. These studies are pragmatic and may be considerably more informative in terms of everyday clinical relevance. Investigation of efficacy in other indications (most commonly neurogenic pain, migraine, anxiety, and bipolar disorder) can be undertaken at this stage, but nowadays these studies often overlap with the formal epilepsy development program.

Monotherapy Trials

Monotherapy is the gold standard of epilepsy treatment, and the vast majority of people with well-controlled epilepsy take a single AED. In contrast, polypharmacy has traditionally been associated with poor tolerability,

complicated drug interactions, and a greater degree of cognitive impairment. Although most new AEDs are initially licensed as add-on therapy in refractory localization-related epilepsy, many manufacturers seek a monotherapy license to increase market-share and encourage first-line use of their drug. Formal regulatory approval is required before such a license can be granted.

The regulatory requirements for a monotherapy license differ between Europe and the United States. The EMEA expects that the study drug will show equivalence to (or at least noninferiority to) an established AED at comparable dosage. This equivalence is usually investigated in a head-to-head comparison (active control study). The FDA takes the opinion that equivalence can mean equally ineffective as well as equally effective, and so insists that the new drug proves superior to placebo or to an established AED, irrespective of dose. A series of monotherapy designs has emerged in the United States that aim to prove that monotherapy with the new drug is better than nothing (placebo) or almost nothing (pseudoplacebo or low dose control).

Active Control

An active control monotherapy study compares the efficacy and tolerability of a new AED with an equivalent dose of an established agent in a randomized, double-blind manner, in people with newly diagnosed epilepsy. Around 50% of this population will respond to their first AED, usually at modest dosing, and so demonstration of superiority would require an unrealistic number of patients. Carbamazepine is the most common choice of comparator, and studies usually involve patients with partial and/or tonic–clonic seizures. Those with other idiopathic generalized epilepsies are specifically excluded. These studies allow a direct comparison without the confounding influence of concomitant agents, thereby negating any positive or negative effects of drug–drug interactions. Data on 6 and 12 month seizure free rates are now requested for monotherapy approval in Europe. Since this patient population typically experiences relatively infrequent seizures, these studies can take upwards of three years to complete.

Withdrawal to Monotherapy

Low dose control monotherapy trials have been designed to meet the demands of the FDA. A therapeutic dose of the study drug is compared with a minimally effective or subeffective dose (pseudoplacebo) of an established AED (often 15 mg kg^{-1} sodium valproate) in a randomized, double-blind design in uncontrolled patients already taking one or two AEDs. Alternatively, low and high doses of the study drug can be compared in the same design. Preexisting AEDs are tapered off, with the aim of maintaining patients on the new monotherapy. Data are typically analyzed on the basis of time to *n*th seizure or percentage of patients exiting the trial. The use of a low dose comparator ameliorates, to some extent, ethical concerns associated with placebo, affords some protection against catastrophic seizures, and provides a paradigm in which superiority can be demonstrated over a relatively short period of time. The use of a pseudoplacebo or a low dose comparator is ethically questionable. Accordingly, the latest version of this design involves comparison of high and low doses of the study drug, with historical controls from previous investigations. Again, one group of patients has to do better (or worse) than the other for the trial to be successful. Many patients withdraw from the study before preexisting AEDs can be successfully tapered off, and as a result, do not actually contribute to appraisal of the test drug as monotherapy. Another concern with this design is that any resulting monotherapy license permits use of the drug in patients with newly diagnosed epilepsy, even though it has not been studied in this population.

Presurgical Studies

Presurgical monotherapy studies enroll patients who have been admitted to specialist centers for assessment of their suitability for epilepsy surgery. In the efforts to localize the seizure focus in these individuals, existing AEDs are withdrawn under careful supervision. During this period, it is possible to undertake a short, randomized, double-blind monotherapy study. Efficacy is typically compared to placebo by measuring the time to *n*th seizure after randomization or the percentage of patients who remain seizure-free throughout the short evaluation period (often no more than 5–10 days). Unsurprisingly, this design has fallen out of favor, predominantly due to concerns about the very short drug exposure and potential interference with the surgical work-up, leading to extended in-patient time and/or failure to localize the seizure focus.

Monotherapy studies designed to satisfy the demands of regulatory authorities have significant limitations. They tend to employ fixed doses, fast titration, and an inflexible design which prevents interindividual adjustment of medication. It is difficult to establish efficacy in an ethical manner and beyond any statistical doubt. It may also be difficult to recruit patients with new onset of seizures, as involvement in research projects is not necessarily their priority when dealing with a potentially life-changing diagnosis of epilepsy. Traditional head-to-head monotherapy studies are unlikely to demonstrate superiority of a novel drug over an established agent at equivalent doses without recruiting an impractical number of patients. Withdrawal to monotherapy studies are ethically dubious; these studies often do not provide efficacy as

monotherapy, and include a patient population different from that in which the new AED will subsequently be licensed.

Novel Designs

The difficulty in proving superiority in monotherapy trials of AEDs has resulted in the search for innovative designs, such as the sequential analysis method. This approach differs from more traditional head-to-head comparisons by incorporating a series of interim analyses of emerging data, which allow for the early termination of the trial at the first sign of a statistically significant difference between treatments. Such designs are likely to require fewer patients than in traditional designs of equal power and can avoid continued recruitment of patients to a trial in which one treatment is evidently inferior. It has been applied in only one AED monotherapy study to date, but that study demonstrated the utility of this approach – to such an extent that it merits further consideration. The sequential analysis method was employed in a randomized, double-blind comparison of remacemide hydrochloride and carbamazepine. The study recruited newly diagnosed epilepsy patients aged 12–75 years, who had experienced two or more partial and/or primary generalized tonic–clonic seizures in the preceding 12 months. Subjects were randomized to either remacemide hydrochloride or carbamazepine in a 1:1 ratio, both being titrated over a 6-week period. Dosage adjustments according to clinical need were allowed, while maintaining the blind. The primary efficacy end-point was time to first seizure after completion of the titration phase. The trial was stopped at the second interim analysis, just 18 months after the first patient had been recruited, when it became apparent that carbamazepine was significantly more effective than remacemide hydrochloride in preventing seizure recurrence. Time to first, second, third, and fourth seizures all significantly favored carbamazepine. This trial, performed over a relatively short duration and including efficacy data on just 449 patients, is the first and only demonstration of superiority of one AED over another at therapeutic doses. Had this trial been performed as a traditional active control monotherapy comparison, it would have required more than 1000 patients studied over a number of years to demonstrate the same effect.

Summary

The clinical development of a new AED follows a well-defined path, through a series of trials that possess a recognized and rigid schedule, which is largely dictated by the demands of regulatory authorities and the desire of the pharmaceutical industry to obtain approval for marketing in as short a time period as possible with the minimum of expense. Phase I studies in healthy volunteers demonstrate tolerability and help determine dose range. Phase II studies in epilepsy patients advance knowledge of tolerability and pharmacokinetics, and offer a preliminary insight into potential efficacy. Phase III studies in large cohorts of people with refractory localization-related epilepsy are fundamental to the demonstration of both efficacy and tolerability; they are the pivotal investigations, two of which provide the minimum requirement for regulatory approval. Phase IV studies and pragmatic trials provide important information about the use of new AEDs in the real world; they serve to address many of the questions that remain unanswered by the development program. Monotherapy studies represent a different problem to add-on trials. Regulatory requirements are geographical, and the inappropriateness of placebo makes demonstration of efficacy as monotherapy more difficult. A number of trial designs have been employed to date but none has, as yet, emerged as the gold standard. Clinical development of novel AEDs is a lengthy and expensive process with no guarantee of success. There is little to suggest that it will become easier in time.

Introduction

Gender-specific side-effects of antiepileptic drugs (AEDs) affect both men and women at several stages throughout life. These side-effects may have a significant impact on various aspects of life, including pubertal development, fertility, sexuality and self-esteem owing to cosmetic problems, and (at older ages) menopause and bone health. In this article, we discuss the potential problems of chronic AED use at different stages of life, and describe potential side-effect problems of relevance to both men and women. Pregnancy issues and contraception will not be discussed here, as this topic has been reviewed recently in various publications.

Background and Recent Results

Puberty

There is a complex interaction between epilepsy, hormones, and AEDs in puberty, and the isolated effects of AEDs are therefore difficult to ascertain. Concerning the effect of AEDs on pubertal maturation, no effect on different indices of sexual maturation, including linear growth, was found in our study of girls with epilepsy taking valproate (VPA), carbamazepine (CBZ), or oxcarbazepine (OXC). We also studied the menarche age in 265 women with epilepsy debut before the age of 18 and on AED treatment. The study did not confirm clustering of epilepsy debut around menarche; however, the onset of epilepsy was more frequent in adolescents than in children. In contrast, two studies from Egypt have indicated a possible effect of AEDs on pubertal maturation in both sexes, including reduced linear growth. The effects were most pronounced in patients on polytherapy, which generally implies a more severe or active epilepsy than patients on monotherapy. It could therefore not be determined whether this reported effect is due to the drug, the epilepsy, or other factors. However, some animal studies on mice and goats suggest delayed pubertal maturation after chronic VPA treatment, a finding that should encourage further studies directed towards a possible effect of this drug on pubertal maturation.

As for gender-specific, late developing effects of antiepileptic drugs, two of our studies have shown that starting VPA in childhood and adolescence increases the risk of having polycystic ovaries later in life. A subsequent study in the same population of pubertal girls also showed similar findings, with increased frequency of polycystic ovaries and hyperandrogenism at a 5 year follow up. A recent publication verified a higher postmenarche serum testosterone level, but no signs of polycystic ovaries in VPA-treated girls with epilepsy. The possibility of late, gender-specific effects of VPA should therefore be born in mind when treating girls with this drug.

Reproductive Endocrine Dysfunction

Reproductive endocrine dysfunction is common in both women and men with epilepsy. In women, menstrual disorders, polycystic ovaries, and infertility have been described; in men, reduced potency and sperm abnormalities have been found. In both sexes, sexual problems and endocrine changes are frequent. The reasons for these problems are multifactorial, and both epilepsy and AEDs have been causally implicated.

It is well established that epilepsy itself may affect concentrations of reproductive hormones, which can lead to reproductive disturbances. Epileptic seizures are associated with increased secretion of pituitary hormones, including an increase in prolactin and LH pulse frequency (which is important for cycle regularity). Even laterality

Introduction

Gender-specific side-effects of antiepileptic drugs (AEDs) affect both men and women at several stages throughout life. These side-effects may have a significant impact on various aspects of life, including pubertal development, fertility, sexuality and self-esteem owing to cosmetic problems, and (at older ages) menopause and bone health. In this article, we discuss the potential problems of chronic AED use at different stages of life, and describe potential side-effect problems of relevance to both men and women. Pregnancy issues and contraception will not be discussed here, as this topic has been reviewed recently in various publications.

Background and Recent Results

Puberty

There is a complex interaction between epilepsy, hormones, and AEDs in puberty, and the isolated effects of AEDs are therefore difficult to ascertain. Concerning the effect of AEDs on pubertal maturation, no effect on different indices of sexual maturation, including linear growth, was found in our study of girls with epilepsy taking valproate (VPA), carbamazepine (CBZ), or oxcarbazepine (OXC). We also studied the menarche age in 265 women with epilepsy debut before the age of 18 and on AED treatment. The study did not confirm clustering of epilepsy debut around menarche; however, the onset of epilepsy was more frequent in adolescents than in children. In contrast, two studies from Egypt have indicated a possible effect of AEDs on pubertal maturation in both sexes, including reduced linear growth. The effects were most pronounced in patients on polytherapy, which generally implies a more severe or active epilepsy than patients on monotherapy. It could therefore not be determined whether this reported effect is due to the drug, the epilepsy, or other factors. However, some animal studies on mice and goats suggest delayed pubertal maturation after chronic VPA treatment, a finding that should encourage further studies directed towards a possible effect of this drug on pubertal maturation.

As for gender-specific, late developing effects of antiepileptic drugs, two of our studies have shown that starting VPA in childhood and adolescence increases the risk of having polycystic ovaries later in life. A subsequent study in the same population of pubertal girls also showed similar findings, with increased frequency of polycystic ovaries and hyperandrogenism at a 5 year follow up. A recent publication verified a higher postmenarche serum testosterone level, but no signs of polycystic ovaries in VPA-treated girls with epilepsy. The possibility of late, gender-specific effects of VPA should therefore be born in mind when treating girls with this drug.

Reproductive Endocrine Dysfunction

Reproductive endocrine dysfunction is common in both women and men with epilepsy. In women, menstrual disorders, polycystic ovaries, and infertility have been described; in men, reduced potency and sperm abnormalities have been found. In both sexes, sexual problems and endocrine changes are frequent. The reasons for these problems are multifactorial, and both epilepsy and AEDs have been causally implicated.

It is well established that epilepsy itself may affect concentrations of reproductive hormones, which can lead to reproductive disturbances. Epileptic seizures are associated with increased secretion of pituitary hormones, including an increase in prolactin and LH pulse frequency (which is important for cycle regularity). Even laterality

of epileptic activity may be of importance, as left-sided temporal foci seem to increase the occurrence of polycystic ovaries while right-sided foci increase the frequency of hypogonadotropic hypogonadism in women.

Effect of AEDs on Reproductive Endocrine Dysfunction in Men

Reproductive endocrine dysfunction in men with epilepsy seems to be, at least in part, related to the use of AEDs (Table 1). Enzyme-inducing drugs, in particular phenytoin (PHT), phenobarbital (PB), and carbamazepine (CBZ), reduce the amount of bioactive androgens, including lowering of DHEAS levels. The reason for this effect is primarily an increase in sex hormone-binding globulin (SHBG). In addition, elevated serum estradiol levels have been reported in men taking PHT, and high estradiol levels were found to be associated with sexual dysfunction in some men.

CBZ has been suggested to affect several semen parameters in both animal and human studies. In humans, this effect was first described in an *in vitro* model demonstrating reduced sperm motility. CBZ also inhibited testosterone formation at clinically relevant doses in an *in vitro* Leydig cell model. In two more recent studies, we have shown reduced sperm motility and an increased frequency of morphologically abnormal sperm in men on CBZ. Changes in sperm morphology are considered to have a predictive value for fertilization as well as significant relationships with several sperm function tests.

Valproate (VPA) does not induce liver enzymes. However, VPA does reduce serum gonadotropin levels and increases concentrations of serum androstenedione. This effect may be caused either by a centrally-mediated modification of GABA-ergic neurotransmission in the hypothalamus or by a direct effect of VPA on endocrine tissue, particularly on the testis. A direct effect on the testis is supported by animal studies demonstrating reduction in testicular size and altered testicular morphology after VPA treatment in dogs, rats, and goats. Similarly, small testicular volumes have also been found in humans taking VPA. Further, semen morphology and motility is affected by VPA. In humans, the number of motile sperm is reduced, and several morphological parameters are changed. In contrast to the findings with CBZ, we found that sperm from men treated with VPA have more tail abnormalities. Several studies of infertile men without epilepsy have shown these types of abnormalities; bent or coiled sperm tails were found to be significantly more frequent when a pregnancy did not occur. The sperm tail changes observed with VPA may therefore, at least theoretically, affect fertility. Carnitine is important for sperm motility, and reduced sperm motility has been noted in men on VPA, in whom VPA reduces the free versus total carnitine ratio.

Lamotrigine (LTG) has so far not been associated with reproductive endocrine disturbances in men with epilepsy or in non-epileptic animals. Few studies have been performed on the endocrine effects of newer drugs, and some drugs have not been studied at all in this respect. Some of our studies have suggested that oxcarbazepine (OXC) taken in high doses may affect serum testosterone and SHBG levels, and may also induce changes in sperm morphology. However, this finding must be confirmed in further studies before conclusions on the clinical significance of these possible reproductive effects of OXC can be drawn. No data are at present available for drugs such as felbamate, gabapentin, pregabalin, levetiracetam, tiagabine, vigabatrine, and zonisamide.

Table 1 Endocrine effects of antiepileptic drugs

Drug		*Men*	*Women*
EIAED	Tot. testosterone	↔	↔
	Tot. estradiol	↔(↑?PHT)	↔
	SHBG	↑	↑
	FAI	↓	↓
	DHEAS	↓	↓
	FSH	↔	↔
	LH	↔	↔
VPA	Tot. testosterone	↔	↑
	Tot. estradiol		↓(?)
	SHBG	↔	↑
	Androstenedione	↔/↑	↑
	DHEAS	↑	
	FAI	↔	↑
	Insulin	↑	↑
	FSH	↓	↔
	LH	↓	↔

The table shows the most frequently reported findings. Differences between studies do occur. EIAED: Enzyme-inducing antiepileptic drugs; VPA: Valproate; PHT: Phenytoin; FAI: total testosterone/SHBG × 100.

Effects of AEDs on Reproductive Endocrine Dysfunction in Women

Women with epilepsy experience menstrual cycle irregularities, polycystic ovaries, sexual problems, and reduced fertility. The epilepsy itself definitely contributes to these problems. In women even more than males, AEDs also seem to play an important role (Table 1).

As in male subjects, enzyme-inducing drugs reduce free fractions of steroid hormones, increase SHBG, and may also lower DHEAS. No consistent abnormalities in basal or stimulated serum gonadotropin or prolactin levels have been reported. The clinical consequences of these endocrine changes are unknown. So far, no large study has demonstrated any increased frequency of menstrual disorders or other reproductive endocrine disorder in women treated with these drugs.

The use of VPA has been associated with menstrual disturbances, hyperandrogenism, and polycystic ovaries.

The first, large study to investigate this in some detail was a cross-sectional study from 1993. Altogether, 238 women participated in the study. The major finding was that menstrual disorders were common among women taking VPA monotherapy for epilepsy (45%), and that this effect was frequently associated with polycystic ovaries (PCO) and/or hyperandrogenism. Serum mean androgen levels were significantly increased in women on VPA. We later obtained similar findings in a three-centre study conducted in three European countries (Finland, Norway, Netherlands).

In the original paper from 1993, Isojärvi and coworkers found that PCO and hyperandrogenism were especially common if VPA medication was started before the age of 20. This age dependency was later confirmed by others. Further, increases in serum androgen levels were detected before and during pubertal development in young girls taking VPA for epilepsy. A five year follow-up of these girls showed that 60% of the girls/women who were on VPA (during the follow-up study) had polycystic ovary syndrome (PCOS) as compared to 25% of girls/women taking other AEDs, 5.5% of girls whose medication had been discontinued, and 8.3% of control subjects. These observations indicate that the young ovary is vulnerable to the effects of VPA.

While several human studies have supported an effect of VPA on reproductive endocrine function, others have not shown any differences between CBZ- and VPA-treated women with epilepsy with regard to reproductive endocrine parameters and PCOS. The interpretation of these latter results is difficult because the patients were older, and the duration or doses of medication, or seizure frequency in the different treatment groups were not given.

It has been suggested that obesity and associated hyperinsulinemia could be implicated in the development of PCO and hyperandrogenism in women taking VPA. However, PCO and hyperandrogenism were also found in many lean VPA-treated women without hyperinsulinemia, and hyperandrogenism in girls taking VPA for epilepsy was not associated with hyperinsulinemia. It does appear, however, that obesity and related hyperinsulinemia may exacerbate the VPA-related reproductive endocrine disorders in women with epilepsy.

The original observation that VPA induces reproductive endocrine changes is also supported by other reports. First, the effect seems to be reversible after withdrawal of VPA treatment. Second, similar findings have been observed in women treated for bipolar depression. Third, our studies in non-epileptic animals have demonstrated both ovarian morphological and endocrine changes after VPA treatment.

With regard to our animal studies, long-term VPA treatment of adult rats induced endocrine and ovarian morphological changes. Female Wistar rats were fed perorally with either 200 or 300 $mg\,kg^{-1}$ VPA, 5 $mg\,kg^{-1}$ LTG, or control solution twice daily for 90 days. A significant, dose-dependent increase in the number of follicular cysts in the ovaries after VPA treatment was observed, together with a reduction in the number of corpora lutea. No effects were observed after LTG treatment. A detailed analysis of a series of other tissues, including liver, kidney, pancreas, lymphatic tissue, heart, and brain did not reveal any changes. The study thus showed that the effect of VPA was drug-specific, independent of epileptic activity, and with the ovaries as a possible target organ. This view is further supported by another study showing that VPA (at a total dose of only 300 $mg\,kg^{-1}\,day^{-1}$ for 30 days) treatment in rats leads to an increase in the number of cystic follicles in the ovary.

Long-term VPA treatment in female non-epileptic rats also markedly increased the testosterone-to-estrogen ratio, mainly by decreasing estrogen levels, with no or minor effects on gonadotropins. To investigate in more detail whether this effect is related to a direct action of VPA on follicular steroidogenesis, we studied the secretion of testosterone and estradiol from isolated porcine ovarian follicles. Using VPA concentrations ranging from approximately 600 to 1500 $\mu mol\,l^{-1}$, we showed that VPA increased testosterone and reduced estradiol secretion, and reduced the conversion of testosterone to estradiol at therapeutically relevant concentrations. These observations point to a direct effect of VPA on steroidogenesis in the ovary. A direct effect of VPA is further supported by the findings of Hattori et al. from 2000, demonstrating the presence of the enzyme microsomal epoxide hydrolase (mEH) in human ovaries – an enzyme which is important in detoxification of several substances. Several studies have shown that VPA inhibits mEH activity. Hattori and coworkers showed that human granulosa cells expressed mEH and that the inhibition of mEH suppressed conversion of testosterone to estradiol. Given that VPA is a mEH inhibitor, this may be a mechanism by which VPA reduces serum estrogen levels and thereby increases the testosterone-to-estrogen ratio. This VPA effect would lead to an androgen-dominant microenvironment in the ovary and then possibly to polycystic changes without an increase in LH levels. However, in a study on Rhesus monkeys, no effects of 12–15 months of VPA treatment were found on endocrine function, cycle regularity, or ovarian morphology. However, only seven animals were examined in that study, and it was unclear whether the animals received therapeutic drug concentrations for a sufficient period. Further, the study did find a trend toward increased testosterone-to-estrogen ratio, lower estrogen levels, and increased LH/FSH ratio. In addition, body weight was significantly increased.

LTG has so far not been associated with endocrine side-effects in either humans or in animal studies. Replacement of VPA with LTG resulted in normalization of endocrine function during one-year follow-up in women with a previously identified reproductive

endocrine disorder likely related to VPA medication. This result suggests that LTG therapy is not associated with changes in endocrine and metabolic functions in women with epilepsy.

Effects of Newer AEDs on Reproductive Endocrine Dysfunction

Among the newer drugs, levetiracetam (LEV) is of special interest since it binds to the synaptic vesicle protein SV2A. SV2A is widely distributed in the nervous system and also in endocrine tissue. If LEV binds to SV2A vesicle protein in the ovary and/or in the pituitary gland or hypothalamus, this action may provide a link between the drug and endocrine function at either a central or peripheral level. In a recent paper, we showed for the first time that LEV affected basal, but not gonadotropin-stimulated testosterone and estrogen secretion from porcine ovarian follicular cells. This observation suggests that LEV may affect reproductive endocrine function. The clinical consequences of this preliminary observation are difficult to assess at this time, but it is possible that in humans LEV could only affect reproductive endocrine function in prepubertal female subjects with low serum gonadotropin levels, whereas fertile-aged women might not be at risk because the ovaries are stimulated by higher levels of gonadotropins. It is too early to draw any firm conclusions on the possible clinical relevance of this observation in an in vitro model. Studies in women with epilepsy on LEV are warranted.

Recently, two papers have indicated possible endocrine effects of topiramate. In females, topiramate (100 mg kg^{-1}) for 12 weeks reduced fertility and ovarian weight. The serum concentrations were not measured and the clinical relevance of the observations is uncertain. It does underline, however, the importance of studying all antiepileptic drugs more closely with regard to possible endocrine effects.

Bone Health

People with epilepsy appear to have a 2–4 times increased risk of fractures compared to the general population. Postmenopausal women are the most vulnerable group in relation to untoward effects of drugs on bone health due to their estrogen deficiency. Reduced bone mineral density at the femoral neck has indeed been shown in postmenopausal women on AEDs, and more than 50% of all postmenopausal women taking AEDs have experienced fractures. In a prospective study, AED use increased bone loss at the heel and hip in women older than 65 years. The bone loss was sufficient to increase the risk of hip fracture by 29% over 5 years.

PHT, primidone, and phenorbarbital, the old liver enzyme-inducing AEDs, have most commonly been related to disturbances in bone metabolism, but CBZ and the non-inducer VPA have also been found to affect bone health. For new drugs, there is little information on this topic. Preliminary data indicate that LTG does not cause bone loss, while drugs which inhibit carbonic anhydrase (topiramate, zonisamide, acetazolamide) may theoretically affect bone health by causing a metabolic acidocis.

The mechanisms underlying the bone-depleting effects of AEDs are still only partly known. For many years, the main theory was that enzyme-inducing AEDs (e.g., phenobarbital, phenytoin, carbamazepine) caused an accelerated vitamin D hydroxylation to inactive forms, resulting in hypocalcemia, secondary hyperparathyroidism, increased bone turnover, and higher rates of bone loss. However, later studies have shown that AEDs may cause bone loss in the absence of vitamin D deficiency. Also, resistance to parathyroid hormone, calcitonin deficiency, interference with vitamin K metabolism, decreased intestinal absorption of calcium, and a direct drug effect on osteoblastic function have been suggested. Changes in markers of bone formation and resorption indicate that drug-induced increased bone turnover may play an important role. Enzyme-inducing AEDs may also increase the metabolism of sex steroids, with resulting decreased levels of bioavailable endogenous estradiol and testosterone; an increased rate of bone loss may therefore be a consequence of this increased steroidal metabolism.

Surprisingly few animal studies have been performed to investigate the mechanisms underlying the effect of AEDs on bone. For that reason, we performed a series of experiments in rats. Non-epileptic animals fed with LEV, PHT and VPA for 3 months were studied. PHT and VPA reduced bone mineral density (BMD) and content (BMC) in one or more bone compartments. VPA induced increased bone turnover, whereas modest changes were observed for PHT. LEV did not affect bone mass density or content in these animals. Surprisingly, low dose LEV was associated with reduced biomechanical strength and reduced levels of the bone formation marker, osteocalcin. Histomorphological analyses indicated retention of cartilage. These results demonstrate that AEDs may affect bone health by affecting bone quality, not only bone mass density – which is the parameter studied in the clinic. It is difficult to interpret the clinical relevance of these observed changes, but our findings emphasize the importance of using animal models in trying to reveal the possible mechanisms of action of the different drugs on bone.

Menopause

Little is known about the relationships between menopause and epilepsy. There are indications that epilepsy may affect the time of the menopause, as recent studies have shown that women with epilepsy may reach

menopause at an earlier stage than women in the general population. This effect has been attributed more to the epilepsy itself than the use of AEDs. With regard to seizure frequency, there is generally an increase at perimenopause but a decrease at menopause, especially in those women who had experienced a catamenial seizure pattern during their reproductive years.

Hormone replacement therapy (HRT) to women with epilepsy seems to increase seizure frequency. In a double-blind, randomized, placebo controlled study, a marked dose-related increase in seizure frequency was observed in postmenopausal women with epilepsy when taking HRT in the form of a combination of conjugated estrogen and medroxyprogesterone. This treatment also seemed to decrease serum LTG levels. However, the current understanding of the impact of HRT on epilepsy in post menopausal women is limited. Initiation of hormonal treatment must be thoroughly discussed between the physician and the patient to highlight the advantages and risks of the treatment. If HRT is considered necessary, a combination of a single estrogenic compound (such as 17-β-estradiol) with natural progesterone has been suggested.

Sexuality

The quality of human life is a summation of many factors, and sexuality is – for both men and women – of the greatest importance. Several studies have shown that sexual problems are common in people with epilepsy. It has been estimated that some kind of sexual problem is present in 20–50% of patients with epilepsy in both sexes. A wide range of different problems have been described.

The reasons for the sexual problems are multifactorial, and include psychological, epileptological and medicational issues. The specific role for the different AEDs is therefore difficult to ascertain. In general, enzyme-inducing AEDs will reduce free fractions of peripheral sex steroid hormone concentrations, a change which is well known to affect sexual function (and in men, also potency). Decreased libido and anorgasmia have been reported in women treated with VPA for bipolar disorder. This finding has been attributed to the increased serotonergic transmission associated with VPA treatment. A few cases of anorgasmia have also been described with gabapentin treatment. LTG, however, was shown not to affect sexual function.

AEDs can affect sexuality through different mechanisms. First, certain AEDs induce liver enzymes which lead to reduction of free fractions of peripheral sex steroid hormones. Second, a more general, depressive effect of AEDs on brain excitability may have a negative impact on sexual functions. It is possible that the more sedating AEDs are more harmful in this respect than some of the newer, less sedating AEDs. Further, a negative impact of AEDs on cognitive function may also be important in this respect. More research has to be done in this field to better understand the possible impact of different AEDs on sexuality and to elucidate the underlying mechanisms.

One possible option for treating sexual problems in epilepsy has been offered by Harden and MacLusky. A sixty-one year old man with epilepsy complained of reduced libido. He also had low serum testosterone levels. He was treated with an aromatase inhibitor which blocks the transformation of testosterone to estradiol. As a consequence of this treatment, his testosterone levels increased and his sexual functioning improved. It is possible, therefore, that aromatase inhibitors may offer a treatment option for some epilepsy patients with sexual problems.

Cosmetic Side Effects

Cosmetic side-effects are an issue for both men and women with epilepsy, with potentially significant impacts on gender-related interactions. One obvious such side-effect, obesity, is associated with several drugs including VPA, CBZ, and gabapentin, and is actually more than a cosmetic problem, as it can evolve into a metabolic syndrome with major negative health effects. Conversely, weight loss can be experienced with the use of topiramate and felbamate. Further, hair loss, acne, coarse facial structure and gingival hyperplasia can be seen after treatment with certain AEDs. Cosmetic problems may have a significant impact on medication compliance, especially in women, and should be considered as important problems, not dismissed as trivial difficulties. With the many drugs currently available, such cosmetic side-effects that the patient considers intolerable, can in many instances be avoided by choosing an alternative drug.

A recent publication has shown gender differences in the frequency of rash induced by AEDs. Problems with rash were significantly more frequent in women than in men, and highest during the reproductive years. This observation is important since rash is often more serious than just a cosmetic side-effect.

Conclusion – Current State of the Field

In conclusion, surprisingly many issues in the treatment of epilepsy are gender specific. Most antiepileptic drugs have gender-specific side-effects. Different gender-specific side-effects are of importance at different ages throughout life. For instance, issues such as contraception and fertility are important for fertile-aged subjects, while issues such as HRT and bone health are more relevant in the elderly. Increased awareness of gender- and age-specific side-effects among patients and professionals will make it possible to better tailor the antiepileptic drug treatment to the individual with epilepsy, whatever his/her stage of life.

Introduction

Classifications of diseases are not only important for clinical research, but for identifying populations of patients who are likely to share common fundamental structural and functional pathology, for purposes of basic research to reveal fundamental neuronal mechanisms, and for gene discovery. Indeed, the rapid recent advances in identifying the genetic bases of epileptic disorders would not have been possible without well-developed phenotypes. Classifications are also important for creating appropriate experimental animal models, to ensure that basic research is relevant to the human condition. Finally, results obtained from research in the animal laboratory have contributed, and undoubtedly will continue to contribute, to concepts that aid clinicians in devising meaningful classification systems. Consequently, even though classification of epileptic seizures and epilepsy syndromes would appear to be

an entirely clinical endeavor, it requires continued intensive collaboration with basic scientists.

Epileptic seizures and epilepsy were clearly described in the ancient writings of Mesopotamia and India during the first millennia: BC 2400 years ago, Hippocrates had already recognized that epileptic seizures were due to disturbances in the brain rather than supernatural causes, and 1900 years ago, Galen used the terms 'idiopathic' when referring to seizures generated by the brain, and 'sympathetic' when referring to seizures due to external causes. More modern efforts to characterize and classify epileptic phenomena began in the nineteenth century. Esquirol introduced the concepts of 'grand mal' and 'petit mal' seizures in 1815, and Bravais described focal motor seizures in 1827. John Hughlings Jackson recognized that focal seizures reflected localized epileptic activities within functionally discrete brain areas and, beginning in the 1860s, described a variety of anatomical substrates of ictal signs and symptoms. These clinical observations made it possible in the 1880s to undertake surgical treatment for lesions that were apparent only intraoperatively, and also contributed to our understanding of localization of normal cerebral function.

The history of the recognition of temporal lobe epilepsy illustrates not only how the concept of a specific epilepsy syndrome can evolve, but also the clinical utility of its classification. Although hippocampal sclerosis was described by Bouchet and Cazauvieilh in postmortem investigations of brains of patients with 'alienation' seizures as early as 1826, Hughlings Jackson correlated lesions in the hippocampus with seizures associated with tasting movements and 'dream states' in 1898, and his contemporary pathologists characterized the hippocampal morphology associated with what we now refer to as mesial temporal lobe epilepsy. Surgery was largely limited to neocortical resections implicated by signs and symptoms reflecting primary motor, sensory, and language localizations until the advent of electroencephalography (EEG) in the late 1920s and early 1930s. Jasper and Kershman demonstrated in 1941 that this new electrophysiological technique had the ability to localize epileptiform abnormalities in the brain, with temporal spike foci being most common. They also carried out intraoperative EEG recordings and observed a psychomotor seizure beginning in mesial temporal structures. Bailey and Gibbs were the first to report temporal lobe resections based solely on EEG-localizing evidence in 1951, although Penfield, Jasper, and the Montreal group had already accumulated a large series of patients treated with temporal resections. Following these observations, there was a much greater interest in surgical treatment for epilepsy worldwide, and temporal lobe surgery was the most common procedure performed. As a result, there was considerable interest in temporal lobe epilepsy as perhaps the most common epilepsy syndrome.

To standardize terminology and facilitate discussion among epileptologists, the International League Against Epilepsy (ILAE) created the first classification of epileptic seizures and epilepsies in 1970. Epileptic seizures were distinguished from epileptic disorders, and were divided into 'partial,' beginning in a part of one hemisphere, and 'generalized,' with bilaterally synchronous onset. Generalized seizures included absences, bilateral massive epileptic myoclonus, infantile spasms, clonic, tonic, tonic–clonic, atonic, and akinetic seizures. Partial seizures were divided into those with elementary symptomatology, mediated by primary sensory, motor and language neocortex, and complex symptomatology, mediated by mesial temporal limbic structures. Although the classification was criticized because of insufficient anatomical and pathophysiological evidence to support the localizing assumptions, the term 'complex partial seizure' became synonymous with temporal lobe, psychomotor, or limbic seizure. The 1970 Classification of the Epilepsies merely divided conditions into generalized and partial, depending upon whether the epileptogenic abnormality existed in a part of one hemisphere, or bilaterally. Generalized epilepsies were further divided into 'primary,' referring to conditions characterized by epilepsy alone, and 'secondary' when seizures were due to an identifiable structural or metabolic disturbance. It was believed at that time that all partial seizures were secondary.

Current International Classifications

1981 ILAE Classification of Epileptic Seizures

Epileptic seizures are currently classified according to the system published by the ILAE in 1981 (**Table 1**). This system was intended to be a purely phenomenological classification based on ictal signs and symptoms and EEG correlates, because the authors acknowledged that there was insufficient information concerning pathophysiology and anatomic substrates of most epileptic seizures to do otherwise. This phenomenological classification differed from previous classifications in several ways: it recognized the evolution of simple partial to complex partial, and both to secondarily generalized seizures; divided absences into typical and atypical; deleted infantile spasms (which were considered to be a syndrome and not a seizure type); and also deleted akinetic seizures because their existence was questioned. At the time, there was considerable objection to the redefinition of simple and complex partial seizures determined solely by whether consciousness was impaired, because this classification no longer permitted the term 'complex partial seizure' to be synonymous with temporal lobe, psychomotor, or limbic seizure. Cortical ictal events could now be associated with impaired consciousness without involvement of the limbic system and thus become

Table 1 International Classification of Epileptic Seizures

I. Partial (focal, local) seizures
A. Simple partial seizures
  1. With motor signs
  2. With somatosensory or special sensory symptoms
  3. With autonomic symptoms or signs
  4. With psychic symptoms
B. Complex partial seizures
  1. Simple partial onset followed by impairment of consciousness
  2. With impairment of consciousness at onset
C. Partial seizures evolving to secondarily generalized seizures
  1. Simple partial seizures evolving to generalized seizures
  2. Complex partial seizures evolving to generalized seizures
  3. Simple partial seizures evolving to complex partial seizures evolving to generalized seizures
II. Generalized seizures (convulsive or nonconvulsive)
A. Absence seizures
  1. Typical absences
  2. Atypical absences
B. Myoclonic seizures
C. Clonic seizures
D. Tonic seizures
E. Tonic–clonic seizures
F. Atonic seizures (astatic seizures)
III. Unclassified epileptic seizures

Reproduced from Commission on Classification and Terminology of the International League Against Epilepsy (1981) Proposal for revised clinical and electroencephalographic classification of epileptic seizures. *Epilepsia* 22: 489–501, with permission from Blackwell Publishing.

complex partial seizures, while classical limbic auras (e.g., sensations of epigastric rising and emotions such as fear) occur in clear consciousness and are simple partial seizures. More recent criticisms are based on the fact that this classification is neither completely phenomenological (as it purports to be), nor does it have reliable mechanistic implications. For this reason, Lüders and his colleagues at the Cleveland Clinic have recommended the use of semiological descriptions only for ictal events, in place of the ILAE classification. Their scheme is used by many of their trainees throughout the world; however, it is not a classification in the true sense of the term. Despite these concerns, the 1981 seizure classification has become widely accepted and is universally used.

The ILAE is currently reevaluating the 1981 Classification of Epileptic Seizures for a number of reasons: it is already over a quarter of a century old; a number of additional seizure types have been identified; and advances in understanding pathophysiologic mechanisms and anatomic substrates now make it reasonable to consider using these features for devising a more scientifically-based classification scheme. In addition, a number of conceptual issues need to be addressed – not only the controversial distinction between complex and simple partial seizures, but also the artificial dichotomy between partial and generalized ictal events (explained later).

1989 ILAE Classification of the Epilepsies, Epileptic Syndromes, and Related Disorders

In 1985, the ILAE made its first attempt to create a classification of epileptic disorders that recognized individual syndromes defined as complexes of signs and symptoms that comprise unique epilepsy conditions with variable etiologies. This classification differed from the 1970 concepts in that it recognized that partial epilepsies could also be primary. There were also changes in terminology. Specifically, the terms 'primary' and 'secondary' were replaced with 'idiopathic' and 'symptomatic.' The term 'idiopathic,' unlike in the rest of American medicine, did not indicate cause unknown, but epilepsy itself, *sui generis*, and nothing else, as derived from the Greek '*idios*,' meaning 'self.' The term 'partial' was replaced by the more cumbersome term 'localization-related' because it was felt that the former incorrectly implied a part of a syndrome rather than a syndrome resulting from an abnormality in part of the brain.

This classification was subsequently revised by the ILAE in 1989 (**Table 2**), and the 1989 classification remains in current use. The major change instituted by the newer system was the introduction of the term 'cryptogenic' to define conditions that were presumed to be symptomatic (because they did not fit any of the known idiopathic syndromes), but the cause was hidden. A 1993 report of the ILAE Commission on Epidemiology and Prognosis, however, defined the term 'cryptogenic epilepsies' to mean unknown as to whether the condition is symptomatic or idiopathic. Although this has introduced an unfortunate ambiguity, these distinctions will become moot as research identifies the mechanistic consequences of aberrant gene expression responsible for idiopathic epilepsies and the genetic predisposition for symptomatic epilepsies.

The syndromes included in the 1989 classification were derived predominantly from studies of epilepsies in infants, children, and adolescents, and the classification is clearly useful for these populations. Most adult patients, however, have what in this classification would be referred to as symptomatic or cryptogenic localization-related epilepsies, and there remains no acceptable way to classify or categorize these conditions. Despite the implications of the 1989 classification, frontal lobe epilepsy, parietal lobe epilepsy, occipital lobe epilepsy, and temporal lobe epilepsy are no longer considered discrete syndromes, because a single seizure type or anatomical location is not 'a complex of signs and symptoms.' There are a variety of possible syndromes ascribed to the frontal and temporal lobes, but even the most common and best understood of these – mesial temporal lobe epilepsy with hippocampal sclerosis – may not constitute a discrete syndrome as opposed to a number of different conditions.

Table 2 International Classification of Epilepsies, Epileptic Syndromes, and Related Seizure Disorders

1. Localization-related (focal, local, partial)
1.1 Idiopathic (primary)
- Benign childhood epilepsy with centrotemporal spikes
- Childhood epilepsy with occipital paroxysms
- Primary reading epilepsy

1.2 Symptomatic (secondary)
- Temporal lobe epilepsies
- Frontal lobe epilepsies
- Parietal lobe epilepsies
- Occipital lobe epilepsies
- Chronic progressive epilepsia partialis continua of childhood syndromes characterized by seizures with specific modes of precipitation

1.3 Cryptogenic, defined by
- Seizure type
- Clinical features
- Etiology
- Anatomical localization

2. Generalized
2.1 Idiopathic (primary)
- Benign neonatal familial convulsions
- Benign neonatal convulsions
- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy (pyknolepsy)
- Juvenile absence epilepsy
- Juvenile myoclonic epilepsy (impulsive petit mal)
- Epilepsies with grand mal seizures (GTCS) on awakening
- Other generalized idiopathic epilepsies
- Epilepsies with seizures precipitated by specific modes of activation

2.2 Cryptogenic or symptomatic
- West syndrome (infantile spasms, Blitz–Nick–Salaam Krämpfe)
- Lennox–Gastaut syndrome
- Epilepsy with myoclonic-astatic seizures
- Epilepsy with myoclonic absences

2.3 Symptomatic (secondary)
2.3.1 Nonspecific etiology
- Early myoclonic encephalopathy
- Early infantile epileptic encephalopathy with suppression bursts
- Other symptomatic generalized epilepsies

2.3.2 Specific syndromes
- Epileptic seizures may complicate many disease states

3. Undetermined epilepsies
3.1 With both generalized and focal seizures
- Neonatal seizures
- Severe myoclonic epilepsy in infancy
- Epilepsy with continuous spike-waves during slow wave sleep
- Acquired epileptic aphasia (Landau–Kleffner syndrome)
- Other undetermined epilepsies

3.2 Without unequivocal generalized or focal features

4. Special syndromes
4.1 Situation-related seizures (*Gelegenheitsanfälle*)
1. Febrile convulsions
2. Isolated seizures or isolated status epilepticus
3. Seizures occurring only when there is an acute or toxic event due to factors such as alcohol, drugs, eclampsia, and nonketotic hyperglycemia

Reproduced from Commission on Classification and Terminology of the International League Against Epilepsy (1989) Proposal for revised classification of epilepsies and epileptic syndromes. *Epilepsia* 30: 389–399, with permission from Blackwell Publishing.

As with the 1981 Classification of Epileptic Seizures, the 1989 Classification of Epilepsies, Epileptic Syndromes, and Related Seizure Disorders is widely accepted and universally used, despite a number of problems, including the fact that it is almost 20 years old; it does not include a number of recognized syndromes; the artificial dichotomy of localization-related versus generalized conditions exists as it does with seizures – and is joined by an artificial dichotomy of symptomatic versus idiopathic conditions, which is equally unsatisfying; and the term

'cryptogenic' remains ambiguous. By its very structure, this attempt to fit all epilepsy conditions into such a framework implies similarities and differences that are not there, and ignores similarities and differences that are. Consequently, the ILAE has also undertaken a review of this classification with a view toward revising it (explained later).

Recent ILAE Efforts to Evaluate and Revise the International Classifications

Although the ILAE has devoted considerable effort over more than a decade to reviewing the 1981 and 1989 classifications, and numerous reports and discussions have been published, no new classifications have yet been proposed. It has been generally accepted that the 1981 and 1989 classifications remain useful, and that they should not be discarded unless, and until, clearly better classifications have been devised. There has been much debate concerning the difference between a 'gardener's classification,' which is purely pragmatic, and a 'botanist's classification,' which is a taxonomy based on scientific knowledge of natural classes that can be reproducibly distinguished from other natural classes (such as the biological classification of life forms: kingdom, phylum, class, etc.). The work conducted by ILAE so far has resulted in lists of epileptic seizure types and epilepsy syndromes as unique diagnostic entities, consisting, for the present time, as clearly recognizable clinical disorders that could (1) serve as a basis for investigation into underlying causes and mechanisms and (2) be of utility to the clinician in evaluating, treating, managing, and counseling patients. These diagnostic entities should be treated as testable working hypotheses, subject to verification, falsification, and revision. The ultimate intention is to use an evidence-based approach to establish scientifically rigorous criteria for recognizing epileptic seizure types and epilepsy syndromes as unique natural classes. As additional evidence becomes available, individual diagnostic entities will be reevaluated, revised, or discarded as appropriate. These diagnostic entities can then ultimately be categorized into one or more classifications. It is further acknowledged that classifications are used for many purposes, such as clinical diagnosis of individual patients, teaching, epidemiologic studies, clinical trials, selection of surgical candidates, research into basic mechanisms, and gene discovery. Although more than one classification may, therefore, be necessary, an ideal solution would be a modular, flexible, multivariate approach that could be reconfigured for different purposes and revised as necessary when new information becomes available.

In 2001, the ILAE proposed a diagnostic scheme for people with epileptic seizures and with epilepsy (**Table 3**). It must be stressed that this is not a new classification, and does not replace either the 1981 seizure classification or the 1989 epilepsy classification. It is, rather, a recommendation for a standardized approach for describing individual patients based on five features: the ictal phenomenology (Axis 1), the seizure type as a diagnostic entity (which is a new concept) (Axis 2), the syndrome (Axis 3), the etiology (Axis 4), and an optional factor of impairment (Axis 5). In this report, the ILAE made recommendations for refining certain terms (**Table 4**) as part of the ongoing process of ultimately revising the 1981 and 1989 classifications. Among the more important terms is the new concept of epileptic seizure types as unique diagnostic entities, which unlike the electroclinical seizure definitions of the 1981

Table 3 Proposed diagnostic scheme for people with epileptic seizures and with epilepsy

Epileptic seizures and epilepsy syndromes are to be described and categorized according to a system that utilizes standardized terminology, and that is sufficiently flexible to take into account the following practical and dynamic aspects of epilepsy diagnosis:
(1) Some patients cannot be given a recognized syndromic diagnosis.
(2) Seizure types and syndromes change as new information is obtained.
(3) Complete and detailed descriptions of ictal phenomenology are not always necessary.
(4) Multiple classification schemes can, and should, be designed for specific purposes (e.g., communication and teaching, therapeutic trials, epidemiological investigations, selection of surgical candidates, basic research, genetic characterizations).

This diagnostic scheme is divided into 5 parts, or Axes, organized to facilitate a logical clinical approach to the development of hypotheses necessary to determine the diagnostic studies and therapeutic strategies to be undertaken in individual patients:

Axis 1: Ictal phenomenology – from the Glossary of Descriptive Ictal Terminology can be used to describe ictal events with any degree of detail needed.

Axis 2: Seizure type – from the List of Epileptic Seizures. Localization within the brain and precipitating stimuli for reflex seizures should be specified when appropriate.

Axis 3: Syndrome – from the List of Epilepsy Syndromes, with the understanding that a syndromic diagnosis may not always be possible.

Axis 4: Etiology – from a Classification of Diseases Frequently Associated with Epileptic Seizures or Epilepsy Syndromes when possible, genetic defects, or specific pathological substrates for symptomatic focal epilepsies.

Axis 5: Impairment – this optional, but often useful, additional diagnostic parameter can be derived from an impairment classification adapted from the WHO ICIDH.

Reproduced from Engel J Jr (2001) A proposed diagnostic scheme for people with epileptic seizures and with epilepsy: Report of the ILAE Task Force on Classification and Terminology. *Epilepsia* 42: 796–803, with permission from Blackwell Publishing.

Table 4 Definitions of key terms

- *Epileptic seizure type*: An ictal event believed to represent a unique pathophysiological mechanism and anatomical substrate. This is a diagnostic entity with etiological, therapeutic, and prognostic implications. (New concept)
- *Epilepsy syndrome*: A complex of signs and symptoms that define a unique epilepsy condition with different etiologies. This must involve more than just the seizure type; thus, frontal lobe seizures per se, for instance, do not constitute a syndrome. (Changed concept)
- *Epilepsy disease*: A pathological condition with a single specific, well-defined etiology. Thus, progressive myoclonus epilepsy is a syndrome, but Unverricht–Lundborg is a disease. (New concept)
- *Epileptic encephalopathy*: A condition in which the epileptiform abnormalities themselves are believed to contribute to the progressive disturbance in cerebral function. (New concept)
- *Benign epilepsy syndrome*: A syndrome characterized by epileptic seizures that are easily treated, or require no treatment, and remit without sequelae. (clarified concept)
- *Reflex epilepsy syndrome*: A syndrome in which all epileptic seizures are precipitated by sensory stimuli. Reflex seizures that occur in focal and generalized epilepsy syndromes that are also associated with spontaneous seizures are listed as seizure types. Isolated reflex seizures can also occur in situations that do not necessarily require a diagnosis of epilepsy. Seizures precipitated by other special circumstances, such as fever or alcohol withdrawal, are not reflex seizures. (Changed concept)
- *Focal seizures and syndromes*: Replaces the terms partial seizures and localization-related syndromes. (Changed terms)
- *Simple and complex partial epileptic seizures*: These terms are no longer recommended, nor will they be replaced. Ictal impairment of consciousness will be described when appropriate for individual seizures but will not be used to classify specific seizure types. (New concept)
- *Idiopathic epilepsy syndrome*: A syndrome that is only epilepsy, with no underlying structural brain lesion or other neurologic signs or symptoms. These are presumed to be genetic and are usually age-dependent. (Unchanged term)
- *Symptomatic epilepsy syndrome*: A syndrome in which the epileptic seizures are the result of one or more identifiable structural lesions of the brain. (Unchanged term)

Reproduced from Engel J Jr (2001) A proposed diagnostic scheme for people with epileptic seizures and with epilepsy: Report of the ILAE Task Force on Classification and Terminology. *Epilepsia* 42: 796–803, with permission from Blackwell Publishing.

classification, or the purely descriptive signs and symptoms used by the Cleveland Clinic, attempts to begin the use of pathophysiologic mechanisms and anatomic substrates to create a list of natural classes of seizures. Because it often is not possible to make a syndromic diagnosis with certainty, diagnosis of a specific epileptic seizure type would have etiologic, therapeutic, and prognostic implications. It was also stipulated that more than one feature is necessary to define an epilepsy syndrome, and that anatomic localization of a seizure onset is not sufficient to warrant designation of a syndrome. Another important new concept is that of 'epileptic encephalopathy,' which acknowledges that epileptic activity itself can contribute to progressive disturbances in cerebral function, and that certain syndromes are progressive apart from their underlying etiology. It was recommended to return to the term 'focal,' rather than 'partial' or 'localization-related,' when referring to seizures and syndromes, because this term is simpler and still more commonly used. The term 'focal' was rejected in the past because it inappropriately implied a point source of the epileptogenic abnormality. Now that it is generally acknowledged that epilepsy, whether generalized or focal, involves distributed networks (i.e., disturbances over wide areas of brain, which may even be bilateral in the case of so-called partial seizures or localization-related epilepsies), ILAE believes that the danger of misinterpreting the term 'focal' no longer exists. This report also recommends that a future classification no longer use impairment of consciousness as a factor for classifying seizures types.

Phenomenology of Epileptic Seizures

A glossary of standardized terms for describing ictal behavior was also published in 2001 to supplement Axis 1 of the diagnostic scheme. Much of this glossary was derived from the Cleveland Clinic approach. Although impairment of consciousness is an important aspect of seizures with respect to the impairment it creates for individual patients, this feature is an extremely difficult concept to define, and has been replaced in the glossary by the term 'dyscognitive,' which describes more specifically a variety of different disturbances of mental function that are not adequately captured by the more global term 'consciousness'. Unlike the Cleveland Clinic approach, the ILAE diagnostic scheme acknowledges that a detailed description of ictal phenomenology is not necessary for diagnosis or treatment of seizure types in most patients, nor is it usually possible without prolonged video monitoring. Accurate detail regarding phenomenology can provide useful information clinically, however, for localizing the epileptogenic region in patients who are candidates for surgical resection, and it is also important for basic scientists who are interested in identifying the anatomic substrates of ictal behaviors.

Epileptic Seizure Types as Unique Diagnostic Entities

A 2006 ILAE report contained an updated list of recognized seizure types (**Table 5**), that were considered to be unique diagnostic entities based on most recent

Table 5 Seizure types

Self-limited epileptic seizures
I. Generalized onset
  A. Seizures with tonic and/or clonic manifestations
    1. Tonic–clonic seizures
    2. Clonic seizures
    3. Tonic seizures
  B. Absences
    1. Typical absences
    2. Atypical absences
    3. Myoclonic absences
  C. Myoclonic seizure types
    1. Myoclonic seizures
    2. Myoclonic-astatic seizures
    3. Eyelid myoclonia
  D. Epileptic spasms
  E. Atonic seizures
II. Focal onset (partial)
  A. Local
    1. Neocortical
      a. Without local spread
        (1) Focal clonic seizures
        (2) Focal myoclonic seizures
        (3) Inhibitory motor seizures
        (4) Focal sensory seizures with elementary symptoms
        (5) Aphasic seizures
      b. With local spread
        (1) Jacksonian march seizures
        (2) Focal (asymmetrical) tonic seizures
        (3) Focal sensory seizures with experiential symptoms
    2. Hippocampal and parahippocampal
  B. With ipsilateral propagation to
    1. Neocortical areas (includes hemiclonic seizures)
    2. Limbic areas (includes gelastic seizures)
  C. With contralateral spread to
    1. Neocortical areas (hyperkinetic seizures)
    2. Limbic areas (dyscognitive seizures with or without automatisms [psychomotor])
  D. Secondarily generalized
    1. Tonic–clonic seizures
    2. Absence seizures
    3. Epileptic spasms (unverified)
III. Neonatal seizures

Status epilepticus
  I. Epilepsia partialis continua (EPC)
    A. As occurs with Rasmussen syndrome
    B. As occurs with focal lesions
    C. As a component of inborn errors of metabolism
II. Supplementary motor area (SMA) status epilepticus
III. Aura continua
IV. Dyscognitive focal (psychomotor, complex partial) status epilepticus
    A. Mesial temporal
    B. Neocortical
V. Tonic–clonic status epilepticus
VI. Absence status epilepticus
    A. Typical and atypical absence status epilepticus
    B. Myoclonic absence status epilepticus
VII. Myoclonic status epilepticus
VIII. Tonic status epilepticus
IX. Subtle status epilepticus

Reproduced from Engel J Jr (2006) Report of the ILAE Classification Core Group. *Epilepsia* 47: 1558–1568, with permission from Blackwell Publishing.

pathophysiologic and anatomic evidence. This list, however, remains a work in progress. To create a list of, and ultimately to categorize or classify, epileptic seizures as diagnostic entities based on pathophysiologic mechanisms and anatomic substrates, it is important to recognize that the ictal semiology may be misleading. The obvious example of this problem is brief loss of consciousness, which could represent a typical absence or a focal seizure that manifests as impaired consciousness only. In contrast, a unique seizure type based on a single discrete neocortical mechanism may have entirely different ictal manifestations, depending on whether it occurs, for instance, in motor cortex or calcarine cortex. In this sense, the anatomic substrate used to define unique diagnostic entities refers to large networks that distinguish neocortical from, for instance, thalamocortical mechanisms – but not precentral neocortex from occipital neocortex with the same cytoarchitecture.

There are still a number of problems with the list of seizure types presented in Table 5. Most importantly, it retains the artificial focal versus generalized dichotomy, which remains unsatisfactory. The focal onset types are based largely on the networks involved and most likely need to be revised. The section on status epilepticus also needs further work – for instance, autonomic status epilepticus is not easily incorporated into any of the listed conditions.

Epilepsy Syndromes

The 2006 ILAE report also contained a list of accepted epilepsy syndromes (Table 6), which includes many conditions that were not recognized at the time of the 1989 classification of the epilepsies. As many epilepsy syndromes begin during specific periods of cerebral development, they are listed by age rather than according to the artificial dichotomies of focal versus generalized and idiopathic versus symptomatic. These terms have been retained, however, for certain syndromes, more because of common usage than the accuracy of this description, recognizing that no condition is truly generalized or truly focal. As yet, no better, more accurate descriptive terms have been suggested.

The list of epilepsy syndromes in Table 6 can be used for diagnostic manuals to be applied to individual patients, or to constitute taxonomic classes, but not all can be used for both. Progressive myoclonus epilepsy, for instance, includes a number of distinct conditions and is not appropriate for taxonomic purposes. The next step is to attempt to organize this list into logical categories based on similarities of natural classes that will constitute a scientifically-based taxonomy of the epilepsies. Potential categories that might be considered for future classification systems include autosomal-dominant epilepsies, epileptic encephalopathies, generalized (genetic) epilepsies with febrile seizures plus (GEFS+), idiopathic

Table 6 Epilepsy syndromes by age of onset and related conditions

Neonatal period
Benign familial neonatal seizures (BFNS)
Early myoclonic encephalopathy (EME)
Ohtahara syndrome
Infancy
Migrating partial seizures of infancy
West syndrome
Myoclonic epilepsy in infancy (MEI)
Benign infantile seizures
Dravet syndrome
Myoclonic encephalopathy in nonprogressive disorders
Childhood
Early onset benign childhood occipital epilepsy (Panayiotopoulos type)
Epilepsy with myoclonic-astatic seizures
Benign childhood epilepsy with centrotemporal spikes (BCECTS)
Late onset childhood occipital epilepsy (Gastaut type)
Epilepsy with myoclonic absences
Lennox–Gastaut syndrome
Epileptic encephalopathy with continuous spike-and-wave during sleep (CSWS), including Landau–Kleffner syndrome (LKS)
Childhood absence epilepsy (CAE)
Adolescence
Juvenile absence epilepsy (JAE)
Juvenile myoclonic epilepsy (JME)
Progressive myoclonus epilepsies (PME)
Less-specific age relationship
Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE)
Familial temporal lobe epilepsies
Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)
Rasmussen syndrome
Gelastic seizures with hypothalamic hamartoma
Special epilepsy conditions
Symptomatic focal epilepsies not otherwise specified
Epilepsy with generalized tonic–clonic seizures only
Reflex epilepsies
Febrile seizures plus (FS+)
Familial focal epilepsy with variable foci
Conditions with epileptic seizures that do not require a diagnosis of epilepsy
Benign neonatal seizures (BNS)
Febrile seizures (FS)

Reproduced from Engel J Jr (2006) Report of the ILAE Classification Core Group. *Epilepsia* 47: 1558–1568, with permission from Blackwell Publishing.

generalized epilepsies, idiopathic focal epilepsies, and reflex epilepsies. Whatever construct of clustering is devised, it is likely that some syndromes may be represented in more than one grouping, while others may fit into none. Ultimately, a multivariate modular approach may be most appropriate, offering flexibility to use variations of the classification for different purposes.

Etiology

The 2001 ILAE report listed diseases frequently associated with epileptic seizures or syndromes, including those causing progressive myoclonus epilepsies, neurocutaneous disorders, malformations due to abnormal cortical development, other cerebral malformations, tumors, chromosomal abnormalities, monogenic Mendelian diseases with complex pathogenic mechanisms, and inherited metabolic disorders. This list, however, was not intended to be comprehensive. The Centers for Disease Control (CDC) is in the process of proposing a classification of etiologies for epileptic disorders for epidemiological purposes, in an effort to define risk factors (**Table 7**). Although etiology is an essential part of the diagnostic scheme for individual patients, it is unclear to what extent etiologies will become important in devising ultimate classifications for epileptic seizures and epilepsy syndromes. Considerable work remains to be done here, and basic research will be essential to our understanding of how specific etiologies result in epilepsy.

Impairment

The World Health Organization (WHO) has developed a classification of impairment for neurologic disorders, referred to as the International Classification of Impairments, Disabilities, and Handicaps (WHO ICIDH), which has undergone several revisions. This classification, however, is designed for persistent disabilities such as blindness and paralysis, and at the present time is inadequate to define disabilities associated with paroxysmal disorders such as epilepsy. The ILAE is currently adapting this document for use in classifying degrees of impairment among people with epilepsy.

Need for Basic Research

It is clear that concerted efforts to elucidate the underlying pathophysiologic mechanisms responsible for epileptic seizures and epilepsy syndromes, and their anatomic substrates, are essential to the development of a taxonomic classification system based on identification of unique diagnostic entities as natural classes. This work must ultimately be carried out in patients; however, continuing research in the animal laboratory is critical to this effort. Parallel reiterative animal and human experiments include the use of clinical observations to determine questions that need to be investigated through basic research; direct invasive and noninvasive investigations in the clinical setting where possible; extension of this work to appropriate experimental animal models when practical, ethical, and financial considerations prevent experiments in patients; and validation of the relevance of insights gained from the animal laboratory through further studies with patients. In addition, there have been tremendous advances in recent years in characterizing the genetics of epilepsy, not only in identifying genetic disturbances responsible for certain

Table 7 Etiology

A. Predominantly or exclusively of genetic origin
  1. Monogenic epilepsy diseases/syndromes (e.g., ADNFLE, Dravet's, BFNS)
  2. Complex epilepsy diseases/syndromes (IGEs, e.g., CAE, JAE, JME; ILRE, e.g., BCECTS, GEFS+)
  3. Epilepsies associated with other neurological specific syndromes and diseases (most, if not all, monogenic)
    a. Neurocutaneous
    b. In-born metabolic disease
    c. Progressive myoclonus diseases
    d. Other genetic diseases and syndromes (e.g., fragile X, Rett, Angleman, Huntington)
  4. Chromosomal (aneuploidy, e.g., Down syndrome)
B. Predominantly or exclusively of acquired origin
  1. Traumatic
  2. Infectious
  3. Cerebrovascular
  4. Hypoxic–ischemic encephalopathy
  5. Metabolic/toxic because of environmental exposures/insults
    a. Alcohol
    b. Other
C. Specific causes and disorders with either unknown basis (genetic vs. acquired) or mixed genetic–acquired nature
  1. Degenerative diseases of adult onset (e.g., Alzheimer's and Parkinson's disease)
  2. Autoimmune (e.g., multiple sclerosis)
  3. Neoplastic
  4. Malformations
D. Unknown or multiple
  1. With otherwise normal examination, intelligence, imaging (when available), and noncontributory history
  2. With abnormal examination, intelligence, or imaging. If possible, distinguish (a) and (b) below.
    a. As evidenced by developmental static encephalopathy (i.e., CP or MR) documented to be present prior to the onset of epilepsy and consistent with a congenital insult.
    b. As evidenced by other indications of CNS dysfunction acquired postnatally
    c. With imaging demonstrated mesial temporal sclerosis and not known as to when it first occurred
  3. Multiple (>1) potential contributing factors. Any one cause cannot be designated as the primary cause with reasonable confidence.

In addition to assigning etiology to the categories above, the stability of the condition should be specified, i.e., whether the underlying condition is *static* or *progressive*.

ADNFLE, autosomal-dominant nocturnal frontal lobe epilepsy; BCECTS, benign childhood epilepsy with centrotemporal spikes; BFNS, benign familial neonatal seizures; CAE, childhood absence epilepsy; GEFS+, generalized (genetic) epilepsy with febrile seizures plus; IGE, idiopathic generalized epilepsy; ILRE, idiopathic localization-related epilepsy; JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy.

Reproduced from the Center for Disease Control and Prevention. Epilepsy Case Definitions & Methods Working Group (DJ Thurman, A Berg, J Buchhalter, A Hauser, D Hesdorffer, T Thomson, *et al.*), with permission.

idiopathic epilepsies (which would not have been possible without a reasonable syndromic classification), but in characterizing groups of susceptibility genes that contribute to classes of epileptic disorders, including conditions currently referred to as symptomatic syndromes. Determining the mechanisms by which these aberrant gene expressions result in epilepsy is also highly dependent upon research with experimental animal models.

Summary

The ILAE created the current International Classification of Epileptic Seizures in 1981, based on electroclinical phenomenology, and the current Classification of the Epilepsies, Epileptic Syndromes, and Related Disorders in 1989. These are generally accepted and widely used. The ILAE, however, has been reviewing these classifications with the intention of revising them according to more rigorous evidence-based criteria, using common underlying pathophysiological mechanisms and anatomic substrates to identify epileptic seizure types, as well as epilepsy syndromes, as unique diagnostic entities, in the same way that other biological classification systems identify and categorize natural classes. The ILAE proposal for a diagnostic scheme for describing individual patients, and lists of recognized epileptic seizure types and epilepsy syndromes, are presented. Classification of pathological phenomena is not only important for clinical purposes, but also for developing appropriate experimental animal models that are relevant to the human condition. Conversely, basic scientists provide the information, from both patient and animal research into fundamental mechanisms and anatomical substrates of pathological phenomena, that make up the basis of biological classification systems. The ongoing effort of classification in epilepsy, therefore, represents a continuing collaborative effort between clinicians and basic scientists.

Statement and Significance of the Problem

Classification deals with two major problems. The first problem is one of communication – being sure that in oral or written communication about an 'object' that is not visible, all parties evoke the same picture or concept. To be classified, the entities in question must be labeled as unique identities with unambiguous names. Once a unique name is given, the object is no longer quite so elusive. Name-giving can imply ownership, as can be read even in the Bible. In Isaiah (Chapter 43), the Lord said "I have called thee by thy name; thou art mine." Although this restrictive sense of naming obviously does not apply to diseases, the custom of name-giving using the name of the person who first described a disease entity as eponym (from the Greek *epi* = by, belonging to, and *onima* = name) might suggest some ownership. Further, use of eponyms may stimulate nationalistic tendencies. In neurology, several disorders have multiple and multinational eponyms – e.g., the syndrome of Tooth (Great Britain), Charcot (France), Hoffmann (Germany) – otherwise known as neurogenic muscular atrophy.

The second problem in classification involves the creation of classes and taxonomies through which known or assumed relations between objects or concepts can be traced. It is fair to say that the observation with which Beigel introduced the German translation of J. R. Reynolds' book *Epilepsy* in 1865 still holds:

> No field of medical literature presents . . . such a confused and such reckless application of names and descriptions as in the field of brain and nerve diseases . . . that this culminates in the case of epilepsy concerns the nature of the disease and the ways and modes in which it manifests, and the way the public and doctors relate to it.

Background

Dealing with the problem of classifying epilepsy or epilepsies, distinguishing between epilepsies and seizures, and in turn classifying seizure types are tasks not only typical for our time but – as can be seen from the earliest written accounts – have been problems for all ages. Wherever a sophisticated society existed, similar concerns arose – and were dealt with in various ways. In this article, we focus on developments in what can be briefly described as the 'western world.' Names given to epilepsy in earlier centuries were of several kinds, and involved different frames or reference. For example

Statement and Significance of the Problem

Classification deals with two major problems. The first problem is one of communication – being sure that in oral or written communication about an 'object' that is not visible, all parties evoke the same picture or concept. To be classified, the entities in question must be labeled as unique identities with unambiguous names. Once a unique name is given, the object is no longer quite so elusive. Name-giving can imply ownership, as can be read even in the Bible. In Isaiah (Chapter 43), the Lord said "I have called thee by thy name; thou art mine." Although this restrictive sense of naming obviously does not apply to diseases, the custom of name-giving using the name of the person who first described a disease entity as eponym (from the Greek *epi* = by, belonging to, and *onima* = name) might suggest some ownership. Further, use of eponyms may stimulate nationalistic tendencies. In neurology, several disorders have multiple and multinational eponyms – e.g., the syndrome of Tooth (Great Britain), Charcot (France), Hoffmann (Germany) – otherwise known as neurogenic muscular atrophy.

The second problem in classification involves the creation of classes and taxonomies through which known or assumed relations between objects or concepts can be traced. It is fair to say that the observation with which Beigel introduced the German translation of J. R. Reynolds' book *Epilepsy* in 1865 still holds:

> No field of medical literature presents . . . such a confused and such reckless application of names and descriptions as in the field of brain and nerve diseases . . . that this culminates in the case of epilepsy concerns the nature of the disease and the ways and modes in which it manifests, and the way the public and doctors relate to it.

Background

Dealing with the problem of classifying epilepsy or epilepsies, distinguishing between epilepsies and seizures, and in turn classifying seizure types are tasks not only typical for our time but – as can be seen from the earliest written accounts – have been problems for all ages. Wherever a sophisticated society existed, similar concerns arose – and were dealt with in various ways. In this article, we focus on developments in what can be briefly described as the 'western world.' Names given to epilepsy in earlier centuries were of several kinds, and involved different frames or reference. For example

- A surmised cause (morbus lunaticus = moon sickness; epilepsy, derived from the Greek word epilambanein = to seize (by a god))
- The impressiveness of the condition (grand mal = megala nosos)
- The symptomatology (falling sickness)
- Its psycho-social effects (morbus insputatus = the illness at which one spits)
- How the medical understanding of the time was (morbus infantilis = childhood's disease)

Notwithstanding the various names found in ancient literature, these labels did not try to distinguish between seizure types or epilepsies. Most names were for generalized tonic–clonic seizures – called by different names according to the knowledge available, the prevailing worldview, cultural trends, and social order. Early classification systems in other fields reflected, for example, the order that according to Aristotle existed in nature and which he described in the 'Scala Naturae.'

As far as epilepsy was concerned, Hippocrates scornfully mentioned in his work *About the Holy Disease* that certain priests and preachers of penitence described different seizure types, for each of which they held a separate god responsible. According to this system, right-sided hemiconvulsions were caused by the mother of Zeus, Rhea; seizures with shaking of the legs and hypersalivation were caused by the god of war, Ares; when a person had fecal incontinence during a seizure, then it was a seizure caused by Hermes or Enodia; and nightly seizures were caused by Hekate. Hippocrates (460–377 BC) strongly opposed the prevalent concept that seizures were caused by gods. He discussed different symptoms and seizure types, and tried to explain them according to the theory of humoral pathology that he had developed, discerning between blood, phlegm, black bile, and yellow bile. Hippocrates, however, never proposed a classification of seizures.

Almost six centuries later, another highly influential physician appeared on the scene – Galen (Galenos, 131–199 AD) from Pergamon. He distinguished three types of epilepsy, with all three afflicting the brain. The first type of epilepsy, according to Galen, develops in the brain itself, as would be the case with most people who suffer from epilepsy. In the second type, the epilepsy rises from the stomach by sympathy to the brain. And in the third type – also a 'sympathic' form of epilepsy – the onset is from any other part of the body, from which the epilepsy invades the brain. Although these ancient writings are mainly of historic interest, one term introduced by Galen, the 'aura,' is still in use. In a case description, Galen mentions that his patient experienced the invasion of his sympathic epilepsy into the brain as a cold wind (aura) that rises up into his head.

The dominating culture of the Christian Church in Europe in the Middle Ages had no place for the Greco-Roman thinking that was so different from those beliefs based upon the New Testament. Disease was considered a punishment by God for sinful behavior. Similar to the 'mythological classification' so much criticized by Hippocrates, The Church instructed that certain saints were especially to be invoked to ask divine mercy for persons with certain type of seizures. For example, in France those with severe seizures were said to suffer from the 'mal de St. Jean' (Saint John), and those with less-severe seizures suffered from the 'mal de St Gilles' (saint Aegidius, died 720 AD).

Fortunately, Byzantine and Arab physicians had taken over the medical teachings of the Greeks and Romans, and recorded these teachings in numerous books, partly elaborated with their own experiences and knowledge. Through this pathway, Greco-Roman insights returned to Europe in the later part of the Middle Ages and in the Renaissance period. However, as far as classification of the epilepsies was concerned, the know-how had not developed beyond the writings of Galen.

Paracelsus (Theophrastus Philippus Aureolus Bombastus von Hohenheim), the colorful doctor and researcher of the Renaissance, had little esteem for Galen's writings, but nevertheless developed a similar localization-based classification of the epilepsies. He distinguished five types of epilepsy, originating respectively in the head, the heart, the liver, the intestines, or the extremities. Contrary to Galen, he believed that the seizures resulted from what happened in these organs, and that they did not involve the brain (were not sympathic), and accordingly drew up his therapies.

In the eighteenth and nineteenth centuries, a series of publications from France and French-speaking Switzerland made important contributions that can be considered to have formed the foundation from which modern epileptology developed. These works were based upon accurate descriptions of signs and symptoms. Prominent among the authors of this set of publications are: SA-Tissot (1728–1797), JE Esquirol (1772–1840), LF Cameil (1798–1895), Th Herpin (1799–1865), L Bravais (1801–1843), and LJF Delasiauve (1804–1893). Although Tissot championed clinical observation, his classification still used some of Galen's ideas – in particular, that epilepsy could have its onset outside the brain. In his epoch-making *Traité de l'épilepsie* of 1770, he posited that idiopathic epilepsy is the type where the origin of the seizures is in the brain itself, while sympathic epilepsy has its origin outside the brain. For the latter epilepsy type, irritation of the nerves at the locus of origin was transported to the brain, where the irritation elicited a seizure. While epilepsy that had its origin in the brain was labeled idiopathic, Tissot further distinguished what he called 'essential epilepsy' that also had its origin in the brain but did not appear to depend on any pathological change other than a propensity to

seizures (nowadays only these types of epilepsies are labeled idiopathic). About 75 years after Tissot's publication, Delasiauve published a book with the same title as that of Tissot, *Traité de l'épilepsie*. In it, he distinguished idiopathic, symptomatic, and sympathic epilepsies; his descriptions of the first two – idiopathic and symptomatic – covered the same concepts as we presently use for these categories. As regards sympathic epilepsy, however, he began to emphasize an extracerebral trigger – as in those conditions we would now call reflex-epilepsies – or a toxic excitant evoking seizure activity in the brain. However, the definition was not crystal clear. There lingers in this description of sympathic epilepsy the concept of a possible extracerebral seizure generator.

Apart from localization-related distinctions between epilepsy types, Tissot also introduced another discriminator related to the extensiveness of the seizure, thus distinguishing between 'grand accès' and 'petit accès' (later designated as 'grand mal' and 'petit mal'). However, as Herpin posited in a book published in 1867, all seizure types – and he distinguished 39 – were gradations of full-blown epilepsy characterized by the grand mal seizure. This concept is also maintained in Binswanger's chapter in Nothnagels *Specielle Pathologie und Therapie*, published in 1904, wherein epilepsy is discussed under the headings (1) Epilepsia gravior, (2) 'Der unvollständige, rudimentäre Anfall (the incomplete seizure), and (3) Abortive Anfälle (petit mal).

From the eighteenth through the twentieth centuries, important discoveries and research further paved the way for our present-day understanding of the epilepsies and their classification. Pivotal were Galvani's (1737–1798) discovery of animal electricity and Hans Berger's (1873–1941) work, resulting in 1924 with the first electroencephalogram in man.

In the twentieth century, a distinction between lumpers and splitters becomes apparent. The lumpers are those who maintain that epilepsy is a single disorder with graded expression. The splitters are those who prefer to speak about 'the epilepsies' as a related group of disorders that can be so classified. *The Epilepsy Handbook* of Gibbs and Stamps placed the different seizure types in a context expanding from normal brain activity to generalized tonic–clonic seizures (**Figure 1**). Lennox and Lennox's *Epilepsy and Related Disorders* may be taken as exemplary for the lumpers; notwithstanding their long list of adjectives (**Table 1**), they made no attempt at categorization. In contrast, Janz exemplifies the splitters in his book *Die Epilepsien* (1969). Janz made a distinction between three major categories: (1) age-related, and presenting with minor seizures (he retains the epithet 'petit mal'); (2) not age-related, but with minor seizures; and (3) grand mal epilepsies.

In more recent times, the members of the International League Against Epilepsy's Commission on Classification and Terminology can be considered splitters. In 1985, they presented to the General Assembly a 'Classification of Epilepsies and Epileptic Syndromes,' which in a revised form was accepted in 1989. This classification of epilepsies and epileptic seizures had been preceded by a

Extrapyramidal	Organic	Temporal (lobe)
Fetal	Paranatal	Thalamic
Focal	Partial	Thermal
Genetic	Petit mal	Unilateral
Grand mal	Photogenic	Vasovagal
Hemiplegic	Postencephalitic	Vegetative
Hereditary organic	Postnatal	Vertiginous
Hydraulic	Posttraumatic	Visceral
Hyperthermia-precipitated	Psychic	

'Clinical and Electroencephalographic Classification of Epileptic Seizures' accepted by the General Assembly in 1969 and revised again in 1981.

In 1969, Gastaut introduced a classification scheme crafted by a large international group of epileptologists with the following words:

> The Executive Committee [of the ILAE] is fully aware of the fact that all attempts at classification of epileptic seizures are hampered by our limited knowledge of the underlying pathological processes within the brain, and that any classification must of necessity be a tentative one and will be subject of change with every advance in the scientific understanding of epilepsy.

This expression of the limitations of classification is relevant still, in our-day attempts to improve on prior classifications.

Introduction and Background

Definitions and Classifications of Status Epilepticus

Clear definition of a condition is a prerequisite for accurate epidemiology. The definition of status epilepticus has proved problematic. Its initial description, by Desiré Bourneville in 1876, confined the term to prolonged tonic–clonic seizures, and this convention was largely retained up until the 1950s. Clark and Prout in 1903/1904, for instance, formulated a definition of status epilepticus – for the 'typical case' – which applied only to convulsive seizures: status epilepticus is 'the maximum development of epilepsy, in which one paroxysm follows

another so closely that the coma and exhaustion are continuous between seizures.' In 1962, the Xth Marseilles Colloquium was the first major meeting devoted to the subject of status epilepticus. It was led by Henri Gastaut who, leaning heavily on EEG data, proposed a comprehensive definition and, for the first time, a systematic classification scheme. A total of 103 participants presented 237 cases, with both clinical and EEG findings "of abnormally prolonged or serially repeated seizures, most of which" (as Gastaut wrote) "did not correspond to the definition of status epilepticus accepted at that time." The conference replaced the 'historical' definition (corresponding to grand mal status) by an 'etymological definition,' which defined status epilepticus as 'a condition characterized by an epileptic seizure, which is so frequently repeated or so prolonged as to create a fixed and lasting epileptic condition.' The seizures (and thus the status epilepticus) could take a variety of forms and, as Gastaut later wrote, implicit in this definition was the view that there are "as many types of status epilepticus as there were types of epileptic seizures."

In parallel to the changing view of status epilepticus were changing views of the classification of epileptic seizures, and the first version of the International Classification of Seizures was in preparation under the direction of Gastaut. In 1964, the proposed classification both of seizures and of status epilepticus was presented to the XIIIth Colloquium in Marseilles, and an approved version of the *International Classification of Seizure Type* was eventually published in 1970. The proceedings of the 1962 colloquium on status epilepticus were published in 1967, and laid out a classification of status epilepticus, which paralleled the *International Classification of Seizure Type*. Status epilepticus was divided into generalized and partial (unilateral) categories: the generalized categories consisted of tonic, clonic, tonic–clonic, absence, and myoclonic status epilepticus; the partial category comprised simple and complex partial status epilepticus. The definition and classification were subsequently included in the World Health Organization (WHO) Dictionary of Epilepsy, where status epilepticus was defined as 'a seizure persisting for a sufficient length of time or is repeated frequently enough to produce a fixed or enduring epileptic condition.' The International League Against Epilepsy (ILAE), in its revision of the seizure type classification in 1981, defined status epilepticus (in an addendum) as follows: 'The term *status epilepticus* is used whenever a seizure persists for a sufficient length of time or is repeated frequently enough that recovery between attacks does not occur. Status epilepticus may be divided into partial (e.g., Jacksonian), or generalized (e.g., absence status or tonic–clonic status).'

The new definitions and classification that were formulated over this period were important steps in the conceptualization of status epilepticus. However, over the next two decades, as the concept of the division of epilepsy into *epileptic syndromes* developed and gained importance, it became also clear that a simple *seizure-type* classification of status epilepticus was becoming obsolete. In the monograph on status epilepticus published in 1994, a more comprehensive composite classification was proposed (albeit 'a provisional classification, necessarily primitive and incomplete, to which future modifications are inevitable, and desirable'). This scheme divided SE into major subdivisions based on age, and within each age group was a mixed classification with categories based on three aspects: clinical and EEG seizure type, pathophysiology and epilepsy syndrome, and clinical phenomenology crossing seizure type and syndromic boundaries. A category of 'boundary conditions' was also included.

The 1973 WHO and the 1981 ILAE definitions of status epilepticus are necessarily rather imprecise, and two questions arise, which are difficult to resolve. The first is the question 'how long should a seizure be considered enduring before it is categorizable as status epilepticus.' The lack of definition of a minimum time period in the early definitions of status epilepticus is problematic from the point of view of epidemiology. Gastaut himself suggested that 60 min was a reasonable minimum period in which to consider a seizure 'enduring,' and this suggestion became the ILAE standard. However, various authors over the next two decades favored a minimum time period of 30 min. These time periods have some physiological justification, as after 30–60 min, major biochemical and physiological cerebral changes begin to occur of ominous import to outcome and therapy. In the 1990s, the suggested minimum time shortened to 20 min (for instance by Bleck in 1991), to 10 min (by Treiman in 1998), and then to 5 min (by Lowenstein in 1999). It was claimed that convulsive seizures lasting longer than 5 min seldom were self-terminating, and this feature was the main reason for proposing a 5-minute minimum time period. This short time interval has some clinical support from a video EEG telemetry study of secondarily generalized tonic–clonic seizures in 47 patients, in which the mean duration of the spontaneously resolving seizures was 62 s, with a range of 16–108 s. However, it is a common clinical experience that many seizures lasting longer than 5 min are self-terminating without therapy. Thus, it seems that the main advantage of defining status epilepticus in this way (i.e., longer than 5 min) is 'operational' rather than physiological. That is, this definition is a response to the perceived need to induce a greater sense of urgency amongst front-line physicians when treating prolonged seizures.

A second issue, which complicates definition of SE, is the definition of 'seizures' in this setting. Prolonged electrographic seizure activity can occur without overt seizures, and the question arises as to the extent to which such states should be included within the rubric of status epilepticus. These are the 'boundary syndromes' in which there is prolonged electrographic seizure

activity, with no signs of a conventional 'epileptic seizure.' There are four main categories in which this issue is relevant: some cases of epileptic encephalopathy; some cases of coma due to acute brain injury, often with myoclonic jerks (*myoclonic status epilepticus in coma*); some cases of epileptic behavioral disturbance or psychosis; and some cases of drug-induced or metabolic confusional states, often with myoclonic jerks (for instance precipitated by toxins or drugs such as tiagabine or metrizamide).

In the 1994 monograph *Status Epilepticus*, a definition of status epilepticus was proposed, which is somewhat more precise and is still widely accepted: "Status epilepticus is a condition in which epileptic activity persists for 30 min or more, causing a wide spectrum of clinical symptoms, and with a highly variable pathophysiological, anatomical, and etiological basis." The question of classification was extensively considered at the recent *London Colloquium of Status Epilepticus* (held in April 2007) and a classification proposed at the congress of convulsive and nonconvulsive forms is shown in **Table 1**.

Results

Incidence and Frequency of Status Epilepticus

The lack of a precise definition of status epilepticus is an obvious bar to accurate estimations of frequency. Most epidemiological studies in recent years have defined status epilepticus as a seizure continuing for 30 min of more, and none (to my knowledge) has adopted the 5-min standard. Five-minute seizures are extremely common, and if status epilepticus was to be defined in this manner, the quoted frequency would be enormously enhanced. Similarly, the epileptic encephalopathies are usually excluded from consideration (although there are sound reasons for including many cases within the rubric of status epilepticus). Another source of major controversy is the inclusion of cases of 'myoclonic status epilepticus in coma' after cerebral anoxia (for instance, after a myocardial infarction) or acute brain injury. These latter cases are common, and have been included in some epidemiological estimates of status epilepticus but not in others.

Table 1 Classification of status epilepticus (SE)

1. SE in the neonatal and infantile epilepsy syndromes
   - West syndrome
   - Ohtahara syndrome
   - Severe myoclonic encephalopathies of infancy (including SMEI)
   - SE in other forms of neonatal or infantile epilepsy
2. SE confined to childhood
   - SE in early-onset benign childhood occipital epilepsy (Panyotopoulos syndrome)
   - SE in other forms of childhood epileptic encephalopathies, syndromes, and etiologies, e.g.: Ring chromosome X, Angelmans syndrome, myoclonic–astatic epilepsy, other childhood myoclonic encephalopathies
   - ESES (Electrical status epilepticus in slow wave sleep)
   - Landau–Kleffner syndrome
3. SE occurring in childhood and adult life

With epileptic encephalopathy
   - Nonconvulsive SE in Lennox Gastaut and similar syndromes [(i) Atypical absence status epilepticus; (ii) tonic status epilepticus]
   - Other forms of nonconvulsive SE in patients with learning disability or disrupted cerebral development (cryptogenic or symptomatic)

Without epileptic encephalopathy
   - Tonic–clonic SE
   - Typical absence status epilepticus
   - Myoclonic status epilepticus
   - Myoclonic SE in coma (NCSE in diffuse cerebral injury)
   - Epilepsia partialis continua
   - Complex partial status epilepticus: (i) Limbic and (ii) nonlimbic
   - Nonconvulsive SE occurring in the postictal phase of tonic–clonic seizures
   - Subtle SE (myoclonic SE occurring at the late stage of tonic–clonic SE
   - Aura continua (simple partial SE)
4. SE confined to late adult life
   - De novo absence status epilepticus of late onset
5. Boundary syndromes[a]
   - Cases of epileptic encephalopathy
   - Cases of acute brain injury, often with irregular myoclonus (myoclonic SE in coma)
   - Drug-induced or metabolic confusional states with epileptiform EEG changes
   - -Cases of epileptic behavioral disturbance or psychosis

[a]Boundary syndromes are defined as cases in which it is not clear to what extent the continuous epileptiform electrographic abnormalities are contributing to the clinical impairment.

Epidemiological Studies of Incidence

In the past few years, there have been a series of well-conducted population-based studies in the United States, United Kingdom, Switzerland, Germany, and Italy (Tables 2 and 3). Most have found an incidence of SE of approximately 10–20 per 100 000 per year. Different studies used different inclusion criteria, and the much higher incidence figures (from Richmond, VA) were in part due to the inclusion of cases of myoclonic status epilepticus in coma (see earlier 'boundary syndromes') (Table 2). Extrapolating the figures from this study, the authors estimate that there would be between 126 000 and 195 000 cases of status epilepticus in the United States every year. The study from London was of children (less than 15 years) and of convulsive status epilepticus only. In the studies based in emergency departments, the

numbers would not include many cases treated in the community. In all, studies, there was marked underascertainment as nonconvulsive forms.

As suggest earlier, case ascertainment in these studies is likely to have been deficient in the following categories: many of the nonconvulsive forms (and in particular, those that are self-limiting or those occurring in the epileptic encephalopathies), convulsive status epilepticus successfully treated in the community emergency departments, and the boundary syndromes. The true frequency of all forms of status epilepticus is thus unknown, but likely to be much higher than generally reported. The frequency of tonic–clonic status epilepticus of more than 30-min duration, estimated in these studies to be between 10 and 40 cases per 100 000 per year, can be considered a reasonably accurate estimate. This frequency is a key point, given the clinical importance of this form of SE.

Factors influencing frequency were also estimated in these studies and include the following:

Age: Age is a dominant factor. The highest incidence of status epilepticus was in young children and in the elderly. The incidence in the elderly is about 3–10 times that of younger adults.

Socioeconomic status and ethnicity: The importance of these variables were highlighted in the study from Richmond, VA, where the incidence of status epilepticus in the African-American population was found to be three times as high as that in the Caucasian population. In another retrospective study of the incidence of generalized tonic–clonic SE in California, the relative risk of the occurrence of status epilepticus, compared to that in the white population, was 1.92 for African-Americans, 0.5 for Hispanics, and 0.4 for Asians. In North London, Asian children (almost entirely from the Indian subcontinent) had a relative risk of 6.5 (compared with age-matched Caucasian children living in the same area) – due mainly to the higher frequency of prolonged febrile seizures.

Gender: In most studies, the incidence of SE was higher in males, although one well-conducted study from Italy found a higher incidence in females.

Other factors known to influence the frequency of status epilepticus are as follows:

Severity of epilepsy: Status epilepticus is much more common in severe epilepsy than in mild epilepsy, although it can occur in both. In a few cases, recurrent status epilepticus is the only manifestation of epilepsy.

Symptomatic versus idiopathic epilepsy: Status epilepticus is far commoner in symptomatic than in idiopathic epilepsy. Indeed, episodes of severe status epilepticus are extremely unusual in all the subtypes of idiopathic generalized epilepsies.

Learning disability: The frequency of status epilepticus is higher in those with learning disability, reflecting the generally more severe epilepsy.

Location of brain lesion: In lesional status epilepticus, lesions situated in the frontal lobes are more likely to result in status epilepticus than lesions in other cortical regions. Subcortical lesions only rarely result in status epilepticus.

Status Epilepticus as a Proportion of Hospital Admissions and as a Proportion of All Epileptic Cases

Various studies have provided data on the numbers of cases of status epilepticus admitted to hospital, and the proportion of cases in relation to the number of patients with epilepsy. These are important statistics for defining the appropriate allocation of resources. Admission figures, of course, will vary according to medical systems and patterns of practice. However, in general terms, about 1–5% of all neurological admissions, about 0.1–0.2% of all emergency unit consultations, and about 5% of all admissions to neurological intensive care units are due to status epilepticus.

About 5% of all adults with epilepsy and 10–20% of all children with epilepsy will have had an episode of status epilepticus at some point in their lives.

The Timing of Status Epilepticus

Tonic–clonic status epilepticus can occur either as the initial epileptic event or as an intercurrent episode in established epileptic patients; this distinction is important, as the etiology and implications of status epilepticus in the two situations are very different. At least 50% of cases occur due to acute brain diseases in adults without a history of epilepsy – and the figure in children is higher. In his review, Hauser estimated that status epilepticus accounts for 12% of all newly diagnosed cases of epilepsy presenting to hospital with a first epileptic event.

Refractory Status Epilepticus

There has been recent interest in the concept of 'refractory status epilepticus,' defined variously as status epilepticus, which does not respond to initial therapy (usually with benzodiazepines and then phenytoin or phenobarbital), or failure of response to three medications, or has continued for over 2 h. These are the cases that require intensive care therapy. Exact figures for refractory status epilepticus are difficult to obtain, partly because of lack of consensus regarding definition. However, estimates suggest that in 31–43% of patients with tonic–clonic status epilepticus, the SE is refractory, with a mortality rate of 16–60%.

Etiology of Status Epilepticus

The occurrence of convulsive status epilepticus in people without epilepsy is almost always due to a sudden cerebral disturbance. In children, fever is an important cause. In people with existing epilepsy, the range of causes differs, and commonly the status epilepticus is due to injudicious antiepileptic drug reduction or withdrawal.

In the population-based survey of children with first-ever episodes of status epilepticus from London, only 30% of the cohort had a history of prior epilepsy (or neurological abnormality) and the commonest cause of the status epilepticus was febrile illness (febrile status epilepticus). This cause accounted for 32% of all cases. Seventeen percent had acute symptomatic status epilepticus, almost all due to acute metabolic derangement (electrolyte imbalance, hypoglycemia, hypocalcemia, or hypomagnesemia) or acute CNS infection. Of the 95 children presenting with fever and status epilepticus, 12% had bacterial meningitis, emphasizing the importance of this treatable cause in young children.

Amongst adults, almost all studies have shown that the majority of cases of status epilepticus occur in previously nonepileptic patients and are due to an acute brain insult. When convulsive status epilepticus does occur in patients with a previous history of epilepsy, many cases are due to antiepileptic drug reduction/withdrawal. In these patients, an acute brain insult is much less commonly the precipitating factor.

In an analysis of the literature in 1994, of 1679 patients in 13 hospital series, status epilepticus had no obvious cause in only 19% of cases (11% in children and 13% in the elderly). Febrile status epilepticus accounted for 12% of cases, and acute metabolic, tonic, and anoxic causes for 14%. Stroke, tumor, trauma, infection, and perinatal causes accounted for between 7 and 10% each. In 554 patients (in five series of largely adult cases), only 41% had a prior history of epilepsy. An acute cause was found in 89% of patients with status epilepticus in previously nonepileptic patients, and in only 41% of patients with a previous history of epilepsy (**Table 4**).

The more recent population-based studies have reported similar findings to those of the older hospital series. In the studies of adult patients from Hessen in Germany, the following etiologies were recorded: remote stroke 36%, other remote symptomatic 27%, Binswanger disease 17%, acute stroke 14%, tumor 13%, medication induced 11%, metabolic disorders 9%, low antiepileptic drug levels 9%, alcohol 9%, remote trauma 8%, and no cause found 9%. In the Bologna study of adults, of the 41 patients with symptomatic status epilepticus, the following etiologies were recorded: stroke 41%, systemic metabolic disorders 24%, head injury 10%, alcoholism

Table 4 The causes of status epilepticus as the presenting symptom of epilepsy, or as an intercurrent event in established epilepsy[a] (in 554 patients from five case series)

	Status as presenting symptom of epilepsy (%) (n = 327)	*Status as an intercurrent event (%) (n = 227)*
Cerebral trauma	12	17
Cerebral tumor	16	10
Cerebrovascular disease	20	19
Intracranial infection	15	6
Acute metabolic disturbance	12	5
Other acute events	14	3
No cause found	11	41

7%, tumors 5%, intracranial surgery 2%, and other factors 27% (undefined acute illness in 20%). These findings probably broadly reflect the situation in most Western European adult populations.

In children, the etiologies identified in the Richmond study were as follows: infection 52%, reduction or withdrawal of antiepileptic drugs 21%, vascular causes 10%, hypoxia 5%, overdose 2%, and remote causes (usually congenital or perinatal) 38%.

The etiology of nonconvulsive forms of status epilepticus clearly depends on the underlying syndrome, age, and type of epilepsy. Amongst the rarer causes of convulsive and nonconvulsive status epilepticus, mitochondrial disease (and especially Alpers disease), inflammation, and rarer infections are all important.

Mortality of Status Epilepticus

Convulsive status epilepticus carries a significant mortality. In 1994, a review of 1686 cases from 12 series, there was an 18% mortality rate. The mortality rate is much higher in patients with acute brain disorders and much lower in patients with existing epilepsy (reflecting the different aetiological profiles). Of the deaths in this series, 89% were thought to be primarily due to the underlying cause (e.g., stroke, CNS infection, etc.) rather than the status epilepticus itself. Death was attributed entirely to the status epilepticus or its treatment in only 2% of cases. Age is also an important determinant of fatality, reflecting largely the different aetiological profile. In the Richmond, VA study, the mortality in pediatric, adult, and elderly populations was 2.5%, 14%, and 38%, respectively. In the London study of 176 children under the age of 15 years with first-ever episodes of status epilepticus, 7 children died. In three of these cases, death was due to acute bacterial meningitis, in one to glutaric aciduria type I, and in three others to progressive neurodegenerative disorders; in none was death due primarily to status epilepticus.

More recent studies have reported generally lower mortality rates associated with status epilepticus, although there have been exceptions. In the population-based epidemiological studies referred to earlier, generally much lower mortality rates were found. The case fatality rate was 9.3% in the study from Hessen, 7.6% in the study from Switzerland, and 3% amongst the children in the study from London. In the study from Bologna, a higher rate (39%) was found (33% if one excluded adults with postanoxic status epilepticus). The poorer outcome in this study was attributed in part to inadequate therapy and selection factors. In the latter study, all deaths occurred in the symptomatic group; there were none in the idiopathic or cryptogenic cases – a constant finding in all studies and consonant with clinical experience. The most common cause of convulsive status epilepticus in children is febrile status epilepticus, which also has low morbidity and mortality rates. In a recent review of all reported outcome studies of febrile seizures, the mortality rate of febrile status epilepticus was found to be 1.6%. This rate can be contrasted to the rates reported in landmark studies of the 1970s, in which the mortality rate was 11%.

The change in rates over time is thought in part to be due to the fact that status epilepticus is now treated earlier and much more vigorously than in the past. The early use of benzodiazepines, the use of prehospital therapy, and the much greater sense of urgency have all contributed to improvements in outcome. This improvement is particularly true of febrile status epilepticus and acute convulsive seizures in the community. However, once a patient has proved refractory to early therapy and requires intensive care and intravenous anesthetic, the mortality rate is between 40 and 50%. Even in this situation, the underlying causal condition remains the primary cause of mortality, and status epilepticus a secondary but important influence.

Nonconvulsive status epilepticus carries much less risk and lower mortality than convulsive SE, but again the outcome depends almost entirely on the underlying condition. Neonatal status epilepticus has a mortality rate of about 15%, infantile spasms of about 5%. Conditions with little or no acute-phase mortality include the syndromes of absence status epilepticus, electrical status epilepticus during slow wave sleep, the Landau–Kleffner syndrome, and the boundary syndromes. Complex partial status epilepticus has a definite but low mortality rate. The 30-day mortality rate of myoclonic status epilepticus in coma is over 60%.

Directions for Future Research

It is clear that the epidemiological data on status epilepticus, and particularly the nonconvulsive forms of SE, are

incomplete, and that the establishment of an accurate database is a challenge for the future. This need is true both for children and adults. A major obstacle is lack of agreement about diagnostic criteria and the inclusion or exclusion of 'boundary syndromes' (for instance, in the epileptic encephalopathies of childhood or the myoclonic status epilepticus in coma in adults). Such variations in inclusion criteria greatly affect the results of investigations and prevent meaningful comparisons between studies. Until accurate figures are available, one of the fundamental goals of epidemiological research, that is, the accrual of data to inform rational service provision, cannot be met. Similarly, there are no data on which one can base identification of environmental factors, knowledge of which could lead to preventative strategies; epidemiology could be usefully employed in this area of investigation. Many aspects of the epidemiological study of status epilepticus would be improved by organization on a multicenter or multinational basis. Such studies carry the potential of providing interesting and valuable epidemiologically based information in areas that cannot be otherwise easily investigated.

Introduction and Background

The great ancient Greek physician Hippocrates recognized the hereditary component to epilepsy in an era when it was regarded not as a physical disease, but rather as a spiritual visitation. Sadly, the familial nature of epilepsies has contributed to much discrimination over the millennia, and likely also retarded the scientific study of epilepsy genetics. From a contemporary perspective, the vast majority of familial epilepsies are benign and easily

treatable, and except in unusual circumstances, the diagnosis of epilepsy should not alter an individual's marital and reproductive choices.

Although the involvement of genetic factors in epilepsy was widely known, systematic study was relatively limited until the latter part of the twentieth century. The major exception to the lack of early data was the contribution of William Lennox, who from the 1930s until 1960 meticulously studied twins and family history in large cohorts of patients with clinical genetic techniques available at that time.

Classification is crucial to genetic analysis, since there is little value in attempts to analyze genetic factors if the clinical classification is imprecisely defined. Indeed, progress in classification and genetics are inherently linked. It took a long time for general recognition of the idea that epilepsy was not one disorder, but rather a group of disorders, more appropriately regarded as 'the epilepsies.' Progress was made with the evolution of the International League Against Epilepsy's (ILAE) classification, which differentiated types of epileptic seizures. The early classification scheme was followed in 1989 by a revised classification incorporating epileptic syndromes. The classification makes the important division of the epilepsies into generalized and partial/focal epilepsies, which are then broken down into idiopathic and symptomatic categories. It provides a framework for research into the genetics of the epilepsies. This classification is currently being updated, incorporating new genetic concepts.

Methods

Problems in Clinical Genetic Assessments

Clinical genetics depends implicitly on quality clinical data, and the quality of clinical data is a major issue in epilepsy research, particularly if the clinical descriptions are based on chart review. Although a family history is usually taken as part of a routine clinical assessment, this history is often only cursory. A detailed family history can be the most important clinical clue to a genetic aetiology.

A formal pedigree can be taken relatively quickly, and a checklist of important information is given in **Table 1**. A history of 'epilepsy' is not sufficient. The clinician should enquire whether family members have had any type of paroxysmal attack, including febrile convulsions, nocturnal attacks, or isolated seizures. The patient often may not know much about his/her family history, but should be encouraged to talk to the mothers in the family and to any elderly matriarchs who may know of early childhood attacks (long since forgotten) in other family members. It is common that the family history is 'fleshed out' by inviting the patient to provide more significant detail at subsequent visits.

Attention to detail is important in constructing a pedigree. It is worth recording the date of birth (if known) of family members, maiden names of partners, and the country of origin of a person's ancestors (**Table 1**). Often first names recur in a family tree, and the date of birth is essential to prevent confusion amongst family members with the same name. The question of possible consanguinity should be raised with each union, as this point may be crucial to understanding the clinical genetics of a seizure disorder. If the parents are not known to be related, but come from the same region or small village, distant consanguinity may be a possibility.

Table 1 Checklist for routine pedigree construction

- Name and date of birth of individuals
- Maiden names of partners
- Countries of origin of ancestors
- Consanguinity
- Obstetric history (miscarriages, stillbirths, neonatal deaths)
- Ask about any seizures (not just epilepsy) including febrile convulsions, nocturnal or paroxysmal attacks
- Ask patient to obtain data from other family members
- Ask older family members, particularly women
- Recheck data on follow-up visits
- Update pedigree when new individuals become affected or new children are born

Source
Scheffer IE and Berkovic SF (2000) Rational diagnosis of genetic epilepsies. In: Schmidt D and Schachter SC (eds.) *Epilepsy: Problem Solving in Clinical Practice*, pp. 111–131. London: Martin Duntz.

It is also important to ask about the patient's mother's obstetric history. If the patient's mother had an undue number of miscarriages or stillbirths, this history may point to a genetic etiology following sex-linked dominant inheritance with lethality in males. Some developmental malformations such double cortex syndrome and periventricular heterotopia have been recognized with this inheritance pattern in certain families – a pattern which is easily missed if the salient questions are not asked.

The familial nature of the patient's epilepsy may only become apparent with time as further extended family history comes to light or new members of the family develop epilepsy. The older generations may initially be reticent to discuss a family history of seizures, as they feel guilty about 'passing on' a disorder. With gentle education regarding genetic issues, as well as time, they may volunteer carefully guarded family secrets of major relevance.

Pedigrees with males solely affected raise the question of X-linked inheritance that may be seen in Fragile X syndrome, ARX mutations, and many other rare disorders. Where only females are affected, X-linked dominant inheritance must be considered; a clue may be an excess of male fetal losses (discussed earlier). Another disorder with only females affected – where paradoxically males are spared – is epilepsy and mental retardation limited to females (see Further Reading).

Methodological Approaches

The clinical genetic assessment described above is a starting point for analyzing epilepsy genetics as subjects present to clinicians or clinical researchers. In approaching the issue of clinical epilepsy genetic studies more broadly, a number of research strategies are used. The choice of strategy depends on the question being addressed and the clinical sample under evaluation.

Genetic Epidemiology

These studies provide a population-based view and seek to measure genetic factors operative across an unselected population. Evidence of a genetic contribution to disease is obtained by examining aggregation in families. Familial aggregation can be assessed by comparing the prevalence of epilepsy in a specific group of relatives (e.g., siblings, second-degree relatives) to the prevalence in the general population. The ratio of these is the recurrence risk ratio. For example, a sibling recurrence risk ratio of 2 means that siblings of patients are at twice the risk compared with the general population.

A common problem with such studies is that it can be difficult to obtain detailed and uniform information about phenotypes across a population. Nonetheless, they provide an important 'big picture' view of the problem.

Multiplex Family Studies

Here, large families with multiple affected individuals (typically 10 or more individuals) are specifically targeted. To date, these studies have provided the most robust advances in clinical epilepsy genetics, with identification of many new syndromes and subsequent molecular genetic discoveries.

Recognition of a new familial syndrome, which is likely to be under the control of a single genetic mutation rather than a random cluster of cases with multifactorial causes, is clinically challenging. Some phenotypes, such as febrile seizures, are relatively common in the general population, so that not all patients may have febrile seizures due to the same underlying mutation in a multiplex family, despite an apparently dominant inheritance pattern. Researchers must hypothesize which individuals are likely to have the familial syndrome in order to enable successful linkage and subsequent gene discovery.

Assessment of smaller multiplex families (e.g., 3–6 affected individuals) can be valuable in understanding the clinical relationship between epilepsy phenotypes. Some families might have a major dominant gene, but most are likely to have a complex genetic structure where multiple genes are involved.

Although multiplex families are not typical of the general population, discoveries about their clinical and molecular genetics have provided insights into the genetics of the common epilepsies.

Endophenotyping

In attempts to simplify molecular analyses in disorders with complex inheritance, endophenotyping may have a role. Here, rather than using the epilepsy syndrome as indicating affected status, a heritable subclinical marker is chosen and attempts are made to map this trait through families. Ideally, such markers should be easily and objectively measured and be present outside the age range of the syndrome under scrutiny. Endophenotypes could include EEG features such as photosensitivity, neuroimaging changes, or subtle differences in seizure phenomena.

Twin Studies

Twin studies, which were first extensively utilized in epilepsy by Lennox, remain a powerful method for demonstrating a genetic contribution in diseases with complex genetics. A comparison is made between concordances in identical (monozygotic) and nonidentical (dizygotic) twin pairs. Concordance refers to the presence of a disease in both twins. The degree of genetic contribution in a particular syndrome is judged by the completeness of the concordance in monozygous twins and by the extent to which it exceeds that in dizygotic twins.

Twin studies allow the distinction of the effects of shared genetic factors from those of shared environmental factors. Moreover, significant results can be achieved in relatively small samples in which detailed and consistent phenotyping is feasible. Study of twins can also aid in classification and nosology, addressing the issue of 'lumping' versus 'splitting.' If two apparently different syndromes (splitter's view) occur in monozygotic twins, then the syndromes are quite unlikely to be genetically different, providing evidence that they would be better regarded as a single entity (lumper's view). Finally, twins can also be used in matched pair designs, where one twin has had an exposure and the other not. Examples include effects of anticonvulsant exposure or postnatal insults.

In assessing twin studies, care must be taken to account for specific ascertainment biases. These biases include an excess of female monozygotic twins in volunteer twin registries, and the tendency to over-report cases of concordant monozygotic twins.

Single Cases and Case Series

Although it may seem counterintuitive to regard isolated cases as useful in genetic studies, it is becoming increasingly apparent that new (de novo) mutations, where there is no family history, form an important part of the genetic architecture of epilepsies.

This has long been known in classical chromosomal syndromes associated with epilepsy, such as trisomy 21, ring 20 syndrome, Angelman syndrome, etc. More recently, it has become clear that most cases of Dravet syndrome have de novo mutations in the sodium channel alpha 1 subunit gene *SCN1A*. De novo mutations are found in a variety of severe epilepsies, but are also know to occur in mild syndromes such as benign neonatal seizures.

Finally, it should be noted that strategies for clinical genetic research are changing with the power of new technology in molecular genetics. On the one hand, discoveries may now be made on only a few patients' samples. For example, the gene for the rare recessive disorder of action myoclonus-renal failure syndrome was identified using only three affected individuals. On the other hand, the current wave of genome-wide association studies, which may detect common variants as susceptibility genes for epilepsy, will need thousands of DNA samples from unrelated individuals with well-phenotyped genetic epilepsies.

Recent Results

Recent reviews highlight the major advances in this rapidly moving field (see Further Reading). Genetic epilepsies continue to be newly described or refined. In 2008, familial occipitotemporal lobe epilepsy and migraine with visual aura was described, POLG1 mutations were identified as an important cause of occipital lobe epilepsy, and the phenotype of epilepsy and mental retardation limited to females was extended.

Pharamcogenetic studies have largely been disappointing or controversial to date, but one finding has emerged of practical clinical importance. The risk of the severe skin reactions, Stevens Johnson syndrome or toxic epidermal necrolysis, in individuals of Asian descent appears to be markedly increased if they carry the HLA-B*1502 allele.

Table 2 shows some gene discoveries made in idiopathic epilepsies to date. The vast majority of these have been in monogenic epilepsies, but the difficult problem of identifying susceptibility genes is beginning to be tractable.

Future Goals

There is an exciting bright future for clinical genetic research in epilepsy. New syndromes continue to be discovered. By collaborating with molecular geneticists, the

clinical researcher can be a key player in a vital team that unlocks fundamental neurobiological discoveries that come from isolating genetic defects.

The relationship of phenotype to genotype is becoming more challenging. Far from the initial vision of particular genes being associated with particular clinical syndromes, it is now clear that many clinically homogeneous genetic epilepsies can be caused by more than one gene, and that defects in one gene may cause different phenotypes. A new level of analysis and interaction between clinical researchers and their molecular genetic colleagues is required to attack this puzzling problem.

Large multicentre studies, with carefully phenotyped cases, are required for genome-wide association studies. It is clear from studies in other disorders that subtleties in phenotyping may be crucial to the success or failure of such endeavors.

Pharmacogenetics of epilepsy is a growing field and will need careful clinical research to use the benefits potentially afforded by the emerging technologies. In the future, it may be possible to determine the likelihood of treatment success and the probability of specific side-effects with particular drugs in individual subjects.

Introduction

How does one identify Mendelian genes (traits whose genetic basis is a single gene), and complex non-Mendelian genes (traits whose genetic bases are multiple genes) in epistases that are responsible for at least half of all epilepsies? These genetic epilepsies represent 25–50 million people worldwide, ranging from the full epilepsy phenotypes (grand mal, absence, and myoclonic seizures), to endophenotypes (lateral temporal lobe auditory hallucinations, nocturnal rolandic bucco-oral, and appendicular motor seizures), including a variety of EEG abnormalities (diffuse polyspike waves, focal temporal spikes, centrotemporal rolandic spikes), speech impairment, oromotor apraxia, and cognitive deficits. These full seizure phenotypes and some endophenotypes endanger life, increase morbidity and mortality, produce social disadvantages, compromise quality of life, and can cost a single nation $11.1–12.5 billion a year. Most researchers now agree that the clear and surest way to develop cures

and repairs for these epilepsies is to define their epilepsy-causing mutations, the biochemical pathways in which these epilepsy genes act, and their consequent pathogenetic mechanisms. Mapping (finding) the chromosomal locations of these epilepsy genes is the first step toward their molecular definition.

Background

Most idiopathic generalized epilepsies and some focal epilepsies show a strong genetic component. In juvenile myoclonic epilepsy (JME), the 56–65% concordance rate for monozygotic twins (who share 100% of their DNA) and 21–12% for dizygotic twins (who share on average 50% of their DNA) suggest a strong genetic influence in its etiology. Janz and colleagues reported about one-third of JME patients had a positive family history for epilepsy; 3.4% of parents were affected with epilepsy, 7.0% of sibling, and 6.6% of children. In a recent review of our sample of 186 JME cases, 49% of our JME probands had an immediate family member with epilepsy or the EEG polyspike-wave trait. About 3.3% of parents, 6.7% of siblings, 3.4% of offspring, and 1.6% of second degree relatives of classic JME, have JME. In contrast, only 0.7–3.4% of the same relatives of classic JME have childhood absence. In terms of relative risks, or risk ratio to a relative, as explained by Risch in 1990 (risk ratio represents the recurrent risk or percent of a specific epilepsy (in this case JME) in a family member divided by prevalence of a specific epilepsy (in this case, JME) in the normal population), JME is 100 times more prevalent in parents and offspring and 200 times more prevalent in siblings, while 50 times more prevalent in second-degree relatives than in the normal population. In contrast, childhood absence is only 0.7–3 times more prevalent in relatives of classic JME patients. The low drop-off rate of recurrence risk from first degree relatives to second degree relatives is highly suggestive of a monogenic disorder. Almost all genetic modes of inheritance have been proposed for JME, including autosomal dominant (AD) transmission, a two-locus dominant–recessive model, and an autosomal recessive (AR) mode of inheritance. We used a dominant model with reduced penetrance (70%) to successfully map a JME gene to 6p12 (Myoclonin1/EFHC1); JME appears to segregate as an AD trait in these samples.

Historically, a strong genetic contribution to the spike-and-wave traits and absence epilepsies have also been supported by 84% concordance for EEG traits and 75% concordance for absence seizures in monozygotic twins. These twin studies support the concept of a major gene, working with additional genetic and environmental factors, in the phenotypic expression of absence epilepsy. In Rolandic epilepsy with centrotemporal spikes, complex genetic inheritance as well as AD inheritance has been observed. The syndrome has been mapped to chromosomes 16p12–11.2, 15q14, and 11p, while SRPX2 mutations have been linked with disorders of language cortex and cognition.

Despite family studies showing heritability and a clear genetic etiology, only 40 Mendelian epilepsy-causing mutated genes (mutations sufficient and necessary by themselves to cause epilepsy) have been defined. These genes account for 1%–10% of all Mendelian epilepsy genes. Moreover, the multiple susceptibility variants or alleles that contribute to the common complex or sporadic epilepsies remain undefined. To address these shortcomings, large scale mapping is now being done by various genetic consortia, through whole genome scans using 440 short tandem repeat polymorphisms (STRPs) (also called microsatellites in family-based cohorts) or 500 000 single nucleotide polymorphisms (SNPs) (in case association studies and linkage disequilibrium studies in trios). Most recently, 500 000 SNPs have also been used in linkage analyses of large families.

Methodological Approaches and Results to Date

Mendelian epilepsy genes, and their mutations that cause monogenic idiopathic epilepsies, are revealed by linkage analyses and positional cloning, using STRPs (microsatellites). Genetic linkage analysis (also called recombination mapping or crossing-over mapping) orders genetic loci (e.g., a disease allele and a DNA marker) on a chromosome and estimates genetic distances among them using the phenomenon of crossing over or recombinations. During meiosis (a stage of cell division), the two homologous chromosomes separate at most places but also maintain one or more zones of contact where crossing over of DNA strands occur. With increasing distance between two loci, an increasing number of crossovers occur. The number of crossovers between two loci serves as a measure of distance (in units of Morgans) between the loci. In a disease state, one can visualize crossovers between markers on a chromosome and place a disease locus into an interval between markers that crossed over together. We observe such phenomena when a disease allele and a marker is passed from a grandparent to a parent and from the parent to an offspring; the disease allele and the DNA marker are genetically coupled and linked. We call this phenomenon genetic linkage. Many new statistical algorithms determine the crossover frequencies occurring between two points on a gamete and the presence of linkage between two loci using the original Elston–Stewart algorithm.

Likelihood for linkage has loosely been called odds for linkage, and a given value indicates a ratio of how much higher the likelihood of the data is under linkage than under

absence of linkage. It is usually convenient to work with the logarithm of this likelihood ratio, which is the so-called Logarithm of Odds (LOD) or LOD score. The maximum of the LOD score denoted Z max serves as a measure for the weight of the data in favor of the hypothesis of linkage. When that maximum exceeds a certain critical value, the data are said to convey significant evidence for linkage. According to Morton, the critical value is three for autosomal loci and two for X-linked loci. As mentioned in the later text, with dense maps and 200–500 microsatellite DNA markers, the pointwise critical LOD scores required for an overall genome wide significance level of 0.05 varies according to the number of tests done with the markers and the diagnostic models used. With five diagnostic models used, the critical LOD score should be raised to 4.0.

There are two ways in which families can be used in linkage analysis: (1) In advanced socioeconomic countries where large multiplex and multigeneration families are rare, small, and medium sized families (with 3–5 affected members) are usually studied in 30–60 families for linkage analyses. LOD scores from each of the families are then pooled together. (2) Dominant Mendelian traits typically occur clustered in large pedigrees, with affected individuals being found in many generations. In developing socioeconomic countries, such large multiplex and multigeneration families are common. In dominantly inherited epilepsies, the ideal situation is to have one large family or a set of large families, each with at least nine affected members over at least three generations. For rare dominant traits, only one parent is heterozygous for the disease allele and potentially informative for linkage. Such a family can independently prove linkage to a given chromosome site (LOD score >3.35 at theta $= 0$ during genome wide scan using microsatellites spaced 1 cM, or LOD score >3.63 at $\theta = 0$ during genome wide scan using microsatellites spaced 0.1 cM) (see **Table 1**).

In recessive epilepsy traits, six affected offsprings belonging to consanguineous matings in one large kindred will usually reveal homozygosities that point to the chromosome site (supported by significant LOD scores). Lander and Botstein called this homozygosity mapping. An affected offspring provides approximately five times more linkage information than an unaffected offspring. With tight linkage of a recessive trait and a marker, each offspring independently contributes 0.602 and each unaffected offspring contributes 0.125 toward the expected LOD score. Using both approaches, we have identified two AD mutation harboring epilepsy genes (myoclonin1/EFHC1 for JME, and GABRB3 for remitting childhood absence) and two AR epilepsy genes (laforin/dual specificity phosphatase and malin/E3 ubiquitin ligase for Lafora progressive myoclonus epilepsy).

In genetically complex epilepsies that are clearly heritable yet do not follow any of the known modes of inheritance and are thought to be due to interaction (epistases) of multiple genes with small genetic effects, at least

Table 1 Large scale mapping of epilepsy chromosome loci and epilepsy gene discovery

	Mendelian epilepsy genes	*Complex non-Mendelian epilepsy genes*
Method for locating chromosome site	Genetic linkage analyses	Case association studies or transmission disequilibrium test (TDT)
Epilepsy subjects	For dominantly inherited epilepsies: • Large families (>9 affected in at least three generations) and • Medium sized families (>2 affected in at least three generations) For recessive epilepsies: • Six offsprings of consanguineous matings in a large kindred	For case association studies: • Two cohorts of 1 200–2000 unrelated index cases and matched controls of equal number For transmission linkage disequilibrium: • Two cohorts of >300 trios (parents and index cases)
Markers used	>400 microsatellites	Universal tag set of SNPs (>500 000 SNPs)
Refinement/reduction of size of chromosome site by recombination and haplotype analyses and linkage disequilibrium	Necessary	SNP haplotype may directly lead to the putative epilepsy variants
Mutation analyses	Mutations segregate with affected members of many generations in many unrelated families from separate cohorts, ideally of different geographic and ancestral origin	For case association studies: • SNPs associate with index cases more than by chance For transmission linkage dysequilibrium: • SNPs are transmitted to index case more than by chance
Replication	Usual	Difficult but possible using two-stage approach
Proof of causality	Knockout or knockin mice reproduce one or all phenotypes of epilepsy syndrome	Difficult and presently not achieved

Modified from Delgado-Escueta AV (2007) Advances in genetics of juvenile myoclonic epilepsies. *Epilepsy Currents* 7(3): 61–67.

1200–2000 unrelated index cases (preferably 10 000–20 000 cases) and an equal number of age, sex, and racial/geographically matched controls would be ideal for a case control association study during a genome – wide scan using a single universal tagging set of SNPs (300 000–500 000 SNPs) aided by the 2005 international HapMap. This situation would allow construction of tag SNP haplotypes that often travel together through generations of recombinations and could directly identify the many common DNA variants that underlie susceptibility to epilepsy in many samples around the world. For this approach, a two-stage analysis is commonly used. In stage one, a test cohort of 1200 individuals is genotyped, and then (stage two) a replication cohort of another 1200 persons is genotyped. Stringent criteria to satisfy the presence of significant association should be followed. An association exists between a disease and a DNA tag SNP when they occur together in the same individuals with the disease more often than expected by chance. To investigate whether the association is present, two groups are collected, the disease group and a control sample. In each group, the proportion of individuals with the disease SNP allele is determined and the usual chi-square test for 2×2 tables is applied to determine significance. The strength of an association is then measured by the relative incidence or relative risk.

For case–control association studies, allele and genotype frequencies are calculated using the gene counting method. Hardy–Weinberg equilibrium calculations are carried out for all SNPs in each test and control population. A population is said to be in Hardy–Weinberg equilibrium when the genotype frequencies in the population depend only on the gene frequencies, under conditions of random mating and in the absence of disturbing forces such as mutations, migration, and selection at the gene in question. Allele and genotype association between epilepsy probands and controls are tested using the Transmission Disequilibrium Test (TDT), whose statistic as discussed earlier is tested using chi square (χ^2). Correction for multiple statistical testing is commonly done using the Bonferroni correction. If different populations from different geographic areas are used, combined cross-population p-values are calculated using Stouffer's weighted-Z-method.

Family-based association study (one offspring and two parents or trios) can also be done for epilepsy families with two or more generation members, both under the null hypothesis of no association and no linkage, and under no association in the presence of linkage with an extension of the TDT.

Mendelian Epilepsy Genes

Other investigators have suggested that since genetic markers no longer constitute a constraint, the greatest limitation to the study of human heredity disease is finding enough families with multiple affected members. In our experience, this limitation can be overcome in cultures such as in Hispanics from Los Angeles (CA, USA), Mexico, Honduras, El Salvador, Brazil, and Peru, since large families are common in these societies and cultures. Among those populations, we can attain the ideal situation for independently proving linkage – a large family with multiple members affected with epilepsy across at least three generations. With marker spacing <0.1 cM, the appropriate critical LOD score limits of 3.3 will give an overall genome-wide significance level of 0.05.

Large families can have rare mutations that are unique to that particular family, and thus may not represent the common forms of idiopathic epilepsies found in the more common smaller families. Hence, steps 1 and 2 of our strategy (see **Figure 1**) require that linkage found in one large family be replicated in another data set of one or two other large families of the same racial ethnic group. Because replication does not carry the burden of multiple testing as a genome screen, the significance level, when replicating a previously significant finding, may be set anywhere from 0.01 to 0.05.

On a practical level, a second large family should replicate a first family's linkage. However, we usually have to screen 5–10 large families before we are able to replicate a linkage claim. Thus, step 1 in our strategy requires that we enlarge the existing original family significantly linked to a chromosome locus by enrolling fourth generation or fifth generation offspring of previously genotyped members. With each new generation of affected members, LOD scores should increase. Otherwise, the significant linkage findings may be spurious.

Once we have two families that each independently prove significant linkage, pooled LOD score will be >5 ($\theta = 0$) and recombinations/crossovers can be confidently used to localize and reduce the size of the candidate chromosome regions. Haplotypes from these two families can then be used with 20–40 surrounding microsatellites and tSNPs as screening sets to narrow the critical gene region, to look for more recombinations in large and medium size families and determine if a common affected haplotype exists segregates with affected members in a set of 30–50 medium size multigeneration families. This approach gives us even more convincing evidence that an epilepsy gene contained within the haplotypes is segregate with epilepsy affected members and also gives us a glimpse of how common the putative candidate region and contained epilepsy gene is amongst familial epilepsy.

With more recombinations, the critical gene interval can be reduced to <1 cM, setting the stage for heteroduplex analyses and sequencing of candidate JME genes. Usually the critical gene interval will contain transcripts, known genes, full-length cDNAs, ESTs, and predicted

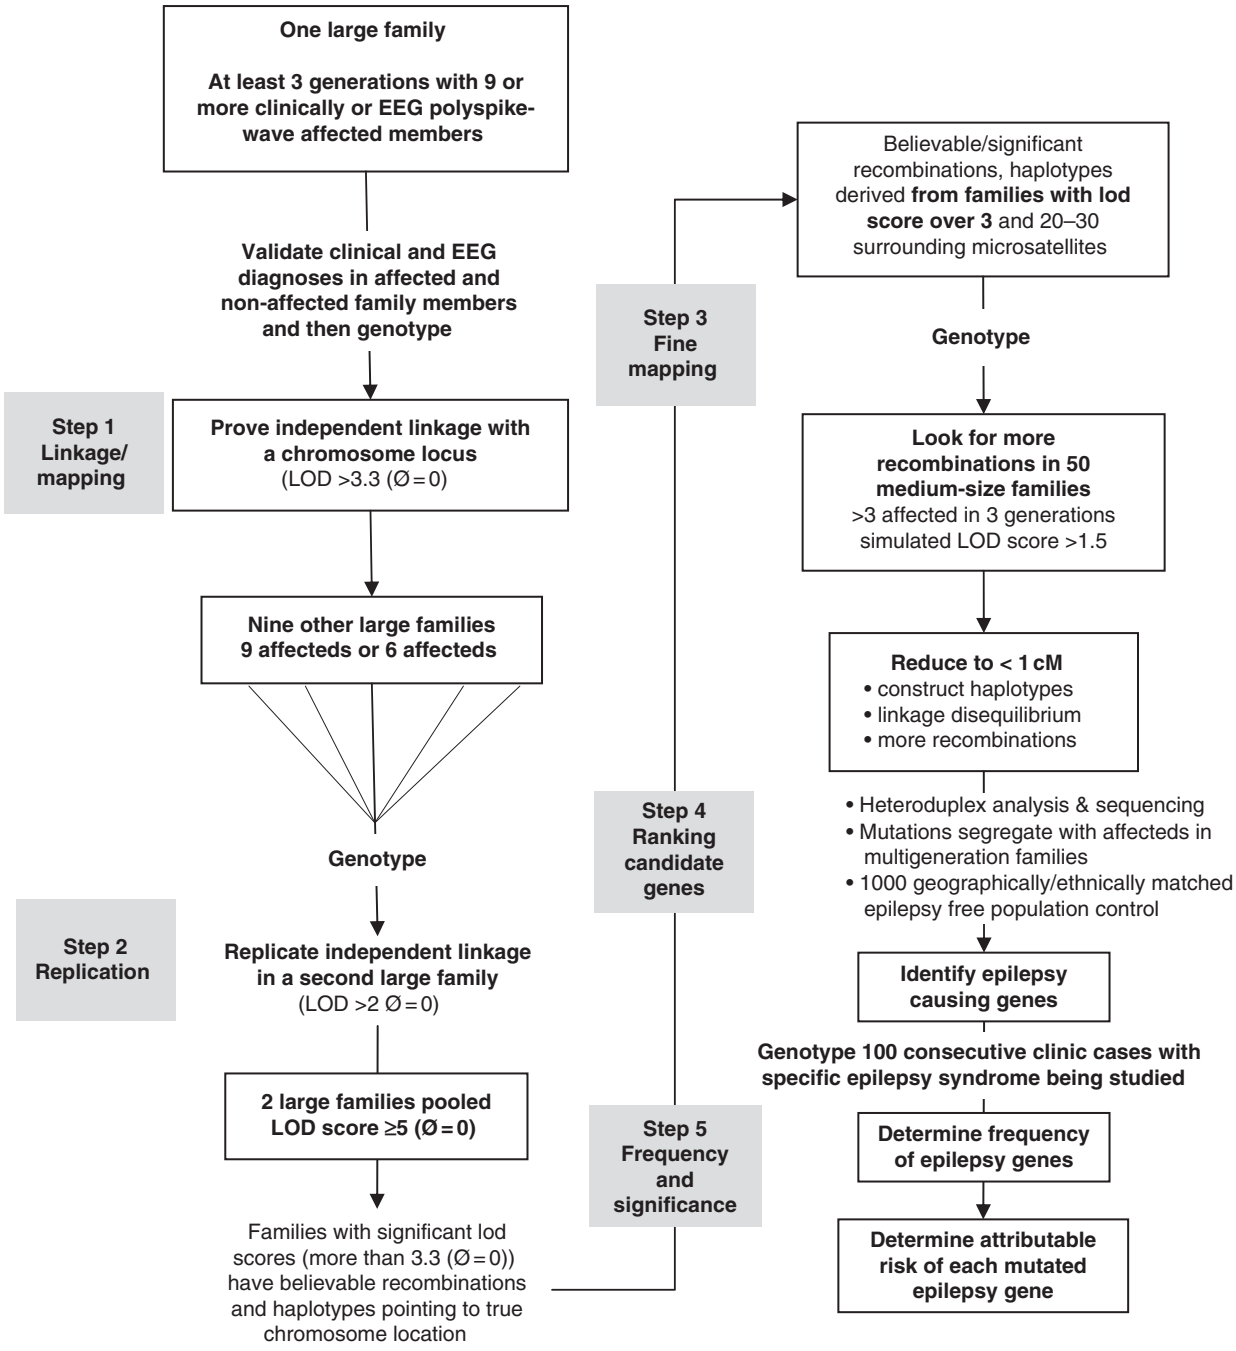

Figure 1 Strategy for search of mutation harboring Mendelian epilepsy genes.

proteins. To reduce the gene list, predicted proteins without a start codon and stop codon should not be studied. In addition, homology searches for translated sequences (by use of BLAST, a program that reveals genes with sequences that are similar to a gene in question, sequences conserved in evolution within various animal species) should be performed to eliminate additional putative genes. Remaining candidate genes must be expressed in brain to receive our attention for direct sequencing or heteroduplex analyses. This outlined strategy has served us well and helped us identify Laforin/DSP (the disease causing gene of Lafora epilepsy), myoclonin/EFHC1 (the epilepsy/polyspike wave EEG causing gene of JME), and GABRb3 (the seizure causing gene of remitting childhood absence epilepsy).

Tables 2–5 list the chromosome loci and mutation containing Mendelian genes found so far in idiopathic epilepsies.

Table 2 Chromosome loci and genes identified in JME as of 2008

Locus	*Gene*	*Country/ethnic group*	*No. of families*	*Mode of inheritance*	*Phenotype*
6p12–11	Myoclonin 1/EFHC1[a]	Native Americans mixed with Europeans (Hispanic) [UCLA]	22	AD	Classic JME and pCAE evolving to JME
		Native Americans mixed with Europeans (Hispanics) [Belize]	1	AD	Classic JME
		Native Americans mixed with Europeans (Hispanics) [Mexico[b]]	31	AD	Classic JME
		Native Americans mixed with Europeans (Hispanics) [Honduras]	2	AD	Classic JME and pCAE evolving to JME
		Japanese [Japan]	2	AD	Classic JME
6p12; 16p13; and 7q32	–	Netherlands Netherlands	18	AD	JME Photosensitive JME
6p21.3	BRD2[b]	Americans of European descent [Los Angeles, California]	24	AD	Classic JME
		Americans of European descent [New York[c]]	85	AD	Classic JME mixed with pCAE evolving to JME
6p21.3	–	Germany	29	AD	JME
15q14	CX36[b]	United Kingdom, Denmark, France, Greece, Portugal, Sweden	25	AR	JME

Table 3 Chromosome loci of idiopathic epilepsies of infancy, childhood, and adulthood

Phenotype	*Genotype*[a]	*Country of origin & No. of families*
Familial febrile seizures (FEB3), (possibly GEFS+)	2q23–24	One family from Utah, USA
Generalized epilepsies with febrile seizures plus (GEFS + type 2)	2q23–q31	One family from Northern Victoria, Australia; SCN1A mutation in two families from France
Generalized epilepsies with febrile seizures plus (GEFS + type 1)	19q13	SCN1B mutation in one Tasmanian family from Australia
Generalized epilepsies with febrile seizures plus (GEFS + type 3)	5q	GABRG2 mutation in one family from France
Febrile seizures and childhood absence	5q	GABRG2 mutation in one family from Australia
AR idiopathic myoclonic epilepsy of infancy	16p13	One family from Sardinia, Italy
Remmitting childhood absence epilepsy	15q11–12; GABARB3 Exon 1a and Exon 2 mutations	Four families from Mexico and Honduras
Childhood absence epilepsy persisting with grand mal	8q24	One large family from India and medium size families from Argentina, Spain, and Los Angeles
Photogenic childhood absence with eyelid myoclonia evolving to JME	Unknown	Five families Mexico and California (USA)
Benign Adult Familial Myoclonic Epilepsy	8q23.3–q24.1	Five families from Japan

[a]Unless indicated all evidence acquired by model dependent linkage analyses.
Modified from Delgado-Escueta *et al.* (2002) *Advances in Neurology* 89: 161–184. (Article includes references for the studies).

Table 4 Chromosome loci of other generalized epilepsies of infancy and childhood

Phenotype	*Geno-type*[a]	*Country of origin & no. of families*
Infantile spasms syndrome (MIM308350)	Xp11.4–Xpter	Two families from Leuven, Belgium
Benign familial neonatal convulsions (EBN1)	20q	KCNQ2 mutation initially detected in one family from Sweden and then in six families from Newfoundland, Sweden, Quebec (Canada), USA, six families from France and one family from Japan
Epilepsy and mental retardation limited to females (EFMR)	Xq22	PCDH19 mutations in seven families from Australia
Ohtahara syndrome	9q33.3–q34.11	STXBP1 mutation in four patients from Japan
Benign familial neonatal convulsions (EBN2)	8q24	KCNQ3 mutation in one family USA (Texas) and one family from Japan
Benign familial infantile convulsions	19q13	Families from Italy
Familial infantile convulsions and Paroxysmal choreoathetosis	16p12–q12	Four families from France and one family from China
Familial febrile seizures(FEB1)	8q13–21	One family from Australia
Familial febrile seizures (FEB2)	19p	One family from the Midwest, USA
Familial febrile seizures (FEB4) by nonparametric GENEHUNTER and transmission linkage disequilibrium	5q14–q15	One large and 39 nuclear families from Japan
Childhood absence epilepsy with or without grand mal	8q24 (ECA1)	Seven families from Bombay, India, Argentina, LA, CA (USA), Spain, Saudi Arabia
Idiopathic generalized epilepsy with generalized spike waves	3p14.2–p12.1	One family from Italy
Adolescent-onset idiopathic generalized epilepsies with generalized spike-waves (NonJME random grand mal and juvenile absence seizures)	8p11–12	23 families (15 grand mal and eight juvenile absence) from New York

Table 5 Chromosome loci of partial epilepsies

Phenotype	*Geno-type*[a]	*Country of origin & no. of families*
Autosomal dominant nocturnal frontal lobe epilepsy	20q	NACHR-α4 subunit mutation in two families from Australia, one family from Norway and one family from Japan
Autosomal dominant nocturnal frontal lobe epilepsy	15q24; 1cen	Three families from Quebec, Canada, Italy, and England; Calabria,Southern Italy
Autosomal dominant nocturnal frontal lobe epilepsy		
TLE with auditory symptoms	10q	One family from New York; one family from Basque region, Spain
Autosomal dominant partial epilepsy with variable foci	2q (preliminary)	One family from Australia
Familial partial epilepsy with variable foci	22q11–q12	Two families from Quebec; one family from Spain
AR Rolandic epilepsy with paroxysmal exercise induced dystonia and writer's cramp	16p12–q12	One family from Italy
Centrotemporal spikes in families with Rolandic epilepsy	15q14	22 families from Germany
Rolandic epilepsy and speech dyspraxia	?	Australia
Familial TLE	?	Australia
Familial TLE with hippocampal scleroses and interleukin (IL)-1β, IL-1α, and IL-1 receptor antagonist gene	2 (association studies)	50 patients with TLE + HS from Japan
Familial Spastic paraparesis and epilepsy	14q; 15q	One family from Italy
Episodic ataxia type I (EA-1) and epilepsy	Mutation in potassium channel gene KCNA1	One family from Glasgow, Scotland
Frontotemporal dementia Parkinosonism-17 (FTDP-17)	17q21–22 (missense mutation at nucleotide 1137 C–T in tau gene)	One family from Germany

Genetically Complex Epilepsies

Genes for complex epilepsies can be found through case-control association studies. However, with the exception of one recent report, most association studies on genetically complex epilepsies have been underpowered in relation to likely effect sizes for risk alleles. Previous claims of associations have either not survived replication or the Bonferroni correction. Three exceptions appear to be: (1) *BRD2* in chromosome 6p21.3 as a risk factor for JME; (2) *Cx-36* in chromosome 15q14 as a risk factor for JME; and (3) *ME2* in chromosome18 as a risk factor for idiopathic generalized epilepsies.

SNPs within the *BRD2* (RING3) gene in chromosome 6p21.3 have been suggested to be susceptibility alleles (odds ratio 6.5) for AR JME families from New York. Linkage disequilibrium found two strongly JME-associated SNP variants in the promoter region of *BRD2*, and a common variant haplotype in over 50% of 20 probands from families that had produced positive LOD scores for 6p21 during linkage analyses. A recent study has confirmed the association between rs3918149 promoter variant of BRD2 with JME samples from Britain, but not in German, Australian, or Indian populations, suggesting the BRD2 risk factor is population-specific.

Both case–control and family-based association studies were used by Greenberg's group in New York in identifying malic enzyme 2 (*ME2*)-centered nine-SNP haplotype in chromosome 18q. When present in the homozygous state, the *ME2*-centered nine-SNP haplotype increased the risk for idiopathic generalized epilepsy (odds ratio 6.1). Studies have suggested that the *BRD2* gene in 6p21.3 epistatically interacts with the *ME2* gene in 18q to produce JME. Another study showed that alleles of *BRD2* also conferred susceptibility to the EEG photoparoxysmal response in JME/idiopathic generalized epilepsy families from Germany; allelic and haplotypes associations were found between the photoparoxysmal response and six BRD2 polymorphisms, but the polymorphisms appeared to be protective against, instead of increasing risk for photoparoxysmal response.

As in the New York population mentioned earlier, susceptibility SNPs in JME families have been found in families from the United Kingdom and Sweden. Investigators sequenced the gene, *Cx-36*, in 29 JME probands previously linked to the 15q14 locus and did not find any epilepsy-causing mutations that segregated with affected members. Instead, a case–control study found significant association between JME and the c.588T polymorphisms within exon 2 of *Cx-36*. With significant differences in both alleles ($p = 0.03$) and genotype ($p = 0.017$) frequencies, subjects with the T/T genotype at position 588 had a significantly increased risk for JME (odds ratio 4.3) compared to those with a C/C genotype. HAP2, a haplotype containing c.588T, was significantly associated with JME ($p = 0.03$). This association of c.588T (dbSNP:rs3743123, S196S) within *Cx-36* was replicated in 247 German JME patients (vs. 621 controls). Investigators observed an increase in homozygotes (13.4%) in JME compared with controls (8.7%), suggesting the allele increased the risk for JME in the homozygous state.

A recent study attempted to remedy the lack of power that plagued previous association studies in epilepsies. They enrolled 2717 cases and 1118 controls collected from four separate research centers from the United Kingdom, Ireland, Australia, and Finland. No clear indisputable common genetic risk factors were found that contributed to selected epilepsy subphenotypes across multiple populations. However, numerous SNPs in four genes contributed to predisposition in an apparent population-specific manner. These genes were (1) KCNAB1 (voltage gated potassium channel subunit beta-1) predisposing to 'secondarily generalized tonic–clonic seizures,' 'all epilepsy phenotype,' and 'partial seizures' in the Finnish cohort. (2) GABRR2 (γ-aminobutyric-acid C receptor subunit rho-2 precursor) predisposing to 'JME,' 'absence,' 'myoclonic seizure,' and 'nonJME grand mal seizures' in British and Irish populations. (3) KCNMB4 (calcium activated potassium channel, subfamily M subunit beta 4) predisposing to the syndrome of medial temporal lobe epilepsy (TLE) with hippocampal sclerosis in the Irish cohort. (4) SYN2 (Synapsin (2) predisposes to 'febrile seizures' in the UK, Irish, and Finnish cohorts). The authors recommend an even larger and more syndromically focused patient cohort be used for association studies exploring intermediate phenotypes and endophenotypes.

Challenges for the Future

Mendelian Epilepsy Genes

Depending on how one measures the epilepsy subsyndrome phenotype, only 1–10% of Mendelian epilepsy genes, have been identified. Large-scale genome mapping of large multigeneration, multiplex families from developing countries, as well as medium sized multigeneration, multiplex families from developed countries, should continue to define more and new chromosome loci for idiopathic epilepsies. The epilepsy genes of more than 10 known chromosome loci in JME, 5 chromosome loci for febrile seizures and infantile convulsions, 6 chromosome loci for partial epilepsies, and 3 chromosome loci for absence epilepsies still remain to be defined. These Mendelian genes will undoubtedly be discovered using the power of linkage analyses and positional cloning.

Genetically Complex Epilepsies

Linkage disequilibrium-based case control association studies, powered to a sufficiently large cohort (perhaps 5000–10 000 syndromically defined epilepsy cases and an equal number of controls), and performed in two stages

for replication or transmission linkage disequilibrium analyses of 300 trios or family based association studies, have not been successfully executed in genetically complex epilepsies. Instead, SNP susceptibility alleles in previously linked chromosome sites have been associated with small cohorts of epilepsies, as discussed earlier.

These proposed susceptibility polymorphisms (i.e., *BRD2* in chromosome 6p21.3; *Cx-36* in chromosome 15q14; and *ME2* in chromosome18) are hypothesized to act in epistases as minor epilepsy genes in the homozygous state, necessary but not sufficient to produce a JME phenotype. The challenge with these SNPs is to show what changes in cell function are altered so as to produce the JME phenotypes. No such tests have yet been performed. A second, more formidable challenge is proving causality (see **Table 1**). It is a difficult challenge to insert SNPs of putative JME genes in a bacterial artificial chromosome (BAC) vector – together with other SNPs of putative JME genes with which they are hypothesized to interact in epistases – and then transgenically reproduce one or all of the JME phenotypes. The *BAC* gene targeted approach rarely has been used to prove that interacting polymorphisms can cause a given disease phenotype.

Introduction

The development of the human cerebral cortex is a dynamic process that can be divided into partially overlapping stages that occur during several gestational weeks. During the first stage, stem cells proliferate and differentiate into young neurons or glial cells deep in the forebrain, in the ventricular and subventricular zones lining the cerebral cavity. During the second stage, after their final mitotic division, cortical neurons migrate away from their place of origin. Most cells migrate in a radial fashion, along the radial glial fibres from the

periventricular region towards the pial surface, where each successive generation passes one another and settles in an inside–out pattern within the cortical plate. A subset of cells (interneurons) migrate tangentially, primarily from the ganglionic eminences. When neurons reach their destination, they stop migrating and order themselves into specific 'architectonic' patterns, according to a complex signalling pathway guiding cells to the correct location in the cerebral cortex. This third phase involves final organization within the typical six layers of cortex, associated with synaptogenesis and apoptosis. When cortical development is complete, the cortex is a six-layered structure, with each layer comprising different types of neurons that form discrete connections within the CNS and perform distinct functions (**Figure 1**). In humans, the proliferation stage ranges from weeks 5–6 to weeks 16–20, migration from weeks 6–7 to weeks 20–24, and organization from week 16 until well into postnatal life. Only a few of the gene products that influence such complex mechanism have been identified in humans and specific disorders arising from mutations in some of these genes have been described.

Abnormal cortical development is increasingly recognized as a cause of developmental disabilities and epilepsy. This recognition is due, in part, to the improved use of magnetic resonance imaging (MRI), which makes it possible to assess the distribution and depth of cortical sulci, cortical thickness, the boundaries between gray and white matter, and variations in signal intensity. Abnormalities of any or all of these features may be observed in different cortical malformations, which may be restricted to discreet cortical areas or may, alternatively, be diffuse. Epilepsy is often present in patients with cortical malformations and tends to be severe, although its incidence and type vary in association with different malformations. The physiopathological mechanisms relating cortical malformations to epilepsy remain elusive.

In the following sections we will discuss the most frequent cortical malformations causing epilepsy and those for which the causative gene has been cloned (see **Table 1**).

Background

Lissencephaly

Definition and histopathology

Lissencephaly (LIS) (derived from the Greek words "lissos" meaning smooth and "enkephalos" meaning brain) is a neuronal migration disorder characterized by absent (agyria) or decreased (pachygyria) convolutions, producing a smooth cerebral surface. Several different types of LIS have been recognized. The most common type, known as classical LIS or type 1 LIS, features a very thick cortex (10–20 mm vs. the normal 4 mm) and no other major brain malformations. The cytoarchitecture consists of four primitive layers, including an outer marginal layer that contains Cajal-Retzius neurons (layer 1), a superficial cellular layer that contains numerous large and disorganized pyramidal neurons (layer 2) corresponding

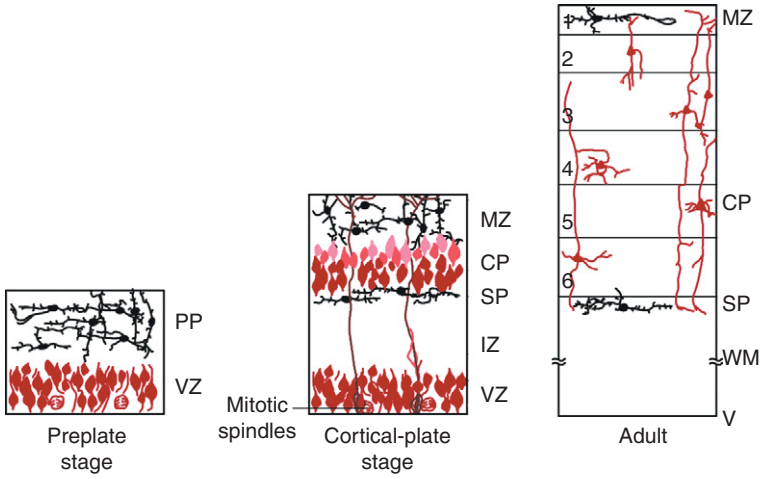

Figure 1 Normal cortical development. Cortical development can be divided into three stages. The preplate stage is marked by the formation of the preplate (PP), a plexiform layer that forms around embryonic-day 10–12 in mice and weeks 8–9 in humans. The cortical-plate (CP) stage is marked by proliferation of neuroblasts in the ventricular zone (VZ) (indicated by mitotic spindles) and migration of these cells along radial glial fibers (brown processes). Migrating neurons penetrate the preplate, split the preplate into the subplate (SP) and the marginal zone (MZ), and deposit in the cortical plate (CP). Neurons generated later must pass through the subplate and past previously deposited neurons to reach the outer limits of the developing CP (indicated by the progressive lighter shades of red in more-superficial CP neurons). The cortical-plate stage lasts from E10–E17 in mouse and weeks 10–18 in humans. The adult stage is marked by the lamination of the CP into a six-layered structure. Abbreviations: IZ, intermediate zone; V, ventricle; WM, white matter. Modified from Gleeson and Walsh, 2000.

Table 1 Most frequent cortical malformations causing epilepsy and their, currently known, causative genes

Cortical malformation	*Inheritance*	*Locus*	*Gene*	*Gene product/function*
Bilateral periventricular nodular heterotopia	X-linked	Xq28	*FLNA*	F-actin-binding protein; coagulation and vascular-related functions
	AR	20q13.13	*ARFGEF2*	Proliferation and migration
Isolated lissencephaly	AD	17p13.3	*LIS1* or *PAFAH1B1*	LIS1: Platelet-activation factor acetylhydrolas E, isoform 1B, α subunit; regulates the level of platelet-activating factor in the brain; interaction with dynein, dynactin, NUDE, and NUDEL proteins
	X-linked	Xq22.3	*DCX*	
	AD	12q12-q14	*TUBA1A*, *TUBA3*	Involved in microtubule formation
Double cortex (subcortical band heterotopia)	X-linked	Xq22.3	*DCX*	Interact with LIS1; effect on microtubules and cytoskeleton
	AD	17p13.3	*LIS1* or *PAFAH1B1*	
Miller–Dieker syndrome	Microdeletion disorder	17p13.3	*LIS1*, *14–3-3*ε and contiguous genes	
Lissencephaly with cerebellar hypoplasia	AR	7q22	*RELN*	Control cell-cell interactions critical for cell positioning in the brain.
			VLDLR	Very low density lipoprotein receptor; involved in reelin signalling pathway
Lissencephaly with abnormal genitalia	X-linked	Xp22.13	*ARX*	Aristaless-related homeobox gene; tangential migration & differentiation of GABAergic interneurons in the ganglionic eminence and neocortex
Fukuyama congenital muscular dystrophy (FCMD)	AR	9q31	*Fukutin (FCMD)*	Maintenance of muscle integrity, cortical histiogenesis, and normal ocular development
Walker-Warburg syndrome (HARD +/-E syndrome)	AR	9q34.1	*POMT1*	Similar to O-mannosyltransferases
		14q24.3	*POMT2*	Similar to O-mannosyltransferases
Muscle-eye-brain disease (MEB)	AR	19q13.3	*FKRP*	Modification of dystroglycan
		1p34-p33	*POMGNT1*	Involved in O-mannosyl glycan synthesis
Polymicrogyria				
Bilateral perisylvian	AD	11p13	*PAX6*	Transcription factor.
	X-linked	Xq21.22-q23	*SRPX2*	Expressed in fetal and adult brain, involved in rolandic seizures (?)
Bilateral frontoparietal	AR	16q13	*GPR56*	G Protein coupled receptor; role in regional patterning of the cerebral cortex
Holoprosencephaly	AD	7q36	*SHH* (Sonic Hedgehog)	Involved in differentiation of ventralized progenitors into motor neurons or interneurons, defining the pattern of neuronal cell types generated in the neural tube

to the true cortex, a variable cell sparse layer (layer 3), and a deep cellular layer (composed of medium and small neurons) that extends more than half the width of the mantle (layer 4) (Figure 2).

Subcortical band heterotopia (SBH) is a related disorder in which there are bilateral bands of grey matter found interposed in the white matter between the cortex and the lateral ventricles. SBH may appear as a solid band of heterotopic tissue or as numerous islands of radially oriented gray matter separated by white matter. Pyramidal cells in the heterotopic band may be smaller than normal compared with those in the overlying cortex, which is usually structurally normal with the exception of shallow sulci.

Genetics

Two major genes have been associated with classical LIS and SBH. The *LIS1* gene (OMIM: *601545) on chromosome 17p13.3 is responsible for the autosomal form of LIS, while the doublecortin gene (*DCX* or *XLIS*) (OMIM: *300121) is X-linked. Although mutations in either gene can result in either LIS or SBH, most cases of classical LIS are due to deletions or mutations of *LIS1*, whereas most cases of SBH are due to mutations of *DCX*.

LIS1 mutations result in more severe LIS in the posterior brain regions (posterior > anterior gradient), whereas *DCX* mutations result in more severe LIS in the anterior brain regions (anterior > posterior gradient) (**Figure 3**). Truncating *LIS1* mutations cause severe LIS, while missense mutations, cause less severe malformations such as pachygyria and SBH usually accompanied by milder motor and cognitive impairment. Mosaic mutations of *LIS1* also cause SBH in the posterior brain.

DCX mutations classically cause the SBH phenotype. Women with *DCX* mutations have anteriorly predominant band/pachygyria. However, rare carrier women harboring missense mutations with normal brain MRI, due to either favourable X-inactivation skewing or to mutations with mild functional consequences, have been described. Mutations of *DCX* have been found in all reported pedigrees, including families in which females have SBH and males have LIS, and in ~80% of sporadic females and 25% of sporadic males of SBH. Genomic deletions of the DCX gene have been identified in females with sporadic SBH and in males with X-linked LIS. Maternal germline or mosaic DCX mutations may occur in about 10% of

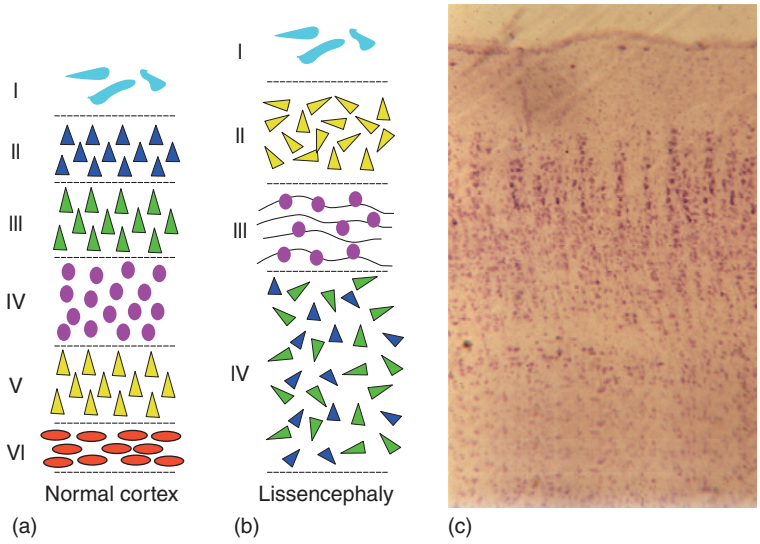

Figure 2 Scheme of normal (a) cortical laminar organization (6 layers) and cortical layering in classical LIS (4 non-organized layers) (b). (c) Histopathological section from a patient with LIS. Modified from Golden JA and Harding BA (2004) Pathology & Genetics. Developmental Neuropathology. Basel: ISN Neuropath Press, with permission from Wiley-Blackwell.

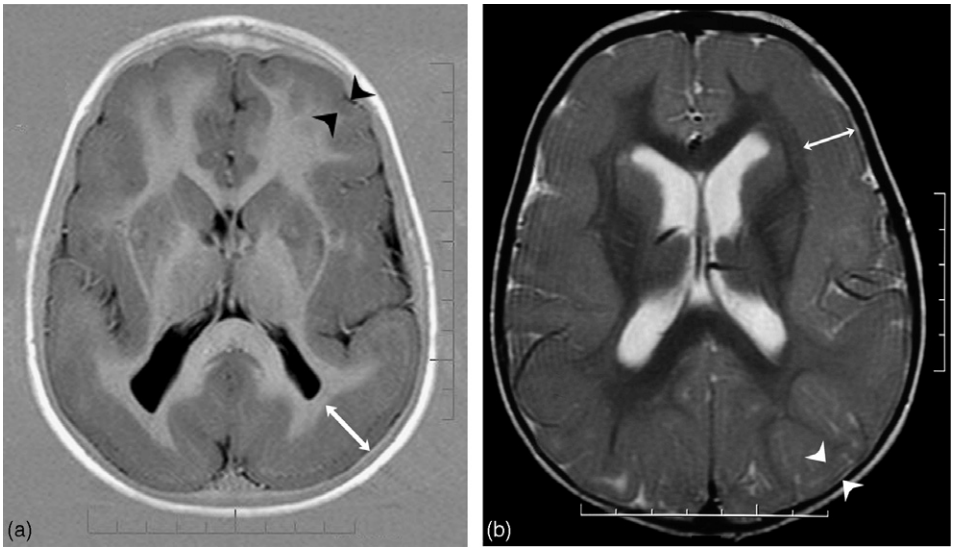

Figure 3 (a) Brain MRI scan; axial section: classical LIS in a boy with *LIS1* gene mutation. There is a typical posterior > anterior malformative gradient with relative preservation of the gyral pattern and cortical thickness in the anterior brain; cortical thickness is around 6 mm in the frontal lobes (black arrows; normal cortical thickness = 4 mm) and around 3 cm in the posterior brain (white arrow). (b) Brain MRI scan; axial section: LIS in a girl with *DCX* mutation. There is a typical anterior > posterior malformative pattern, cortical thickness is around 2 cm in the frontal lobes (single white arrow) and around 4 mm in the posterior brain (double white arrows).

cases of either SBH or XLIS. Hemizygous males with *DCX* mutations have classical LIS, but rare boys with missense *DCX* mutations with an anteriorly predominant SBH have also been described.

Recently, a mutant mouse was generated with abnormalities in the laminar architecture of the hippocampus and cortex, accompanied by impaired neuronal migration. This animal had a mutation in the guanosine triphosphate (GTP) binding pocket of alpha-1 tubulin (Tuba1). *TUBA1A* is one of three α-tubulin genes in a cluster on human chromosome 12q, and is highly homologous to the mouse and rat *Tuba1* gene. Mutations in this human homolog of *Tuba1* (*TUBA1A* or *TUBA3*) were subsequently identified in patients with LIS. The clinical and anatomic spectrum of severity TUBA1A-related LIS appears to be wide.

Experimental models and pathogenesis

LIS1 encodes a 45 kDa protein (PAFAH1B1), which is similar to the α-subunit of heterotrimeric G proteins and functions as a regulatory subunit of platelet-activating factor acetylhydrolase (PAF-AH). PAFAH1B1 homozygous mutant mice die at the blastula stage of embryonic development, whereas heterozygous mice are grossly normal but show a dose-dependent histopathological disorganization of cortical lamination as well as hippocampal and cerebellar cortical defects. The LIS1 protein has been shown to co-localize with microtubules and to promote their stabilization; thus, the LIS1 protein probably exerts its effects on migration through microtubules.

DCX encodes a 40 kDa microtubule-associated protein (DCX) that is expressed in migrating neuroblasts of the fetal brain. The DCX protein contains two tandem evolutionarily conserved repeats (doublecortin domain). Each of the repeats binds to tubulin but not to microtubules, so that both repeats are necessary for microtubule polymerization and stabilization. Mice in which DCX was disrupted did not have any cortical defects. However, in a recent study, DCX function was reduced by RNAi in a rat model, resulting in SBH resembling that seen in humans. Lis1 and Dcx display overlapping localization and may interact.

TUBA1A belongs to the α-tubulin protein family. α- and β-Tubulin heterodimers assemble to form microtubules that are essential for neuronal migration, neurite extension, and nucleokinesis. The pattern of expression of TUBA1A is limited to early-born postmitotic migrating neurons throughout development, and to specific neurogenic regions in the adult brain.

Epidemiology and clinical features

Classical LIS is rare, with a prevalence of about 12 per million births. Patients with severe LIS have early developmental delay, early diffuse hypotonia, later spastic quadriplegia, and eventual severe or profound mental retardation. Some children with LIS have lived more than 20 years, although anecdotal experience suggests that the lifespan is less than 10 years in most patients. Patients with less severe cortical malformations have moderate mental and motor impairment and may have a normal life-span expectancy. Seizures occur in over 90% of LIS children, with onset before 6 months in about 75% of cases. About 80% of children have infantile spasms, although EEG does not show typical hypsarrhythmia. Most LIS children subsequently have multiple seizure types. The EEG shows diffuse, high-amplitude, fast rhythms, which are considered to be highly specific for this malformation.

The main clinical manifestations of SBH are mental retardation and epilepsy. Epilepsy is present in almost all patients and is intractable in about 65% of cases. About 50% of these epilepsy patients have focal seizures, and the remaining 50% have generalized epilepsy, often within the spectrum of Lennox–Gastaut syndrome. Those with more severe MRI abnormalities have significantly earlier seizure onset and are more likely to develop Lennox–Gastaut syndrome. Depth electrode studies have demonstrated that epileptiform activity can originate directly from the heterotopic neurons, with nearly constant simultaneous involvement of the 'true' cortex. Callosotomy has been associated with worthwhile improvement in drop attacks in a few patients. Epilepsy surgery for focal seizures yields poor results.

Miller–Dieker syndrome (MDS) is caused by a contiguous deletion in the *LIS1* gene. Classical LIS is accompanied by distinct dysmorphic facial features, including prominent forehead, bitemporal hollowing, flattened ear helices, mild hypertelorism, epicanthic folds, short nose and anteverted nares, prominent lateral nasal folds, and round philtrum. Additional malformations can be observed. Affected children have severe delay, epilepsy, and feeding problems. Deletions of 17p13.3, including the *LIS1* gene, are found in almost 100% of patients. Deletion of two additional genes, *CRK* and *14-3-3ε*, telomeric to *LIS1*, may contribute to the most severe LIS grade and dysmorphic features observed in MDS.

X-linked LIS with absent corpus callosum and ambiguous genitalia (XLAG) is a severe malformation syndrome that is only observed in boys (**Figure 4**). The anatomoclinical spectrum includes LIS with posterior-to-anterior gradient and only moderate increase of the cortical thickness (only 6–7 mm), absent corpus callosum, poorly delineated and cavitated basal ganglia, postnatal microcephaly, neonatal-onset epilepsy, hypothalamic dysfunction, including deficient temperature regulation, chronic diarrhoea, and ambiguous genitalia with micropenis and cryptorchidism. Early death is not uncommon. Brain neuropathology reveals an abnormally laminated cortex exclusively containing pyramidal neurons, with a pattern suggesting disruption of both tangential and radial migration, dysplastic basal ganglia, hypoplastic olfactory bulbs and optic nerves, abnormal gliotic white matter containing

numerous heterotopic neurons, and complete agenesis of the corpus callosum without Probst bundles.

Mutations of the X-linked *aristaless*-related homeobox gene (*ARX*) (OMIM: *300382) were identified in individuals with XLAG, and in some female relatives. Females carrying *ARX* mutations usually have normal cognition and may either have normal brain MRI scan or show partial or complete agenesis of the corpus callosum. However, mild mental retardation and epilepsy have been reported in rare carriers. Mouse *Arx* and human *ARX* are expressed at high levels in both dorsal and ventral telencephalon. The murine *Arx* gene is specifically expressed in the GABAergic neural lineages, both during development and in adulthood. *Arx*-deficient mice show deficient tangential migration and abnormal differentiation of interneurons containing γ-aminobutyric acid (GABAergic interneurons) in the ganglionic eminence and neocortex. These findings suggest that the different *ARX* mutations may affect the overall GABAergic system functionality, leading to the clinical features of XLAG in humans; this deficit might account for the severe neonatal epileptic encephalopathy with suppression burst EEG that is often observed in affected boys. The mutations of the *ARX* gene in XLAG patients tend to be premature termination mutations.

Autosomal recessive LIS with cerebellar hypoplasia associated with severe abnormalities of the cerebellum, hippocampus, and brainstem was mapped to 7q22, and mutations were identified in the *RELN* gene (OMIM: *600514). Patients presented dysmorphic facial features and generalized seizures. *RELN* encodes a large (388 kDa) extracellular matrix protein that acts on migrating cortical neurons by binding to the very low-density lipoprotein receptor (VLDLR), the apolipoprotein E receptor 2, and α3-β1 integrin and cadherins-related receptors (CNRs). In mice, *Reln* mutations cause cerebellar hypoplasia, abnormal cerebral cortical neuronal migration and abnormal axonal connectivity. Neurons in affected mice fail to reach their correct location in the developing brain, disrupting the organization of the cerebellar and cerebral cortices and other laminated regions. In this animal model, the cortical layering appears inverted. Thus, Reln is thought to control cell–cell interactions critical for cell positioning in the brain.

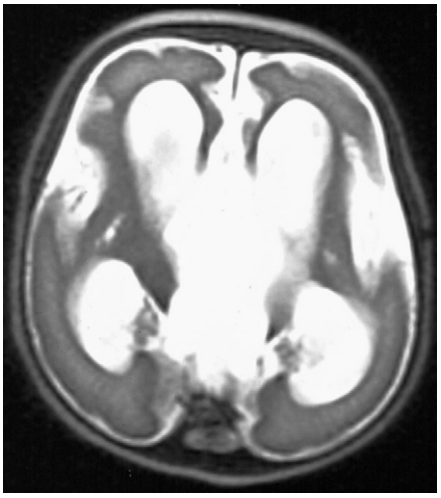

Figure 4 Brain MRI scan; axial section. 1 year-old boy with X-linked LIS, with corpus callosum agenesis and ambiguous genitalia due to mutation of the ARX gene. Note absence of the corpus callosum with ventriculomegaly and LIS.

Periventricular Nodular Heterotopia

Definition and histopathology

Periventricular nodular heterotopia (PNH), most often bilateral, consists of nodules of grey matter located along the lateral ventricles; these neurons have failed to migrate into the cortex (**Figure 5**). PNH can be highly variable in extent, ranging from isolated single nodules to confluent bilateral lesions. PNH is most common near the angle of the lateral ventricles and around the temporal horns. Nodules of PNH may sometimes show some rudimentary lamination, and neurons within the nodules show change in size consisting with developmental age. Although most patients with PNH come to medical attention because they have focal epilepsy of variable severity, there is a wide

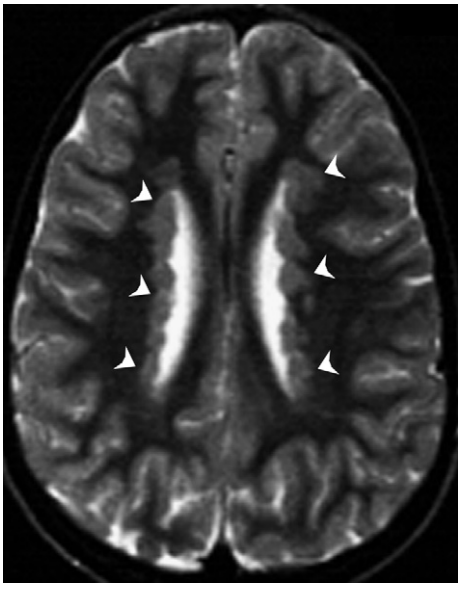

Figure 5 Brain MRI scan; axial section. Typical, classic bilateral periventricular nodular heterotopia in a woman with a missense mutation of the *FLNA* gene. Bilateral nodules of subependymal heterotopia are contiguous and rather symmetric, extensively lining the ventricular walls (white arrows). Patients with periventricular heterotopia different from that reproduced in this picture have very low chances of carrying a mutation on the *FLNA* gene.

spectrum of clinical presentations, with some correlation between the size of PNH and the likelihood of concomitant structural abnormality of the cortex and clinical severity. Approximately 90% of patients with periventricular nodular heterotopia have epilepsy, which can begin at any age. Functional MRI studies suggest that heterotopic nodules can assemble in functionally active aggregates and can participate in integrated networks. Indeed, depth electrode studies have demonstrated that either the heterotopic cortex or the overlying cerebral cortex, or both, can be epileptogenic. In one series, temporal lobectomy, which did not include the area of heterotopia, did not result in any significant improvement.

Genetics

PNH occurs much more frequently in women as an X-linked trait. It is associated with high rates of prenatal lethality in male fetuses, and in a 50% recurrence risk in the female offspring of affected women. Almost 100% of families with X-linked bilateral PNH, and 26% of sporadic patients, harbor mutations of the *filamin A* gene (*FLNA*) (OMIM: +300017). The low percentage of *FLNA* mutations in sporadic cases might be explained by somatic mosaicism, although this mechanism remains hypothetical. Heterozygous females have normal to borderline intelligence and epilepsy. Coagulopathy and cardiovascular abnormalities have been observed in some patients. Only a few living male patients with bilateral PNH owing to *FLNA* mutations are on record.

Other genes can cause PNH. A rare recessive form owing to mutations of the adenosine diphosphate-ribosylation factor guanine nucleotide exchange factor 2 (*ARFGEF2*) (OMIM: *605371) has been reported in two consanguineous pedigrees. *ARFGEF2* encodes for the protein brefeldin A-inhibited GEF2 (BIG2), which is involved in proliferation and migration during cortical development. Affected children have microcephaly, severe delay, and early-onset seizures, including infantile spasms. PNH may also be observed in patients with chromosomal rearrangements, such as duplication of 5p15.1 or 5p15.33.

Experimental models and pathogenesis

FLNA maps to Xq28 and codes for the F-actin-binding cytoplasmic cross-linking phosphoprotein Filamin A (FLNA). Filamin homologues are involved in regulation of cell stability, and filopodial protrusion and motility, across various biological systems. The mouse *Filamin A* ortholog is abundantly expressed in the cell soma and leading processes of migratory neurons, and is widely distributed across the cortical mantle, reaching the highest levels in the ventricular zone within the cortex during neurogenesis. FLNA likely influences neuroblast migration during cortical development in vertebrates, and PH in humans likely results from disruption of this process. FLNA also promotes orthogonal branching of actin filaments and is important for coagulation and vascular development. These coagulation and vascular-related functions of FLNA might account for the prenatal male lethality observed in most pedigrees. Cardiovascular or gut malformations may also account for prenatal male lethality. Complete loss of Flna in mice results in embryonic lethality with severe cardiac structural defects involving ventricles, atria, and outflow tracts, as well as widespread aberrant vascular patterning.

Polymicrogyria Phenotypes

The term 'polymicrogyria' refers to an excessive number of small and prominent convolutions separated by shallow and enlarged sulci, giving the cortical surface a lumpy aspect. Cortical infolding, as well as secondary, irregular, thickening due to packing of microgyri, is visible on MRI – although mild forms are difficult to recognize on neuroimaging. Two histological types are recognized. In 'unlayered polymicrogyria,' the molecular layer is continuous and does not follow the profile of the convolutions; the underlying neurons have radial distribution but no laminar organization. In 'four-layered polymicrogyria,' there is a layer of intracortical laminar necrosis with consequent impairment of late migration and post-migratory disruption of cortical organization. The two subtypes do not necessarily have a distinct origin as both may coexist in contiguous cortical areas.

Several syndromes featuring bilateral polymicrogyria have been described, including bilateral perisylvian polymicrogyria, bilateral parasagittal parietooccipital polymicrogyria, bilateral frontal and frontoparietal polymicrogyria, and unilateral perisylvian or multilobar polymicrogyria. These different forms might represent distinct entities that reflect the influence of regionally expressed developmental genes.

In *bilateral perisylvian polymicrogyria* (BPP; *OMIM 300388), the polymicrogyric malformation is limited to the cortical area surrounding the sylvian fissure (**Figure 6(a)**). Typically, this malformation will be associated with mild to moderate mental retardation, epilepsy (often of the symtomatic generalized type), and difficulties with speech. Most cases are sporadic; however, numerous families have been described, exhibiting heterogeneous inheritance patterns including X-linked, autosomal recessive, and autosomal dominant. Recently, a missense mutation in the Xq22 gene *SRPX2* was found in a 15-year-old Australian male with rolandic seizures and BPP. The same mutation was also found in his unaffected mother and aunt, as well as in two maternal aunts with mild mental retardation but normal brain MRI. A second mutation in the *SRPX2* gene was also identified in a 3-generation French family presenting with rolandic seizures, oral and speech dyspraxia,

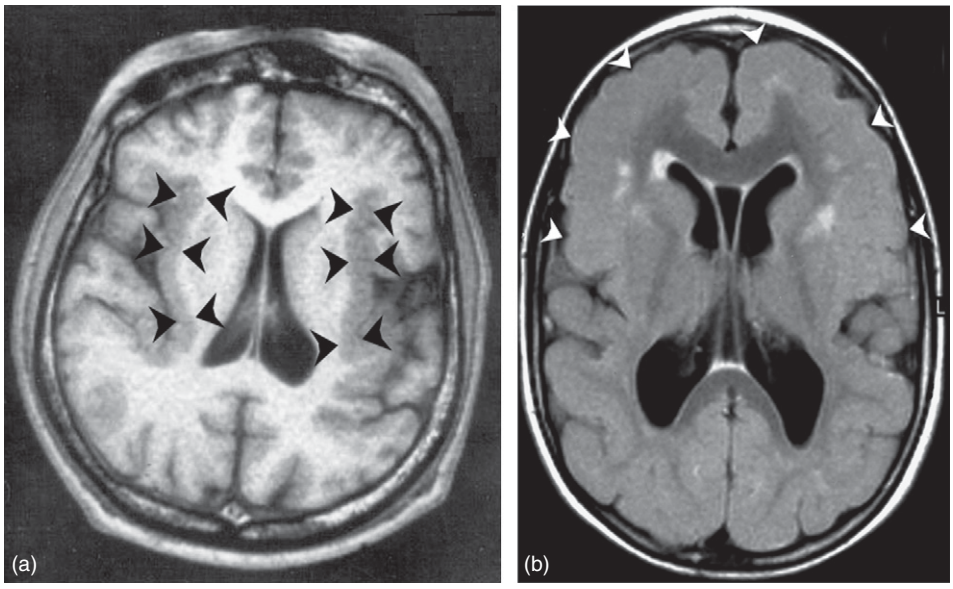

Figure 6 (a) Brain MRI; T1weighted axial section. *Bilateral perisylvian polymicrogyria*. Sylvian fissures are open and the perisylvian cortex is thickened and irregular (black arrows). Young man with Lennox–Gastaut syndrome. (b) Brain MRI; T1 weighted axial section, *bilateral frontoparietal polymicrogyria* (black arrows) in a girl with the *GPR56* gene mutation and Lennox–Gastaut Syndrome.

and a variable degree of mental retardation. In cultured cells, both mutations were associated with altered patterns of intracellular processing that suggested protein misfolding. SRPX2 is a secreted sushi-repeat containing protein, which carries a signal peptide and three consensus sushi-repeat motifs. Expression of SRPX2 has been detected in most human tissues, including both the fetal and adult brain, particularly in neuronal perikarya of the rolandic area. In the murine brain, Srpx2 protein expression appeared in neurons at birth, suggesting that SRPX2 may play an important role in the development and/or function of the perisylvian region critical for language and cognitive development.

Bilateral frontal polymicrogyria was described in children with developmental delay, mild spastic quadriparesis, and epilepsy. Indeed, *frontoparietal polymicrogyria*, a malformation extending a few centimeters back into the parietal lobes (**Figure 6(b)**), has been reported in several consanguineous and non-consanguineous families with recessive pedigrees, and was initially mapped to chromosome 16q12.2-21 and subsequently associated with mutations of the G protein-coupled receptor gene 6 (GPR56). GPR56 belongs to the G-protein-coupled receptor family – the largest gene family in the human genome, representing about 1% of all genes. The pattern of expression of mouse Gpr56, as well as the topography of the cortical abnormality in patients harboring homozygous mutations, strongly suggests that Gpr56 regulates cortical patterning. Epilepsy, seen in the majority of patients, is mainly associated with partial seizures and atypical absences, and can be of variable severity.

Unilateral multilobar polymicrogyria is often observed as a sporadic malformation. However, familial cases with unilateral polymicrogyria, or both unilateral and bilateral polymicrogyria, are on record. In some children with unilateral or bilateral polymicrogyria, epilepsy with electrical status epilepticus during sleep can develop, exhibiting the typical age-related course.

Other Gene-Related Malformation Syndromes

Several other genes, including fukutin (FCMD) and Sonic Hedgehog (SHH), have been associated with complex malformation syndromes that involve abnormal cortical development and epilepsy. The malformation spectrum of the most well-known syndromes, causative genes, and gene product function are reported in **Table 1**.

Methods

Since 1992, we have been collecting clinical, neurophysiological, and neuroimaging information on a cohort of 900 patients with epilepsy and malformations of the cerebral cortex. Since 1999, we have performed mutation analysis of the main genes causing cortical malformations in order to define the spectrum of genotype–phenotype correlations. In particular, we have studied *LIS1*, *DCX*, *FLNA*, *ARX*, and

GPR56 genes, using denaturing high-performance liquid chromatography (dHPLC) and direct sequencing.

X-inactivation studies were performed using the androgen receptor (AR) assay with a fluorescent-labeled primer to test.

The rate of mutant allele in patients with somatic mosaicism was quantified by carrying out single nucleotide primer extension (SnuPE) studies associated with dHPLC.

Multiplex ligation-dependent probe amplification (MLPA) was performed to search for whole-exon deletions or duplications of the DCX gene, using the 'Lissencephaly probe kit,' which includes seven paired probes specific for DCX.

Recent Results

Our laboratory has contributed to better define the clinical, anatomic, and molecular features of some genetically determined epileptogenic malformation of the cerebral cortex.

To offer new insights into the nosology of PH, we examined the clinical and brain MRI characteristics of a large cohort of individuals with PH, including bilateral PNH and other types of PH. These studies led to the definition of 15 distinct malformation patterns. Classical bilateral PNH represented the largest group. The 14 additional phenotypes included: PNH with Ehlers–Danlos syndrome (EDS), temporo-occipital PNH with hippocampal malformation and cerebellar hypoplasia, PNH with fronto-perisylvian or temporo-occipital polymicrogyria, posterior PNH with hydrocephalus, PNH with microcephaly, PNH with frontonasal dysplasia, PNH with limb abnormalities, PNH with fragile-X syndrome, PNH with ambiguous genitalia, micronodular PH, unilateral PNH, laminar ribbon-like and linear PH. We found *FLNA* mutations in 100% of familial cases with X-linked PNH and in 26% of sporadic patients with classical bilateral PNH. Furthermore, we did not observe significant differences between the type and location of mutations, and the severity of the associated phenotype. The overall information that could be drawn from that study is that PH is a heterogeneous disorder in which clinical and brain imaging presentation and genetic causes are variable.

We have observed that missense germline mutations and distal truncating mutations of the *FLNA* gene are compatible with survival of affected males; however, insertions, deletions, or truncating mutations are lethal in males. Partial or residual function of the protein presumably accounts for male viability. We have also demonstrated that somatic mosaicism in patients with truncating mutations may attenuate the severity of the phenotype. We have described a mosaic mutation in a man with a moderate PNH phenotype and an healthy daughter, demonstrating that, although maternal transmission is much more likely, father-to-daughter transmission is also possible (i.e., either parent can transmit the mutation to a female proband). Lack of transmission may mask the X-linked nature of the disorder.

We have characterized a family in which a deletion in the *FLNA* gene led to early death of boys. Postmortem neuropathologic study in an affected member of this family revealed bilateral PNH similar to that observed in female patients. The boy had multiple congenital abnormalities, including short and malrotated intestine and coagulopathy. Therefore, it seems likely that lethality in men is caused by the phenotypic effects of *FLNA* mutations on the cardiovascular system, homeostasis, or internal organs rather than on severity of the brain malformation.

We also investigated how specific genetic mechanisms may explain the mild phenotypes observed in some patients with *DCX* or *LIS1* mutations. We described four families segregating missense mutations of *DCX*. In each family, one or more carrier women had normal brain MRI, mild mental retardation, or borderline IQ, with or without epilepsy. These women were ascertained through their affected sons or brothers, all of whom had pachygyria–SBH. Molecular studies indicated that the mechanisms leading to seemingly normal neuronal migration in carrier women may result from either mild loss of gene function or skewed X-inactivation.

We also reported patients with SBH and epilepsy with somatic mosaicism for mutations of the *LIS1* gene. Coexistence of two genetically distinct neuronal populations, resulting from somatic mosaicism, may explain the unusually mild phenotype observed in these patients.

We applied the MLPA technique to evaluate the frequency of deletions or duplications encompassing one or few exons of the *DCX* gene in patients with SBH in whom gene sequencing had failed to reveal any mutation. The MLPA assay uncovered exon deletions in 3 out of 11 women (27%) with SBH, and raised the percentage of *DCX* mutations from 52% to 65% in our series. Our data indicate that deletions of *DCX* appear to be an underascertained cause of SBH, making MLPA a useful complement to DNA sequencing for mutation detection. These results offer additional tools for genetic counseling to be offered to the families of patients with SBH.

Future Directions

Genetic studies of cerebral cortex development and neuronal migration have been remarkably successful over the past few years, uncovering several genes that, when mutated, cause disorders of neuronal migration and

cerebral cortical development. However, the genetic etiology for patients with cortical malformations, but not harboring mutations in the known genes, remains unexplained. New genes or cryptic chromosomal abnormalities might be involved in these phenotypes. Array CGH can now be used as a molecular genetic tool to search for new genes associated with cortical malformations. Array CGH is a method based on the hybridization of the genomic DNA with clones or oligomers (targets) covering the entire genome; this method is able to reveal cryptic chromosome abnormalities. Screening of candidate genes that map to specific target regions, and are deleted or duplicated, can then be performed in order to identify their causative role in individuals with similar phenotypes but no visible rearrangements. Expression analysis and functional studies in experimental animal models can be then employed to further investigate the candidate gene association to biological pathways linked to the malformation conditions. In particular, advanced molecular biology techniques such as RNA interference and/or targeted deletion allow investigators to 'knock down' the expression of the targeted gene and investigate the functional consequences in experimental models, both in vitro and in vivo. Furthermore, expression studies in human tissue, both from malformed and normal brains, could provide insight into the pathophysiology of the malformation conditions.

Introduction

Of the 0.5–1% of the population suffering from epilepsy, half of the cases have no identified etiology. Moreover, in almost 25% of patients with epilepsy, the seizures are medically-refractory; that is, they do not respond to multiple anti-epileptic medications. In these patients, surgical resection of the epileptogenic brain tissue may alleviate the seizures provided that the preoperative evaluation identifies the brain region to be resected so as to achieve seizure control. Electrographic determination of epileptogenic brain regions, combined with various types of neuroimaging, often provide reasonable localization of epileptic cortex. In this article, we discuss the role of functional neuroimaging with positron emission tomography (PET) in the evaluation and management of epilepsy and epileptic syndromes.

PET is a medical imaging technique, which has an unparalleled capability to generate images of body function and metabolism. Quite often, internal biochemical or physiological changes predate or exceed changes in the structural appearance of tissue or organ; in such cases, PET can detect alterations earlier than changes in anatomy. In PET, positron-emitting radionuclides, such as ^{18}F, ^{11}C, ^{15}O, and ^{13}N, are used to label various natural biological substrates and drugs or pharmaceuticals. These substrates all contain hydrogen, carbon, oxygen, or nitrogen, which can be replaced with their radioactive positron-emitting counterpart. The resulting radioactive substance, also known as a radiotracer or PET tracer, will show similar behavior and will follow the same physiological pathways as the biological substrate do. At the same time, they will be emitting paired high-energy (511 Kev) photons traveling in opposite direction as a result of positron decay of the radioactive atom; these photons can be detected by external detectors and the whole process can be traced or 'imaged.' Further, as the process is captured temporally in a dynamic fashion, kinetics can also be calculated. Therefore, virtually any physiological or metabolic process, such as glucose metabolism, protein synthesis, enzymatic processes, or receptor–ligand interactions, can be studied using an appropriate radiotracer. This capability is particularly useful in studying epileptic brain, in which basic anatomical features or physiological processes undoubtedly contribute to, or reflect, the epileptogenic nature of the tissue.

Background

The most commonly used PET tracer in epilepsy is 2–^{18}F-fluoro-2-deoxy-D-glucose (FDG), which is an analogue of glucose. Since glucose is widely used as a substrate for obtaining energy, metabolism of various organs can be assessed by imaging FDG uptake of that organ. Other PET tracers with the potential for detecting epileptic brain regions include ^{11}C-alphamethyl-L-tryptophan (AMT), which measures tryptophan metabolism; ^{11}C-flumazenil (FMZ), which binds to α subunits of the $GABA_A$-benzodiazepine receptor; and other radioligands, which bind to opioid receptors, histamine receptors, *N*-methyl-D-aspartate (NMDA) receptors, peripheral benzodiazepine receptors, serotonin receptors, or

Table 1 PET tracers, their targets and uptake pattern in epileptogenic lesions

PET tracer	*Target*	*Uptake pattern in epileptogenic region*
2–^{18}F-fluoro-2-deoxy-D-glucose (FDG)	Glucose Metabolism	Interictal decrease Ictal increase
^{15}O-H_2O (Water)	Blood flow	Interictal decrease Ictal increase
^{11}C-Alpha Methyl-L-Tryptophan (AMT)	Tryptophan metabolism to serotonin or quinolinic acid	Interictal increase
^{11}C-Leucine	Protein synthesis	Variable
^{11}C-Flumazenil (FMZ)	$GABA_A$/Benzodiazepine receptor (antagonist)	Interictal decrease

acetylcholine receptors (Table 1). Normal age-related uptake patterns of the three most important PET tracers used in epilepsy are given below, since knowledge of the normal pattern is necessary to appreciate any change from the norm.

Normal FDG uptake pattern

The metabolic rate of glucose utilization in the newborn brain is markedly different from that in adults. During birth, the child's local cerebral metabolic rate of glucose (LCMRglc) in cortex is usually 30% less than that in adult. LCMRglc then increases and reaches adult values by the second year of life. However, LCMRglc exceeds adult values by the third year, reaches the peak value by 3–4 years of age and then plateaus. This plateau persists until about 10 years of age, and then gradually declines to adult values by the age of about 16–18 years. The spatial glucose metabolism pattern across the brain, and thus the visual appearance in PET scans, also changes with age. In the newborn, glucose metabolic activity is most prominent in primary sensory- and motor cortex, thalamus, brain stem, and cerebellar vermis. More recent studies with high-resolution PET scanners have suggested that the cingulate cortex, amygdala, hippocampus, and striatum may also show relatively prominent activity in the newborn period (Figure 1).

Between age of 2 and 4 months, glucose utilization increases in parietal, temporal, and primary visual cortex (medial occipital or calcarine cortex), as well as in the basal ganglia and cerebellar hemispheres. Between 6 and 8 months of age, glucose utilization increases in lateral and inferior prefrontal regions, with medial and dorsal frontal cortex becoming active between 8 and 12 months of age. The adult pattern of glucose utilization is seen by 1 year of age (Figure 1), although the absolute metabolic rates for glucose utilization undergo a more protracted nonlinear course, as described already.

Normal FMZ binding pattern

FMZ binding, or FMZ VD (volume of distribution), is high at 2 years of age and then decreases exponentially with age until adult values are reached at around age 20. Since no data are available for children less than 2 years of age, it is difficult to say when FMZ binding is highest. It is possible that binding is highest at the time of, or even before birth, and then decreases to reach adult values. In adults, FMZ VD is 10% higher in females than in males. The order of brain region (from highest to lowest FMZ binding) at 2 years of age is as follows: primary visual cortex, superior frontal cortex, medial temporal cortex, temporal lobe, pre-frontal cortex, cerebellum, basal ganglia, and thalamus. Medial temporal lobe structures,

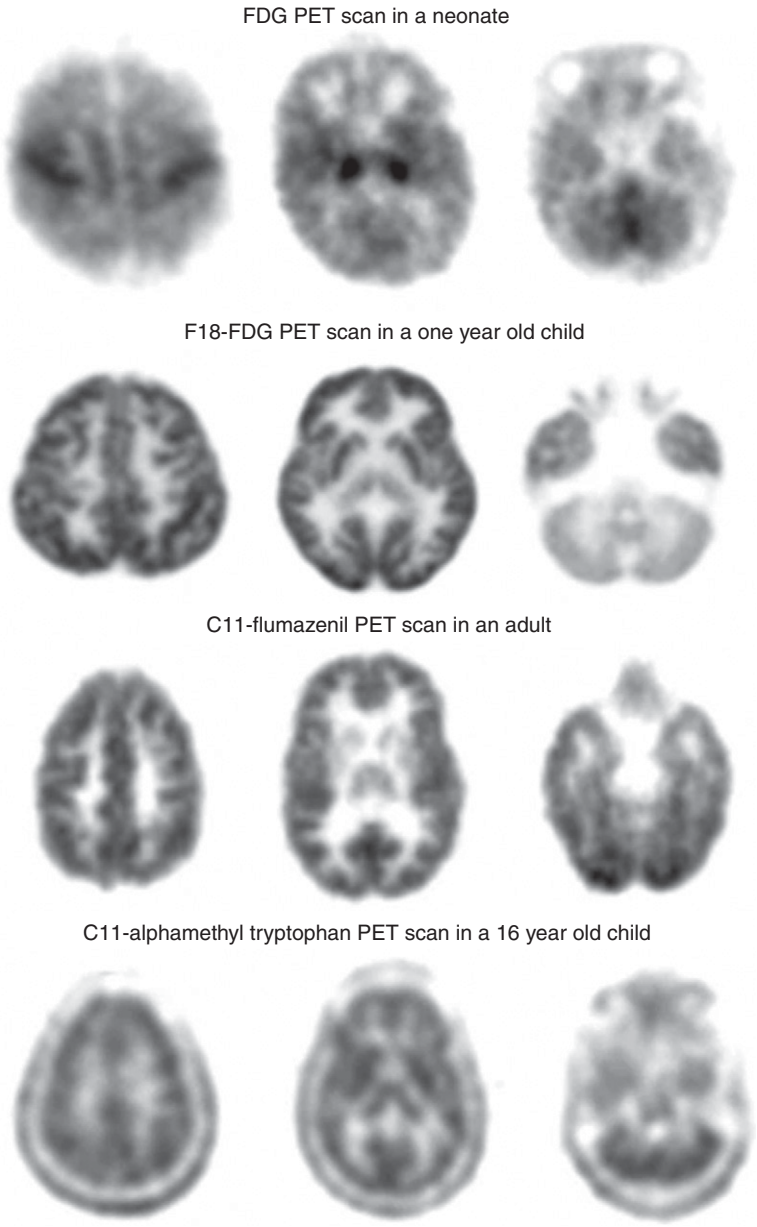

Figure 1 Normal FDG PET scan in a 7 day old newborn (first row) and a1 year old child (second row), normal FMZ PET scan in an adult (third row), and a normal AMT PET scan in a 16 years old child (lowermost row).

primary visual cortex, and thalamus show the largest temporal decrease in FMZ VD (approximately 50% decreases) compared with basal ganglia, cerebellum, and other cortical regions (25–40% decreases). Subcortical brain regions reach adult values earlier (14–17.5 years) than the cortical regions do (18–22 years) (Figure 1). The medial temporal region shows the fastest decline and has the lowest adult FMZ VD value among cortical areas. Nevertheless, FMZ binding is robust enough for its good visualization (compared with FDG PET, where the medial temporal region, particularly hippocampus, is often not well visualized). Thus, FMZ PET can play an important role in evaluating epileptic patients in whom medial temporal lobe abnormalities are suspected.

Normal AMT uptake pattern

AMT is an analog of tryptophan, the precursor for serotonin synthesis. However, unlike tryptophan, AMT is not incorporated into protein in significant amounts. AMT is converted to alpha-methyl-serotonin (AM-5HT) by tryptophan hydroxylase, but because AM-5HT (unlike serotonin) is also not a substrate for the degradative enzyme monamine oxidase (MAO), it accumulates in neurons and

nerve terminals along with the releasable pool of serotonin. After intravenous injection, AMT accumulates in the brain for the first 20 min (less than 2% of the injected dose is present in the brain at peak values), after which a plateau is reached and maintained for up to 60 min, with no right-left asymmetry in normal brain. Since AMT PET does not allow the measurement of absolute rates of serotonin synthesis, the term 'serotonin synthesis capacity' (an index of serotonin synthesis) has been applied. This measurement increases after birth, reaches twice the adult value by 3 years of age, remains at a plateau until 5 years of age, and then declines, reaching adult values by 14 years of age. In adults, the highest serotonin synthesis capacity values are seen in putamen, followed by caudate nucleus, transverse temporal gyrus, thalamus, anterior cingulate cortex, cerebellar hemispheres, cerebellar vermis, posterior cingulate cortex, hippocampus, rectal gyrus, middle temporal gyrus, brain stem, inferior and superior temporal gyrus, frontal cortex, primary visual cortex, parietal cortex, and lateral occipital cortex (**Figure 1**). Values in women are 10–20% higher throughout the brain, and particularly higher in the transverse temporal gyrus, anterior cingulate cortex, and cerebellar vermis.

Methods

Standard Protocol for Doing FDG PET Scan

The patient should be fasted for 4 h before the FDG PET scan, and blood glucose level should be below 100 mg dl^{-1}. In a diabetic patient with a high blood glucose level and having an urgent need for a FDG PET scan, insulin can be used – under the supervision of a trained physician or pediatrician – to bring down the blood glucose to an acceptable level. EEG electrodes are placed on the head (if EEG monitoring is required, such as in epilepsy where seizure during the FDG uptake period – usually the first 30 min after the injection – may change its uptake value) and FDG is injected IV in a quiet, dimly lit room. The patient and any family members in attendance are asked to remain quiet. Thirty minutes after the injection, electrodes are removed and the patient is brought to the scanner room and placed supine, with the head positioned (in a head holder) in the field of view of the scanner. If required, the patient is kept under sedation. Subsequently, a 30 min emission scan of the brain is acquired. A calculated attenuation correction is performed. In PET-CT, a CT scan of the head is acquired for attenuation correction, followed by a 20 min emission scan.

Standard Protocol for Doing FMZ PET Scan

No fasting is required for an FMZ scan unless the patient is to be sedated. EEG electrodes are placed on the head and the patient is brought into the scanner room. If needed, the patient is sedated. A transmission scan of the head is acquired to be used for the attenuation correction. Subsequently, radiotracer is injected and a 60 min emission scan is acquired.

Standard Protocol for Doing AMT PET Scan

Children are advised to fast for 6 h, and adults for 8 h prior to the AMT PET scan. EEG electrodes are placed on the head and the patient is brought into the scanner room. Two IV lines are started; one IV line is used to take blood samples to be used in tracer kinetic analysis and the other for the injection of the radiotracer. If needed, the patient is sedated. A transmission scan of the heart (15 min) is then acquired, to be used for the attenuation correction. Subsequently, with patient's heart in the field of view of the scanner, the AMT radiotracer is injected and an emission scan of heart is acquired for 20 min. The transmission and emission scan of the heart is necessary to calculate the initial input function for tracer kinetics. After the completion of the transmission and emission scans of the heart, the patient's head is positioned under the scanner and emission scan for the head is started (typically 25 min after the injection of the radiotracer and continuing for another 40 min). In the end, a 15 min transmission scan of the head is acquired for the attenuation correction of the head. Fiducial markers are also placed on the patient's forehead and behind each ear for motion correction. Blood sampling is performed at 20, 30, 40, 50, and 60 min post-injection of AMT. If tracer kinetic analysis is not planned, and one is interested in only seeing the uptake pattern, IV blood sampling and heart transmission and emission scans are not required. After the radiotracer is injected, an emission scan of the head for 40 min is acquired followed by a transmission scan for 15 min.

The patient/parent/guardian must fill out the medication and information list and sign the informed consent form for all research procedures.

Results – Applications of PET

The various applications of PET in the evaluation and management of epilepsy are summarized in **Table 2**.

Evaluation of Seizure Etiology

An underlying cause for epilepsy is apparent in only 50% of cases, where it is linked to infection, head trauma, stroke, brain tumors, brain malformations, and other causes. In most of these conditions, PET does not contribute further to the etiology. However, in mild cortical dysplasia not evident on structural imaging (including MRI), FDG PET shows hypometabolism in the area of cortical dysplasia and can be a useful guide in the

Table 2 Role of PET scan in epilepsy

1. To evaluate the underlying cause, such as subtle brain malformations
2. To search for cellular (including synaptic) and molecular (including receptors and transmitters) changes associated with epilepsy
3. To assess seizure effects on the brain
4. To help in treatment selection (by demonstrating altered cellular or molecular processes for specific targeted medical therapy or focal lesions in cases of cryptogenic epilepsy for possible surgery)
5. Evaluation of treatment response
6. To predict seizure intractability
7. In epilepsy surgery
   a. To delineate (lateralize and/or localize) epileptogenic regions along with secondary epileptic foci, particularly in cases of normal structural imaging or discordance between structural and electrophysiological data or multiple lesions shown by one or other investigative modalities.
   b. To search for dual pathology
   c. To evaluate for the presence of potential secondary epileptic foci
   d. To evaluate the functional integrity of the rest of the brain
   e. To evaluate eloquent cortex
   f. Postsurgical evaluation
8. To evaluate neonatal seizures

Figure 2 FDG PET scan showing an area of hypometabolism in the Lt parietal lobe (arrow) in a 10 year old child with intractable seizures and normal MRI. Post-surgical histopathology revealed mild cortical dysplasia.

placement of intracranial EEG electrodes, if scalp EEG also shows ictal epileptic discharges arising from that general area (Figure 2). If intracranial EEG confirms and defines the extent of the epileptogenic cortex, this area can then be removed, even if MRI appears normal. Many times these resected cortical regions show evidence of microdysgenesis (heterotopic neurons in white matter can contribute to epileptogenesis by providing an aberrant circuitry). Similarly, FMZ PET can help in identifying microdysgenesis, which can show either decreased or increased FMZ binding, depending upon the number and subunit composition of $GABA_A$-benzodiazepine receptors in that tissue.

Evaluation of Seizure Pathology

An injury to neurons may cause a wide variety of changes, from subtle membrane change to neuronal loss, followed by gliosis. Injury may lead to structural and functional changes in various receptors and ion channels. There may also be a loss of inhibitory interneurons, synaptic changes with increased or decreased density, or abnormal axonal arborization with associated changes in synaptic strength. All these changes may alter neuronal firing thresholds, and lead to loss of hyperpolarization and progressive depolarization, which may be further augmented by extracellular ionic changes, ultimately leading to the formation of an epileptic focus. By applying appropriate ligand radiotracers, PET can be used to assess the receptors and ion channels. To study the change in number or distribution of various receptors, some of the PET tracers listed in table-1 can be used. However, if there is a structural and configurational change in the receptor, as in the case of suspected channelopathies, new PET ligands must be developed. Neuronal and glial proliferation can be imaged by applying specific cell markers tagged with positron-emitting isotopes. As synaptic reorganization is usually associated with new protein synthesis, so ^{11}C-leucine PET scaning can be used – at least theoretically – to measure the altered protein synthesis rate.

Neuroinflammation may be the underlying cause for intractable epilepsy in some cases, such as in Rassmussen's disease. Neuroinflammation is mediated by activated microglia, which secrete a number of proinflammatory molecules such as cytokines (IL-1, IL-6, TNF-α), chemokines (MIP-1α,β, MCP-1) and neurotoxins, free radicals, nitric oxide, proteinases, eicosanoids, and excitotoxins – many of which may play an important role in epileptogenesis. Although the exact mechanisms are still unclear, it appears that the inflammatory mediators may act by increasing glutamatergic neurotransmission, decreasing GABA-mediated currents, inducing neovascularization, and damaging the blood-brain barrier. Detection of microglia is not possible with current radiological methods or biochemical techniques, but requires histopathological examination of CNS tissues, which is quite invasive or possible only post-mortem. Since activated microglia express peripheral-type benzodiazepine receptors, they can be imaged with PET using ^{11}C-PK11195, a radioligand which binds specifically to the peripheral-type benzodiazepine receptors, thus making the in vivo detection of neuroinflammation possible (Figure 3).

Figure 3 PK11195 PET scan showing increased radiotracer binding in the right fronto-parietal area, indicating microglial mediated neuroinflammation.

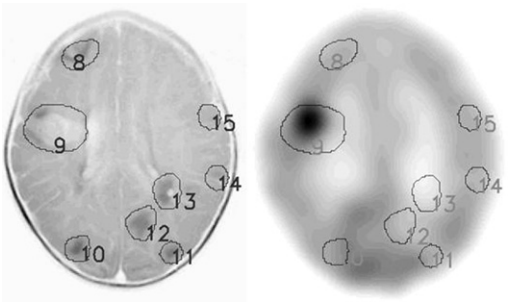

Figure 4 MRI scan showing multiple tubers (left image) in a child with tuberous sclerosis and intractable seizures with the majority of seizures coming from right parietal lobe. AMT PET scan showed intense uptake in a right parietal tuber (right image), corresponding to the EEG focus.

Figure 5 FDG PET showing significantly reduced glucose metabolism in the thalamus and lenticular nuclei with some sparing of the caudate nucleus in a neonate with hypoxic ischemic injury. Compare pattern of glucose metabolism with the normal pattern shown in **Figure 1**.

Patients with tuberous sclerosis may have multiple brain tubers. However, only one or two of them may be epileptogenic. It has been found that these tubers and/or the tissue around them contain a high amount of quinolinic acid, a product of tryptophan metabolism by indolamine 2,3-dioxygenase through increased activity of kynurenine pathway (induced under certain pathological conditions). Quinolinic acid is a strong convulsant through its agonist action at excitatory NMDA receptors, thus probably confering epileptogenicity to these tubers. AMT PET shows increased AMT uptake in these tubers and can help identify epileptogenic tubers (**Figure 4**).

PET can also be useful in investigating the structural basis for seizures associated with specific neurological conditions. For example, in neonates with some types of hypoxic ischemic brain injury in the perinatal period, FDG PET shows either absent or significantly reduced glucose metabolism in the thalamus and lenticular nuclei, with some sparing of the caudate nucleus (**Figure 5**). The cerebral cortex is also relatively spared compared to the subcortical structures, but may show focal areas of hypometabolism corresponding to the seizure foci. These findings are typical of children with the choreoathetoid or dystonic form of cerebral palsy and are consistent with the clinical observation that most of these children have relative preservation of cognitive function compared with their severe motor impairment (with chorea, athetosis, or dystonia). MRI may not be able to show all these details. Therefore, FDG PET can be used to provide a better understanding of anatomical-functional correlations in these children.

In patients with infantile spasms, FDG PET may reveal a single or multiple areas of cortical abnormality and can provide evidence of complex cortico-subcortical interactions believed to be important in the secondary generalization of focal cortical discharges, resulting in spasms. PET studies have shown that, regardless of the type or extent of cortical abnormality, increased glucose metabolism in lenticular nuclei and brain stem is a common feature in infants with spasms (**Figure 6**), consistent with the hypothesis that the spasms result primarily from the interaction of cortical abnormalities with brain

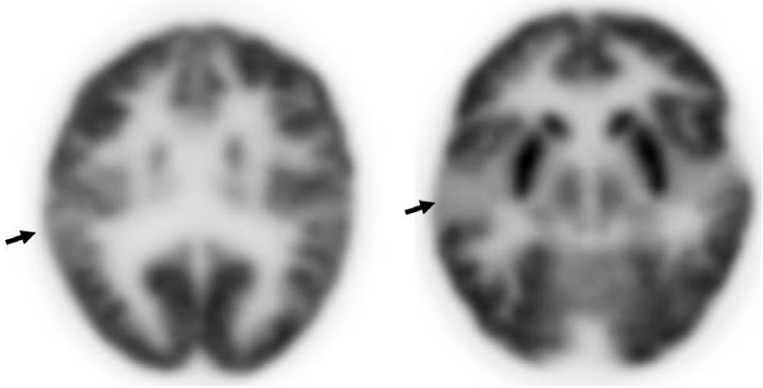

Figure 6 FDG PET scan showing an area of hypometabolism in right superior temporal region (arrows) and increased metabolism in bilateral basal ganglia in a child with infantile spasms.

stem and lenticular nuclei – and that this pathway of generalization accounts for the bilateral motor involvement and relative symmetry of the majority of spasms (even in the presence of a discrete focal lesion).

Assessment of Seizure Effects on Brain

FDG PET can be used to assess the effect of seizures on function in the rest of the brain. The spread of hypometabolism to neighboring areas from the presumed epileptogenic area is usually associated with some degree of functional suppression, and its extent has been shown to increase with time and depends upon overall seizure control. Hypometabolism of the ipsilateral thalamus and basal ganglia can be seen in cases of focal epilepsy (mostly from frontal and temporal cortex) (**Figure 7**). Contralateral cerebellar hypometabolism (diaschisis) is usually seen in cases of frontal or parietal lobe seizures. Occasionally, hypometabolism is seen in a contralateral 'mirror' region and represents the functional suppression of these regions through callosal fibers (transcallosal diaschisis) or through the fornix in the case of contralateral hippocampus. After long-standing seizures or in cases of severe status epilepticus, FDG PET scan shows diffuse hypometabolism of the entire cerebral cortex, particularly of the primary sensory areas, and is probably related to a temporary functional suppression (**Figure 8**). Therefore, whenever possible, it is important not to perform an FDG PET scan immediately after a seizure, but to wait at least 24 h. This delay is often not possible in young children with intractable epilepsy who have many seizures per day.

Treatment Selection

By achieving a better understanding of the altered cellular or molecular processes in human epilepsy *in vivo* using PET, new specific targeted therapies can be developed. Furthermore, response to treatment can be monitored

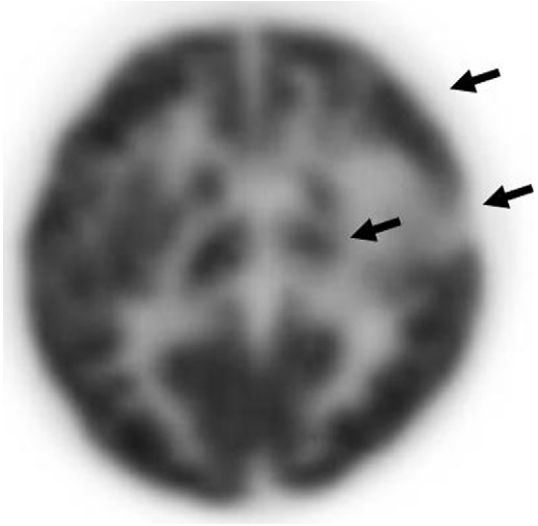

Figure 7 FDG PET scan in a child with a left fronto-temporal epileptic focus showing hypometabolism in the seizure onset zone (arrow). Note also the left thalamic hypometabolism (arrow).

using PET. Similarly, application of FDG PET has improved our understanding of the possible pathological mechanisms of epilepsy in various pediatric epilepsy syndromes, and has had an impact on their clinical management. For example, on PET scanning, most infants diagnosed with 'cryptogenic' *infantile spasms* will have focal or multifocal cortical hypometabolism. In cases of intractable spasms and a single focal PET abnormality that corresponds to the EEG focus, resective surgery can be planned with good results. Even in some cases showing multifocal areas of hypometabolism, but with all seizures arising from one area, resective surgery can sometimes be performed as a palliative procedure with improved quality of life; however, the developmental outcome may be less favorable than if a single focus were present. When the pattern of glucose hypometabolism is generalized and symmetric, a lesional etiology is not likely and

Figure 8 FDG PET scan showing diffuse hypometabolism of the entire cerebral cortex compared to basal ganglia in a child with status epilepticus.

neurometabolic or neurogenetic disorders should be considered in further evaluation and management.

Children with *Lennox-Gastaut syndrome* (triad of multiple seizure types including tonic seizures, developmental delay, and 1–2.5 Hz generalized 'slow' spike and wave EEG pattern), may have four metabolic patterns on FDG PET scan: unilateral focal, unilateral diffuse, or bilateral diffuse hypometabolism, as well as normal. Patients with unilateral focal and unilateral diffuse patterns may be occasionally considered for cortical resection, provided there is concordance between PET and ictal EEG findings.

In cases of *Sturge-Weber syndrome* (SWS), FDG PET usually identifies additional areas of abnormal cortex extending beyond the lesion visible on MRI. Serial FDG PET can be used to assess the dynamic nature of the disease process and can help in treatment selection. In some patients, serial FDG PET scans may show rapidly progressing and severe hypometabolism in the affected area, probably because of rapid demise of the brain tissue associated with the angioma: these patients will have improvement in seizure status and cognitive function and therefore may not require surgical intervention. Early and rapid progression in unilateral cases of SWS forces early and more efficient reorganization in the brain due to plasticity mechanisms. In contrast, persistent mild hypometabolism of the cortex underneath the lesion may indicate ongoing functional disturbance, and these patients may show persistent seizures and developmental arrest. These are the patients who require surgical intervention for seizure control and possible cognitive improvement, by promoting effective reorganization in the contralateral hemisphere while brain plasticity is still at a maximum during development.

PET scanning using FDG as well as ^{11}C-PK-11195 can help in the early diagnosis and management of Rasmussen's syndrome or other inflammatory conditions with intractable seizures, where CT and MRI are often normal for several months after the clinical manifestation of the disease. Treatment measures may include anti-inflammatory drugs, steroids, immunoglobulins, plasmapharesis, or surgical removal of the affected region. Localization of the most affected brain regions may also provide a guide in deciding the site of brain biopsy in order to avoid sampling errors.

Treatment Response Evaluation

Although treatment response is best evaluated clinically, cellular and biochemical substrates can be monitored and followed, either non-specifically with FDG PET (e.g., improvement versus worsening of hypometabolism, or appearance of any new area of hypometabolism) or more specifically using relevant PET tracers (such as receptor-ligands, radio-labeled neurotransmitters, and ligands for ion channels). In cases of suspected neuroinflammation as an underlying cause of seizure, ^{11}C-PK11195 is currently being tested to monitor its evolution (by imaging activated microglia). Similarly, dynamics of neurons, astrocytes and other glial cells can potentially be imaged using specific radio-markers as they become available.

Almost one third of epileptic patients will develop refractory epilepsy. P-glycoprotein (P-gp) and members of the multidrug resistance-associated proteins have been found to be increased in the seizure focus of patients with intractable epilepsy. These proteins actively extrude various lipophilic drugs, including anticonvulsants, out of the cell, and they may be responsible for a diminished or failed response to treatment. There is no way to detect in vivo the presence of increased expression of these drug transporters, except by PET. By using appropriate and specific radioligands, such as ^{11}C-verapamil for P-gp, one can measure the expression of these proteins in vivo and predict treatment response or help in selecting some treatment for P-gp modulation.

Prediction of Seizure Intractability

As in the case of PET scanning for P-gp, if any receptor or ion-channel change can be shown to be associated with seizure refractoriness, specific PET tracers could be developed and used to image their expression in vivo. Likewise, if some genetic changes are the cause of intractable seizures, PET potentially can be used to assess gene expression either

at the mRNA or at the protein expression level, using specific molecular imaging probes to study the dynamic processes in vivo in real-time and in a quantitative and noninvasive manner. For example, reporter gene imaging can be used to measure gene expression levels in tissues outside of the central nervous system. When cloned into promoter/enhancer sequences or engineered into fusion proteins, imaging reporters can be used to study the expression levels of any gene product. However, at present, engineering these molecules so that they cross the blood-brain barrier remains problematic.

Role in Epilepsy Surgery

In cases of intractable seizures, surgery may be considered. The most important aspect of presurgical evaluation is to identify a discrete epileptogenic region, which can be resected without causing an unacceptable loss of neurological function, and the removal of which will lead to complete seizure control. PET has little localization role in cases in which MRI-visible structural lesions are concordant with electrophysiological and clinical data. However, in cases of discordant results, or normal MRI, or multiple lesions with inconclusive EEG, PET can play a very important role. In cases of multifocal lesions associated with partial seizures showing a consistent semiology, the goal of PET (using selected radiotracers) is to identify the epileptogenic lesions. Sometimes, the epileptogenic lesion may be medially-located and be associated with generalized epileptiform activity due to secondary bilateral synchrony. In such cases, PET may allow a surgical option when otherwise the patient may not be considered for surgery. Further, FDG PET can provide some useful prognostic information; for example, when contralateral thalamic hypometabolism or bilateral temporal metabolism is present, the surgical outcome is usually poor.

Epileptogenic Region

2–^{18}F-fluoro-2-deoxy-D-glucose PET scan (FDG PET)

Interictal FDG PET typically shows reduced radiotracer uptake (hypometabolism) in the epileptogenic region. Although the exact mechanism of hypometabolism is unknown, it may result from a variety of mechanisms, including neuronal loss, diaschisis, suppressed function or reduction in synaptic density. It appears that cortical hypometabolism may be associated with duration, frequency and severity of the seizures, as hypometabolism is usually found in only one fourth of children with new onset temporal lobe epilepsy compared to 80–85% of adults with intractable seizures. Persistent or increased seizure frequency may lead to enlargement of the hypometabolic area, whereas seizure control may be associated with decrease in the size of hypometabolic cortex or even its resolution. The time interval between PET acquisition and the most recent seizure also may affect the extent and severity of the cortical abnormality; FDG PET done a short interval after a seizure may show more extensive and severe hypometabolism.

The sensitivity of FDG PET to identify the epileptogenic temporal lobe is estimated to be around 85–90%, and can show temporal lobe hypometabolism in more than 50% of patients with non-lateralized scalp ictal EEG findings. FDG PET can provide additional information about the epileptogenic zone in 77% of cases, and can impact surgical decision making in almost 50% cases. Although it rarely provides additional clinical information when hippocampal atrophy is obvious on MRI, FDG PET can lateralize the epileptic focus in temporal lobe epilepsy patients with subtle or absent quantitative MRI abnormalities. It has been found that interictal hypometabolic regions are not strictly confined to the presumed temporal epileptogenic zone or to the brain tissue showing pathologic changes. They commonly extend beyond temporal structures to ipsilateral parietal and frontal cortex as well as thalamus and also occasionally to the contralateral temporal lobe. Since this extension may reflect the epileptogenic network involved in the seizure propagation, these extratemporal regions should be investigated with intracranial EEG if scalp EEG over these areas are not completely normal.

In case of extratemporal lobe epilepsy, the sensitivity of FDG-PET in localizing the epileptogenic zones has been reported in the range of 45–73%. However, using a high-resolution PET scanner, we found a sensitivity of 92% and a specificity of 62.5% for FDG PET in the detection of the epileptic foci in children with frontal lobe epilepsy. In cases of occipital lobe epilepsy, a lower localization value (60%) for FDG PET has been reported.

As FDG PET usually shows an area of hypometabolism extending beyond the epileptogenic region, it can not be reliably used to precisely determine the surgical margin. However, it can be used for lateralization and general localization of the seizure focus. Further, this information can help in making a priori plans for subsequent subdural electrode placement, which may be very useful, particularly in cases of normal MRI. However, use of more specific tracers can help in providing a more precise delineation of the epileptogenic tissue; this enhanced localization becomes particularly important when the epileptic focus potentially involves eloquent brain regions (primary motor, speech or visual areas).

^{11}C-Flumazenil PET Scan (FMZ PET)

Among various neuro-receptor PET tracers used in epilepsy, FMZ has been the most widely applied clinically and appears to be quite promising. FMZ PET shows

decreased FMZ binding in the presumed seizure focus of both temporal and extratemporal lobe epilepsy; the extent of decreased binding is usually less than the area of hypometabolism shown by FDG PET. Rarely, FMZ PET may show increased uptake in some cases of cortical malformation and dysplasia, depending upon the number and/or affinity of the $GABA_A$/benzodiazepine receptors expressed in the abnormal tissue. Using ^{3}H-FMZ autoradiography on surgically resected human epileptic brain cortex, we found increased receptor density in cortical layers V–VI of spiking cortex; however, there was also decreased receptor affinity, and this change outweighed the increased density such that the net effect was a decrease in volume of distribution. At the PET level, this net decrease appeared as an area of decreased FMZ uptake on images obtained prior to surgery. FMZ PET is highly sensitive in temporal lobe epilepsy and shows decreased FMZ binding in the sclerotic hippocampus in patients with medial temporal lobe epilepsy that is largely confined to the affected temporal lobe. After correcting for partial volume effects, the sensitivity of FMZ in detection of unilateral hippocampal sclerosis has been reported to be 100%, with contralateral abnormalities in one-third of patients. In neocortical epilepsy, FMZ PET has been reported to have 60–100% sensitivity when compared to intracranial ictal EEG. In MRI negative patients, FMZ PET has been found to be abnormal in 84% and 70% of patients with temporal lobe and extratemporal lobe epilepsy, respectively. FMZ PET appears to be more sensitive than FDG PET in identifying an epileptogenic region and is associated with excellent surgical outcome both in temporal and extratemporal lobe epilepsy, even when the MRI is normal.

^{11}C-Alpha-Methyl Tryptophan PET Scan (AMT PET)

Another PET tracer, AMT, appears to have strong clinical applications in selected cases of epilepsy. In fact, AMT PET was the first and is still the only PET tracer capable of differentiating between epileptogenic and nonepileptogenic lesions in the interictal state in children with tuberous sclerosis. Subsequently, it was found to be useful also in patients with other types of neocortical epilepsy, showing increased uptake of AMT in the epileptogenic cortex. While the specificity of AMT PET is very high, its sensitivity is suboptimal, and appears to be related to the underlying pathology as well as the method of image analysis. For example, in patients with tuberous sclerosis and intractable epilepsy, we found that MRI-based quantitative assessment increased the sensitivity of AMT PET to 79% from 44.4% with visual assessment. This increased sensitivity is due to the fact that nonepileptogenic tubers typically show decreased AMT uptake, and that some epileptogenic tubers showing relatively increased AMT uptake cannot be easily differentiated from adjacent normal cortex without quantitative analysis.

Although clinical experience with AMT PET is limited in patients with medial temporal lobe epilepsy, this method does not appear to be particularly useful in cases of hippocampal sclerosis. However, we found that histologically-verified (macroscopic or microscopic) cortical dysplasia is associated with a higher occurrence of increased AMT uptake as compared to cases with nonspecific gliosis. Also, the area of increased AMT uptake is significantly more restricted than the extent of corresponding glucose hypometabolism. In some instances, AMT PET can identify epileptogenic cortex even if FDG and/or FMZ PET scan is normal.

Other PET Tracers

Clinical experience with opiate, histamine, NMDA, acetylcholine, dopamine and other neuro-receptor PET tracers is limited. Their uptake patterns, based on the studies available so far, are given in table-1. However, because of the paucity of data, their current role in presurgical evaluation is not yet established.

Dual pathology

Undiagnosed dual pathology (co-existence of neocortical lesion and hippocampal sclerosis) can be a source of surgical failure, since resection of both the cortical lesion and the affected hippocampus is necessary to optimize the surgical results. Although FDG PET can be used to evaluate for an abnormally functioning hippocampus, the higher sensitivity of FMZ PET makes it more useful in such cases, particularly when the MRI does not reveal an abnormal signal or atrophy in the hippocampus.

Secondary epileptic foci

A 'secondary' epileptic focus is an additional focus that is located at a different site from the primary focus, along the path of seizure propagation. Secondary epileptic foci evolve over a period of time. In the beginning they may be dependent upon the primary focus, in which case they tend to disappear after removal of the primary focus. With passage of time, they may become independent and are one of the major contributors to surgical failure in patients with longstanding intractable epilepsy. It is not known, however, at which stage these foci become independent and whether these areas of so called secondary epileptogenic foci require a critical period of seizure or some other aggravating factors for their activation. Histopathological examination of these secondary foci usually shows gliosis. FMZ PET can play a very important role in the detection of secondary epileptic foci. It appears that complete removal of the primary *and* secondary foci improves the surgical outcome.

Functional status of the rest of the brain

FDG PET can be very valuable in assessing the integrity of brain regions outside of the epileptogenic zone during the surgical planning process, and allows certain prognostic implications. These non-epileptogenic but dysfunctional areas are often associated with specific clinical manifestations.

For example, in patients with unilateral temporal lobe epilepsy based on EEG, the presence of bitemporal glucose hypometabolism is associated with poor memory performance and prefrontal hypometabolism is associated with impaired executive function. Similarly, there may be associated hypometabolism and/or reduced FMZ binding in the ipsilateral insular cortex (in 60% of the patients), usually correlating with emotional or somesthetic symptoms (depending upon the involvement of the anterior versus the posterior part of the insula). Bilateral lateral temporal (neocortical) and bilateral medial prefrontal hypometabolism (**Figure 9**) may be associated with interictal aggressive behavior, probably because of the removal of the inhibitory effects of temporal neocortex (and perhaps medial prefrontal cortex) on medial temporal lobe. In infants with epileptic spasms, bilateral temporal hypometabolism (affecting both hippocampus and superior temporal gyri) is strongly associated with an autistic or pervasive phenotype.

In children with hemimegalencephaly, FDG PET often shows additional less pronounced abnormalities in the opposite hemisphere, which probably accounts for the suboptimal cognitive outcome even with complete seizure control after surgical removal of the profoundly abnormal hemisphere. Thus, FDG PET can be useful in such cases to assess the functional integrity of the contralateral hemisphere prior to hemispherectomy and help predict cognitive outcome.

Eloquent cortex

Although ^{15}O-water PET has been used in the past to assess eloquent cortex (e.g., motor and language cortex), this type of evaluation has been, for the most part, replaced by functional MRI. The latter can be repeated and offers the advantage of no radiation exposure. As a result, PET has a very limited role in activation studies for presurgical evaluation in epilepsy.

Postsurgical evaluation

In surgical failures where a second surgery is being considered, there are very few neuroimaging options to pinpoint remaining epileptic tissue. Occasionally, ictal SPECT may be helpful in this regard, but in most cases the epileptologist is left with the scalp EEG and seizure semiology to guide placement of intracranial electrodes. We have found AMT PET to be particularly useful in this setting. Unlike MRI, interictal FDG or FMZ PET, AMT PET can differentiate epileptogenic cortex from non-epileptic tissue damage caused by the initial surgery in about half of cases (**Figure 10**); clearly, more work is required in this difficult group of patients undergoing reoperation.

FDG PET can be also useful in the post-surgical evaluation and monitoring of previously hypometabolic non-epileptogenic brain regions (i.e., regions that had no EEG correlate) in the pre-surgical FDG scan. Resolution of this hypometabolism, which occurs in some of these cases, will suggest the functional nature of the suppression. Further, persistence of a remote but connected region, or appearance of a new area, of hypometabolism may suggest a secondary potentially epileptogenic focus.

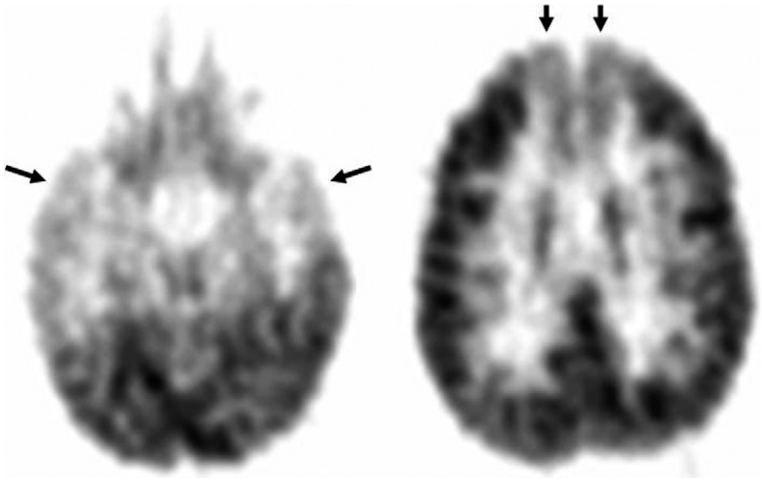

Figure 9 Bilateral temporal neocortical and bilateral medial prefrontal hypometabolism (see arrows) on FDG PET scan in a child with temporal lobe epilepsy and interictal aggressive behavior.

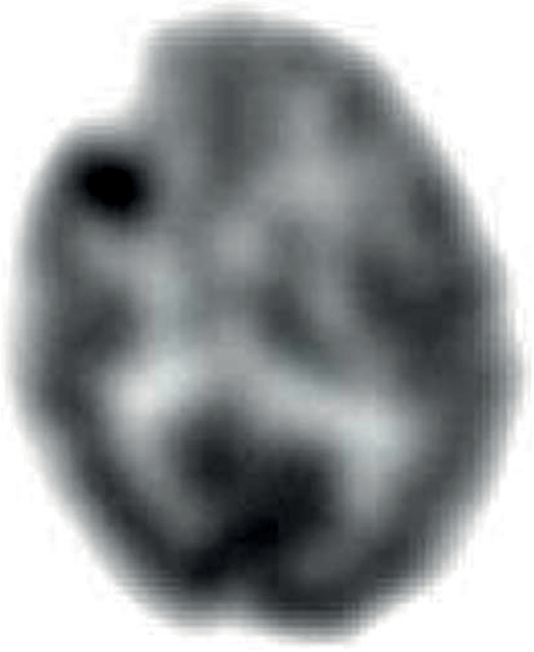

Figure 10 AMT PET scan showing a focal area of increased AMT uptake near the surgical margin in a child with failed epilepsy surgery. All other imaging investigations were noncontributory.

Neonatal seizures

Seizures occur more frequently in the neonatal period than at any other time of life. Population-based studies indicate that seizures occur in approximately 2.5–3.5/1000 live births in North America and may be caused by virtually any condition that affects neonatal brain function.

The most important factor in the therapy of neonatal seizures is accurate diagnosis. In neonates with no obvious metabolic abnormality, structural imaging studies (particularly MRI) may be useful to detect major malformations that are associated with seizures. However, the diagnostic value of MRI in this age group, to identify subtle cortical developmental malformations that are one of the commonest underlying causes of partial seizures, is limited. In fact, in young children less than 2 years of age, even macroscopic cortical malformations may not be apparent on MRI until myelination processes advance and blurring between gray and white matter disappears in normal cortex.

Application of PET can greatly improve the sensitivity of the detection of brain abnormalities causing neonatal seizures. FDG PET has been found to clearly lateralize or localize patterns of abnormal glucose metabolism in the majority of infants, even if CT or MRI fails to show localized structural abnormalities. In newborns (2–5 days of age) suffering from perinatal asphyxia and moderate or severe hypoxic-ischemic encephalopathy, FDG PET has demonstrated focal areas of decreased metabolism in the thalamus and lentiform nucleus with some sparing of the caudate nucleus, and can provide valuable information for the prediction of neurological outcome. However, in the past, neonatal PET studies were scarce, probably because scanners developed for adult studies are not ideal for imaging small babies owing to the limited spatial resolution. Further, transport of sick neonates to the PET scanners outside of the intensive care nursery is always troublesome. These problems can be circumvented by using specifically designed microPET scanners, or adapting animal PET scanners for human use and installing them in or around the neonatal intensive care unit.

Future Directions

PET scanning, along with the development of newer and 'designer' (e.g., targeted to a specific cellular/sub-cellular structure) radiopharmaceuticals, can help in identifying the cellular and molecular mechanisms of epilepsy, and may eventually lead to a more precise identification of the epileptogenic zone – an area that remains elusive and unidentifiable by any other technique (except, perhaps, invasive EEG). Newer PET techniques may also help in developing improved treatments and in the selection of patients for various therapeutic strategies. PET can play a very important role in identifying biomarkers for seizure intractability, information that may radically change our current approach towards epilepsy management. Future studies are also required to establish the role of PET scans in the detection of dual pathology and in identifying any potential secondary epileptic focus.

Introduction

Mesial Temporal Lobe Epilepsy

Structural correlates of MTLE include hippocampal sclerosis (HS), glial tumors, vascular malformations, and neurodevelopmental lesions. Gliotic lesions due to trauma or infections can also give rise to MTLE. HS is the major neuropathological substrate in patients with MTLE, and it is present in 60–70% of patients with MTLE who undergo surgery for treatment of medically refractory seizures. HS most likely has different causes in different individuals, and may result from complex interactions among genetic and environmental factors. Histopathological hallmarks include segmental loss of pyramidal neurons, granule cell dispersion, reactive gliosis, and axonal sprouting of surviving neurons. The mechanisms underlying the development of MTLE remain undetermined. It has been hypothesized that developmental malformations or precipitating events in early development, such as febrile seizures, may initiate a lasting and progressive change that leads to a propensity of the hippocampus to generate seizures in later life. Animal models of febrile seizures suggest that, indeed, early life seizures cause lasting changes in the excitability of hippocampal neurons.

The hallmarks of MTLE are typical limbic seizures with or without loss of consciousness. The first recurring seizures usually occur in late childhood or early adolescence. The most common initial ictal symptom is a visceral sensation, described usually as rising epigastric sensation (also refereed to as epigastric aura) that may be followed or accompanied by other features including emotional disturbances such as fear, autonomic symptoms, and olfactory or gustatory sensations. Auras typically occur in isolation and can precede seizures with impairment of consciousness (complex partial seizures). The latter commonly begin with a motionless stare and oroalimentary automatisms (e.g., lip smacking, chewing), during which the patient may be unresponsive. Gestural and reactive automatisms of the limbs or sometimes the whole body are also common. Dystonia of one extremity is usually contralateral to the side of ictal onset. Seizures typically last 1–2 min.

The neurological examination is usually normal. Most atients have deficits in episodic memory. Verbal memory is mostly affected with left MTLE, whereas visuospatial memory is more affected with right MTLE. The interictal electroencephalogram (EEG) of patients with MTLE typically shows unilateral or bilateral independent mesial temporal spikes, best seen with basal (sphenoidal, inferior temporal) derivations. Ictal EEG patterns commonly consist of rhythmic 5–7-Hz discharges seen in the mesial temporal region on the side of onset. High-resolution MRI often demonstrates unilateral and sometimes bilateral hippocampal atrophy associated with hyperintense T2 signal in one or both hippocampi, which is highly specific for HS. More detailed high resolution MRI analyses reveal a network of gray matter atrophy that involves mesial temporal and other structures interconnected with the limbic system, including amygdala, entorhinal, perirhinal, and parahippocampal cortices, and thalamus. Most patients are sporadic, but familial aggregation also occurs.

Introduction

Mesial Temporal Lobe Epilepsy

Structural correlates of MTLE include hippocampal sclerosis (HS), glial tumors, vascular malformations, and neurodevelopmental lesions. Gliotic lesions due to trauma or infections can also give rise to MTLE. HS is the major neuropathological substrate in patients with MTLE, and it is present in 60–70% of patients with MTLE who undergo surgery for treatment of medically refractory seizures. HS most likely has different causes in different individuals, and may result from complex interactions among genetic and environmental factors. Histopathological hallmarks include segmental loss of pyramidal neurons, granule cell dispersion, reactive gliosis, and axonal sprouting of surviving neurons. The mechanisms underlying the development of MTLE remain undetermined. It has been hypothesized that developmental malformations or precipitating events in early development, such as febrile seizures, may initiate a lasting and progressive change that leads to a propensity of the hippocampus to generate seizures in later life. Animal models of febrile seizures suggest that, indeed, early life seizures cause lasting changes in the excitability of hippocampal neurons.

The hallmarks of MTLE are typical limbic seizures with or without loss of consciousness. The first recurring seizures usually occur in late childhood or early adolescence. The most common initial ictal symptom is a visceral sensation, described usually as rising epigastric sensation (also refereed to as epigastric aura) that may be followed or accompanied by other features including emotional disturbances such as fear, autonomic symptoms, and olfactory or gustatory sensations. Auras typically occur in isolation and can precede seizures with impairment of consciousness (complex partial seizures). The latter commonly begin with a motionless stare and oroalimentary automatisms (e.g., lip smacking, chewing), during which the patient may be unresponsive. Gestural and reactive automatisms of the limbs or sometimes the whole body are also common. Dystonia of one extremity is usually contralateral to the side of ictal onset. Seizures typically last 1–2 min.

The neurological examination is usually normal. Most atients have deficits in episodic memory. Verbal memory is mostly affected with left MTLE, whereas visuospatial memory is more affected with right MTLE. The interictal electroencephalogram (EEG) of patients with MTLE typically shows unilateral or bilateral independent mesial temporal spikes, best seen with basal (sphenoidal, inferior temporal) derivations. Ictal EEG patterns commonly consist of rhythmic 5–7-Hz discharges seen in the mesial temporal region on the side of onset. High-resolution MRI often demonstrates unilateral and sometimes bilateral hippocampal atrophy associated with hyperintense T2 signal in one or both hippocampi, which is highly specific for HS. More detailed high resolution MRI analyses reveal a network of gray matter atrophy that involves mesial temporal and other structures interconnected with the limbic system, including amygdala, entorhinal, perirhinal, and parahippocampal cortices, and thalamus. Most patients are sporadic, but familial aggregation also occurs.

Familial Temporal Lobe Epilepsy

Familial MTLE

The best definition of familial MTLE is based on the familial recurrence of MTLE in the absence of any suggestion of other partial (including lateral TLE symptoms) or generalized epilepsy syndromes in other affected family members. The finding of at least two MTLE patients in one family is suggestive of familial MTLE. The observation of an autosomal dominant inheritance pattern with incomplete penetrance implies the presence of asymptomatic carriers of the genetic abnormalities, who can transmit the disease to their offspring. Therefore, we should consider inclusion of not only families with affected first-degree relatives, but also those with affected second and third degree relatives. This criterion has not been employed in some reported series, leading to exclusion of many possible familial MTLE kindreds.

Most affected individuals with familial MTLE have a benign clinical course, and in some families all affected members have good seizure control or remit after a short period of seizures. However, as in patients with nonfamilial MTLE, some affected family members may have poor seizure control and require surgical treatment. Although magnetic resonance imaging (MRI) signs of hippocampal sclerosis, including hippocampal atrophy (HA) and hyperintense T2 signal, are more frequent and more pronounced in patients with refractory seizures, these changes are also observed in patients with good clinical outcome, and even in asymptomatic family members. These are strong indicators that genetic factors play a role in the genesis of hippocampal pathology in patients with familial MTLE. While the pattern of inheritance is autosomal dominant with incomplete penetrance, the genetic background in familial MTLE does not imply a more widespread structural abnormality on MRI.

Familial TLE with auditory auras

Familial TLE with auditory auras (also described as autosomal dominant partial epilepsy with auditory features (ADPEAF)) is a benign epilepsy syndrome, characterized by auras described as buzzing, roaring, radio or motor like sounds, distortions in sounds and words. Although other manifestations such as psychic, cephalic, and other sensory and motor phenomena can occur, the auditory auras are a hallmark of this syndrome. Sometimes ictal aphasia and visual misperceptions can occur and, in some families, secondarily generalized tonic–clonic seizures (GTCS) are frequent before treatment. The EEG may show posterior temporal epileptiform discharges, but is frequently normal.

The pattern of inheritance observed is autosomal dominant with incomplete penetrance. Molecular studies identified linkage to chromosome 10q, and mutations in the *leucine-rich, glioma-inactivated 1* gene *(LGI-1)* have been identified. However, only 50% of families presenting the typical phenotype have LGI-1 mutations suggesting genetic heterogeneity.

Age of onset is variable, usually in the second or third decade of life, and seizures are easily controlled by AEDs. No signs of HA or HS-related signal changes on MRI have been described in different series: however, we have found subtle abnormalities in the neocortical aspects of the temporal lobes.

The prevalence and incidence of these two forms of familial TLE are unknown. However, familial MTLE is apparently more common than familial TLE with auditory auras. There is no predominance in any particular ethnic group, and families with MTLE and with TLE with auditory auras have been described in several countries. There is probably an underestimation of the real prevalence of both forms of familial TLE worldwide, especially in families with predominantly good outcomes.

Ascertainment of these families requires detailed questioning of patients and family members, a practice that has only been emphasized recently, as MTLE, as well as other partial epilepsies, has generally been considered to be symptomatic and largely due to environmental factors.

There is no evidence to suggest that familial partial epilepsy with variable foci, partial epilepsy with auditory features, or temporal lobe variants of benign childhood epilepsy with centrotemporal spikes ever evolve into MTLE with HS. This observation suggests a clear distinction between familial MTLE and these other familial epilepsy syndromes.

Background

Neuroimaging in Familial MTLE

MRI evaluation in familial MTLE has shown a high frequency of HA and other signs of HS (**Figure 1**), even in individuals with seizure remission and asymptomatic family members (**Figure 2**). The identification of MRI signs of HS in familial MTLE patients with a benign clinical course supports the view that the presence of HA is not always associated with refractory epilepsy. Available data indicate that MRI abnormalities, determined by visual analyses, are similar in familial and sporadic MTLE with HS.

Patients with intractable familial MTLE present a clinical profile and most histological findings comparable to patients with sporadic MTLE. Interestingly, mossy fiber sprouting may be more pronounced in patients with sporadic MTLE. This finding suggests that, when compared with sporadic MTLE, patients with familial MTLE may respond differently (i.e., display different plastic changes) to cell loss, neuronal deafferentation or epileptic seizures. This finding is in keeping with our recent MRI studies with voxel-based morphometry

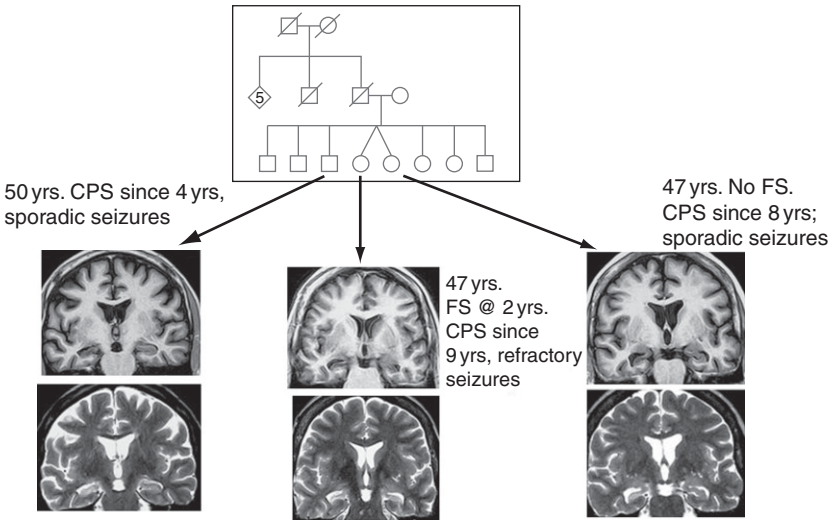

Figure 1 Reduced pedigree from one family with familial MTLE, showing coronal T1 and T2 MRIs showing signs of hippocampal sclerosis: atrophy, hyperintense T2 signal, abnormal shape and abnormal internal structure of right hippocampus in three sibs. CPS: complex partial seizures; FS: febrile seizures.

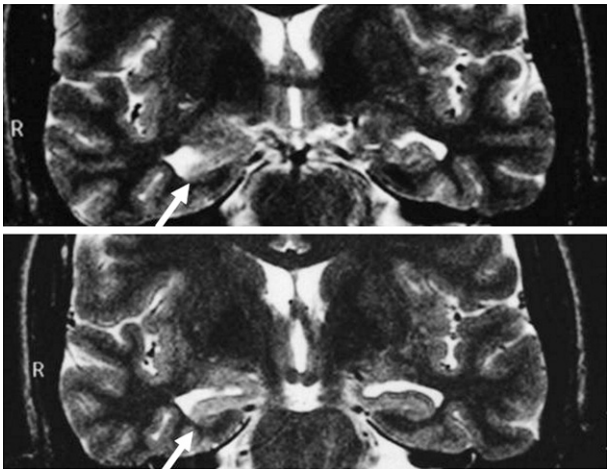

Figure 2 Coronal T2-weighted MR images in a 39 years old man from a family with MTLE. He had his first seizure at 17 years of age and a few other seizures during life. He has been seizure free without medication for several years. Observe the right hippocampal atrophy with hyperintense T2 signal and abnormal shape (arrows).

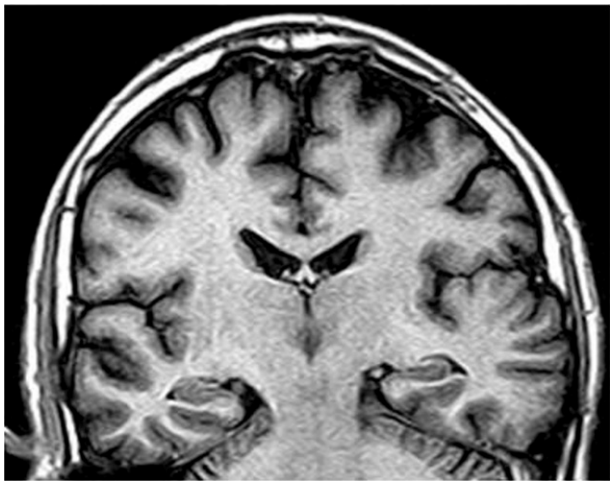

Figure 3 Coronal T1-invertion recovery MRI showing enlargement of left temporal lobe in a patient with familial TLE with auditory auras. Observe also an abnormal pattern of the first and second temporal sulci as compared to the right side.

(VBM), demonstrating more widespread gray matter atrophy in patients with sporadic MTLE compared to familial MTLE as discussed below.

Neuroimaging in Familial TLE with auditory auras

No signs of HA are found on MRI studies, but we have observed a lateral temporal malformation pattern in 45% of affected individuals, including one asymptomatic carrier of the mutation. The left temporal lobes of these individuals seemed enlarged (Figure 3), and these patients sometimes show a protrusion of the brain parenchyma laterally, with an 'encephalocele-like' appearance. Anterior temporal lobe volumetry showed a significant global increase in only two individuals. The epileptogenic significance of these structural abnormalities is unknown.

Methods

Familial MTLE

Our group has performed a genome-wide scan with 332 microsatellite markers at ~12 cM intervals to identify the region harboring the main gene associated with HA

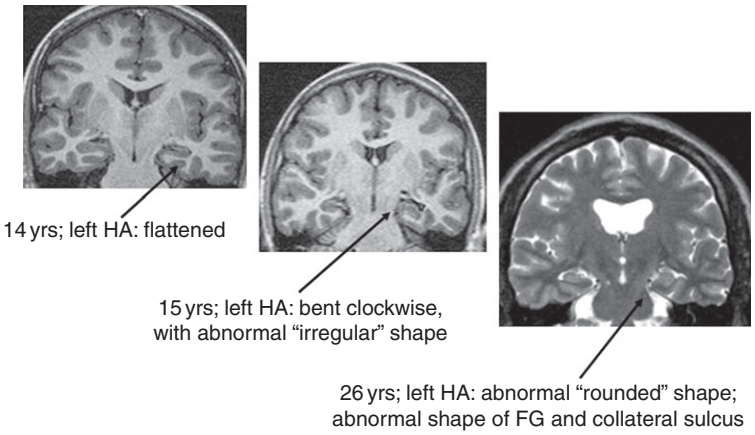

Figure 4 Coronal MRIs from asymptomatic family members of families with MTLE showing different patterns of hippocampal malformation (arrows). HA: hippocampal atrophy. FG: fusiform gyrus.

in a large kindred with familial MTLE. Additional 14 markers were genotyped in the candidate region. Two-point and multipoint LOD scores were calculated with the LINKAGE computer package. All genotyped individuals underwent MRI for evaluation of hippocampal abnormalities. Previous pedigree and complex segregation analysis provided evidence for the presence of a major gene predisposing to HA in familial MTLE.

In addition, we performed visual and volumetric analysis of all MRIs in 12 patients from this kindred who had seizures. Hippocampal measurements were made on 3 mm coronal T1-weighted images. Hippocampal malformation was defined according to previous publications (see Further Reading), and included hippocampi that were abnormally round, pyramidal in shape, with abnormal rotation or vertically orientated (**Figure 4**). All patients had clinical and EEG diagnosis of MTLE, except one patient who had had two generalized tonic–clonic seizures.

In a different study, we used an MRI automatic segmentation protocol and VBM to investigate 92 consecutive patients with benign MTLE (55 women and 37 men; mean age 42 years). Benign MTLE was defined as no disabling seizures reported by the patients, with only mild simple partial seizures occurring once a month or less. All patients and 40 controls (22 women, 18 men; mean age 32 years) were submitted to a 2T MRI scan. The volumetric 3D T1 *gradient echo* (GRE) sequence was used for the analysis. MRIs were normalized using linear and nonlinear transformations, and were automatically segmented using SPM5 (Wellcome Trust Centre for Neuroimaging, London, England; www.fil.ion.ucl.ac.uk) built-in routines. For VBM analysis, the images were smoothed further with an 8 mm Gaussian Kernel. Images were also normalized based on the total intracranial volumes of the controls. We compared differences between sporadic and familiar MTLE versus controls. For these comparisons, images were horizontally flipped according to the smaller hippocampus to avoid side to side cancellation. ANOVA was used, and a $p < 0.05$ false discovery rate correction was selected.

We also followed prospectively 64 individuals with familial MTLE from 28 families. Patients who fulfilled clinical criteria for MTLE (according to the ILAE classification scheme) were divided into three groups. (i) *Remission*: seizure-free for at least 2 years; (ii) *Benign*: less than six complex partial seizures (CPS)/year and no more than two secondary generalized tonic–clonic seizures per year; and (iii) *Refractory*: more than six partial seizures per year despite adequate antiepileptic drugs (AEDs). Thirty-five of these individuals had hippocampal volumetric measurements in two MRI scans, performed with a minimum of 1 year interval, which did not show progression of atrophy.

Familial TLE with Auditory Auras

We acquired MRIs in a 2T scanner (Elscint Prestige, Haifa, Israel) using a spoiled GRE sequence (TR = 22 ms, TE = 9 ms, flip angle = 35°, matrix = 256 × 220). These T1-weighted images were acquired with 1 mm isotropic voxels, and were subsequently transformed into ANALYZE format using MRIcro software (Chris Rorden, www.mricro.com). VBM analysis was performed using SPM99 (www.fil.ion.ucl.ac.uk). Images were then normalized to the standard space using 12 linear parameters and 7 × 8 × 7 nonlinear basis functions, using a brain mask. Spatially normalized images were resliced to an isotropic 1.5 mm and underwent segmentation of gray matter and modulation of the estimated concentration of tissue, based on the spatial deformations encountered during normalization. This technique preserves the quantity of gray matter and ensures a good spatial alignment between patients and controls. Finally, the images were convolved with an Isotropic Gaussian Kernel of 10 mm to minimize gyral interindividual variability. The resulting images were then compared using *t*-tests, to

determine differences in grey matter concentration (GMC) between controls and subjects with the LGI1 mutation from one large family. Contrasts were defined to estimate the probability of each voxel being gray matter. This analysis included grand mean scaling and proportional threshold masking (set to 0.8) and implicit masking. The results from the analysis are given in a parametric map of t-statistic (SPM(t)), and the SPM(t) is corrected for normal distribution (SPM(z)). Considering the previously observed subtle structural abnormalities in the temporal lobes of these same individuals, and the relative small number of participants, we examined clusters with at least 32 voxels that exceed $p < 0.01$, uncorrected threshold ($T = 2.39$). Group differences for age were assessed using one-way ANOVA, and the gender distribution was evaluated with χ^2 test.

Recent Results

Familial MTLE

We have identified linkage to chromosome 18p in a single family with MTLE. Multipoint and haplotype analysis localized the locus within a 13 cM interval. From the 12 patients in this family with seizures, one patient – who had had two generalized tonic–clonic seizures – did not have the haplotype, and MRI was normal. The remaining 11 patients with diagnosis of MTLE had MRI signs of hippocampal malformation, including hippocampal atrophy in 8 of them. All except one of these 11 patients had the haplotype. Further evaluation including asymptomatic family members would be helpful for clarifying the genetic basis of hippocampal malformation and hippocampal sclerosis in familial MTLE. However, our success in this linkage analysis provides clear evidence that HA may be caused by genetic factors, which can have major implications in the study of the pathophysiological mechanisms underlying MTS and its relationship with TLE.

For the MRI VBM study of benign MTLE, there were 52 patients in the sporadic MTLE group and 40 patients in the familial MTLE group. Our investigation evidenced a high frequency of structural abnormalities in patients with benign MTLE. VBM showed areas of gray matter atrophy that were more widespread in patients with sporadic TLE compared to familial MTLE (Figure 5), which

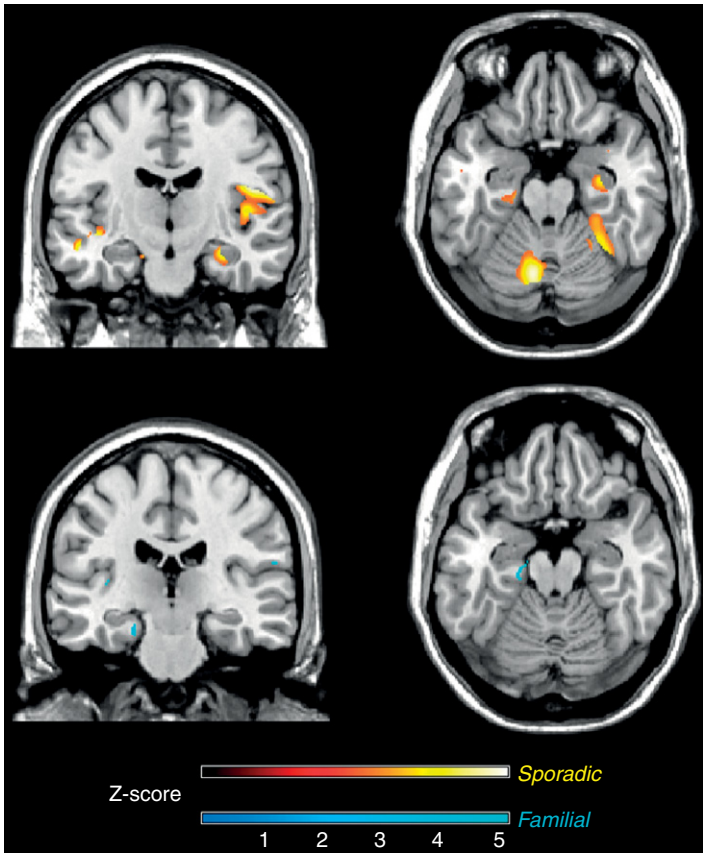

Figure 5 Results of the VBM comparisons among 40 patients with mesial temporal lobe epilepsy and positive family history (TLE, top row – hot colors), 52 patients with sporadic TLE (negative family history, bottom row – cold colors) and 40 controls showing areas of gray matter atrophy. The results are overlaid with an anatomical T1 template and displayed in two orthogonal planes (coronal and axial). The color bar in the inferior portion of the figure represents the number of standard deviations as compared to controls.

is in agreement with another study comparing postoperative histopathology studies in refractory sporadic and familial MTLE. Familial and sporadic TLE showed different patterns of atrophy, as observed in the VBM group comparisons. Multiple mechanisms involved in the pathogenesis of TLE are the probable explanation for this diversity. These findings indicate that environmental factors and modifier genes play an important role in the outcome of TLE.

We followed prospectively 64 individuals, from 28 families, with familial MTLE. Patients who fulfilled clinical criteria for MTLE were divided into three groups, as described above. Mean follow up was 93.4 ± 15.8 months (ranging from 45 to 121.9 months). At baseline they were divided as follows: benign – $n = 29$; remission – $n = 28$; and refractory – $n = 7$. At the last follow-up visit, 12 (41.4%) patients with benign FMTLE remained classified as benign, 6 (20.7%) became refractory, and 11 (37.9%) were in remission. In the subgroup of familial MTLE in remission, 21 (75%) remained without seizures; 6 (21.4%) were classified as benign familial MTLE, and one died (3.6%) from causes unrelated to epilepsy. All refractory patients remained refractory. Prospective follow-up of more than 7 years in patients with familial MTLE revealed that those with refractory seizures are unlikely to achieve seizure control with AEDs. In contrast, patients with benign familial MTLE for more than one year are likely to remit or remain under good seizure control. The majority of patients who had achieved seizure remission remained seizure-free and none became refractory.

Familial Temporal Lobe Epilepsy with Auditory Auras

Studies have reported no signs of HS in MRIs of patients from families with LGI-1 mutation. Enlargement and abnormal gyration, suggesting developmental abnormalities in the lateral cortex of the temporal lobe, were described in 53% of affected individuals in one family with LGI-1 mutation (**Figure 3**), a finding that requires confirmation. The MRI findings in that family are clearly distinct from the MRI findings in familial MTLE, and are consistent with the distinct seizure semiology in these two forms of familial TLE.

We performed a VBM study in 17 family members from a large kindred with familial TLE with auditory auras (three of them asymptomatic), all being carriers of the LGI1 mutation. We observed areas of increased GMC (compared to normal controls) in the left cerebellum, right parietooccipital region, and left hippocampus. In addition, these individuals presented with decreased GMC in the anterior portion of both temporal lobes, in the left precentral area, and in the right cerebellum.

The functional properties of the LGI1 gene remain unknown. This gene was cloned from the breakpoints of a glioblastoma cell line and its expression is reduced or absent in many high-grade gliomas. This evidence suggests a possible function related to cellular proliferation and/or tumor suppression. Furthermore, this gene is characterized by a central leucine-rich repeat region, which is involved in regulation of cell growth, adhesion, and migration. Therefore, LGI1 mutations could, possibly, be leading to subtle abnormalities of neuronal proliferation or migration that would result in dysgenetic lesions not easily detected by MRI.

Future Goals

Further structural and functional imaging and histopathological studies will shed light on the processes involved in genesis and progression of HS, and on other underlying mechanisms of sporadic and familial TLE epilepsies. The finding of a major gene mutation will be crucial for a better understanding of these functional and anatomic changes related to epileptogenesis in MTLE. The presence of structural brain abnormalities, e.g., in the form of GMC excess in patients with familial TLE with auditory auras, could be a consequence of the LGI-1 mutation and requires further investigation.

Magnetic Resonance Imaging in Epilepsy Research: Recent and Upcoming Developments

B Weber, K Fliessbach, and C E Elger, University Hospital of Bonn, Bonn, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Magnetic resonance imaging (MRI) of the brain has become an indispensable tool in the diagnosis and treatment of epilepsy patients. Since its introduction to the clinical routine in the early 1990s, the detection and characterization of epileptogenic lesions by MRI has improved substantially. This imaging progress has opened up the possibility of epilepsy surgery to more patients, and improved the prognosis for those who are finally undergoing surgery.

Major recent advances lie in the improvement of magnetic resonance (MR)-acquisition techniques, which include improvements in the scanner hardware (e.g., more powerful gradient systems and scanner magnets with increased field strengths) as well as the development of new MR sequences with better contrasts. Besides these developments, the postprocessing of structural MRI data has yielded increasingly insightful results in the detection of cortical and subcortical lesions. Finally, functional MRI (fMRI) has shown its powerful potential to predict postsurgical outcome or complications and to contribute to focus detection.

Developments in MR-Acquisition Techniques

High Field Strengths

During the early years of clinical MRI, the field strength used was rather low (<0.5 T). The majority of clinical magnets today are operated at a field strength of 1.5 T, but the improved signal-to-noise ratio (SNR) with stronger magnets (3 T and above), and the growing experiences with the pitfalls and problems of higher field strengths, have lead to a growing number of these stronger clinical magnets. The drawbacks of higher field strengths, such as increased radiofrequency-energy (applied to the patients) and larger field inhomogenieties and susceptibility artifacts, as well as differences in relaxation rates, have been overshadowed by the ability for faster imaging and/or increased resolutions. Although the use of 3-T magnets becomes more and more routine (at least in larger hospitals and special centers), even higher field strengths of 7 or 9.4 T are now constructed for use in patients by all the vendors. Although these high field-strength magnets are currently viewed rather critically (as were the first 3-T magnets when they were introduced), the increased SNR provided by this enhancement can be used for even more rapid imaging or increased resolution. Exemplary images show promising results (**Figure 1**), but the applicability of these magnets in routine clinical function is debatable – not only due to the much higher costs but also due to an increased ratio of side-effects (e.g., nausea or vertigo) experienced by initial subjects.

Multichannel Coils and Parallel Imaging

Besides the increase in field strength, the development of multichannel coils was one of the cornerstones that improved neuroimaging by enabling parallel data reconstruction, and thereby increasing SNR, allowing decreased scanning time and artifacts. The decrease in acquisition times (by a factor of 4 or even more) alleviates movement artifacts and reduces the influence of field inhomogenieties, which is especially important for fast echo planar imaging (EPI) acquisitions which are used for fMRI to measure the blood oxygen level dependent (BOLD) contrast and diffusion weighted imaging, and also provides higher resolution images (if the same

Magnetic Resonance Imaging in Epilepsy Research: Recent and Upcoming Developments

B Weber, K Fliessbach, and C E Elger, University Hospital of Bonn, Bonn, Germany

Introduction

Magnetic resonance imaging (MRI) of the brain has become an indispensable tool in the diagnosis and treatment of epilepsy patients. Since its introduction to the clinical routine in the early 1990s, the detection and characterization of epileptogenic lesions by MRI has improved substantially. This imaging progress has opened up the possibility of epilepsy surgery to more patients, and improved the prognosis for those who are finally undergoing surgery.

Major recent advances lie in the improvement of magnetic resonance (MR)-acquisition techniques, which include improvements in the scanner hardware (e.g., more powerful gradient systems and scanner magnets with increased field strengths) as well as the development of new MR sequences with better contrasts. Besides these developments, the postprocessing of structural MRI data has yielded increasingly insightful results in the detection of cortical and subcortical lesions. Finally, functional MRI (fMRI) has shown its powerful potential to predict postsurgical outcome or complications and to contribute to focus detection.

Developments in MR-Acquisition Techniques

High Field Strengths

During the early years of clinical MRI, the field strength used was rather low (<0.5 T). The majority of clinical magnets today are operated at a field strength of 1.5 T, but the improved signal-to-noise ratio (SNR) with stronger magnets (3 T and above), and the growing experiences with the pitfalls and problems of higher field strengths, have lead to a growing number of these stronger clinical magnets. The drawbacks of higher field strengths, such as increased radiofrequency-energy (applied to the patients) and larger field inhomogenieties and susceptibility artifacts, as well as differences in relaxation rates, have been overshadowed by the ability for faster imaging and/or increased resolutions. Although the use of 3-T magnets becomes more and more routine (at least in larger hospitals and special centers), even higher field strengths of 7 or 9.4 T are now constructed for use in patients by all the vendors. Although these high field-strength magnets are currently viewed rather critically (as were the first 3-T magnets when they were introduced), the increased SNR provided by this enhancement can be used for even more rapid imaging or increased resolution. Exemplary images show promising results (**Figure 1**), but the applicability of these magnets in routine clinical function is debatable – not only due to the much higher costs but also due to an increased ratio of side-effects (e.g., nausea or vertigo) experienced by initial subjects.

Multichannel Coils and Parallel Imaging

Besides the increase in field strength, the development of multichannel coils was one of the cornerstones that improved neuroimaging by enabling parallel data reconstruction, and thereby increasing SNR, allowing decreased scanning time and artifacts. The decrease in acquisition times (by a factor of 4 or even more) alleviates movement artifacts and reduces the influence of field inhomogenieties, which is especially important for fast echo planar imaging (EPI) acquisitions which are used for fMRI to measure the blood oxygen level dependent (BOLD) contrast and diffusion weighted imaging, and also provides higher resolution images (if the same

acquisition time is maintained). Currently, 8- or 12-channel head coils are most commonly used in routine scanners, but even higher numbers of array coils are being produced and are finding their way into the clinical setting. Preliminary data with 32 (or even more) receiver coils show promising results, with increased SNR up to 3.5 fold (Figure 2).

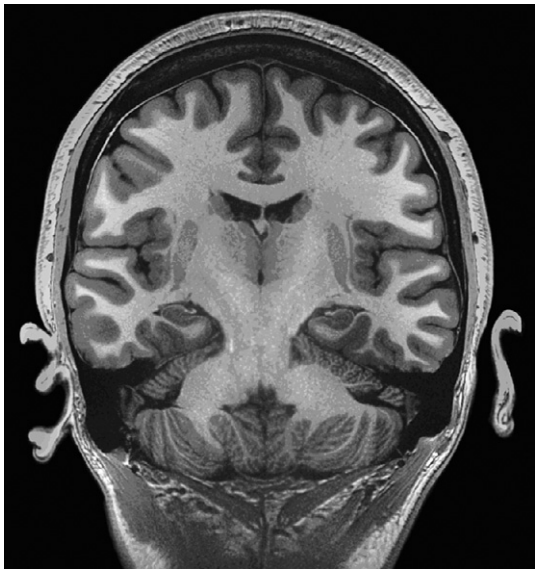

Figure 2 T1 3D turbo FLASH inversion recovery, 32-channel head coil, with GRAPPA PAT Factor 2, 512 × 512 matrix.

New Methods for k-Space Data Sampling

Besides the development of parallel data acquisition, considerable effort has been put into the creation of new data sampling procedures in the spatial-frequency domain (k-space). Images of patients, especially in pediatric context, are frequently disturbed by movement artifacts, rendering their interpretation difficult if not impossible. Based on the different impact of specific parts of the k-space on the contrast and signal intensities in MR images, methods have been invented that are much less susceptible to the movement of patients inside the scanner (e.g., ROTATOR – periodically rotated overlapping parallel lines with enhanced reconstruction – also called BLADE). This method samples the k-space via multiple echo trains, rotating around the center of the k-space (in contrast to a regular rectangular method). Hence, the center of the k-space is sampled during every train, allowing for the correction of spatial shifts by the comparison of the repeated acquisitions of the k-space center (Figure 3). Other trajectories, as spiral k-space acquisition, have not yet proven additional performance increases but have potentially an application in fMRI.

The Role of MR Postprocessing

Voxel-Based Morphometry

Probably the most challenging aspect of MRI in epilepsy is the investigation of patients classified as having a 'cryptogenic' focal epilepsy. A significant amount of 'cryptogenic' epilepsies is thought to be due to focal cortical dysplasias (FCDs). The difficulty of detecting these FCDs on MRI scans lies in the subtlety of their appearance on conventional images, and the complexity and variability of cortical convolutions concealing these abnormalities of development. Much effort by different research groups has been put forward to enhance the visualization of conventional MR images by means of automated postprocessing of the images. The basic idea behind most of the studies is to build a normative database, and to compare individual patients to this database to identify significantly differing structures. While some studies have been focused on rather simple voxel-based comparisons of gray- or white-matter distributions, other approaches have tried to highlight the characteristics of FCDs by means of texture analyses – i.e., blurred gray–white-matter line or more intense T1-weighted signal within the dysplastic cortex (Figure 4).

These approaches show very promising results, but the available studies on their specificity and sensitivity are mostly retrospective. Thus, they should be considered as heuristic tools that can complement findings from other sources. For routine clinical use, they need to be

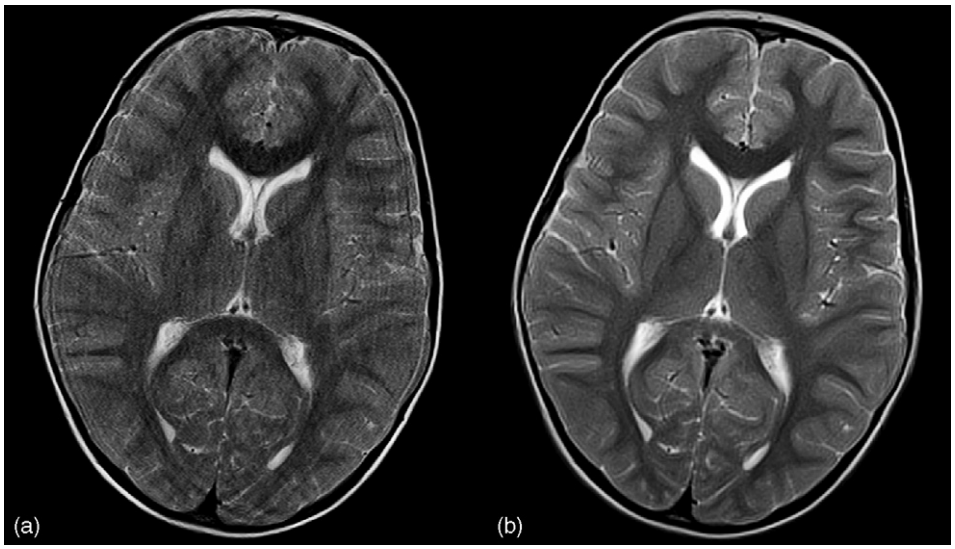

Figure 3 T2 TSE transversal (a) without BLADE (matrix 448 × 448; TA, 2:06 min) and (b) with BLADE (matrix 384 × 384; TA, 1:57 min). Provided by Siemens Medical, Erlangen, Germany.

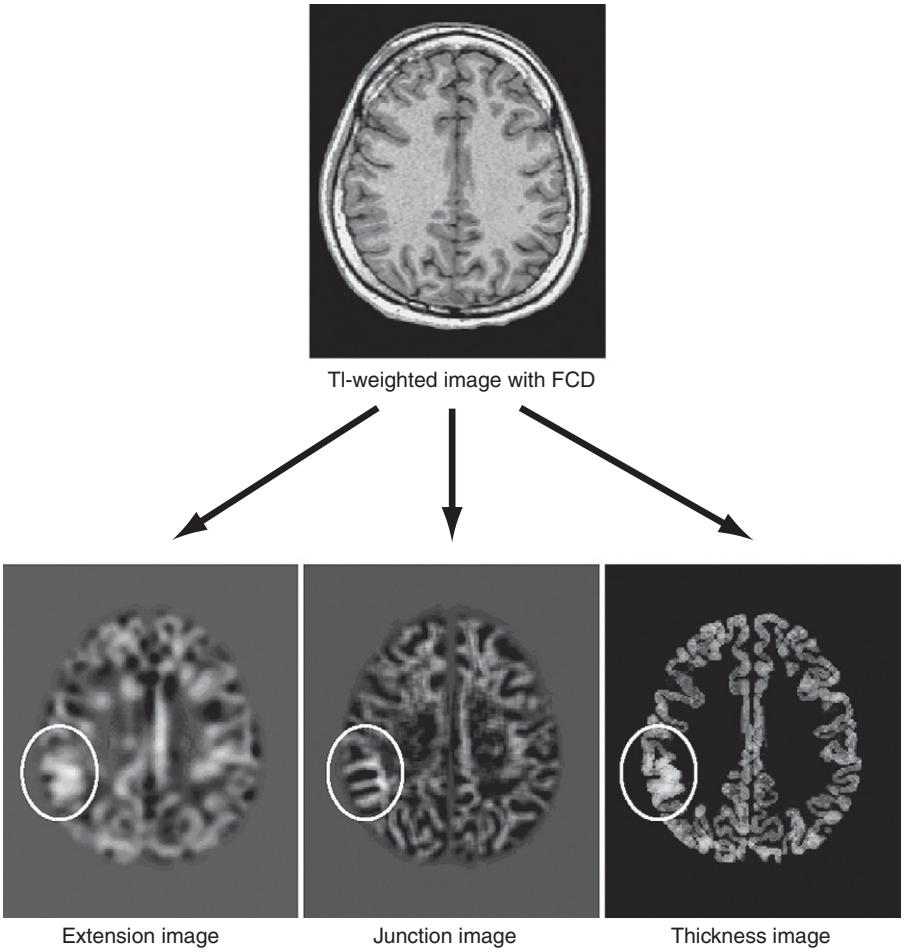

Figure 4 Example of a texture-based postprocessing of a cortical dysplasia not visible on a conventional T1-weighted MRI. Provided by Hans-Juergen Huppertz.

prospectively validated in larger number of patients, to prove their utility for the presurgical evaluation of epilepsy patients.

Multimodal Segmentation and Quantitative Imaging

One major problem of the approaches mentioned earlier is the dependency on the segmentation and delineation of the gray–white-matter boundary. Most segmentation procedures are based on signal intensities and (with more modern approaches) prior probabilities of specific tissue types. Recent approaches have tried to enhance the segmentation process by adding additional information by means of different MR contrasts (e.g., fluid-attenuated inversion recovery (FLAIR), T2-weighted, proton density, T1-weighted) and applying a cluster analysis. This approach promises a more precise segmentation, and might prove useful to apply to the investigation of cryptogenic epilepsy. In this context, the application of quantitative MRI data, such as T2-relaxation times or water content, might additionally enhance the segmentation process. Quantitative MRI approaches have the strong advantage of being less sensitive to perturbing factors (such as gradient drifts or field inhomogenieties) and hence may be more sensitive when used for individual patient diagnostics.

Cortex Reconstructions and Fractal Dimension

A different approach to investigate pathological differences in cortical structures is to generate three-dimensional models of the cortex, which can be parameterized and then entered into an analysis. Different procedures have been developed for the parameterization of cortical surfaces and applied to different neurological or psychiatric diseases (e.g., schizophrenia and multiple sclerosis) as well as to medial temporal lobe epilepsies (e.g., describing extratemporal changes in gyral complexity). To what extent these methods may be used in individual diagnostics remains to be evaluated.

Diffusion Tensor Imaging and Tractography

Diffusion tensor imaging (DTI) is an MRI technique that measures water molecule diffusion and its directionality. The most commonly used outcome measures are fractional anisotropy (FA) and (rotationally indifferent) mean diffusivity (MD). Tractography is an additional DTI-based technique for the mapping of discrete fiber tracks, using defined originating regions ('seeds') and statistical procedures that can follow the trajectories of white-matter tracks from this region. Because water diffusion in the brain is mainly restricted by fiber tracts, DTI has been suggested as an indirect marker for white-matter integrity. In several types of brain lesions, including tumors, multiple sclerosis plaques, or ischemic lesions, DTI has been found to complement other clinical data in the characterization of these lesions.

In epilepsy, DTI might help identify and characterize epileptogenic lesions such as hippocampal sclerosis or FCD. In proven hippocampal sclerosis, the epileptogenic hippocampus demonstrates increased MD and decreased FA. Prospective studies are needed to investigate the potential of DTI to detect the epileptogenic side in medial temporal lobe epilepsy *without* clear MRI abnormalities. Besides changes in the mesial temporal lobe structures themselves, other white-matter abnormalities (e.g., in the corpus callosum and internal capsule) have been found to be associated with hippocampal sclerosis. At present, no clear relation between the extension of extrahippocampal abnormalities and success of surgery has been found, but comprehensive studies on this interesting topic are missing.

In FCD and other types of cortical malformations, DTI and tractography have been used to characterize changes in subcortical connectivity. In many cases, diffusion changes are found not only close to the cortical lesion but also in adjacent subcortical regions that appear unremarkable in conventional MRI. This finding again raises the question of whether the extent of subcortical involvement can be used to predict surgery outcome and improve surgical planning. DTI might also prove useful in the detection of lesions undetected by conventional MRI. A recent study by Rugg-Gunn and colleagues found a significant increase in diffusivity in 8 of 30 patients with cryptogenic focal epilepsy; in 6 of these patients, the locus of the increase overlapped with the localization of EEG abnormalities, suggesting that DTI might be an additional tool for the detection of MRI-negative epileptogenic foci.

Besides the potential of DTI in characterizing epileptogenic regions, it is a promising tool for investigating the association between structural connectivity and functional changes associated with epilepsy and epilepsy surgery. Powell and colleagues found, e.g., a reduced left and enhanced right-hemispheric interconnectivity in patients with left temporal lobe epilepsy (TLE) than in healthy controls and patients with right TLE. These structural changes might be related to language dominance. Because language dominance shows interindividual fluctuations (e.g., during the menstrual cycle in women, or after successful epilepsy surgery), longitudinal studies that correlate functional imaging changes with DTI seem warranted.

New Developments of fMRI in Epilepsy Patients

fMRI of Cognitive Functions

fMRI in the domain of epilepsy has widely been applied for research purposes, but has also entered into the

clinical evaluation process of individual patients. The most established application of fMRI in clinical routine is the investigation of language dominance. Many studies have shown a high correlation with the gold standard of the Wada (amobarbital) test, and thereby its applicability as a less-invasive method. If language fMRI shows a good signal and a clear lateralization, the Wada test can be regarded as dispensable. Limitations of fMRI are its use in children and patients with severe cognitive deficits. Besides the use in language dominance, other cognitive domains are being investigated with fMRI in an effort to predict (and thereby potentially improve) postsurgical neuropsychological outcomes. On a group level, it has been shown that postsurgical memory function can be predicted by presurgical memory fMRI. Again, the method first has to be prospectively evaluated in larger patient groups, to determine the value of the method for the evaluation of individual patients.

Pharmaco-fMRI

The application of pharmacological challenges in fMRI studies has been performed mainly in the domain of psychiatric diseases such as schizophrenia or major depression, with the aim to obtain surrogate markers of successful drug treatment. The use of this method as a prognostic tool for the evaluation of drug success for seizure control is rather unlikely. Pharmaco-fMRI has, however, been applied to study the patient's susceptibility to cognitive side-effects of antiepileptic drugs (AEDs). A recent study by Jansen and colleagues has investigated the cognitive effects of topiramate and found decreased prefrontal cortex activation in patients treated with topiramate in contrast to a patient group without this drug. This finding raises the possibility that fMRI might predict longstanding cognitive side-effects, which are otherwise difficult to monitor. The investigation of other drugs, with their special side-effect profiles (e.g., levetiracetam), is being performed in preliminary studies.

Combined fMRI-EEG

By overcoming several technical difficulties, the combined acquisition of fMRI and EEG data has shown very promising results in recent years. By the improvement of artifact-reduction algorithms, both on EEG as well as on fMRI time series, several epilepsy centers are integrating spike-triggered fMRI into the presurgical workup program of their patients. When interpreting these data, one must keep in mind the technical limitations and basis of the acquired BOLD signal used in fMRI. The signal does not originate from neural activity directly, but rather from differences in blood oxygenation (i.e., from the blood vessels). The coupling of these two signals – especially in pathological tissue – is still not completely understood, and is complicated by spatial incongruence of the signals. Larger studies are still needed, and because of safety and technical issues, combined invasive EEG-fMRI recordings, which would shed light on some of these issues, are not yet performed. Hence, the usefulness of combined fMRI-EEG remains to be evaluated further, before epilepsy-surgical recommendations can be drawn from the observed activations.

Outlook for the Future

The future of MRI in the domain of epilepsy is very promising. The continuing development in scanner hardware, MR sequences, and postprocessing tools will improve the presurgical evaluation of patients with symptomatic epilepsy even further. While some applications mentioned in this article are already close to routine clinical use, others still have to prove their utility in larger studies. Without doubt, the further development in this field will prove very valuable for the patients, with advances anticipated in improved surgical outcome to better counselling in regard to drug treatment.

Introduction

Unlike conventional MRI studies, which detect the concentration of water and are sensitive to its cellular environment, MR spectroscopy provides specific biochemical information. For example, ^{1}H spectroscopic measurements have utilized decreases in *N*-acetyl aspartate (NAA), a compound synthesized only in neuronal mitochondria, to identify regions of neuronal loss and injury. Increases in total creatine (both phosphorylated and nonphosphorylated forms) and choline have been interpreted as reflecting gliosis and altered membrane turnover. In temporal lobe epilepsy, where neuronal loss and reactive gliosis are common findings, decreases in NAA and or increases in creatine and choline have been shown to have lateralization sensitivities as high as 97%. Using ^{31}P spectroscopy, in vivo concentrations of phosphocreatine, ATP, and inorganic phosphate can be imaged noninvasively along with intracellular pH to provide a measure of bio-energetic status. In this article, we review the role that MR spectroscopy has had as a clinical tool in identifying epileptic foci and monitoring the effects of various antiepileptic medications. We then discuss the biological significance of these findings, and particularly the role that bioenergetic impairment may play in the pathophysiology of seizure disorders. We also identify and discuss some of the technical hurdles that must be overcome in acquiring and accurately interpreting in vivo MR spectroscopy data.

Background

^{1}H NMR Spectroscopy and Spectroscopic Imaging

Nuclear magnetic resonance (NMR) spectroscopy allows the measurement of compounds with nonzero nuclear spin. A detailed description of the theory behind NMR is beyond the scope of this review. Briefly, in the presence of a magnetic field, these compounds absorb and emit radiofrequency signals. These signals have varying frequencies, depending upon the nucleus (^{1}H, ^{31}P, ^{13}C, etc.) and the type of chemical bonds present. NMR spectroscopy allows different chemical compounds to be identified by their unique fingerprint of frequencies. In the field of organic chemistry, NMR spectroscopy has been widely used to determine the presence, purity, and structure of the sample of interest. In biochemistry, the interaction of different resonances has been used to help identify the structure of different proteins. With the development of wide-bore magnets capable of accommodating human beings, NMR spectroscopy has been extended to studies of a variety of different organs including the brain. In the human brain the most widely investigated resonances include NAA (a compound synthesized only in neuronal mitochondria), creatine (both phosphorylated and nonphosphorylated compounds), and choline (elevated in high grade tumors and cells with increased membrane turnover) (**Figure 1**). Additional compounds of interest include lactate (a product of anaerobic glycolysis), the neurotransmitters glutamate and GABA. Unlike NMR spectroscopy studies of small aqueous samples as carried out by biochemists and chemists, in vivo measurements of the human brain require some form of spatial localization so as to link a metabolic profile with a specific anatomical structure. Depending upon the methods and hardware used, the spatial resolution of these measurements range from a few tens of cubic centimeters to a few hundred microliters. To achieve spatial localization of the signal, a variety of techniques based on the concepts used for MRI have been developed to select specific regions of the brain. More recently, spectroscopic imaging methods have been developed which allow spectra from

Background

^{1}H NMR Spectroscopy and Spectroscopic Imaging

Nuclear magnetic resonance (NMR) spectroscopy allows the measurement of compounds with nonzero nuclear spin. A detailed description of the theory behind NMR is beyond the scope of this review. Briefly, in the presence of a magnetic field, these compounds absorb and emit radiofrequency signals. These signals have varying frequencies, depending upon the nucleus (^{1}H, ^{31}P, ^{13}C, etc.) and the type of chemical bonds present. NMR spectroscopy allows different chemical compounds to be identified by their unique fingerprint of frequencies. In the field of organic chemistry, NMR spectroscopy has been widely used to determine the presence, purity, and structure of the sample of interest. In biochemistry, the interaction of different resonances has been used to help identify the structure of different proteins. With the development of wide-bore magnets capable of accommodating human beings, NMR spectroscopy has been extended to studies of a variety of different organs including the brain. In the human brain the most widely investigated resonances include NAA (a compound synthesized only in neuronal mitochondria), creatine (both phosphorylated and nonphosphorylated compounds), and choline (elevated in high grade tumors and cells with increased membrane turnover) (**Figure 1**). Additional compounds of interest include lactate (a product of anaerobic glycolysis), the neurotransmitters glutamate and GABA. Unlike NMR spectroscopy studies of small aqueous samples as carried out by biochemists and chemists, in vivo measurements of the human brain require some form of spatial localization so as to link a metabolic profile with a specific anatomical structure. Depending upon the methods and hardware used, the spatial resolution of these measurements range from a few tens of cubic centimeters to a few hundred microliters. To achieve spatial localization of the signal, a variety of techniques based on the concepts used for MRI have been developed to select specific regions of the brain. More recently, spectroscopic imaging methods have been developed which allow spectra from

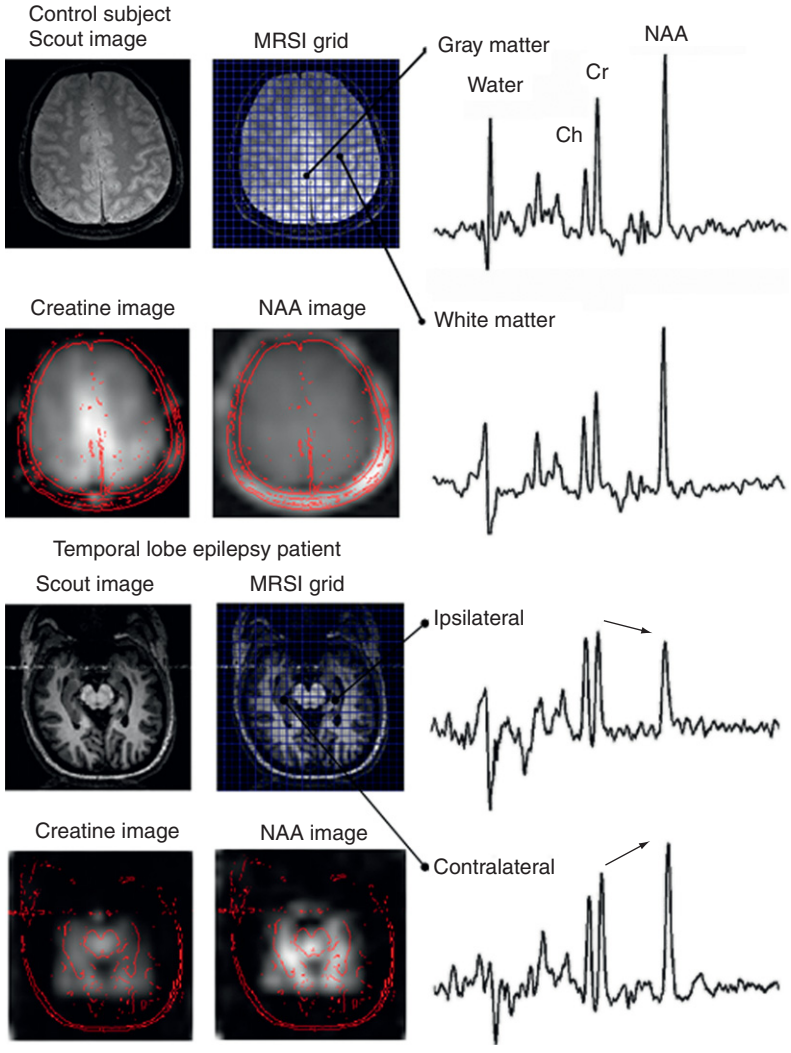

Figure 1 Displays a set of images including a scout image (upper left), a scout image with the sampling grid for the spectroscopic imaging data superimposed (upper right). This data was acquired using a whole plane acquisition with suppression of the lipid resonances provided by an inversion recovery sequence. Displayed to the left are two spectra from the spectroscopic image (gray matter upper, white matter lower). The labeled resonances are *N*-acetyl aspartate (NAA), creatine (Cr), choline (Ch) and the residual water signal (H_2O). Integration of the creatine and NAA resonances provides a metabolic image of creatine (lower left) and NAA (lower right). The increased creatine content from gray matter is easily visualized as increased intensity in the Cr image along the intrahemispheric gray matter. The bright ring surrounding the brain in the NAA image is due to residual lipid surrounding the brain from skeletal muscle and fat. Displayed below are the equivalent images from a patient with unilateral temporal lobe epilepsy. This data was acquired using two dimensions of in-plane localization, restricting the sampled data to a rectangle (80 mm $\times$ 100 mm) centered about the medial temporal lobe. The spectra shown to the left demonstrate a large decrease in NAA/Cr in the ipsilateral hippocampus in comparison to the contralateral hippocampus.

multiple locations to be acquired simultaneously (i.e., imaged) which allows the formation of metabolic images (Figure 1). These methods provide a highly efficient method for probing for focal changes in metabolism characteristic of pathology.

Methods

Although a large number of methods have been developed for acquiring ^{1}H spectroscopic imaging data from the human brain, all sequences carry the following common elements: (1) some form of water suppression; (2) some form of slice or slab selection to restrict the data collection in the cranial–caudal direction; (3) some form of lipid or in-plane selection to eliminate extracerebral lipids; and (4) two or three dimensions of spatial phase encoding to generate images. Due to the high concentration of water in the body (40–55 M, depending upon tissue type), some form of water suppression is required for adequate digitization and visualization of the resonances from ^{1}H metabolites (1–10 mM). Fortunately, the lipids signals intrinsic to brain tissue are relatively immobile, which results in extremely broad lines that are

typically not visible in ^{1}H spectra. However, extracerebral lipids, which are molar in content, must be suppressed. Due to large differences in their physical properties in comparison with most ^{1}H metabolite resonances, the extracerebral lipids can be suppressed by spin echo sequences and inversion recovery sequences. Additionally, based on their location outside of the brain, they can also be excluded when spatially selective pulses are used to restrict the acquired signal to being entirely within the brain (in-plane selection). Once a slice or slab of brain tissue has been selected for imaging, two (slice selection) or three dimensions (slab selection) of phase encoding are used to further subdivide the region into an array of pixels, each containing its own spectrum. Depending upon the size of coil used and field strength, typical volume sizes for individual pixels range from 0.25 to 1.0 cm^3 for the human brain. Examples of inversion recovery based lipid suppression for whole slice coverage and in-plane selection where only the medial temporal lobes were of interest are presented in **Figure 1**. These studies were acquired with 0.5–0.64 cm^3 resolution, with a volume head coil at 4T, and required 19 (0.64 cm^3) or 34 (0.5 cm^3) min.

In contrast, due to the lack of interfering unwanted resonances (i.e., lipids and water for ^{1}H measurements), ^{31}P data are typically acquired using three dimensions of phase encoding without any other form of spatial or spectra suppression. However, due to the low sensitivity of the ^{31}P nucleus, the spatial resolution is much lower than in ^{1}H measurements, with spatial resolutions of ~6 cm^3 for volume head coils (achievable for acquisitions of ~40 min at 4T). Finally, it should be noted that these resolutions are typical for human brain studies. In rodent models where the radiofrequency coils used for detection are much smaller (e.g., ~1–2 cm for rat brain), spatial resolutions of ~1–2 ul (^{1}H spectroscopic images) and 6–12 ul (^{31}P spectroscopic images) are readily achievable with acquisition times of ~40 min.

Results

^{1}H Spectroscopy and Temporal Lobe Epilepsy

In the mid 1990s, a number of investigators from different laboratories demonstrated the sensitivity of magnetic resonance spectroscopy (MRS) measurements of NAA to the lateralization of the epileptogenic region in patients with temporal lobe epilepsy. Specifically, changes in NAA content, and its ratio to other metabolites such as creatine, (NAA/Cr), choline (NAA/Ch), and the sum of creatine and choline (NAA/(Cr + Ch)) were used to lateralize the seizure focus in patients with intractable temporal lobe seizures (**Figure 1**). As a lateralization and localization tool, the reported sensitivities have ranged from 60% to 97%, somewhat higher than the 70–80% typically reported for conventional MRI studies. For example, one study reported that MR spectroscopic imaging, when combined with tissue segmentation, correctly lateralized the epileptogenic hippocampus in patients without MRI detectable volumetric loss. The ability of MR spectroscopy to attain higher sensitivities in comparison to standard imaging is most likely the result of the following factors: (1) that the metabolic perturbation seen in temporal lobe epilepsy is widespread, affecting not only the hippocampus (3–4 cm^3 in volume) but also surrounding temporal gray and white matter and (2) detectable decreases in hippocampal volume by conventional MRI may require neuronal losses of up to 50%. Thus, for temporal lobe epilepsy where the effects of the disease are macroscopic and submillimeter spatial resolution is not required, the biochemical specificity afforded by spectroscopy provides significant advantages over higher spatial resolution measurements of tissue water (as obtained with MRI).

In addition to providing a highly sensitive method for lateralizing the seizure focus, spectroscopic imaging studies may also provide some predictive insight into surgical outcome. Notably, among the patients classified as having unilateral temporal lobe epilepsy based on EEG measurements, some 40–50% have significant decreases in NAA in the contralateral hemisphere. These data indicate that although the seizures may emanate from one hippocampus, the effects are clearly manifesting themselves in the contralateral hemisphere. One study has correlated the severity of NAA/Cr alterations in the ipsilateral and contralateral hippocampi with surgical outcome; although the severity of NAA/Cr abnormality in the ipsilateral hippocampus did not appear to have a significant impact on surgical outcome, more severe alterations in the contralateral hippocampus were associated with poorer surgical outcomes (i.e., continuing seizures). Similarly, investigators have found that in MRI-negative patients, the presence of more severe reductions in NAA in the contralateral hippocampus also correlated with poorer outcomes following surgery. Further, in patients with bilateral disease, poorer surgical outcomes were associated with the presence of more severe reductions in the contralateral hippocampus. Thus, the presence of MRS defects in the contralateral lobe (in the presence or absence of MRI defects) is predictive of poorer surgical outcomes.

The significant decreases in NAA in patients with temporal lobe epilepsy is not restricted to the temporal lobe; reductions in NAA have also been reported in the frontal and parietal lobes. Further, using FDG PET, a number of investigators have reported that the thalamus is also affected in temporal lobe epilepsy. This latter work suggested the possibility of a network of metabolic defects involving the thalamus. To evaluate the relationship between various components of the macroscopic network,

we carried out an MRS study in which individual loci within the hippocampus, thalamus, and basal ganglia were averaged; a correlation analysis was then performed to evaluate the relationships between the ipsilateral and contralateral hippocampi with the other structures. This analysis identified highly significant correlations in decrements in NAA/Cr between the ipsilateral hippocampus (i.e., the side from which seizures arose) and the bilateral thalami and basal ganglia. An exceptionally strong correlation was detected between the ipsilateral hippocampus and the anterior thalamus ($R = +0.76$, $p < 1 \times 10^{-5}$). The contralateral hippocampus showed generally weaker correlations, and primarily with structures ipsilateral to the epileptic focus (hippocampus, anterior thalamus, and putamen ($p < 10^{-3}$–0.04). In contrast to the very strong correlations between the hippocampi, thalami and putamen in patients, no significant correlations were observed in controls between the hippocampi and thalamus within the same hemisphere or across hemispheres. Thus, it is clear that decreases in NAA not only reflect neuronal injury and the processes that give rise to epileptogenic foci, but also reflect injury/dysfunction in regions which are involved in the spread and or propagation of seizures.

NAA and Neocortical Epilepsy

The finding of decreased NAA is not solely restricted to temporal lobe epilepsy. Reduced NAA levels have been reported in a variety of other forms of epilepsy, including frontal lobe epilepsy and malformations of cortical development. Unlike temporal lobe epilepsy where the seizure focus is relatively well defined, in patients with neocortical epilepsy, the epileptogenic regions are often poorly defined anatomically, and there may be no accompanying MRI abnormality. This situation poses significant additional demands for MRS studies with regard to data acquisition and analysis. In addition to evaluating the observed ratios of NAA, Cr, and Ch in hundreds, if not thousands, of locations, such studies must also consider natural tissue-specific alterations. For example, as seen in Figure 1, white matter concentrations of Cr have been reported to be ~6 mM, while gray matter values are ~8–9 mM – and variations in the content of these same compounds have been reported between different lobes. Thus, depending upon the location of the region of interest and its mixture of gray and white matter, the 'normal' levels of metabolites will vary, complicating detection of 'abnormal' regions.

To overcome the effects of tissue heterogeneity, some investigators have employed linear regression analyses to compensate for the inclusion of varying levels of gray and white matter. Although these methods are most commonly used in global pathologies to identify gray or white matter specific alterations in comparison with control subjects, they can also be employed on a voxel by voxel basis within subjects. Using segmented anatomical images, the gray and white matter content of each spectroscopic imaging voxel can be determined. From these data, a regression analysis can be performed in healthy volunteers to obtain the 'pure' gray and white matter metabolite contents and ratios (Figure 2). With these population statistics, one can calculate the probability that any voxel of specific gray and white matter content in a patient is abnormal. Voxels that are statistically abnormal ($p < 0.05$) can then be color-coded according to p-value and superimposed on the anatomical images for easy evaluation and interpretation (Figure 2). When these regression based statistical methods are applied in patients with temporal lobe epilepsy, false negatives and incorrect lateralizations are reduced in comparison with simple left right voxel comparisons.

Interpretation of Decreased NAA levels

Despite the obvious linkage between neuronal loss in epilepsy and decreases in NAA, there have been few correlative in vivo studies. In epilepsy patients with malformations of cortical development, significant reductions were also observed in NAA/Cr in the epileptogenic region – but in the absence of neuronal loss. Resected tissue from these patients showed normal or elevated numbers of neurons, although morphologically the neurons were abnormal. Subsequently, Kuzniecky and colleagues demonstrated that NAA losses in patients with temporal lobe epilepsy were also not significantly correlated with neuronal densities. To further probe the histological basis for the alterations in NAA, we correlated in vivo measurements of NAA from the hippocampi of patients with intractable TLE with quantitative measurement of neuronal loss and reactive astrocyte proliferation in the resected tissue. Regression analyses of NAA/Cr measured in vivo with quantitative neuronal counting across CA1–CA4 and the dentate gyrus, revealed statistically significant correlations only in the CA2 sector. Interestingly, GFAP staining was also correlated with neuronal number only in the CA2 sector of the hippocampus. However, statistically significant correlations were found between NAA/Cr and GFAP staining across all four hippocampal sectors, suggesting that reductions in NAA/Cr are more closely correlated with the presence of reactive astrocytes than alterations in neuronal density in TLE. The presence of reactive astrocytes is largely interpreted as a marker for recent or ongoing neuronal injury. Interestingly, neuronal loss in the CA1, CA3, and dentate gyrus is typically believed to be largely due to the initial precipitating insult in temporal lobe epilepsy, while neuronal loss in the CA2 is more generally believed to correlate with the progression of the disease.

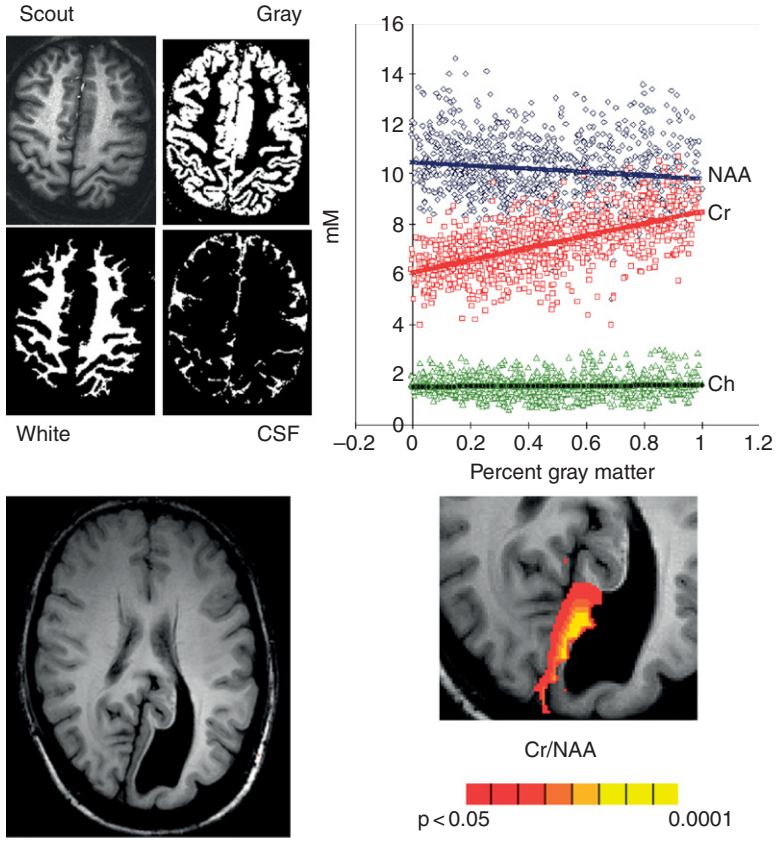

Figure 2 Displays a scout image and tissue segmented images of gray matter, white matter and CSF (upper left). Using the tissue composition data the concentrations of *N*-acetyl aspartate (NAA), creatine (Cr) and choline (Ch) for 10 volunteers (96 locations each) are plotted as a function of fraction gray matter. Displayed in the lower panel (left) is the scout image of an epilepsy patient with a cortical malformation. Using the regression data displayed in the upper right panel, the pixels from this patient which were metabolically abnormal ($p < 0.05$) based on an increased ratio of Cr/NAA (equivalent to a decrease in NAA and or increase in Cr) were color-coded according to significance and overlaid on the anatomical image. As can be seen, there is an excellent correspondence between the anatomical location of the cortical malformation and the metabolically abnormal region.

Given the lack of correlation between NAA levels and degree of neuronal loss in temporal lobe epilepsy and malformations of cortical development, the biochemical changes underlying the reductions in NAA are of significant interest. NAA has been reported to act as a source of acetate transfer from the mitochondria to the cytoplasm for lipid synthesis. Additionally, NAA has been proposed to act as a transporter of amino nitrogen from the mitochondria to the cytoplasm. NAA has also been proposed to act as an osmotic agent, based on its redistribution between extracellular/intracellular compartments in response to osmotic stress. Investigations of agents that perturb mitochondrial function have been demonstrated to affect NAA levels and production rates, and investigators have shown that with application of mitochondrial poisons (in isolated rat brain mitochondria) there is a significant decrease in ATP production, oxygen consumption, and NAA production. Such in vitro findings, identifying a linkage between NAA and bioenergetics, have also been found support in vivo studies. In a study of healthy control subjects, there was a highly significant correlation between hippocampal NAA levels and ADP. This relationship displayed a positive slope (with higher NAA levels associated with higher ADP levels), suggesting that NAA levels are responsive to demand for energy as reflected by increased ADP. This result is consistent with the finding that in epilepsy patients, who are well controlled (<4 seizures year), with cortical malformations of development, NAA levels are not altered despite the presence of structural abnormalities. Thus, in epilepsy patients with intractable seizures, the decreased NAA levels may reflect an inability to respond to energetic demand due to mitochondrial injury. This interpretation of NAA decreases would suggest that bio-energetic deficits (decreased PCr/ATP) should also be present in the hippocampi of patients with temporal lobe epilepsy – and that upon successful treatment, the decrement in NAA from affected loci should normalize.

This reversibility of the NAA changes in temporal lobe epilepsy has indeed been reported; NAA recovered in the

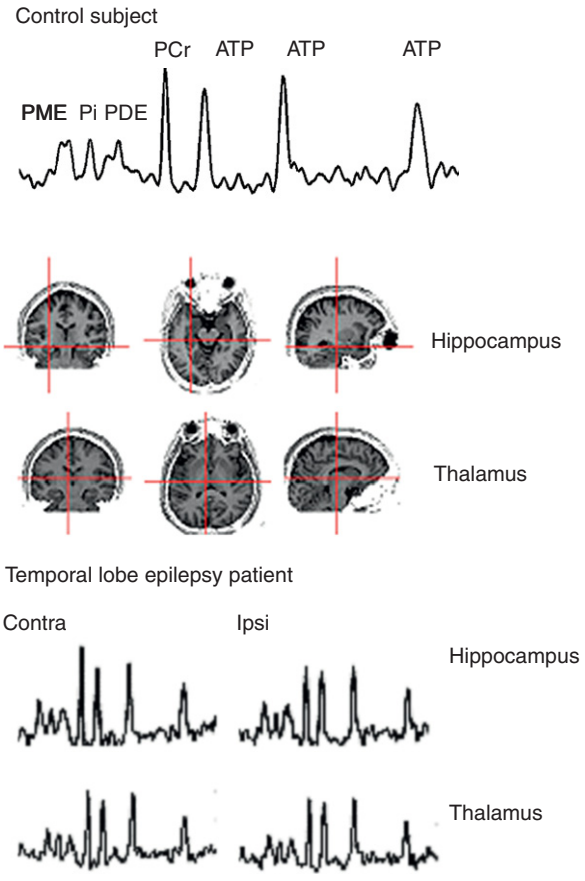

Figure 3 Displays a ^{31}P spectrum ~6 cm^3, acquired at 4 T. The labeled resonances from left to right are: phosphomonoesters (PME), inorganic phosphate (Pi), phosphodiesters (PDE), phosphocreatine (PCr), and ATP (γ, α, β). Displayed in the middle panel are anatomical scout images showing the locations of the ^{31}P spectra acquired from the hippocampus and thalamus. In the lower panel are ^{31}P spectra from the contralateral and ipsilateral hippocampus and thalamus from a patient with temporal lobe epilepsy. Note the reduction in PCr relative to ATP in the ipsilateral lobe in comparison to the contralateral lobe.

contralateral hippocampus in patients with bilateral abnormalities 1 year after successful surgery. In a follow up study, Arnold and colleagues found that, on average, 50% of the metabolic recovery occurred over a period of less than 6 months, demonstrating a slow but responsive nature of neuronal NAA levels. The reversibility of decreased NAA in the contralateral hippocampus with successful surgical outcome (i.e., cessation of seizures) suggests that the recovering NAA levels reflect a 'healing' or 'normalization' of cellular process in the contralateral hippocampus. The fact that NAA normalization is associated with 'normalization' of neuronal function suggests that the processes associated with NAA decrease directly reflect the dysfunction seen in epilepsy. However, it is not clear if the impairment in bioenergetics, as reflected by decreased NAA, is merely a secondary effect of the presence (reduced NAA) or absence (normalization of NAA) of seizures.

^{31}P Spectroscopic Measurements of Bioenergetics in Human Epilepsy

Prior to the widespread availability of ^{1}H spectroscopy on clinical MR systems, Weiner and colleagues evaluated the use of ^{31}P spectroscopy (for the lateralization of epileptogenic regions). In these initial studies at 2.0 T, significant increases in inorganic phosphate were reported in the temporal lobe ipsilateral to the focus, in comparison with the contralateral temporal lobe, in patients with temporal lobe epilepsy. Subsequent studies at 1.5 T showed that PCr/Pi was reduced by 50% in the ipsilateral (to the focus) temporal lobe and by 24% in the contralateral lobe in comparison with healthy controls – a result generally confirmed by a 4.1 T study (decreased ipsilaterally (32%) and contralaterally (19%)). Within this group, 73% of the patients were correctly lateralized using the PCr/Pi ratio. Similar to results with ^{1}H MRS, these effects were also seen throughout the epileptic network, including the thalamus (Figure 3). As patients with recent seizures (<24 h previous to the study) were excluded, these effects are believed to reflect a chronic impairment of energy metabolism (not an acute effect of seizures), consistent with a mitochondria-based deficit leading to NAA reductions.

Declines in bioenergetics are also seen in a variety of other forms of epilepsy, including children with Lenox–Gasteau syndrome and absence seizures, and in adults with frontal lobe epilepsy. In children with Lenox–Gasteau and absence seizures, a nonfocal form of epilepsy, PCr/ATP was decreased in the cortical gray matter in comparison with control subjects. Notably, no such change was seen in white matter, reflecting a specificity for neuronal cell bodies/dendrites and their high energetic demands. In patients with frontal lobe epilepsy, investigators reported elevations of inorganic phosphate, consistent with a decrease in overall energy charge. Thus, the finding of bioenergetic impairment is not restricted solely to temporal lobe epilepsy, but may reflect a basic mechanism underlying many forms of epilepsy.

Factors Affecting the Interpretation of ^{31}P Data

Although ^{31}P studies have shown that abnormalities in bioenergetics are present, their use to date has been limited. Limited use of ^{31}P spectroscopy can be attributed, in part, to the large range of normal values for cerebral PCr (3–5 mM) and ATP (2–4 mM) in low field studies, and the resulting perception that ^{31}P spectroscopy is highly inaccurate. This view was due to the fact that initial reports used large volumes (25–100 cm^3) and did not attempt to account for tissue or regional heterogeneity. Although spatial resolution for ^{31}P studies is limited by the signal to noise ratio, recent studies at high field strength have identified clear regional and tissue specific heterogeneities in ^{31}P metabolites using regression

analyses. Depending upon the content of gray matter in the tissue, the ratio of PCr/ATP in cerebral structures varied by ~40% Thus, failure to account for these differences can result in substantial variability that is not reflective of underlying pathology, but rather normal heterogeneity based on tissue composition.

Interpretation of Alterations in ^{31}P Metabolism in Epilepsy

As seen in the ^{1}H studies, ^{31}P spectroscopic imaging suggests that the energetic deficits seen in TLE patients are reversible with successful surgery. In pediatric epilepsy patients being treated with the ketogenic diet, bioenergetic impairments present prior to initiation of the diet were reversed as the seizures were brought under control. Specifically, after 4 months of the ketogenic diet therapy, the PCr/Pi and PCr/ATP ratios had improved by 22% and 14% respectively. Thus, both reductions in NAA and impairments in bioenergetics appear to be tightly linked with seizure activity and can be reversed with successful treatment. This finding also indicates that the alterations in ^{31}P metabolites are not solely due to neuronal death, but reflect a dynamic and reversible process. Although the exact mechanism for the ketogenic diet remains controversial, it is known that ketones can supplement or replace glucose as a fuel source for oxidation, thus potentially modulating bioenergetics. While it appears clear that there is a significant bioenergetic component to the etiology of seizure disorders, it remains unclear as to whether this association reflects general damage associated with seizures or is a causative factor.

Glutamate and GABA: Intracellular Alterations in Neurotransmitters

As described, most measurements using MR spectroscopy and spectroscopic imaging have focused on measurements of NAA, creatine, choline, and to a lesser extent, ^{31}P metabolites. Together, these measurements have suggested a strong role for metabolism and bioenergetics in the pathophysiology of epilepsy. However, these measurements do not directly assess the neurotransmitter changes which occur in epilepsy. Both glutamate and GABA can be measured in vivo, using ^{1}H MRS and other specialized methods.

Glutamate is the primary excitatory neurotransmitter in human brain. The finding of elevated extracellular glutamate and decreased rates of glutamate uptake in epileptogenic hippocampi have sparked substantial interest in measuring in vivo glutamate levels in patients with epilepsy. However, unlike the main resonances of NAA, Cr, and choline, which are singlet resonances, glutamate's primary resonances are triplets or higher order multiplets (**Figure 4**). This feature substantially reduces their detection, because the signal intensity is distributed over a broader range of frequencies. Further, unlike NAA and other singlet resonances, the appearance of these multiplets is strongly dependent upon the exact timings of the acquisition method used. As such, specialized sequences and timings are required for their detection, making their measurement more demanding. Due to spectral overlap with glutamine, low field measurements (1.5 T) are exceptionally difficult to interpret. However, with increasing field strength (3 T, 4 T and most recently 7 T), these hurdles can be overcome.

Although much less common than measurements of NAA, a number of investigators have evaluated glutamate content in patients with temporal lobe epilepsy. For example, one study reported that the combined resonance of glutamate and glutamine (the signals were not resolvable at 1.5 T) was decreased in EEG-defined neocortical epileptogenic regions (in comparison with the corresponding contralateral location). Others have reported that the combined resonance of glutamate and glutamine was alternately elevated in ipsilateral or contralateral hippocampus of MRI negative TLE patients. Using 4 T (where the resonances of glutamate and glutamine can be better resolved), Pan and colleagues evaluated a group of temporal lobe epilepsy patients, and showed that ipsilateral glutamate and NAA were significantly decreased (5.1 ± 1.2 and 8.0 ± 1.1 mM) in comparison with controls (6.7 ± 1.5 and 9.5 ± 1.0 mM), respectively, yielding declines of ~25% in glutamate and ~16% in NAA (**Figure 4**). Notably, the MRS measurement of glutamate reflects total tissue glutamate levels including both intracellular levels of glutamate (5–10 mM) and extracellular levels (1–10 μM). Thus, even moderate losses in cytosolic glutamate, or of glutamatergic neurons, can dominate significant elevations in the extracellular concentration of glutamate (as reported from microdialysis studies). As such, the reductions in total glutamate level reported by Pan are consistent with glutamatergic neuron loss. The greater fractional decline in glutamate, as opposed to NAA, suggests that measurements of glutamate may be more sensitive than measurements of NAA in identifying epileptogenic regions. However, this advantage is likely to be realized only at very high field strengths (7 T) where SNR and spectral resolution are less limiting.

As the primary inhibitory neurotransmitter for mammalian brain, GABA and its receptor systems have been an area of intense study. Due to its low concentration (~1 mM) and spectral overlap with glutamate, glutamine, and creatine, the measurement of GABA requires the use of specialized methods, commonly referred to as 'spectral editing.' These methods typically utilize the unique frequencies of the ^{1}H resonances of GABA to selectively perturb the GABA resonance in alternating scans, and through that interaction modulate the appearance of the

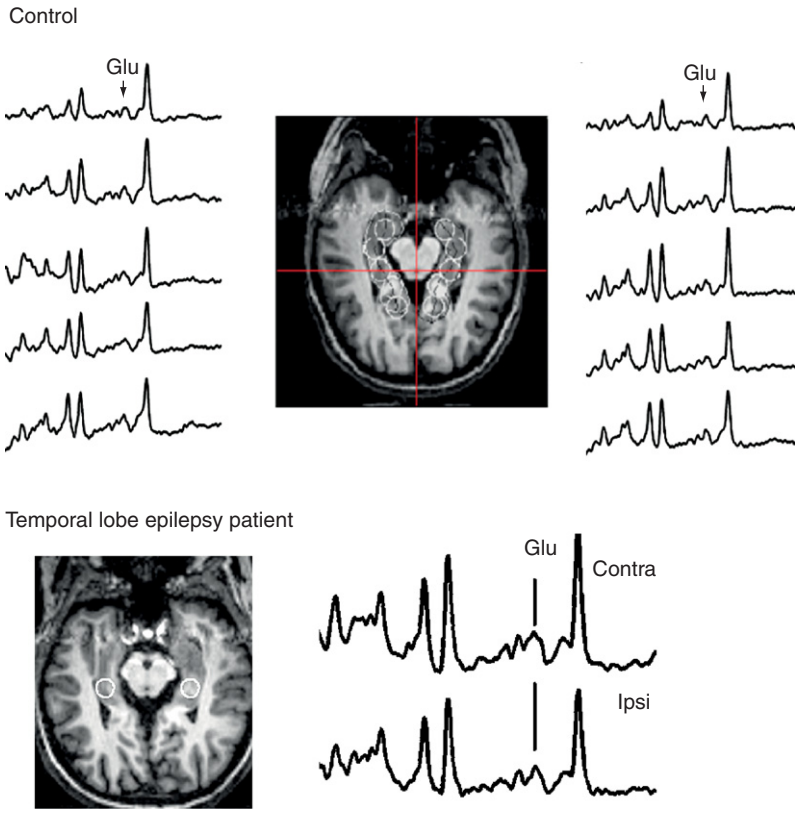

Figure 4 The upper panel displays ^{1}H spectra of glutamate (glu) from the right and left hippocampus of a control subject. The locations of the spectra are identified with white circles on the anatomical image. Displayed in the lower panel are data acquired from a patient with temporal lobe epilepsy. Note that that the glutamate (glu) and NAA resonances are significantly decreased in the ipsilateral hippocampus in comparison to the contralateral hippocampus.

adjacent ^{1}H resonance on the GABA molecule. As other resonances are not affected by the selective perturbation, subtraction of the two measurements results in an 'edited' spectrum, displaying the GABA resonance free of spectral overlap (**Figure 5**).

Given the difficulties of low SNR, the majority of MR studies have evaluated the occipital lobe, where small highly sensitive surface coils can be placed in close proximity to the tissue. For example, one study examined the resting levels of occipital GABA in patients with complex partial seizures (CPS) and juvenile myoclonic epilepsy (JME). In the CPS group, low GABA was associated with poor seizure control, while JME patients showed low GABA independent of seizure control. These findings of reduced in vivo GABA are similar to those reported by Petroff in a variety of other forms of epilepsy. Notably, the occipital lobe represents a site distant from the presumed epileptogenic region. To evaluate the role of GABA in the seizure focus, another study acquired data from patients with occipital lobe seizures, but failed to identify a decrease in GABA. This result may be due to the fact that the study used a volume coil (lower sensitivity) and the test–retest accuracy for GABA in controls was only 38%. Thus, whether GABA is increased or decreased in the epileptogenic region remains and open issue.

Despite this uncertainty of the status of intracellular GABA levels in the seizure focus, in vivo measurements of GABA have become highly useful in assessing the response of various antieplipetics. For example, Petroff and colleagues established an in vivo dose–response curve for vigabatrin, an inhibitor of GABA transaminase. Dose escalation revealed increases in cerebral GABA as a function of vigabatrin level up to 3 g day^{-1}. Above 3 g day^{-1}, brain GABA levels were constant (did not rise further), indicating a maximal effect on brain GABA. Although the mechanism for the elevation of GABA in response to vigabatrin is clear, other common antiepileptic drugs (AEDs) have also been shown to result in elevation of GABA. For example, Kuzniecky and colleagues demonstrated that topiramate, gabapentin, and lamotrigine can all raise brain GABA levels in control subjects under acute (topiramate and gabapentin) and chronic (lamotrigine) conditions. Conversely, other AEDs such as levetiracetam have been shown to have no effect on brain GABA. One limitation of this work is that due to the low sensitivity of the GABA measurements (arising from its low concentration in human brain – about 1 mM), the majority of studies of brain GABA have been performed in the occipital lobe, where the measurements reflect a global response of the brain to seizures and pharmaceutical interventions.

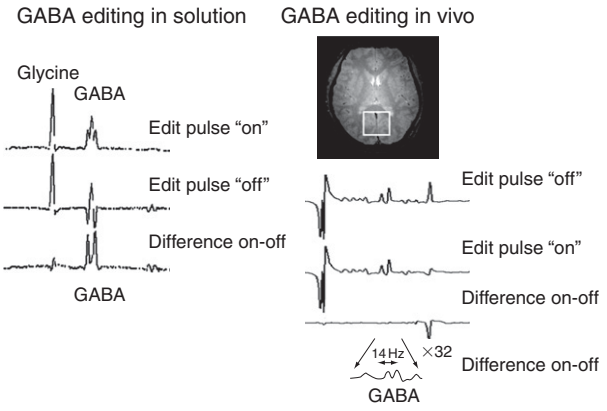

Figure 5 Displays spectral editing data acquired from a solution of GABA and glycine (left panel) and from the occipital lobe of a healthy control subject (right panel). In the solution (left panel), the triplet resonance of GABA is upright with the editing pulse 'on' while the outer lines invert when the editing pulse is 'off.' Differencing the two spectra results in: (a) elimination of the glycine resonance (not affected by the editing pulse); and (b) preservation of the outer two lines of the GABA triplet which are separated by ~14 Hz. In the panel on the right, the GABA resonance is overlapped by the creatine resonance and only visible after editing (difference on-off). Note the elimination of the creatine and choline resonances in the difference spectrum. Displayed at the bottom of the panel is an expanded region about the creatine resonance where the vertical scale has been increased by a factor of 32 to allow the two outer lines of the GABA resonance (separated by 14 Hz) to be visualized.

Finally it is important to note that the findings of increased GABA in response to gabapentin and topiramate were contrary to those described in the rodent literature. In subsequent studies, Petroff and colleagues demonstrated that the differential effect of gabapentin was due to a species difference. Specifically, gabapentin had no effect on GABA levels in the rat brain slices, but significantly increased GABA levels in the slices from human brain. Similarly, no effects of gabapentin on GABA levels were seen in the in vivo rat brain as assessed by tissue extracts. Thus, while investigating the effects of various drugs or interventions with the potential to affect the GABAergic system, it is important to take into account the species difference between humans and rodents.

Directions for Future Research

Despite the ability of MR spectroscopic imaging to noninvasively localize epileptogenic regions, determine the status of bioenergetics, and monitor change in brain GABA levels, its use remains relatively limited to research studies. This fact is primarily due to limitations in the signal to noise ratio and spectral resolution achievable in conventional (1.5 T) clinical studies. Over the past several years, new ultra-high field (7 T) MR imaging systems have become available from major vendors of clinical MRI systems. In addition to dramatic improvements in sensitivity, more than fivefold greater than standard 1.5 T clinical systems, the systems also offer dramatic improvements in spectral resolution, substantially enhancing the accuracy of MRS measurements of GABA and glutamate. With these newer systems becoming more common, the use of MRS in the localization of epileptogenic regions in neocortical epilepsy and in monitoring the response to therapy should be significantly enhanced. However, at 7 T, interactions between the radiofrequency pulses used to generate the data and the tissue become complex. These interactions result in complex spatial inhomogeneities in detector sensitivity and significant increases in tissue heating for conventional head coil designs and pulse sequences. Such effects are sufficiently severe that standard MRS spatial localization methods used at 1.5 T can easily exceed FDA guidelines for power deposition when applied at 7 T. Thus, to achieve the substantial benefits of this new generation of MR systems for spectroscopic imaging studies, new methods which incorporate novel detector designs and pulse sequences need to be developed.

PET Neurotransmitter Receptor Imaging in Epilepsy

W H Theodore, NINDS NIH, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Positron emission tomography (PET) is a technique that offers the opportunity to build a bridge from epilepsy investigations in cellular and animal models to clinical research. Hypotheses developed in experimental animals can be tested in man using radiolabelled neurotransmitter receptor ligands as PET tracers. Questions about the mechanisms of action of antiepileptic drugs can be addressed. Investigation of depression in people with epilepsy is an excellent example of the value of PET. Depression is one of the most common co-morbidities of the disorder, occurring in more than 30% of patients in some studies, and contributing to reduced quality of life. A wide range of etiological factors could lead to depression. Social and psychological mechanisms include stigma, inability of work with reduced income, and social isolation. Some studies have suggested that patients with temporal lobe epilepsy, or a left temporal focus, or mesial temporal sclerosis, may be more likely to be depressed. PET receptor imaging offers an opportunity to assess the role of neurotransmitter systems that have been implicated in the etiology of major depressive disorders in preclinical investigations.

Background/Methodologic Issues

Several methodological issues affect PET investigations. PET depends on radiochemistry, and successful ligand development can take years of work. For interpretation of neurotransmitter receptor ligand imaging, a mathematical model is needed that relates injected tracer to radioactive decay counts (measured by the scanner), and takes into account tracer protein binding and metabolites. The 'input function' can be derived from arterial blood samples, or from radioactivity in a structure thought to have no specific binding (and thus to represent activity from blood flow alone). Although fluorodeoxyglucose PET has become a routine tool, for cardiac and oncologic as well as neurologic applications, the visual interpretation often used in these studies never is appropriate for receptor binding investigations (and may be misleading in clinical contexts).

^{18}F or ^{11}C-labeled neuroreceptor ligands or precursors are important for epilepsy. The half-life of ^{11}C is 20 min, so an on-site cyclotron is needed to produce it; in contrast, ^{18}F (half-life 110 min) can be brought in from outside the scanning facility. Current PET scanners produce sets of 30–50 images that can be reconstructed with true 3-D resolution. The spatial resolution of the newest PET scanners is 2–3 mm.

Given the limitations of human radiation exposure, as well as the difficulty and expense of performing multiple studies, it generally is not possible to obtain the multiple data points needed to distinguish between changes in receptor number or dissociation constant, either of which could explain a change in binding potential. However, the former is much more likely on theoretical grounds.

In patients with epilepsy, and particularly those with focal lesions such as mesial temporal sclerosis or malformation of cortical development, alterations in tissue structure (including gray-white ratio due to volume loss) may affect neurotransmitter ligand binding. MRI-based partial volume correction programs should be used to correct for this effect.

PET Neurotransmitter Receptor Imaging in Epilepsy

W H Theodore, NINDS NIH, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Positron emission tomography (PET) is a technique that offers the opportunity to build a bridge from epilepsy investigations in cellular and animal models to clinical research. Hypotheses developed in experimental animals can be tested in man using radiolabelled neurotransmitter receptor ligands as PET tracers. Questions about the mechanisms of action of antiepileptic drugs can be addressed. Investigation of depression in people with epilepsy is an excellent example of the value of PET. Depression is one of the most common co-morbidities of the disorder, occurring in more than 30% of patients in some studies, and contributing to reduced quality of life. A wide range of etiological factors could lead to depression. Social and psychological mechanisms include stigma, inability of work with reduced income, and social isolation. Some studies have suggested that patients with temporal lobe epilepsy, or a left temporal focus, or mesial temporal sclerosis, may be more likely to be depressed. PET receptor imaging offers an opportunity to assess the role of neurotransmitter systems that have been implicated in the etiology of major depressive disorders in preclinical investigations.

Background/Methodologic Issues

Several methodological issues affect PET investigations. PET depends on radiochemistry, and successful ligand development can take years of work. For interpretation of neurotransmitter receptor ligand imaging, a mathematical model is needed that relates injected tracer to radioactive decay counts (measured by the scanner), and takes into account tracer protein binding and metabolites. The 'input function' can be derived from arterial blood samples, or from radioactivity in a structure thought to have no specific binding (and thus to represent activity from blood flow alone). Although fluorodeoxyglucose PET has become a routine tool, for cardiac and oncologic as well as neurologic applications, the visual interpretation often used in these studies never is appropriate for receptor binding investigations (and may be misleading in clinical contexts).

^{18}F or ^{11}C-labeled neuroreceptor ligands or precursors are important for epilepsy. The half-life of ^{11}C is 20 min, so an on-site cyclotron is needed to produce it; in contrast, ^{18}F (half-life 110 min) can be brought in from outside the scanning facility. Current PET scanners produce sets of 30–50 images that can be reconstructed with true 3-D resolution. The spatial resolution of the newest PET scanners is 2–3 mm.

Given the limitations of human radiation exposure, as well as the difficulty and expense of performing multiple studies, it generally is not possible to obtain the multiple data points needed to distinguish between changes in receptor number or dissociation constant, either of which could explain a change in binding potential. However, the former is much more likely on theoretical grounds.

In patients with epilepsy, and particularly those with focal lesions such as mesial temporal sclerosis or malformation of cortical development, alterations in tissue structure (including gray-white ratio due to volume loss) may affect neurotransmitter ligand binding. MRI-based partial volume correction programs should be used to correct for this effect.

Once the data are obtained, a number of statistical approaches (such as the widely used program 'statistical parametric mapping (SPM),' developed by the Wellcome Institute) can be used to compare patient results with control databases. Each of the available statistical methods has underlying assumptions, advantages and disadvantages that are important to keep in mind.

In standard region of interest (ROI) analysis, anatomic regions are drawn, preferably on co-registered MRI images, and compared with contralateral or control regions. Here, there usually is an a priori hypothesis to be tested. Increasing the number of regions necessitates correction for multiple comparisons. This approach has important advantages when patients with focal dysfunction or lesions are being studied.

SPM uses spatial normalization of individual images to a standard spatial template, which facilitates group comparisons, but may mask some inter-patient differences. It is, however, observer independent, and avoids ROI drawing errors, which can be particularly serious for small structures or regions with indistinct borders. Correction for multiple comparisons is built into the program. Since all brain regions are compared, unexpected findings may emerge.

Single photon emission tomography (SPECT) also can be used for receptor imaging. Compared with PET, spatial resolution is lower, and quantitation is much more difficult, reducing SPECT's value for research.

Recent Results of Potential Clinical and Physiologic Importance

One of the recurring themes of PET receptor imaging in epilepsy has been transient enthusiasm for a receptor system, often due to availability of a particular ligand, followed by sudden abandonment of the research direction. Studies of opiate receptors in patients with temporal lobe epilepsy are a good example. Several investigators used a reference region method (with occipital cortex as a measure of non-specific binding) to show that μ opiate-receptors were increased in inferior temporal lateral neocortex ipsilateral to epileptic foci, and decreased in amygdala, compared with the contralateral structures. δ receptors were increased in more widespread ipsilateral temporal regions and κ receptors reduced. An interesting study using arterial blood sampling to obtain voxel-based parametric images showed reduced ^{11}C-diprenorphine (a ligand with little receptor subtype specificity) binding during reading-induced seizures, suggesting ictal opiate release in left parieto-temporo-occipital cortex, possibly associated with seizure termination.

However, theses studies have not been pursued in recent work. One important reason was that their clinical relevance and utility remained unclear. Instead, focus has shifted to other receptor systems, including benzodiazepines, and dopaminergic and serotoninergic ligands. These studies will be discussed below to illustrate potential implications of the results and approaches to interpretation.

[^{11}C]flumazenil (FMZ) PET benzodiazepine receptor binding has been the focus of greatest interest; since loss of receptors is presumed to be associated with increased cortical excitability. Binding is reduced ipsilateral to temporal and frontal lobe epileptic foci. In patients with hippocampal sclerosis, reduction often is confined to mesial temporal regions, even when hypometabolism on FDG-PET scans is widespread. Ocassionally, reduced benzodiazepine receptor binding can be detected in patients with intractable localization-related epilepsy even when MRI and FDG-PET are normal. In patients with cortical dysplasia, benzodiazepine receptor binding may correlate well with the ictal onset zone (determined by invasive electrode recording within the dysplastic region). In some studies, white matter binding increases for flumazenil have been reported, possibly due to the presence of heterotopic gray matter.

Receptor binding could be affected by various physiologic processes. In one study, patients with drug-resistant epilepsy underwent two FMZ-PET scans at a 1 week interval, in order to investigate seizure-related short-term receptor plasticity. Five of ten patients, but no controls, had variability in the binding ratio between mesial temporal structures ipsilateral and contralateral to the epileptic focus. For two patients with normal structural MRI, significant binding reduction ipsilateral to the focus was found in only one of the two PET scans. In a third patient, reversal of the asymmetry occurred, and one of the scans was falsely lateralizing. A shorter interval between the last seizure and the FMZ PET scan was associated with closer agreement between imaging and EEG seizure focus localization. The shorter the time since the last seizure, the lower the benzodiazepine receptor binding in the epileptogenic region. This study used a partial saturation approach with combined injection of labeled and cold FMZ, allowing calculation of parametric binding images without arterial blood sampling. Several issues may affect interpretation of the results. For example, interictal discharges, which were not analyzed in this study, could have led to fluctuations in receptor availability and FMZ binding. In addition, the PET scan with the shorter interval since the ictal event would also have had a shorter interval since the pre-ictal events that preceded that seizure. Thus, it is uncertain whether the decrease in receptor availability is attributable to ictal or pre-ictal events. Recent EEG studies show that increased subclinical epileptiform discharges may precede clinical seizures by hours or even days, suggesting a potential correlate of pre-ictal alterations in

GABA-benzodiazepine receptor binding. The FMZ results parallel earlier results with fluorodeoxyglucose, showing metabolic variability in the peri-ictal period. However, these results suggest that PET studies cannot be assumed to reflect steady-state conditions in people with epilepsy, and that careful clinical observation is crucial for their interpretation.

Antiepileptic drugs (AEDs) might also affect receptor binding, especially when the AED is thought to have a mechanism of action directly related to the system in question. Vigabatrin (VGB) is an antiepileptic drug that acts by elevating brain gamma-aminobutyric acid (GABA) levels, and thus might affect ^{11}C-FMZ binding at the GABA-benzodiazepine receptor complex. FMZ binding was significantly lower in children with intractable epilepsy who had been taking VGB for prolonged periods than those on other AEDS. VGB increases synaptic GABA availability, and long-term exposure to supra-physiologic levels might have led to decreased receptor availability, or possibly changes in maturational patterns, and altered FMZ binding. The investigators suggested that their data showed how PET could be used to pose questions about the long-term developmental effects of AEDs.

Almost all epilepsy receptor studies have been performed in patients with long-term uncontrolled seizures. One study used the parallel SPECT benzodiazepine receptor ligand ^{123}I-iomazenil tracer in patients with new onset temporal lobe epilepsy (median duration seven months) and normal MRI. Nineteen of 40 patients (including some with infrequent seizures) had reduced tracer activity in mesial temporal regions. Since these patients had only had seizures for a short time, and MRI was normal, it is possible that the reduced BZP receptor binding found here preceded seizure onset, and was not a consequence of persistent epilepsy. PET studies of glucose metabolism in children with new-onset seizures have shown that the presence of focal hypometabolism at initial evaluation predicts development of intractable epilepsy.

Recent studies have shown reduced basal ganglia ^{18}F-fluoro-L-DOPA binding in patients with several epilepsy syndromes, suggesting that these regions may be involved in secondary seizure spread. Occipital cortex activity was used as the input function to calculate relative striatal isotope uptake using multiple-time graphical analysis. Patients with three epilepsy syndromes (ring chromsome 20 epilepsy, drug-resistant generalized 'absence-like' epilepsy, and drug-resistant temporal lobe epilepsy with hippocampal sclerosis) were studied. Comparing all epilepsy patients to normal controls, binding decreases were found bilaterally in caudate and putamen. Reduced substantia nigra tracer uptake was found only on analysis with SPM, but not with a region of interest approach. SPM, but not ROI analysis, also detected reduced binding ipsilateral to hippocampal sclerosis in the TLE patients. The difference in results using alternative analytic approaches in these studies illustrates the problems inherent in the small sample sizes typical for receptor PET investigations. Other potential confounders include the effects of antiepileptic drugs and structural atrophy. ^{18}F-fluoro-L-DOPA is a relatively non-specific ligand, and cannot discriminate among alterations in receptor subtype binding; an important change in one subtype but not others might be difficult to detect. Moreover, as with other receptors, it may be hard to determine whether reduced dopaminergic receptor binding is a cause or consequence of epilepsy.

Several studies by a number of research groups have shown reduction of 5HT1A receptor binding in patients with TLE. Regions affected include hippocampus, amygdala, parahippocampal gyrus, entorhinal cortex, and varying neocortical regions (both ipsilateral to the epileptic foci, as well as sometimes contralaterally). In addition, the midbrain raphe, where serotoninergic fibers projecting to cortex originate, show reduced presynaptic autoreceptor binding. Similar results have been found with three different ligands ([Carbonyl-^{11}C]WAY-100635, ([^{18}F]FCWAY, and ^{18}F-MPPF), and using region of interest as well as SPM analysis. Each of the three ligands has advantages and disadvantages. The long half-life of ^{18}F allows longer imaging time and higher decay counts. WAY-100635 has higher specific binding than MPPF, but FCWAY has a fluoride metabolite that has to be measured and corrected for in image analysis. The magnitude of reduction appears greatest in the zone of seizure onset, usually in hippocampus, with receding effects in zones of seizure spread or regions where only interictal spikes are seen. After MRI-based partial volume correction, only about 20% of the reduced binding could be attributed to volume loss (**Figure 1**). Moreover, reduced binding occurs in patients with mesial temporal lobe foci but normal MRI. It is interesting that patients with juvenile myoclonic epilepsy, a generalized rather than localization-related epilepsy syndrome, showed reduced 5HT1A receptor binding in the dorsolateral prefrontal cortex, raphe nuclei, and hippocampus.

PET studies using the serotonin precursor, alpha methyl tryptophan (AMT) labeled with ^{11}C, using ROI-based asymmetry indices, showed increased uptake in epileptogenic tubers in patients with tuberous sclerosis, as well as in malformations of cortical development in children. In patients with partial epilepsy, AMT uptake was increased in patients with normal MRI (including several with negative FDG-PET results) but not those with hippocampal volume loss; partial volume correction was not performed in these studies.

These PET findings are consistent with the antiseizure effects of 5HT1A receptor activation in experimental models. Although it is uncertain if reduced binding occurs at the onset of epilepsy, or is related to progression of the epileptic process, 5HT1A receptor loss

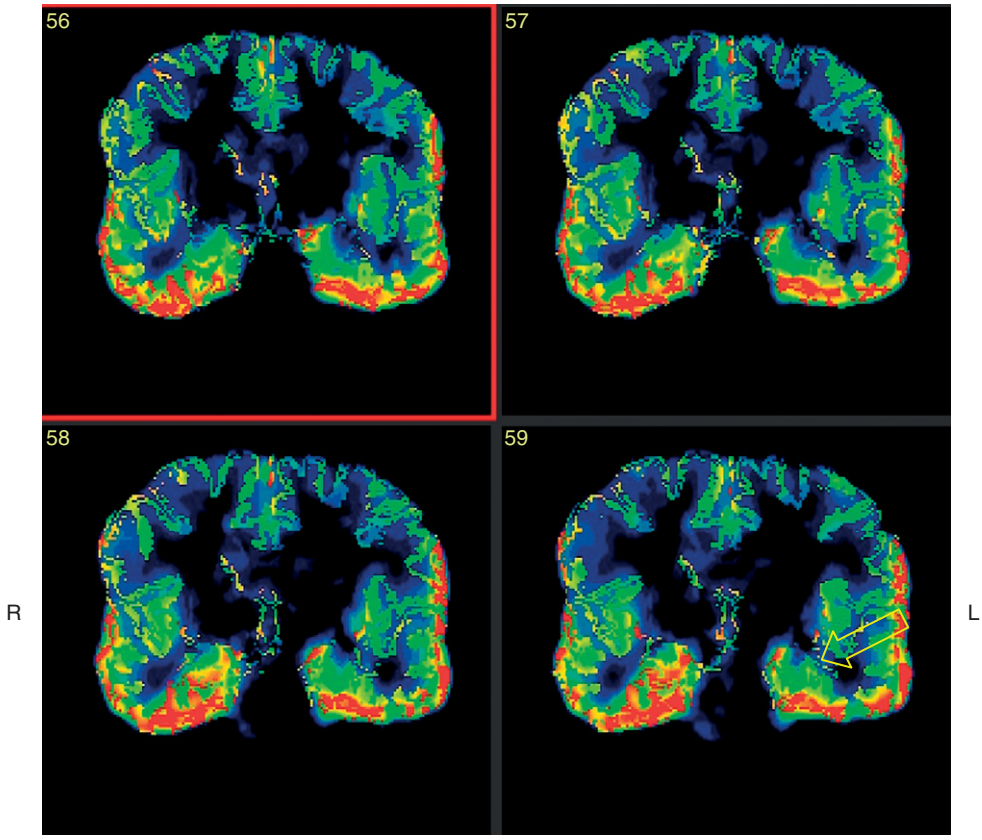

Figure 1 ^{18}F-FCWAY PET scan showing reduced tracer volume of distribution, after partial volume correction, in left hippocampus and parahippocampal gyrus in a patient with left mesial onset temporal lobe epilepsy.

might occur in an early stage in the development of mesial temporal sclerosis. 5HT1A receptor activation promotes cell proliferation in hippocampus by a direct post-synaptic effect. Reduced receptor binding is found in patients with depression, in association with hippocampal atrophy (although not the gliosis seen in TLE). It has been suggested that the increased precursor uptake seen in AMT PET studies might be due to diversion of the serotonin precursor AMT into alternate, excitatory pathways, as well as to increased serotonin synthesis in response to receptor loss.

Patients with depression as well as epilepsy have greater 5HT1A binding reduction than those with epilepsy alone (Figure 2). Reduced binding in regions beyond the focus, such as the cingulate gyrus, have been shown to be associated with depression in epilepsy as well as primary major depressive disorders. In these studies, focus side and the presence of mesial temporal sclerosis were not associated with the presence of co-morbid depression.

One PET study targeted to a known physiologic abnormality in a specific epilepsy syndromes was performed in patients with autosomal dominant nocturnal frontal lobe epilepsy (who have mutations in the nAChR alpha4 or beta2 subunit). PET studies using [^{18}F]-F-A-85380, a high affinity agonist at the alpha4beta2 nAChRs, showed increased binding in mesencephalon, pons and cerebellum, and decreases in the dorsolateral prefrontal region when compared to control subjects. The nAChR density increase in mesencephalon may reflect altered ascending cholinergic arousal mechanisms.

Challenges for the Future

PET receptor studies depend on the radiochemical synthesis of interesting ligands. One system that would be of particular interest is the excitatory amino acid system. Several attempts to produce a useful tracer have been unsuccessful so far. Attempts to develop useful excitatory amino acid receptor ligands have been unsuccessful, in part due to high non-specific binding. In an older study, the *N*-methyl-*D*-aspartate (NMDA) receptor ligand ^{11}C-labeled (*S*)-[*N*-methyl]ketamine, showed reduction of tracer radioactivity in epileptogenic temporal lobes, possibly due to focal atrophy. Some recently g-protein coupled metabotropic gluR5 receptor ligands may be promising.

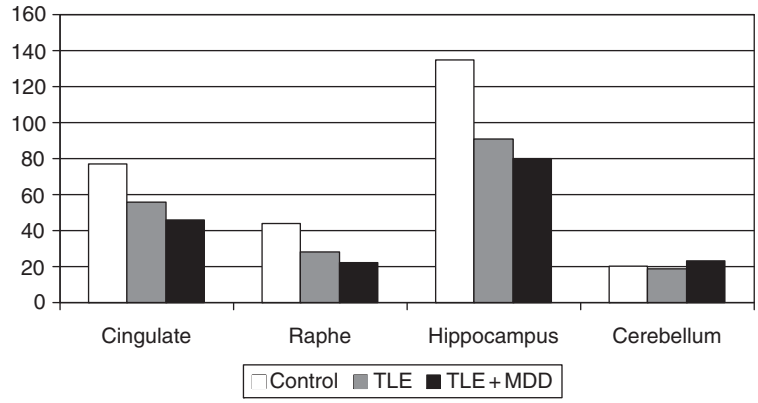

Figure 2 Comparison of 5HT1A receptor binding potential in patients with temporal lobe epilepsy with and without major depressive disorder as assessed by the standardized clinical interview for depression, and normal volunteers. Reduced binding was found in patients with both epilepsy and depression, compared to patients with epilepsy alone and controls. Overall binding is greater for all groups in the hippocampus, a structure wit the greatest concentration of 5HT1A receptors. No differences were found in cerebellum, a structure with a very low receptor concentration.

It would also be very useful to have a way to investigate binding at the GABA receptor site itself (in addition to the linked benzodiazepine receptor), and to have a means to study possible receptor conformation changes. For serotonin, other receptor subtypes in addition to 5HT1A are of interest.

Finally, ligands that can be used to image brain inflammatory changes are under development. These ligands will be helpful in testing recent hypotheses, e.g., regarding the viral and immunologic mechanisms for epilepsy.

Physiologic Correlates of Metabolic Imaging in Human Epilepsy

J W Pan, A Williamson, I Cavus, H Zaveri, D Spencer, and H P Hetherington, Yale University School of Medicine, New Haven, CT, USA

Introduction

There is extensive evidence that metabolic dysfunction is common in human epilepsy. The regional localization of such dysfunction is frequently specific enough to identify the seizure onset zone in many patients. As a measure of total glucose consumption, ^{18}fluorodeoxyglucose PET is commonly used to identify hypometabolic areas. The success rate of FDG PET in identifying the seizure onset zone depends very much on the nature of the epilepsy, with the best localization rates of ~80–90% in temporal lobe epilepsy. FDG PET is clearly less successful in the nonlesional neocortical epilepsy patients. In the mid-1990s, a number of investigators demonstrated the high sensitivity (70–100%) of magnetic resonance spectroscopy (MRS) and MRS imaging (MRSI) based methods using decrements in *N*-acetyl aspartate (NAA) to localize the seizure onset zone in mTLE patients. As NAA is synthesized only in neuronal mitochondria, and is strongly correlated with oxidative metabolism, it provides a complementary approach to PET, which evaluates total glucose consumption. More recent work in healthy volunteers has also shown a tight positive relationship between NAA and ADP, a key regulator of metabolic flux. Thus, NAA and its ratio to creatine may well be expected to sensitively reflect the mitochondrial capacity to meet metabolic demand.

Background

Studies in epilepsy patients with cortical malformations have revealed that NAA changes are specific to the epileptogenic zone, and are 'normal' in patients whose seizures are well controlled. Furthermore, in patients with on-going seizures, the regions that are anatomically abnormal but nonepileptogenic also displayed normal NAA levels. An important aspect of the MRSI approach has been its ability to provide more quantitative evaluations – i.e., without the use of asymmetry indices and without being biased by tissue loss. As a result, many of the studies using spectroscopy have shown the frequent occurrence of bilateral involvement in temporal lobe epilepsy (**Figure 1**), which has since also been reported by conventional and diffusion weighted imaging.

In addition to the role of metabolic imaging for seizure localization and lateralization, an important aspect of MRSI has been its contribution to our understanding of how metabolic dysfunction may contribute to the pathophysiology and pathology of human epilepsy. Using data obtained from intracranial monitoring, pathology, and electrophysiology obtained from resected specimens, we may better define the clinical and pathophysiologic meaning of aberrant NAA/Cr, high energy phosphates and glutamate. In turn, the dynamic range of MRSI-determined bioenergetic and mitochondrial dysfunction (as reflected across different patients) may help to explain how energetic state and capacity influence key parameters of hyperexcitability. In this article, we discuss how metabolic imaging may relate to neural activity and neurotransmitter levels.

Methods

MRS (magnetic resonance spectroscopy) and MRSI (MR spectroscopic imaging) are closely related MR approaches to the acquisition of spectroscopic data. MRS acquires spectroscopic data from a single voxel – that is, a measure of the chemical compounds within a voxel (e.g., $2 \times 2 \times 2\ \text{cm}^3$ or $8\ \text{cm}^3$), with the data typically presented as a single spectrum. MRSI acquires spectroscopic data from many contiguous voxels simultaneously; that is, many spectra are acquired from a region of interest, thus allowing construction of an image showing a metabolite's distribution within that region (e.g., see the spectroscopic image (SI) in **Figure 1**). While many clinical radiology MR facilities allow single voxel MRS studies, the acquisition and analysis of MRSI data is more complex. However, as the intrinsic volume averaging that is present in the single voxel MRS acquisition can clearly dilute abnormalities, many recent research studies in human spectroscopy use MRSI. The data that are discussed in this article are MRSI data, acquired at 4T using a Varian Inova whole body MR system.

Depending on the type of spectroscopic data to be obtained (e.g., ^{1}H data of creatine, NAA, etc., or ^{31}P data of ATP or phosphocreatine), different acquisition protocols are implemented. In this article, the ^{1}H data are acquired along the temporal plane to include bilateral medial temporal lobes, with the planar region of interest (ROI) being 10 mm thick × 8 cm (anterior–posterior) × 10 cm (left-right) (**Figure 1**). 24 × 24 phase encoding is applied over this ROI, resulting in a nominal voxel size of

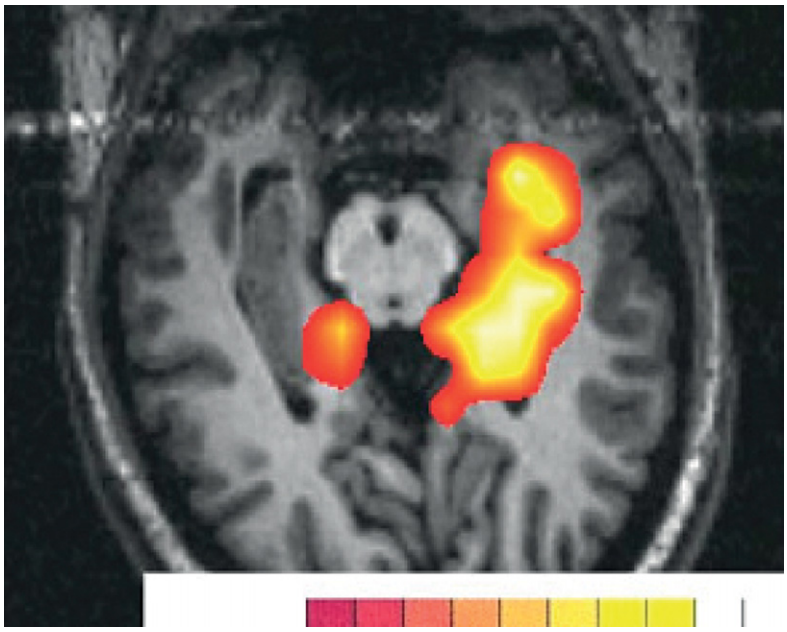

Figure 1 MRSI statistical map showing the bilateral, but dominant left, hippocampal abnormalities in NAA/Cr. The data are corrected for tissue content variability and are independent of CSF and parenchymal tissue volume. The color bar indicates level of statistical significance, starting at $p < 0.05$ (red), going to $p < 0.0001$ (white).

0.64 cm^3 (acquisition time of 20 min). ^{31}P data are acquired in whole brain spectroscopic imaging format, using a 3D spherical encoding strategy to provide a voxel size of ~12 cm^3 (acquisition time of 46 min).

Results

Hyperexcitability and Metabolic Imaging

While ATP is the cell's fundamental energy source, phosphocreatine (PCr) is the major alternative high-energy phosphate compound. Its role is to ensure the continual availability of ATP. ATP is produced in the mitochondrion, but is consumed at varying cytoplasmic sites (e.g., the membrane based Na–K ATPase, which is a large consumer of ATP). PCr serves to shuttle and buffer ATP, keeping the ATP concentration in healthy brain at ~3 mM (depending on tissue type and CSF content). In situations where production and/or consumption of ATP may be abnormal, the concentrations of PCr may be much more dynamic than the concentrations of ATP. The ratio of PCr/ATP is a measure of how well PCr is maintained per unit of ATP, and has been experimentally shown to be highly sensitive to abnormalities in epilepsy. Evidence for a link between energetics and physiologic function comes from studies of temporal lobe epilepsy (MTLE), where lowered PCr/ATP levels are found, and where the ratio is worse at the site of seizure onset. Moreover, following temporal lobectomy, there is an improvement in contralateral temporal metabolism as measured by NAA/Cr.

Thus, alterations in bioenergetics are part of the spectrum of changes that characterize MTLE, along with cell loss and synaptic reorganization. We have found that in MTLE patients, the pre-operative measures of mesial temporal lobe PCr/ATP correlate well with several parameters as determined from electrophysiologic study of the resected hippocampal dentate granule cells. As membrane repolarization is known to be an energetically consumptive process, we anticipated and verified that the rate of recovery of the granule cell membrane potential after a suprathreshold orthodromic stimulus (applied at the outer molecular layer at twice the intensity needed to evoke a single action potential) train (10 Hz, 10 s duration) correlated with PCr/ATP ($R = +0.85$, $p < 0.01$) (**Figure 2(a)**). The higher PCr/ATP was associated with a faster membrane potential recovery rate, consistent with a functional relation between energetics and Na–K ATPase flow. This relationship was not seen with milder stimuli, and most likely reflects the substantive demand on energetic function with the more intense, 10 s stimulus train paradigm. We also determined that hyperexcitability, as measured by synaptic bursting, correlates significantly with PCr/ATP ($R = -0.62$, $p < 0.02$). Synaptic bursting (multiple action potentials fired in response to a single suprathreshold stimulus) is an abnormal response of granule cells (in normal tissue, such a stimulus evokes only a synaptic response with no or perhaps one action potential), and is much more commonly seen in tissue with extensive cell loss and synaptic reorganization. As shown in **Figure 2(b)**, more bursting was associated with lower PCr/ATP.

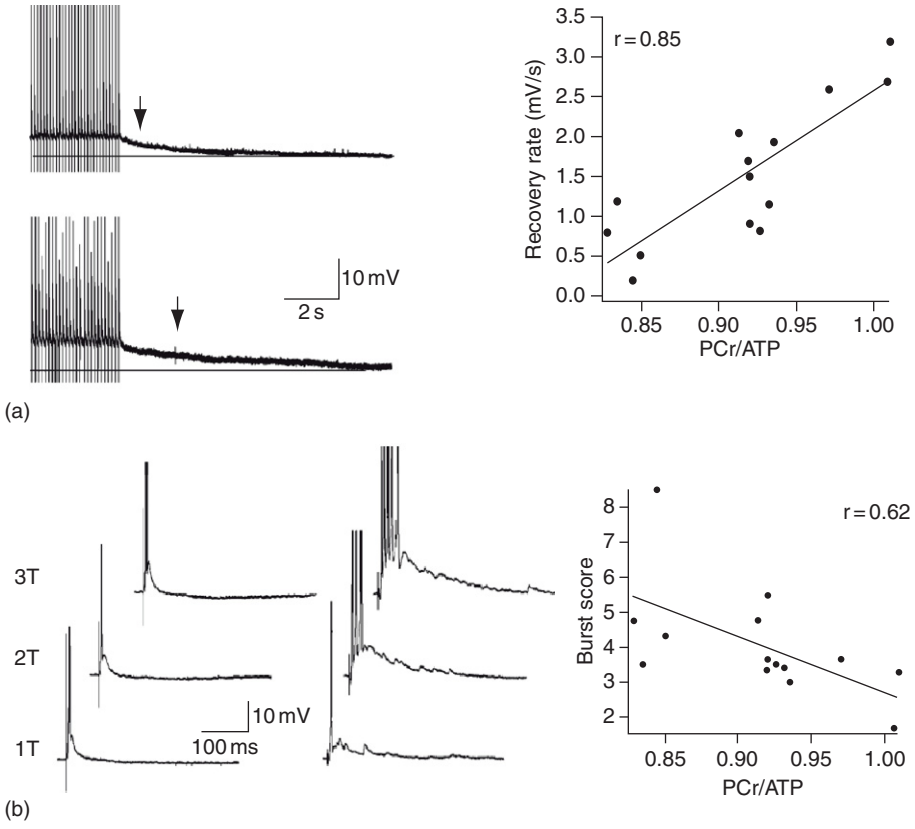

Figure 2 Electrophysiological function relates to bioenergetic status of PCr/ATP. (a) Left: Membrane potential recovery after a 10-Hz 10-s stimulus train obtained from two different MTLE patients. Right: The rate of membrane repolarization after this suprathreshold train of stimulation is significantly related to PCr/ATP, $R = +0.85$, $p < 0.01$. (b) Left: Action potential data are shown in response to three different levels of stimulation (measured relative to the action potential threshold T that provokes a single action potential). In patient #1 (far left), the increasing stimulation intensity to 3T elicited a single spike. In patient #2 (middle), the increasing stimulation intensity elicited a three and then five spike burst of action potentials. The extent of abnormally increased synaptic bursting is also related to PCr/ATP, $R = +0.62$, $p < 0.02$.

It is notable that in these relationships, contributing data were obtained from patients with sclerotic ($n = 11$) and nonsclerotic ($n = 3$) hippocampi, with no major discrepancies seen between them. While the number of patients is clearly limited, the consistency of the data argues that these findings reflect a common characteristic of electrophysiologically determined hyperexcitability, and may be independent of specific disease etiology.

In vivo microdialysis has proved to be another key approach to studying in vivo human epilepsy. This procedure has provided an opportunity to study more carefully the physiology of the extracellular inhibitory and excitatory neurotransmitters, and serves as a useful complement to intracranial EEG monitoring, which has been demonstrated to be a highly sensitive and successful approach for identifying the seizure onset zone. We have linked MRSI with microdialysis studies to evaluate how glutamate may be influenced by the bioenergetic state. These measurements have been made most consistently within the hippocampus, because of the frequency of the pathology and identifiably consistent location of dysfunction. The full range of metabolic abnormalities associated with extracellular glutamate becomes clear under these conditions. In these in vivo studies electrophysiologic function was measured as 'Teager energy' – which is believed to represent a greater degree of abnormality in electrical activity. Within the ipsilateral hippocampus of MTLE patients, increasing Teager energy is well linked with increased extracellular glutamate as shown in **Figure 3(a)**. In this same population of patients, significant correlation between the bioenergetic state with extracellular glutamate is seen (**Figure 3(b)**), with lower PCr/ATP linked with higher glutamate. Thus, if we view PCr/ATP as a measure of the local energetic state, it is clear that those processes that cause energetic perturbation (e.g., changing cerebral demand, fuel availability or stress) alter the ambient extracellular glutamate concentrations – which in turn contribute to altered tissue excitability.

Neuropsychologic Performance and Metabolic Imaging

The abnormalities seen with metabolic imaging are also associated with clinical functional parameters – for example,

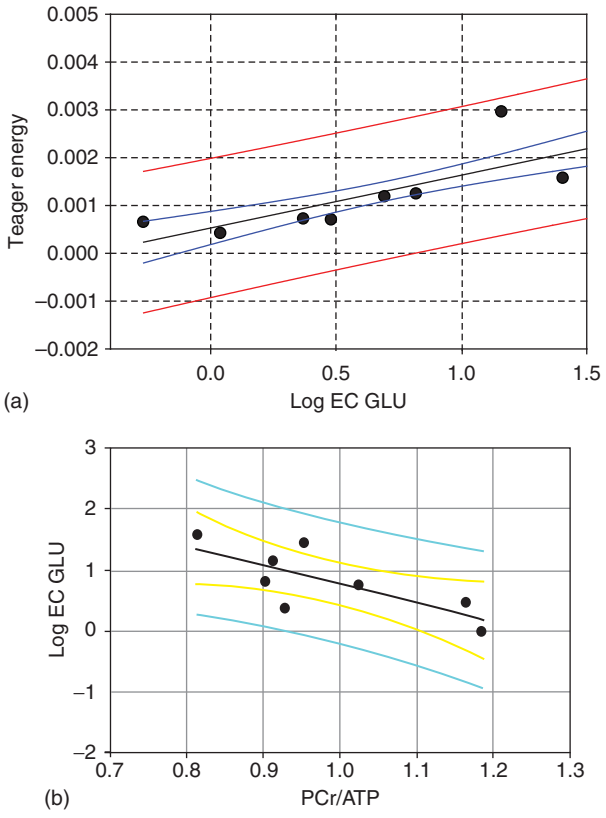

Figure 3 (a) In vivo measures of extracellular glutamate increases with increasing Teager energy ($R = +0.75$, $p < 0.001$); 95% confidence interval and prediction bands are shown. (b) Relationship between preoperative PCr/ATP and microdialysis measurements of log extracellular glutamate ($R = -0.76$, $p < 0.03$); 95% confidence intervals and prediction bands are shown.

with neuropsychologic performance. As part of the epilepsy evaluation, neuropsychologic function is often assessed as an important reflection of local injury, and these measures are commonly used to suggest hemispheric and/or lobar dysfunction. Thus, several groups have found that NAA regional measurements parallel neuropsychologic performance. We have also accumulated data from clinical tests of memory function – using the verbal selective reminding test (vSRT, dominant hippocampal function) and visuomotor selective reminding test (vmSRT, nondominant hippocampal function). As anticipated, the SRT relates significantly to the mitochondrial function, as measured from the epileptogenic mesial temporal lobe ($R = +0.56$, $p < 0.0001$, Figure 4(a), $n = 24$ patients). What is also notable is the similar relationship between the same SRT score with contralateral mesial temporal lobe ($R = +0.57$, $p < 0.0001$, Figure 4(b)). These relationships may reflect the bilateral injury that is frequently present in temporal lobe epilepsy patients, and/or shared memory function between the hippocampi. As discussed by other investigators, both of the mesial temporal lobes contribute to visual memory. Consequently, performance on the vmSRT is likely to reflect both right and left temporal lobe contributions, as suggested from the present data, showing a significant relationship between performance with the vSRT and vmSRT ($R = 0.55$, $p < 0.0005$, Figure 4(c)).

Summary and Directions for Future Research

The overall integration of these data argues for the view that metabolic and energetic states are closely related to experimental and clinical measures of cerebral dysfunction. It is notable that bioenergetics (as measured by PCr/ATP) appear to link well with measures of hyperexcitability (from ex vivo and in vivo electrophysiology and microdialysis studies), while similar relationships have not been seen with the mitochondrial measures of NAA and NAA/Cr. This dissociation may be a consequence of the distinct aspects of metabolism that are evaluated in these different studies. For example, as a direct measure of energetics, interictal PCr/ATP appears to be only moderately reduced even in the face of very abnormal NAA/Cr, most likely as a result of both depressed tissue energy demand and energy production. NAA/Cr may best be viewed as a capacitive measure of mitochondrial function. To date, NAA/Cr has been used by a number of groups to identify the region of seizure focus; it has also been linked with a range of measures including neuropathology (measures of injury, in particular as seen with GFAP immunocytochemistry and glial counts) and cognitive performance.

The methods and issues briefly described in this article open several avenues of clinical and scientific investigation in human epilepsy. Given the large body of evidence showing metabolic abnormalities in the seizure focus, and given that many of the spectroscopically detected compounds (we have only mentioned a few in this article; e.g., NAA, glutamate, glutamine, GABA, glutathione, lactate, ATP, and phosphocreatine) are important for metabolic and neurotransmission function, MR spectroscopy can make significant contributions in the clinical localization and lateralization of epilepsy. Beyond this contribution, the studies of both animals and humans have provided evidence that mitochondrial and metabolic dysfunctions make key pathophysiologic contributions toward determining susceptibility to epilepsy. For example, animal studies have shown that conditions of deteriorating redox and mitochondrial function can induce seizures. Conversely, studies in seizure models have shown that injected fructose diphosphate (which is believed to increase glutathione, a key reducing agent) reduces seizure activity and severity significantly. In vivo MR spectroscopy can help ascertain the dynamics of such compounds, and – based on such measures – may be

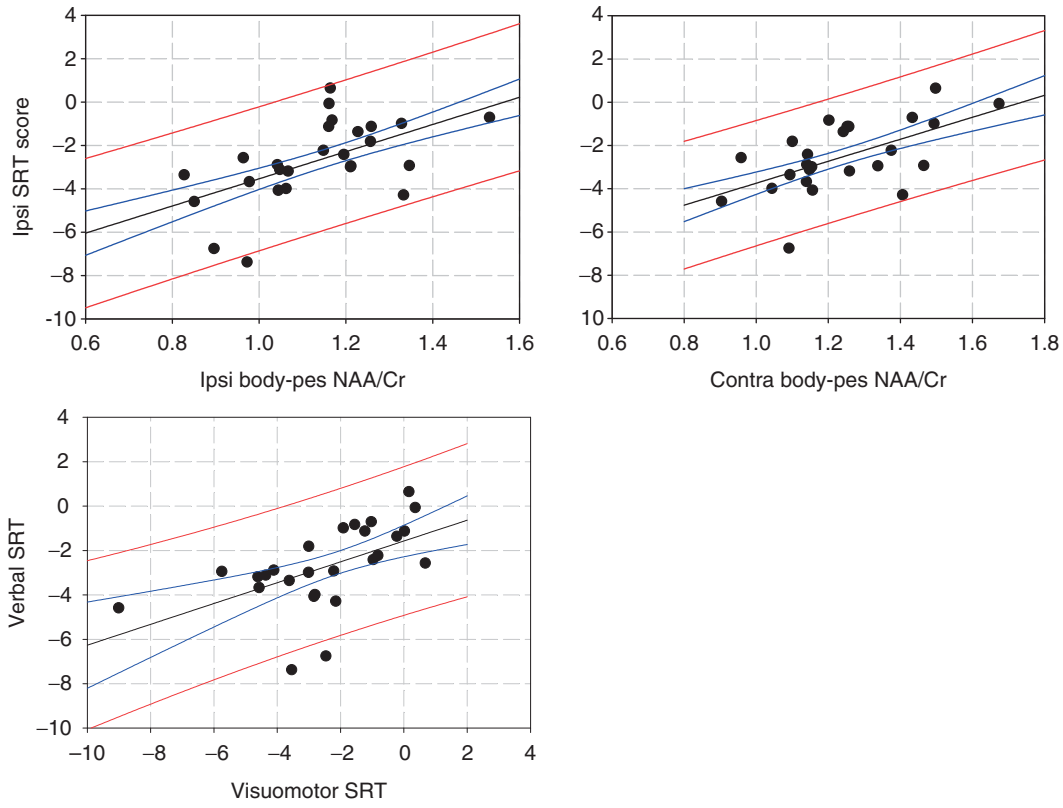

Figure 4 NAA/Cr correlations with ipsilateral selective reminding tests. (a) Ipsilateral hippocampal NAA/Cr value is correlated with the matching ipsilateral SRT score ($R = +0.56$, $p < 0.0001$). (b) Contralateral body-pes NAA/Cr value is correlated with the ipsilateral SRT score ($R = +0.57$, $p < 0.0001$). For both (a) and (b), hemispheric dominance, as determined from Wada testing, was used to determine whether the verbal or visuomotor SRT score was used. (c) Verbal and visuomotor SRTs are linked in mTLE patients ($R = +0.55$, $p < 0.0005$).

able to predict the epileptic outcome. With both clinical and investigative roles, the integration of MRSI with other monitoring modalities (e.g., electrophysiology and microdialysis) will be fruitful in better defining the interdependence of abnormal metabolism with icto- and epileptogenesis.

Seizure-Related Acute MRI Changes

Introduction

Brain imaging is a mainstay in the approach to patients with epilepsy. With the advent of magnetic resonance imaging it is possible to identify the cause, and sometimes the consequences, of epileptic seizures in perhaps 50% of patients with epilepsy. Over the last decade, it has become increasingly apparent that, in addition to identifying genetic, congenital, and acquired lesions that lead to seizures, MRI also has the ability to reveal acute brain changes related to epileptic activity that we have termed 'peri-ictal' imaging abnormalities. Peri-ictal MRI abnormalities may be reversible, evolving, or permanent – and may occur in the region of the epileptic discharge or remote from it. Their occurrence seems highly variable but frequently correlates with the duration and severity of ictal activity, the so-called duration–severity integral. Here, we propose a classification of peri-ictal imaging findings, provide examples, and comment on potential pathophysiological mechanisms for their occurrence.

MRI Techniques

Modern anatomic MR imaging relies on a series of pulse sequences designed to highlight differing aspects of tissue composition – such as lipid content, water content and its microenvironment, diffusivity, and anisotropy. The major MRI modalities emphasize the T1 and T2 relaxation times of the tissue being imaged. Specific sequences are chosen to highlight either T1 or T2 characteristics (T1- or T2-weighted images), although no specific pulse sequence is solely sensitive to T1 or T2 content. Diffusivity is measured by applying a pulsed gradient magnetic field across a subject of interest and calculating diffusivity based on the signal loss that occurs due to Brownian motion between pulses in the gradient. As the distance that a molecule will diffuse is a function of the structure of the tissue in which it is located, diffusivity varies between differing brain compartments such as fluid, myelin, and gray matter. Moreover, diffusivity is sensitive to certain pathological states, such as edema, ischemia, and neuronal loss. Anisotropy is a measure of the coherence or directionality of diffusion. In a fully anisotopic material, diffusion occurs in all directions equally anisotropic, whereas in a tissue with a low fractional anisotropy (FA), diffusion occurs in a highly coherent fashion. FA maps are increasingly used to evaluate connectivity between neuronal structures.

Diffusion imaging changes are prominent among both local and remote peri-ictal findings described in the following sections and are frequently reversible. It is, therefore, important to consider the origin of these findings and their significance. Diffusivity is an intrinsic property of tissue. The apparent diffusion coefficient (ADC) is independent of both T1 and T2 relaxation times. T2 relaxation time is largely reflective of local brain water content. Whereas increased T2 signal suggests edema or gliosis, restricted diffusion is usually associated with metabolic dysfunction or energy deficiency. Some of the hypothesized causes of restricted diffusion are listed in **Table 1**.

Table 1 Causes of restricted diffusion

Na+-K+-ATP-ase pump failure
Cytotoxic edema
Increased intracellular viscosity due to cytoskeletal fragmentation
Increased tortuosity of intracellular space
Decreased extracellular volume

Introduction

Brain imaging is a mainstay in the approach to patients with epilepsy. With the advent of magnetic resonance imaging it is possible to identify the cause, and sometimes the consequences, of epileptic seizures in perhaps 50% of patients with epilepsy. Over the last decade, it has become increasingly apparent that, in addition to identifying genetic, congenital, and acquired lesions that lead to seizures, MRI also has the ability to reveal acute brain changes related to epileptic activity that we have termed 'peri-ictal' imaging abnormalities. Peri-ictal MRI abnormalities may be reversible, evolving, or permanent – and may occur in the region of the epileptic discharge or remote from it. Their occurrence seems highly variable but frequently correlates with the duration and severity of ictal activity, the so-called duration–severity integral. Here, we propose a classification of peri-ictal imaging findings, provide examples, and comment on potential pathophysiological mechanisms for their occurrence.

MRI Techniques

Modern anatomic MR imaging relies on a series of pulse sequences designed to highlight differing aspects of tissue composition – such as lipid content, water content and its microenvironment, diffusivity, and anisotropy. The major MRI modalities emphasize the T1 and T2 relaxation times of the tissue being imaged. Specific sequences are chosen to highlight either T1 or T2 characteristics (T1- or T2-weighted images), although no specific pulse sequence is solely sensitive to T1 or T2 content. Diffusivity is measured by applying a pulsed gradient magnetic field across a subject of interest and calculating diffusivity based on the signal loss that occurs due to Brownian motion between pulses in the gradient. As the distance that a molecule will diffuse is a function of the structure of the tissue in which it is located, diffusivity varies between differing brain compartments such as fluid, myelin, and gray matter. Moreover, diffusivity is sensitive to certain pathological states, such as edema, ischemia, and neuronal loss. Anisotropy is a measure of the coherence or directionality of diffusion. In a fully anisotopic material, diffusion occurs in all directions equally anisotropic, whereas in a tissue with a low fractional anisotropy (FA), diffusion occurs in a highly coherent fashion. FA maps are increasingly used to evaluate connectivity between neuronal structures.

Diffusion imaging changes are prominent among both local and remote peri-ictal findings described in the following sections and are frequently reversible. It is, therefore, important to consider the origin of these findings and their significance. Diffusivity is an intrinsic property of tissue. The apparent diffusion coefficient (ADC) is independent of both T1 and T2 relaxation times. T2 relaxation time is largely reflective of local brain water content. Whereas increased T2 signal suggests edema or gliosis, restricted diffusion is usually associated with metabolic dysfunction or energy deficiency. Some of the hypothesized causes of restricted diffusion are listed in **Table 1**.

Table 1 Causes of restricted diffusion

Na+-K+-ATP-ase pump failure
Cytotoxic edema
Increased intracellular viscosity due to cytoskeletal fragmentation
Increased tortuosity of intracellular space
Decreased extracellular volume
Microvacuolization of myelin

Restricted diffusion has commonly been identified as a marker of irreversible ischemic injury, but in some situations decreased diffusion associated with seizures is reversible without the subsequent appearance of tissue injury. The temporal relationship between the appearance of restricted diffusion and T2 signal change in association with seizures may be variable. Whereas in acute ischemia DWI images reveal restricted diffusion before any abnormality of T2 signal becomes apparent, in ongoing status epilepticus DWI and T2 signal changes appear to occur roughly synchronously. These differences in the timing of DWI and T2 signal change suggest a difference in the underlying pathophysiology. Whereas in ischemia there is early energy failure, in ongoing status epilepticus activity-induced injury with cytotoxic edema may precede overt energy deficiency.

Peri-Ictal Imaging Changes

Peri-ictal imaging changes may occur in the region of the epileptic discharge (local) or in distant structures (remote). Some of the findings that have been described are listed in Table 2. Each of these findings may be reversible or irreversible.

Local Findings

The pathophysiological basis of local peri-ictal imaging findings, which include localized increases in volume of specific structures (swelling), increased T2 signal, reduced ADC, and vascular changes, is seemingly related to increased neuronal activity and its associated metabolic and vascular responses.

Local Anatomic Abnormalities

Local swelling of hippocampus has been described in children with prolonged febrile convulsions and in adults with seizures related to paraneoplastic or nonparaneoplastic limbic encephalitis. In both conditions there is suggestive evidence that there is involution over time of the hippocampus, with residual sclerosis and atrophy. Effacement of gyri in the region of epileptic discharge may be seen in all age groups. Increased T2 signal intensity, indicating an increase in brain water, occurs in areas of cortex and subcortical white matter in association with some prolonged or intense seizures (Figure 1). Many of these lesions show restricted diffusion (bright on DWI, dark on ADC maps). While restricted diffusion suggests the presence of cytotoxic (arising from neuronal injury) rather than vasogenic (arising from abnormally leaky blood vessels) edema, these lesions are reversible, at least initially, raising a question about the actual cause – and indicating that cell death is not an inevitable sequel.

In several studies, localized reduction in ADC has been observed soon after a single seizure. Diehl *et al.* examined patients 45–150 min after a single seizure and found significantly decreased ADC in 1 of 6 patients studied, while Hufnagel *et al.* found similar changes in 5 of 9 patients studied. In these cases, the site of change in ADC appeared to correlate well with the presumed site of maximal seizure activity; however, the variability in occurrence of this finding makes its current utility in routine diagnostic evaluation uncertain. Diffusivity appears to evolve over time. Several studies indicate that in patients with chronic epilepsy, at least during the interictal period the ADC is modestly increased. This finding may be the consequence of progressive neuronal loss with increased extracellular space.

Migratory Anatomic Abnormalities

In occasional patients with multifocal epilepsy, T2 and DWI lesions appear to be migratory (see Figure 2). These lesions appear to colocalize with regions of focal hypermetabolism as illustrated by ^{18}FDG-PET or ^{99}Tc-SPECT scanning (Figure 3) – and these hypermetabolic regions, in turn, corresponded to areas of maximal EEG abnormality. These features, in conjunction with the timing with which T2 and DWI abnormalities appear, suggest that the lesions are the consequence of the epileptic activity, and not its cause.

Abnormalities of Blood Flow and Perfusion

Special MR techniques can be utilized to measure perfusion of a local brain region. Perfusion-weighted MR imaging may show initial hyperperfusion in the area of ictal activity, with subsequent relative hypoperfusion. This complex temporal evolution of postictal imaging points to the need for careful electroclinical correlation when assessing the significance of findings on postictal scans. MR angiography in patients in status epilepticus may demonstrate increased flow-related enhancement, and this finding corresponds well to the observation of arterialization of venous blood reported by surgeons examining the cortex during provoked or spontaneous

Table 2 Classification of peri-ictal imaging abnormalities

Remote	*Local*
Unilateral/bilateral diencephalic lesions	Mass effect
Cerebellar diaschesis	Hippocampal swelling
Splenium abnormalities	Focal cortical edema
Reversible posterior leukoencephalopathy	Migratory lesions
	Blood-brain barrier breakdown
	Increased vessel caliber/flow
	Increased perfusion

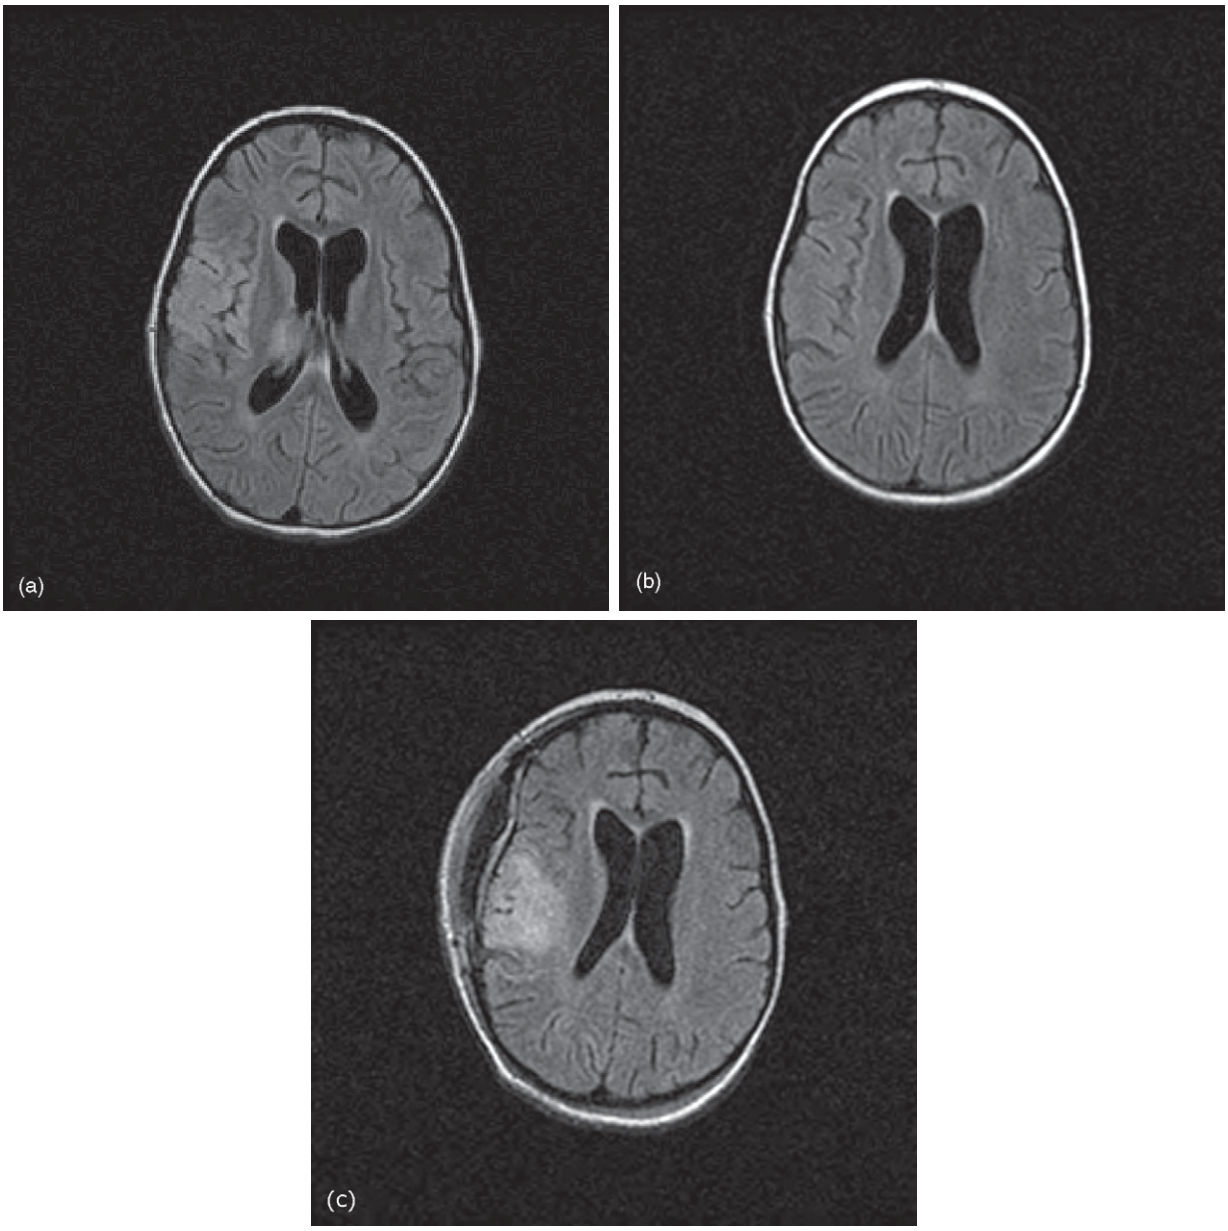

Figure 1 Resolution and recurrence of increased T2 signal associated with focal status epilepticus after 7 days of pentobarbital anesthesia. The patient was a 12-year-old girl who presented 14 days before with epilepsia partialis continua arising from the right hemisphere. (a) Axial FLAIR MR image obtained on day 14 prior to anesthetic treatment. (b) Axial FLAIR MR image obtained after 7 days of pentobarbital anesthesia titrated to produce burst suppression on continuous EEG monitoring. Note that T2 signal changes have largely resolved. (c) Axial FLAIR MR image obtained 7 days after anesthetics were discontinued and epilepsia partialis had recurred. Reproduced from Doherty CP, Cole AJ, Grant PE, *et al*. (2004) Multimodal longitudinal imaging of focal status epilepticus. *Canadian Journal of Neurological Sciences* 31: 276.

epileptic seizures (Figure 4). SPECT studies in this circumstance may not demonstrate evidence of increased perfusion at the microvascular level, suggesting that some portion of the locally increased blood flow represents arteriovenous shunting. That is, if there is increased flow at the macrovascular level, but no increased perfusion at the microvascular level, then the increased flow must be shunted to bypass the microvascular circulation.

Remote Findings

The pathophysiological bases of lesions that occur remote from the site of ictal activity are not understood.

Diencephalic and Cerebellar Diaschesis

The term 'diaschesis' refers to a change in function and electrical activity in an area of the brain due to a lesion in

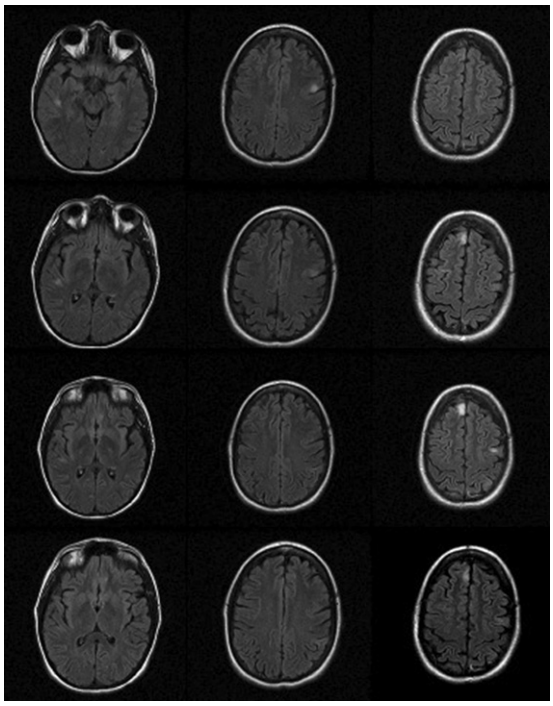

Figure 2 Migratory peri-ictal imaging changes. FLAIR images obtained at multiple levels at time of presentation (top row), on day 14 (second row), on day 28 (third row), and on day 35 (fourth row) from a 28-year-old woman with recurrent partial seizures associated with a mitochondrial disease. Reproduced from Cole AJ (2004) Status epilepticus and periictal imaging. *Epilepsia* 45(supplement 4): 72, with permission from Wiley-Blackwell.

a remote area that is connected with it. Classically, this term was applied to the observation that frontal lesions were associated with altered function of the contralateral cerebellar hemisphere. In patients with focal epilepsy, we have commonly observed hypometabolism – using ^{18}FDG-PET scanning – in the cerebellar hemisphere contralteral to the epileptic focus. Ipsilateral diencephalic and contralateral cerebellar lesions, including restricted diffusion and increased T2 signal, may be a striking finding in status epilepticus (**Figure 5**). These lesions appear to resolve over days to weeks when seizures are controlled, but may presage the appearance of local atrophy of the affected structures in some cases. The pathophysiology of these lesions is unknown, but they presumably result from the recruitment and driving of thalamic and cerebellar circuits in the expression of epileptic activity.

Lesions of the Splenium of the Corpus Callosum

Transient lesions of the splenium of the corpus callosum have been described in patients with epilepsy. Splenial lesions are typically ovoid and well-circumscribed regions of increased T2 signal with restricted diffusion (**Figure 6**), and may reflect abnormal activity in white matter tracts driven by the epileptic focus. Neither the mechanism nor the precise nature of the white matter change responsible for these imaging alterations is understood. One study suggested that corpus callosum lesions

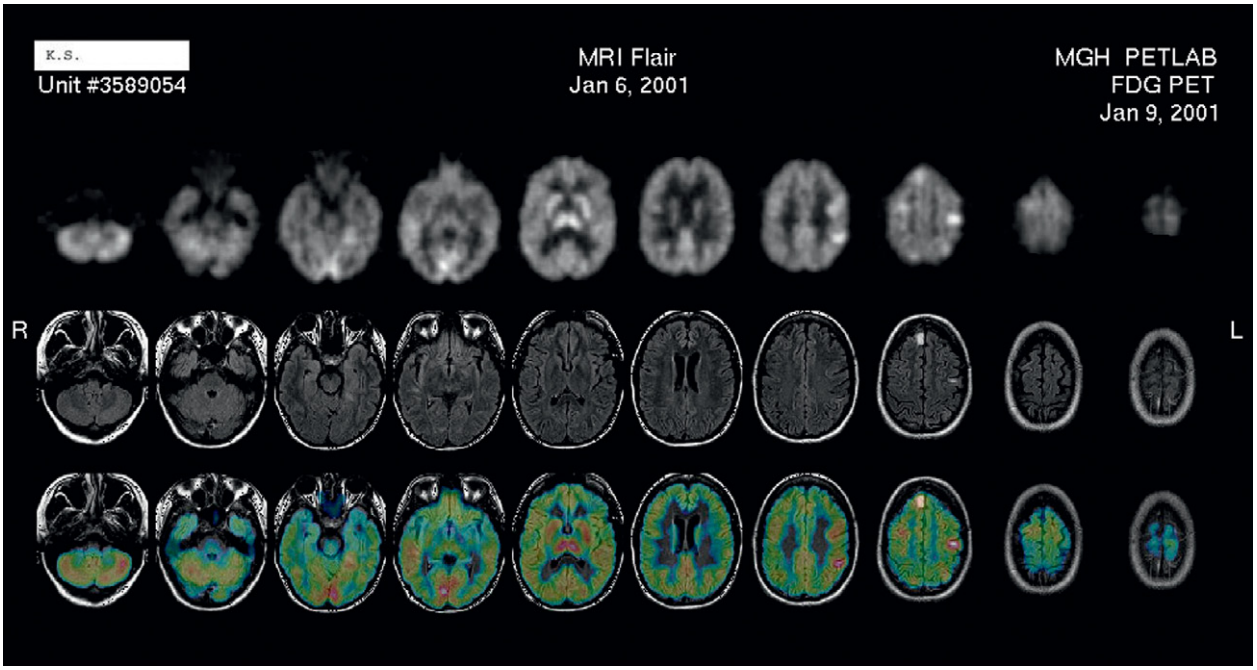

Figure 3 Multimodal imaging using MRI and PET. Upper panel: ^{18}FDG-PET images from patient described in **Figure 4** obtained on day 25 showing multiple focal areas of hypermetabolism. Middle panel: FLAIR images obtained on day 28. Lower panel: Coregistration showing colocalization of areas of hypermetabolism and areas with FLAIR abnormalities. EEG recording (not shown) demonstrated a similar localization of ictal activity involving right frontal pole and left central region. Figure 5 Crossed cerebellar diaschesis. Images obtained from a 38-year-old patient who presented with recurrent right hemispheric seizures. Upper panels show abnormal signal on fluid-attenuated inversion recovery (FLAIR) images in the ipsilateral cortical ribbon and in the contralateral cerebellar hemisphere. Lower panels show reduced diffusion on diffusion-weighted images in corresponding regions . Reproduced from Cole AJ (2004) Status epilepticus and periictal imaging. *Epilepsia* 45(supplement 4): 72, with permission from Wiley-Blackwell.

were due to anticonvulsant drug toxicity, but this explanation seems unlikely given the large number of patients on anticonvulsants who undergo MR imaging and do not show such lesions. Moreover, several cases have been reported in patients off anticonvulsants who had flurries of seizures. Polster *et al.* suggested that drug withdrawal might underlie this splenial phenomenon, but their argument rested on the notion that the splenium lesion was

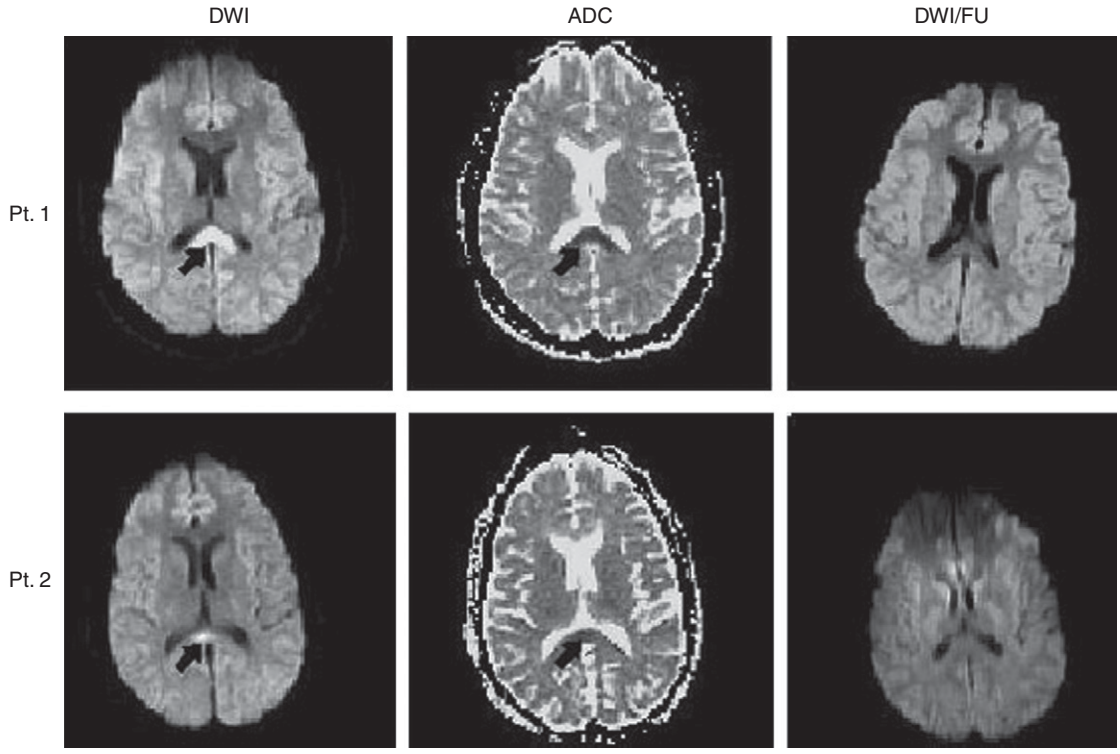

Figure 6 Transient diffusion-weighted imaging changes in the splenium after seizures. Representative images from two patients (upper and lower panels) demonstrate restricted diffusion (left hand images) with associated decreased apparent diffusion coefficients (center images) that resolved in 4–6 weeks (right hand images). Reproduced from Oster J, Doherty C, Grant PE, *et al*. (2003) Diffusion-weighted imaging abnormalities in the splenium after seizures. *Epilepsia* 44: 852.

vasogenic edema. Our studies indicate that the lesion demonstrates a decreased apparent diffusion coefficient (ADC), a finding that is not consistent with their hypothesis but rather supports the idea that in most cases the lesion is related to the ictal activity per se. As shown in Table 1 (which lists potential causes of restricted diffusion), microvacuolization of the myelin is one pathological substrate that could account for the increased T2 signal, the decreased ADC, and the reversibility of lesions of the splenium. Similar lesions have also been reported in association with encephalitis, osmotic disturbances, or altitude sickness. It remains unclear whether the pathophysiology of callosal lesions is similar in each of these situations.

Posterior Reversible Leukoencephalopathy

Reversible posterior leukoencephalopathy (RPLE), described in patients with hypertension, eclampsia, and sometimes in association with certain immunosuppressive drugs, may be associated with repeated seizures. Some patients with seizures, but without another obvious cause for RPLE, have been described – suggesting that seizures per se may contribute to the occurrence of this finding. However, it is difficult to exclude moderate changes in systemic blood pressure with respect to the patient's baseline as a cause in most cases.

Issues for Discussion and Future Research

Variability in Occurrence of Peri-Ictal Imaging Changes

An important and unresolved issue is why local acute peri-ictal changes on MRI occur in some, but not all patients after focal seizures. The fact that such changes are sometimes first apparent days or weeks after the start of focal status epilepticus suggests that there is a threshold of seizure duration and/or severity below which changes will not occur. Most reports of acute imaging changes on MRI describe patients experiencing prolonged seizures or status epilepticus; however, current knowledge does not allow us to predict where that threshold might lie. Importantly, as with most threshold phenomena in biology, it is likely that there are differences between individuals with respect to when imaging findings will become apparent,

Table 3 Critical Variables that may determine occurrence or severity of local peri-ictal imaging changes

Seizure type/location
Duration/severity of ictal discharge
Host characteristics
Age
Preexisting conditions
Cardiovascular/Metabolic reserve
Pharmacological intervention

and when they will become irreversible. Some critical variables that might determine whether seizures in a specific individual are sufficient to trigger acute imaging changes are listed in Table 3.

Impact of Seizure-Related Acute MRI Findings on Clinical Management

Local and remote peri-ictal imaging findings – including T2 signal change, restricted diffusion, local swelling, and altered perfusion – must be interpreted with caution in the setting of acute or ongoing seizures or status epilepticus. It is important to recognize that these changes can occur as the consequence of seizure activity per se, and therefore may not be helpful in establishing the cause of the seizures. In extreme cases, acute findings may mimic tumor or stroke, but if misinterpreted these would lead to inappropriate diagnostic or therapeutic interventions. As peri-ictal imaging changes evolve over time, it may be possible to use serial imaging to assess the efficacy of antiseizure treatment. For example, in focal status epilepticus, we have shown that anesthesia sufficient to suppress seizure activity also results in reversal of imaging abnormalities. Serial studies of brain perfusion after seizures suggest that replacement of hyperperfusion with hypoperfusion may be a useful index of therapeutic efficacy in some patients. Similarly, it may be possible to use careful analysis of the degree of T2 signal change and local volumetric measurements to better assess the efficacy of therapy. As some imaging findings after seizures are remote from the site of maximal ictal activity, it is important to evaluate imaging abnormalities in conjunction with clinical and electrographic data that provide information about the localization of ictal activity. Particularly when these modalities are convergent, the imaging findings may support a plan for early surgical intervention and help in the process of surgical planning.

Structural Imaging in Epilepsy

D M Gazzola and R I Kuzniecky, New York University School of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Structural neuroimaging has greatly contributed to the overall understanding of epilepsy pathogenesis, and currently plays a valuable role in the diagnosis and management of epilepsy patients. Improvement in image quality and resolution over the past several decades has translated clinically into greater sensitivity, and as a result has increased the detection of focal brain lesions. This technical progress ultimately impacts treatment and clinical outcome, particularly when patients are offered the chance of cure through lesionectomy.

The further advancement of structural imaging is essential. Currently, many patients must undergo intracranial EEG (IEEG) monitoring because the location of epileptogenic origin is unclear. In the analysis of pathology specimens following surgical resection, it is not uncommon to find small focal cortical dysplasias (FCDs). Should structural neuroimaging resolution continue to improve to the point of detecting FCDs, IEEG could be used in a more limited fashion, requiring the implantation of fewer electrodes that are more precisely placed. It is also possible that highly sensitive structural neuroimaging, combined with functional neuroimaging studies, will in some cases obviate the need for invasive monitoring altogether.

The following section discusses the two most commonly applied modalities in structural neuroimaging, computed tomography, and magnetic resonance imaging. Each modality's current application to the field of epilepsy, as well as its short-comings, is reviewed. This section is followed by a detailed discussion of recent developments and improvements in the field of structural neuroimaging, and the potential impact such advancements might have on the clinical management of patients.

Background

Presently, the two primary modalities of structural neuroimaging are computed tomography (CT) and magnetic resonance imaging (MRI). Each modality serves a different purpose in the clinical evaluation of a patient with epilepsy. The basic physiologic principles of these two imaging techniques are explained, followed by a discussion of the general utility of, and indication for, each type of study.

Computed Tomography

Computed tomography (CT) uses ionizing radiation, which passes through the tissue being studied. The radiation is absorbed at varying levels, depending upon tissue composition. Different tissue compositions will produce different absorption patterns and images. As a result, CT imaging of the brain is able to delineate bone, CSF, and soft tissue. Overall, imaging contrast is excellent with regard to bone, but soft tissue structures are less clearly distinguishable. Despite this short-coming, CT offers certain advantages over other imaging modalities such as MRI. For example, its relatively low cost, broad accessibility, and speed of image acquisition are features which make CT an appealing imaging modality. In the emergent setting, CT tends to be the first line of diagnostic imaging due to its aforementioned rapidity. Especially when the patient has an altered mental status or focal findings on neurologic exam, rapid imaging is the most sensible course of action to rule out acute pathology. For this reason CT is also the imaging study of choice in the perioperative state, when the quick detection of recent hemorrhage, hydrocephalus, and major structural changes is paramount.

However, CT is less sensitive in the detection of small focal cortical and white matter abnormalities when compared to MRI. Studies have shown that CT does not reliably detect small tumors or hippocampal sclerosis (HS), which is a major disadvantage. HS is one of the more common abnormal findings in patients with temporal lobe epilepsy, and often serves as an indication of localization-related epilepsy, potentially amenable to surgical treatment. The failure to detect such a lesion could negatively impact the patient's clinical course, deviating from a path optimal treatment. As a result, when it comes to the evaluation of patients with epilepsy, the utility of head CT is limited.

In 2007, the International League Against Epilepsy (ILAE) published guidelines on performing a head CT in the emergent setting of a patient presenting with a first time seizure. The ILAE study group concluded that 'immediate noncontrast CT is possibly useful for emergency patients presenting with seizure, to guide appropriate acute management especially where there is an abnormal neurologic examination, predisposing history, or focal seizure onset.' This statement speaks to the three primary attributes of CT – speed, accessibility, and affordability – as well as the ability of CT to quickly detect brain hemorrhage, ischemia, or large structural

abnormalities, all of which are potentially life-threatening and epileptogenic. The ILAE also recommends that an MRI be performed if an initial head CT is normal in patients with intractable epilepsy. Overall, MRI is preferable to CT in the nonemergent, outpatient setting. CT becomes the imaging modality of choice when MRI is not available or not possible secondary to patient characteristics (implanted devices, obesity), or not suitable due to an emergent clinical situation.

Magnetic Resonance Imaging

When performing a routine evaluation of a patient with epilepsy, magnetic resonance imaging (MRI) is the imaging procedure of choice as it offers multiple advantages over CT, including its excellent soft tissue contrast and high anatomical resolution.

MRI does not employ ionizing radiation. Rather MRI utilizes the natural magnetic properties of hydrogen atoms, which are present in human tissue to varying degrees depending upon the water component. The hydrogen nucleus possesses a single proton which rotates haphazardly on its own axis, producing a small magnetic field. The MRI magnet produces its own intense field, which aligns all of the hydrogen nuclei in the tissue being imaged. Energy in the form of a pulsed radiofrequency is then emitted by MRI coils, which collides with the protons, pushing them out of alignment. As the protons relax back to their original energy state, they emit a signal which is detected by the MRI coils. The variation of water composition between different tissues results in the investigator's ability to visually delineate structures; the higher the water content in an area, the more hydrogen protons there will be emitting signals. These signals are translated into shades of gray which vary depending upon signal strength. Through this process, the radiologist is able to differentiate between bone, CSF, white matter, and gray matter.

The strengths of MRI, particularly its superior resolution and delineation of structures, make this imaging modality well suited to evaluate epilepsy patients. One of the most common pathologic findings in patients with temporal lobe epilepsy (TLE) is mesial temporal sclerosis (MTS). MTS is pathologically characterized by hippocampal sclerosis (HS), with neuronal loss and gliosis seen on histology. This pattern is readily detected on MRI by hippocampal atrophy, increased signal on T2-weighted images or fluid-attenuated inversion recovery (FLAIR) sequences, and decreased signal on inversion recovery sequences. Part of a typical 'epilepsy MRI protocol,' which includes angulated coronal sections perpendicular to the long axis of the hippocampal structures, increases the likelihood of detecting MTS. Similarly, prior studies have illustrated the importance of the imager's level and area of training and expertise. HS detection rates are higher when the interpreting physician is experienced in reading epilepsy protocol MRIs. MRI is currently felt to be the most effective imaging modality for the detection of MTS, with over 90% of cases being successfully identified.

MRI is also useful in the detection of malformations of cortical development (MCDs) which are common in children with epilepsy. MCDs are characterized as being either diffuse or focal in nature. Diffuse malformations such as lissencephaly, band heterotopia, and periventricular nodular heterotopia, as well as focal malformations consisting of hemimegalencephaly, schizencephaly, and focal cortical dysplasias (FCDs), can be defined accurately through structural imaging. The latter tend to be the most common developmental abnormalities observed in children with extratemporal lobe epilepsy. An abnormal cortical mantle with altered gray–white matter architecture and thickened cortex are characteristic features of FCDs on MRI. However, these lesions are often small. The likelihood of their being detected increases if one targets a clinically suspected region, using three-dimensional (3D) volume techniques, surface coils, and inversion recovery sequences. Recent advances in this area, and application of the technology to the neuroimaging of tuberous sclerosis (TS), are discussed in greater detail in the following section.

Imaging Indications

Not all patients with epilepsy require neuroimaging. Patients with uncomplicated febrile convulsions and a normal neurological exam may not require imaging studies. In addition, patients with well-defined idiopathic generalized epilepsy, or with typical idiopathic benign partial epilepsy with centro-temporal spikes (Rolandic epilepsy), usually do not require imaging. However, structural MRI abnormalities have been reported in each of the latter two cases, making it difficult to dictate absolutely when imaging should and should not be performed. While further studies are needed, in general the presence of atypical clinical features, or the development of an atypical clinical course in patients with seemingly benign or nonfocal epilepsy, should raise a red flag and prompt an imaging study.

As opposed to the primary generalized epilepsies, all patients with symptomatic generalized or focal seizures should have an MRI. An MRI should be performed if a patient's seizures do not fit into any of the recognized epilepsy syndromes. When seizures persist in the presence of a previously normal CT scan, or when there are progressive neurologic changes on the clinical exam of a patient with epilepsy, an MRI is indicated. MR imaging should be routinely repeated 2–5 years following a previously normal MRI in any patient whose seizures remain refractory. Furthermore, an MRI should be repeated if the seizure semiology or pattern changes. Again, an epilepsy-specific protocol with fine cuts through the hippocampus should be performed, and preferably using a high strength magnet.

Limitations

Despite the obvious utility of MRI in the evaluation and treatment of patients with epilepsy, the technology is not perfect. While MRI is far superior to CT with regard to sensitivity and delineation of gray–white structures, there is still room for improvement in the differentiation of structures and cortical layers. In addition MRIs can be laden with artifact caused by implanted devices, and it is not uncommon that patient movement distorts images, rendering studies uninterpretable. The sections which follow explore some of these issues by focusing on current research and new developments in the field of structural neuroimaging.

Methods and Results – Recent Advances in Structural Neuroimaging Techniques

The utility of structural neuroimaging in the management of patients with epilepsy will likely continue to increase as technology advances. In that context, it is useful to address three major limitations of structural neuroimaging: (1) suboptimal sensitivity and limited detection of small lesions; (2) unidimensional representation of cortical structures – which limits the investigator's ability to accurately localize lesions; and (3) unavoidable introduction of artifact, which degrades image quality and limits interpretation. These issues are discussed separately in the following sections by focusing on some of the latest research developments in neuroimaging. There is special focus on a study currently underway at the New York University Comprehensive Epilepsy Center, where voxel image analysis is being used to study relationships between epilepsy and psychiatric symptoms. A final section of this article explores the application of neuroimaging to the diagnosis and treatment of tuberous sclerosis (TS), a genetically determined abnormality that often presents with seizures.

Refining Sensitivity and Delineation of Structures: High Field MRI

The quest for better imaging has resulted in the development of high field magnets such as 3–7 Tesla (T) units. Three Tesla (3 T) MRI was first approved in 2001 for clinical use. The theoretical doubling of signal (compared to the conventional 1.5 T MRI magnet) affords more detailed imaging, particularly important when small focal lesions are sought. However, despite the increased magnet strength, there are some drawbacks to 3T MRI, chiefly due to the limitation of individual specific absorption rates (SARs) and the doubling of chemical shift misregistration. The latter problems result in decreased contrast between gray and white matter on T1 weighted images, a major drawback when attempting to identify MCDs in epilepsy patients. However, recent refinements in 3 T imaging have helped to address this issue. Development of the eight-channel coil has led to dramatic improvement of image quality and gray–white contrast. Schmitz and colleagues reduced the refocusing pulse (RF2) of spin echo pulse sequences from 180° to 120°, which similarly improved contrast (see Delano *et al.* in Further Reading). Some investigators have found that using the conventional spin echo technique produces an image superior to one produced using the fast spin echo technique, as the latter can be associated with image blurring, also noted in the Delano et al. article. The use of inversion-prepared sequences, such as inversion-prepared 3D fast spoiled gradient echo (FSPGR), also produces images with excellent gray–white contrast, as do fluid-attenuated inversion recovery (FLAIR) sequences.

Unlike T1-weighted 3 T imaging, which has been fraught with problems concerning gray–white contrast, T2-weighted images generated on a 3 T MRI are of very high quality. T2-weighted sequences have excellent gray–white differentiation, as well as superior delineation of pathological structures. Through the adjustment of different imaging parameters, T2-FLAIR sequences have even greater gray–white contrast than the latter. This trend will undoubtedly progress as magnet strengths continue to increase and imaging parameters, in response, are refined.

Improving Dimensionality: Volumetric MRI

When viewed in isolation, the images produced by conventional MRI are 2D representations of a patient's neuroanatomy. By incorporating the third dimension, voxel-based morphometry (VBM) more accurately represents the location of a proposed epileptogenic focus or lesion, and its relation to other surrounding cortical and subcortical structures. The latter can be especially helpful to neurosurgeons performing epilepsy surgery.

VBM typically measures gray matter voxels. A voxel is the smallest measurable box-shaped unit of volume that comprises a larger 3D image. More simply, it can be thought of as a 3D version of a pixel. Thus, gray matter voxels are the smallest measurable volumetric units that together make up the total volume of gray matter on a brain image. Following a series of steps involving image processing and statistical analysis, a 3D surface rendering of the cortical gyri can be produced. Such images can be used to describe cerebral malformations, and to illustrate surface anatomy. Using VBM, one can also assess the thickness and volume of mesial temporal structures such as the hippocampus – particularly useful to epileptologists who often rely on imaging to determine whether HS is present. A recent study by Bonilha *et al.* (see Further Reading section) went one step further, demonstrating

that patients with left mesial temporal lobe epilepsy (MTLE) had a wider area of atrophy related to hippocampal gray matter loss, compared to patients with right MTLE. The authors suggested that this finding may help to explain the larger degree of cognitive impairment usually observed in patients with left versus right hippocampal atrophy.

Currently at the NYU Comprehensive Epilepsy Center, structural neuroimaging research in volumetric analysis is underway. Specifically, VBM is being performed on epilepsy patients who suffer from post-ictal psychosis (PIP), comparing their cortical thickness with that of other epilepsy patients without this history. The proposed hypothesis is that epilepsy patients who experience psychotic episodes post-ictally are anatomically different from those epilepsy patients who do not. It is possible that differences in cortical volume exist between PIP patients and non-PIP controls. This study employs the automated method for measuring cortical thickness as described by Fischl and Dale (see Further Reading secion). The technique generates very accurate models of both the gray/white and pial surfaces of the brain through image segmentation. The segmentation process uses both intensity and continuity information from a 3D high-resolution, high signal-to-noise MR image volume to produce accurate representations of both the gray matter–white matter boundary and the outer cortical surface (Figure 1). As noted in Fischl and Dale, by measuring the distance between gray/white and pial surfaces, the thickness of the cortical gray matter can be determined at any location with submillimeter accuracy. Cortical thickness maps can then be generated on an inflated brain surface, allowing for comparisons of cortical thickness across the whole brain surface between patient groups (Figure 2). Such imaging methods may not only prove to be useful in the analysis of epilepsy patients with PIP, but also may one day serve as a routine method for assessing temporal lobe volume in patients with presumed temporal lobe epilepsy, or the progression of cortical volume loss in patients with neurodegenerative disease.

Decreasing Artifact: The PROPELLER Technique

At times, patient movement in the MRI scanner is unavoidable and generalized anesthesia must be administered. When present, movement artifact can render images largely uninterpretable. In an attempt to resolve this problem, a new method of image acquisition was developed. Termed 'periodically rotated overlapping parallel lines with enhanced reconstruction' ('PROPELLER'), this sequence provides excellent contrast between gray and white matter despite the presence of patient movement.

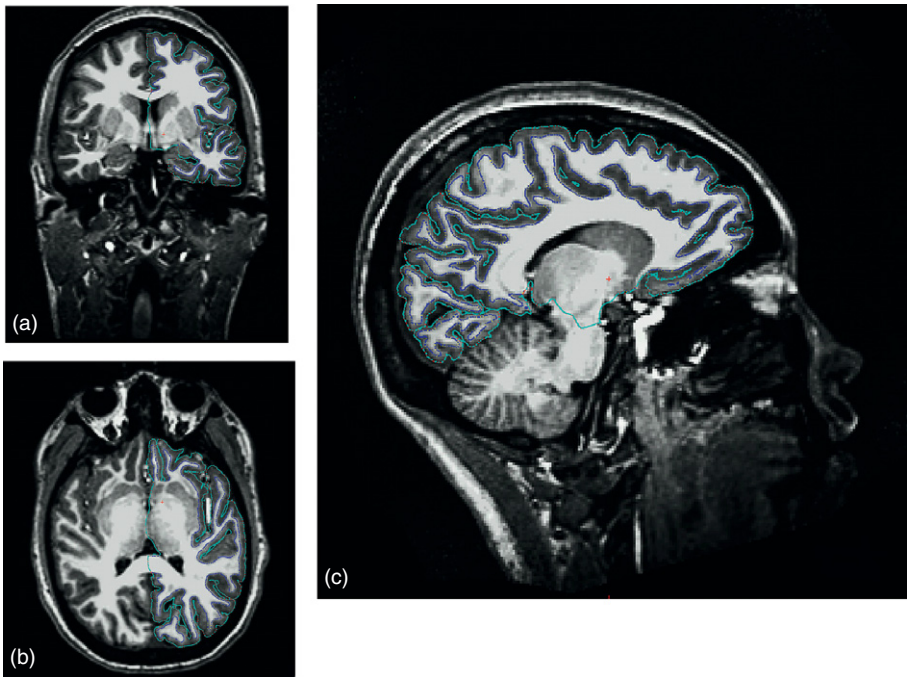

Figure 1 Cortical reconstruction. Example of MR image segmentation in the coronal (a), axial (b), and sagittal planes (c, enlarged view). The segmentation procedure uses both intensity and continuity information from a 3D high-resolution, high signal-to-noise MR image volume to produce accurate representations of both the gray matter/white matter boundary (blue line) and that of the outer surface of the cortex (green line). Thickness measurements are obtained by calculating the distance between the two surfaces across the entire volume in each hemisphere. Images provided by Dr. Thomas Thesen, NYU Comprehensive Epilepsy Center.

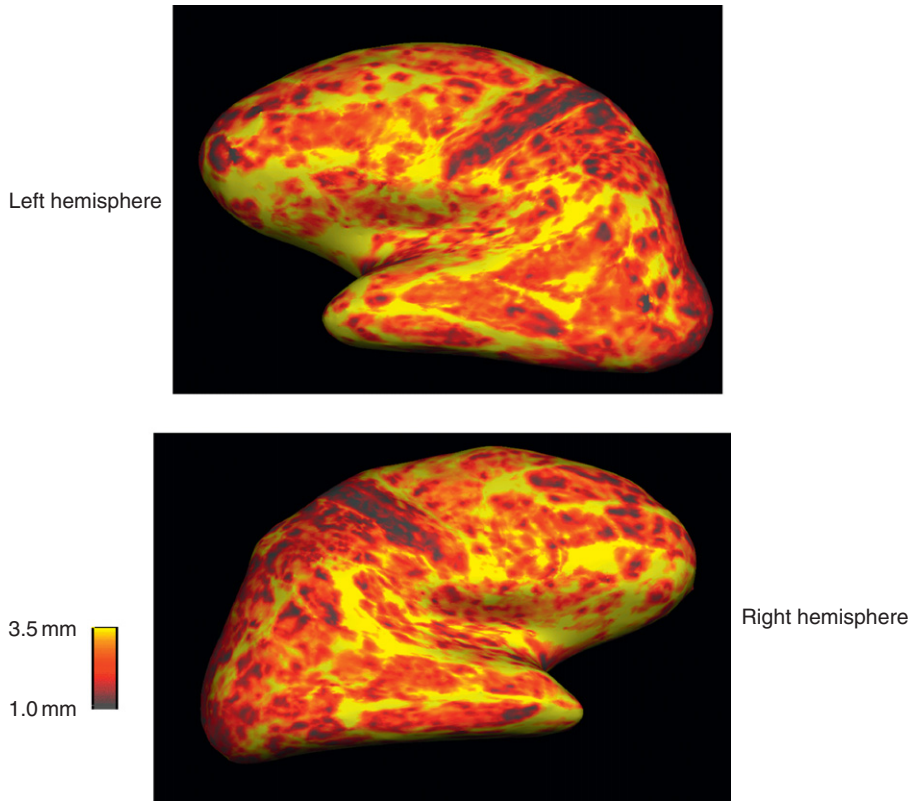

Figure 2 Example of cortical thickness maps of one patient on an inflated brain surface. Yellow indicates greater thickness (scale from 1.0 to 3.5 mm). Averaged maps in a standardized space allows for comparisons of cortical thickness across the whole brain surface between patient groups. Images provided by Dr. Thomas Thesen, NYU Comprehensive Epilepsy Center.

Both translational and rotational head movements are accounted for, greatly reducing motion artifact. This advance is achieved by averaging images and rejecting those data that correlate with through-plane motion. The latter explanation is provided by Eriksson *et al.* (see Further Reading section), who sought to compare imaging of the hippocampus on PROPELLER T2-weighted images with routine T2-weighted images. They concluded that PROPELLER images had superior tissue contrast, showing the internal hippocampal structures and tissue changes associated with hippocampal sclerosis. By refining this imaging technique and making it more readily available to all epilepsy centers, one could avoid the need for sedation, which carries its own set of morbidity and mortality risk factors. This capability would be a great advancement, particularly for the field of pediatric epilepsy where sedation for imaging is fairly commonplace.

Further Applications: The Neuroimaging of Tuberous Sclerosis

The successful treatment of epilepsy in the setting of tuberous sclerosis (TS) is often heavily reliant on invasive EEG monitoring and structural neuroimaging. By clearly identifying the presence of cortical tubers, structural neuroimaging can both define the extent of disease within the central nervous system and help guide intracranial electrode placement in those patients bound for surgery.

Tubers are characterized as well-circumscribed areas of signal hypointensities on T1-weighted MRI and as signal hyperintensities on T2-weighted sequences (see Luat *et al.* in Further Reading section). The reverse pattern is observed in neonates and young infants due to incomplete myelination. The detection of tubers is even better using fluid attenuated inversion recovery (FLAIR) sequences. Complementing these more conventional sequences is the newly developed technique termed magnetization transfer imaging (MTI), which can detect tubers obscured by myelination as noted in the Luat et al. article. Another potentially valuable tool is the magnetization transfer ratio (MTR), which reflects brain lesion histology. For example, Zikou *et al.* (see Further Reading section) found that the MTRs of TS brain lesions were significantly lower compared to controls. They determined that this finding likely correlates with the depleted myelin sheaths and microscopic cystic degeneration typical of TS lesions. In contrast, subependymal nodules – which are composed of more densely packed cells – were associated with a higher MTR.

Another investigational technique is diffusion tensor magnetic resonance imaging (DT-MRI). DT-MRI detects alterations in two primary parameters: apparent diffusion coefficient (ADC) and fractional anisotropy, both of which can be used to characterize TS lesions. Increased ADC values have been noted in epileptogenic hamartomas for instance. In addition, Peng *et al.* (see Further Reading section) found that the fractional anisotropy value of tubers in TS patients was significantly lower versus controls. Lastly, DT-MRI can potentially track white matter fibers and assess their integrity. It is hoped that application of this imaging technique will lead to the identification of any anatomical abnormalities that may exist beyond the borders of a tuber, including fiber networks involved in neuronal recruitment and ictal spread. The ability to delineate such a neuronal network with imaging would have a profoundly positive impact on the treatment of TS-related epilepsy; comprehensive excision of all nonessential tissue with epileptogenic potential is the ultimate goal.

Future Goals

Clearly, many of the imaging techniques described above are in their infancy, and further development and refinement are needed. Once the sensitivity, reproducibility, and efficiency of such techniques are optimized, larger-scale clinical trials studying efficacy and clinical utility of the new technology will be warranted. The impact of these new imaging modalities on the field of epilepsy has yet to be determined, but certainly seems promising.

Structure and Function: Imaging Connectivity Using Tractography

M Yogarajah, J S Duncan, and M J Koepp, Institute of Neurology, UCL and National Society for Epilepsy, Chalfont St Peter, Bucks, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The anatomy of white matter pathways is crucial to our understanding of both normal and abnormal brain function. To date, these connections have been studied using direct visualization, predominantly in animal brain specimens. Because this work is intrinsically slow, and drawing inferences from animal models is difficult, our knowledge of cerebral white matter connections in humans is still very limited. MRI-based tract mapping techniques offers the prospect of noninvasive, in vivo imaging of white matter tracts for the first time. Furthermore, this technique can be employed synergistically with clinical, fMRI, PET, and electrophysiological data to obtain insights into both the anatomy and the function of these connections. This knowledge has diverse clinical applications to patients with epilepsy.

The goal of structural MRI in epilepsy patients is to identify those patients suitable for surgery, and locate the epileptogenic lesion or zone (by using concurrent clinical, electrophysiological, and other imaging data). The epileptogenic lesion can then be resected with minimal collateral damage to eloquent cortex. In patients with cerebral lesions, the localization of cognitive activation may differ from the pattern in normal subjects, and therefore functional MRI (fMRI) is useful to delineate areas of eloquent cortex such as primary sensorimotor cortex, essential language areas, occipital visual areas, and mesial temporal regions crucial for episodic memory. By noting the anatomical relation of these areas to the planned resection, postoperative complications can be minimized. The use of tractography makes it possible to delineate white matter fiber tracts that connect these eloquent cortical areas, so inadvertent surgical damage can be avoided, thus further reducing postoperative complications. Moreover, this technique also lends itself to explore the reorganization of white matter networks in chronic epilepsy, which may underlie changes in cognitive function.

Background

The Biological and Physical Basis of Diffusion Based Imaging

In a free medium, the molecular diffusion of water refers to the random translational motion (Brownian motion) of molecules resulting from the thermal energy carried by these molecules. In the brain, diffusion is restricted by intra and extracellular boundaries, and represents the effects of several variable, independent factors. These factors include the presence of impermeable or semipermeable membranes, macromolecules that hinder the diffusion of small molecules, and intra and extracellular microcirculatory effects. The measurement of water diffusion, therefore, provides a means of probing cellular integrity and pathology.

The principles of diffusion MRI were first developed in vivo in the mid-1980s. In diffusion-weighted imaging (DWI), images are sensitized to the diffusional properties of water by the incorporation of pulsed magnetic field gradients into a standard spin echo sequence. By taking measurements in at least three directions, the mean diffusion properties could be characterized within a voxel in the image; these properties are expressed by way of a single scalar apparent diffusion coefficient (ADC). Early diffusion studies discovered that ADC measurements depended on a subject's orientation relative to the magnet and gradient coils. White matter tracts parallel to an applied gradient had the greatest ADC whereas those lying oblique or transverse to a gradient had smaller ADC values. This observation gave rise to the concept of asymmetry of diffusion of molecules in three directions, or 'anisotropy.'

Diffusion tensor imaging (DTI) enables not only the quantification of water molecule diffusion, but also the characterization of the degree and direction of anisotropy. The diffusion tensor is a mathematical construct that can be calculated from a nondiffusion-weighted image plus six or more diffusion-weighted measurements along noncollinear directions. The tensor can be diagonalized to give three eigenvectors – ε_1, ε_2, and ε_3 – representing the principal directions of diffusion, and three eigenvalues – λ_1, λ_2, and λ_3 – representing the magnitudes of diffusion (or the corresponding ADC values) along these directions. The eigenvectors are ordered with decreasing values of their eigenvalues, so that ε_1 represents the principal direction of diffusivity, and λ_1 will be the ADC value along ε_1. This value corresponds to the maximum diffusion in each voxel, regardless of the orientation of the subject's head.

Furthermore, several diffusion parameters can be derived in each voxel, which are insensitive to subject positioning and fiber tract alignment within the diffusion gradients of the MRI scanner. Mean diffusivity (MD) is a

summary measure of the average diffusion properties of a voxel and is equivalent to the estimated ADC over three orthogonal directions. Fractional anisotropy (FA), in contrast, is an estimate of what proportion of the magnitude of the diffusion tensor is due to anisotropic diffusion. Anisotropy in white matter results from the organization of tissue as bundles of axons and myelin sheaths run in parallel; the diffusion of water is freer and quicker in the long axis of the fibers than in the perpendicular direction. Malformations or acquired insults cause disruption to the microstructural environment, and more often than not, a reduction in anisotropy. Such abnormalities may also lead to a reduction in cell density and/or expansion of the extra cellular space, resulting in an increase in MD/ADC.

From DTI to Tractography

With conventional MRI, variations in white matter signal are subtle and white matter tracts cannot be accurately parcellated. In most studies, DTI quantitative measures have been assessed using either region of interest (ROI) or voxel-based analysis. The former has limitations in that it is user-dependent, and can lack precision (i.e., other white matter tracts, gray matter or CSF may be included erroneously in the analysis). Voxel-based analysis, although observer-independent, has problems associated with the need for spatial normalization and smoothing due to anatomical variations in ventricular size, gyral patterns etc. Both methods have limited ability to quantify specific white matter pathways along their entire trajectories. Tractography is an extension of DTI whereby the directional information obtained in each voxel is used to generate virtual, three-dimensional white matter maps. These maps are based on similarities between the diffusion properties of neighboring voxels in terms of shape (quantitative diffusion anisotropy measures) and orientation (principal eigenvector map). Tractography does not, therefore, trace fibers in the sense that injected tracers do; rather it demonstrates the path of least resistance to water diffusion.

Methods

Selecting a Seed Region

In most tractography experiments, to delineate the white matter structure of interest, a 'seed' region within or adjacent to the structure needs to be defined. These seed regions, from which tracking will commence, are often defined using anatomical reference points. As a result, they are susceptible to operator bias, and this bias can introduce a source of variability into tractography results. The combination of fMRI and tractography enables the use of operator-independent placement of seed regions. Furthermore, it offers an opportunity to study the relationship between brain structure and function by providing a selective tracing of white matter pathways within a behaviorally-characterized network. In our studies of language networks, therefore, our group has used verbal fluency, verb generation, and reading comprehension paradigms to define functional regions, which were then used to generate start regions for tractography.

Tractography Algorithms

Various algorithms have been devised to generate white matter maps using the information provided by diffusion imaging. Linear or streamline methods use the orientation of maximum diffusion at each voxel, and are performed by following these orientation estimates to reconstruct pathways that, within a coherent bundle, correspond to the underlying fiber pathway. They therefore define a single route of connection for each start point(s) or ROI, from voxel to voxel. These streamline approaches are susceptible to errors in the orientation of ε_1 due both to noise and to instances in which the direction of the underlying tract anatomy is ambiguous or reflects the presence of multiple noncollinear fiber pathways. These streamline approaches also assume absolute knowledge in fiber direction at every point, with no representation of the uncertainty present in the recovered pathway. An erroneous pathway, due to noise or partial volume effects, is therefore assigned as much significance as 'true' pathways.

For this reason, in our laboratory we use a probabilistic tractography approach to exploit the inherent uncertainty in the orientation of ε_1 for each voxel to generate maps of connection probability. Orders of uncertainty based on the anisotropy of the tensor and the relative magnitudes of the eigenvalues are used to generate probability density functions (PDFs) of the result of the diffusion tensor mixture model. These PDFs are a means of describing the local uncertainty in fiber orientation. Each PDF is intended to interpret the information from a diffusion imaging acquisition in terms of the likely underlying fiber structure at each point within the brain. The end result is that for every voxel, a distribution of directions rather than a single principal eigenvector is obtained. Any of these points can then be selected as a starting place for running a streamline propagation process. This process can be repeated a large number of times (N), and the number of times that any voxel in the brain is encountered over N repetitions provides an index of connectivity for that voxel to the start point. This process eventually yields a map of probability of connection, or a Probabalistic Index of Connectivity (PICo), to the chosen seed point. The probability of connection in any experiment generally decreases with distance from the start point due to the cumulative effect of the uncertainties in propagation at each step in the streamline process.

The effects of noise on this model are also explicitly simulated and used to analyze the uncertainty associated with the principal diffusion direction of each diffusion tensor. This uncertainty, and therefore the distribution of the principal diffusion direction, decreases as the FA increases.

Tract Analysis

The tracts generated in individual subjects can be analyzed at a qualitative level. Tracts from different individuals can also be combined to generate group maps, which give an indication of how reproducible a given connection is across a population of subjects.

Finally, the white matter tracts can also be used to derive quantitative information, including volume and anisotropy parameters. These measures can then be compared across groups, or tested for correlations against fMRI or clinical data.

Results

Language – The Superior Longitudinal Fasciculus

Temporal lobe epilepsy (TLE) may be associated with disrupted lateralization of language, and may be further impaired by anterior temporal lobe resections (ATLR). Indeed, selective language deficits have been reported in up to 30% of patients following dominant hemisphere ATLR. The superior longitudinal fasciculus is known to be a crucial part of the language network, connecting anterior (Broca's) and posterior (Wernicke's) language areas. In a study of 14 patients with unilateral TLE and 10 controls, the language paradigms described earlier were used to generate seed regions for tractography in both Broca's and Wernicke's area. Controls and right hemisphere TLE patients were found to have a left-lateralized pattern of both language-related activations and associated white matter organization; measures of FA and volume were statistically greater on the left than those on the right side. Left TLE patients showed more symmetrical language activations (in comparison with both controls and right TLE patients), along with reduced left hemisphere and increased right hemisphere white matter pathways (**Figure 1**).

Correlations between measures of structure (FA) and function in both patient groups were found, with subjects with more lateralized functional activation having more lateralized white matter pathways. The findings of this study, therefore, demonstrate that tractography is able to identify the structural network underpinning the lateralization of language function elucidated by fMRI studies.

Memory – The Parahippocampal Gyrus

Parahippocampal structures, which are critically implicated in the generation and propagation of seizures in TLE, are also essential for declarative memory. Longitudinal neuropsychological studies have shown that persisting epilepsy is associated with progressive memory impairment. Those who undergo ATLR are at further risk of memory impairment, the nature of which depends on whether surgery is on the dominant or nondominant side. Patients typically show a decline in verbal memory following surgery involving the language-dominant hemisphere and deficits in topographical memory following nondominant temporal lobe resection. Neuropsychological assessment, quantitative MRI, and (more recently) fMRI indicate that the medial temporal lobe structures (MTL) play a role in sustaining material specific memory functions; these studies have also demonstrated that reorganization of memory occurs with TLE and that memory deficits after ATLR are related to the functional integrity of the parahippocampal structures. The strength of connections, or structural connectivity, of the parahippocampal gyrus in TLE has not been evaluated or related to function.

Our group performed tractography in 18 patients with unilateral TLE undergoing presurgical evaluation, and in 10 healthy controls. An anatomically-derived seed region in the anterior parahippocampal gyrus was selected from which to trace the white matter connections of the medial temporal lobe. A correlation analysis was also carried out between volume and mean FA of the connections on the one hand, and preoperative material specific memory performance on the other hand. There was no significant difference between the left- and right-sided connections in controls. In the left TLE patients, the connected regions ipsilateral to the epileptogenic region were found to be significantly reduced in volume and mean FA compared with the contralateral region (**Figure 2(a)**). Significant correlations were found in left TLE patients between left and right FA, and verbal and nonverbal memory, respectively. Though there was a trend towards ipsilateral reduction in volume and FA in right TLE patients, this difference was not significant (**Figure 2(b)**). Similarly, no correlations between left or right FA and memory measures were found in this group of patients. It is unclear why no differences were seen in right TLE patients. It is possible that the speech-dominant hemisphere has greater and denser connectivity to the rest of the brain, and that it is more sensitive to damage than is the nonspeech-dominant hemisphere. The finding of fewer occipital connections in the left TLE group compared with right TLE patients and controls may also be significant in this respect (**Figure 2(a)** and **2(b)**). Animal models suggest that potential roles for these connections may involve the priming of mesial temporal lobe structures

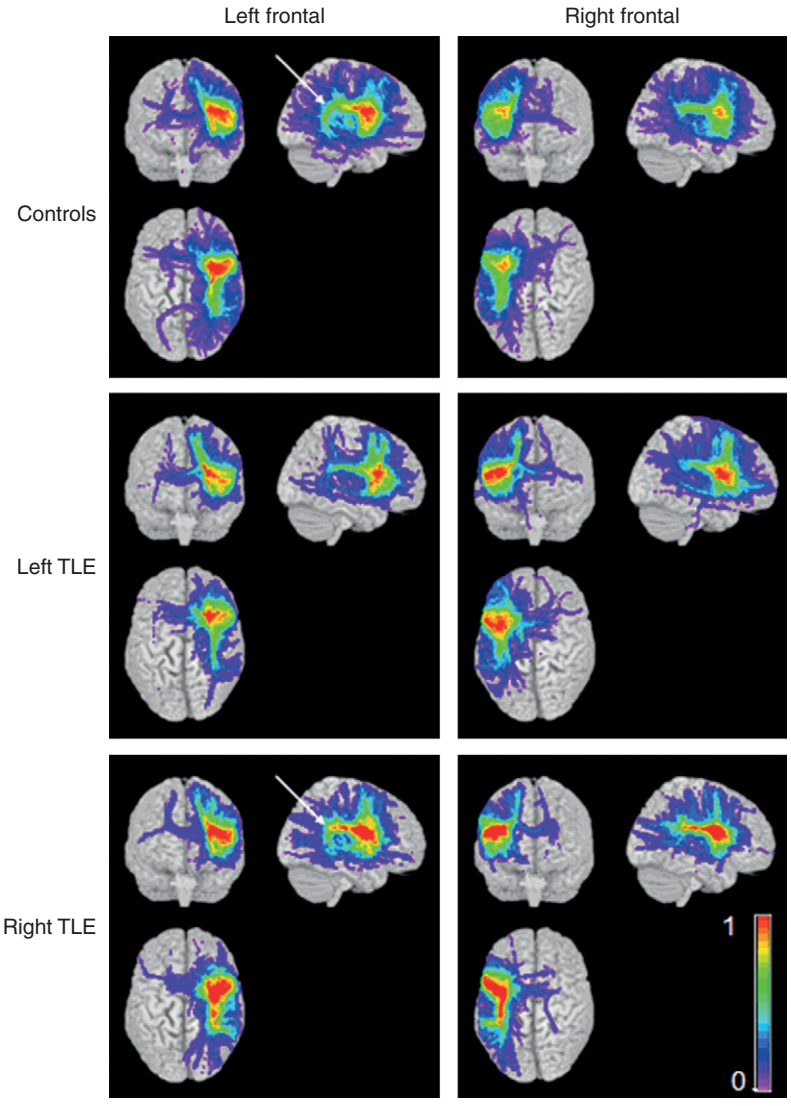

Figure 1 Group variability maps of the connecting paths tracked from left and right functionally defined frontal ROIs for each of the three groups controls, Left TLE and Right TLE patients. Each image shows the maximum intensity of the commonality maps in each plane of view as a brain surface rendering. The color scale indicates the degree of overlap among subjects (expressed as commonality value); for example, a value of 1 (pure red) represents 100% subject overlap (i.e., every subject's identified tract contains the voxel in question). Controls and right TLE patients show a similar pattern of connections with greater SLF connections to the temporal lobe on the left (arrowed) than the right. In the left TLE group the opposite pattern is seen with greater temporal lobe connections on the right. Reprinted from Powell HW, Parker GJ, Alexander DC, Symms MR, Boulby PA, Wheeler-Kingshott CA, Barker GJ, Koepp MJ, Duncan JS (2007) Abnormalities of language networks in temporal lobe epilepsy. *Neuroimage* 36(1): 209–221, with permission from Elsevier.

to facilitate the consolidation of visual memory or to enhance the visual processing of emotionally significant stimuli. Visual cues may be important not only for nonverbal memory but also for verbal memory. This could explain the correlation of FA found with verbal and nonverbal memory in left TLE patients. In the right TLE patients, the occipital connections did not seem to be as severely affected, and hence these patients may have been able to use visual cues to aid both verbal and nonverbal memory.

Other groups have assessed other memory structures within the limbic system. Concha *et al.* found that patients with unilateral TLE have bilateral changes in the fornix and cingulum bundle, characterized by impaired tracking of these pathways, and increased MD and reduced FA along them. This result was thought to be consistent with the degeneration of pathways connecting to the hippocampus (**Figure 3**). Studies by the same group have assessed the progression of Wallerian degeneration in the limbic structures in patients with refractory epilepsy after corpus callostomy and temporal lobe resections.

Taken together, these results suggest that the use of tractography-derived quantitative measures may have a significant role to play in the longitudinal evaluation of the effects of epilepsy on the brain, and on cognitive

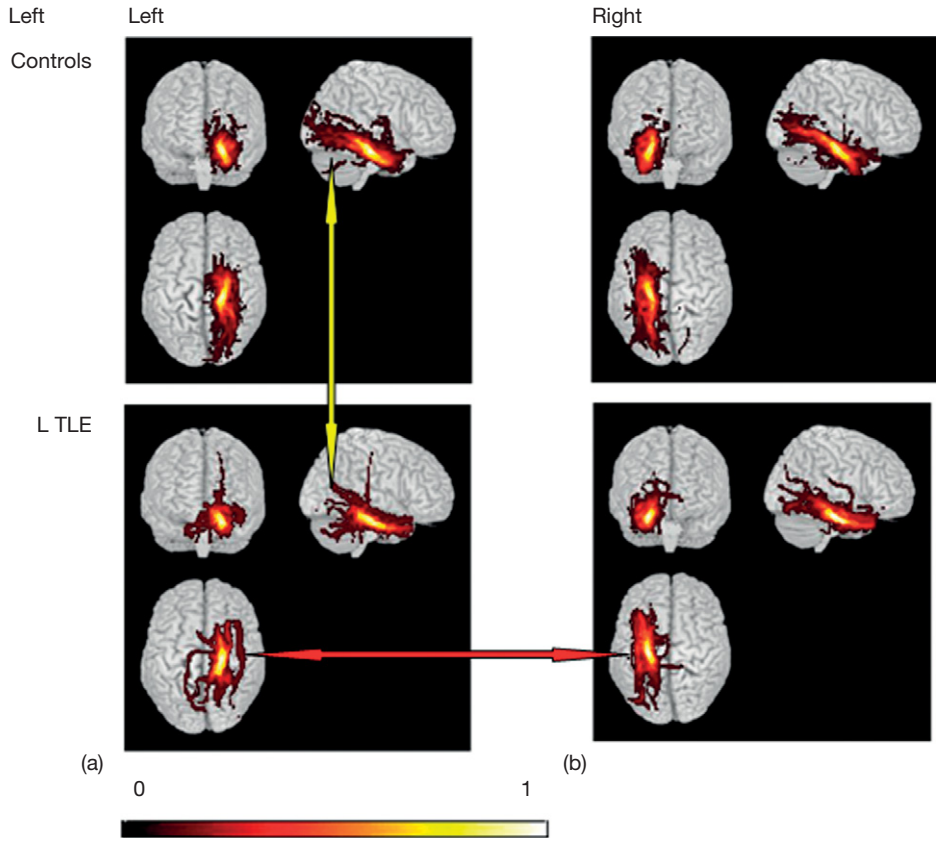

Figure 2 Group maps of the parahippocampal gyrus tracts comparing left (a) and right (b) TLE patients against controls. Tracts are overlaid upon a 3D rendered brain template. A voxel commonality value of 1.0 indicates that each individual had a connection identified in this voxel while a *C* value of 0.0 indicates that none of them did. In controls, PHG connections were symmetric. There is more marked asymmetry of connections in left TLE patients compared with controls and right TLE patients. There is a decrease in ipsilateral compared with contralateral connections in left TLE, such that the body of the PHG appears smaller (red arrow). In addition, fewer connections to the occipital lobe are present in left TLE patients compared with controls and right TLE patients (yellow arrow). Reprinted from Yogarajah M, Powell HW, Parker GJ *et al*. (2008) Tractography of the parahippocampal gyrus and material specific memory impairment *Neuroimage* 40: 1755–1764, with permission from Elsevier.

functions such as memory and language, particularly when correlated with neuropsychological measures.

Preoperative Planning – Visual Pathways

ATLR can also cause visual field defects (VFD) in up to 80% of patients. Indeed, in up to 10% of patients this defect can be severe enough to render the patient ineligible for a driving license, despite the patient's being seizure-free. Typically, VFDs after ATLR occur in the superior homonymous field contralateral to the resection, and are due to disruption of fibers of Meyer's loop. The anterior extent of the Meyer loop is not visualized on conventional imaging and varies from person to person. As a consequence, the occurrence and extent of a postoperative VFD cannot be accurately predicted by conventional MRI, or from the extent of resection performed. Tractography has been used to demonstrate the optic radiation in normal subjects, and has previously been applied to pre and postoperative surgical patients with AV malformations and tumors in and around the visual pathways. A study by our group demonstrated the application of this approach to temporal lobe surgery for epilepsy (**Figure 4**). The optic radiation was visualized before and after ATLR, and disruption of Meyer's loop was clearly demonstrated in a patient who developed a quadrantanopia. More recent studies by other groups have confirmed the utility of this technique.

Future Goals

The development of tractography-based techniques is still at its infancy, and faces several major challenges. The most pressing of the current problems is the lack of a 'gold standard' method of validation. Tractography is essentially a user-defined process, and tracking results may vary according to the algorithm used, size and definition of a ROI, FA threshold for termination of tracking, angular threshold, step length, and numbers of sampling

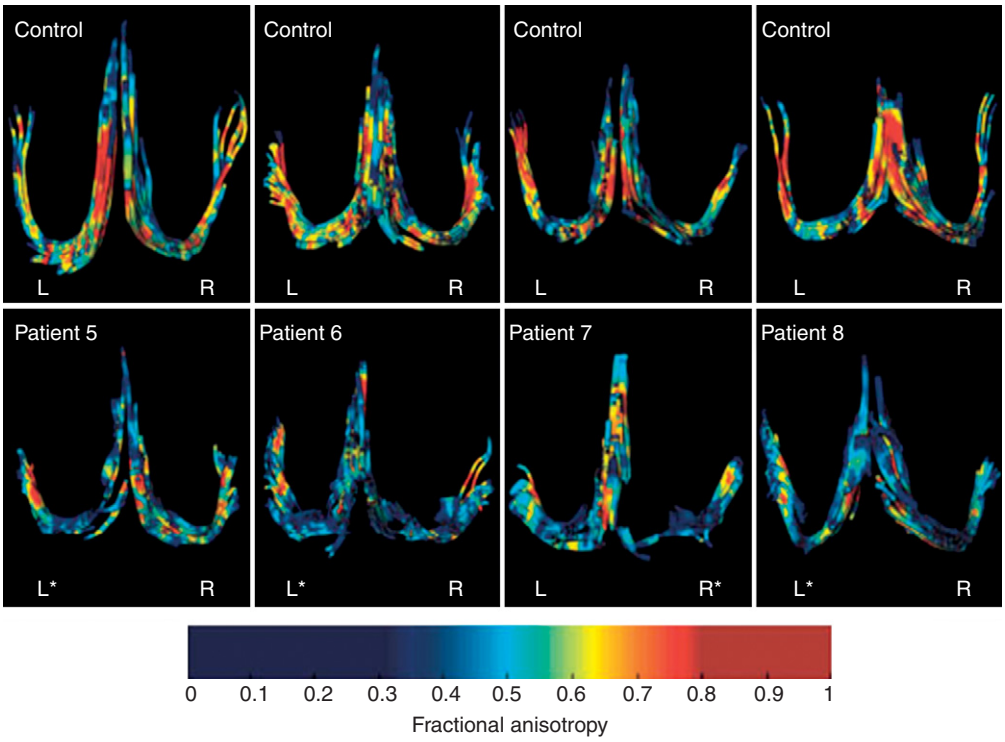

Figure 3 Tractography of the fornix in four control subjects and four patients with unilateral hippocampal sclerosis (HS). Bilateral three-dimensional visualisation of the fornix viewed from above, where fractional anisotropy (FA) values are color-coded for each voxel. The hemisphere with MTS is denoted by an asterisk. Note that patients show overall lower FA values and less continuous tracts bilaterally compared with control subjects. These results imply marked degradation of the fornix in both hemispheres. Reprinted from Concha L, Beaulieu C, and Gross D (2005) Bilateral limbic diffusion abnormalities in unilateral temporal lobe epilepsy. *Annals of Neurology* 57(2): 188–196, with permission from Wiley.

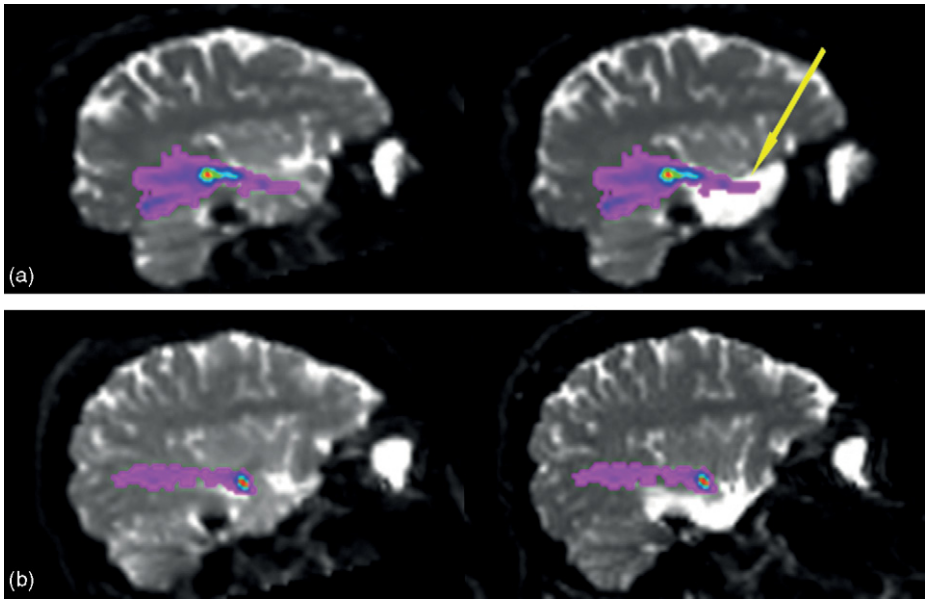

Figure 4 Tractography of the optic radiation in two patients who underwent anterior temporal lobe resections (ATLR), superimposed on sagittal MR images. Preoperative images on the left and postoperative images on the right. Patient A suffered a quadrantic field deficit postoperatively due to surgical interruption of the optic radiation (arrow). The visual fields of patient B remained intact. Reprinted from Powell HW, Parker GJ, Alexander DC *et al*., (2005) MR tractography predicts visual field defects following temporal lobe resection. *Neurology* 65: 188–196, with permission from Wiley.

within a voxel. Despite the concordance of results in studies on language, and studies showing that the technique can reconstruct (and is consistent with) major fiber tract trajectories, there is a need for robust standardized tests to assess the different algorithms and data acquisition techniques. Pre and postoperative tractography studies in epilepsy surgery may be in a prime position to rectify this problem. The use of tractography together with MEG, fMRI, and fMRI–EEG has the potential to provide complementary but equally important information in these patients. Furthermore, concordance of results derived from these techniques in the same patient groups would be very helpful in the validation of tractography-based techniques.

The other challenges of tractography relate to the quality of data acquisition and the tracking algorithms. Current problems include eddy current distortions, gradient nonlinearities, motion artifact, signal loss due to susceptibility variations, and low resolution acquisition. The relatively low signal-to-noise ratio (SNR) of DTI data introduces errors; SNR is inversely proportional to spatial resolution, in that increasing spatial resolution (i.e., decreasing voxel size) leads to a reduction in SNR. Using a higher magnetic field or longer acquisition times can compensate for this loss of SNR. Even at higher spatial resolutions, however, the size of a typical imaging voxel is 2–3 mm cubed, so a single voxel could contain thousands of axons. This limited spatial resolution can lead to false positives, and can lead to the false definition of a tract direction in a voxel, especially in the presence of fibers crossing or touching within individual voxels. In addition, low SNR may also lead to false negatives by ignoring small fiber tracts that may be functionally important.

Despite these limitations tractography is the only technique available for tracing white matter pathways in vivo. Furthermore, as methodological developments occur in orientational and spatial resolution, and in diffusion modeling and tractography algorithms, these limitations should prove less of a problem. By applying tractography both postoperatively and in a longitudinal fashion, it is hoped that tractography-derived data, in synergy with fMRI and neuropsychological data, may provide valuable prognostic information regarding cognitive outcomes in patients with refractory epilepsy. In addition, when the technical challenges of coregistration of preoperative tractography with the T1-weighted MR images are surmounted, preoperative tractography of the optic radiation and other vital white matter connections will be helpful in planning and undertaking surgical procedures. Further, the advent of intra-operative MRI will allow the correction of the movement of tracts caused by craniotomy, and will improve the accuracy of the data used in surgical planning, resulting in a lower risk of postoperative deficits. Finally, it is hoped that this imaging approach may lead to the development of novel approaches that allow us to functionally disconnect the seizure focus from the surrounding brain.

Introduction

Among the large spectrum of brain tumors, a distinct group of neoplasias can be identified in patients suffering from chronic focal epilepsies, i.e., long-term epilepsy-associated tumors (LEATs). With few exceptions, these tumors share one or more of the following features: (1) LEATs behave, clinically, in a benign manner and correspond to grade I or II, as defined by the World Health Organization (WHO); (2) LEATs occur predominately in the temporal lobe; (3) LEATs have a histologically variable appearance consisting of neuronal and glial components (glio-neuronal tumors); (4) LEATs are likely to originate during early brain development and are often associated with cortical dysplasias; (5) LEATs do not share those oncogenes or tumor suppressor genes typically observed in common brain tumors, i.e., malignant gliomas. In contrast, neurodevelopmentally regulated genes and signaling pathways are likely to be involved, i.e., reelin and mTOR.

LEATs can be detected in epilepsy patients using modern neuroimaging techniques. However, the characterization of the epileptogenic zone remains challenging and should be examined in specialized centers. It remains to be shown whether the tumor itself or adjacent brain parenchyma, often characterized by structural as well as molecular reorganization patterns, contribute to seizure susceptibility and pharmaco-resistance.

Increasing availability of surgical tumor specimens open the possibility to address, neuropathologically as well as neurobiologically, the origins and epileptogenicity of tumor-associated focal epilepsies. Intriguingly, most studies of these tissues have failed to identify genetic or chromosomal aberrations that are usually associated with neoplastic transformation – i.e., loss of TP53 tumor suppressor gene or EGFR oncogene amplification. In contrast, neurodevelopmentally regulated genes are likely to play a role, such as the insulin growth factor receptor pathway involved in the tuberous sclerosis complex (TSC, mTOR) or reelin signaling associated with neuroblast migration and cortical layering. Research analysis of LEAT opens, therefore, also new avenues to understanding brain development under physiological as well as pathophysiological conditions.

Background

Neuropathological Classification of LEATs

The benefit of tailored resection strategies is increasingly recognized for the treatment of patients with intractable focal seizures and benign brain tumors. Surgical resection strategies that encompass the lesion as well as the epileptogenic area result in seizure freedom in ~80% of cases. The comprehensive database of the German Neuropathological Reference Center for Epilepsy Surgery currently includes 3319 samples, of which 938 were diagnosed as LEATs (Table 1).

Unfortunately, many tumors escape early detection in patients with early seizure onset (duration of epilepsy showed a mean 13.2 years), and the various consequences of long-term seizure disorders on mental as well as social development and behavior are considerable. Histopathological diagnosis of LEAT remains challenging. There is a large spectrum of morphological phenotypes, even within neuropathologically defined entities (Table 2). Neuropathological evaluation should, therefore, be obtained from experienced centers. The need for such expertise is critical, since the variability of histopathological phenotypes may often result in a high-grade tumor diagnosis, whereas the long-term clinical course of LEAT behaves very modestly, without enhanced risk of recurrence and/or malignant transformation.

LEAT and Epileptogenesis

Pathogenic mechanisms underlying focal hyperexcitability in LEAT patients need further clarification. Two major hypotheses should be considered. The

Table 1 Neuropathological findings in focal chronic epilepsies

Diagnosis	*Number*	*Age (years)*	*Onset (years)*	*Duration (years)*
Mesial temporal sclerosis	1109	33.9	10.7	22.7
Tumors	938	28.2	14.8	13.2
Dysplasias	407	18.5	4.7	11.6
No lesions	225	28.3	12.4	15.8
Vascular	195	35.9	20.1	12.3
Scars	167	23.9	9.2	14.7
Dual pathology	150	23.1	8.4	13.1
Inflammation	52	20.7	13.7	8.4

Number = number of cases; age = age at operation; onset = age at onset; duration = duration of epilepsy. Data obtained from the German Neuropathological Reference Center for Epilepsy Surgery (www.epilepsie-register.de).

Table 2 Neuropathological spectrum of brain tumors in epilepsy patients

Diagnosis	*in %*	*Age (years)*	*Onset (years)*	*Duration (years)*
GG (WHO I)	46.0	25.1	25.1	13.7
GG (WHO II)	5.0	26.3	12.2	11.7
GG (WHO III)	0.9	38	29.3	4.7
DNT (WHO I)	16.4	26.6	13.8	12.7
A (ISO)	1.7	28.9	15.3	16.2
A (WHO I)	4.9	25.4	11.9	14.5
NOS	4.8	29.1	16.1	16.0
PXA (WHO II)	2.4	30.8	19.2	15.2
SEGA (WHO I)	1.4	18.8	4.5	14.8
A (WHO II)	4.4	33.8	25.7	6.8
A (WHO III)	2.4	39.5	37.0	10.3
O (WHO II)	2.7	35.6	20.6	13.9
O (WHO II)	0.9	40.7	14.7	22.3
OA (WHO II)	2.6	34.8	18.8	10.7
OA (WHO III)	1.2	43.0	21.0	16.3
Cysts	1.9	33.4	21.0	14.2
Others	0.4	6.3	3.0	3.3

The upper half of the table refers to typical LEAT entities, which represent more than 80% of all brain tumors detected in patients with chronic focal epilepsies: GG, ganglioglioma; DNT, dysembryoplastic neuroepithelial tumor; A (ISO), isomorphic astrocytoma variant; A (WHO I), pilocytic astrocytoma; NOS, these tumors cannot be classified according to the revised WHO classification system (2007); PXA, pleomorphic xanthoastrocytoma; SEGA, subependymal giant-cell astrocytoma. The remaining cases (lower half of table) belong to the group of common glial tumors, although malignant variants are rare: A, astrocytoma; O, oligodendroglioma; OA, mixed oligo-astrocytoma; cysts, epidermoids, dermoids, or arachnoidal cysts. In %, % of the 938 tumor samples obtained from the German Neuropathological Reference Center for Epilepsy Surgery (see **Table 1**), age = age at operation; onset = age at onset; duration = duration of epilepsy.

neuronal component of the tumor itself may contribute to epileptogenic activity. Immunohistochemical studies have identified aberrant expression of neuroactive molecules in dysplastic neurons, such as glutamatergic neurotransmitter receptors. Whether these neurons functionally integrate and excite neuronal pathways remains to be shown. A recent study applying intracerebral recordings from electrodes implanted to localize seizure onset identified early ictogenic discharges from a ganglioglioma (GG). Such findings would support a hyperexcitable neuronal tumor component functionally integrated into excitatory circuitries. An alternative mechanism involves tumor-associated, epileptiform changes in the adjacent brain. Altered expression patterns of neuroactive molecules within the perilesional brain parenchyma, as well as the clinical observation that the epileptogenic area may be substantially larger than the tumor mass itself, would be consistent with this hypothesis. In many patients, seizure relief cannot be achieved if only the lesion is resected. Neuronal hyperexcitability within perifocal brain areas may be evoked by kindling mechanisms in limbic structures such as hippocampus and amygdalae, as has been observed in experimental animal models. Besides molecular reorganization phenomena in adjacent brain tissue, enhanced epileptogenicity may also evolve from architectural disturbances of cortical layering (similar to those observed in focal cortical dysplasia type I). Such alterations are frequently encountered in LEAT patients, in particular with dysembryoplastic neuroepithelial tumors (DNTs). Whether such cortical dysplasias should be considered as 'dual pathology' – i.e., underlying a different pathomechanism compared with adjacent tumorigenesis – awaits further clarification.

Methods: Neuropathology of LEAT Entities

Neuropathological examination and diagnosis relies on microscopical inspection of surgical brain specimens obtained from patients with chronic, focal epilepsies and follows the current WHO classification and grading scale (last revised in 2007). This classification scheme has proven useful for the prediction of the biological behavior of an individual tumor entity. However, the large spectrum of LEATs and their variable histomorphological appearance is not fully reflected by the WHO grading system. The following description will, therefore, summarize the most frequent LEAT entities (see **Table 2**).

Gangliogliomas

Whereas gangliocytomas (i.e., Lhermitte–Duclos disease) are homogeneously composed of a dysplastic neuronal-cell population, GGs present with a broader spectrum of histopathological alterations (**Figure 1(a)–(d)**). Besides the recognition of dysplastic neurons (more than one nucleus, condensed Nissl-substances along the cell membrane, irregular anatomical orientation), an additional

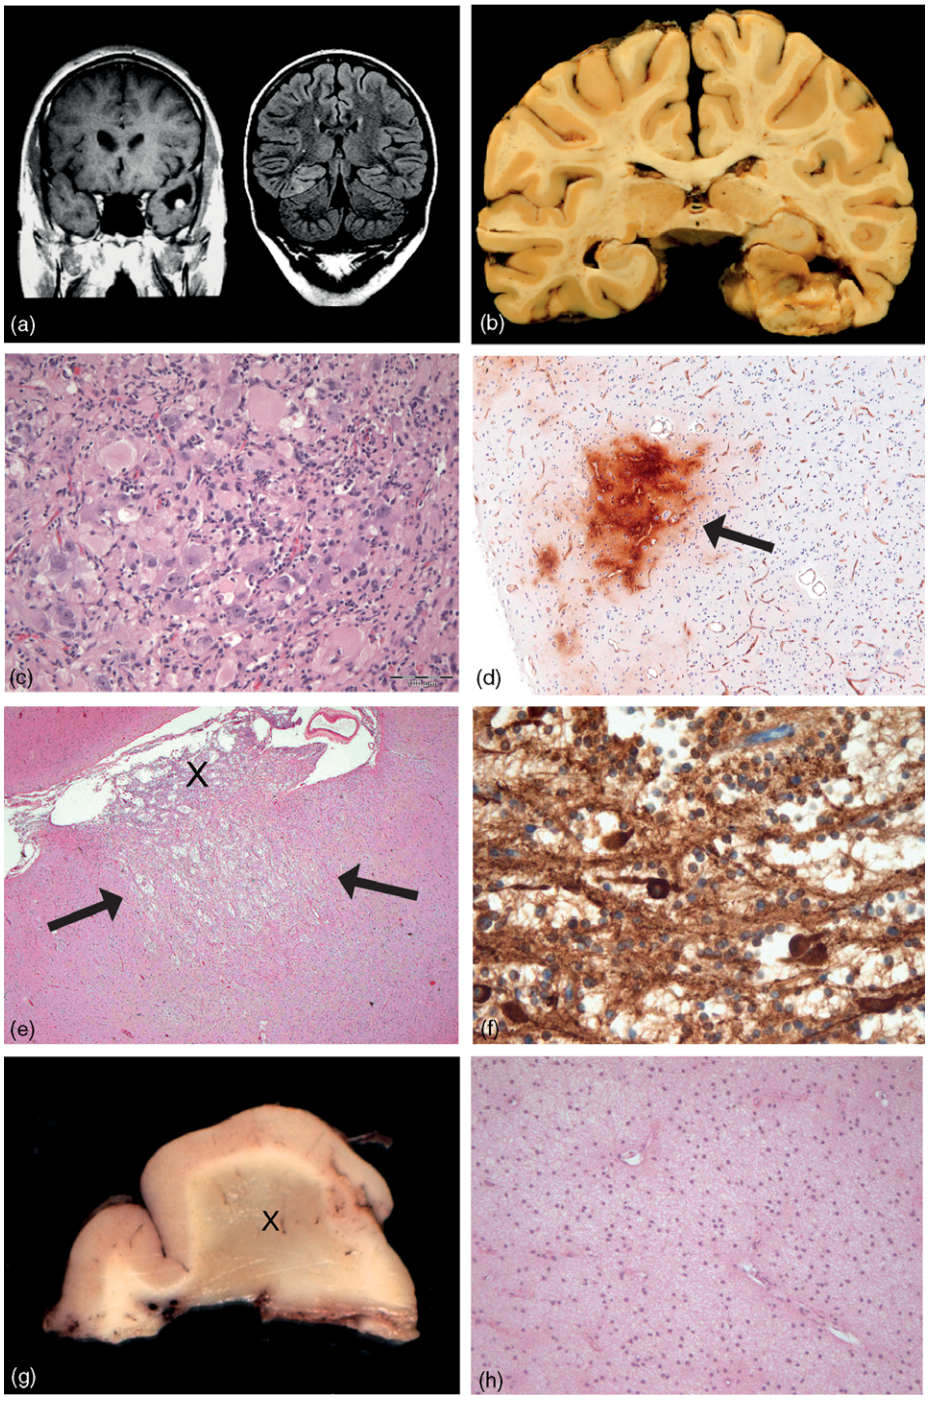

Figure 1 Long-term epilepsy-associated tumors (LEATs). (a) Magnetic resonance imaging in two patients with intractable temporal lobe epilepsies and histopathologically confirmed gangliogliomas (GGs). The different gross appearance of both lesions exemplifies the large spectrum of morphological variants. (b) Autopsy specimen obtained from an elderly patient with a GG located in the right temporal lobe, courtesy of Dr. P Kleihues, Freiburg, Germany (with kind permission). (c) High-power magnification of a GG (WHO grade I). Note the admixture of irregular oriented, dysplastic neurons (larger nuclei and prominent nucleoli) and neoplastic glia cells (200× magnification). (d) Adjacent to the tumor shown in (c), a cluster of CD34-immunoreactive tumor cells was detected in adjacent neocortex. (40× magnification). (e) Dysembryoblastic neuroepithelial tumors (WHO grade I) predominantly occur in superficial neocortical localization (arrows). This tumor also involves also the subarachnoidal space (x) and is characterized by a microcystic appearance (25× magnification). (f) At high-power magnification, mature neurons (MAP2-immunoreactivity) are recognized among tubules of neuropil, which are aligned by oligodendroglial-like cells (specific glio-neuronal element) (200× magnification). (g) Surgical specimen obtained from a young epilepsy patient with a suspicious tumor in the temporal lobe (X), courtesy of Dr. V Hans, Bielefeld-Bethel, Germany. (h) Histopathological examination revealed an isomorphic astrocytoma variant with a benign cellular phenotype (100× magnification).

neoplastic glial-cell population can be identified. This glial component most commonly shows features of astrocytic differentiation, but oligodendroglial-like cells are also recognized. The composition of neuronal and glial cells varies to a considerable extent, with tumors presenting a predominantly neuronal phenotype (in these cases, the differential diagnosis of a gangliocytoma (WHO grade I) should be considered) or predominantly glial phenotype (the differential diagnosis of an astrocytoma (WHO grade II) needs consideration). Additional histopathological features, which can be observed in GGs, are calcification, lymphocytic infiltrates, as well as microcysts. Tumors may also present with an increased vasculature, mimicking cavernomas. Subarachnoidal spread of the tumor can be detected in superficially located tumors and confirm autonomous growth. Additional variants with papillary organization or rosetted neuropil islands have been identified; the latter may present with a less-favorable prognosis.

Immunohistochemistry

Immunohistochemical reactions are mandatory to establish the diagnosis of GGs (Table 3). Almost 80% of tumors are labeled with antibodies against the stem-cell epitope CD34, which does not occur in normal, mature neuroepithelial tissue. In GGs, CD34 immunoreaction product is confined to the outer cellular membrane of glial and neuronal cells, either within the bulk tumor mass or small tumor clusters in adjacent, microscopically unsuspicious cortical regions. Dysplastic neurons accumulate neurofilament proteins or harbor a perisomatic rim of synaptophysin ('corona'). The glial tumor population often expresses glial fibrillary acidic protein (GFAP) whereas glial MAP2-staining is absent. The proliferation index is low (1–2% of cells are labeled with the Ki67 epitope). Higher proliferation activities may result from CD68-positive microglia cell infiltration and should be further investigated. If the glial-cell component contributes to higher proliferation activity, atypical or anaplastic variants of GGs should be considered (see later).

Table 3 Differential diagnosis of LEAT according to their immunohistochemical profile

LEAT	*GFAP*	*MAP2*	*CD34*	*P53*	*Ki67*
GGs	+	+(N)	+	−	1–2%
DNT	+	+(G/N)	−	−	1%
Astrocytoma (isomorphic variant; WHO I)	+	−	−	−	<1%
Astrocytoma (pilocytic; WHO I)	+	+	(+)	−	1–5%
Astrocytoma (WHO II)	+	+	−	(+)	<5%
PXA (WHO II)	+	+	+	−	var.
SEGA (WHO I)	+	+	−	−	var.

DNT, dysembryoplastic neuroepithelial tumor; GG, ganglioglioma; PXA, pleomorphic xanthoastrocytoma; SEGA, subependymal giant-cell astrocytoma; GFAP, glial fibrillary acidic protein; MAP2, microtubule-associated protein; +, epitope is present within the neoplastically transformed glial-cell population; in GG, only the neuronal component (N) is labeled, a few DNT neurons and glia (G) are immunodecorated; CD 34, stem-cell epitope; p53, gene product of the TP53 cell-cycle regulator/tumor suppressor gene; (+), TP53 mutations are present in almost 50% of diffuse astrocytomas; Ki67, proliferation antigen; numbers relate to those areas of the tumor with the highest labeling index.

Differential diagnosis

Since GGs are usually associated with a benign prognosis (WHO grade I), distinction from pilocytic astrocytomas (WHO grade I), diffuse astrocytomas (WHO grade II) and oligodendrogliomas (WHO grade II) should be confirmed. A critical issue to be addressed is the presence of dysplastic neurons within cortical tumor spread, which can also be mimicked by infiltration of diffuse gliomas. However, immunohistochemical reactions for CD34 and MAP2 are most helpful. Distinction from other mixed glio-neuronal tumors (i.e., DNTs) or cortical dysplasia may be difficult to obtain in small surgical specimens.

Molecular pathology

Although characteristic glioma-associated tumor suppressor genes or oncogenes are not affected, neurodevelopmentally regulated signaling cascades appear to play a role. Increased frequency of rare polymorphisms in those genes associated with the tuberin/insulin growth receptor pathway (mTOR) support this hypothesis. In addition, decreased expression of the reelin-signaling cascade has been identified. However, the pathomechanism underlying abundant expression of the stem-cell marker CD34 in GGs remains to be elucidated. Biphasic differentiation patterns in GGs challenge molecular neuropathology and stress the need for cell lineage-specific analysis. Laser-assisted microdissection indeed supports a dysontogenic origin from a glioneuronal precursor lesion with neoplastic, clonal proliferation of the glial-cell component.

Grading

In a large series of 184 patients with supratentorial GGs, a median follow up of 8 years identify tumor recurrence in only 3%. However, malignant progression (2%) and death (1%) have been encountered (Figure 2). Favorable clinical outcome associates with (1) tumor location within the temporal lobe, (2) complete surgical resection, and (3) histopathological classification according to WHO grade I. Although the current WHO classification system 2007 does not specify histological parameter of atypical

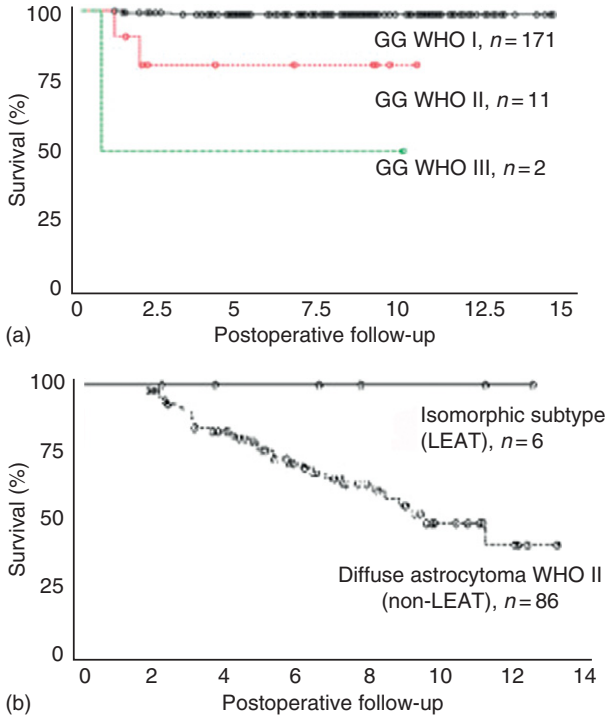

Figure 2 Clinico-pathological correlation in two different LEAT entities. (a) Follow up of 184 gangliogliomas according to the current WHO classification system 2007. Note the favorable survival after complete resection. Modified from Luyken C, Blumcke I, Fimmers R, Urbach H, Wiestler OD, and Schramm J (2004) Supratentorial gangliogliomas: Histopathologic grading and tumor recurrence in 184 patients with a median follow-up of 8 years. *Cancer* 101: 146–155. (b) In contrast to diffusely infiltrating astrocytomas (WHO grade II) obtained in 86 nonepileptic (non-LEAT) patients, the histopathological distinct isomorphic variants associates with a benign long-term outcome. Modified from Schramm J, Luyken C, Urbach H, Fimmers R, and Blumcke I (2004) Evidence for a clinically distinct new subtype of grade II astrocytomas in patients with long-term epilepsy. *Neurosurgery* 55: 340–347.

GGs (WHO grade II) or anaplastic variants (WHO grade III), increased cellularity, nuclear pleomorphy, and proliferation (>5% Ki67 labeling index) within the glial component may indicate a semibenign nature of the tumor. Significantly increased proliferation index above 10% and tumor necrosis should be regarded as signs of anaplastic progression (WHO grade III).

Dysembryoplastic Neuroepithelial Tumors

DNTs manifest with multiple nodules within the neocortex and are associated with intractable seizures (**Figure 1(e)–(f)**). The histopathological hallmark is the 'specific glio-neuronal element,' characterized by axonal tubes lined by oligodendroglia-like cells and floating neurons embedded in a mucoid matrix. However, many tumors display additional histopathological features such as cortical dysplasia or other neoplastic differentiation patterns, resembling pilocytic astrocytomas, oligodendrogliomas, or GGs. Whereas the detection of dysplastic neurons in the vicinity of the tumor should be regarded as component of its dysontogenic origin (and not as 'dual pathology'), variants with additional features of vascular malformations, pilocytic astrocytomas, or GGs are regarded as complex form of DNTs (WHO grade I). There is no hint for unfavorable prognosis in these variants.

Immunohistochemistry

Floating neurons are usually mature and can be immunohistochemically characterized by neurofilament protein, MAP2 or synaptophysin. The glial component of this tumor usually does not stain for GFAP, but expresses S-100. CD34 is absent in neuroepithelial tumor cells. Ki67-positive nuclei are rare (below 1%), supporting the concept of a dysembryoplastic origin of this tumor entity.

Differential diagnosis

Confirmation of the 'specific glio-neuronal element' and multinodular occurrence should be decisive for the diagnosis. However, a prominent clear cell phenotype warrants the differential diagnosis of oligodendrogliomas. In fact, the DNT was recognized almost 20 years ago from a cohort of epilepsy-associated oligodendrogliomas with benign prognosis. The complex form of DNTs may be more challenging for routine histopathology. Since histological features of astrocytomas, oligodendrogliomas, and GGs can be recognized in this tumor entity,

immunohistochemistry using CD34, MAP2, synaptophysin, and S-100 is mandatory for the differential diagnosis.

Molecular pathology

Histomorphological similarities with other clear cell tumors of the nervous system – i.e., oligodendrogliomas, mixed oligoastrocytomas, or neurocytomas – have initiated molecular genetical analysis of specific chromosomal regions. Compared with oligodendrogliomas, however, loss of heterozygosity testing has not revealed alterations at chromosome 1p and 19q, nor have TP53 mutations been identified. Although the molecular pathogenesis of DNT appears to be entirely unknown, a recent report described familial occurrence at same age and cortical location. Thus, genetic analysis of affected family members may provide novel clues to its pathogenesis.

Astrocytomas

Histopathological grading and differential diagnosis of low-grade gliomas are challenging in epilepsy patients, and investigators should consider a large spectrum of morphological variants – i.e., pilocytic astrocytomas (WHO grade I), diffusely infiltrating astrocytomas (WHO grade II or III), or the recently described angiocentric glioma and isomorphic astrocytoma variants. In recent years, molecular–genetic findings emerged as valuable means to support this distinction. In low-grade diffuse astrocytomas, a significant portion of tumors presents with mutations in cell-cycle control genes, i.e., TP53, and associates with a higher risk for anaplastic progression. In contrast, there is still no reliable genetic marker available for the identification of pilocytic astrocytomas or pleomorphic xanthoastrocytomas (PXAs), nor for their risk of tumor recurrence and malignant progression.

Pilocytic astrocytomas

PAs are common tumors of the cerebellum in children and young adults. However, pilocytic astrocytomas may occur at all other sites of the CNS, i.e., as intraspinal tumors or optic pathway gliomas ('optic gliomas') in patients suffering from neurofibromatosis type 1. Since pilocytic astrocytomas can occur in any age group, this tumor has to be always considered in the differential diagnosis of low-grade gliomas and LEAT.

Histopathological hallmarks of pilocytic astrocytomas include prominent 'hairy (piloid)' cellular processes, Rosenthal fibers, and eosinophilic granular bodies. In contrast to diffusely infiltrating astrocytomas, microvascular proliferation and tumor necrosis may occur but are not associated with anaplastic transformation. An increasing number of reports deal with the risk for tumor recurrence and malignant progression in pilocytic astrocytomas. The pilomyxoid variant should, therefore, be differentiated (WHO grade II).

Isomorphic astrocytoma

Recently, we identified a novel astrocytoma variant in a series of 19 patients with chronic seizures and diffuse astrocytomas (**Figure 1(g)–(h)**). Histopathological hallmarks included low cellularity, lack of mitotic activity, and highly differentiated astroglial elements infiltrating into adjacent brain parenchyma. Compared with 'classical' variants of diffuse astrocytomas (WHO grade II), immunohistochemical reactions reveal cellular proliferation below 1%, absence of nuclear p53 accumulation, as well as lack of glial MAP2 and CD34 expression. These features distinguish the isomorphic astrocytoma subtype from GGs, pilocytic astrocytomas, and DNTs as well as from cortical dysplasia or reactive gliosis. Long-term survival and lack of tumor progression after a maximal follow-up time of 13 years further support the distinction of this clinically and histopathologically benign astrocytoma variant, and are consistent with classifying this tumor as WHO grade I (**Figure 2**).

Pleomorphic Xanthoastrocytoma

This glioma variant frequently infiltrates the subarachnoidal space, and shows a histopathological pattern consisting of pleomorphic glial cells, presenting with multinucleated giant cells, and intermingled with vacuolated, xanthochromic cells. The latter results from intracellular accumulation of lipids, and are usually responsible for the macroscopically recognizable yellowish appearance of the tumor. There is an ongoing debate with respect to the malignant behavior of this tumor entity. The WHO consortium assigns PXAs to WHO grade II or III (anaplastic variant). Molecular genetic studies may advance our understanding of this intriguing tumor entity.

Subependymal Giant-Cell Astrocytoma

This rare low-grade glioma is always associated with the TSC. Exophytic tumor growth originating from the ependymal-cell layer extending into the ventricular system is usually observed. Histopathologically, these tumors are composed of ganglioid astrocytes. Clinically, malignant progression has not been encountered and this tumor entity is classified according to WHO grade I. Hence, the presence of prominent cellular atypia in a subependymal giant-cell astrocytoma (SEGA) is not a criterion for anaplastic transformation.

Future Goals

Tumor-associated epilepsies represent a fascinating interface between clinical and basic research. To understand pathogenic mechanisms of neoplastic transformation in neuroepithelial cells remains a major topic in the

neurosciences, but the glio-neuronal phenotype of most LEAT entities challenge modern neurodevelopmental concepts as well. Early disease onset, benign clinical courses, variable pathomorphological patterns, and detection of the onco-fetal marker CD34 point rather towards compromised developmental signaling pathways than enhanced proliferation or apoptosis of genetically transformed tumor progenies (as reasoned in high-grade tumors). With increasing availability of surgical epilepsy specimens, these intriguing issues can be directly addressed in human brain using a large variety of modern anatomical, molecular, genetic, as well as electrophysiological techniques. Recent evidence for the involvement of the reelin-signaling cascade as well as mTOR pathway (associated with insulin growth factor receptor and TSC) support this notion and will further corroborate our understanding of human brain development under physiological as well as pathophysiological conditions.

However, poorly understood epileptogenicity of focal (neoplastic) brain lesions represents another challenging issue in the field of LEATs. Since appropriate animal models are not yet available, the investigator must turn to human brain slices; slices from within the tumor itself or within adjacent brain parenchyma can be examined with respect to cellular and molecular alterations. Recent studies describe different brain 'compartments' to be involved, including neurotransmitter systems, blood–brain-barrier disturbances, altered composition of extracellular matrix molecules, or even aberrant drug transporter expression. Human brain tissue can be directly retrieved from the operation theater and, therefore, successfully used for most experimental studies. Notwithstanding, any alteration detected in individual patients then needs to be confirmed in animal models with respect to its involvement in altered 'epileptogenic' network signaling and/or enhanced seizure susceptibility.

Last but not least, molecular genetic studies addressing brain tumors should be further advanced to determine predictive factors in those patients suffering from increased risk of tumor recurrence or malignant transformation. The proportion of these patients is rather small in LEATs, but will help to improve clinical treatment strategies in patients with chronic focal epilepsies and brain tumors.

Introduction and Background

Neuropathology refers to the study of the diseases of the nervous system. The term, however, is traditionally referred to the study of morphological alterations that can be observed by means of macro- and microscopic inspection. The term 'neuropathology' generally evokes the image of a scientist sitting in front of a microscope in a room smelling of paraffin and formalin traditionally the major tools of neuropathologists. Although this basic picture remains valid, numerous tools have been added to the traditional techniques; those diseases determined by morphological and functional alterations of the brain can now be examined through the application of innovative technologies. This advance in the general field is particularly applicable to epilepsy, since epilepsy is basically a functionally defined disorder. In modern clinical practice, in addition to formulating a 'correct' diagnosis based on anatomical alteration(s), the neuropathologist is often also assigned the task of offering insights into the pathogenesis of the primary lesion. In dealing with epilepsy-related lesions, the neuropathologist may be asked to hypothesize about the genesis of the epilepsy, as reflected in the neuropathological findings. Thus, although it remains important to produce a detailed description of the observed morphological alterations, this description is not sufficient. It is also fundamental to provide evidence of the related 'etiopathogenesis,' in order to provide insight into functional features of the epilepsy.

In the last two decades, the increasing development of neuroradiological techniques, particularly the high resolution Magnetic Resonance Imaging (MRI), has provided a dramatic improvement of the 'in vivo' diagnosis of many symptomatic epilepsies, thanks to the early recognition of underlined structural alterations of the brain. The neuroradiologist and the neuropathologist now work together to provide structural observations that help explain the functional abnormality. Furthermore, integrated approaches of different branches of the neurosciences, such as neurophysiology, neurogenetics, and molecular biology, combined with new technologies in neuroimaging and neurosurgery, have given rise to an increasing interest in epilepsy, in order to achieve a better understanding of basic and pathogenetic mechanisms.

Finally, since many symptomatic epilepsies are unresponsive to pharmacological therapies, their treatment frequently relies on the surgical removal of areas thought to be responsible for seizures. As a consequence, the last decade has seen an increase in the number of epileptic patients surgically treated, with a parallel increase in the availability of surgical specimens for neuropathological analysis. This developing new perspective highlights the role of the neuropathologist, who has become a primary actor in an integrated, interdisciplinary, 'non traditional' team that spans both bench and bedside (**Figure 1**).

In the epilepsy field, the neuropathologist is instrumental in characterizing the different types of epilepsies, from the idiopathic to the symptomatic forms, in the wide spectrum of their etiologies. In the past, the neuropathological identification of underlying causes was achieved through autopsy investigations. However, in increasingly available surgical specimens from patients with intractable focal epilepsies have now become the major focus of interest for the neuropathologist. The partial epilepsies from which these specimens derive may be caused by a variety of different lesions, including vascular disorders, head trauma, tumors, malformations of cortical development (MCD), infections, neurodegenerative, and inflammatory disorders. Although the basic cellular mechanisms of epilepsy have a common functional output (reflected in an abrupt, excessive, and synchronous discharge of a certain neuronal population – i.e., a seizure), each one of the above mentioned pathological processes may determine this abnormal discharge through different mechanisms.

Glial tumors, for example, are generally not intrinsically epileptogenic per se, since the tumoral tissue generates paroxysmal discharges only indirectly, by its effect on the surrounding neuronal tissue. In contrast, MCD may be intrinsically epileptogenic, presumably due to an abnormal rearrangement of the intrinsic circuitry. Indeed, in the last decade, there has been a progressively increasing number of publications devoted to epileptogenesis related to cortical dysplasia. In this respect, the in vivo localization and definition of these alterations, greatly improved by neuroimaging techniques, have determined an increasing number of partial epilepsies – previously defined as 'cryptogenetic' – that are now recognized to be associated with malformative cortical lesions. Today, MCDs represent one of the most challenging problems in epilepsy, involving basic issues about both normal and abnormal brain development.

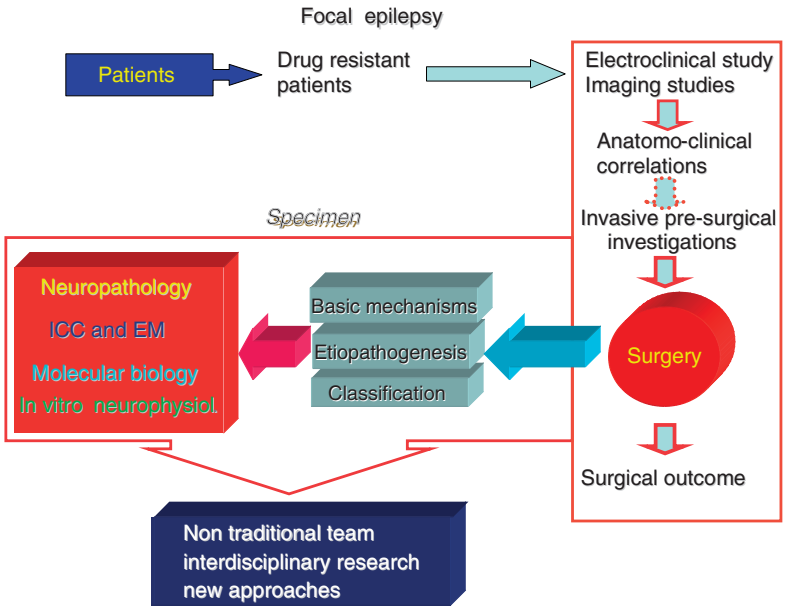

Figure 1 Neuropathological involvement in the diagnosis and treatment of patients with epilepsy.

Relevant to this topic of MCDs, some major questions include:

1. How do malformations develop?
2. Why, in the majority of cases, do they generate epileptic activity?
3. Do the different types of malformations have the same mechanisms for generating epilepsy; in other words, do the different subtypes of malformations have the same pathophysiological mechanism for epileptogenesis?

These questions are fundamental to our understanding of MCD-related epilepsies, and neuropathology plays a key role in interpreting and decoding the content of this black box.

Methodological Caveats

In addition to the traditional routine histological methods, neuropathologists have in their hands powerful 'new' techniques such as immunocytochemistry using different antibodies against structural and functional proteins (such as neurotransmitters and receptors) and in situ hybridization using several mRNA probes that can be fruitfully used on human tissue obtained from surgical specimens. It is, however, of fundamental importance that the neuropathologist be present in the surgical theater during surgery. When a specimen containing the malformation is resected, it is mandatory to obtain an accurate record of the orientation of the piece of ablated cortex to determine precisely, from the surgeon and from comparison with imaging data, the exact position of a given sample. Moreover, when (as frequently it happens) the surgery is performed after pre-surgical invasive recordings, it is important to know not only the exact location of the lesion but also that of the epileptogenic zone and of the surrounding areas (as identified by electrophysiological recordings), in order to establish the morphofunctional correlations of the different ablated regions.

Recent Results

To provide a realistic picture of the role of the neuropathologist in the study of epileptic lesions, let us consider in detail the above mentioned questions about MCDs. This exercise will depict the framework in which we are moving, explain the methodological possibilities, and provide a perspective for future developments in this field.

How Do Malformations Develop?

The mechanism of outward displacement of neurons in the developing cortex remained unknown for decades. It was only in the early 1970s that active radial migration was finally recognized as the basic mechanism for building the cerebral cortex. In addition, early reports concerning the existence of cells with tangential orientation were revisited, providing evidence for distinct, non-radial routes of some cell cohorts in which migration travels parallel to the pial surface. Lastly, the history of radial glia has been recently enriched by novel exciting data indicating that these cells are capable, by asymmetric division, of giving

rise to neurons and glial cells, and that radial glial cells are, therefore, neurogenic.

Thus, two main trajectories – a radial and a tangential route – were identified for neuronal migration. The process of radial migration implies that new neuroblasts, generated from the ventricular proliferative zone, migrate to the cortical plate, climbing along radially oriented fibers that extend from the ventricle to the pial surface. Radially migrating neurons give rise primarily to pyramidal neurons (i.e., projection neurons), which are excitatory and utilize glutamate as neurotransmitter. In contrast, non-radially migrating neurons, generated in the ganglionic eminence – the primordium of the future basal ganglia located in the ventral forebrain – follow a long tangential migratory route to reach the cortical plate and form the majority of non-pyramidal neurons (i.e., cortical interneurons), which are GABAergic.

This brief summary suggests that during cortical development, a spatial and ordered sequence of migratory events is necessary to construct the cerebral cortex. These mechanisms become extremely complex in the formation of the large neocortex of primates. Both intrinsic (genetic) and environmental mechanisms are involved in corticogenesis, although the intimate processes leading to the mature cortical structure are not yet completely understood. Disturbances of these processes can lead to a wide range of alterations, from diffuse and severe brain malformations to local disruption of cortical structure.

MCD, recognized by neuropathologists since the end of the 19th century, and now attributed to a defect of neuronal migration during a crucial period of cortical development, are a heterogeneous group of focal or diffuse anatomical derangements. The pathological features largely depend on the timing of the defect in the developmental process and to a lesser extent on its cause. The advent and development of imaging techniques has had a great diagnostic impact in this area of neuropathology, allowing the investigator to recognize MCDs in vivo. Since most of these malformations are epileptogenic, the advances in imaging have also been helpful in providing correlations between imaging features and electroclinical findings. The cortical malformations previously grouped under the general term of 'neuronal migration disorders' (NMDs) have now been reclassified, in order to reflect our improved knowledge of their pathological substrates, their possible etiological factors, and the relationship between the structural features of the malformation and the type of epilepsy. Indeed, not all the so-called NMDs have been shown to be due directly to impaired neuronal migration; other mechanisms are thought to be involved. And despite many efforts, it is widely recognized that the classification of these disorders is far from satisfactory, and there is no general consensus on these complex structural abnormalities. While it can be argued that classification is an old-fashioned problem, it appears to be a fundamental issue, as stated by Sarnat: 'Classification of simple concepts is almost reflexive but, at high level of abstraction, classification requires the greatest creativity that the human mind can muster and in no categories of disorders is classification more complex than in the field of diverse malformation of the nervous system.' Neuropathology thus has much to do with this aspect of the research. Furthermore, the etiology of malformative disorders is often uncertain and the mechanisms by which they generate epilepsy are unclear.

Over the past decade, molecular biologic and genetic studies of cortical development have greatly expanded our knowledge of the mammalian brain's normal development and derangements. Several disorders of cortical development have been recognized, and for some of them specific causative genetic defects have been identified. For example, periventricular nodular heterotopia (PNH) can be causally related to mutation of specific genes, such as Filamin A and adenosine dipphosfate-ribosylation factor guanine exchange factor 2 (ARFGEF2). However, other nodular heterotopia, presenting single or multiple unilateral or bilateral nodules, sometimes associated with other brain malformations and extending from the periventricular region to involve the adjacent overlying cortex, are not genetically determined. In these cases, the presence of risk factors for prenatal brain damage and the absence of obvious genetic causes of the PNH suggest that extrinsic factors (damaging more or less limited regions of the developing brain) may be involve. Such cases provide evidence that nodular heterotopia represent a heterogeneous disorder. Neuropathological investigations performed on autopsy cases with genetically determined PNH and on surgical specimens from patients without genetically determined forms, have shown great similarities between genetic and non-genetic forms. The neuropathological data, obtained using immunocytochemical procedures to reveal the different subpopulations of excitatory and inhibitory neurons, suggested that the final structure and intrinsic organization of the nodules may be independent of their etiology and unrelated to whether the heterotopia is unilateral or bilateral, subependymal or subcortical. Nodular heterotopia are currently considered to be the result of defective neuronal migration in early development. However, some authors have suggested that the defective gene product linked to one genetic form – an actin-binding protein necessary for the movement of certain cells – is required to signal the end of neuroblast division, and that lack of (or abnormality in) this product results in the neuroblast over-proliferation that characterizes nodular heterotopia. This possibility would explain the neuropathological similarities between the different forms of nodular heterotopia and why an exuberant number of neurons are clustered between the ventricles and the neocortex. Moreover, neuropathological investigations

revealed that the cortex overlying the nodules is frequently disorganized, and is characterized by an alteration of excitatory–inhibitory circuits that gives morphological and functional support to the electrophysiological data showing that in some cases seizures start from this nearby cortex and not only from the heterotopic nodules.

However, nodular heterotopia are quite rare. Recently, particular attention has been given to the most frequent cortical disorganization, represented by the so-called focal cortical dysplasia (FCD), some of which have specific electroclinical, neuroradiological, and histopathological characteristics. Although there is a general consensus that FCD can be highly epileptogenic, this feature of the disorder does not per se imply a correlation between the lesion and the epileptogenic area. The possibility of such dissociation has led to a continuing debate concerning the relative advantages of selective lesionectomy versus less conservative surgical approaches. One crucial issue is the extent of the surgical excision in relation to the lesion revealed by MRI. It has been reported that the extent of the resection of cortical structural abnormalities is the most important determinant of surgical outcome, but it has also been suggested that the epileptogenic areas may exceed the MRI-visible lesion and that, in many cases, surgical resection should be guided by the results of pre-surgical invasive recordings. Neuropathology could help to resolve this issue by supplying pertinent data, not only in order to estimate the extent and type of the malformation, but also to establish the extent of the epileptogenic zone. This task could be accomplished by studying, in homogeneous and selected populations of epileptic patients with FCD, the morphological aspects and the basic pathological mechanisms in the surgically excised tissue that correlate with the imaging signals, and with the electrophysiologically identified epileptogenic zone.

Once again, the problem of terminology and classification appears of fundamental importance, not only for establishing a diagnosis but particularly for providing a useful prognosis for the patients who undergo epilepsy surgery.

Thanks to accurate neuropathological investigations, two main forms of FCD, type I and type II, have been recognized. Both type I and II FCD have as a common feature a disruption of the cortical lamination, but they differ in intrinsic cellular organization, in alterations of the GABAergic system, and in cytological aspect (**Figure 2** and **3**).

Recent data provided evidences that type I FCDs are mainly found in temporal regions while type II are detected in extra-temporal areas. Furthermore, a more favorable post-surgical outcome is reported in type II FCD, probably because this type of dysplasia, intrinsically epileptogenic, is more localized than type I and thus accessible for complete resection. We still do not know the etiology of these malformations; the two forms may have different pathological mechanisms at their origin. One of the future challenges will be to determine if the two types of FCD have common origin. For this type of investigation, new tools are now available for molecular classification of cortical cells, and to reveal and map neuronal position within cortical layer in normal and malformed cortex. A common pathogenetic mechanism has been suggested, by the presence of histopathologic similarities, between FCD and dysplastic areas in autosomal inherited phacomatosis such as tuberous sclerosis. The determination of molecular genetic alterations in specific epilepsy-associated malformations would help to identify molecular pathways with potential pathogenetic relevance. The correlation between clinical, imaging, neuropathologic, and molecular analysis will help to further develop comprehensive classification systems and treatment strategies in epileptic patients with MCD.

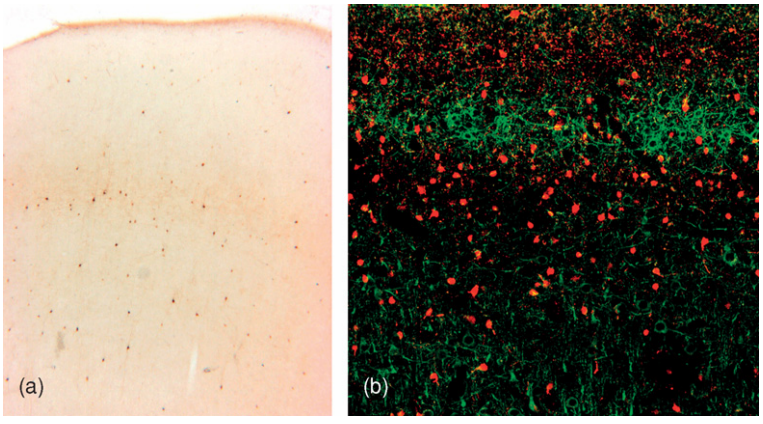

Figure 2 (a) Reduced immunoreactive staining for Parvalbumine (PV; a calcium binding protein specifically staining a subpopulation of GABergic interneurons) suggestive for an impairment of GABA circuitry in type 1 FCD. (b) Architectural abnormality in type I FCD as observed at confocal microscope. A double fluorescent staining using MAP-2 (green signal) and Calbindine (red signal).

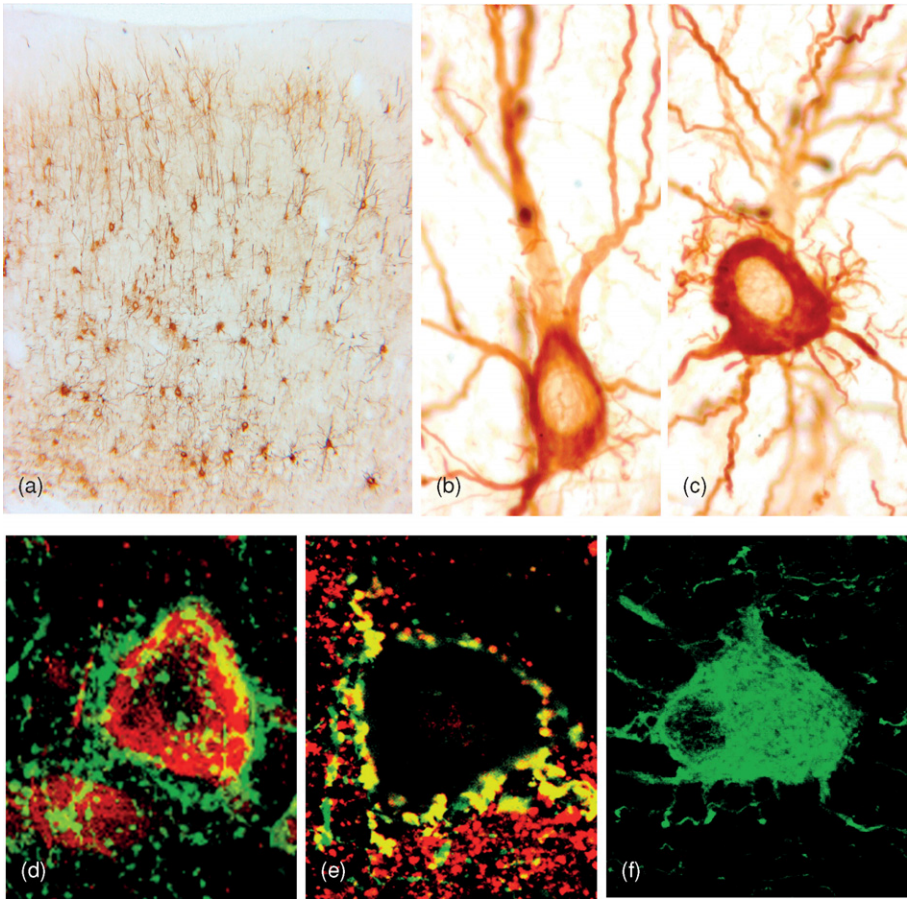

Figure 3 (a) Cortical disorganization in type II FCD as observed using an antibody against neurofilaments; note the presence of giant and dismorphic neurons (at high magnification in (b) and (c)) representing typical elements in this dysplasia. (d) Confocal image showing an increased concentration of PV terminals (green signal) surrounding the dimorphic neuron labeled with an antibody against neurofilaments (red signal). These terminals are double labeled (yellow signal) with PV and GAT1 (a transporter of GABA) demonstrating that they are inhibitory terminals (e). Another typical cellular element of this type of FCD is represented by balloon cells specifically labeled by Vimentin (f).

Why, in the Majority of Cases, do these MCDs Generate Epilepsy? Do the Different Types of Malformations Employ the Same Mechanisms for Generating Epileptiform Discharge/Epilepsy?

Human epileptic dysplasia exhibit a spectrum of abnormal cell aggregation and orientation patterns, as well as a variety of and laminar disruptions. It is, therefore, likely that many 'plastic' axodendritic and cellular changes occur during development. For example, intrinsic circuitry alterations and remodeling of receptor assemblies could be responsible for neuronal hyperexcitability – giving rise to imbalanced excitatory and inhibitory mechanisms leading to seizures. Despite considerable research, the exact mechanisms by which seizures are generated in dysplastic brain remain largely unknown. Combined morphologic and molecular approaches, investigating the neurotransmitters and related receptors, have been developed. One line of research suggests that NMDA impairment is associated with altered molecular structure of postsynaptic membrane, and that different malformations may be associated with different alterations of these receptors, contributing to the genesis of epileptic phenomena. A second line of research, devoted to the study of the inhibitory circuitry, suggests a critical role for GABA-mediated inhibition in the overall control of neuronal excitability in cortical dysplasia. That the aberrant expression of NMDA receptors play a role in the genesis of seizures is not surprising, since a large body of data is consistent with the conclusion that glutamate-mediated excitation is enhanced in epileptogenic cortical malformations. It should be noted, however, that the sophisticated functional analysis performed on glutamate-mediated excitation in dysplastic brain has not yet been applied to the GABAergic system. The impairment of the two

systems is not mutually exclusive, and perhaps coexists at different levels of efficacy in the diverse forms of malformations.

Many mechanisms may be implicated in the epileptogenesis involving both neurons and glial elements and several lines of evidence link glial cells to modulation of synaptic transmission showing that functional alterations of specific glial membrane channels receptors and transporters are involved in epilepsy.

Although intercellular communication in the mammalian cortex is generally thought to take place through chemical transmission, recent studies showed that intercellular communication via gap junctions represents an important pathway through which cells exchange ions, second messengers and low molecular weight metabolites to maintain tissue homeostasis and to control growth and differentiation. Gap junctions are the morphological correlates of electrical coupling (low resistance pathways), and have been implicated in the genesis of several diseases of the nervous system, including epilepsy. New lines of research, based on RNA blot analysis and on morphological studies using specific antibodies against connexins, have focused on the relationship between gap junctions and epilepsy; such studies have suggested that increased intercellular coupling may be implicated in contributing to the synchronization of discharges in epileptic foci. This relatively new line of research has also generated new interest in pharmacology approaches – i.e., gap junction blockers that might act as potent antiepileptic drugs.

Challenges for the Future

The complex pathology of focal epilepsies, and particularly those related to MCDs, should now give rise to functional genomic investigations. The recent development of new technologies, such as microarray and gene-expression profiling techniques, can identify large numbers of genes with potential involvement in these structural abnormalities. Thus, the integration and interpretation of the data from neuropathologically characterized tissue or specific cellular populations (e.g., using laser-microdissection approaches) represent a future challenge that may provide new, important insights into the pathogenesis of many forms of epilepsy.

Introduction

Seizure detection usually refers to the detection of the electroencephalographic (EEG) correlate of an epileptic seizure, which is primarily an event generated in/by a large group of neurons. Seizure prediction similarly refers to the possibility of predicting, before its clinical or encephalographic onset, the occurrence of an epileptic seizure from analysis of the EEG signal. Towards these ends, it is conceivable that measurements other than EEG could be analyzed (e.g., electrocardiogram, electromyogram, movement, oxygen saturation), but these measures have not retained the attention of many researchers. Therefore, our discussion here will review the problems of detection and prediction from the point of view of EEG analysis.

Seizure Detection

Why Detect Epileptic Seizures?

Patients who are investigated for severe epilepsy are often subjected to long-term EEG/video monitoring, a procedure that can last from a few hours to 2 or 3 weeks. Its purpose is to record the EEG and observe behavioral manifestations during seizures, in order to determine the type and frequency of seizures to better adjust medication, or in order to localize the seizure onset when surgical treatment is considered. During such a procedure, the patients are usually asked to press a button when they feel a seizure coming. If patients could always feel their seizure coming, there would be no need for automatic seizure detection. It is frequently the case, however, that patients are not aware of their seizures, and observers are not always present and/or not always able to recognize a seizure. Furthermore, some seizures have very minimal clinical signs – and sometimes no visible signs at all. Finding all seizures may require the review of days and days of EEG, a process that is long and tedious – and not always effective inasmuch as short seizures can be missed, particularly if there are many channels, as in intracerebral recordings. Automatic seizure detection can be helpful in this context, as it provides a means for marking the EEG sections that are likely to include seizure patterns. For this purpose, the detection can take place at any time during the seizure (not necessarily early) because the EEG will be reviewed a posteriori.

Seizure detection could also be used in real time, to warn the patient or observer that a seizure has just started. In this case, the detection must occur early to allow the patient to take protective measures (if he or she is still able to do so), to assist an observer in providing protective measures in a timely fashion, and to facilitate the observer's attempts to question the patient so as to improve our understanding of clinical signs (e.g., can the patient follow commands, talk, remember?). Such an early seizure detection system can be used during monitoring in the clinic,

Introduction

Seizure detection usually refers to the detection of the electroencephalographic (EEG) correlate of an epileptic seizure, which is primarily an event generated in/by a large group of neurons. Seizure prediction similarly refers to the possibility of predicting, before its clinical or encephalographic onset, the occurrence of an epileptic seizure from analysis of the EEG signal. Towards these ends, it is conceivable that measurements other than EEG could be analyzed (e.g., electrocardiogram, electromyogram, movement, oxygen saturation), but these measures have not retained the attention of many researchers. Therefore, our discussion here will review the problems of detection and prediction from the point of view of EEG analysis.

Seizure Detection

Why Detect Epileptic Seizures?

Patients who are investigated for severe epilepsy are often subjected to long-term EEG/video monitoring, a procedure that can last from a few hours to 2 or 3 weeks. Its purpose is to record the EEG and observe behavioral manifestations during seizures, in order to determine the type and frequency of seizures to better adjust medication, or in order to localize the seizure onset when surgical treatment is considered. During such a procedure, the patients are usually asked to press a button when they feel a seizure coming. If patients could always feel their seizure coming, there would be no need for automatic seizure detection. It is frequently the case, however, that patients are not aware of their seizures, and observers are not always present and/or not always able to recognize a seizure. Furthermore, some seizures have very minimal clinical signs – and sometimes no visible signs at all. Finding all seizures may require the review of days and days of EEG, a process that is long and tedious – and not always effective inasmuch as short seizures can be missed, particularly if there are many channels, as in intracerebral recordings. Automatic seizure detection can be helpful in this context, as it provides a means for marking the EEG sections that are likely to include seizure patterns. For this purpose, the detection can take place at any time during the seizure (not necessarily early) because the EEG will be reviewed a posteriori.

Seizure detection could also be used in real time, to warn the patient or observer that a seizure has just started. In this case, the detection must occur early to allow the patient to take protective measures (if he or she is still able to do so), to assist an observer in providing protective measures in a timely fashion, and to facilitate the observer's attempts to question the patient so as to improve our understanding of clinical signs (e.g., can the patient follow commands, talk, remember?). Such an early seizure detection system can be used during monitoring in the clinic,

but could also be incorporated in an implantable device that would provide a warning (e.g., auditory) to the patient during normal everyday activities.

Seizure Warning vs. Seizure Prediction

Although the terminology is not obvious and not necessarily universally recognized, there is a large difference between what we will call 'seizure warning' and 'seizure prediction.' Seizure warning refers to a signal given *because a seizure has just started* – as discussed above. Seizure prediction refers to the ability to forecast the *future occurrence of a seizure*. The difference is large from the point of view of signal analysis: in the first case, the objective is to detect the seizure as soon as it has started; in the second case, it is necessary to search for what may be taking place in the EEG that precedes a seizure, to search for a change that has not been identified by visual analysis – and that may not always exist in the EEG (see below). For a method to be effective for seizure warning, the following requirements must be met: high sensitivity (detect most seizures), early detection (the warning is only useful if it arrives within a few seconds of seizure onset), and low false alarm rate (a warning is likely to be ignored if it occurs erroneously too often). By providing a warning only for seizures that resemble a specific template (and not for any type of seizure), it is possible to reach a good 'compromise' regarding these requirements. Recent efforts have also made it possible to provide a warning with good reliability without relying on a specific template. Seizure warning methods have been developed separately for scalp and for intracerebral EEG.

Methods and Results

Seizure Detection Methods

In epileptic patients and in experimental animals, the EEG is recorded either on the scalp, on the surface of the brain (epidural or subdural), or inside the brain (intracerebral). Our current understanding is that seizures consist of paroxysmal rhythmic activity generated by a large number of synchronized neurons. This activity usually evolves, with changes in spatial distribution, frequency, and amplitude, although there are exceptions (e.g., the spike and wave bursts typical of generalized epilepsy present with very little evolution). The patterns that are actually recorded depend not only on the discharge itself, but also on the respective position of the electrodes and the generator. In some cases, no seizure discharge may be visible because the electrodes are too far from the generator. For the same reason, the seizure discharge may appear only as a mild modification of the ongoing EEG. It is therefore important to distinguish the seizure itself from its manifestations (i.e., from the vantage point of the recording electrodes). As seizure detection is performed from analyzing the EEG, it is only the seizures that have a clear manifestation in the EEG that can be detected. **Figures 1** and **2** show examples of seizures recorded from the scalp, and **Figure 3** shows a seizure recorded from intracerebral electrodes. In **Figures 1** and **3**, the specific moment of onset is not easily identified. In **Figure 2**, the onset is clear, consisting of a few seconds of rhythmic discharge followed by irregular slow waves.

For the reasons given above (at least in part), there is no formal definition of what a seizure consist of in the EEG. Qualitative definitions usually include the terms 'paroxysmal, rhythmic, evolving' – but an unambiguous definition has not been formulated. Automatic detection methods have therefore relied on trying to encode these qualitative characteristics into algorithms, and improving the algorithms by trial and error in an effort to increase detection sensitivity and decrease the false seizure detection rate. The first general-purpose seizure detection method that was validated on a large data sample, characterized each two-second epoch by measures of frequency, rhythmicity, and amplitude change and compared these measures with a constantly updated background. A set of empirical rules then combined the findings in multiple epochs and multiple channels to reach a decision on detection. The concept of a 'constantly updated background' plays an important role in the analysis of long-term data, as the background changes considerably with different states of vigilance of the subject. It is also important that the results of detection not be dependant on the selection of a particular background epoch, a dependence that would introduce a significant degree of arbitrariness into the process.

A method specifically designed for intracerebral recordings was based on the detection of a repetitive spiking pattern, as well as of possible flattening at seizure onset. Another approach for seizure detection consisted of using leaky integrators functioning as simulated neurons to assess increases in amplitude and slope over a certain time (the simulated neurons fired 'action potentials' as a function of the composition of the EEG). Because the patterns and the artifacts are quite different in scalp and intracerebral EEGs, recent wavelet-based methods have been developed separately for scalp EEG and for intracerebral EEG, with performance much better than that of the older common methods.

Artificial neural networks (ANNs) have found broad applications in many areas, including seizure detection. Early work showed their utility in detecting bursts of spike-and-wave in experimental models of epilepsy. Several methods have been published that involve various EEG features as inputs to an ANN. The AAN is presented with a large number of training examples which comprise both seizure and nonseizure data, and gradually learns to differentiate seizures from nonseizure EEG. A set of features characterizing the EEG needs to be specified in

Figure 1 Scalp-recorded right temporal seizure occurring in the context of muscle and eye movement artifacts. This early part of the seizure consists in a discharge in the theta range of frequencies, commonly seen in temporal lobe seizures.

advance (e.g., amplitude, rhythmicity, dominant frequency, etc.), but it is not necessary to describe seizure patterns explicitly. The ANN automatically determines which combinations of features are characteristic of seizures by adapting its internal structure to reflect the training data. The performance of ANN methods depends on its being given an appropriate set of features and on its exposure to a sufficiently large training set containing a variety of seizure patterns. It is also necessary to specify a priori the structure of the ANN; large networks can handle complex classification tasks, but risk overfitting the training data so that it is unable to generalize other types of seizures. It is also difficult to investigate the operation of a large ANN; the network acts as a black box that provides output regarding classification values, depending on the features it receives as inputs. To circumvent this black box issue, some researchers have used an algorithm based on a set of rules, each rule being implemented using a small ANN; this approach makes it easier to analyze the operation of the system.

Performance of a detection system can be improved by incorporating a wide context in detection algorithms. Rather than defining the event only locally (i.e., comparing the characteristics of a 5-s epoch in one channel with the 30-s epoch that precedes it), it is helpful to include measurements of spatial context (activity in other channels) and of temporal context (state of the subject: awake, stages of sleep, previously recorded events). This approach has been used to reduce false detections by allowing a detection method to remember the patterns that caused frequent false detections in each subject. Another detection method uses spatial and temporal clustering of elementary detections made on individual channels and epochs, thus resulting in a global representation of seizures. This approach reduced false detections by only detecting a seizure with a number of elementary detections adjacent in space and time.

Wavelet methods allow for the analysis of the temporal evolution of frequencies; these methods are thus well suited for the identification of paroxysmal rhythmic activity. However, intracerebral EEGs also include frequent rhythmic bursts as part of normal background activity. Therefore, it may be necessary for an algorithm to adapt automatically to the background of each patient by deactivating the

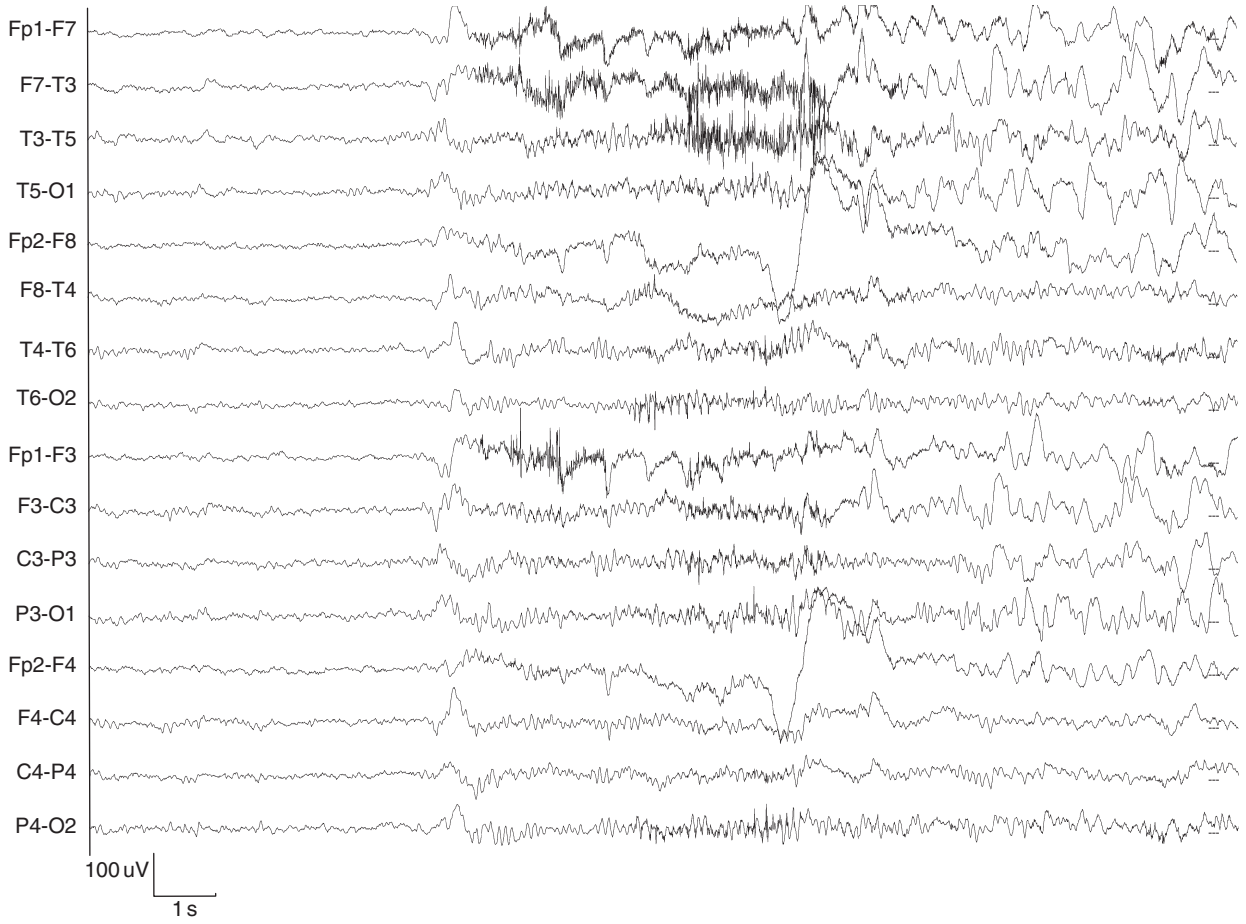

Figure 2 Scalp-recorded seizure with a generalized and abrupt onset. A few seconds of rhythmic theta frequency activity are followed by irregular slow waves in the delta range.

detection of paroxysmal activity that occurs consistently in the same channels and at the same frequencies. This deactivation results in an important decrease in false detections. It has also been shown that better performance can be obtained when analyzing the scalp EEG with a midline reference rather than with a bipolar montage (which has been most commonly used in other methods) or with an average reference.

An extension to the above concept of context is to incorporate a particular patient's seizure characteristics in the context. In this case, the method is aimed at detecting seizures in that particular patient, and only seizures that look like the sample seizures (that have been incorporated in the context) are detected. The method can then be labeled 'patient-specific' – or more correctly, 'seizure-specific' – as a patient can have several types of seizure. Better detection performance can thus be obtained, if it is acceptable to detect only a specific seizure pattern in a given patient.

Newborns have an incidence of seizures much higher than older children and adults. When they occur, seizures are also more frequent. For these reasons, it is often necessary to monitor newborns, but the monitoring does not require such prolonged observation periods (usually a few hours to a day or two is sufficient). Seizure patterns are quite different in the newborn EEG than in older children and adults: the discharges are often much slower and sometimes very focal (limited to one electrode). For these reasons, methods specific to the newborn have been developed, with the particular aim of detecting the very slow discharges often present during newborn seizures. Recent methods have proposed a neuronal model of EEG generation, for both seizures and background activity. Fitting the model to the EEG gives a reflection of how much of the EEG may be due to seizure activity. Interchannel synchronization, an approach that has been rarely used in seizure detection, has also shown promising results in newborns, as has time–frequency analysis to detect low-frequency rhythmic activity, as well as high-frequency bursts of spikes. Another approach has been to design a multistage system based on a large number of features, and then retaining only the most appropriate of these features for use in an ANN to classify seizure and nonseizure EEG.

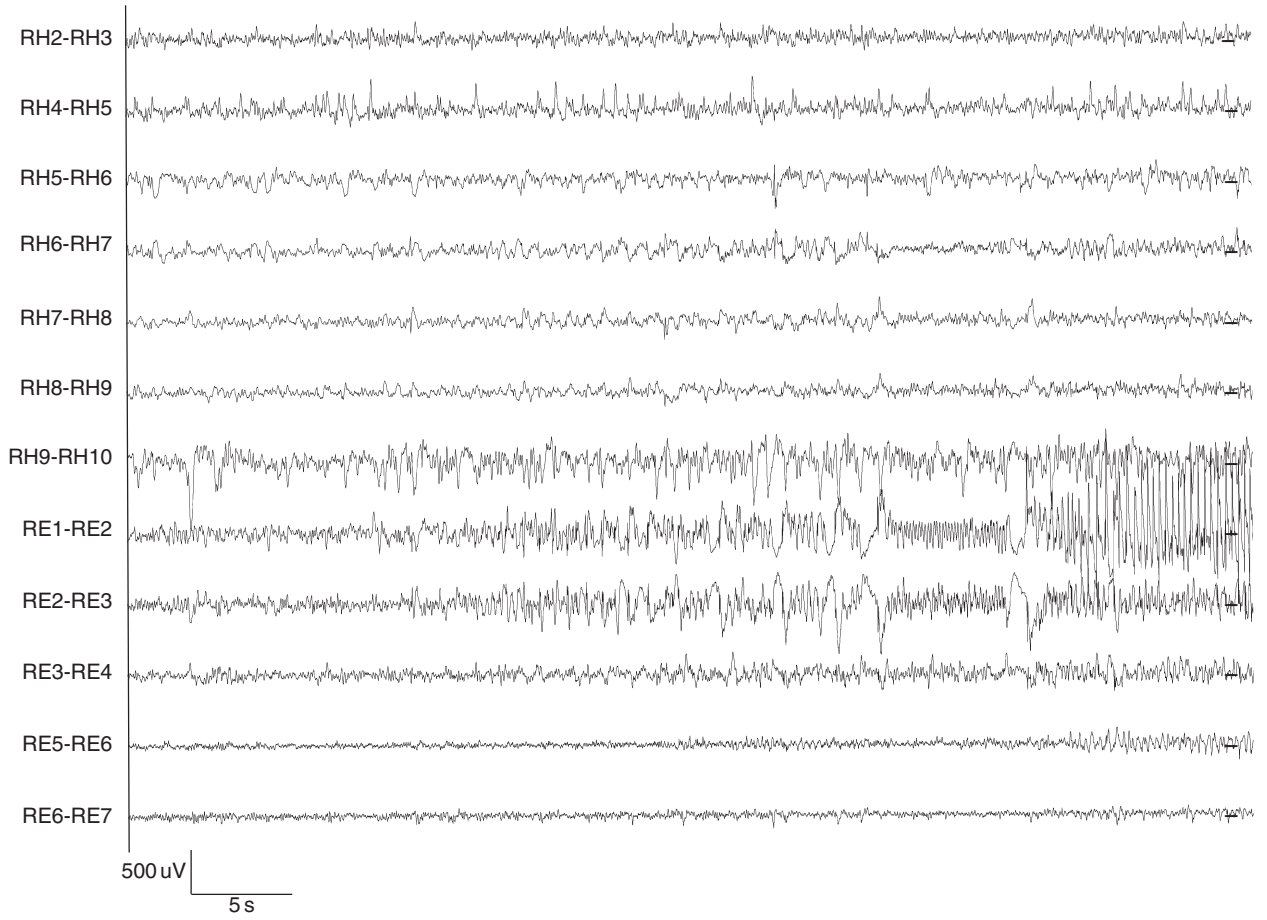

Figure 3 Seizure recorded from intracerebral electrodes placed on the temporal lobe. The RH contacts are along an orthogonal multicontact depth electrode having its deepest contacts (lower numbers) in the hippocampus and most superficial contacts in the second temporal convolution. The RE electrodes are epidural electrodes placed along the first temporal convolution. The seizure onset consists of mixed frequency activity, followed by a more rhythmic discharge. Note compressed time scale. For the purpose of clarity, this EEG illustrates only a fraction of the electrodes implanted in this patient's brain.

Validation

Validation of seizure detection and seizure warning methods requires particular care if one is to obtain results that are predictive of future performance in a realistic clinical context. Whereas early studies often did not follow legitimate validation protocols, recent methods have usually been validated in an appropriate context. Most importantly, the method must be tested on a set of data completely independent from that on which it was developed. It is critical, then, that the testing data be representative of the context in which the method will be used: it should include a large variety of seizures, and a much larger amount of nonseizure data than of seizure data (to ensure that all types of interictal data – quiet and active wakefulness, different sleep stages, and different types of artifacts common during long-term monitoring – are well represented). The best way to avoid selection bias is probably to select all data between two given dates.

An important issue in validating a method is the definition of a seizure itself. Although there is no ambiguity with a clear seizure lasting 30 s or 1 min, significant questions arise for short events: What is the minimum duration of a seizure? Should a seizure having clinical manifestations, but no change in the EEG, be counted as an event to detect? What if the EEG changes are very minor, such as a brief flattening or a short burst of slow waves? When presenting validation results it is imperative that these issues be addressed.

Methods that were evaluated on extensive data sets (hundreds or thousands of hours, tens of patients) report detection sensitivities varying from 75% to 90%. Sensitivity is often lower in newborns than in adults, as some newborn seizure patterns are very subtle. The false detection rate, the most often quoted measure of failure, was ~1–3 per hour in the early methods, and is more in the range 0.3–1 per hour in more recent studies. Few studies

report results with intracerebral electrodes, but these types of recordings have important distinguishing characteristics: the most prominent scalp artifacts (EMG, movement, eye blinks) are absent, thus reducing false detections; the dynamic range of the spontaneous fluctuations in background is much larger in intracerebral than in scalp EEG – thus resulting in more false detections; the intracerebral EEG often includes many paroxysmal bursts of uncertain significance, which can also contribute to false detections; and seizure patterns are often more prominent in intracerebral EEG, thus resulting in better sensitivity.

Seizure Prediction

Why Predict Epileptic Seizures?

Seizures can be, in themselves, harmful but most are not, and the main difficulty encountered by patients with epilepsy is the unpredictability of seizure occurrence. A loss of consciousness and automatisms lasting 30–60 seconds would be only an annoyance if the patient could be warned a few minutes ahead of time that it will happen. In addition to simply providing a warning, it is possible to consider interventions that could prevent the seizure from occurring, or at least make its occurrence less likely. When such a warning is generated, one could consider the use of chronically implanted devices that could inject an antiepileptic agent or generate electrical currents capable of preventing seizure occurrence. Although it has not been demonstrated at this point that any such intervention is efficacious, the aim of predicting a seizure is clearly of interest even if there is no possible intervention, simply to alert the patient.

When discussing seizure prediction, a methodological issue must first be addressed. One can only talk about prediction if the seizure onset is unambiguously defined. If the onset is not well defined, it becomes impossible to separate what may be a preictal change (that could be used as a warning that a seizure *will* occur) from an early sign indicating that a seizure *has just started*. Such an unambiguous definition of seizure onset is difficult. Seizures are mostly phenomena that are observed through clinical manifestations and EEG. Given these methods of observation, one could define the seizure onset as the first clear change which leads to an unambiguous seizure – either in the internal state of the patient (as reported by the patient), the patient's behavior, or the EEG. One has to be aware that such a definition may lead to different results, depending on what we call 'the patient's behavior' and 'the EEG.' Simple examples illustrate the issues: If the first clinical sign of a seizure is that the patient stops talking, this 'change' will only be observed if the patient is talking or if someone is asking a question; if the patient is not talking, this sign will be missed and the next clinical sign will be interpreted as the first. With respect to the EEG, the earliest change may vary greatly, depending on where the electrodes are. The first change may occur at time T with scalp electrodes, at time T-10s with intracerebral temporal electrodes, and at T-20s with intracerebral orbitofrontal electrodes. It is not trivial to define the seizure onset, and this question remains an important issue when evaluating the performance of seizure prediction algorithms (see below).

Methods and Results

Seizure Prediction Methods and Performance

A few patients are able to predict their seizure either a long time ahead of time ('I feel like I will have a seizure today') or just a few seconds ahead of time (as a result of a particular sensory or experiential phenomenon). In the latter case, it is most likely that the patient is actually aware of the onset of the seizure, and that the so-called premonitory sign is simply the first clinical sign of the seizure. One cannot, then, talk about seizure prediction per se. Studies of patients' abilities to predict their seizure have shown that about 20% of patients are quite capable of predicting their seizures (one day in advance); stress and lack of sleep are important precipitants that patients can incorporate into their predictions. Dogs able to predict seizures have often been mentioned, but controlled studies are required to determine if this phenomenon is more than simply anecdotal.

A few observations have indicated that there may be changes in metabolism prior to seizures. In one study, changes in the BOLD (blood oxygenation level dependent) signal several minutes prior to seizure were described, but there has been no further report on such changes, despite their obvious interest. A change in the SPECT (single photon emission computed tomography) signal, recorded by chance prior to a seizure, has also been reported, as has a change in deoxyhemoglobin and blood volume about 20 s prior to seizure onset (as defined in the electrocorticogram). These observations are interesting, and may indicate that sometimes something is changing prior to seizures. However, there is no simple way to monitor continuously oxygen concentration or metabolism in patients, and there has consequently been no further effort to predict seizures with such measurements.

The scalp and intracranial EEG have been the main tools used for attempting to predict seizures. The EEG has the obvious advantages of being recorded relatively simply and continuously, and of showing clear changes at the time of seizures. Because the EEG changes so dramatically during seizures, one might hope that preictal changes – if they exist – are present in the EEG. It is sometimes thought that interictal epileptic activity (spikes and sharp waves) increases in frequency prior to seizures.

Long-term studies have shown that this is not the case, so increased frequency of such events has not been pursued as a predictive measure.

Most analyses aimed at seizure prediction have examined changes in the EEG background. Early reports were very optimistic that seizures could be predicted, particularly using nonlinear analysis methods, but also using simple linear methods. These reports indicated that changes occurred several minutes prior to most seizures. Most work was done with intracerebral EEGs, but widespread preictal changes were also observed in the scalp EEG. Synchronization between EEG signals from intracerebral channels was also used as a measure for predicting seizures. An important weakness of several of these studies was the fact that they analyzed mostly relatively short sections of EEG, including seizures and a short preictal interval (e.g., 1 h). When more extensive recordings were analyzed, it became clear that the changes that were observed prior to seizures were also observed at other times, independently of seizure occurrence. It was shown that most false prediction occurred during sleep, probably as a result of the frequent changes in EEG patterns corresponding to the changes in stages of sleep. Preictal changes, therefore, appeared relatively sensitive but lacked specificity.

Much of the early work on seizure prediction relied on nonlinear methods (e.g., Lyapunov exponent, correlation dimension), but it later became clear that more traditional linear methods did not necessarily perform less well. It was shown that multivariate methods (those analyzing simultaneously several channels) tended to perform better than univariate methods (analyzing one channel at a time).

The methodology appropriate to evaluate seizure prediction methods has now been well established. One approach that is promising is that of seizure time surrogates: to test if prediction results are significantly better than chance in a long recording including several seizures, results are compared with those obtained after randomly shuffling seizure times in the recording. There have been no recent reports using this methodology and indicating a reliable seizure prediction performance, although promising preliminary results have been reported.

Conclusions and Directions for Future Research

Although seizures are most often very prominent events in the EEG, automatic detection methods remain imperfect, in large part because of the difficulty of capturing within an algorithm the many features that constitute a seizure and differentiate it from a background that is changing continuously – and that sometimes changes in ways that resemble a seizure. Sensitivities of 80–90% can be reached but average false detection rates remain in the vicinity of one false detection per one or two hours of recording, with much higher rates in a few patients. Progress has been incremental in the last few years; there has not been any new method that has led to a quantum jump in performance.

The possibility to warn a patient (or observer) that a seizure has just started has become a reality, with current methods able to give a warning a few seconds after the seizure onset in the EEG. The performance of such methods can be greatly enhanced if they aim at warning only of a seizure of which a template is available (as opposed to any seizure). Because most patients have only one seizure type, and its pattern is relatively stable, this is a reasonable approach.

Seizure prediction, in contrast, remains more a dream than a reality at this point. Early optimism has been tempered by the subsequent understanding of the many issues involved in making a reliable prediction algorithm. Now that the validation methodology is well in place, the stage is set for the realization of this dream. Interestingly, it is often stated that focal seizures are more likely to be predictable than primarily generalized seizures, although no evidence has been presented to support this view. As most results point to pre-ictal changes that are not limited to the region of seizure onset, but encompass widespread regions, it is not clear why such changes could not precede generalized seizures.

Introduction

Epileptic seizures are transient events that produce clinical symptoms ranging from brief sensory phenomena to loss of consciousness and convulsive activity. Seizures can be focal (partial) or generalized (bilateral), and the clinical manifestations reflect the regions of brain involved by the seizure activity. Although the average seizure lasts less than 2 min, this short period can be enough to have a significant impact on quality of life for the patient with uncontrolled epilepsy, especially if the seizures produce altered consciousness.

Only about 50% of partial onset seizures (the most common seizure type) can be controlled with antiepileptic drugs (AEDs), even with the approval of a number of newer medications in the last decade. With the development of digital video and EEG recordings, there has been a corresponding growth in epilepsy monitoring units to record and analyze actual seizures. Patients may be admitted to these units for a variety of reasons, but common indications are for seizures that have not been controlled with AEDs and for presurgical evaluations. Presurgical evaluations include ictal scalp monitoring, and may in some patients require further intracranial monitoring if seizures cannot be adequately localized with scalp recordings or if the focal onset is close to eloquent cerebral regions. Appropriately selected patients with medically intractable partial epilepsy may have ~70% chance of becoming seizure free after surgery (e.g., temporal lobectomy for mesial temporal sclerosis) compared to ~5% with additional AED trials.

In order for seizure surgery to be successful, the seizure focus must be identified and the region to be resected must be determined. Visual analysis of ictal and interictal EEG can provide considerable useful information. Interictal recordings can reveal focal or multifocal spikes, while ictal recordings (the current gold standard for presurgical evaluations) can reveal the localized dramatic changes that occur with seizure onset. With the introduction of computational methods, many epilepsy centers have begun implementing signal processing methods for analysis of epileptic scalp and intracranial EEG (ICEEG). In particular, with the introduction of digital EEG machines, it has become easier to employ digital analytic methods. Understandably, much of the interest in clinical assessment is in seizure detection and in determining the location (focus) of seizure onset. Several centers have focused on spike and seizure detection, and have developed methods to that end. It is recognized that seizures that originated from a single focus in a given patient often have similar patterns of onset; this reproducible pattern has allowed for the tuning of detection algorithms for improved sensitivity and specificity.

In some instances, eloquent areas (e.g., motor or language) may limit the extent of safe resection; in other patients more extensive resections can be made. While intracranial electrode arrays (e.g., depth electrodes, subdural strips and grids) can provide considerable information regarding seizure onset and propagation, seizure onset (particularly in neocortical foci) may at times be regional or ill-defined. The concept that there is not just

Introduction

Epileptic seizures are transient events that produce clinical symptoms ranging from brief sensory phenomena to loss of consciousness and convulsive activity. Seizures can be focal (partial) or generalized (bilateral), and the clinical manifestations reflect the regions of brain involved by the seizure activity. Although the average seizure lasts less than 2 min, this short period can be enough to have a significant impact on quality of life for the patient with uncontrolled epilepsy, especially if the seizures produce altered consciousness.

Only about 50% of partial onset seizures (the most common seizure type) can be controlled with antiepileptic drugs (AEDs), even with the approval of a number of newer medications in the last decade. With the development of digital video and EEG recordings, there has been a corresponding growth in epilepsy monitoring units to record and analyze actual seizures. Patients may be admitted to these units for a variety of reasons, but common indications are for seizures that have not been controlled with AEDs and for presurgical evaluations. Presurgical evaluations include ictal scalp monitoring, and may in some patients require further intracranial monitoring if seizures cannot be adequately localized with scalp recordings or if the focal onset is close to eloquent cerebral regions. Appropriately selected patients with medically intractable partial epilepsy may have ~70% chance of becoming seizure free after surgery (e.g., temporal lobectomy for mesial temporal sclerosis) compared to ~5% with additional AED trials.

In order for seizure surgery to be successful, the seizure focus must be identified and the region to be resected must be determined. Visual analysis of ictal and interictal EEG can provide considerable useful information. Interictal recordings can reveal focal or multifocal spikes, while ictal recordings (the current gold standard for presurgical evaluations) can reveal the localized dramatic changes that occur with seizure onset. With the introduction of computational methods, many epilepsy centers have begun implementing signal processing methods for analysis of epileptic scalp and intracranial EEG (ICEEG). In particular, with the introduction of digital EEG machines, it has become easier to employ digital analytic methods. Understandably, much of the interest in clinical assessment is in seizure detection and in determining the location (focus) of seizure onset. Several centers have focused on spike and seizure detection, and have developed methods to that end. It is recognized that seizures that originated from a single focus in a given patient often have similar patterns of onset; this reproducible pattern has allowed for the tuning of detection algorithms for improved sensitivity and specificity.

In some instances, eloquent areas (e.g., motor or language) may limit the extent of safe resection; in other patients more extensive resections can be made. While intracranial electrode arrays (e.g., depth electrodes, subdural strips and grids) can provide considerable information regarding seizure onset and propagation, seizure onset (particularly in neocortical foci) may at times be regional or ill-defined. The concept that there is not just

an epileptic focus but an epileptic zone has evolved from these observations.

Background

Epileptic seizure evolution is characterized by rapidly changing dynamics at the seizure focus, as well as in regions involved in seizure propagation. While surgical treatment is directed to the seizure focus and not remote regions of propagation, patterns of seizure propagation can determine the clinical manifestations and provide insights into the self-limited nature of epileptic seizures. Early approaches to seizure analysis employed mostly single channel linear signal processing methods, including spectral analysis (e.g., fast Fourier transformation, FFT) or autoregressive methods. Changes in spectral content of the signal could be observed at seizure onset and during seizure evolution. Analyses of interactions between different brain regions involved during seizure propagation were performed using multichannel analysis based on correlation and coherence. More recently, nonlinear methods of analysis have been applied to understand the underlying dynamics of the systems that generate epileptic activities, with the ultimate goal of being able to predict the occurrence of the seizures (if that, indeed, is possible). Current intracranial recording arrays employ high sampling rates, have more extensive coverage, and use special electrodes to better define seizure dynamics, particularly the involvement of high frequency activity. Still, there is a need for additional methods of analysis to assist in the presurgical clinical analysis and to better understand the mechanisms of seizure generation and termination.

No single technique has proven to be able to fully describe the dynamics of the epileptic seizure generation, onset, and propagation – because of the complexity and variability of the problem encountered. Two methods for signal analysis that have recently been applied to intracranial recordings of ictal events are the Gabor atom density (GAD), based on the matching pursuit (MP) time–frequency decomposition, and the short-time direct transfer function. These two methods will be discussed further as examples of advanced techniques that can provide additional information about seizure dynamics, propagation, and patterns of the flow of activity. These techniques can provide complimentary information for clinicians to more effectively assess the onset and propagation of partial seizures.

Methods

ICEEG monitoring is performed with subdural grid or strip arrays, or depth electrodes. Depth electrodes and subdural strips are often used (with bilateral implantation) for seizure lateralization when there is not sufficient evidence from ictal scalp recordings. Subdural grid arrays are typically employed when seizure lateralization has been determined, but better localization of the seizure focus is needed. In all instances of intracranial recordings, the observations made are limited by the spatial sampling done by electrodes. For depth electrode recordings, the goal is usually to assess the involvement of certain structures in seizure onset (e.g., amydgala, hippocampus); for subdural strips and grids, the participation of neocortical regions in seizure onset is commonly sought. Compared to scalp recordings, ICEEG electrodes provide a much better localization of brain activity, often allowing a more precise assessment of the seizure onset zone. Nevertheless, the spatial resolution remains low in comparison to the underlying neural networks.

The interpretation of the recordings obtained in the epilepsy monitoring unit is done visually by neurologists who are trained to recognize patterns of onset and evolution of epileptic events. Electrographic changes are correlated with clinical manifestations. Most of the time, the evaluation is done visually – with little or no quantification of the pattern beyond the approximate frequency of the activity at seizure onset (when it can be determined). Determining the region(s) of focal seizure onset is the goal of the presurgical evaluation. Considering the importance of stereotyped patterns in the evaluation of focal seizure onset, there are potential benefits in being able to quantify these onset patterns in a more deterministic way.

Matching Pursuit and Gabor Atom Density

MP is a decomposition algorithm recently introduced to advance the analysis of spectral content. One of its advantages is that this algorithm does not have a requirement for signal stationarity – a signal property criterion that often limits the applicability of traditional analysis as it requires that the mean and variance of the signal do not change over the time period analyzed. MP also has the advantage that the time–frequency reconstructions that it allows do not have cross-term components. Cross-terms components are spectral components that do not really exist in the signal, but are often produced by other spectral analysis methods – a problem that has hindered previous methods of representation in the time–frequency space.

The original MP method was described in 1993 by Mallat and Zhang. The algorithm decomposes the signal on a nonorthogonal base of functions called atoms; i.e., the $(m+1)$th atom in the decomposition depends on the previous m atoms. However MP still maintains conservation of energy, so the time-frequency decomposition obtained has the same total energy than the original signal.

These atoms are mathematically defined by Gabor functions, which are modulated Gaussian functions:

$$g_\gamma(t) = \frac{1}{\sqrt{s}}\, g\left(\frac{t-u}{s}\right) e^{i\xi} \quad \text{with} \quad g(t) = 2^{1/4} e^{-\pi t^2} \quad \text{and} \quad \gamma = (s, u, \xi)$$

where $\frac{1}{\sqrt{s}}$ normalizes the norm of g_γ to 1, which allows the conservation of energy of the decomposition.

The signal f can be written as the sum of m atoms g_n and a residue.

$$f = \sum_{n=0}^{m=1} \langle R^n f, g_n \rangle g_n + R^m f$$

Several methods exist to determine the number m of atoms needed to obtain a sufficiently precise representation. One highly effective method for the analysis of epileptic seizures was introduced in 2003, and limits the decomposition based on a threshold of the energy of the last atom added to the decomposition.

A composite index, called the GAD, has been introduced to describe the complexity of the signal based on that number of atoms. GAD is used to assess the complexity of the EEG signal by normalizing the number of atoms to the time–frequency region analyzed:

$$\text{GAD} = \frac{2\text{m}}{N}$$

where N is the number of points in the time frame considered. When applied to all channels, the composite information gathered can also be used to assess the propagation of epileptic activity to other brain regions remote from the seizure focus.

Multichannel Analysis of the Flow of Brain Activity

One important feature of epileptic seizures is the pattern of regional and remote seizure propagation to different parts of the brain. Indeed, this pattern is (at least in part) what produces the clinical manifestation of a seizure. Single channel analyses, either alone or combined with multichannel composites, provide tools only for quantifying patterns of spread, but do not provide information regarding the actual flow of activity.

Late in the last century, methods for analysis of flow – based on multichannel autoregressive models – were developed and first applied to analysis of EEG. The directed transfer function method (DTF) uses a multivariate autoregressive process (MVAR) to evaluate the flow of activity patterns in a set of several time series. The model assumes that the value of the signal $\boldsymbol{x}$ at a time t depends on its p previous values and the random component $\boldsymbol{e}$. Analyzed signals (from K different channels) are treated as realizations of one multivariate stochastic process. The MVAR process can be expressed as:

$$\boldsymbol{x}(t) = -\sum_{j=1}^{p} \boldsymbol{A}_j \boldsymbol{x}(t-j) + \boldsymbol{e}(t)$$

where $\boldsymbol{A}_j$ is a $K \times K$ MVAR coefficients matrix, $\boldsymbol{e}(t)$ is a zero mean uncorrelated residual noise vector with covariance matrix $\boldsymbol{V}$, and p is the model order. Estimation of the $\boldsymbol{A}_j$ coefficients and matrix $\boldsymbol{V}$ can be obtained from estimated covariance matrix $\boldsymbol{R}(n)$ by solving the Yule–Walker equation:

$$\sum_{j=0}^{p} \boldsymbol{A}_j \boldsymbol{R}(-r+j) = 0$$

Where $\boldsymbol{A}_0$ is equal to the $K \times K$ identity matrix. To determine the correct value of model order p, the Akaike Information Criterion is used.

Because EEG activity may be understood in terms of rhythms and oscillations, it is useful to describe the spectral properties of their signals. For this purpose the MVAR equation may be transformed to the frequency domain. Then,

$$\boldsymbol{X}(f) = \boldsymbol{H}(f)\boldsymbol{E}(f) \quad \boldsymbol{H}(f) = \left(\sum_{j=0}^{p} \boldsymbol{A}_j e^{-i2\pi f f \Delta t}\right)^{-1}$$

where $\boldsymbol{H}(f)$ is the transfer function of the multichannel system, f is frequency, and Δt is the sampling interval.

The element h_{kl} of the matrix $\boldsymbol{H}(f)$ describes the transfer function between the kth output and the lth input of the system. If the element h_{kl} of $\boldsymbol{H}$ is equal to zero, the hypothesis that $\boldsymbol{x}_k(t)$ causes $\boldsymbol{x}_l(t)$ can be rejected. The matrix is not symmetric, meaning that transfer from channel k to channel l is different from that in the opposite direction. In this way, the directional properties of a multichannel system may be obtained and interpreted as causal relationships, signal flows, or activity transfers. The $\boldsymbol{H}$ matrix has been used to calculate DTF which is a normalized $|H_{kl}(f)|^2$.

The first applications to EEG from epileptic patients showed flows of activity from the epileptic focus not only at the seizure onset but also during later phases of seizure evolution. The limitation of the original DTF method is that it requires at least weak stationarity of data during analysis period; too short periods of analysis lead to overestimation of parameters. This constraint limits applicability of the DTF method in analysis of seizure activity to relatively few periods during the seizure when at least 5 s of data can be regarded as quasistationary.

Recently, the DTF method has been applied to the analysis of event-related potentials. The new method, short-time DTF, takes advantage of multiple trials available for analysis to improve the data-to-parameter ratio in short analysis windows. Since it is common in individual patients for seizures originating from the same focus to produce very similar EEG signals (especially when recorded intracranially), the same method was thought

to be applicable to epileptic seizures. In the short-time DTF, the estimator of covariance matrix $\boldsymbol{R}(n)$ is computed from all data epochs which are assumed to be realizations of the same stochastic process. However, this method does not distinguish between direct and indirect flow. To address that problem, the short directed DTF (SdDTF), which multiplies the original DTF values $|H_{kl}(f)|^2$ by the partial coherence function, was introduced to allow for identification of direct flows between two channels.

The SdDTF provides information of flow for each frequency separately. Usually these values are integrated in frequency bands of interest to represent average flow within a specific band. To better visualize the flow of activity in brain, we represent them as arrows between relevant electrode sites projected on an MRI image (see Figure 3); the color and width of each arrow represent relative strength of the flow.

Results

Seizure Complexity

There are misperceptions that rhythmic seizure activity like the organized activity (theta–alpha) often seen in mesial temporal lobe seizures is a low complexity signal. This belief seems to originate from early work on chaos theory. However, several definitions of complexity exist – and many references often only use it as a concept without proper mathematical definition of the quantity. The mathematical definition of a single measure to quantify the complexity of the EEG signal is a necessary step to assess the pattern of complexity associated with epileptic seizures. The GAD was therefore introduced to provide this quantitative measure of signal complexity. GAD computation relies on the MP decomposition to obtain a description of the time–frequency content of the signal which can be quantified. Both MP reconstruction and GAD complexity are represented together as a convenient way to assess the frequency and dynamical properties of a seizure simultaneously. GAD reveals that there is often an increase of signal complexity associated with the onset of epileptic seizures and associated with the dynamical changes of each seizure.

Figure 1 shows an example of such a representation, with the time–frequency reconstruction of a complex partial seizure and the GAD complexity superimposed on it. The original ICEEG signal of the epileptic seizure recorded from a contact near the seizure focus is plotted (a) above the reconstruction. Two different zoom levels are added below to show a more detailed view of the dynamic changes in the EEG during the seizure (b) and at the seizure onset (c).

Intrinsic dynamics of a seizure vary during seizure evolution but typically include various phases with different levels of complexity corresponding to different phases of the seizure. The seizure onset period is associated with a dramatic increased complexity. Later in the seizure, the relatively lower complexity of a clearly rhythmic pattern is often observed; the complexity at this point, however, remains much greater that the default baseline complexity. The termination pattern is associated with higher complexity also, and in this example is followed by a common low complexity (but high amplitude) postictal pattern. The complexity in this example dropped below preictal levels and returns to normal baseline level quasiexponentially.

Seizure Onset

The stereotyped nature of epileptic seizures in a given patient is a characteristic that clinicians rely on to help assess the origin of epileptic seizures. Even a sophisticated measure of complexity (e.g., GAD) reveals epileptic seizures of the same type, which often follows a similar time course in a given patient. This similarity of complexity pattern is observed for mesial temporal onset seizures as well as for neocortical onset seizures. This similarity of pattern of onset is even seen with partial seizures and partial seizures with secondary generalization. Again, for both mesial temporal and neocortical onset seizures, the early period of the seizure evolution has similar dynamics, regardless of the subsequent electrical and clinical evolution of the seizure.

The link between EEG patterns of seizure onset and region of onset – which has been previously explored by traditional means of analysis – requires further study to assess the localization potential of epileptic seizures onset based on the focal ictal increase in GAD. The time–frequency decomposition and GAD appear to be suitable for detecting the occurrence of high-frequency activity at the onset of seizure. Such high frequency activity is often regarded as a strong indicator of epileptogenesis in the corresponding area.

Seizure Propagation

Despite the similarity of onset pattern within a given patient, seizures can vary in degree of propagation. The clinical definition of simple partial seizures and complex partial seizures, with or without secondary generalization, fail to distinguish the whole spectrum of propagation patterns that can be observed.

When GAD information is computed for all channels, multichannel propagation patterns can be displayed for each seizure. Figure 2 represents three different complex partial seizures from the same patient with left temporal neocortical onset and variable degrees of propagation to the frontal lobes. The stereotyped nature of epileptic

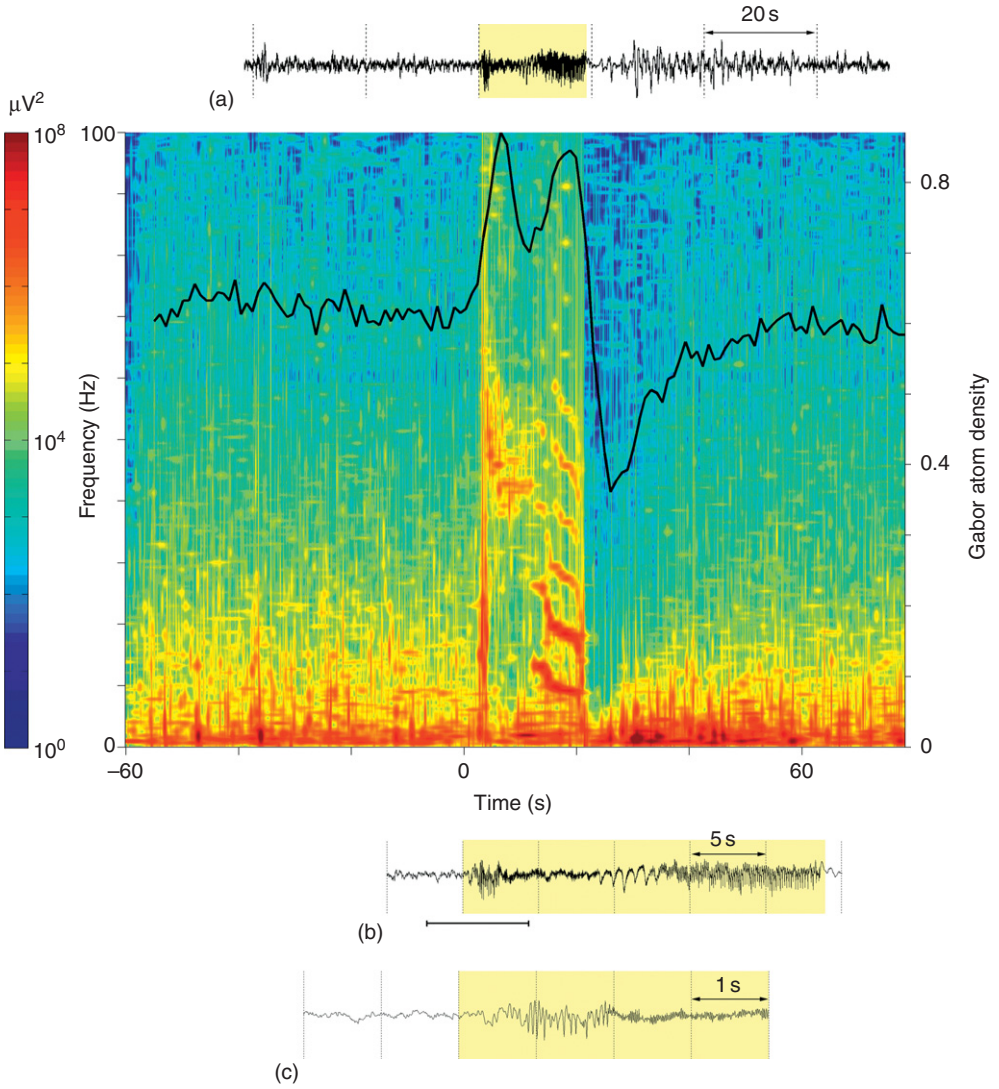

Figure 1 Time–frequency reconstruction and GAD complexity for a single channel intracranial EEG (ICEEG) recorded from a neocortical onset seizure. The time–frequency decompostion is obtained by matching pursuit analysis and then reconstructed in time–frequency. Black trace represents the GAD measure of complexity of the signal. Above (a) is the full EEG signal analyzed for this decomposition. Below the EEG of the seizure is zoomed over the entire seizure (b) and over the onset (c).

events is remarkable in the early period of the seizure, with almost identical timing and patterns of propagation of the epileptic activity over the temporal lobe channels. However, the extent and duration of that propagation is variable within the same clinical definition of a complex partial seizure. The existing seizure classification is currently under review, with much discussion regarding links to clinical symptoms; for example, alteration of consciousness is a variable which is at times difficult to quantify (e.g., with frontal lobe partial seizures). While it appears that a certain degree of partial seizure propagation is needed to affect consciousness, there has not yet been any clear determination of the extent and duration required to produce these alterations in awareness.

Analysis of Flow

While GAD can clearly show the patterns and extent of seizure propagation, its single channel basis does not reveal the direction of flow of activity that produces these patterns of propagation. SdDTF and other methods based on multichannel autoregressive modeling derive all information from cross-correlation between channels. Thus, SdDTF complements the analysis of the seizure dynamics from a single channel by providing additional information regarding flow of activity that underlies the pattern of seizure propagation. Figure 3 shows such example of determination, with the application of the SdDTF method to intracranial recordings during several

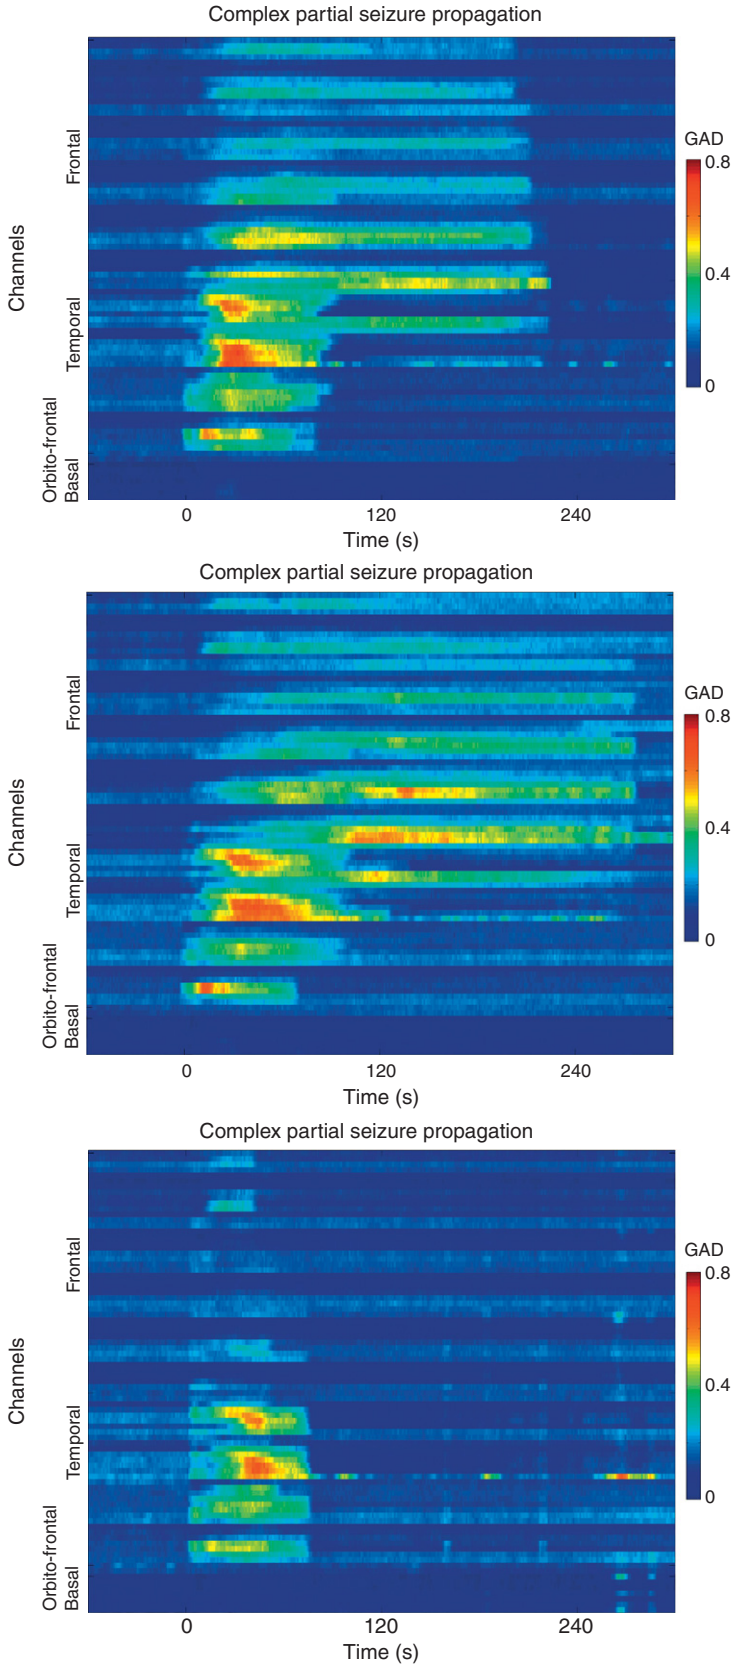

Figure 2 GAD-based propagation maps for three complex partial seizures from a given patient. All three seizures present similar pattern of onset and two of them a similar pattern of propagation.

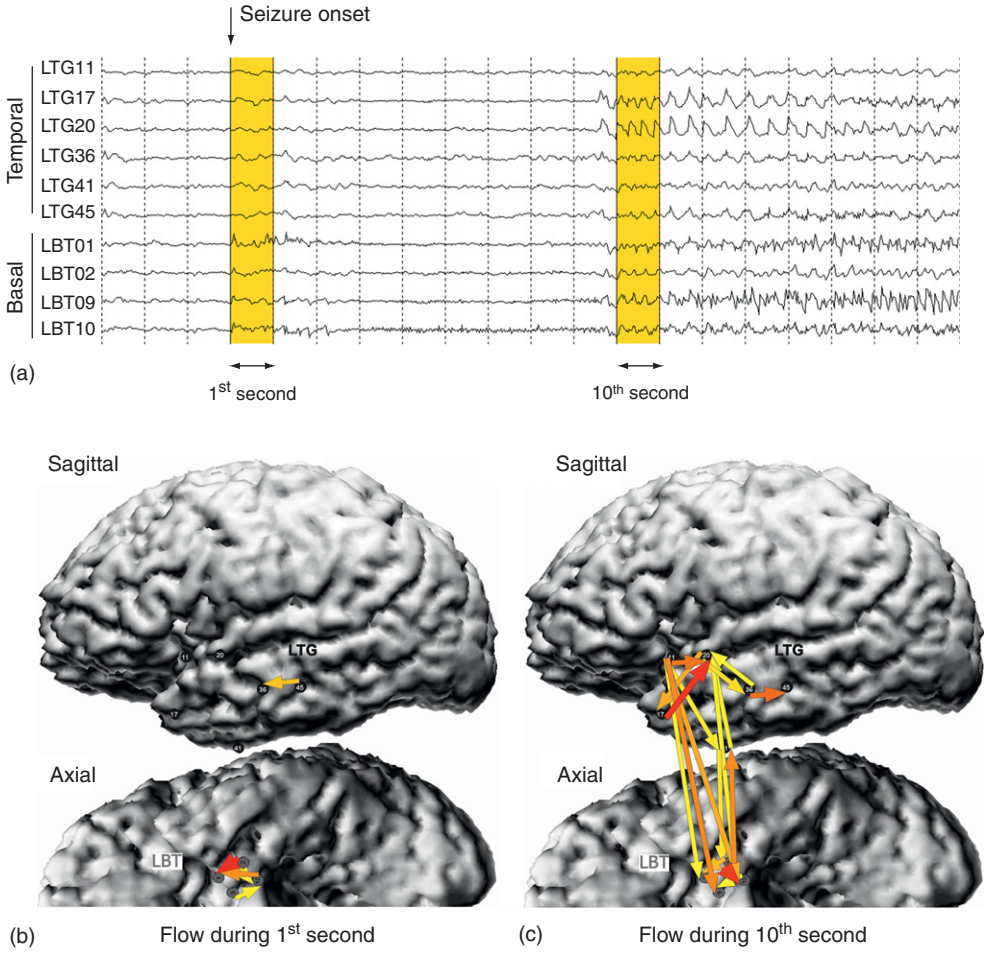

Figure 3 Illustration of changes in the pattern of flow of activity during seizure integrated from SdDTF in 0.5–25 Hz frequency band. The arrows projected on MRI image represent flow of activity computed from 10 similar seizures in same patient during first (b) and tenth (c) second after onset. The width and color of arrows are proportional to the integrated value of SdDTF in the 0.5–25 Hz band (low: yellow; high: red). For clarity, only flows with values greater than 75% of maximum flow during the whole seizure interval are shown. (a) Intracranial EEG of one of the seizures used in the analysis with the first and tenth second shaded.

complex partial seizures. The analysis was performed using 10 similar seizures. Panel (a) shows a 20 s recording of 10 channels during one of a series of temporal lobe onset seizures from a given patient. The results of the SdDTF analysis of the first and tenth second after onset (shown as shaded in panel (a)) are projected on an MRI of the brain (panels (b) and (c), respectively). The size of each arrow represents the strength of the flow. During the first second, the significant flows are visible only in the focal area (left mesial temporal lobe channels LBT), with the most prominent flow from LBT02 toward LBT01. During the tenth second after the onset, activity spread to other areas; the flow pattern clearly shows that there is now feedback between the basal temporal region LBT and the upper temporal grid area LTG. There is still strong flow within the basal area (red arrowhead LBT10 → LBT02), but there is also a strong flow within the temporal grid LTG17 → LTG20. There are also multiple flows between both regions, suggesting a possible feedback to the original seizure focus.

Future Applications

Both techniques described here are complementary and attempt to give a more detailed understanding of the dynamics of epileptic seizures. From seizure dynamics at the focus, to patterns of flow of activity and regional or global seizure propagation, these elements are offering new ways to examine epileptic seizures, particularly for seizure epochs after seizure onset.

The GAD and SdDTF methods allow for analysis of different characteristics of seizure dynamics and propagation. On the one hand, the GAD method allows for analysis of each seizure separately and provides excellent description of dynamical properties of the recorded signal

with very limited assumptions. In particular it does not rely on assumptions about linearity or stationarity. It gives clear information about changing seizure patterns over time for signals recorded from different brain regions. On the other hand, the SdDTF analysis provides information about interactions between regions – i.e., how the activity in one region may influence other regions. However, there are more limitations associated with this method than with the MP or GAD analysis. SdDTF requires multiple seizures for analysis, and as a result it shows only flow patterns which are common for all seizures. Also, the analysis can only optimally be performed on a limited number of channels, which leads to less spatial resolution than the available multichannel ICEEG recordings. However, both methods can be used in parallel to complement each other. The initial analysis with GAD method may suggest which channels are most involved in seizure propagation, and these channels can then be included in SdDTF analysis. Then SdDTF analysis may help in interpretation of the spread of activity shown by GAD. For example, it can show if there is significant feedback from areas of spread to the original focal area later in the seizure.

These methods of analysis can be applied to any electrical activity. Application to other modalities – for instance magnetoencephalographic (MEG) signals – could allow for more complete description of other activity during seizures.

Current recording techniques are employing increased frequency ranges, both high frequency and DC, requiring higher sampling rates and larger storage capability. Collection of larger amounts of data will provide more information, but in addition to requiring larger storage capability, also requires development of more efficient software for managing and processing these data.

Challenges remain for seizure localization. There is considerable interest in looking at high frequency and ultra-high frequency activity at the time of seizure onset, in the hope that these discharges may assist in defining the seizure focus. Recording this activity requires specialized high-density electrodes and appropriate sampling rates. Whether seizures, particularly neocortical onset seizures, originate from focal or broader regional areas is still not resolved. While there are patterns of ictal onset activity that are readily acknowledged, less clear is whether there are earlier preictal changes that can be detected and could assist in seizure localization. Indeed understanding what causes the transition from the interictal to the ictal state, both at the network and cellular levels, could lead to improved strategies to reduce these transitions. The stereotyped ictal patterns of onset and evolution seen in seizures from a given patient suggest that there are potential interventions (e.g., neurostimulation) that could interfere with this evolution and the number of disabling events experienced by the patient.

Multidrug Resistance

Introduction

Resistance to treatment with drugs is a problem across human disease, from cancers to infections. In epilepsy, a wide range of drugs is available for the control of seizures. These antiepileptic drugs (AEDs) have, putatively, a range of mechanisms of action, though in practice most AEDs share many mechanisms, and act primarily either on sodium channels or GABAergic processes. Most patients (70%) with epilepsy respond to AEDs and become seizure free – although the questions of how much of this response is intrinsic to the natural history of epilepsy and how much is caused by treatment with AEDs remain an issue. But in common with those with other diseases, there are patients who do not respond to treatment. Their epilepsy continues despite treatment with AEDs; they continue to have seizures despite using AEDs that work in other patients with the same type of epilepsy, and despite taking as much of a given drug or drugs as they can tolerate. This is a real clinical problem in need of a solution. For these patients, drug-resistant epilepsy is responsible for increased morbidity, and increased risk of premature mortality. Apart from the pervasive consequences for the patients with drug-resistant epilepsy themselves, drug resistance in epilepsy accounts for much of the costs of epilepsy to health service providers, not least through AED budgets. This article considers some of the latest developments and research in this area. The potential gains from advances in understanding drug resistance in epilepsy are enormous, and relate directly to other central nervous system diseases which may share similar mechanisms of resistance. Understanding the mechanisms of resistance might also cast light on the basic processes and mechanisms in epilepsy.

Background

There are many conceptual approaches to drug resistance in epilepsy. For example, one could apply a 'bottom-up' approach, attempting first to understand the mechanisms of the epilepsies, and related or relevant pathways and processes, and then from this knowledge attempt to predict or explore mechanisms of drug resistance. Enormous amounts of work have been undertaken to elucidate the basic processes that may underlie the generation of epileptic seizures. Of necessity, much of this work has been done in animal models. Undoubtedly, there has been tremendous progress, but it is still the case that for any single seizure type, we do not yet have a complete depiction of the underlying mechanisms at any level, from the genetic to the whole organism. Any 'bottom-up' approach is further complicated by the spectrum of epilepsies that exist, although of course there may be shared mechanistic final common pathways in the generation of seizures. With respect to drug resistance specifically, the 'bottom-up' approach has received comparatively little attention, although it is relatively easy to generate hypotheses from such an approach. For example, one could propose that there are likely to be epilepsies in some people caused by inherited abnormalities of the neuropeptide Y neurotransmitter system (which has been demonstrated to be antiepileptic); as far as we understand currently, there are no AEDs that act on this system, and therefore one might predict that patients whose epilepsy is due to a defect in the neuropeptide Y neurotransmitter system would have epilepsy that would currently be classed as refractory or drug-resistant – either because none of our drugs works directly on that system, and/or because drugs working on other systems might not be able to compensate sufficiently for defects in the neuropeptide Y system.

At the other end of the spectrum, one might consider what could be called a 'top-down' approach. One could consider the key agents, the AEDs themselves, examine in detail how they work, and thus propose hypotheses based on disruptions of the processes normally involved in their activity. This approach has been much more widely taken up in research of drug resistance in epilepsy.

One can consider the actions of AEDs on the body as pharmacodynamic effects, and the actions of the body on

AEDs as pharmacokinetic effects. Pharmacokinetic effects are likely to take place at several levels, including systemic absorption, metabolism in various tissues (including the liver), and also possibly in the brain itself. Drug distribution depends not only on intestinal and hepatic processes, but also on microdistributive processes occurring across the blood–brain barrier and in the immediate vicinity of neuronal and glial cells within the brain. Pharmacokinetic factors also include excretory processes, again occurring at various tissue levels in various organs. Pharmacodynamic effects, in contrast, occur at a much finer level of resolution, in or on neurons and glia in the brain. A parallel formalization of these two classes of events (pharmacokinetic, pharmacodynamic), alterations in which might contribute to drug resistance, effectively leads to the 'transporter' and 'target' hypotheses of drug resistance in epilepsy.

The target hypothesis states that drug resistance in epilepsy results from an altered interaction between drugs and their targets, when the concentration of the drug at the target would normally be sufficient to bring about the desired effect of those AEDs. The transporter hypothesis states that drug resistance in epilepsy comes about as a result of the inadequate local concentration of AEDs at their target(s), resulting from the pathological overactivity of multidrug transporter mechanisms.

One conceptual framework for considering candidates for either mechanistic hypothesis is as follows and any mechanism postulated to be involved must satisfy the following criteria:

1. mechanisms must be detectable in epileptogenic brain tissue
2. mechanisms must have appropriate functionality
3. mechanisms must actually be active in drug resistance
4. overcoming the mechanisms should affect drug resistance

Most researchers consider that if either of these classes of mechanism turns out to be relevant, combinations of these (and possibly other) mechanisms will contribute to drug resistance to varying degrees in individual patients. It must be mentioned that other possible mechanisms have also been proposed, but have received less research attention.

Methods

In our laboratory, two main methods of investigation have been used to address the transporter and target hypotheses. These methods are neuropathological studies, and population genetic studies. Neuropathological studies address the fundamental issue of the presence, distribution, and quantity of multidrug transporters, and other entities, within and beyond epileptogenic tissue. No hypothesis based on the activity of a protein putatively involved in drug resistance in epilepsy could be sustainable if that protein were truly not detectable within relevant areas of human epileptogenic brain tissue. Beyond this issue of detectability, the specific distribution, orientation, and quantity of such a protein would have implications for finer structures of the hypotheses – for example, proposed mechanisms of activity of transporter proteins in mediating resistance.

Determining the activity of any detected proteins, particularly given possible complexities of the distribution of the proteins, is very difficult in living human brain tissue, whether in vivo or ex vivo. Whilst microdialysis experiments are occasionally undertaken in living human beings, usually during epilepsy surgery, the precise positioning of a microdialysis probe can never be fully known, and is unlikely ever to achieve the degree of resolution required to formally test the potential role of proteins with specific microscopic distributions (see **Figure 1** for an example of the microscopic distribution of multidrug transporters). However, surrogate estimations of the role and activity of particular proteins, and associated mechanisms, might be achieved through population genetic studies. In principle, if a protein has a role in a given process, then genetic variation in the encoding gene that affects the function of that protein might have an association with a relevant clinical phenotype, thus providing supportive – if not more definitive – evidence for a role for that protein in the proposed process. Both of these areas of study are be described below.

Tissue Studies

Research in epilepsy benefits uniquely from the availability of freshly resected brain tissue, which of course must first be studied for clinical neuropathological diagnostic purposes; however, any surplus tissue may be used for detailed experimentation. This tissue is a valuable resource, which we must use as carefully and as comprehensively as possible. With the evolving 'omic' methodologies (genomic, transcriptomic, proteomic, and metabolomic), truly comprehensive tissue profiling at several levels has become impossible. There remains, nevertheless, an important position for detailed neuropathological studies of the distribution and quantity of proteins, for example using immunohistochemistry.

We have used tissue resected for therapeutic purposes from patients with drug-resistant epilepsy. Surgery is undertaken according to clinical imperatives, usually in the context of a comprehensive multidisciplinary assessment, when the benefits of focal resective surgery considerably outweigh the risks. The most common procedure undertaken is the resection of the mesial temporal structures, including the amygdala and hippocampus. This surgery is undertaken by different centres in different ways; in our own centre, removal of the mesial temporal structures follows the en bloc removal of the anterior

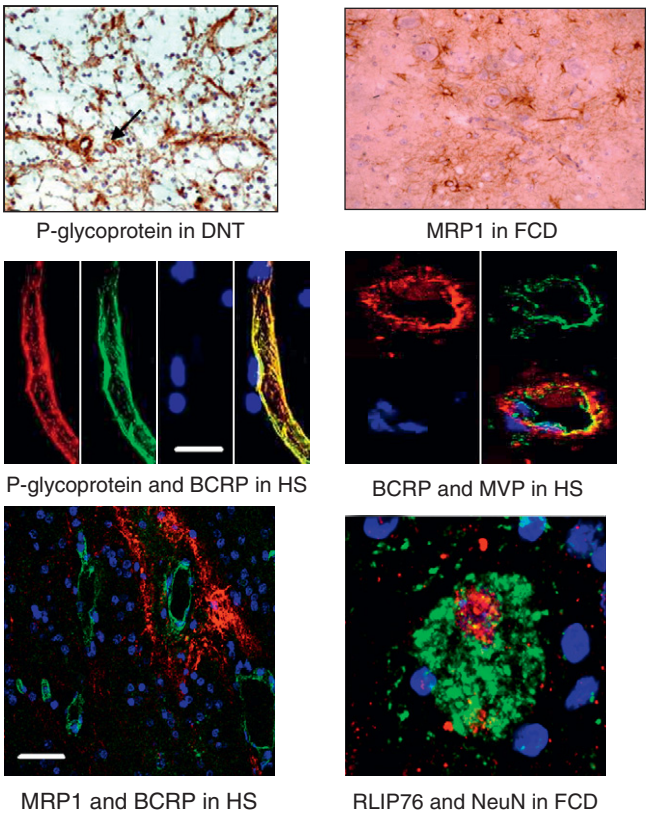

Figure 1 Examples of immunohistochemical studies in resected human epileptogenic tissue of putative multidrug transporters or related proteins. Reproduced from Sisodiya SM, Lin WR, Harding BN, Squier MV and Thom M (2002) Drug resistance in epilepsy: expression of drug resistance proteins in common causes of refractory epilepsy. *Brain* 125: 22–31; and Sisodiya SM, Matinian L, Scheffer GL, *et al*. Neuropathology and Applied Neurobiology 32: 51–63.

temporal lobe. A spin-off of this standard procedure is the availability of hippocampal and temporal neocortical tissue for clinical neuropathological, as well as research, purposes.

A major hurdle in such neuropathological studies is the lack of availability of completely normal control brain tissue from comparable regions. Histologically normal material does rarely become available, for example, when otherwise normal tissue has to be resected for purposes of access to lesions or relief of pressure following trauma. Histologically normal post mortem tissue is occasionally also available, but of course would often have suffered from agonal and post mortem changes, which to some extent limits its utility for various purposes. Temporal neocortical tissue, when histologically normal, can provide a class of comparative tissue for control purposes, having the advantages that it will be from the same individual, with the same germline genotype, the same history of epilepsy, the same exposure to AEDs, and the same post resection treatment. However, temporal neocortex is clearly anatomically different from mesial temporal (i.e., hippocampal) structures, and there are some limitations in possible comparisons. It is also likely to be the case that at the gene expression level, there are normal, and disease-related, differences between the hippocampus and temporal neocortex. Ideally, a variety of control tissues should be employed in such investigations.

Several immunohistochemical methods have been used in our own laboratory, ranging from routine single antibody studies in formalin-fixed, paraffin-embedded tissue, to semiquantitative analysis using immunofluorescently labeled antigens – all with preservation of anatomical specificity and the ability to provide some degree of quantitative information.

Population genetic studies offer a conceptually simple and powerful approach to testing mechanistic hypotheses. The principle is to compare distributions of genetic measures, such as genotype or allelic frequencies, between clinical cases (that have the trait in question) and controls (that do not). In such case–control association studies, critical aspects are a robust definition and application of phenotypes (traits) of interest, sufficient numbers of patients to be able to test a given hypothesis with sufficient power to produce a definitive result, comprehensive coverage of the variation-bearing structure in question (e.g., the gene encoding the protein of interest) and a competent genotype–phenotype association statistical framework. Subsequently, replication of association findings is often required, as well as functional work to identify the action of the variant.

Results

Tissue Studies

We have used standard immunohistochemical methods, in epileptogenic brain tissue containing a variety of pathologies and in comparator tissue, to study a range of transporters considered to be potential candidates for mediating resistance to AEDs. We have studied P-glycoprotein (also known as MDR1 or ABCB1), multidrug-resistance associated protein 1 (MRP1 or ABCC1), breast cancer resistance protein (BCRP, also known as MXR or ABCG2), major vault protein (MVP), and RLIP76. At various times and in various publications, these proteins have been implicated in the causation of drug resistance in various cancer cell lines and human tumours, or in other experimental studies of epilepsy. Other groups have also looked at these and other proteins. In general, the results tend to be concordant, although with some important differences with respect to the cell specificity of expression. In this article, we present only our own results (in summary form). Neuropathological findings from other groups are detailed extensively in the excellent review articles listed in Further Reading.

We have identified expression of P-glycoprotein in cells in which it is not normally or commonly detected (such as glial cells), within epileptogenic regions, at much greater levels than in comparator control regions. In our studies, we have not detected P-glycoprotein in normal or abnormal neurons from normal or epileptogenic brain regions. Other researchers *have* detected the presence of P-glycoprotein in neurons. This discrepancy raises an important point, which is that the specificity and sensitivity of antibodies and experimental protocols are known to vary between laboratories and tissues, making standardized procedures important.

We have also noted that MRP1 is detectable in glia, again with a much greater emphasis in epileptogenic regions compared with control regions. We also detected MRP1 in dysplastic neurons in regions of focal cortical dysplasia (FCD). In contrast to P-glycoprotein, which can be detected in the microvasculature, we have not detected MRP1 in the microvasculature in the brain. We have identified BCRP only in the microvasculature, and not in glia or neurons, from epileptogenic or other regions. We also noted the strong expression of major vault protein within dysplastic neurons and within blood vessels, but not within glia. Normal neurons did not appear to express major vault protein. We did not find RLIP76 expression within microvasculature or glial cells, but detected it only in neurons, especially within dysplastic neurons from areas of FCD.

More recently, we have explored P-glycoprotein expression at a quantitative level. In contrast to our expectations, quantitative immunofluorescence showed that there was less signal in the microvasculature from epileptogenic regions in comparison with comparator control regions. This finding was surprising. It clearly requires replication, but were it to be correct, this finding could suggest that there is less P-glycoprotein quantity, and possibly less P-glycoprotein activity, in epileptogenic brain region microvasculature compared to control regions. Most workers in the field have assumed, although no one has formally tested in situ (in vivo or ex vivo) that there is *more* P-glycoprotein within the microvasculature in epileptogenic regions compared to control regions. Our findings, although in contrast to expectations, nevertheless are in keeping with other work that suggests that the blood–brain barrier may in fact be impaired in epileptogenic brain regions in chronic epilepsy, both in animal models and human epileptogenic brain tissue. It also supports the view that overexpression of P-glycoprotein, in particular, in epileptogenic brain regions in glia, might represent a 'second' blood–brain barrier, as a pathophysiological response to impairment of the normal blood–brain barrier at the level of the microvasculature.

Some of these immunohistochemical findings are illustrated in **Figure 1**.

Population Genetic Association Studies

In cohorts of patients with drug-resistance or drug-responsive epilepsy (with specific definitions), we examined the distribution of a particular variant in the gene *ABCB1*, encoding P-glycoprotein. This study was undertaken some time ago, but remains a robust study. We demonstrated an over-representation of the CC genotype (in comparison to the TT genotype) at the 3435 locus in *ABCB1* in patients with drug-resistant epilepsy, in comparison with patients with drug-responsive epilepsy. There is a considerable body of evidence demonstrating that the C allele is associated in western European populations with an increased quantity and activity of P-glycoprotein. These initial association findings were therefore in keeping with the hypothesis that an increased quantity and activity of P-glycoprotein were associated with the drug-resistant phenotype in epilepsy.

However, this initial finding was not replicated in the only published study structured exactly as our study. The second study utilized a larger cohort, and concluded that this polymorphism in *ABCB1* could not have a major role to play in the drug-resistant phenotype. Several other association studies have examined the same problem, but all have used different phenotypic definitions and varied in their coverage of genotypic variation. None can be considered a formal replication of our study. Formal comparison of the studies is therefore difficult, but it would be reasonable to consider that it is unlikely that the 3435 variant has a major role to play in mediating drug resistance in all patients with epilepsy. Currently, studies of larger sample sizes and more comprehensive

representation of variation within *ABCB1* would be deemed appropriate.

It is of great interest that in almost every other human disease phenotype in which an association with this polymorphism in *ABCB1* has been sought, there has been equal ambiguity. Whilst some disagreement between studies might be attributed to methodological differences, very recent work suggests that: (1) this synonymous polymorphism might affect mRNA stability, leading to allelic imbalance for expression despite the polymorphism being noncoding and (2) even more interestingly, any allelic influences on expression might additionally depend on rates of gene expression. One implication of these findings is that very careful matching of replication cohorts is necessary, as the impact of the polymorphism on protein levels and substrate specificity might depend on expression demand – as influenced, for example, by seizures, drug treatment, or hypoxia. There is clearly much complexity yet to be explored, with exciting possibilities still in play for P-glycoprotein and *ABCB1*. For example, it seems that substrate-specificity changes may be plastic, and themselves influenced by the presence of various factors, including functional inhibitors of P-glycoprotein. Another implication of this complexity is that we are still some way from human trials of P-glycoprotein inhibitors.

In conclusion, whilst association studies to-date would seem to rule out a major role for the C3435T variant in *ABCB1* in the causation of drug resistance overall, a role for this variant, particularly in patients with more resistant epilepsy, has not yet been excluded.

We have also employed association studies to consider the target hypothesis of drug resistance, focusing particularly on variants in *SCN1A*, encoding the shared target of many AEDs, the brain-expressed sodium channel alpha-subunit. Whilst we have not been able to demonstrate any direct association with response phenotypes, such as seizure freedom or drug resistance as defined in the *ABCB1* study, we have shown that a common variant in *SCN1A* associates with maximum clinical dose of the alpha-subunit binding AEDs, carbamazepine, and phenytoin, used in individual patients. We have gone on to show that the associated polymorphism is itself likely to be causal, directly influencing alternative splicing of *SCN1A*. This work illustrates the power of pharmacogenetics not only to explain drug-related parameters such as drug dosing, but also to contribute to an understanding of disease biology – in this case, throwing new light on the role of alternative splicing of *SCN1A* in neuronal biology (its control and disruption).

Finally, others and we have shown alterations at a neuropathological level of the expression of cation-chloride transporters, NKCC1, and KCC2. Such expression changes can alter the transmembrane chloride gradient and thus the action of GABAergic neurotransmission on neuronal function – in turn, affecting drug targets.

As we see more and more influences on drug targets and transporters, mechanisms of drug resistance can be seen to be increasingly complex and interdependent. Candidate gene studies become obsolete in this setting and in the context of rapidly falling costs of genotyping. It is now possible to undertake population genetic association studies at the level of genome-wide assessment of variation, for example typing 550 000 single nucleotide polymorphisms (SNPs) in thousands of individual patients. We have started using these methods which, although complex, will permit comprehensive evaluation of genetic influences and mechanisms in drug resistance.

Future Goals

A detailed definition and description of mechanisms of drug resistance in epilepsy is an important goal for those involved in caring for patients with epilepsy. Drug resistance remains a major problem. It increases risks at all levels for patients who are affected. Understanding mechanisms of such resistance might lead to new therapeutic approaches, or to better use of current treatments. With significant advances in technology, including advances in 'omic' methodologies, and with increasing cohort sizes being assembled at all levels (ranging from the tissue to DNA data banks), the potential now exists for definitive and comprehensive studies of drug resistance. With the possibility of thorough coverage of the entire human genome, and with the possibility of sophisticated postgenomic studies at the level of individual cell populations, for example using laser cell microdissection, a thorough mechanistic explanation of drug resistance should be possible. For any such studies, however, careful phenotype definition, robust statistical analysis, replication, and continued testing of the implications of such research will be necessary if proper progress is to be made. The potential benefits, both for understanding and treatment, are great. It remains important to learn from other fields that may be more advanced, especially from the field of oncology, with respect to drug resistance. It remains critical to be clear about potential mechanisms and the consequences of their manipulation before treatment trials are attempted in humans.

Introduction

Despite the use of anticonvulsant drugs, a considerable number of epilepsy patients still suffer from pharmacoresistant seizures. Of these, 2000–5000 patients per year may be candidates for epilepsy surgery.

Epilepsies can be differentiated into different epileptic disorders with individually varying focal, regional, or generalized involvement of neuronal networks. For the optimal selection of suitable candidates for epilepsy surgery, presurgical evaluation strategies have been developed aiming at (1) localizing the focal epileptic activity responsible for the seizure generation; (2) establishing the relationship of the epileptic network to functionally-important brain areas; and (3) determining the 'reserve capacity' of the nonresected brain tissue.

Because of the existence of a large number of pharmacoresistant epilepsies, and the growing clinical awareness that delayed surgical intervention can result in a severe impact on quality of life (injuries, sudden unexpected death, school performance impairment, driving license, loss of employment, and indirect economic consequences for the society), early surgical intervention is required.

Presurgical Evaluation Techniques

For the detection of the networks responsible for generating epileptic activity, as well as for determining functionally-eloquent regions in the brain that are not readily accessible for surgery, invasive surgical recordings using subdural or intracerebral electrodes are still used. These approaches

provide excellent information from neocortical and subcortical brain regions. But there are also disadvantages – e.g., distortions produced by these recording approaches, and risks of hemorrhage and infection – that have led to a more and more restricted use of invasive electrodes. High resolution imaging (MRI, fMRI, PET, SPECT) has improved the detection of epileptogenic lesions and functional changes associated with those lesions. Although fMRI, SPECT, and PET provide indirect measurements of brain function by changes of perfusion (interictually or ictally), direct measurements of epileptic activity and function is obtained by EEG and MEG. Long-term video-EEG monitoring proves the epileptic nature of seizures, and in addition is necessary for a detailed classification of seizure types. MEG recording has been used predominately to document interictal activity. With MEG techniques, the differential conductivities of different tissues in the head (e.g., skull, meninges, cerebral spinal fluid, large lesions, asymmetries from previous surgery) are less influential in determining localization of epileptic networks, as compared to EEG. Both techniques are complementary for presurgical evaluation. Magnetic source imaging (MEG source localization visualized within brain anatomy) is helpful in correlating the localization of the epileptic activity with lesion or function (somatosensory, motor, visual, auditory, and language areas). Although this source localization does not strictly provide a physical point, the MEG approximation of the center of focal activity can provide important information for early optimization – i.e., classification of epilepsies with regard to differentiation into lobar categories.

In addition, the noninvasive and safe screening of patients for epilepsy surgery has improved. These noninvasive data can then be used to guide invasive electrode implantations – or even help determine that electrode implantation should be avoided. These presurgical procedures, and additional neuropsychological investigations of material specific memory and other cognitive functions – before and after surgery – have improved the basis for our understanding of brain function. In a dialectic process, they also critically participate in developing the strategies for presurgical evaluation and surgical interventions (Figure 1).

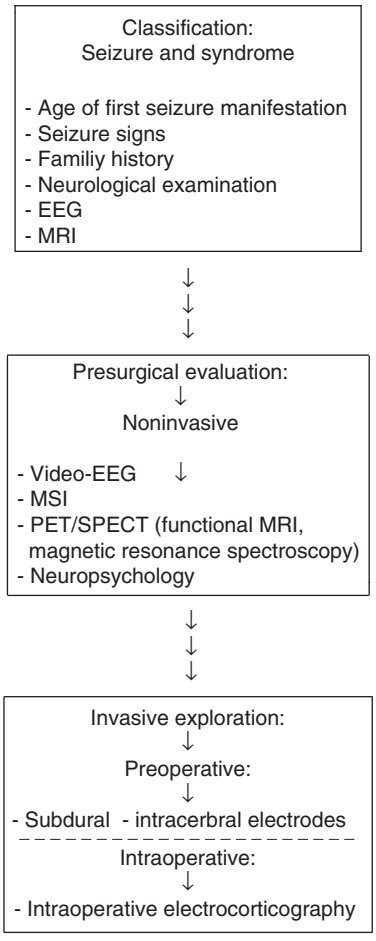

Figure 1 Diagnostic strategies in different phases of presurgical evaluation.

Surgical Interventions

Resective Surgery

A first single systematic approach for resective epilepsy surgery was performed by Victor Horsley and Ferrier. Later, in specialized epilepsy centers like those in Montreal, Paris, Zurich, and Cleveland, epilepsy surgery was performed in large numbers, particularly for temporal lobe and extra temporal lobe epilepsies. Currently, epilepsy surgery is carried out world-wide. The aim of successful epilepsy surgery is twofold: to provide seizure control, and to preserve normal brain function. Therefore, tailoring the resection to the individual patient should be carried out. Compared with drug treatment, resective surgery can control seizures more effective if a careful selection of candidates is provided. The profile of efficacy and side effects of epilepsy and resective epilepsy surgery are shown in Table 1.

Undercutting

If no resection can be performed – e.g., because of a major risk of considerable functional deficit – the microsurgical cutting of horizontal fibers (cuts spaced at ~5 mm) was suggested by Morrell. Although this procedure can lead to improvement, most clinical experience suggests that only a reduction of the intensity of seizures can be obtained by this technique. As a simplified model for the interpretation of such effects, the nucleus shell structure model can be used. In this model, the onset region of the seizure is viewed as the 'nucleus,' and phases of seizure propagation (during the temporal evolution of the

Table 1 Profile of efficacy

Surgery	*Seizure free (%)*	*Improved (%)*	*Complication quote (%)*
Temporal lobe resections			
Antero-mesial standard resection	50–70	20–30	3–10
Selective amygdala-hippocampectomy	50–70	20–30	3–10
Extratemporal neocortical resection	30–50	30–40	3–10
Lesionectomy	40–60	10–25	3–10
Hemispherectomy	70–90	5–15	5–20
Multilobar resection	40–50	30–40	5–20
Callosotomy	0–10	60–70	5–15
Multiple subpial transection	20–30	40–50	5–15

seizure) viewed as 'shells.' If only the networks belonging to the shell are disconnected (by this subpial cutting procedure), only a reduction of seizure intensity may occur. If the nucleus is extinguished, the whole seizure is controlled. Multiple subpial transection appears to influence only the shell networks.

Callosotomy

In multifocal generalized epilepsies (e.g., Lennox–Gastaut syndrome), parts of the corpus callosum can be selectively transected in order to prevent rapid propagation of seizure activity from the side of origin to the contralateral hemisphere. There are anterior and posterior variants of this procedure, with the anterior two-third section of the corpus callosum being the most frequently used. Callosotomy leads to control of predominantly severe tonic seizures. In rare cases, as side effect, a 'split brain' defect can occur.

Brain Stimulation

Electrical stimulation of different brain structures, such as paleocerebellum, centromedian thalamic nuclei, hippocampus, and cortex involving a focal epileptic region, may result in varying effects with regard to seizure control. Seizure reduction up to 96% has been reported in single cases, but other studies report no differences comparing stimulation on and off periods. The pathophysiological mechanisms for a possible deep brain stimulation antiepileptic effect remain to be clarified. Mechanisms that have been postulated include effects on synaptic transmission, long-term potentiation, kindling, quenching, and depotentation.

Focal Radio Surgery

In cases where no resection or transection can be performed, an alternative treatment approach involves precise focal irradiation by sterotactic linear accelerator radiation (LINAC/NOVALIS systems) or ^{60}Co sources (gamma knife). Although the first strategy aims to modulate focal epileptic activity by inducing functional changes, the gamma knife can be used for destroying tissue – e.g., in pharmacoresistant mesial temporal lobe epilepsies – as well as for callosal radiosurgery. Seizure reduction or control has been observed in 40–70% of cases, using the gamma knife or linear accelerator radiation. Seizure control often occurs at a long latency – as much as one and a half years after radiation.

Implantation of Anticonvulsants

The implantation of pumps containing anticonvulsant agents, triggered by seizure activity, is another novel, and still experimental, therapeutic approach that is under development.

Newer Integrative and Pre- and Intraoperative Approaches for Tailored Surgical Interventions

A large array of noninvasive and invasive pre- and intraoperative procedures can be used within a neuronavigation system. After completing a tailored resection, resected brain volume can be determined by intraoperative MRI to determine the adequacy of the resection. An example of this approach is shown in a patient with pharmacoresistent focal epilepsy and periventricular nodular heterotopia (**Figure 2**). Because invasive presurgical long-term monitoring was not possible in this case, MSI (magnetic source imaging) was used together with fMRI/DTI to correlate the localization of the focal epileptic activity with the course of the visual pathways (MR tractography), neuronavigation, intraoperative ECoG and MRI. The periventricular heterotopia in **Figure 2** (marked by white arrow) and a radial band extending to the thinner temporal lateral cortex (marked by red arrow) were the suspected anatomical substrates of the functional abnormality. The relationship of two zones of focal epileptic activity (localized by means of MSI) to the optic radiation is shown in **Figure 3**.

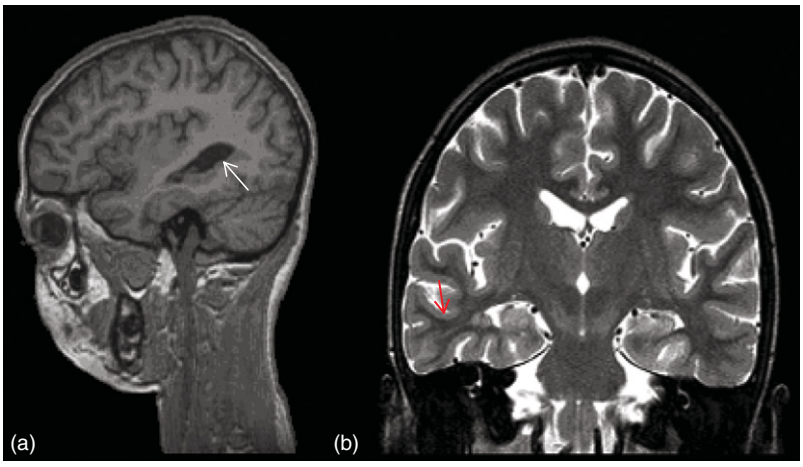

Figure 2 T2-weighted (axial) and MPRAGE (sagittal) MR imaging show periventricular heterotopia in the right basal temporo-occipital area (marked by arrow).

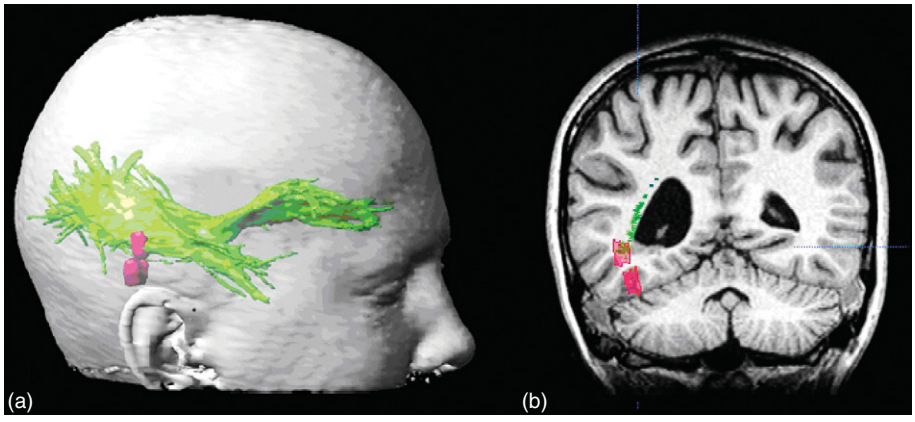

Figure 3 (a) Streamtube visualization of the right optic radiation based on diffusion tensor imaging. For navigation, a 3-D object representing the optic radiation (wrapping the individual fibers) and two distinct MSI foci (red) are generated. (b) Relation of optic radiation (visualized as streamlines) to MSI foci.

Intraoperative MSI-guided electrode implantation (intracerebral depth and subdural) confirmed the MSI localization and the predominance of the laterobasal focus, which was resected without functional deficit (Figure 4).

This case gives rise to several important questions. For example, what is the large mesial periventricular lesion, and what are the functional consequence of the abnormal shape of the hippocampus and the thinner laterobasal temporal cortex? In this case, the epileptic neuronal network extends from the heterotopia to the temporal neocortex, with predominance of epileptic activity in the laterobasal neocortex. It is known that developmental lesions in mesial periventricular structures can produce pathological wiring with distant lateral neocortical areas, which may explain why epileptic activity was found in the laterobasal cortical area. This latter area was resected, but focal activity close to the heterotopia was not resected because of a significant risk of a visual disturbance (as indicated by fiber tract imaging in the neuronavigation). Within the first month after surgery, there were three complex partial seizures (two provoked by fever); in the following 18 months, no more seizure occurred. Therefore, we conclude that important epileptic networks must have been resected or disconnected from the major epileptic lesion.

Clearly, consideration of these results must stimulate discussion concerning the definition of the epileptic 'zone.'

Although Penfield and Jasper required resection of the epileptic zone in their early work, and recommended in addition the elimination of the 'early propagation area,' the above case suggests that severing subnets of epileptic networks may lead to seizure control, leaving even larger lesions untouched. It should be noted that the early use of the term 'epileptic zone' was derived from a basically

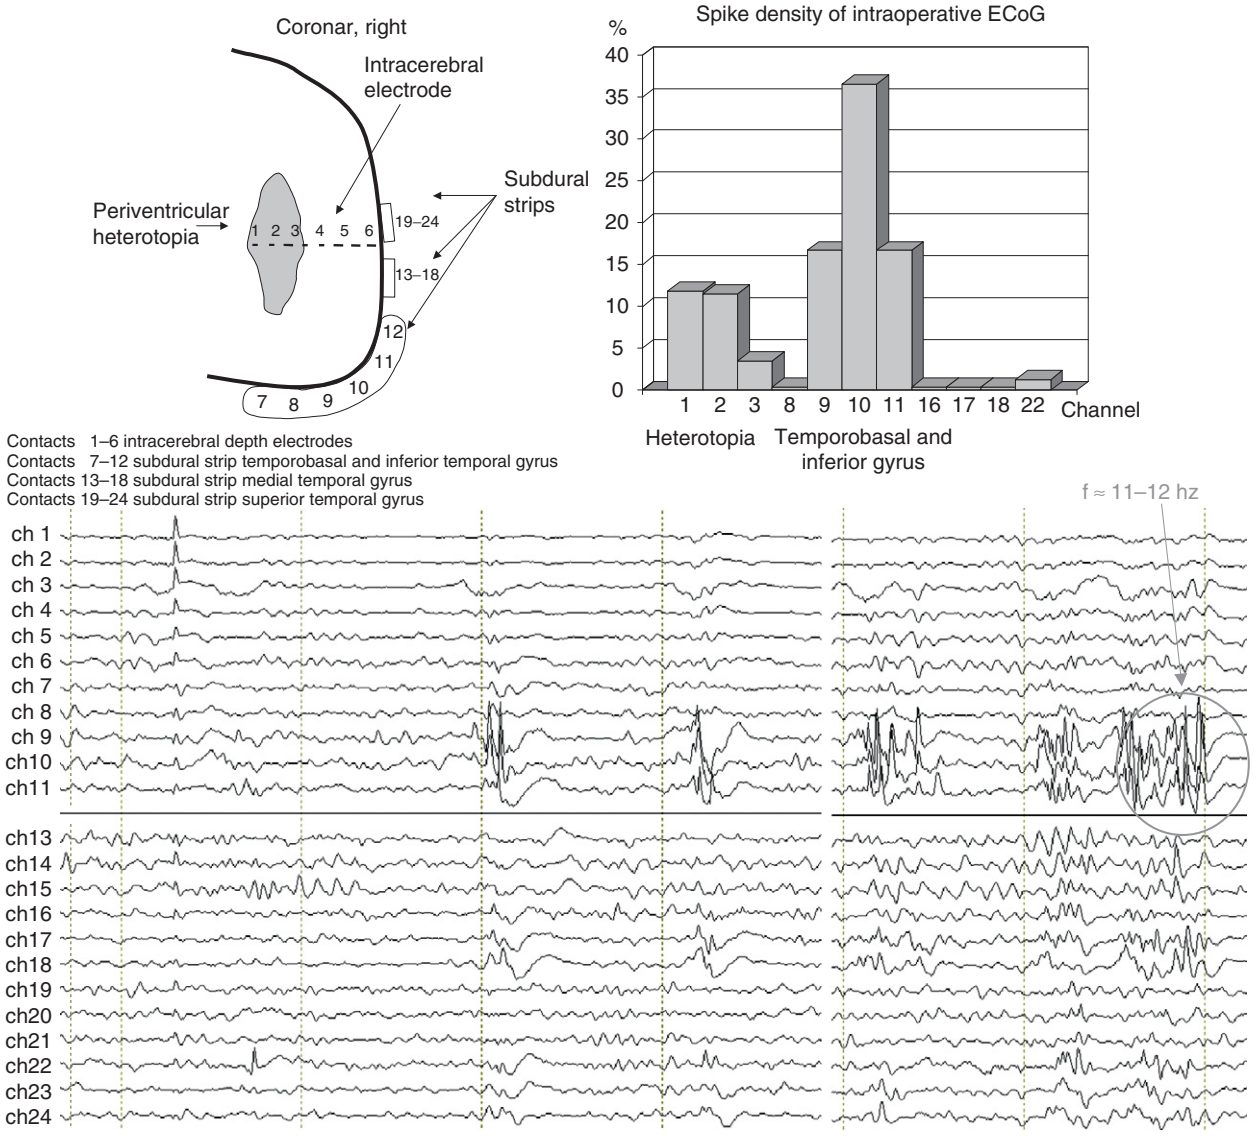

Figure 4 Intraoperative electroencephalographic recordings with platinum electrodes close to the two suspected spike foci as suggested by MSI (white arrows: temporobasal strip, thin white arrow: depth electrode to heterotopia). Additional measurements were picked up from the lateral cortical surface. The electrode position was confirmed by intraoperative T1- and T2-weighted high-field-MR imaging. MSI-guided electrode implantation of intracerebral depth and subdural electrodes; spike activity in lateral cortex and periventricular heterotopia. The neocortex shows predominant spike wave activity and 11–12 s^{-1} polyspikes during intraoperative ECoG.

two-dimensional view to the brain. In the future, a more realistic view of 'epileptic networks' should be developed, based on a three-dimensional approach.
