This book is dedicated to the scientists and clinicians who have developed the technology and life-saving procedures that we use to diagnose and treat our patients

Preface to the Second Edition

The role of nuclear medicine and molecular imaging in the diagnosis and therapy of cancer patients is growing. The rapid pace of change has been fueled by advances in understanding tumor biology, on the one hand, and the development of specifically targeted medical therapies, diagnostic agents, and radiotherapies, on the other. These advances suggested that an update and expansion of the contents of *Nuclear Oncology* would be timely. The second edition offers specialists in imaging, radiotherapy, cancer surgery, and oncology information that is current to manage patients with cancer.

There are three major changes in this edition: first, the text has been expanded to include more detailed information on performing specific procedures (e.g., radioguided surgery); second, the number of clinical cases has been increased to 170, to provide a broader range of examples, reflecting the clinical range of findings; and third, this edition will be available on Springer's electronic platform, allowing authors to continuously update the content of their chapters.

The second edition is divided into seven parts:

Part 1 consists of 13 chapters of basic science. The first chapter describes our understanding of cancer biology, including mechanisms of initiation of cancer and key tumor pathways that are attacked by specific therapeutic agents. This is followed by a discusion of mechanisms of molecular targeting and approved radiopharmaceuticals for single photon and positron imaging as well as therapy. These chapters are mirrored by three chapters describing agents in development for diagnosis and therapy. Chapters on physics, instrumentation, and radiobiology complete the basic science section.

Part 2 has 26 chapters that address the roles of imaging in the diagnosis and staging in specific types of cancer. Each chapter starts with a review of the epidemiology of the cancer, followed by a description of the typical clinical presentation, criteria for staging, therapeutic alternatives, and monitoring the effectiveness of treatment and suveillance following therapy.

Part 3 has seven chapters that address radionuclide therapy for the treatment of:
- Lymphoma
- Multiple myeloma and leukemias
- Thyroid cancer
- Neuroendocrine tumors, with separate chapters discussing the use of MIBG and peptide therapy
- Skeletal metastases
- Tumors of the liver and biliary tree with radiolabeled particulates

Part 4 has four chapters on specific applications of radioguided surgery. Three chapters describe the instrumentation, radiopharmaceuticals, and clinical goals of radioguided surgery in patients with breast cancer, malignant melanoma, and head and neck cancer. The last chapter of this section covers novel applications of the technology.

Part 5 describes the detection and management of heart disease in the cancer patient.

Part 6 presents adverse effects of cancer therapy.

Part 7 consists of 25 chapters of cases. These chapters of cases supplement the case examples illustrating specific points in each of the clinical chapters.

The text has a detailed index, which will help readers locate the information they seek to care for their patients.

We would like feedback from our readers about the text. Please address your comments to the editors.

Preface to the First Edition

Cancer is a disease that was first described over 3500 years ago. While the designation *cancer* was coined by Hippocrates centuries later, descriptions of individual patients with the disease are found in Egyptian papyri dating from 1600 BCE [1]. Two papyri, the Edwin Smith papyrus (circa 1600 BCE) and the George Ebers papyrus (circa 1500 BCE), contain case descriptions consistent with modern observations of patients with cancer [2]. Hippocrates, in the fifth century BCE, suggested there was no cure for these maladies. Clinical observations and laboratory studies in the intervening 2500 years have led to a better understanding of the pathophysiology of cancer and the realization that the disease can be effectively treated.

There are four phases of most common malignant tumors: (1) Multiple genetic alterations lead to a cell losing control of cell division, apoptosis, and DNA repair, resulting in a malignant change, commonly referred to as transformation. (2) The transformed cells are genetically programmed to grow. (3) The proliferating transformed cells invade surrounding local tissues. (4) Some of the transformed cells depart from the local tumor mass and colonize a distant site, resulting in distant metastases [3].

Our current understanding of the pathophysiology of neoplasia has provided specific information on the numerous genetic changes in the transformed cell and on the impact of these changes on protein production by the transformed genome. Altered protein production may lead to an increase or decrease in the expression of receptors, production of unique epitopes on the cell surface, and changes in substrate utilization by the transformed cells.

Understanding the molecular mechanisms of specific neoplasms has led to the development of novel therapies, addressing specific control points in the life cycle of the transformed cell, and defined the need for detailed staging and characterization of the tumor, to develop a plan of treatment for the patient. This textbook provides the reader with information on the role of nuclear medicine in the diagnosis, staging, and treatment of patients with specific cancers. Each chapter provides material on the incidence, main pathophysiologic and clinical aspects of the disease, staging, and management of specific tumors, with a major focus on the points to be addressed by the nuclear medicine procedures.

The book is composed of seven parts: Basic science is covered in Chaps. 1–6: The first chapter reviews fundamental aspects of the biology of cancer and the tumor mass. The next two chapters describe the chemistry and

radio pharmacy for manufacturing single photon and positron emitting radiopharmaceuticals. The next three chapters deal with the physics of radionuclide decay, principles of instrumentation, followed by radiobiology and dosimetry. Clinical applications are covered in Chaps. 7–25. Radionuclide therapy is covered in Chaps. 26 and 27, and radioguided surgery is discussed in Chap. 28. Heart disease in the cancer patient is covered in Chap. 29, and adverse effects of cancer therapy in Chap. 30. In Part VII, Teaching Cases, the book concludes with a series of cases.

Each clinical chapter discusses the radionuclide procedures within an integrated framework identifying the information required for effective treatment of that specific tumor. The first part of each chapter provides a description of the epidemiology, etiology, histologic and pathophysiologic classification, prognosis, treatment, and the most common outcome for each type of cancer. This information on basic/clinical oncology is essential for the nuclear medicine specialist to understand how radionuclide imaging and therapy should be integrated with other imaging/therapeutic modalities to the benefit of the cancer patient. These discussions also highlight elements that should be contained in the report of the nuclear imaging procedure(s): depending on the type of cancer and the specific goal of imaging (initial staging, evaluation of response to therapy, or surveillance for recurrence), the Impression section of the report should clearly answer the clinical question.

Acknowledgment

The editors are indebted to our colleagues from different groups who contributed additional teaching cases in the concluding section of the book. Their contributions provide examples of how nuclear oncology plays a practical role in patient management at critical points in the care of patients. The following is a list of the groups and contributors:

- Biomedical Photonic Imaging Group, University of Twente, Enschede, The Netherlands: R.H.J.A. Slart.
- Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark: K. Bouchelouche, C.M. Hoff, M.R. Jochumsen, M.A. Pedersen.
- Department of Nuclear Medicine and Molecular Imaging, University Medical Center Groningen, The Netherland: E.D. Telenga, A.W.J.M. Glaudemans, R.H.J.A. Slart.
- Division of Nuclear Medicine, Department of Biomedical Sciences, Humanitas University, Milan, Italy: A. Chiti, M. Kirienko, G. Manfrinato, L. Olivari.
- Endocrine Unit, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy: V. Cappagli, R. Elisei, C. Giani, A. Matrone, E. Molinaro, L. Pieruzzi, D. Viola.
- Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK: K. Al-Riyami, S. Al Shammari, J.P. Connelly, F. Fraioli, D. Neriman, S. Wan.
- Nuclear Medicine Department, Hospital Clinic Barcelona, Barcelona, Spain: S. Vidal-Sicart.
- Nuclear Medicine Service, Great Ormond Street Hospital, London, UK: L. Biassoni.
- Nuclear Medicine Unit, "S. Andrea" Hospital, La Spezia, Italy: A. Ciarmiello, V. Duce.
- Nuclear Medicine Unit, "S. Orsola-Malpighi" Hospital, Bologna, Italy: I. Bossert, S. Fanti, C. Nanni, E. Tabacchi.
- Nuclear Medicine Unit, "Santa Maria della Misericordia" Hospital, Rovigo, Italy: A.M. Maffione.
- Nuclear Medicine, University of Pretoria and Steve Biko Academic Hospital, Pretoria, South Africa: T. Boshomane, T. Lengana, F. Reyneke, M. Sathekge.

- Nuclear Medicine/PET-CT, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts, USA: H.A. Jacene, C.G. Sakellis, A.D. Van den Abbeele, V. Yerubadi.
- Radiotherapy Unit, "Maggiore della Carità" University Hospital and Department of Translational Medicine, University of "Piemonte Orientale," Novara, Italy: L. Deantonio, M. Krengli.
- Section of Medical Physics, "Maggiore della Carità" University Hospital, Novara, Italy: R. Matheoud.
- Section of Nuclear Medicine, "Maggiore della Carità" University Hospital, Novara, Italy: F. Orsini, G.M. Sacchetti.

Contents

Volume 1

Part I Basic Science 1

1 Cancer Biology of Molecular Imaging 3
Steven M. Larson

2 Principles of Molecular Targeting for Radionuclide Therapy 35
William C. Eckelman, Marie Boyd, and Robert J. Mairs

3 Single-Photon-Emitting Radiopharmaceuticals for Diagnostic Applications 67
Federica Orsini, Erinda Puta, Alice Lorenzoni, Paola Anna Erba, and Giuliano Mariani

4 Positron-Emitting Radiopharmaceuticals for Diagnostic Applications 85
Federica Orsini, Alice Lorenzoni, Erinda Puta, and Giuliano Mariani

5 Radiopharmaceuticals for Therapy 99
Federica Orsini, Sara Mazzarri, Erinda Puta, Federica Guidoccio, Alice Lorenzoni, and Giuliano Mariani

6 Novel Single-Photon-Emitting Radiopharmaceuticals for Diagnostic Applications 115
Federica Orsini, Federica Guidoccio, Erinda Puta, and Giuliano Mariani

7 Novel Positron-Emitting Radiopharmaceuticals 129
Mirkka Sarparanta, Dustin W. Demoin, Brendon E. Cook, Jason S. Lewis, and Brian M. Zeglis

8 Novel Radiopharmaceuticals for Therapy 173
Federica Guidoccio, Sara Mazzarri, Federica Orsini, Paola Anna Erba, and Giuliano Mariani

9 Physics of Nuclear Oncology 199
Dale L. Bailey and John L. Humm

10 Instrumentation for Positron Emission Imaging 217
Pat Zanzonico

11 Instrumentation for Single-Photon Emission Imaging 251
Pat Zanzonico

12 Instrumentation for Intraoperative Detection 275
Pat Zanzonico

13 Radiobiology and Radiation Dosimetry in Nuclear Medicine 305
Massimo Salvatori, Marta Cremonesi, Luca Indovina, Marco Chianelli, Massimiliano Pacilio, Carlo Chiesa, and Pat Zanzonico

Part II Diagnostic Applications of Nuclear Medicine 351

14 Diagnostic Applications of Nuclear Medicine: Lymphomas 353
Heather A. Jacene, Sree Harsha Tirumani, and Richard L. Wahl

15 Diagnostic Applications of Nuclear Medicine: Multiple Myeloma 395
Martina Sollini, Sara Galimberti, Roberto Boni, and Paola Anna Erba

16 Diagnostic Applications of Nuclear Medicine: Leukemias 435
Martina Sollini, Sara Galimberti, Roberto Boni, and Paola Anna Erba

17 Diagnostic Applications of Nuclear Medicine: Brain Tumors 467
Giampiero Giovacchini, Mattia Riondato, Elisabetta Giovannini, and Andrea Ciarmiello

18 Diagnostic Applications of Nuclear Medicine: Head and Neck Cancer 507
Heiko Schöder

19 Diagnostic Applications of Nuclear Medicine: Thyroid Tumors 545
Rossella Elisei, Laura Agate, Sara Mazzarri, Valeria Bottici, Federica Guidoccio, Eleonora Molinaro, Giuseppe Boni, Marco Ferdeghini, and Giuliano Mariani

20 Diagnostic Applications of Nuclear Medicine: Parathyroid Tumors 585
Federica Guidoccio, Sara Mazzarri, Salvatore Mazzeo, and Giuliano Mariani

21 Diagnostic Applications of Nuclear Medicine: Breast Cancer 613
Marsha Camilla Lynch, Jean H. Lee, and David A. Mankoff

22 Diagnostic Applications of Nuclear Medicine: Lung and Mediastinal Tumors 639
Elite Arnon, Thida Win, Ora Israel, Ludmila Guralnik, and Simona Ben-Haim

Volume 2

23 Diagnostic Applications of Nuclear Medicine: Esophageal Cancers 685
Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

24 Diagnostic Applications of Nuclear Medicine: Gastric Cancers 697
Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

25 Diagnostic Applications of Nuclear Medicine: Gastrointestinal Stromal Tumors 709
Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

26 Diagnostic Applications of Nuclear Medicine: Tumors of the Liver and Biliary Tract 725
Mustafa Raoof, Steven M. Larson, and Yuman Fong

27 Diagnostic Applications of Nuclear Medicine: Pancreatic Cancer 749
Elena Tabacchi, Cristina Nanni, Irene Bossert, Anna Margherita Maffione, and Stefano Fanti

28 Diagnostic Applications of Nuclear Medicine: Colorectal Cancer 777
Ettore Pelosi, Désirée Deandreis, Laura Cassalia, and Daniele Penna

29 Diagnostic Applications of Nuclear Medicine: Neuroendocrine Tumors 799
Lisa Bodei, Mark Kidd, Laura Gilardi, Duccio Volterrani, Giovanni Paganelli, Chiara M. Grana, and Irvin M. Modlin

30 Diagnostic Applications of Nuclear Medicine: Kidney and Bladder Cancer 839
Kirsten Bouchelouche

31 Diagnostic Applications of Nuclear Medicine: Prostatic Cancer 883
Emilio Bombardieri, Maria Grazia Sauta, Lucia Setti, Roberta Meroni, Gianluigi Ciocia, and Laura Evangelista

32 Diagnostic Applications of Nuclear Medicine: Testicular Cancer 925
Abedallatif AlSharif, Serena Chiacchio, and Giampiero Giovacchini

33 Diagnostic Applications of Nuclear Medicine: Penile Cancer 943
Serena Chiacchio, Abedallatif AlSharif, Zia Saad, Giampiero Giovacchini, and Jamshed Bomanji

34 Diagnostic Applications of Nuclear Medicine: Vulvar Cancer 959
Sonia Mahajan, Weining Ma, and Neeta Pandit-Taskar

35 Diagnostic Applications of Nuclear Medicine: Uterine Cancers 979
Neeta Pandit-Taskar, Sonia Mahajan, and Weining Ma

36 Diagnostic Applications of Nuclear Medicine: Ovarian Cancer 1021
Neeta Pandit-Taskar, Sonia Mahajan, and Weining Ma

37 Diagnostic Applications of Nuclear Medicine: Sarcomas . . . 1047
Janet F. Eary

38 Diagnostic Applications of Nuclear Medicine: Malignant Melanoma 1065
Andrew M. Scott, Marika Ciprotti, and Sze-Ting Lee

39 Diagnostic Applications of Nuclear Medicine: Pediatric Cancers 1103
Thomas Pfluger, Andrea Ciarmiello, Giampiero Giovacchini, Françoise Montravers, Hubert Ducou Le Pointe, Judith Landman-Parker, Martina Meniconi, and Christiane Franzius

Part III Radionuclide Therapy **1139**

40 Radionuclide Therapy of Lymphomas 1141
Heather A. Jacene, Sree Harsha Tirumani, and Richard L. Wahl

41 Radionuclide Therapy of Leukemias and Multiple Myeloma 1157
Martina Sollini, Sara Galimberti, Roberto Boni, and Paola Anna Erba

42 Radionuclide Therapy of Thyroid Tumors 1197
Rossella Elisei, Laura Agate, Sara Mazzarri, Valeria Bottici, Federica Guidoccio, Eleonora Molinaro, Giuseppe Boni, Marco Ferdeghini, and Giuliano Mariani

43 Neuroendocrine Tumors: Therapy with Radiolabeled Peptides 1243
Lisa Bodei, Laura Gilardi, Duccio Volterrani, Giovanni Paganelli, Chiara M. Grana, Mark Kidd, and Irvin M. Modlin

44 Neuroendocrine Tumors: Therapy with ^{131}I-MIBG 1269
Jorge A. Carrasquillo and Clara C. Chen

45 Targeted Radionuclide Therapy for Bone Metastasis 1307
Neeta Pandit-Taskar and Chaitanya R. Divgi

46 Radionuclide Therapy of Tumors of the Liver and Biliary Tract 1337
Giuseppe Boni, Federica Guidoccio, Duccio Volterrani, and Giuliano Mariani

Volume 3

Part IV Radioguided Surgery **1361**

47 Radioguided Surgery for Breast Cancer 1363
Francesco Giammarile, Federica Orsini, Renato A. Valdés Olmos, Sergi Vidal-Sicart, Armando E. Giuliano, and Giuliano Mariani

48 Radioguided Surgery for Malignant Melanoma 1401
Sergi Vidal-Sicart, Federica Orsini, Francesco Giammarile, Giuliano Mariani, and Renato A. Valdés Olmos

49 Radioguided Surgery for Head and Neck Cancer 1433
Federica Orsini, Erinda Puta, Renato A. Valdés Olmos, Sergi Vidal-Sicart, Francesco Giammarile, and Giuliano Mariani

50 Radioguided Surgery: Novel Applications 1451
Renato A. Valdés Olmos, Federica Orsini, Francesco Giammarile, Sergi Vidal-Sicart, and Giuliano Mariani

Part V Heart Disease in the Cancer Patient **1481**

51 Imaging the Heart in the Cancer Patient 1483
H. William Strauss and Josef J. Fox

Part VI Adverse Effects of Cancer Therapy **1511**

52 Nuclear Medicine in the Assessment of Adverse Effects of Cancer Therapy in the Lung, Kidney, and Gastrointestinal Tract 1513
Diego Alfonso López Mora and Ignasi Carrió

Part VII Teaching Cases in Nuclear Oncology (with Contributions from Various Authors) 1529

53 Teaching Cases in Nuclear Oncology: Lymphomas 1531
Kimiteru Ito, Somali Gavane, and Heiko Schöder

54 Teaching Cases in Nuclear Oncology: Multiple Myeloma . . . 1545
Kimiteru Ito, Somali Gavane, and Heiko Schöder

55 Teaching Cases in Nuclear Oncology: Brain Tumors 1557
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

56 Teaching Cases in Nuclear Oncology: Head and Neck Cancer 1569
Kimiteru Ito, Somali Gavane, and Heiko Schöder

57 Teaching Cases in Nuclear Oncology: Thyroid Tumors 1585
Kimiteru Ito, Somali Gavane, and Heiko Schöder

58 Teaching Cases in Nuclear Oncology: Parathyroid Tumors 1607
Kimiteru Ito, Somali Gavane, and Heiko Schöder

59 Teaching Cases in Nuclear Oncology: Breast Cancer 1613
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

60 Teaching Cases in Nuclear Oncology: Lung and Mediastinal Tumors 1627
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

61 Teaching Cases in Nuclear Oncology: Esophageal Cancers 1643
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

62 Teaching Cases in Nuclear Oncology: Gastric Cancers 1655
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

63 Teaching Cases in Nuclear Oncology: Small Bowel Cancers 1667
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

64 Teaching Cases in Nuclear Oncology: Tumors of the Liver and Biliary Tract 1681
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

65 Teaching Cases in Nuclear Oncology: Pancreatic Cancer . . . 1699
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

66 Teaching Cases in Nuclear Oncology: Colorectal Cancer . . . 1715
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

67 Teaching Cases in Nuclear Oncology: Neuroendocrine Tumors 1729
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

68 Teaching Cases in Nuclear Oncology: Kidney and Bladder Cancer 1749
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

69 Teaching Cases in Nuclear Oncology: Prostatic Cancer 1771
Duccio Volterrani, Giulia Puccini, Sara Mazzarri, and Federica Guidoccio

70 Teaching Cases in Nuclear Oncology: Testicular Cancer . . . 1799
Kimiteru Ito, Somali Gavane, and Heiko Schöder

71 Teaching Cases in Nuclear Oncology: Penile Cancer 1805
Kimiteru Ito, Somali Gavane, and Heiko Schöder

72 Teaching Cases in Nuclear Oncology: Vulvar Cancer 1813
Alice Lorenzoni, Alessandra Alessi, and Flavio Crippa

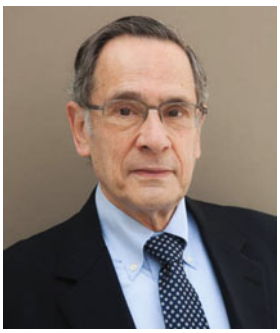
About the Editors



H. William Strauss, M.D., is Professor of Medicine at Icahn School of Medicine, Mount Sinai Hospital, and Attending Physician Emeritus of Molecular Imaging and Therapy Service at Memorial Sloan Kettering Cancer Center. He additionally serves as Professor of Radiology in the Department of Nuclear Medicine at Cornell University, Weill School of Medicine. He is a prolific writer with over 550 original articles, over 70 book chapters, and nine books in his portfolio. He has additionally served on the editorial board of several peer-reviewed journals, including *Journal of Nuclear Medicine*, *European Journal of Nuclear Medicine and Molecular Imaging*, *Journal of Nuclear Cardiology*, *Quarterly Journal of Nuclear Medicine*, and *Annals of Nuclear Medicine*.

Giuliano Mariani From 2001 to 2014, Giuliano Mariani has been Full Professor of Nuclear Medicine, Director of the Regional Center of Nuclear Medicine, and Director of the Specialty School of Nuclear Medicine at the University of Pisa (Pisa, Italy). From 1994 to 2001, he was Associate Professor of Nuclear Medicine, Director of the Nuclear Medicine Service, and Director of the Specialty School of Nuclear Medicine at the University of Genoa (Genoa, Italy).

He obtained his medical degree in 1968 at the Catholic University of Rome (Italy). For the next decade, his postgraduate training prepared him as a specialist in internal medicine, nuclear medicine, medical nephrology, and radiology. He has been a Visiting Scientist at the National Cancer Institute in Bethesda (Maryland, USA) from 1975 to 1977 and a Visiting Professor at the Harvard Medical School in Boston (Massachusetts, USA) from 1986 to 1990.

Initial investigations carried out at the CNR Institute of Clinical Physiology and at the University of Pisa (Pisa, Italy) dealt with the pharmacokinetics of radiolabeled tracers for metabolic studies of endogenous proteins and hormones in various clinical conditions. In the subsequent studies, the interests of Giuliano Mariani have broadened to encompass virtually all fields of Nuclear Medicine for both diagnostic and therapeutic applications. Nevertheless, his main research interests have focused on tumor targeting for diagnosis or therapy with radiopharmaceuticals; he has been the Senior or Principal Investigator on many research projects, several of which were international collaborations. Thanks to his important contributions to the whole field of Nuclear Medicine, in 2014 Giuliano Mariani has been granted honorary membership in the European Association of Nuclear Medicine (EANM), while the Italian Association of Nuclear Medicine (AIMN) bestowed to him the same recognition in 2017. He is a member of the Society of Nuclear Medicine and Molecular Imaging (SNMMI).

Giuliano Mariani serves or has served on the Editorial Board of several journals including, among others devoted to Nuclear Medicine and diagnostic imaging in general, *The Journal of Nuclear Medicine* (currently as an Associate Editor – International), the *European Journal of Nuclear Medicine and Molecular Imaging*, the *American Journal of Roentgenology*, the *Journal of Nuclear Biology and Medicine*, the *Journal of Nuclear Medicine and Allied Sciences*, and the *Quarterly Journal of Nuclear Medicine*. He is also an active referee for many international journals and has been Author/Editor of 16 books and over 80 chapters in books. In addition, he has authored/coauthored over 315 papers in international peer-reviewed journals.

Over the past decade, Giuliano Mariani has served on several occasions as and Expert Consultant for the International Atomic Energy Agency (IAEA, Vienna, Austria), both for in-the-field training missions mostly in low- and middle-income countries to initiate specific Nuclear Medicine applications and for hosting at the Regional Center of Nuclear Medicine in Pisa IAEA Fellows for training in the practice of Nuclear Medicine. These activities have been conducted in collaboration with countries with such diverse levels of development as Albania, Algeria, Chile, Colombia, Cuba, Egypt, Estonia, India, Japan, Lithuania, Lybia, Malaysia, Pakistan, People's Republic of China, South Africa, Sudan, Sultanate of Oman, and Thailand.

Duccio Volterrani is currently Full Professor of Nuclear Medicine, Director of the Regional Center of Nuclear Medicine, and Director of the Post-graduate Specialty School in Nuclear Medicine of the University of Pisa (Pisa, Italy). In 2014, he became Associate Professor of Nuclear Medicine at the University of Pisa, after serving as Assistant Professor at the same University since 1998. Before joining the University of Pisa in 1998, Duccio Volterrani had served as Attending Physician at the Nuclear Medicine Service of the University Hospital of Siena (Siena, Italy) between 1993 and 1998.

After obtaining his medical degree in 1987 at the University of Pisa (Pisa, Italy), Dr. Volterrani was granted Research Fellowships (up until 1993) at the CNR Institute of Clinical Physiology for the analysis of data from the European multicenter study on the diagnostic efficacy of captopril renography in renovascular hypertension and for the investigations on the pathophysiologic changes of systolic and diastolic parameters, assessed by means of radionuclide techniques, in hypertensive cardiomyopathy.

Dr. Volterrani currently holds official courses on diagnostic imaging and nuclear medicine at the University of Pisa, including courses for the Medical School and for the School of Technologists in Diagnostic Imaging and Radiation Oncology, as well as courses for the Post-graduate Specialty Schools in Nuclear Medicine, in Diagnostic Radiology, and in Medical Oncology of the University of Pisa (Pisa, Italy). In 2003, he has been a Visiting Professor at the Nuclear Medicine Service of the Memorial Sloan-Kettering Cancer Center (New York, NY, USA).

Dr. Volterrani's current interests in clinical investigations span virtually the whole spectrum of applications of nuclear medicine (both for diagnosis and for therapy with radionuclides), with a major focus on radionuclide evaluation of dementias and parkinsonisms (through regional blood flow, receptor analysis, and amyloid imaging), PET/CT in oncology, radionuclide therapy of tumors, diagnostic imaging of coronary artery disease, and new tracers for tumor targeting.

Dr. Volterrani is a member of the Italian Association of Nuclear Medicine (AIMN, for which he has served several terms in the Board of Directors and as responsible for quality management for the continuing medical education program), of the European Association of Nuclear Medicine (EANM), and of the Society of Nuclear Medicine and Molecular Imaging (SNMMI). He serves in the Editorial Board of the *Quarterly Journal of Nuclear Medicine* and is also an active referee for many international journals in the field of Nuclear Medicine. He has authored/coauthored over 80 papers in international peer-reviewed journals, and in addition has been Coeditor of 3 books and over 40 chapters in books.

Steven M. Larson M.D., FACNM, FACR is the Donna and Benjamin M. Rosen Chair and Attending in the Molecular Imaging and Therapy Service within the Department of Radiology, as well as the Coleader of the Imaging and Radiation Sciences Program, a component of the Cancer Center Support Grant, at Memorial Sloan Kettering Cancer Center. He serves as Director of the Center for Radioimmunotherapy and Theranostics at the Ludwig Center and member and Lab Head of the Molecular Pharmacology Program at Sloan Kettering Cancer Institute. He is also a Professor of Radiology at Cornell University Medical Center in New York, NY.

Larson's primary expertise is in molecular imaging, targeted radiodiagnosis, and therapy using small molecules and monoclonal antibodies. Dual-boarded in nuclear medicine and internal medicine, Larson has clinical skills in oncology, cancer immunology, and clinical thyroid cancer. He has been responsible for directing and developing successful nuclear medicine and PET programs at several major institutions in the USA, including the Veteran Administration Hospitals in Portland and Vancouver; University of Oregon, Portland; Seattle Veterans Administration Hospital; Clinical Center, National Institutes of Health (NIH); and Memorial Sloan Kettering Cancer Center. He has extensive experience as an Advisor to public and private institutions, having served, among other appointments, as a member of what is now the

MEDI grant review committee of NIH, the Department of Energy Office of Science's Advisory Committee, and the American Board of Nuclear Medicine, and as Chair of the Radiopharmaceutical Advisory Committee of the USFDA, Cochair of the National Research Council of the NAS Committee on Molybdenum-99 production with nonenriched Uranium 235, and Chair of the Molecular Imaging Committee of RSNA. He is now Chair of the Clinical Imaging Steering Committee of the National Cancer Institute and Chair of the Clinical "Impact" Study Section of NIH, as well as a member of the National Academy of Medicine. He has received numerous awards for excellence including the Wylie Prize of the USFDA, the Hevesy Award, and Cassen Prize of the Society of Nuclear Medicine, USA. He is an inventor on seven patents. He has published over 600 peer-reviewed publications in prestigious journals, and his current H-factor is approximately 100. He has trained more than 50 residents in nuclear medicine who are now ABNM-certified.

Cancer Biology of Molecular Imaging

1

Steven M. Larson

Abstract

Cancer is a complex series of stepwise genetic alterations resulting in common biologic changes in the transformed cells. Distinguishing features of cancer include rapid proliferation of cells, immortality, resistance to apoptosis, resistance to suppression of proliferation, metastatic behavior, characteristic changes in metabolism, and resistance to immunologic attack. Cancer cells recruit normal host tissues to support growth of the tumor mass.

Fibrocytes and collagen producing cells provide structure for the tumor cells. Endothelial cells are recruited to form blood vessels. Tumor blood vessels have incomplete endothelium, making the vessels leaky. This allows large molecules to leak into the tumor interstitium.

The middle of the tumor mass has few, if any, lymphatic vessels. The combination of vessel leakiness and few lymphatics results in an increased interstitial pressure in the tumor, making it difficult for chemotherapy to diffuse into the tumor mass.

A common anatomic approach to measure tumor response (RECIST) employs measurements of the size of the mass on CT before and 4 weeks after therapy. Total disappearance of the lesion is required for a complete response, a 30% reduction in the sum of long dimensions defines a partial response, and >20% increase in the sum of long diameters identifies progressive disease. Adding metabolic information recorded with [^{18}F]FDG-PET/CT and the PERCIST criteria may refine these measurements. In addition to [^{18}F]FDG, radiopharmaceuticals are available to measure other attributes of the tumor. Depending on the radiopharmaceutical, images can provide information on tumor hypoxia, expression of integrins, or specific tumor markers that are overexpressed by the lesion, such as carbonic anhydrase, expressed by renal cell cancer, or receptors, such as somatostatin, expressed on neuroendocrine tumors.

Keywords

Biology of cancer • Molecular imaging in cancer • Molecular imaging • Tumor response post-therapy • [^{18}F]FDG and tumor therapy

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FACBC	*Anti*-1-amino-3-^{18}F-fluorocyclobutane-1-carboxylic acid
^{18}F-FDHT	16β-^{18}F-Fluoro-5-dihydrotestosterone
^{18}F-FGln	^{18}F-Fluoroglutamine
^{18}F-FLT	2-^{18}F-Fluoro-L-thymidine
^{18}F-MISO	^{18}F-Fluoromisonidazole
2-HG	2-Hydroxyglutarate

^{68}Ga-PSMA	Glu-urea-Lys-(Ahx)-[^{68}Ga (HBED-CC)]
ABC	ATP-binding cassette, a transport system superfamily
ABL	Abelson murine leukemia
AKT	Protein kinase B
AML	Acute myeloid leukemia
APC	Antigen-presenting cell
AR	Androgen receptor
ASCO	American Society of Clinical Oncology
ATP	Adenosine triphosphate
BRAF	Gene encoding for the B-Raf protein, a serine/threonine-protein kinase; the gene is also known as the proto-oncogene B-Raf and v-Raf murine sarcoma viral oncogene homolog B
BRCA1	Breast cancer type 1 susceptibility protein
BRCA2	Breast cancer type 2 susceptibility protein
BRS	BRAF-RAS score
BSI	Bone scan index
c-Kit	Gene encoding for tyrosine-protein kinase Kit (or CD117), also known as Mast/stem cell growth factor receptor (SCFR)
CA9	Carbonic anhydrase 9 (or carbonic anhydrase IX, CAIX)
CML	Chronic myeloid leukemia
CRPC	Castrate-resistant prostate cancer
CT	X-ray computed tomography
CTL	Cytotoxic T cell
CTLA4	Cytotoxic T-lymphocyte antigen 4, also known as CD152
CTLC	Cutaneous T-cell lymphoma
DHT	Dihydrotestosterone
DOTA	1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid
DOTATATE	DOTA- Tyr^3-octreotate
EGFR	Epidermal growth factor receptor; the mutated form EGFRvIII plays a prominent role in tumorigenesis and pro-angiogenic signaling
EORTC	European Organisation for Research and Treatment of Cancer
EPR	Extravasation and passive retention
ERK	Extracellular signal-regulated kinase
GIST	Gastrointestinal stromal tumor
H&E	Hematoxylin and eosin staining
HER2	Human epidermal growth factor receptor 2, also known as receptor tyrosine-protein
HIF-1	Hypoxia-inducible factor
HK2	Hexokinase 2
hsvTK	Herpes simplex virus-1 thymidine kinase
IDH1	Isocitrate dehydrogenase 1, a cytoplasmic enzyme
IDH1	Isocitrate dehydrogenase enzymes
IDH2	Isocitrate dehydrogenase 2, a mitochondrial enzyme
IL2	Interleukin 2
MEK	Mitogen-activated protein kinase
MI	Molecular imaging
MRI	Magnetic resonance imaging
MSKCC	Memorial Sloan-Kettering Cancer Center
mTOR	Mammalian target of rapamycin
Myc	Regulator gene that encodes for a transcription factor (also known as c-Myc)
NAALADase	N-Acetylated-alpha-linked-acidic dipeptidase, also known as glutamate carboxypeptidase II
NADPH	Nicotinamide adenine dinucleotide phosphate
NIH	United States National Institutes of Health
NSCLC	Non-small cell lung cancer
p53	Tumor protein p53, also known as cellular tumor

	antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PARP	Poly adenosine diphosphate ribose polymerase
PARPi	Poly adenosine diphosphate ribose polymerase inhibitor
PD-1	Programmed cell death protein 1, also known as CD279
PERCIST	Positron emission tomography response criteria in solid tumors
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PI13K	Phosphoinositide 3-kinase
PI3K/AKT/mTOR	Intracellular signaling pathway regulating the cell cycle
PR	Partial response
PSMA	Prostate-specific membrane antigen
PTEN	Gene encoding for the phosphatase and tensin homolog protein, a tumor suppressor; PTEN deletions indicate a poor prognosis
Ras	Oncogene regulating signalling cascades
RB	Gene encoding for the retinoblastoma protein
RCHOP	Rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone
RECIST	Response evaluation criteria in solid tumors
SCLC	Small cell lung cancer
STEAP	Family of transmembrane epithelial antigens of prostate comprising six members
SUL	Lean body mass corrected standard uptake value
SUL_{peak}	Lean body mass corrected standard uptake value at voxels of maximum
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
SUV_{peak}	Standardized uptake value at voxels of maximum, based on correction for lean body mass
TCR	T-cell receptor
TDS	Thyroid differentiation score
TIL	Tumor-infiltrating lymphocyte
VEGF	Vascular endothelial growth factor
VEGFR	Vascular endothelial growth factor receptor
VHL	Von Hippel-Lindau

Author's Introduction

This is the second edition of this chapter with emphasis on the nexus of cancer biology and molecular radio-imaging and targeted therapy. Those who have read the first edition will find much that is familiar, because the foundations for the cancer biology of molecular radiotargeting have not fundamentally changed, even though enrichments have occurred in relevant knowledge. To this end, I have done my best to include updates. The Cancer Genome Atlas is a huge source of knowledge for molecular radiotargeting and has already impacted thyroid cancer radiotherapy. Also, I have expanded the discussion of metabolomics to include glutamine imaging, provided an example of molecular imaging of an oncogene, and elaborated on androgen receptor (AR) and the integrated biochemical system that it drives (the AR axis in advanced prostate cancer). I added a more complete section on tumor immunology, setting the stage for imaging advances that will undoubtedly come in the years ahead. I have discussed the prospective role of radioantibody imaging, as I truly believe that the future will show astonishing advances based on our ability to perform optimization of immune targeting reagents. Elsewhere in this book, much information about specific applications of radiopeptide imaging and therapy, as well as organ-specific applications, is provided. This chapter does not comprehensively cover all molecular imaging but instead discusses key features of relevant cancer biology, as I see it, from the perspective of someone who has focused on oncologic applications of radiotracers for more than 40 years.

When I was a medical student, I was awarded an NIH fellowship to develop a radiotracer probe, technetium sulfur colloid, which is still in use today. This effort set me on the path of nuclear medicine and targeted probe development. As part of my education, my mentor, Wil B. Nelp of the University of Washington, took me to a conference in Richland, Washington, site of the Hanford National Laboratories. Much testing on the radiobiology of radiation was conducted on this campus, which was also the site of development of bomb-grade weapon materials. At this conference, in 1966, I met Shields Warren, a pathologist who was, at that time, a chairman of the Atomic Bomb Casualty Commission, an effort jointly supported by both the Japanese and US Academy of Sciences and the source of much of the current information on human dosimetry and biologic effects. Dr. Warren wrote an inscription on my program that I will never forget: "Congratulations to a student who can start a career with today's sciences." To all students of molecular imaging and targeted therapy, now 50 years later, these words are more apt than ever!

Molecular imaging offers quantitative detection of the molecules and molecular-based events that are fundamental to the malignant state, in vivo in living subjects. This is nothing new to nuclear medicine and its clinical applications of the tracer principle, but the opportunities have become so vast in the last decade that new excitement extends well beyond nuclear medicine to energize the whole of oncology. This new excitement stems from the recognition that molecular imaging has the potential to expedite laboratory discovery and personalize the care of individual patients with cancer. In this chapter, we will touch on how facets of the biology of cancer can be exploited in the performance of molecular imaging. This chapter is a revision of that presented in the first edition, with key updates and additions regarding cancer immunology, cancer genomics, pharmacology, and theranostics.

The Evolving Context of Molecular Imaging Practice: The Rapid Pace of Discovery in Cancer Genomics

As we have seen, an important hallmark of cancer is genomic instability and mutation that leads to changes in the genome, some of which have a direct consequence on the development of malignant phenotype (driver mutations), but others (passenger mutations) may be alterations that make the cancer different from normal tissues but have no direct effect on tissue phenotype.

In the last 10 years, revolutionary developments in rapid genomic sequencing have led to a sea change in our understanding of the genetic events important to the process of malignant transformation and maintenance of the malignant state. The practical importance of this new understanding of the cancer genome is that it allows a path forward to implement specific therapies that suppress tumor growth. For patients with lung cancer, for example, modern clinical practice includes a rapid genomic profile that may identify an alteration in the patient's own tumor, which will likely make it responsive to treatment with specific drugs. As an example, detection of driver mutations based on substitution of leucine for arginine (L858R mutation) in the gene for epidermal growth factor receptor (EGFR) in some lung cancers allows treatment and likely response with erlotinib-targeted therapy. This kind of precision medicine will undoubtedly lead to expanded opportunities for molecular imaging to monitor these targeted treatments and determine, as is often the case, the point in time when the cancer mutates again and escapes from drug control.

As a high-level first pass, most genes that are directly linked to cancer causation fall into two categories: oncogenes, which are driver mutations for a process that leads to cancer, and suppressor genes, which must be disabled to permit expression of the malignant state. Current estimates are that about 140 such genes have been identified in the genome of tumors to date, of which 80 are tumor suppressor genes and 60 are oncogenes [1]. Oncogenes have received more attention from the molecular imaging community because it is easier to image a molecule or molecular-related event that is additive or increased relative to the tissue of origin. Examples include oncogene mutations that lead to HER2 overexpression seen in breast cancer, c-Kit mutations seen in gastrointestinal stromal tumors, and EGFR mutations seen in brain tumors and lung cancers. Examples of suppressor genes include BRCA 1 and 2 mutations, associated with breast, ovarian, and pancreatic cancer; p53 mutations; breast, sarcoma, and brain tumors; and RB gene in retinoblastoma. See specific examples described in the section entitled "Oncogene and Non-oncogene Addiction" below.

Hallmarks of Cancer

There is growing acceptance of the view that cancer is "a complex collection of distinct genetic diseases, united by common hallmarks." Thus, a general and uniting property of cancer is a common phenotype set of "hallmarks," i.e., the biologic characteristics of malignant tissues that distinguish them from the tissues from which they arise (summarized in Fig. 1).

Distinguishing features of cancer cells include rapid proliferation, immortality, resistance to apoptosis, resistance to suppression of proliferation, metastatic behavior, and a variety of stress responses, which include a characteristic pattern of metabolism such as the Warburg effect and resistance to immunologic attack that allow cancer cells to better survive in hostile environments. The characteristic behaviors that make a cancer cell malignant are now generally believed to occur through a series of stepwise genetic alterations. In principle, the phenotypic alterations of each of these characteristics are associated with underlying key molecules that can be targeted with selective tracers and images.

The Tumor Mass

A general property essential to the long-term growth of cancer cells is the recruitment of a supporting framework to create the mass that

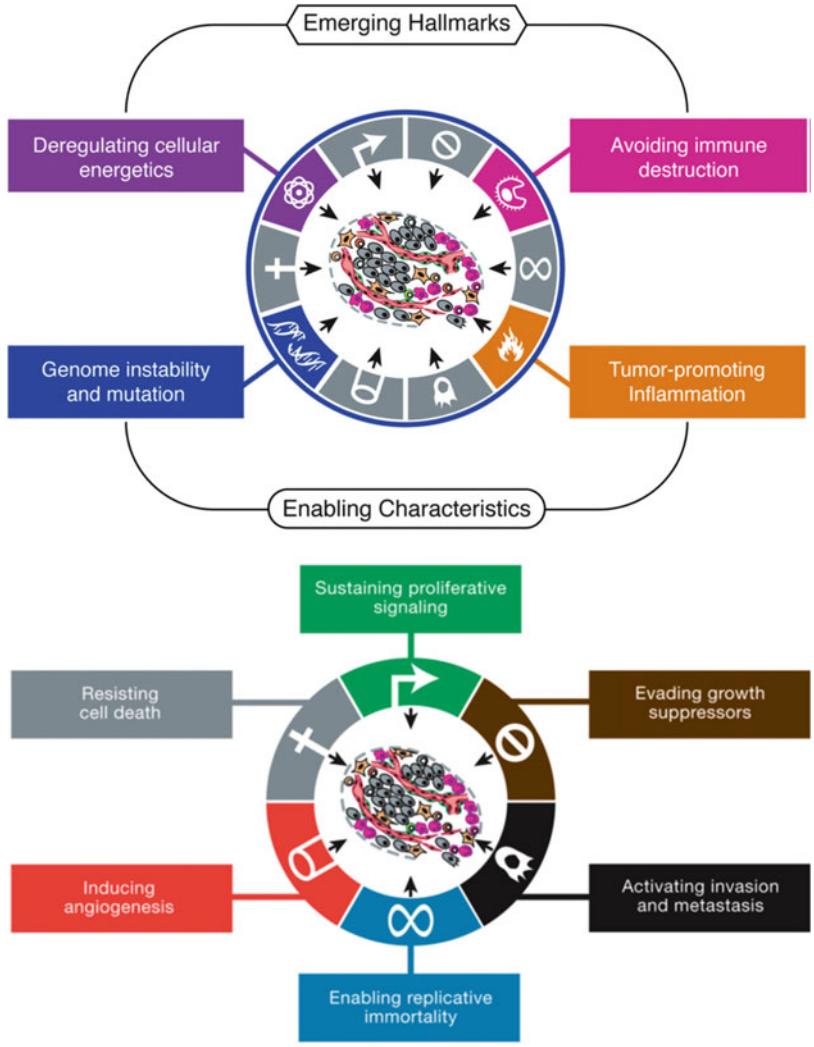

Fig. 1 Emerging hallmarks and enabling characteristics of cancer (*top*) and hallmarks of cancer (*bottom*) (From [2]; permission requested)

characterizes clinical malignancies. Prior to recruitment of blood vessels, the tumor size is limited by the diffusion distance of oxygen in tissues, which is approximately 100–200 microns. Once a blood supply is established, the tumor mass can grow [2].

Imaging the Tumor Mass

For several decades, observing changes in the size of the tumor mass has been the basis for monitoring treatment response. At first, this was done using palpation, but high-resolution cross-sectional CT imaging rapidly became the gold standard for treatment monitoring once it was developed. At present, clinical imaging criteria have serious limitations for detection of masses, and in most situations, 1 gram of tissue or about 10^8 cells is a practical limit. The current criteria depend on the measurement of two perpendicular diameters in up to five soft-tissue masses (RECIST 1.1). For a partial response (PR), >30% change is required in the sum of long dimensions of up to two per organ, and for complete response (CR), disappearance of all lesions is required. Progressive disease is >20% in sum of long diameters, validated at 4 weeks after treatment (Fig. 2).

With the widespread introduction of [^{18}F]FDG-PET imaging, there is recognition that metabolic

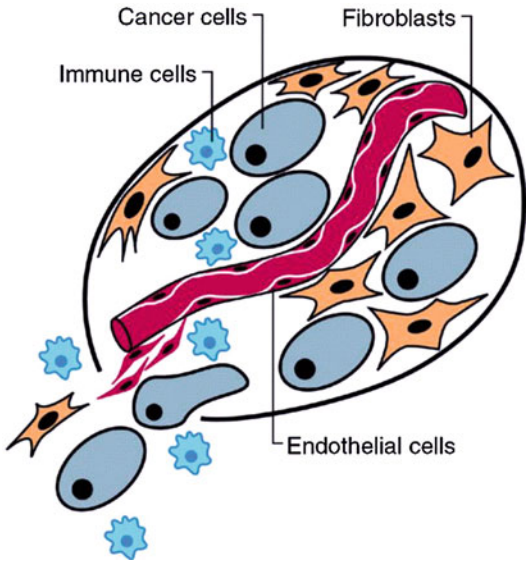

Fig. 2 Fibrocytes, endothelial cells that form vessels which provide nutrients, and immune cells are common constituents of the tumor mass (e.g., which are typically imaged as part of the tumor on CT) (From [2], with permission)

change should also be incorporated into the measurement of tumor treatment response. Initial assessment was based on the EORTC recommendation and employed standardized uptake values for [^{18}F]FDG uptake, normalized to body weight (SUV_{max}) [3]. Expert opinion offers alternative response parameters for making this assessment, such as PERCIST, which incorporates PET SUV measurements into treatment response. PERCIST uses an SUV measure, SUV_{peak}, which is based on lean body mass, and uses a circular region of 1.2 cm in diameter (with an approximate mass of 1 gram) centered around the hottest voxel, over which the standardized uptake value (SUV) is averaged. In order for PERCIST criteria to be applied to measure tumor response to treatment, the SUL_{peak} must be >/SUL average liver, + 2 standard deviation SUL liver. In this way, tumor and liver SUV are compared [4].

Fox and colleagues have recently proposed an alternative that takes advantage of semiautomated lesion-tracking software to look at all the lesions simultaneously in advanced patients; clearly the size and metabolism of the mass in some combination appear likely to be an important measure of treatment response [4]. It is important to keep in mind that when imaging a tumor mass, changes in a particular parameter involve all of the cells in the mass, both malignant and benign; this is true whether imaging gross anatomic measures obtained by CT or a more tumor cell-associated hallmark such as [^{18}F]FDG uptake due to the Warburg effect.

Neovasculature

Once cancer cells are collected into a mass, the cells must recruit blood vessels in order to grow. The blood vessel system in a tumor, called "neovasculature," has some unique characteristics. The vessels are poorly organized, extremely permeable, and often have an incomplete endothelial barrier. Most tumors have minimal lymphatics in the tumor mass, which causes the mass to have a higher pressure than normal tissue, limiting the diffusion of many molecules (especially antibodies) into the tumor mass. The incomplete endothelial barrier of the neovasculature allows tumor cells direct entry to the host vasculature, providing a path for the tumor cells to circulate and metastasize.

Folkman was the first to recognize that inhibition of angiogenesis could inhibit tumor growth and coined the tumor "angiogenic switch," for the moment when a small collection of tumor cells begins the vascularization process [5]. Ferrara discovered that vascular endothelial growth factor (VEGF) played a crucial role in the development of neovasculature [6]. In response to VEGF produced at the site of the tumor cells, stem cells are recruited from the bone marrow and migrate to the tumor mass, where they serve an essential role in the production of neovasculature.

Agents that target VEGF and its receptor include the antibody, bevacizumab, and the peptides sorafenib and sunitinib. Bevacizumab binds to VEGF while the peptides interfere with the receptor. Both show strong antitumor activity against some highly vascular tumors, which exert their antitumor effects by inhibiting the VEGF receptor expressed on tumor cells. Bevacizumab has been radiolabeled with zirconium-89 and

localizes in breast cancer [7]. In patients treated with these agents, serial imaging with [^{18}F]FDG has shown a marked decrease in [^{18}F]FDG uptake, reflecting the effectiveness of anti-VEGF therapy on tumor size and metabolism. The response of tumors to therapy such as single high-dose fraction radiation has been linked by some to endothelial damage, whereby radiation induces catastrophic apoptosis in endothelial cells, which results in irreversible damage to tumors.

In contrast to normal vessels, the leaky neovasculature can be exploited to image the tumor mass. The "leaky" incomplete endothelium allows passage and retention of large molecules and nanoparticles into tumors. This process is called the "extravasation and passive retention (EPR) effect" and is thought to occur because the larger molecules and nanoparticles enter into the perivascular space through relatively large pores, but have difficulty getting back out into the vasculature, much like a lobster has trouble finding its way out of a lobster trap. The continuous expression of angiogenesis factors by the tumor causes a concomitant increased expression of integrin receptors, such as $\alpha_v\beta_3$ integrin or other members of the integrin family, to provide a homing signal for the cells mobilized to create the new blood vessels for the tumor. Agents binding to this integrin have been synthesized and localized in sites of neovascularity, such as tumors [8] and healing infarcts [9, 10]. Other endothelial sites for imaging include the antigens PSMA, which can be imaged with the antibody J591. In fact, in a review by Schliemann and Neri, nine vascular targets were described for which antibodies have been developed [11].

Hypoxia

Solid tumors tend to outgrow their blood supply, causing cancer cells to become hypoxic [12]. The reduced cellular oxygen content that accompanies hypoxia can be imaged using a class of compounds called nitroimidazoles. F-18 misonidazole has been used most often, although numerous alternatives are being developed. The principal localization is passive diffusion into the tumor. Once in the cell, nitroimidazoles undergo a single-electron reduction. In the presence of oxygen, the molecule is immediately reoxidized. As a result, the molecule diffuses back out of normoxic tissue. In the presence of hypoxia, the reoxidation cannot occur, trapping the molecule within the hypoxic but viable tissue. Hypoxia is a key property of tumors that reduces the effectiveness of radiation therapy. Well-oxygenated tissue is about three times more sensitive to radiation damage than hypoxic tissue. Some investigators suggest using ^{18}F-fluoromisonidazole (^{18}F-MISO) to image hypoxic regions within tumors to allow a boost of radiation to the hypoxic region without damaging normal tissues.

Cellular Constituents and Cell-Cell Synergism of the Tumor Mass

The tumor mass contains a mixture of tumor cells and cells recruited from the adjacent normal tissues of the host, such as fibroblasts, collagen fibrils, and vascular endothelium. The amount of stroma is highly tumor dependent, with lesions such as lymphoma having relatively little stroma, and others such as those in the pancreas having relatively few tumor cells and abundant stroma. In addition, tissue macrophages and other immune cells are represented in the mass. Typically, about 3% of cellular mass is represented by endothelial cells. But recent evidence suggests that single-dose fraction radiation's major effect occurs by selectively damaging the vascular endothelium, the most sensitive cell in the tumor [13].

The mass cannot grow without the active synergism of each cellular component. There is also evidence that cells interact with one another in more subtle ways. Small molecules, large molecular complexes, and entire pieces of membrane are exchanged between tumor cells and supporting stroma. For example, P glycoprotein, an ABC transporter protein responsible for multidrug resistance, was shown to transfer from resistant to sensitive cells, as a functional entity, so that sensitive cells could acquire sufficient resistance to resist otherwise lethal levels of anticancer drugs [14].

Immune Cell Cancer Immunotherapy

Cancer cells may be immunogenic enough to be killed by the natural immunity of the body, as described in Fig. 3. The basis for cancer immunity is thought to be immunogenic products formed as a result of the cancer's characteristic of rapid mutation leading to "neoantigens," which are recognized as foreign. Figure 3 depicts the process of immune attack on cancer cells in diagrammatic form, starting with the release of neoantigens by damage to tumor cells, with recognition and process of these antigens by dendritic cells (2), and presentation to T cell in the regional lymph nodes (3). The now immunized T cells migrate through the blood and traverse through the endothelial layer into the tumor mass (5), where they encounter tumor cells (6), recognizing the presence of neoantigens. T cells, most commonly CD8-expressing cells, attack the cancer cell (7). Normally, however, cancer cells escape immune attack based on a system of checks and balances within the tumor cell environment.

The cellular component of the tumor mass includes a variety of tumor immune cells, including T cells, macrophages, and dendritic cells, a group of specialized immune cells that are involved as the first line of defense in alerting the immune system to foreign antigens. In particular, activated T cells, especially CD8 expressing cells within the cancer mass, can play a role in cancer therapy. In the last few years, treatment of cancers with immune therapy has led to significant responses—even complete responses—in advanced cancers, especially advanced melanoma and non-small cell lung cancers. The results are so exciting that in 2013, *Science* magazine selected cancer immunotherapy as the most significant breakthrough of the year [16]. Effective treatments are based on growing knowledge of the role the immune system plays in the delicate balance of immune modulation, a series of checks

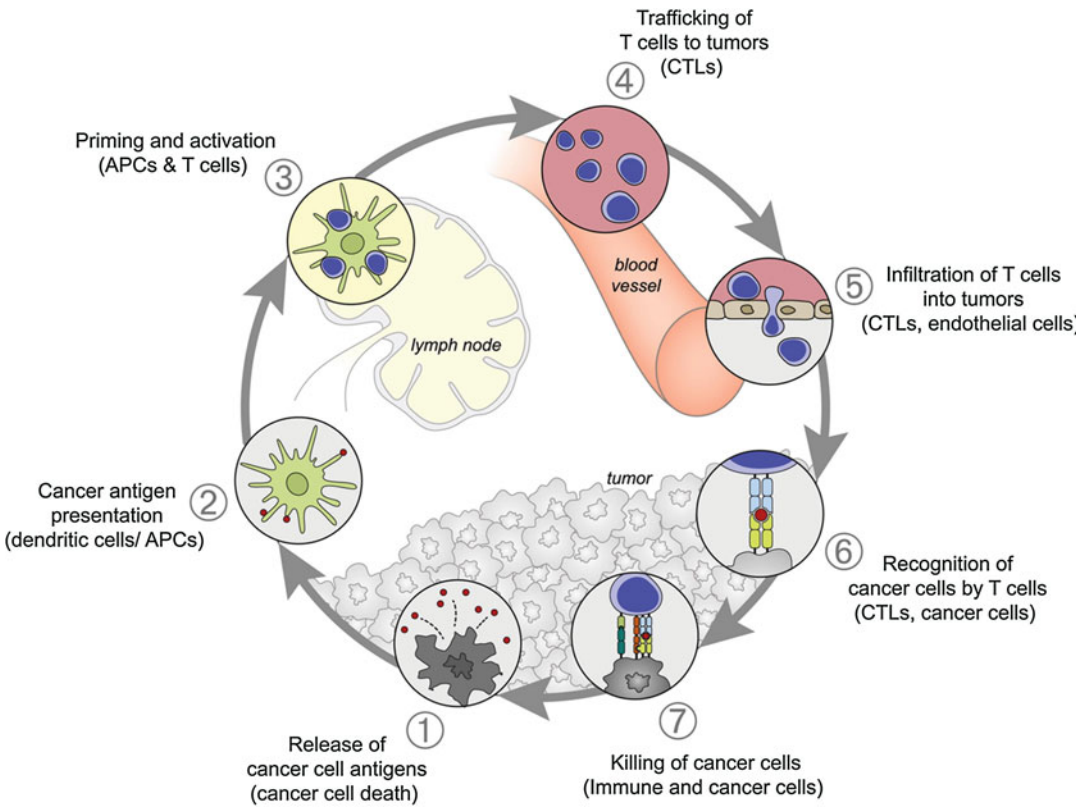

Fig. 3 The cancer immunity cycle (From [14, 47]; permission requested)

and balances on the immune response. One of the newly recognized hallmarks of cancer is the ability of cancer cells to suppress the body's immune response, so much so that the tumor mass is most frequently a sanctuary for proliferation of cancer cells within the tumor mass. Specialized antibody therapies can neutralize key molecules that modulate immune response, and for some tumors, this treatment ("immune checkpoint blockade") can be part of a potent defense against even the most advanced tumors.

Immune checkpoint blockade. Human T cells are a critical component of the activity of the human immune system as part of body's primary defense against invasion by foreign tissue and aberrant normal tissues such as cancer. In general, the native proteins in the body do not provoke an immune response in T cells, but among the millions and millions of T cells in the human body, it is thought that there may be a few that can even be immunized against normal macromolecules of normal tissues. But also, a plethora of antigens can be recognized as foreign, including those that may be only slightly different from the native molecules. These differences could arise due to mutation in the gene from which they arise, or from mistakes in the formation of molecules that lead to a slightly altered structure.

One of the ways the immune system is kept in check so that the body does not destroy itself depends on immune suppressor molecules produced by T cells. CTLA4 is an important suppressor molecule expressed by human T cells that are activated against particular antigens. The role of CTLA4 is to downregulate immune response, and CTLA4 increases on the cell surface whenever a T cell is activated, after recognizing an antigen to which it has been immunized. The mechanism whereby this occurs is illustrated in Fig. 4. CTLA4 checkpoint to suppress inappropriate immunity against normal tissues is obviously of great importance for avoiding immunity against self (often called autoimmunity).

It turns out that cancers, and some cancers in particular (i.e., melanoma, non-small cell lung cancer), have a large number of these slightly altered antigens (often called neoantigens) that can create immunized T cells. These genetic changes may be either driver mutations or passenger mutations, but in any event represent altered features of the tissue, which may be recognized by the immune system. This immunity can be enhanced by therapies that block the action of immune suppressor molecule CTLA4 (such as the antibody Ipilimumab), and the result may be long-term anti-cancer response.

In effect, the anti-CTLA4 treatment "takes the brakes off" the human immune system and may

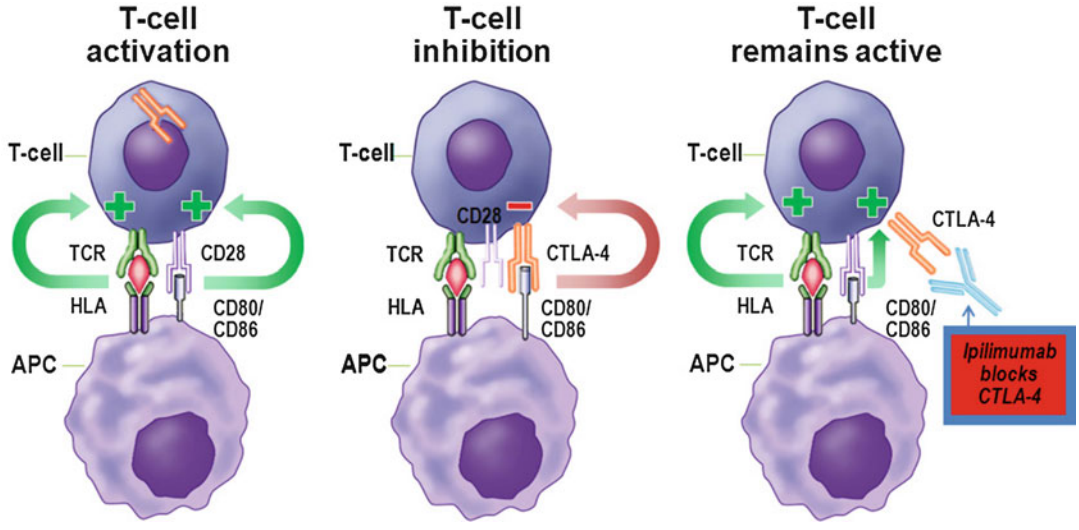

Fig. 4 Ipilimumab augments T-cell activation and proliferation (Adapted from O'Day et al. plenary session presentation, abstract #4, ASCO 2010)

have remarkable effects in killing tumor, even in patients with advanced metastatic disease. An additional immune checkpoint system, shown in Fig. 5, involves PD-1, which is expressed on T cells but may be used in the treatment of solid tumor. Some tumor cells, such as lung cancer, downregulate PD-1 by binding to a high-affinity cognate receptor PD L1, which is expressed on some tumors such as NSCLC. The suppressor action of PD-1 is blocked by the antibody nivolumab, and the antibody PD-L1 may have a similar clinical effect. Immune checkpoint alone, and in combination, offers the possibility of curing major human cancers at the stage of clinical development when patients were previously guaranteed to die of their disease.

It is important to remember that the immune checkpoint inhibitor antibody is not the agent that actually kills the tumor; it is the body's own immune cells which do the killing. An additional fact is that the immune cells must be in direct contact with the tumor in order to kill it, and so the immune cells must be able to enter the tumor, if "immune checkpoint" therapy is to be effective.

The tumor mass is an immunologic sanctuary, in that neo-antigens and oncoproteins manufactured by the malignant cell should be more immunogenic than they are in real life. In an exciting new development with profound clinical implications, so-called immune checkpoint blockade antibodies such as ipilimumab (anti-CTLA4) and nivolumab (anti-PD-1) target molecules on tumor-specific T cells that can suppress this antitumor immunity. Both ipilimumab and nivolumab, either alone or in combination, have been introduced into clinical trials and have induced long-term remissions in a significant portion (20–30%) of very advanced and hitherto intractable solid tumors, such as melanoma and lung cancer [17].

The immunologic invasion that follows immune checkpoint treatment, predominantly T cells, can be intense, enough to cause false positives on cross-sectional volumetric PET-[^{18}F]FDG imaging. Similar findings were observed after ipilimumab and nivolumab therapy and in this case include increase in size of tumor mass because of immune cell infiltration and false positives on PET. For this reason, modified response criteria have been suggested for monitoring the response profile of solid tumors after these powerful immunologic treatments [18].

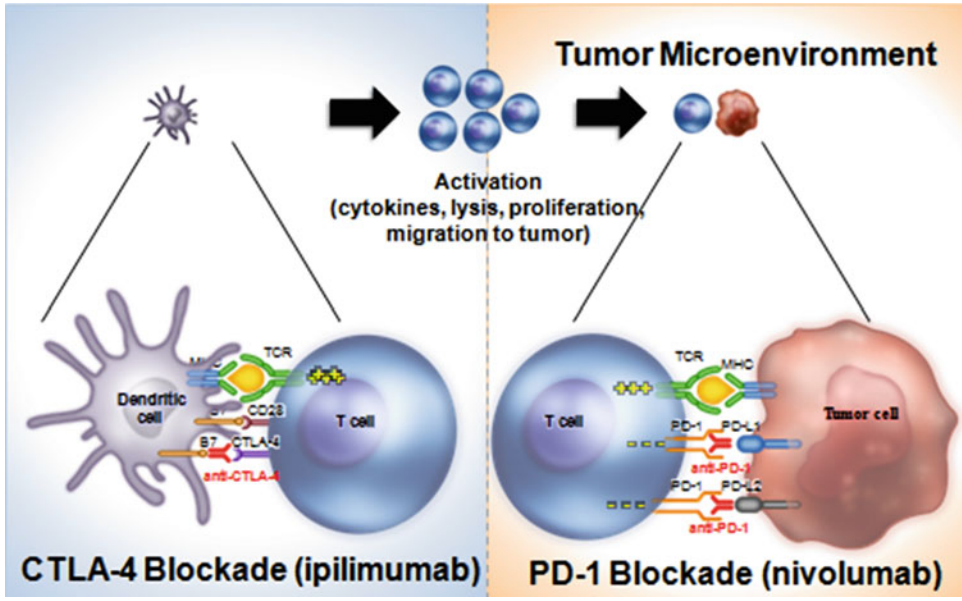

Fig. 5 Blocking CTLA4 and PD-1

Imaging the Immune T Cells

Because of the growing importance of cancer immunotherapy to the treatment of solid tumors, there has been a great deal of interest in imaging the targeting of effector T cells to human tumors. Since the killing of tumor appears to be very dependent on CD8 T cells, this is the group of cells that has been a particular focus. Table 1 summarizes current activity in this area.

Although immune cell imaging in man is limited, the data available is revealing in light of current knowledge about the importance of tumor to tumor. Figures 6 and 7 illustrate data from a patient with malignant melanoma who was injected with ^{111}In-oxine-labeled lymphocytes, which were elutriated from surgically removed tumors after expansion under IL2 stimulation. Six patients with widely metastatic melanoma were studied. An aliquot of approximately 10^{10} cells were labeled with 185–399 microcuries of ^{111}In-oxine, rinsed, and, after resuspension in saline, were infused through a filter into the patient. The amount of labeled activity was 3.9 microcurie per 10^8 cells. Initial distribution as seen in Fig. 8 was observed in the liver, bone marrow, and lung by 2 h, as imaged by planar gamma camera. Sequential studies showed that selective uptake occurred in tumor tissue (see arrows) of up to 40 times the amount in surrounding tissue. Figure 6 shows the time course of uptake, based on regions of interest drawn around six individual tumors in five patients. Localization is seen to increase over time, with a peak at about 72 h. We interpreted this data to indicate that TIL's were capable of trafficking to tumor after injection. These findings were subsequently confirmed in a larger series of 16 patients. It was of interest that the radiolabeled T cells targeted tumor but did not target lymph nodes.

Table 1 Examples of radiolabeling of immune T cells in cancer

Radiotracer	Disease application (reference)
^{111}In-oxine	TIL in melanoma [19]
^{131}I-FAIU /hsvTK	Lymphoma immune cell targeting [20]
^{111}In-anti-CD5 antibody	CTCL in humans [21]
^{89}Zr-anti-CD8 minibody	CD8 imaging [22]

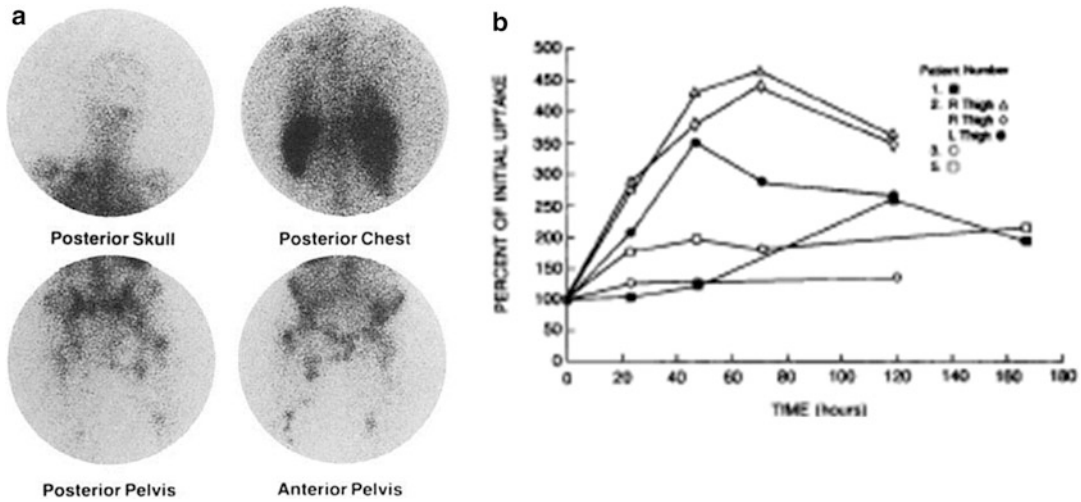

Fig. 6 (**a**) Planar images of head and shoulders, thorax and upper abdomen, and anterior and posterior pelvis (moving clockwise from left upper to left lower) 72 h after injection of ^{111}In-oxine-labeled tumor-infiltrating lymphocytes. Localization in the lungs, liver, bone marrow, and melanoma; tumor in lymph nodes of the pelvis and lesions on upper thighs. (**b**) Time-activity curves over known melanoma tumors, showing migration of radiolabeled TILs into melanoma tumor sites. (For more details, see [18])

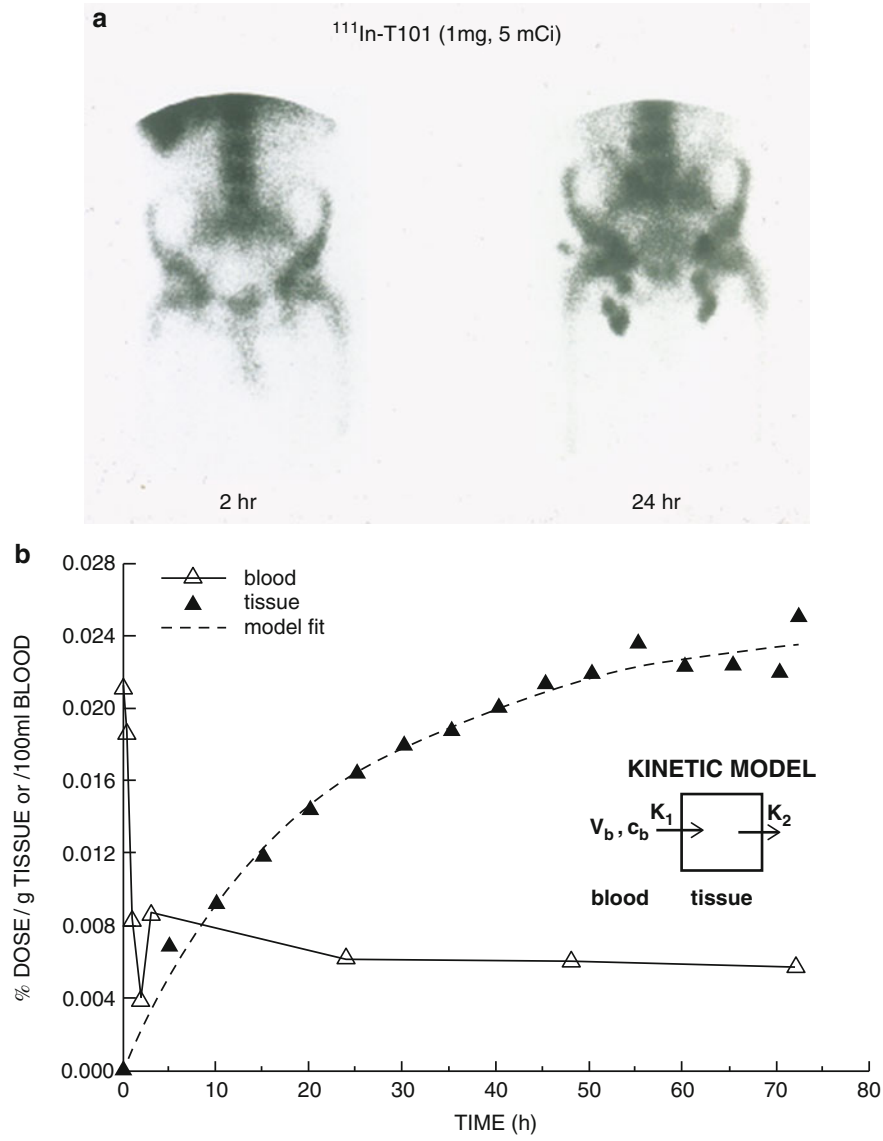

Fig. 7 (**a**) Anterior pelvis images at 2 and 48 h after intravenous injection of ^{111}In-T101 (anti-CD5 antibody) in patients with cutaneous T-cell lymphoma (CTCL). The antibody binds to the cells circulating in the blood and is internalized, migrating eventually to neoplastic lymphadenopathy in the lymph nodes of the groin. (**b**) Kinetics of T101-labeled lymphocyte uptake in lymph nodes. The indicated T-cell activity concentrations in blood (c_b) and the lymph node tissues are averages of data obtained in four patients. The blood data were used in a nonlinear, least squares fit of the indicated compartmental model to the tissue data. The blood volume parameter V_b was fixed at a representative value of 0.05 ml/g, while the best-fit values (mean ± sem) of the parameters K1 and k2 were determined to be 12.6 ± 0.5 ml/g/h and 0.029 ± 0.002 h-1, respectively

An indium-111-labeled anti-CD5 antibody, T101, was used to image malignant T-cell lymphocytes as part of a study in mycosis fungoides (cutaneous T-cell lymphoma). Images of the pelvis are shown, at 2 h and 24 h after injection. More than 95% of the radiolabeled T-101 cleared from the blood within 2 h, binding to T65 antigen on T cells, followed by rapid localization, in liver spleen and bone marrow with subsequent gradual clearing of these tissues and

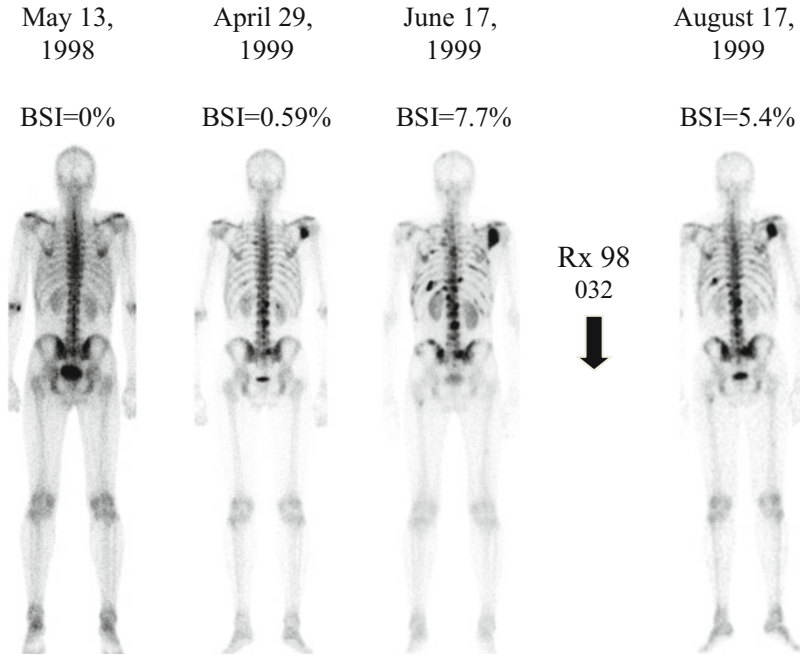

Fig. 8 Progression on bone scan of prostate cancer tumor in bone, measured using the bone scan index (BSI) technique

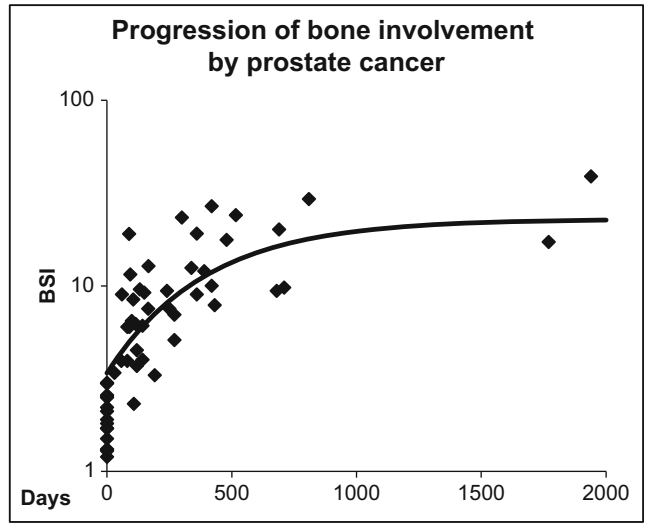

Fig. 9 The rate of progression of tumor in a group of patients followed a Gompertzian group curve, of the form $BSI(t) = BSI_0 \times [\exp^{a/b} \times (1 - \exp^{-bt})]$ with an initial doubling time of 45 days, at 3% BSI involvement. Of note is the characteristic decline in rate of growth until a plateau is reached

concomitant localization to lymph nodes in tumor-involved regions, such as bulky inguinal nodes. Subsequently, using a kinetic model, we estimated the rate of localization of malignant T cells to lymph node in this patient. We calculated that about 3.3×10^7 cells/g/h localized to malignant lymph nodes in this patient and that a plateau occurred at 72 h, when influx was equal to output. At this point, the ratio of cell concentration between lymph node and blood was about 434. Similar studies will likely be performed with improved T-cell labeling methodologies in adoptive tumor cell therapy in man and are likely to give important information about the effectiveness of treatment in individual patients.

The Metastatic Process

Massague and colleagues used a series of passages of human tumors through experimental animals, as a basis for identifying tumor cells with tropism for particular sites of metastases, such as the bone, brain, and adrenals. In breast cancer, individual cells with this tropism were cloned and found to express specific molecules that enabled cells to migrate from the primary site and survive in the new environment [23–25]. Cells in a metastatic site may reseed the primary tumor, and vice versa, in a continuous exchange [26, 27]. These findings have been observed in animal models of breast, colorectal, and lung cancer and melanoma. This process involves circulating tumor cells in blood, including those which appear "differentiated" for tropism to specific tissues. This "tumor reseeding" may help explain why the growth of solid tumors follows Gompertzian kinetics, namely, an exponentially declining exponential growth in which the tumor doubling times are most rapid at the very earliest stage of tumor growth. Another feature of metastatic growth that supports that concept that tumor cells seed organs via circulation in the blood comes from prostate cancer studies that showed that the sites of early bone metastases correlate with regional distribution within the bony skeleton with active red bone marrow, where blood flow is particularly rich. It was also observed in these patients that progression of tumor volume as a proportion of the bony skeleton followed a Gompertzian kinetic form (Fig. 10).

Imaging the Cancer Cell

Imaging the cancer cell phenotype: metabolomics. The altered metabolism of malignancy has been exploited for decades to image human tumors (see Table 2 for a list of commonly used metabolic tracers in malignancies). New knowledge is emerging on the metabolomics of human cancers, and there appears to be a growing role for glutamine.

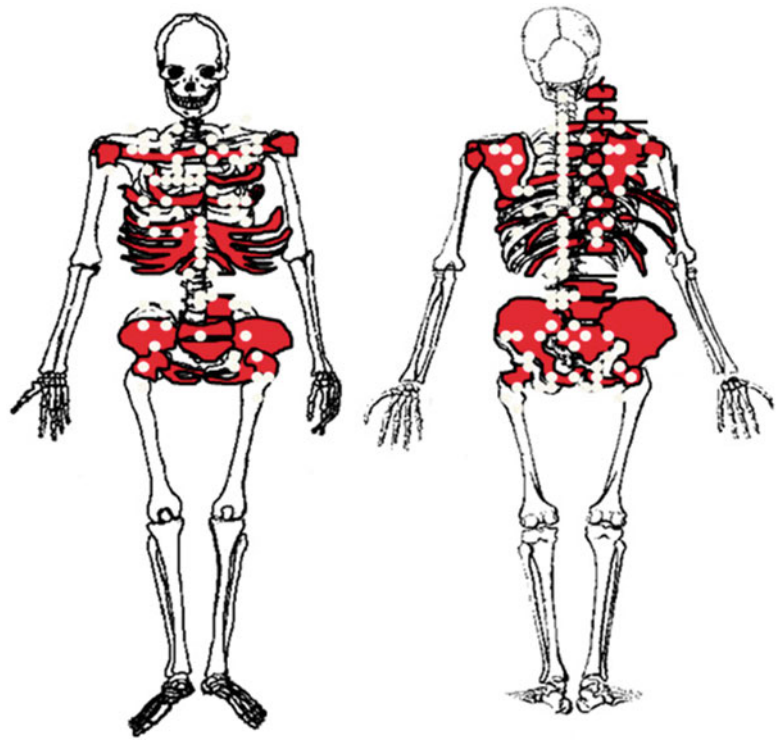

Fig. 10 The initial metastases in these 27 patients occurred exclusively within the pattern of red marrow distribution in the adult male

The Warburg effect. The Warburg effect (Fig. 11) is the term given to a characteristic metabolic pattern of cancer, in which glycolysis is the dominant means of energy production, even in the presence of oxygen, where most of the carbon atoms from metabolism are secreted in the form of lactate [37]. This excessive glucose utilization by many tumors provides the rationale for [^{18}F]FDG PET/CT imaging to identify sites of tumor and evaluate the impact of therapy. More than two million patients per year are imaged with [^{18}F]FDG mostly for the purpose of improved tumor staging, detection of recurrence, and monitoring treatment response.

Table 2 Increasing [^{18}F]FDG uptake and adverse outcome (From [28], with permission)

Tumor type [Ref]	Clinical feature
NSCLC [29]	Survival
SCLC [30]	Survival
Breast cancer [31]	Survival
Thyroid cancer [32]	Survival; ^{131}I uptake
Esophageal cancer [33]	Survival; recurrence
Glioma [34]	Survival
Lymphoma [35]	Survival
Head and neck cancer	Survival; recurrence
Ovarian cancer	Survival
Osteosarcoma	Survival
Prostate cancer [36]	Survival

The initial observation of Warburg was that proliferating tumor cells consume glucose at a higher rate compared to normal cells and that they secrete most of the glucose-derived carbon in the form of lactate rather than oxidizing glucose completely. Warburg's initial hypothesis included the view that mitochondria must be defective in cancer cells as a basis for the shift to aerobic glycolysis. Recent experiments indicate that in most cancer cells at least, there is no problem with oxidative metabolism in mitochondria, and indeed the conversion of pyruvate to lactate based on lactic dehydrogenase enzyme is an important promoter of growth and tumorigenicity [38].

There is growing awareness that the activation of aerobic glycolysis is just one of the metabolic programs that are crucial to the rapidly proliferating

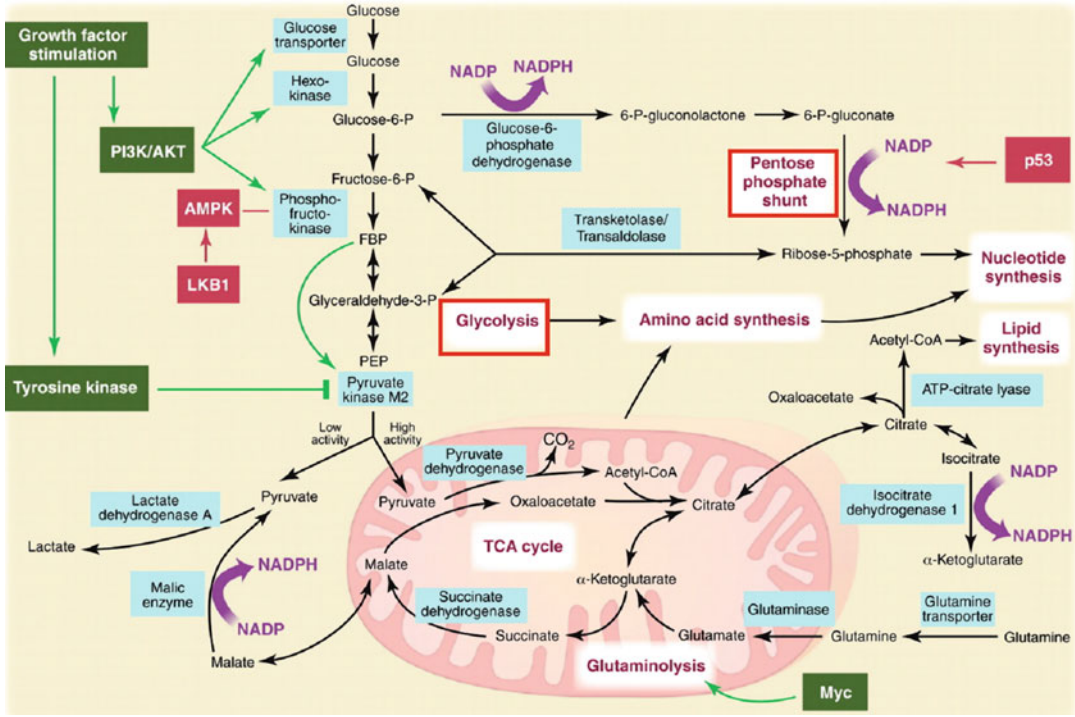

Fig. 11 Emerging view of the Warburg effect

tumor cell. In addition, there is lipid biosynthesis and glutamine-dependent anaplerosis, a term used to describe replacement of intermediates within the Krebs cycle. The purpose of these metabolic flux pathways appears to be threefold: (1) to provide energy for the biochemical processes of growth and metabolism required by proliferating cells; (2) to provide the carbon backbone for key macromolecules such as nucleic acids, lipids, and proteins; and (3) to help control the redox balance within the tumor cell. Signal transduction molecules and gene expression have now been identified that are the natural regulators of these fluxes and include the signal transduction pathways, especially PI3K\AKT\mTor axis, hypoxia-induced growth factor alpha (HIF-1 alpha), and Myc, as some of the more important cellular modulators of metabolism [39].

Thus, a more complete picture is emerging with regard to the altered metabolism of cancer cells. Among the drivers that stimulate the altered metabolism, the tumor microenvironment tends to be hypoxic with increased concentrations of HIF-1 alpha and oncogenic signaling, through a variety of known oncogenes such as Ras or Myc. In addition, suppressor proteins like p53 may play a role. The p53 suppressor protein stimulates the gene encoding synthesis of cytochrome c oxidase protein, so when p53 is disabled by mutation, there is direct interference with the mitochondrial respiratory chain. The altered metabolism confers certain advantages, such as increased biosynthesis of nucleotides, proteins, phospholipids, and fatty acids; increased glycolysis also directly inhibits apoptosis by neutralizing reactive oxygen species through the production of NADPH. In addition, there are liabilities with this approach, because toxic metabolites such as lactate and noncanonical nucleotide species tend to accumulate. Finally, a high energetic demand requires that alternative substrate such as fatty acids may need to be converted to ATP in order to meet the energy requirements of the cell [40].

Recently, glutamine has been recognized as an essential nutrient for cell growth and viability of some cancers, and in fact, tumor cells can become "addicted" to glutamine. In this case, the tumor cells fuel their growth by a combination of glucose and glutamine. Whereas PI3K and AKT are the important signal transduction molecules which control glucose uptake, recent studies suggest that MYC oncogene may be crucial for the control of glutamine uptake. Glutamine plays a key role in maintenance of Krebs cycle intermediates, as well as providing energy in the form of ATP [41]. Thus in the situation of active glutaminolysis, glucose and glutamine are the source of energy, and most of the other substrates which are taken up contribute to macromolecular synthesis.

Figure 12 shows glutamine uptake in brain tumor compared to [^{18}F]FDG imaging. In some cases, ^{18}F-glutamine may be superior to [^{18}F]FDG imaging, because there is negligible uptake of glutamine into cerebral cortex, unlike [^{18}F]FDG uptake driven by glycolysis, and the brain is an obligate user of glucose. From this, it is clear that certain oncogenes, with known functions such as the receptor tyrosine kinases, interact with metabolism through PI3K/AkT/mTor pathway. PTEN, as a natural inhibitor of this pathway, would be expected to have a role in metabolic activation. Other tumor suppressor proteins such as p53 are also thought to have an emerging role in modulating cancer cell metabolism, particularly by favoring oxidative phosphorylation and reducing glycolysis when active. When p53 is deactivated by mutation, glycolysis is favored.

Additional metabolic enzymes that may have oncogenic function include fumarate hydratase (associated with leiomyosarcoma) and succinate dehydrogenase (paraganglioma). When these enzymes are defective, accumulation of fumarate and succinate occurs. The excess of these metabolites causes overexpression of HIF-1 alpha, which promotes the vascularization of tumor as well as increased glycolysis, and may explain the tumor development. Recently, 70% of gliomas have been found to have mutations in isocitrate dehydrogenase enzymes (IDH1 and IDH2), suggesting a role for metabolic enzymes as oncogenes or tumor suppressors [42]. Data recently reported suggests that this mutation in IDH1 is not a loss of function but instead leads to the ability to produce 2-hydroxygutarate, a metabolite whose excess has been associated with human malignancy in patients with inborn errors of 2-HG metabolism [43].

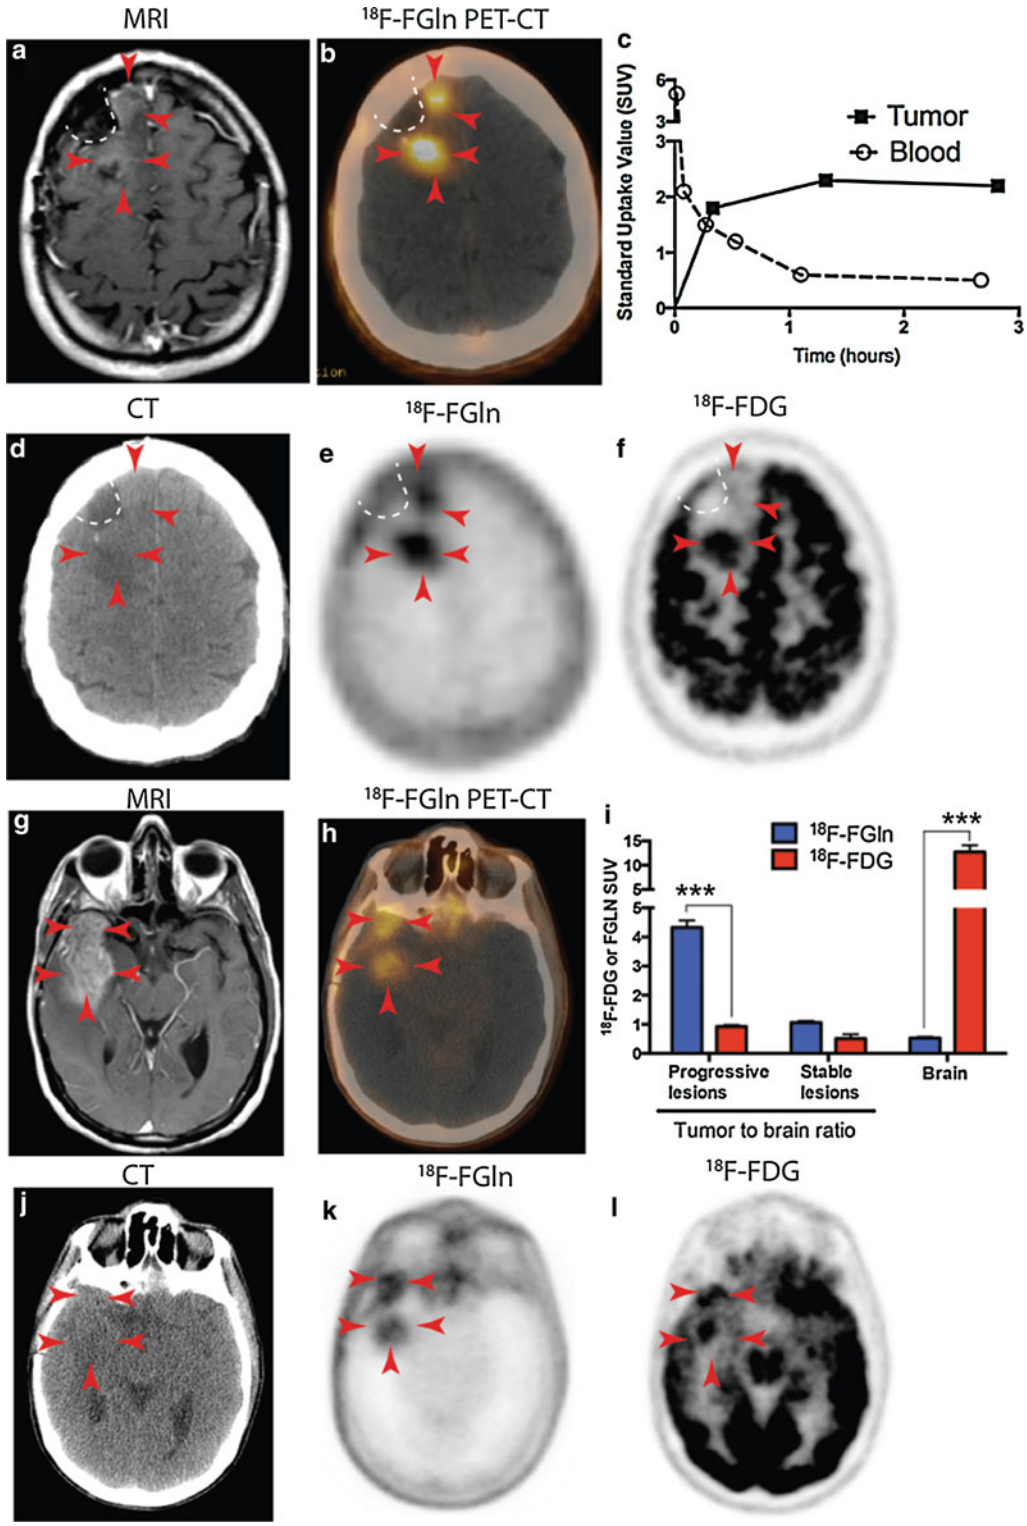

Fig. 12 Uptake in brain tumor: glutamine vs. [^{18}F]FDG (Courtesy of Mark Dunphy, DO of MSKCC)

Correlation of increased [^{18}F]FDG uptake with poor prognosis. Molecular imaging of radiotracers has been greatly enhanced by the introduction of relatively simple quantitative concepts, such as standardized uptake value (SUV). The SUV is a relative uptake in tissue (commonly tumor), corrected for body size and amount of injected activity, and may be expressed as maximum SUV in a region, average SUV, corrected for body weight, lean body mass [44]. (As a mass correction, lean body mass is preferred, since there is the least correlation of this parameter with tumor uptake and blood SUV. Tumor response based on SUV measures has recently been proposed in the "PERCIST" algorithm, and the advantages of PET-[^{18}F]FDG imaging based on SUV measures for monitoring treatment response has been proposed [4]. The SUV in various forms is available as a standard measure on most PET cameras in use over the past 10 years. Therefore it is no surprise that correlations with prognosis and SUV have been estimated for a variety of tumors. Table 2 is a list of tumor types which have shown a strong inverse correlation of SUV with prognosis.

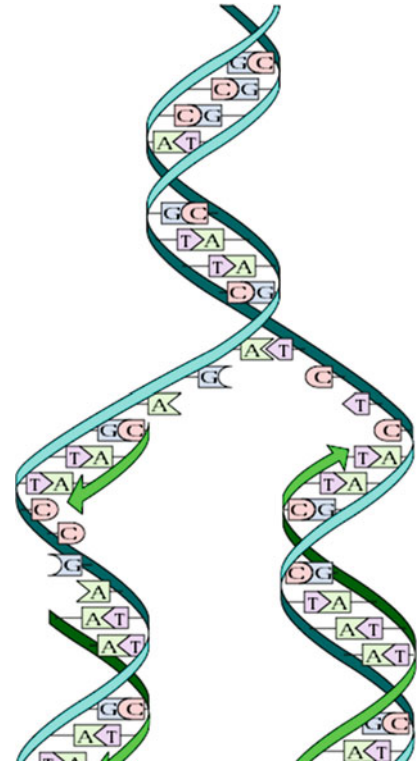

Fig. 13 DNA synthesis. The four component bases found in DNA are adenine (abbreviated *A*), cytosine (*C*), guanidine (*G*), and thymidine (*T*)

Proliferation Imaging

Tumor tissue has an accelerated rate of growth, and this process can be measured by evaluating changes in volume by CT imaging or by molecular imaging of processes that are accelerated during cell division, in particular, the synthesis of DNA and its intermediates. A diagram of the key biochemical form is provided showing the structure of several of these. Several tracers have been proposed to study this phenomenon. DNA may be built up from component bases, as shown in Fig. 13. The bases are added to the pentose sugar ribose to form the nucleoside cytosine, uridine, and thymidine, with subsequent phosphorylation, to the triphosphate, using thymidine kinase. The exchange is quite rapid between tissue and blood during periods of tumor growth, and nucleosides like thymidine are rapidly added to the DNA chain, at the appropriate site (see below). The DNA strand is built up base by base along a backbone formed by the linked sugar molecules, proceeding from the replication fork, thymidine binds to adenine (T-A), cytosine binds to guanine (C-G), and a triplet of bases encode for a single amino acid.

^{18}F-FLT Imaging of Proliferation After Chemotherapy

Several tracers have been proposed to study this phenomenon, and chemical structures of a group of pyrimidine-based tracers are shown in Fig. 14. Of these, ^{18}F-FLT or fluoro-L-thymidine, is the

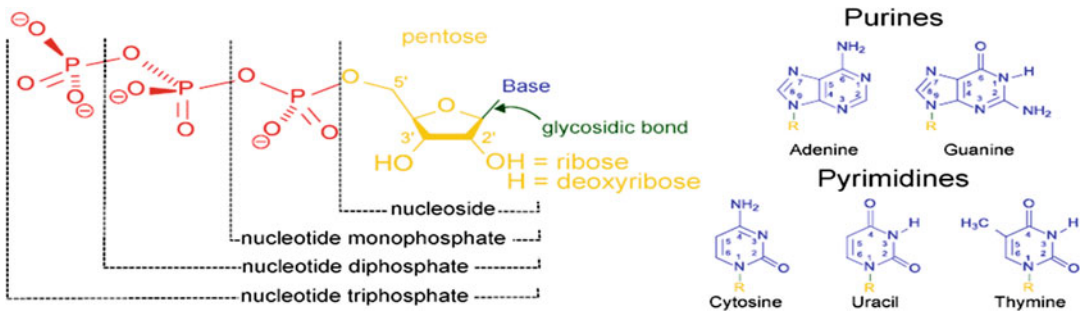

Fig. 14 Chemical structure of key purine and pyrimidine intermediates, along with pattern of phosphorylation prior to incorporation into DNA

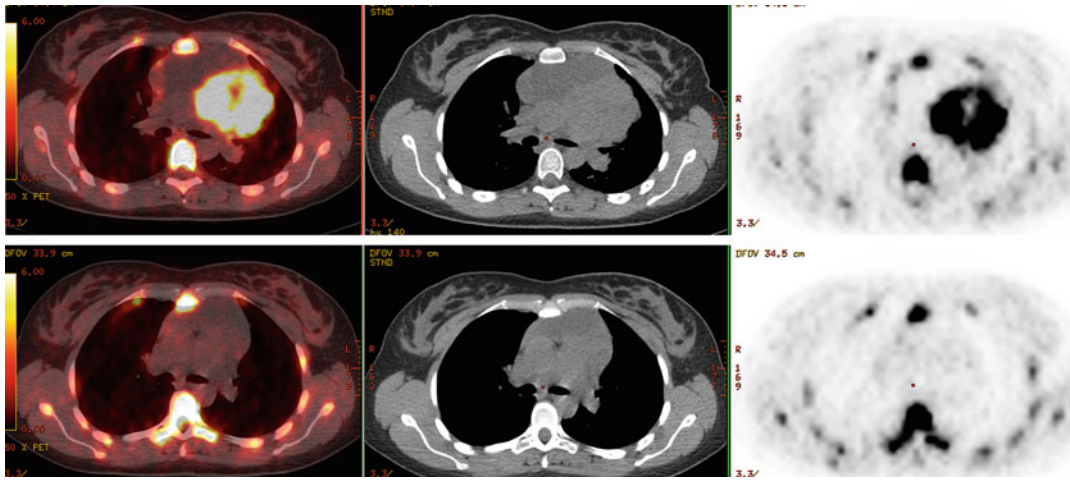

Fig. 15 ^{18}F-FLT imaging after chemotherapy in non--Hodgkin's lymphoma. The patient is imaged after two cycles of RCHOP chemotherapy. The upper row is the baseline study and the *bottom row* is post-therapy. There is rapid proliferation at baseline, which is stopped by effective therapy

most important and has been used extensively in clinical trials. An example is shown of the effect of chemotherapy on the uptake of ^{18}F-FLT in lymphoma is shown in Fig. 15.

The patient in Fig. 15 was imaged after two cycles of RCHOP chemotherapy. The upper row is the baseline study and therapy. Abnormal proliferation is an important component of the malignant state, and a tracer such as ^{18}F-FLT has potential for major benefit in evaluating tumors. ^{18}F-FLT is taken up by nucleoside transporters on the membrane of tumor cells, is phosphorylated by thymidine kinase, and used in the exogenous pathway under the enzymatic control of thymidine kinase, but is not incorporated into DNA. The phosphorylated form is retained in tumor.

Apoptosis

Apoptosis is an important process in the life cycle of normal cells. Programmed cell death allows the cell to undergo an energy-dependent well-orchestrated process of involution. Apoptosis can

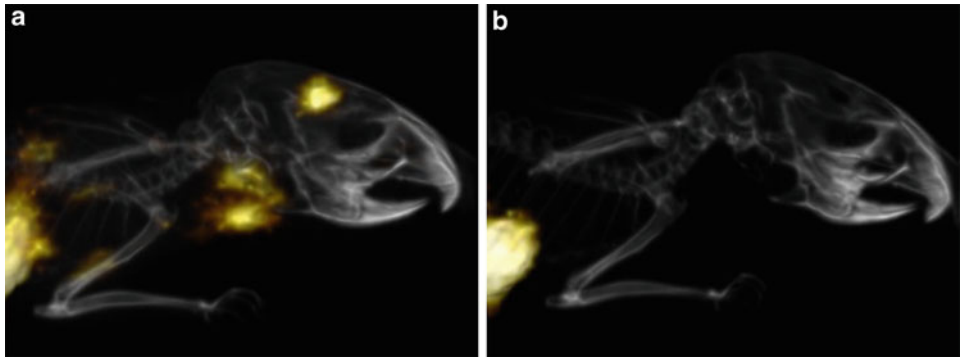

Fig. 16 In vivo whole-body PET/CT imaging of [^{18}F] PARPi in orthotopic brain tumor-bearing mice. (**a**) Fused PET/CT coronal images of a brain orthotopic U251 MG tumor-bearing mouse acquired at 2 h postinjection of [^{18}F] PARPi (*left*) or the blocking agent olaparib (500-fold excess) followed by [^{18}F]PARPi (*right*). (**b**) PET quantification of U251 MG tumors from images acquired at 30 min and 2 h postinjection ($n = 10$) (Courtesy of Drs. Thomas Reiner and Wolfgang Weber, MSKCC; from [46])

be induced by both intrinsic and extrinsic pathways, and one of the hallmarks of cancer is resistance to the apoptotic process [45]. Overcoming this resistance through therapy may contribute to accelerated treatment response in some patients. One of the earliest events in the process of apoptosis is a reversal of the normal cell membrane lipid structure, with exposure of phosphatidylserine on the outer leaflet of the cell membrane. In normal cells, phosphatidylserine is confined to the inner leaflet of the cell membrane. The externalization of this phospholipid allows the involuting cell to bind selectively to clotting factors and proteins. A physiologic protein, annexin V, has an affinity of $>10^{-8}$ for membrane-bound phosphatidylserine. This protein has been labeled with technetium-99 m and was found to localize at sites of apoptosis both in experimental animals and in patients undergoing chemo- or radiotherapy. Apoptosis also occurs in non-neoplastic conditions, such as immune-induced inflammation and acute myocardial infarction. An alternative to annexin as a marker of apoptosis has been developed by comparing many different factors that bind to apoptotic cells.

PARP is an important enzyme in the repair of DNA and is highly overexpressed in cancer. Recently PARP-1 has been recognized as an important therapeutic target in many tumor types. Imaging agents have been developed that successfully image animal models of orthotopic glioblastoma tumors, with uptake that can be blocked by therapeutic PARP-1 inhibitor drugs (Fig. 16).

Oncogene and Non-oncogene Addiction

Cells that are nonmalignant reside within a particular tissue and receive growth and other control signals through a network of signal transduction molecules, which are illustrated diagrammatically as a series of interconnecting lines (Fig. 17). In cancer cells, the process of intracellular communication may be co-opted by specific driver mutations in *otherwise* normal genes, leading to an abnormal gene called the oncogene. The oncogene produces abnormal gene products, oncoproteins, that drive oncogenesis and lead to malignant cell behavior. Driver mutations that are examples of oncogene addiction include overexpression of HER2 in breast cancer, c-Kit mutation in GIST, and ABL kinase mutation in leukemias. Mutations can occur in kinases, which have a signal transmitting function; this

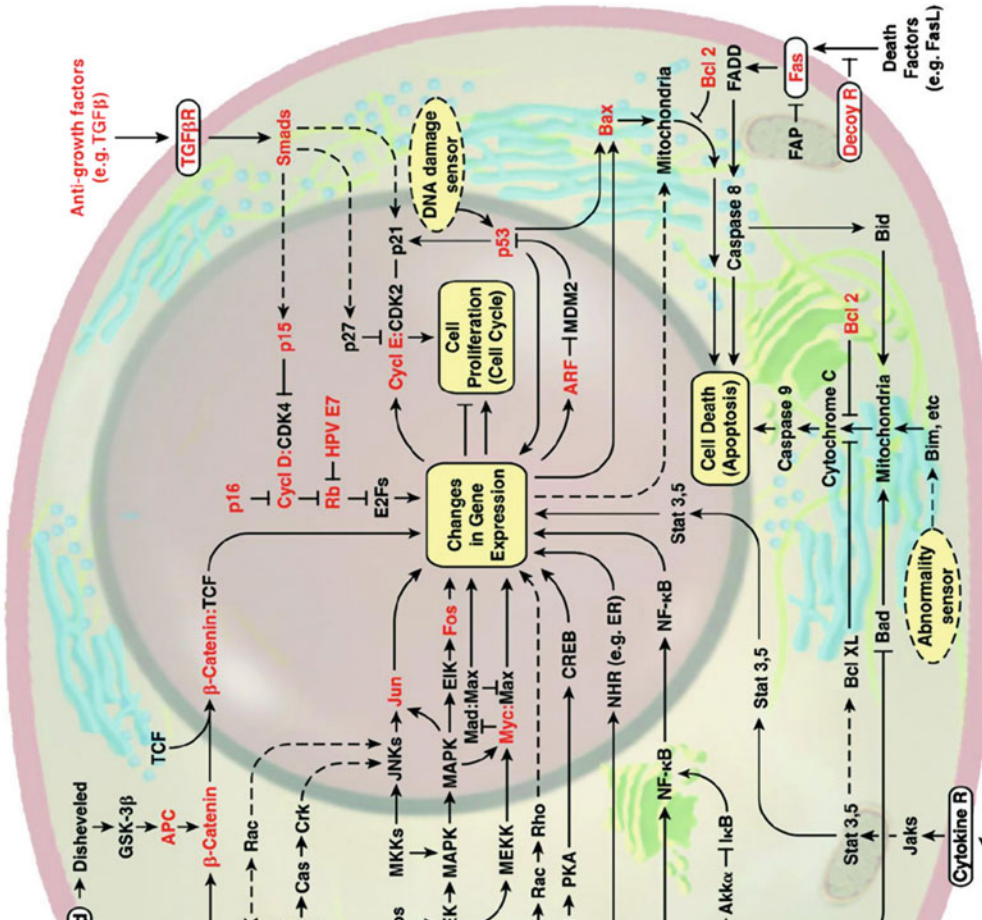

Fig. 17 Diagrammatic illustration of a network of signal transduction molecules as a series of interconnected lines. They transmit growth and other control signals to nonmalignant cells that reside within a particular tissue (From [2, 47], with permission)

can disrupt functioning. Examples include EGFR mutations, c-KiT mutations, and ABL kinase mutations. Other commonly mutated oncogenes include genes controlling Rb, P53, and PTEN, proteins that suppress a tendency toward tumor formation. In fact, cancer occurs when a series of mutations have developed that cooperate to create the complex malignant phenotype.

Examples of Imaging the Action Driver Mutations in Cancer Cells Indirectly Through Effects on Metabolism

The mutations that drive the cancer cell into the malignant state can be thought of in three categories: gain-of-function mutations, translocations, and amplifications. Treatments and imaging are focused on these driver mutations, and in particular, the success of kinase inhibitors has validated this concept.

BRAF Inhibition in Advanced Melanoma with V600E Mutation

The highly specific tyrosine kinase inhibitor PLX 4032 appears effective in patients with metastatic malignant melanoma. About 70% of melanomas have a significant response based on RECIST 1.1 criteria when treated with PLX 4032. Eighteen patients had a CR and one patient had a PR. Patients had a rapid response to the drug, with marked reduction of [^{18}F]FDG uptake. For therapy to be effective, PLX 4032 must be administered at a dose sufficient to inhibit >80% of the BRAF pathway [48] (Fig. 18).

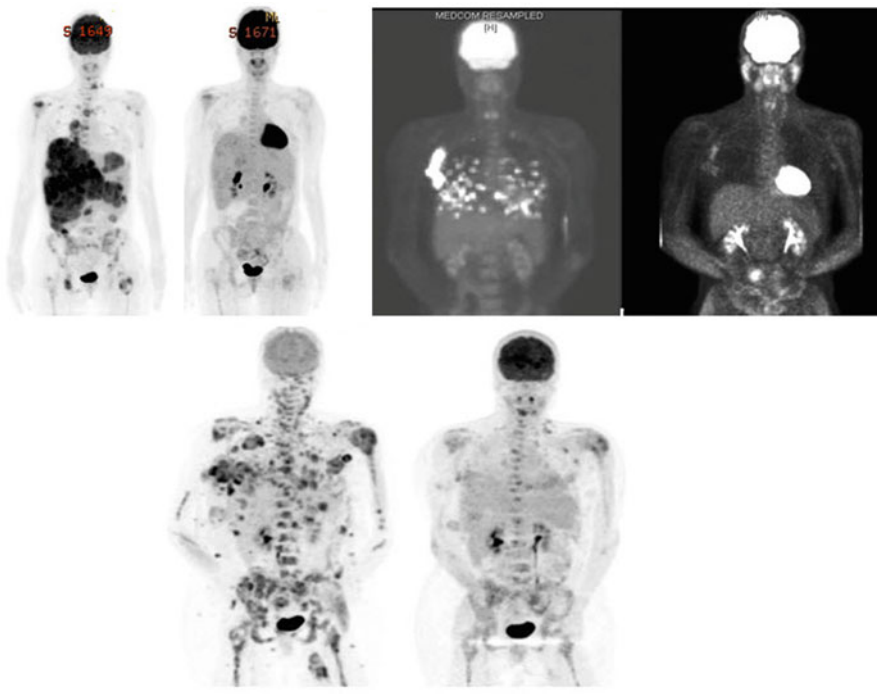

Fig. 18 Of 27 patients, three are shown: baseline study (*left*) and follow-up at 2 weeks posttreatment (*right*) (From [47], with permission)

Inhibition of MEK, a Downstream Signal Transduction Molecule in the RAS/BRAF/ERK Pathway, Can Reverse ^{131}I Resistance in Patients with Thyroid Cancer

Thyroid uptake of iodine in papillary thyroid cancer occurs because of a set of thyroid genes responsible for iodine transport and organification in normal thyroid tissue. These genes are often lost during cancer formation. Recent data mining in the databases for papillary thyroid cancer has led to important correlations between driver mutations responsible for tumor formation, such as the V600E mutation in BRAF, as well as driver mutations in RAS. Agrawal and colleagues have developed a thyroid differentiation score (TDS) consisting of nine genes integral to iodine uptake and differentiation. A heat map of these genes is shown in Fig. 19. In general, the vertical columns, which are mostly red, have higher differentiation scores.

Abnormalities of the BRAF/ERK signaling pathway promote the malignant state in thyroid cancer, and inhibition of MEK leads to redifferentiation of experimental models of human thyroid cancer in animals (James Fagin, personal communication, Sloan Kettering Institute). Patients with ^{131}I refractory thyroid cancer were treated with the MEK inhibitor AZD 6244 for 5 weeks and then restudied with quantitative PET imaging using iodine-124. Approximately two-thirds of the patients had restoration of radioiodine uptake and went on to be treated with ^{131}I-iodide, with excellent clinical response to treatment (Fig. 20) [50].

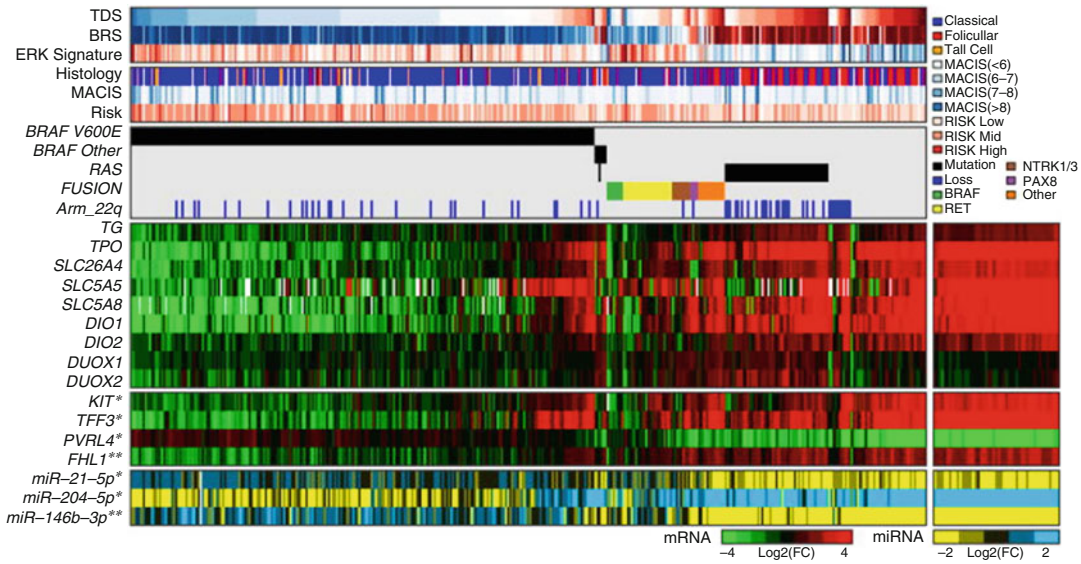

Fig. 19 Thyroid differentiation score (TDS) across the cohort with tumors sorted by driver mutation and TDS. Below TDS are the *BRAF*^{V600E}-*RAS* score (BRS), ERK signature, histological type, MACIS score, risk of recurrence, driver mutations, and gene expression data for nine thyroid genes used to derive the TDS [*TG*, *TPO*, *SLC26A4* (pendrin), *SLC5A5* (Na/I symporter), *SLC5A8* (apical iodide transporter), *DIO1*, *DIO2*, *DUOX1*, and *DUOX2*)], four selected mRNAs correlated to TDS, and three selected miRs correlated to TDS. Featured mRNA (except for 16 thyroid genes) and miRNA genes were selected based on Spearman correlation to TDS in the *BRAF*^{V600E} cohort (*) and the full cohort (**) (From [49], with permission)

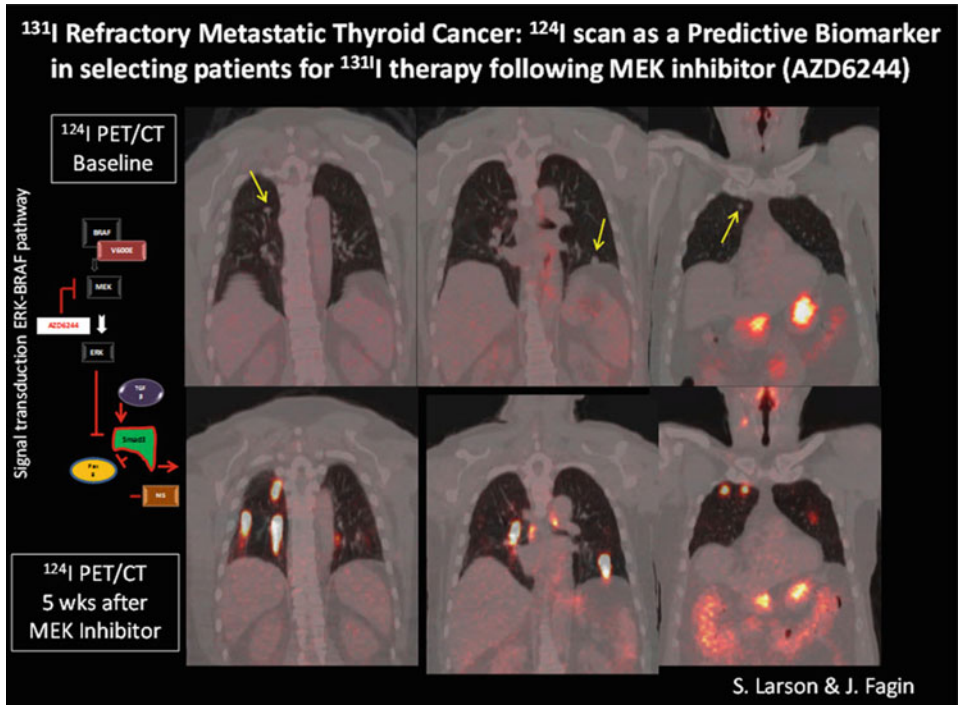

Fig. 20 In baseline scan, *upper image*, coronal projection, *arrows* point out metastatic sites of pulmonary metastases that do not take up radioiodine at 48 h after oral administration. In the *lower image*, taken 5 weeks later after treatment with the MEK inhibitor AZD 6244, all of these lesions have taken up sufficient amounts of radioiodine to predict therapeutic effect. This patient had a reduction in size of pulmonary nodules as well as significant fall in serum thyroglobulin (Data not shown)

Imaging the Driver Oncogene in Castrate-Resistant Prostate Cancer: The Androgen Receptor Axis

Dihydrotestosterone, a metabolite of testosterone, is the most abundant androgen at the tissue level in vivo and binds to AR in vivo. We have extensively studied a radiolabeled analog, ^{18}F-FDHT, to explore AR expression and in vivo binding in patients with the lethal form of prostate cancer, namely, castrate-resistant prostate cancer (CRPC). Toxicity, patient dosimetry, conditions of use, and optimized analysis were assayed, and ^{18}F-FDHT continues to be used in a variety of clinical trials that are ongoing, e.g., 00–095 in metastatic CRPC [51–54].

We have adapted this approach to the study of AR expressing primary and metastatic prostate cancers. We directly image AR under a short-time medical castration to testosterone levels < 50 pg/mL. We have also used glycolysis marker [^{18}F]FDG, a clinical standard tracer, within 24–48 h as a marker of active tumor metabolism, and have demonstrated high patient acceptance of a two-day sequence of imaging, requiring about 1 h of scanning each day. In addition, we have analyzed imaging biopsies to explore the presence of the downstream androgen effector proteins, particularly HK2, PSMA, and STEAP [55–57] for consideration of later AR-axis monitoring using radiolabeled antibody approaches as a possible pharmacodynamic approach of AR-axis inhibition in later drug trials.

The rationale for this approach is summarized in Fig. 21, which is a diagrammatic representation

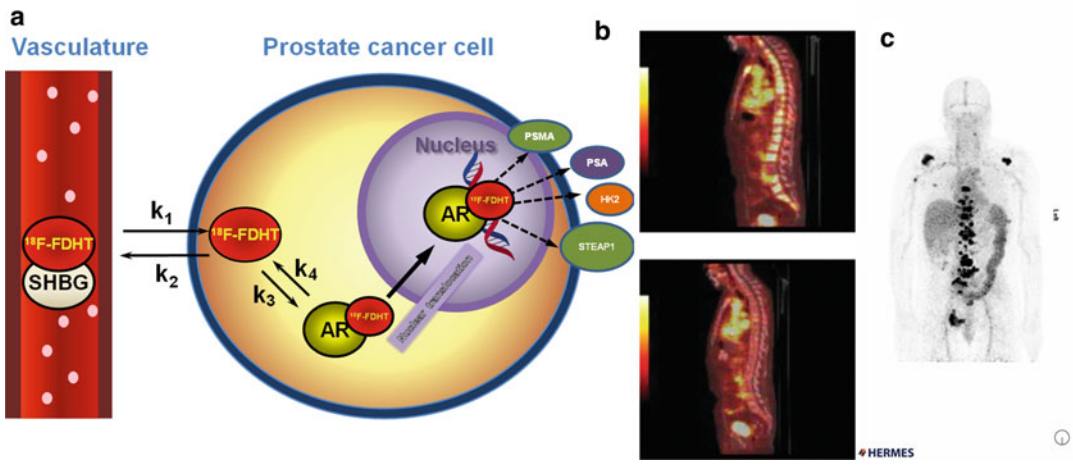

Fig. 21 (**a**) Model of AR axis. (**b**) ^{18}F-FDHT before (*top*) and after (*bottom*) treatment with enzalutamide to suppress AR uptake of ^{18}F-FDHT along the spine. (**c**) ^{89}Zr-anti-STEAP imaging shows uptake in metastases along the spine. The AR axis is driven by androgens that bind to AR in cytoplasm and transport to the nucleus, where the AR complex binds to hormone-responsive elements. Downstream effectors that are activated may be imaged, such as PSMA, PSA, HK2, and STEAP (See [58] for details)

of the binding of the radiolabeled agonist, ^{18}F-FDHT to AR, with the subsequent translocation to the nucleus with binding to hormone-responsive elements on DNA that cause downstream androgen effects.

Androgen Receptor (AR) as Oncogenic Driver in Prostate Cancer

AR is activated in CRPC, the lethal form of the disease. AR inhibitors are an important component of therapy in this disease. Figure 21 shows the application of MI in the form of ^{18}F-FDHT (16β-^{18}F-dihydrotestosterone), an AR-binding ligand. Recently, effective androgen blockade agents have been introduced for therapy of prostate cancer. Figure 22 shows baseline uptake of ^{18}F-FDHT in the metastatic tumor in the vertebrae of a patient with CRPC. All 22 patients treated in this Phase I trial showed displacement of ^{18}F-FDHT tracer by the AR-binding drug MDV3100, indicating that the AR displacement agent was hitting the AR target. The AR axis is responsible for downstream effector molecules that are a part of the androgen effects. For example, common proteins produced by prostatic-like tissues include the four listed in Fig. 21: STEAP, a membrane transport protein; PSMA, a NAALADase enzyme; and PSA and HK2, kallikrein-related peptidases produced to keep semen liquified, thus enhancing sperm motility.

Imaging of Carbonic Anhydrase 9 as a Pathognomonic Indication of Clear Cell Renal Cancer

A driver mutation occurs in renal cancer with mutation of the von Hippel-Lindau (VHL) protein. At normal levels of tissue oxygen, VHL is tightly bound to the transcription factor HIF-1alpha, inactivating it. In renal cell cancer, there is an inactivating mutation of VHL, and HIF-1 alpha is continuously activated, with chronic production of downstream effector proteins, especially VEGFR, and also carbonic anhydrase 9 (CA9), as proteins that are normally

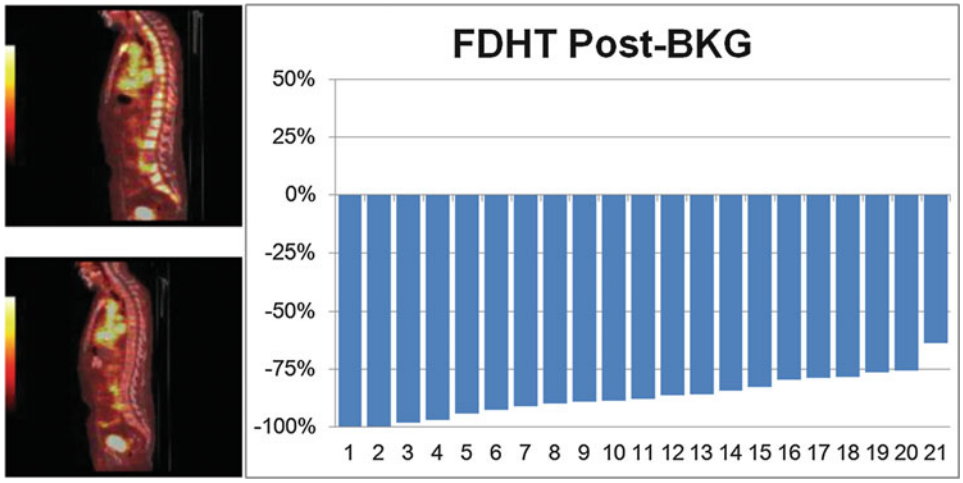

Fig. 22 *Left*, *top*: Baseline sagittal PET imaging obtained with the radiotracer ^{18}F-FDHT (16β-^{18}F-dihydrotestosterone). *Left*, *bottom*: Image obtained 4 weeks after injection of beginning treatment with MDV3100, an AR blocker. The radiotracer is the analog of the dominant androgen at the tissue level in man, namely, dihydrotestosterone (DHT). *Right*: background-corrected changes in average SUV_{max} for all lesions in the treated patients. Therapy of prostate cancer. Fig. 8 shows baseline uptake of ^{18}F-FDHT in the metastatic tumor in the vertebrae of a patient with CRPC. All 22 patients treated in this Phase I trial showed displacement of ^{18}F-FDHT tracer by the AR-binding drug MDV3100, indicating that the AR displacement agent was hitting the AR target

activated in hypoxic tissues. Clear cell renal cancer is produced in this setting. ^{124}I-cG250 is a positron-emitting antibody that targets CA9, which has been introduced to assist in surgical planning of masses of the kidney. As shown in Fig. 23, there is uptake in a mass in the kidney bed with excellent contrast, at 7 days after injection of ^{124}I-cG250 [59]. Targeted therapy with sunitinib and sorafenib is used in this clinical setting to block the action of VEGFR.

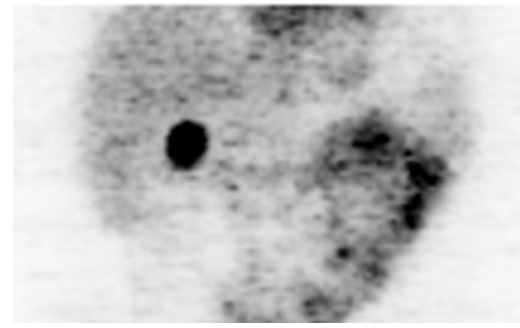

Fig. 23 Uptake in a mass in the kidney bed with excellent contrast, at 7 days after injection of ^{124}I-cG250

Future Applications

Many other molecular imaging approaches are available to characterize one or more aspects of a neoplasm, including ^{18}F-estradiol for breast cancers, amino acid incorporation (FACBC, glutamate), ^{68}Ga-PSMA-ligand for prostate imaging, and ^{68}Ga-DOTATATE for neuroendocrine imaging. Some of these have been approved, and others will likely be available within the next 5 years. However, due to the lengthy process of regulatory approval, the major radiopharmaceutical for evaluation of the tumor patient will remain [^{18}F]FDG. With increased understanding of changes in glucose transporter expression by the tumor cell, it is likely that more sophisticated prognostic indices than SUV_{max} may be developed.

It is also likely that genomic analysis of circulating tumor cells may be used as a gatekeeper, to determine if a more selective MI probe PET/CT study is likely to provide clinically useful information.

The development of radiotracer probes for molecular imaging continues to proceed at a very rapid pace. Moreover, drug companies are beginning to recognize the important role that molecular imaging can play in facilitating drug development through an improved understanding of the biology of the cancer process. It is highly likely that very soon we will see ever more remarkable radiotracers, probably in combination with MRI agents and optical agents, because of the ease with which fusion imaging may be obtained in order to exploit the combined information. The field of nanotechnology offers many opportunities for probe development, including serving as a carrier for highly selective radiotracers such as complementary probes like DNA-binding or RNA-binding proteins, as well as radiolabeled drugs. Theranostic agents combine the potential for diagnosis and therapy, so that agents are not only intended to visualize tumors but in effect guide therapeutic delivery. This is already beginning in the exciting field of image-guided interventional radiology, but will extend to tracers with both diagnostic and therapeutic potential. For example, it is easy to contemplate the radiolabeled drug carried in nanoparticles so that the quantification of the payload delivered will serve as a sensor that provides, through quantitative imaging, the total amount of drug that is both taken up and retained within the tissues. Such theranostic approaches will improve selection of patients for a given type of therapy and may allow for tailoring treatment to the individual patient.

Table 3 Commonly used radioantibodies at MSKCC

Radioantibody	Target
^{68}Ga-Fab'$_2$ herceptin	HER2 receptor (breast, prostate, lung) [60, 61]
^{124}I-A33	A33 antigen (colorectal) (see Fig. 20)
^{124}I-cG250	Carbonic anhydrase 9 (hypoxia, renal cell) [59]
$^{124/131}$I-3F8	GD2 (neuroblastoma, melanoma) [62]
$^{124/131}$I-8H9	B7H3 (melanoma, prostate, pediatric cancers, sarcoma) [63]
^{233}Ac-^{213}Bi-M195	CD33 (AML, CML) [64]
^{89}Zr-J591	PSMA (prostate, tumor vasculature) [65, 66]

Radioantibody and Radiopeptide Imaging and Therapy (Theranostics) Will Drive Our Field for the Next Decade and Beyond

Radiolabeled antibodies and peptides have been used for molecular imaging and in some cases therapy due to the highly selective nature of the antibody-antigen bond. Advances in the molecular biology of antibody production have greatly improved antibodies both as therapeutics and as carriers of radioactive, toxin, or chemotherapy payloads. A table of commonly used antibodies for targeting and therapy applications at MSKCC is shown below (Table 3). Antibodies fall in one of the most rapidly expanding categories of new drugs, and successful drugs include Herceptin (HER2), Avastin (VEGF), rituximab (CD20), ipilimumab (CTLA4), cetuximab (Erbitux), and panitumumab (Vectibix; EGFR). Tumors overexpress antigens that may occur at earlier developmental stages of the cell. Common terms to describe such antigen expression include differentiation antigen (CD33, GD2, PSMA), tumor-testis antigen (A33), oncofetal antigen (GD2, B7H3), and driver mutation-associated antigen (HER2, CA9). There is much more to come, and, in fact, these just represent the tip of the iceberg of biologic agents that will offer new staging and diagnostic benefits in the age of precision medicine. There is great promise, even laboratory evidence [67, 68], that in the decade ahead, we shall be able to achieve therapeutic ratios of radiotargeting to tumor that are curative, even possibly for the most highly resistant solid tumors (Fig. 24)!

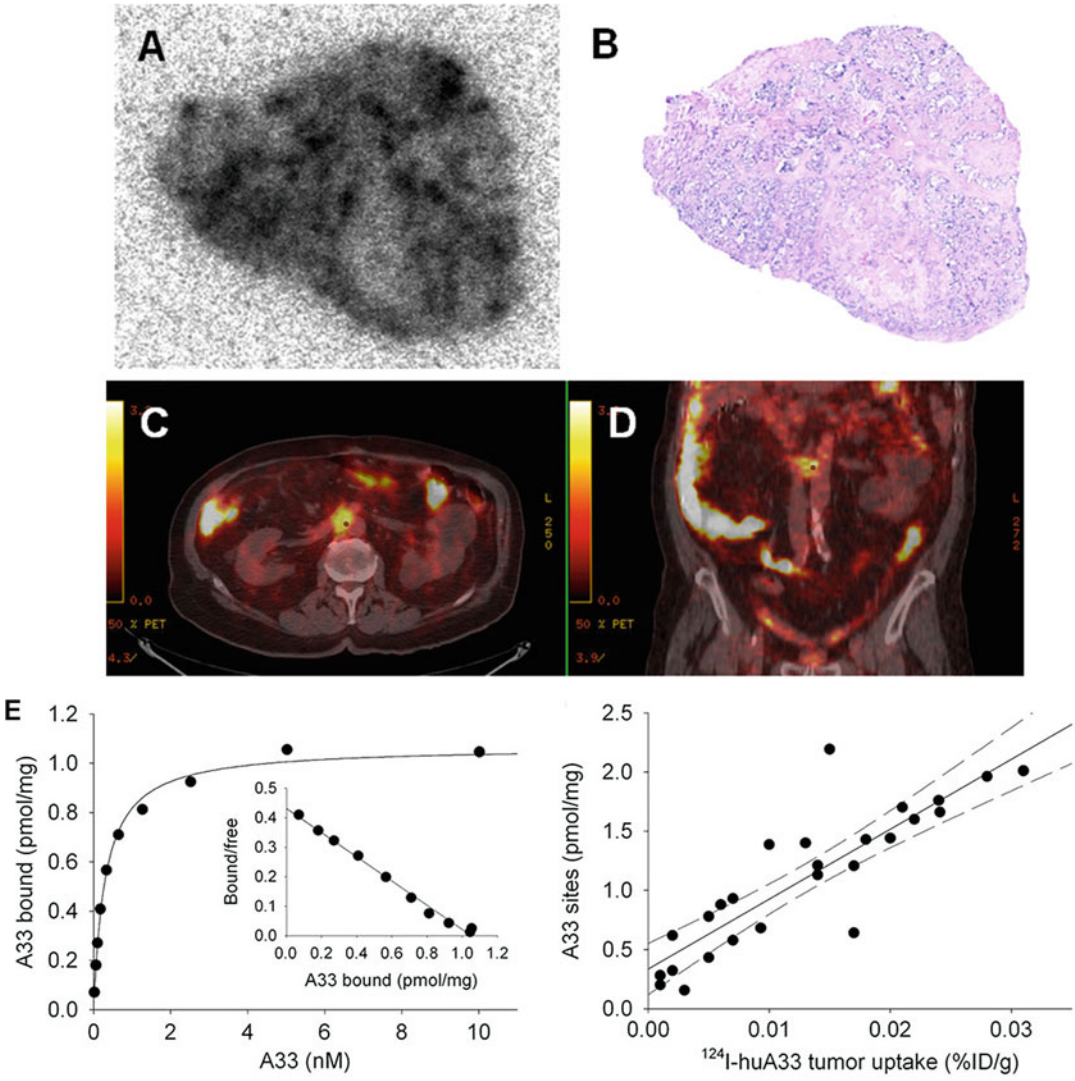

Fig. 24 ^{124}I-A33 images obtained at 5 days postinjection. Protocol involved surgical sampling, which revealed an occult periaortic lymph node containing tumor. Autoradiography (**a**) and H&E histology (**b**) showing that the antibody targets the cellular component of the mass. Fusion images with PET displayed in hot body format, so that the most intense radioactivity is white and the least intense in *red*, overlaid onto the axial (**c**) and coronal (**d**) (Images courtesy of Jorge Carrasquillo, MD). Perhaps the most important concept illustrated by these images is the fact that radioantibody uptake is driven by antigen concentration at the tumor level (**e**). This has important implications, including nonlinear uptake kinetics. Another important fact derived from this study was that occupancy of the tumor receptor (A33, in this case) was in fact at 20–50% occupancy, not at tracer dose levels (From [69])

Principles of Molecular Targeting for Radionuclide Therapy

2

William C. Eckelman, Marie Boyd, and Robert J. Mairs

Abstract

Molecular targeting requires assessing several factors that come into play such as the location of the target, the choice of radionuclide, the inertness of the bifunctional chelate and stability of the covalently bound halogens, matching the residence time in the tumor with the physical half-life of the radionuclide, the scale and scope of the disease, and the absorbed dose sensitivity of the targeted tumor compared to normal tissue. The principles of molecular targeting are well established, but a paradigm shift from designing a medium-affinity radiotracer used to determine target density to designing a high-affinity, high-target density radioligand to maximize the target-to-nontarget ratio should increase the probability of detecting lesions smaller than the instrument resolution.

Developing and validating a therapeutic radiopharmaceutical for a single target is necessary, but often not sufficient to produce a toxic event because of other mechanisms that are only partially understood. These include nontargeted effects due to radiation emitted from neighboring, targeted cells as well as bystander effects produced by the cellular processing of radiation not necessarily impinging on DNA. Both of these indirect consequences of cellular radiation could make a substantial contribution to the efficacy of targeted radionuclide therapy. These mechanisms should be exploited to optimize the efficacy of targeted radiotherapy and overcome the inefficiency of tumor control due to nonuniform distribution of radiation dose. The design approach to take advantage of the indirect consequences of cellular radiation depends heavily on further elucidation of the indirect effect. The successful combination of these two should lead to more effective nuclear radiotherapy.

Introduction

An important criterion for designing a successful targeted molecule is the choice of a particular cancer or a recently defined pathway [1] for which there are relatively few effective therapeutic options [2, 3]. From this information a target can be proposed. The key issue is targeting a saturable site unique to the disease. Most often this is a protein, but lipids are also possibilities (Table 1). Enhanced permeability and retention (EPR) is not considered to be targeted imaging [4].

Once that target unique to a disease is identified, the principles of molecular targeting can be applied to identify and validate therapeutic radiopharmaceuticals. The ligands from these targets are small molecules, often based on endogenous ligands or pharmaceuticals, peptides, sugars, protein, antibody fragments, and antibodies (Table 2, [5]).

Except for radionuclides of iodine, bromine, and astatine, i.e., halogens, therapeutic radionuclides are metals and require a bifunctional chelate conjugated to the targeting molecule. Halogen radionuclides most often are linked via a residualizing group [6]. Based on the cellular location and density of the target, the design of the targeted radiotracer will follow the approach for nuclear diagnostics with certain changes required for therapeutic radiopharmaceuticals [7, 8]. Relevant properties for a diagnostic radiopharmaceutical are an inexpensive radionuclide, high radiochemical yield, high radiochemical purity, and high specific activity including effective specific activity. These are required for therapeutic

Table 1 Potential targets for radioligands

Receptor is defined as a molecule in a cell membrane that responds to a particular neurotransmitter, hormone, antigen, or other substance. To facilitate imaging, radiolabeled antagonists to the receptor rather than lower-affinity, natural ligands are usually employed
Acceptor is defined as a molecule in a cell membrane whose biological activity is not known. The mannose receptor in the liver and the prostate-specific membrane antigen are examples
Enzyme is defined as a substance that acts as a catalyst to bring about a specific biochemical reaction. Inhibitors of the enzyme as often used, for example, radiolabeled fludeoxyglucose at hexokinase, but substrates as well, for example, ^{18}F-DOPA is used to quantify DOPA decarboxylase activity in the brain
Transporter protein is defined as a protein that serves the function of transporting ligands within the cell
Protein antigen is a specific antigen, usually cell surface, that is unique to the tumor. Antibodies and antibody fragments are produced by recombinant and proteolytic methods

Table 2 Potential platforms used in radioligand design

Small molecules are chemical entities that have a molecular weight of <500 Da. They are especially used in neurochemical applications given the requirement to cross the blood-brain barrier
Nanoparticles are usually defined as having a diameter of 100 nanometers or less. They are used in situations where the number of ligands for either diagnostic or therapeutic use can be bound to the surface
Antibodies and fragments: scFv (∼28 kDa), diabody (∼55 kDa), minibody (∼80 kDa), F(ab')$_2$ (100 kDa), and IgG (∼150 kDa). Various proteolytic or recombinant methods result in a combination of the binding region that targets the tumor cell antigen and other fragments present in the IgG
Enhanced permeability and retention (EPR)
This does not involve a single target, but a difference in EPR in target and normal tissue. In the 1980s, Maeda and colleagues found that macromolecules such as polymers and proteins with molecular weights larger than 40–50 kDa showed selective accumulation in tumor tissues, far more than that observed in normal tissues; moreover, they retained in tumor tissues for long periods, i.e., >24 h. They coined this unique phenomenon enhanced permeability and retention (EPR) effect. Accordingly, an EPR-based tumor-targeting strategy (macromolecular therapy) was developed by using polymer modification, nanoparticles, micelles, liposome, etc.

radiopharmaceuticals as well, although a high specific concentration of a therapeutic dose will produce radiolysis unless a radical scavenger is included. High specific activity is still a necessity to avoid saturation of the target and pharmacologic effects given the higher mass dose. For diagnostics, given that external imaging detects photons and not chemical structure, important criteria in vivo are metabolic stability; efficient transfer to the target only, i.e., target specificity; and pharmacokinetics that are more heavily weighted by biochemistry than by delivery although there is an ongoing paradigm shift to favor maximal delivery combined with optimal specific uptake and retention. The same criteria apply for therapeutic radiopharmaceuticals although pharmacokinetics heavily weighted for efficient extraction fraction may have an advantage in delivering a toxic dose to a larger percentage of cancer cells. A higher input area under the curve is also important for therapeutic radiopharmaceuticals. For positron-emitting radionuclides, the distinction between what constitutes diagnostic and therapeutic injected radioactivity is often blurred by the focus on the external emissions of positron annihilation rather than the high LET of the emitted positron.

The major challenge is to deliver the therapeutic radiopharmaceutical to the target whether it is on the cell surface, in the cytosol, or in the nucleus or more generally whether it is a well-characterized target or a phenotypic target obtained by screening [9]. The latter is most often the approach for antibodies obtained by screening antibodies and fragments to the tumor cell surface for specificity and high affinity. Another challenge is to demonstrate binding to the chosen target in the absence of specific and nonspecific binding to other sites

using an array of drugs known to bind to the specific target or to closely related targets including subtypes. Using target-specific knockout mice can also demonstrate specificity [10, 11]. In general, the probability of achieving the therapeutic goal decreases when moving from targets on the cell surface to targets in intracellular compartments.

Another major challenge in radiopharmaceutical design requires a clear approach to the optimal pharmacodynamics, i.e., the ideal combination of flow and permeability, which constitute delivery and kinetics at the target, which is based on the on-rate and the off-rate of radiopharmaceutical binding. The early diagnostic radiopharmaceuticals had very high affinities leading to high target retention to maximize the potential for external imaging, but with this came pharmacokinetics that are heavily delivery related. For example, diagnostic radiotracers such as N-[^{11}C]methylspiperone [12] and 3-quinuclidinyl-4-[^{123}I]iodobenzilate [13] (IQNB) have high affinities and high retention, and therefore their biodistribution is heavily delivery related. For IQNB, given the longer half-life of ^{123}I, the distribution in vivo with time shifted to dependence on muscarinic receptor density [14]. Investigators most often used IQNB to determine if new drugs involve the muscarinic receptor [15]. Experimentally, the ideals of delivery-related radiopharmaceuticals are those that are trapped in capillaries smaller than the particle size. For example, microspheres administered intravascularly, by virtue of efficient trapping in the capillaries, are the gold standard for heavily flow-related agents. In the clinic ^{99m}Tc-labeled microspheres are used to measure lung perfusion in vivo. The therapeutic application that best matches microspheres is intra-arterial radiotherapy, using radiolabeled ^{90}Y microspheres of glass or resin to treat lesions in the liver [16]. Small molecules can approach the extraction efficiency of microspheres if the extraction and retention of the injected radiopharmaceutical in the tumor is >90%, but given the cardiac output to the target after IV injection, only the lung will retain a high percentage of the injected dose.

Most of the diagnostic radiotracers developed subsequently were "more reversible" with slightly lower affinity so although the original distribution might be weighted toward delivery, subsequently (within the time frame of the radionuclide half-life), the distribution would be proportional to the biochemistry involved. Separating flow, permeability, and target binding has been a challenge because rapid and efficient uptake is advantageous for both diagnostic and therapeutic radiopharmaceuticals from a total delivery point of view; therefore, the measure of changes in biochemistry as a function of disease often required a measurable off-rate from the target.

But for diagnostic radiotracers, it is clear that efflux of radioligand not specifically bound to the target in the tissue compartment must be rapid and efficient within the time frame of the radionuclide half-life. In cardiology, radioligands designed to measure changes in biochemical pathways are heavily weighted by distribution and require saturation studies in vivo to determine adrenoceptor density [17]. One example of a reversible ligand from neurochemistry studies is 3-[4-[(3-[^{18}F] fluoropropyl)thio]-1,2,5-thiadiazol-3-yl]-1,2,5,6-tetrahydro-1-methylpyridine (^{18}F-FP-TZTP), whose early distribution correlated with perfusion as measured by [^{15}O]H_2O, i.e., within the range of cerebral blood flow (CBF) values measured, there is excellent agreement between CBF and the K1 of ^{18}F-FP-TZTP [18]. But the later distribution was weighted by a combination of muscarinic receptor density and synaptic acetylcholine concentration [19, 20]. The goal of the "reversible" ligands is to determine the change in target density as a function of disease or treatment. But is this the most valuable use for nuclear diagnostics with the inherent goal of whole-body imaging?

For theranostics and therapeutic radiopharmaceuticals, a high-affinity ligand approach appears to be superior. It seems that detecting the total tumor burden before and after treatment, especially lesions smaller than the twice the instrument resolution, is an important alternative in diagnostic design and is an important approach to developing therapeutic radiopharmaceuticals as well. Not only should the affinity be high, but the target should be present in the highest density possible and not vary to a large extent during treatment, whether during radionuclide therapy alone or combination therapy. The highest affinity (K_i) and the highest density (B_{max}) given

PCa: prostate cancer

adequate delivery will yield the potential for a high target-to-nontarget ratio based on the equilibrium equations used in in vitro assays (B_{max}/K_i) [21] (Table 3). In addition, total delivery is important to radiotoxicity; therefore, the metabolite-corrected input function should be as extended by design as possible for therapeutic radiopharmaceuticals, whereas clearance and minimizing nontarget binding are important to obtain a diagnostic image with a high target-to-nontarget ratio.

The design criteria (maximum delivery and retention at the target) serve therapeutic radiopharmaceuticals. The target-to-nontarget ratio is important, but relative clearance is also based on dosimetry considerations that maximize absorbed dose to the tumor and minimize absorbed dose to the normal tissue. For example, to detect/treat prostate cancer, two prostate-specific membrane antigen (PSMA) inhibitors, (S)-2-(3-((S)-1-carboxy-5-(4-[^{123}I]iodobenzylamino)pentyl)ureido) pentanedioic acid ([^{123}I]MIP-1072) and (S)-2-(3-((S)-1-carboxy-5-(3-(4-[^{123}I]iodophenyl) ureido) pentyl)ureido)pentanedioic acid ([^{123}I]MIP-1095) (Fig. 1), have similar characteristics with high affinity for PSMA on the cell surface of human prostate cancer LNCaP cells ($K_d = 3.8 \pm 1.3$ nM and 0.81 ± 0.39 nM, respectively). Both [^{123}I] MIP-1072 and [^{123}I]MIP-1095 are internalized in LNCaP cells at 37°C. The association of [^{123}I] MIP-1072 and [^{123}I]MIP-1095 with PSMA is specific for these two glutamate urea analogs since binding was blocked by co-incubation with 2-(phosphonomethyl)pentanedioic acid (PMPA). There was no binding to human prostate cancer PC3 cells, which lack PSMA [24].

The area under the time-activity curve (AUC) for the tumor and the critical organ are key metrics to differentiate between radiotracers with similar physical-chemical properties. The blood AUC is much less for MIP-1072 than for MIP-1095, and the kidney and tumor AUCs are much less also as would be expected based on the input function (Fig. 2). The first study in humans gave similar results to those obtained in rats [23] and led to subsequent clinical studies with the therapeutic radiopharmaceutical analog radiolabeled with ^{131}I [25].

The kidney-to-tumor ratios of AUC are different but given the variability in the two values and the expectation that changes in structure may make only small differences. To reduce the dose to the kidney, the kidney uptake can be blocked using a similar compound if the uptake is receptor based [26] or an FDA-approved positively charged amino acid solution if it is not receptor mediated [27]. A third approach is to bind the targeted radioligand to

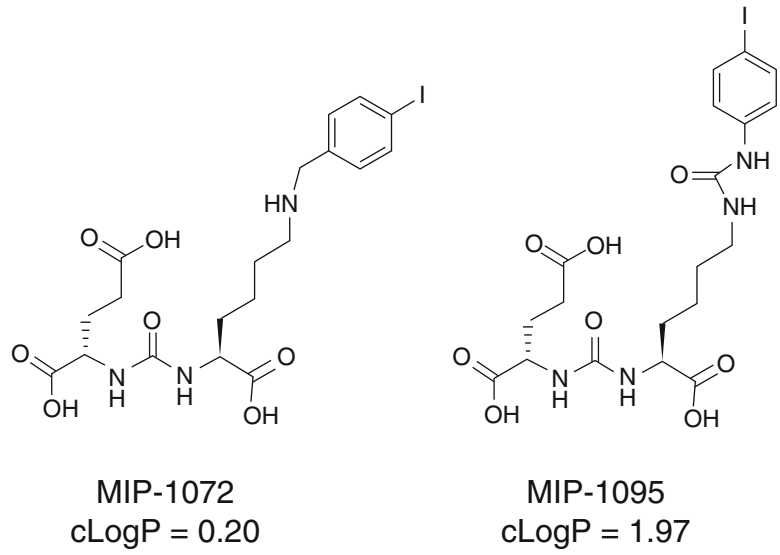

Fig. 1 The structures of (S)-2-(3-((S)-1-carboxy-5-(4-[^{123}I]iodobenzylamino)pentyl)ureido)pentanedioic acid ([^{123}I]MIP-1072) and (S)-2-(3-((S)-1-carboxy-5-(3-(4-[^{123}I]iodophenyl)ureido)pentyl)ureido)pentanedioic acid ([^{123}I]MIP-1095) (Taken from Ref. [23] with permission)

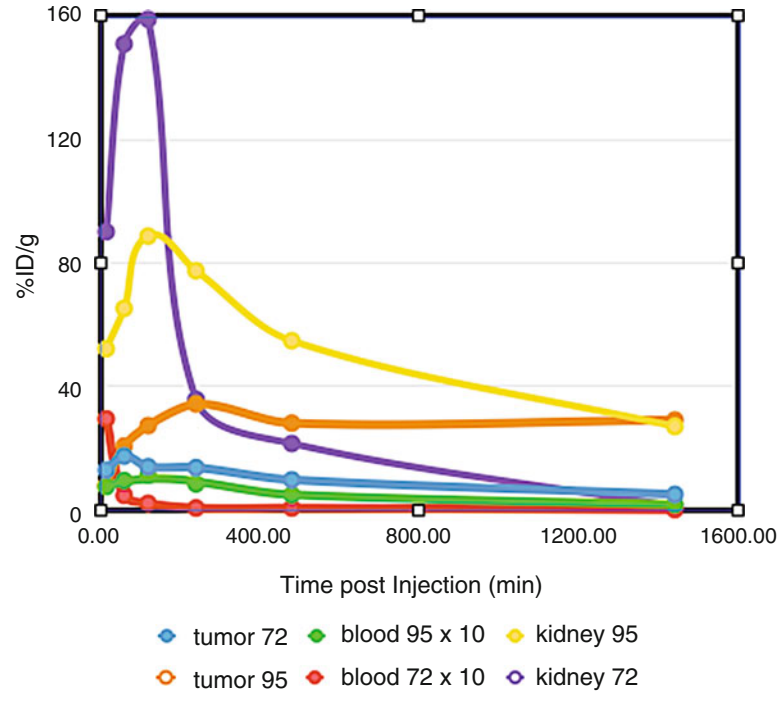

Fig. 2 The time-activity curve for [^{123}I]MIP-1072 and [^{123}I]MIP-1095 for radioactivity in tumor, kidney, and blood (x10) in mice with LNCaP tumors (Plot of data from distribution data from Ref. [24] with permission)

albumin reversibly [28]. This led to a study of therapeutic effectiveness in tumor-bearing mice of a ^{177}Lu-labeled folate analog containing an albumin-binding moiety (Fig. 3) which extended the input function and decreased the kidney uptake versus the bifunctional chelate without the albumin-binding moiety (Fig. 4) [29]. In both situations, design of the molecule to be retained longer in the blood depending on physical-chemical parameters of small molecules and strategies that minimize the biodistribution to normal organs are both key in improving the potential of therapeutic radiopharmaceuticals. The AUC has been the

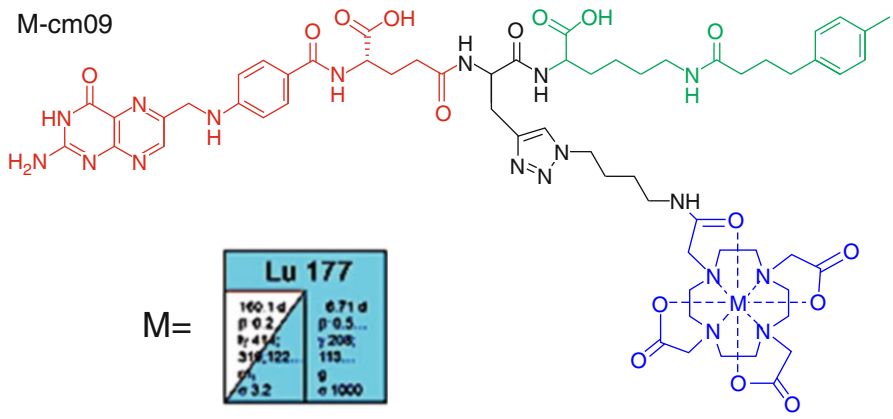

Fig. 3 Structure of ^{177}Lu-DOTA bifunctional chelate (*black*) with folic acid (*red*) and the albumin-binding moiety (*Green*) (Taken from Ref. [28] with permission)

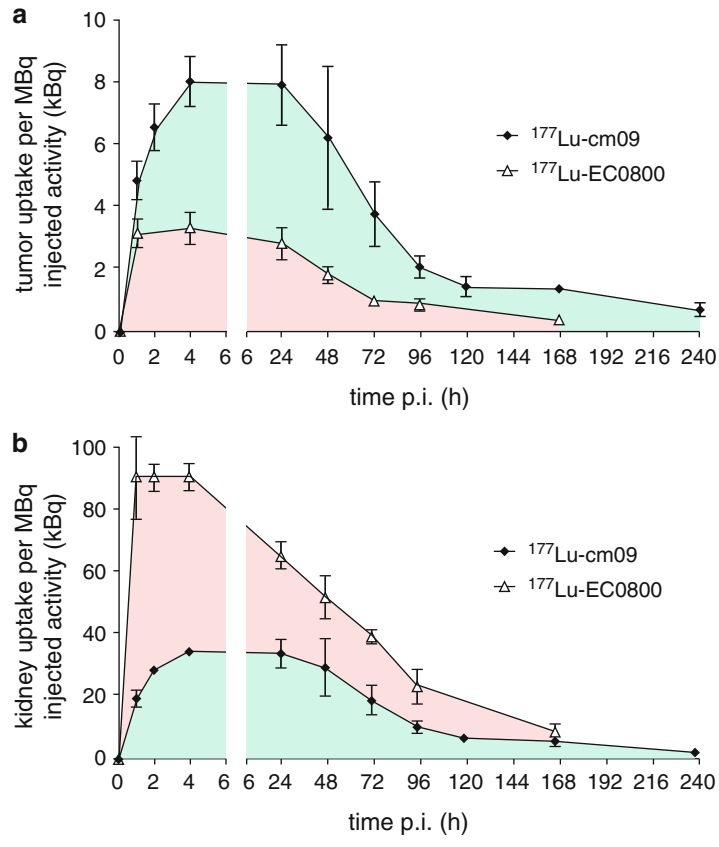

Fig. 4 Time-activity curve showing the relative area under the curve for tumor and kidney. The bifunctional chelate without the albumin-binding moiety (^{177}Lu-EC0800) and the bifunctional chelate with the albumin-binding moiety (^{177}Lu-cm09) at 1 h after injection (Taken from Ref. [29] with permission)

traditional approach to comparing the relative absorbed radiation dose to the target and to normal tissues. However, the AUC analysis does not evaluate the potential of a therapeutic radiopharmaceutical to affect patient outcome. This can only be addressed by outcome studies to determine the therapy operating characteristic (TOC) extracted from a plot of the probability of

tumor control versus the probability of normal tissue complications from clinical data obtained in Phase II/III [30].

Although the location of the target (extra- versus intracellular) is a major design criterion, the development of a therapeutic radiopharmaceutical also depends on the clinical need and the subsequent location of the key target and on a number of other design criteria, which are discussed in the following sections.

The Choice of Radionuclide

Nuclear Properties

Choosing the radionuclide is dependent not only on the location of the target (cell surface, cytosol, nucleus, specifically RNA and DNA) but also on matching the radionuclide physical half-life with the biological half-life of retention at the target. For example, the choice of half-lives for directly labeling antibodies binding to a cell surface target is of the order of days not hours. Matching the emission properties to the scale and scope of the disease being treated is also of critical importance.

There are several possible radionuclides for therapy [31–33] (Table 4). The radionuclides should be listed according to the predominant therapeutic emission (alpha particle, beta particle, Auger electrons) and whether there is a theranostic radioisotope. The alpha emitters most often studied are ^{211}At, ^{212}Pb, ^{212}Bi, ^{213}Bi, and ^{223}Ra. Recent interest has extended the focus to ^{225}Ac and ^{227}Th. Overall, the most frequently proposed beta emitters are those used to treat bone metastases in patients with intractable bone pain The therapeutic radionuclide is administered either as a salt (^{32}P, ^{89}Sr, ^{223}Ra) or a chelate (^{117m}Sn, ^{153}Sm). Metals for other applications, including ^{90}Y, ^{186}Re, ^{166}Ho, ^{131}I, ^{67}Cu, ^{64}Cu, ^{177}Lu, and ^{230}Pa, have half-lives differing from less than 1 day (^{188}Re = 0.71 days) to 50 days (^{89}Sr = 50.5 days) and beta mean energies from 0.13 to 0.93 MeV. The radionuclides recommended for Auger electron therapy are ^{125}I, ^{123}I, ^{111}In, and $^{44m/44}$Sc. In addition, several other therapeutic radionuclides have been proposed given the availability of a 70 MeV cyclotron capable of increased production and purity of ^{211}At, ^{232}Th, and $^{44m/44}$Sc [34].

The approved radionuclide therapies by the FDA and the EMA include iodine-131 iodide for differentiated thyroid cancer, strontium-89 chloride (Metastron) for bone pain, samarium-153 lexidronam (Quadramet) for bone pain, yttrium-90 ibritumomab tiuxetan (Zevalin®) for NHL, iodine-131 tositumomab (Bexxar) for NHL, radium-223 dichloride (Xofigo) for bone metastases, and ^{177}Lu-DOTA-octreotate (Lutathera) for NE tumors. It is interesting that [^{131}I]iodide and [^{223}Ra]radium dichloride are most often used in the clinic. It may be that the unmet need of these two radiotherapeutics at the time of FDA approval was a key metric for their clinical impact.

Generators, as has been the case for the ^{99}Mo/^{99m}Tc generator (67-h half-life of ^{99}Mo and 6-h half-life of ^{99m}Tc), would likely be the most economical if the pharmaceutical requirements, namely, retaining apyrogenicity, sterility, radionuclide yield and purity, and effective specific activity, can be met over the lifetime of the generator. ^{68}Ge/^{68}Ga (271-day half-life of ^{68}Ge and 68-min half-life of ^{68}Ga) is the generator most often used in PET diagnostic procedures and has been registered in Europe. Generators for therapeutic radiopharmaceuticals will most likely be used by central radiopharmacies given

Table 4 Radionuclides of current interest in targeted therapy

Radionuclide	Half-life	Emission	Mean range
^{90}Y	2.7d	β^-	3.8 mm
^{131}I	8 d	β^-	0.4 mm
^{177}Lu	6.7d	β^-	0.2 mm
^{67}Cu	2.6d	β^-	0.2 mm
^{199}Au	3.1d	β^-	0.3 mm
^{211}At	7.2 h	α	0.05 mm
^{212}Bi	1 h	α	0.05 mm
^{125}I	60.5 d	Auger	~1 μm
^{123}I	13.3 h	Auger	~1 μm
^{124}I	4.2 d	β^+	3.8 mm
^{77}Br	0.3 mm	2.4 days	β^+

the pharmaceutical requirements, but the half-lives of the parent nuclide, e.g., ^{225}Ac (with 10-day half-life) for ^{213}Bi (with 46-min half-life) and ^{212}Pb (with 10.6-h half-life) decaying to ^{212}Bi (with 60-min half-life), will limit shipping range.

In most alpha-emitting radionuclides, there is also question of the chemical composition of radioactive daughters in the radiopharmaceutical if there is a delay between the separation of the parent and the injection, for example, the time required for synthesis, quality control, and shipping if produced in a central radiopharmacy (Fig. 5 [35]). Lead-212 is by far the most complicated alpha emitter chain. The alpha emissions come from decay of ^{212}Bi, and so it is important that the Bi is still bound to the targeting molecule. The interesting point is that after 4 h, the ^{212}Pb (61 min) is in secular equilibrium with the daughters. Given that there is no easy method by which to separate the daughters from the radiolabeled antibody or peptide and most likely 4 h has passed since purification, the injection will contain radionuclides in different chemical forms, i.e., not all bound to the chelating agent [36].

Bismuth-213 decays by beta minus emissions (97.9%) to the very short-lived ^{213}Po and 2% by alpha decay to ^{209}Tl. This is interesting because if the ^{213}Bi is purified and chelated, the daughter has such an extremely short half-life that it will remain in the vicinity of the ^{213}Bi [35].

Astatine-211 has been used most often alpha emitter. The challenge is the chemistry of astatine because there is no stable isotope to carry out the necessary analytical studies. Astatine-211 has a half-life of 7.2 h. It decays with 58.3% probability through the electron capture process to ^{211}Po, which has a half-life of 0.52 s, and decays by emitting a 7.45 MeV alpha particle to stable ^{207}Pb. As a consequence of the electron capture process, polonium K X-rays are emitted that permit external imaging, and the two most abundant of these X-rays have energies of 77 and 80 keV with yields of 0.1 and 0.2 per disintegration [35].

Theranostics

Which of the therapeutic radionuclides have gamma-emitting radioisotopes that could be used in a theranostic application? In this situation, it is important to have the same metal (or halogen) for both applications to maintain identical chemistry. For example, it appears that ^{111}In as a gamma-emitting partner for ^{90}Y is not acceptable, whereas

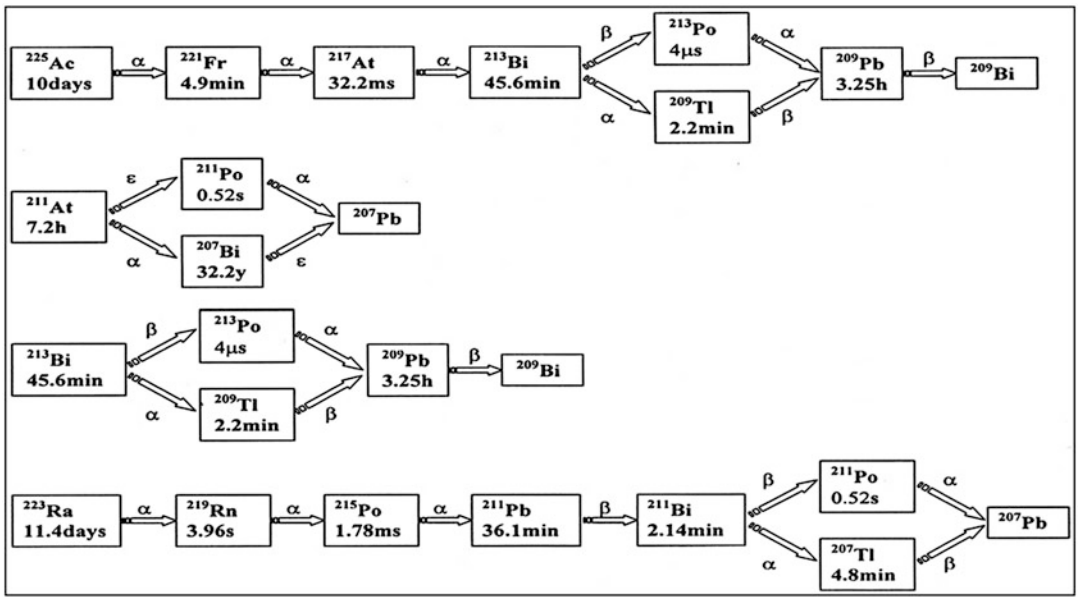

Fig. 5 Decay schemes for ^{225}Ac, ^{211}At, ^{213}Bi, and ^{223}Ra (Taken from Ref. [35] with permission)

^{86}Y is [37]. ^{211}At does not have a high-abundance gamma-emitting radioisotope (nor a stable isotope either), and so surrogates are necessary. The fission product metals generally do not have gamma-emitting radionuclides for imaging although some daughters emit gamma rays. But in decay schemes with multiple radioactive daughters, it is best if the gamma rays are emitted with the decay of the parent and not the decay of the daughters. Suggestions have been made to use bremsstrahlung imaging for ^{90}Y, which only emits high-energy annihilation gamma rays at very low abundance [38, 39].

Instrument Resolution and Biological Resolution

For theranostics, whether the use is in pre-approval studies to choose the optimal therapeutic and to monitor the success of that therapy, the goal of imaging smaller-volume lesions using quantitative emission tomography is crucial. External nuclear imaging is unique in its ability either to identify the target on cancer cells on a whole-body basis or to monitor the number of tumor cells using a radiolabeled biomarker that is targeting a high-density site that is independent of the treatment paradigm. The challenge of monitoring the same site targeted by the therapeutic is in the interpretation of a decrease in targeted radioactivity because a decrease could represent changes in the number of targets per tumor cells or a decrease in the number of tumor cells with the number of targets per cell constant or blocking by the mass dose of the therapeutic. This latter is less of a challenge in high specific activity therapeutic radiopharmaceuticals, but even in that case, achieving the maximal tumor dose may very well represent enough mass to occupy more than 5% of the target.

Monitoring the extent of the disease to include small lesions that are smaller than two to three times the instrument resolution requires a high target-to-nontarget (T/NT) ratio. Counting statistics, spatial resolution blurring, and target-to-background ratios influence the detection of small volumes by external imaging. In one example from 1999, Raylman et al. determined the detectability of small objects using a PET camera of that era with a resolution of ~9 mm [40]. In phantom studies, they found that spheres were detectable when larger than 9 mm in diameter if the target-to-background ratios exceeded 3:1. For smaller-diameter spheres, larger target-to-background ratio was required (18:1) to overcome the resolution blurring and the statistical uncertainty of background radioactivity. However, endogenous ligands radiolabeled with ^{11}C and radiofluorinated analogs of glucose, thymidine, choline, and acetate, along with other radioligands such as ^{18}F-fluoromisonidazole, ^{64}Cu-ATSM, and ^{18}F-florbetapir, have standardized uptake values (SUV) of 3 or lower for the cutoff between normal and abnormal lesions.

The lower resolution of SPECT can be countered with higher target-to-nontarget ratios for diagnostic radiopharmaceuticals. Furthermore, the higher target-to-nontarget ratios favor efficacious monitoring of therapeutic radiopharmaceuticals as described above. Togawa et al. imaged phantoms without scatter and attenuation corrections using a Toshiba three-head rotating SPECT system filled with $^{99m}TcO_4^-$. The FWHM of the SPECT system in this study was 13 mm, and the target-to-nontarget ratio obtained from the image of the phantom with a diameter of 46 mm (3.5 times that of the FWHM) shows a count recovery of 96.7 ± 6.2% of the actual target-to-background (T/B) ratio in the phantom as measured in a gamma counter. In contrast, the count recovery was 81.3 ± 7.2% and 68.1 ± 5.5%, respectively, even when the diameter was 37 mm (2.8 times that of the FWHM) and 29 mm (2.2 times that of the FWHM). For actual target-to-background ratios in the phantom ranged from 2.0 to 8.1 as measured in a gamma counter, the correlation coefficients increased from 0.037 to 0.165, respectively. The authors also reported the target-to-background ratio (T/B) multiplied by the diameter (d) to correct for the partial volume effect. Also, there was a significant linear correlation between T/NT • d obtained from the images and the actual T/B obtained from the gamma counter [41].

Recently, Zeintl et al. demonstrated the ability to obtain accurate data from phantoms in vitro and

in patients after injection of ^{99m}Tc-diphosphonate using SPECT/CT. Although the accuracy in phantom studies and measurements in vivo of radioactivity in the bladder were within 5%, the standard error reflects a need to increase the precision even further [42, 43].

A recent publication using a ^{68}Ga-radioligand for targeting PSMA gave tumor-to-gluteal musculature ratios at 3 h of 28.3 with a wide range between 2.9 and 224.0. These were based on 65 lesions considered typical for metastases or local relapse. The metastases were present in the bone and lymph nodes. Factors such as the radioactivity injected, the mass injected, the PSA value, the size of the lesion, partial volume losses, etc. were not correlated with the ratio by the authors. In a patient study, the ^{68}Ga-ligand uptake was detected in more tumors than were detected with ^{18}F-fluoroethylcholine, which has a lower tumor-to-background ratio [44].

Radiobiological Properties Affecting the Choice of Radionuclide

The most significant limitation of targeted radionuclide therapy is the heterogeneity of binding of radiopharmaceuticals in tumor deposits. Attempts have been made to overcome the nonuniformity of radiopharmaceutical uptake that results in underdosing of some tumor regions by the application of radionuclides that decay to emit long-range particles, so that neighboring nontargeted cells might receive a radiation dose by cross fire. Even with long-range radionuclides such as ^{131}I or ^{177}Lu, because their emissions are of low linear energy transfer (LET), subpopulations of tumor cells might experience less than a sterilizing dose.

An important aspect of targeted radiotherapy is the existence of radiation cross fire between cells, giving rise to a "radiological bystander effect," depending on the range of particles emitted by radionuclide disintegration. In other words, the dose absorbed by a cell depends on the radionuclide delivered to adjacent cells as well as to the cell itself. The principles guiding the selection of radionuclide for the treatment of tumor deposits of various sizes are illustrated in Fig. 6. The treatment of small clusters of malignant cells with a radionuclide whose decay particles are of long range may be energetically unfavorable (Fig. 6a). On the other hand, targeting a heterogeneous mass with a short-range emitter could result in underdosing of some regions (Fig. 6b). Alternatively, the treatment of a heterogeneous clump with a medium-range emitter may overcome the nonuniform deposition of radiation energy and increase the likelihood of delivering a lethal dose of radiation to all cells (Fig. 6c).

Radiation Microdosimetry and Particle Range

The killing of tumor cells by targeted radiotherapy is a consequence mainly of injury to DNA resulting from the traversal of particles (alpha, beta, Auger electrons) ejected from nuclides during radioactive disintegration (Fig. 7a, b, c). The contribution to cell kill by gamma photons is much less significant.

Decay particles have specific energy spectra and capacities for tissue penetration. Some features of therapeutic radionuclides are presented in Table 4. The finite ranges of emitted particles give rise to radiation microdosimetry considerations which are unique to targeted radiotherapy.

Most clinical experience has been acquired with beta emitters whose mean particle range is equivalent to several cell diameters. Therefore, the radiation dose to individual cells is the sum of *cross fire* – radiation emanating from neighboring cells which have accumulated radiolabeled agents – and radiation from radionuclide concentrated within the cell itself. In the case of radionuclides that decay to emit beta particles, cross fire is the most significant constituent of dose received by any cell. Conversely, no cross fire is associated with the uptake by cancer cells of Auger electron emitters. Accordingly, high-LET Auger therapy, while expected to be tumor specific, is anticipated to provide no compensation for heterogeneity of targeting. Then again, emerging evidence suggests that radioactive emission from targeted cells is not the only bystander effect operating in radionuclide

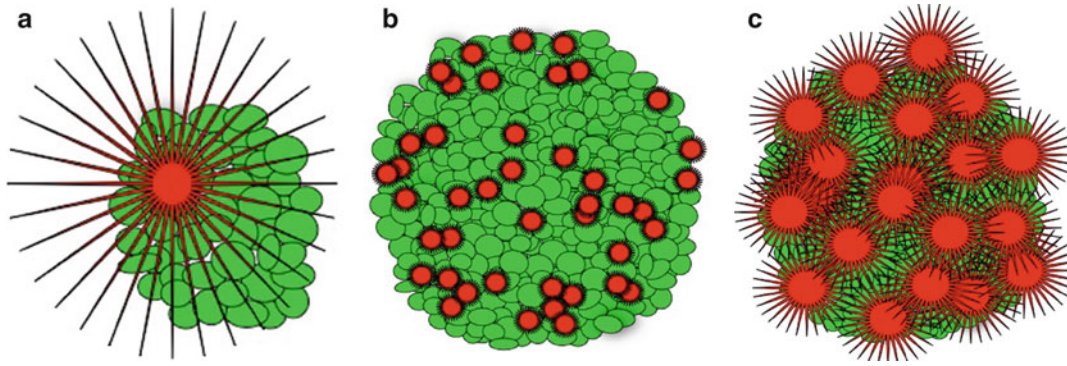

Fig. 6 The effect of target size and the LET of radionuclides. (**a**) Targeting a small heterogeneous clump of tumor cells with a long-range emitter. (**b**) Targeting a heterogeneous clump with a short-range emitter. (**c**) Targeting a heterogeneous clump with a medium-range emitter

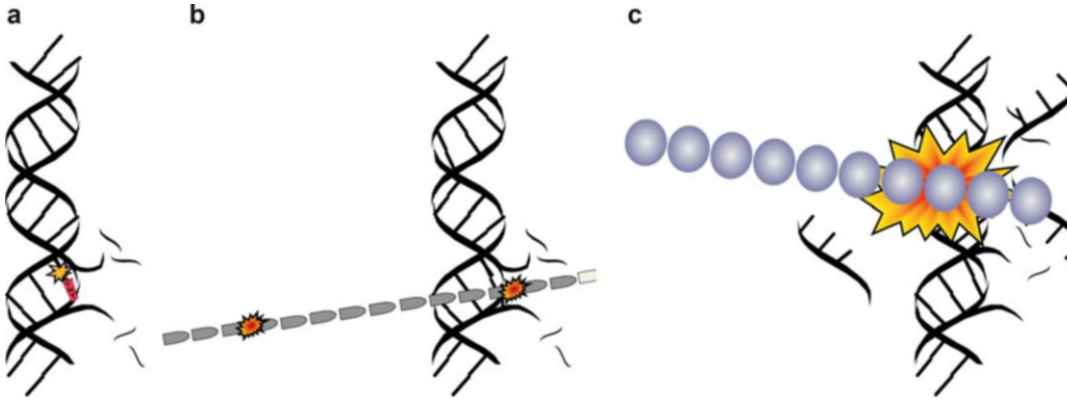

Fig. 7 The killing of tumor cells by targeted radiotherapy. (**a**) Localized damage by incorporation into DNA of an Auger electron emitter conjugated to a DNA building block – e.g., the thymidine analog [^{123}I]IUdR. treatment of cancer. It is becoming clear that radiation-induced biological bystander effects (RIBBEs) deriving from the cellular processing of the physical radiation insult, which need not interact directly with DNA, may play an important part in the overall efficacy of radionuclide targeting (see section "Radiation-Induced Biological Bystander Effects (RIBBEs)").

The dimensions of the tumor itself are very important. For micrometastases whose diameter is less than the range of decay particles, absorption of radiation energy is inefficient. Indeed a significant fraction of this energy is deposited outside the tumor [45]. Hence, microtumors will be underdosed and more resistant to sterilization. As tumor size increases, more decay energy is absorbed and the probability of cure is enhanced. However, as tumor size increases beyond particle range, the absorption efficiency reaches a plateau. Furthermore, the presence of a larger number of cells decreases the likelihood of successful treatment.

Such considerations were responsible for the concept of an optimal tumor size for maximal curability by specific radionuclides. Mathematical modeling has demonstrated that the optimal tumor diameter is slightly greater than the mean particle range of the radionuclide. For example, in the case of ^{131}I, homogeneously distributed throughout a tumor, the ideal diameter range for curability is 2.6–5.0 mm [46, 47]. However, with increasing

tumor size, the uptake of radionuclide will be increasingly nonuniform, resulting in greater resistance to radionuclide therapy of macroscopic tumors.

These predictions are supported by experimental evidence of the differential susceptibility to growth inhibition of multicellular tumor spheroids of a range of sizes treated with meta-iodobenzylguanidine (MIBG) labeled with [^{123}I]iodine, [^{125}I]iodine, [^{131}I]iodine, or [^{211}At]astatine [48]. MIBG is selectively accumulated by an active mechanism in cells of neural crest origin [49, 50], and conjugates of ^{123}I and ^{131}I are used for the imaging and therapy, respectively, of neuroendocrine tumors.

The Auger electron-emitting conjugates ([^{123}I]MIBG and [^{125}I]MIBG) and the alpha-emitting conjugate ([^{211}At]MABG) were highly toxic to small spheroids, whereas the beta-emitting conjugate [^{131}I]MIBG was relatively ineffective. Furthermore, the Auger electron emitters were more effective than expected, given the extranuclear localization of MIBG. As dosimetrically predicted, however, [^{211}At]MABG was extremely potent in terms of both concentration of radioactivity and number of atoms per unit volume administered. In contrast, the Auger electron emitters were ineffective in the treatment of larger spheroids, while the beta emitter showed greater efficacy [48]. These findings suggest that short-range emitters would be well suited to the treatment of circulating tumor cells or small clumps, whereas beta emitters would be superior in the treatment of subclinical metastases or macroscopic tumors. Such experimental results provide support for a clinical strategy of combinations ("cocktails") of radioconjugates in targeted radiotherapy.

The Choice of a Chemical Platform

Salts and Covalent Bonds

Some of the diagnostic and therapeutic radionuclides are simple salts: sodium ([^{123}/^{131}I]iodide), [^{67}/^{68}Ga]Ga citrate, ^{201}Tl chloride, ^{223}Ra dichloride, and Na [^{18}F]fluoride. Others are covalently bound to the targeting molecule, for example, *meta* [^{123}/^{131}I]iodobenzylguanidine (MIBG). Likewise, ^{211}At is covalently bound to the targeting molecule. In all cases the stability of the covalent bond is crucial given that in diagnostic agents, the emitted photons do not reveal the chemical structure of the radiotracer and in therapeutic applications it is important that the radionuclide remains with the targeting molecule for maximal therapeutic index [51].

Chelating Agents

To develop a true tracer of a targeting peptide or protein using a bifunctional chelate, the metal must be kinetically inert to hydrolysis and exchange labeling with endogenous proteins in vivo. In addition, metal targets to produce the radioactive metal, solvents, and all containers are potential sources of nonradioactive metals, which can reduce the effective specific activity and lead to possible saturation of a targeted site [52]. The same is true for the residualizing agents labeled with radiohalogens. The effective specific activity of [^{76}Br]bromide can also be lower than the specific activity itself given impurities in the metal target as well as the reagents used in the purification [53].

Brechbiel has pointed out that many chelating agents are misnamed because one of the functional groups has been used to link to the targeted molecule. His recommendation is to link to the targeted molecule using a carbon atom in the backbone to maintain the full functionality of the chelating moiety. He has demonstrated the relative inertness for both acyclic and cyclic (macrocyclic) chelating agents using the latter approach [54].

Endogenous proteins are strong competitors for Ga, Zr, and Cu. Transferrin has a high affinity for Ga. The Ga in Ga-citrate is thought to be transferred to transferrin after injection, and therefore Ga-transferrin is the targeting entity. There may be other proteins that bind Ga as well such as lactoferrin and serum proteins [55].

^{89}Zr-desferrioxamine B (DFO) appears to be stable to metal exchange with serum in vitro, but

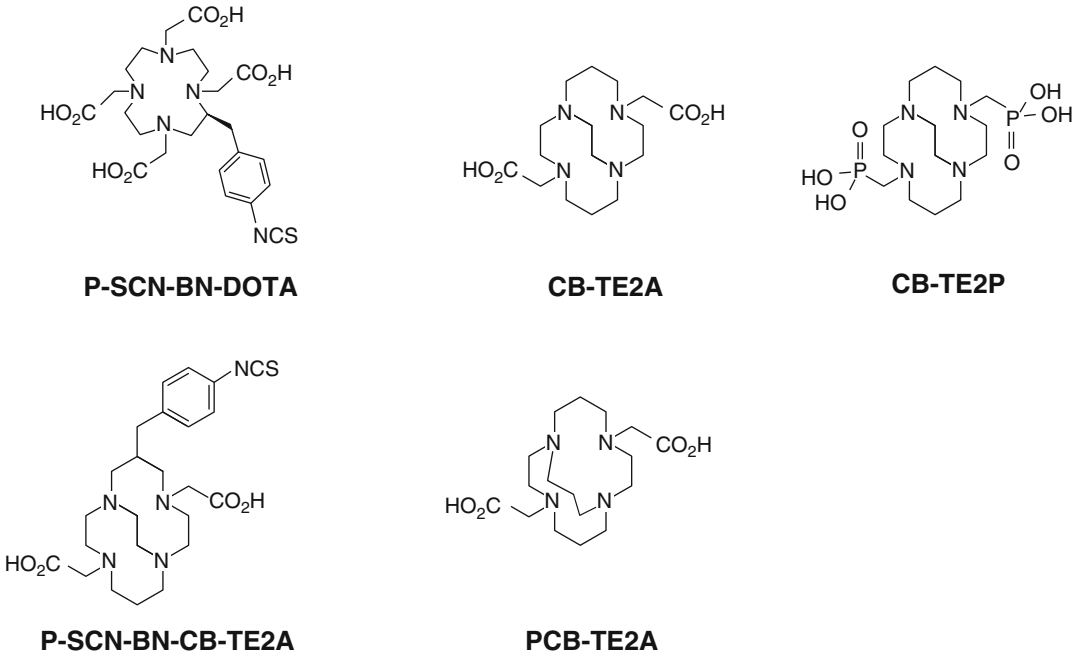

Fig. 8 Structure of ^{64}Cu chelating agents based on 1,4,8,11-tetraazacyclododecane-1,4,8,11-tetraacetic acid (TETA) (Taken from Ref. [61] with permission)

in vivo Zr-DFO shows bone uptake, but significantly less than Zr-citrate [56]. In vivo, transferrin may also be involved in trans-chelation of Zr. Although transferrin receptor upregulation has been demonstrated in specific tumors, enhanced permeability and retention (EPR) effect [57] could also be a factor in the uptake [58]. Earlier studies comparing ^{18}F-albumin and ^{18}F-transferrin in a tumor model containing upregulated transferrin receptor reported higher uptake with albumin rather than transferrin illustrating that the EPR effect could produce higher uptake compared to receptor binding. With the ^{18}F label, the transferrin and albumin were directly assayed by radiolabeling the protein rather than via the chelated metal [59].

Superoxide dismutase (SOD) competes with weaker chelating agents for Cu in vivo and has been identified as one competing protein for Cu that results in higher liver uptake in vivo [60]. Cai and Anderson outlined a more complete listing of Cu-binding proteins in vivo including ceruloplasmin, metallothionein, copper transporters, and chaperones. A cross-bridged macrocyclic chelator, namely, CB-TE2A, was the most inert of the first generation, but the labeling conditions were too harsh for peptides or proteins. One of the first cross-linked macrocyclic chelators that had a propylene bridge in place of the ethylene bridge in CB-TE2A proved to yield milder labeling conditions, followed by the phosphonate-armed chelators which also can be radiolabeled at room temperature (Fig. 8) [61].

The copper transporter has drawn interest because Cu salts appear to localize in cells via the copper transporter. If the Cu can be transferred to the Cu transporter present in hepatocytes and upregulated in tumor cells, this constitutes another pathway to use Cu radionuclides in diagnostic or therapeutic radiopharmaceuticals. The earliest report appears to be from Apelgot et al., who found that 42% of the ^{64}Cu in mouse ascites fluid after i.p. injection of [^{64}Cu]$CuCl_2$ was isolated with the DNA fraction. The electron capture emissions are effective if the metal is associated with DNA. Then the nuclear transformation (transmutation) with the associated changes with decay can produce a lethal event [62]. Others have

followed these early studies with in vivo studies in tumor-bearing mice [63–66].

There is an interesting analogy with the chemotherapeutic, cis-diamminedi-chloroplatinum(II) (cis-Pt), which enters cells via the copper transporter and then binds to the guanine bases in DNA after the two chlorine atoms hydrolyze in the lower pH milieu. Cross-linking DNA through either inter- or intrastrand cross-links seems to be the mechanism of action. Wolf carried out experiments with ^{195m}Pt cis-platinum and reported that the ^{195m}Pt catabolite was bound irreversibly to plasma proteins [67]. The subcellular distribution %ID/g ($\times 10^{-2}$) of ^{195m}Pt 4 h after injection of ^{195m}Pt cis-platinum in tumor-bearing rats was 0.43 in DNA, 4.13 in chromosomal proteins, and 4.2 in cytosolic ligands [68]. However, the DNA binding seems key to the therapeutic action of the drug.

Whether a copper salt will be as effective as a bifunctional chelate containing radiocopper is a question not yet answered. Certainly, the copper salt is taken up in the liver via the receptors in hepatocytes, whereas the biodistribution between the liver and kidney for the bifunctional chelates can be altered, for example, by changes in the linker between the chelate and the targeting molecule.

There is some question of the therapeutic index of fission product radionuclides if through multiple decays the daughter radionuclides do not remain with the chelating agent. Boswell and Brechbiel report a general percentage of released radionuclide to be 30% [33]. The loss of decay product daughters from beta decays is variable. Recently a publication on ^{44m}Sc/^{44}Sc indicates that there is no release during decay [69]. And, of course, catabolism of the linker between the chelating agent and the targeting molecule must be stable to various enzymatic and hydrolytic processes.

Another key consideration for bifunctional chelates is whether the perturbation caused by the linker and metal chelate alters or hinders binding to the target. The tracer principle at least for the biochemistry required for the diagnosis or therapy must be validated. Concern for the perturbation caused by the metal chelate is most often reported, but simple replacement of a hydrogen or hydroxy group with fluorine is not without consequences [70, 71].

In summary, since external imaging for diagnostics and therapeutic index are based on localization of the injected radiopharmaceutical, a kinetically inert covalent bond for the halogens and an inert metal chelate are crucial. It is key for therapeutic radiopharmaceuticals that the radionuclide remains as part of the targeted bifunctional chelate to maximize tumor damage and minimize normal tissue damage. The bystander effect is important. In small animals it could represent a significant effect that won't be characteristic of the human distribution. Furthermore, the lesser effect in Auger electron therapy may necessitate the need for nuclear uptake in a higher percentage of cells.

The Location of the Target: The Challenges of Designing Radiotracers for Intracellular Compartments

Cell surface targets represent a large percentage of the therapeutic targets to date. Internalization of the cell surface target is an advantage if it is a residualizing radiopharmaceutical, that is, it remains within the cell. Metal chelates have been superior to iodinated compounds in that respect because if iodide or iodotyrosine is a catabolic product, the efflux from the cell will be significant. For metal chelates, anion production is less likely, and trans-chelation to an endogenous protein is also a possibility for retaining radioactivity within a cell [6].

DNA and mRNA have been targets, but the small copy number and the challenge to design radiopharmaceuticals that demonstrate efflux of non-bound therapeutic radiopharmaceutical have prevented widespread success. Recently, Lewis et al. have targeted mRNA of bcl-2 using an antisense approach [72]. In this case alpha and beta emitters are preferred depending on the size of the tumor. In general, the targeting of intracellular epitopes is not as developed as targeting a cell surface protein [73].

The emission that is most dependent on location is Auger electron emissions, which must

localize in the nucleus, preferably binding to DNA, to be effective. Radioiodinated estradiol is an interesting example of transfer to the nucleus. DeSombre et al. studied two Auger electron emitters, namely, ^{80m}Br and ^{125}I. 2-[^{80m}Br]Bromo-l,l-bis(4-hydroxyphenyl)phenylethylene (^{80m}Br-BHPE) and the steroidal estrogen 17-alpha-[^{80m}Br]bromovinylestradiol both showed saturable binding to the estrogen receptor, but the decay product of ^{80m}Br, namely, ^{80}Br, emitted beta particles and gamma rays and therefore produced radiation dose, but lower cell killing [74]. ^{80m}Br is also not readily available. Next DeSombre compared [^{125}I]iododeoxyuridine ([^{125}I]IdU) and E-17-alpha ([^{125}I]iodovinyl-11-beta-methoxyestradiol ([^{125}I]IVME2) in vitro in MCF-7 cells expressing estrogen receptors. Both cell kill and double-strand breaks were equivalent for the two radiopharmaceuticals [75]. The analysis of the number of receptors per cell, the achievable specific activity, and the residence time dictated that ovarian cancer metastases in the peritoneal cavity may be a more successful approach [76]. Nevertheless, experiments in animals and theoretical calculations demonstrate the need for a large number of receptors per cell, near-theoretical specific activity of ^{123}I, and hundreds of millicuries of ^{123}I. Given the cost of cyclotron production of very high specific activity of ^{123}I, human studies to affect metastases in the peritoneal cavity have not begun, but rather there is a search for a much higher-affinity constant radioligand to increase the residence time in the cell nucleus.

Antibodies and other high molecular weight proteins or particles have advantages and challenges. Many of the challenges of the size and the consequent lower permeability can be overcome by targeting proteins in the "peritoneum, pleura or intrathecal space or to radiosensitive tumors associated with the hematological system" [77]. The challenges in designing a therapeutic radiopharmaceutical such as radiolabeled estradiol and radiolabeled antibodies are similar. The location plays a part, but the choice of radionuclide, the inertness of the bifunctional chelate, the residence time in the tumor matched with the physical half-life of the radionuclide, the scale and scope of the disease, and the absorbed dose sensitivity of the targeted tumor all come into play.

For small molecules, cell surface targets have been used most often given the access from the blood stream after IV injection. Internalization is a function of the cell as is active transport. To reach a target in the cytosol, the radiopharmaceutical must cross the cell membrane either by passive diffusion or active transport. 2-Fluoro-2-deoxyglucose enters cells via the GLUT transporter and then is metabolically trapped in the cell as the 6-phosphate. [^{11}C]-*meta*-Hydroxyephedrine is taken up in myocytes by the norepinephrine receptor and metabolically trapped. To target DNA or another target in the nucleus requires transfer across another barrier. Estradiol is carried to the nucleus by several active processes.

The major questions in both cytosolic and nuclear localization are whether enough radiopharmaceutical can be delivered to the compartment and whether radiotracer not bound to the target can be removed quickly so that the detected emissions are bound radioactivity and for radionuclide therapy the decay occurs at the target.

Critical Subcellular Sites of Interaction with Ionizing Radiation (Direct Effects)

The Auger electron emitter ^{125}I is highly cytotoxic when concentrated in the cellular nucleus as the thymidine analog 5-[^{125}I]iodo-2′-deoxyuridine (^{125}IUdR) [78]. Moreover, the antitumor efficacy of Auger electron-emitting ^{123}I or ^{125}I conjugated to IUdR has been demonstrated in an ascites tumor model [79, 80]. Therefore, the observation that Auger electron emitters conjugated to benzylguanidine are capable of killing neuroblastoma cells raises questions about the intracellular site of concentration of MIBG and the mechanism of cell kill. Several postulates could account for these findings. MIBG may be taken up by the cell's nucleus. It is also possible that other cellular structures are susceptible to bombardment with Auger electrons – for example, mitochondria. Alternatively, particles other than Auger electrons emitted during the decay of ^{123}I and ^{125}I may have

sufficient range to penetrate the nucleus of a targeted cell. A fourth possibility is that MIBG labeled with Auger electron emitters mediates cell kill through apoptosis triggered by a novel mechanism.

The conventional opinion is that the critical cellular target for ionizing radiation damage is nuclear DNA. Therefore, ultrashort-range radionuclides, such as Auger electron emitters, should be toxic only if delivered to the nucleus of the target cell (Fig. 7a) [81]. This is supported by studies in vitro – using extracellular $Na^{125}I$, cytoplasmic [^{125}I]iododihydrorhodamine, and nuclear ^{125}IUdR, which demonstrated that significant toxicity was associated only with the ^{125}I located in the nucleus [82]. Similar results have also been observed in vivo by Link et al. who compared the therapeutic efficacy of ^{125}I- and ^{211}At-labeled methylene blue to treat mice bearing malignant melanoma [83]. Only ^{211}At-labeled methylene blue produced significant therapeutic effects. As the subcellular fate of this targeting agent is cytoplasmic, it was concluded that ^{125}I-labeled methylene blue was located too far away from the genome to be cytotoxic [83]. Although it has been shown that MIBG concentrates mainly in the cytoplasm of neuroblastoma cells [84, 85], the demonstration that significant cell kill can be achieved with ^{125}I- or ^{123}I-labeled MIBG could represent evidence for a nuclear localization of MIBG. The amount of drug accumulated at this site may be undetectable by conventional means but nevertheless capable of delivering a toxic dose of radiation to the cell nucleus.

Alternatively, MIBG conjugated to Auger electron emitters could be cytotoxic through damage to the mitochondria. Subcellular localization studies have identified mitochondria as sites of MIBG accumulation [84]. Mitochondrial toxicity could result from disruption of inner mitochondrial membrane proteins or by direct effects on the mitochondrial genome. Indeed, mitochondrial DNA is particularly susceptible to radiation damage because of its limited capacity for repair [86].

It is also conceivable that some particles emitted during the decay of ^{123}I and ^{125}I may have sufficient range to reach genomic DNA of a targeted cell despite cytoplasmic or perinuclear localization. Although the entire Auger and Coster-Kronig electron spectra for these radionuclides have not been measured experimentally, calculations using theoretical transition rates and energies indicate that both isotopes emit some electrons with ranges of the order of the radius of a mammalian cell [87, 88]. Assuming a cytoplasmic location for MIBG, it is possible that such emissions would deliver significant doses of radiation to the nucleus. However, this possibility is not supported by the classical experiments of Kassis and colleagues described earlier [82].

A more exotic possibility is that Auger electron irradiation of cytoplasmic targets achieves cell kill by an indirect route, such as the triggering of apoptosis in susceptible cells. Some workers have reported that apoptosis-mediated cell death may result from membrane damage and the consequent generation of ceramide [89, 90] and that this process may be initiated by ionizing radiation damage to cell membranes [91].

Insight into the consequences of nonnuclear targeting of Auger electrons has been provided by Pouget and colleagues (see also section "Critical Subcellular Sites of Interaction with Ionizing Radiation (Indirect Effects)"). Using in vitro and in vivo models, they reported substantial antitumor efficacy of membrane-bound ^{125}I-labeled monoclonal antibodies (^{125}I-mAbs). Moreover, the observed cytotoxicity was greater than that associated with internalizing ^{125}I-mAbs [92, 93].

Previous supporting experimental evidence demonstrating Auger electron-induced cell kill at a distance greater than its path length was provided by Xue et al. following treatment of human colon LS174T adenocarcinoma cells with ^{125}IUdR [94].

Radiation-Induced Biological Bystander Effects (RIBBEs)

The foregoing account of investigations designed to overcome the inefficiency of targeted radiotherapy due to nonuniform uptake of radionuclide in tumors considered only the damage inflicted to neighboring nontargeted cells resulting from cross fire irradiation. According to conventional

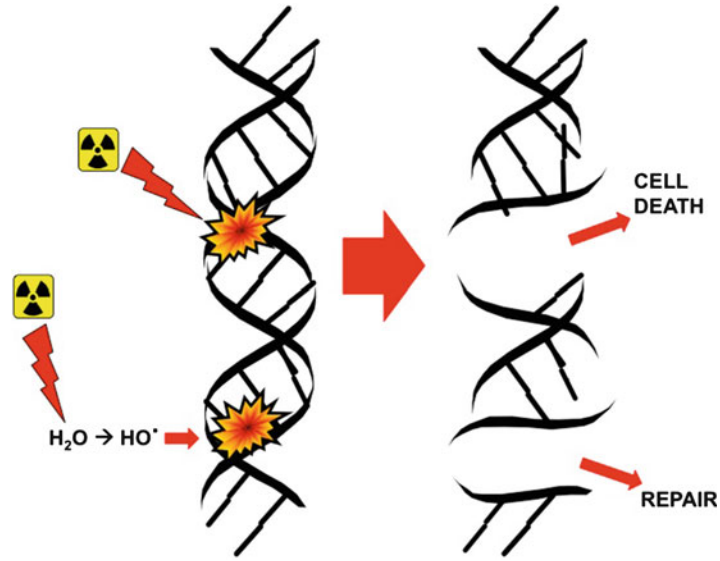

Fig. 9 Traditional concept of the effect of ionizing radiation

opinion, radiation bombardment of DNA (hitherto assumed to be the only significant subcellular structure), either directly or through the intermediacy of oxygen-containing radicals, creates damage which is lethal or repairable (Fig. 9). However, in recent years, numerous studies have demonstrated that factors other than physical aspects of ionizing radiation are responsible for the death of malignant cells that are not directly irradiated during a course of radiotherapy (Fig. 10). It is becoming clear that radiation-induced biological bystander effects (RIBBEs) deriving from the cellular processing of the physical radiation insult, which need not interact directly with DNA, may play an important part in the overall efficacy of targeted radiotherapy (Fig. 11).

After irradiation, cells expel toxins whose consequences to neighboring, unirradiated (bystander) cells include mutation, chromosomal breakage, long-term genomic instability, and death [95–101]. Bystander effects may be induced by radiation dosage as low as 3 mGy. Such exposures are of **safety** concern in diagnostic imaging and intensity-modulated radiotherapy. Accordingly, it is important to understand the mechanisms underlying bystander effects and how these may be manipulated to enhance tumor cell kill.

RIBBEs are most appreciable at low radiation dose and low dose rate [102–106]. These are features of targeted radionuclide treatment of cancer [107]. Therefore, bystander effects induced by radiopharmaceuticals may play a disproportionately large part in their efficacy, and understanding their nature should enable the refinement of this form of radiotherapy. The mechanisms involved are as yet undefined. However, studies using γ-ray and α-particle beams have provided some insight into possible factors. These include oxidative stress [108] (leading to increased radical formation [109, 110]), nitric oxide release [111, 112], cytokine release [113], gap junctional intracellular communication [114], and cellular immunity [115–117]. Agents implicated in bystander signaling have been reviewed [104, 108, 118, 119].

Although substantiation of bystander effects has been gained predominantly through studies involving external beam γ-irradiators and microbeams, some studies have been conducted of RIBBE consequent to the intracellular concentration of radiolabeled drugs. In clusters of unlabeled and [^{3}H]thymidine-labeled cells, death of unlabeled cells was deemed to result from transmission of cytotoxins from cells which had incorporated [^{3}H]thymidine in their DNA rather than

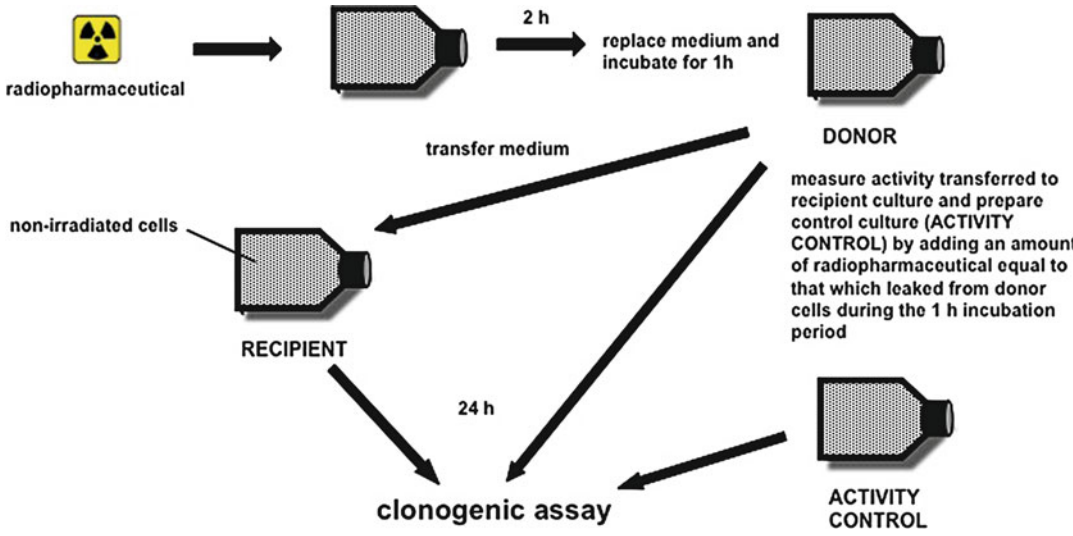

Fig. 10 Manifestation of radiation-induced biological bystander effects (RIBBEs)

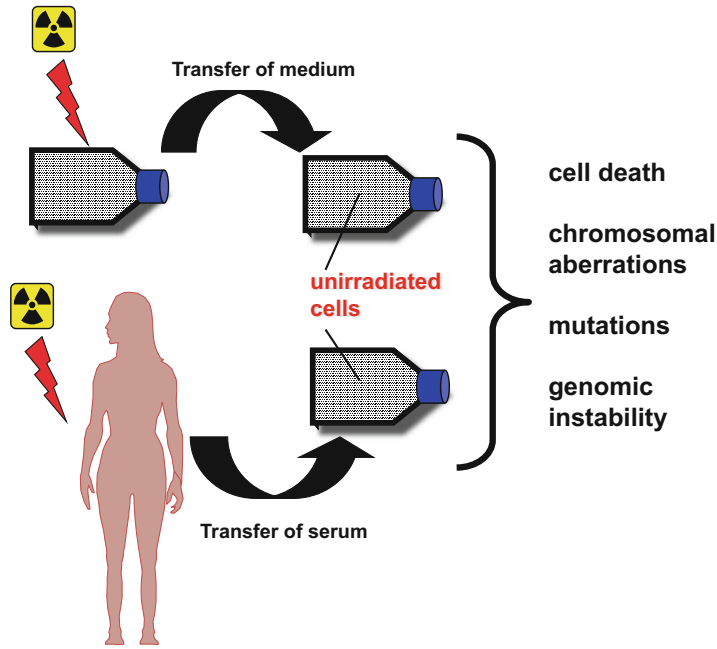

Fig. 11 The radiation-induced biological bystander effect entails the transfer of death signals from irradiated to unirradiated cells

cross fire irradiation because ^{3}H beta-decay particles have insufficient range to impinge upon adjacent cells [120]. Unlabeled cells were protected by dimethyl sulfoxide and lindane, implicating free radicals and gap junctional communication, respectively [121, 122]. Similarly, Xue et al. created tumors in nude mice composed of colon carcinoma cells, unlabeled or containing ^{125}IUdR [94].

Again, inhibition of tumor growth was attributed to RIBBEs because the path length of ^{125}I Auger electrons is too short for direct interaction with neighboring cells. The latter investigation demonstrated that RIBBEs are not simply artifacts

of in vitro manipulations but are significant growth inhibitory factors in vivo [123]. In an analogous study, Mamlouk et al. co-cultured [^{125}I]IUdR-treated lymphocytes with LS174T colon adenocarcinoma cells. This induced a reduction in the rate of proliferation of the malignant cells due to the release of inhibitory factors from the irradiated lymphocytes. The absence of cross fire as a confounding element was confirmed, by the mixture of unlabeled with labeled cells, resulting in loss of bystander response [124]. Akudugu et al. demonstrated that the capacity to succumb to ^{125}I-induced bystander signals is not universal but is dependent on phenotype [125]. The treatment of lymphoid cells with antibodies, labeled with the alpha and beta-particle emitter ^{213}Bi, produced a greater than expected cytotoxicity indicative of RIBBE [126]. This notion was supported by subsequent modeling studies of the outcome of cellular labeling with the alpha emitter ^{210}Po [127].

Significantly, distinct signaling pathways have been observed to participate in the restitution of DNA in directly irradiated compared with untargeted cells. In directly irradiated cells, the kinases ataxia telangiectasia mutated (ATM), ATM and RAD3 related (ATR), and DNA-dependent protein kinase were all required for DNA restitution, whereas the activity of ATR and ATM, but not DNA-dependent protein kinase, resulted in diminished survival of bystander cells [128]. This indicates opportunities for either sensitization or protection specifically of targeted or bystander cells or tissues through alteration of the activity of DNA damage sensors and repair enzymes.

Critical Subcellular Sites of Interaction with Ionizing Radiation (Indirect Effects)

Cell Membrane While DNA has long been regarded as the main target of the harmful consequences of ionizing radiation, it was proposed more than 50 years ago that damage to intracellular sites other than DNA could account for the cytotoxicity of ionizing radiation [129]. Experimental evidence indicates that the cell membrane is an important location for interaction with radiation and free radicals, resulting in the formation of cross-linkage between protein and DNA [130]. Radiation exposure stimulates translocation from lysosomes to the cell membrane of sphingomyelinase [131]. This catalyzes the hydrolysis of membrane-associated sphingomyelin to ceramide which, in turn, activates various kinases and transcription factors resulting in programmed cell death [132]. The plasma membranes of cells contain combinations of glycosphingolipids and protein receptors organized in glycolipoprotein microdomains termed lipid rafts. Notably, ceramide-cholesterol complexes are responsible for the development of lipid rafts which play a significant role in cell signaling [119].

In contrast to the expectation that ultrashort-range, Auger electron emitters must localize in the vicinity of DNA to have cytotoxic effect, it has been demonstrated, in vitro and in vivo, that non-internalizing antibodies, directed against carcinoembryonic antigen (CEA) and labeled with ^{125}I, have significant antitumor effectiveness. Moreover, the potency of these membrane-associated ^{125}I-antibodies was greater than that of internalizing ^{125}I-antibodies with specificity for human epidermal growth factor receptor (HER1). DNA damage-centered signaling pathways are effectively activated during low dose-rate Auger radioimmunotherapy [133]. The antitumor efficacy of ^{125}I-non-internalizing antibodies was not due to a deficiency in DNA damage recognition; nor was it induced by membrane-activated apoptosis; nor was it related to the mean absorbed dose to the nucleus. Instead, it was proposed that bystander factors were involved [106]. These findings imply that nuclear accumulation of ^{125}I is not necessary for its toxicity which is mediated predominantly by bystander effects independent of the subcellular site of localization (nuclear or cell membrane) of ^{125}I.

Mitochondria Mitochondria make up 4–25% of cell volume, rendering them prospective targets for radiation trajectory, and it has been suggested

that cells can be sensitized to radiation as a result of impaired mitochondrial function [134]. Mitochondrial DNA is more susceptible to oxidative damage than nuclear DNA due to its proximity to the main site of generation of reactive oxygen species (ROS), the electron transport chain. Furthermore, mitochondrial DNA is not associated with protective histone proteins and has lower efficiency repair mechanisms [135]. Reports of oncogenic products acting to maintain, in cancer cells, elevated numbers of mitochondria [136] which generate excessive ROS, particularly in response to hypoxia [137], have stimulated the development of agents that enhance mitochondrial ROS production, resulting in the apoptosis selectively of cancer cells [138]. According to the ROS threshold hypothesis [139, 140], low levels of ROS are necessary for the maintenance of cellular metabolism, whereas excessive ROS can be cytotoxic. Therefore, the lethality of ionizing radiation and some chemotherapeutic agents is hypothesized to be due to increasing ROS concentrations to cytocidal levels preferentially in tumors which typically have elevated levels of ROS and impaired antioxidant activity as a consequence of higher rates of proliferation and metabolism [141]. The sensitivity of cancer cells to therapeutic schemes which stimulate cell death through ROS production encourages their application in combination with the specificity afforded by targeted radiotherapy.

Significantly, mitochondria of both directly and indirectly irradiated cells are also involved in the initiation of programmed cell death [142] via the loss of apoptosis-inducing proteins – cytochrome C and apoptosis-inducing factor [143]. Improved understanding of the involvement of mitochondria in the cellular response to ionizing radiation is expected to stimulate innovative targeted therapeutic strategies.

Transfectant Mosaic Spheroid Model

To adequately represent therapeutic effects upon micrometastases (a major aim of targeted radionuclides), a three-dimensional culture system is necessary. Multicellular tumor spheroids were first described by Sutherland et al. [144], and since then, they have been utilized for a variety of experimental applications including tumor response to various treatments [145–148], basic cell biology [149], and investigations of microenvironmental influences on cell growth [150]. Beyond about 300 μm diameter, spheroids from most cell lines have a well-characterized structure, comprised of a necrotic core composed of quiescent or moribund cells surrounded by a viable rim of proliferating cells. This arrangement loosely mimics the initial avascular stages of solid tumor growth in vivo, with highly proliferative activity in proximity to capillaries ranging to necrotic regions at larger distances [151]. As a result, multicellular tumor spheroids have been utilized in a variety of experimental cancer therapy studies relevant to the treatment of micrometastases [152].

Transfectant mosaic spheroids (TMS), composed of different proportions of transfected and non-transfected cells [153], are representative of small tumors in which a range of efficiencies of tumor cellular targeting are achieved (Fig. 12). In order to discriminate between the different cells,

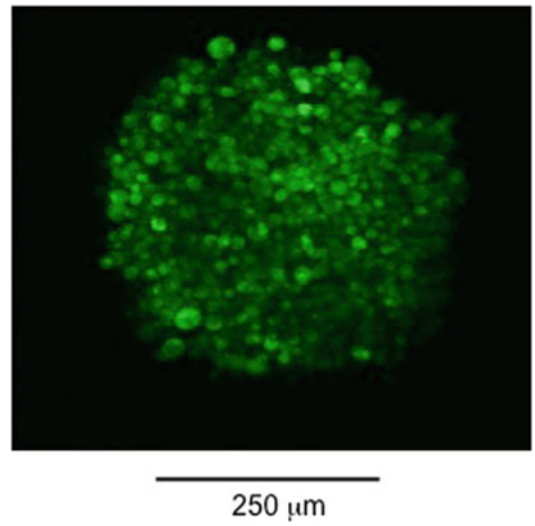

Fig. 12 Expression of jellyfish green fluorescent protein (GFP) in a transfected mosaic spheroid composed of 50% norepinephrine transporter-expressing cells and 50% GFP-expressing cells

the green fluorescent protein (GFP) gene was utilized as a transfection marker for identification, by fluorescence-activated cell sorting analysis and fluorescent confocal microscopy [154], of the cells which had not been transfected with the therapeutic transgene – the norepinephrine transporter gene – enabling MIBG targeting. Fluorescence imaging revealed uniform distribution of GFP-expressing transfectants in TMS. The observed heterogeneous dispersal of the two different transfected cell types was independent of their proportional contribution to the total spheroid mass. FACS analysis of disaggregated TMS confirmed that the ratio of norepinephrine transporter gene transfectants to GFP transfectants in various single-cell mixtures used for the production of TMS was accurately reflected in the percentage of the two types of cell in the spheroids [155]. The TMS model could be used to represent various densities of target expression in metastases. However, it should also be possible to create mosaic spheroids composed of transfected peripheral rims or central regions. Such models could be used to represent heterogeneous uptake of radiopharmaceutical which are dependent upon cellular proliferation or hypoxic promotion of expression, respectively.

TMS were used in the preliminary study of a gene therapy/targeted radiotherapy strategy which conferred the potential for uptake of radiolabeled MIBG by introduction of the norepinephrine transporter gene to cells which previously did not express it [156]. This facilitated the evaluation of the minimum percentage of transfection required to achieve cure of various sizes of metastases. A potentially beneficial substitute for ^{131}I is the heavy halogen astatine-211 (^{211}At) [157]. The α-decay particles of ^{211}At are highly cytotoxic and have a range of 55–70 μm, enhancing the prospect of tumor-selective damage. Moreover, the cytocidal efficiency of α-particles is independent of tumor hypoxia and growth rate [158]. Boyd et al. [153] reported that radioactivity concentrations <20 kBq/ml of [^{211}At]MABG induced the complete sterilization of all clonogens in 250 μm diameter mosaic spheroids composed of only 5% NAT gene transfectants. Because the path length of ^{211}At α-particles is only 55–70 μm, cross fire irradiation from targeted to untargeted cells would be considerably less extensive than that from a β-emitter such as ^{131}I. Therefore, this observation suggests that bystander effects, over and above cross fire irradiation, are operating in α-particle targeted therapy.

These studies indicate the potential for bystander-mediated cell kill and improved clinical efficacy of tumor targeting when only a small proportion of the tumor mass expresses the radiotherapeutic molecular target, in this case, introduced via gene modification. Moreover, RIBBE could compensate for the low levels of gene delivery currently achievable in vivo in cancer gene therapy strategies when married with targeted radionuclide therapy. Rational selection of radiohaloconjugates of MIBG will enable the enhancement of cross fire to maximize neuroblastoma cell kill.

Transfectant Mosaic Xenograft Model

To determine the toxicity of bystander signals in vivo elicited by cells which accumulated Auger electron-emitting radionuclides, Xue et al. incorporated [^{125}I]IUdR into adenocarcinoma cells and mixed these with unlabeled cells before implantation in rodents [94] (see sections "Critical Subcellular Sites of Interaction with Ionizing Radiation (Direct Effects)" and "Radiation-Induced Biological Bystander Effects (RIBBEs)"). They reported inhibition of tumor growth as a consequence of factors released from the labeled cells. The transfectant mosaic xenograft (TMX) model described by Mairs et al. is an alternative means of determining the importance of bystander effects in vivo [159]. TMX were established by subcutaneous injection into athymic mice of tumor cells comprising various proportions of norepinephrine transporter (NET) gene transfected to parental cells – a likely clinical scenario during the development of metastases of neuroendocrine tumors in vivo.

In TMX, following the administration of [^{131}I]MIBG, retardation of tumor growth was observed in tumors comprising only 5% NET

positivity. Moreover, the inhibition of TMX growth by [^{131}I]MIBG treatment was directly related to the proportion of NET-expressing cells. TMX may be suitable for the examination of quantitative aspects of radionuclide treatment and gene therapy. For example, this model will allow, for the first time, the determination of the minimal NET expression necessary for the imaging and sterilization by radiolabeled MIBG of tumors of a range of sizes which are one to two orders of magnitude greater than TMS. The TMX model will also facilitate the determination of optimal therapeutic dosage in relation to normal tissue toxicity and the evaluation of the influence of bystander effects in targeted radiotherapy in vivo.

Media Transfer

For determining radiopharmaceutical-induced biological bystander responses in vitro, Boyd et al. [103] employed an adaptation of the media transfer system developed by Mothersill and Seymour [96]. This allowed their comparison of the induction of bystander effects by external beam γ-radiation with those generated by MIBG labeled with radionuclides emitting ß-particles, α-particles, or Auger electrons [103] (see section "LET and Dose Rate"). The cells used in these experiments were transfected with the norepinephrine transporter (NET) gene to facilitate the active uptake of radiolabeled MIBG. Control cells were untransfected, hence incapable of active accumulation of MIBG. For investigation of RIBBE following γ-irradiation, donor cells were directly irradiated, and their medium was transferred to recipient cells which were not directly irradiated. Twenty-four hours later, cell kill was determined by clonogenic assay. To control for killing of recipient cells due to the transfer of effluxed radiopharmaceutical, a set of cells, designated activity controls, was prepared. Their medium received radiopharmaceutical activity equivalent to that which had leaked from donor cultures (treated with a range of activity concentrations) and would have been transferred to recipient cells (Fig. 13).

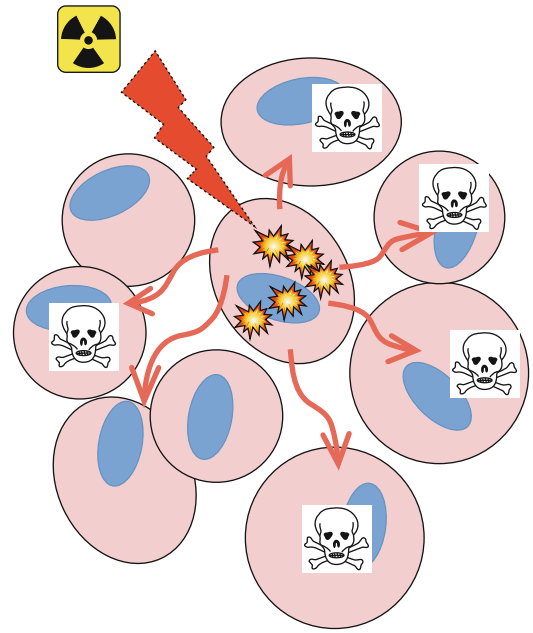

Fig. 13 Procedure for evaluation of cytotoxic bystander effect induced by radiopharmaceutical treatment

LET and Dose Rate

Using the media transfer methodology described in section "Experimental Models," Boyd et al. [103] observed that glioma or bladder carcinoma cell lines exposed to media derived from external beam irradiated cells produced a dose-dependent reduction in survival fraction, at low dosage, followed by a plateau with respect to clonogenic cell kill at levels >2 Gy. In contrast, cells receiving media from cultures treated with [^{211}At]MABG or [^{123}I]MIBG exhibited dose-dependent toxicity at low dose but elimination of cytotoxicity with increasing radiation dose. Cells treated with media from [^{131}I]MIBG demonstrated a dose-response relationship with respect to cell death and no annihilation of this effect at high radiopharmaceutical dosage. These findings suggested that bystander effect mechanisms following radiopharmaceutical administration may be LET dependent and distinct from those elicited by conventional radiotherapy.

To determine the effect of subcellular localization of radiolabeled drugs on direct and indirect

cell kill, Boyd et al. [160] treated NET gene-transfected HCT116 cells (derived from a human colorectal carcinoma) with [^{131}I]MIBG, [^{123}I]MIBG, [^{131}I]IUdR, or [^{123}I]IUdR. [^{131}I]MIBG and [^{131}I]IUdR both caused a dose-related decrease in the survival of cells that had concentrated the radiopharmaceutical and in recipients of the medium from irradiated cells. The concentration of [^{123}I]MIBG and [^{123}I]IUdR by HCT116 cells also induced direct dose-responsive toxicity. However, bystander HCT116 cells succumbed in a dose-responsive manner to the transfer of conditioned medium from donor cultures exposed to low radioactivity concentrations of [^{123}I]MIBG and [^{123}I]IUdR, but the toxic effect diminished with increasing dose of radiopharmaceutical to donors. This biphasic response was similar to the previously reported effect on the survival of clonogens derived from glioma and bladder carcinoma cell lines and treated with medium from cells which had concentrated [^{123}I]MIBG or [^{211}At]MABG [103].These findings not only support previous observations of the toxicity of Auger electron emitters conjugated to compounds which do not covalently bind to DNA [76, 103, 161, 162] but also indicate that the response of bystander cells to internalized Auger electron emitters does not depend on intracellular site of concentration. Further support for this notion has been provided by Pallais et al. [106] who demonstrated significant inhibition of tumor growth by ^{125}I localized to the cell membrane (see section "Critical Subcellular Sites of Interaction with Ionizing Radiation (Indirect Effects)").

Kishikawa et al. observed, in vitro and in vivo, opposing indirect effects induced by the concentration in the DNA of adenocarcinoma cells of ^{123}I or ^{125}I in the form of IUdR. The bystander effect induced by ^{125}I was growth inhibition, whereas that induced by ^{123}I was stimulation of proliferation [163]. These two high-LET, Auger electron emitters have similar emission spectra, but ^{123}I ($t_{1/2}$ = 13.3 h) is characterized by >100-fold greater dose rate than ^{125}I ($t_{1/2}$ = 60.5 days). Therefore, the potency of the RIBBE may be influenced not only by radiation quality but also by dose rate.

Conclusion

Targeting a single protein, whether on the cell membrane or in the nucleus, is necessary, but often not sufficient to produce a toxic event because of other mechanisms that are only partially understood. In targeting a specific protein, the primary factor is the location of the target, but the choice of radionuclide, the inertness of the bifunctional chelate or the stability of the covalently bound halogens, the residence time in the tumor matched with the physical half-life of the radionuclide, the scale and scope of the disease, and the absorbed dose sensitivity of the targeted tumor compared to normal tissue all come into play. But the analysis is complicated from an increasing number of observations that move toxicity from radiation at the target to the total effect. These include untargeted effects due to radiation emitted from neighboring, targeted cells as well as bystander effects produced by the cellular processing of radiation which need not impinge on DNA. Both indirect consequences of cellular radiation could make a substantial contribution to the efficacy of targeted radionuclide therapy. As more knowledge is gained of radiation-induced biological bystander effects in normal and malignant tissue, it is expected that these mechanisms will be exploited to optimize the efficacy of targeted radiotherapy and overcome the inefficiency of tumor control due to nonuniform distribution of radiation dose. The principles of molecular targeting are well established except for the paradigm shift from high-affinity, high-target density approach rather than the medium-affinity approach. Detecting lesions smaller than 2x machine resolution may favor the former approach over the latter. The design approach to take advantage of the indirect consequences of cellular radiation depends heavily on further elucidation of the indirect effect.

Single-Photon-Emitting Radiopharmaceuticals for Diagnostic Applications

3

Federica Orsini, Erinda Puta, Alice Lorenzoni, Paola Anna Erba, and Giuliano Mariani

Abstract

Radiopharmaceuticals contain a radionuclide and an agent to direct the radionuclide to a receptor, antigen, ionic pump, or other sites of interest. Some radiopharmaceuticals are simple, such as the ionic form of the radionuclide, while most radiopharmaceuticals have a complex chemical structure where the radionuclide provides a signal, indicating the site of localization of the carrier molecule.

Common single-photon radiopharmaceuticals used for oncological diagnosis include the agents labeled with ^{99m}Tc such as ^{99m}Tc-bisphosphonates (that accumulate at sites of bone mineral deposition), ^{99m}Tc-labeled colloids (that are used for lymphoscintigraphy and for imaging of the liver and spleen), ^{99m}Tc-hexakis-methoxy-isobutyl-isonitrile, and ^{99m}Tc-tetrofosmin (initially employed for myocardial perfusion imaging, and also used for localization of parathyroid adenomas and for identification of other malignant tumors).

The most commonly used radiopharmaceuticals labeled with radioiodine (^{123}I or ^{131}I) include iodide itself (for localization of thyroid tissue) and the catecholamine analog meta-iodobenzylguanidine (MIBG, for localizing pheochromocytoma and neuroblastoma). Thallium-201 chloride (^{201}Tl) is used for myocardial perfusion imaging as well as tumor perfusion imaging, while ^{111}In-pentetreotide detects overexpression of somatostatin receptors, especially in neuroendocrine tumors and in lesions arising from the neural crest, such as carcinoid, paragangliomas, and medullary thyroid carcinomas. ^{111}In-capromab pendetide is a murine monoclonal antibody recognizing a transmembrane glycoprotein expressed by poorly differentiated and metastatic prostate adenocarcinomas. ^{67}Ga-citrate receptors are overexpressed on membranes of both tumor and inflammatory cells.

Background

A radiopharmaceutical is a sterile, pyrogen free compound containing a radionuclide for the detection, characterization, or treatment of disease usually coupled to a directing agent - such as a peptide, antibody, or small molecule. Fundamental properties commonly associated with radiopharmaceuticals are: (1) they are administered in mass amounts that rarely elicit a pharmacologic response, and (2) interaction of radiopharmaceuticals with physiological systems is not linked to their physical properties (emission of ionizing radiation) but rather to their chemical nature.

The chemistry of some radiopharmaceuticals is very simple (such as the ionic form of the radionuclide itself), whereas most radiopharmaceuticals have a complex chemical structure in which the radionuclide only serves for emission of the physical sign (see below), while interaction with the biological systems is due to the chemical structure of the main carrier molecule.

Radiopharmaceuticals employed for diagnostic purposes produce a physical signal, i.e., emission of γ-rays or β^+-particles (the latter in turn undergoing annihilation when combining with a β^--particle, with ensuing emission of two high-energy photons). Dedicated radiation sensors can detect either the γ-rays and/or the high-energy annihilation photons. The nuclear medicine

equipment employed for imaging (scintigraphy) produces an image that represents the distribution of the radiopharmaceutical in the body.

The diagnostic information provided by scintigraphic imaging (or the desired therapeutic effect) derives from the characteristic distribution within the body of any given radiopharmaceutical. Most radiopharmaceuticals are administered systemically (i.e., intravenously); less frequent modalities of administration include the oral, interstitial, intracavitary, or even the intra-arterial routes. The main parameters that determine the scintigraphic information are the rate of disappearance (or clearance) from blood, accumulation, retention, and washout at a specific tissue/organ of interest. Changes in the distribution reflect pathophysiological changes of function or metabolism. Many of the abnormalities that can be demonstrated using radiopharmaceuticals occur at an early stage of the pathogenetic cascade that characterizes a disease, often before morphological modifications in shape, size, and/or structure of the tissue/organ of interest can be detected using anatomic imaging modalities.

Radiopharmaceuticals consisting of only the radionuclide in its ionic form usually concentrate in specific target tissue/organs either because they are radioisotopes of a naturally occurring element of biological interest (such as ^{123}I, ^{124}I, or ^{131}I undergoing the same physiologic distribution of native ^{127}I) or because they share chemical similarities/analogies with native elements of biological interest (such as ^{201}Tl or ^{82}Rb mirroring the physiologic distribution of native ^{39}K).

For more complex radiopharmaceuticals, the radionuclide is incorporated in the main carrier molecule through a chemical process denominated "radiolabeling" (see also ▶ Chap. 2, "Principles of Molecular Targeting for Radionuclide Therapy" of this book). The radionuclides most widely employed in nuclear medicine for imaging based on single-photon emission and their main physical characteristics are reported in Table 1.

Radiopharmaceuticals can also be classified based on physical characteristics of the radionuclide (type and energy of the characteristic emissions, physical half-life) or else on the physicochemical properties of the molecule (size, hydro- or lipophilicity, positive, negative, or neutral electrical charge) and mechanism of localization (Table 2).

Table 3 schematically summarizes the main radiopharmaceuticals used in conventional nuclear medicine for single-photon imaging.

^{99m}Tc-Labeled Radiopharmaceuticals

Because of its favorable gamma energy (140 keV), lack of particulate radiation, its ready availability and its 6-h half-life, ^{99m}Tc (a transition metal radionuclide) is employed

Table 1 Most widely used radionuclides in conventional nuclear medicine imaging and their main physical and chemical properties

Radionuclide	Chemical nature and charge	$T_{1/2}$	Energy (keV)	Emission
^{123}I[a]	Halogen, 1^-	12.8 h	159	γ
				Auger electrons
^{131}I	Halogen, 1^-	196.8 h	284, 364, 637	γ
			810	β^-
^{99m}Tc	Transition metal, 4^+, 5^+, 6^+, 7^+	6.06 h	140	γ
^{111}In[a]	Post-transition rare metal, 3^+	67.9 h	172, 245	γ
				Auger electrons
^{67}Ga[a]	Rare metal, 3^+	78.3 h	93, 185, 296	γ
^{201}Tl[a]	Post-transition metal, 1^+ (3^+)	72 h	135–167	γ
			69–83	x-ray

[a]Decay also with electron capture and secondary emission of a characteristic x-ray; decay is also associated with 1.4% incidence of 528 keV photon, which requires the use of medium energy collimation

Table 2 Main mechanisms of in vivo distribution/localization of radiopharmaceuticals

Mechanism(s)	Rationale	Example
Mechanical trapping (capillary blockade)	The regional distribution of perfusion in an organ can be assessed by administering in the afferent blood vessel radiolabeled particles that, because of their large size (tens of μm), cause microembolization in the precapillary bed of an organ	^{99m}Tc-MAA for planning radioembolization of liver tumors (intra-arterial injection)
Phagocytosis	Upon interstitial administration, micellar-size radiopharmaceuticals are drained through the lymphatic system and are engulfed by macrophages lining the sinusoidal spaces of lymph nodes	^{99m}Tc-radiocolloid for lymphoscintigraphy and radioguided sentinel lymph node biopsy
Ion exchange (chemisorption)	Exchange of ions between two electrolytes or between an electrolyte solution and a complex (binding to hydroxyapatite crystals or to amorphous calcium phosphate)	^{99m}Tc-labeled bisphosphonates for bone scintigraphy
Membrane transport: simple, facilitated, and active transport	Passive transmembrane diffusion of lipophilic, cationic molecules that bind to cytosolic components or accumulate into mitochondria	^{99m}Tc-tetrofosmin or ^{99m}Tc-sestamibi
	Active, energy-dependent transmembrane transport of molecules against a concentration gradient: sodium–iodide symporter	Radioiodine and ^{99m}Tc-pertechnetate for thyroid scintigraphy
Receptor-mediated probes	The radiopharmaceutical competes with the physiologic ligands for binding with the target receptor	Somatostatin analogs used for neuroendocrine tumors as vehicles to guide radioactivity to tissues expressing somatostatin receptors
Radioaerosols and radioactive gases	Direct inhalation	Radiopharmaceutical for lung ventilation

for about 80% of single-photon imaging procedures performed in nuclear medicine. The main characteristics that make this radionuclide almost ideal for use in diagnostic nuclear medicine based on single-photon emitting radiopharmaceuticals are:

- Emission of a γ-radiation with a monoenergetic emission peak (140 keV) which is optimal for detection using the current gamma camera detector systems and instrumentation for radioguided surgery
- Lack of particulate emission, thus limiting the radiation burden to patients
- High chemical reactivity with a variety of compounds and chemical species, thus making it possible to prepare a wide range of diagnostic agents labeled with the same radionuclide
- A physical decay half-life (6 h) which is relatively short yet is compatible with the time frame within which most of the diagnostic procedures currently performed with conventional gamma cameras are completed
- A physical decay half-life which is sufficiently short for limiting not only the radiation burden to patients linked to γ-emission but also the unwanted radiation to the general population (when the patient leaves the imaging department after completing the scan), as well as handling of radioactive waste

In principle, a short physical decay half-life would constitute a limitation in the distribution logistics of radionuclides/radiopharmaceuticals to remote locations. Despite its short physical half-life, ^{99m}Tc is widely available in any nuclear medicine center – whichever is the distance from the manufacturers – thanks to the possibility of in situ production starting from a parent radionuclide with longer half-life through the use of a molybdenum-99-based generator (^{99}Mo/^{99m}Tc).

Table 3 Common single-photon radiopharmaceuticals used for diagnosis

Radionuclide	Radiopharmaceutical
^{99m}Tc	^{99m}Tc-sodium pertechnetate has similar biological distribution to iodide and concentrates mainly in thyroid tissue
	^{99m}Tc-bisphosphonates accumulate at sites of bone mineral rearrangement
	^{99m}Tc-labeled colloids are used for lymphoscintigraphy and for imaging liver, spleen, bone marrow
	^{99m}Tc-hexakis-methoxy-isobutyl-isonitrile and ^{99m}Tc-tetrofosmin (both cationic compounds) are used for myocardial perfusion imaging, identification of parathyroid adenoma, and identification of some tumors
^{123}I or ^{131}I	Iodide, used for localization of functioning thyroid tissue and follicle-derived tumors
	Metaiodobenzylguanidine (MIBG), a catecholamine analog localizing in pheochromocytoma and neuroblastoma, as well as in other tumors arising from the neural crest
^{201}Tl	Ionic thallium used for myocardial perfusion and tumor imaging
^{111}In	Pentetreotide, a somatostatin analog that detects overexpression of somatostatin receptors, especially in neuroendocrine tumors and lesions arising from the neural crest, such as carcinoid, paragangliomas, and medullary thyroid carcinomas
	Capromab pendetide is a murine monoclonal antibody which recognizes a transmembrane glycoprotein expressed by poorly differentiated and metastatic prostate adenocarcinomas
^{67}Ga	At physiological pH, the Ga ion dissociates from the radiopharmaceutical ^{67}Ga-citrate, and forms a complex with transferrin or lactoferrin. Receptors for this complex are overexpressed on membranes of tumor and inflammatory cells

Molybdenum is a transition metal (with electrical charge 2^-) normally found as a constituent of different minerals. There are numerous isotopes of molybdenum, some of which occurring naturally while others can be produced artificially. In particular, most of the ^{99}Mo utilized for the ^{99}Mo/^{99m}Tc generators is produced through a nuclear fission reaction in highly enriched uranium-235 targets (a process that results in the production of ^{131}I and ^{133}Xe as well), while other sources can be through the use of a linear accelerator or of low enriched uranium targets. ^{99}Mo decays with a physical half-life of 66 h, mainly with the emission of high-energy β^--particles (1.214 MeV) and of γ-rays with a wide energy spectrum; the end product of ^{99}Mo decay is ^{99m}Tc.

In the ^{99}Mo/^{99m}Tc generator, the parent radionuclide (^{99}Mo, which is insoluble in water or in physiological saline) is bound to a chromatography anion exchange resin, which constitutes the stationary phase of the system usually designed as a small glass column (about 40 mm long and less than 10 mm wide) containing the resin with ^{99}Mo firmly bound to it in the form of molybdate. The ^{99m}Tc produced during the continuous decay of ^{99}Mo is periodically removed from the column (every approximately 24 h) by elution with physiological saline. In fact, in this system the daughter radionuclide (^{99m}Tc) is produced in the chemical form of pertechnetate anion ($[^{99m}TcO_4]^-$); the chloride ions present in the saline solution exchange with the $[^{99m}TcO_4]^-$ ions in the column, thus permitting their elution in physiological saline for any subsequent use.

$[^{99m}TcO_4]^-$ is a coordination compound with a very compact structure with tetrahedral geometry and oxidation state +7. Pertechnetate, the highest possible oxidation state for this metal, is also a very stable chemical species in aqueous solution. Thus, to use $[^{99m}TcO_4]^-$ to label a given molecule, it is necessary to remove the oxygen atoms bound to the metal through a reducing agent and to replace them with new ligand-coordinated atoms. During this process, the oxidation state of technetium is reduced to values lower than +7. The stannous ion (Sn^{2+}) is generally used as a reducing agent, being added in aqueous solution as a chloride salt ($SnCl_2$) in such small amounts that it does not alter solubility of the preparation or cause toxicity to the patient. Removal of the oxygen atoms from $[^{99m}TcO_4]^-$ occurs through the formation of $Sn(OH)_4$ and other similar compounds. The atom of technetium is now free to coordinate with a binder (or chelating agent, such

as DTPA) that has been preattached to the molecule to be labeled. The binder must have a high technetium coordinating ability to ensure stability of new ^{99m}Tc-labeled radiopharmaceutical and prevent it from recombining with the oxygen atoms in aqueous solution and thus return back to the anion pertechnetate or form technetium dioxide (TcO_2), a secondary compound of oxygen that tends to form colloidal particles. Other ^{99m}Tc-labeling reactions involve different chemical approaches, such as derivatization with 6-hydrazinopyridine-3-carboxylic acid (HYNIC) for cross-linking.

^{99m}Tc-Sodium Pertechnetate

^{99m}Tc-sodium pertechnetate ($Na^{99m}TcO_4$) is obtained when eluting a ^{99}Mo/^{99m}Tc generator with saline and can be used as a radiopharmaceutical by itself. After i.v. administration, the pertechnetate ions circulate in the blood partly in their free form and partly bound to plasma proteins; free ions leave the vascular compartment and migrate to the interstitial fluids. As their concentration in blood diminishes other $[^{99m}TcO_4]^-$ ions are released from their binding to plasma proteins. Therefore, visualization of the vascular space observed in early scintigraphic acquisitions decreases gradually over time. $Na^{99m}TcO_4$ half-life in plasma is about 3 h and approximately 25% is excreted through the kidneys during the first 24 h.

Pertechnetate ions have similar biological distribution to iodide and perchlorate, as they concentrate in tissues such as the thyroid, stomach, salivary glands, intestine, choroid plexus, and kidney. Sodium pertechnetate is commonly used for thyroid scintigraphy. Accumulation of $[^{99m}TcO_4]^-$ in thyroid follicular cells is mediated by the sodium–iodide symporter (NIS), a transmembrane protein consisting of 643 amino acids arranged in 13 domains with extracellular amino-terminal and intracellular carboxy-terminal (molecular weight ranging between 79 and 90 kDa, depending on the degree of glycosylation). NIS is located on the basolateral membrane of thyroid cells, and it is able to simultaneously transport sodium and iodide (with a stoichiometric ratio of 2:1) from the extracellular space within the thyroid cells. Expression of this protein is regulated, by thyroid-stimulating hormone (TSH, with upregulation) and by the concentration of iodide in extracellular fluids (downregulation), and is encoded by a gene on chromosome 19p12–13.2. The extraction of iodine from plasma and its concentration in thyroid cells is a saturable and active process that takes place against an electrochemical gradient (the intracellular concentration of iodine is 20–40 times higher than in plasma) and requires energy, which is ensured by the Na/K-dependent ATPase system.

The pertechnetate ion is transported by NIS from the extracellular to the intracellular compartment because it mimics the iodide ion, to which $[^{99m}TcO_4]^-$ is similar in terms of mass, size, and charge density; however, once inside the thyroid cell, $[^{99m}TcO_4]^-$ does not undergo subsequent organification as iodide does to participate in the synthesis of thyroid hormones.

In nuclear oncology, $[^{99m}TcO_4]^-$ is used in patients with thyroid nodules to define a nodule as either "hot" (increased uptake of the radiopharmaceutical relative to normal parenchyma) or "cold" (decreased uptake). Hot nodules correspond to hyperfunctioning tissue and are very rarely malignant. Cold nodules correspond to thyroid tissue with reduced function, and they can harbor malignancy. Differential diagnosis of a cold nodule as benign or malignant can only be made with fine-needle aspiration cytology. As mentioned above, the prevalence of thyroid cancer in hot nodules is very low (between 0% and 4% in adults), while up to 20% of the cold nodules are malignant.

Sodium pertechnetate is indicated as well for the salivary gland scintigraphy and the localization of ectopic gastric mucosa (Meckel's diverticulum).

^{99m}Tc-Diphosphonates

Virtually all radiopharmaceuticals employed for bone scintigraphy exhibit a similar pattern of distribution, characterized by accumulation in the bone linked to deposition of the mineral component. Early investigations on bone metabolism employed radionuclides with unfavorable

physical properties. Agents such as ^{32}P (in the chemical form of orthophosphate), radioactive calcium (^{45}Ca, ^{47}Ca, both beta emitters, suitable for turnover studies, but not suitable for imaging) or calcium analogs (^{85}Sr, ^{87m}Sr) in ionic form, and ^{18}F-fluoride (a positron emitting nuclide, (see also ▶ Chap. 4, "Positron-Emitting Radiopharmaceuticals for Diagnostic Applications" of this book) were used for evaluating the rate of bone turnover. Although images were obtained with ^{85}Sr, it was only after the introduction of ^{99m}Tc-labeled phosphate agents (including pyrophosphate, polyphosphates, and phosphonates) that bone scintigraphy actually became one of the most frequently performed diagnostic nuclear medicine procedures.

Present-day radiopharmaceuticals for bone scintigraphy are ^{99m}Tc-bisphosphonates, also called diphosphonates. The P–C–P bond between the two phosphates makes the molecule extremely resistant to hydrolysis by the enzyme phosphatase. Slightly different chemical forms of radiolabeled bisphosphonates are now being used in clinical practice. The most commonly used diphosphonates are ^{99m}Tc-medronate (MDP) and ^{99m}Tc-oxidronate (HDP) with equivalent lesion detectability properties (Fig. 1).

^{99m}Tc-bisphosphonates accumulate at sites of bone mineral rearrangement by chemisorption on the surface of newly formed hydroxyapatite crystals. Tin (involved in the radiolabeling reaction, see above) and ^{99m}Tc are hydrolyzed and bind to the bone, individually or jointly, in the form of tin hydroxide and TcO_2, respectively. ^{99m}Tc-MDP probably also binds to the organic matrix (after interaction with different enzymes), but in a proportion that is not exactly known. Uptake of the radiopharmaceutical in the bone is also directly correlated with local blood flow, although not in a linear relationship; in fact, a three- to fourfold increase in blood flow enhances uptake by only 30–40%.

After i.v. administration, the radiopharmaceutical rapidly diffuses into the extracellular space, and uptake in bone begins immediately. About 10% of the initial activity remains in the circulation 30 min after injection, decreasing to about 1% by 4 h after administration. The mechanism of radiopharmaceutical clearance from the body is through renal excretion, and about 50% of the intact radiopharmaceutical is excreted in the first 6 h after injection.

In bone scintigraphy the intensity of uptake of ^{99m}Tc-diphosphonate reflects the deposition of new hydroxyapatite crystals. This event is an intrinsic component of the osteoblastic reaction, which is associated with both osteolytic and osteoblastic lesions. Such conditions include both benign bone disease, primary bone tumors (benign as osteoid osteoma or malignant such as osteosarcoma), and bone metastases.

^{99m}Tc-Radiocolloids

From the biological point of view, a "colloid" includes all particles ranging from 1 nm to about 4 μm that are found in the body fluids. These particles are generally constituted by debris

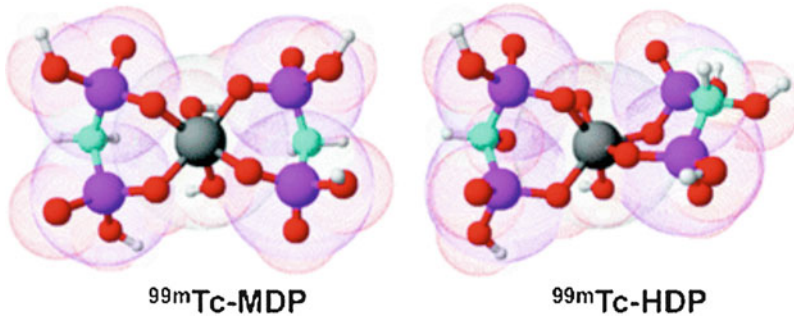

Fig. 1 Tridimensional representation of chemical structure of ^{99m}Tc-labeled bisphosphonates employed for diagnostic bone scintigraphy. The *gray* atom at the center of each 3-D structure represents ^{99m}Tc. Other elements are represented with the following color codes: *red* = O, *white* = H, *fuchsia* = P, *light blue* = C

of microorganisms, fragments of cells produced during the physiologic processes of tissue renewal, or products of intestinal absorption (especially fat). Colloids are generally removed from circulation by phagocytosis (a mechanism by which materials in the extracellular space are internalized into cells, a process that is especially active in macrophages), except for products of intestinal absorption that undergo their physiological metabolism in the liver or at other metabolic sites. Although macrophages are ubiquitous cells, they are concentrated mostly in the reticuloendothelial system, especially in the liver, spleen, bone marrow, and lymph nodes, as well as at sites of infection/inflammation. Phagocytosis is facilitated by several properties of the particles, such as size between 2.5 nm and 1 μm, negative charge, and possible opsonization by a class of macromolecules that include the complement fractions C3, C4B, and C5, as well as some α- and β-globulins.

Radiopharmaceuticals with colloidal properties include ^{99m}Tc-labeled albumin colloids consisting of particles of denatured human albumin ranging in size between 30 and 1,000 nm (i.e., 0.03–1 μm). Albumin colloid is used for lymphoscintigraphy mainly as a preliminary phase to radioguided sentinel lymph node biopsy. The radiocolloid is administered intradermally or interstitially at the site of the tumor. From the site of injection, radiocolloids migrate through the lymphatic system; in fact, their size prevents them from entering the venous blood capillaries (that have tight intercellular junctions), while intercellular junctions of the lymphatic capillaries are quite loose. Along the route of such lymphatic drainage, radiocolloids reach lymph nodes, the first one of which is called the "sentinel lymph node" (SLN); this is the lymphatic station where tumor cells possibly entering lymph vessels and migrating along the route of lymphatic drainage encounter the first lymph node (or nodes) of the lymphatic basin draining that specific tumor region. Once inside such lymph nodes, the radiocolloids are engulfed by macrophages lining the sinusoidal spaces enabling scintigraphic localization of the lymph nodes.

The ideal radiopharmaceutical for sentinel lymph node biopsy should allow a rapid visualization of the first lymph node draining from the tumor/injection site and prolonged retention in the SLN possibly without further migration to higher-echelon nodes. In principle, radiocolloids with relatively large-size particles (between 200 and 300 nm) have efficient retention in the first lymph node encountered along the migration route, with very little progression to higher-echelon nodes. Nevertheless, particles of this size migrate quite slowly from the injection site. Since the speed of migration of radiocolloids injected interstitially is inversely related to particle size, some compromise must be found between the speed of lymphatic migration and the degree of phagocytosis of the colloidal particles in lymph nodes.

In patients with breast cancer, 18–37 MBq given as a single intradermal injection over the cutaneous projection of the tumor or subdivided into two to four aliquots for peritumoral or for periareolar injection (0.2–0.4 mL each aliquot) is usually used. In patients with melanoma, multiple intradermal injections are generally performed around the tumor or the surgical scar, each 0.1–0.2-mL aliquot containing about 7–10 MB; total injected activity should not exceed 74 MBq. Another parameter that affects the activity to be selected for injection is the time between tracer injection and surgery, which can range from 1 to 24 h depending on local logistics and organization. With longer waiting times, the injected activity should be increased to compensate for physical decay of ^{99m}Tc.

There are different sizes of radiopharmaceuticals used in nodal mapping and the choice is based usually on local availability. The most widely used radiocolloids are ^{99m}Tc-albumin (Europe), ^{99m}Tc-sulfur colloid (USA), and ^{99m}Tc-antimony sulfide (Canada and Australia). In addition, ^{99m}Tc-stannous phytate, ^{99m}Tc-tin colloid, ^{99m}Tc-rhenium sulfide nanocolloid, and ^{99m}Tc-sulfide nanocolloid can also be utilized. ^{99m}Tc-tilmanocept is now being used as an alternative to radiocolloids for mapping and localization of SLNs:

^{99m}Tc-sulfur colloid is commonly used in the USA, with a wide range of particle sizes (15–5,000 nm) depending on the preparation method. ^{99m}Tc-sulfur colloid has an average

size from 305 to 340 nm and is used for liver imaging and oral gastric emptying imaging. Often, the filtered colloidal form (particle size ranges from 100 to 220 nm) is used for lymphoscintigraphy.

^{99m}Tc-albumin nanocolloid is most frequently used in Europe and represents a good compromise between speed of migration and lymph node retention. It is made up of particles (maximum size 100 nm, mean 5–80 nm) most of which are smaller than 80 nm in size, which easily migrate through the lymphatic system but are not totally retained in the sentinel node. Lymphoscintigraphy will therefore usually display multiple lymph nodes along a certain lymphatic route, an occurrence that can complicate the intraoperative search for the "true" sentinel lymph node using the gamma probe.

^{99m}Tc-mannosyl-DTPA-dextran (^{99m}Tc-Tilmanocept®) is a receptor-targeted radiotracer approved by the FDA (and more recently also by the EMA) for SLN mapping in breast cancer and melanoma as well for lymphatic mapping in other solid tumors. ^{99m}Tc-Tilmanocept® has a molecular size of 7 nm, but, at variance from the other radiocolloids, its uptake mechanism is not dependent on particle size. In fact, ^{99m}Tc-Tilmanocept® binds avidly to the CD206 receptors for mannose on the surface of macrophages and dendritic cells in lymph nodes. The advantages of Tilmanocept® include rapid clearance from the injection site, high sentinel lymph node extraction, and low accumulation on second-echelon nodes.

^{99m}Tc-Magroaggregated Albumin

Magroaggregated albumin (MAA, particle size range 10–90 μm and no greater than 150 μm) labeled with ^{99m}Tc is mainly used for lung perfusion imaging.

When performing a lung perfusion scan, an important factor is the number of particles injected. The standard activity administered to an adult patient is 40–150 MBq containing approximately 400,000 labeled particles. These particles will obstruct only a very small number of pulmonary vessels, negligible from the hemodynamic point of view since there are over 280 billion pulmonary capillaries and 300 million precapillary lung arterioles. Particles in size >150 μm would occlude arterioles of greater caliber with possible undesirable effect.

In patients with known pulmonary hypertension or right-to-left heart shunt, the number of ^{99m}Tc-MAA particles should be reduced to 100,000–200,000. In infants and children, the number of administered macroaggregated albumin particles should be further reduced as a function of age.

After i.v. administration, over 90% of the ^{99m}Tc-MAA particles are trapped in the pulmonary capillaries and precapillary arterioles because of their dimensions. The particles are removed from the pulmonary bed (effective half-life 1.5–3 h) due to enzymatic degradation into smaller particles that enter the circulation assuming nanocolloid characteristics and thus are phagocytized from the macrophages of the reticuloendothelial system.

^{99m}Tc-MAA is also used for radioguided occult lesion localization (ROLL) prior to radioguided surgery. A small volume of a radiopharmaceutical is injected into the lesion under imaging guidance. Because of their size, the ^{99m}Tc-MAA particles remain in the lesion and do not undergo clearance via lymphatic drainage. The lesion is then located and excised intraoperatively using a gamma-detecting probe, according to the same principles as those of SLN biopsy.

^{99m}Tc-MAA scintigraphy after intrahepatic artery administration of 75–150 MBq of the radiopharmaceutical is very important to assess for possible shunt(s) to the pulmonary and/or gastrointestinal circulation, as well as for treatment planning prior to transarterial radioembolization therapy with ^{90}Y-labeled microspheres in patients with primary or metastatic liver malignancies.

^{99m}Tc-Sestamibi

^{99m}Tc-hexakis-2-methoxy-2-isobutyl-isonitrile (^{99m}Tc-sestamibi) is a positively charged lipophilic radiopharmaceutical originally introduced into clinical routine for myocardial perfusion scintigraphy. Its uptake and retention depend on the regional blood flow, cell viability, cell membrane potential, and mitochondrial density/activity.

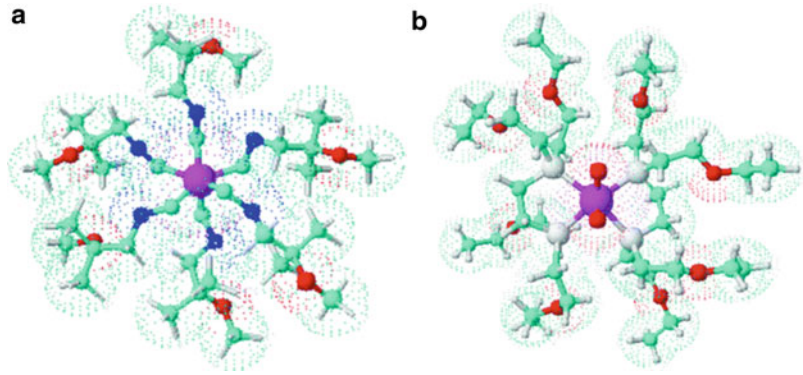

Fig. 2 Tridimensional representation of chemical structure of ^{99m}Tc-sestamibi (**a**) and ^{99m}Tc-tetrofosmin (**b**). The fuchsia atom at the center of each 3-D structure represents ^{99m}Tc. Other elements are represented with the following color codes: *red* = O, *small white* = H, *light blue* = C, *large white* = P, *dark blue* = N

Labeling of ^{99m}Tc-sestamibi occurs through the isonitrile groups with a chemical reaction that requires the presence of stannous ion in reduced state. The structure of ^{99m}Tc-sestamibi consists of a central atom of technetium linked to six octahedral ligands (Fig. 2a).

After i.v. administration, this radiopharmaceutical diffuses rapidly in the extracellular spaces and then crosses cell membranes by passive diffusion (because of its lipophilicity) following a concentration and electrical gradient (as the intracellular space is negatively charged). ^{99m}Tc-sestamibi accumulates in the mitochondria, which are particularly abundant in cells with high energy demand, such as cardiomyocytes and tumor cells. Thus, uptake and retention of ^{99m}Tc-sestamibi depends on local blood flow, cell density, and metabolic activity. ^{99m}Tc-sestamibi is used for myocardial perfusion imaging, for detection of parathyroid adenomas, and for scintimammography.

^{99m}Tc-sestamibi is rapidly cleared from the blood, with only 8% of the administered activity in the circulation 5 min postinjection. The tracer is excreted through the hepatobiliary system (33% at 48 h) and to a lesser extent through the kidneys (27% at 24 h). Its biological half-life in the myocardium is approximately 6 h.

^{99m}Tc-Tetrofosmin

^{99m}Tc-tetrofosmin is a lipophilic cationic diphosphine with localization properties similar as those of ^{99m}Tc-sestamibi. ^{99m}Tc-tetrofosmin is also employed primarily for myocardial perfusion scintigraphy. Myocardial uptake of ^{99m}Tc-tetrofosmin as well as of ^{99m}Tc-sestamibi is proportional to blood flow up to about 2 mL/min per gram, which is twice the resting level, reaching a plateau of extraction at higher flow rates.

Its molecular structure is characterized by a core of four atoms of phosphorus-binding ^{99m}Tc, stabilized by two oxygen atoms (O = Tc = O) and two diphosphines (Fig. 2b). After entering cells with a mechanism similar to that of ^{99m}Tc-sestamibi, ^{99m}Tc-tetrofosmin is retained intracellularly mostly bound to cytosol proteins.

Similarly to ^{99m}Tc-sestamibi, ^{99m}Tc-tetrofosmin undergoes rapid blood clearance following systemic administration, so that less than 5% of the administered activity remains in the circulation 10 min postinjection. About 65% of the administered activity is excreted within 48 h, 40% in the urine and 25% through the hepatobiliary tract. The hepatic clearance of ^{99m}Tc-tetrofosmin is more rapid than that of ^{99m}Tc-sestamibi, thus allowing earlier myocardial imaging.

^{99m}Tc-EDDA/HYNIC-Octreotate

^{99m}Tc-EDDA/HYNIC-octreotate is a ^{99m}Tc-labeled somatostatin (SST) analog with high affinity for SSTR2 used for detecting and staging neuroendocrine neoplasms. It has a similar physiological biodistribution as ^{111}In-pentetreotide (Octreoscan®, see further below). Mainly because of the favorable physical properties and wide availability of ^{99m}Tc, ^{99m}Tc-EDDA/HYNIC-octreotate offers several advantages as compared to Octreoscan®, such as ready availability (because of the possibility to label the lyophilized

kit "on demand" when needed), possibility to administer higher activity amount (because of more favorable dosimetry parameters), faster imaging completed within 4–6 h versus up to 24 h, better image quality and detection capability (with higher target/nontarget ratios because of more favorable counting statistics), and overall better cost-effectiveness.

There are also other ^{99m}Tc-labeled SST analogs, such as ^{99m}Tc-HYNIC-octreotide, ^{99m}Tc-vapreotide, ^{99m}Tc-depreotide, and ^{99m}Tc-demotate. ^{99m}Tc-HYNIC-octreotate differs from ^{99m}Tc-HYNIC-octreotide by the more hydrophilic tyrosine in the third position and the terminal threonine showing a higher receptor affinity and better internalization properties. The administered activity is 370–740 MBq, the higher amounts being preferred when contemplating SPECT acquisition. The highest target/nontarget ratios are usually observed at 4 h postinjection.

Lung Ventilation Radiopharmaceuticals

The multiple radiopharmaceuticals proposed for lung ventilation scintigraphy can be divided into two classes: radioaerosols (^{99m}Tc-DTPA and ^{99m}Tc-technegas) and radioactive gases (^{127}Xe, ^{133}Xe, ^{81m}Kr). An aerosol is a two-phase system consisting of particles that may be liquid, solid, or a combination of two suspended in gas. Ventilation studies using radioactive gases allow dynamic single-breath, equilibrium, or washout phase imaging, while radioaerosol ventilation scintigraphy rather maps the distribution of the aerated lung volume.

^{99m}Tc-DTPA

This is the most commonly used radiolabeled liquid aerosol. ^{99m}Tc-DTPA can be aerosolized by using a nebulizer to produce particles (ideal size 0.1–0.2 μm, diameter <2 μm) capable of being readily inhaled. ^{99m}Tc-DTPA is cleared from the alveolar region by transepithelial diffusion and enters the circulation where it is cleared by the kidneys. The biological half-life in the lung is 55–108 min in healthy people and 15–33 min in healthy smokers.

Even though the activity of ^{99m}Tc-DTPA dispensed in the nebulizer is approximately 900–1,300 MBq, the activity actually reaching the lungs is only 20–40 MBq. This amount is much lower than the activity of ^{99m}Tc-MAA normally injected i.v. for a lung perfusion scan; therefore, when planning a ventilation/perfusion scan in patients with suspected acute pulmonary embolism, the ^{99m}Tc-DTPA ventilation scan (with multi-view planar imaging or with SPECT) should be performed first.

^{99m}Tc-Technegas

The aerosol ^{99m}Tc-technegas, mostly used in Europe, consists of ^{99m}Tc-labeled solid graphite particles (diameter 0.005–0.2 μm) generated at high temperature. The particles tend to grow by aggregation; thus, ^{99m}Tc-technegas should be used within 10 min of generation. The administered activity to the lung is 20–30 MBq. Inhaled ^{99m}Tc-technegas particles adhere to the walls of the alveoli and are slowly cleared by reabsorption. The images obtained with ^{99m}Tc-technegas have superior quality than those obtained with ^{99m}Tc-DPTA or ^{133}Xe; moreover, its use has minimized the problem of particle clumping in patients with chronic obstructive pulmonary disease (COPD) observed when using ^{99m}Tc-DTPA.

Xenon-133

^{133}Xe is a noble, liposoluble radioactive gas, which decays with a physical half-life of 5.3 days through emission of β^-- and γ-radiations. The energy of its γ-emission photopeak (81 keV) is lower than that of ^{99m}Tc (140 Kev); therefore, when performing a ventilation/perfusion scan in patients with suspected acute pulmonary embolism, lung perfusion scintigraphy with ^{99m}Tc-MAA is acquired after the ^{133}Xe ventilation study. After being inhaled in an airtight closed system, ^{133}Xe (370–740 MBq) enters the alveolar wall and the pulmonary venous circulation via the capillaries, returning then to the lungs and being exhaled after a single pass through the peripheral circulation with a short biological half-life (30 s). ^{133}Xe single deep-breath inspiration, equilibrium, and washout

images are acquired allowing high sensitivity for detection of COPD. For radiation safety and in order to avoid dispersion of the radioactive gas in the environment, the room where the scan is performed must be equipped with a special closed system for inhaling ^{133}Xe, and the air conditioning system must include an activated charcoal filter for trapping any radioactive gas before exhaustion of the filtered air in the normal environment.

Xenon-127

The radioactive gas ^{127}Xe has a physical half-life of 36 days, and it decays by electron capture with principal γ-emission with energy photopeaks at 172 keV (25%), 203 keV (63%), and 375 keV (18%). These physical properties make ^{127}Xe preferable to ^{133}Xe for ventilation studies. Furthermore, the radiation burden from ^{127}Xe is lower than that from ^{133}Xe. Due to the higher-energy γ-emission, ^{127}Xe ventilation imaging can be acquired also after performing a lung perfusion scintigraphy with ^{99m}Tc-MAA. Limitations in the use of ^{127}Xe are its high cost and limited availability.

Radioiodinated Agents

Two radioisotopes of this halogen, ^{131}I and ^{123}I, are frequently utilized in the simple form of iodide anion in clinical practice for investigations and/or treatment of patients with thyroid diseases. Furthermore, radioiodine can be introduced into complex molecules through nucleophilic or electrophilic substitution. The most common modality employed to radioiodinate complex molecules is based on the possibility of replacing a hydroxyl radical ($-OH^-$) in the native molecule with the I^- ion. The iodide ion has the same valency and approximately the same spatial volume as the $-OH^-$ radical. Similarities in valency and volume also constitute the basis for substituting a methyl radical ($-CH_3^-$) with radioiodine. Both the $-OH^-$ radical and the $-CH_3^-$ radical are abundant in many molecules of biological interest (due to the presence of amino acids such as tyrosine).

^{131}I (historically one of the first radionuclides available for medical applications) is used both for therapeutic purposes (due to its emission of β^--particles) and for diagnostic purposes (due to its γ-emission). ^{131}I has a relatively high-energy principal photon emission (364 keV) and a long half-life (8 days), both features resulting in a relatively high radiation dose to the patient. On the other hand, ^{123}I offers a reduced radiation burden (because of its short physical half-life of 13.2 h); furthermore, the energy of its γ-emission is optimal for gamma camera imaging (the principal γ-emission photopeak energy is at 159 keV). ^{124}I, which decays with positron emission, offers the advantages of advanced PET imaging quantitation. As a final note, ^{125}I, which has a half-life (60 days) and emits γ-rays unsuitable for gamma camera imaging (35 keV), has been widely used for in vitro investigations (radioimmunological techniques) as well as for biodistribution studies in animal models of disease and for early-stage trials in humans.

Sodium Iodide

Radioiodine (^{123}I) is most commonly administered as sodium–iodide for imaging or (^{131}I) for treating thyroid disorders. The radioactive I^- ions present in the circulation and in interstitial fluid are transported into the thyroid cells by the sodium/iodide symporter. Once inside the thyroid cell, iodine is oxidized by the enzyme peroxidase; this starts the organification process that incorporates iodine into tyrosine, an amino acid contained in the thyroglobulin molecules produced by the endoplasmic reticulum and Golgi apparatus. Molecules of monoiodotyrosine (MIT) and diiodotyrosine (DIT) are thus formed. These two chemical species are then combined to produce the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Thyroid hormones are finally secreted into the circulation by pinocytosis following stimulation by TSH.

In addition to the thyroid, iodine is also concentrated by the salivary glands, sweat glands, stomach, mammary glands, and placenta. These sites of physiologic concentration can produce unwanted side effects when using ^{131}I-iodide for high-dose therapy in patients with differentiated thyroid cancer, possibly causing sialadenitis (sometimes with persistent xerostomia) and gastritis (with nausea and vomiting). ^{131}I uptake in

the placenta and mammary gland would expose the fetus or the baby, respectively, to an unacceptable radiation dose.

^{131}I-iodide has been often used to measure uptake prior to therapy both for hyperthyroidism and for total-body scintigraphy in patients with differentiated thyroid cancer. Administered activities in these two cases are very different: only 0.37–1.85 MBq (or 10–50 μCi) to measure thyroid uptake in hyperthyroid patients and up to 185 MBq (or 5 mCi) for total-body scintigraphy in thyroid cancer patients. In both cases, the radiopharmaceutical is generally administered orally as a capsule, while in pediatric patients or in patients with swallowing problems, a liquid formulation is also available, for either oral or intravenous administration.

^{131}I-iodide, due to its high radiation-absorbed patient dose and high-energy photons, has generally been replaced by ^{99m}Tc-pertechnetate or ^{123}I-iodide for thyroid scintigraphy in patients with benign thyroid disease. ^{123}I-iodide is generally administered orally but an i.v. formulation is also available. The standard activity administered for thyroid scintigraphy in a 70-kg adult patient is 2–111 MBq (2 MBq for uptake studies while up to 111 MBq for thyroid scintigraphy). Higher ^{123}I activities are required for whole-body scans (40–200 MBq) and even higher for SPECT imaging, with images being acquired 24 h after administration.

Radioiodinated Metaiodobenzylguanidine

Metaiodobenzylguanidine (MIBG) is a catecholamine analog in which the benzyl group of bretylium is combined with the guanidine group of guanethidine (Fig. 3). It was developed in 1980 to image tumors of the adrenal medulla. It can be labeled either with ^{123}I (for diagnostic use) or with ^{131}I (for either diagnostic or therapeutic applications).

MIBG is taken up by chromaffin cells through an ATPase-linked energy-dependent process physiologically utilized for the intracellular accumulation of noradrenaline. This accumulation process is abundantly expressed in the sympathetic ganglia, the adrenal medulla, and in all tissues with high adrenergic innervations (myocardium, salivary glands). After being initially stored in the cytoplasmic neurosecretory vesicles, MIBG is then secreted through an exocytosis mechanism following depolarization induced by high transmembrane flux of calcium ions. Neuroendocrine tumors originating from the neural crest typically accumulate this radiopharmaceutical.

MIBG does not bind to postsynaptic adrenergic receptors and is not degraded by the enzymes normally degrading catecholamines, that is, monoamine oxidase (MAO) and catecholamine-O-methyltransferase (COMT). Blood-pool activity early after injection is due to binding of MIBG to circulating platelets. Moderate physiological

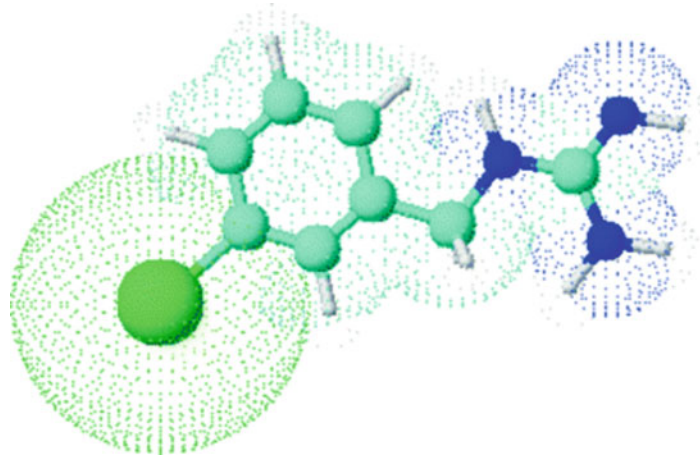

Fig. 3 Tridimensional representation of chemical structure of radioiodinated metaiodobenzylguanidine (*MIBG*). The *green* atom represents radioiodine. Other elements are represented with the following color codes: *white* = H, *light blue* = C, *dark blue* = N

uptake is also observed in the liver (especially the medial portion of the liver), spleen, lungs, salivary glands, myocardium, nasal mucosa, brown fat, colon, musculoskeletal system, and uterus. Visualization of the thyroid is due to free radioactive I^- released during in vivo degradation of the radiopharmaceutical; for this reason, a thyroid-blocking agent (either supersaturated potassium iodide solution or similar) is usually administered prior to injection. Since there is no physiological uptake of MIBG in bones, focal or diffuse bone uptake must be considered expression of skeletal metastases and/or tumor invasion of the bone marrow.

The main clinical applications of MIBG scintigraphy are detection, localization, staging, and follow-up of neuroendocrine tumors and their metastases, especially pheochromocytoma, paraganglioma, neuroblastoma, medullary thyroid carcinoma, and other tumors originating from the neural crest. [^{123}I]MIBG is the radiopharmaceutical of choice for diagnostic applications (especially in children), both because of its more favorable radiation dosimetry and because of the more favorable imaging properties compared to [^{131}I]MIBG.

Following i.v. administration, about 50% of the administered activity is excreted in the urine within the first 24 h, 70–90% of the activity being cumulatively excreted within 48 h. Since more than 95% of radioactivity excretion occurring through the kidneys, the bladder and the excretory urinary tract are seen on the scan; about 3% of MIBG activity is excreted via the gastrointestinal tract. Normal adrenal glands are visualized in 15% of the cases at 48–72 h after injection.

The standard activity administered to adult patients is 40–80 MBq for [^{131}I]MIBG and 370 MBq for [^{123}I]MIBG. Such amounts are reduced in pediatric patients, according to body weight. Due to a certain "mass" effect of radiolabeled MIBG (especially when high doses of [^{131}I]MIBG are given for therapy and/or with low-specificity radiopharmaceuticals), administration may induce the release into circulation of catecholamines previously accumulated in neurosecretory granules, with ensuing possible pharmacologic effect (such as tachycardia and an arterial hypertensive crisis in patients with pheochromocytoma). Some precautions are therefore necessary, such as slow infusion of the radiopharmaceutical (over 1–5 min in the case of a diagnostic procedure, over 1–4 h after dilution in 50 mL of saline in case of therapy), while also monitoring heart rate and blood pressure until about 1 h after administration. Moreover, since many drugs can interfere with MIBG uptake, the patient's medication list should be reviewed and interfering drugs discontinued before MIBG administration.

Non-tumor indications of [^{123}I]MIBG are for functional studies of adrenal medulla, movement disorders, and sympathetic innervation of the myocardium.

^{201}Tl-Chloride

The monovalent cation Tl^+ has biochemical characteristics similar to those of the K^+ ion. Therefore, in excitable cells (typically neurons and muscle cells), it undergoes the continuous transmembrane flux that physiologically occurs during depolarization (a passive process) and repolarization (an energy-dependent process linked to the so-called Na^+/K^+ pump). These sustained transmembrane exchanges explain the high intracellular concentration of Tl^+ ions, mimicking the distribution of the K^+ ions.

Besides typical high accumulation in myocardial cells, $^{201}Tl^+$ ions tend to accumulate in all metabolically active cells, including cancer. ^{201}Tl-chloride is then used for tumor imaging as an indicator of cell viability, particularly for discriminating viable tumor tissue (as due to, e.g., recurrence posttreatment) from fibrous scar tissue after surgery and/or radiation therapy (especially in brain gliomas).

^{201}Tl decays by electron capture with a physical half-life of 73.1 h and emission of X-rays with 68–80-keV energy. Following i.v. administration, $^{201}Tl^+$ ions undergo fast extraction from circulating blood by cardiomyocytes (about 85% at first pass). There is also rapid clearance from the blood so that about 2 min after administration

<5% of the injected activity is still circulating. The tracer has a biological half-life of approximately 10 days.

^{111}In-Pentetreotide

Somatostatin (SST) is a 14-amino acid peptide produced endogenously mainly in the central nervous system. Physiologic functions of SST include inhibition of secretion of various hormones, such as insulin and glucagon, and inhibition of cell growth in neuroendocrine tumors. Five different types of receptors for SST have been identified and cloned, named SSTR1-5 (type 2 being divided into subtypes 2a and 2b). Native SST has a very short biological half-life (3 min), which limits its use both as a therapeutic drug as such and, upon radiolabeling, as a radiopharmaceutical. Several SST analogs have therefore been developed for therapy and for nuclear medicine applications. Octreotide (an eight-amino acid peptide) has longer biological half-life and a biological activity very similar to native SST, with high affinity for SST receptor types 2 and 5.

The presence of a chelating group (DTPA) in DTPA-D-Phe^1-octreotide (pentetreotide) makes radiolabeling with ^{111}In possible (Fig. 4). The cyclotron-produced radiometal ^{111}In has a physical half-life of 2.83 days and emits γ-rays with energy peaks of 172 and 247 keV (in addition to a 23–26-keV X-ray emission). The radiopharmaceutical ^{111}In-pentetreotide (commercial name Octreoscan®) has high binding affinity to type 2 and type 5 SST receptors, which are highly expressed on the cell membrane of many tumors of different origins but especially of neuroendocrine tumors. ^{111}In-pentetreotide scintigraphy is employed primarily in patients with neuroendocrine tumors (especially gastroenteropancreatic and carcinoid tumors) for localization, staging, and follow-up of lesions expressing somatostatin receptors. Increased expression of SST receptors also occurs in tumors originating from the neural crest (paragangliomas, medullary thyroid carcinomas, neuroblastomas, pheochromocytomas) as well as in pituitary tumors and in meningiomas, although in a smaller proportion of patients than observed in patients with other neuroendocrine neoplasms. Varying degrees of SST receptor expression are also observed in non-neuroendocrine tumors, such as breast cancer and some lymphomas (both Hodgkin's and non-Hodgkin's lymphomas). Finally, increased SST receptor expression occurs even in nonneoplastic disorders, especially in subacute and chronic inflammation (mainly of the granulomatous type, as in sarcoidosis).

^{111}In-pentetreotide is mainly excreted by the kidneys, about 90% of injected activity being recovered in the urine 24 h after i.v. administration. A smaller fraction of administered activity (about 2%) is excreted through the hepatobiliary system. Scintigraphic images show physiological uptake in the spleen (about 2.5% of injected activity at 24 h),

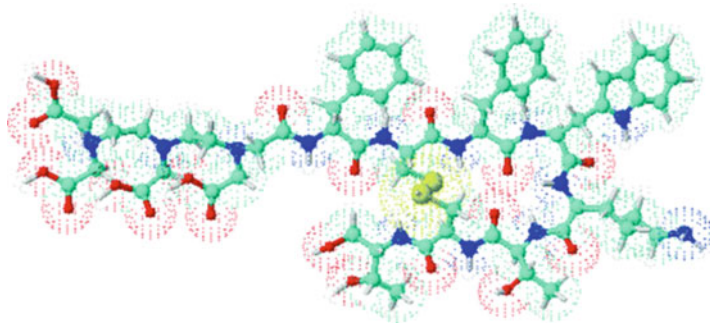

Fig. 4 Tridimensional representation of chemical structure of pentetreotide. The chelating moiety (*DTPA*) is shown on the left end of the molecule (^{111}In atom not represented here), while the receptor-binding moiety is on the right end. Elements are represented with the following color codes: *red* = O, *white* = H, *light blue* = C, *dark blue* = N, *yellow* = S

liver (2%), and kidneys. In most patients, the thyroid, pituitary, and intestine are also visualized during scintigraphy with ^{111}In-pentetreotide.

The standard injected activity into an adult patient is 110–220 MBq. In pediatric patients, the administered activity is reduced according to body weight or body surface area.

Several additional peptide-based radiopharmaceuticals are being evaluated for characterization of neuroendocrine tumors, in particular new SST analogs with more favorable binding characteristics than Octreoscan®. Furthermore, the tumor-targeting properties of new radiopharmaceuticals with high affinity for other receptors overexpressed by neuroendocrine tumors (such as bombesin, bioactive fragments of cholecystokinin, vasoactive intestinal peptide, etc.) are also being tested for possible use in nuclear oncology.

^{111}In-Capromab Pendetide

Capromab pendetide is a murine monoclonal antibody (IgG_k) directed against the prostate-specific membrane antigen (PSMA), a 120-kDa transmembrane glycoprotein expressed by prostate epithelium whose epitope is located on the cytoplasmatic domain. PSMA seems to be maximally expressed in poorly differentiated and metastatic prostate adenocarcinomas. This antibody (7E11-C5.3) is conjugated to the linker-chelator glycyl-tyrosyl-DTPA-lysine hydrochloride for labeling, to form ^{111}In-capromab pendetide.

Immunohistochemistry studies have shown that the antibody reacts with epithelial cells of more than 95% of prostatic adenocarcinomas, in both primary and metastatic lesions. Although expression of PSMA is present in other tissues and in subsets of various types of malignancies, PSMA is still considered to be sensitive and highly specific for prostatic carcinoma.

Use of this radiopharmaceutical is indicated to image newly diagnosed patients who have high risk for pelvic lymph node metastasis as well as post-prostatectomy patients with a rising PSA and a negative or equivocal conventional imaging in whom there is a high clinical suspicion of occult metastatic disease.

Approximately 10% of administered radioactivity is excreted in the urine over 72 h after intravenous infusion of ^{111}In-capromab pendetide. Non-antigen-dependent localization is observed in the liver, spleen, and bone marrow and in some inflammatory sites such as colostomy sites or postoperative bowel adhesions, bowel inflammatory diseases, or degenerative joint disease. Physiologic localization of radioactivity can also be seen in the bowel, blood pool, kidney, and urinary bladder.

The radiopharmaceutical (which is approved by the FDA and available only in the USA) is administered by intravenous infusion in 5 min. The recommended amount of capromab pendetide is 0.5 mg labeled with 185 MBq of ^{111}In. Images should be acquired between 72 and 120 h after administration. In some centers, an early SPECT acquisition is performed 30 min after administration in order to delineate distribution in the blood pool; this procedure helps in differentiating radioactivity localization in the blood pool versus tumor uptake in the late images.

^{67}Ga-Citrate

^{67}Ga is cyclotron produced by the proton irradiation of enriched zinc. It has a physical half-life of 78.3 h and decays by electron capture to stable zinc (^{67}Zn) emitting γ-rays with multiple energy peaks, principally 93 keV, 184 keV, 300 keV, and 394 keV. ^{67}Ga reacts with citric acid to form ^{67}Ga-citrate.

After i.v. administration of ^{67}Ga-citrate, $^{67}Ga^{++}$ ions are formed at physiological pH. Physiological uptake is seen in the liver, spleen, bone marrow, bone, and (less intense) lacrimal, salivary, and mammary glands. The metabolic fate of $^{67}Ga^{++}$ in the body is similar to that of the Fe^{++} ions. About 90% of injected activity binds to plasma proteins, especially transferrin, with ensuing slow blood clearance. During the first 24 h, up to 25% of the injected activity is excreted through the kidneys, while at later time points, the main excretion route becomes the bowel.

The mechanism of ^{67}Ga accumulation in tissues is quite complex and not yet fully clarified, but most of this process is due to intracellular

accumulation mediated by the transferrin receptors. Both human and animal studies have shown that if the number of binding sites is altered by a variety of conditions (such as congenital deficiency of transferrin receptors, iron overload, chemotherapy, or radiotherapy), then physiologic biodistribution is altered.

The main mechanism of accumulation in tumor and inflammation sites appears to be linked to the complex formed by $^{67}Ga^{++}$ with transferrin, for which membrane receptors are present ubiquitously, especially on membranes of tumor and inflammatory cells. In fact, cells undergoing active proliferation and metabolic activation overexpress transferrin receptors to meet the increased metabolic requirements (presence of the Fe^{++} ions is mandatorily required in some enzymatic processes involved in energy production). Therefore, tissues with rapid cell growth and high levels of DNA synthesis (such as cancer or inflammatory cells) express a higher number of transferrin receptors, ensuing an increased uptake of $^{67}Ga^{++}$ ions.

An additional mechanism of ^{67}Ga accumulation is mediated by its binding to lactoferrin. Extracellular inflammatory spaces are rich of lactoferrin, which has slightly greater affinity for ionic compounds than transferrin. Thus, ^{67}Ga reaching inflammation sites bound to transferrin may migrate to lactoferrin, which in turn binds to specific receptors present on macrophage surface. Enhanced expression of lactoferrin receptors has been shown also in lymphoma cells, and this event seems to contribute to ^{67}Ga uptake in this tissue for 10–25% of total uptake.

Following its introduction into clinical practice in the late 1960s, ^{67}Ga-citrate has had a well-defined role both in benign conditions (localization of infection/inflammation, characterization of chronic granulomatous diseases such as sarcoidosis) and in neoplastic conditions (lymphoma, sarcoma), especially for staging, prognosis, and evaluation of residual disease in lymphoma. Many of the traditional applications of scintigraphy with ^{67}Ga-citrate have currently been replaced by [^{18}F]FDG PET imaging. Nevertheless, when [^{18}F]FDG imaging is not available, some specific indications are still of value for nuclear oncology, particularly in patients with Hodgkin's or non-Hodgkin's lymphomas. Regarding availability/access to PET with [^{18}F]FDG, it should be noted that this imaging option – which now constitutes an integral part of the clinical routine in most nuclear medicine centers for the middle- to high-income countries – is not available for most of the low-income countries where the majority of the world population live. In these conditions and assuming that a nuclear medicine center is nevertheless present and accessible, scintigraphy with ^{67}Ga-citrate still remains the only radionuclide imaging option for patients with lymphoma.

The administered activity of ^{67}Ga-citrate to an adult patient for SPECT tumor imaging is approximately 370 MBq. Images should be ideally acquired 48 h after i.v administration due to the optimal tumor to background ratio; sometimes, images are also recorded at 72 and 96 h to determine if subtle regions of activity become more prominent. In this regard, recent reports on the successful use of the positron emitter ^{68}Ga-citrate for PET imaging of infection within about 1 h postinjection question the validity of current knowledge on the mechanisms of $^{67}Ga^{++}$ accumulation in infection. In fact, considering that the chemical species of ^{67}Ga is clearly identical to that of ^{68}Ga, it is unclear why accumulation of the positron emitter at sites of infection is so much faster than that of the single-photon emitter, even taking into account the much more favorable counting statistics of PET versus gamma camera imaging. A possible explanation for this striking difference is represented by the much greater specific activity of ^{68}Ga than ^{67}Ga, probably favoring one type of accumulation versus others – although further investigations are required to elucidate the exact reasons for such discrepancy.

Positron-Emitting Radiopharmaceuticals for Diagnostic Applications

4

Federica Orsini, Alice Lorenzoni, Erinda Puta, and Giuliano Mariani

Abstract

Positron emission tomography is one of the most important tools in medical imaging with many applications in neurology, oncology, cardiology, neuroscience and infection. Over the past 30 years, technological advances in radiochemistry have led to the development of many radiotracers at the present used in clinical routine.

In this chapter we will discuss the main physical property of PET radionuclide and the main pharmacokinetic characteristics of PET radiotracers commonly used for molecular imaging.

Introduction

Positron emission tomography (PET) is based on the coincidence detection of the paired 511 keV γ rays produced in the annihilation process that takes place when a β^- particle (the negative electron, or negatron) in the surrounding matter combines with a β^+ particle (the positive electron, or positron) emitted during nuclear decay of a positron-emitting radionuclide. Neutron-deficient nuclei reduce their proton surplus by emitting positrons; atomic mass of these elements is usually one unit smaller than the most common form of the stable isotope (e.g., positron-emitting ^{15}O, ^{13}N, and ^{11}C versus stable ^{16}O, ^{14}N, and ^{12}C). The annihilation event between a β^+ particle and a β^- particle, which occurs at a certain distance from the decay point (positron range) over which the positron loses part of its energy, creates two 511 keV photons, coincidence detection of the photons constitutes the basis for PET imaging (see ▶ Chap. 10, "Instrumentation for Positron Emission Imaging" of this book).

Some of the positron-emitting radionuclides are low atomic mass elements (e.g., C, N, and O) that are the radioactive counterparts of the fundamental constituents of biological matter; they can therefore be used to directly label molecules of interest without interfering with their biological activity. The maximum energy of positrons emitted by different radionuclides varies considerably, from about 0.635 MeV for ^{18}F to 3.15 MeV for ^{82}Rb (see Table 1 and Fig. 1). Typical specific activities of PET radiopharmaceuticals (radioactivity per unit mass of labeled compound) can be extremely high, so that generally low mass amounts of the radioactive compound are administered, typically in the submicrograms order. The half-life of the radionuclide utilized for a PET investigation should be commensurate with the time scale of the biological process to be explored (see ▶ Chap. 2, "Principles of Molecular Targeting for Radionuclide Therapy" of this book).

Positron-Emitting Radionuclides

Carbon-11 (^{11}C)

Carbon-11 is generally produced by the ^{14}N(p,α)^{11}C nuclear reaction and decays with a 99.8% positron emission and half-life of 20.4 min. ^{11}C-labeled molecules of biological interest in which a native ^{12}C atom has been replaced with an ^{11}C atom behave chemically and biologically exactly as their unlabeled equivalents. ^{11}C is often incorporated into PET radiopharmaceuticals through methylation reactions using [^{11}C]methyl iodide or [^{11}C]triflate. The most common precursors for synthesis are [^{11}C]cyanide, [^{11}C]carbon dioxide, and [^{11}C]carbon monoxide.

Table 1 Main physical characteristics of the β^+ emitting radionuclides most frequently employed for clinical purposes (arranged in increasing order of atomic mass number)

Isotopes	Half-life (min)	Maximum specific activity (GBq/μmol)	Branching β^+ emission (%)	E_{max} β^+ (MeV)	Modality of production	Maximum β^+ range in water (mm)
^{18}F	109.8 min	46.22	96.9	0.634	$^{18}O(p,n)^{18}F$	2.4
^{11}C	20.4 min	249.19	99.7	0.96	$^{14}N(p,\alpha)^{11}C$	4.1
^{15}O	2.03 min	2,479.19	99.9	1.73	$^{14}N(d,n)^{15}O$	8
^{13}N	9.98 min	510.81	99.8	1.199	$^{16}O(p,\alpha)^{13}N$	5.4
^{68}Ga	68.3 min	74.76	87.7	1.899	$^{68}Ge/^{68}Ga$	9
^{82}Rb	1.25 min	4,064.87	95.5	3.36	$^{82}Sr/^{82}Ru$	14.1
^{86}Y	14.7 h	5.76	33	1.25	$^{86}Sr(p,n)^{86}Y$	5.2
^{124}I	4.18 days	0.84	23.3	2.13	$^{124}Te(p,n)^{124}I$	10.2

Data extracted and elaborated from the National Institute of Standards and Technology [http://www.nist.gov/], from the Brookhaven National Laboratory [www.nndc.bnl.gov/nndc/nudat], and from the Laboratoire National Henri Becquerel [http://laraweb.free.fr/]

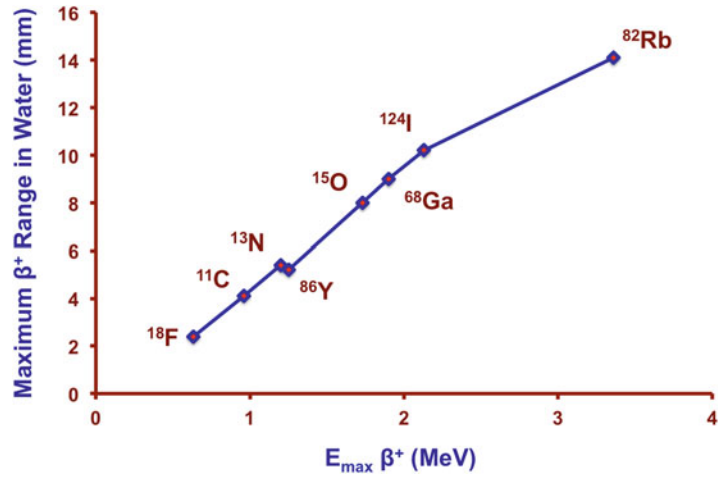

Fig. 1 Correlation between maximum energy (E_{max}, expressed in MeV) and maximum range of β^+ particles emitted during decay of different radionuclides employed for diagnostic PET imaging. Most of the energy deposited by each emission is nevertheless limited within a much shorter range (about 20–25% of the maximum range)

Nitrogen-13 (^{13}N)

Nitrogen-13 can be produced through different nuclear reactions. The $^{16}O(p,\alpha)^{13}N$ reaction is the most commonly used, and it is performed using a solution of ethanol (5 mM) or water; ethanol serves to reduce the amount of [^{13}N] nitrates or nitrites formed in situ. Similarly as for carbon, the stable isotope of nitrogen (^{14}N) is ubiquitous in biologically active organic molecules. Nevertheless, the half-life of ^{13}N (9.96 min) is too short to perform radiochemical synthesis of complex biological molecules. Thus, the most common application of ^{13}N-labeled molecules is in the form of [^{13}N] ammonia, which is routinely employed to assess myocardial blood flow. [^{13}N]Ammonia can also been used to prepare [^{13}N]*cis*platin for investigational purposes.

Oxygen-15 (^{15}O)

Oxygen-15 is produced using either the $^{14}N(d,n)^{15}O$ or the $^{15}N(p,n)^{15}O$ nuclear reactions. The very short half-life (2.04 min) of this radionuclide restricts its use to label simple molecules such as water, gaseous oxygen, and carbon monoxide. [^{15}O]Water is used to investigate cerebral and myocardial perfusion, as well as tumor perfusion, while gaseous $^{15}O_2$ can be

used to investigate oxygen metabolism; [^{15}O]carbon monoxide are employed to image the blood pool.

Fluorine-18 (^{18}F)

Fluorine-18 is the most widely used radionuclide for clinical PET investigations. ^{18}F (which decays to stable ^{18}O with nearly 97% positron emission) can be produced either by the ^{20}Ne(d,a)^{18}F or by the ^{18}O(p,n)^{18}F nuclear reactions. The former reaction leads to the formation of [^{18}F]F_2, while the latter results in the formation of [^{18}F]F^-. The short range in tissues of positrons emitted by ^{18}F (max 2.3 mm in water) contributes to the high-resolution PET images obtained with this radionuclide. The relatively long half-life of this radionuclide (almost 110 min) permits multistep labeling reactions for the synthesis of relatively complex molecules (with radiolabeling yields as high as 20–40%) and also allows for shipment from the production site to peripheral PET centers. Fluorine reacts with many organic and inorganic chemicals, since it is the most electronegative of all the elements; the chemistries most widely employed for incorporating ^{18}F into organic molecules are nucleophilic substitution and electrophilic substitution. Since the electrophilic labeling approach (which uses [^{18}F]F_2) results in molecules with low specific activities, the nucleophilic approach (based on the use of [^{18}F]F^-) is most frequently employed, not only because of the higher specific radioactivity of the compounds so produced but also because of greater selectivity of the radiolabeling reactions.

Gallium-68 (^{68}Ga)

Gallium-68 (half-life 68.3 min, maximum positron energy 1.9 MeV) is eluted from a ^{68}Ge/^{68}Ga radionuclide generator system, similar in concept to that of the ^{99}Mo/^{99m}Tc generator (see ▶ Chap. 3, "Single-Photon-Emitting Radiopharmaceuticals for Diagnostic Applications" of this book). ^{68}Ge decays by electron capture with a physical half-life of 271 days; a single generator allows therefore continuous production of ^{68}Ga for almost 1 year. ^{68}Ga is an excellent positron emitter (88% branching emission of positrons), with a low photon emission (3.22% at 1.077 MeV). This metallic radionuclide is used mostly for labeling peptides, such as somatostatin analogs and a ligand for the prostate specific membrane antigen (PSMA), and yields compounds with high radiochemical purity.

Rubidium-82 (^{82}Rb)

The ultrashort-lived ^{82}Rb (half-life 76 s, with emission of 3.15 MeV positrons) is a potassium analog eluted from a ^{82}Sr/^{82}Rb generator for myocardial perfusion imaging. It decays to stable ^{82}Kr by positron emission (nearly 96%) associated with only about 4% electron capture. Since the parent radionuclide ^{82}Sr has a physical half-life of 25 days, the generator can be used for approximately 1 month.

PET Radiopharmaceuticals

Positron emission tomography is one of the most important tools in medical imaging with many applications in neurology, oncology, cardiology and neuroscience, and infection – just to mention the most frequent clinical applications. Over the past 30 years, advances in radiotracer chemistry have led to the development and evaluation in preclinical and clinical studies of many radiotracers with high specificity and suitable pharmacokinetic characteristics for molecular imaging.

2-Deoxy-2-[^{18}F]fluoro-D-glucose

The glucose analog 2-Deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG, Fig. 2) is the most commonly used radiopharmaceutical for clinical PET imaging. 2-Deoxy-D-glucose was initially developed in 1960 as an antitumor chemotherapy agent, with the rationale of inhibiting glucose utilization by cancer cells. In 1976 Dr. Wolf and his colleagues at Brookhaven National Laboratory developed the synthesis of [^{18}F]FDG to explore glucose metabolism in the brain; the first [^{18}F]FDG brain imaging studies were performed in 1977 at the University of Pennsylvania, Philadelphia (Table 2).

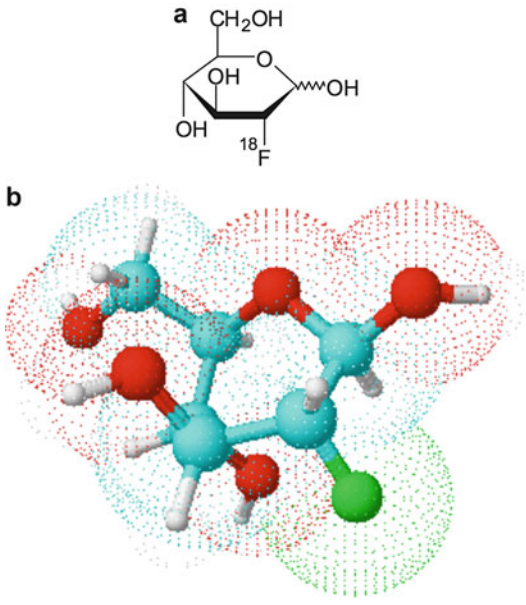

Fig. 2 Chemical formula in extenso (**a**) and tridimensional representation of chemical structure (**b**) of [^{18}F]FDG. Elements are represented with the following color codes: *green* = ^{18}F, *red* = O, *gray* = H, and *light blue* = C (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

As shown in Fig. 3, [^{18}F]FDG is transported through the cell membrane via glucose transport proteins (GLUTs) and phosphorylated by hexokinase to [^{18}F]FDG-6-PO_4. [^{18}F]FDG-6-PO_4 is not a substrate for the subsequent enzymatic conversion to fructose-6-phosphate by phosphohexose and neither is for other endogenous routes of metabolism; therefore, it does not further participate in the glycolytic pathway and becomes trapped in the cell because of its negative charge. The low activity of the reverse enzyme, glucose-6-phosphatase (which has relevance only in hepatocytes), leads to the tumor cell accumulation of [^{18}F]FDG-6-PO_4. [^{18}F]FDG uptake reflects therefore the magnitude of glucose metabolism, the most intense activity occurring in the brain (9% within 80–100 min), in the sites of inflammation and infection, and in neoplastic cells. Myocardial uptake is variable, and significant [^{18}F]FDG uptake can be seen also in the myocardium even in the fasting state, when the predominant energy source should be fatty acid consumption. Physical activity occurring shortly preceding or during [^{18}F]FDG administration increases tracer accumulation in skeletal muscles. Cancer cells exhibit

Table 2 Main mechanisms of in vivo distribution/localization of PET imaging agents in nuclear oncology

Mechanism(s)	Rationale	Example
Membrane transport: simple, facilitated, and active transport	Facilitated transport mediated by specific transport proteins: glucose transporters (GLUTs 1–5) expressed on the cell membrane as a function of energy demand	[^{18}F]FDG for PET of tumors with enhanced glucose consumption
Enzyme-mediated intracellular trapping	Trapping into cells as the result of a specific interaction of the radiopharmaceutical with an enzyme: phosphorylated [^{18}F]FDG not being the substrate for subsequent metabolic pathways	[^{18}F]FDG for PET of tumors with high glucose demand
Competitive substrates for tumor cell structure	The radiopharmaceutical competes with the endogenous substrate for the same metabolic pathways for the synthesis of proteins or phospholipids	Various imaging agents for tumors: amino acids (protein synthesis) and choline-based tracers (phospholipid synthesis)
Competitive substrates for tumor cell functional processes	The radiopharmaceutical competes with endogenous catecholamine synthesis and storage in neurosecretory vesicles	Imaging agents for neuroendocrine tumors derived from the neural crest: ^{18}F-DOPA
Receptor-mediated probes	The radiopharmaceutical competes with the physiologic ligands for binding with the target receptor	Somatostatin analogs for neuroendocrine tumors expressing somatostatin receptors

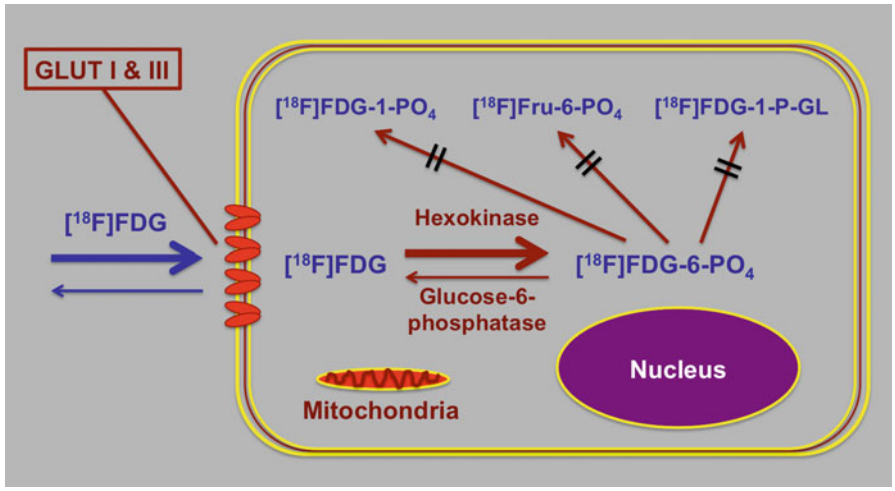

Fig. 3 Diagrammatic representation of the fate of the glucose analog [^{18}F]FDG. The tracer enters cells with the same mechanism as native glucose (GLUT system); intracellular [^{18}F]FDG undergoes enzymatic phosphorylation to [^{18}F]FDG-6-PO_4 through the action of hexokinase, in the same manner as native glucose, whereas the reverse enzyme (glucose-6-phosphatase, which would revert [^{18}F]FDG-6-PO_4 back to [^{18}F]FDG, diffusible outside the cell) normally operates at very low levels and almost exclusively in hepatocytes; [^{18}F]FDG-6-PO_4 cannot be a substrate for any of the metabolic routes that glucose-6-PO_4 normally undergoes and therefore remains trapped inside the cell (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

high rates of metabolism with increased glucose metabolism (Warburg effect), correlated also to proliferative activity. Gene-mediated regulation of the GLUT system and hexokinase activity contributes to the increased accumulation of [^{18}F]FDG in tumor cells relative to normal tissues; due to this factor, the time-related pattern of [^{18}F]FDG accumulation in malignancy may be different from that of benign lesions and inflammatory processes.

The mechanisms leading to elevated glucose metabolism in cancers are multifactorial and include tumor-related components, biochemical and molecular alterations (e.g., glucose metabolic pathway, hypoxia), and nontumor-related constituents (e.g., inflammation). [^{18}F]FDG is excreted through the kidneys, about 20% of injected activity being excreted in the urine within 2 h after administration. The uptake of [^{18}F]FDG, which competes with endogenous glucose, by tumor tissue depends on plasma glucose levels; in case of high blood glucose levels (as well as low insulin level), the uptake of [^{18}F]FDG is reduced. In the same way, some drugs that modify glucose level (e.g., valproic acid, glucocorticoids, carbamazepine) can alter radiotracer uptake. Many other factors (e.g., chemotherapy, radiation therapy, or recent administration of granulocyte-colony-stimulating factor) interfere with [^{18}F]FDG uptake, thus possibly resulting in false-positive or false-negative imaging data.

[^{11}C]Glucose, the perfect radioactive counterpart of endogenous glucose, has been synthesized, but the short physical half-life of the radionuclide and the production of labeled metabolites with fast washout from tissues and return to circulating blood limit the clinical application of this tracer.

Nitrogen-13 Ammonia

Nitrogen-13 ammonia ([^{13}N]ammonia) is used mostly for quantitative imaging of myocardial blood flow. In physiologic conditions, the majority of [^{13}N]ammonia circulates in the form of the ammonium ion, NH_4^+. Following i.v. injection, [^{13}N]ammonia is rapidly cleared from the bloodstream and diffuses across the cell capillary membrane entering the cells via the ammonium transporter. Once in the cell, it is metabolized to

^{13}N-glutamine by glutamine synthetase and trapped within tissues such as the myocardium, liver, brain, and other organs. Its uptake in the tissues is proportional to blood flow. The main metabolite of [^{13}N]ammonia is [^{13}N]urea, which is excreted through the kidneys.

[^{13}N]ammonia is used clinically for myocardial perfusion studies and quantification of myocardial blood flow and flow reserve. The high net extraction fraction of $^{13}NH_3$ by myocardial cells (80%) and its short positron range (0.4 mm) yield very high-quality PET images.

Oxygen-15 Water

Oxygen-15 water ([^{15}O]H_2O) is excellent to trace blood flow. It is a freely diffusible agent, most frequently used to investigate cerebral and myocardial perfusion, as well as tumor perfusion. Thanks to the short physical half-life, perfusion studies can be repeated every 8–10 min. As a cyclotron product with a very short half-life (2.04 min), its use in the clinical setting is to institutions with an on-site cyclotron.

Rubidium-82 Chloride

Rubidium-82 chloride (^{82}RbCl) is a potassium analog used for PET myocardial perfusion imaging. Once administered intravenously, ^{82}RbCl dissociates rapidly, and the $^{82}Rb^+$ ion is rapidly extracted by the myocardium in a fashion which is proportional to blood flow and enters the myocardial cells through the Na^+/K^+ ATPase pump, similarly to ^{201}Tl. Myocardial activity is noted within the first minute after the i.v. injection. The first-pass extraction fraction is about 50–60% at resting blood flow levels, and several studies have demonstrated that extraction decreases in a nonlinear manner at high blood flow rates. ^{82}Rb decays to stable krypton-82 (^{82}Kr), which is exhaled through the lungs.

Due to the short half-life of ^{82}Rb (76 s) and the rapid replenishment of ^{82}Sr/^{82}Rb generator (making it possible to elute every 10 min), fast sequential resting and pharmacological stress myocardial perfusion studies can be performed, in order to quantitatively assess not only myocardial blood flow but also the coronary artery blood flow reserve.

Despite the ultrashort half-life and the high kinetic energy (3.15 MeV) resulting in a relatively long positron range, ^{82}RbCl still provides very good-quality PET images, and it has been demonstrated that myocardial perfusion studies with ^{82}Rb-PET have superior accuracy than scans based on the use of ^{99m}Tc-labeled agents.

[^{11}C]Methionine and Other Tracers for Protein Synthesis

Tumor cells generally exhibit increased amino acid transport and increased protein synthesis rates. Several processes contribute to enhance amino acid transport per se in addition to overall protein synthesis, including transamination and transmethylation, a specific role of methionine in initiating protein synthesis, and the use of amino acids as glutamine for energy.

Many amino acids and analogs labeled with β^+ emitters have been developed to measure either the rate of protein synthesis or the rate of uptake into the cells; these tracers differ in ease of synthesis, biodistribution, and formation of radiolabeled metabolites in vivo, but only a few have substantial impact in clinical oncology.

The first tracer used for PET imaging to assess protein synthesis was [^{11}C]carboxyl L-leucine (Fig. 4); however, recycling of radiolabeled amino acids deriving from the degradation of radiolabeled proteins greatly limited the feasibility and clinical usefulness of this approach.

Methyl-[^{11}C]-L-methionine ([^{11}C]MET) (Fig. 5) has been used widely in PET imaging. The uptake is increased in brain tumors (even low grade), head-and-neck cancers, lung cancer, and breast cancer. Physiological uptake of this tracer (which is excreted mostly through the kidneys – thus resulting in considerable accumulation in the urinary bladder) is observed in the liver, pancreas, and intestine. Moreover, [^{11}C]MET has been proposed also for localization of parathyroid adenomas (sensitivity 83%, specificity 100%).

Nevertheless, several problems are linked to the use of amino acids labeled with ^{11}C, such as recycling of radiolabeled metabolites, slow incorporation of the amino acid tracers into proteins, and above all the short half-life of ^{11}C. These problems have stimulated ongoing efforts to develop amino acids labeled with β^+ emitters with a longer half-life. In particular, tyrosine analogs such as L-3-[^{18}F]-fluoro-a-methyltyrosine (^{18}F-FMT) and *O*-(2-[^{18}F]fluoroethyl)-L-tyrosine (^{18}F-FET) (Fig. 6) or phenylalanine analogs have been synthesized. ^{18}F-FET enters the cells through amino acid transporters, but does not appear to be directly involved in protein synthesis. Both ^{18}F-FMT and ^{18}F-FET accumulate rapidly (within 30 min postinjection) in brain tumors and then wash out slowly.

Nontumoral uptake of all radiolabeled amino acids (though generally less intense than in tumors) includes ischemic brain areas, scar tissue, sarcoidosis, recently irradiated areas, and hemangiomas. Whereas, their uptake in inflammatory tissue is much lower than [^{18}F]FDG uptake.

Choline-Based Tracers for Phospholipid Synthesis

The synthesis of cell membrane is very rapid in neoplastic tissue, reflecting indirectly the rate of cell proliferation. Choline, an essential element of the phospholipid constituents in the cell membrane, is transported into cells and phosphorylated by choline kinase before being incorporated into

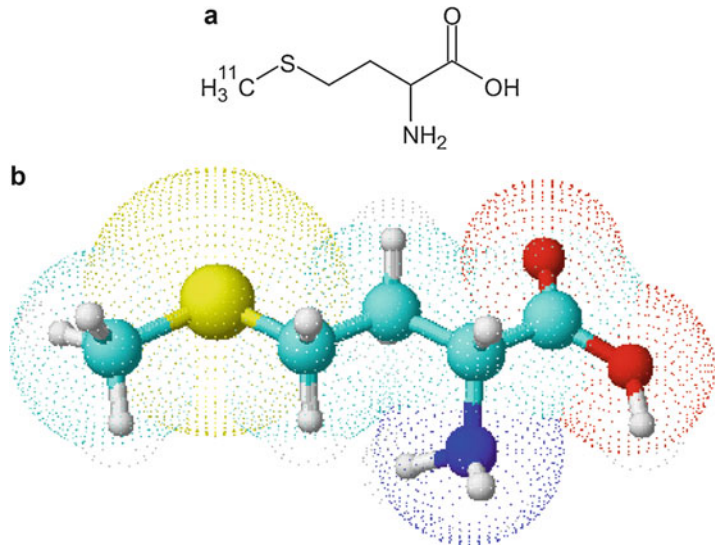

Fig. 5 Chemical formula in extenso (**a**) and tridimensional representation of chemical structure (**b**) of methyl-[^{11}C]-L-methionine ([^{11}C] MET). Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

the membrane phospholipids. Besides other molecular signatures of increased energy expenditure and accelerated proliferation, tumor cells have enhanced levels of choline kinase.

[^{11}C]Choline (Fig. 7) has mostly been used for imaging of prostate tumors, non-small cell lung cancer, urinary bladder, and brain neoplasms. The increased incorporation in prostate cancer is linked to enhanced phosphatidylcholine production, phospholipid synthesis, and upregulation of choline kinase and other enzymes. Limitations in the widespread clinical use of [^{11}C]choline are common to other radiopharmaceuticals labeled with ^{11}C, i.e., in situ availability of a cyclotron for the production of this short half-life radionuclide (approximately 20 min).

More usable choline analogs labeled with ^{18}F include ^{18}F-fluoroethylcholine (^{18}F-FEC) (Fig. 8) and ^{18}F-fluoromethylcholine (^{18}F-FCH, the PET agent commercially available) (Fig. 9); they have similar biodistribution patterns, with higher urinary excretion than [^{11}C]choline. Physiologic bowel and liver uptake of radiolabeled cholines limits suitability of these tracers for PET imaging of gastrointestinal and liver cancers.

Fluorine-18 Sodium Fluoride

Fluorine-18 sodium fluoride ([^{18}F]fluoride) was first introduced as a bone-imaging agent for skeletal scintigraphy in the early 1960s and approved by the FDA in 1972. It was then withdrawn from the approval list in 1984 because of technical limitations at that time, that is, the difficulty in imaging the 511 keV annihilation photons with

Elements are represented with the following color codes: *red* = O, *gray* = H, *light blue* = C, *deep blue* = N, and *green* = ^{18}F (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

gamma cameras optimized for 100–200 keV γ rays; the concomitant wide diffusion of ^{99m}Tc-labeled diphosphonates contributed to the declining interest in ^{18}F-fluoride for bone scintigraphy.

Interest in the clinical use of [^{18}F]fluoride as a bone-scanning agent has more recently been revived after the development of modern PET scanners. [^{18}F]Fluoride is administered intravenously (185–370 MBq), and the intensity and extent of its uptake reflects blood flow and bone remodeling. This agent has high and rapid bone uptake combined with a fast, biexponential blood clearance that results in achievement of a high bone-to-background ratio within a short time; in fact, imaging can be performed less than 1 h after administration. ^{18}F-ion exchanges for an OH^- ion on the surface of the hydroxyapatite matrix of the bone and remains then chemisorbed into the crystalline matrix where it is retained until the bone is remodeled. Red blood cell uptake (30% of the injected activity) does not interfere with bone uptake. Within the first 1–2 h upon administration of Na^{18}F, about 20% is excreted through the urinary tract.

The normal biodistribution of Na^{18}F is in general rather uniform, but the axial skeleton has a higher uptake than the appendicular skeleton, and the bone around joints has higher uptake than the shafts of long bones.

Increased fluoride uptake has been reported in both sclerotic and partly lytic metastases. As for ^{99m}Tc-labeled diphosphonates, purely lytic lesions have lower or no uptake at all. ^{18}F-Fluoride is not a tumor-specific tracer, and its clinical usefulness has been demonstrated also for a wide range of benign diseases of the bone.

Fluorine-18 Misonidazole and Other Hypoxia Tracers

The irregular development of tumor-induced neoangiogenesis results in tissue hypoxia, which is associated with the promotion of various metabolic mechanisms; hypoxia is also a prognostic indicator

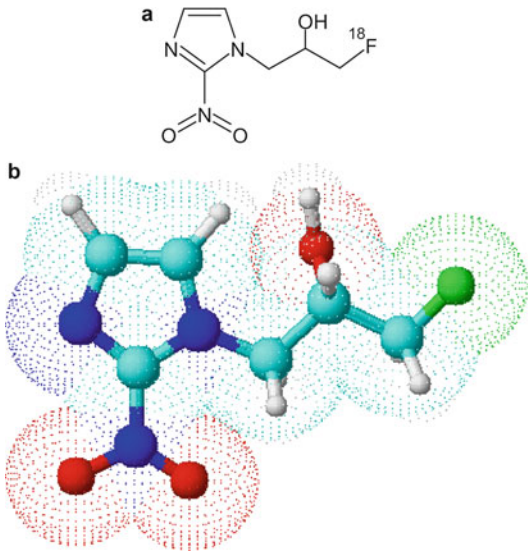

Fig. 10 Chemical formula in extenso (**a**) and tridimensional representation of chemical structure (**b**) of ^{18}F-misonidazole (^{18}F-MISO). Elements are represented with the following color codes: *red* = O, *gray* = H, *light blue* = C, *deep blue* = N, and *green* = ^{18}F (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

of poor response to radiotherapy and chemotherapy, as it induces resistance to these treatments. Tumors may consist of up to 50–60% hypoxic or anoxic tissue heterogeneously distributed. The first radiotracer, ^{18}F-misonidazole (^{18}F-MISO, Fig. 10) is a nitroimidazole derivative developed in 1984. ^{18}F-MISO is relatively hydrophilic and diffuses slowly across cell membranes; such a passive distribution in normal tissues results in a relatively long waiting time before acquisition of PET imaging, since the lesion-to-background ratio is typically <2:1 at about 90 min after injection. The oxygen-dependent intracellular metabolism of nitroimidazole consists in one-electron reduction and in selective binding to macromolecules within hypoxic cells. The tracer undergoes renal excretion.

PET imaging with ^{18}F-MISO is used to quantitatively assess tumor hypoxia in lung, brain, and head-and-neck cancers (as well as for the evaluation of myocardial ischemia).

Fluorine-18-labeled fluoroetanidazole (^{18}F-FETA), a fluorinated analog of etanidazole, has similar oxygen-dependent binding and tumor retention compared to ^{18}F-MISO, but it releases fewer metabolites in plasma and urine. ^{18}F-Fluoroerythronitroimidazole (^{18}F-ETNIM) is an additional novel promising radiopharmaceutical with faster elimination from well-oxygenated tissues, because it is more hydrophilic.

Fluorine-18 DOPA and Other Amine Precursors

The process of amine precursor uptake and decarboxylation (APUD) is a common feature shared by many endocrine cells producing peptide hormones, including neuroendocrine tumors, and indicates a common embryological origin from the neural crest. Neuroendocrine tumors (NETs) accumulate and decarboxylate the amino acid L-dihydroxyphenylalanine (L-DOPA) due to increased activity of L-DOPA decarboxylase. Following systemic administration, L-3,4-dihydroxy-6-[^{18}F]fluorophenylalanine (^{18}F-DOPA, Fig. 11), an analog of L-DOPA, enters the catecholamine metabolic pathway both in the brain and in peripheral tissues. Based on this property, PET with ^{18}F-DOPA is used in the evaluation of presynaptic striatal dopaminergic function in some neurologic disorders (chiefly movement disorders such as Parkinson's disease and parkinsonisms), as well as for the evaluation of patients with brain tumors, with NETs, with insulinoma (particularly in pediatric patients), with medullary thyroid cancer, with pheochromocytoma, and with extra-adrenal paraganglioma.

After i.v. administration, up to 1% of the injected ^{18}F-DOPA crosses the blood–brain barrier and is transported into presynaptic neurons via the amino acid transport system, where an amino acid decarboxylase converts it to ^{18}F-fluorodopamine, which is stored in intraneuronal vesicles within the striatum.

In peripheral tissues, ^{18}F-DOPA is metabolized to ^{18}F-fluorodopamine or to 3-*O*-methyl-6-fluoro-L-DOPA and excreted mainly through the kidneys. The renal excretion may be reduced by

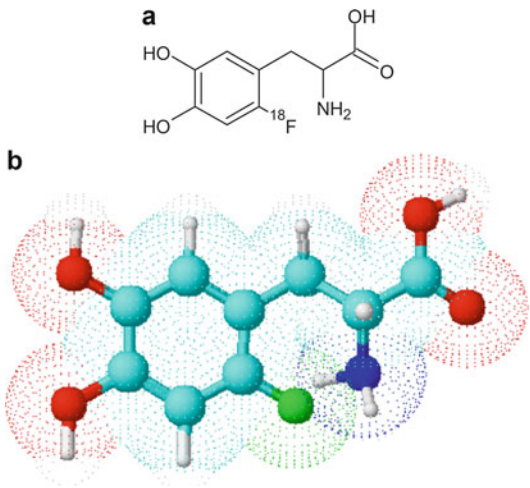

Fig. 11 Chemical formula in extenso (**a**) and tridimensional representation of chemical structure (**b**) of [^{18}F] fluorophenylalanine (^{18}F-DOPA). Elements are represented with the following color codes: *red* = O, *gray* = H, *light blue* = C, *deep blue* = N, and *green* = ^{18}F (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

premedication with the decarboxylase inhibitor carbidopa, with the goal of improving in general the tumor uptake, except in patients with insulinomas or β-cell hyperplasia.

[^{11}C]hydroxytryptophan is another PET tracer used for the localization of NETs, including insulinomas; this tracer is taken up by tumor cells, decarboxylated, and then stored and irreversibly trapped in vesicles as [^{11}C]serotonin.

Gallium-68 DOTATOC (Edotreotide) and Other Somatostatin Analogs

Neuroendocrine tumors (NETs) are characterized by the presence of peptide receptors on the cell membrane, particularly the somatostatin (SS) receptors. Somatostatin analogs have been radiolabeled with diagnostic radionuclides as well as with emitters of β^- particles for targeted radionuclide therapy. Five specific SS receptor subtypes (SSTR1–SSTR5) with different tissue distribution and affinity for somatostatin analogs have been identified. They are expressed also in peritumoral vessels and in inflammatory and immune cells, and this can account for visualization of those tumors whose cells do not express the receptors. The most commonly used somatostatin analog is octreotide that has high binding affinity to somatostatin receptor subtypes 2 and 5 but binds varyingly to the SSTR3 and SSTR4 subtypes. DOTA-Tyr^3-octreotide (DOTA-TOC, or DOTATOC) can be variously labeled with either γ or β^+ emitters (for imaging), as well as with β^- emitters (such as ^{90}Y or ^{177}Lu, for therapy) (see also ► Chap. 8, "Novel Radiopharmaceuticals for Therapy" of this book). DOTA (1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid) is a macrocyclic chelating agent that forms stable complexes with the metal radionuclide of interest. At variance with DTPA (which is an open structure enabling to label radioconjugates at room temperature), DOTA is a closed structure, and labeling must be performed at high temperature (90 ± 5°C) in order to open the ring circumscribed by the four nitrogen atoms; in turn, the radioconjugates obtained with DOTA derivatives are much more stable in vivo than those obtained with DTPA. The time required to recover ^{68}Ga from the ^{68}Ge/^{68}Ga generator, to synthesize, and to purify the ^{68}Ga-labeled DOTA-conjugated peptides is less than 20 min, resulting in an overall simple and radiochemically efficient processing.

^{68}Ga-DOTATOC (Fig. 12) has a fast pharmacokinetic profile (about 80% of activity being rapidly cleared from circulating blood already at 10 min postinjection) and fast tumor accumulation (maximum after 70 ± 20 min after injection); these features enable effective PET imaging already 1 h after radiotracer administration; excretion occurs predominantly through the kidneys. The accumulation in tissues that do not express somatostatin receptors is generally very low, thus resulting in high tumor/background ratios; nevertheless, particular attention must be paid to imaging interpretation concerning the sites of physiological accumulation such as the spleen, the liver, the

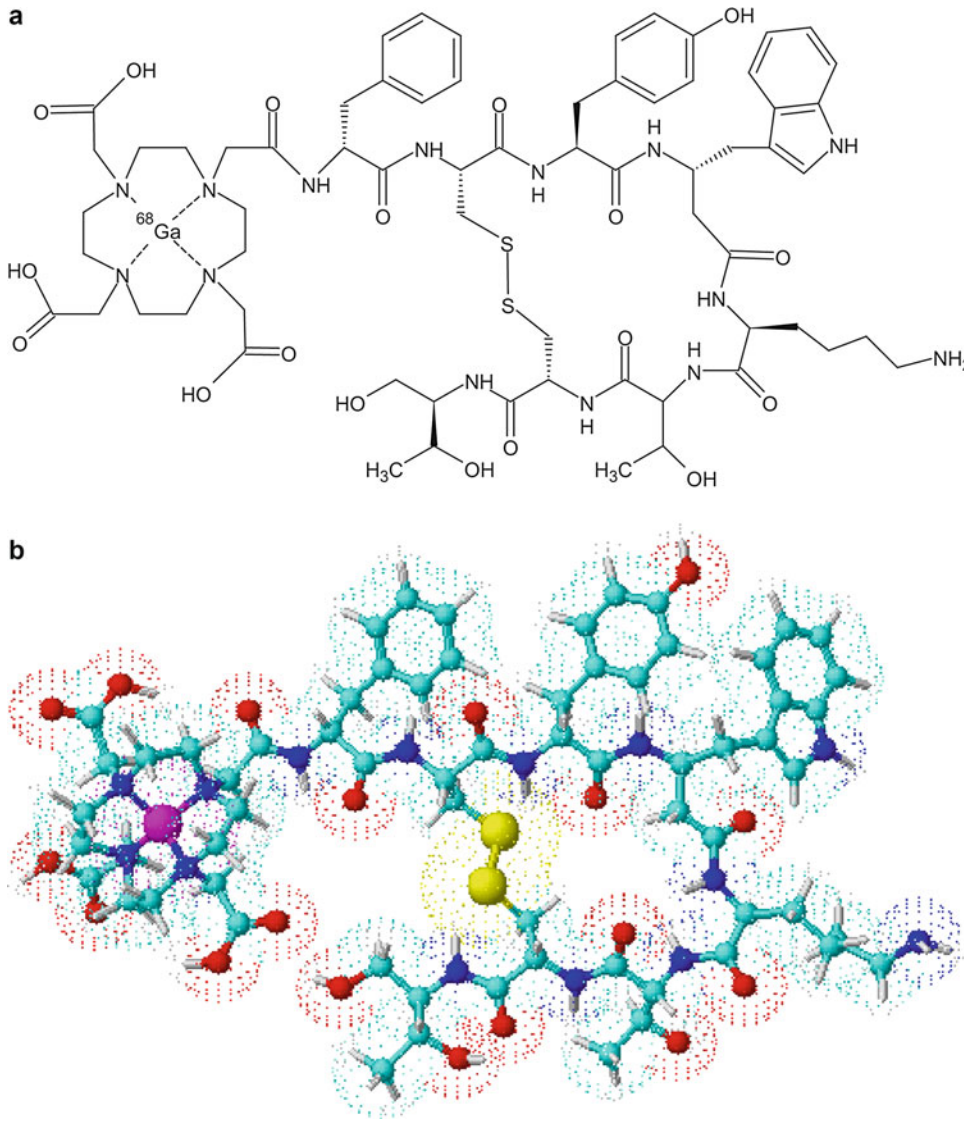

Fig. 12 Chemical formula in extenso (**a**) and tridimensional representation of chemical structure (**b**) of ^{68}Ga-DOTA-Tyr^3-octreotide. Elements are represented with the following color codes: *red* = O, *gray* = H, *light blue* = C, *deep blue* = N, *yellow* = S, and *fuchsia* = ^{68}Ga (Reproduced with permission from: Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare – Tecniche e applicazioni. Milan: Springer; 2010)

adrenal glands, the urinary pathways, and the pituitary gland.

Other radiolabeled somatostatin analogs for PET imaging include ^{68}Ga-DOTA-1-Nal^3-octreotide (^{68}Ga-DOTANOC, with better binding affinities for SSTR2, SSTR3, and SSTR5) and ^{68}Ga-DOTA-Tyr^3,Thr^8-octreotide (^{68}Ga-DOTATATE, with predominant affinity for SSTR2).

Abstract

Common radionuclides used for radiometabolic therapy include ^{131}I, ^{153}Sm, ^{89}Sr, ^{223}Ra, and ^{90}Y. In this chapter we will focus on therapeutic radiopharmaceuticals are employed for therapy of differentiated follicular thyroid carcinomas,for therapy of pheochromocytoma/paraganglioma/neuroblastomas, for bone pain palliation, for radioimmunotherapy of lymphomas, for peptide radioreceptor therapy of neuroendocrine tumors, and for intra-arterial radioembolization of hypervascularized tumors of the liver.

Background

A radiopharmaceutical is a compound containing a radionuclide, which is employed clinically for the detection, characterization, or treatment of disease. While diagnostic radiopharmaceuticals are γ or β^+ emitters, therapeutic radiopharmaceuticals exert their action through the emission of electrically charged particles (β^- or α^{++} particles) that deposit their energy within a relatively limited range in the tissue, thus causing radiation damage to the site of localization, the desired radiobiological effect resulting in cell death. Depending on their energy, the β^- particles emitted by radionuclides utilized for therapeutic radiopharmaceuticals typically travel a few millimeters from their emission point (or even few micrometers, as in the case of the very low-energy Auger electrons); on the other hand, α^{++} particles typically travel few tens of micrometers in tissues. In addition to particle emission causing a cytocidal radiobiological effect, some therapeutic radiopharmaceuticals also emit γ-rays, which can be detected with a conventional gamma camera and thus can provide information on their distribution in the body. This information is useful to confirm that the administered radiopharmaceutical has in fact concentrated in the target tissue of interest (usually tumor lesions) and to allow a posteriori calculation of the radiation dose to the target lesion (s) and to normal tissues/organs.

Therapeutic radiopharmaceuticals can be administered systemically through the i.v. route or orally, intracavitary, or even via the intra-arterial route. Although the focus of this chapter is on radionuclide therapy employed for treatment of various forms of cancer with either curative or palliation purposes, in some instances radionuclide therapy is utilized to reduce an organ's function (e.g., for hyperthyroidism).

Table 1 lists the most widely used radionuclides for labeling currently approved radiopharmaceuticals to be used in nuclear oncology and their main physical properties. Radiopharmaceuticals can be classified based on physical characteristics of the radionuclide (type and energy of the characteristic emissions, physical half-life) or

Table 1 Most widely used radionuclides and their main physical properties for approved therapeutic radiopharmaceuticals in oncology

Radionuclide	$T_{1/2}$	E_{max}/E_{mean} (MeV)	Emissions (main)	Max penetration in water (mm)
^{32}P	14.3 days	1.71/0.694	β^-	7.6
^{89}Sr	50.5 days	1.46/0.58	β^-	6.7
^{90}Y	64.1 h	2.28/0.937	β^-	11–11
^{131}I	8.02 day	0.606/0.18	β^-	2–4

		0.113, 0.208	γ	
^{188}Re	16.8 h	2.12/0.76	β^-	11
		0.155	γ	
^{223}Ra	11.4 days	5–7.5	α^{++}	<0.01

Table 2 Main mechanisms of distribution/localization of radiopharmaceuticals used for therapeutic purpose.

Mechanism(s)	Rationale	Example
Mechanical trapping (capillary blockade)	The regional distribution of perfusion in an organ can be assessed by administering in the afferent blood vessel radiolabeled particles that, because of their large size (tens of μm), cause microembolization in the precapillary bed of an organ	^{90}Y-microspheres for treatment of liver tumors (intra-arterial)
Membrane transport: simple, facilitated, and active transport	Active, energy-dependent transmembrane transport of molecules against a concentration gradient: sodium-iodide symporter	^{131}I-ioide for the treatment of malignant or benign thyroid disease
Accumulation in intracellular, neurosecretory vesicles	ATPase-linked energy-dependent process physiologically utilized for the intracellular accumulation of noradrenaline	[^{131}I]MIBG for the treatment of neural-crest-derived neuroendocrine tumors
Non-receptor-mediated binding	Radiolabeled antibodies (whole antibodies or engineered minibodies) targeting specific antigen sites on the surface of tumor cells	^{90}Y-Ibritumomab tiuxetan (anti-CD20) for radioimmunotherapy of non-Hodgkin's lymphoma (NHL)
Receptor-mediated probes	The radiopharmaceutical competes with the physiologic ligands for binding with the target receptor	Somatostatin analogs used for neuroendocrine tumors as vehicles to guide radioactivity to tissues expressing somatostatin receptors
Ion exchange (chemisorption)	Exchange of ions between two electrolytes or between an electrolyte solution and a complex (binding to hydroxyapatite crystals or to amorphous calcium phosphate)	Bone-seeking, bisphosphonate-based radiopharmaceuticals for the treatment of metastatic bone disease

else on their physicochemical properties of the molecule (size, hydro- or lipophilicity, positive, negative, or neutral electrical charge) and mechanism of localization (Table 2).

Selection of the most appropriate radionuclide for any given therapeutic application should take into account the nature of the particulate radiations and their energies, physical half-life, and chemistry in relation to the carrier molecule (see also ▶ Chap. 2, "Principles of Molecular Targeting for Radionuclide Therapy" of this book). The possibility of deriving pretreatment dosimetric

estimates is also very important. The ionizing radiations with therapeutic potential involve β^- particle emitters, α-particle emitters, and emitters of Auger electrons. These radionuclides are linked to carrier molecules capable of (selectively) transporting the radiotracers to the target tissue. The main target for the biologic effects of ionizing radiation is DNA. Biologic response to ionizing radiation depends on many factors: cell radiosensitivity, localization of the radiopharmaceutical, and physical properties such as absorbed dose and linear energy transfer (LET) of the emitted radiation (see also ▶ Chap. 13, "Radiobiology and Radiation Dosimetry in Nuclear Medicine" of this book). The latter parameter, expressed in keV/μm, reflects energy deposition and, therefore, ionization density along the track of a charged particle. Any γ-emission possibly associated to the particle emission does not contribute to the effectiveness of therapy and may even lead to an increase of irradiation to nontarget tissues. Nevertheless, this emission can be exploited to obtain sequential scintigraphic images, therefore to determine the time course of in vivo localization of the radiopharmaceutical, to be used for radiation dosimetry calculations.

Alpha-Particle Emitters

Alpha particles are positive helium nuclei; their emission leads to a daughter nucleus with two fewer protons and two fewer neutrons than in the original radionuclide. These monoenergetic particles are usually emitted with high energy (5–8 MeV) and produce a high density of ionization along their short linear tracks of 40–100 μm, corresponding to about five to ten cell diameters. LET values of α-particles are typically in the 80–100-keV/μm range. Their biologic effect is independent of the oxygenation state or cell cycle phase, as their interaction with the cell nucleus results in single- and/or double-strand DNA breaks that are lethal per se for the cell. The tumoricidal effect is maximal if the α-particles are emitted within the cell nucleus. Despite the existence of over 100 α-emitting radionuclides, investigations on the therapeutic potential of α-particle emitters has focused mainly on five radionuclides (^{223}Ra, ^{211}At, ^{212}Bi, ^{213}Bi, and ^{225}Ac), because either the physical or chemical characteristics of the remainders are not appropriate for therapeutic use.

Radium-223 (^{223}Ra)

^{223}Ra (energy 5.7 MeV, half-life 11.4 days) for medical use is normally produced by a ^{227}Ac generator (half-life 21.8 years), with the intermediate decay step of thorium-227 (half-life 18.7 years); this system guarantees availability of the radionuclide for long periods. ^{223}Ra ultimately provides for the emission of four α-particles per decay. There are also minor associated emissions resulting in the production of β^- (3.6%) and γ (1.1%) radiations with different energies and emission probabilities. Administered as a chloride salt, the $^{223}Ra^{++}$ ion behaves in vivo as a calcium analog and has therefore bone-seeking properties that make this radionuclide useful for treating bone pain from skeletal metastases.

Auger Electron Emitters

Auger electrons are low-energy orbital electrons emitted after electron capture. Electron capture causes a vacancy, which is filled by electrons moving from an outer shell and thus initiating a cascade of electron transitions that shift the vacancy toward the outermost shell. Auger electrons have an extremely short path length in tissues (2–500 nm), with LET ranging from 4 to 26 keV/μm. Localization of the radionuclide within the cell, especially within the cell nucleus, is required to achieve cell killing, as mitochondrial or cell surface localization does not produce significant cytotoxic effects. Auger-electron emitters of radiobiologic interest include ^{67}Ga, ^{75}Se, ^{77}Br, ^{111}In, ^{125}I, ^{123}I, ^{165}Er, ^{197}Hg, ^{117m}Sn and ^{201}Tl.

Emitters of β^- Particles

Radionuclide therapy is presently based almost exclusively on radioisotopes emitting β^- particles. These negatively charged particles have low LET

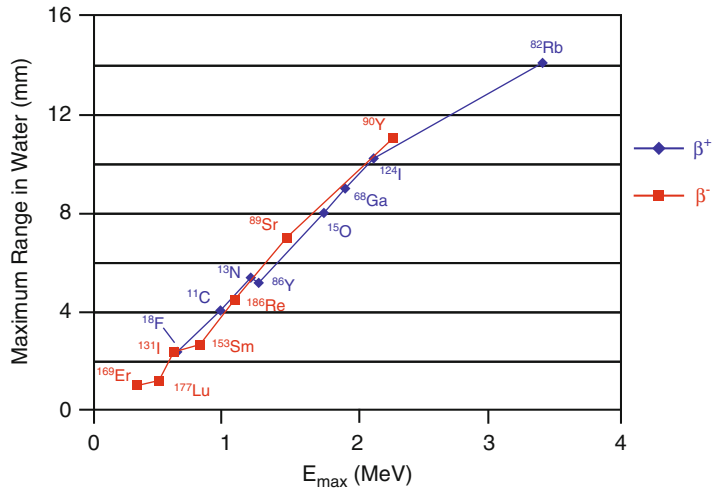

Fig. 1 Correlation between maximum energy (E_{max}, expressed in MeV) and maximum range in water of either β^+ or β^- particles emitted during decay of different radionuclides employed for either diagnostic purposes (β^+) or therapeutic purposes (β^-). Most of the energy deposited by each emission is nevertheless limited within a much shorter range (about 20–25% of the maximum range). The plot demonstrates that electrical charge does not influence the path of β particles, as the only determinant factors are mass and energy

(0.2 keV/μm) and a continuous spectrum of energy. After their emission, the daughter nucleus has one more proton and one less neutron than the original radionuclide. Their maximum path length in tissues ranges from 0.05 to 12 mm (at least for the radionuclides currently employed for therapy), depending on the energy of the particle (see Fig. 1). Therefore, optimal therapeutic activity requires a higher radionuclide concentration within the target tissue compared to α emitters, in order to obtain comparable radiobiologic efficacy. However, the longer path length in tissues results in the so-called crossfire effect, thus irradiating also the cells that have not directly accumulated the radionuclide (Fig. 2). This effect reduces the problems possibly caused by inadequate uptake and heterogeneous distribution of a given radiopharmaceutical within the target tissue.

Iodine-131 (^{131}I)

In addition to γ-rays, the radiohalogen ^{131}I (half-life 8.04 days) emits β^- particles with maximum energy of 0.61 MeV and a maximum path range of 2–4 mm in tissues (mean 0.7 mm). In the chemical form of ^{131}I-iodide, this radionuclide is extensively employed since several decades for treating benign and malignant thyroid diseases. Other therapeutic applications involve radiolabeling with ^{131}I of more complex molecules, such as MIBG or monoclonal antibodies. Incorporation of radioiodine is generally achieved through an oxidation reaction involving, for example, an OH^- radical in a tyrosine residue or a $-CH_3$ group; within certain limits (i.e., number of radioiodine atoms per molecule not to exceed 1), the resulting molecule of biologic interest has a metabolic fate very close to that of the native, unlabeled molecule, since the steric radius of the halogen atom is very similar to that of the hydroxyl or methyl groups.

Yttrium-90 (^{90}Y)

The radiometal ^{90}Y (half-life 64 h) emits high-energy β^- particles (2.2 MeV) with a maximum path length of 11–12 mm. This radionuclide is produced by the generator system ^{90}Sr/^{90}Y and decays to stable ^{90}Zr. Decay is associated with pair production of β^+ particles, although in a minimal proportion (32 β^+ particles per million decays). Radiolabeling of peptides and monoclonal antibodies requires the use of a bifunctional chelate, for example, DOTA or tiuxetan.

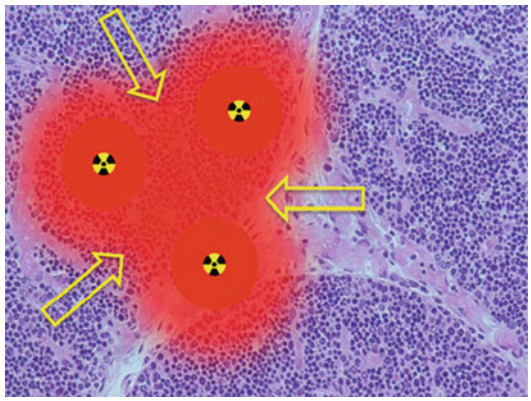

Fig. 2 Schematic representation of the so-called crossfire effect for particle-emitting radionuclides employed for therapy (assumed to be β^- particles for this representation). Because of delivery of energy within a certain range from the point of emission, the radiotoxic effect is not limited to the cells that specifically accumulate the radiopharmaceutical but also involves nearby cells (either they be neoplastic or tumor cells). In this representation, it is assumed that the radiopharmaceutical has accumulated at three specific locations within a tumor lesion (the uptake points are indicated by the radioactivity symbol). The *red* area with decreasing intensity from the center depicts the range in tissue along which the particles travel and deposit their energy, with maximum in the center and decreasing delivery of energy toward the periphery. The *arrows* indicate the tissue zones between the different radionuclide localization points; these are the cells exposed to the crossfire effect (From Volterrani D, Erba PA, Mariani G, eds. Fondamenti di medicina nucleare—tecniche e applicazioni. Milan (Italy): Springer; 2010, with permission)

There are currently three major clinical uses of ^{90}Y: to label a monoclonal antibody for radioimmunotherapy of lymphomas, bound to resin or glass microspheres for transarterial radioembolization of liver tumors, and to label somatostatin analogs for peptide receptor radionuclide therapy of neuroendocrine neoplasms. During radioimmunotherapy with ^{90}Y-tiuxetan-ibritumomab, the radiolabeled antibody binds to lymphocytes expressing the CD20 antigen, resulting in death of these cells. Treatment with ^{90}Y-tiuxetan-ibritumomab is approved for previously untreated follicular NHL that achieve a partial or complete response to first-line chemotherapy and relapsed or refractory, low-grade, or follicular B-cell NHL. Resin or glass microspheres containing ^{90}Y are approved forms of treatment for either primary or metastatic liver tumors, to be administered during selective or super-selective catheterization of the main or the segmental branches of the hepatic artery. Effective forms of peptide receptor radionuclide therapy of neuroendocrine neoplasms expressing somatostatin receptors has initially been based solely on the use of somatostatin analogs labeled with ^{90}Y, although more recently interest is also focusing on peptide analogs labeled with ^{177}Lu (see below). Regarding the use of ^{90}Y for therapy of non-tumoral diseases, ^{90}Y-colloid can be used for radiosynoviorthesis of the large joints.

Lutetium-177 (^{177}Lu)

The radiolanthanide ^{177}Lu (half-life 6.7 days) decays through the emission of β^- and γ-radiations. The β^- particles emitted by ^{177}Lu have a maximum energy of 0.49 keV and a maximum path range of 2 mm in water. The γ-emission has energy photopeaks of 113 keV (6.4%) and 208 keV (11%), which is suitable for imaging with conventional gamma cameras. Lutetium-177 is increasingly being used in patients for receptor-targeted radionuclide therapy with peptides such as DOTA^0-Tyr^3-octreotate. Other possible uses of ^{177}Lu include conjugation with bisphosphonates (e.g., ^{177}Lu-EDTMP), to produce a bone-seeking radiopharmaceutical for treatment of bone pain from skeletal metastases.

Samarium-153 (^{153}Sm)

This radiolanthanide is produced by neutron capture using a samarium target enriched in ^{152}Sm. Its physical decay half-life is 1.9 days, and it emits β^- particles with maximum energy of 0.81 MeV and maximum path range in water of approximately 3 mm. ^{153}Sm also emits γ-rays (103-keV photo peak) suitable for gamma camera imaging. The prevalent use of ^{153}Sm is in the chemical form of a radiolabeled diphosphonate (^{153}Sm-EDTMP; see Fig. 3a), which is employed in the clinical routine for treating osteoblastic bone metastasis.

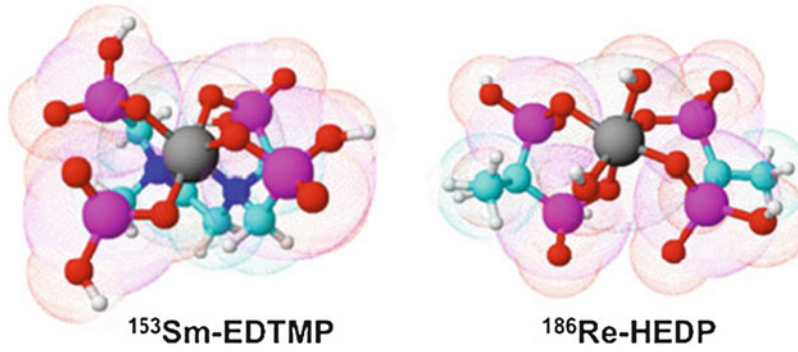

Fig. 3 Chemical structure of the radiolabeled bone-seeking bisphosphonates employed for palliation therapy of bone pain from skeletal metastasis. For simplicity of representation, the *gray* atom at the center of each 3-D structure represents the radionuclide (^{153}Sm for ^{153}Sm-EDTMP, ^{186}Re for ^{186}Re-HEDP). Other elements are represented with the following color codes: *red* = O, *white* = H, *fuchsia* = P, *light blue* = C, *dark blue* = N

Strontium-89 (^{89}Sr)

This alkaline earth metal radionuclide (half-life 50.5 days) is a pure emitter of β^- particles with a maximum energy of 1.46 MeV (average 0.58 MeV). The maximum path length in tissues of these β^- particles is 6–8 mm. Its current clinical use is for treatment of osteoblastic bone metastasis, in the simple chemical form of chloride salt; the $^{89}Sr^{++}$ behaves in vivo as a calcium analog and is therefore rapidly adsorbed on the newly formed bone mineral component, where it is retained with a physical half-life of 50.5 days.

Rhenium-186 (^{186}Re) and Rhenium-188 (^{188}Re)

Rhenium is a group VII metal with labeling chemistry properties similar to those of technetium; for this reason, its radioactive isotopes have attracted attention for the potential of directly translating to rhenium radionuclides the vast radiochemistry experience accumulated with ^{99m}Tc. Rhenium-186 is normally produced by direct neutron activation of metallic rhenium enriched with ^{185}Re via the ^{185}Re(n,γ)^{186}Re nuclear reaction; alternative routes through the ^{186}W(p,n)^{186}Re and the ^{186}W(d,2n)^{186}Re nuclear reactions yield no-carrier-added ^{186}Re. ^{186}Re (half-life 3.7 days) decays with the emission of β^- particles (maximum energy 1.09 MeV and path range 1–2 mm) and a low abundance (9%) of γ-ray (137 keV). Although also ^{188}Re (half-life 16.9 h) can similarly be produced in a thermal reactor through the ^{186}W(n,γ)^{188}Re nuclear reaction, the radionuclide for medical uses is more conveniently produced in the no-carrier-added form using a ^{188}W/^{188}Re generator; ^{188}W has a half-life of 69 days, thus making use of the generator especially convenient for immediate local availability of ^{188}Re on demand with the use of instant-labeling kits also in remote locations. ^{188}Re has maximum energy of 2.12 MeV and decays to stable ^{188}Os, with a γ-ray emission of 155 keV (15%).

These two radionuclides are currently used clinically for treatment of bone pain from skeletal metastases, after conjugation to diphosphonates (see Fig. 3b).

Phosphorus-32 (^{32}P)

Phosphorus-32 is a pure emitter of β^- particles (physical half-life of 14.3 days) with a maximum energy of 1.71 MeV (average 0.659 MeV). The maximum path length in tissues of these β^- particles is 8 mm. Treatment for ^{32}P in the chemical form of orthophosphate is indicated for palliation of bone pain from skeletal metastases, polycythemia vera, and essential thrombocythemia.

Treatment of Thyroid Disease with ^{131}I-Iodide

Iodine-131 is commonly administered as sodium iodide for treating thyroid disorders. The radioactive I^- ions present in the circulation and in interstitial fluid are transported into the thyroid cells by the sodium-iodide symporter (NIS), an active transport mechanism located on the basolateral membrane of thyroid follicular cells that allows entry of iodine into the cell against a concentration gradient, based on energy from the electrochemical gradient of sodium. Similarly as for other parameters of thyroid cell function and growth, the intracellular accumulation of iodine is regulated by serum TSH. Once inside the thyroid cell, iodine is oxidized by the enzyme peroxidase; this starts the organification process that enables to incorporate iodine (either native or radioactive) into tyrosine, an amino acid contained in the thyroglobulin molecules produced by the endoplasmic reticulum and Golgi apparatus. Molecules of monoiodotyrosine (MIT) and diiodotyrosine (DIT) are thus formed. These two chemical species are then combined to produce the thyroid hormones thyroxine (T4) and triiodothyronine (T3). Thyroid hormones are finally secreted into the circulation by pinocytosis, again following stimulation by TSH.

Although with a lower efficiency level, iodine ions are taken up also by other systems, such as the salivary glands, sweat glands, gastric glands, mammary gland, and the placenta. These physiological processes can induce unwanted side effects when using ^{131}I for high-dose therapy in patients with differentiated thyroid cancer, thus possibly causing sialoadenitis (sometimes with persistent xerostomia) and gastritis (with nausea and vomiting). ^{131}I uptake in the placenta and mammary gland would expose the fetus or the baby, respectively, to an unacceptable radiation dose.

^{131}I-iodide is commonly used both in benign thyroid diseases (such as hyperthyroidism in Grave's disease or multinodular goiter or hyperfunctioning Plummer's adenoma) and in malignant disease (differentiated thyroid carcinomas).

Although radiation safety regulations can vary from country to country, radioiodine treatment of hyperthyroidism is generally performed on an outpatient basis, after adequate preparation and dosimetric evaluations. Two methods are commonly used to select the amount of ^{131}I-iodide activities to be administered: (1) administration of a fixed activity based on clinical experience and (2) administration of an activity personalized on the basis of dosimetric calculations according to the target volume and radioiodine uptake of the individual patient. The aim of radioiodine therapy in hyperthyroid patients is to restore euthyroidism or, more commonly, to induce permanent hypothyroidism (which will then be treated with simple thyroid hormone replacement therapy).

The initial step in the treatment of differentiated thyroid carcinoma derived from follicular epithelium (papillary and follicular carcinoma) is thyroidectomy. After surgery, an ablative dose of ^{131}I-iodide is generally administered to patients with intermediate- to high-risk cancer, in order to eliminate any remaining thyroidal cells. Whole-body scintigraphy is then performed 4–7 days after administration of the high-dose amount of ^{131}I-iodide, based on the consistent γ-ray emission of ^{131}I. The images so obtained (often integrated with spot acquisitions – possibly with SPECT/CT) often enable to depict metastatic lesions not recognized at the time of surgery. In addition to ablation of the postsurgical thyroid residue, therapy with ^{131}I-iodide is also used for the treatment of locoregional recurrences and/or distant metastases.

Since the amounts of ^{131}I to administer for radioiodine therapy of patients with thyroid cancer vary from 1.1 to 7.4 GBq (30–200 mCi), in Europe this treatment requires hospitalization in specially equipped rooms for adequate handling of radioactive wastes. In the US, activities up to 200 mCi are usually outpatient procedures. Prior to therapeutic ^{131}I administration, patients are counseled by radiation safety. Patients are discharged when measurements of their radioactivity emissions fall below certain limits, which can vary according to local radiation safety regulations.

Early side effects of treatment with radioiodine are generally mild and usually do not require specific treatments. They consist of pain in the

anterior cervical region (caused by inflammation induced by the cytotoxic action of radioiodine), dysgeusia, anosmia, nausea, and vomiting. In 10–60% of cases, acute or chronic sialadenitis can occur, due to radioiodine accumulation in the salivary glands; it affects mainly the parotid gland, which is particularly rich in ductal cells. In order to prevent this occurrence, some precautions are recommended, such as abundant hydration and frequent stimulation of salivary flow (for instance, with lemon juice). Nausea (rarely vomiting) is the direct effect of some degree of radiation-induced gastritis, since the stomach is the first recipient of a highly concentrated amount of radioiodine; these side effects are prevented by pre-administration of metoclopramide and proton-pump inhibitors. Actinic cystitis (caused by the ionizing radiation due to the presence of urinary excretion of radioiodine in the urinary bladder) is rare and can be prevented by abundant hydration and frequent urination.

About 6 weeks after treatment, a reduction in the circulating levels of platelets and white blood cells can occur; nevertheless, this occurrence is very rare and usually transient if the absorbed dose to the bone marrow is maintained below 200 cGy. As to the long-term side effects of therapy with ^{131}I-iodide in the amounts utilized for patients with differentiated thyroid cancer, the induced risk of a second solid cancer or leukemia is very low, approximately in the same order of magnitude as that determined by other antineoplastic therapeutic approaches, such as chemotherapy.

As for all therapy with radionuclides, absolute contraindications to radioiodine treatment are pregnancy and lactation. Since the specific activity of the radiopharmaceutical used for therapy is very high (typically >200 MBq/μg), the amounts of iodine contained in a therapeutic dose of ^{131}I-iodide is considerably lower than the recommended daily dose in a normal diet. Thus, allergy to iodine is not considered a contraindication.

The administration of ^{131}I-iodide is generally performed orally (capsules or liquid solutions), while the intravenous administration is needed only in uncooperative patients or in case of uncontrolled vomiting; to facilitate and accelerate intestinal absorption, fasting should be observed for at least 6 h prior to and for 3 h after administration.

Treatment of Neuroendocrine Neoplasms Originating from the Neural Crest with [^{131}I]MIBG

Meta-iodobenzylguanidine (MIBG) or iobenguane is a catecholamine analog in which the iodinated benzyl group of bretylium is combined with the guanidine group of guanethidine (see Fig. 4). This molecule was developed in the early 1980s to visualize tumors of the adrenal medulla, and it can be labeled either with ^{123}I (for diagnostic use only) or with ^{131}I (for use either diagnostic or therapeutic applications).

Due to its structural analogy with catecholamines, MIBG is taken up by chromaffin cells through a physiologic active uptake mechanism via the epinephrine transporter used for noradrenaline accumulation in neurosecretory granules. MIBG is then secreted through an exocytosis mechanism following depolarization induced by high transmembrane flux of calcium ions. This accumulation process is abundantly expressed in the sympathetic ganglia, the adrenal medulla, and in all tissues with high adrenergic innervations (myocardium, salivary glands).

Tumors that typically accumulate this radiopharmaceutical are tumors originating from the neural

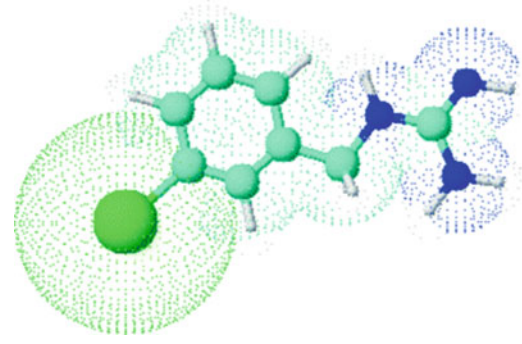

Fig. 4 Tridimensional representation of the chemical structure of radioiodinated *meta*-iodobenzylguanidine (MIBG). The *green* atom represents radioiodine. Other elements are represented with the following color codes: *white* = H, *light blue* = C, *dark blue* = N

crest. The main clinical applications of MIBG scintigraphy are therefore detection, localization, staging, and follow-up and response to treatments of NETs and their metastases, particularly in those of the sympathoadrenal system such as pheochromocytoma, paraganglioma, and neuroblastoma, although other neuroendocrine tumors such as medullary thyroid carcinoma and carcinoids can also be visualized. Diagnostic MIBG scintigraphy is crucial when planning treatment with high activities of [^{131}I]MIBG, to adequately select patients who will most likely benefit from such therapy.

For therapy, the radiopharmaceutical is usually administered through a slow i.v. injection (see further below). About half of the administered activity is excreted in the urine within the first day, 70–90% of the activity being cumulatively excreted within 2 days; therefore, the kidneys, the bladder, and the excretory urinary tract can be intensely visualized even in the late scans. About 3% of MIBG excretion occurs via the gastrointestinal tract.

The most important precaution in the preparation of patients for [^{131}I]MIBG therapy includes discontinuing drugs interfering with MIBG uptake (such as labetalol, tricyclic antidepressants, reserpine, and some sympathomimetic drugs) for an appropriate period before MIBG administration. These drugs can in fact interfere with and reduce MIBG uptake. Free radioiodine produced during in vivo [^{131}I]MIBG degradation can cause accumulation of radioactivity in thyroid and the gastrointestinal tract. Thyroid blocking using potassium iodide (KI) or lugol solution, also in combination with potassium perchlorate, is therefore necessary, generally starting 1 or 2 days prior to treatment and continuing for up to 14 days after treatment.

Administration of [^{131}I]MIBG must be performed very slowly (over 1–4 h after dilution in 50 mL of saline), because therapy dose levels involve injecting a sizable amount of a catecholamine analog that may induce the sudden release into circulation of catecholamines previously accumulated in neurosecretory granules, with possible pharmacologic effect (such as tachycardia, arterial hypertension, nausea, vomiting). For the same reason, the specific activity of [^{131}I]MIBG for therapy should be higher than that for diagnostic purpose (up to 1.8 GBq/mg), with the aim of reducing the incidence of pharmacologic effects.

The role of [^{131}I]MIBG therapy has been best defined in patients with pheochromocytoma and paraganglioma. In these patients symptomatic and biochemical improvements are frequently observed after treatment, while complete response rates are low. In neuroblastoma patients, [^{131}I]MIBG can be used with therapeutic intent, as good responses have been obtained in selected patients with advanced disease where first-line therapy failed. The response rates in these studies using single doses or large cumulative doses of [^{131}I]MIBG were between 25% and 46%. The actual benefit of multiple treatments is still debated. There is currently no consensus on the optimal dosing strategy. In patients treated with median activities of 10 GBq versus 5.5 GBq, higher activities seem to deliver the desired dose faster with a modest increase in toxicity but similar overall response rates.

Peptide Receptor Radionuclide Therapy

The biological basis of peptide receptor radionuclide therapy (PRRT) is the receptor-mediated internalization and intracellular retention of the radiopeptide, linked in turn to the overexpression of somatostatin receptors (SSTR) in most neuroendocrine neoplasms. The rationale for such therapy is to convey radioactivity inside the tumor cells, where the sensitive targets, such as DNA, can be hit as a result of internalization of the somatostatin receptor and radiolabeled analog complex.

The somatostatin analogs (ligands) that are currently in clinical use with the most promising results include DTPA-octreotide, DOTA-D-Phe^{1}-Tyr^{3}-octreotide (DOTA-TOC), DOTA-D-Phe^{1}-Tyr^{3}-octreotate (DOTA-TATE), and DOTA-lanreotide.

The macrocyclic chelator 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid (DOTA) forms stable complexes with metallic isotopes such as ^{90}Y and ^{177}Lu. The DOTA-coupled somatostatin-based radiopharmaceuticals are ^{90}Y-DOTA-Tyr^{3}-octreotide (^{90}Y-DOTA-TOC), ^{90}Y-

DOTA-lanreotide, and ^{177}Lu-DOTA-Tyr^3-Thre^8-octreotide (^{177}Lu-DOTA-TATE). These compounds differ in their SSTR affinity profile. In particular, the DOTA-TATE derivative exhibits the highest affinity for SSTR2, while DOTA-lanreotide has highest affinity for SSTR5. Tyr^3-octreotide has similar kidney uptake (the dose-limiting organ) as Tyr^3-octreotate but faster renal clearance. Advantages of ^{177}Lu-DOTA-TATE over ^{90}Y-DOTA-TATE include the emission of an associated γ-radiation, which makes it possible to acquire conventional scintigraphic imaging for radiation dosimetry estimates; furthermore, the shorter tissue range of the β^- particles emitted by ^{177}Lu justifies the assumption that use of this radionuclide allows a higher radiation dose be delivered to smaller tumors. On the other hand, the use of ^{90}Y (which emits β^- particles with higher energies and longer tissue ranges) would be more suitable for the treatment of larger tumors, in case of bulky and/or heterogeneous masses.

These radiolabeled peptides are cleared through the kidneys, where they are and reabsorbed and partially retained in the proximal tubules, causing dose-limiting nephrotoxicity. Since residence times of DOTA-TATE in tumor and kidney are longer than those of DOTA-TOC, ^{177}Lu appears more beneficial when using DOTA-TATE for therapy, while ^{90}Y appears more convenient to label DOTA-TOC. The administration of L-lysine and/or L-arginine in order to competitively inhibit the proximal tubular reabsorption of the radiopeptide is now part of the clinical routine, to reduce the renal dose.

Tumor candidates for PRRT are basically all the somatostatin receptor-expressing tumors; scintigraphy with ^{111}In-pentetreotide is currently the most accurate and validated method to assess for the presence of SSTR overexpression. Nevertheless, it is likely that ^{68}Ga-DOTA-TOC and ^{6}8Ga-DOTA-TATE will become the new standard analogs, since they mimic as closely as possible the in vivo pattern of their ^{90}Y- or ^{177}Lu-labeled counterparts used for PRRT.

The radiopeptide that has been most extensively evaluated for PRRT is ^{90}Y-DOTA-TOC, with a recommended activity per cycle of about 5 GBq (cumulative activities: 13–18.5 GBq). Complete and partial remissions have been recorded especially in patients with gastrointestinal neuroendocrine tumors. Promising clinical results of PRRT with the newer radiopeptide ^{177}Lu-DOTA-TATE have been also obtained. More recently, a combination radionuclide therapy using ^{177}Lu- and ^{90}Y-labeled peptides has been proposed in order to improve efficacy in patients with tumors of various sizes and nonhomogeneous receptor distribution.

Other radiopeptide analogs are in less advanced stages of clinical validation. They include cholecystokinin (CCK8) and bombesin for GRP receptors expressed in prostate, breast, lung, and pancreatic cancers (^{188}Re(H_2O)$(CO)_3$-diaminopropionic acid-SSS-bombesin(7-14)NH_2 and ^{177}Lu-DOTA-8-Aoc-BBN[7-14]NH_2), arginine-glycine-aspartate (RGD) peptides to target $\alpha_v\beta_3$ receptors upregulated on tumor cells and neovasculature, glucagon-like peptide-1 (GLP-1), and melanocortin 1 receptor for various tumors.

Bone-Seeking Radiopharmaceuticals

Bone metastases are a frequent and serious complication in advanced stages of neoplastic disease, occurring in about 70% of patients with prostatic cancer or breast cancer and in 30–50% of those with cancers of the lung, bladder, and thyroid. The major complications associated with this condition are pain (initially mild to medium intensity, then increasing), hypercalcemia, radicular compression, and/or spinal cord and pathological fractures. Treatment of patients with pain from skeletal metastases should be based on a multidisciplinary approach, since it can include (in sequence or, sometimes, in association) external beam radiation therapy, surgery, chemotherapy, hormone therapy, pain-killing medications (from simple anti-inflammatory nonsteroidal drugs to opioids), bisphosphonates, and therapy with radiopharmaceuticals.

In patients with metastatic involvement of multiple skeletal segments (therefore not amenable to external radiotherapy and/or surgery), bone-seeking radiopharmaceuticals represent an important strategy for palliation of bone pain (in some cases also with survival benefits). All these agents bind to the mineral component of bone either

because they are calcium analogs or in a similar manner as any typical bisphosphonate agent labeled with ^{99m}Tc for diagnostic purposes, with increased uptake at the sites of active osteogenesis; thus primary bone tumors (osteosarcomas) as well as areas of metastatic involvement predominantly osteoblastic in nature (or of mixed type) can accumulate significantly greater concentrations of the radiopharmaceuticals than the surrounding normal bone. This treatment is therefore indicated in patients with multiple painful osteoblastic skeletal metastases exhibiting high uptake of ^{99m}Tc-labeled bisphosphonates confirmed on a conventional bone scan prior to therapy.

Besides the historical interest *^{32}P-sodium orthophosphate* (which is nevertheless still used in some low-income countries where other agents are not available), the bone-seeking radiopharmaceuticals currently available include strontium-89 chloride ($^{89}SrCl_2$), samarium-153 ethylenediamine tetramethylene phosphoric acid (^{153}Sm-EDTMP), rhenium-186 or rhenium-188 hydro-ethylidene diphosphate (^{186}Re- or ^{188}Re-HEDP), and radium-223 dichloride ($^{223}RaCl_2$). For all these agents, the dose-limiting toxicity is bone marrow suppression, which is generally reversible.

Upon administration of *$^{89}SrCl_2$* (Metastron®), the $^{89}Sr^{++}$ ions follow the same in vivo metabolic fate as calcium, with rapid incorporation into the inorganic matrix of bone. ^{89}Sr is quickly cleared from the blood and selectively localizes in bone mineral, with at least 50% of the injected activity localized in the skeleton within few hours post-administration. The unbound excretion pathways are two-thirds urinary and one-third through the fecal route. Urinary excretion is greatest in the first 2 days following administration. The recommended activity of $^{89}SrCl_2$ is 148 MBq (4 mCi) or alternatively 1.5–2.2 MBq/kg body weight.

^{153}Sm-EDTMP (Quadramet®) also accumulates avidly in the skeleton, where it remains adsorbed on the surface of the newly formed hydroxyapatite crystals. Osteoblastic metastatic lesions accumulate about fivefold more ^{153}Sm-EDTMP than does the healthy skeleton. Following i.v. administration (37 MBq/kg), ^{153}Sm-EDTMP is cleared rapidly from the blood with a half-life of 5.5 min; less than 1% of the administered activity remains in the circulation 5 h postinjection. Up to 55–60% of injected activity remains stably bound to the skeleton and accumulates in metastatic lesions in a 5:1 ratio compared with normal bone uptake. The main excretory route is through the kidneys. The onset of pain relief is generally noted within 2 weeks of radiopharmaceutical administration, with a mean duration of pain relief of 3–4 months; since the critical organ from the radiation dosimetry point of view is the bone marrow, a minimum interval of 8 weeks should be allowed between subsequent administrations in order to allow adequate recovery of bone marrow function.

^{186}Re-HEDP is cleared from the circulation with a relatively long half-life (41 h), since it undergoes some binding with plasma proteins. Its uptake in bone is due to conjugation with the hydroxyapatite crystals through a hydrolysis reaction, and its mean effective biological half-life in bone is about 16 h. About 70% of the administered ^{186}Re-HEDP (usually in a standard activity of 5 GBq) is excreted in the urine within 24 h.

As a calcium analog, *$^{223}RaCl_2$* (Xofigo®) shows a similar pattern of biodistribution as $^{89}SrCl_2$, less than 1% of injected activity remaining in the circulation 24 h after administration. Nevertheless, at variance with other bone-seeking radiopharmaceuticals, a non-negligible fraction of excretion occurs through the gastrointestinal tract and constitutes the basis for the reported gastrointestinal toxicity of this radiopharmaceutical. Each treatment cycle includes four to six administrations at 4-week intervals, and it has been recognized that therapy with $^{223}RaCl_2$ induces not only palliation of bone pain but also a significant benefit in survival. Since this is the latest radiopharmaceutical approved by regulatory agencies for therapy, a much more detailed discussion of the clinical observations that have led to this approval is presented in ▶ Chap. 8, "Novel Radiopharmaceuticals for Therapy" of this book.

Radioimmunotherapy for Hematologic Malignancies

The introduction of immunotherapy in the clinical routine has opened new opportunities for the treatment of some hematologic diseases. In fact,

antigens expressed on the surface of neoplastic cells (usually of the B lineage) are suitable targets for the development of monoclonal antibodies used for immunotherapy. In radioimmunotherapy (RIT), the cytotoxicity caused by an ionizing radiation is conveyed to the neoplastic cells through binding to tumor-specific antigens at the molecular level, a monoclonal antibody acting as carrier of a suitable radionuclide.

Efforts in the past 20 years have focused on the so-called molecular therapy to identify possible tumor antigens against which to address the monoclonal antibody. The selection of the appropriate antigen plays a key role for the efficacy of treatment. The ideal antigen should be densely and uniformly expressed on the surface of malignant cells (but not in normal cells), it should form a stable complex with the antibody, and the antigen/antibody complex should not be internalized (although the latter property is not so crucial).

Another important issue concerns the origin and structure of these antibodies; many monoclonal antibodies were in fact initially developed from murine cells, thus being intrinsically heterologous proteins with immunogenic activity when administered to humans. This immunogenicity is much lower for the chimeric antibodies (made up of components for 60% human and 40% murine) or for those humanized (with 95% of human components, while generally only the binding site for the antigen is murine) developed through genetic engineering techniques. In fact, the formation in the patient receiving these preparations of human anti-mouse antibody (HAMA), anti-chimeric (HACA), or anti-human (HAHA) can alter the pharmacokinetic profiles of the monoclonal antibody or predispose to allergic reactions during repeated administration. The monoclonal products currently used for the preparation of radiopharmaceuticals are characterized by greatly reduced immunogenicity compared to their initial products.

The radiolabeled anti-CD20 antibody ^{90}Y-ibritumomab tiuxetan (Zevalin®) has been approved for the treatment of relapsed or refractory, low-grade, or follicular B-cell non-Hodgkin's lymphoma (NHL) or treatment of previously untreated follicular NHL in patients who achieve a partial or complete response to first-line chemotherapy.

^{90}Y is chelated to tiuxetan, which is covalently linked to the antibody via arginine and lysine. The basis for therapy with ^{90}Y-ibritumomab tiuxetan is that CD20 antigen is expressed on the surface of normal B-lymphocytes (except pre-B cells and secretory B cells) and of more than 90% of B-cell lymphomas. Unlabeled monoclonal antibody (rituximab) is given as part of ^{90}Y-ibritumomab tiuxetan therapy in order to block CD20 antigens on normal B cells and spleen and to facilitate deeper penetration into the tumor. The unlabeled monoclonal antibody itself induces several mechanisms of tumor cell killing.

^{90}Y-ibritumomab tiuxetan is administered as a slow i.v. infusion over 10 min; the pharmacokinetics of ^{90}Y-Ibritumomab tiuxetan is characterized by a plasma half-life of 28 h. The administered activity is generally 15 MBq/kg body weight (0.4 mCi/kg), with a maximum limit of 1.2 GBq (32 mCi). In patients with mild thrombocytopenia (platelet count between 100.000 and 149.0000 per mm^3), the administered activity should be reduced to 11 MBq/kg (0.3 mCi/kg).

Dose-limiting toxicity for ^{90}Y-ibritumomab tiuxetan is bone marrow suppression, which is reversible. However, no statistically significant correlation was noted between the development of hematological toxicity and pharmacokinetic parameters of the compound.

Since ^{90}Y does not emit γ-rays (and on the other hand scintigraphic visualization of the secondary X-rays emitted by the reaction of Bremsstrahlung is not satisfactory), biodistribution can be evaluated by administering a diagnostic-level dose of the surrogate radiopharmaceutical ^{111}In-ibritumomab tiuxetan. The early images (up to about 24 h) typically show activity in the blood pool, with significant uptake in the liver and spleen, while accumulation in the lung and bone is generally low. Dosimetric studies have demonstrated an up to 850-fold greater radiation dose to the tumor lesions than to normal organs, and cumulative urinary excretion is only 7% of administered activity at 7 days post-administration.

Another monoclonal antibody (tositumomab) labeled with ^{131}I has been approved in the United States in 2003, with similar indications as Zevalin® in patients with non-Hodgkin's lymphomas.

^{131}I-tositumomab (Bexxar®) is specifically directed against a different epitope of the same CD20 surface antigen, and the reported response rate is about 70%. However, it has recently withdrawn from the market because of declining sales.

Radionuclide Therapy of Primary and Metastatic Liver Tumors

Liver tumors (both primary and metastatic) have always been considered a major cause of morbidity and mortality in oncologic patients. The treatment options are represented by surgical resection, liver transplantation, systemic chemotherapy, or locoregional treatments. The locoregional treatments consist of percutaneous ablative techniques (radiofrequency ablation, laser coagulation, cryotherapy, percutaneous ethanol injection) and transarterial methods, such as chemoembolization and radioembolization.

Early attempts at radionuclide therapy for primary or metastatic liver cancers began in the 1970s with the use of albumin colloids labeled with ^{32}P, under the rationale that radiocolloids administered systemically accumulate in the reticuloendothelial system, which is particularly abundant in the liver. This approach was soon abandoned due to significant bone marrow toxicity.

Transarterial radioembolization of liver tumors (also defined as "selective internal radiation therapy") can be performed using either ^{131}I-lipiodol or microspheres containing the β^- emitter ^{90}Y. ^{131}I-lipiodol, a mixture of iodized esters of poppy seed oil fatty acid, is still employed for treatment of hepatocellular carcinoma. The rationale for using transarterial ^{131}I-lipiodol is its entrapment and embolization in the microvessels of the tumor as well as endocytosis of this agent by the endothelial cells and the tumor cells themselves.

Nevertheless, this approach is most commonly based on the use of resin or glass microspheres containing ^{90}Y. The advantages of this type of therapy consist in the favorable toxicity profile and in the possibility to combine it with other forms of therapy (such as systemic chemotherapy or hepatic resection) without an increase in toxicity. The rationale for this therapy is radiomicroembolization of the hypervascularized tumor lesions in the liver, which receive their blood supply primarily from the hepatic artery, whereas the normal liver parenchyma receives blood primarily via the portal vein. Thus, microspheres injected into the hepatic artery (most commonly into the right or left hepatic artery – or even more selectively into the proper segmental artery) are trapped within the tumor microvasculature and deliver radiation selectively to the tumor liver lesion. The two types of ^{90}Y–microspheres currently available commercially (resin and glass microspheres) are biocompatible but not biodegradable nor metabolized.

^{90}Y-resin-based microspheres (SIR-Spheres®) are an acrylic polymer in which ^{90}Y is bound to the carboxylic group of the polymer after production of microspheres. They have a diameter size between 20 and 60 μm with a specific activity of 50 MBq per sphere. There are about 40–80 million microspheres per vial, with a total activity of 3 GBq, which can be subdivided to treat two or more patients. Because of their elevated number, resin microspheres used for this treatment may have a moderate embolic effect and must be delivered at a slow rate (no more than 5 mL/min) to avoid reflux down the hepatic artery and into other organs. The shelf-life of the device is 24 h, which restricts clinical flexibility and patient scheduling.

In the ^{90}Y-glass spheres (TheraSphere®), ^{89}Y is embedded in the glass matrix, to be activated to ^{90}Y in a nuclear reactor. Their medium diameter size is 20–30 μm, and the specific activity is 2,500 Bq per sphere. The number of ^{90}Y-glass spheres required for treatment ranges between 1.2 and 8 million, and the preparation is supplied in six sizes of activities: 3, 5, 7, 10, 15, and 20 GBq. The embolic effect linked to treatment with the glass ^{90}Y-microspheres is limited because a lower number of microspheres is injected intraarterially. They can be used also in patients with portal vein thrombosis. The shelf-life of the glass spheres is 15 days from the date of calibration; therefore, no physical manipulation is required to prepare the desired, patient-based activity for administration, which is obtained simply by letting a certain activity to decay to the desired level.

Novel Single-Photon-Emitting Radiopharmaceuticals for Diagnostic Applications

6

Federica Orsini, Federica Guidoccio, Erinda Puta, and Giuliano Mariani

Abstract

The armamentarium of approved radiopharmaceuticals for either diagnosis or therapy is at the core of the clinical practice of today's nuclear medicine. Nevertheless, both because the currently approved agents do not meet all the clinical needs for radionuclide targeting and because advancing knowledge in the pathophysiology of tissues/organs open in turn new opportunities, investigations continue at the preclinical and clinical validation level for the development of new radiopharmaceuticals, most of which are not approved yet for commercial use. Concerning in particular the diagnostic applications of nuclear medicine to oncology, ongoing investigations in the search for tumor-targeting agents with better specificity and sensitivity are countless, possibly within the scenario of theranostics – that is, with the dual potential for imaging and for therapy, depending on the specific radionuclide employed for radiolabeling. We will focus this chapter on the most promising imaging agents labeled with single-photon-emitting radionuclides based on some of the mechanisms that are typical for tumor cells/tissues.

Keywords

Cancer biology • Molecular imaging in cancer • Single-photon emission imaging • Radiopharmaceuticals

Glossary

BTAP	Bis(thioacetamido)pentanoyl
DOTA	2-(4-Isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetra-acetic acid (macrocyclic coupling agent to label compounds of biological interest with metal radionuclides)
DTPA	Diethylenetriaminepentaacetic acid
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
FDA	United States Food and Drug Administration
GMP	Good manufacturing practice
HER	Human epidermal growth factor receptor
HPLC	High-performance liquid chromatography (formerly known as high-pressure liquid chromatography)
HYNIC	6-Hydrazinopyridine-3-carboxylic acid, also known as hydrazido-nicotinic acid/hydrazinonico-tinamide (a chelating agent)
MMP	Metalloproteinases, a family of matrix enzymes

Introduction and Background

The armamentarium of approved radiopharmaceuticals for either diagnosis or therapy is at the core of the clinical practice of today’s nuclear medicine. Nevertheless, advancing knowledge in the pathophysiology of tissues/organs opens new opportunities, for the development of new radiopharmaceuticals, most of which are not approved yet for commercial use. There is an ongoing search for tumor-targeting agents with better specificity and sensitivity. There are many new developments of agents with the dual potential for imaging and for therapy, depending on the specific radionuclide employed for radiolabeling [1–3].

Tumor cells and tissues exhibit different characteristics compared to normal cells and due to the altered physiology, tissue composition, and expression of intra- and extracellular molecules [4, 5]. These attributes can be the basis for developing new imaging targets for diagnostic applications as well as for developing new anticancer drugs and for assessing tumor response to treatment [6–9] (see also ▶ Chaps. 1, “Cancer Biology of Molecular Imaging,” and ▶ 2, “Principles of Molecular Targeting for Radionuclide Therapy” of this book).

Single-photon-emitting radiopharmaceuticals can be classified according to different properties, such as their biodistribution and targeting characteristics, their different chemical and physical properties, and their specific interaction with a target. Tumors are known to display an aberrant vascular network and microcirculation, which in turn influence an increase in interstitial pressure, as well as hypoxia and acidosis; all these features contribute to the expression of malignant phenotypes and to resistance to various treatments [10]. Within this environment, tumor cells can also display altered energy metabolism, as reflected, for example, in increased glucose uptake and shifted balances in metabolic products.

Thus, at the preclinical level, a variety of single-photon-emitting tracers are under evaluation for use as markers for (neo)angiogenesis [11–13], hypoxia [14, 15], acidosis [16], metabolic activity [17], and proteolytic activity [18, 19]. Besides metabolic tracers, efforts are being directed also toward the development and validation of single-photon probes specific for tumor target molecules such as cell surface antigens, receptors, or other molecules similarly overexpressed in tumor tissues [20]. The use of peptides interacting with receptors [21], of antibodies or antibody fragments targeting different epitopes of tumor-associated antigens [22], of vitamin-based radiopharmaceuticals [23], and of

nucleoside analogs [24–27] significantly increases the possibilities for tumor detection, localization, and staging. Specific issues of interest in translational preclinical imaging studies include efforts directed at improving specificity for tumor types [28], tumor uptake/retention [29], yet with minimal pharmacological effects of the imaging probes.

The successful choice of a target molecule potentially leads to the development not only of a molecular imaging probe but also of a therapeutic agent capable to inhibit the disease process – according to the approach of theranostics. Receptor targeting with small radiolabeled peptides for receptor-targeted tumor imaging (PET and SPECT) as well as for radionuclide therapy provides good examples of such theranostics potential.

Peptide Receptor Targeting

The best-known examples of this tumor-targeting mechanism are based on the use of somatostatin analogs. For imaging purposes either single-photon-emitting radionuclides (chiefly ^{111}In) or positron-emitting radionuclides (chiefly ^{68}Ga) are used in the clinical routine. For therapeutic purposes, different β^--emitting radionuclides (chiefly ^{90}Y and ^{177}Lu) are currently being used clinically or undergoing extensive validation; although the chief indications for the use of these radiopharmaceuticals regard neuroendocrine neoplasms (see ▶ Chaps. 29, "Diagnostic Applications of Nuclear Medicine: Neuroendocrine Tumors," and ▶ 43, "Neuroendocrine Tumors: Therapy with Radiolabeled Peptides" of this book), the indications for the use of these tracers, with either diagnostic or therapeutic purposes, are expanding to other tumors as well. Thus, the radiolabeled somatostatin analogs are prototypes for a whole spectrum of other peptide receptor systems that are overexpressed in a variety of tumors. The common feature shared by all these systems is that they are members of the so-called G-protein-coupled receptor superfamily and play a major role in the progression and angiogenesis of a number of malignancies.

Briefly, the peptide ligands that have yielded the most promising results so far are the analogs of bombesin, of cholecystokinin, of the vasoactive intestinal peptide, of gastrin, of glucagon, of substance P, of exendin, and of the α-melanocyte-stimulating hormone [30–36]. The use of the so-called RGD-based peptides for targeting the integrin receptor system (another member of the G-coupled family) is discussed further below in this chapter.

Apoptosis

Apoptosis is a process of regulated or programmed cell death, which in its classic form, does not cause inflammation. The mitochondria and ribosomes of the cells undergoing apoptosis remain intact, and surrounding cells internalize them along with the other components of the post-apoptotic cell. Necrotic cells, in contrast, lose membrane integrity, swell, and then release their contents to the surrounding tissue, causing inflammation and possibly initiating an immune response.

Lipid composition of the outer and inner leaflets of the plasma membrane is normally not symmetrical; for instance, some molecules such as phosphatidylserine and phosphatidylethanolamine are normally retained on the intracellular face of the cell membrane. When cells undergo apoptosis, this distribution is altered, so that these molecules are rapidly exposed to the outside of the cell membrane. The most promising single-photon-emitting radiopharmaceuticals targeting phosphatidylserine and phosphatidylethanolamine are represented by radiolabeled annexin and duramycin, respectively.

^{99m}Tc-Annexin V

The discovery of phosphatidylserine externalization as the event initiating apoptosis has opened the way to the search for compounds that have an affinity for phosphatidylserine and could therefore be used to localize in sites of apoptosis. To date, the compound that has received major interest in both the preclinical and clinical arena is annexin V, a non-glycosylated single-chain protein physiologically involved in the inhibition of hemostasis [37]. Annexin V, which is part of a protein family that binds to negatively charged

phospholipids in a Ca^{2+}-dependent manner, is distributed ubiquitously in the human body. Complete functional details of the annexin V pathway have yet to be clarified, but a large body of evidence suggests that annexin acts as a specific ligand for phosphatidylserine, and it is able to prevent activation of the immune response when cells undergo apoptosis [38].

In translational research, annexin V labeled with radionuclides has been used for studying, localizing, visualizing, and measuring apoptosis in vitro as well as in vivo, both in preclinical animal models and in patients [39, 40]. Radiolabeled annexin was first proposed to image blood clots in patients with atrial fibrillation; subsequently this compound gained attention for imaging of apoptosis in tumors [41]. Annexin V used for development of radiolabeled imaging agents is produced by the expression of annexin V complementary DNA in *Escherichia coli*. Several radiolabeled probes and other agents bearing different moieties have been explored preclinically to image annexin V uptake by means of SPECT, PET, MRI, and near-infrared fluorescence (NIRF).

As single-photon imaging probes, numerous methods for labeling annexin with ^{99m}Tc have been identified through the use of chelators such as the bifunctional N_2S_2 chelate to form ^{99m}Tc-4,5-bis(thioacetamido)pentanoyl-annexin V (or ^{99m}Tc-BTAP-annexin V, also known as ^{99m}Tc-Apomate) or hydrazinonicotinamide (HYNIC) to form ^{99m}Tc-HYNIC-annexin V. The former formulation is also available as a good manufacturing practice (GMP) product in a radiolabeling kit [42].

Moreover, animal experiments suggest an improved protocol for annexin labeling via the use of self-chelating annexin V mutants. In this case, the radiotracer exhibits reduced abdominal background and decreased renal radiation dose [43]. At the clinical level, various studies support the notion that ^{99m}Tc-annexin V SPECT allows for noninvasive, reproducible, quantitative apoptosis imaging and for assessing tumor response as early as 24 h after the start of treatment, with the goal of monitoring the effectiveness of therapy in cancer patients. With pioneering work, Belhocine et al. used ^{99m}Tc-BTAP-annexin V to monitor chemosensitivity in a variety of cancer types (e.g., lung cancer, lymphoma, and breast cancer), demonstrating that ^{99m}Tc-BTAP-annexin V uptake after chemotherapy was significantly related to survival and progression-free survival in cancer patients [44].

More recently ^{99m}Tc-annexin V has been probed in clinical studies to assess the efficacy of chemotherapy and radiotherapy [45, 46]. The promising results so far obtained offer the possibility also in this scenario to develop a personalized medicine approach, now primarily explored in genome-based medicine, applicable to all cancer patients.

However, the main problems in a wide clinical application remain the absence of ideal biological properties; experiences with radiolabeled annexin V have indicated that issues such as biodistribution and target-to-background ratio require further improvement [47]. In an attempt to reduce renal uptake, annexin V was also labeled with ^{123}I. ^{123}I-annexin V does indeed show good imaging features for imaging the abdominal region compared to ^{99m}Tc compounds (no liver nor renal radioactivity accumulation 12-h post-injection) but is subject to rapid in vivo dehalogenation and is more expensive, and the labeling procedure is more complex [48].

^{99m}Tc-Duramycin

Duramycin, a 19-amino acid peptide cross-linked by a disulfide bond, has been found to be capable of binding to phosphatidylethanolamine with high affinity and high selectivity; therefore, the radiolabeled ^{99m}Tc-duramycin represents now a novel molecular compound for apoptosis imaging [49].

Similar to phosphatidylserine (the target marker of the earliest apoptosis probe, annexin V), phosphatidylethanolamine is a major component of the inner leaflet of the cell membrane, and its expression on the surface of normal viable cells is extremely low [50–52]. When apoptosis occurs, phosphatidylethanolamine is exposed on the cell surface [53], because of redistribution of phospholipids across the bilayer. Phosphatidylethanolamine becomes accessible to the extracellular milieu during necrosis, because of the

compromised plasma membrane integrity. Thus, phosphatidylethanolamine constitutes a potential target molecule for cell death imaging in general.

Phosphatidylethanolamine expressed on the apoptotic cell surface appears to play a regulatory role in the so-called blebbing and formation of apoptotic bodies. In these constitutive processes of apoptosis, intracellular components are discretely packaged and earmarked for engulfment by scavenger cells without causing inflammation. As one of the morphologic hallmarks of apoptosis, blebbing includes profound membrane structural remodeling. The trans-bilayer movement of phosphatidylethanolamine is especially enhanced on the blebs of apoptotic cells. These morphologic changes are in part attributed to the phosphatidylethanolamine-mediated reorganization of actin filaments [54, 55].

As a novel molecular probe to target apoptosis imaging, duramycin is produced by *Streptoverticillium cinnamoneus* [56, 57]. Biologic activities of duramycin have been well characterized, and their phosphatidylethanolamine binding activity explored with in vitro biologic studies [58–62]. In particular, duramycin binds the head group of phosphatidylethanolamine with high affinity at a molar ratio of 1:1 [63–65]. Duramycin has a compact cyclic configuration, with a single binding pocket that specifically interacts with phosphatidylethanolamine. Stabilized by three internal thioether bonds, duramycin is the smallest known polypeptide that has a defined three-dimensional binding site [56, 57].

In 2008, Zhao et al. originally described the preparation of ^{99m}Tc-labeled duramycin, using a HYNIC ligand with tricine and phosphine as coligands [66]. The low molecular weight of duramycin (~2 kDa) confers favorable pharmacokinetics and biodistribution properties for in vivo imaging of apoptosis. However, in the original formulation, HPLC purification after radiolabeling was a prerequisite for intravenous injection in humans, a cumbersome procedure that limited clinical investigations. The goal to produce high-quality ^{99m}Tc-curamycin in a single-step kit formulation, without additional purification steps, was achieved in 2012 by Zhao and coworkers, with the development of a single-step kit formulation for ^{99m}Tc-labeling of HYNIC-duramycin [67]. An optimal formulation with tricine-to-TPPTS molar ratio of 10:1 was determined, which led to consistent production of high radiochemical purity ^{99m}Tc-duramycin without the need for further purification. The radiopharmaceutical so produced retained phosphatidylethanolamine binding affinity and specificity, while its clearance properties and in vivo biodistribution were consistent with those obtained in prior studies using radio-HPLC-purified preparation.

In a rat model of myocardial ischemia/reperfusion injury, ^{99m}Tc-duramycin showed specific higher uptake in apoptotic cells than in viable control cells, with favorable pharmacokinetic and biodistribution profiles. The tracer was rapidly cleared from the circulation via the renal system with a blood half-life of less than 4 min in rats and a very low liver and gastrointestinal uptake [67, 68]. Similar favorable targeting and biodistribution properties have been observed also in a porcine model of myocardial ischemia/reperfusion, showing high accumulation of ^{99m}Tc-duramycin in tissue sites of injury with high apoptotic activity [69]. In addition, ^{99m}Tc-duramycin has been evaluated for imaging ischemia/reperfusion injury in the brain using the rat model of middle cerebral artery occlusion [70], as well as in a model of oxidative lung injury [71–73], and finally in susceptible tissues after exposure to high-dose radiation [74].

Taken altogether, these investigations suggest the high potential of ^{99m}Tc-duramycin for use in oncology, an assumption that has recently been confirmed by preclinical studies demonstrating high specific uptake of ^{99m}Tc-duramycin in apoptotic cells of colon cancer or breast cancer xenografts responding to chemotherapy [75–77], thus supporting the hypothesis that ^{99m}Tc-duramycin is a potential candidate in cancer patients to assess response to therapy.

Angiogenesis

The formation of the new vessels ("angiogenesis") is an essential process in the growth of solid tumors. Once tumors have reached a size of >1 mm^3, diffusion alone from the capillary bed is no longer sufficient to supply the tumor cells with

adequate amounts of oxygen and nutrients. Further tumor growth is only possible when new blood vessels are formed. Nevertheless, while normal angiogenesis is orderly and highly regulated, tumor angiogenesis is chaotic and irregular. Angiogenesis represents an interesting molecular target not only for imaging but also for targeted forms of therapy. Examples for target anti-angiogenic therapies currently used in the clinical practice are cilengitide (that inhibits integrin receptors $\alpha_v\beta_3$ and $\alpha_v\beta_5$) and bevacizumab, an antibody targeting the vascular endothelial growth factor (VEGF).

Different potential molecular targets to monitor angiogenesis are potentially available for imaging purposes. At the moment the most suitable candidates for tracer development are represented by integrin antagonists, expressed extracellular matrix protein inhibitors or matrix metalloproteinase, as well as by tracers binding to tyrosine kinases or growth factor receptors.

Integrins

Integrins are heterodimeric membrane receptors constituted by α and β subunits that mediate interactions between cells and the extracellular matrix and soluble molecules (such as growth factors). So far 18 different α and 8 different β subunits have been identified, corresponding to 24 different integrin receptors. Integrin $\alpha_v\beta_3$ is one of the most studied in oncology, because it is highly expressed on the cell surface of activated endothelial cells in newly formed blood vessels. In the preclinical setting, a large variety of imaging strategies have been successfully employed for imaging integrin expression.

All the tracers that are used for imaging of integrin expression are based on the tripeptide sequence arginine-glycine-aspartic acid (or RGD in the single letter code) [78]. RGD binds to the integrin containing the α_v subunit, which represents an abundant physiologic integrin-binding ligand in proteins of the extracellular matrix. Accordingly, a variety of radiolabeled RGD-based peptides have been developed for noninvasive imaging of integrin $\alpha_v\beta_3$ expression with either SPECT or, in most of the cases, PET. The ^{99m}Tc-labeled RGD peptides have been the subject of few investigations, and few peptides have been translated into clinical use, such as ^{99m}Tc-NC100692 and ^{99m}Tc-labeled RGD dimeric peptides with PEG_4 and Gly_3.

^{99m}Tc-αP2

This 10-amino acid ^{99m}Tc-peptide first described in 1988 contains two copies of the RGD motif for integrin-specific binding. It has been tested in a clinical study in a patient with malignant melanoma, resulting in a good detection rate of metastases in the neck, axilla, abdomen, and soft tissue 60–120 min after injection; however, sensitivity was somewhat lower for lesions located in the thorax, due to high blood pool activity in the heart and large vessels [79].

^{99m}Tc-NC100692 (or ^{99m}Tc-Maraciclatide)

^{99m}Tc-NC100692 is a new RGD-containing peptide labeled with ^{99m}Tc that binds to integrin $\alpha_v\beta_3$ with high affinity [80]. Clinical studies in patients with breast and lung cancer showed a good detection rate for malignant lesions greater than 1 cm, in the breast, brain, and lung, whereas the detection rate was considerably lower for bone and liver metastases [81–83].

On the other hand, in the scenario of theranostics, some investigators confirm that ^{99m}Tc-NC100692 does target the $\alpha_v\beta_3$ integrin in mice bearing glioma tumors and may, therefore, be useful for identifying patients prior to anti-$\alpha_v\beta_3$ therapy as well as for monitoring tumor response to antiangiogenetic therapy in these patients [84].

^{99m}Tc-3PRGD$_2$

^{99m}Tc-PEG_4-E[PEG_4-c(RGDfK)]$_2$ (or ^{99m}Tc-3PRGD$_2$) is a new single-photon tracer targeting

the integrin $\alpha_v\beta_3$-receptor and has been used preclinically for tumor imaging, for evaluating angiogenesis, and for monitoring antiangiogenic drug efficacy [85, 86].

The new types of RGD peptides show much higher in vitro integrin $\alpha_v\beta_3$-binding affinity than the single RGD tripeptide sequence and exhibit significantly increased tumor uptake and improved in vivo kinetics in animal models. ^{99m}Tc-3PRGD2 is excreted predominantly by the kidneys and has a rapid blood clearance, with less than 1% of the initial radioactivity remaining in the blood circulation at 60 min after injection. No adverse reactions have been observed in animal models or in humans to date. ^{99m}Tc-3PRGD$_2$ can easily be prepared in a kit formulation and has shown excellent in vivo patterns of biodistribution in nonhuman primates [87].

Recently, ^{99m}Tc-3PRGD$_2$ has been used in patients, in particular for characterizing solitary pulmonary nodules [88], as well as palpable and nonpalpable breast lesions [89]. It has also been used with satisfactory results in patients with lung cancer [90], in patients with iodine-refractory thyroid cancer [91], for imaging bone metastases in patients with lung cancer (versus the conventional ^{99m}Tc-MDP bone scan) [92], and for monitoring the response to treatment with antiangiogenetic therapy in a mouse model of glioma [93].

^{99m}Tc-RGD-BBN

A dual receptor-targeted probe, integrin $\alpha_v\beta_3$ and gastrin-releasing peptide receptor (GRPR)-targeted peptide, Glu-c(RGDyK)-bombesin (RGD-BBN) labeled with technetium-99m (^{99m}Tc-RGD-BBN), has been tested with promising results in an animal model [94] and then with pilot studies in humans. In particular, its biodistribution has been evaluated in healthy volunteers (exhibiting a safe profile) and in patients with breast cancer as a novel agent for scintimammography. In this clinical setting, ^{99m}Tc-RCD-BBN has shown excellent properties for tumor detection [95], with the potential of avoiding surgical biopsy in patients with equivocal breast lesions, thanks to its very high negative predictive value for malignancy [96].

Hybrid Radioactive/Fluorescent RGD

^{111}In-labeled RGD has been coupled with a fluorescent dye to produce a hybrid tracer, with the purpose of allowing visualization of tumor margins during surgery as well as the in vivo detection of the tumor and its distant metastases. Only very preliminary preclinical studies have been performed so far with this new hybrid tracer, which appears to exhibit optimal properties for targeted $\alpha_v\beta_3$ integrin detection, with very high tumor-non-tumor ratios [97].

Extracellular Matrix

Fibronectin is a polymorphic matrix protein belonging to the widely distributed family of universal cell-adhesion molecules. Fibronectin can exist in several isoforms implied in a variety of processes such as cell migration, wound healing, and oncogenic transformation. A particular isoform (the splicing variant ED-B) is important in vascular proliferation and is widely expressed in neoplastic tissues while showing a highly restricted distribution in normal tissues [98].

^{99m}Tc-AP39

The ^{99m}Tc-anti-ED-B fibronectin L19-(Gly)$_3$-Cys-Ala scFv antibody fragment (^{99m}Tc-AP39) is a radiolabeled molecular imaging agent developed for single-photon emission imaging of tumor angiogenesis and for guidance during antiangiogenic treatment for tumors.

The single-chain antibody fragment (scFv) derived from the L19 monoclonal antibody (with a high affinity to ED-B fibronectin) was developed by Pini et al. [99] and initially labeled with radioiodine for biodistribution in different animal models, where it exhibited excellent targeting to tumor vessels, without selective accumulation in the vessels of other organs [100].

In order to prepare a stable ^{99m}Tc-labeled L19 fragment, Berndorff et al. [101] inserted the amino

acid sequence $(Gly)_3$-Cys-Ala at the C terminus of L19 to produce the recombinant protein, AP39. These authors demonstrated that the ^{99m}Tc-labeled compound so formed (^{99m}Tc-AP39) has favorable biodistribution and imaging properties in mice bearing a murine embryonal teratocarcinoma. Since high levels of ED-B expression have been found in a variety of cancers including primary and metastatic breast, colorectal, and non-small cell lung cancers [102–104], this anti-fibronectin tracer has the potential of being useful for noninvasive imaging of tumor angiogenesis in all such cancers, virtually as a pancarcinoma-targeting agent.

Besides the potential for tumor targeting with imaging purposes as described above, the very high uptake of the anti-fibronectin ED-B monoclonal constructs in tumor tissues opens promising perspectives for developing new agents for radioimmunotherapy, as described in details in ► Chap. 8, "Novel Radiopharmaceuticals for Therapy" of this book.

Matrix Metalloproteinases

Due to their involvement in tumor metastasis and angiogenesis, the matrix metalloproteinases (MMP) are potential targets for molecular imaging. The MMP family consists of more than 18 different members, with levels in tissues that are controlled by a balance between synthesis of the proenzyme and expression of endogenous MMP inhibitors [105]. Increased proenzyme production causes degradation of the basement membrane and of the extracellular matrix, thus preparing the structural requirements for migration of endothelial cells and formation of vessels [106]. In particular, the MMP-2 and MMP-9 gelatinases are often detected in malignant tissue, and their overexpression correlates with tumor aggressiveness and metastatic potential. Ongoing investigations aim at developing synthetic compounds for targeting MMPs.

Although most studies are in a preliminary phase, some hydroxamate-based tracers with promising binding properties have been identified. In particular, among single-photon-emitting agents, the peptidomimetics [^{111}In]-DTPA-RP782 and [^{99m}Tc]-(HYNIC-RP805)(tricine)(TPPTS) and the picolyl-benzenesulfonamide [^{123}I]I-HO-CGS 27023A appear to specifically target the enzymatic action of MMPs in animal models of various diseases. Nevertheless, preclinical studies in animal models prove that these imaging agents might be more successful for investigating atherosclerosis than for tumor targeting [107].

Epidermal Growth Factor Receptor (EGFR)

The EGFR family consists of four transmembrane receptors, respectively, EGFR properly said (HER1/erbB-1), HER2 (erbB-2/neu), HER3 (erbB-3), and HER4 (erbB-4). EGFR is a glycosylated transmembrane protein composed of an extracellular ligand-binding region, a transmembrane region, and an intracellular tyrosine kinase domain. The extracellular domain binds endogenous growth factors, like epidermal growth factor (EGF) or transforming growth factor alpha (TGF-α). Binding of one of these endogenous ligands triggers erbB receptor aggregation, thus resulting in the formation of receptor homodimers and/or heterodimers, and internalization. Dimer formation leads to activation of the intrinsic receptor tyrosine kinase domain and to a cascade of intracellular signaling pathways.

This mechanism is involved in the regulation of cell growth, as well as in differentiation and survival of cells. These properties have attracted the interest of investigators especially in oncology, and EGFR has been investigated as a major target for the treatment of uncontrolled tumor growth [108]. In fact, EGFR is often overexpressed in human malignancies such as head and neck squamous cell carcinoma, gastrointestinal and abdominal carcinomas, lung carcinomas, carcinomas of the reproductive tract, melanomas, glioblastomas, and thyroid carcinomas [109]. Although data are heterogeneous in this regard, overexpression is often associated with an aggressive tumor phenotype and poor prognosis. To target tumor cell proliferation or growth via EGFR, monoclonal antibodies (mAbs) against this receptor have been developed for therapeutic purpose. One of these agents, cetuximab,

has been approved by the Food and Drug Administration (FDA) in 2004 for treatment of colorectal cancer.

Two predominant classes of EGFR inhibitors have been developed including mAbs that target the extracellular domain of EGFR, such as cetuximab (Erbitux) or trastuzumab (Herceptin), and small molecule tyrosine kinase inhibitors (TKIs) that target the receptor catalytic domain of EGFR, such as gefitinib (Iressa) and erlotinib (Tarceva) [110]. Several SPECT single-photon radiopharmaceuticals have been developed in preclinical trials, such as ^{99m}Tc-Cetuximab as stable complex with ethylenedicysteine [111,112]. Besides an unexpected high kidney uptake observed in rates bearing a human breast tumor, the 6-h physical half-life of ^{99m}Tc was too short for imaging, considering that mAb preparations like cetuximab the highest tracer accumulation in the tumor is expected 2–3 days post-injection. In a pilot clinical study, high uptake of this cetuximab conjugate in tumors was observed, however, without a sufficiently high target-to-background ratio and without a clear correlation with other clinical features in patients with head and neck cancer.

With its relative longer physical half-life (2.8 days), ^{111}In-labeled mAb conjugates obtained using the chelators DOTA or DTPA are in principle more suitable for tumor imaging than the ^{99m}Tc-labeled counterparts. Accordingly, these have been investigated in animal models [113, 114] and in humans [115]. Radiolabeled pertuzumab, a HER2 dimerization inhibitor that binds to an epitope different from that of trastuzumab, was also evaluated to image HER2 downregulation after 3 days of treatment with trastuzumab in human breast cancer xenografts. ^{111}In-diethylenetriaminepentaacetic acid-pertuzumab (^{111}In-DTPA-pertuzumab [116]) demonstrated a reduction in viable, HER2-positive tumor cells after 3 weeks of therapy [117].

Folate Receptor Overexpression

Due to their increased metabolic and structural requirements, tumor cells usually consume high amounts of folate, a compound involved in many biosynthetic processes including DNA synthesis. The folate transporter is usually overexpressed on the surface of tumors such as ovarian cancer and lung cancer, thus representing a possible target for molecular imaging, both for therapeutic [118] and for diagnostic purpose (^{99m}Tc-Etarfolatide or ^{111}In-DOTA-folate) [119]. Interference by important accumulation of this tracer in normal tissues, particularly in the kidneys, makes it difficult to analyze the results of clinical trials with ^{99m}Tc-etarfolatide. To prevent such problem, folic acid or pemetrexed combined with thymidine was administered in patients before tracer injection as an antidote to the potential toxicity [120]. The results of trials with this combination are promising, particularly in patients with ovarian cancer [121–123], and the compound is currently under review by the European Medicines Agency.

Abstract

Over the past two decades, nuclear imaging has transformed cancer care. Positron emission tomography (PET) and single photon emission computed tomography (SPECT) can provide clinicians with functional and biochemical information about tumor tissue that complement the anatomical data acquired through magnetic resonance imaging (MRI) and computed tomography (CT). In this chapter, we highlight a number of emerging radiotracers in oncology that are currently employed in clinical trials in the USA and worldwide yet are awaiting regulatory approval in the USA. The radiotracers discussed range from small molecule probes that target cellular transport mechanisms and metabolic pathways to antibody-based agents that target cell-surface receptors. In order to help the reader appreciate the diversity and potential of each of these imaging agents, we present the underlying mechanisms of each agent's targeting and trapping in tumor tissue and provide examples of clinical studies in diverse cancer types as well as descriptions of the utility of each tracer for staging and treatment monitoring.

Introduction

Over the past two decades, nuclear imaging has transformed cancer care. Both positron emission tomography (PET) and single photon emission computed tomography (SPECT) have empowered clinicians with imaging tools capable of providing *functional* and *biochemical* information about tissues that complement the *anatomical* maps created by magnetic resonance imaging (MRI) and computed tomography (CT). A remarkable array of radiotracers has been created that enables the visualization of targets ranging from the expression of biomarkers by individual cancer cells to the pH of the tumor microenvironment.

The most widely used radiotracer in oncology – 2-[^{18}F]fluoro-2-deoxyglucose, [^{18}F]FDG – is only one of a few PET radiopharmaceuticals that has been approved by the US Food and Drug Administration. Yet despite its utility, [^{18}F]FDG is limited in many cases and cannot possibly be expected to fulfill all of the imaging needs of clinicians as we enter the era of personalized medicine. As a result, recent years have played witness to ever-increasing efforts toward the development and translation of novel, molecularly targeted imaging agents. *In this chapter, we will focus on radiopharmaceuticals that have reached a particularly critical point in their journey from bench to bedside*: *imaging agents that have been the subject of multiple clinical trials but have yet to be approved by regulatory agencies for routine clinical use*. While a multitude of radiopharmaceuticals have reached the clinic in some capacity, we have chosen to discuss a handful of particularly promising agents as case studies. We truly believe that these radiotracers represent the next generation of clinical nuclear imaging agents. We have organized these imaging agents into three groups according to their target: (I) the machinery of cellular metabolism and biosynthesis, (II) cell surface receptors, and (III) the tumor microenvironment, with a focus on imaging hypoxia. Importantly, the intrinsic technological advantages of PET over SPECT – principally the former's quantitative output and higher resolution – mean that over the past half decade (the time span covered by this chapter), the vast majority of newly translated radiopharmaceuticals have been PET tracers. As a result, this chapter will focus on these agents.

Before we begin, we believe that a brief tutorial on the anatomy of a radiotracer is in order (Fig. 1). Broadly speaking, the vast majority of radiopharmaceuticals are composed of two parts: a targeting vector and a radioisotope. A wide

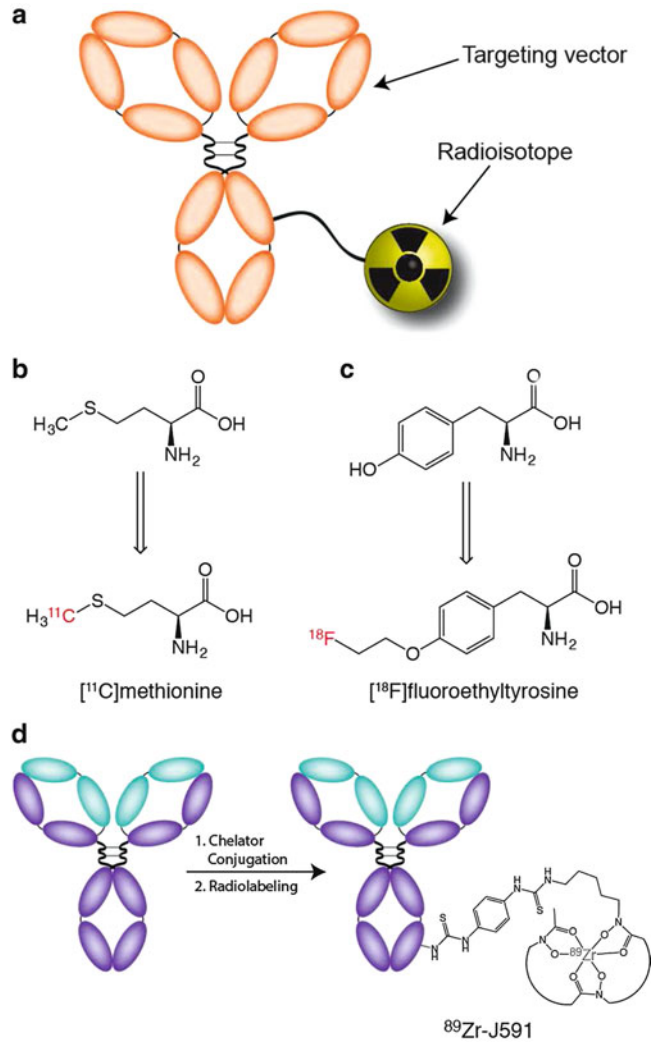

Fig. 1 The basic anatomy of a radiotracer (**a**) as well as three different strategies for the design of radiotracers: the direct replacement of an atom in the parent molecule with a radioactive isotopologue (**b**), the use of a small structural modification to create a "handle" for the incorporation of a radioisotope (**c**), and the use of a chelator along with a radiometal (**d**)

range of molecules has been employed as vectors, including small molecules, peptides, proteins, antibodies, and nanoparticles (and even whole cells!). A similarly varied array of radioisotopes has been used. In this arena, two physical considerations are particularly important: the type of radioactive emission and the half-life of decay. While SPECT radiotracers employ gamma-emitting isotopes such as ^{111}In and ^{99m}Tc, PET agents use positron-emitting nuclides such as ^{18}F, ^{64}Cu, and ^{68}Ga. Radioisotopes with half-lives ranging from 9.97 min (^{13}N) to 4.18 days (^{124}I) have been employed in radiotracers. A key consideration is matching the physical half-life of the radioisotope to the pharmacokinetic half-life of the targeting vector. As a result, short-lived isotopes such as ^{11}C ($t_{1/2} = 20.4$ min) and ^{18}F ($t_{1/2} = 110$ min) are typically used for radiolabeling small molecules, while long-lived nuclides such as ^{89}Zr ($t_{1/2} = 78.4$ h) and ^{111}In ($t_{1/2} = 67.3$ h) are more commonly employed for radiolabeling proteins and antibodies. Finally, the chemistry of radionuclides plays an important role in the design of radiotracers. While nonmetallic radioisotopes such as ^{11}C, ^{15}O, ^{18}F, and ^{124}I can often be incorporated directly into the structure of the radiotracer (e.g., [^{15}O]H_2O or [^{11}C]CO_2), radiometals such as ^{111}In, ^{68}Ga, and ^{89}Zr require that a metal chelator (e.g., DOTA or desferrioxamine) be attached to the vector in order to stably coordinate the radiometal in vivo.

Targeting Cellular Transport, Metabolism, and Proliferation

Overview

The aberrant growth of cancer cells results in numerous metabolic changes that can be targeted for diagnostic imaging. A classic example of a metabolism-targeting radiotracer is 2-[^{18}F]fluoro-2-deoxyglucose ([^{18}F]FDG), a radiolabeled glucose analog that is avidly taken into cancer cells trying to meet their augmented energy requirements by increasing the expression of glucose transporters. Unfortunately, however, because of the ubiquitous role of glucose as an energy source, the increased uptake of [^{18}F]FDG is not a phenomenon specific to cancer cells. Needless to say, this deficiency has spurred significant interest in the development of new, more tumor-selective radiotracers. Over the last decade, several small-molecule radiotracers specific for various metabolic pathways have been developed and clinically evaluated with promising results. Broadly speaking, these tracers can be divided into two groups: (i) radiolabeled amino acids and amino acid analogs that target amino acid transport and metabolism and (ii) acetate, choline, and analogs thereof that target lipid biosynthetic pathways. It is important to note that many of these radiotracers were originally developed for other purposes and only recently have been reevaluated for oncologic imaging. For example, [^{11}C]acetate was initially created for imaging cardiac oxidative metabolism, while *L*-3,4-dihydroxy-6-[^{18}F]fluorophenylalanine ([^{18}F]FDOPA) was developed for imaging dopaminergic neurons in the central nervous system. Lastly, we will highlight the potential for imaging proliferating tumor cells using 3′-deoxy-3′-[^{18}F]fluorothymidine ([^{18}F]FLT), a nucleoside analog that is taken up and retained in proliferating cells without incorporation into DNA.

Imaging Amino Acid Transport and Metabolism

Amino acids are vital sources of carbon and nitrogen and are precursors for the biosynthesis of proteins. Thus, they are an extremely valuable commodity to rapidly proliferating tumor cells. In order to accommodate the increased need for these molecular building blocks, cancer cells often overexpress cell membrane-bound amino acid transporters [1]. Radiolabeled amino acids and their analogs are therefore enticing options for the development of cancer-specific radiotracers. Although radiolabeled amino acids can participate in a variety of metabolic processes, the currently available amino acid radiotracers exclusively visualize the upregulation of transporter expression and the rate of amino acid uptake [2]. More specifically, the amino acid transporter systems known to be upregulated in various cancers are the ASC transporter 2 (ASCT2) and L-type amino acid transporter 1 (LAT1) systems [3, 4]. ASCT2 is responsible for the Na^+-dependent transport of small neutral amino acids – such as alanine, serine, and cysteine (which give the abbreviated name of the transporter) – and is the principal route for the uptake of glutamine. LAT1, in contrast, transports bulky, hydrophobic payloads including leucine, phenylalanine, and tyrosine. The overexpression of amino acid transporters in cancer cells induces nutrient-sensitive mTOR (mammalian target of rapamycin) signaling pathways, resulting in the upregulation of cell growth and proliferation [4]. In addition, unlike in normal cells, the metabolism of cancer cells relies on ASCT2-transported glutamine, which is used as a carbon source for the synthesis of tricarboxylic acid (TCA) cycle intermediates and to maintain pools of nonessential amino acids [5]. The transporter-mediated uptake of amino acid radiotracers and their postulated participation in cellular processes are presented in Fig. 2.

The radiolabeled amino acids currently in clinical use include ^{11}C-labeled L-[^{11}C-methyl]methionine ([^{11}C]methionine), *anti*-1-amino-3-^{18}F-fluorocyclobutane-1-carboxylic acid ([^{18}F]FACBC), 3,4-dihydroxy-6-[^{18}F]fluorophenylalanine ([^{18}F]FDOPA), and O-(2-^{18}F-fluoroethyl)-L-tyrosine ([^{18}F]FET). Moreover, out of the many radiofluorinated analogs of glutamine evaluated to date, 4-[^{18}F]-(2*S*,4*R*)fluoroglutamine ([^{18}F]FGln) looks to be the most promising candidate for clinical

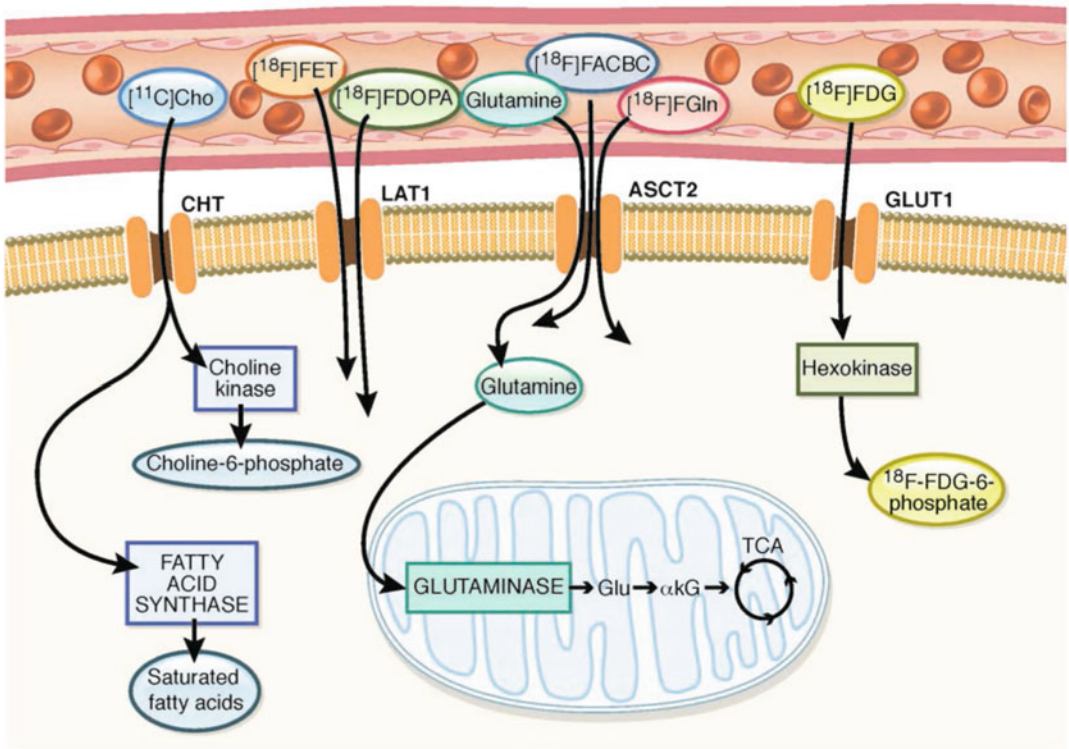

Fig. 2 The transport mechanisms of amino acid radiotracers and the postulated routes of their downstream participation in cellular processes

translation. The structures of these amino acid radiotracers are shown in Fig. 3. As the reader will note, all of these tracers are radiolabeled with the short-lived positron-emitting radioisotopes ^{11}C and ^{18}F. It is important to note that despite their common mode of decay, there are fundamental differences between ^{11}C- and ^{18}F-labeled tracers, and care should be taken to select the appropriately labeled radiotracer for the purpose. Since fluorine is not a common constituent in natural compounds, the introduction of the ^{18}F radiolabel generally yields nonidentical structural analogs in which the label is attached via substitution for another halogen, substitution for a hydroxyl group, or incorporation of an ^{18}F-labeled prosthetic group. In contrast, most radiotracers labeled with ^{11}C are typically chemically *identical* to their non-labeled counterparts, with the only difference being the replacement of a ^{12}C atom with a ^{11}C atom (making the two compounds *isotopologues*). Consequently, the pharmacokinetic and biochemical behavior of the ^{11}C-labeled isotopologue is *identical* to the non-labeled parent compound, and the radiotracer undergoes transport, metabolism, and elimination in the *exact same manner* as the compound it "traces." There are, however, advantages to using ^{18}F-labeled tracers. For example, the longer physical half-life of the isotope allows for multistep syntheses and the transportation of tracers to remote imaging facilities. In addition, in some cases, the chemical differences between the natural molecule and its ^{18}F-labeled counterparts can be useful. For example, the ^{18}F label can block the downstream metabolism of a tracer after it has entered a cell, resulting in intracellular accumulation and higher tumor signal. By far the best example of this phenomenon is the trapping mechanism of [^{18}F]FDG.

One metabolism-targeting radiotracer provides a particularly good example of a case in which a drastic structural modification to the tracer facilitates metabolic trapping. The alicyclic amino

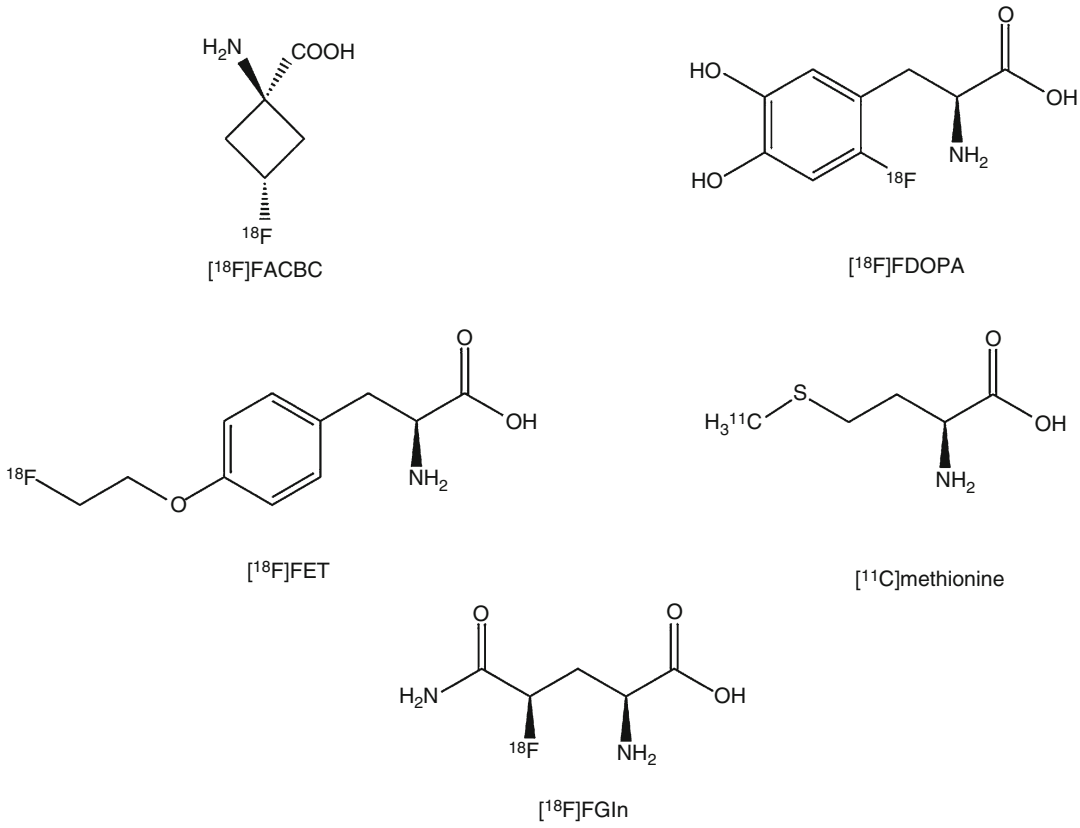

Fig. 3 The structures of selected amino acid radiotracers

acid [^{18}F]FACBC – a compound in which the amino and carboxylic acid termini are joined by a nonnatural ^{18}F-substituted cyclobutane – is still recognized and transported into cells by ASCT2, but the cyclobutane moiety renders the compound immune to subsequent metabolism [6]. To date, [^{18}F]FACBC has been evaluated in clinical studies primarily for the imaging of prostate cancer. Prostate cancer imaging is a particularly promising application of [^{18}F]FACBC, as it takes advantage of the low background accumulation of the tracer in the urinary bladder [7]. In recent clinical trials in patients with primary prostate cancer from Emory University, the National Cancer Institute, and Uppsala University in Sweden, [^{18}F]FACBC uptake was found to correlate well with intraprostatic lesions, while metastases remained largely undetected (Fig. 4) [8–10]. Furthermore, Schuster et al. originally reported a good correlation between [^{18}F]FACBC uptake and histopathology and the Gleason score. However, later reports have challenged this by showing nonspecific uptake of the radiotracer by B and T lymphocytes [11] and, consequently, in inflammatory lesions including prostatitis and benign prostatic hyperplasia as well as benign growths such as osteomata [12]. The sensitivity of [^{18}F]FACBC PET toward malignant lesions was, however, drastically improved when combined with positron-emission tomography/magnetic resonance imaging (PET/MRI). The current consensus on the potential utility of [^{18}F]FACBC PET for clinical applications is that it has potential for the diagnosis of the most aggressive prostate cancer lesions to support radiotherapy planning.

Standing in stark contrast to the unnatural [^{18}F]FACBC, ^{11}C-labeled methionine (L-[^{11}C-methyl]methionine) is a radiotracer in which the radiopharmaceutical is *chemically identical* to the natural amino acid. Developed in the 1970s as part of

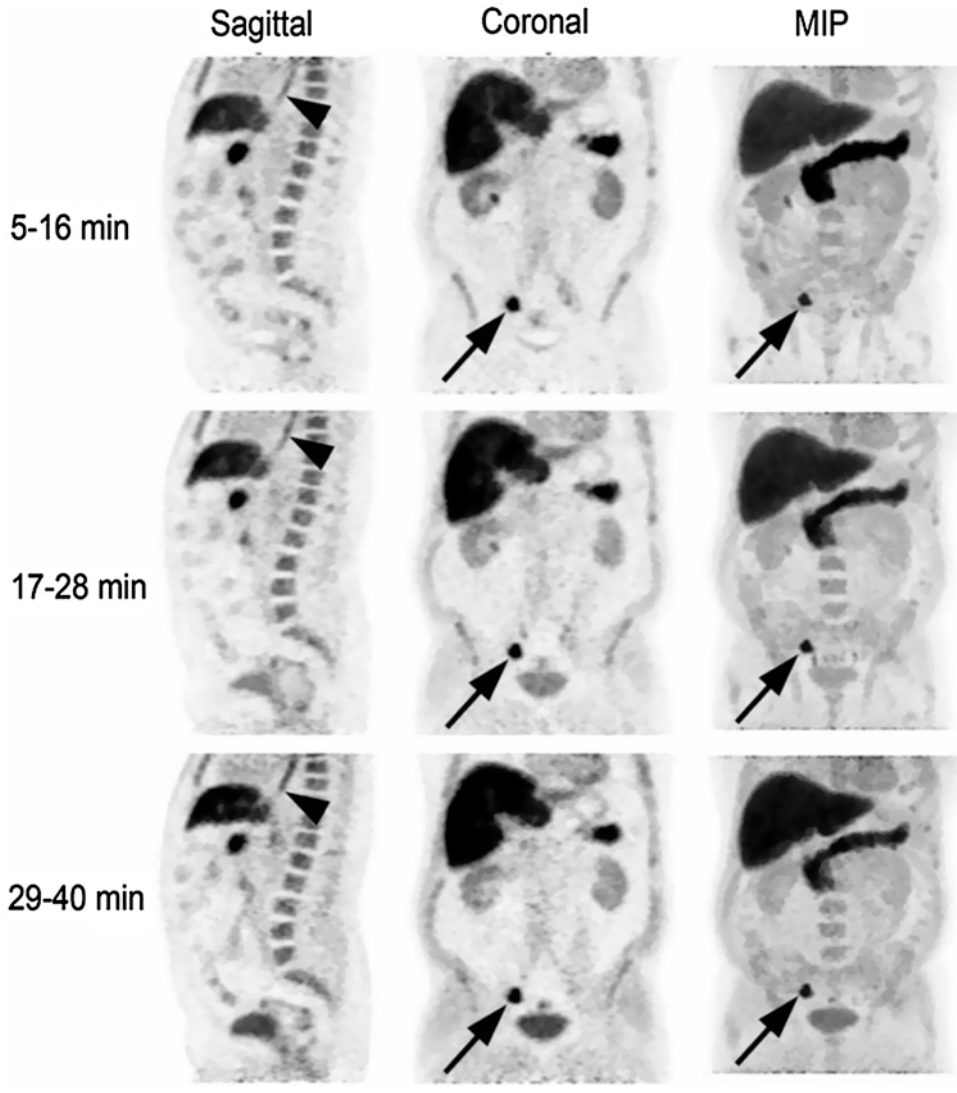

Fig. 4 Sagittal, coronal, and maximum intensity projection (MIP) [^{18}F]FACBC PET images acquired over three time intervals in a patient with recurrent prostate cancer. Uptake can be seen in the right iliac lymph node (*arrows*) at a site of metastatic recurrence. Bladder activity initially is absent but moderately increases with time upon tracer excretion. Also noted is mild to moderate diffuse activity in the esophagus (*arrowheads*) (This research was originally published in *The Journal of Nuclear Medicine*, Schuster et al. [12]. © by the Society of Nuclear Medicine and Molecular Imaging, Inc.)

a series of ^{11}C-labeled amino acid tracers for the assessment of the rate of protein synthesis, [^{11}C] methionine is the only radiotracer from this lot in active clinical use today and can be efficiently radiolabeled in a single-step reaction using [^{11}C] methyl iodide [13]. [^{11}C]methionine is a substrate of the LAT1 transporter and is readily incorporated into proteins during translation. Consequently, [^{11}C]methionine uptake in subjects with glioma and non-small cell lung cancer (NSCLC) has been shown to correlate with both tumor microvessel density (i.e., the upregulation of LAT1) and proliferative capacity (i.e., the rate of tracer incorporation into cells) [14, 15]. Due to their high expression levels of LAT1 and prominent exocrine activity, both healthy liver and pancreas display high uptake of [^{11}C]methionine, limiting the utility of the tracer to visualize

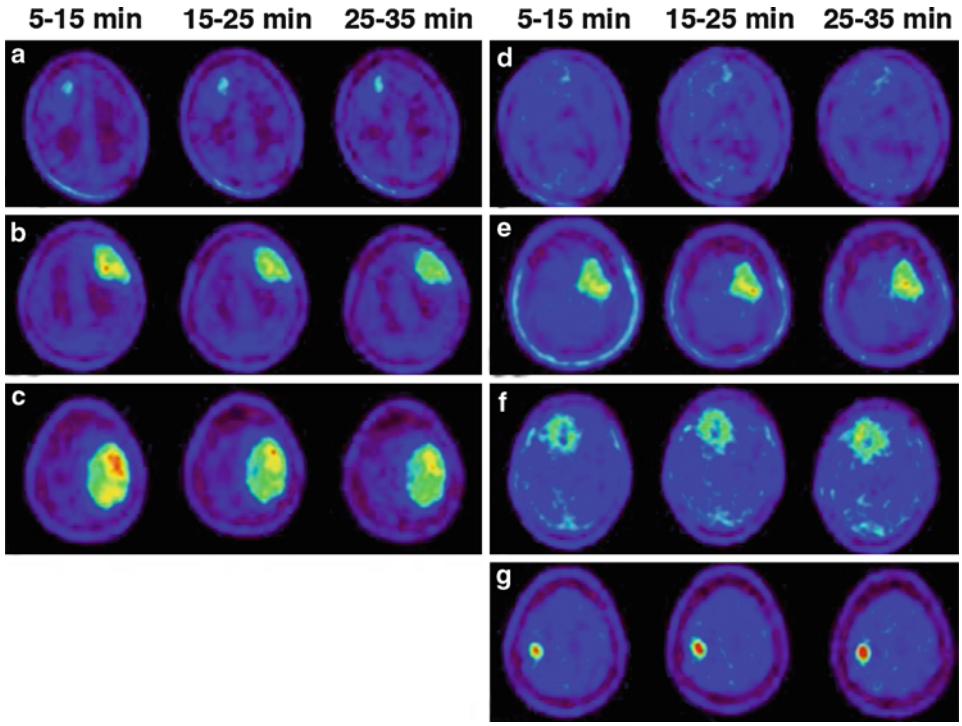

Fig. 5 Dynamic changes in [^{11}C]methionine accumulation in various brain malignancies. (**a**) Oligodendroglioma, (**b**) anaplastic oligodendroglioma, (**c**) meningioma, (**d**) diffuse astrocytoma, (**e**) anaplastic astrocytoma, (**f**) glioblastoma, and (**g**) malignant lymphoma (Reproduced with permission from Springer from Aki et al. [146])

neoplasms in those organs [16, 17]. In contrast, the background accumulation of [^{11}C]methionine in the brain is low. As a result, the tracer's greatest potential lies in the imaging of tumors of the CNS (Fig. 5). Current clinical use of [^{11}C]methionine for the diagnosis and post-treatment follow-up of brain tumors is widespread in both Europe and Japan, where several clinical studies have established the potential of ^{11}C-methionine PET for the sensitive and specific diagnosis of primary gliomas. This allows for the identification of the proliferating tumor margin, which is important for radiotherapy planning [18]. The uptake of [^{11}C]methionine in gliomas may also be used as a survival factor, as initially low tracer uptake correlates with a more favorable prognosis [19]. However, reliable correlation between tracer uptake and the grade of the disease has not been achieved. Additionally, [^{11}C]methionine has been shown to aid in differentiating between tumors and radiation necrosis in conjunction with anatomical imaging modalities MRI and CT (Fig. 6).

^{18}F-labeled *o*-(2-[^{18}F]-fluoroethyl)-L-tyrosine ([^{18}F]FET) is another nonnatural amino acid that localizes into tissues via LAT1-mediated transport [20]. Unlike [^{11}C]methionine, however, [^{18}F]FET cannot be incorporated into proteins and is thus considered non-metabolic. [^{18}F]FET is commonly prepared either using a two-step synthesis based on ^{18}F-labeled fluoroethyltosylate and a protected tyrosine *or* a single-step reaction using an ethyltosylate-substituted tyrosine precursor [21, 22]. As with [^{11}C]methionine, clinical studies with [^{18}F]FET have focused on tumors of the CNS, for which radiolabeled amino acids seem to offer the advantage of low background uptake compared to [^{18}F]FDG [23]. Dynamic [^{18}F]FET imaging has proven to be especially useful in patients with glioma, as differences in the kinetic parameters of [^{18}F]FET uptake allow for the differentiation between low-grade and high-grade gliomas. The time-activity curves for [^{18}F]FET uptake in low-grade and high-grade gliomas from the study of Pöpperl et al. [24] are presented in Fig. 7. More recently,

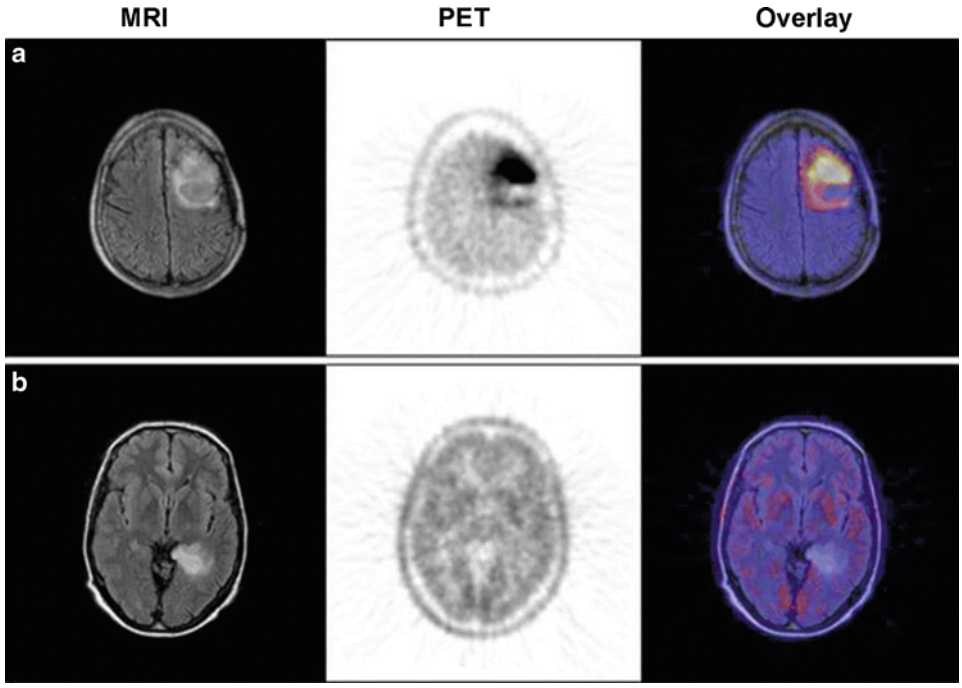

Fig. 6 The MRI, PET, and fused images depicting differences in [^{11}C]methionine uptake in a brain tumor (**a**) and an area of radiation necrosis (**b**) (Reproduced with permission from Springer from Glaudemans et al. [18])

select kinetic parameters – including the minimum time to peak (TTP_{min}) – have been proposed to derive quantitative data from dynamic [^{18}F]FET imaging for the grading and functional characterization of primary brain tumors [25].

A fluorinated analog of the brain-permeable dopamine precursor *L*-dihydroxyphenylalanine (*L*-DOPA) – *L*-3,4-dihydroxy-6-[^{18}F]-fluorophenylalanine ([^{18}F]FDOPA) – was first developed for the study of changes in dopaminergic signaling in the brains of patients with Parkinson's disease [26]. Unlike other fluorinated amino acid analogs, [^{18}F]FDOPA *is* readily metabolized in vivo in the same manner as natural *L*-DOPA by catechol-*o*-methyl transferase (COMT) and aromatic amino acid decarboxylase (AACD) to yield 3-*O*-methyl-6-[^{18}F]-fluoro-L-dopa ([^{18}F]3-OMFDOPA) and [^{18}F]6-fluorodopamine ([^{18}F]FDA), respectively (Fig. 8) [27]. Recently, [^{18}F]FDOPA PET has been explored in oncology for the diagnosis of neuroendocrine tumors (NET). NETs are often challenging imaging targets, as the tumors are small and dispersed and constitute a metabolically and biologically diverse group. The current clinical standards for the diagnostic imaging of NETs are somatostatin receptor (SSR)-targeted PET/CT, [^{18}F]FDG, and SPECT with [^{123}I]-*meta*-iodobenzylguanidine ([^{123}I]MIBG) or ^{111}In-pentetreotide. The preferential uptake of [^{18}F]FDOPA in NETs is a result of the ability of the tumors to synthesize and store biogenic amines and polypeptide hormones [28]. The NET lesions most efficiently delineated with [^{18}F]FDOPA PET are those that originate from the chromaffin cells of the adrenal medulla (pheochromocytomas), paragangliomas of the sympathetic nervous system, and medullary thyroid cancer (MTC) [29]. Figure 9 shows a pancreatic NET lesion that remains completely undetected by [^{18}F]FDG but is clearly visualized with [^{18}F]FDOPA. Comprehensive comparisons between SSR PET/CT and [^{18}F]FDOPA are scarce, but in general, a higher

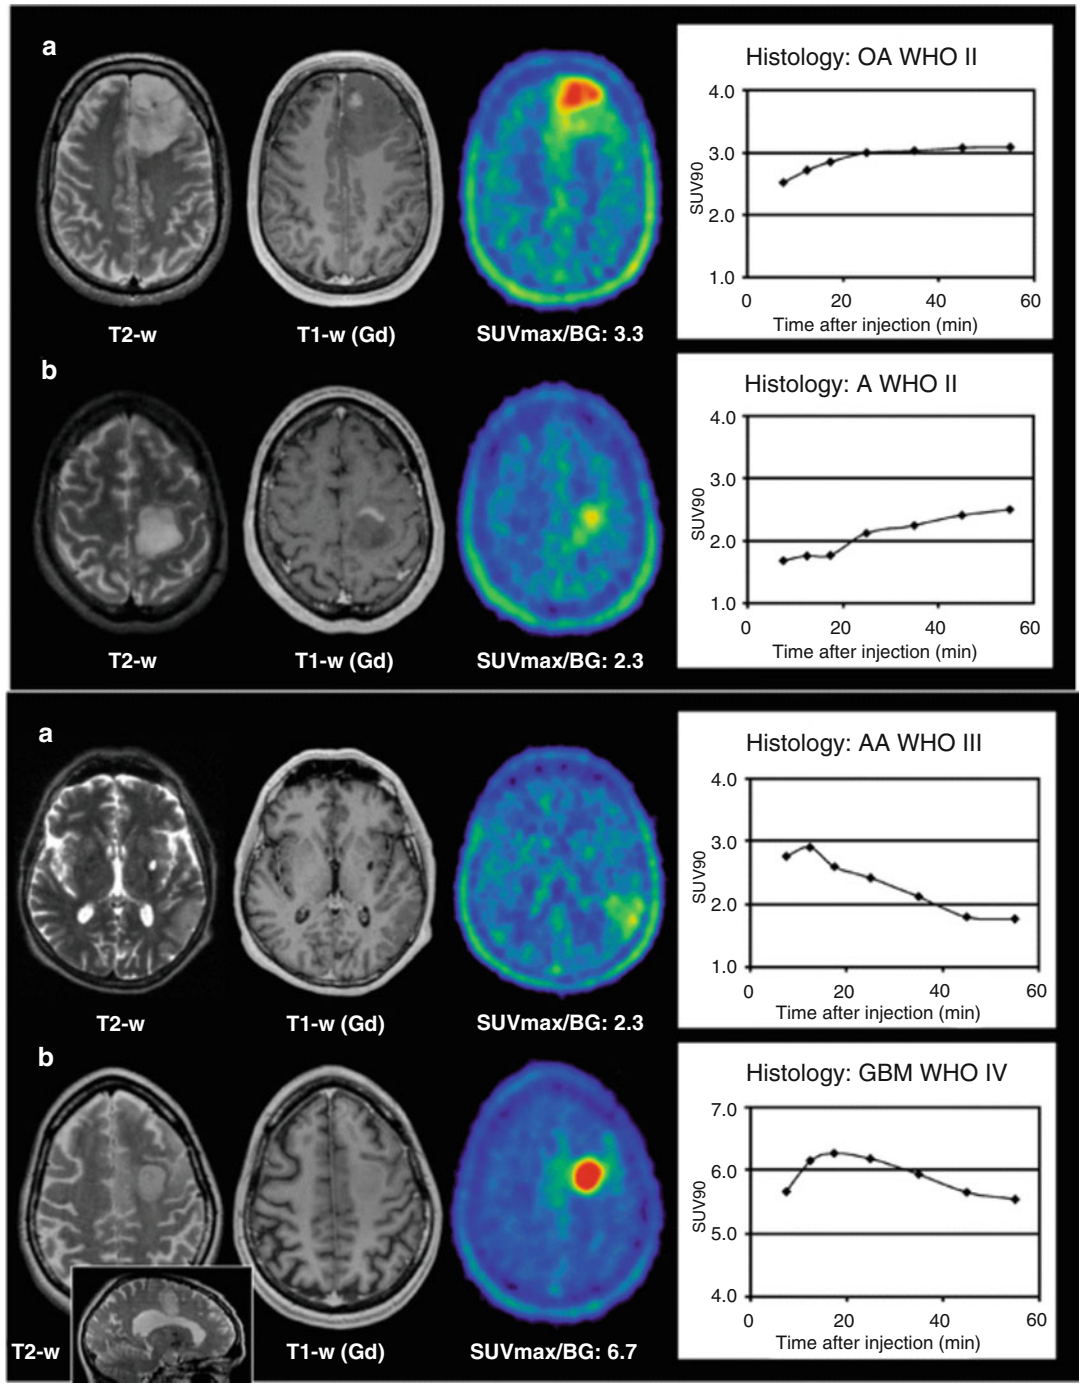

Fig. 7 Differences in the uptake kinetics of [^{18}F]FET in subjects with low-grade (WHO II) and high-grade (WHO III) gliomas. In the latter, a sharp peak in the SUV at early time points after administration can be seen (Reproduced with permission from Springer from Pöpperl et al. [24])

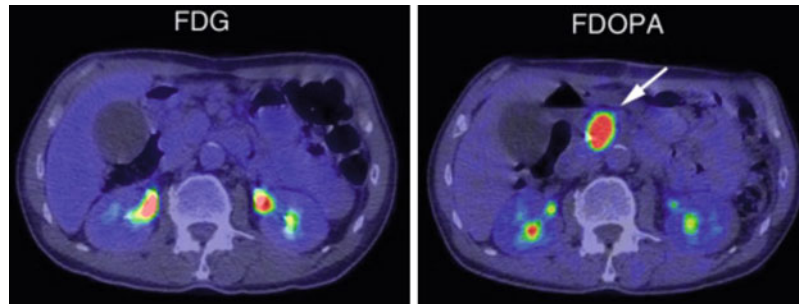

Fig. 9 [^{18}F]FDG and [^{18}F]FDOPA PET images of a patient with a low-grade metastatic pancreatic neuroendocrine tumor showing the lack of [^{18}F]FDG tumor detection and the positive [^{18}F]FDOPA uptake in the lesion (Reprinted from Minn et al. [29], with permission from Elsevier)

tumor burden is detected with SSR PET/CT [30]. Despite these alternative techniques, the utility of [^{18}F]FDOPA PET/CT imaging in NET is highlighted in cases with variable or low SSR expression like medullary thyroid carcinoma or in which a closer metabolic dissection of the tumor is warranted [31]. In CNS tumors, including high-grade glioma, [^{18}F]FDOPA has been shown to yield comparable results to [^{18}F]FET in tumor delineation [32]. However, widespread clinical use of [^{18}F]FDOPA is currently limited by its complex radiosynthesis and the low specific activity of the compound when synthesized via electrophilic radiofluorination. As a result, only a handful of institutes worldwide have access to high specific activity [^{18}F]FDOPA [33]. Thankfully, this is expected to change in the future due to recent developments in the automated enantioselective synthesis of [^{18}F]FDOPA from 2-[^{18}F]fluoro-4,5-dimethoxybenzyl iodide using a phase transfer catalyst [34].

As a source of both carbon and nitrogen, glutamine is a vital feedstock for a number of biosynthetic pathways in cancer cells. This efficient use of glutamine by cancer cells is achieved by the upregulation of glutamine transporters on the cell membrane as well as the increased expression of mitochondrial glutaminase that drives the synthesis of glutamate from glutamine to feed the TCA cycle [35]. The creation of a PET tracer for glutamine-based imaging has required the careful consideration of radiolabeling strategies. The seemingly obvious choices for a radiolabel are ^{11}C and ^{13}N ($t_{1/2}$ = 9.97 min) both of which

could yield chemically identical isotopologues of glutamine. However, in addition to the synthetic challenges posed by the short physical half-lives of the two radioisotopes, ^{11}C- and ^{13}N-labeled glutamine radiotracers undergo rapid degradation and elimination of the radiolabel from the tracer in tumor cells as a result of glutaminolysis.

This has left ^{18}F-radiofluorinated glutamine analogs as the only feasible alternative. The most promising ^{18}F-labeled glutamine analog – 4-[^{18}F]-(2*S*,4*R*)fluoroglutamine ([^{18}F]FGln) – was recently evaluated for the imaging of gliomas in a pilot, open-label human microdosing study [36]. The uptake of [^{18}F]FGln in gliomas was comparable to [^{18}F]FDG, though the uptake of [^{18}F]FGln in healthy brain was markedly lower (Fig. 10). As a result, the use of [^{18}F]FGln was proposed over [^{18}F]FDG due to its improved contrast. However, later studies revealed that [^{18}F]FGln is prone to defluorination in vivo in humans, a problem which could result in the deposition of high concentrations of ^{18}F-fluoride in the bone. Studies investigating new [^{18}F]fluoropropyl-substituted derivatives as alternatives to [^{18}F]FGln with more selective radiosyntheses and improved in vivo stability are underway [37]. The final utility of glutamine-based radiotracers in oncology will remain unknown until these tracers become widely available for clinical studies. Nevertheless, glutamine PET holds great promise as a novel tool for metabolic imaging in oncology.

Imaging Lipid Biosynthesis

In addition to glucose and amino acids, tumor cells also crave nutrients to drive the biosynthesis of the cell membrane lipids needed to sustain rapid cell division. The PET radiotracers suitable for imaging lipid biosynthesis include ^{11}C-labeled acetate, ^{11}C-labeled choline and its ^{18}F-labeled analogs, ^{18}F-fluoromethylcholine, and ^{18}F-fluoroethylcholine (structures are given in Fig. 11).

[^{11}C]Acetate participates in the synthesis of fatty acids and is readily incorporated in phosphatidylcholine in tumor cells [38, 39]. In contrast to normal cells (in which the preferred fate for acetate is oxidative metabolism), cancer cells seem to utilize [^{11}C]acetate almost exclusively as a building block [39, 40]. Fatty acid synthase (FAS, EC 2.3.1.85) catalyzes de novo lipogenesis: the synthesis of saturated fatty acids like myristate, palmitate, and stearate from acetyl-CoA, malonyl-CoA, and NADPH [41, 42]. FAS has been found to be upregulated in many cancers and is considered a potential target for chemotherapy, prompting the use of [^{11}C]acetate in oncologic imaging [43]. To date, the most promising application of [^{11}C]acetate PET lies in prostate cancer, a malignancy in which FAS upregulation is an important part of pathogenesis. Furthermore, the enzyme has been established as a measure of aggressiveness of the disease via correlation with high Gleason scores [44, 45]. Figure 12a shows a typical finding in [^{11}C]acetate PET, in which anatomical (MRI) and histopathological findings correlate well with the uptake of the radiotracer in the primary tumor. In Fig. 12b, a representative whole-body scan of a patient with recurrent prostate carcinoma is shown to illustrate both the avid uptake of the tracer in the pancreas and liver as well as the lack of urinary excretion. These two characteristics combine to make [^{11}C]acetate ideal for the imaging of prostate cancer but of limited value in tumors proximal to the gastrointestinal tract. In addition to the detection of primary tumors, [^{11}C]acetate PET has been shown to be especially effective for the delineation of bone and lymph node metastases and in the diagnosis of recurrent disease with predictive value for treatment response [46, 47]. Recently, Leisser et al. showed that the predictive value of [^{11}C]acetate PET has a positive correlation with serum PSA levels [44].

In addition to FAS, cancer cells upregulate choline kinase (ChoK, EC 2.7.1.32), the first enzyme in the synthetic pathway for another constituent of the cell membrane: phosphatidyl choline. Consequently, ^{11}C-radiolabeled [^{11}C]choline and ^{18}F-labeled choline analogs have been proposed as diagnostic agents in oncology. As with [^{11}C]acetate, the most promising applications of both choline tracers have been found in prostate cancer, in which energy metabolism favors fatty acid oxidation. Like [^{11}C]acetate, [^{11}C]choline behaves in exactly the same way as natural

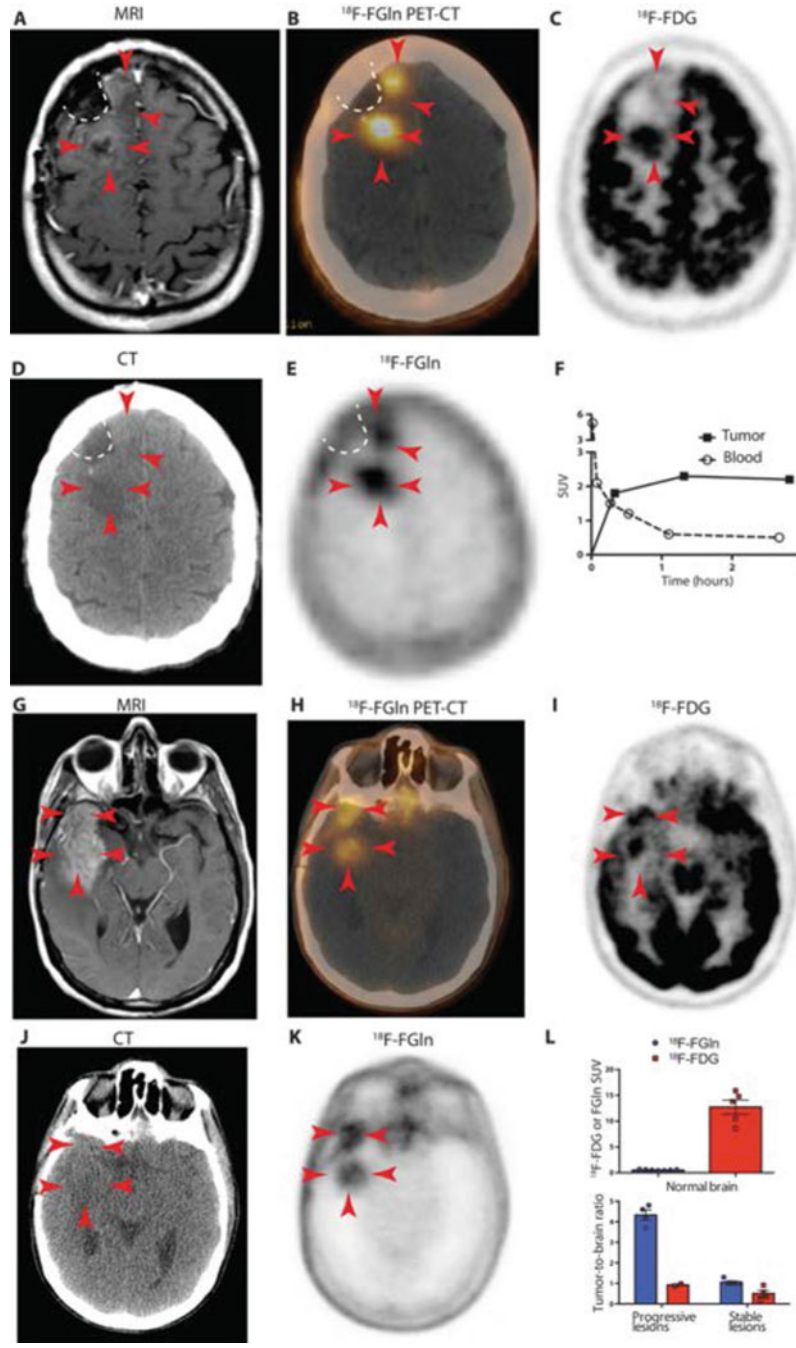

Fig. 10 [^{18}F]FGln PET shows uptake in glioma under progression of the disease in a patient with a IDH1m oligodendroglioma (**a**–**k**) and a patient with a glioblastoma (**g**–**k**). The standard uptake values (SUV) of [^{18}F]FGln corresponding to tumor uptake (*black squares*) and blood clearance (*clear circles*) plotted over time (**f**). Comparison of [^{18}F] FGln (*blue bars*) and [^{18}F] FDG (*red bars*) illustrates differences in background uptake with both radiotracers in normal brain (*top panel*) and tumor-to-brain ratios from three clinically stable glioma patients and three glioma patients with clinically progressive disease (**l**) (From Venneti et al. [36]. Reprinted with permission from AAAS)

choline: it is metabolized into ^{11}C-labeled phosphatidyl choline and incorporated into cells. Curiously, while two of the methyl groups in choline are necessary for ChoK specificity, longer alkyl chains in the third position *are* well tolerated [48], allowing for the creation of ^{18}F-labeled fluoromethyl and fluoroethyl analogs with favorable imaging properties. The vast majority of recent clinical studies has been carried out using [^{18}F]fluoromethylcholine, which has shown potential for the detection of lymph node and bone metastasis in patients with castration-resistant

prostate cancer (Fig. 13). However, contrasting observations have also been reported, warranting further studies before firmly establishing the clinical utility of ^{18}F-fluoromethylcholine PET in the diagnosis and prognosis of prostate cancer [49]. Regardless of the tracer used, the uptake of choline in prostate cancer seems to be dependent on serum PSA levels, allowing for the detection of disease recurrence at a sensitivity exceeding 40% at serum PSA levels of 1 ng/mL [50, 51]. Moving beyond prostate cancer, the upregulation of ChoK and increased intracellular concentrations of phosphocholine have also been observed in breast and epithelial ovarian carcinomas, prompting clinical imaging studies with radiolabeled choline tracers in patients with these malignancies [52, 53]. Figure 14 shows the uptake of [^{11}C]choline in HER2-positive breast cancer at baseline and 3 days after the initiation of trastuzumab chemotherapy, illustrating the potential value of [^{11}C]choline PET for monitoring treatment response. That said, more studies are warranted to establish the utility of [^{11}C]choline PET in malignancies other than prostate cancer.

Imaging Cellular Proliferation with [^{18}F]FLT

Elevated rates of cellular proliferation are one of the hallmarks of cancer [54]. Given that these increased rates of proliferation are often accompanied by the upregulation of free nucleotide scavenging, the latter has attracted a great deal of attention as a target for the imaging of proliferation. Radiolabeled analogs of thymidine have emerged as particularly promising imaging agents for the evaluation of cell proliferation and viability. Chosen for their exclusive incorporation into DNA rather than RNA, thymidine-based radiotracers have yielded varying degrees of success. Easily the most promising variant is 3′-deoxy-3′-[^{18}F]fluorothymidine (FLT), modified from the original nucleoside structure via the substitution of the 3′ hydroxyl group with ^{18}F (Fig. 15). ^{11}C-labeled tracers such as [^{11}C]methionine and [^{11}C]thymidine have been proposed, but the 20-min half-life of ^{11}C has proven to be too short for effective PET imaging [55].

The structure of FLT allows it to interact with enzymes specific to nucleoside uptake, processing, and metabolism. However, the absence of a 3′ hydroxyl group prevents its incorporation into cellular DNA (^{3}H-FLT inclusion <1%) [56]. FLT enters cells either through passive diffusion or facilitated transport via Na^{+}-dependent channels. In a mechanism reminiscent of [^{18}F]FDG, intracellular FLT is phosphorylated by thymidine kinase 1 (TK1) to form [^{18}F]FLT-monophosphate. This traps the radiotracer within the cell where it can undergo further phosphorylation to form FLT-diphosphate and FLT-triphosphate [56]. TK1 activity has been found to be higher in some malignant cell lines, leading to increased retention of FLT and higher uptake within the proliferating tissue [57]. The mechanism of uptake and retention of [^{18}F]FLT is illustrated in Fig. 16.

[^{18}F]FLT PET has been utilized in dozens of clinical trials with a variety of cancers [56, 58]. One of the most common uses of [^{18}F]FLT has been as a noninvasive tool for assessing the viability of tumors. Such scans can be administered following a cycle of chemotherapy or radiation therapy and have been repeatedly confirmed as an

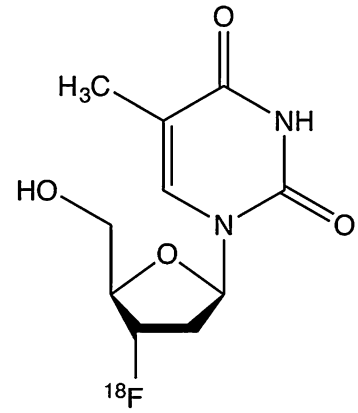

Fig. 15 The structure of [^{18}F]FLT

effective predictive measure of whether a patient will benefit from further treatment. For example, Contractor et al. found that a reduction in [^{18}F]FLT uptake in the weeks following the treatment of breast cancer with docetaxel correlated significantly to lesion size evaluated via ultrasound and CT ($P = 0.004$) [59]. Such results are mirrored in nearly every case: the overall uptake of [^{18}F]FLT decreases significantly in response to therapy, providing an effective method to monitor the progression of treatment [58].

The current clinical standard for monitoring tumor response to treatment is through the use of [^{18}F]FDG. Not surprisingly, there are many studies comparing [^{18}F]FLT and [^{18}F]FDG uptake [60–62]. One potential advantage of FLT over [^{18}F]FDG is that the former does not show increased uptake in inflammatory lesions, a common source of false-positive indications with [^{18}F]FDG [56, 63]. Additionally, due to the low rates of proliferation in healthy brain tissue, excellent tumor-to-background ratios have been achieved in clinical trials with [^{18}F]FLT in gliomas (Fig. 17). Furthermore, [^{18}F]FLT is also able to significantly distinguish high- vs. low-grade tumors, while [^{18}F]FDG was not [64].

Interestingly, in some instances, it has been noted that a "flare effect" can occur immediately following the administration of therapeutic agents, during which there is a marked increase in [^{18}F]FLT uptake at the tumor. This may be due to the inhibition of de novo thymidine synthesis

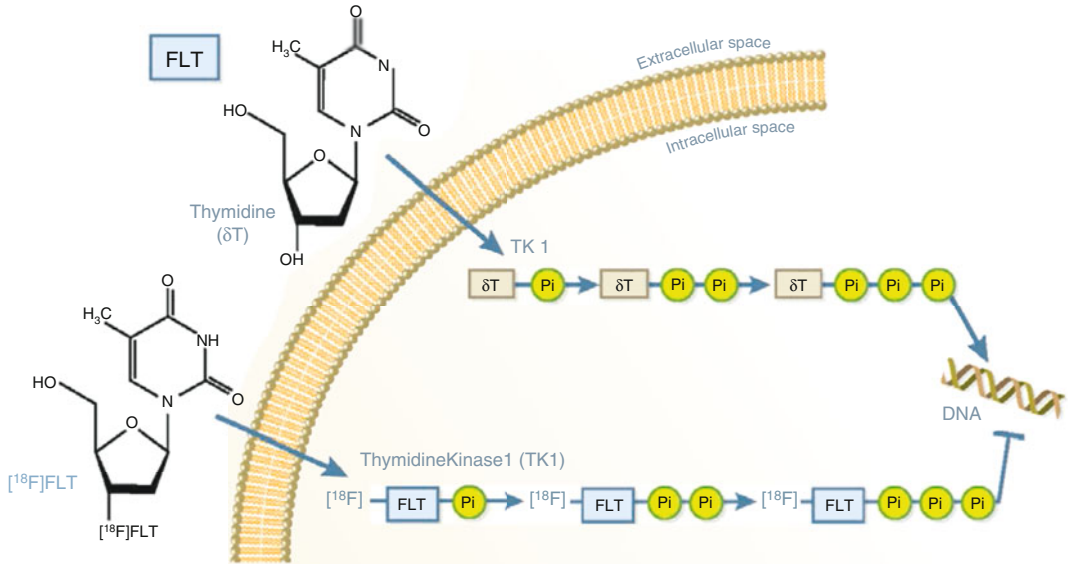

Fig. 16 [^{18}F]FLT enters the cell through identical pathways to thymidine (δT), becoming phosphorylated and trapped in the cell by thymidine kinase 1 (TK1). However, FLT is not incorporated into the DNA due to the absence of a 3′ hydroxyl group

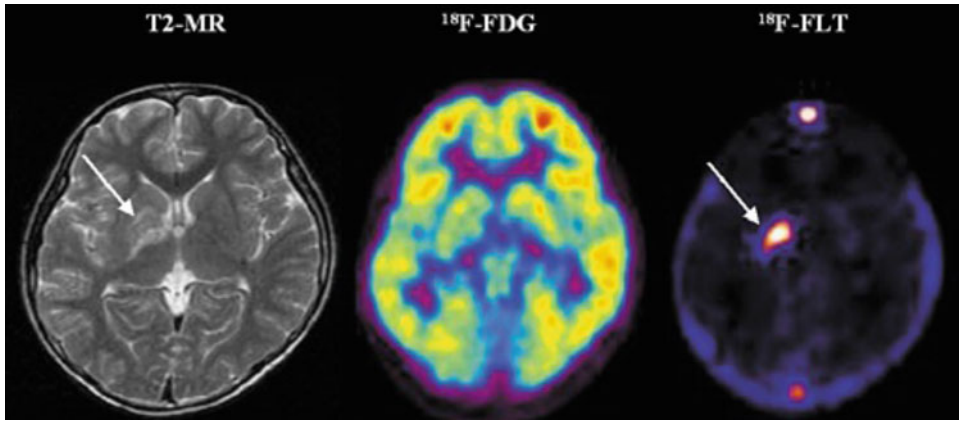

Fig. 17 A germ cell tumor located in the right basal ganglia is obscured by background signal in the [^{18}F]FDG PET scan (*middle*) and shows very slightly decreased uptake. In contrast, the [^{18}F]FLT PET image (*right*) demonstrates significant uptake, revealing a malignant tumor with greater certainty than either MRI (*left*) or [^{18}F]FDG (Reproduced with permission from Springer from Choi et al. [64])

pathways [65]. A greater flare response was found to be associated with poorer patient prognosis and survival rate [66]. Such flares may be useful indicators to evaluate the efficacy of chemotherapy on a patient-by-patient basis.

A significant mechanistic obstacle to the widespread use of [^{18}F]FLT is the ability of some cancers to convert deoxyuridine monophosphate to thymidine monophosphate [67]. Therefore, [^{18}F]FLT uptake does not necessarily correlate to overall cellular proliferation but rather reflects the activity of the thymidine salvage pathway. Going forward, clarifying the relationship between cellular viability, cellular

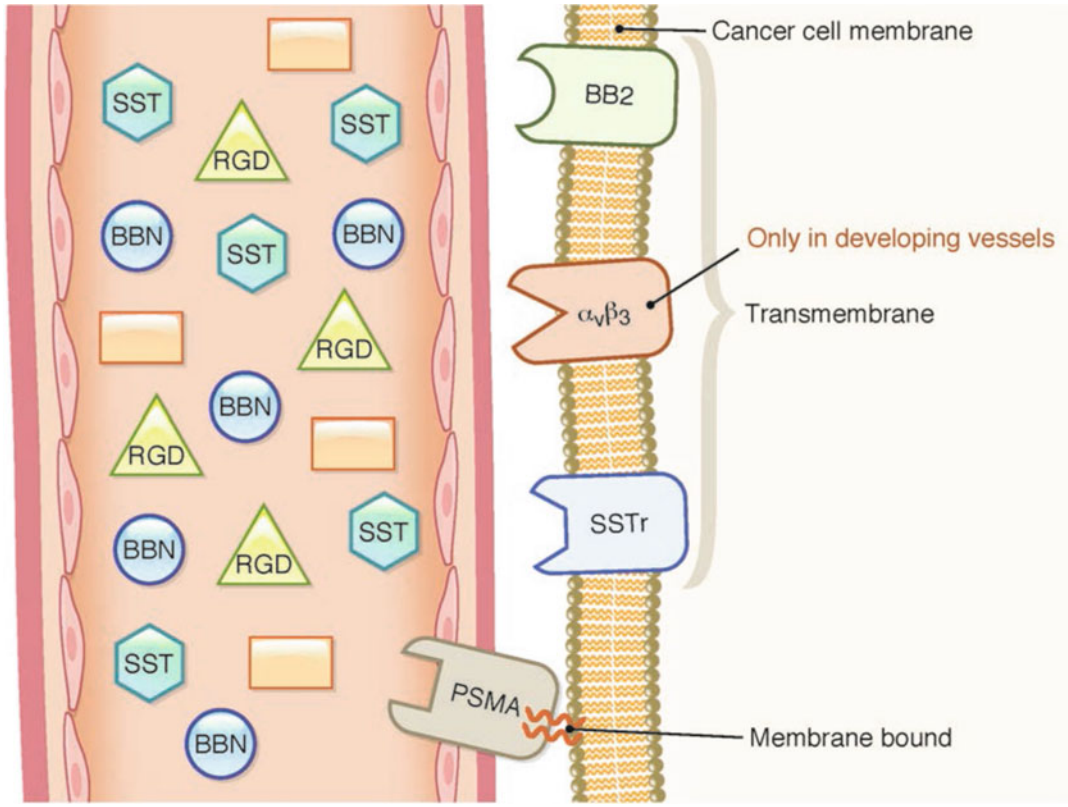

Fig. 18 A schematic illustrating cell surface receptor targeting with molecules designed for molecular imaging

proliferation, and [^{18}F]FLT uptake is crucial to the further clinical implementation of this imaging agent.

Targeting Cell Surface Receptors

Overview

Targeting cancer cells can also be achieved through the use of molecules that interact with cell surface receptors (Fig. 18). In this way, imaging can guide clinicians during the planning and monitoring of receptor-targeted therapies. The caveat to this approach, however, is that many of the cell surface receptors found on cancer cells are *also* expressed on noncancerous cells. Thus, the *specific* targeting of cancer cells requires that the cell surface receptor be expressed in much higher quantities on malignant cells than on healthy cells. Broadly speaking, ligands that target cell surface receptors can be subdivided into two classes: *agonists*, which potentiate the receptor activity, and *antagonists*, which bind to the receptor and render it inactive.

Imaging the Expression of Somatostatin Receptors

Somatostatin receptors (SSTr) are a group of transmembrane G protein-coupled receptors that have been subdivided into five subtypes, numbered 1–5 [68]. Specifically, somatostatin subtype-2 (SST2) receptors are prevalent throughout the body (brain, pituitary gland, pancreatic islets, stomach, and kidney) [69] but are expressed in higher amounts on certain tumor types, including neuroendocrine, pituitary, breast, brain, and small cell lung cancers [70]. Naturally occurring somatostatin (SST) is a cyclic polypeptide that has been used to inspire

Table 1 Naturally occurring SST and a subset of SST2-targeting peptides used to deliver PET radioisotopes to tumor sites. Also shown are two common chelators conjugated to these peptides

Name(s)	**Peptide sequence**[a]

[a]Standard amino acids are represented by their single-letter abbreviation; nonstandard amino acids are given via common abbreviations [*Thr(ol)* is threoninol, *βNal* is 3(2-naphthyl)alanine, *p-NO₂-Phe* is *p*-nitrophenylalanine, *Aph(Cbm)* is 4-(aminocarbonyl)amino phenylalanine, *Cpa* is cyano-propionic amino acid, *Aph(Hor)* is 4-(4S)-hexahydro-2,6-dioxo-4pyrimidinylcarbonylamino phenylalanine, *p-Cl-Phe* is *p*-chlorophenylalanine]. D amino acids are signified by lowercase letters or superscripted D. Bolded and italicized letters indicate cyclized peptide sequence portions
[b]Naturally occurring peptides that target SSTr

synthetic analogs that have greater receptor affinity while retaining selectivity toward SST2 (Table 1). These compounds consist of a cyclic portion that targets the receptor along with a radiometal chelator moiety coupled to the *N*-terminus of the peptide sequence. In the search for optimal pharmacokinetic properties, a number of different somatostatin analogs have been created; perhaps most notably, altering the *C*-terminal amino acid from Thr(ol) to Thr changes octreotide (OC) to octreotate (TATE) (see Fig. 19). In addition, altering the amino acid sequence has led to some compounds that are agonists [e.g., octreotide (OC), Tyr^3-octreotide (TOC), lanreotide (NOC), and vapreotide] and others that are antagonists [e.g., JR10, JR11(OPS202), and LM3]. Currently, the FDA has approved the use of ^{111}In-DTPATOC – variously known as ^{111}In-DTPA-Tyr^3-octreotide, ^{111}In-DTPA-pentetreotide, Octreoscan™ – for the SPECT imaging of somatostatin receptor-expressing tumors. Additionally, the United States FDA has designated an orphan drug status for ^{68}Ga-DOTATOC in an effort to allow continued investigation of the radiopharmaceutical for the imaging of neuroendocrine tumors and carcinoids.

In the clinic, ^{68}Ga-DOTATOC has been shown to quickly target cranial meningiomas with very good image quality (Fig. 20) [71]. In these studies, there was striking contrast between the meningioma and the pituitary gland, which was further delineated using PET/MRI. Because of the utility of imaging SST-positive tumors with ^{68}Ga-DOTATATE, patients receiving peptide receptor radionuclide therapy (e.g., ^{177}Lu-DOTATATE) have been imaged using PET throughout treatment to assess the efficacy of therapy [72, 73]. In studies in which treatment was monitored by ^{68}Ga-DOTATATE, patients receiving two or more doses of ^{177}Lu-DOTATATE showed no significant progression of disease for longer than those with only one round of therapy [73]. A DOTANOC variant has also been used in the clinic. Lococo et al. showed that pulmonary carcinoids that showed an absence of [^{18}F]FDG uptake were clearly visible in ^{68}Ga-DOTANOC PET scans, while other tumors displayed decreased or similar uptake relative to [^{18}F]FDG [74]. As a result, the authors of this study suggest using both radiopharmaceuticals in concert to identify tumors. Additionally, this multicentered trial showed

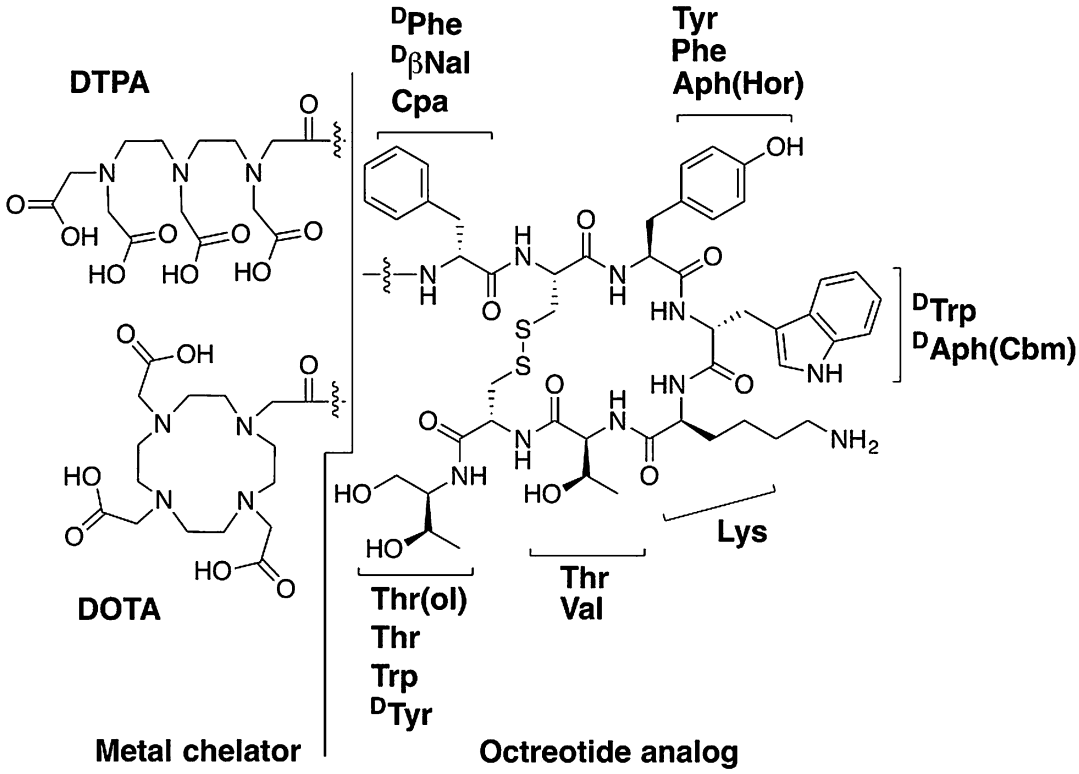

Fig. 19 A schematic depiction of octreotide-like pharmacophores that can be radiolabeled for the PET imaging of SSTr positive tumors. The two most commonly conjugated chelators for octreotide-like radiopharmaceuticals are provided to clarify how they are each attached to the peptide. The amino acid labels indicate variations from octreotide (structure drawn) at each position for the peptides listed in Table 1

that including nonstandard amino acids in the octreotide sequence (i.e., DOTANOC) might not strongly impact the overall targeting ability of the imaging agent. However, other studies have indicated that varying the metal-chelator complex or the peptide sequence *does* impact the radiopharmaceutical's binding affinity for SSTr [75–77]. Specifically, Fani et al. showed that the tumor uptake of antagonist-based radiotracers was greater than that of agonist-based imaging agents [77].

Imaging the Expression of Integrins

Integrin receptors are comprised of two binding regions – α and β – that can be made up of a variety of amino acid sequences, ultimately yielding 24 unique combinations [78]. One of these combinations, the $\alpha_v\beta_3$ integrin receptor, has been associated with cells responsible for angiogenesis in melanoma, neuroblastoma, and glioblastoma as well as ovarian, breast, and lung cancers [70]. Also, it has been shown that the $\alpha_v\beta_3$ integrin receptors are not expressed in most noncancerous tissues [78]. Peptides containing an arginine-glycine-aspartic acid (RGD) sequence mediate cell adhesion and have been shown to target $\alpha_v\beta_3$ integrin receptors [79, 80]. Due to the unique function of RGD peptides, attempts to utilize these peptides to treat or target disease (by tracking angiogenesis or metastatic tumor formation) have been carried out [81, 82]. Notably, three PET imaging agents based on RGD peptides have entered clinical trials: [^{18}F]FPPRGD$_2$, alfatide, and [^{18}F]galacto-RGD. The structures of each of these compounds (as well as a few related structures) are presented in Fig. 21.

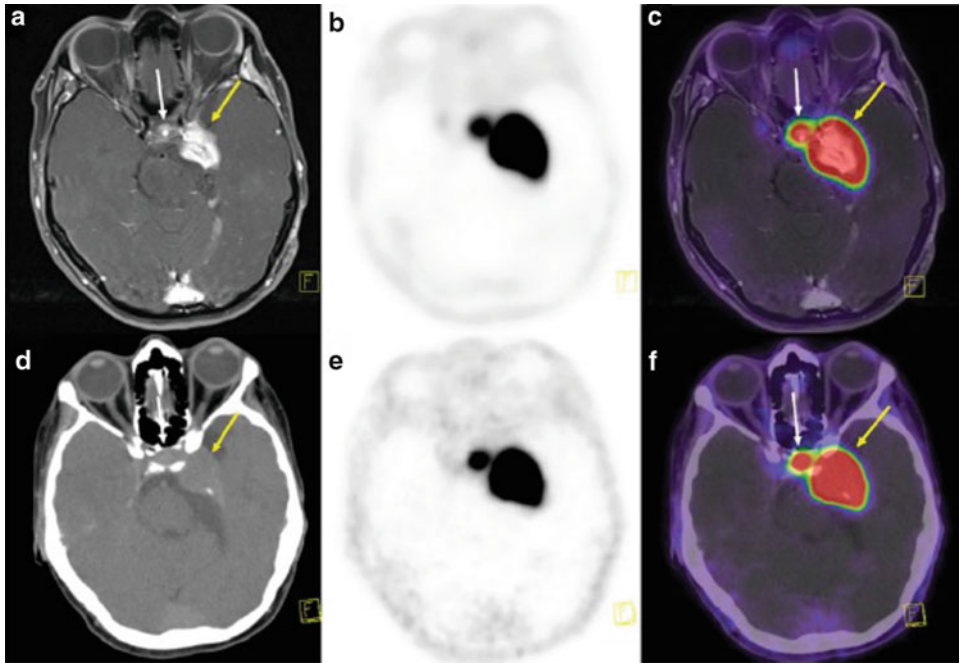

Fig. 20 PET/MRI imaging of a patient injected with ^{68}Ga-DOTATOC at 30 min p.i. (**a**–**c**) and 1 h p.i. (**d**–**f**) indicating tumors (*arrows*) using T1-weighted MRI (**a**, **d**), PET (**b**, **e**), and PET/MRI fusion (**c**, **f**) (Afshar-Oromieh et al. [71], reproduced by permission of the Society for Neuro-Oncology)

Several review articles covering clinical imaging with radiolabeled RGD peptides have cataloged the achievements of these radiopharmaceuticals [83–86]. A variety of modifications to the core RGD structure have been tested to improve the in vivo behavior of the radiotracers. For example, the introduction of a sugar onto a single RGD peptide sequence resulted in improved in vivo stability while maintaining favorable tumor-to-background ratios [87, 88]. Studies with [^{18}F]galacto-RGD showed variation in uptake between patients, indicating differences in tumor vascularization and cancer stage [89]. In a different investigation, in order to decrease the labeling time, a click reaction was used to conjugate an ^{18}F-labeled prosthetic group to galacto-RGD to form [^{18}F]flotegatide-RDG (or [^{18}F]RGD-K5) [90]. In initial human studies, [^{18}F]RGD-K5 uptake did not correlate with that of [^{18}F]FDG, a result similar to that observed with [^{18}F]galacto-RGD. However, [^{18}F]RGD-K5 PET was determined to be an effective tool for the delineation of integrin expression in breast cancers [91]. Thus, the principal utility of [^{18}F]RGD-K5 may be in monitoring response to therapy rather than tumor identification [92]. Yet another RGD-based radiotracer features a polyethylene glycol (PEG) spacer that is radiolabeled with ^{18}F. This compound, [^{18}F]fluciclatide (^{18}F-AH111585), was injected into a small number of patients with metastatic breast cancer and displayed uptake in lesions that were also visible via CT. Unfortunately, in these patients, the liver uptake of the tracer was too high to identify liver metastases. Further [^{18}F]fluciclatide imaging studies in patients with brain tumors, lung cancer, squamous cell carcinoma of the head and neck, differentiated thyroid carcinoma, sarcoma, and melanoma will focus on the ability of the tracer to delineate angiogenesis [92]. In a study utilizing [^{15}O]H_2O as a comparison to [^{18}F]fluciclatide in patients with non-small cell lung cancer and melanoma, Kenny et al. showed that the uptake of [^{18}F]fluciclatide was not merely a function of perfusion and suggested using later imaging time points to determine sites of neovasculature [93].

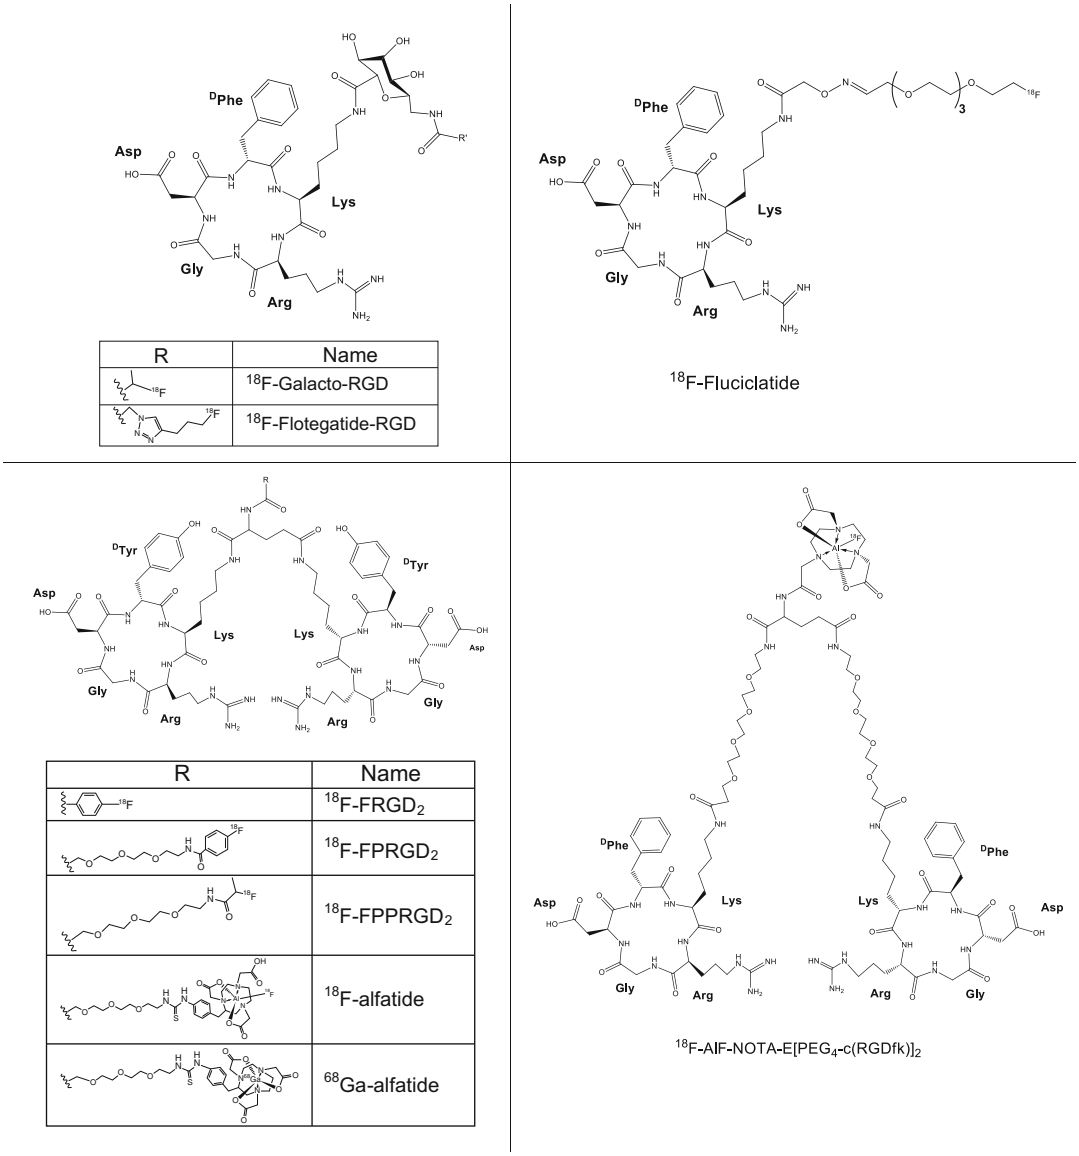

Fig. 21 A schematic of PET tracers used to target $\alpha_v\beta_3$ integrin receptors in clinical studies

Due to their relatively low uptake in tumor lesions (<5%ID/g), suboptimal background contrast, and synthetic complexity, the aforementioned ^{18}F-labeled RGD peptides have shown limited utility in the clinic. This has led to investigations using ^{68}Ga-labeled peptides in hopes of increasing the uptake of the tracer in the tumor or decreasing its uptake in nontarget tissues [94]. For example, ^{68}Ga-NOTA-RGD has been used in patients to identify colorectal cancer metastases prior to therapy [92]. These studies suggest that PET scans using RGD-based peptides could aid in the selection of patients for anti-angiogenic therapy [92].

In another effort to improve the tumor retention of RGD-based peptides, multimeric radiopharmaceuticals have also been investigated. In light of this topic, it is important to diverge – if only briefly – to discuss a concept known as "bivalent targeting." Bivalent targeting strategies are

predicated on the use of two biological targeting moieties that are tethered together (1) to increase the probability of interactions with a single cell surface receptor or (2) to facilitate the binding of two cell surface receptors simultaneously. Homodimers (or homomultimers) utilize the same biological targeting vector to achieve greater cell surface receptor occupancy, whereas heterodimers target different receptors often in an effort to increase the types of cancer targeted by the radiopharmaceutical [95, 96]. The use of two targeting moieties may also increase the chance that the peptide will interact with the cell surface in the correct orientation for receptor binding. Because the distance between any two cell surface receptors is unknown, researchers have attempted to investigate various linking molecules that can accommodate cell surface variations [97]. Additionally, increased linker size may decrease the metabolism rate of the radiopharmaceutical and alter its pharmacokinetic properties, ensuring a longer biological half-life and possibly resulting in greater tumor uptake.

One class of homodimers containing two RGD cyclic peptide sequences (RGD_2) has shown utility across multiple tumor types in a complementary role to [^{18}F]FDG PET imaging. First, Gao et al. noted positive results in identifying lung cancers from hamartomas with the bivalent RGD-based radiotracer ^{18}F-alfatide (Fig. 21) but noted difficulties distinguishing disease from inflammation [98]. Second, Yu et al. used another bivalent agent – [^{18}F]AlF-NOTA-E[PEG_4-c(RGDfk))]$_2$ (^{18}F-alfatide II, Fig. 21) – to visualize 20 brain metastases in nine patients and illustrated that in the same patients, [^{18}F]FDG and CT only identified 10 and 13 metastases, respectively [99]. Third, the analysis of several clinical patient scans with both [^{18}F]FDG and [^{18}F]$FPPRGD_2$ (Fig. 21) has demonstrated differences in maximal uptake in lesions and biodistributions, which may indicate that the information gained from an [^{18}F]$FPPRGD_2$ PET scan may compliment those results from an [^{18}F]FDG scan [100]. Similarly, a preliminary study of [^{18}F]$FPPRGD_2$ uptake in patients with breast cancer demonstrated primary and metastatic imaging utility (Fig. 22) [101]. ^{68}Ga labeling of these agents can also be achieved through the use of NOTA chelators attached to the homodimers; not surprisingly, comparative studies using ^{68}Ga-NOTA-labeled compounds are currently underway.

Imaging the Expression of Bombesin Receptors

Bombesin – a linear, 14-amino acid homolog to the gastrin-releasing peptide – is found in the skin of the European fire-bellied toad (*Bombina bombina*, Fig. 23). Bombesin-based peptides target bombesin receptor subtype-2 (seen in the literature as BB2 and BB2r and originally referred to gastrin-releasing peptide receptor or GRPr), which has been shown to be highly expressed by prostate, breast, pancreatic, small cell lung, and colorectal cancers [70]. BB2 is also highly expressed in the murine pancreas; consequently, preclinical studies with radiolabeled bombesin peptides show increased uptake in the pancreas in non-tumor-bearing mice if the biological targeting portion of the peptide is functioning properly. Importantly, Coy et al. have shown that only the 7th-14th amino acids were necessary for binding to the BB2 [this is commonly abbreviated in the literature as BBN(7-14)] [102]. Further variation in the amino acid sequence has led to a number of bombesin analogs, including RM2, BAY86-7548, and Demobesin 4 (Table 2). Various linkers and chelators have been conjugated to the end of the peptide sequence to alter the pharmacokinetics of the radiopharmaceutical and allow for the use of radiometals with different physical properties and half-lives.

^{68}Ga-labeled BBN analogs have been quickly translated to the clinic. BBN(7-14) conjugated to a radiometallated NOTA chelator via an aminocaproic acid – ^{68}Ga-NOTA-Aca-BBN(7-14) – has been investigated to image primary gliomas. Normal, healthy subjects showed rapid clearance of the ^{68}Ga-NOTA-Aca-BBN(7-14) through the kidneys and had higher accumulation of the radioactivity in the bladder [103]. Twelve patients with high- to low-grade gliomas also showed rapid accumulation of ^{68}Ga-NOTA-Aca-BBN(7-14) in lesions within 30 min with very high tumor-to-background ratios (24 ± 9), and

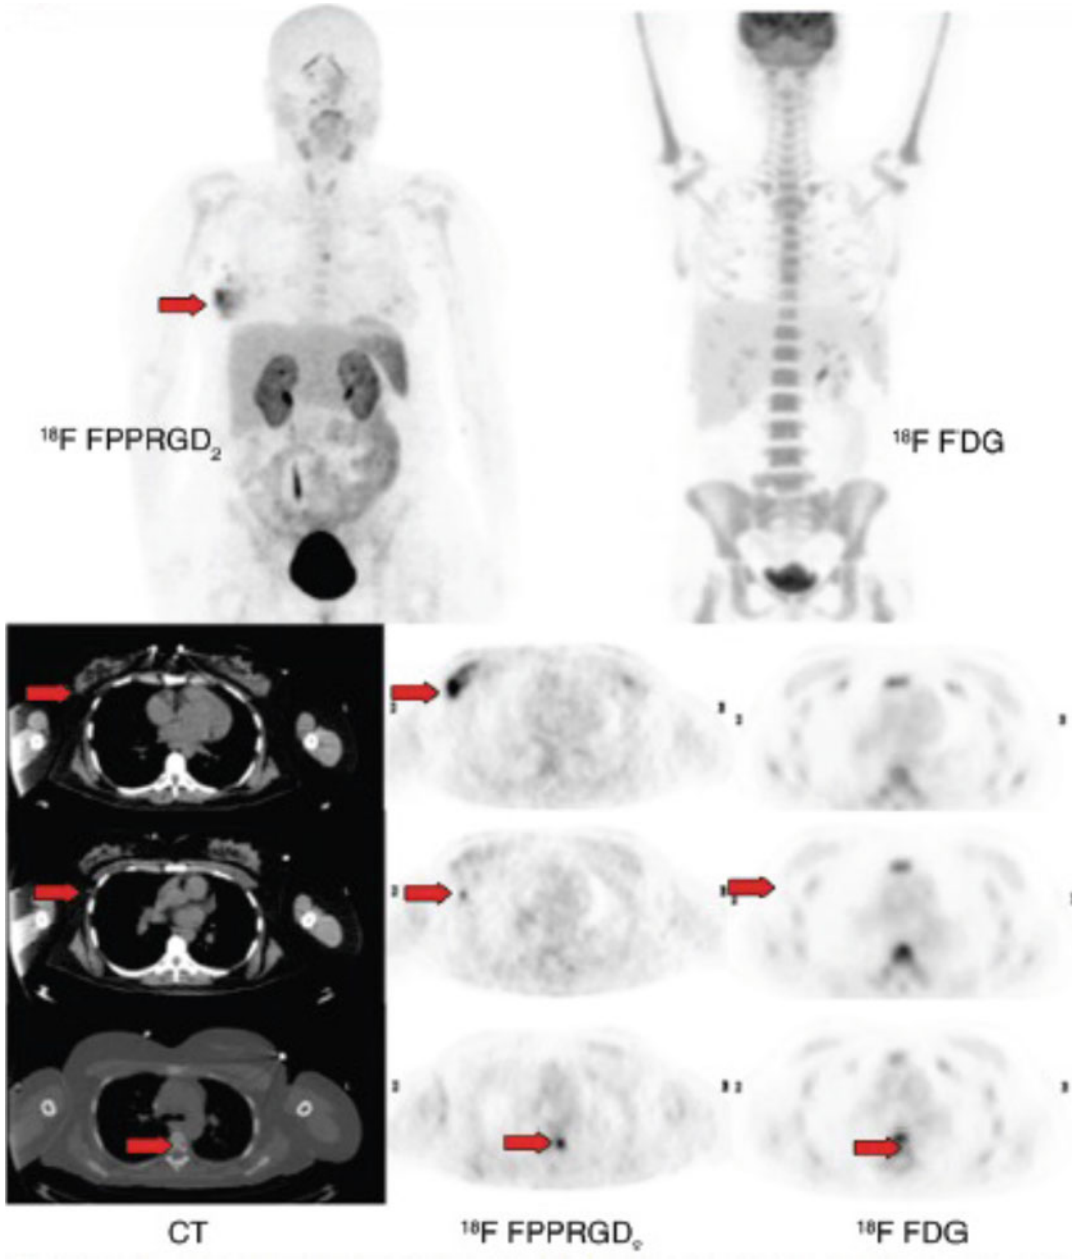

Fig. 22 Comparison of [^{18}F]FPPRGD2 and [^{18}F]FDG in a woman diagnosed with multicentric lobular carcinoma of the right breast. [^{18}F]FDG uptake was not observed at the lesions indicated by the *red arrows* (areas proven to be tumors through biopsy) (From Iagaru et al. [101]. Reprinted with permission from the Radiological Society of North America)

all 14 lesions in the 12 patients were identified [103]. Zhang et al. suggested the possible utility of ^{68}Ga-NOTA-Aca-BBN(7-14) PET not only to identify tumors but also to delineate tumor margins that are difficult to determine clinically using five-aminolevulinic acid (ALA) [103].

Another BB2-targeting radiotracer, ^{68}Ga-BAY86-7548 (^{68}Ga-DOTA-RM2), has been

extensively investigated for imaging prostate cancers. Roivainen et al. reported the clearance and metabolism of ^{68}Ga-BAY86-7548 in normal, healthy patients [104] and indicated that ^{68}Ga-BAY86-7548 was rapidly cleared through the renal-urinary pathway and rapidly metabolized in vivo. Kähkönen et al. demonstrated that ^{68}Ga-BAY86-7548 can be used to visualize primary lesions in the pancreas but is less successful at identifying metastases (Fig. 24) [105]. Borkowski et al. similarly remarked that no off-target binding was observed in prostate cancer patients and that there was high and prolonged uptake in PC-3 tumor xenografts in mice [106].

Utilizing a SPECT radiometal, ^{99m}Tc-Demobesin-4 (Fig. 25) has been investigated for the possible identification of primary and metastatic prostate cancer. Initial studies with ^{99m}Tc-Demobesin-4 indicate that SPECT/CT images of bone metastases in patients with prostate cancer can be visualized as early as 1 h postinjection [107]. However, Mather et al. have also indicated that imaging metastases with ^{99m}Tc-Demobesin-4 in patients who had undergone extensive therapy was not feasible [107]. Thus, ^{99m}Tc-Demobesin-4 may be useful in identifying new patients, but its suitability to visualize response to therapy is limited.

Imaging the Expression of Prostate-Specific Membrane Antigen

Prostate-specific membrane antigen (PSMA) is a transmembrane glycoprotein with a large extracellular portion and small intracellular segment. PSMA expression has been shown in normal prostate tissue, but the level of expression increases in prostate cancer, making it an enticing target for the imaging and therapy of prostate cancers. Despite the number of studies implicating PSMA expression in the diagnosis of prostate cancer, the normal function of PSMA is still unknown [108]. The elevated levels of shed PSMA in the serum of patients require that PSMA-targeting agents must localize in cancerous tissues in high enough abundance to compensate for high background activity concentrations.

The only commercially available PSMA-targeted imaging agent is ^{111}In-capromab pendetide (ProstaScint®), a murine monoclonal antibody that targets the intracellular portion of the antigen [108]. Unfortunately, ^{111}In-capromab pendetide has two major drawbacks. First, the radiotracer only targets PSMA in apoptotic or necrotic tissues, in which the intracellular portion of PSMA is available due to membrane damage. And second, because of the limited sensitivity and selectivity of the radiolabeled antibody, the clinical use of ^{111}In-capromab requires a relatively long delay between injection and

Table 2 Naturally occurring BBN and a subset of the BB2-targeting peptides used to deliver PET radioisotopes to tumor sites

Name(s)	Peptide sequence[a]
Gastrin	VPLPAGGGTVLTKMYPRGNHWAVGHLM-NH_2
Bombesin (BBN)	pGlu-QRLGNQWAVGHLM-NH_2
Bombesin7-14 [BBN(7-14)]	QWAVGHLM-NH_2
BAY86-7548 [DOTA-RM2]	DOTA-4-amino-1-carboxymethyl-piperidine-fQWAVGHSta-L-NH_2

imaging in order to increase target-to-background contrast [108, 109].

Due to the higher image resolution and improved quantification in PET and PET/CT, most recent efforts have focused on the creation of tracers for PET rather than SPECT. Specifically, [^{18}F]DCFBC (*N*-[*N*-[(*S*)-1,3-dicarboxypropyl] carbamoyl]-4-fluorobenzyl-L-cysteine, Fig. 26) – a low-molecular-weight urea-based inhibitor of PSMA – shows rapid uptake in PSMA-positive metastases with predominantly renal excretion but with some prolonged liver uptake and blood-pool activity [110]. These limitations in clearance could limit the efficacy of [^{18}F]DCFBC in delineating disease from healthy tissue near major blood vessels [110], but clinical studies have shown the usefulness of [^{18}F]DCFBC in detecting high-grade prostate cancer lesions and differentiating these from nonmalignant tissue (Fig. 27) [111]. The use of [^{18}F]DCFBC in conjunction with MR may also aid in directing clinicians toward which tissues to biopsy [111].

In order to produce a ^{68}Ga-labeled PSMA-targeting small molecule, ^{68}Ga-PSMA – (Glu-urea-Lys-(Ahx)-[^{68}Ga(HBED-CC)]) – was synthesized by conjugating HBED-CC (a chelator for gallium) to a lysine attached via a urea linker to glumatic acid and subsequently radiolabeled with ^{68}Ga (Fig. 26) [112]. In healthy volunteers, high levels of uptake of ^{68}Ga-PSMA-ligand were observed in the salivary

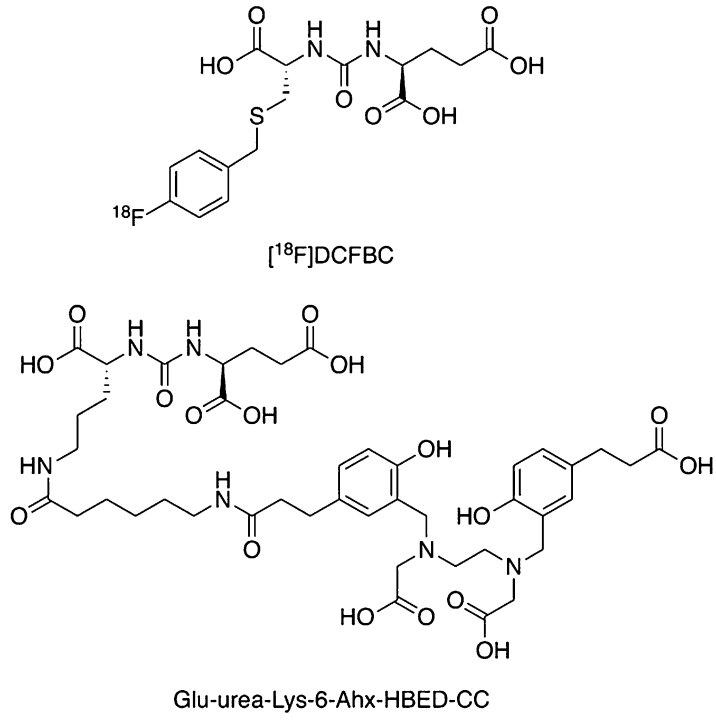

Fig. 26 The chemical structures of [^{18}F]DCFBC and Glu-urea-Lys-6-Ahx-HBED-CC

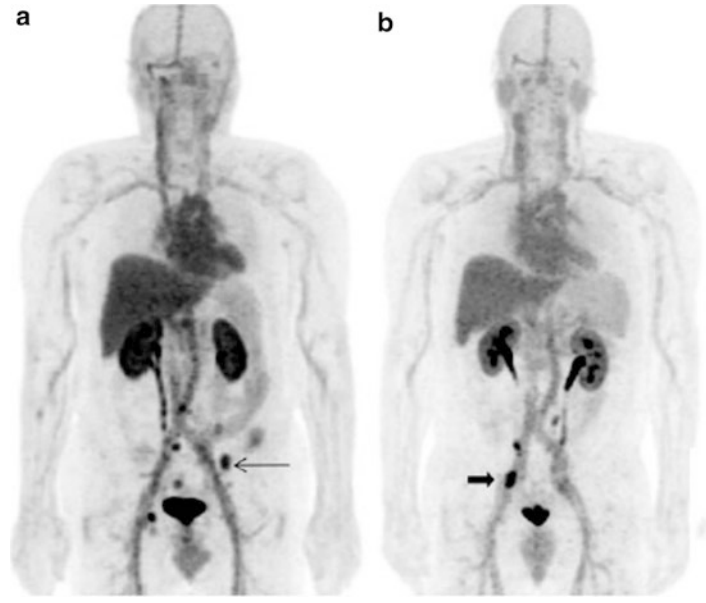

Fig. 27 Anterior MIP at 2 h p.i. of [^{18}F]DCFBC in a patient with bone metastases indicated with an *arrow* (**a**) and a patient with lymph node metastases indicated with an *arrow* (**b**) using PET (This research was published in *The Journal of Nuclear Medicine*, Cho et al. [110]. © by the Society of Nuclear Medicine and Molecular Imaging, Inc.)

glands and the kidneys, while moderate uptake was seen in the lacrimal glands, liver, and gallbladder (Fig. 28) [113]. Afshar-Oromieh et al. noted that 60% of lesions in patients with <2.2 ng/mL PSMA expression in blood and 100% of lesions in patients with >2.2 ng/mL PSMA expression in blood were identified with ^{68}Ga-PSMA-ligand within 1 h of injection, but image contrast may improve with scanning 3 h post-injection (Fig. 28) [113].

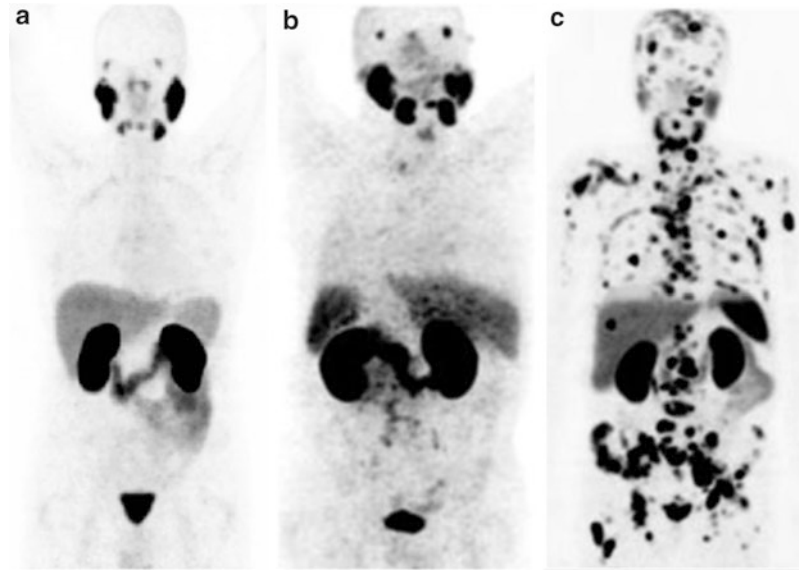

Fig. 28 Maximum intensity projections (MIP) of ^{68}Ga-PSMA-ligand showing in vivo distribution in a healthy patient (**a**, anterior view), a patient with minimal lymph node metastatic prostate cancer (**b**, posterior view), and a patient with extensive lymph node and bone metastatic prostate cancer (**c**, anterior view) (Reproduced with permission from Springer from Afshar-Oromieh et al. [113])

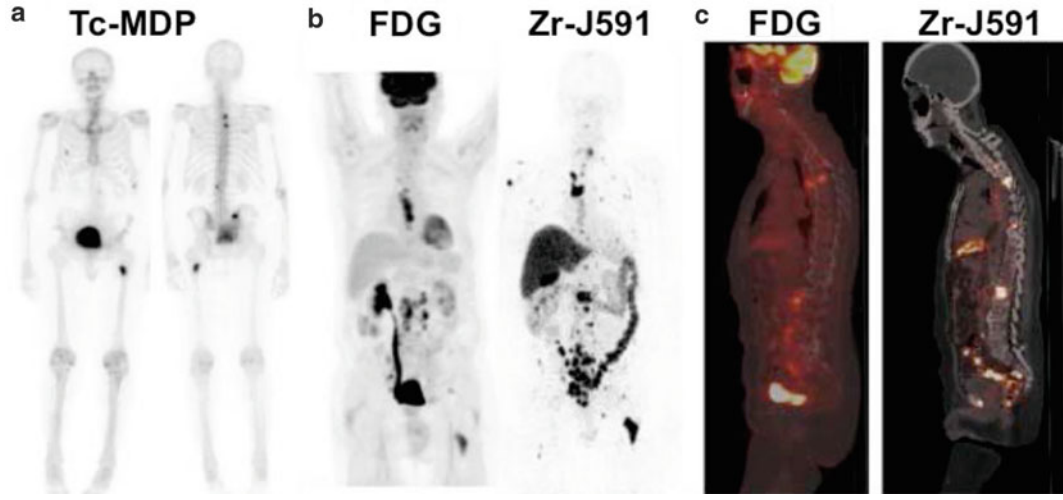

Fig. 29 Comparison of ^{99m}Tc-MDP, [^{18}F]FDG, and ^{89}Zr-J591 uptake in a patient with metastatic prostate cancer using SPECT anterior and posterior images (**a**), PET MIPs (**b**), and planar images of fused PET/CT (**c**) (Reproduced with permission from Springer from Pandit-Taskar et al. [115])

Due to the longer residence times of antibodies in the blood, longer-lived isotopes are necessary for the radiolabeling of antibody-based tracers. Zirconium-89 is a positron-emitting radiometal with a half-life of 3.3 days, which complements the multiday circulation time of antibodies. J591, a humanized monoclonal antibody that targets the extracellular portion of PSMA, has been conjugated to the siderophore-derived chelator desferrioxamine (DFO) to prepare the PET tracer ^{89}Zr-J591 (^{89}Zr-huJ591, ^{89}Zr-DFO-J591). Clinical studies by Pandit-Taskar et al. have indicated that the optimal time to image patients is 7 ± 1 days after the administration of the radiolabeled antibody. Critically, these data reveal significant uptake in tumor tissue with 11 of 12 lesions imaged with ^{89}Zr-J591 and 10 of 12 lesions imaged with [^{18}F]FDG PET/CT [114]. Figure 29 provides an

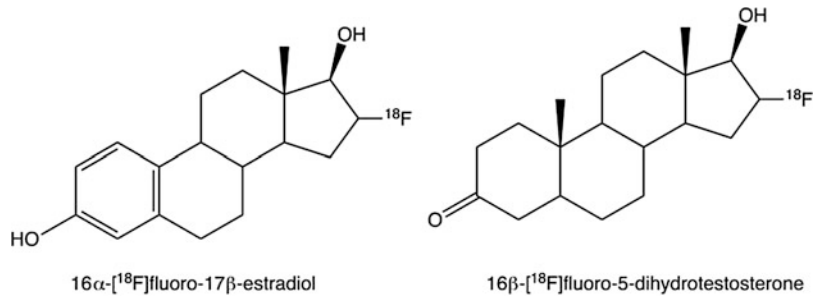

Fig. 30 The structures of [^{18}F]FES and [^{18}F]FDHT

illustration of the potential of ^{89}Zr-J591 compared to [^{18}F]FDG, ^{99m}Tc-MDP, and CT for the imaging of patients with metastatic prostate cancer [114]. Similarly, ^{111}In-labeled J591 has also shown clinical utility for identifying metastases in patients with a variety of PSMA-positive tumor types [115].

Imaging the Expression of Steroid Hormone Receptors

Steroid hormone receptor (SHR) status has been established as an important biomarker in breast and prostate cancer. While the assessment of SHR status in primary tumors is often easily achieved with histological methods, noninvasive molecular imaging could be used to address temporal changes in SHR levels, delineate metastases, and monitor response to treatment [116]. The molecular imaging of steroid hormone receptors relies primarily on the use of ^{18}F-radiolabeled analogs of the endogenous SHR ligands estrogen (17β-estradiol) and testosterone, which target the estrogen (ER) and androgen receptors (AR), respectively. The structures of 16α-[^{18}F]fluoro-17β-estradiol ([^{18}F]FES) and 16β-[^{18}F]fluoro-5-dihydrotestosterone ([^{18}F]FDHT) are presented in Fig. 30. The estrogen and androgen receptors share a common mechanism of action in which the ligand is bound by the intracellular receptor, and the ligand-receptor complex is transported to the nucleus, where it then binds to the respective steroid response elements in DNA and initiates the transcription of hormone-induced genes (Fig. 31) [117, 118]. Additionally, steroid hormones exert nonnuclear actions via a subpopulation of cell surface SHR, but the mechanisms of these nonnuclear effects remain poorly understood. Another notable feature of the biochemistry of sex steroids is their transport in the circulation by the steroid hormone-binding globulin (SHBG). Because of the ^{18}F substitution in the radiotracers, the affinity of [^{18}F]FES and [^{18}F]FDHT for SHBG is lower than that of estradiol and testosterone; consequently, the radiotracers are primarily distributed in the bloodstream nonspecifically bound to serum albumin, which is more abundant than SHBG [119]. Furthermore, both [^{18}F]FES and [^{18}F]FDHT are rapidly metabolized in humans, with only about 20% of the tracer remaining intact 20 min after injection [120, 121].

Estrogen receptor status is an important prognostic indicator of disease-free and overall survival in breast cancer. Figure 32 shows typical PET imaging results in a patient with ER-positive primary breast tumor. In the same study, the authors demonstrated that [^{18}F]FES PET could be used to delineate metastatic sites in the bone and axillary lymph nodes, with the degree of lymph node uptake correlating with disease burden [122]. However, the degree of ER expression in distant sites is variable, and [^{18}F]FES imaging can provide insight on the heterogeneity of metastatic disease, especially when combined with [^{18}F]FDG PET [123]. In a retrospective study of patients undergoing chemotherapy with ER blockade or ligand-depleting agents, Linden et al. have been able to demonstrate that the standard uptake values (SUV) of [^{18}F]FES in tumors is sensitive to changes in circulating estrogen levels as well as ER blockade. In addition, [^{18}F]FES PET imaging was used to distinguish between the pharmacological effects of tamoxifen and fulvestrant, two ER modulators with different

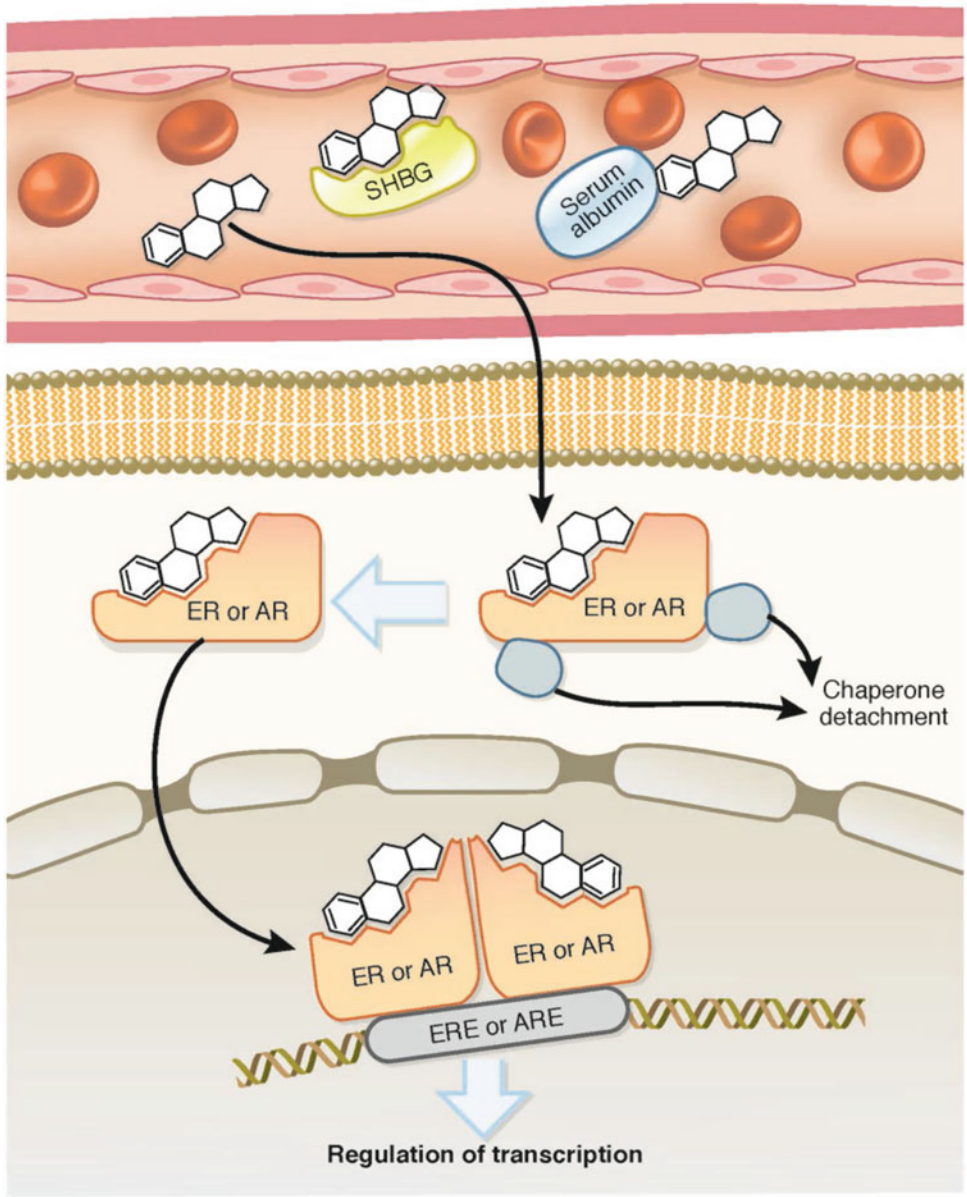

Fig. 31 The uptake mechanisms and interactions of SHR radioligands in cells

mechanisms of action (as illustrated in Fig. 33) [124]. Recently, [^{18}F]FES has been evaluated in small patient populations with various gynecologic cancers including endometrial adenocarcinoma and uterine sarcoma and compared to histopathological findings. These data suggest that [^{18}F]FES PET shows some promise for the evaluation of disease severity and the differentiation of malignant lesions from benign growths like leiomyoma [125].

The use of [^{18}F]FDHT in prostate cancer is, in principle, analogous to that of [^{18}F]FES in breast cancer. Indeed, an estimated 80–90% of newly diagnosed prostate cancers are androgen dependent and thus are likely to benefit from endocrine therapy through AR blockade or androgen depletion [126]. However, [^{18}F]FDHT PET does not exhibit similar predictive value for the success of endocrine therapy because of the relatively high

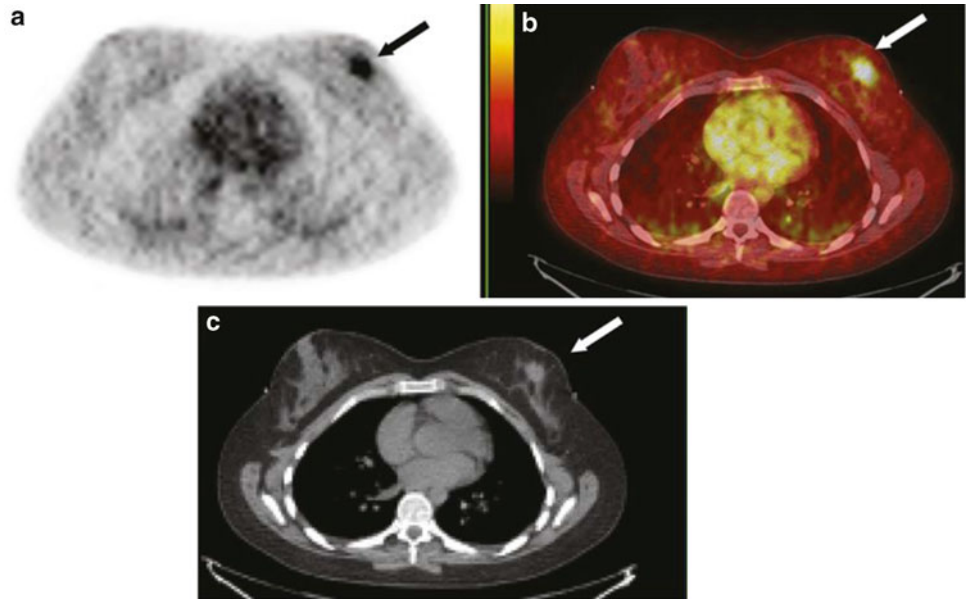

Fig. 32 Axial [^{18}F]FES image in ER-positive breast cancer showing intense uptake (*arrow*) in the left breast lesion (**a**), corresponding to a 2.3-cm lesion seen on CT (**c**) and confirmed by [^{18}F]FES PET/CT overlay (**b**) (This research was published in *The Journal of Nuclear Medicine*, Gemignani et al. [122]. © by the Society of Nuclear Medicine and Molecular Imaging, Inc.)

prevalence of "androgen withdrawal syndrome," whereby clinical improvement is seen after the discontinuation of endocrine therapy as a result of ligand-independent activation of AR [127]. Understandably, the downstream effects of ligand-independent activation and genomic silencing of AR go undetected in molecular imaging studies with [^{18}F]FDHT. Nevertheless, [^{18}F]FDHT has proven to be a powerful tool for imaging AR status in metastatic, progressive, and advanced prostate cancers. The initial patient studies by the groups at Memorial Sloan Kettering Cancer Center [128] and Washington University in St. Louis [129] focused on lesion-by-lesion comparisons of [^{18}F]FDHT and [^{18}F]FDG uptake, as shown in representative images in Fig. 34. In both studies, [^{18}F]FDHT PET allowed for the detection of 79–89% of [^{18}F]FDG-positive lesions, and the tumor uptake of the tracer was established to be AR-mediated. The studies of Vargas et al. [130] established a significant association between the number of bone lesions detected by different imaging modalities including [^{18}F]FDHT PET with overall survival in patients with castration-resistant prostate cancer. Furthermore, the negative correlation of the intensity of [^{18}F]FDHT accumulation in bone metastases with patient survival supports the prognostic value of the tracer in prostate cancer patients undergoing AR blocking therapies.

Targeting the Hypoxic Tumor Microenvironment

Overview

Cancer cells release growth factors such as vascular endothelial growth factor to stimulate angiogenesis from neighboring vasculature. However, these new blood vessels are often poorly formed and inefficient at facilitating the transport of nutrients and oxygen. Within the tumor microenvironment, high rates of cellular proliferation and metabolism combine with this poorly defined vasculature to create local regions of hypoxia [131]. Tumor hypoxia is often indicative of aggressive and metastatic malignant phenotypes and frequent portend

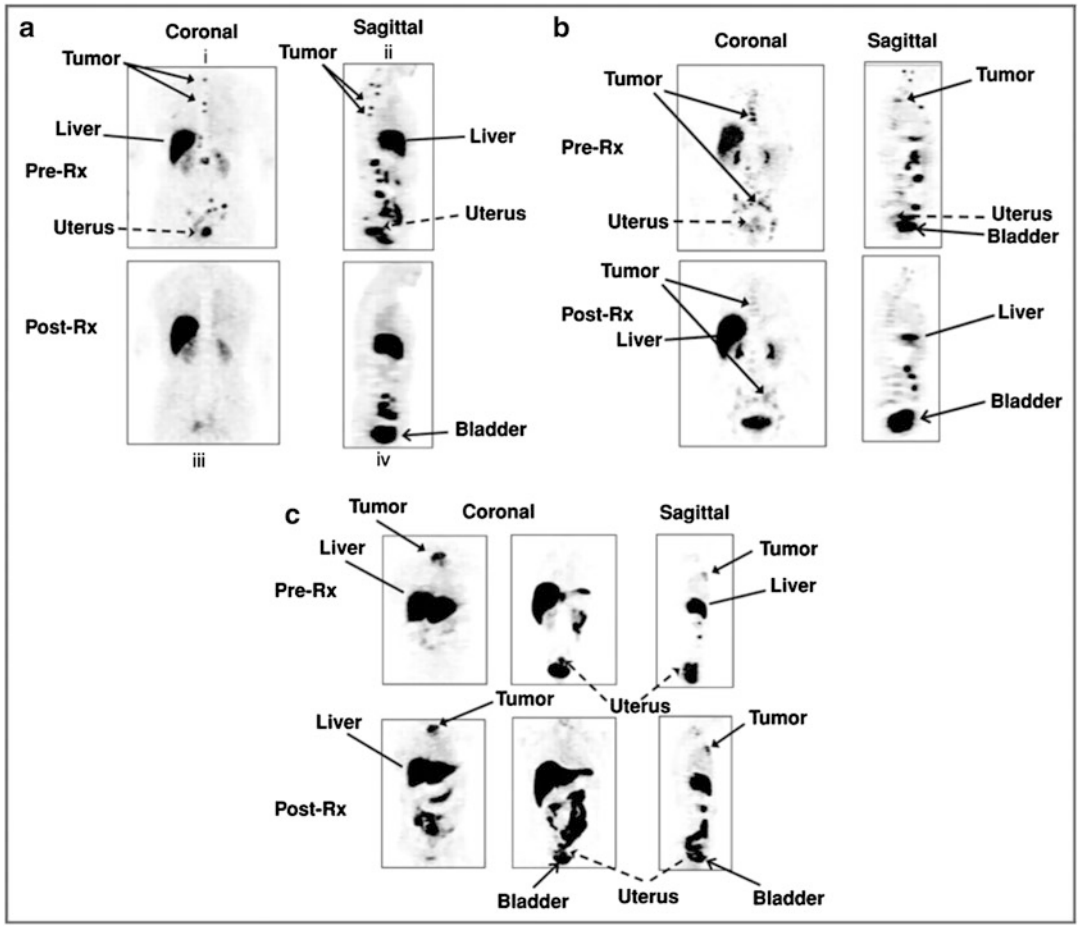

Fig. 33 Pre- and posttreatment [^{18}F]FES PET images in representative patients treated with ER-blocking and estrogen-lowering therapies. Top coronal (i) and sagittal (ii) views pretreatment and bottom panels show the same patient following treatment with coronal (iii) and sagittal (iv) views. Tumor in the upper spine shows baseline uptake and complete ER blockade in the tumor and uterus following 21 days of tamoxifen (**a**). Tumor in mediastinal nodes shows baseline uptake and incomplete ER blockade in tumor and uterus following 68 days of fulvestrant (**b**). Sternal tumor shows ER uptake and no blockade in the tumor and uterus following 29 days of letrozole (**c**) (Reprinted from Linden et al. [124]. © the American Association for Cancer Research)

complications during disease management. As a result, it follows that the ability to noninvasively delineate hypoxic from normoxic tumors could benefit clinicians during staging, prognosis, treatment planning, and treatment monitoring. The presence of tumor hypoxia is often associated with increased resistance to radiation therapy as well, as much of the damage done by radiation is mediated by reactive oxygen species. Therefore, the identification and mapping of hypoxia are also important for planning optimal radiation therapy treatment regimes.

Imaging Tumor Hypoxia with [^{18}F]FMISO

Any imaging agent that is intended to target poorly vascularized tissue must be transported through cellular membranes, thereby allowing it to diffuse through tissue independently of the circulatory system. One of the most widely utilized hypoxia-targeting imaging agents is [^{18}F]FMISO – ([^{18}F]-fluoromisonidazole, 1-fluoro-3-(2-nitroimidazol-1-yl)-propan-2-ol) (Fig. 35) – which was designed to have a partition coefficient

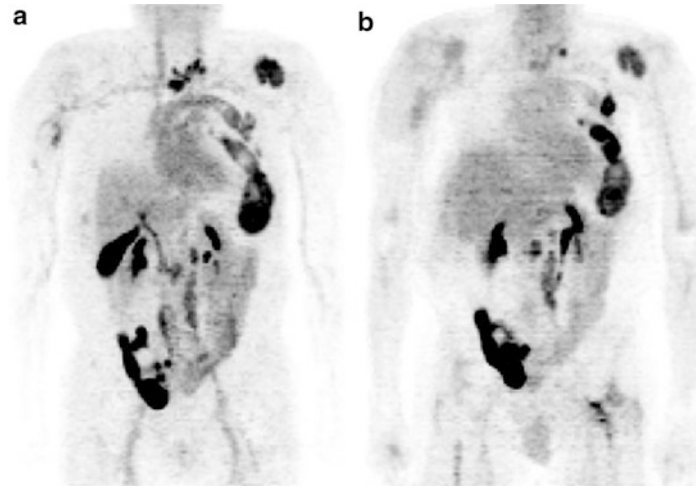

Fig. 34 Maximum intensity projections of [^{18}F]FDHT (**a**) and [^{18}F]FDG (**b**) PET images of a patient with prostate cancer. A greater number of extraprostatic lesions are detected by [^{18}F]FDHT compared to [^{18}F]FDG (This research was published in *The Journal of Nuclear Medicine*, Larson et al. [128]. © by the Society of Nuclear Medicine and Molecular Imaging, Inc.)

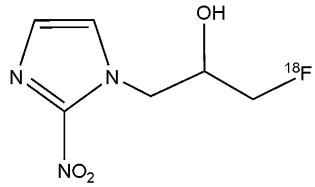

Fig. 35 The structure of [^{18}F]FMISO

of 0.4. This allows the radiotracer to strike a delicate balance: *lipophilic* enough to reach hypoxic tissue but *hydrophilic* enough to be cleared quickly from the blood [132]. The key to [^{18}F]FMISO's selectivity for hypoxic tissue is the redox chemistry of its nitro group. The mechanisms of [^{18}F]FMISO escaping in normoxic and trapping in hypoxic tissues are shown in Fig. 36.

[^{18}F]FMISO accumulation has been shown to be indicative of hypoxia in gliomas, breast, head and neck, lung, and renal tumors [133]. Figure 37 shows a representative [^{18}F]FMISO scan in a patient with a glioma. [^{18}F]FMISO PET has been used to differentiate levels of uptake between grades of glioblastomas, in which low-grade gliomas (grades I and II) were found to have no increased uptake of [^{18}F]FMISO, while all high-grade gliomas studied (grades III and IV) demonstrated increased [^{18}F]FMISO uptake [134] (Fig. 38). Another study showed that images generated through [^{18}F]FMISO PET can help guide the precision targeting of hypoxic regions by intensity-modulated radiation therapy (IMRT), which resulted in an estimated 17% increase in tumor control probability (TCP) [135]. In addition, high uptake of [^{18}F]FMISO in non-small cell lung carcinomas was predictive of increased rates of tumor recurrence following radiation therapy in 90% of patients [136]. Thus, [^{18}F]FMISO has been shown to be useful in determining glioma lesion grades, directing radiation therapy, and predicting subsequent tumor response. Unfortunately, however, [^{18}F]FMISO displays comparatively low contrast between hypoxic tissue and background tissues, which likely results from slow clearance from normoxic tissue. Alternative nitroimidazole-based agents are under investigation to mitigate the limitations of [^{18}F]FMISO.

Imaging Tumor Hypoxia with ^{64}Cu-ATSM

Discussions centered upon the imaging of tumor hypoxia must invariably include ^{64}Cu-ATSM [^{64}Cu-diacetyl-bis(N_4-methylsemicarbazone)] as well (Fig. 39). This tracer – initially developed for the diagnosis of cardiac ischemia – was applied to the imaging of cancer as an alternative to [^{18}F]FMISO. Cu-ATSM is a planar tetradentate metal complex in which a central copper atom is coordinated by two nitrogen and two sulfur atoms. The ATSM ligand has been used to chelate a number of the positron-emitting isotopes of copper, including ^{60}Cu ($t_{1/2}$ = 23.7 min), ^{61}Cu ($t_{1/2}$ = 3.3 h), ^{62}Cu ($t_{1/2}$ = 9.7 min), and ^{64}Cu

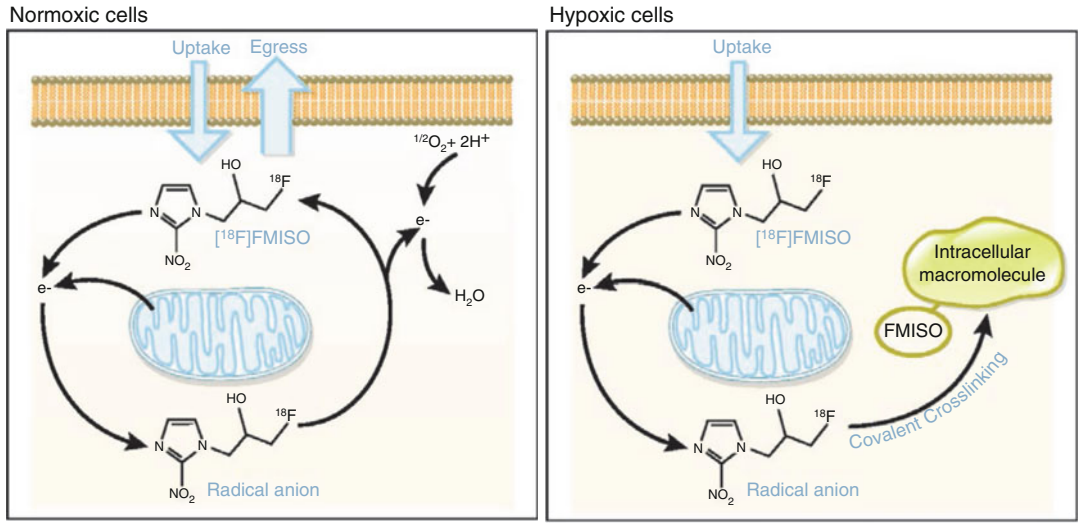

Fig. 36 The mechanism of the uptake and retention of [^{18}F]FMISO. In both hypoxic and normoxic cellular environments, the nitro group of [^{18}F]FMISO picks up electrons released from the electron transport chain, generating a radical anion. Under normoxic conditions, oxygen is able to reduce the nitro group, allowing for the subsequent egress of [^{18}F]FMISO from the cell. Under hypoxic conditions, there is far less O_2 to serve as an oxidizing agent. This permits the radicalized [^{18}F]FMISO to undergo covalent cross-linking with nearby macromolecules, effectively trapping it within the cell

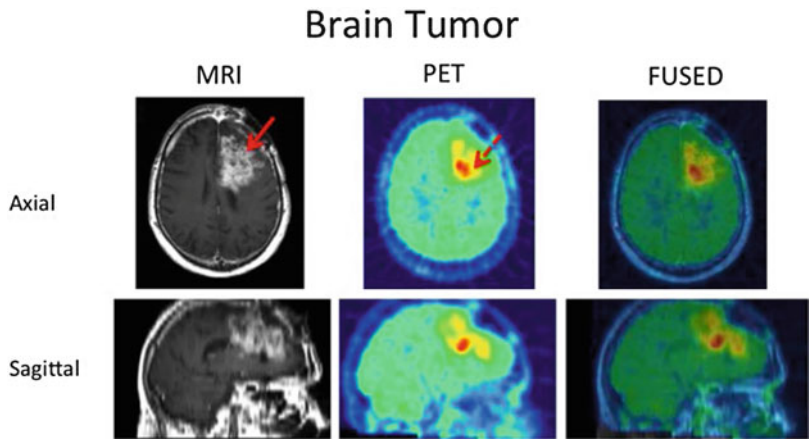

Fig. 37 A glioblastoma in the right superior frontal lobe as imaged by MRI (*left*), [^{18}F]FMISO PET (*middle*), and a PET/MRI overlay (*right*). The fused image shows the areas of highest [^{18}F]FMISO uptake, correlating to localized regions of hypoxia within the tumor mass (Reprinted from Rajendran and Krohn [150], with permission from Elsevier)

($t_{1/2}$ = 12.7 h). Of these, the physical half-life of ^{64}Cu has been shown to best match the biological half-life of the compound and, interestingly, may even produce images with higher tumor-to-background activity concentration ratios than other isotopes of copper [137]. There is some controversy regarding the exact mechanism by which Cu-ATSM is retained in hypoxic cells. Currently, the accepted mechanism of Cu-ATSM retention involves the reduction of Cu(II)-ATSM to Cu(I)-ATSM by reductases present in both hypoxic and normoxic cells (Fig. 40). This reduction causes a conformational shift from Cu(II)-ATSM's initial planar conformation to a less-stable geometry. Under normoxic cellular conditions, molecular oxygen can reoxidize the copper center, thereby restoring the complex to its more stable planar geometry and allowing the compound to diffuse

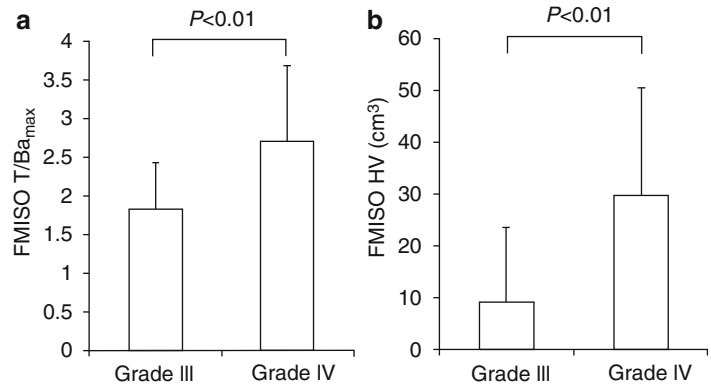

Fig. 38 There is a significant difference ($P < 0.01$) between the T/Bamax of [^{18}F]FMISO (**a**) and the hypoxic volume (HV) of Grade III and Grade IV gliomas (Reproduced with permission from Springer from Kawai et al. [151])

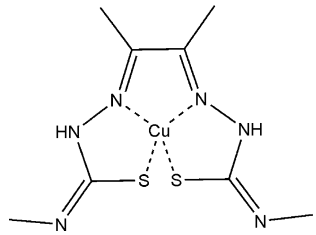

Fig. 39 The structure of ^{64}Cu-ATSM

freely out of the cell. Importantly, however, this reoxidation step does not occur in hypoxic cells. Instead, in these cells, the Cu(I)-ATSM complex is subjected to an acid-catalyzed dissociation reaction, leading to the formation of H_2ATSM and free Cu(I). The Cu(I) can then become irreversibly trapped within the cell by thiol-bearing proteins. This mechanism has been supported by a range of experimental evidence [138–143].

Cu-ATSM has seen clinical applications as a prognostic indicator in head and neck cancer, non-small cell lung cancer, rectal carcinoma, and cervical cancer. As with [^{18}F]FMISO, Cu-ATSM can be utilized to visualize and evaluate the extent of tumor hypoxia (Fig. 41), to direct the application and intensity of IMRT [144], and to determine patient prognosis. ^{64}Cu-ATSM has also shown limited promise as a therapeutic agent in a hamster model of colon cancer, in which ^{64}Cu-ATSM treatment increased survival by six times over control animals [145].

Despite the utility of Cu-ATSM in some cancer models, there is variability in its hypoxia-dependent uptake between different cell lines, which could be due in part to the complexity – and particularly the pH dependence – of its intracellular trapping mechanism. As with [^{18}F]FMISO, a series of Cu-ATSM derivatives have been developed in hopes of improving the hypoxia-selective uptake and tumor retention [143].

Concluding Remarks

In the preceding pages, we have covered a number of extremely promising imaging agents that stand on the cusp of regulatory approval and routine clinical use. The diversity of these radiopharmaceuticals reflects the wide array of information that clinicians seek as they make patient care and treatment decisions. The case studies we have discussed have included small molecules and antibodies, short-lived radiohalogens and long-lived radiometals, and targets ranging from cell surface antigens to tumor hypoxia. Yet despite the potential of these radiopharmaceuticals, the final obstacle (regulatory approval) is often the biggest hurdle of all. In the United States, this has been particularly true – and frustrating – in the case of ^{68}Ga-DOTATOC. In light of this, we are eager to take this opportunity to underscore the paramount importance of the standardization of procedures across clinical trials and institutions, as this is absolutely essential to developing the substantial body of evidence required for regulatory approval. Hopefully, such measures will streamline the path of these imaging agents from the

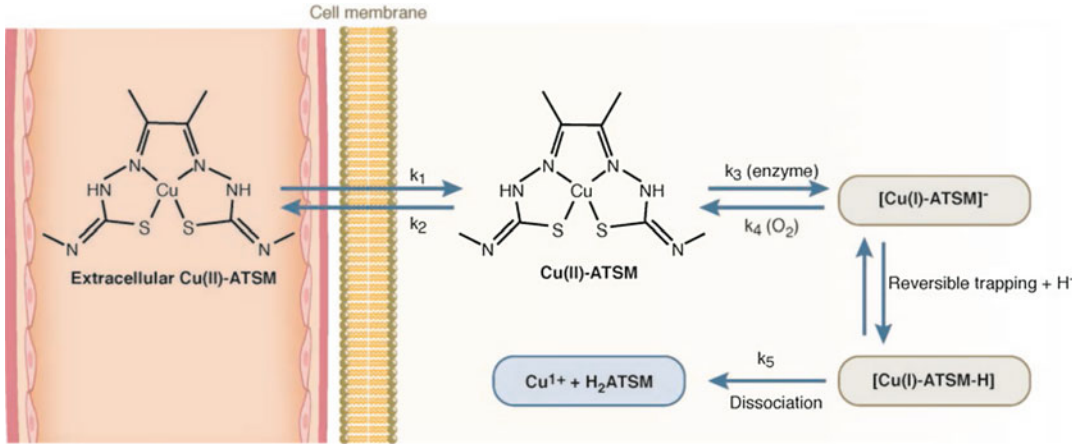

Fig. 40 A schematic depicting the uptake and retention mechanisms of Cu-ATSM. Under anoxic conditions, oxidation by molecular O_2 (k_4) cannot occur, therefore promoting the irreversible trapping of Cu(I) within the cell

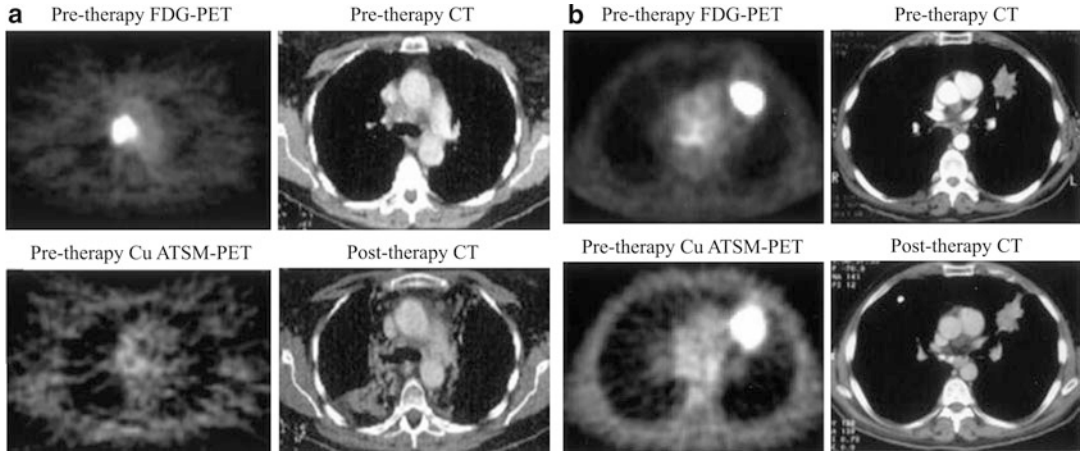

Fig. 41 ^{60}Cu-ATSM uptake can be an indicator of patient response to radiation therapy, as demonstrated here in two lung cancer patients. The responding patient (**a**) exhibited only a minimal increase in uptake of ^{60}Cu-ATSM (T/M = 1.3) and exhibited negligible growth after treatment. In contrast, the non-responding patient (**b**) had a significantly increased uptake (T/M = 3.0), and the tumor size increased over the 3 months following treatment (Reproduced with permission from Springer from Dehdashti et al. [144])

laboratory to the clinic and thus expedite the positive impact that they will undoubtedly have on patient care.

Novel Radiopharmaceuticals for Therapy

8

Federica Guidoccio, Sara Mazzarri, Federica Orsini, Paola Anna Erba, and Giuliano Mariani

Abstract

In the era of personalized medicine, "target radionuclide therapy" (TRT) is designed to damage only the cancerous cells while sparing unnecessary damage to the adjacent healthy cells/tissues. Unlike conventional external beam radiation therapy, TRT is intended to cause less or no collateral damage to normal tissues, as it aims at achieving targeted drug delivery either to a clinically diagnosed cancer not amenable to surgery or to metastatic tumor cells and tumor cell clusters, thus providing systemic therapy of cancer. Currently there are hundreds of new pathway-targeted anticancer agents undergoing phase II and phase III clinical trials. TRT is just one type within the domain of "targeted therapies." In addition to the effective targeted radiopharmaceuticals already well validated for routine clinical use, newer radiolabeled agents are still in the phase of either preclinical or clinical validation.

This chapter describes the main physical and radiochemical characteristics of radionuclides that have potential or have already been employed to label biologically reactive molecules for the development of novel radiopharmaceuticals for therapy. Some of these agents have entered advanced clinical trials in tumor-bearing patients. Results of these clinical trials cover a wide spectrum of potential clinical usefulness.

The chapter is divided into two main parts depending on the type of particle emission (α- or β-associated or not with the emission of either γ- or β^+-radiation). Within each domain, there is some exchange of experience and shift of focus in the various phases of development, depending on the modalities of ascertaining efficient tumor targeting according to the principles of theranostics. The example of a novel α-emitting radiopharmaceutical that has most recently achieved approval by regulatory agencies for clinical use (^{223}Ra-dichloride) is presented in detail as the paradigm for an agent that is showing a survival advantage besides the original target of pain palliation from bone metastases.

Introduction

Targeted radionuclide therapy (TRT), is based on the use of high-affinity molecules as carriers of radionuclides to tumor cells (see also ▶ Chap. 2, "Principles of Molecular Targeting for Radionuclide Therapy" of this book). After intravenous administration these radiopharmaceuticals are distributed to tissues, so that they can reach their target molecule on the surface of tumor cells.

In clinical practice, TRT is often administered for the treatment of the most radiosensitive tumors, such as leukemias and lymphomas. Whereas solid tumors are usually more radioresistant, therefore greater ionizing radiation doses are needed for therapy. Because of the combination of a short path length in tissues (50–80 μm) with a high linear energy transfer (100 keV μm^{-1}), targeted α-particle therapy offers the potential for more specific tumor cell killing with less damage to surrounding normal tissue than therapy with β-particle emitters. These favorable physical properties, for which a routine clinical application has already been developed with the novel radiopharmaceutical ^{223}Ra-chloride for therapy of bone metastatic disease, offer the real possibility of targeted (or pre-targeted) α-therapy suitable for clearing minimal residual or micrometastatic disease.

Alpha-Emitting Agents

One of the most intensely explored options for local and/or systemic cancer treatment is TRT based on α-particle emission. Nevertheless, with the noticeable exception mentioned above for ^{223}Ra-chloride, most of the studies have so far not progressed beyond the phases of in vitro experiments with tumor cells or experimental tumor models in animals. Preclinical studies and clinical trials have shown that alpha-emitting radionuclides are able to kill cancer cells while sparing the normal tissues with an ensuing clear reduction of toxicity. The α-emitting radionuclides that are medically relevant and available for potential clinical use at this time are ^{211}At, ^{213}Bi, ^{225}Ac, ^{223}Ra, and ^{212}Pb/^{212}Bi (although a pure β-particle emitter, ^{212}Pb decays to ground state after emission of α-particles through the intermediate daughter radionuclide ^{212}Bi). Table 1 summarizes the main physical characteristic for the radionuclides of interest for targeted alpha therapy in nuclear oncology and their method of production.

The first alpha-emitting radiopharmaceutical that has obtained registration in the USA for treatment of bone metastases from prostate cancer is $^{223}RaCl_2$ (Xofigo®), as described in detail further below in this chapter.

The alpha-emitting radioisotopes ^{211}At, ^{213}Bi, ^{225}Ac, and ^{227}Th are being used to label targeting vectors such as monoclonal antibodies for specific cancer therapy indications. In this review, safety and tolerance issues are considered with respect to microdosimetry, specific energy, Monte Carlo model calculations, biodosimetry, equivalent dose, and mutagenesis. When radiolabeled antibodies against the VEGF receptors are used, the clinical efficacy of targeted alpha therapy (TAT) may be enhanced also by their anti-neoangiogenesis effects, especially in the case of solid tumors. This review emphasizes key aspects of TAT investigations with respect to the PAI2-uPAR complex and the monoclonal antibodies (mAbs) bevacizumab, C595, and J591. Clinical trial outcomes are reviewed for neuroendocrine tumors, leukemia, glioma, melanoma, non-Hodgkin's lymphoma, and bone metastases from prostate cancer.

Table 1 Main characteristics of radionuclides already used or with potential for use in alpha-targeted therapy that are discussed in this chapter (arranged according to rising mass element number)

Radionuclide	$T_{½}$, hr	E_{max}, MeV[a]	Production
^{211}At	7.21	α, 5.9 (42)	Cyclotron
^{213}Bi	0.7	α, 5.8 (97%); β, 1.4 (100%); α/β[b], 0.02	Generator ^{229}T→^{225}Ac→^{213}Bi
^{223}Ra	273.6	α, 5.7 (100%)	Cyclotron
^{225}Ac	240.2	α, 5.7 (100%)	Generator ^{229}T→^{225}Ac
^{227}Th	448.8	α, 6.0 (48%)	Generator ^{227}A→^{227}Th

[a]Percentage of quanta with the indicated energy value in the total amount of quanta of this type emitted by a given radionuclide
[b]Ratio of the amount of quanta of different emission types

Radium-223 (^{223}Ra) is commercially available for therapy of patients with metastatic castration-resistant prostate cancer (mCRPC). Radium-223 has a half-life of 11.4 days and releases 94% of its energy as α-particles with very little γ-emission. It is produced from the ^{227}Ac/^{227}Th system and purified using actinium-resin to immobilize ^{227}Ac and ^{227Th} [1]. α-emission has certain advantages over β-emission, in particular lower bone marrow toxicity due to its narrow range in tissues. Similar to cationic strontium, the radium-223 ion is a calcium analog and therefore constitutes a natural bone seeker as it complexes with hydroxyapatite crystals in osteoblastic bone metastases, inducing non-repairable DNA strand breaks in cells.

The convenient biologic characteristics for alpha-emitters have fueled investigations on the use of radium-223 (administered as the dichloride salt) in preclinical models. In particular, an early study has reported a significant antitumor effect of radium-233 on experimental skeletal metastases [2]. The model used for bone metastases was based on laboratory studies where the human cancer cells were injected intravenously into athymic nude rats. The authors used MTA-1 cells which are an estrogen and progesterone receptor-negative human breast cancer cell line. This model results in bone and bone marrow metastases as well as in the growth of tumor lesions in the spinal cord and in soft tissues. Biodistribution studies in this model identified selective uptake of radium in bone when compared to soft tissue. Over the course of time, the relative content of radium-223 in non-bone metastatic sites (including the liver, spleen, and kidney) increased relative to content in the femur. All tumor-bearing control animals (receiving no therapy) were sacrificed between 20 and 30 days, following the onset of secondary to paralysis caused by spinal infiltration of tumor. In contrast, mice receiving radium-223 developed symptoms significantly later, and many of them (7 out of 19, or 37%) were alive beyond 67 days. Furthermore, examination of sacrificed animals showed no significant changes of the bone marrow after radium-223. In a separate report, Henriksen et al. [3] directly compared the biodistribution of radium-223 with that of strontium-89 in murine xenograft models. Both compounds were found to accumulate in a higher concentration at bony surfaces as compared to soft tissues. Conversely, distribution at soft tissue sites was limited with both compounds. Supporting the notion that beta-emitters may be more myelotoxic than alpha-emitters, radium-223 was found to cause less damage to normal marrow when compared with strontium-89 based on an equal dose-deposition basis.

Phase I Assessment

Results of the first clinical trial with radium-223 dichloride were reported by Nilsson et al. with reference to a phase I study in which 25 patients were enrolled, including 15 with prostate cancer and 10 with breast cancer [4]. Five dose levels of the compound were explored: 46, 93, 163, 213, and 250 kBq kg^{-1}. At each dose level, five patients received a single dose of the agent with evaluation of pain response at weeks 1, 4, and 8. Fifty to sixty percent of patients experienced

improvement in bone pain at each time point. A median overall survival of approximately 20 months was noted, and declines in alkaline phosphatase (ALP) levels were noted in 29% and 52% of breast and prostate cancer patients, respectively. Toxicities were generally mild, even at the highest dose levels explored. The incidence of grade 3 neutropenia was only 12%. In particular, imaging studies (based on the X-ray and gamma emission associated with decay of ^{223}Ra) indicated that the majority of radium-223 accumulated in metastatic bone lesions.

A second phase I study reported by Carrasquillo et al. [5] evaluated a total of ten patients with mCRPC. A different array of dose levels of radium-223 than with the aforementioned experience was explored (50, 100, and 200 kBq kg^{-1}). All patients received a single dose of the agent, while six patients (60%) received a second dose of 50 kBq kg^{-1}. In this small cohort of patients, no dose-limiting toxicities were observed. Radium-223 was rapidly cleared from the circulation, with pharmacokinetic studies suggesting that only 0.5% of the drug remained in the circulating blood 24 h after administration. Most of the excretion occurred through the fecal route, as 52% of administered radium-223 was detected in the gastrointestinal tract at 24 h. As in the previously mentioned phase I experience, most of the observed toxicities were hematologic, with 60%, 70%, and 30% of patients developing any grade anemia, leukopenia, and thrombocytopenia, respectively. Besides grade 3–4 leukopenia observed in three patients (30%), grade 3–4 toxicities were limited.

Phase II Assessment

Three phase II studies have further assessed the activity of radium-223 in the setting of mCRPC. These studies differ slightly regarding eligibility and treatment schedule. The first study followed a randomized placebo controlled design and included 64 patients with mCRPC and either one painful bony lesion or multiple bony metastatic sites [6]. All patients received external beam radiation therapy (EBRT) to a metastatic site and then were randomized to receive four concurrent treatment cycles with radium-223 or saline. Two primary endpoints were evaluated in this study: (1) change in bone ALP levels and (2) time to first skeletal-related event (SRE). The study met the first of these two primary endpoints, with a more significant decline in bone ALP levels with radium-223 (−65.6% vs. +9.3%, $P < 0.0001$). Furthermore, there was a substantial (albeit at borderline of statistical significance) difference in time to first skeletal-related events (SRE, $P = 0.065$). Notably, a follow-up report from this trial suggests a survival advantage with radium-223 (65 vs. 46 weeks, $P = 0.056$), consistent with the subsequently noted phase III experience [7]. A separate phase II study assessed a total of 100 patients with mCRPC and painful bony metastases [8]. In contrast to the previous study design, patients did not receive concomitant external beam radiation therapy (EBRT) and were randomized to receive a single dose of radium-223 at one of four dose levels (5, 25, 50, or 100 kBq kg^{-1}). The primary endpoint of the study was to characterize pain responses using two primary indices: (1) the visual analog scale (VAS) for pain and (2) the use of analgesics for pain control. The study met its primary endpoint, with an increased pain response at higher dose levels of radium-223 observed as early as week 2 ($P = 0.035$). At week 8, the proportions of individuals with a decrease in pain and stable analgesic use (at increasing dose levels) were 40%, 63%, 56%, and 71%, respectively ($P = 0.040$). As with the prior phase II experience, changes in markers of bone turnover were correlated with increasing dose levels, a significant reduction being observed in patients treated with 100 kBq kg^{-1}.

The third and largest randomized phase II trial assessed 122 patients with mCRPC who had failed all available therapeutic modalities [9]. While the previous two studies were designed to evaluate palliative endpoints (time to SRE, pain response, etc.), this study was powered to evaluate the proportion of individuals who achieved a prostate-specific antigen (PSA) decline of $\geq$50%. Patients were randomized in a double-blind fashion to receive a total of three 6-weekly doses of

radium-223 at 25, 50, or 80 kBq kg^{-1}. There was a dose-response relationship, with 0%, 6%, and 13% of the patients achieving ≥50% PSA decline in the respective cohorts ($P = 0.0297$). Greater declines in ALP values were also seen at higher dose levels, with a ≥50% decline in just 16% of patients treated at 25 kBq kg^{-1}, as compared with 66% and 67% of patients treated at 50 and 80 kBq kg^{-1}, respectively.

Phase III Assessment

Radium-223 dichloride is the first radiopharmaceutical to demonstrate a clear survival benefit, as reported by Parker and colleagues in an international phase III randomized trial (ALSYMPCA) [9]. A total of 922 patients with mCRPC received six injections of ^{223}Ra (50 kBq kg^{-1}, every 4 weeks) or placebo. Eligibility criteria included symptomatic patients with progressive mCRPC with two or more bone metastases, no known visceral metastases, and castrate serum testosterone <1.7 nMol/L. In both groups, 57% of patients had received docetaxel, while the remainders did not (either because they were not good candidates for such chemotherapy or because docetaxel was not available).

Planned interim analysis found an improved median survival in the ^{223}Ra group [14.9 vs. 11.3 months, hazard ratio (HR) for survival = 0.7; 95% CI 0.55–0.88, two-sided $P = 0.002$]. This study also demonstrated increased time to SREs (15.6 vs. 9.8 months, HR = 0.66; 95% CI 0.52–0.83, $P < 0.001$) and improved quality of life in the ^{223}Ra-dichloride group [9, 10]. Radium-223 dichloride and placebo shared similar rates of all adverse events (93% vs. 96%, respectively), adverse events of grade 3 or higher (56% vs. 62%) and serious adverse events (47% vs. 60%). Only 16% of the patients enrolled discontinued treatment due to adverse events in the ^{223}Ra arm compared with 21% in the placebo arm. Given the improvement in survival, excellent tolerance and ease of use, ^{223}Ra-dichloride is likely to become the radiopharmaceutical of choice for treating patients with mCRPC and predominant skeletal metastasis. In this regard, it should be noted that other bone-seeking radiopharmaceuticals had been approved by regulatory agencies (FDA in the USA, EMA in Europe) for "palliation of bone pain" from skeletal metastases. Whereas based on the results described above regarding the impact of ^{223}Ra-dichloride on overall survival, this agent has been approved for "therapy" of mCRPC – a notion that has been recognized and embedded in the most recent international guidelines on treatment of mCRPC [11, 12].

Astatine-211 (^{211}At) is a cyclotron-produced α-particle emitter that has a 7.2-h half-life [13]. It offers many potential advantages for α-particle therapy; however, its use for this aim is constrained by its limited availability.

This radionuclide is an attractive option for TAT, such as quantitative α-particle emission with each ^{211}At decay, no long-lived α-particle-emitting daughter products, a half-life well suited for use with a diversity of chemistry applications, and possibility for conjugation with a variety of carrier molecules capable of efficient tumor targeting in vivo. Astatine-211 can be produced in reasonable yield from natural bismuth targets via the ^{209}Bi(α,2n)^{211}At nuclear reaction utilizing straightforward methods. There is some debate as to the best incident α-particle energy for maximizing ^{211}At production while minimizing production of ^{210}At; the latter occurrence is in fact problematic because of its 138.4-day half-life α-particle-emitting daughter, ^{210}Po. The intrinsic cost for producing ^{211}At is reasonably modest and comparable to that of commercially available ^{123}I. The major limitation to ^{211}At availability is the need for a medium energy α-particle beam for its production. On the other hand, there are about 30 cyclotrons in the world that have the beam characteristics required for ^{211}At production [14]. Considering its half-life of only 7.2 h, the current scarcity of ^{211}At production sites limits the ability to ship it to distant sites for therapeutic applications.

Despite this drawback, there are many potential advantages of ^{211}At as a therapeutic α-particle emitter, including cost, satisfactory experience regarding radiochemistry of conjugation, and evidence derived from proof-of-concept clinical

trials. In addition, the decay of ^{211}At also results in the emission of a 77- to 92-keV polonium X-ray, which enables noninvasive imaging of real-time biodistribution with either planar or SPECT scintigraphy [11]. It is conceivable that the current supply bottleneck will be overcome as more clinical evidence provides further proof-of-concept for the use of ^{211}At.

In 1989, labeling of a monoclonal antibody (mAb) with ^{211}At using *N*-succinimidyl 3-(trimethylstannyl) benzoate as a synthon was reported [15]. Studies with an internalizing mAb labeled with ^{211}At using *N*-succinimidyl 5-[^{211}At] astato-3-pyridinecarboxylate ([^{211}At]SAPC) as a synthon showed that astatine-211 was intracellularly retained after internalization [16]. Additional preclinical studies have recently shown that combined treatment with ^{211}At-labeled anti-CD45 combined with bone marrow transplantation prolonged survival in a murine model of disseminated acute myeloid leukemia [17]. Biodistribution studies showed excellent localization of the ^{211}At-anti-murine CD45 mAb 30F11 to the bone marrow and spleen within 24 h. In syngeneic hematopoietic stem cell transplantation studies, radioimmunotherapy (RIT) with a ^{211}At-conjugate improved the median survival of leukemic mice in a dose-dependent fashion, with minimal toxicity.

Feasibility of ^{211}At-RIT was reported in two clinical trials. The first study assessed ^{211}At-RIT with an anti-tenascin mAb followed by chemotherapy in patients with glioblastoma [18]; the radioimmunoconjugate was injected into the resection cavity and the maximal injected activity was 347 MBq (9.4 mCi). Six patients out of 18 had reversible grade 2 neurotoxicity, but no grade 3–4 toxicities were observed. Maximal tolerated activity was not reached and the observed median survival favorably compared with that of historical control groups. In the second phase I study, ^{211}At-MX35-F(ab′)$_2$ was assessed in women in complete response (CR) after a second-line chemotherapy for recurrent ovarian carcinoma; MX35 is a mAb against the sodium-dependent phosphate transport protein 2b (NaPi2b) [19]. The aim was to determine dosimetry and toxicity. MX35-F(ab′)$_2$ was labeled with ^{211}At using *N*-succinimidyl-3-(trimethylstannyl)-benzoate. Nine patients underwent laparoscopy 2–5 days before ^{211}At-RIT. Before intraperitoneal infusion of ^{211}At-MX35-F(ab′)$_2$, the abdominal cavity was inspected to exclude the presence of macroscopic tumor growth or major adhesions. The radioimmunoconjugate was infused at the activity concentration of 22.4–101 MBq/L in the peritoneal dialysis solution via a transcutaneous catheter. The estimated absorbed dose to the peritoneum was 15.6 ± 1.0 mGy per MBq/L, to the red bone marrow 0.14 ± 0.04 mGy per MBq/L, and to the unblocked thyroid 24.7 ± 11.1 mGy per MBq/L (decreasing to 1.4 ± 1.6 mGy per MBq/L when the thyroid was blocked). No adverse effects were reported. This study indicates that intraperitoneal ^{211}At-RIT delivers therapeutic absorbed doses in microscopic tumor clusters, without significant associated toxicity.

Actinium-225 (^{225}Ac) is a particularly attractive radionuclide for therapy, since each decay is associated with the emission of four α-particles; this feature holds high promise for a very potent radiobiological effect – assuming that this radionuclide is conjugated with a selective and efficient tumor-targeting carrier. Actinium-225 has a half-life of 10 days and is produced as a decay product of uranium [20, 21]. In addition to α-particle emission, ^{225}Ac decay also results in the emission of a 440-keV gamma ray that can be used for imaging after administration of a therapeutic agent. The relatively long half-life of ^{225}Ac allows its shipment to potential users from a centralized production or purification site. In the USA, the Oak Ridge National Laboratory currently purifies ^{225}Ac for commercial use from uranium stockpiles. The limiting factor for ^{225}Ac is its cost, which currently exceeds $1,000/mCi. Besides purification from a uranium source, small amounts of high purity ^{225}Ac can also be produced employing a standard proton-beam cyclotron, although using very long irradiation times (7–50 h) [22]. Thanks to the widely available radiochemistry based on macrocyclic bifunctional chelators, ^{225}Ac can be easily conjugated to antibodies and peptides without damaging the in vivo targeting properties of the antibody or peptide

[23, 24]. Nevertheless, in the process of ^{225}Ac conjugation to compounds of biological interest, there is an important radiochemical challenge; in particular, production of radiotoxic daughter products (such as ^{213}Bi) during decay of ^{225}Ac introduces in the system elements that have chemical properties different from those of ^{225}Ac – therefore dissociate from the targeting moiety. A solution to this problem can probably be found in a novel approach based on the so-called ^{225}Ac nanogenerator; in this approach the delivery system is designed to be internalized into the targeted tumor cell, where the toxic daughter elements may dissociate from the targeting molecule but will be trapped inside the cell, thus adding to the therapeutic effect of ^{225}Ac [21, 25]. Moreover, nanotechnology techniques have also been explored to induce intracellular retention of several daughter products during ^{225}Ac-based therapies [26, 27]. In particular, the retention of ^{225}Ac and its radioactive daughters in the targeted tumor cell after internalization, according to the concept of an "in vivo generator," was demonstrated using a mAb derivatized with DOTA [14, 28].

Clinical studies are ongoing in the USA with an ^{225}Ac-labeled anti-CD33 antibody in patients with acute myeloid leukemia. An ongoing phase I trial of alpha-RIT based on the ^{212}Pb/^{212}Bi generator concept uses instead an anti-HER2 mAb infused intraperitoneally in patients with peritoneal carcinomatosis from HER2-expressing tumors [29, 30]. Production of daughter radionuclides during ^{225}Ac decay complicates radiation dosimetry issues to nontarget organs, such as the kidneys, as an excretion route [31].

An interesting approach to the use of an ^{225}Ac-labeled ligand for TAT is based on the high selectivity of the prostate-specific membrane antigen (PSMA) and on the long tumor retention of ligands for PSMA. In particular, a ligand named PSMA-617 has been developed, characterized by optimized tumor cell internalization and reduced kidney excretion versus the PSMA-11 ligand used for PET imaging after labeling with ^{68}Ga. In addition, the PSMA-617 ligand contains DOTA as more universal chelator that makes radiolabeling of this compound with a variety of metal nuclides possible [32, 33]. Besides initial clinical trials with ^{177}Lu-PSMA-617 [34–36], the results of a pilot, proof-of-concept study for the therapeutic use of ^{225}Ac-PSMA-617. This treatment was offered as salvage therapy to two patients with mCRPC who had failed all lines of treatment and had widespread metastatic disease [37]. Therapy consisted in the administration of three cycles of 100 kBq/kg body weight ^{225}Ac-PSMA-617 at bimonthly intervals, followed in one of the two patients by further administration of 6 MBq 2 months later for consolidation. The results achieved following this regimen were impressive both from the imaging point of view (disappearance of virtually all tumor lesions visualized at PET imaging with ^{68}Ga-PSMA-11) and from the biochemical point of view (reduction of serum PSA to $<$0.1 ng/mL from the initial levels $>$3,000 ng/mL in one patient and about 300 ng/mL in the other patient, respectively). Clearly, this pilot experience will need to be confirmed by additional controlled clinical trials, but will most likely open new perspectives in the treatment of advanced mCRPC.

Thorium-227 (**^{227}Th**) is a radionulide that decays to ^{223}Ra, a long-lived radionuclide with proven good tolerance [38]. A recent preclinical study reported the contribution of mAb internalization in the therapeutic efficacy of intraperitoneal ^{212}Pb-RIT for small volume carcinomatosis, compared targeting of HER2 (internalizing) or CEA (non-internalizing) [39, 40]. An advantage was observed using internalizing anti-HER2 compared with non-internalizing anti-CEA ^{212}Pb-labeled antibodies.

Bismuth-213 (**^{213}Bi**) is a short-half-life (46 min) α-particle emitter that is generally supplied through an ^{225}Ac generator. The useful radionuclide production life of such a generator is about 10 days. The main drawbacks in the use of ^{213}Bi as a label for therapy agents are its very short half-life and a somewhat high cost linked to the use of ^{225}Ac, the starting material for the ^{213}Bi generator. Another technical problem with ^{213}Bi is the possible failure of the generator due to radiation damage, causing breakthrough of contaminant radionuclides such as ^{225}Ac [41]. ^{213}Bi is limited by time constraints for radiolabeling and administration into patients of the

tumor-targeting carrier molecule. Nevertheless, despite these limitations, a number of groups that have used ^{213}Bi-labeled agents have been investigated for feasibility studies both in preclinical and in clinical trials [42, 43]. The results of these studies suggest however the superior therapeutic efficacy of the ^{225}Ac-based nanogenerator described above over ^{213}Bi-labeled antibodies, due to its greater α-particle yield per decay; additional roles are played by the longer half-life of ^{225}Ac and its daughter products, which match the longer biologic half-life of large-molecular-weight antibodies [25]. On the other hand, conjugation of ^{213}Bi with biological tumor-targeting peptides might offer advantages because of the faster clearance of these compounds.

An early trial with a ^{213}Bi-labeled anti-CD33 humanized mAb administered to 18 patients with acute myeloid leukemia showed a reduction in circulating blasts in about 80% of the patients, without detectable extramedullary toxicity [44]. In another pilot clinical study, ^{213}Bi-DOTA-substance P was injected intratumorally via an implanted catheter in five patients with WHO grade II–IV gliomas; radiation-induced tumor necrosis was demonstrated after this form of therapy [45]. More recently, an anti-mouse CD138 mAb labeled with ^{213}Bi was employed for ^{213}Bi-RIT in a syngeneic multiple myeloma mouse model [46]; when administered 10 days after engraftment, this treatment significantly prolonged survival and caused only moderate and transient hematologic toxicity.

Lead-212 (^{212}Pb), one of the radionuclides generated during the decay of thorium-232, is currently being investigated to develop new antitumor treatments [47]. There is a definite potential for the clinical use of ^{212}Pb (10.6-h half-life). ^{212}Pb itself is not an α-emitter, but its physical decay results in the emission of two short-lived α-particles with potent therapeutic efficacy to cellular nuclei. ^{212}Pb decays to ^{212}Bi via β-emission. ^{212}Bi, with a 60-min half-life, has a split decay chain and emits an α-particle at 36% frequency with an average energy of 6.1 MeV; ^{212}Bi decays to ^{212}Po for the remaining 64% via β-emission. In turn, ^{212}Po decays to stable ^{208}Pb in microseconds by emission of an 8.8-MeV α-particle. Betas are of low energy and/or frequency such that they are not expected to contribute significantly to toxicity or efficacy. Cumulative energy from the γ-emissions is <12% of those from the α-particles, but the 238.6-keV γ-ray with a 43% yield can provide the basis for imaging with a gamma camera. In preclinical studies, ^{212}Pb has shown significant therapeutic efficacy in both in vitro and in vivo model systems [48, 49]. With the advent of the first clinical trial that employed ^{212}Pb as the therapeutic agent (^{212}Pb-TCMC-trastuzumab), this radionuclide has finally reached a landmark position in the family of α-emitters validated as suitable for such applications [14].

Among the variety of technologies that are available to conjugate radionuclides to a monoclonal antibody (mAb), two chelating systems have been used successfully for labeling with ^{212}Pb, namely, the macrocyclic agents 2-(4-isothiocyanatobenzyl-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (C-DOTA)) and 2-(4-isothiocyanatobenzyl-1,4,7,10-tetraaza-1,4,7,10-tetra-(2-carbamonylmetyl)-cyclododecane (TCMC)). The TCMC chelate was specifically developed for chelating Pb(II) radionuclides, while C-DOTA is more multipurpose and has been used for chelating other metals including ^{111}In, ^{90}Y, ^{177}Lu, and ^{212}Bi. Although DOTA is known to form strong complexes with both Bi and Pb, a significant portion of ^{212}Bi (~35%) is released from the carrier following the ^{212}Pb/^{212}Bi radioactive decay, thus resulting in the formation of highly ionized daughter atoms. Release of ^{212}Pb after internalization of mAb delivery to cells has been reported as a source of marrow toxicity when using a DOTA conjugate, as the dissociated ^{212}Pb was free to be transported to the bone and subsequently decay to ^{212}Bi [50]. In contrast, the differences in susceptibility to acidic conditions by the Pb(II)-TCMC complex were well demonstrated by Chappell et al. The Pb (II) [4-NCS-Bz-TCMC] complex, which has been very efficiently radiolabeled with Pb(II) radionuclides, was less labile at pH 3.5 than the corresponding DOTA complex, thus conferring enhanced resistance to acid-catalyzed dissociation with the cell. More recently, the structure of the Pb (II)-TCMC complex revealed that Pb(II) is fully

encapsulated by TCMC with the eight-coordinate sphere saturated by the four ring nitrogen and four amide oxygen atoms; this complex is extremely stable and has decreased acid lability for in vivo sequestration of Pb(II) [51–53].

Based on the successful ^{212}Pb preclinical data published from Milenic et al. [54] and from Anderson et al. [55], ^{212}Pb-TCMC-trastuzumab may have potential for an improved therapeutic ratio over β-emitters such as ^{90}Y- and ^{177}Lu-targeted conjugate therapy and thus have beneficial activity against patients with malignancies expressing HER2. Recently, a phase I clinical trial with i.p. ^{212}Pb-TCMC-trastuzumab at the University of Alabama (Birmingham, Alabama, USA) was designed to determine distribution, pharmacokinetics, and safety of i.p. ^{212}Pb-TCMC-trastuzumab in patients with HER2-expressing malignancy [30]. In this study, ^{212}Pb-TCMC-trastuzumab was administered i.p. to three patients with HER2-expressing cancer who had failed standard therapies. After administration of 7.4 MBq/m^2, gamma camera imaging studies showed no distribution of radioactivity out of the peritoneal cavity, nor normal organ uptake. These data were consistent with preclinical studies. Cumulative urinary excretion was <6% in 2.3 half-lives. The maximum external exposure rate immediately post-infusion at skin contact over the abdomen averaged 7.67 mR/h and dropped to 0.67 mR/h by 24 h. The data points correlate closely with ^{212}Pb physical decay. Follow-up for over 6 months showed no evidence of agent-related toxicity, thus indicating good tolerance.

In the second study using ^{212}Pb-TCMC-trastuzumab, Meredith et al. [29] evaluated the safety, pharmacokinetics, immunogenicity, and tumor response of ^{212}Pb-TCMC-trastuzumab administered i.p. in patients with HER2-expressing malignancy [56]. Five dose levels of treatment with i.p. ^{212}Pb-TCMC-trastuzumab resulted in little toxicity in patients with ovarian cancer. Limited redistribution of radioactivity out of peritoneal cavity to circulating blood, which cleared via urinary excretion, and no specific uptake in major organs were observed at 24 h. The highest administered activity concentration at 500 Bq/mL was needed for high therapeutic efficacy without any side effects. Therefore, the phase study I with i.p. ^{212}Pb-TCMC-trastuzumab confirmed its clinical potential and feasibility. The data obtained are consistent with those of prior nonhuman studies showing prolonged retention of ^{212}Pb-TCMC-trastuzumab within the peritoneal cavity, with no evidence for localization to normal organs on planar images. The relatively low radiation dose is also closely comparable to dosimetry data obtained with the use of ^{211}At-MX35-F(ab′)$_2$.

Beta-Emitting Agents

There are currently eight β-emitting agents approved by the FDA for therapy of cancer in humans: ^{131}I-iodide (for differentiated thyroid cancer), ^{131}I-metaiodobenzylguanidine (^{131}I-MIBG, for neural-crest-derived neuroendocrine tumors), ^{131}I-tositumomab and ^{90}Y-ibritumomab tiuxetan (Bexxar® and Zevalin®, respectively, both for CD-20-expressing non-Hodgkin's lymphomas), ^{89}Sr-chloride and ^{153}Sm-EDTMP (Metastron® and Quadramet®, respectively, both for palliation of bone pain from skeletal metastases), and finally ^{90}Y-labeled microspheres (TheraSphere® and SIR-Spheres®, for radioembolization of primary and metastatic liver tumors). Not all these agents meet the criteria to be considered as true "tumor-targeted" therapeutic agents based on specific interaction/binding of the radiopharmaceutical with antigens/receptors on the surface of tumor cells.

On the other hand, numerous preclinical and clinical investigations have addressed a much broader spectrum both of carrier molecules targeting tumor-specific sites and of additional β-emitting radionuclides. A tentative list of the latter includes at least eight radionuclides: lutetium-177 (^{177}Lu), holmium-166 (^{166}Ho), rhenium-186 (^{186}Re), rhenium-188 (^{188}Re), copper-67 (^{67}Cu), promethium-149 (^{149}Pm), gold-198 (^{198}Au), and rhodium-105 (^{105}Rh).

The main physical characteristics are summarized in Table 2.

Table 2 Main characteristics of radionuclides already used or with potential for use in beta-targeted therapy that are discussed in this chapter (arranged according to rising mass element number)

Radionuclide	$T_{½}$, hr	E_{max}, MeV[a]	Production
^{67}Cu	61.9	β, 0.4 (100%)	Cyclotron
^{90}Y	64.8	β, 2.2 (100%)	Generator $^{90}Sr \rightarrow ^{90}Y$
^{177}Lu	160.8	β, 0.5 (100%)	Nuclear reactor
^{188}Re	17.0	β, 2.0 (100%)	Generator $^{188} \rightarrow ^{188}Re$
^{212}Pb	10.6	β, 0.6 (~80%); γ, 0.2 (44%); 0.08 (18%)	Generator $^{228} \rightarrow ^{220}Rn \rightarrow ^{216}Po \rightarrow ^{212}Pb$
^{131}I	8 days	β, 0.6(89%); γ, 0.364 (81%)	Nuclear reactor
^{166}Ho	26.83	β, 1.854 (50%), 1.774 (48.7%); γ, 0.8 (6.7%)	Nuclear reactor
^{175}Y		β, 0.480 (86.5%), 356.2 (3.3%), 0.7 (10.2%)	Nuclear reactor
^{149}Pm	2.21 days	β, 1.07(97%); γ, 0.28 (3%)	Nuclear reactor
$^{198}Gold$	2.7 days	β, 0.96 (100%)	Nuclear reactor
^{105}Rh	36	β, 0.56 (70%); γ, 0.25 (30%)	Nuclear reactor

[a]Percentage of quanta with the indicated energy value in the total amount of quanta of this type emitted by a given radionuclide

Iodine-131 (^{131}I)

Although certainly not the latest emerging β-emitter for therapy, iodine-131 still fulfills an important role in the development of new tumor-seeking radiopharmaceuticals with therapeutic intent. In particular, this radionuclide is being employed in a series of clinical trials based on monoclonal antibody constructs against a family of target antigens that are essential components of the extracellular matrix (ECM). The molecular architecture of the ECM is extremely heterogeneous with wide variation in its constituents in different organs and tissue compartments as well as within the same tissue depending on different developmental and physiologic states [57]. The main components of the ECM are laminins, collagens, fibronectins, and elastins, along with other compounds such as tenascin, thrombospondins, members of the coagulation system, neuronal guidance molecules, and specific growth factor-associated proteins [58, 59]. During oncogenesis, the molecular composition and structure of the ECM is dynamically modified [59].

One of the principal constituents of ECM is fibronectin (FN), a large protein that exists in different isoforms (240–270 kDa) and different molecular forms [57]. FN usually exists as a dimer of two nearly identical ~250 kDa (≈2,500 amino acids) subunits, covalently linked by a pair of disulfide bonds near the C-terminal end of the subunits. Although FNs are the product of a single FN gene, the resulting protein can exist in multiple forms, which – apart from posttranslational modifications – arise from alternative splicing of its primary RNA transcript. This polymorphism leads to the production of as many as 20 different isoforms for human FN. The 3D structure of the alternatively spliced-in EDB domain, a 91-amino acid sequence, is identical in the mouse, rat, rabbit, dog, monkey, and human. EDB has a restricted pattern of expression: undetectable in normal adult tissues and in mature blood vessels, but highly expressed in regenerating tissues and around new blood vessels [60, 61]. The FN isoform containing the ED-B domain is an ideal tumor target since it is widely expressed in the ECM of all solid tumors and is constantly associated with angiogenic processes (i.e., wound healing) [62], but is otherwise undetectable in normal adult tissues [63]. The EDB-FN selective expression pattern has been extensively demonstrated in many different tumor types, in particular on invasive ductal carcinoma [64], brain tumors [63], lymphomas [65], and prostate cancer [66]. High EDB expression is found around the newly forming blood vessels, thus suggesting that EDB is an important target for tumor-associated angiogenesis [67–70].

After the identification of the EDB domain, monoclonal antibodies specific for EDB-FN

were raised. A series of molecular biology experiments finally yielded a high-affinity clone with $K_D = 54$ pM for EDB, termed clone L19 [71, 72]. The enhanced binding affinity of L19 as well as valence (monomeric scFv vs. dimeric scFv) lead also to improved targeting of tumoral angiogenesis, as was shown in biodistribution studies in F9 murine teratocarcinoma-bearing nude mice, where L19 labeled with ^{125}I demonstrated rapid specific localization around tumor blood vessels [73]. Biodistribution experiments in F9 tumor-bearing mice using radioiodinated L19 $(scFv)_2$, L19-SIP ("small immunoreactive protein" format), and L19 IgG_1 showed that L19-SIP offers the best compromise between molecular stability, clearance rate, and tumor accumulation [74–76]. In addition to the established therapeutic benefit, the dosimetric estimates obtained with ^{131}I-L19SIP in murine models of cancer are among the most promising reported so far for radioimmunotherapy (RIT) [77].

The first immunoscintigraphy study in patients with primary tumors and metastatic lesions using ^{123}I-L19 showed selective targeting in aggressive types of lung cancer and colorectal cancer [78]. Following this proof-of-concept study, phase I and phase I/II dose-finding and efficacy studies with ^{131}I-L19SIP in patients with a variety of cancers were initiated. ^{131}I-L19SIP showed an excellent tolerability at radioactive amounts as high as 7,400 MBq (200 mCi) in patients with solid tumors, associated with therapeutic benefit for some patients [65]. During the phase I study, 50 patients received a single dose of 4 mg of ^{131}I-L19SIP radiolabeled with up to 185 MBq (5 mCi) for dosimetric purposes ("dosimetric phase" of the study). Whenever the radiation dose in at least one tumor lesion was found to be at least tenfold higher compared to the dose delivered to the bone marrow (the rate-limiting organ), the patient became eligible for RIT with a single dose of 5 mg ^{131}I-L19SIP radiolabeled with 3,700 MBq (100 mCi) or 5,550 MBq (150 mCi), which constituted the "therapeutic phase" of the study. In an extension of the study, repeated treatments were performed, and patients with hematologic malignancies were included, based on the evidence that EDB is strongly expressed in almost all malignant lymphomas and in certain leukemias. The most impressive therapeutic effect in this study was demonstrated in a young female patient suffering from Hodgkin's lymphoma [79]. In general, uptake of ^{131}I-L19SIP was observed both in primary tumor lesions and in distant metastasis, irrespective of cancer type and location of the lesions. RIT caused G3/G4 hematologic toxicity, but this was not predictable from the dosimetric estimates. Nevertheless, the treatment showed an excellent tolerability profile. Side effects were mostly hematological in nature and all were easily manageable and recovered spontaneously. Concerning in particular patients with hematologic malignancies, 18 patients with either relapsed, progressing lymphoma or multiple myeloma were enrolled as candidates for RIT with ^{131}I-L19SIP. Tumor uptake of sufficient degree to justify RIT was observed in 11/15 patients with lymphoma and in 3/3 myeloma patients. Following a single course of RIT with ^{131}I-L19SIP (standard activity of 3.7 GBq, reduced in some cases to 1.85 GBq because of low body weight), complete response was achieved in two patients with Hodgkin's lymphoma and one patient with large B-cell lymphoma, while partial response was observed in one patient with Hodgkin's lymphoma and patients with multiple myeloma experienced stabilization of disease. The objective response rate was therefore 40%, a highly promising outcome for these patients who had failed all lines of treatment, also considering that RIT with ^{131}I-L19SIP was associated with low toxicity [79].

Labeling of L19SIP with ^{124}I rather than with ^{131}I during the dosimetric phase of the study allows serial PET imaging, with more accurate dosimetric estimates [80]. Further advances in this field include proof of the therapeutic potential in prostate cancer patients [66].

Lutetium-177 (^{177}Lu) is a very promising β-emitter for targeted radiotherapy. Its β-emission, with a maximum energy of 498 keV, is useful in destroying small tumors and metastasis (optimal size 1.2–3.0 mm), while at the same time reducing damage to normal tissues. From this point of view, ^{177}Lu can be seen as a complement to yttrium-90 or to iodine-131 [81]. ^{177}Lu also emits low-energy gamma rays (208 and 113 keV with 10% and 6%

abundance, respectively) [82], which allow direct imaging of the activity distribution in the patients' body for dosimetry calculations following administration of the therapeutic activity.

With its 6.71-day half-life, lutetium-177 lends itself to the use of more sophisticated procedures to synthesize and purify radiopharmaceuticals and to transport them to more distant nuclear medicine departments. As to the potential applications of lutetium-177 for RIT, prostate carcinoma (PCa) seems to be a favorable solid tumor because of its radiosensitivity and the typical metastatic diffusion to sites where there is potentially a high exposure to circulating mAbs (such as bone marrow and lymph nodes). In preclinical and clinical PCa therapy studies, different antibodies or peptides with affinity to mucin, ganglioside (L6), Lewis Y (Ley), adenocarcinoma-associated antigens, the TROP-2 pancarcinoma marker, and prostate-specific membrane antigen (PSMA) have been linked to radionuclides; PSMA appears the most specific of these targets [83, 84].

PSMA is a non-secreted, integral, type II membrane protein with abundant and nearly universal expression on epithelial prostate cells that is strongly upregulated in PCa [85, 86]. PSMA expressed in normal prostatic cells (brush border/luminal location) is not typically exposed to a circulating mAb, and the PMSA's level of expression in non-prostate tissues is 100–1,000-fold less than in prostate tissue. The de-immunized J591 mAb, which links the PSMA's external domain, seems to be the best clinical candidate for clinical RIT in patients with PCa [87].

In a ^{177}Lu-J591 phase I trial, 35 patients were enrolled [88]. The maximum tolerated dose (MTD) was determined to be 2,590 MBq/m^2. In addition, it was shown that repeated dosing (up to three doses of 1,110 MBq/m^2 each) could safely be injected. In all patients, the sites of metastatic disease were successfully imaged with gamma camera scintigraphy after administration of ^{177}Lu-J591. As to the biochemical PSA response, the median duration of posttreatment PSA stabilization was 60 days (range between 28 and 601 days).

A phase II ^{177}Lu-J591 clinical trial has been conducted in mCRPC patients [89]. Patients were enrolled in two cohorts: 2,405 MBq/m^2 in cohort 1 versus 2,590 MBq/m^2 in cohort 2. Fifteen patients were enrolled in cohort 1, while cohort 2 was expanded to enroll 17 patients instead of the 15 patients as originally planned; targeting of 93.6% of the known sites of metastasis was detected by scintigraphy. Hematologic toxicity consisted in reversible thrombocytopenia and neutropenia and observed in 46.8% and 25.5% of the patients, respectively. The cohort 2 patients exhibited a higher PSA responses (46.9% vs. 13.3%, $P = 0.048$) associated with a longer survival (21.8 vs. 11.9 months, $P = 0.03$), but also more frequent hematologic toxicity. This trial shows that radiolabeled de-immunized J591 is well tolerated and non-immunogenic. Radiolabeled J591 effectively targets PCa metastases and induces PSA reduction with a dose-effect relation.

Among several alternative possibilities, pretargeting may be achieved using a first injection of an unlabeled bispecific monoclonal antibody (BsMAb), followed by subsequent injection of a radiolabeled bivalent hapten-peptide [90, 91]. In this approach, the radiolabeled bivalent peptide binds avidly to the BsMAb attached to the antigen at the cell surface, whereas non-targeted hapten-peptide in the circulation clears rapidly through the kidneys. Medullary thyroid cancer (MTC) cells express high amounts of CEA, and encouraging therapeutic results have been obtained using anti-CEA pre-targeted ^{131}I-di-DTPA peptide in two phase I/II and one phase II clinical trials [90, 92].

New-generation BsMAb and bivalent hapten-peptides are currently available. Humanized, recombinant, trivalent BsMAb and the histamine-succinyl-glutamine (HSG) hapten and bivalent HSG hapten-peptides have been created [93, 94]. The use of humanized BsMAb should reduce immunogenicity and the dock-and-lock procedure allows large-scale production. Accordingly, a series of bivalent HSG haptens have been created, offering the possibility of labeling with many radionuclides, including yttrium-90 and lutetium-177 for therapy purposes [95]. The first clinical study evaluating the anti-CEA anti-HSG BsMAb TF2 and the radiolabeled hapten-peptide, ^{177}Lu-IMP288, in patients with mCRPC has been

published recently [93]. Different approaches were explored in four cohorts of five patients each, to identify the optimal molar doses of TF2 and IMP-288 and the optimal holdup between the two infusions: (1) shortening the interval between the BsMAb and peptide administration (1–5 days), (2) escalating the TF2 dose (from 75 to 150 mg), and (3) reducing the peptide dose (from 100 to 25 μg). Rapid and selective cancer uptake was observed within 1 h after the peptide injection, with high tumor-to-tissue ratios at 24 h. The best tumor targeting was obtained with a 1-day pre-targeting interval and with the 25-μg peptide amount. High activities of ^{177}Lu-IMP288 (2.5–7.4 GBq) were well tolerated. Some controllable reactions during the TF2 infusions occurred, and transient grades 3–4 thrombocytopenia was reported in 10% of the patients. Dosimetric analysis showed that red bone marrow and renal uptake of ^{177}Lu-IMP288 were relatively low, although marrow doses increased in subsequent cohorts as the TF2/Lu-IMP288 ratio was improved [95]. The predicted kidney-absorbed doses (<0.50 mGy/MBq) did not restrict the maximum activity that could be injected. None of the patients would exceed the limit of 15 Gy to the kidneys with four cycles of 7.4 GBq ^{177}Lu-IMP288. These data indicate that pre-targeting using dock-and-lock bispecific BsMAb would be most practical to deliver short-half-life radionuclides.

Bound with methylene phosphonic acid (EDTMP), ^{177}Lu can be used as a bone pain palliation radiopharmaceutical. Preclinical studies and initial clinical trials with ^{177}Lu-EDTMP have resulted in encouraging data [96]. Results of clinical studies show that ^{177}Lu-EDTMP is an effective radiopharmaceutical for palliation of metastatic skeletal pain in patients with breast or prostate cancer. An amount of 1,295 MBq (35 mCi) is sufficient for bone pain palliation therapy, but doses as high as 2,590 MBq (70 mCi) have been shown to be safe.

Holmium-166 (^{166}Ho) decays by β-emission to ^{166}Er (stable) with $E\beta_{max}$ of 1.854 MeV (50.0%) and 1.774 MeV (48.7%). It decays with a half-life of 26.83 h. It emits 81-keV gamma photons (6.7%), which are suitable for external imaging to track the in vivo distribution and uptake of the radionuclide. The maximum soft tissue penetration of the β-particles is ~8.5 mm and hence is suitable for certain specific therapeutic applications. Holmium-166 is a very attractive candidate for therapeutic purposes, as this radionuclide emits gamma rays in addition to high-energy beta particles, thus allowing both nuclear imaging and radionuclide therapy, according to the principles of "theranostics." Moreover, holmium can be visualized by computed tomography and magnetic resonance imaging owing to its high attenuation coefficient and paramagnetic properties [97].

Also favorable is its half-life of 26.9 h, which is long enough to overcome logistic problems encountered with the short-lived radionuclides and is sufficient to provide a high radiation dose rate. Its nuclear reaction cross section is comparable with that of rhenium, but ^{165}Ho has a natural abundance of 100%; thus, only one radioisotope, ^{166}Ho, is formed by neutron bombardment. Taking these characteristics into consideration, ^{166}Ho is therefore an attractive candidate for use to tailor the future needs for treatments. The first study with this radionuclide was for the development of radiosynovectomy agents for treatment of rheumatoid arthritis [98, 99]. Development of ^{166}Ho-labeled polylactic acid microspheres was also reported [100, 101]. Hydroxyapatite (HA) particles were selected as they are biodegradable and hence thought to be good as a matrix for radiolabeling with ^{166}Ho and developing a radiosynovectomy agent. An experimental knee joint lesion that closely resembles rheumatoid arthritis was developed in rabbits by injecting ovalbumin. Bioevaluation of the ^{166}Ho-HA particles was carried out by injecting ~2 mCi (74 MBq) of the radiotracer in 200 μL of saline solution which contained ~8 mg of ^{166}Ho-HA particles into the knee joints of New Zealand white rabbits. The ^{166}Ho-HA particles were injected into the arthritis-induced knee joints as well as into knee joints of healthy rabbits. Images of the injected joints of the animals recorded at regular intervals using a gamma camera showed good retention of the radiopharmaceutical. Blood samples were collected from the animals and the blood activity was assayed in a scintillation detector. Experiments

were also carried out under identical conditions in normal rabbits. In both the cases, it was observed that there was no significant extra-articular leakage of the injected activity over the study period of 96 h postinjection and the particles are retained within the synovial joints [99]. About 185 MBq (5 mCi) of the labeled preparation in sterile saline was injected intra-articularly under fluoroscopic guidance to the affected knee joints of the patients. The knee is flexed three to four times after injection and the patients were kept under observation. Gamma camera imaging was recorded to ascertain the localization of the injected dose. More than 100 joints were studied in the clinical trial. Patients suffering from rheumatoid arthritis and hemophilia showed good response from the treatment. Seventy-five percent of the 50 patients treated with the new radiopharmaceutical showed significant reduction in pain.

Although not strictly related to oncological applications, the results of the above study are nevertheless interesting because they constitute the rationale for applying to cancer therapy some of the concepts of using ^{166}Ho-labeled particles and of locoregional administration described above. In this regard, ^{166}Ho-microspheres have recently been introduced as an alternative radiopharmaceutical for intra-arterial therapy in patients with liver tumors. The efficacy of radioembolization for the treatment of liver tumors depends on the selective distribution of radioactive microspheres to tumor tissue. The distribution of ^{166}Ho-poly(L-lactic acid) microspheres can be visualized in vivo both by SPECT and by MRI. In a phase I clinical trial, Smits et al. [102] evaluated the safety and the maximum tolerated radiation dose (MTRD) of ^{166}Ho-radioembolization in patients with liver metastases. Patients were treated with intra-arterial ^{166}Ho-radioembolization in cohorts of three patients, with escalating aimed whole-liver absorbed doses of 20, 40, 60, and 80 Gy. Cohorts were extended to a maximum of six patients if dose-limiting toxicity occurred. Patients were assigned a dose in the order of study entry, with dose escalation until dose-limiting toxicity was encountered in at least two patients of a dose cohort. The most frequently encountered toxicities (including grade 1) were lymphocytopenia, hypoalbuminemia, raised alkaline phosphatase, raised aspartate aminotransferase, and raised gamma-glutamyltransferase, which were all noted in 12 of 15 patients. Stable disease or partial response regarding target lesions was achieved in 14/15 patients (93%, 95% CI 70–99) at 6 weeks and in 9/14 patients (64%, 95% CI 39–84) at 12 weeks after radioembolization. Compared with baseline, the average global health status and quality of life score at 6 weeks after treatment had decreased by 13 points ($P = 0.053$) and by 14 points at 12 weeks ($P = 0.048$). In all patients, ^{99m}Tc-macroaggregated albumin SPECT, ^{166}Ho scout dose SPECT, and ^{166}Ho treatment dose SPECT showed similar patterns of the presence or absence of extrahepatic deposition of activity. The authors concluded by stating that ^{166}Ho-radioembolization is feasible and safe for the treatment of patients with unresectable and chemorefractory liver metastases, and it enables image-guided treatment. Clinical ^{166}Ho-radioembolization should be performed aiming at achieving a whole-liver absorbed dose of 60 Gy [102].

Ytterbium-175 (^{175}Yb) is another low-energy β-emitter, which has been proposed for labeling bone-seeking agents to be employed for bone pain palliation. The low β-energy of ^{175}Yb (480 keV) will induce minimum radiation dose to bone marrow and hence will allow administration of higher levels of radioactivity, to potentially obtain even a therapeutic efficacy similar to that demonstrated for ^{153}Sm and ^{188}Re. Similar to ^{153}Sm, ^{175}Yb can also be chelated to polyamino-poly phosphonate ligands [103].

Thulium-170 (^{170}Tm) conjugated with EDTMP is considered as an alternative to $^{89}SrCl_2$ in palliative therapy of bone metastases. The use of ^{170}Tm would induce low myelosuppression, since it emits lower-energy β-particles ($E\beta_{max} = 968$ keV) than those emitted by ^{89}Sr, and the gamma photons emitted can be used for scintigraphy to detect the accumulated activity and biokinetics at the target sites [104]. The long half-life of 128.6 days could be advantageous in an approach based on mixed radionuclide therapy using ^{170}Tm together with ^{153}Sm, ^{177}Lu, or ^{175}Yb. Such combination could provide both early and sustained long-term pain relief to patients in early stage of disease.

Copper-67 (^{67}Cu) has favorable radiophysical characteristics for RIT, with a half-life of 3.4 days (well suited to pharmacokinetics of whole antibodies) and an emission of β-particles with energy comparable to that of iodine-131 and lutetium-177. Moreover, it emits gamma rays with energy suitable for imaging and a relatively weak abundance, thus reducing irradiation of patients and medical staff as that occurring with iodine-131. The production capacity of copper-67 is limited by a low cross section of the nuclear reaction, which needs high-intensity and high-energy proton beams. Only a limited number of accelerators in the world have such high energy and high intensity. This situation explains the quite limited number of clinical studies performed in the last 30 years.

Two groups of investigators carried out clinical studies in the 1990s in a limited number of patients. De Nardo and coworkers pioneered this field and compared clinical results obtained with the Lym-1 mAb against non-Hodgkin's lymphoma (NHL) labeled with ^{67}Cu, ^{131}I, and ^{90}Y, respectively [105, 106]. The authors concluded that the therapeutic indices (ratio of radiation doses to tumor relative to those to normal tissues) for ^{67}Cu-2IT-BAT-Lym-1 and, to a lesser extent, for ^{90}Y-2IT-BAD-Lym-1 were more favorable than those observed for ^{131}I-Lym-1. The same conclusions were drawn in a clinical study comparing the anti-CEA mAb35 antibody labeled with ^{67}Cu and ^{125}I in patients with colorectal cancer [107]. Copper-67-labeled mAb35 was more favorable than its radioiodine-labeled counterpart due to higher tumor-to-blood ratio; however, the authors observed a potential problem with ^{67}Cu, i.e., non-specific liver and bowel uptake.

In conclusion, copper-67 seems to be more suitable than iodine-131 and possibly than yttrium-90 for labeling mAbs for therapy, but currently lutetium-177 is a radionuclide of choice for RIT. Thus in the future, copper-67 should be compared to lutetium-177 in clinical studies when the production of large activities of copper-67 will be made possible by new high-energy/high-intensity accelerators.

Yttrium-90 (^{90}Y) undergoes ß-decay to zirconium-90 with decay energy of 2.28 MeV (average energy of 0.94 MeV) that allows for high-dose deposition with an average and maximum soft tissue penetration of 2.5 mm and 11 mm, respectively [108–110]. Yttrium-90 has a physical half-life of 64.1 h [111] which makes it amenable for a variety of targeted radiotherapy applications including ^{90}Y-labeled colloid [112, 113], somatostatin receptor-targeting peptides [114, 115], tumor-targeting antibodies [116, 117], and resin/glass microspheres for selective/super-selective embolization of hepatic malignancies and metastases [118–120]. Regardless of the targeted delivery agent used, the selection of ^{90}Y and its use for radiotherapy are complex and necessitate close collaboration among various medical specialties including nuclear medicine, interventional radiology, medical oncology, and radiation oncology [121]. ^{90}Y can be administered via direct injection into a space or cavity (e.g., radiosynovectomy), intravenously for peptide receptor radionuclide therapy (PRRT) and radioimmunotherapy (RIT), and intra-arterially for radioembolization (RE) therapy. Yttrium-90 emits pure β-particles, but lacks gamma photons, and therefore conventional scintigraphic imaging and assessment of the post-therapy distribution cannot be performed. This lack of gamma photons led to the development and use of surrogate gamma-emitting agents such as indium-111-labeled peptides to be used before PRRT and RIT or ^{99m}Tc-labeled macroaggregated albumin (MAA) used as a surrogate radiotracer for planning ^{90}Y-microsphere radioembolization. Yet, using surrogate tracers may still be problematic as to the accuracy of predicting ^{90}Y radiotheraphy effects in vivo and the precise post-therapeutic distribution [122–125]. However, β-particle emission from ^{90}Y produces bremsstrahlung photons which can also be imaged scintigraphically, although with poor-quality images [116]. The ^{90}Y bremsstrahlung photons are generated when the high-energy β-particle is emitted from the ^{90}Y nucleus and then loses its kinetic energy while interacting with adjacent atoms. As the electron slows down, its kinetic energy is converted into the continuous energy spectrum of both primary and scattered photons with no dominant energy photopeak for conventional scintigraphic imaging (i.e., bremsstrahlung radiation).

However, it is important to note that, even if in an extremely small proportion (32 per million), some ^{90}Y decay occurs through internal pair production that generates 511-keV annihilation photons that can be imaged in vivo using positron emission tomography (PET). This emission is in general too small to allow for efficient PET imaging within a reasonable acquisition time when a therapeutic ^{90}Y-radiopharmaceutical is administered systemically and distributes throughout the body (as in the case of RIT or PRRT). Instead, when the therapeutic agent is administered locoregionally and is retained at the site of administration (as in the case of radioembolization of liver tumors with ^{90}Y-microspheres), then even this extremely small fraction of ^{90}Y decay occurring through internal pair production is sufficient to acquire clinically useful PET images that are useful for dosimetric purposes [126].

Gold-198 (^{198}Au) is a β-emitter (β-max = 0.96 MeV) with a relatively short half-life (2.7 days). Thanks to its characteristics, ^{198}Au has been used as a permanent implant either alone or as an adjunct to external beam radiation therapy [127, 128].

Recently, due to the development of nanotechnologies, a paradigm shift in the way diagnostic and therapeutic drugs are designed is occurring. This paradigm is based on achieving target specificity and increasing retention for significant improvement in the treatment of various tumors, including prostatic cancer [129–133]. Nanosized particles have extraordinary capabilities to image or treat cancers at the cellular and molecular levels [134–139]. In this regard, gold nanoparticles (AuNPs) exhibit very high tumor uptake, due to their natural affinity to the leaky tumor vasculature, which is particularly pronounced during tumor's neoangiogenesis [140, 141].

Chanda et al. have reported promising results in a preclinical model of prostatic cancer using gum arabic glycoprotein (GA)-functionalized gold nanoparticles (12–18 nm core diameter, 85 nm hydrodynamic diameter) loaded with 198Au (GA-198AuNPs). This agent exhibited high tumor affinity in severely compromised immunodeficient (SCID) mice bearing human prostate tumor xenografts. In this experiment, a single intratumoral administration of the β-emitting GA-198AuNPs (70 Gy) was performed, to achieve a calculated radiation dose of 70 Gy. This procedure resulted in clinically important cancer regression and successful control in the growth of prostate tumors over 30 days [142]. This observation might constitute the basis for possible clinical translation of this agent in patients with newly diagnosed PCa who are candidate to surgery, in order to reduce tumor size before surgical resection. The study by Chanda et al. revealed no hematologic toxicity, thus confirming that the therapeutic efficacy of this treatment is associated with high in vivo tolerance.

Promethium-149 (^{149}Pm) is a radiolanthanide recently made available characterized by a moderate-energy β-emission (1.07 MeV, 95.9%) and a half-life of 2.21 days. ^{149}Pm also emits a low abundance of an imageable γ-ray (286 keV, 3%) that might permit in vivo imaging after therapy. In a preclinical trial, three ^{149}Pm-complexes with the DO3A-amide chelator with zero and three carbon spacers to the bombesin peptide analog BBN (7–14)NH_2 were synthesized and characterized. The biological properties of the ^{149}Pm-DO3A-amide-βAla-BBN complexes were compared with biodistribution studies in normal mice. Its in vivo behavior as the ^{149}Pm-DO3A-amide-Ala-BBN conjugate is virtually identical to that of the ^{153}Sm- and ^{177}Lu-analogs. This supports the hypothesis that, given the appropriate chelate, the radiolanthanides are similar allowing fine-tuning of the nuclear properties necessary for a particular disease target. No in vivo tumor-targeting trials have as yet been carried out with ^{149}Pm-DO3A-amide-Ala-BBN in patients; however, the fast biological clearance of this conjugate suggests that a longer spacer (five or eight carbon) may be necessary to increase the lipophilicity of the complex and reduce its clearance rate [143].

Rhodium-105 (^{105}Rh) is a reactor-produced radionuclide with properties suitable for radiotherapeutic applications. It is a moderate low-energy β-emitter (0.560 MeV [70%], 0.250 MeV [30%]) with a 36-h half-life, and it is available in "no-carrier-added" (NCA) concentrations. ^{105}Rh also emits a low abundance of imageable γ-rays (306 keV [5%], 319 keV [19%]) that would allow in vivo tracking of the therapeutic dose. ^{105}Rh is

produced by a neutron capture reaction of an enriched ^{104}Ru target to produce ^{105}Ru, which decays to ^{105}Rh with a 4.4-h half-life [144]. The cis-[Rh(III)Cl_2(2,5,8,11-tetrathiadodecane-1,12-dicarboxylic acid)]$^+$ complex shows the most promising in vivo characteristics on which to base the development of a potential therapeutic radiopharmaceutical [145]. For example, ^{105}Rh can be simply conjugated with EDTMP, by heating for 30 min in boiling water, with >99% radiochemical yield. Ando et al. have tested this radiopharmaceutical in animals, and observed that ^{105}Rh-EDTMP has fast blood clearance and selective uptake in the bone, with rapid elimination from irrelevant tissues; thus, it appears to have suitable features for palliative treatment of pain of bone metastases[146].

Other Radionuclides

A few other radionuclides could be of interest for RIT. For example, the use of scandium-47 has been suggested by Pietrelli et al. [147]. This radionuclide can be produced carrier-free by neutron irradiation of titanium-47. It decays into stable titanium by emitting low-energy β^- with a half-life of 3.35 days, with the additional emission of a 159 keV γ-ray (68%) that is suitable for imaging. Very little has been published on scandium-47 because of a poor availability, but interest in scandium-44, a positron emitter, has revived interest in scandium-47 according to the β^+-/β-radionuclide pair concept. Similarly as scandium-44, it may be efficiently complexed by several chelating agent, including DOTA [148].

Terbium-161 has also been proposed recently as a β-emitter of interest in targeted radionuclide therapy [149]. It decays with a half-life of 6.88 days into stable dysprosium-161 by emitting low-energy β-particles. A very interesting feature of the element terbium is the possibility of using other terbium radionuclides, such as terbium-149 (which is an α-particle emitter), terbium-152 (a β^+-emitter), and terbium-155 (a γ-emitter). All these radionuclides possess manageable half-life and decay properties, thus making it possible to perform β- and α-targeted radionuclide therapy, as well as PET and SPECT imaging with isotopes of the same element – according to the principles of theranostics.

Concluding Remarks

It should be emphasized that the development of novel radiopharmaceuticals for therapy often includes several steps that imply the use of different radionuclides before identifying the most suitable ligand-chelator-radionuclide conjugate for clinical use. In general, proof-of-principle studies are based on the demonstration – obtained by imaging studies – that the candidate compound of interest accumulates efficiently and is retained at the tumor site sufficiently so as to predict high radiation dosimetry with a potential therapeutic effect. This demonstration can be achieved using the compound labeled with either a γ-emitter (for single-photon imaging) or a β^+-emitter (for PET imaging). Some of the radionuclides described above decay by emitting both γ-radiation and β-particles (e.g., ^{131}I, ^{153}Sm, ^{177}Lu), a feature that facilitates the studies on tumor targeting. When instead the therapeutic radionuclide is a pure α- or β-emitter, a surrogate γ- or β^+-emitter must be used for imaging in the exploratory phase.

The example described here below will serve to illustrate the multifaceted approach that is being followed for developing a novel therapeutic radiopharmaceutical starting from a monoclonal antibody that has initially been employed primarily for diagnostic purposes in patients with clear-cell renal carcinoma. The murine G250 mAb was raised against the carbonic anhydrase isoenzyme 9 (CAIX), a transmembrane glycoprotein [150–152] that is expressed on the cell surface of the majority (>95%) of these tumors, which constitute approximately 80% of all renal cell carcinomas [153]. The murine mAb G250 labeled with ^{131}I was initially tested to explore its tumor-targeting potential. However, due to the formation of human anti-mouse antibodies (HAMA) [154], a chimeric variant of G250 (cG250) was constructed, with high affinity for the G250 antigen ($Ka = 4 \times 10^9$ L/mol). Immunoreactivity of mAb cG250 with normal human tissues is limited to the upper gastrointestinal mucosa and gastrointestinal-related structures

(bile ducts, pancreas) [155, 156]. Studies on the therapeutic potential of mAb G250 can be divided into studies with the "naked" antibody (administered alone or in combination with cytokines) and radioimmunotherapy (RIT) trials, respectively. In the first dose-escalating RIT study, ^{131}I-G250 was administered to patients with progressing metastatic renal cell carcinoma (mRCC) [154]. Hepatic toxicity occurred, mostly as the result of specific hepatic accumulation of the murine G250 mAb, which declined with increasing doses (thus suggesting saturation of the G250 binding sites). Nevertheless, hepatic toxicity was mild and not dose limiting, whereas dose-limiting toxicity was hematologic. Overall survival of patients treated with ^{131}I-G250 appeared to be improved versus historic control patients (17/33 stable disease and two minor responses). However, high HAMA levels developed in virtually all patients, thus precluding retreatment, a problem that was overcome with the development of cG250.

Following the protein dose-escalation trial with ^{131}I-cG250, which established the most favorable amount of protein for administration, a phase I ^{131}I-cG250 activity escalation study was performed to establish dose-limiting toxicity [157]. A pretherapy imaging phase with ^{131}I-cG250 (administered as a tracer activity of 222 MBq per 5 mg protein) was included with the purpose of selecting CAIX-positive patients for the therapeutic administration of 1.665–2.775 GBq ^{131}I-cG250 (still with 5 mg protein). No hepatic toxicity was observed in this study, probably because the liver compartment was saturated. Dose-limiting toxicity of ^{131}I-cG250 was established at 2.775 GBq/m^2; the maximum tolerated dose was therefore set at 2.220 GBq/m^2. An antitumor response was observed in two out of eight patients: one stable disease for 3–6 months and one partial response >9 months.

A fractionated dose RIT trial was subsequently designed, based on whole-body radiation-absorbed dose [158], under the rationale that in animal models fractionated RIT is more successful than a single administration schedule and is associated with lower toxicity. The primary target of this study was to determine the maximum tolerated whole-body radiation-absorbed dose. Fifteen patients with measurable mRCC were enrolled for this trial, during which it was found that dose-limiting toxicity was hematologic. Moreover, the total dose that could be delivered was relatively low.

In a subsequent study [159], two sequential high doses of ^{131}I-cG250 (2.22 GBq/m^2) were administered after a tracer activity of ^{131}I-cG250 (185 MBq/m^2) to ascertain effective tumor targeting; 29 patients with sufficient cG250 uptake received a first therapeutic dose of ^{131}I-cG250. Patients who did not show a grade 4 hematologic toxicity received a second therapeutic administration 3 months later, with dose escalation from 1.110 to 1.665 GBq/m^2. None of the 16 patients who completed the protocol (out of the 29 enrolled) showed an objective response, but five had stabilization of disease for 3–12 months. The low therapeutic efficacy observed in this trial was probably due to the quite large tumor burden present in these patients. In this regard, dosimetric estimates proved that therapeutic radiation doses (>50 Gy) could be achieved only for lesions smaller than 5 g [160].

Subsequent clinical studies have adopted ^{90}Y or ^{177}Lu to label cG250 for RIT trials. The results of a phase I/II trial with ^{177}Lu-cG250 were recently published [161], a study that was conducted in parallel with a trial based on the use of ^{90}Y-cG250 at Memorial Sloan Kettering Cancer Center (www.clinicaltrials.gov/NCT00199875). In the ^{177}Lu-cG250 trial, 23 patients with progressive mRCC received a diagnostic activity of ^{111}In-cG250 (185 MBq), to ascertain adequate tumor uptake; this was followed by administration of ^{177}Lu-cG250 1 week later. The staring dose of ^{177}Lu-cG250 was 1.110 GB/m^2, with increments of 370 MBq/m^2 (three patients/dose level). In the absence of grade 4 toxicity, patients were suitable for receiving a second (13/23) and a third cycle (4/23), at 75% of the dose level of the previous administration. Hematologic toxicity was dose limiting, and the maximum tolerated dose was 2.405 GBq/m^2 [161]. The majority of patients responded with stabilization of disease, while a partial response that lasted for 9 months was observed in one patient at the 1.850 GBq/m^2 dose level. The tumor-to-red marrow dose ratio was higher for ^{177}Lu-cG250 than for ^{90}Y-cG250, indicating a wider therapeutic window for the

^{177}Lu-conjugate. Stillebroer et al. concluded that RIT with ^{177}Lu-cG250 may stabilize previously progressive metastatic ccRCC [162].

More evidence is needed to prove that cG250 imaging can be used to guide clinical management. As suggested by Divgi et al. [163], the role of cG250 imaging in influencing outcome would perhaps be best assessed in a clinical trial carried out in patients with small renal tumor mass and fewer associated comorbidities. Another issue that needs further investigation is choice of the radionuclide for imaging. ^{111}In-cG250 SPECT may provide the same information as ^{124}I-cG250 PET, with the advantage that it can be made available as an off-the-shelf product to be used on site. Other radionuclides (e.g., ^{89}Zr) might provide a useful alternative for PET imaging. In summary, the cG250 mAb agent has shown significant tumor-targeting capacity; although the main clinical value of the compound seems at present to be its potential as a diagnostic agent, its use as a delivery vehicle for RIT requires further investigations – possibly regarding also choice of the best radionuclide for therapy.

Physics of Nuclear Oncology

9

Dale L. Bailey and John L. Humm

Abstract

The study of the basic physics used in nuclear oncology involves understanding the way energy associated with radioactive emissions can be best utilized to image, diagnose, stage, treat, and monitor the patient with cancer. In this chapter we will cover the physics involved in these processes.

Structure of the Atom

To describe nuclear processes and the energy associated with radioactive decay, we will make use of a simple conceptual model of the atom. At the turn of the twentieth century, soon after the discovery of natural radioactivity and the first production of X-rays, the British physicist Lord Rutherford proposed a model for the atom similar to that used to describe the orbit of the planets of the solar system about the sun (the "planetary" model, see Fig. 1). The Rutherford model had a central positive core, the nucleus, about which a cloud of electrons circulated. It predicted that most of the space in matter was unoccupied (thus allowing particles and electromagnetic radiation to pass through, as had been observed experimentally). The Rutherford model, however, presented a problem because classical physics predicted that the revolving electrons would emit energy continuously, resulting in a spiraling of the electrons into the nucleus. In 1913, Niels Bohr introduced the constraint that electrons could only orbit at certain discrete radii, or energy levels, and that in turn only a small, finite number of electrons could exist in each energy level. Most of what was required to understand the subatomic behavior of particles was now in place. This is referred to as the Bohr (planetary) model of the atom. Later in 1932, the neutron was proposed by James Chadwick as a large particle roughly equivalent to the mass of a proton, but without any charge, that also existed in the nucleus of the atom.

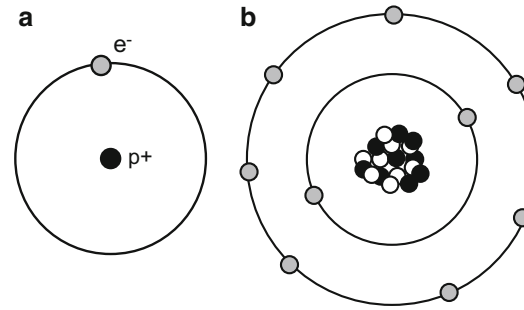

Fig. 1 Examples of the planetary model of the atom are shown for (**a**) hydrogen ($^{1}_{1}H$) and (**b**) fluorine-18 ($^{18}_{9}F$). Protons are indicated by the *solid circles*, neutrons by the hollow *circles*, and circulating electrons by the *gray circles*

We shall continue to use this basic model of the atom for much of our discussion. The model breaks down in the realm of quantum mechanics, where Newtonian physics and the laws of motion no longer apply, and particles approach relativistic speeds (i.e., approaching the speed of light). Also, there are times when we must invoke a nonparticulate model of the atom where the particles need to be viewed as waves (or, more correctly, *wave functions*). Electrons, for example, can be considered at times to be waves. This helps to explain how an electron can pass through a "forbidden" zone between energy levels and appear in the next level without apparently having passed through the forbidden area, defined as a region of space where there is zero probability of the existence of an electron. It can do so if its wave function is zero in this region. For a periodic wave with positive and negative components, this occurs when the wave function takes a value of zero. Likewise, electromagnetic radiation can be viewed

as particulate at times and as a wave function at other times. The planetary model of the atom is composed of nucleons (protons and neutrons in the nucleus of the atom) and circulating electrons. It is now known that these particles are not the fundamental building blocks of matter but are themselves composed of smaller particles called *quarks*.

Energy and Mass

Energy and Frequency

In 1900 Max Planck made the important observation that the energy (E) of electromagnetic radiation was simply related to the frequency of the radiation (υ) by a single constant (Planck's constant, h):

$$E = h\upsilon$$

Planck's constant has a value of 6.626×10^{-34} $J.s$. This provided support to the notion that electromagnetic radiation behaved like a wave. In addition, experiments indicated that the radiation was only released in discrete "bursts." This was a startling result as it departed from the classical assumption of continuous energy to one in which electromagnetic radiation could only exist in integral multiples of the product of $h\upsilon$. The wave-like radiation was said to be quantized, where each quantum contained an amount of energy that was an integer multiple of $h\upsilon$. The unit of energy in the SI system is the Joule (J); however, a derived unit used frequently in discussions of the energy of electromagnetic and particulate radiation is the electron volt (eV). The electron volt is defined as the energy acquired when a unit charge is moved through a potential difference of one volt. Energy in Joules can be converted to energy in electron volts (eV) by dividing by the conversion factor $1.6 \times 10^{-19}\text{J.eV}^{-1}$. Thus the energy in Joules for visible light photons of, for example, 450 nm would be:

$$\begin{aligned} E = h\upsilon = \frac{hc}{\lambda} &= \frac{6.63 \times 10^{-34} J.s \times 3 \times 10^{8} m.s^{-1}}{450 \times 10^{-9} m} \\ &= 4.42 \times 10^{-19} J \end{aligned}$$

which can be expressed in units of eV as:

$$\begin{aligned} E = 4.42 \times 10^{-19}\, J &\equiv \frac{4.42 \times 10^{-19} J}{1.6 \times 10^{-19} J.eV^{-1}} \\ &= 2.76\, eV \end{aligned}$$

X-rays and gamma rays have energies of thousands to millions of electron volts per photon (keV–MeV).

Energy and Mass

Einstein's special theory of relativity published in 1905 predicted, among other things, that the speed of light was constant for all observers independent of their frame of reference (and therefore that time was no longer constant) and, importantly, that mass and energy were *equivalent*. This means that we can talk about the rest-mass equivalent energy of a particle, which is the energy that would be liberated if all of the mass were to be converted to energy. By rest mass we mean that the particle is considered to be at rest, i.e., it has no kinetic energy. Consider the electron, which has a rest mass of 9.11×10^{-31}kg; we can calculate the amount of energy this mass is equivalent to using Einstein's equation:

$$\begin{aligned} E &= mc^2 \\ &= 9.11 \times 10^{-31} kg \times \left(3 \times 10^{8}\right)^2 m.s^{-1} \\ &= 8.2 \times 10^{-14} J \\ &\equiv 8.2 \times 10^{-14} J / 1.6 \times 10^{-19} J.eV^{-1} \\ &= 511\ keV \end{aligned}$$

The reader may recognize this as the energy of the photons emitted in positron–electron annihilation.

Radioactivity and Radiation

Radiation can be classified into electromagnetic or particulate. Ionizing radiation is radiation that has sufficient energy associated with it to remove electrons from atoms, thus causing ionization. This is restricted to high-energy electromagnetic radiation (X- and γ-radiation) and charged particles (α, β^-, β^+). Examples of non-ionizing electromagnetic radiation include light, radio, and microwaves (see Fig. 2). We will concern ourselves specifically with ionizing radiation as this is of

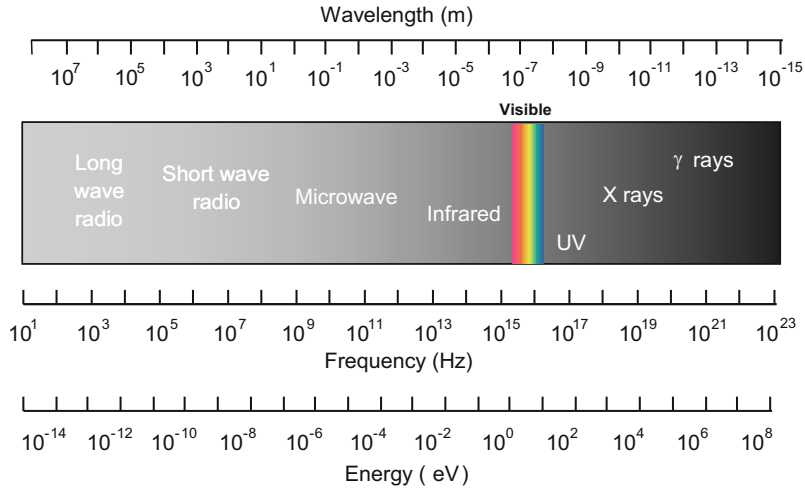

Fig. 2 The electromagnetic spectrum showing energy in units of eV

most interest in nuclear medicine and radiological imaging.

Electromagnetic Radiation

Electromagnetic radiation is pure energy. The amount of energy associated with each "bundle," or quantum, of energy is determined by the frequency or wavelength (λ) of the radiation. Human senses are capable of detecting some forms of electromagnetic radiation, for example, thermal radiation, or heat, ($\lambda \approx 10^{-5}$m), and visible light ($\lambda \approx 10^{-7}$m). The energy of the radiation can be absorbed to differing degrees by different materials: light can be stopped (absorbed) by paper, whereas radiation with longer wavelength (e.g., radio waves) or higher energy (γ-rays) can penetrate the same paper.

It had long been known that light acted like a wave, most notably because it caused interference patterns from which the wavelength of the light could be determined. Radiation was thought to emanate from its point of origin like ripples on the surface of a pond after a stone is dropped into it. This concept was not without its difficulties, most notably, the nature of the medium through which the energy was transmitted. This proposed medium was known as the "ether," and many experiments sought to produce evidence of its existence to no avail. Einstein, however, interpreted some experiments performed at the turn of the twentieth century where light shone on a photocathode could induce an electric current (known as the *photoelectric effect*) as showing that light acted as a particle. Einstein proposed that radiant energy was quantized into discrete packets, called photons. Thus, electromagnetic radiation could be viewed as having wave-like and particle-like properties. This view persists to this day and is known as the wave-particle duality. In 1924 Louis Victor, the duc de Broglie, proposed that if wave-particle duality could apply to electromagnetic radiation, it could also apply to matter. It is now known that this is true: electrons, for example, can exhibit particle-like properties such as when they interact like small billiard balls or wave-like properties as when they undergo diffraction. Electrons can pass from one position in space to another, separated by a "forbidden zone" in which they cannot exist, and one way to interpret this is that the electron is a wave that has zero amplitude within the forbidden zone. The electrons could not pass through these forbidden zones if viewed strictly as particles. An important subsequent postulate proposed by Niels Bohr was that de Broglie's principle of wave-particle duality was complementary. He stated that either the wave or the particle view can be taken to explain physical phenomena, but not both at the same time.

Electromagnetic radiation has different properties depending on the wavelength, or energy, of

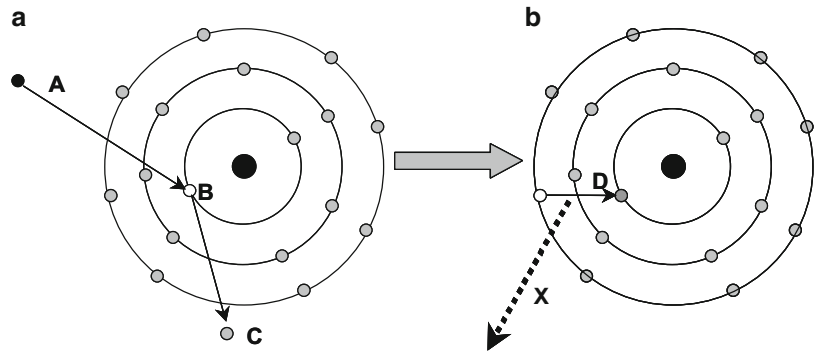

Fig. 3 The production of characteristic X-rays is shown. The electron (*A*) causes a vacancy at *B* with the liberated electron (*C*) leaving the atom. An outer-shell electron (*D*) drops down to fill the vacancy and, in doing so, gives off a discrete amount of radiation as a characteristic X-ray

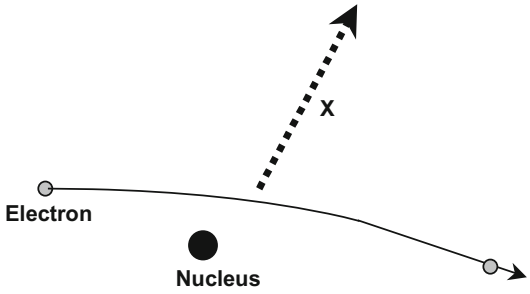

Fig. 4 Continuous radiation emitted by an electron under the influence of the nucleus is known as Bremsstrahlung

the quanta. Only higher-energy radiation has the ability to ionize atoms, due to the energy required to remove electrons from atoms. Electromagnetic radiation which can cause ionization is restricted to X- and γ-rays, which are discussed in the following sections.

X-Rays

X-rays are electromagnetic radiation produced within an atom, but outside of the nucleus. Characteristic X-rays are produced when orbital electrons drop down to fill vacancies in the atom after an inner-shell electron is displaced, usually by firing electrons at a target in a discharge tube. As the outer-shell electron drops down to the vacancy, it gives off energy and this is known as a characteristic X-ray as the energy of the X-ray is determined by the difference in the binding energies between the electron levels (see Fig. 3).

As any orbital electron can fill the vacancy, the quanta emitted in this process can take a number of energies. The spectrum is characteristic, however, for the target metal and this forms the basis of quantitative X-ray spectroscopy for sample analysis. The spectrum of energies emerging in X-ray emission displays a continuous nature, however, and this is due to a second process for X-ray production known as *Bremsstrahlung* (German: "braking radiation"), as shown in Fig. 4.

Bremsstrahlung radiation is produced after a free electron with kinetic energy is decelerated by the influence of a heavy target nucleus. The electron and the nucleus interact via a Coulomb (electrostatic charge) interaction, the nucleus being positively charged and the electron carrying a single negative charge. The process is illustrated in Fig. 6. The electron loses kinetic energy after its deceleration under the influence of the target nucleus, which is given off as electromagnetic radiation. There will be a continuum of quantized energies possible in this process depending on the energy of the electron, the size of the nucleus, and other physical factors, and this gives the continuous component of the X-ray spectrum.

X-rays generally have energies in the range of $\sim 10^3$–10^5 eV and can be used for imaging as well as therapy.

Gamma Radiation (γ)

Gamma rays are electromagnetic radiation emitted from the nucleus after a spontaneous nuclear decay. This is usually associated with the emission of an alpha or beta particle although there are alternative decay schemes. X- and γ-rays are

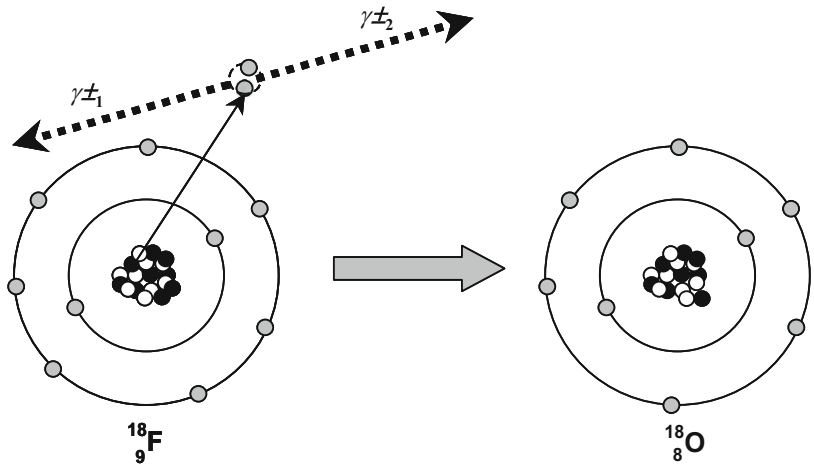

Fig. 5 The radioactive decay of ^{18}F by positron emission is shown. The emitted positron annihilates with an electron in the surrounding environment, and two annihilation photons (γ±) are emitted

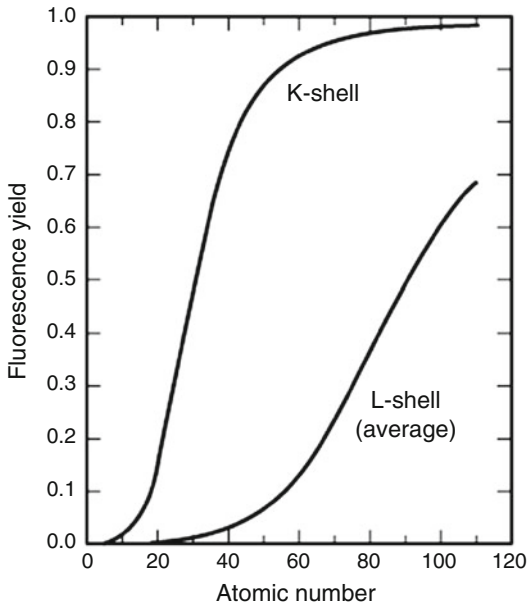

Fig. 6 Fluorescence yield of Auger electrons from the K and L shells is shown as a function of atomic number

indistinguishable after they are emitted from the atom and only differ in their site of origin. After the emission of a particle in a radioactive decay, the nucleus can be left in an excited state and this excess energy is given off as a γ-ray.

Gamma ray emission is characteristic, and it is determined by the difference in energy levels between the initial and final states of the energy level transitions within the nucleus.

Annihilation Radiation (γ±)

Annihilation radiation is the energy produced in the form of photons (usually two) by the positron–electron annihilation process. The energy of the radiation is equivalent to the rest mass of the electron and positron. Annihilation radiation, arising from positron–electron annihilation, is produced outside of the nucleus and often outside of the positron-emitting atom. There are two photons produced by each positron decay and annihilation. Each photon has energy of 0.511 MeV, and the photons are given off at close to 180° opposed directions (see Fig. 5). It is this property of collinearity that we exploit in positron emission tomography (PET), allowing us to define the line of sight of the event without the need for physical collimation. The general equation for β^+ decay is:

$$ {}^{A}_{Z}X \rightarrow {}_{Z-1}{}^{A}Y \quad + \quad \beta^{+} $$

Particulate Radiations

Particle emission from radioactive decay was the first observation of natural radioactivity. Wilhelm Röntgen had produced X-rays in 1896, and a year later, Henri Becquerel showed that naturally occurring uranium produced radiation spontaneously. While the radiation was thought initially to be similar to Röntgen's X-rays, Lord Rutherford showed that some types of radiation were more penetrating than others. He called the less penetrating radiation

alpha (α) rays and the more penetrating ones beta (β) rays. Soon after, it was shown that these radiations could be deflected by a magnetic field, i.e., they carried charge. It was clear that these were not electromagnetic rays and were, in fact, particles.

Alpha Radiation (α)

Alpha particles are emitted from large nuclei, often as part of a radioactive series (e.g., thorium series, radium series). An α-particle consists of two protons and two neutrons and thus is identical to a doubly ionized helium atom. For this reason it is often written as ${}_2^4He^{2+}$. Alpha decay results in a daughter nuclide with an atomic number of 2 less than the parent nuclide and a mass number of 4 less. The equation for α decay is:

$$ {}_Z^AX \rightarrow {}_{Z-2}^{A-4}Y + {}_2^4He^{2+}(\alpha \text{ particle}) + \gamma $$

Over the last several years, researchers have taken an interest in the use of α-particle-emitting radionuclides attached to tumor-specific targeting agents, such as antibodies. The advantage of α-particles for targeted radionuclide therapy is their high energy (5–9 MeV) and short range (50–90 μm) resulting in a high density of local energy deposition close to the decay site. Therefore α-emitters are especially suited to the treatment of disseminated cancers such as leukemias or micrometastatic disease. In addition, the high rate of the energy loss per unit track length, referred to as the linear energy transfer (LET), results in a greater radiobiological effectiveness of cell kill for α-particles relative to β-s and photon (low LET) radiations. Radiation dose estimates to normal tissues for α-particle-emitting radionuclides can be made (if imaging data resulting from concomitant X- or γ-rays emitted have been obtained) using the medical radiation dose committee (MIRD) assumption of total local absorption for non-penetrating radiations. However, the calculated organ and tissue doses need to be accepted with the following caveats: (i) at low doses the stochastic nature of energy deposition must be considered, i.e., an average dose of 0.2 Gy is the consequence of a Poisson distribution of cellular hits in which some cell nuclei receive α-particle hits, while others receive no hits; (ii) the microdistribution of the agent may be non-homogenously distributed with respect to the biological organ or structure, e.g., radium bone-seeking agents may deposit on bone surfaces, leading to high doses at the marrow–bone interface with zero dose to the central marrow regions; and (iii) the selective uptake or accumulation of α-emitters to cells can result in local doses that greatly exceed the average tissue dose.

Although not common, α-particle-emitting radionuclides have begun to be employed in the clinic. Current indications include ^{213}Bi (and ^{225}Ac)-labeled M195 antibody against leukemia, [^{211}At]-anti-tenascin antibody against brain tumors, [^{211}At]-methylene blue for melanoma, and, perhaps most importantly, the recent approval in Europe and the USA of $^{223}RaCl_2$ (Xofigo®) as a therapy for bone metastases in patients with castrate-resistant prostate cancer. Radium, as a calcium analog, localizes in regions of bone remodeling, frequently the sites of metastatic disease. The extremely short range (<80 μm) of the α-emissions mean that the radiation dose is highly locally deposited, killing cancer cells residing at the bone surfaces, yet sparing hematopoietic stem cells, many of which are located deeper within the marrow spaces and beyond the range of the alpha radiation dose.

Beta Radiation (β^-)

Beta decay is any process in which the nuclear charge changes by one. This includes β^-, β^+, and electron capture decays. Beta-minus particles are emitted from nuclei which have an excess of neutrons and are done in an attempt to approach the line of nuclear stability in terms of the relative number of protons and neutrons within the atomic nucleus. A β^- particle consists of an electron ejected from the nucleus after a neutron is converted into a proton. The β^- is ejected so that charge is conserved during this transformation. Beta-minus decay results in a daughter nuclide with an atomic number of 1 greater than the parent nuclide and a mass number which is unchanged. Beta-minus particles have a continuous range of energies up to a maximum. This appeared at first to be a violation of the conservation of energy. To overcome this problem, in 1931 Wolfgang Pauli

proposed that another particle was emitted which he called the neutrino (ν). He suggested that this particle had a very small mass and zero charge. It could carry away the excess momentum to account for the difference between the maximum beta energy and the spectrum of energies that the emitted beta particles displayed. In fact we now refer to the neutrino emitted in beta-minus decay as the antineutrino, indicated by the "¯" over the symbol ν.

The equation for β^- decay is

$$ {}^{A}_{Z}X \rightarrow {}_{Z+1}{}^{A}Y + \beta^- \quad + \overline{\nu} $$

The nucleus of the daughter nuclide is often left in an excited state with excess energy, and therefore this energy is often emitted in the form of a gamma ray after β^- decay.

The following shows an example of a beta-decay scheme for ^{131}I:

$$ {}^{131}_{53}I \rightarrow {}^{131}_{54}Xe + {}^{0}_{-1}\beta^- + \gamma + \overline{\nu} $$

The half-life for ^{131}I decay is 8.02 days. The most abundant β^- particle emitted has a maximum energy of 0.606 MeV, and there are many associated γ-rays, the most abundant (branching ratio = 0.81) having an energy of 0.364 MeV.

β^- Dosimetry

The most commonly used radionuclide for nuclear medicine therapies is ^{131}I, which is used for the treatment of a variety of thyroid disorders, benign and malignant, as well as for a several therapeutic radiolabeled antibody therapies such as ^{131}I-tositumomab (Bexxar®) for the treatment of follicular, non-Hodgkin's lymphoma. The pure β^- emitter ^{90}Y has also become routinely used for radioimmunotherapy applications, e.g., ibritumomab tiuxetan (Zevalin®), for the treatment of B-cell non--Hodgkin's lymphoma. The use of ^{90}Y-resin microspheres (SIR-Spheres®) has also become used as a new intra-arterial therapy for the treatment of hepatocellular carcinoma (HCC) and other diseases metastatic to liver. An advantage of ^{90}Y is the extremely low yield of penetrating photon emissions (only Bremsstrahlung radiation) facilitating the handling of large activities and resulting in lower radiation exposures to personal within proximity of the patients. However, the lack of photons for imaging can be a disadvantage when using ^{90}Y radiopharmaceuticals, and therefore to verify safety of delivery, protocols usually incorporate a pre-scan using the ^{111}In-labeled agent. Another β^--emitting radionuclide in increasing clinical use is ^{188}Re. This radionuclide has the advantage that it is produced from a tungsten-188 generator system, making it more readily available for use in developing nations, without access to radionuclide production facilities. ^{188}Re-lipiodol is an alternative to ^{90}Y-microspheres for the treatment of HCC and has the advantage of allowing imaging (using the 155 keV γ – 15% abundance)-based treatment planning. The average β^--emission energy is high at 795 keV, comparable to the 935 keV of ^{90}Y.

The dose versus distance for a point source of beta particles obeys the relationship first described by Loevinger [1], which consists of an inverse square geometric term and a power term to account for absorption. The dose from a point source therefore falls more sharply than the inverse square law. However, for distributed sources as in most medical applications of radiopharmaceuticals employing β^- sources, the dose is assumed to be uniform within most organ structures. The MIRD methodology classifies all β^- particles as non-penetrating radiations that are deposited locally within the source organ, i.e., cross fire between different organs is considered to be negligible. A detailed discussion of the heterogeneity of β^--emitting radiopharmaceuticals and the dosimetric implications is provided in ICRP Report 67 [2].

Positron Decay (β^+) and Electron Capture (EC)

A proton-rich radionuclide has two options for converting a proton into a neutron in an attempt to reach the line of stability: (i) positron decay and (ii) electron capture. Positron emission from the nucleus is secondary to the conversion of a proton into a neutron as in:

$$ {}^{1}_{1}p^+ \rightarrow {}^{1}_{0}n + {}^{0}_{1}\beta^+ \nu $$

with in this case a neutrino being emitted. The positron is the antimatter conjugate of the electron emitted in beta-minus decay.

The general equation for β^+ decay from an atom is

$$ {}^{A}_{Z}X \rightarrow {}_{Z-1}{}^{A}Y + {}^{0}_{1}\beta^{+} + \nu $$

The atom X is proton rich and achieves stability by converting a proton to a neutron. The positive charge is carried away with the positron. As the daughter nucleus has an atomic number one less than the parent, one of the orbital electrons must be ejected from the atom to balance charge. This is often achieved by a process known as internal conversion, where the nucleus supplies energy to an orbital electron to overcome the binding energy and leave it with residual kinetic energy to leave the atom. As both a positron and an electron are emitted in β^+ decay, the daughter nucleus must be at least two electron masses lighter than the parent.

The β^+ will have an initial energy after emission, which, similar to the case of beta-minus decay, can take a continuum of values up to a maximum. After emission from the nucleus, the β^+ loses kinetic energy by interactions with the surrounding matter.

The competing process, electron capture, occurs when an electron passing in the vicinity of the nucleus is "captured" by the nucleus and combined with a proton to produce a neutron. This has the same effect as positron emission, i.e., that a proton is converted into a neutron. This process, which in many proton-rich radionuclides competes with positron emission, may occur in a significant fraction of nuclear transformations. Many β-emitting tracers involve a competition in which a fraction of the decays occur by each process. For example, ^{18}F decays 96.9% by β^+ emission and 3.1% by electron capture. It is important to note that it is an advantage for β^+ emitters used for PET functional imaging to have shorter half-life to minimize the radiation dose to the patient. However, for applications in which tumor-specific macromolecules such as antibodies that exhibit both slow blood clearance and tumor uptake are employed, long-lived PET radionuclides are mandatory, examples of which are ^{124}I (4.2 days half-life) and ^{89}Zr (3.3 days half-life). These diagnostic PET radionuclides can result in a radiation dose burden to a patient per unit administered activity, which is similar to ^{131}I, the β^- emitter commonly used for therapeutic applications. This places significant restraints on the multiplicative usage of radioimmuno-PET and is a major impetus in the rapid interest in tumor-targeting peptides, whose rapid blood clearance allows the use of short-lived PET radionuclide such as ^{68}Ga; examples include DOTATATE which binds to somatostatin receptors and ^{68}Ga-binding PSMA peptides.

Several of the radionuclides most widely employed in nuclear medicine are those which decay exclusively by electron capture such as ^{67}Ga, ^{123}I, and ^{201}Tl. The equation for electron capture (EC) is

$$ {}^{A}_{Z}X + e^{-} \rightarrow {}_{Z-1}{}^{A}Y + \nu $$

From the dosimetric perspective, such radionuclides have been preferred because instead of high-energy β^- emissions, they emit very low-energy X-ray and particulate emissions called Auger and Coster–Kronig electrons.

Auger Electrons

Auger electrons are emitted as a consequence of atomic relaxation after the electron captured by the nucleus leaving the atom with an inner-shell atomic electron shell vacancy. Most commonly we learn that any inner shall vacancy is rapidly filled by an electron transition from a higher orbital, thereby resulting in a characteristic X-ray of energy equal to the difference between the binding energies of the two electron shells (E_{b1}–Eb_2). However, this same energy can be instantaneously transferred to an additional outer-shell orbiting electron of binding energy E_{b3}, which is ejected with energy equal to (E_{b1}–E_{b2}) – E_{b3}. Electrons emitted from the atom in this way are referred to as either Auger electrons or Coster–Kronig electrons if the ejected electron emanates from the same orbital as the electron involved in the transition to fill the initial

inner-shell vacancy. Electrons are classified by the electron shells involved. For example, an Auger electron could be K–L–M, which would mean that the initial vacancy arose in the K shell was filled by an electron from the L shell resulting in an electron ejected from the M shell (see Fig. 6). Since Auger and Coster–Kronig electrons are the consequence of transitions between electron orbitals, they have discrete energies (unlike β^- particles) which are emitted as an energy spectrum. The energies of Auger and Coster–Kronig electrons range from that just below the characteristic X-ray energies to a few electron volts. The ranges of these electrons are mostly submicron.

The fraction of initial inner-shell vacancies filled by radiative or fluorescent transitions, i.e., with characteristic X-ray emission, relative to the total radiative and non-radiative (Auger) is given by the fluorescent yield. The fluorescent yield decreases with increasing atomic number. This means that radiative transitions for high-Z radionuclides, e.g., ^{201}Tl, the filling of a K-shell vacancy is almost always by radiative transition. However, such transitions are mostly K–L transitions, moving the vacancy to the L shell. Since the fluorescent yield for the L shell is small, these vacancies as well as subsequent to higher shells are mostly non-radiative. A consequence of non-radiative transition is a cascade of inner-shell electron transitions (and Auger electron emission) until all vacancies have reached the outermost atomic shell. Therefore the number of Auger and Coster–Kronig electrons increases with increasing atomic number of the radionuclide.

The total energy emitted during the atomic de-excitation is shared between the Auger and Coster–Kronig electrons and fluorescent X-ray photons emitted. Since the total energy emitted is small, it has often been disregarded in organ and total body dosimetry estimates. In general the dose contribution from Auger and Coster–Kronig electrons is extremely small, hence the appropriate selection of electron capture (and isomeric transition – see later) decaying radionuclides for imaging purposes. However, under specific circumstances, the cascade of soft electrons emitted as a consequence of electron capture decay can produce high-LET-like biological effects. This was first observed in experiments in which the electron capture decaying radionuclide ^{125}I was directly incorporated into the cellular DNA via the thymidine analog [^{125}I]-iododeoxyuridine. However, for decays at other intracellular locations such as in cytosol or membrane bound, the radiation effects were comparable of β^- particles. For a detailed summary of Auger electron dosimetry and their biological effects, the reader is referred to the paper by AAPM Nuclear Medicine task group no. 6 [3].

Auger electron emitters have been used in clinical studies in order to selectively exploit the high-LET effectiveness of these agents when targeted to cancer cells. Such work has included the use of [^{125}I]-thymidine precursors as well as ^{125}I-labeled antibodies. A review of these efforts in Auger targeting therapies can be found by Mariani et al. [4].

Isomeric Transition (IT) and Internal Conversion (IC)

If, subsequent to a nuclear decay, an excited nuclear state exists for a defined period of time (>1 ns), with subsequent release of the excess energy by γ-emission, this is termed an *internal* or *isomeric transition*. We have seen that both α- and β^--emissions are often both associated with spontaneous γ-ray emission. In some cases, however, the nucleus remains in an excited state for an appreciable time, and this is termed an *isomeric* state denoted by the symbol *m* (for "metastable") appended to the mass number (e.g., ^{99m}Tc, ^{113m}In, etc.). As the energy is released via γ-emission, there is no change to the number of nucleons and the only change is the loss of energy. The equation for an isomeric transition is

$$ {}^{Am}_{Z}X \rightarrow {}^{A}_{Z}X + \gamma $$

An alternative to an isomeric transition is a process known as *internal conversion*. In this process, the energy that would have been emitted as a γ-ray is transferred to an orbital electron and the electron is ejected from the atom. The energy of the liberated IC electron is equal to the energy of the corresponding γ-ray minus the binding energy of the electron shell the electron was liberated from.

As with electron capture, internal conversion results in the atom being left in a state with an inner-shell vacancy from which a cascade of inner-shell electron transitions ensues yielding both characteristic X-rays and Auger and Coster– Kronig electrons.

The most common radionuclide used in nuclear medicine is ^{99m}Tc that undergoes this type of decay with a half-life of 6.02 h. De-excitation of the metastable state occurs 88.9% through the emission of a 140.5 keV γ-ray and 11.1% through internal conversion. In addition to radionuclides undergoing isomeric transitions, rapid internal conversion may occur subsequent to any β-decay process. For example, ^{123}I decays by electron capture, but a significant percentage (∼18%) of the 159 keV γ-rays undergoes internal conversion.

Radioactive Decay

The rate at which nuclei spontaneously undergo radioactive decay is characterized by the parameter called the half-life of the radionuclide. The half-life is the time it takes for half of the unstable nuclei present to decay. It takes the form of an exponential function, where the number of atoms decaying at any particular instant in time is determined by the number of unstable nuclei present and the decay constant (λ) of the nuclide. The rate of decay of unstable nuclei at any instant in time is called the activity of the radionuclide. The activity of the nuclide after a time t is given by

$$A_t = A_0 e^{-\lambda_d t}$$

where A_0 is the amount of activity present initially, A_t is the amount present after a time interval t, and λ_d is the decay constant. The decay constant is found from:

$$\lambda_d = \frac{\log_e(2)}{t_{1/2}}$$

where the units for λ_d are time^{-1}. The SI unit for radioactivity is the Becquerel (Bq). One Becquerel (1Bq) equals one disintegration per second.

Interaction of Radiation with Matter

When high-energy radiation interacts with matter, energy can be transferred to the material. A number of effects may follow, but a common outcome is the ionization or excitation of the atoms in the absorbing material. To facilitate the description of these interaction processes, radiations are commonly divided into particulate and non-particulate or photon radiation. Particulate radiations are then further divided into whether they are charged (electrons, protons, α-particles) or uncharged (neutrons) particles.

Interaction of Particulate Radiation with Matter

The particulate emissions encountered in nuclear medicine applications include electrons (β^- particles) and α-particles. β^- particles are light charged particles and therefore continuously undergo electrostatic interactions with the outer-shell atomic electrons of the medium through which they traverse. Each interaction may result in an elastic or nonelastic scattering, changing the direction of the electron. With inelastic scattering events, sufficient energy may be transferred to the orbiting atomic electrons of the medium to either excite or ionize the atom. It is this energy deposition resulting in ionization to tissue that results in the biologically relevant radiation dose. Such energy transfers along the track of the β^- so that the particle slows down until it has no more energy and reaches the end of its range. A small fraction of the electrons pass through the electron clouds and are deflected by the nucleus. The strong positive charge field of the nucleus causes the electron to undergo a massive angular deflection and therefore decelerate. This process of rapid deceleration causes the charged electron to lose energy radiatively by X-ray emission. The X-rays released by this mechanism are referred to as Bremsstrahlung which means "braking radiation." In tissue, the dominant means of energy transfer is through collisional losses from electron– electron interactions. However, the yield of Bremsstrahlung increases with increasing β-particle energy (is important for ^{90}Y or ^{32}P but insignificant for ^{3}H) and

becomes especially important for high-Z materials such as lead (the Bremsstrahlung yield varies with Z^2). It is for this reason that it is better to contain a high-energy β-source, e.g., ^{90}Y, in a plastic vial behind which is lead, rather than place such sources directly into a lead container. β-Sources would produce a significant Bremsstrahlung fluence from a high-Z container, resulting in a greater radiation exposure than from the defined range resulting from the β-particles themselves.

Charged α-particles lose their energy through the same interaction processes as β^- particles. However, α-particles lose their energy much more quickly. Even an 8 MeV α-particle can travel only ~80 μm in the soft tissue. This is because of the much high stopping power associated with the higher (+2) charge and large mass of the He nucleus. As a consequence α-particles are not a significant radiation protection concern unless radionuclides emitting such particles are directly ingested.

Neutrons are uncharged particles that interact with matter through direct collisions with intranuclear nucleons (protons and neutrons). It is through "knock-on" protons that charged particles are set in motion and atomic ionizations occur. Since neutron (or proton) sources are not used in nuclear medicine applications, they are beyond the scope of this book.

Interaction of Photons with Matter

High-energy photons interact with matter by three main mechanisms, depending on the energy of the electromagnetic radiation. These are (i) the photoelectric effect, (ii) the Compton effect, and (iii) pair production. In addition, there are other mechanisms such as coherent (Rayleigh) scattering, an interaction between a photon and a whole atom which predominates at energies less than 50 keV, triplet production, and photonuclear reactions, where high-energy gamma rays induce decay in the nucleus and which require energies of greater than ~10 MeV. We will focus on the three main mechanisms which dominate in the energies of interest in imaging in nuclear medicine.

Photoelectric Effect

The photoelectric effect occupies a special place in the development of the theory of radiation. During the course of experiments which demonstrated that light acted as a wave, Hertz and his student Hallwachs showed that the effect of an electric spark being induced in a circuit due to changes in a nearby circuit could be enhanced if light was shone upon the gap between the two coil ends. They went on to show that a negatively charged sheet of zinc could eject negative charges if light was shone upon the plate. Philipp Lenard demonstrated in 1899 that the light caused the metal to emit electrons. This phenomenon was called the photoelectric effect. These experiments showed that the electric current induced by the ejected electrons was directly proportional to the intensity of the light. The interesting aspect of this phenomenon was that there appeared to be a light intensity threshold below which no current was produced. This was difficult to explain based on a continuous wave theory of light. It was these observations that led Einstein to propose the quantized theory of the electromagnetic radiation in 1905, for which he received the Nobel Prize.

The photoelectric effect is an interaction of photons with orbital electrons in an atom. This is shown in Fig. 7. The photon transfers all of its energy to the electron. Some of the energy is used to overcome the binding energy of the electron,

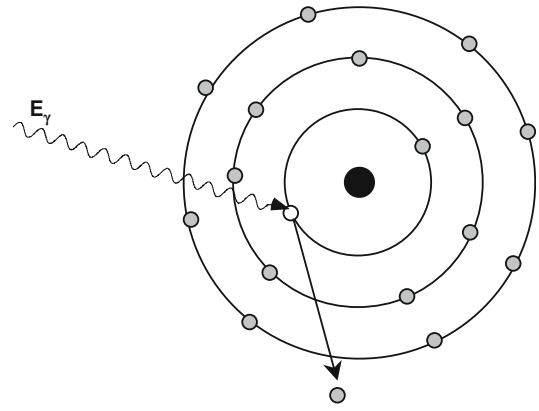

Fig. 7 The photoelectric effect. An incident photon displaces an inner-shell electron, thereby ionizing the atom. X-rays and Auger electrons may be produced after as the vacancy is filled by an outer-shell electron

and the remaining energy is transferred to the electron in the form of kinetic energy. The photoelectric effect usually occurs with an inner-shell electron. As the electron is ejected from the atom (causing ionization of the atom), a more loosely bound outer orbital electron drops down to occupy the vacancy. In doing so it will emit radiation itself due to the differences in the binding energy for the different electron levels. This is a characteristic X-ray. The ejected electron is known as a photoelectron. Alternately, instead of emitting an X-ray, the atom may emit a second electron to remove the energy and this electron is known as an Auger electron. This leaves the atom doubly charged. Characteristic X-rays and Auger electrons are used to identify materials using spectroscopic methods based on the properties of the emitted particles.

The photoelectric effect dominates in human tissue at energies less than approximately 100 keV. It is of particular significance for X-ray imaging and for imaging with low-energy radionuclides. It has little impact at the energy of annihilation radiation (511 keV), but with the development of combined PET/CT systems, where the CT system is used for attenuation direction of the PET data, knowledge of the physics of interaction via the photoelectric effect is extremely important when adjusting the attenuation factors from the X-ray CT to the values appropriate for 511 keV radiation.

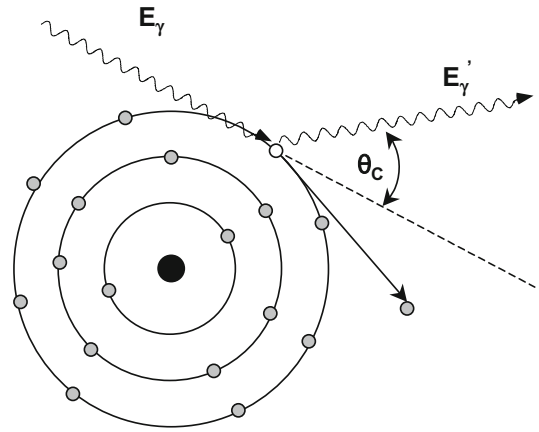

Fig. 8 Compton scattering occurs when a photon interacts with a loosely bound electron in an outer orbital shell. The atom is ionized and the photon undergoes a deflection causing a change in direction through the angle $\boldsymbol{\theta}_C$. This interaction is of most interest as a degrading factor in nuclear medicine imaging and quantification

Compton Scattering

Compton scattering is the interaction between a photon and a loosely bound orbital electron. The electron is so loosely connected to the atom that it can be considered to be essentially free. This effect dominates in the human tissue at energies above approximately 100 keV and less than ~2 MeV. The binding potential of the electron to the atom is extremely small compared with the energy of the photon, such that it can be considered to be negligible in the calculation. After the interaction, the photon undergoes a change in direction and the electron is ejected from the atom. The energy loss by the photon is divided between the small binding energy of the energy level and the kinetic energy imparted to the Compton recoil electron. The energy transferred does not depend on the properties of the material or its electron density.

The energy of the photon after the Compton scattering can be calculated from the Compton equation:

$$E'_\gamma = \frac{E_\gamma}{1 + \frac{E_\gamma}{m_0 c^2}(1 - \cos(\theta c))}$$

where E_γ and E'_γ are the incident and resulting gamma ray energies, respectively, m_0c^2 is the rest-mass equivalent energy of the electron, and θ_C is the scattering angle of the photon (see Fig. 8). From the consideration of the Compton equation, it can be seen that the maximum energy loss occurs when the scattering angle is 180° (cos $\{180°\}) = -1$), i.e., the photon is backscattered.

Pair Production

The final main mechanism for photons to interact with matter is by pair production. When photons with energy greater than 1.022 MeV (twice the energy equivalent to the rest mass of an electron) pass in the vicinity of a nucleus, it is possible that

they will spontaneously convert into two electrons with opposed signs, to conserve charge. This direct electron pair production in the Coulomb field of a nucleus is the dominant interaction mechanism at high energies. Above the threshold of 1.022 MeV, the probability of pair production increases as energy increases. At 10 MeV, this probability is about 60%. Any energy left over after the production of the electron–positron pair is shared between the particles as kinetic energy, with the positron having slightly higher kinetic energy than the electron as the interaction of the particles with the nucleus causes an acceleration of the positron and a deceleration of the electron.

Pair production was first observed by Anderson using cloud chambers in the upper atmosphere, where high-energy cosmic radiation produced tracks of diverging ionization left by the electron–positron pair.

The process of pair production demonstrates a number of conservation laws. Energy is conserved in the process as any residual energy from the photon left over after the electron pair is produced is carried away by the particles as kinetic energy; charge is conserved as the incoming photon has zero charge and the outgoing positive and negative electrons have equal and opposite charge; and momentum is conserved as the relatively massive nucleus absorbs momentum without appreciably changing its energy balance (see Fig. 9).

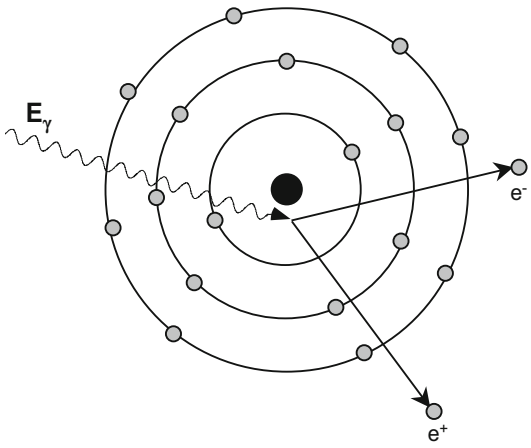

Fig. 9 Pair production occurs when a high-energy photon passes in the vicinity of the strong nuclear force. A positron–electron pair may be spontaneously created

At energies above four rest-mass equivalents of the electron, pair production can take place in the vicinity of an electron. In this case it is referred to as "triplet production" as there is a third member of the interaction, the recoiling electron.

Attenuation and Scattering of Photons

In the previous section, we have seen how radiation interacts with matter at an atomic level. In this section we will examine the bulk "macroscopic" aspects of the interaction of radiation with matter, with particular reference to positron emission and detection.

Calculations of photon interactions are given in terms of atomic cross sections (σ) with units of cm^2/atom. An alternative unit, often employed, is to quote the cross section for interaction in barns/atom (b/atom) where 1 barn = 10^{-24} cm^2. The total atomic cross section is given by the sum of the cross sections for all of the individual processes, i.e.,

$$\sigma_{\text{tot}} = \sigma_{\text{pe}} + \sigma_{\text{incoh}} + \sigma_{\text{coh}} + \sigma_{\text{pair}} + \sigma_{\text{tripl}} + \sigma_{\text{nph}}$$

where the cross sections are for the photoelectric effect (pe), incoherent Compton scattering (incoh), coherent (Rayleigh) scattering (coh), pair production (pair), triplet production (tripl), and nuclear photoabsorption (nph). Values for attenuation coefficient are often given as mass attenuation coefficients (μ/ρ) with units of $cm^2.g^{-1}$. The reason for this is that this value can be converted into a linear attenuation coefficient (μl) for any material simply by multiplying by the density (ρ) of the material:

$$\mu_l\left(\text{cm}^{-1}\right) = \mu/\rho\left(\text{cm}^2 \cdot \text{g}^{-1}\right)\mu/\rho\left(\text{g} \cdot \text{cm}^{-3}\right)$$

The mass attenuation coefficient is related to the total cross section by

$$\mu/\rho\left(\text{cm}^2 \cdot \text{g}^{-1}\right) = \frac{\sigma_{\text{tot}}}{u(g)A}$$

Table 1 Narrow-beam (scatter-free) linear attenuation coefficients for some common materials at 140 keV (the energy of ^{99m}Tc photons) and annihilation radiation (511 keV) (Tabulated from Hubbell [5] and *ICRU Report 44 [6] and [7], [8]). ¶This is the density of non-inflated lung. §Measured experimentally

Material	Density(ρ) [g×cm^{-3}]	μ (140 keV) [cm^{-1}]	μ (511 keV) [cm^{-1}]
Adipose tissue*	0.95	0.142	0.090
Water	1.0	0.150	0.095
Lung*	1.05¶	∼0.04–0.06§	∼0.025–0.04§
Smooth muscle	1.05	0.155	0.101
Perspex (Lucite)	1.19	0.173	0.112
Cortical bone*	1.92	0.284	0.178
Pyrex glass	2.23	0.307	0.194
NaI(Tl)	3.67	2.23	0.34
Bismuth germanate (BGO)	7.13	∼5.5	0.95
Lead	11.35	40.8	1.75

where $u(g) = 1.661 \times 10^{-24}$g is the atomic mass unit ($1/N_A$ where N_A is Avogadro's number) defined as 1/12th of the mass of an atom of ^{12}C and A is the relative atomic mass of the target element.

Photon Attenuation

We have seen that the primary mechanism for photon interaction with matter at energies in the range 0.1–2 MeV is by a Compton interaction. The result of this form of interaction is that the primary photon changes direction (i.e., is "scattered") and loses energy. In addition, the atom where the interaction occurred is ionized.

For a well-collimated source of photons and detector, attenuation takes the form of a mono-exponential function, i.e.,

$$I_x = I_0 e^{-\mu x}$$

where I represents the photon beam intensity; the subscripts "0" and "x" refer, respectively, to the unattenuated beam intensity and the intensity measured through a thickness of material of thickness x; and μ refers to the attenuation coefficient of the material (units: cm^{-1}). Attenuation is a function of the photon energy and the electron density (Z number) of the attenuator. The attenuation coefficient is a measure of the probability that a photon will be attenuated by a unit length of the medium. The situation of a well-collimated source and detector is referred to as narrow-beam condition. The narrow-beam linear attenuation coefficients for some common materials at 140 keV and 511 keV are shown in Table 1.

However, when dealing with in vivo imaging, we do not have a well-collimated source, but rather a source emitting photons in all directions. Under these uncollimated, broad-beam conditions, photons whose original emission direction would have taken them out of the acceptance angle of the detector may be scattered such that they are counted. This is known as a "broad-beam" conditions indicating increased acceptance of scattered photons leading to an overall lower effective attenuation coefficient.

Radionuclides Used in Nuclear Oncology

Nuclear medicine uses radionuclides for both diagnostic studies (including some non-imaging ones) and therapeutic applications. Diagnostic studies include γ-emitting radionuclides produced in nuclear reactors or cyclotrons as well as β^+-emitting radionuclides. Therapeutic radionuclides always emit a particle and may or may not emit a γ-ray which can be used to image the radionuclide distribution and uptake. Table 2 summarizes the main radionuclides of interest in nuclear oncology and their principal emissions and other characteristics. Only the dominant emissions are shown.

Table 2 Radionuclides of interest in nuclear oncology

Radionuclide	Half-life	Principal radiations emitted	Energy of emission (MeV)	Abundance (in same order as emissions)
^{11}C	20.5 min	$\beta^+(\gamma\pm)$	0.39	100%
^{13}N	9.97 min	$\beta^+(\gamma\pm)$	0.49	100%
^{15}O	122.2 s	$\beta^+(\gamma\pm)$	0.74	100%
^{18}F	109.8 min	$\beta^+(\gamma\pm)$	0.24	96.9%
^{32}P	14.2 days	β^-	0.695	100%
^{64}Cu	12.8 h	$\beta^+(\gamma\pm),\beta^-$	0.28 (β^+),0.19 (β^-)	17% (β^+),39% (β^-)
^{67}Cu	61.8 h	β^-,γ	0.116, 0.149, 0.184 (β^-), 0.185 (γ_1), 0.093 (γ_2)	57% (β^+_1), 22% (β^+_2), 20% (β^+_3), 49% (γ_1), 16% (γ_2)
^{67}Ga	78 h	γ	0.093, 0.184, 0.300, 0.394	38%, 24%, 16%, 4%

Instrumentation for Positron Emission Imaging

10

Pat Zanzonico

Abstract

This chapter reviews the underlying physical principles of positron emission tomography (PET) and the design and operation of state-of-the-art PET scanners. Although now a mature technology, PET has undergone, and continues to undergo, steady advances in hardware and software and, as a result, ongoing improvements in performance and functionality. Recent noteworthy advances include improvements in detector technology and image reconstruction, implementation of time-of-flight (TOF) technology, and the introduction of PET/MRI (positron emission tomography/magnetic resonance imaging) scanners.

Introduction

This chapter reviews the underlying physical principles of positron emission tomography (PET) and the design and operation of state-of-the-art PET scanners. Although now a mature technology, PET has undergone, and continues to undergo, steady advances in hardware and software and, as a result, ongoing improvements in performance and functionality. Recent noteworthy advances include improvements in detector technology and image reconstruction, implementation of time-of-flight (TOF) technology, and the introduction of PET/MRI (positron emission tomography/magnetic resonance imaging scanners.

Basic Principles of Radiation Detection

Radiation detectors are generally characterized as either scintillation or ionization detectors [1–3]. The application of scintillation and ionization detectors in gamma cameras and single-photon emission tomography is discussed in ▶ Chap. 11, "Instrumentation for Single-Photon Emission Imaging". In scintillation detectors, visible light is produced as radiation excites atoms of a crystal and is converted to an electronic signal, or pulse, and amplified by a photomultiplier tube (PMT) or other photodetector. In ionization detectors, free electrons produced when radiation ionizes a stopping material are collected to produce a small electronic signal. Clinical devices based on solid-state ionization detectors are available for single-photon (i.e., non-PET) imaging but remain far less common than scintillation detector-based devices.

Scintillation detectors. In scintillation detectors (Fig. 1) [1, 2], radiation interacts with and deposits energy in a scintillator. The radiation energy thus deposited is converted to visible light, with the amount of light produced being proportional to the radiation energy deposited. Because the light is emitted isotropically, the inner surface of the light-tight crystal housing is coated with a reflective material so that light emitted toward the sides and front of the crystal is

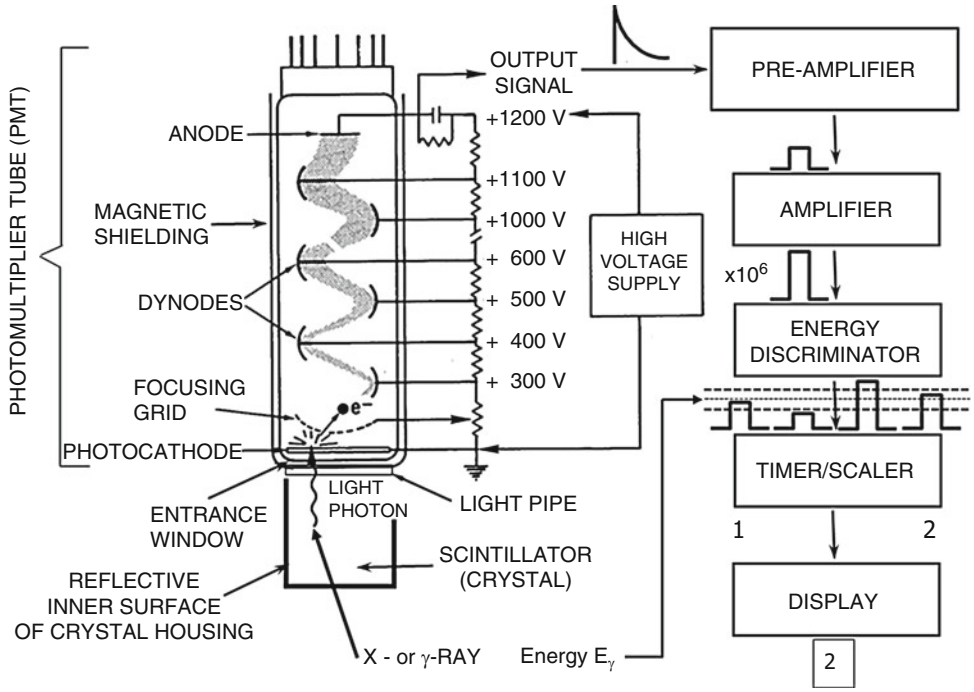

Fig. 1 Basic design and operation of a scintillation detector. Note that only two of the four pulses have heights lying between the preset pulse height ranges (indicated by the *two dash horizontal lines* below the energy discriminator, that is, corresponding to photon energies within the preset photopeak energy window) (see Fig. 1c). Thus, only those two photons are counted (in the case of a radiation counter) or included in the image (in the case of a radiation imager). The other two photons, with pulse heights and therefore energies outside the photopeak energy window, are not counted or included in the image (Adapted from references [1, 2] with permission)

reflected back toward the PMT; this maximizes the amount of light collected and therefore the overall sensitivity of the detector and ensures that the amount of light detected is proportional to the energy of the absorbed photon. Interposed between the back of the crystal and the entrance window of the PMT is the light guide, sometimes simply a thin layer of transparent optical gel. The light guide optically couples the crystal to the PMT and thus maximizes the transmission of the light signal from the crystal into the PMT.

The PMT consists of an evacuated glass enclosure, containing a series of electrodes maintained at different voltages. Coated on the inner surface of the PMT's entrance window is the photocathode. When struck by the light from the crystal, the photocathode ejects electrons. The probability that each visible light photon will eject an electron from the photocathode is 15–25%. Immediately beyond the photocathode is the focusing grid, maintained at a relatively low positive voltage relative to the photocathode. Once the "focused" electrons pass through the focusing grid, they are attracted by a relatively large positive voltage relative to the photocathode, ~300 V, on the first of a series of small metallic elements called dynodes. The resulting high-speed impact of each electron results in the ejection from the dynode surface of an average of three electrons. The electrons thus ejected are then attracted by the even larger positive voltage, ~400 V, on the second dynode. The impact of these electrons on the second dynode surface ejects an additional three electrons on average for each incident electron. Typically, a PMT has 10–12 such dynodes (or stages), each ~100 V more positive than the preceding dynode, resulting in an overall electron amplification factor of 3^{10}–3^{12} for the entire PMT. At the

collection anode, an output signal is generated. The irregularly shaped PMT output signal is shaped into a logic (i.e., square-wave) pulse that can be electronically manipulated. In the past, this was accomplished by a preamplifier; nowadays, pulse shaping, amplification, etc. are performed using solid-state electronics and computer software. The amplitudes (or "heights") of the resulting electrical pulses are proportional to the number of electrons produced at the PMT photocathode and thus the energy of the incident radiation. These pulses can then be sorted according to their respective heights by an energy discriminator (also known as a pulse height analyzer), and those pulses with a pulse height (i.e., energy) within a preset photopeak energy window are counted or included in the image. Importantly, implicit in the foregoing discussion, the amount of light produced in a scintillation detector is proportional to the radiation energy deposited in the scintillator.

In recent years, new PMT configurations have been developed that allow enhanced approaches to position determination in PET scanners. These include the position-sensitive PMT (PSPMT), which provides two-dimensional position information via two sets of wire anodes perpendicular to one another. The electrons from the last dynode stage are read out on each set of anode wires. The position of the incident light on the photocathode can then be estimated from the electron distribution on each wire. Readout of the wire anodes is typically accomplished via separate internal resistors (or functionally equivalent components) for x- and y-position information.

The silicon photodiode is an alternative to the PMT for conversion of scintillation light into electronic signals. Photodiodes typically have a gain of only 1 (compared to the ~10^6-fold gain of PMTs) and thus require low-noise electronics. The so-called avalanche photodiodes (or APDs), in which the number of electrons produced by the visible light is amplified, have considerably higher gains, of the order of 100–1,000, but still require low-noise readout electronics. An alternative to traditional vacuum-tube PMTs, Si photomultipliers (or "SiPMs"), are single-photon-sensitive devices built from a multi-pixel APD array on a Si substrate [4] and achieve essentially one-to-one correspondence between each detector element and the PMT [5]; this so-called digital SiPM design has been implemented in the Philips Vereos™ PET scanner. In the "analog" SiPM design, the signals from multiple pixels in the APD array are summed, effectively minimizing the impact of electronic noise but at the cost of additional circuitry [5]. The dimension of each single APD can vary from 20 to 100 μm and their density can be up to 1,000/mm^2. The supply voltage typically varies between 25 and 70 V, 30- to 50-fold lower than that required for traditional PMTs. Performance parameters of SiPMs are comparable to those of traditional PMTs but with a much more compact form factor.

The scintillation detection materials most widely used in Nuclear Medicine – all inorganic scintillators – are bismuth germanate (BGO, $Bi_4Ge_3O_{12}$), cerium-doped gadolinium oxyorthosilicate (GSO (Ce) or GSO, Gd_2SiO_5:Ce), cerium-doped lutetium oxyorthosilicate (LSO(Ce) or LSO, Lu_2SiO_5:Ce), and cerium-doped lutetium-yttrium oxyorthosilicate (LYSO(Ce) or LYSO, Lu_2YSiO_5:Ce) as well as thallium-doped sodium iodide (NaI(Tl)) (Table 1) [1, 2, 6, 7]. PET scanners primarily use BGO, GSO, LSO, or LYSO. The most important practical features of scintillation detectors include:

high mass density (ρ) and effective atomic number (Z_{eff}) – to maximize the photon stopping power (i.e., intrinsic efficiency ε) of the detector;
high light (scintillation) output – to maximize the signal and thus minimize statistical uncertainty in the energy of the detected signal;
for PET, speed of the output light pulse – to shorten the coincidence timing window (τ) and thus minimize the number of random events (see below) without sacrificing a significant portion of the signal.

As noted, higher-ρ and higher-Z_{eff} atomic materials such as BGO, GSO, LSO, and LYSO have emerged as the detectors of choice for PET because of their greater stopping power for 511-keV annihilation γ-rays. The mean free path (MFP) for 511-keV γ-rays is at least twice as long in NaI(Tl) than in BGO, GSO, or LSO. GSO,

Except for NaI(Tl), which is the scintillator used almost exclusively in gamma cameras, the other scintillators are used for PET

[a]The intrinsic efficiency of 2-cm thick coincidence detectors for 511-keV annihilation γ-rays

LSO, and LYSO have almost tenfold faster light output than BGO, with LSO and LYSO having a much greater (two- to threefold greater) light output than either BGO or GSO. The light output of scintillators (expressed as the number of light photons produced per MeV of radiation energy absorbed) is largely determined by quenching (i.e., the combined effect of all radiationless de-excitation processes in which the deposited energy is ultimately degraded to heat). GSO has somewhat better energy resolution, and therefore scatter rejection capability, than either BGO or LSO. A notable disadvantage of LSO and LYSO is the presence of a naturally occurring long-lived radioisotope of lutetium, lutetium-176 (^{176}Lu) [6]. ^{176}Lu has an isotopic abundance of 2.6% and a half-life of ~4×10^{10} years and emits two prompt γ-rays (88% abundance) of 201 and 306 keV in energy; their summed energy of 507 keV falls well within the 511-keV energy windows commonly used in PET scanners. For example, the presence of ^{176}Lu results in a measured background count rate of 240 cps/cm^3 of LSO. For most applications, however, this has a negligible impact on typical PET scans.

Semiconductor-based ionization detectors. Semiconductor radiation detectors represent the main alternative to scintillator detector-based imaging systems. Such detectors are so-called direct-conversion devices, a major advantage of which is that they avoid the random effects associated with scintillation production and propagation and conversion of the optical signal to an electronic signal. When an x- or γ-ray interacts in a semiconductor detector, one or more energetic electrons are created and subsequently lose energy through ionization, among other processes. The ionization creates electron-hole (e-h) pairs, where a hole is the positively charged electron vacancy in the valence band left when the electron has been raised into the conduction (i.e., mobile-electron) band. Application of a bias voltage creates an electric field that causes the two types of charge carriers to migrate in opposite directions. These moving charges induce transient currents in the detector electrodes, thereby allowing measurement of the detector's response to an incident x- or γ-ray.

Semiconductor detectors offer several potential advantages over scintillator detectors [8]. By eliminating the need for bulky PMTs, semiconductor imaging systems can be made much more compact, simplifying their mechanics in comparison to those of a conventional PMT-based imaging system (see below). More importantly, the direct conversion of energy deposited by x- or γ-rays into electron-hole pairs eliminates the light-to-electrical signal transduction step and the associated loss of signal. Further, since the energy required to create an e-h pair in most semiconductors employed as radiation detectors is sufficiently small (typically 3–5 eV), each incident photon generates a large number of charge carriers. In principle, therefore, Poisson noise is considerably less and energy resolution considerably better in semiconductor detectors than in scintillation detectors. Defects (i.e., inherent irregularities in the crystal lattice) can trap electrons produced by radiation and thus reduce the total charge collected. As a result of such incomplete charge collection due to "charge trapping," statistical uncertainty (i.e., noise) is increased and energy spectra broadened, that is, the otherwise excellent energy resolution of semiconductors is degraded. Thin semiconductors have fewer traps overall than thick detectors, but also have a lower intrinsic efficiency. Trapping can be reduced by increasing the bias voltage across the detector, but at the expense of increasing its leakage current. This results in greater electronic noise and therefore poorer overall performance. Practical, reasonably economical crystal-growing techniques have been developed for cadmium telluride (CdTe), mercuric iodide (HgI_2), and cadmium zinc telluride (CdZnTe) (also known as "CZT"), which have been incorporated into commercial intraoperative gamma probes and gamma cameras [8, 9] but not PET scanners.

PET Scanner Design

PET is based on the annihilation coincidence detection (ACD) of the two colinear (approximately 180° apart) 511-keV photons resulting from the mutual annihilation of a positron and an

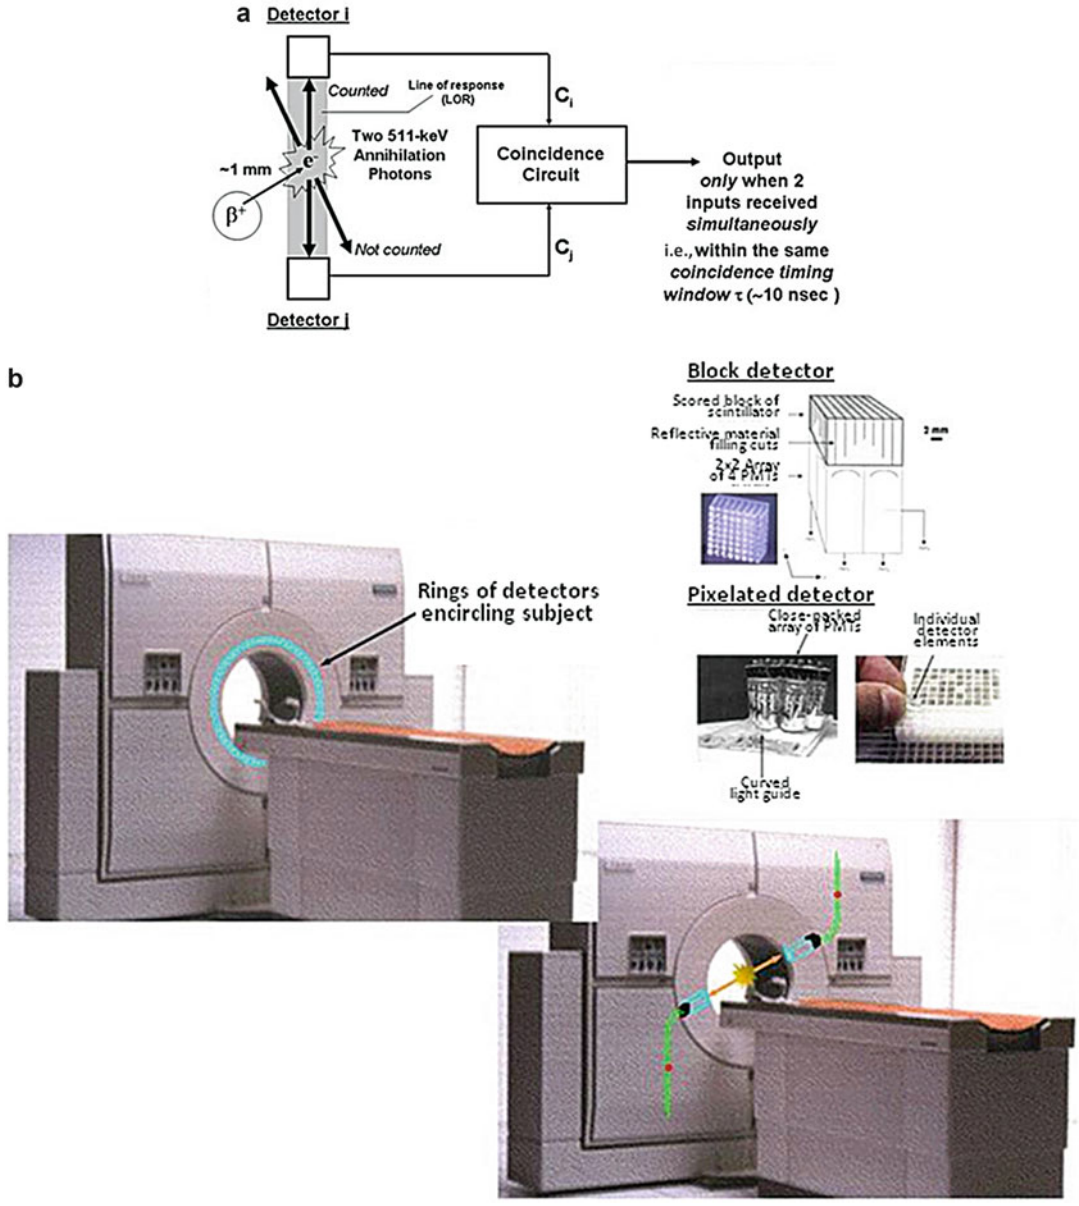

Fig. 2 **a** Annihilation coincidence detection (ACD) of the two opposed 511-keV photons resulting from positron decay and positron-electron annihilation. Note that the true coincidence (or "trues") count rate is much less than C_i and C_j. The short coincidence timing window, τ, is short (<10 ns) which minimizes the number of random coincidence events (see Fig. 8). At the same time, however, most of the annihilation photons therefore do not produce coincidence events. **b** A photograph of a PET scanner, illustrating one of a number of rings of discrete detectors encircling the subject (*left-hand panel*) and ACD of an annihilation photon by a pair of these detectors. In the insert are shown a block detector (*top*) and pixilated detectors (*bottom*) used in PET scanners. The block detector consists of a cubic piece of scintillator scored to variable depths into a two-dimensional array of detector elements, typically backed by a 2 × 2 array of PSPMTs. Pixilated detectors consist of individual scintillator detector elements backed by a continuous light guide and a close-packed array of PMTs. For both the block and pixilated detectors, the individual detector elements are typically ~2 × 2 mm in area (Adapted from reference [7] with permission)

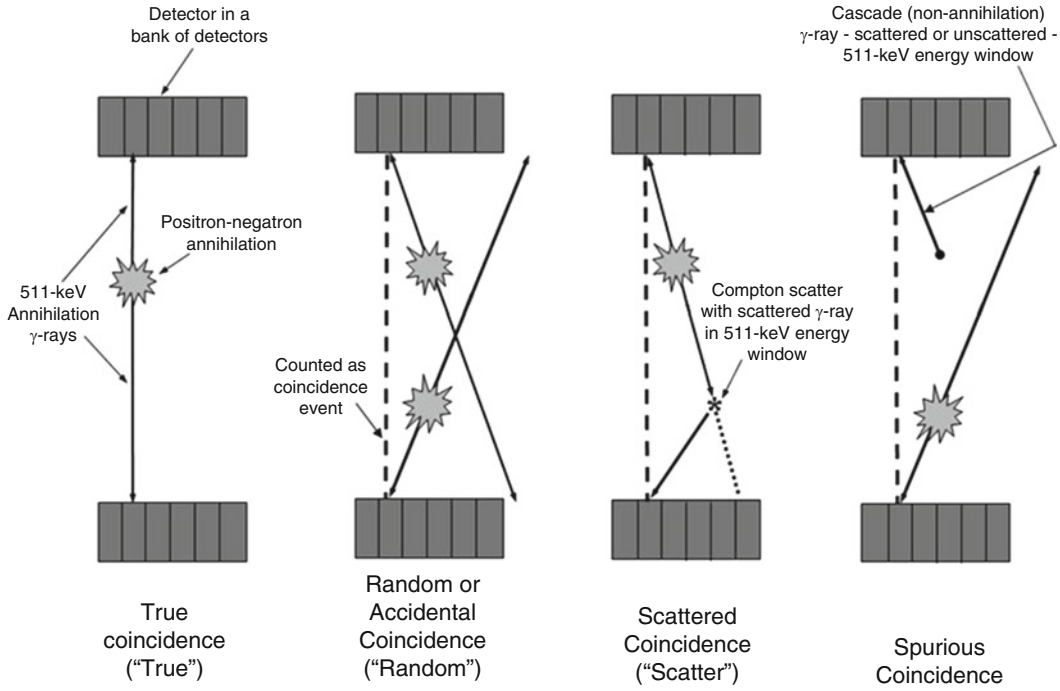

Fig. 3 The various events associated with ACD of positron-emitting radionuclides, illustrated for two opposed banks of coincidence detectors and assuming only one opposed pair of detectors, are in coincidence. A true coincidence ("true") is counted only when each of the two 511-keV annihilation photons for a single positron-electron annihilation are not scattered and are detected within the timing window τ of the two coincidence detectors. A random or accidental coincidence ("random") is an inappropriately detected and positioned coincidence (the *dashed line*) which arises from two separate annihilations, with one γ-ray from each of the two annihilations detected within the timing window τ of the coincidence-detector pair. A scattered coincidence ("scatter") is a mispositioned coincidence (the *dashed line*) resulting from a single annihilation, with one of the γ-rays undergoing a small-angle Compton scatter but retaining sufficient energy to fall within the 511-keV energy window. A spurious coincidence is an inappropriately detected and positioned coincidence (the *dashed line*) which arises from an annihilation and a cascade γ-ray, scattered or unscattered but having sufficient energy to fall within the 511-keV energy window. Spurious coincidences occur only for radionuclides which emit both positrons and high-energy prompt cascade γ-rays, that is, γ-rays with an energies (either scattered or unscattered) lying within the 511-keV energy window (From reference [7] with permission)

electron (Fig. 2a) [1, 2, 7]; a typical PET scanner and the detector configurations used in modern scanners are shown in Fig. 2b. Each individual annihilation photon is referred to as a "single" event, and the total count rate of individual annihilation photons is called the "singles count rate." When both photons from an annihilation are detected simultaneously (in coincidence), this triggers the coincidence circuit, and a "true coincidence event" ("true") is generated. The various events associated with ACD of positron-emitting radionuclides, including trues, randoms, scatter, and spurious coincidences, are illustrated in Fig. 3 [7].

The volume between the opposed coincidence detectors absorbing the two annihilation photons (the shaded area in Fig. 4) is referred to as a "line of response (LOR)" even though it is actually a volume of response. In PET, LORs are defined electronically, and an important advantage of ACD is that absorptive collimation (as is used in gamma cameras) is not required. As a result, the sensitivity of PET is two to three orders of magnitude higher than that of SPECT. Modern PET scanners generally employ a series of rings of discrete, small-area detectors (i.e., scored block detectors or pixilated detectors) encircling the subject (Fig. 2b) and, in clinical PET scanners,

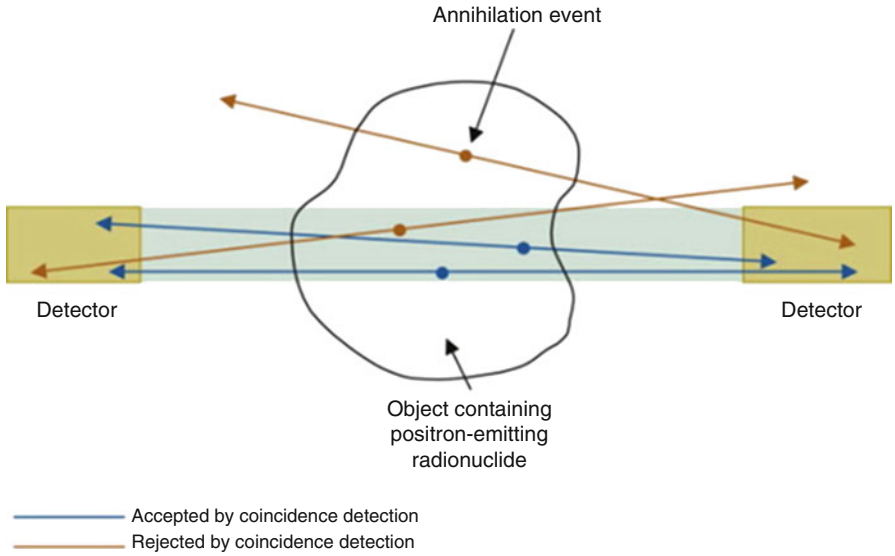

Fig. 4 For PET and annihilation coincidence detection, the 3D "line" (actually, volume) of response corresponds to the elongated cube whose cross-sectional area is defined by that of the opposed detector elements (Adapted from reference [29] with permission)

typically spanning a distance (or axial field of view (FOV)) of 15–20 cm in the patient's longitudinal direction. Recently, however, at least one PET scanner (the General Electric Discovery IQ™ scanner) with an axial FOV up to 26 cm has been marketed. Thus, a whole-body PET scan will typically require data acquisition at six to seven discrete bed positions and subsequently merge, or "knit," the discrete images into a single whole-body image. Of course, scanners with longer axial FOVs require fewer bed positions but require more detectors and front-end electronics. As its name implies, the Siemens continuous bed motion (CBM) feature allows whole-body scanning with continuous motion of the patient bed, analogous to the bed motion in spiral CT.

PET ring scanners originally employed lead or tungsten walls, or septa, positioned between and extending radially inward from the detector blocks [7] (Fig. 5). In this approach, known as two-dimensional (2D) PET, these inter-ring annular septa define plane-by-plane LORs and largely eliminate out-of-plane annihilation photons. By eliminating most of the contribution from out-of-plane randoms and scatter, image quality is improved, especially for large-volume sources (i.e., as in whole-body PET). However, 2D PET also eliminates most of the trues as well and thus reduces sensitivity. Removing the septa altogether and including coincidence events from all of the LORs among all the detectors significantly increase PET detector sensitivity. This is known as three-dimensional (3D) PET and is the prevailing design among state-of-the-art PET scanners [7, 10]. Sensitivity is increased up to ~fivefold in 3D relative to 2D PET – but with a considerable increase in the randoms and scatter count rates. Clinically, the scatter-to-true count rate ratios range from 0.2 (2D) to 0.5 (3D) in the brain and from 0.4 (2D) to 2 (3D) in the whole body [11].

A notable refinement in PET detectors has been the use of adjacent layers of two different materials with significantly different scintillation decay times (such as LSO and GSO, with decay times of approximately 40 and 60 ns, respectively); these are known as phoswich detectors [11]. Based on the pulse shape of the scintillation signal, the depth of the interaction of the annihilation photon in the detector can therefore be localized in the upper or lower layer [12]. As a result, the resolution-degrading depth-of-interaction (DOI) effect (see below) is

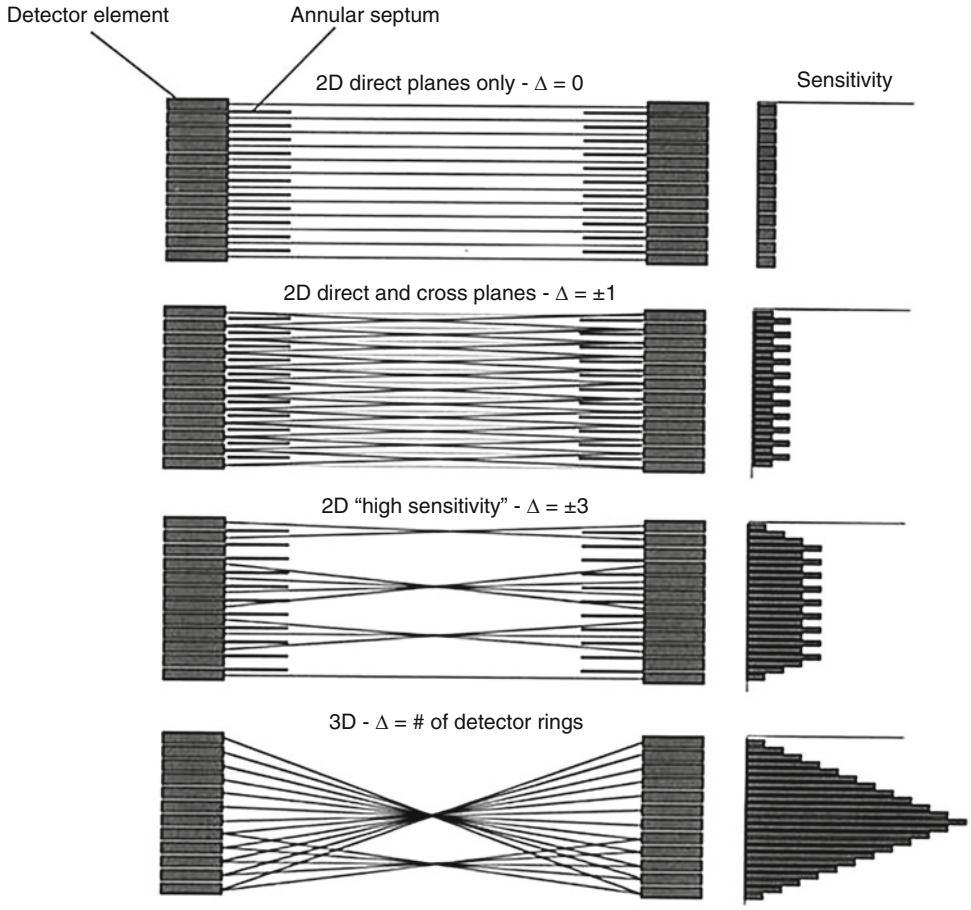

Fig. 5 Two-dimensional (2D) and three-dimensional (3D) PET data acquisition schemes (axial cross-sectional views of a multi-ring scanner) and the corresponding axial sensitivity profiles. **a**–**c** 2D data acquisition with a ring difference Δ of 0, 1, and 3, respectively. The ring difference refers to the number of different detector-element rings between which coincidence events are allowed. A ring difference of Δ of 0, for example, indicates that only intra-detector ring (i.e., direct planes) coincidences are allowed. **d** 3D (septa-less) data acquisition. The sensitivity profiles show the nonuniformity of response as a function of position along the axial FOV (Adapted from reference [11] with permission)

reduced. However, the fabrication of phoswich detectors is more complex than that of single-component detectors, and to date it has seen only limited use in commercial PET scanners, specifically preclinical scanners.

Increasingly important, time-of-flight (TOF) PET scanners utilize the measured difference between the detection times of the two annihilation photons arising from the decay of a positron (Fig. 6). This allows at least approximate spatial localization (to within ~10 cm) of the annihilation event along the LOR with current values, ~500 psec, of coincidence time resolution [13, 14]. This does not improve the spatial resolution of state-of-the-art PET scanners (~5 mm), but reduces the random coincidence rate and thus improves the signal-to-noise ratio (SNR), especially for large subjects [15]. This is important, as conventional (i.e., non-TOF) PET image quality is degraded with increasing patient size due to more pronounced attenuation and scatter and fewer trues. The use of faster digital SiPMs should improve the performance of TOF PET scanners.

The overall spatial resolution of PET scanners results from a combination of physical and instrumentation factors. There are several important

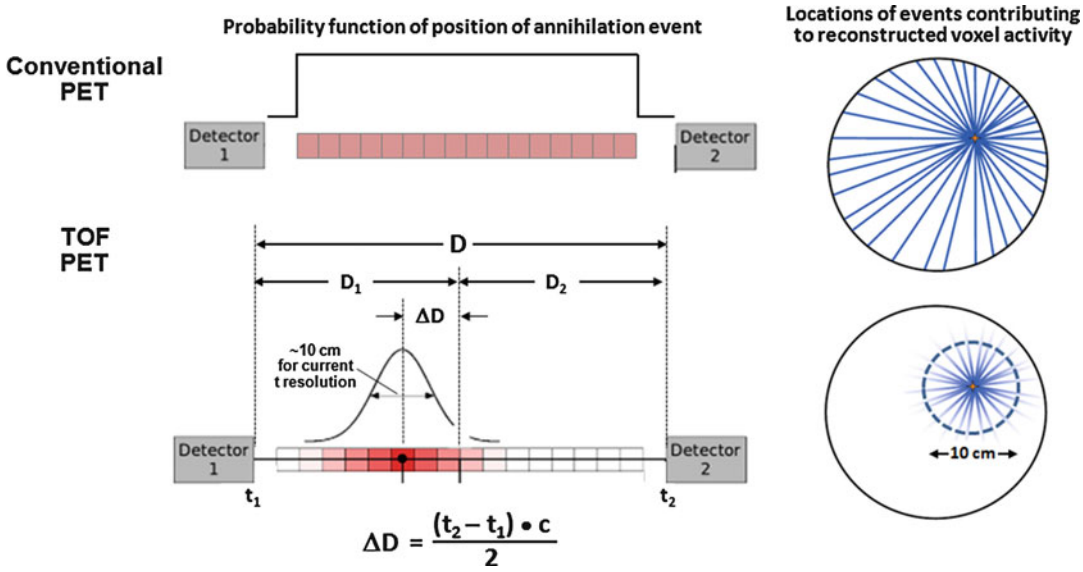

Fig. 6 Time-of-flight (TOF) PET. In conventional (i.e., non-TOF) PET, the position of a detected annihilation event may be anywhere along the LOR between the coincidence detectors. In TOF PET, the most likely position of the coincidence event along the LOR is a distance ΔD from the midpoint of the two coincidence detectors, where ΔD is proportional to the difference, $t_2 - t_1$, in times of arrival of the two annihilation photons at the two detectors (t_2 and t_1, respectively) and the speed of light, (**c**). As shown in the right panel, by localizing the position of the annihilation event, even approximately, the contribution of scatter, randoms, etc. to the reconstructed counts in each image voxel is reduced, and the SNR therefore improves. The shorter the coincidence time resolution, the more precisely the distance ΔD and the position of the coincidence event can be determined and the greater the improvement in the SNR

limitations imposed on resolution by the basic physics of positron-electron annihilation. First, for a given radionuclide, positrons are emitted over a spectrum of initial kinetic energies ranging from 0 to a characteristic maximum, or end point, energy, $E_{\max}$; the associated average positron energy, $\bar{E}$, is approximately one-third of its end point energy, $\bar{E} \approx \frac{1}{3} E_{\max}$. As a result, emitted positrons will travel a finite distance from the decaying nucleus ranging from 0 to a maximum called the extrapolated range, R_e, corresponding to its highest-energy positrons (Fig. 7a) [16]. For positron emitters used to date in PET (Table 2), the maximum energies ($E_{\max}$) vary from 0.58 to 3.7 MeV, the extrapolated ranges (R_e) from 2 to 20 mm, and the root-mean-square (rms) ranges (R_{rms}) from 0.2 to 3.3 mm. Although the finite positron range acts to blur PET images (i.e., degrade spatial resolution), the range-related blurring is mitigated by the spectral distribution of positron energies for a given radioisotope as well as the characteristically tortuous path positrons travel [16, 17]; these effects are reflected by the fact the rms positron ranges are much shorter than the extrapolated positron ranges (Table 2). The radial distance the positron travels is thus considerably shorter than its actual path length. The overall effect of positron range on PET spatial resolution, $FWHM_{\mathrm{range}}$, is illustrated quantitatively in Fig. 7b [16]. The positron range degrades spatial resolution by only ~0.1 mm for ^{18}F (E_{max} = 0.640 MeV) and ~0.5 mm for ^{15}O (E_{max} = 1.72 MeV) [16]; these values are much shorter than the respective extrapolated positron ranges.

The second physics-related limitation on PET performance is the non-colinearity of the two annihilation photons: because a positron typically has some small residual (nonzero) momentum and kinetic energy at the end of its range, the two annihilation photons are not always emitted exactly back to back (i.e., 180° apart) but deviate from colinearity by an average of 0.25° [18]. The non-colinearity-related blurring, $FWHM_{180°}$, varies from

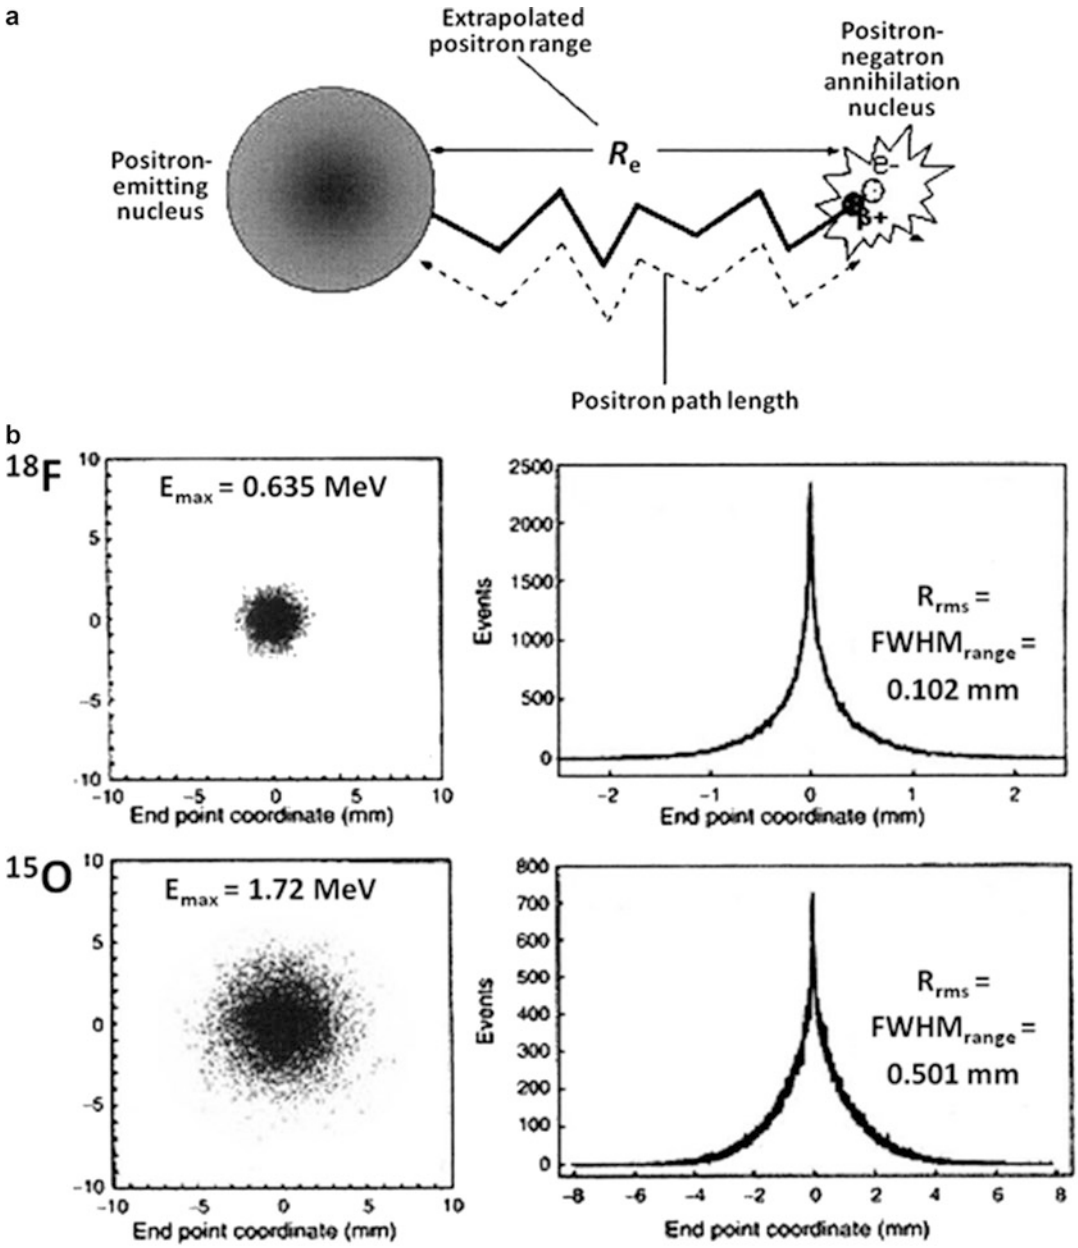

Fig. 7 Effect of positron range on PET spatial resolution. **a** Positrons travel a finite distance before undergoing annihilation, resulting in blurring of PET images. **b** The spatial dispersion of positron-electron annihilations for ^{18}F (E_{max} = 0.640 MeV) and ^{18}O (E_{max} = 1.72 MeV) as determined by Monte Carlo simulation. The annihilations for the higher-energy ^{18}O positrons are clearly more widely dispersed than those for the lower-energy ^{18}F positrons (*left panel*). A graphical representation of the resulting range-related blurring in PET, $FWHM_{range} = R_{rms}$: 1.03 mm and 4.14 mm for ^{18}F and ^{18}O, respectively (Reproduced from reference [16] with permission)

~2 mm for a 90-cm-diameter whole-body PET to ~0.7 mm for a 30-cm-diameter brain PET to ~0.3 mm for a 12-cm-diameter small-animal PET (Fig. 8) [11].

Among instrumentation-related determinants of overall spatial resolution are the intrinsic detector resolution and the depth-of-interaction effect. For discrete detector elements, the intrinsic

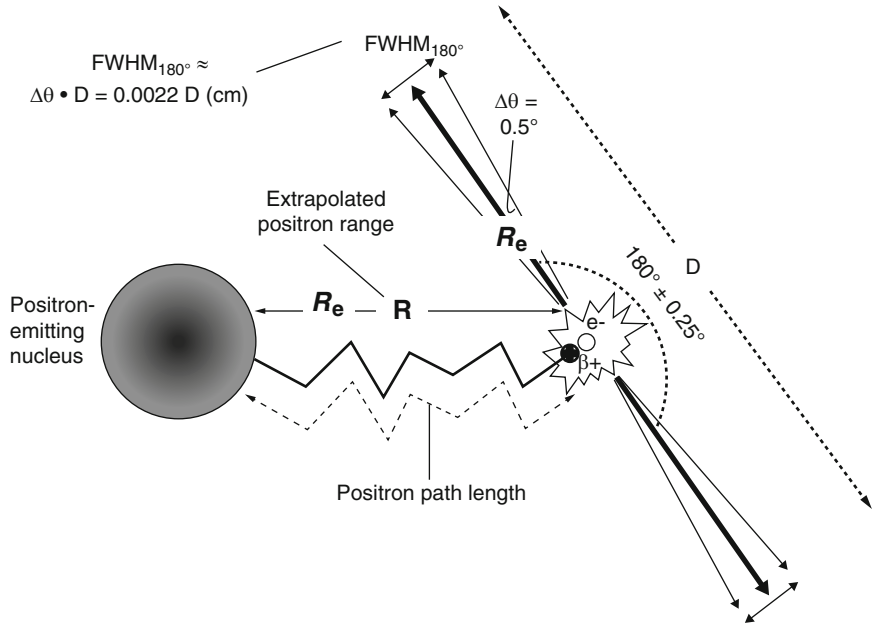

Fig. 8 Effects of the non-colinearity of the annihilation photons on PET spatial resolution. The 511-keV annihilation photons resulting from positron-electron annihilation are not always exactly colinear but may be emitted $180° \pm 0.25°$ apart [18]. The non-colinearity-related blurring, $FWHM_{180°}$, may be calculated geometrically and depends on the separation, D, of the coincidence detectors (Adapted from reference [11] with permission)

resolution, $FWHM_{\text{intrinsic}}$, is determined by the detector element width (d), increasing from $\frac{d}{2}$ midway between opposed coincidence detectors to d at the face of either detector [11].

For PET systems employing rings of discrete, small-area detectors, the depth (x) of the detector elements (2–3 cm) results in a degradation of spatial resolution termed the depth-of-interaction (DOI), or parallax, effect [11]. As illustrated in Fig. 9, with increasing radial offset of a source from the center of a detector ring, the effective detector width (d') and, with it, the intrinsic resolution, $FWHM_{\text{intrinsic}}$, increases [11]:

$$d' = d \cos\theta + x \sin\theta \tag{1}$$

and, along chords of the ring,

$$FWHM_{\text{intrinsic}} = \frac{d'}{2} \tag{2a}$$

$$= \frac{d}{2}\left(\cos\theta + \frac{x}{2}\sin\theta\right) \tag{2b}$$

where θ is the angular position of the coincident detector pair, d is the detector element width, and x is the detector element depth. In whole-body PET scanners, the detector depth (x) is typically 2–3 cm (20–30 mm), the detector width (d) about 4 mm, and the detector ring diameter about 80 cm (800 mm), and the DOI effect thus degrades spatial resolution by up to 50% at 10 cm from the center of the detector ring. Because the DOI effect decreases as the detector ring diameter increases (Fig. 9), clinical PET systems have detector rings substantially larger in diameter than that needed to accommodate patients. A variety of approaches have been developed to correct for the DOI effect in small-diameter, preclinical PET scanners, where the DOI effect is pronounced [11, 12, 19].

The spatial resolution at the center of the FOV (where the DOI effect is negligible) of a PET system, $FWHM_{\text{system}}$, can be obtained by combining the resolution of the respective components of the system:

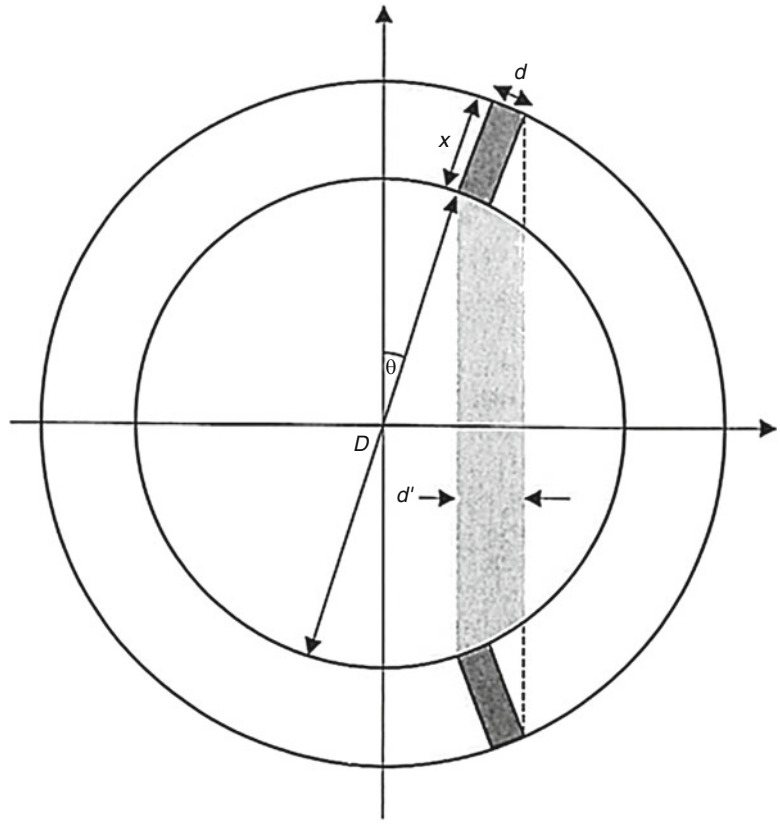

Fig. 9 The depth-of-interaction (DOI) effect. In PET scanners, the apparent width of a detector element, d′, increases with increasing radial offset from the center of the scanner. Because the depths with the detector elements at which the annihilation γ-rays interact are unknown, the apparent detector element width and therefore the effective line of response (i.e., the shaded volume) are wider than those corresponding to the actual detector element width d. The angle θ increases, and therefore the magnitude of this resolution-degrading effect, increases for sources offset further from the center of the rotation and for scanners with a smaller diameter D and a larger detector element depth x. (Reproduced from reference [11] with permission)

$$FWHM_{\text{system}} = \sqrt{FWHM_{\text{intrinsic}}{}^2 + FWHM_{\text{range}}{}^2 + FWHM_{180^\circ}{}^2} \quad (3)$$

Data "Corrections"

Even optimally performing PET scanners exhibit some nonuniformity of response [7, 20, 21]. Among the thousands of detector elements in a PET scanner, slight variations in detector thickness, light emission, optical coupling, electronic performance, etc. result in slightly different measured count rates for the same activity. In principle, such nonuniform response can be corrected by acquiring data from a uniform flux of γ-rays and normalizing to the *mean* count rate from all the LORs. This "normalization" table corrects for the nonuniform count rates among the individual LORs. One example of the effects of nonuniformity of scanner response and of the correction for nonuniform response is illustrated in Fig. 10 [20]. The normalization may be acquired using a positron-emitting rod source (e.g., germanium-68 (^{68}Ge)) spanning the entire axial FOV and rotating around the periphery of the FOV, exposing the detector pairs to a uniform photon flux per revolution. Alternatively, a uniform cylinder of a positron-emitting radionuclide can be scanned and the data thus acquired analytically corrected for attenuation; for a well-defined geometry such as a uniform cylindrical source, this correction is straightforward. However, for 3D PET, the contribution of and correction for scatter with such a large-volume source are nontrivial. Acquisition of the data required for uniformity correction is somewhat problematic in practice because of statistical considerations: typically, hundreds of millions (PET) of counts must be acquired to avoid possible "noise"-related artifacts in the uniformity correction table.

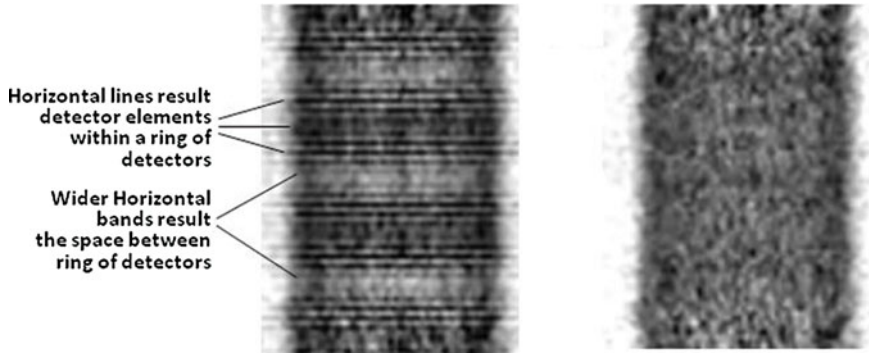

Fig. 10 Normalization (uniformity) corrections and their effects. Reconstructed PET images (coronal view) of a germanium-68 uniform-cylinder phantom without (*left panel*) and with (*right panel*) the normalization applied. The un-normalized (i.e., uncorrected) image has obvious artifacts attributable to the differences in sensitivities between direct and cross planes and the presence of separate rings of detectors. Appropriate normalization virtually eliminates these and other artifacts related to non-uniformity of the scanner response (From reference [20] with permission)

Radiation detectors are characterized by a finite "dead time" and associated count losses [11]. The dead time, typically of the order of 1–10 μsec, is the interval of time required for a counting system to record an event, during which additional events cannot be recorded. As a result, the measured count rate is systematically lower than the actual count rate. Such count losses are significant, however, only at "high" count rates (i.e., greater than ~100,000 counts per second (cps) per detector, which is of the order of the inverse of the dead time in seconds, for modern detectors). Real-time correction for dead time count losses is routinely applied in PET to the measured count rates, most commonly by scaling up the measured count rate based on an empirically derived mathematical relationship between measured and true count rates.

In PET, randoms increase the detected coincidence count rate by introducing mispositioned events and thus reduce image contrast and distort the relationship between image intensity and activity concentration [7]. One approach to random correction is the so-called delayed-window method, based on the fact that the random-coincidence photons are temporally uncorrelated (i.e., not simultaneously emitted) [22]. Briefly, once events in the coincidence timing window (typically ~10 ns or less) are detected, the number of events in a timing window equal in duration to, but much later (>50 ns later) than, the coincidence timing window is determined. More specifically, the coincidence timing window accepts events whose time difference is $\pm \tau$, while the delay window accepts events whose time difference is the delay $\pm \tau$. The number of events in the delayed timing window thus provides an estimate of the number of randoms in the coincidence timing window. Real-time subtraction of the delayed-window counts from the coincidence-window counts for each LOR thus corrects for randoms.

Another random-correction method, the "singles" method, uses the measured singles count rate for each detector and the coincidence timing window τ to calculate the random rate for each pair of coincidence detectors [23]. This approach does not require a separate measurement in a delayed-coincidence window and thus lessens the data-processing requirements on the coincidence electronics. Further, because the singles count rate is typically at least an order of magnitude higher than the coincidence-event count rate, the statistical uncertainty (noise) in the estimate of the number of randoms is much smaller than that in the number of prompt coincidences. The singles method is thus the method of choice for random correction in modern PET scanners.

Scatter results in generally diffuse background counts in reconstructed images, like randoms,

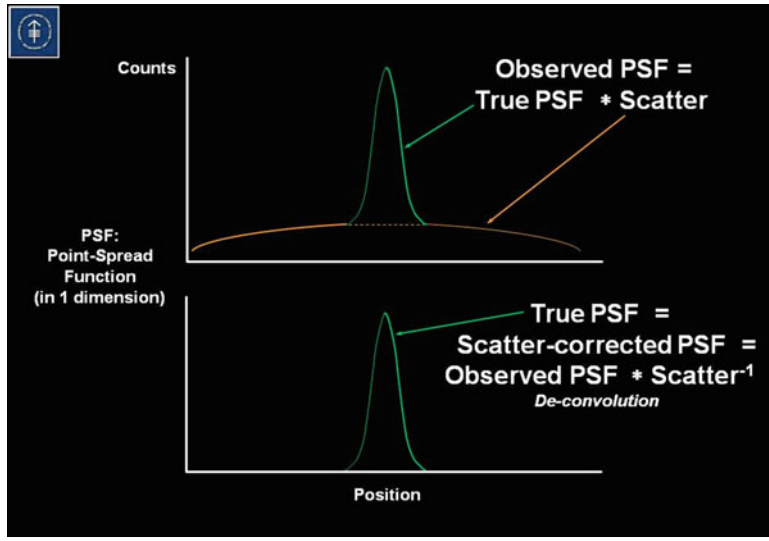

Fig. 11 The "Gaussian-fit" scatter-correction method. In practice, the point-spread function (PSF) of a PET scanner includes both primary (unscattered) and scattered counts, with the former corresponding to the Gaussian, or bell-shaped, curve and the latter corresponding to the peripheral tails extending from the Gaussian curve. The tails can be subtracted (deconvolved) from the total PSF to yield scatter-corrected PSF. In a similar manner, this scatter correction can be applied to projection images prior to reconstruction to yield scatter-corrected reconstructed images

reducing contrast and distorting the relationship between image intensity and activity concentration [24–26]. Scatter as a portion of the total PET events is far more abundant in 3D than in 2D PET (especially for body imaging of larger (i.e., adult) patients), and its correction is more challenging in 3D than in 2D PET. Perhaps the simplest scatter correction method is the "Gaussian-fit" technique [27, 28] (Fig. 11). Once the random correction has been applied, the peripheral "tails" in the projection-image count profiles, presumably due to scatter, are fit to a mathematical function and then subtracted (or deconvolved) from the measured profile to yield scatter-corrected profiles for tomographic image reconstruction. While this approach works reasonably well for 2D PET and small source volumes (e.g., the brain) in 3D PET, it is not adequate for 3D PET generally. Scatter corrections for 3D PET include dual-energy window-based approaches, convolution-/deconvolution-based approaches (analogous to the correction in 2D PET), direct estimation of scatter distribution (by computer modeling of the imaging system), and iterative reconstruction-based scatter compensation approaches (also employing computer modeling) [25, 26].

The correction for the attenuation of the photons as they pass through tissue is generally the largest correction in PET. The correction factors can range up to ~15 for a PET scan of the abdomen (equivalent to a 30-cm diameter water-equivalent cylinder). The magnitude of the correction depends on the energy of the photons (511 keV for PET studies), the thickness of tissue(s) that the photons must travel through, and the attenuation characteristics of the tissue(s). One of the attractive features of PET is the relative ease of applying accurate corrections for attenuation, based on the fact that attenuation depends only on the total thickness of the attenuation medium (at least for a uniformly attenuating medium) (Fig. 12). For a positron-emitting source and a volume of thickness L, the attenuation factor is $e^{-\mu L}$ and the attenuation correction factor $e^{\mu L}$ regardless of the position (i.e., depth) of the source. Accordingly, if a rod source of a positron emitter such as ^{68}Ge is extended along the axial FOV and rotated around the periphery of the FOV first with and then without the subject in the imaging position – the

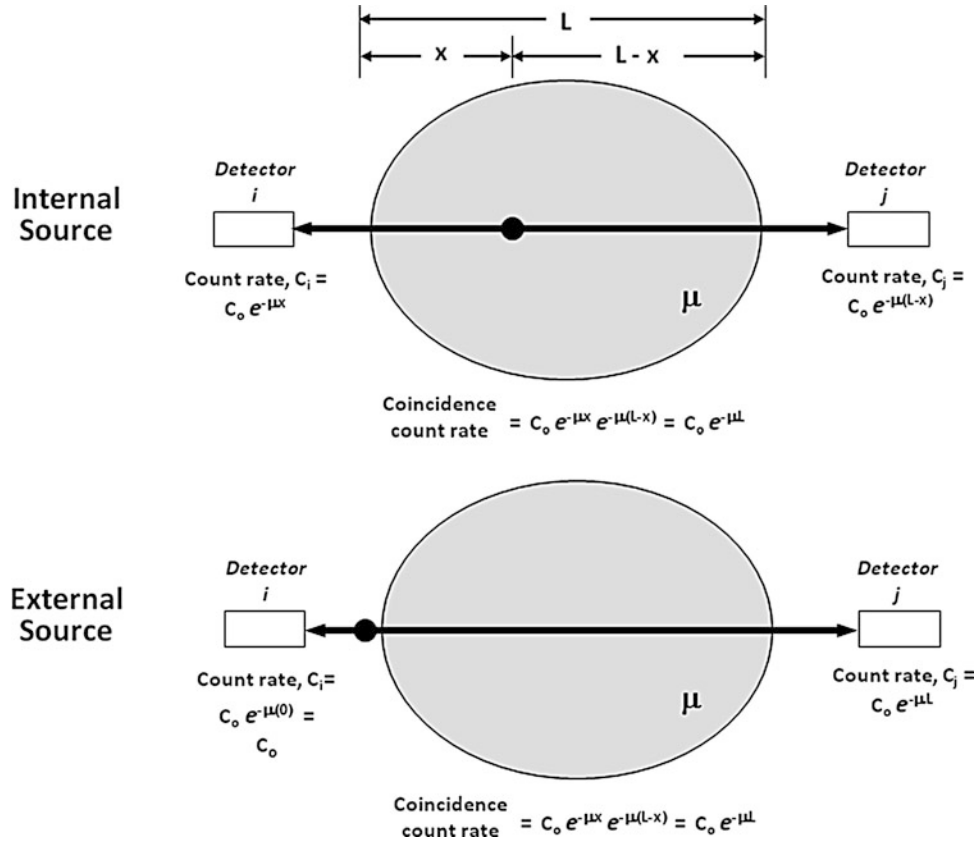

Fig. 12 In PET, attenuation of the annihilation photons for a uniformly attenuating medium depends only on the total thickness (L) of the absorber, that is, it is independent of the position (depth x) of the source in the absorber (*upper panel*). An external positron emitter can therefore be used for attenuation correction (*lower panel*). C_o is the actual source count rate, and C_i and C_j are the count rates measured by detectors i and j, respectively; μ is the linear attenuation coefficient of the absorber for 511-keV photons (Adapted from reference [7] with permission)

transmission and the blank scans, respectively – the attenuation correction factor (*ACF*) can be derived from the ratio of the counts in these respective scans:

$$ACF_{ij} = e^{\mu L}ij \tag{4}$$

$$= \frac{\left[(C)_{Blank}\right]_{ij}}{\left[(C)_{Trans}\right]_{ij}} \tag{5}$$

where ACF_{ij} is the attenuation correction factor between coincident detectors *i* and *j*, L_{ij} is the thickness of the volume between coincident detectors *i* and *j*, and $((C)_{Blank})_{ij}$ and $((C)_{Trans})_{ij}$ are the external-source counts between detectors *i* and *j* in the blank and transmission scans, respectively. In practice, a blank scan is acquired only once a day. The transmission scan can be acquired before the subject has been injected with the radiotracer, after the subject has been injected with the radiotracer but before or after the emission scan, or after the patient has been injected with the radiotracer and at the same time as the emission scan. Preinjection transmission scanning avoids any interference between the emission and transmission data but requires that the subject remain on the imaging table before, during, and after injection of the radiotracer. It is the least efficient operationally and is rarely used in practice. Postinjection transmission scanning minimizes the effects of motion, relying on the much higher external-source count rates for reliable

subtraction of the emission counts from the transmission counts. It was the most commonly used approach in "PET-only" scanners. Simultaneous emission/transmission scanning is obviously the most efficient (fastest) approach but may result in excessively high randoms and scatter counter rates in the emission data.

With the introduction of hybrid PET/CT scanners, attenuation correction is now performed using CT rather than transmission sources. A CT image is basically a two-dimensional map of attenuation coefficients at the CT X-ray energy (~80 keV). For attenuation correction of the PET emission data, however, these must be appropriately scaled to the 511-keV energy of the annihilation photons. The mass-attenuation coefficients (μ_m) for CT X-rays (~80 keV) and for 511-keV annihilation photons are 0.182 and 0.096 cm^2/gm, 0.209 and 0.093 cm^2/gm, and 0.167 and 0.087 cm^2/gm in soft tissue, bone, and lung, respectively. The corresponding μ_m ratios are therefore 1.90, 2.26, and 1.92, respectively. Thus, ACFs derived from CT images cannot be scaled to those for 511-keV annihilation photons simply using a single global factor. Accordingly, CT-based attenuation correction in PET has been implemented using a combination of segmentation (to delineate soft tissue, bone, and lung compartments) and variable scaling (to account for the different μ_m ratios in these respective tissues).

Noise-Equivalent Count Rate (NECR)

A PET scanner actually measures a so-called prompt coincidence count rate (R_{prompt}) that comprises true, scatter, and random coincidence count rates (R_{true}, $R_{scatter}$, and R_{random}, respectively):

$$R_{true} = R_{prompt} - R_{scatter} - R_{random} \qquad (6)$$

The noise-equivalent count rate (NECR) is a commonly cited performance parameter of PET scanners which accounts for the additional statistical noise introduced by the corrections for randoms and scatter (see below) [29]. It is defined as the equivalent count rate that yields the same noise level as the observed count rate after correction for randoms and scatter:

$$\mathrm{NECR} = \frac{{R_{true}}^2}{R_{true} + aR_{scatter} + bR_{random}} \qquad (7)$$

where a is the fraction of each projection that is occupied by the object being imaged and b equals 1 or 2 if the singles method or the delayed-windows method, respectively, is used for random correction. A typical plot of the NECR as function of the activity concentration is shown in Fig. 13. Because the NECR depends on the size of the object being imaged (as indicated by parameter a in Eq. 7), the plot in Fig. 13 is

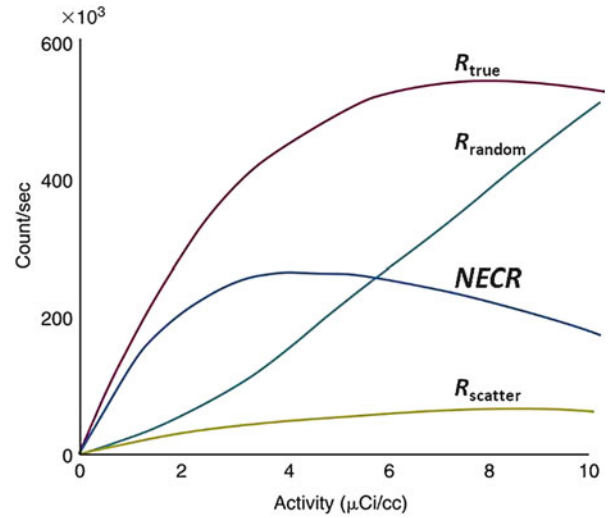

Fig. 13 The NECR and the true, scatter, and random coincidence count rates (R_{true}, $R_{scatter}$, and R_{random}, respectively) as functions of activity concentration in the fields of view for a typical clinical whole-body 3D PET scanner. The NECR indicates that the best signal-to-noise ratio is achieved at an activity concentration of ~4 μCi/cc (Adapted from reference [29] with permission)

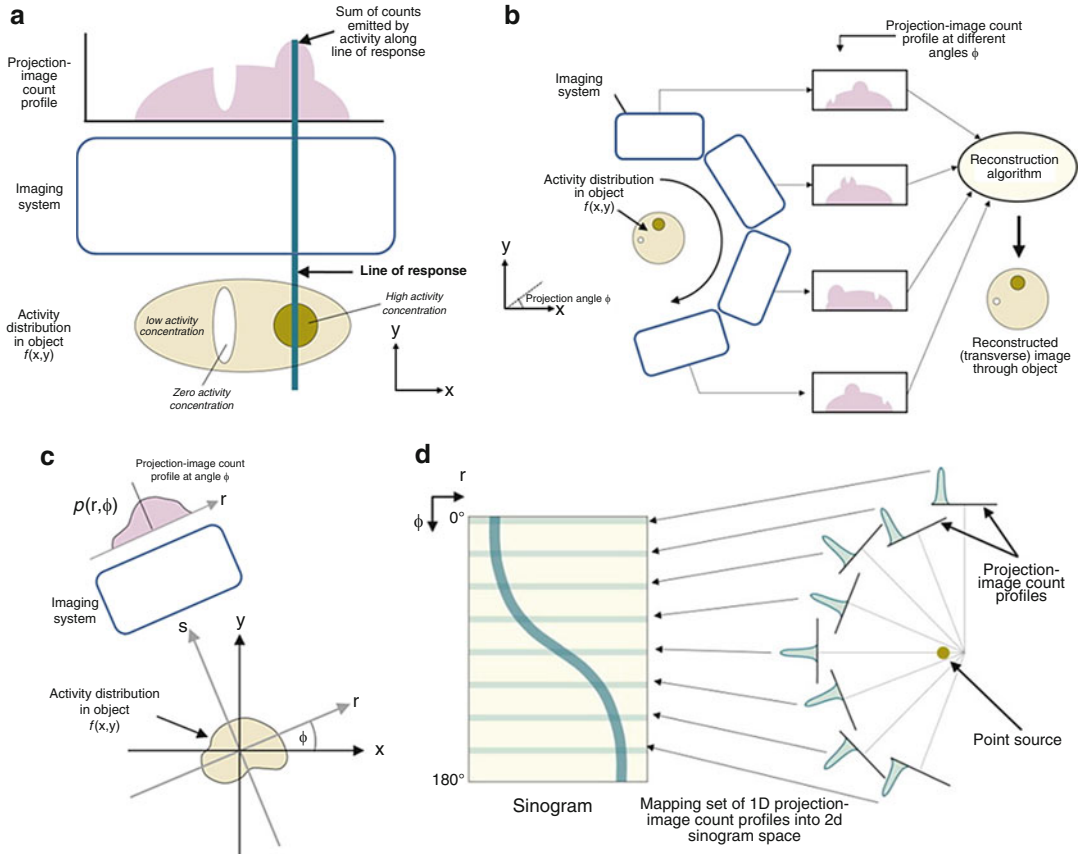

Fig. 14 Emission tomography data acquisition and sinogram display. **a** Projection-image count profile under idealized conditions (such as no attenuation or scatter). **b** Acquisition of multiple projection images and their corresponding count profiles at various projection angles ϕ about the longitudinal axis of the object being imaged. **c** The (*r*, *s*) coordinate system is rotated by projection angle ϕ with respect to the (*x*.*y*) coordinate system of the cross-section of the object being imaged. The (*r*, *s*) coordinate system is fixed with respect to the imaging system and the (*x*.*y*) coordinate system is fixed with respect to the object. **d** Two-dimensional (2D) count display, or sinogram, of a set of projection-image count profiles. Each row in the sinogram corresponds to an individual projection-image count profile, displayed for increasing projection-image angle ϕ from top to bottom. As shown, a point source of radioactivity traces out a sinusoidal path in the sinogram (Adapted from reference [29] with permission)

neither unique nor unambiguous for a particular scanner. Nonetheless, for purposes of comparison of the performance among scanners, a standard phantom can be used for derivation of the activity concentration-dependent NECR.

Image Reconstruction

In emission tomography generally, the emission data which are reconstructed to yield the tomographic images correspond to the projected sum of counts (or parallel-ray integrals) in two dimensions at various angles about the axis of the scanner (Fig. 14). In 3D PET, the projections correspond to a set of two-dimensional (x_r, y_r) integrals with azimuthal angle ϕ *and* oblique, or polar, angle θ (Fig. 15) [30]. (Correction of the emission data after the real-time dead time and random corrections and before image reconstruction – namely, normalization, scatter correction, and then attenuation correction – is typically performed in sinogram space (Fig. 14d).) The first step in deriving the 2D parallel-ray

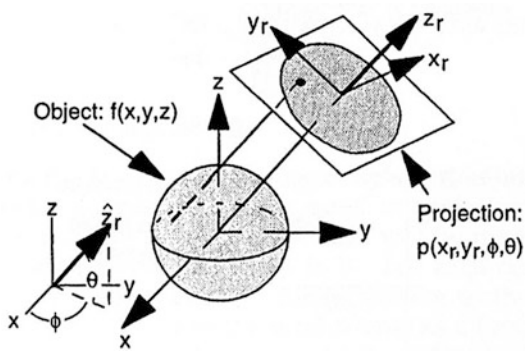

Fig. 15 In 3D PET, the projections are two-dimensional (x_r, y_r) parallel line integrals with azimuthal angle ϕ and oblique angle θ. The 3D projection data are represented as a set of sinograms, with one sinogram per polar angle θ, each row representing the projected intensity across a single polar angle θ and each column the projected intensity at the same position x_r across the projection at successive azimuthal angles ϕ (From reference [30] with permission)

projection-image data is to re-bin the 3D PET data set into a 2D data set such that each oblique (or indirect) projection ray is placed within the data for a particular non-oblique (or direct) transverse slice. The simplest approach to 3D-to-2D re-binning is known as "single-slice re-binning (SSRB)," wherein an oblique projection ray between a detector at axial position a and a detector at axial position b is positioned as if it were a projection from a directly opposed detector pair midway between these detectors (i.e., at axial position $(a + b)/2$) (Fig. 16a) [29, 31]. For projection rays at a large angle with respect to the transverse planes (i.e., corresponding to LORs between detectors located at opposite ends of the gantry), significant repositioning errors and degraded tomographic image quality result. SSRB has been replaced, therefore, with a more sophisticated and more accurate repositioning technique known as Fourier re-binning [32, 33] (Fig. 16b). In contrast to SSRB, however, Fourier re-binning cannot be performed in real-time and thus requires the full 3D data set.

Once the 3D data have thus been re-binned into 2D data, the resulting 2D fanbeam data must then be reformatted into parallel-beam data for the actual image reconstruction. The procedure for creating parallel-beam projections from fanbeam projections is shown in Fig. 17a. The resulting parallel-ray spacing Δx_r is given by:

$$\Delta x_r = \Delta d_t \sqrt{1 - \left(\frac{X_r}{R_D}\right)^2} \tag{8}$$

where $\Delta d_t = \frac{2\pi R_D}{N_D}$ is the center-to-center detector spacing of the detector elements in the transverse plane, R_D is the radius of the transaxial detector ring, and N_D is the number of detector elements in a single transaxial detector ring (Fig. 17b). Thus, as a result of the curvature of the PET gantry, the parallel-ray spacing decreases with increasing distance from the center of the detector ring. Near the center of the detector ring (i.e., for $x_r << R_D$), Δx_r can be equated with Δd_t; toward the periphery of the detector ring, however, interpolation must be performed to yield uniform parallel-ray spacing across detector gantry. This is known as the "arc correction."

The foregoing 2D parallel-beam data derived from the PET emission data (i.e., the 3D fanbeam data) can then be reconstructed into the tomographic images. There are two basic classes of image-reconstruction methods, analytic and iterative. Historically, perhaps the most widely used analytic algorithm for reconstruction of tomographic images from 2D data (or 3D data re-binned into 2D projections) has been filtered back projection (FBP) [21, 30]. In PET, however, FBP has been replaced by iterative reconstruction methods. FBP is still used rather widely in single-photon emission computed tomography (SPECT) and is discussed in ▶ Chap. 11, "Instrumentation for Single-Photon Emission Imaging". Iterative algorithms [33] attempt to progressively refine estimates of the activity distribution, rather than directly calculating the distribution, by maximizing or minimizing some "target function." The solution is said to "converge" when the difference of the target function between successive estimates (iterations) of the activity distribution is less than some prespecified value. Importantly, iterative reconstruction algorithms allow incorporation of realistic modeling of the data acquisition process (including effects of attenuation and of scatter), modeling of statistical noise,

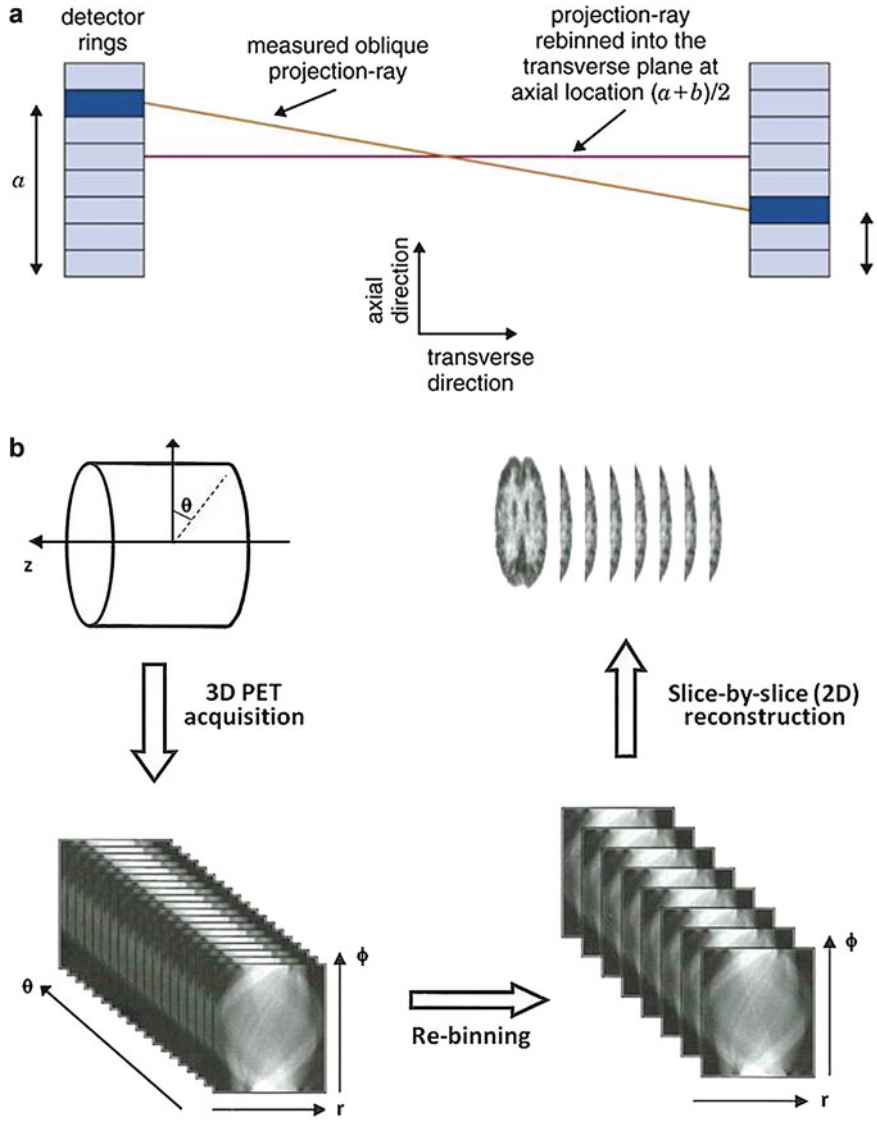

Fig. 16 **a** The single-slice re-binning algorithm in which an oblique (i.e., indirect) projection ray between detector pairs a and b is placed within the projection data for a non-oblique (i.e., direct) slice corresponding to a traverse detector pair at axial location $(a + b)/2$ (from reference [29] with permission). **b** The Fourier re-binning algorithm for re-binning 3D PET data into 2D data. The basic steps of Fourier re-binning are creating a stack of oblique sinograms, calculating the 2D Fourier transform for each oblique sinogram, normalizing the resulting 2D sinogram for the number of oblique slices contributing to the oblique sinogram, and calculating the 2D inverse Fourier transform of the resulting normalized sinograms to yield the 2D re-binned data for image reconstruction (From reference [33] with permission)

and inclusion of pertinent a priori information (e.g., only nonnegative count values). The maximum-likelihood expectation maximization (MLEM) algorithm is based on maximizing the logarithm of a Poisson-likelihood target function [34, 35]. The MLEM algorithm suppresses statistical noise, but large numbers of iterations typically are required for convergence, and therefore processing times are long. To accelerate this slow convergence, the ordered-subset expectation maximization (OSEM)

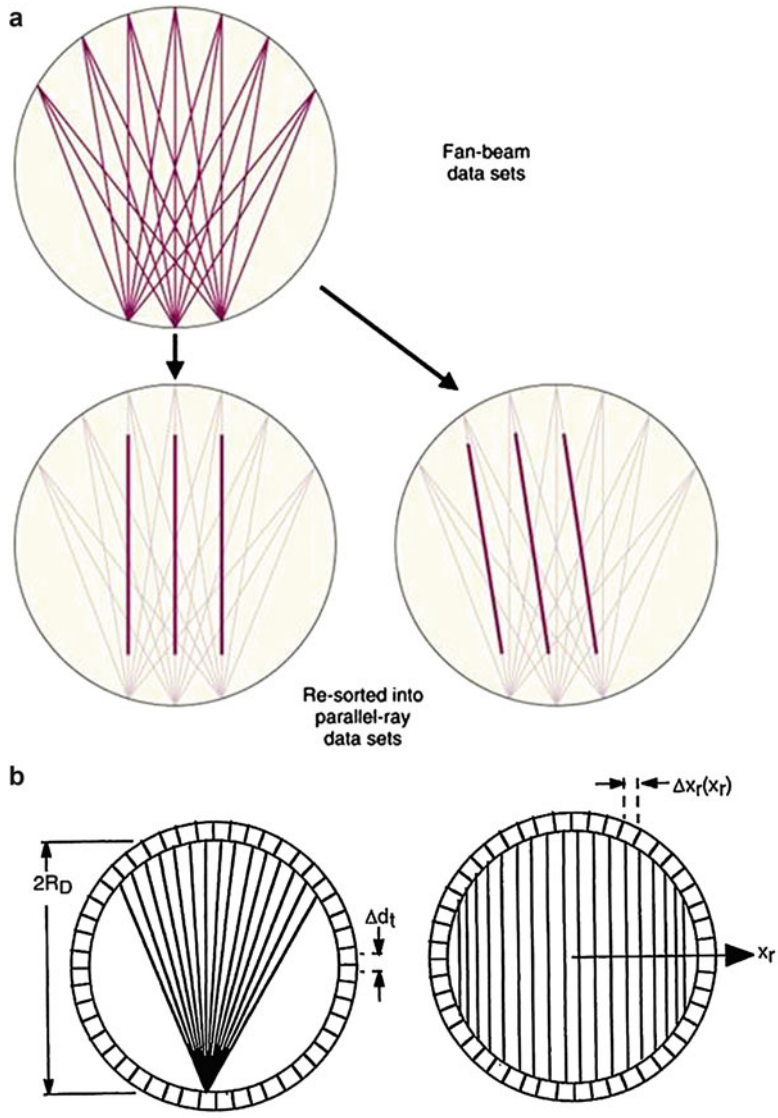

Fig. 17 **a** Procedure for creating parallel-beam projections from fanbeam projections (from reference [29] with permission). **b** Nonuniform parallel-ray spacing when creating parallel-beam projections from fanbeam projections, necessitating the so-called arc correction. (From reference [30] with permission)

algorithm [36] groups the projection data into subsets comprised of projections uniformly distributed around the source volume. The OSEM algorithm, which is a modified version of the MLEM algorithm in that the target is still maximization of the log-likelihood function, converges more rapidly than MLEM and is now the most widely used iterative reconstruction method in PET as well as SPECT [37].

In practice, OSEM is usually stopped after a relatively small number of iterations and post-filtered to dampen image noise and therefore may not achieve optimal quantitation accuracy. As an alternative to OSEM, Ahn et al., among others, have recently implemented a penalized likelihood (PL) image reconstruction algorithm in order to improve quantitation accuracy without compromising visual image quality [38]. Preliminary studies have demonstrated visual image quality including lesion conspicuity in images reconstructed by the PL algorithm is better than or at least as good as that in OSEM-reconstructed images. Despite the benefits, PL methods have not yet been widely adopted in clinical PET. Besides

computational time and complexity, the limited use of such methods in clinical PET may be that it has not been convincingly demonstrated that PL methods can provide improved quantitation accuracy compared to OSEM while maintaining clinically acceptable visual image quality.

The row-action maximization-likelihood algorithm (RAMLA), related to the OSEM algorithm, has been implemented for direct reconstruction of 3D PET data. The so-called 3D-RAMLA, which eliminates 2D re-binning of the 3D data, employs partially overlapping, spherically symmetric volume elements called "blobs" in place of voxels [37, 39, 40]. Reconstruction times are fairly long by clinical standards but the results have been excellent [41].

An important, recently introduced feature of iterative reconstruction is the 3D modeling of the scanner-specific point-spread function (PSF) map. Scanner spatial resolution deteriorates toward the periphery of the FOV but can be modeled in image reconstruction to not only improve the uniformity of spatial resolution across the FOV but also to improve spatial resolution overall. This correction is known as "resolution recovery" and is now available on most modern PET scanners. Effective tomographic image resolution as low as 2 mm has been achieved using resolution recovery.

Quantitation

Once the emission data have been corrected for dead time, randoms, system response (by normalization), scatter, and attenuation, the count rate per voxel in the reconstructed tomographic images is proportional to the local activity concentration. A factor which adversely effects the quantitative accuracy of PET is partial-volume averaging: for a source which is "small" relative to the spatial resolution of the imaging system, the image-derived activity or activity concentration in such a source underestimates the actual value, and the smaller the source, the greater the degree of the underestimation [24, 42]. The dimensions of a source must be at least two times the FWHM spatial resolution of the imaging system to avoid such underestimation of the activity or activity concentration [42]. Since the source-size dependence of the partial-volume effect can be measured (e.g., by phantom studies), the underestimated activity or activity concentration can be corrected if the source dimensions can be independently determined (e.g., by CT) [43]. Another key factor which limits the quantitative accuracy of SPECT and PET is subject motion. As in photography, subject motion blurs PET images, dispersing the counts in a source region over an apparently larger volume than the actual volume of that region. This results not only in an overestimate of the source region volume but also an underestimate of the source region activity concentration. For sources (e.g., tumors) in the lung and the dome of the liver, a particularly important source of such inaccuracies is respiratory motion [44–47]. Practical, reasonably accurate methods for respiratory gating of PET studies have been developed and result in more reliable estimates of the volumes and activity concentrations in pulmonary lesions [44–47].

To make the images absolutely quantitative, the count rate per voxel (cps), $\dot{C}_{ijk}$, in voxel *ijk* must be divided by a measured system calibration factor ((μCi/cc)/(cps/voxel)), CF, to yield the activity concentration [7]:

$$\{A\}_{ijk} = \frac{\dot{C}_{ijk}}{CF} \tag{9}$$

where $\{A\}_{ijk}$ is the activity concentration (e.g., μCi/cc) in voxel *ijk*. The calibration factor (CF) can be derived by scanning a calibrated standard, that is, a water-filled or water (tissue)-equivalent volume source with all linear dimensions at least twice that of the system spatial resolution and with a uniform, well-defined activity concentration at the time of the scan. The requirement for water equivalence is to ensure that effects such as scatter and attenuation are comparable in both the subject and the standard. And the requirement for linear dimensions at least twice that of the system spatial resolution is to ensure that the effect of partial-volume averaging and associated underestimation of local count rates is negligible. Activity concentration

is often expressed in terms of the decay-corrected fraction or percent of the administered activity per cubic centimeter (cc) or, more commonly in clinical PET, in terms of the standard uptake value (*SUV*):

$$SUV = \frac{\mu\text{Ci/cc of tissue}}{\mu\text{Ci injected/gm body mass}} \qquad (10)$$

An advantage of using *SUV* to express activity concentration is that, in first order, it is independent of the body mass of the subject.

The practical quantitative accuracy of PET (expressed, e.g., as the percent difference between the image-derived and actual activity or activity concentration in a source region) is difficult to characterize unambiguously, as it depends on such factors as the count statistics, the size of the source region, the source-to-background activity concentration ratio, the subject motion, and the accuracy of all applicable corrections. Under favorable circumstances (i.e., for a high-count study of a large, stationery source region with a high source-to-background ratio), the accuracy of the PET is of the order of 10% [42].

Multimodality Devices

Image registration and fusion have become increasingly important components of both clinical and laboratory imaging and have led to the development of a variety of pertinent software and hardware tools, including multimodality devices which transparently provide registered and fused 3D image sets [48–52]. In addition to anatomic localization of signal foci, image registration and fusion provide intra- as well as inter-modality corroboration of diverse images and more accurate and more certain diagnostic and treatment-monitoring information. There are two practical approaches to image registration and fusion, "software" and "hardware" approaches. In the software approach, images are acquired on separate devices, imported into a common image-processing computer platform, and registered and fused using the appropriate software. In the hardware approach, images are acquired on a single, multimodality device and transparently registered and fused with the manufacturer's integrated software. Both approaches are dependent on software sufficiently robust to recognize and import diverse image formats. The availability of industry-wide standard formats, such as the ACR-NEMA DICOM standard (i.e., the American College of Radiology (ACR) and National Electrical Manufacturers Association (NEMA) for Digital Imaging and Communications in Medicine (DICOM) standard [53, 54]), is therefore critical.

PET/MRI. All manufacturers of PET and CT scanners market multimodality scanners, combining PET with CT scanners in a single device. These instruments provide near-perfect registration of images of in vivo function (PET) and anatomy (CT) using a measured, and presumably fixed, rigid transformation (i.e., translation and rotation in three dimensions) between the image sets. The rigid transformation matrix can be used to align the PET and the CT image sets. This matrix can be measured using a phantom, that is, an inanimate object with PET- and CT-visible landmarks arranged in a well-defined geometry. The transformation matrix required to align these landmarks can then be stored and used to automatically register *all* subsequent multimodality studies, since the device's geometry and therefore this matrix should be fixed. Although generally encased in a single seamless housing, the PET and CT gantries in such multimodality devices are separate; the respective fields of view are separated by a distance of the order of 1 m, and the PET and CT scans are performed sequentially.

PET/MRI. Despite its unquestioned clinical utility, PET/CT has certain notable shortcomings, including the inability to perform simultaneous data acquisition, the significant radiation dose to the patient contributed by CT, and the inability of non-contrast CT to distinguish different soft tissues [55–57]. Compared to CT, MRI provides not only better contrast among soft tissues but also functional imaging capabilities. The combination of PET/MRI may thus provide advantages which go well beyond simply combining functional

information with structural MRI information. Among multimodality imaging studies, therefore, PET/MRI may ultimately provide the greatest yield of information by combining the quantitative molecular imaging capabilities of PET (including the large number and variety of radiotracers) with the excellent anatomic resolution, marked soft tissue contrast, and functional imaging capabilities provided by MRI (e.g., perfusion by dynamic contrast-enhanced (DCE) imaging) and magnetic resonance spectroscopic imaging (MRSI) (e.g., quantitation of regional concentrations of metabolites such as lactate, citrate, and choline) [55–57].

As noted, an important advantage of PET/MRI is that the image data can be acquired *simultaneously* because the PET and MR imaging signals (i.e., gamma- or X-rays and radiofrequency (RF) waves, respectively) do not interfere with one another. Registration of sequentially acquired functional and structural images is very forgiving of the short time interval (typically only several minutes) between the PET and CT scans, as anatomy does not actually change over such short time intervals (except, perhaps, for filling of the urinary bladder, transit of gas through the bowel, etc.). Registration of sequentially acquired functional images, however, is potentially more problematic, as functional properties, such as blood flow, hypoxia, neuronal activation, etc., may change transiently over time frames of minutes and even seconds. However, many technical challenges, related to possible interference between the modalities' hardware, have to be solved when combining PET and MRI [55, 57–65]. Most notably, conventional PET and SPECT detectors are based on PMTs, which do not operate properly in the presence of a magnetic field, and various approaches have been pursued to overcome this and other challenges in combining nuclear and MR modalities. The most straightforward approach is placement of the PET and MR scanners in series in a manner analogous to current PET/CT devices. However, this would require magnetic shielding of the PET scanner and/or imposition of a relatively large distance between the PET and MR scanners. Further, because data acquisition for PET and MRI individually is time-consuming, sequential imaging may result in prohibitively long overall study times (well over 1 h) in a clinical setting. Space constraints are also a consideration. Most importantly, physical separation of the scanners would eliminate the ability to perform the nuclear and MR scans simultaneously, which, as noted, is perhaps the most compelling feature of such hybrid devices. The preferable approach, therefore, is integration of the PET hardware into the MR gantry.

Due to its various hardware components, the PET subsystem can interfere with the performance of the MRI subsystem by compromising the homogeneity of the MRI's main magnetic field and the RF field and thereby degrade MR image quality. BGO and LSO crystals, for example, produce only minor magnetic-field distortion, while GSO and LYSO have sharply different magnetic susceptibilities than tissue and thus markedly distort MR images. At the same time, the variable MR gradients may induce eddy currents in conductive materials of the nuclear detectors and distort the effective applied gradient field. As noted, the effects of the high magnetic fields of the MR subsystem exclude the use of PMTs employed in conventional PET detectors, as the path of the electrons between the dynodes in the evacuated PMT is deflected from their normal trajectory by the external magnetic field [55, 66]. In addition, the RF fields and also the gradient system pulses of the MR subsystem can degrade the performance of and even damage the PET electronics. One approach to overcoming this limitation is the use of long optical fibers (up to several meters in length) to couple the detector crystal to a PMT positioned outside the MR subsystem's fringe field (i.e., at magnetic fields of no greater than 10 mT). In this way, only the X-ray and γ-ray detection elements lie within the magnetic field, and the scintillations are directed out of the field by the fibers. Despite the challenges presented by such systems, including the large number of optical fibers required (one per detector element) and partial loss of the light signal over the length of the fibers, several prototypes of such PET/MRI scanners (with field strengths up to 3 T) have been fabricated.

An alternative, and ultimately more practical approach, to PET/MRI is elimination of the PMTs

altogether by using solid-state scintillation detectors such as APDs or SiPMs. APDs and SiPMs are relatively insensitive to magnetic fields and thus can be coupled directly to the scintillation detector blocks via conventional (i.e., short) light guides. It is still important, however, to provide RF shielding of the PET subsystem components within the magnetic field, for example, using copper mesh.

MR images do not directly provide attenuation information, and in PET/MR systems, the attenuation correction maps must therefore be estimated indirectly. Software methods have been proposed for MR-based attenuation correction, based on image segmentation or co-registration of templates with preassigned tissue-specific attenuation coefficients. A method proposed by Martinez-Moeller et al. has been utilized in clinical systems, with a two-point Dixon VIBE MR sequence to obtain fat and water compartments for calculating attenuation. Lung tissue in the MR images is identified by image segmentation. Software-constructed attenuation maps obtained from MR may not reflect true photon attenuation, since several classes of tissue can be defined. In addition, the actual attenuation coefficients may be different than standard assumed values.

Commercial Devices

Clinical. All of the major manufacturers of medical imaging equipment, including General Electric, Philips, Siemens, and Toshiba, currently market clinical PET devices (Tables 4 and 5, respectively). Since 2005, PET scanners have been marketed exclusively as multimodality (i.e., PET/CT) scanners; clinical "PET-only" scanners are no longer marketed. The PET subsystems of commercial PET/CT scanners utilize BGO, LSO, or LYSO as the detector material, with most now operating exclusively in 3D mode and all except the BGO-based systems incorporating TOF capability. The dimensions of the detector elements are typically $4 \times 4 \times 20$ mm^3, though slightly larger-area and thicker detector elements are found in some units. The axial fields of view are typically 20 cm in length, and whole-body studies therefore require six or seven bed positions. PET system spatial resolution (FWHM) is of the order 5 mm among clinical systems. The design and performance parameters of the PET subsystem of currently marketed clinical whole-body PET/CT scanners are summarized in Table 3 [5].

Several "special-purpose" clinical scanners have been marketed as well. These include positron emission mammographs (PEMs) [67]. The PEM Flex Solo II (Naviscan PET Systems, Inc.) [68] is a limited-angle, focal-plane tomography system with two opposed 6×16.4-cm^2 LYSO detectors ($2 \times 2 \times 13$-mm^3 detector elements) backed by PSPMTs and mounted inside compression paddles for immobilization and compression of the breast. The detectors, mounted on an articulating arm that rotates to allow imaging from different views, can scan up to 24 cm across the FOV in the direction of their 6-cm dimension, yielding a maximum FOV of 24×16.4 cm^2. The PEM Flex Solo II, with an in-plane spatial resolution of ~2.5 mm, thus differs markedly from conventional PET scanners in that the detectors do not encircle the object (in this case, the breast) being imaged.

At least two PET/MRI systems capable of simultaneously collecting MR and PET image data with almost no degradation of either MR or PET performance are now commercially available from Siemens and General Electric [5]. As previously discussed, simultaneous acquisition of MR and PET data presents significant engineering challenges due to cross interference between PET and MR hardware. To minimize this cross interference in the PET subsystem, PMTs are replaced with APDs and SiPMs in the Siemens and General Electric systems, respectively. The Siemens mMR™ system is based on a Verio™ MR scanner with a modified body radiofrequency (RF) coil, gradient coil, and patient-handling system. In this system, the APD PET detectors are arrayed around a cylinder that is inserted into the bore of the MR scanner, reducing the bore diameter from 70 to 60 cm. LSO scintillator crystals ($4 \times 4 \times 20$ mm^3) are arranged in eight rings of 56 blocks comprised of 8×8 crystals backed by a 3×3 array of APDs per block. The MR

gradient system is cooled and the PET detectors are shielded with copper to reduce electromagnetic interference. The APDs do not distort the main magnetic field, and the acquisitions of the MR and PET subsystems are synchronized to reduce possible distortion of the PET signals by the MR RF and gradient pulses. The PET component of the Siemens scanner has a 25.8-cm axial FOV. However, this system does not offer TOF capability, due to relatively low timing resolution of APDs. The GE Signa™ PET-MR uses SiPMs to achieve TOF with a coincidence timing resolution of 400 and 390 ps with RF "on" and "off," respectively. It offers a 25-cm PET axial FOV and a sensitivity of 2.1%. The PET subsystem comprises five rings of 112 detector blocks (each a 4 × 9 array of LYSO crystals, 3.95 × 5.3 × 25 mm^3) backed by a 1 × 3 arrays of SiPMs. The PET detector ring is centered inside the MR gradient set of a GEMR750w™ 3 T scanner on the outer diameter of the RF body coil. Figure 18 shows the digital PET detector modules used in the Siemens mMR™ and the GE Signa™ PET/MR systems [5] and Table 4 [5] the design and performance parameters of these systems.

Preclinical. A number of preclinical PET devices are commercially available, both from major manufacturers and smaller "niche" companies. Preclinical PET scanners, which operate exclusively in 3D mode, are diverse in design, utilizing different scintillation detectors in combination with either PSPMTs or APDs. The superior spatial resolution of preclinical versus clinical PET scanners, 1–2 mm versus 4–6 mm, is due in part to the much smaller gantry diameter and therefore a less pronounced resolution-degrading effect of the non-colinearity of the annihilation γ-rays. Preclinical devices are currently marketed as "PET-only" scanners or as multimodality devices with integrated CT scanners, typically conebeam devices with flat-panel detectors. The Carestream Albira™, Gamma Medica Triumph LabPET Solo™, and Siemens Inveon™ are available as trimodality PET-SPECT/CT systems. The design and performance parameters of currently marketed preclinical PET scanners are summarized in Table 5.

Concluding Remarks

The use of PET and of PET/CT has grown dramatically over the last several decades. In contrast to PET/CT, however, where there are temporal and spatial offsets between the PET and the CT studies, PET and MRI studies (including dynamic studies) can be performed simultaneously. The recent introduction of PET/MRI [55–57, 64] multimodality devices will no doubt lead to new and important applications of molecular imaging [69].

Instrumentation for Single-Photon Emission Imaging

11

Pat Zanzonico

Abstract

This chapter reviews the underlying physical principles of single-photon emission tomography (SPECT) and the design and operation as well as the capabilities and limitations of SPECT scanners used clinically and preclinically. This is the "companion" chapter to the earlier chapter on positron emission tomography (PET) instrumentation; the material in that chapter on the basic principles of radiation detectors, iterative image reconstruction, and multimodality imaging applies as well to SPECT.

Introduction

This chapter reviews the underlying physical principles of single-photon emission tomography (SPECT) and the design and operation as well as the capabilities and limitations of SPECT scanners used clinically and preclinically [1–4]. This is the "companion" chapter to ▶ Chap. 10, "Instrumentation for Positron Emission Imaging" of this book; the material in that chapter on the basic principles of radiation detectors, iterative image reconstruction, and multimodality imaging applies as well to SPECT.

SPECT, like PET, is now a mature but continually improving technology. Among the most noteworthy refinements in recent years have been the application of solid-state ionization detector (i.e., semiconductor)-based gamma cameras, the introduction of novel, application-specific detector and collimator configurations (most notably in nuclear cardiology), and the improved quantitative accuracy.

Radionuclides for SPECT

Implicit in the suitability of a radionuclide for in vivo imaging is that it emits sufficient abundance radiations penetrating enough to escape from the body and interact with external detectors. These emissions include γ-rays and characteristic x-rays ("single photons") used for SPECT and planar gamma camera imaging generally or the 511-keV annihilation photons associated with positron (β^+) decay and used for PET. In addition, imaging radionuclides ideally should emit few or no non-penetrating radiations, that is, particulate radiations such as β particles and electrons (excluding, of course, positrons necessary for signal generation in the case of PET). Such particulate radiations typically have ranges in tissue of the order of 1 mm or less and thus cannot escape from the body and be detected externally. These contribute to the radiation dose to tissues and organs without providing any imageable signal. High-energy ($\geq$ ~1-MeV) beta particles (e.g., those emitted by the pure beta-particle emitter yttrium-90) produce a small but imageable amount of *bremsstrahlung* ("braking radiation" x-rays) as they slow down in tissue. *Bremsstrahlung* imaging is not widely used, however, and produces rather poor-quality images. Further, an imaging radionuclide ideally should have a physical half-life comparable to the time required for the administered radiotracer to localize in the tissue of interest. This will provide sufficient time for it to localize in that tissue while still retaining a near-maximal imaging signal, followed by elimination of the radioactivity by a combination of physical decay and biological clearance. The radiation dose to patients and individuals around them and the potential problem of radioactive contamination are thereby minimized. The pertinent physical properties of single-photon radionuclides for imaging are summarized in Table 1 [1, 2, 5, 6].

For planar imaging as well as SPECT, a radionuclide emitting x- and γ-rays with energies of 100–200 keV and with an abundance of 100% (i.e., one x- or γ-ray emitted per decay) and with minimal emission of particulate radiations and of higher-energy x- and γ-rays is ideal. The abundance of imageable x- or γ-rays relative to

Table 1 Physical properties of single-photon-emitting radionuclides used in gamma camera imaging and SPECT [1, 2, 5, 6]

Radionuclide	Physical half-life	Decay mode	Energies of imageable x- and γ-rays (MeV)	Abundance imageable x- and γ-rays (%)	x- and γ-ray-to-β particle, conversion electron, and Auger electron energy-per-decay ratio[a]	Production
Gallium-67	3.26 days	Electron capture	0.0933	40	4.5	Cyclotron
			0.185	24		
			0.300	16		
Technetium-99m	6.01 h	Isomeric transition	0.140	89	7.8	Generator (Molybdenum-99)

			0.247	94		
Iodine-123	13.2 h	Electron capture	0.159	84	6.1	
Iodine-131	8.04 days	β^- decay	0.364	82	2.0	Reactor

[a]As discussed, the ratio of the energy emitted per decay in the form of β particles, conversion electrons, and Auger electrons (i.e., non-penetrating particulate radiations) to that emitted in the form of x- and γ-rays should be high for a radionuclide for gamma camera imaging

particulate radiations is expressed by the x- and γ-ray-to-β particle, conversion electron, and Auger electron energy-per-decay ratio in Table 1; the higher the value of this parameter, the better a radionuclide will be for imaging. With a mean free path in soft tissue of the order of 10 cm and in NaI (Tl) of less than 0.5 cm, 100- to 200-keV photons provide adequate penetrability through tissue but are low enough in energy to be efficiently collimated (see below) and stopped in relatively thin scintillation and even ionization detectors, yielding optimum-quality images with reasonably low radiation doses. The absence of higher-energy x- and γ-rays (i.e., with energies in excess of several hundred keV) is important because such radiations cannot be efficiently collimated and detected. Yet, they may undergo scatter in the patient and/or detector hardware and contribute, even with energy discrimination, mispositioned, and otherwise spurious counts to the image. Based on the foregoing criteria (Table 1), ^{99m}Tc is a near-ideal radionuclide for gamma camera imaging, emitting only a 140-keV γ-ray and little particulate radiations. Iodine-131 (^{131}I), on the other hand, emits a relatively high-energy, difficult-to-collimate 364-keV γ-ray and abundant β particles.

Gamma Camera Design

Developed in the late 1950s by Hal Anger, the gamma camera (Fig. 1), also known as the scintillation or Anger camera, has long been the predominant imaging device in nuclear medicine [1, 3]. Its large detector area allows simultaneous and therefore rapid data acquisition over a large area of the body. Gamma camera crystals, almost universally, are composed of a plate of NaI(Tl) and vary in thickness from 6.35 to 25.4 mm. A 9.53-mm-thick crystal thus provides a reasonable balance between sensitivity and resolution and is the most widely used for general gamma camera imaging. About 95% of the 140-keV photons from ^{99m}Tc are absorbed in a 9.54-mm crystal. For clinical applications, gamma camera crystals are most commonly rectangular in shape and ~50 × 60 cm in area for general-purpose imaging.

Once the incident radiation passes through the collimator (see below), it strikes, and may produce a scintillation within, the crystal. The resulting light signal is distributed among a two-dimensional array of photomultiplier tubes (PMTs) backing the crystal, the light intensity varying inversely with the distance between the scintillation and

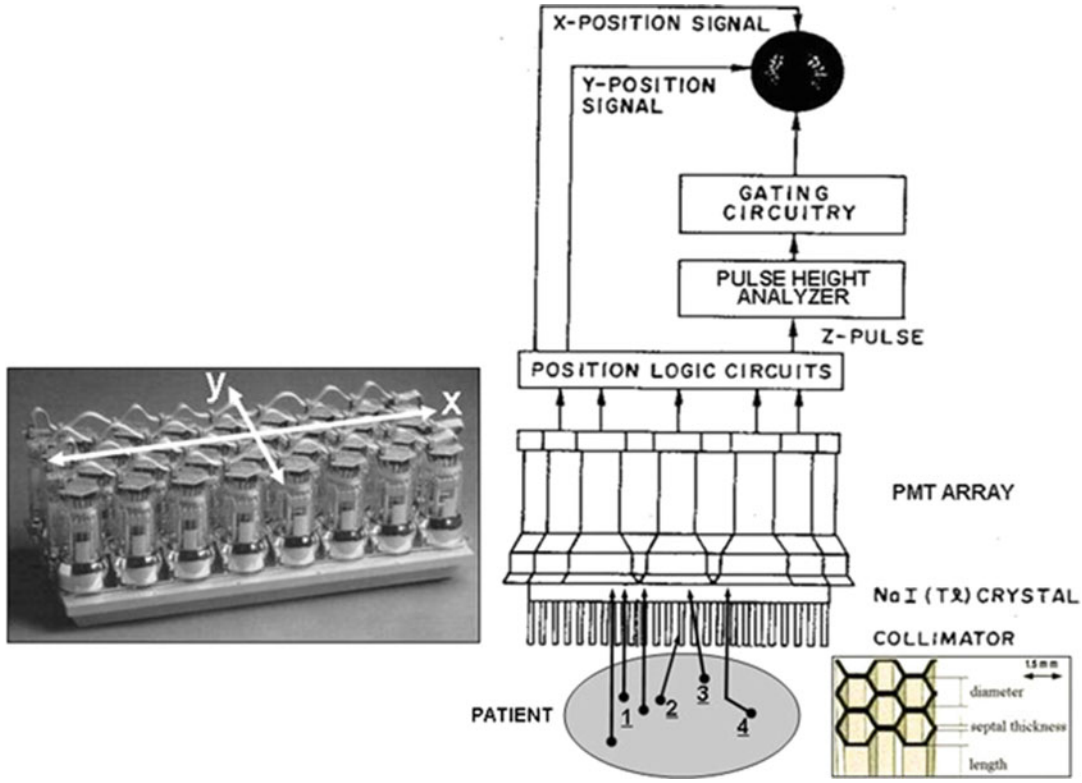

Fig. 1 Basic design of a conventional gamma camera, consisting of a multi-hole collimator, a thin large-area NaI(Tl) crystal, a two-dimensional array of PMTs and associated electronics (high-voltage power supply, preamplifier, and amplifier), position logic circuitry, energy discriminator, and image display. Note that there are actually two position logic circuits – for the determination separately of the x- and y-positions of the scintillation within the crystal. Note further that the output signal from each PMT is actually split into three parts, one (the z pulse) for the determination of the energy of the incident radiation as well as one each for the determination of its x- and y-positions. In current-day gamma cameras, the output signal from each PMT is digitized, and the position of each event is determined with computer software. The *left inset* shows a photograph of the two-dimensional PMT array backing the crystal in a typical *rectangular* field-of-view gamma camera. The *right inset* shows a drawing of a portion of a parallel-hole collimator, identifying the dimensions – aperture diameter, septal thickness, and septal length – of such a collimator. The "desirable" events (*arrows* labeled "1") are unscattered (i.e., photopeak) photons traveling in a direction parallel or nearly parallel to the axes of the apertures and thus yielding correctly positioned counts in the gamma camera image. "Undesirable" events include (1) scattered as well as unscattered photons traveling in a direction oblique to the axes of the apertures (2) and thus eliminated by attenuation by one or more collimator septa; septal penetration (3), that is, unscattered photons traveling in a direction oblique to the axes of the apertures yet passing through the septa and yielding mispositioned counts; scatter (4), that is, photons undergoing Compton scatter within the patient and either eliminated by energy discrimination or not eliminated and yielding mispositioned counts (From Refs. [1, 3] with permission)

the respective PMT: the farther the PMT is from the scintillation, the less light it receives, and the smaller is its output pulse. This inverse relationship is the basis of the Anger position logic circuitry for determining the precise location of a scintillation within the crystal. In the older gamma cameras, the x- and y-coordinates were calculated by analog circuitry, that is, using matrices of resistors. In current models, this is done by digitizing the output signal from each PMT and using digital electronics.

The gamma camera collimator, almost always comprised of lead, "directionalizes" the incoming radiation (Fig. 1). Any radiation traveling at

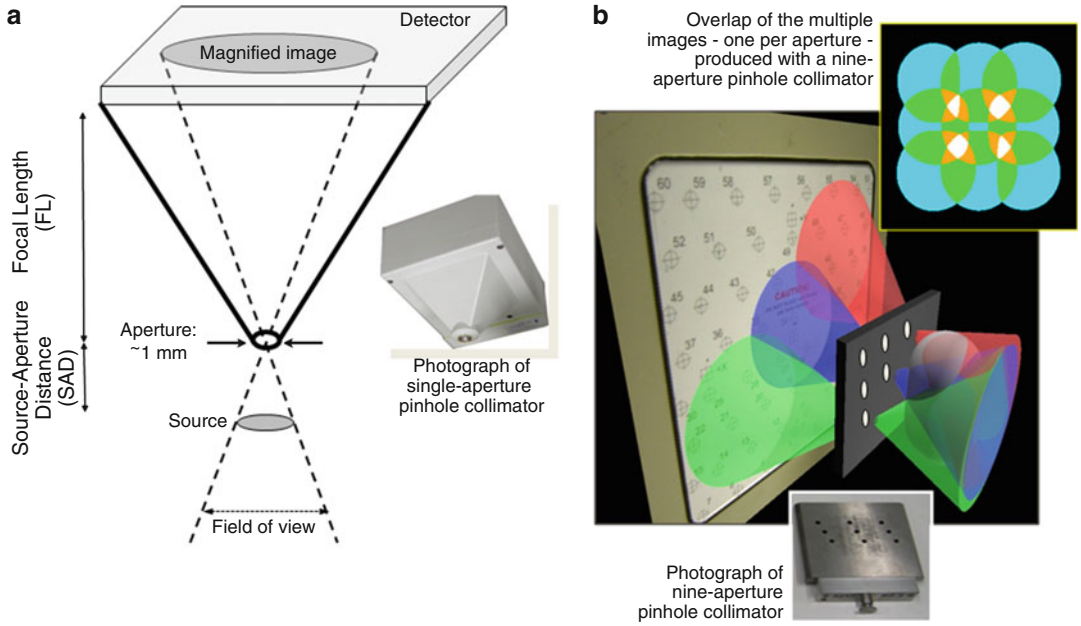

Fig. 2 Pinhole collimation for gamma cameras. (**a**) A single-aperture pinhole collimator. Pinhole collimation provides a magnification effect and thereby improved "effective" resolution. For example, if a source were placed at distance of 3 cm from the aperture (i.e., source-to-aperture distance (*SAD*) = 3 cm) of a pinhole collimator having a focal length of 9 cm (i.e., focal length (FL) = 9 cm) fitted to a detector with an intrinsic spatial resolution of 3 mm (i.e., FWHM = 3 mm), the magnification is FL/SAD = 9/3 cm = 3, and the effective resolution therefore improves to FWHM/(FL/SAD) = 3 mm/(9/3 cm) = 3 mm/3 = 1 mm (Photograph courtesy of Gamma Medica (Northridge, CA)) (**b**) A multi-aperture pinhole collimator, now the standard approach to preclinical (i.e., mouse and rat) SPECT imaging. As shown, however, each of the apertures produces an image, and the resulting multiple images – one per aperture – overlap. The apertures are angled with respect to one another to minimize this overlap. If larger-area detectors are used, this angulation can be increased and therefore the image overlap further minimized and image quality improved (Courtesy of Bioscan (Washington, DC))

an oblique angle to the axes of the holes (apertures) will strike the lead walls (septa) between the holes and not reach the crystal. As a result, only radiations traveling perpendicular to the crystal surface pass through the apertures and contribute counts to the resulting image. A certain fraction of photons striking the septa will nonetheless pass through them and reach the crystal; this phenomenon, which degrades image quality, is known as septal penetration. Most collimators used clinically are parallel-hole collimators, with the apertures and septa parallel to one another. In addition, single-aperture pinhole collimators, most commonly used for thyroid imaging because of their pronounced magnifying effect, are available as well (Fig. 2a). Pinhole collimators, however, suffer from low sensitivity, limited field of view, and geometric distortion, since image magnification varies with both source-aperture distance and lateral position in the field of view, and therefore are rarely used for clinical imaging other than for the thyroid (normally a small, relatively flat organ). For preclinical (i.e., mouse and rat) imaging, multi-aperture pinhole collimation is now the standard approach, since it combines the magnification effect (and improved resolution) of pinhole collimation with the greater sensitivity afforded by multiple apertures (Fig. 2b).

Gamma camera collimators are "rated" with respect to photon energy and resolution/sensitivity. Low-energy, or "technetium," collimators, including "low-energy all-purpose (LEAP)" (or "general all-purpose (GAP)"), "low-energy high-resolution

(LEHR)," and "low-energy high-sensitivity (LEHS)" collimators, are designed to image radionuclides emitting x- and γ-rays less than 200 keV in energy. These include ^{99m}Tc (photopeak energy: 140 keV) as well as thallium-201 (^{201}Tl) (68–80 keV) and iodine-123(^{123}I) (159 keV). Medium-energy, or "gallium," collimators are designed for radionuclides emitting x- and γ-rays 200–300 keV in energy, including gallium-67 (^{67}Ga) (93, 185, and 300 keV) as well as indium-111 (^{111}In) (172 and 247 keV). High-energy, or "iodine," collimators are designed to image radionuclides emitting x- and γ-rays greater than 300 keV in energy, including ^{131}I (364 keV). In progressing from low- to medium- to high-energy collimation, the collimators are made longer and the septa thicker in order to interpose more lead between the subject and the crystal. This is done in order to maintain septal penetration (i.e., expressed as the percent of counts in an image attributable to photons penetrating the septa) at or below an acceptably low level, typically set at 5%. This, in turn, reduces the overall fraction of emitted x- and γ-rays reaching the crystal. To compensate, at least in part, for the resulting lower sensitivity, the apertures are made wider in progressing from low- to medium- to high-energy collimators. This, however, degrades spatial resolution by dispersing the counts passing through each aperture over a large area of the crystal (Figs. 3 and 4). Overall, therefore, gamma camera images are progressively poorer in quality for radionuclides emitting low- versus medium- versus high-energy x- and γ-rays. For each energy rating (and as indicated above for low-energy collimators), collimators may also be further rated as "general purpose" (or "all purpose"), "high resolution," or "high sensitivity." High-resolution collimators have narrower apertures (and therefore lower sensitivity), and high-sensitivity collimators have wider apertures (and therefore coarser resolution), respectively, than general-purpose collimators. In instances where a radionuclide emits multiple photons, it is the highest-energy photon which dictates the collimator to be used. For example, a medium-energy collimator must still be used to image gallium-67 (photon energies: 93, 185, and 300 keV) even if only the two lower-energy (i.e., the 93 and 185 keV) photons are used for imaging.

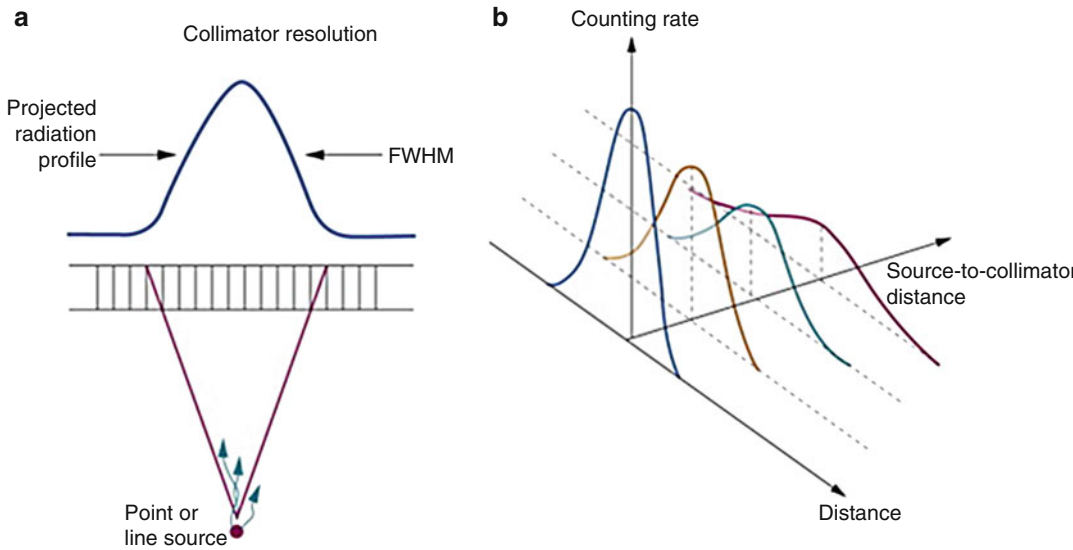

Fig. 3 (**a**, **b**) In gamma camera imaging with parallel-hole collimation, the 3D volume subtended by a point source of radiation is a cone, with the area of the detector over which radiations from the source are dispersed increasing, and therefore the spatial resolution worsens, with increasing source-to-collimator distance (Adapted from Ref. [40] with permission)

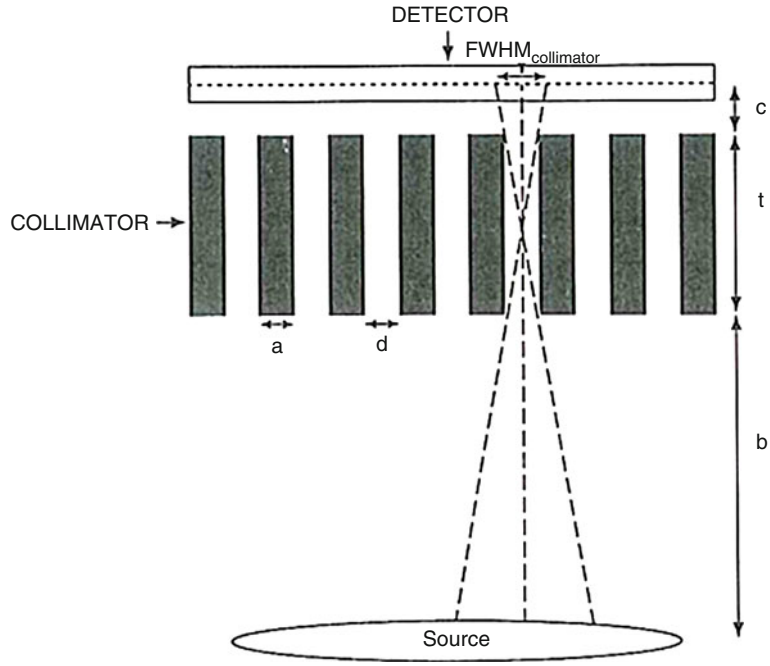

Fig. 4 Collimator spatial resolution, $FWHM_{collimator}$, for a parallel-hole collimator with thickness *t*, aperture diameter *d*, septal thickness *a*, and source-to-collimator face distance *b*. The collimator is fitted to a detector whose midplane is at a distance *c* from the back surface of the collimator (From Ref. [9] with permission)

Solid-state ionization (i.e., semiconductor)-based gamma cameras utilizing cadmium zinc telluride (or CZT) are now commercially available [7, 8]. CZT detectors are more expensive than detectors based on NaI(Tl) crystal coupled with PMTs in the conventional Anger camera but offer several important advantages, including improved energy resolution (typically resulting in a 30% reduction of the scatter counts in the photopeak energy window) and superior intrinsic spatial resolution [7, 8]. The mass density of CZT is higher than that of NaI(Tl) (5.8 vs. 3.7 g/cc), but due to considerations of the higher cost and in order to maintain excellent energy resolution, CZT detectors are thinner (~5 mm) than the typical 3-/8-in. (9.5-mm) NaI(Tl) crystals. The intrinsic sensitivities of CZT and NaI(Tl) are therefore comparable. However, the compact form factor of CZT detectors (Fig. 5) allows for novel detector geometries and, in turn, high-sensitivity collimation.

The full-width half-maximum (FWHM) spatial resolution, $FWHM_{system}$, of gamma cameras is determined by a combination of physical and instrumentation factors. Intrinsic resolution, $FWHM_{intrinsic}$, is the component of spatial resolution contributed by the crystal and associated electronics and is

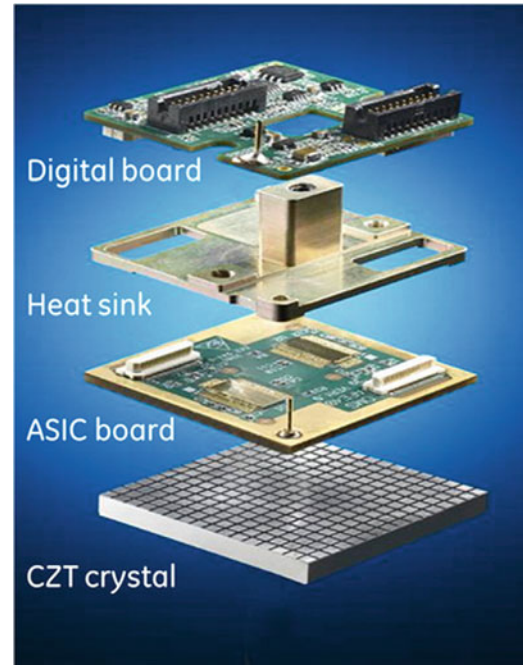

Fig. 5 Typical configuration of a CZT-based semiconductor detector. *ASIC*, application-specific integrated circuit (From Ref. [8] with permission)

related to statistical fluctuations in pulse formation; typical values are of the order of 5 mm. These statistical fluctuations include variations in the production of light photons resulting from x- or γ-ray interactions in the crystal and in the number of electrons emitted by the photocathode and the series of dynodes in the PMTs. Collimator, or geometric, resolution, $FWHM_{collimator}$, represents the major contribution to system resolution and is determined by the collimator design (Figs. 3a and 4). The spatial resolution of a parallel-hole collimator, the most common type, is determined by the geometric radius of acceptance of each aperture, as illustrated in Fig. 4:

$$FWHM_{\text{collimator}} = \frac{d(t_e + b + c)}{t_e} \qquad (1)$$

where d is the diameter of the collimator aperture, b the source-to-collimator face distance, c the collimator back-to-mid-crystal distance, and $t_e = t - 2/\mu$ the effective thickness of the collimator where t is the actual collimator thickness and μ is the radiation energy-dependent linear attenuation coefficient of the collimator material [9]. As indicated by Eq. 1, collimator resolution is improved (i.e., lowered) by reducing the diameter d of the collimator aperture, the source-to-collimator face distance b, and the collimator thickness t. System resolution is further degraded by the contributions of septal penetration resolution, $FWHM_{penetration}$, and by scatter resolution, $FWHM_{scatter}$. The spatial resolution of a gamma camera system, $FWHM_{system}$, can be obtained by combining the resolution of the respective components of the system [9]:

$$FWHM_{\text{system}} = \sqrt{FWHM_{\text{intrinsic}}{}^2 + FWHM_{\text{collimator}}{}^2 + FWHM_{\text{penetration}}{}^2 + FWHM_{\text{scatter}}{}^2} \qquad (2)$$

In clinical practice, the collimator resolution generally dominates the system resolution.

SPECT Data Acquisition

Although there are many possible combinations of detector number, geometry, and motion that can acquire the necessary projection data, rotating gamma camera-based SPECT systems are the most common [4]. Nowadays, two-detector systems predominate clinically and two- to four-detector systems preclinically. The basic SPECT imaging paradigm includes acquisition of planar projection images from multiple angles around the subject, correction of the acquired data for nonuniform scanner response and possibly other signal-degrading effects, and mathematical reconstruction of thin (several-millimeter-thick) transverse tissue section images [4]. The raw data are acquired as a series of discrete planar images at multiple angles about the longitudinal axis of the patient (Fig. 6). The number of counts recorded in each projection-image pixel represents the ray sum, or line integral, of the sampling line perpendicular to and extending from the detector through the subject. The following are typical SPECT acquisition parameters: 20–30 min for data acquisition; ~60 to ~120 projection images at ~6 to ~3° angular increments, respectively; and a 180 or 360° rotation for cardiac or noncardiac studies, respectively. An angular increment in excess of 6° between successive projection images will result in prohibitive undersampling artifacts in the reconstructed images. Because of the length of time (20–30 min) required for an acquisition, dynamic SPECT and whole-body SPECT remain largely impractical at the current time. It should be emphasized that SPECT images can in principle be quantitative in absolute terms, with voxel values representing the local activity concentration [10–12]. However, in contrast to PET, this is often not the case in routine practice because of the confounding effect of scatter and attenuation as well as limited count statistics. Accurate correction for

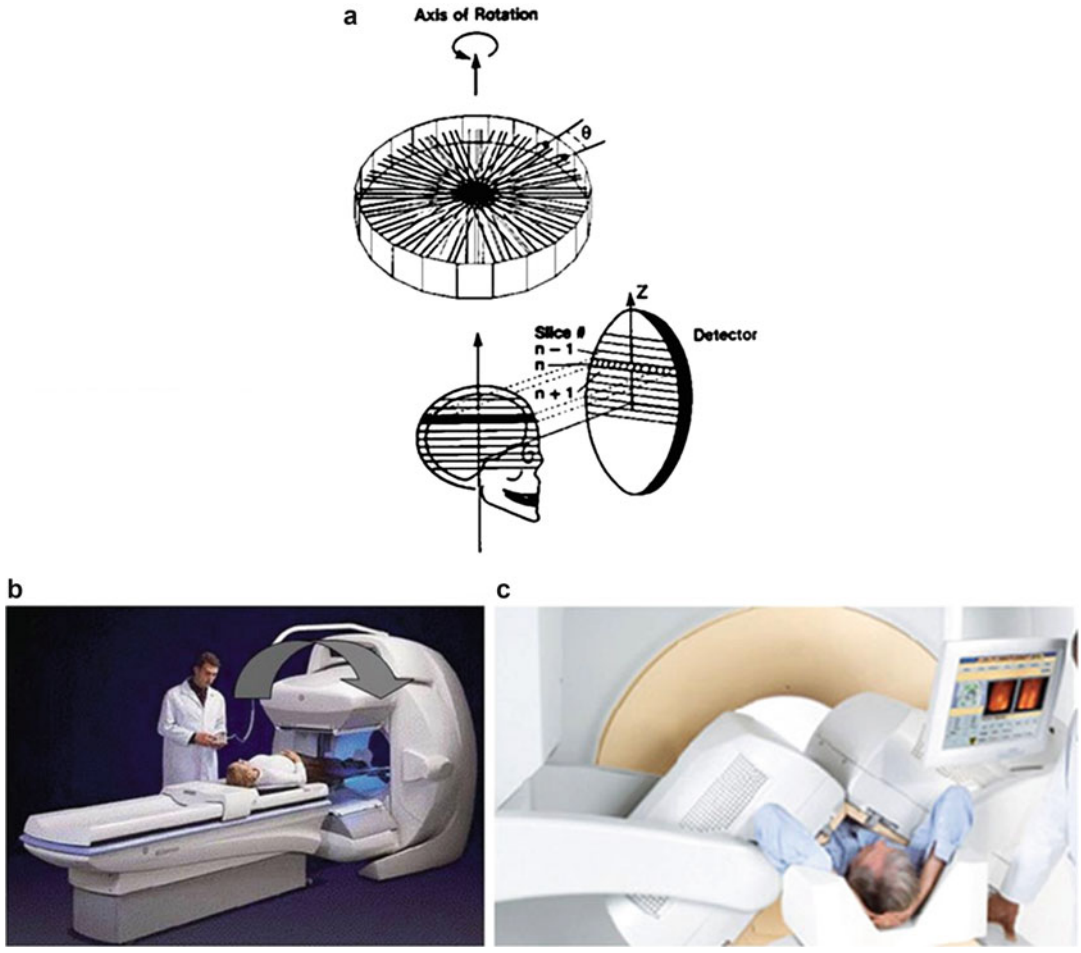

Fig. 6 (**a**) The basic data acquisition paradigm in rotating gamma camera SPECT. Photographs of a dual-detector gamma camera, with (**b**) the two detectors in opposed positions, as routinely used for a 360° rotation and general (noncardiac) SPECT and (**c**) the two detectors perpendicular to each other, as routinely used for a 180° rotation and cardiac SPECT (with projection images acquired from approximately right anterior oblique to left posterior oblique). The advantage of such two-detector systems is that two projection images can be acquired simultaneously and, in first order, either the acquisition time halved or the acquired counts doubled (From Ref. [4] with permission)

these effects remains more challenging in SPECT than in PET [10, 11].

Although PET offers important advantages over SPECT (i.e., generally better spatial resolution, higher sensitivity, and more accurate activity quantitation), SPECT offers the capability of multi-isotope imaging. Because different SPECT radionuclides emit x- and γ-rays of different energies, multiple isotopes and therefore multiple radiotracers can be imaged simultaneously using distinct, isotope-specific photopeak energy windows.

Data "Corrections"

Uniformity correction. Even optimally performing SPECT scanners exhibit some nonuniformity of response [4, 13, 14]. Among the thousands of pixels in a SPECT projection image, slight variations in detector thickness, light emission or coupling properties, electronics performance, etc. result in slightly different measured count rates for the same activity. In principle, such

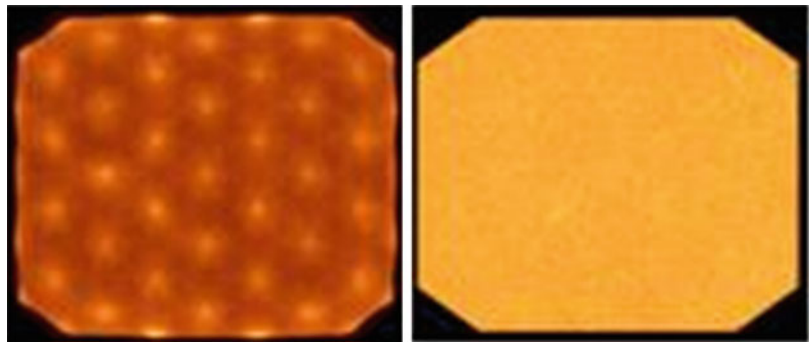

Fig. 7 Uniformity correction and its effects. The *left panel* shows gamma camera image of a uniform source of radioactivity without the uniformity correction applied. The pattern of PMTs is apparent in this grossly nonuniform, uncorrected image. In contrast, the corrected image in the *right panel* is uniform

nonuniform response can be corrected by acquiring data from a uniform flux of γ-rays and normalizing to the *mean* count rate from all the pixels in SPECT. This "uniformity map" corrects for the nonuniform count rate of the individual pixels or lines of response (LORs) to thereby yield a pixel-by-pixel uniformity correction. The effects of nonuniformity of scanner response and of the correction for nonuniform response are illustrated in Fig. 7 [14].

For gamma camera imaging, a correction table may be acquired using either a uniform flood source placed on the detector or a point source placed sufficiently far (typically 1–2 m) from the uncollimated detector to deliver a uniform photon flux. Acquisition of the data required for uniformity correction is somewhat problematic in practice because of statistical considerations: tens of millions must be acquired to avoid possible "noise"-related artifacts in the uniformity correction table.

Deadtime correction. In SPECT, deadtime count losses are generally minimal at diagnostic administered activities. While real-time correction for deadtime count losses is routinely applied in PET, this is generally not the case in SPECT. Count rates encountered in PET are much higher than in SPECT – in part because of the use of electronic rather than absorptive collimation – and therefore accurate deadtime correction is more critical in PET.

Center-of-rotation misalignment correction. In rotating gamma camera SPECT, the location of the projection of the center of rotation (COR) on the projection-image matrix must be constant [14–16]. If the mechanical and electronic CORs are aligned, the pixel location of the projection of the COR onto the projection-image matrix will be the same for all projection images, and, for all such images, the counts in each pixel will then be projected across the appropriate row of pixels in the tomographic image matrix. If, however, the mechanical and electronic CORs are not aligned, the pixel location of the COR will vary among the projection images, and the counts in each projection-image pixel will be projected across different locations in the tomographic image matrix, and blurred images will result (Fig. 8a). In today's SPECT systems, COR misalignment may be easily measured, and corrections are created and automatically applied using the system's software (Fig. 8b). In contrast, PET scanners typically utilize fixed rings of detectors and thus do not suffer from COR misalignment.

Scatter correction. Scatter results in generally diffuse background counts in reconstructed images, reducing contrast and distorting the relationship between image intensity and activity concentration [10, 17, 18]. Several methods, characterized as energy distribution- or spatial distribution-based methods, have been proposed for SPECT scatter correction [12]. However, only the dual-energy window-based or triple-energy window (TEW)-based estimation and the effective scatter source estimation (ESSE) method have been

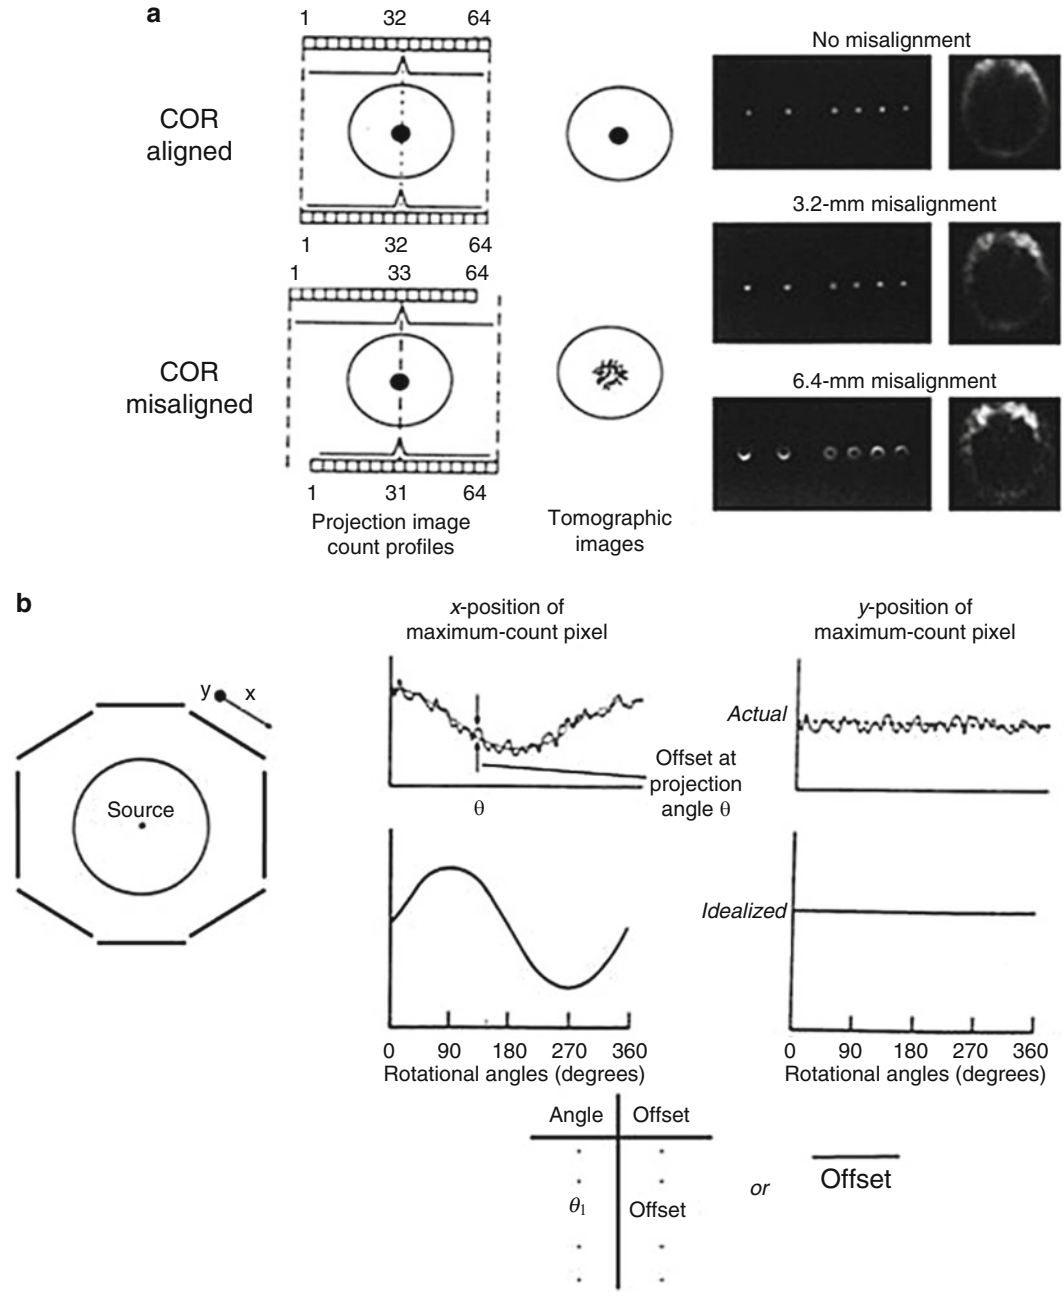

Fig. 8 (**a**) Center-of-rotation (*COR*) misalignment and resulting image-blurring artifacts in rotating gamma camera SPECT. The degree of blurring is related to the magnitude of the spatial misalignment of the mechanical and electronic CORs. A misalignment as small as 3.2 mm (or ½ a pixel for a 64 × 64 image matrix) can produce perceptible blurring in SPECT images, with the blurring substantially worse for a misalignment of 6.4 mm (1 pixel) (Adapted from Ref. [15] with permission). Note that for a cross-sectional image of a line source, COR misalignment blurs the expected point into a full or partial circle depending on the position of the source in the FOV: if it is at or near the center of the FOV, the line source appears as a full circle in cross section; if it is near the periphery of the FOV, it appears as a partial circle. (**b**) COR misalignment can be measured and corrected based on acquiring a 360° circular SPECT study of a ^{99m}Tc point source and constructing graphs of the x- and y-positions (perpendicular

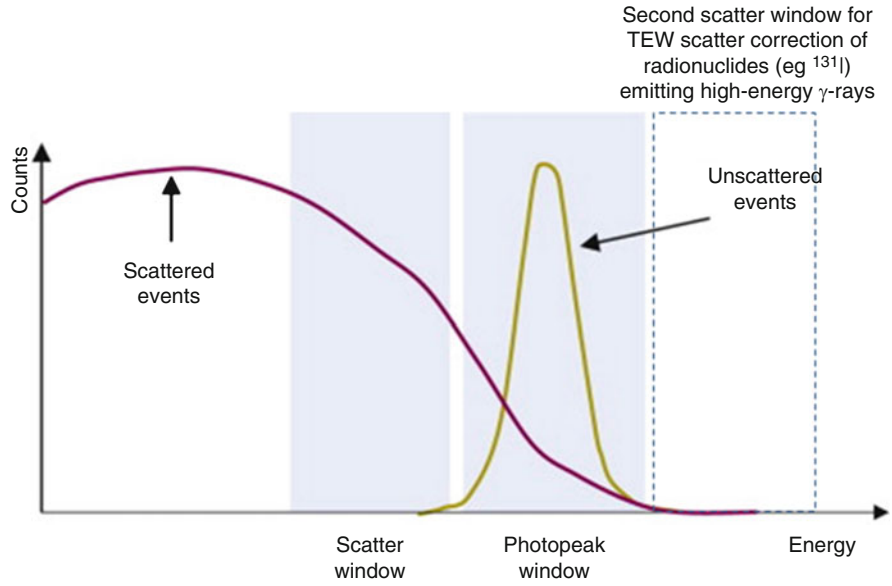

Fig. 9 Dual-energy windows (*shaded boxes*) superimposed on the energy spectrum of unscattered and scattered events for a patient-sized phantom filled with ^{99m}Tc. In contrast to ^{99m}Tc, a radionuclide such as ^{131}I emits a higher-energy γ-ray which will produce scattered events in the photopeak (unscattered-event) energy window in addition to those from scatter of the primary "imaging" γ-ray. For such radionuclides, the dual-energy window method may be generalized to the triple-energy window (*TEW*) method by using a second scatter energy window (indicated by the *dashed-line box*) immediately above the photopeak window (Adapted from Ref. [40] with permission)

implemented clinically. In multi-energy window-based methods [19] (Fig. 9), the number of scattered photons in the photopeak energy window is estimated based on counts in one or more scatter windows. In the TEW method, for example, the scatter is estimated as the area of the trapezoid beneath the line joining the two adjacent narrow scatter windows; for radionuclides emitting a single x- or γ-ray, the upper scatter window can be omitted. For each projection-image pixel *i,j*, the number of scatter counts in the photopeak window, $(C_{i,j})_{\text{scatter}}$, is calculated as:

$$(C_{i,j})_{\text{scatter}} = \left\{ \frac{(C_{i,j})_{\text{lower}}}{W_{\text{lower}}} + \frac{(C_{i,j})_{\text{upper}}}{W_{\text{lower}}} \right\} \frac{W_{\text{photopeak}}}{2} \tag{3}$$

where $(C_{i,j})_{\text{lower}}$ and $(C_{i,j})_{\text{upper}}$ are the counts in the lower and upper scatter energy windows, respectively, for projection pixel *i,j* and $W_{\text{photopeak}}$, W_{lower}, and W_{upper} are the widths (in keV) of the photopeak, lower scatter, and upper scatter windows, respectively. Typically, 20% photopeak and ~5% scatter energy windows are used. Because of the use of such narrow scatter energy windows, the

Fig. 8 (continued) and parallel to the axis of rotation, respectively) of the position of the maximum-count pixel in each projection image versus angular position. The x- and y-position-versus-angle graphs should be a sinusoidal curve and a straight line, respectively. The angle-by-angle deviation between the x-position on the best-fit sine curve and the x-position of the actual maximum-count pixel thus yields a correction table indicating the offset by which each projection image must be shifted at each angular position to align the CORs. Alternatively, the average of the offsets may be used at each angular position (Adapted from Ref. [14, 15] with permission)

TEW estimate of scatter counts tends to be noisy. In the ESSE method [20], a model-derived scatter function is used to calculate and correct for the scatter in the projection data based on the estimate of the activity distribution. An effective scatter source is calculated, and the attenuated projection of that source yields the scatter component of the SPECT projections. Other, more sophisticated and presumably more accurate approaches to scatter modeling include Monte Carlo simulation-based methods [21–23] and analytic methods using the Klein-Nishina formula for Compton scattering [24]. These methods are computationally intensive, however, and have been limited to use in research settings but likely will become clinically practical as computing power continues to increase.

Attenuation correction. As in PET, correction for the attenuation of the γ-rays as they pass through tissue is generally the largest correction in SPECT. The correction factors for a ^{99m}Tc SPECT scan of the brain (roughly equivalent to a 10-cm diameter water-equivalent cylinder) are ~2, for example. The magnitude of the correction depends on the energy of the γ-rays, the thickness of tissue(s) that the γ-rays must travel through, and the attenuation characteristics of the tissue(s).

Like scatter corrections, attenuation corrections in SPECT are not yet as well developed or as reliable as those in PET – because, for single photons, the attenuation correction factor (ACF) also depends on the depth of the source [4]. For many years, if attempted at all, SPECT attenuation correction factors were calculated (as in Chang's first-order correction and the Sorenson method [25, 26]) based on the assumptions – neither of which is generally accurate – that the body is a uniform medium with a single, well-defined value of μ and that the body's contour is known. At one time, manufacturers incorporated long-lived radioactive sources (such as gadolinium-153 (^{153}Gd)) into SPECT scanners to perform attenuation correction. As part of the SPECT procedure, a shutter opens at each projection-image angle to expose a highly collimated line source, and a transmission image is acquired. The transmission images thus acquired are reconstructed into an ACF map for correction of the SPECT study. The introduction of hybrid SPECT/CT scanners (see below) is resulting in more practical and more accurate CT-based attenuation correction in SPECT [27].

Image Reconstruction

In emission tomography, the emission data correspond to the projected sum of counts (or line integrals) at various angles about the axis of the scanner. The full set of 2D projection data is usually represented and stored as a two-dimensional matrix in polar coordinates (distance r, angle ϕ) known as a "sinogram" [28] (see Fig. 14 in the chapter entitled "Instrumentation for Positron Emission Tomography").

There are two basic classes of image reconstruction methods, analytic [4, 28] and iterative [29]. For PET, iterative reconstruction is used almost exclusively nowadays and was reviewed in the earlier chapter on PET instrumentation. For SPECT, on the other hand, analytic image reconstruction (i.e., filtered back projection [4, 28]) is still widely used, though the use of iterative methods is increasing. The basic procedure for image reconstruction by filtered back-projection (FBP) is as follows: each angular projection is Fourier transformed from real to frequency (or "k") space; the projection is filtered in frequency space using a ramp filter (to enhance high and suppress low spatial frequencies and thereby minimize blurring artifacts) (Figs. 10a–c); the filtered projection is inverse Fourier transformed from frequency back to real space; and the filtered projection data in real space are uniformly distributed, or back projected, over the reconstructed image matrix [4, 28]. To compensate for the high noise levels resulting from the relatively low counts in most nuclear imaging studies, low-pass, or apodizing, filters (known as Shepp-Logan, Hann, etc.) are used in place of the ramp filter to eliminate those spatial frequencies above a specified cutoff frequency (Fig. 10d–g). In this way, the high spatial frequencies characteristic of statistical noise are eliminated (or at least minimized) in the reconstructed images.

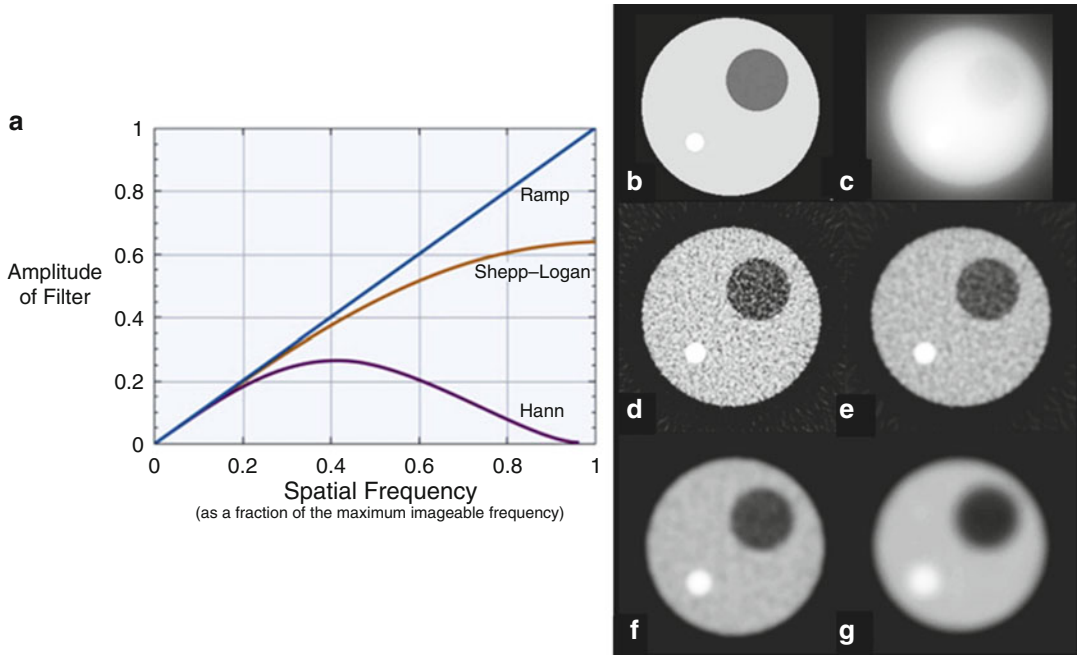

Fig. 10 (**a**) Graphical representation of the ramp and two other mathematical filters used in reconstruction of tomographic images. Note that the cutoff spatial frequencies of all three filters are set to the maximum frequency that can be imaged with the system being used to reduce noise amplification artifacts in the reconstructed images. Note further that the Shepp-Logan and Hann filters "roll off" gradually with increasing spatial frequency to further reduce noise amplification and other artifacts. (**b**) Cross section through a phantom containing high (*white*), intermediate (*light gray*), and low (*dark gray*) activity concentrations. (**c**) Tomographic image of phantom reconstructed by "simple" back-projection, that is, with no mathematical filtering of the projection images. Note the resulting blurring and other artifacts in the reconstructed image. (**d**–**g**) Tomographic images of phantom reconstructed by filtered back-projection using a Shepp-Logan filter with cutoff frequencies equal to 1, 0.8, 0.6, and 0.2 times of the maximum spatial frequency that can be imaged with the system. Note the reduction in noise (i.e., graininess or mottle) but coarser delineation of edges (i.e., poorer resolution) as the cutoff frequency is reduced. For clinical SPECT studies, which generally have limited numbers of counts, cutoff frequencies lower than the maximum imageable frequency are used routinely (Adapted from Ref. [40] with permission)

Quantitation

Once the SPECT emission data have been corrected for dead time, system response (by uniformity correction), scatter, and attenuation, the count rate per voxel in the reconstructed tomographic images is proportional to the local activity concentration [10, 17, 18]. In routine practice, however, scatter and attenuation corrections are generally less accurate for SPECT than for PET (as previously noted) and reconstructed SPECT images less quantitatively accurate than PET images. Further, acquired SPECT data generally include far fewer counts than do PET data because of the use of absorptive collimation for SPECT and electronic collimation for PET, increasing the statistical uncertainties in SPECT.

Another consideration which adversely effects the quantitative accuracy is partial-volume averaging: for a source which is "small" relative to the spatial resolution of the imaging system, the image-derived activity or activity concentration in such a source underestimates the actual value, and the smaller the source the greater the degree of the underestimation [10, 30]. The dimensions of a source must be at least two times the full-width

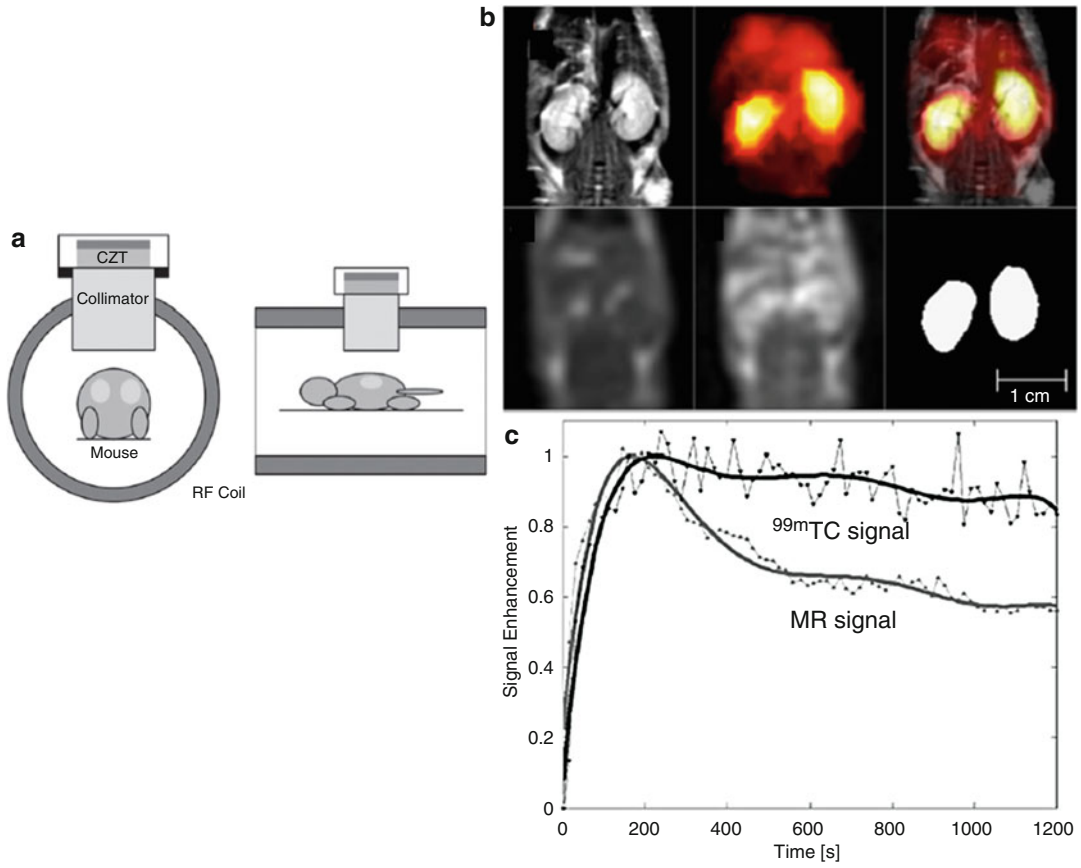

Fig. 11 Proof-of-principle single-photon scintigraphy-MR imaging study in a mouse. (**a**) Diagrammatic representation of the system for simultaneous single-photon scintigraphy using a CZT ionization detector and MR imaging. Note that this is not a SPECT (i.e., tomographic) system but rather a planar imaging system. (**b**) Static non-contrast T1-weighted MR image (*upper left panel*). Frame from dynamic ^{99m}Tc-sestamibi study (*upper middle panel*). "Fusion" of T1-weighted MR and ^{99m}Tc-sestamibi images. Since the ^{99m}Tc-sestamibi image is a planar image (*upper right panel*), the MR and scintigraphic images are not truly fused. (**c**) Frame from a dynamic MR study prior to injection of gadopentetate dimeglumine contrast (*lower left panel*). Frame from a dynamic contrast (gadopentetate dimeglumine)-enhanced MR study (*lower middle panel*). Kidney ROIs extracted from the static non-contrast T1-weighted MR image (*lower right panel*). (**d**) Renal signal-versus-time curves following the ^{99m}Tc-sestamibi and gadopentetate dimeglumine injections (Adapted from Ref. [37] with permission)

half-maximum (FWHM) spatial resolution of the imaging system to avoid such underestimation of the activity or activity concentration [30]. Since the source size dependence of the partial-volume effect can be measured (e.g., by phantom studies), the underestimated activity or activity concentration can be corrected if the source dimensions can be independently determined (e.g., by CT) [31]. Another key factor which limits quantitative accuracy is, of course, subject motion.

As noted in the earlier chapter on PET instrumentation, under favorable circumstances (i.e., for a high-count study of a large, stationery source region with a high source-to-background ratio), the quantitative accuracy of the PET is of the order of 10% [30]. A comparable accuracy, ~10%, is achievable for SPECT with state-of-the-art attenuation and scatter corrections [32]. With routinely available corrections, however, the quantitative accuracy of SPECT generally exceeds 20% [33].

Multimodality Imaging: SPECT/CT and SPECT/MRI

SPECT/CT scanners are, of course, now commercially available [27]. The paradigm for SPECT/CT scanners is similar to that of PET/CT in that the SPECT and CT gantries are separated and the SPECT and CT scans are acquired sequentially, not simultaneously. In such devices, the ~1-m separation of the SPECT and CT scanners is more apparent because the rotational and other motions of the SPECT detectors effectively preclude encasing them in a single housing with the CT scanner. Multimodality imaging devices for small animals (i.e., rodents) – PET/CT, SPECT/CT, and even SPECT-PET/CT devices – are now commercially available as well.

Unlike PET/MR devices, neither clinical nor preclinical SPECT/MR scanners are commercially available at the present time. Investigational preclinical SPECT/MR devices have been developed, however, and proof-of-principle studies have been performed (Fig. 11) [34–37]. As an alternative to scintillation detectors coupled to either PMTs or APDs, prototype SPECT/MR scanners have utilized solid-state (i.e., semiconductor) ionization detectors [34–37]. However, when a semiconductor detector is placed in a magnetic field, electron-hole pairs created by the absorption of x- and γ-rays are subject to the so-called Lorentz force. As a result, when such a detector is placed in any orientation other than parallel or antiparallel to the magnetic field, electrons traveling toward the anode will undergo a shift in their detected position (Fig. 12). For the prototype "MRSPECT" system described by Hamamura et al., for example, a mean "Lorenz shift" of 1.4 mm was measured [34, 35]. In this system, the correction for the Lorentz shift was performed prior to SPECT image reconstruction by shifting the nuclear projection data to their proper locations; this pixel-by-pixel correction was derived by imaging of a uniform flood source, analogous to derivation of gamma camera uniformity corrections generally. The detector elements were coupled to an application-specific integrated circuit (ASIC) readout board, and the detector-ASIC board housing and cables were wrapped with a fine copper mesh for RF shielding.

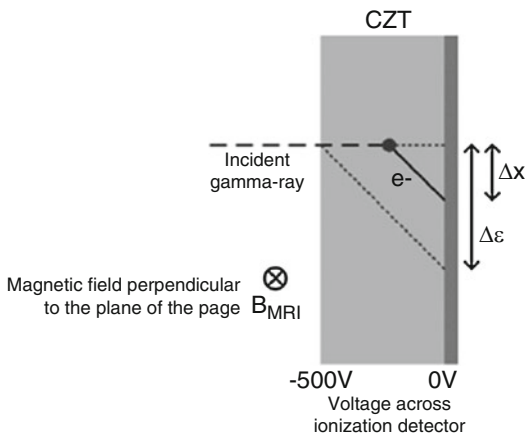

Fig. 12 Diagrammatic illustration of the Lorentz shift. After the interaction of an incident gamma ray with an ionization detector such as CZT, the resulting electron is deflected by a distance Δx due to the Lorentz force. Since the exact depth of the interaction of the gamma ray in the detector is statistical and can occur anywhere along the thickness of the element, there is a range of possible deflected distances Δε (Adapted from Ref. [34] with permission)

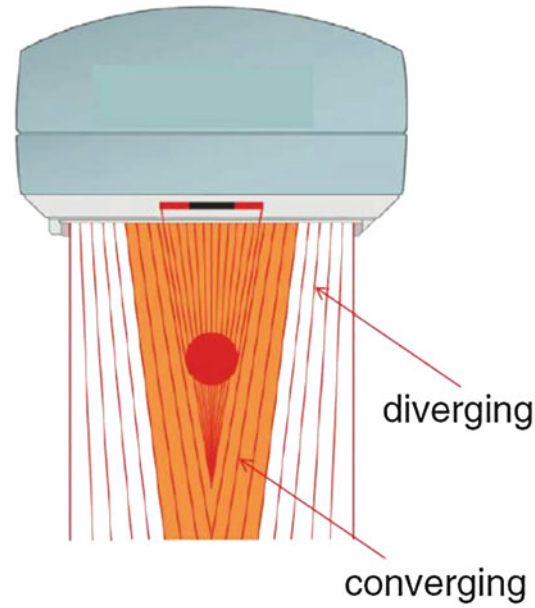

Fig. 13 Data acquisition geometry with the Siemens SmartZoom™ cardio-focal (diverging/converging) collimator. It provides higher sensitivity in the heart region by selective maximal magnification of that region (From Ref. [7] with permission)

Commercial Devices

Clinical. All of the major manufacturers of medical imaging equipment, including General Electric, Philips, Siemens, and Toshiba, currently market clinical SPECT devices. SPECT scanners continue to mainly utilize dual NaI(Tl) detectors (most commonly ~10 mm in thickness) in an opposed configuration; many commercial systems allow rotation of the detectors to an angle of 90° with respect to one another for cardiac studies. SPECT system spatial resolution (FWHM) with low-energy, high-resolution (LEHR) collimation is typically 7–8 mm for ^{99m}Tc at a source-to-collimator distance of 10 cm.

Conventional dedicated cardiac SPECT scanners generally employ two scintillation detectors fixed at a right angle to one another and, in some models, radioactive sources for transmission imaging-based, patient-specific attenuation correction [7, 8]. Cardiac imaging typically involves acquisition of projection data over only a 180° orbit (instead of the 360° orbit used for general SPECT imaging) – from right anterior oblique to left posterior oblique – because of the left, anterior position of the heart within the thorax. By positioning the two detectors at a right angle to one another, both detectors can simultaneously acquire usable data over the 180° orbit; if the two detectors were in the usual opposed position, only one of the two detectors would actually acquire usable data. Dedicated cardiac SPECT scanners with two scintillation detectors fixed at a right angle to one another include the Philips CardioMD™ and the Siemens CCam™.

Siemens has also introduced so-called "cardiofocal" (SmartZoom™) field-upgradeable collimators for high-sensitivity cardiac imaging with conventional dual-head gamma cameras (Fig. 13) [7, 8].

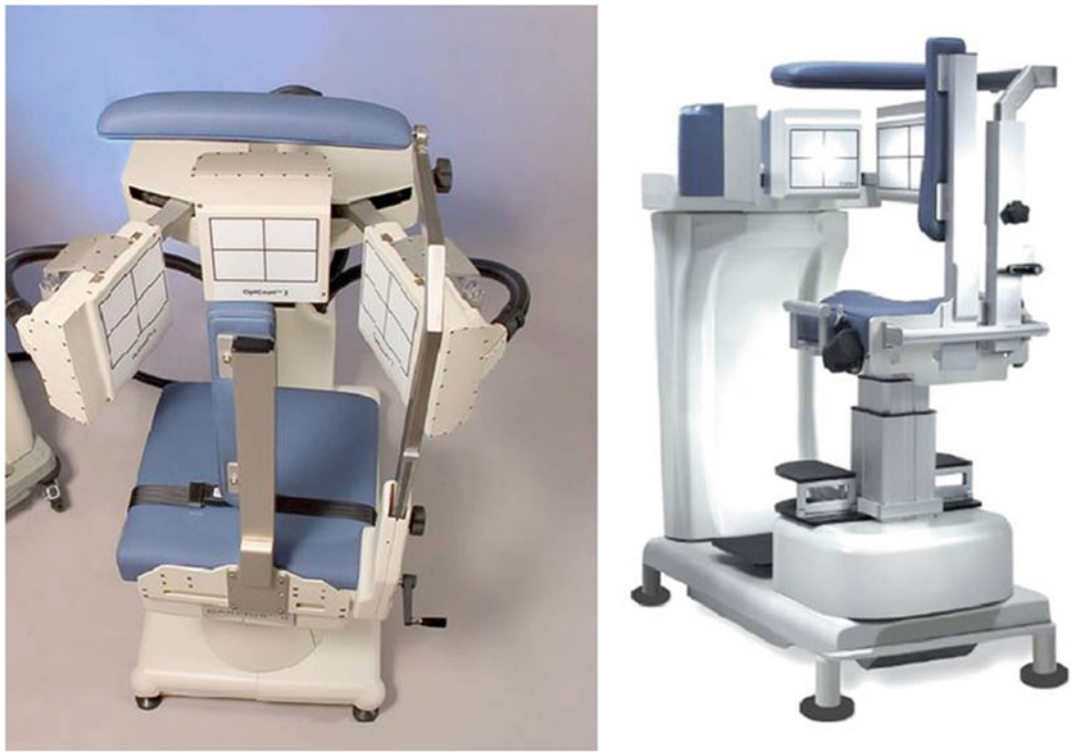

Fig. 14 Photographs of the Digirad Cardius 3 XPO™ system. The patient is seated upright, and the chair rotates to achieve the required angular sampling (From Ref. [7] with permission)

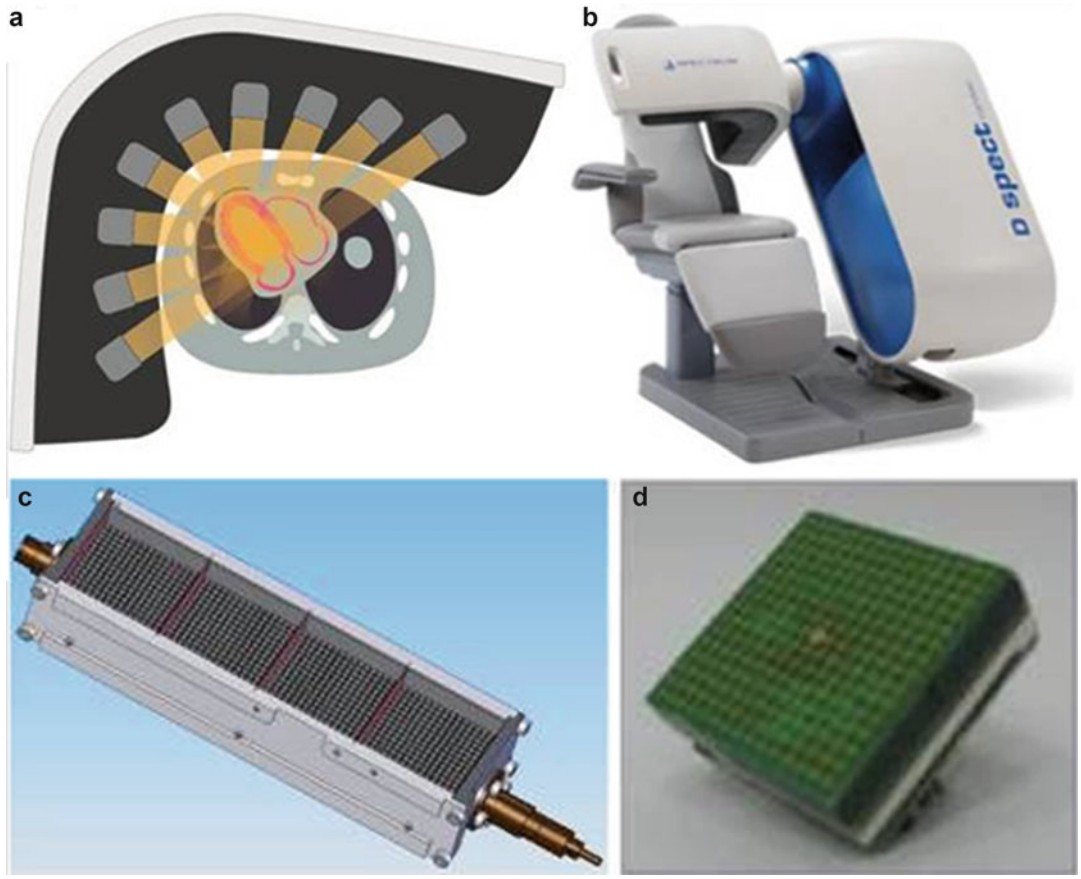

Fig. 15 (**a**) Detector configuration (*top view*) of the Spectrum Dynamics D-SPECT™ system with nine angularly directed detector blocks. (**b**) Photograph of the system. The patient may be seated upright or the chair reclines so that the patient may lie nearly supine. (**c**) One of the nine detector blocks. (**d**) One of the CZT detectors (From Ref. [7] with permission)

Also known as "astigmatic" collimation, with such a converging/diverging collimator, the converging collimation magnifies the center of the field of view (FOV) in both the axial and transaxial directions, while the diverging collimation minifies the periphery of the FOV to provide coverage of the entire body and thereby avoid truncation artifacts commonly seen with fanbeam collimators when imaging the torso. Such cardio-focal collimators can increase sensitivity for cardiac imaging by approximately twofold compared to that with high-resolution parallel-hole collimator.

The Digirad Cardius 3 XPO™ cardiac scanner employs three pixilated CsI(Tl) scintillation detectors and images patients in an upright seated position (Fig. 14) [7, 8]; one- and two-detector Cardius systems are available as well. It uses fanbeam collimators in the three-detector configuration coupled to photodiode detectors. The two outer detectors are positioned at a 67.5° angle relative to the central detector. Data are acquired by rotating the chair (rather than detectors) by 67.5°, yielding an acquisition arc of 202.5°. Its SPECT spatial resolution (FWHM) is 11.0 mm (radius of rotation: 20 cm) and sensitivity 160 cpm/μCi for ^{99m}Tc and LEHR collimation. The Digirad Cardius X-ACT™ system augments the Cardius 3 XPO™ with a fanbeam x-ray source for CT imaging. The CardiaArc HD-SPECT™ [38] also images patients in an upright seated position. It is comprised of three curved stationery NaI (Tl) crystals backed by three rows of 20 PMTs,

[f]*LEHR* low-energy high-resolution

with a thin curved lead collimator (the so-called aperture arc) having six vertical slots for horizontal collimation and rotating slowly back and forth every 10 s. The CardiaArc™ quotes a spatial resolution of 3.6 at an 82-mm source-to-detector distance to 7.8 mm at a 337-mm source-to-detector distance.

Two vendors have introduced CZT-based cardiac SPECT systems [7, 8]. The Spectrum Dynamics D-SPECT™ utilizes pixilated CZT detector arrays mounted in nine vertical columns, with four detectors in each column, placed in a 90° gantry geometry (Fig. 15). Each column consists of an array of 1,024 CZT elements (2.46 × 2.46 × 5-mm thick) arranged in a 16 × 64 element array with a size of 40 × 160 mm, achieving 16 cm of coverage of the thorax. Each detector array is fitted with square aperture, high-sensitivity, parallel-hole collimators such that the dimensions of each hole are matched to the size of a single detector element. Spectrum Dynamics also recently introduced a less expensive six-detector column system. In the other CZT-based camera design found in the General Electric Discovery NM 530c™ and Discovery NM/CT 570c™, a curved array of 19 5-mm-thick CZT-pixilated detector arrays each with a focused pinhole collimator is used (Fig. 16). Each detector array consists of four detectors, each with 246 CZT detector elements (2.46 × 2.46 × 5-mm thick) arranged in a 16 × 16 element array. In these two systems, the detector gantry does not rotate or otherwise move [7, 8]. The remarkably high sensitivity of these systems is not related to the intrinsic sensitivity of the CZT detectors but rather the high-sensitivity geometric arrangement and collimation of the detectors.

The foregoing dedicated cardiac scanners provide better spatial resolution and higher sensitivity than conventional gamma cameras, as illustrated in Fig. 17 [7, 8, 39]. These systems provide up to a sevenfold increase in sensitivity and twofold improvement in reconstructed image resolution compared with those of conventional dual-head systems. Cardiac imaging times with these scanners thus range from 2 to 3 min for systems with solid-state detectors to 4 min on scintillation detector systems with cardio-focal collimation [7, 8, 39]. The design and performance parameters of other commercially available clinical SPECT scanners are summarized in Table 2.

Table 3 Design and performance parameters of commercially available preclinical SPECT scanners[a,b]

	Mediso NanoSPECT™	Carestream Albira™	Gamma Medica Triumph™	MI Labs Vector™[c]	Siemens Inveon™
Detectors	NaI(Tl)	NaI(Tl)	CZT	NaI(Tl)	NaI(Tl)

[a]Preclinical scanners are currently marketed as "SPECT-only" scanners or as multimodality devices with integrated CT and/or PET scanners. As noted, the Carestream Albira, Gamma Medica Triumph LabPET Solo, and Siemens Inveon are available as trimodality PET-SPECT/CT systems

[b]Extracted from the marketing literature of the respective manufacturers

[c]The MI Labs Vector also functions as a PET scanner by collimated single-photon (i.e., noncoincidence) detection of the 511-keV annihilation gamma rays accompanying positron emission

Preclinical. A number of preclinical SPECT devices are commercially available. The various preclinical SPECT scanners are rather similar in design, generally utilizing multiple NaI(Tl) scintillation detectors fitted with multi-aperture pinhole collimators. The superior spatial resolution of preclinical versus clinical SPECT scanners, ~1 versus ~10 mm, is due to the magnification effect afforded by the pinhole collimation (Figure 2b). Of course, this is achieved at the cost of lower sensitivity, though the use of multi-aperture collimators and multiple (up to four) detectors as least partially mitigates the reduction in sensitivity. Preclinical devices are currently marketed as "SPECT-only" scanners, as multimodality devices with integrated CT scanners (typically conebeam devices with flat-panel detectors) or even as trimodality PET-SPECT/CT systems. The design and performance parameters of commercially available preclinical SPECT scanners are summarized in Table 3.

Concluding Remarks

Although the spatial resolution of SPECT (~1 and ~10 mm for preclinical and clinical devices, respectively) is excellent by historical standards for this modality, it remains relatively coarse compared to that of such high-resolution "anatomic" imaging modalities as CT and MRI (0.1–1 mm). Nonetheless, the distinctive and important advantages of radionuclide-based imaging – high detection sensitivity, "image ability" of non-perturbing doses of radiotracers, quantitative accuracy, and a vast array of radiotracers – ensure that SPECT (particularly in combination with CT and, potentially, MRI) will remain an invaluable molecular imaging modality in clinical practice and in clinical and preclinical research.

Instrumentation for Intraoperative Detection

12

Pat Zanzonico

Abstract

Focusing on nuclear and optical modalities, the current chapter reviews the rapidly advancing technologies in intraoperative detection and imaging. This chapter reviews not only currently routine intraoperative imaging technologies but also investigational technologies potentially adaptable to the intraoperative setting.

Keywords

Intraoperative imaging • Optical imaging • Gamma probes • Beta probes • Cerenkov imaging • Photoacoustic imaging • Raman effect

Glossary

[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
ALA	5-aminolevulinic acid
CARS	Coherence anti-Stokes Raman scattering
CCD	Charge-coupled detector
CdTe	Cadmium telluride
CdZnTe (or CZT)	Cadmium zinc telluride
CMOS	Complementary metal oxide semiconductor
CsI(Na)	Sodium-doped cesium iodide
CsI(Tl)	Thallium-doped cesium iodide
CT	X-ray computed tomography
DOT	Diffuse optical tomography
EPR	Enhanced permeability and retention
FITC	Fluorescein isothiocyanate
FLI	Intraoperative fluorescence imaging
FLuc	Gene encoding for firefly luciferase
FOV	Field of view
FWHM	Full-width half-maximum
GFP	Green fluorescent protein
GSO	Cerium-doped gadolinium orthooxysilicate
HgI_2	Mercuric iodide
ICG	Indocyanine green
LED	Light-emitting diode
LEHR	Low-energy high-resolution
LSO	Cerium-doped lutetium orthooxysilicate
MBq	Mega-Becquerel (10^6 Becquerel)
MR	Magnetic resonance
MRI	Magnetic resonance imaging
MSOT	Multispectral optoacoustic tomography
NaI(Tl)	Thallium-doped sodium iodide

Introduction

Focusing on nuclear and optical modalities, the current chapter reviews the rapidly advancing technologies in intraoperative detection and imaging. This chapter reviews not only currently routine intraoperative imaging technologies but also investigational technologies potentially adaptable to the intraoperative setting. The reader is referred to a recently published volume entitled, "Imaging and Visualization in the Modern Operating Room: A Comprehensive Guide for Physicians," which provides a detailed overview of the many logistical as well as technical considerations in modern intraoperative imaging [1].

Nuclear Counting and Imaging

Beginning with the pioneering studies of Sweet [2] 60 years ago, intraoperative probes (i.e., counters) have evolved into an important, well-established technology in the management of cancer [3–6]. Such probes (see Fig. 1) are used in radioguided surgery to more expeditiously identify and localize sentinel lymph nodes and thereby reduce the extent and potential morbidity of surgical procedures and, to a much lesser extent, to identify and localize tumor margins as well as visually occult disease following systemic administration of a tumor-avid radiotracer (e.g., 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG)).

Radionuclide-based detection and localization of tumors, especially small tumors, has several well-known limitations [7] which are mitigated through the use of intraoperative probes and, potentially, intraoperative gamma cameras. First, absolute tumor uptake of cancer-targeted radiotracers remains generally quite low, typically ~0.1% or less of the administered activity per gram. Second, overall radiation detection sensitivity in vivo is low as well, ranging from about 0.1% for gamma camera imaging (including SPECT) to ~10% for PET. This is exacerbated, of course, by the signal-degrading effect of attenuation of emitted radiation by overlying tissue. Third, a significant portion of the counts apparently emanating from a tumor or other targeted tissue may actually include counts originating elsewhere (i.e., from background activity in adjacent tissues) because of contrast- and resolution-degrading Compton scatter. However, because of the close proximity of a collimated detector to a tumor or sentinel lymph node which can be achieved at surgery, radionuclide detection of such structures can be enhanced using intraoperative probes or gamma cameras. In a study of simulated tumors in a torso phantom having uniform background activity, for example, Barber et al. demonstrated that a scintillation probe detected tumors with greater sensitivity than a gamma camera over a wide range of conditions provided the probe was placed within 1 cm of the tumor [8]. Alternatively, tumor or sentinel lymph node detection may also

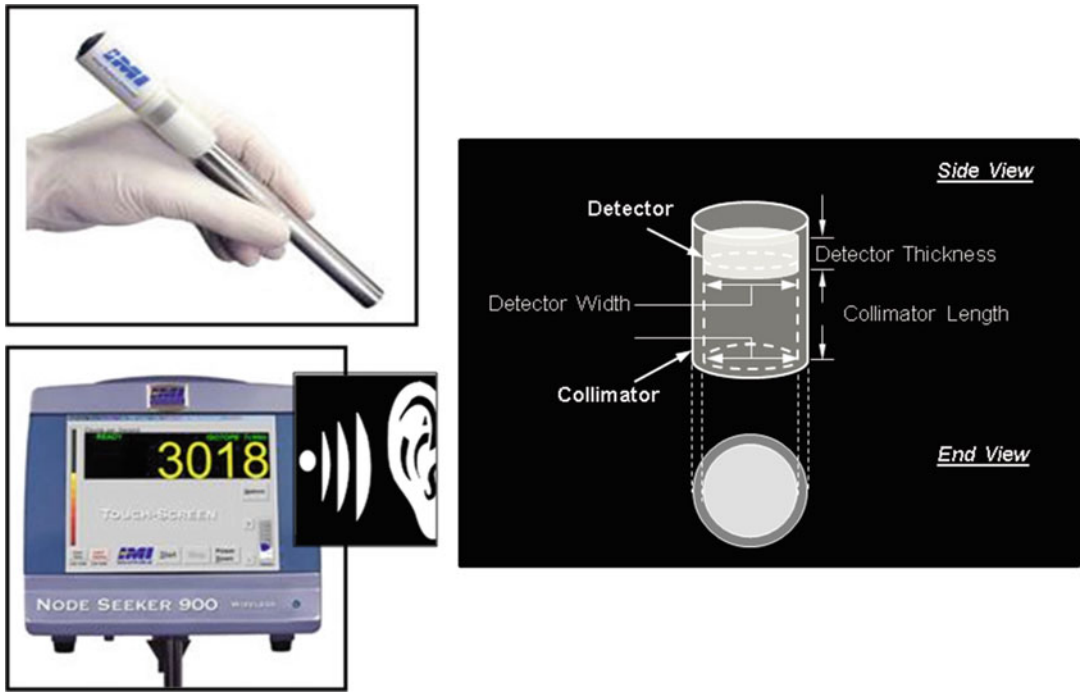

Fig. 1 The general design and operating principles of an intraoperative gamma probe. The handheld probe (*upper left panel*) is comprised of a collimated, small-area (typically ~1 cm in diameter) scintillation or solid-state ionization (i.e., semiconductor) detector (*right panel*). The probe itself is connected to a control unit (*lower left panel*) which typically provides both a visual readout of the count rate and an audible signal related to the count rate, with the frequency of the latter signal increasing or decreasing in relation to the detected count rate [12–14]

be improved under some circumstances using beta (negatron or positron), rather than gamma, detection [9–11] because the very short range (typically ~1 mm or less) of such particulate radiations eliminates the contribution of confounding counts from activity other than in the immediate vicinity of the detector. Of course, the short range of particulate radiations also limits the application of beta probes to intraoperative or endoscopic settings with the lesion near the surface of the exposed tissue.

Gamma probes. The most widely used type of intraoperative probe (e.g., in sentinel node detection) is the general-purpose "gamma" probe (Fig. 1), designed for counting of radionuclides emitting x- and/or γ-rays; such "single-photon" (i.e., non-positron) emitters include technetium-99m (^{99m}Tc), indium-11 (^{111}In), iodine-123 (^{123}I), and iodine-131 (^{131}I) [12–14]. Gamma probes generally use inorganic (i.e., nonplastic) scintillation detectors or solid-state (i.e., semiconductor) ionization detectors and lead or tungsten shielding and collimation. Scintillators used in such probes include thallium-doped sodium iodide (NaI(Tl)), thallium- and sodium-doped cesium iodide (CsI(Tl) and CsI(Na), respectively), and cerium-doped lutetium orthooxysilicate (LSO). Semiconductors used in intraoperative probes include cadmium telluride (CdTe), cadmium zinc telluride (CZT), and mercuric iodide (HgI_2). The former offer high sensitivity while the latter better energy resolution (and therefore better scatter rejection). Clinically, however, scintillation detector- and ionization detector-based probes provide generally comparable performance [12–14]. Positron emitters such as fluorine-18 (^{18}F) may also be counted with such probes by single-photon (i.e., noncoincidence) counting of the 511-keV annihilation γ-rays. As illustrated in Fig. 2, however, this requires thicker collimation and shielding to prevent penetration of significant numbers of such highly energetic γ-rays emitted from

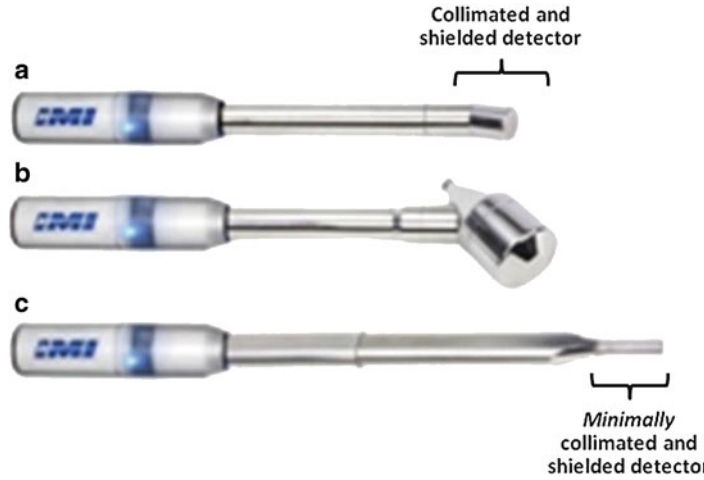

Fig. 2 Comparative thickness of gamma probe collimation and shielding required for low- to medium-energy x- and γ-rays of single-photon emitters (**a**), for high-energy (511-keV) annihilation γ-rays of positron emitters (**b**), and for negatrons and positrons of beta particle emitters (**c**). Note the much thicker collimation and shielding required for counting of the annihilation γ-rays and the minimal collimation and shielding for counting of beta particles [12] (Courtesy of IntraMedical Imaging, Los Angeles, CA)

outside of the field of view (FOV) (as defined by the collimator aperture) from reaching the detector and thereby degrading spatial resolution as well as target-to-background contrast. This has also been demonstrated in preliminary clinical and preclinical studies [15–18]. GF&E Tech GmBH (Seeheim, Germany) has marketed a novel probe for 511-keV annihilation photons using "electronic collimation" based on the time differences in activation among multiple CsI(Tl) crystals [19].

Beta probes. Because x- and γ-rays penetrate relatively long distances (circa 10 cm) of soft tissue, a major limitation of the use of gamma probes to specifically identify the target tissue in radioguided surgery is the presence of variable, generally high levels of background activity in normal tissues. Thus, even with a gamma probe centered over a tumor, the contribution of counts originating from activity in normal tissue underlying the tumor and even outside the field of view (due to penetration of the collimation and shielding) may degrade the tumor-to-normal tissue contrast (e.g., reducing tumor-to-normal tissue count ratios to less than 1.5:1 [15, 20, 21]) and thus tumor detectability to the point where lesions may be missed. A potential solution to this limitation of radioguided surgery is the use of so-called "beta" probes, that is, intraoperative probes which specifically count only charged particle (negatrons or positrons) radiation. Because they have such short ranges in soft tissues (typically of the order of 1 mm or less), beta particles emitted by a tracer source outside the probe's FOV or underlying the surface tissue do not reach the detector and are not counted (by the same token, minimal if any collimation and shielding is required (Fig. 2c). As a result, the discrimination between higher-activity tumor and lower-activity normal tissues is enhanced (i.e., the tumor-to-normal tissue count ratios are increased). Of course, the short path length of beta particle restricts the use of such probes to surface lesions; beta probes could not be used, for example, for (percutaneous) detection of sentinel lymph nodes.

Beta probes generally utilize either semiconductor or plastic scintillator detectors, since such detectors have lower effective atomic numbers and mass densities than inorganic scintillators such as NaI(Tl) and thus lower intrinsic efficiencies for x- and γ-rays, minimizing the potentially confounding count contribution of tracers emitting both beta (or conversion electron) and gamma radiation (e.g., iodine-131) [9–11, 21, 22]. For a

pure beta particle emitter such as phosphorus-32, this would not be a problem [9, 23]. Daghighian et al. [9] have developed and evaluated a plastic scintillator-based positron probe (Fig. 3). The basic design of this dual-detector probe (Fig. 3a) includes two scintillation detectors, a central solid cylinder detector (designated "Detector 1" in Fig. 3a) and a hollow cylinder detector (designated "Detector 2" in Fig. 3a) in 1-mm-thick stainless steel cladding; the outputs of the two detectors are passed by fiber-optic cabling to separate PMTs (PMT 1 and PMT 2, respectively). The Detector 1 counts result from both positrons and the 511-keV annihilation photons associated with positron emission, while the stainless steel cladding of Detector 2 completely attenuates the positrons and allows only the annihilation photons to enter the detector and generate counts from that detector. Because of the differences between Detectors 1 and 2, their sensitivities for the 511-keV photons are different. The Detector 1-to-Detector 2 ratio of the measured sensitivities for 511-keV photons is the weighting factor by which the Detector 2 count rate is multiplied and then subtracted from the Detector 1 count rate to yield the Detector 1 positron-only count rate. This probe was evaluated using the phantom setup shown in Fig. 3b, with a small ^{18}F-containing capsule simulating a tumor and a uniform ^{18}F-filled cylindrical container simulating underlying normal

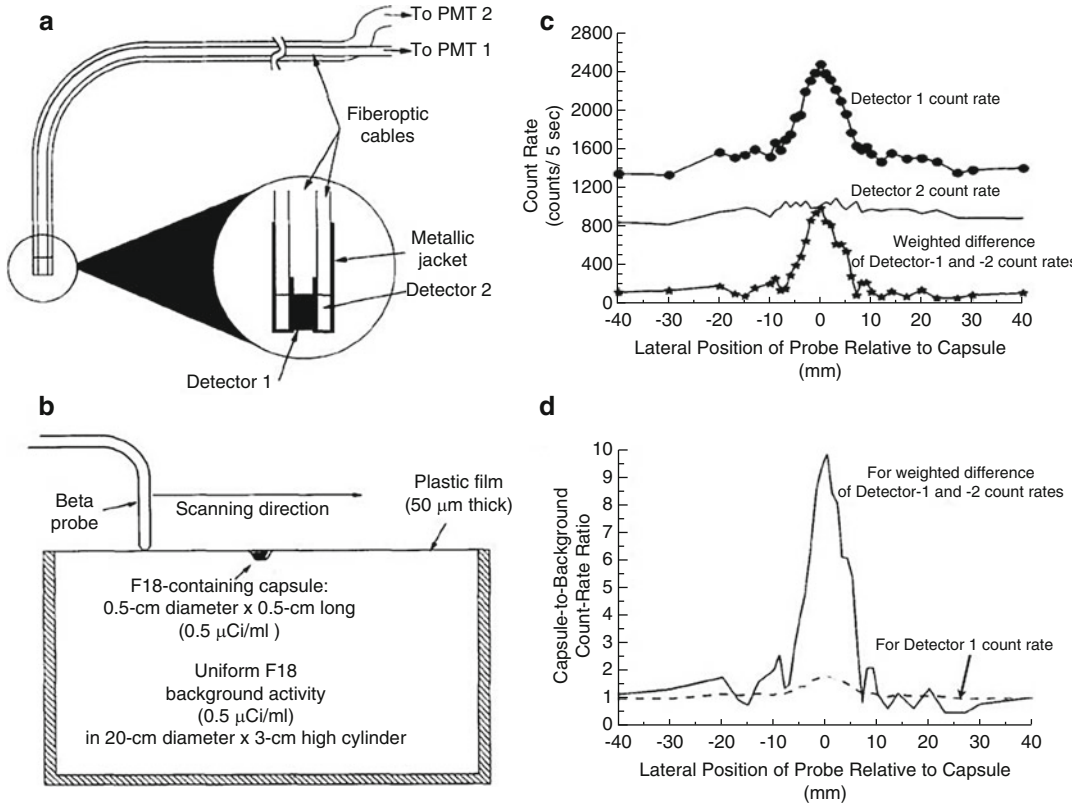

Fig. 3 (**a**) Basic design of a dual-detector beta probe [9]. (**b**) Experimental phantom setup for evaluation of the performance of the probe shown in (**a**). The phantom consisted of a small ^{18}F-containing capsule simulating a tumor and a uniform ^{18}F-filled cylindrical source simulating underlying normal tissue activity. The probe was then scanned across the phantom. Note that the capsule (i.e., tumor)-to-background (i.e., normal tissues) activity concentration ratio was 10:1. (**c**) The measured Detector 1 and 2 count rates and the calculated weighted difference of the Detector 1 and 2 count rates (see text) as a function of the lateral position of the probe relative to the capsule. (**d**) The capsule (i.e., tumor)-to-background count rate ratios for Detector 1 with and without weighted subtraction of the Detector 2 count rates (see text) (From [9] with permission)

tissue activity. The probe was then scanned across the phantom and the Detector 1 and 2 count rates at lateral positions relative to the "tumor" (i.e., capsule) recorded; the results, in terms of the measured count rates and the capsule (i.e., tumor)-to-background ratios, are plotted in Fig. 3c and d, respectively. These results (particularly the dramatic improvement – from ∼2 to ∼10 – in the tumor-to-background ratios (Fig. 3d)) clearly demonstrate the feasibility of this dual-detector design and weighted subtraction algorithm for beta probes in general and positron probes in particular. This has also been demonstrated in preliminary clinical and preclinical studies [17, 18].

Intraoperative gamma cameras. The sensitivity and specificity of detection of sentinel lymph nodes using current approaches such as the preoperative gamma camera imaging, gamma probes, and "blue dye" technique are quite high. Newman [24], for example, performed a meta-analysis of nearly 70 published studies and found an overall sensitivity of over 90% and a false-negative rate of only 8.4% for detection of such nodes in breast cancer. For preoperative gamma camera imaging, detection rates of 72–85% have been reported [25]. Sentinel lymph nodes were successfully detected using intraoperative gamma probes in 98% of patients in whom such nodes were successfully imaged preoperatively, with a false-negative rate of only 7%. And, for sentinel nodes not visualized by preoperative lymphoscintigraphy, there was a 90% detection rate intraoperatively. Importantly, however, negative preoperative lymphoscintigraphy often predicted a negative intraoperative probe result, and the foregoing improvement in the detection rate intraoperatively was primarily due to the use of blue dye [25]. The American Society of Breast Surgeons has recommended a sensitivity of at least 85% and a false-negative rate of less than 5% as acceptable for sentinel node detection in breast cancer [26]. There remains a need, therefore, to develop techniques to improve the sensitivity and the false-negative rates of sentinel lymph node detection. Intraoperative gamma camera imaging may provide the improvement required to satisfy the foregoing requirements. Mathelin et al. [27–29], for example, found that the use of an intraoperative small (5 × 5 cm) FOV gamma camera for detection of sentinel lymph nodes in breast cancer was practical. In a case report [28], intraoperative gamma camera imaging allowed detection of an additional sentinel lymph node (metastatic and with low radiotracer uptake) that was not detected by preoperative imaging or with a gamma probe, suggesting that intraoperative gamma camera imaging may reduce the false-negative rate. In addition to gamma camera and probe technology, the tracer employed (e.g., sulfur colloid versus nanocolloid, versus tilmanocept) and the injection site (e.g., intradermal versus subcutaneous, versus peri-tumoral) may account for the variation in lymph node detection.

Despite such promising preliminary data, it is not clear that the development and deployment of intraoperative gamma camera technology and the incremental improvement in the sentinel lymph node detection rate that such technology may provide will prove to be cost-effective. Certain considerations, however, lend support to the development of this technology. One such consideration is the variable level of proficiency among surgeons in gamma probe-based detection of sentinel lymph nodes [26]: even with considerable training and experience, not all surgeons achieve a detection rate of 90% or better. In addition, certain sentinel lymph nodes are problematic anatomically or otherwise in terms of detectability. These include nodes which are unusually deep, close to (less than 30 mm from) the injection site or high-activity normal tissues, or have a low (less than 1%) radiotracer uptake [25, 29–31]. A gamma camera system having a spatial resolution of 3 mm or better at a distance (depth) of the order of 1 cm would likely visualize such problematic nodes intraoperatively. Such an imaging system would offer other practical advantages over probes: the signal is provided in the familiar format of a scintigraphic image rather than a numerical display or variable-frequency tone; the larger FOV of even small gamma cameras (several centimeters) than that of probes (less than 1 cm) allows more rapid interrogation of large areas and/or longer sampling, with collection of more counts and reduction in statistical uncertainty (noise); more straightforward reexamination of the surgical site post-lymph node excision to verify removal of

foci of activity; and less reliance on potentially obliterated and otherwise ambiguous preoperative skin markings directing where measurements are to be performed intraoperatively [31]. Intraoperative gamma camera systems thus merit development and evaluation.

A number of small FOV intraoperative gamma camera systems have been developed [12, 32, 33]. The earliest systems were handheld devices having FOVs of only 1.5–2.5 cm in diameter and using conventional NaI(Tl) or CsI(Tl) scintillation detectors. Later units used two-dimensional arrays (mosaics) of scintillation crystals connected to a position-sensitive PMT and, more recently, semiconductors such as CdTe or CdZnTe (CZT). The main problems with these early units were their very small fields of view and the resulting large number of images required to interrogate the surgical field and the difficulty in holding the device sufficiently still for the duration (up to 1 min) of the image acquisition. More recently, larger field-of-view devices have developed which are attached to an articulating arm for convenient and stable positioning. These systems are nonetheless fully portable and small enough overall to be accommodated in typical surgical suites.

Abe et al. [34] evaluated a handheld CZT-based semiconductor gamma camera known as the eZ-SCOPE (Anzai Medical, Tokyo, Japan). As illustrated in Fig. 4, the device is light enough (820 g) to hold for a short time (up to ~1 min). The CZT detector has a 3.2 × 3.2-cm FOV and is 5 mm thick, with an efficiency of 87% and energy resolution of 9% for ^{99m}Tc γ-rays. Its collimators are easily exchanged. The CZT crystal is divided into a 16 × 16 array of 2 × 2-mm pixels, with integral and differential uniformities of 1.6% and 1.3%, respectively, with low-energy high-resolution (LEHR) collimation. System spatial resolution with the LEHR collimation was 2.3-, 8.0-, and 15-mm full-width half-maximum (FWHM) at source-to-collimator distances of 1, 5, and 10 cm, respectively. As shown in Fig. 4b, c, this camera is able to clearly image sentinel lymph nodes as well as lymphatic vessels. The small 3.2 × 3.2-cm FOV remains limiting, however; as shown in Fig. 4b, c, for example, a single lymph node occupies nearly half of the FOV and searching the surgical field can thus be time-consuming. A pinhole collimator was therefore subsequently incorporated into a newly designed version of the system, the Sentinella 102 (see below). In order to generate a larger

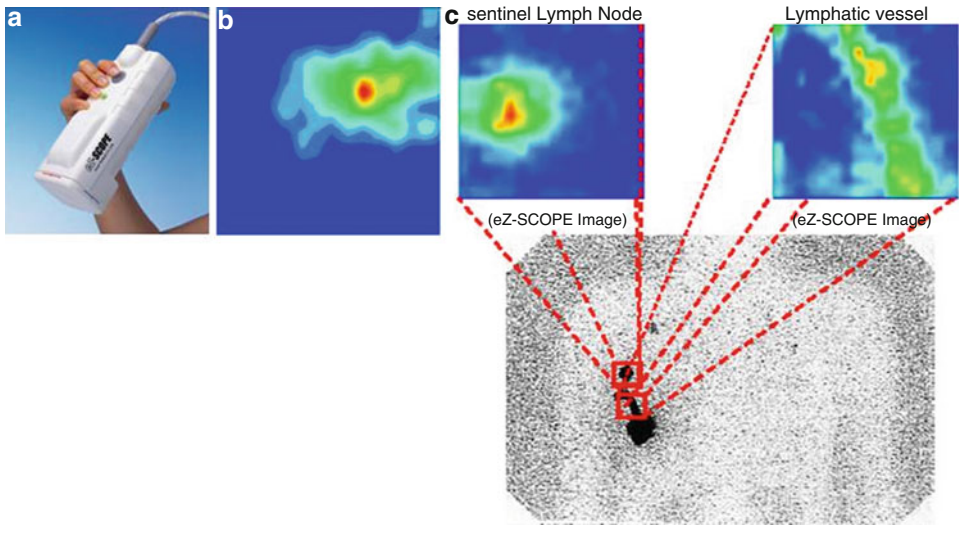

Fig. 4 (**a**) Photograph of the eZ-SCOPE intraoperative gamma camera (Anzai Medical, Tokyo, Japan). (**b**) Sample eZ-SCOPE image of a lymph node in a patient. (**c**) Sample eZ-SCOPE images of a lymph node (*top left*) and lymphatic vessel in a patient (*top right*) and conventional gamma camera image of the same patient obtained preoperatively (*bottom*). See text for additional details

effective FOV (30 × 30 cm), a computer program to integrate multiple adjacent images was developed and tested in mouse studies. The exact spacing of the individual images and the occasional low-count pixels at the periphery of the images were problematic, however. Initial experience with the eZ-SCOPE was nonetheless favorable overall.

A CZT-based semiconductor gamma camera with a larger FOV, 4 × 4 cm, than that of the eZ-SCOPE was developed by General Electric (Haifa, Israel). The 4 × 4-cm pixilated detector consists of a 16 × 16 array of 2.5 × 2.5-mm pixels. Using parallel-hole collimation, the spatial resolution was 5-mm FWHM at a distance of 5 cm with a sensitivity of 100 cps/MBq. Energy resolution for ^{99m}Tc was 8.0%, somewhat better than the ~10% value typically quoted for conventional gamma cameras. In one experiment, this system could clearly resolve ^{99m}Tc-filled spheres 1 cm in diameter in contact with one another at distances of up to 6 cm; a gamma probe could only distinguish the two sources at a 1-cm depth and only when separated by at least 2 cm. A potential advantage of gamma camera imaging is the ability to resolve sources that may overlap one another in one view by acquiring additional views at different angles, as illustrated by the results of the phantom experiment shown in Fig. 5. This may be helpful, especially in breast cancer, in localizing a sentinel lymph node at a different depth from the injection site and obscured by the injected activity.

A handheld camera, known as the POCI ("perioperative compact imager") and utilizing a CsI (Na) scintillation crystal coupled to a focusing image intensifier tube and position-sensitive diode, was developed in France [35] (Fig. 6a). Its field of view is 4.0 cm in diameter. With

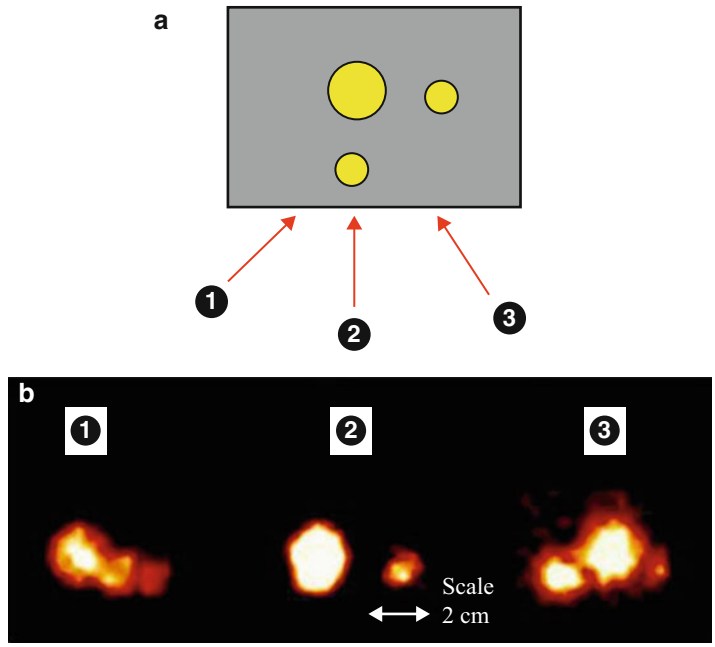

Fig. 5 Setup and results of a ^{99m}Tc phantom imaging experiment with the intraoperative gamma camera developed by General Electric (Haifa, Israel) [88, 89]. (**a**) Schematic diagram (*side view*) of phantom, with two 1-cm spheres at depths of 2 and 4 cm and a third sphere, 1.4 cm in diameter, at a depth of 2 cm and directly over the 2-cm sphere at a depth of 4 cm. The two small spheres and the large sphere had activity concentrations of 1 and 2.5 μCi/ml, respectively. (**b**) Images (identified as "1," "2," and "3," respectively) were acquired at angles of −45°, 0°, and +45° relative to an axis perpendicular to the top of the phantom (i.e., an axis in the plane of the diagram). The resulting gamma camera images demonstrate the ability to resolve overlying foci of activity by acquiring views at multiple angles (From [88, 89] with permission)

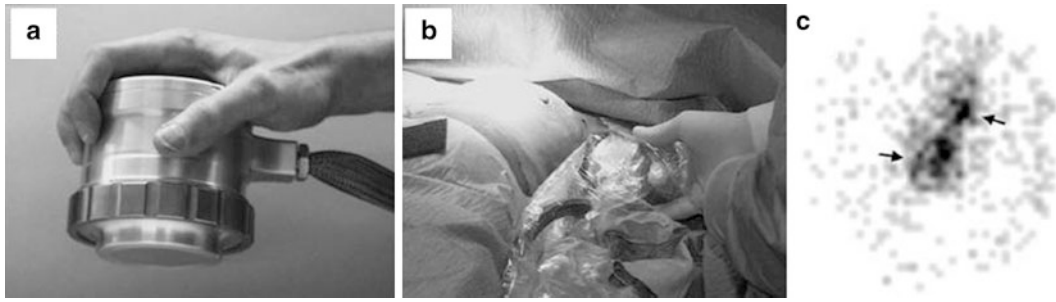

Fig. 6 (**a**) Photograph of the POCI (per-operative compact imager) intraoperative gamma camera. (**b**) Intraoperative lymphoscintigraphy, with the POCI in position for imaging of the patient's left axilla. (**c**) POCI image (10 s acquisition time), showing two foci of activity corresponding to two neighboring lymph nodes (From [35] with permission)

high-resolution parallel-hole collimation, its ^{99m}Tc sensitivity with scatter is 250 cps/MBq at 1 cm and 125 cps/MBq at 5 cm and its spatial resolution 3.9-, 4.8-, and 7.6-mm FWHM at 1, 2, and 5 cm, respectively. Images are acquired in a matrix of 50 × 50 pixels. The energy resolution of the POCI, 28%, is rather poor, however, and the wide energy windows thus required result in inclusion of substantial amounts of scatter in the image, a particular disadvantage when a lymph node is close to the injection site. Figure 6b illustrates the manual positioning of the POCI camera during intraoperative lymphoscintigraphy. Figure 6c presents a representative intraoperative image, with clear visual discrimination of two adjacent lymph nodes. In a preliminary clinical study, lymph nodes in all three patients were identified with the POCI, including one in whom two deep nodes were missed with a gamma probe (most likely due to depth-related loss of sensitivity and proximity of the nodes to the injection site). The total imaging times depended upon the scan area and varied from 15 s to 3 min.

Another semiconductor gamma camera, utilizing CdTe, was developed by Tsuchimochi and colleagues in Japan [36–38]. Their choice of CdTe was based on its superior uniformity (integral uniformity, 4.5%) and energy resolution (7.8%) compared to CZT. The camera, referred to as the "small semiconductor gamma camera (SSGC)," uses an array of 32 × 32 5-mm-thick CdTe elements, with a matrix of 1.2 × 1.2-mm pixels and a 4.5 × 4.5-cm FOV. The collimation, comprised of tungsten, had 1.2 × 1.2-mm square apertures to match the pixel arrangement. Spatial resolution without scatter was 3.9-, 6.3-, and 11.2-mm FWHM at 2.5, 5, and 10 cm, respectively. The ^{99m}Tc sensitivity at the surface without scatter was 300 cps/MBq, comparable to that of the POCI and better than that of a conventional gamma camera with LEHR collimation (∼100 cps/MBq). The results of preliminary phantom and clinical imaging studies with the SSGC were encouraging.

A small FOV gamma camera equipped with pinhole collimation, known as the Sentinella 102, has been developed by General Equipment for Medical Imaging, Spain [39–43]. It uses a single 4 × 4-cm CsI(Na) scintillation crystal and a position-sensitive PMT, with images acquired in a 300 × 300 matrix. Interchangeable pinhole apertures 1.0, 2.5, and 4.0 mm in diameter are available, yielding an effective FOV of 20 × 20 cm at a distance of 18 cm. The detector assembly weighs 1 kg and is mounted on an articulating arm (Fig. 7a). The ^{99m}Tc sensitivity ranged from 200 to 2,000 cps/μCi at 1 cm and 60 to 160 cps/μCi at 10 cm, depending on the pinhole aperture used. The FWHM spatial resolution over the detector face is 5.4–8.2 mm, 7.3–11 mm, and 10–18 mm at 3, 5 and 10 cm, respectively, again depending on the pinhole aperture used. Beyond ∼3 cm, therefore, the spatial resolution is poorer than that of cameras with parallel-hole collimation. However, despite the coarser resolution, the advantage of a pinhole collimation lies in the larger effective FOV at such distances. Such a system can therefore be used at a large distances to rapidly

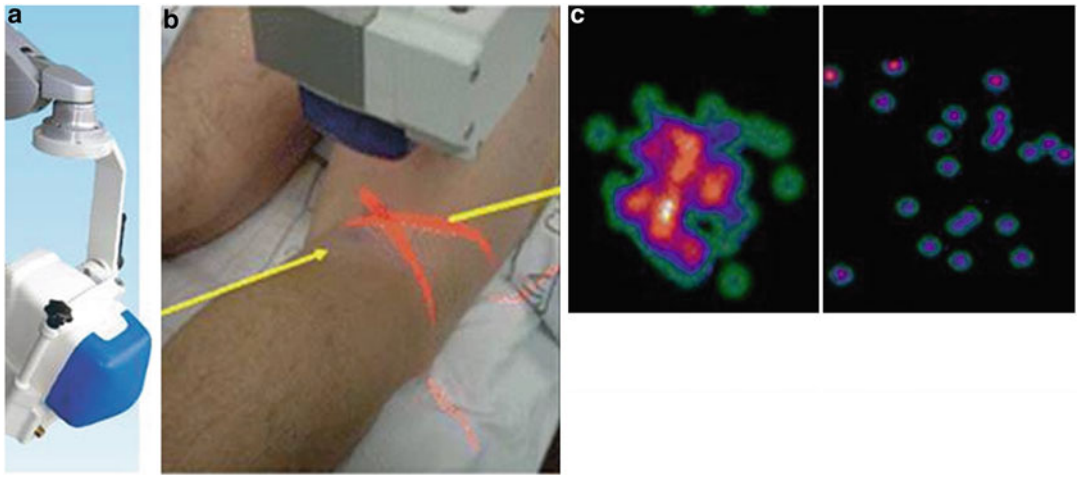

Fig. 7 (**a**) Photograph of the Sentinella 102 small FOV gamma camera (General Equipment for Medical Imaging, Spain). The detector assembly is shown mounted on the system's articulating arm. (**b**) Illustration of the device's laser positioning system, with two intersecting *red lines* projected onto posterior surface of the patient's right knee joint. This patient had malignant melanoma of the right heel, and lymphoscintigraphy was performed to identify the popliteal sentinel lymph node. (**c**) Posterior gamma camera images of the patient's right knee joint before (*left*) and after (*right*) surgical excision of the popliteal node. The pre-excision image (*left*) clearly shows the node centered in the field of view, and the post-excision image (*right*) is notably absent of any such focus of activity, demonstrating complete removal of the node

survey, with coarser resolution, a large area and then examine suspicious areas at smaller distances and finer resolution [39, 40, 44]. In initial clinical studies, acquisition times of 20–60 s per image were required. Because the distortion associated with pinhole collimation varies with position within the FOV (i.e., is worse toward the periphery) as well as distance, the Sentinella 102 camera is equipped with a laser positioning system, with two intersecting lines being projected onto the surface of the region being imaged (Fig. 7b). This allows positioning of suspicious foci of activity at the center of the field of view, where image quality is best (Fig. 7c). The Sentinella 102 camera is also equipped with a long-lived gadolinium-153 (^{153}Gd) pointer for real-time positioning; the image of the ^{153}Gd pointer source is acquired in a separate energy window from the ^{99m}Tc image and is displayed as a small marker superimposed on the ^{99m}Tc image.

The Institut Pluridisciplinaire Hubert Curien (Strasbourg, France) developed an intraoperative gamma camera known as the "CarollReS" [27–29]. This device has a relatively large-area 50 × 50-mm cerium-doped gadolinium orthooxysilicate (GSO) scintillation crystal and parallel-hole collimation with 2-mm-wide apertures. Its ^{99m}Tc spatial resolution was 10-mm FWHM at 5 cm, sensitivity 130 cpm/kBq, and energy resolution 45%. A prototype version of this device with a larger 100 × 100-mm FOV has been fabricated as well. In a preliminary clinical study with the CarollReS camera, Mathelin et al. [29] compared the depth of lymph nodes estimated by imaging to their actual depth measured at surgery and found a generally good correlation, except in instances where only a portion of the sentinel lymph node was in the camera's FOV. For 7 of 11 nodes whose depth could be estimated, the image-derived depth was correct.

Crystal Photonics GmbH (Berlin, Germany) markets a light (800-g) handheld gamma camera with a 5-mm-thick CZT detector having a 40 × 40-mm field of view, a photon energy range of 40–250 keV, and interchangeable tungsten or lead parallel-hole collimators. The spatial resolution at 3.5 cm is 5.4 mm with the high-resolution collimator to 9.2 mm with the high-sensitivity collimator, with the latter providing ~fourfold higher sensitivity than the former.

The SurgicEye GmbH (Munich, Germany) has introduced an intraoperative SPECT imaging technology termed "freehand SPECT" [45, 46]. In contrast to conventional SPECT systems, the Declipse® SPECT does not employ a gantry-mounted gamma camera rotating around the patient, but a handheld gamma probe interfaced to an infrared 3D tracking system. A 1- to 2-min scan is performed at anterior-posterior and lateral directions around the patient. The device can be used with low-energy photon emitters such as ^{99m}Tc and is compatible with different commercially available gamma probes. The Declipse™ SPECT website reports a reconstructed spatial resolution of 5 mm; details of the data acquisition and processing yielding this resolution were not specified, however.

Overall, small FOV gamma cameras have demonstrated detection rates for sentinel lymph nodes equal to or better than those of non-imaging gamma probes, despite having sensitivities (e.g., expressed in cps/MBq) typically about tenfold lower than those of such probes. The ability of such devices to image a surgical field intraoperatively and thus insure complete excision of lesions is a potentially useful enhancement of surgical management of cancer. The acquisition times per image are typically well under 1 min, so the overall duration of the surgical procedure should not be significantly prolonged. In addition, the use of pinhole collimation, despite having lower sensitivity than parallel-hole collimation, permits initial imaging at longer distance to visualize a larger anatomic area of interest followed by imaging at shorter distance to pinpoint and otherwise characterize suspicious foci of activity. Importantly, the scintigraphic image format is familiar to surgeons, likely facilitating clinical acceptance and integration of intraoperative imaging.

Intraoperative PET scanners. Prescient Imaging LLC is currently developing a portable compact whole-body PET scanner adaptable to intraoperative imaging [47]. It incorporates a 360-degree detector with an axial FOV of 22 cm. The detectors are assembled into three sets, one planar and the other two circular arcs of 90° each connected with a hinge. One of the arcs is fixed while the other can be rotated about the hinge and thereby opened and closed. The planar detector is fixed horizontally such that it can fit under a patient table. By placing the moveable arc in the closed position, the 360° of detector coverage about the patient is achieved. Attenuation correction will be performed using a rotating rod transmission source.

Optical and Near-Infrared (NIR) Imaging

Despite the very limited penetrability of optical and near-infrared (NIR) light in tissue, specialized technologies have led to widespread and very productive use of light – both bioluminescence and fluorescence – for in vivo imaging of rodents [48, 49] and, to a much more limited extent to date, of human subjects; in the case of the latter, this has been restricted to fluorescence imaging [50]. In the most common (i.e., preclinical) optical imaging paradigm, animals are placed in a light-tight imaging enclosure, and the emitted optical or NIR signal is imaged by a charge-coupled detector (CCD). In bioluminescence imaging (Fig. 8a), cells (e.g., tumor cells) which are to be localized or tracked in vivo must first be genetically transduced ex vivo to express a so-called reporter gene, most commonly, a luciferase gene (such as the firefly luciferase, or *FLuc*, gene). After the cells have been implanted, infused, or otherwise administered to the experimental animal, the luciferase substrate (e.g., D-luciferin in the case of firefly luciferase) is systemically administered. Wherever the administered substrate encounters the luciferase-expressing cells, the ensuing reaction (such as the D-luciferin-luciferase reaction) emits light, which is detected and localized by the imaging system. The CCD in bioluminescence imaging is maintained at a very low temperature (of the order of −100 °C), thereby ensuring that any electronic output it produces results from light striking the CCD rather than the background "dark current" (which would be prohibitively high at ambient temperatures). In this way, the otherwise undetectably small signal originating in vivo and escaping from the surface

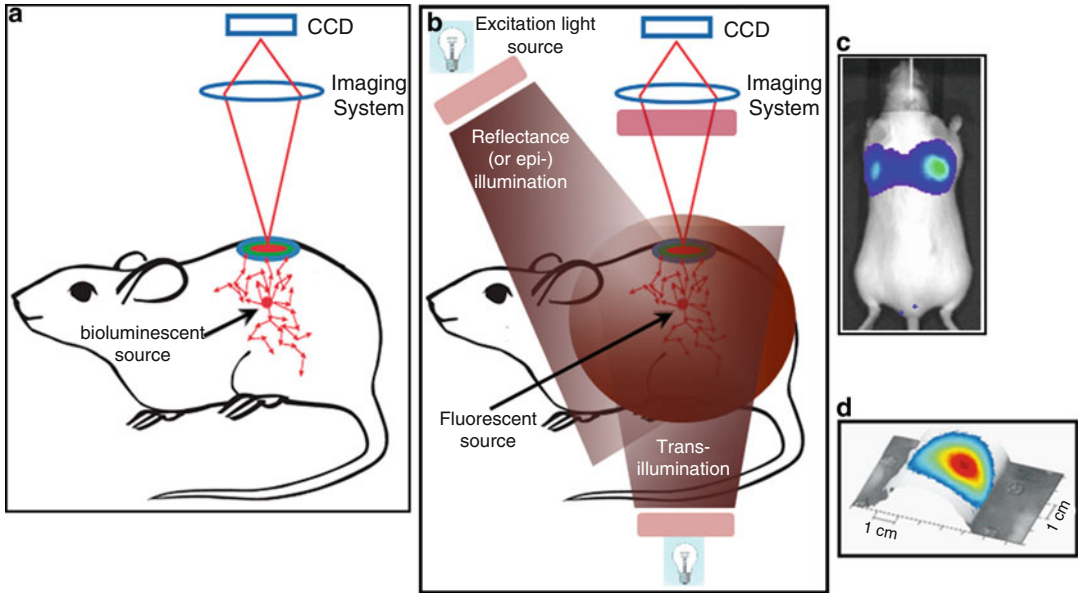

Fig. 8 (**a**) Bioluminescence and (**b**) fluorescence optical or NIR in vivo imaging. For fluorescence imaging, the excitation light source may be a white-light source whose emitted light is passed through conventional glass filters to yield a light over a narrow wavelength range centered about the excitation wavelength of the fluorophore being imaged. Alternatively, it may be a laser light source tuned to the appropriate wavelength. In so-called "multispectral" systems, multiple excitation and emission wavelengths and thus multiple fluorophores may be imaged simultaneously. (**c**, **d**) These sample images show a pseudo-color bioluminescence images superimposed on a *gray*-scale photograph and on a three-dimensional rendering of a mouse, respectively (From [90] with permission)

of the animal can produce an image. In fluorescence imaging (Fig. 8b), cells to be imaged may either be genetically transduced ex vivo to express a fluorescent molecule (or fluorophore) such as green fluorescent protein (GFP) or a fluorophore probe targeting the cells of interest may be systemically administered. In either case, the animal is then illuminated with light at an appropriate excitation wavelength (obtained by filtration or with a laser) to energize the fluorophore in situ, and the resulting emitted light (which has a slightly different wavelength than the excitation light) is itself filtered and detected by the CCD; the difference in wavelengths between the excitation and emitted light is known as the Stokes shift. The excitation light may be provided by reflectance (or epi-illumination) or by transillumination of the animal. Further, by computer processing, the abundant spontaneous fluorescence of the animal's tissues as well as of foodstuffs in the gut must be mathematically separated, or "de-convolved," from the overall fluorescence to yield an image specifically of the fluorophore; this is sometimes known as "spectral unmixing." In practice, the resulting luminescence or fluorescence image is generally superimposed on a conventional (i.e., white-light) photograph of the animal to provide some orientation as to the anatomic location of the signal(s) in vivo (Fig. 8c).

Because light emitted at any depth of tissue is scattered and otherwise dispersed as it passes through overlying tissue before emanating from the surface of the animal, the apparent size of the light source (Fig. 8c, d) is considerably larger than its actual size. Despite the excellent spatial resolution of the CCDs themselves, the effective resolution of optical and NIR imaging is generally rather coarse. Further, for planar optical and NIR imaging, the resulting images are only semiquantitative: absorption and scatter of the emitted light as it passes through overlying tissue makes the measured signal highly depth dependent. Thus, a focus of cells lying deep within tissue may appear less luminescent or fluorescent than an identical focus of cells at a more shallow depth; if excessively deep, such a focus of cells may be

undetectable altogether. NIR radiations, however, have a substantially higher penetrability through tissue than blue to green radiations. Importantly, therefore, by using laser transillumination for excitation of administered NIR molecular probes in situ, tomographic fluorescence images can be mathematically reconstructed [49]. The resulting three-dimensional images – in contrast to planar images – are at least semiquantitative: the signal intensity thus reconstructed is related to the local concentration of the fluorophore.

Bioluminescence imaging, because it requires genetic modification of the cells to be imaged, likely has very limited applicability in patients but has proven invaluable in preclinical research. However, with recent advances in adoptive immunotherapy of cancer, bioluminescence imaging conceivably may have some clinical utility in an intraoperative or endoscopic setting to assess tumor targeting of immune effector cells. To date, however, no such studies have been performed. Intraoperative, endoscopic, and even surface fluorescence imaging of patients has been performed and continues to advance (see below).

Fluorescence imaging. As noted, the clinical application of optical imaging to date has utilized fluorescence imaging in endoscopic and intraoperative settings. Fluorescence cystoscopy, for example, is now widely used to identify and localize urinary bladder cancer [51]. The photosensitizer 5-aminolevulinic acid (ALA) is a precursor of the photoreactive (at 375–440 nm) protoporphyrin IX (PpIX). Although the mechanism is not yet well understood, ALA accumulates selectively in cancerous tissue, yielding tumor-to-non-tumor activity concentration ratios of ∼20:1 within 2 h of topical administration within the bladder. As illustrated in Fig. 9, fluorescence cystoscopy allows more sensitive and specific visualization of bladder cancer in vivo than conventional (i.e., white-light) imaging.

Narrowband imaging (NBI) is a notable refinement of non-fluorescence optical cystoscopy that improves the visualization of blood vessels and bladder mucosa and thereby enhances the contrast between cancerous and normal bladder epithelium (given that urothelial lesions are typically hypervascularized due to elevated microvessel density) [52]. NBI exploits these angiogenic features of bladder cancers by filtering white light into two discrete wavelength bands, one blue (415 nm) and one green (540 nm), both of which are absorbed by hemoglobin. The shorter-wavelength 415-nm light penetrates only the superficial layers of the mucosa and yields brownish images of the superficial capillaries. The longer-wavelength 540-nm light penetrates deeper into the bladder wall and produces greenish images. Bladder tumors are thus

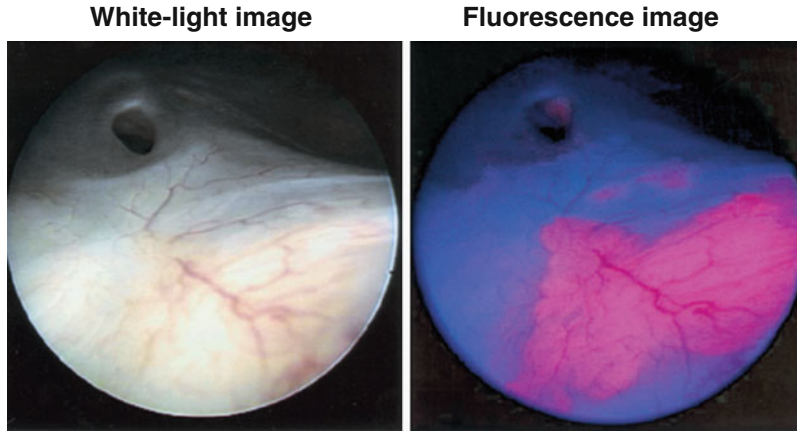

Fig. 9 Cystoscopic imaging of urinary bladder cancer. Conventional (i.e., white-light) image (*left panel*) and fluorescence image (*right panel*) following topical administration of the protoporphyrin IX (PpIX) precursor 5-aminolevulinic acid (*ALA*). The red coloration of the cancerous tissue makes it far more apparent in the fluorescence image than in the white-light image (From [51] with permission)

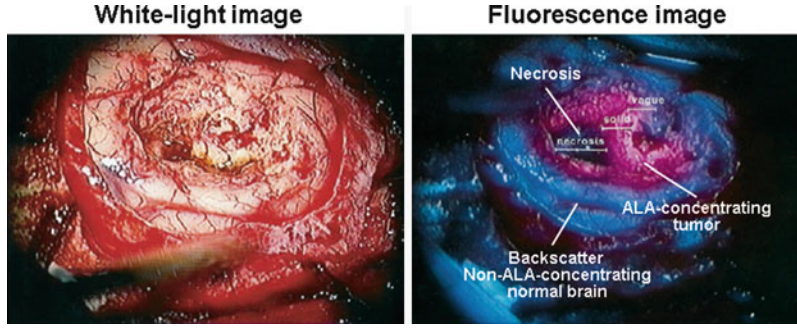

Fig. 10 Intraoperative white-light image (*left panel*) and fluorescence image (*right panel*) following systemic administration of ALA (20 mg/kg 3 h prior to surgery) of the intracranial resection site of a glioblastoma. The *red* coloration of the cancerous tissue, *blue* coloration of normal brain, and lack of color of non-perfused, necrotic tissue allow easier discrimination of these respective tissues than does the white-light image. This in turn should facilitate a more complete resection of the tumor and, presumably, better local control (From [53] with permission)

visually identified by the intensity of brown-green coloration that is characteristic of the elevated vessel density of tumors and distinct from the pink-to-white coloration of the normal mucosa.

In addition to endoscopic fluorescence imaging, large-field, planar optical, and NIR fluorescence imaging potentially may improve human surgery by providing real-time image guidance to surgeons to identify tissue to be resected (such as tumors) and tissue to be avoided (such as blood vessels and nerves). As illustrated in Fig. 10, the use of ALA has been extended to systemic administration and fluorescence imaging-guided resection of glioblastomas [53]. Based on the overexpression of folate receptor-α, intraoperative fluorescence imaging has also been applied to resection of ovarian cancer using folate conjugated via an ethylene diamine spacer to fluorescein isothiocyanate (FITC) (Fig. 11). To further advance the practical implementation of fluorescence imaging-guided surgery, Dr. John Frangione and colleagues have developed the so-called Fluorescence-Assisted Resection and Exploration (FLARE™) system [54–60]. Briefly, the FLARE™ system consists of an imaging head mounted on an articulated arm and a cart containing control equipment, computer, and monitors (Fig. 12). The imaging head includes light-emitting diodes (LEDs) as the excitation light source, heat dissipation technology to maintain stability of the LEDs, and complementary metal oxide semiconductor (CMOS) cameras; it can be positioned anywhere in 3D space with six degrees of freedom. A customized software system enables the real-time display of color video and two NIR fluorescence channels at a rate of up to 15 frames per second. The software is capable of displaying the NIR fluorescence signal as a pseudo-colored overlay on the color video, thereby providing anatomic guidance to the surgeon. Among its many applications to date, the FLARE™ system has been applied to sentinel lymph node resection in breast cancer surgery (Fig. 13) [60] and has demonstrated improved visualization of nodes and of tumors [54–61].

In collaboration with Dr. Michelle Bradbury and colleagues, Quest Medical Imaging has developed an enhanced intraoperative NIR imaging device, the ArteMIS™ (now Spectrum™) handheld fluorescence camera system (Fig. 14a) for either minimally invasive laparoscopic or open surgery configurations [62]. This system is capable of true multiplexing, with simultaneous imaging (at a frame rate of 30 frames per second) and real-time spectral unmixing of the signals in two NIR channels (700 and 800 nm, respectively) and a conventional color channel, as illustrated in Fig. 14b [63].

Cerenkov imaging. Cerenkov imaging is a new approach to optical imaging based on the emission of a continuum of visible light associated with the decay of certain radionuclides (actually, with the particles emitted as result of the radionuclide decay) [64–73]. This phenomenon, now known as the "Cerenkov effect," was first observed in the 1920s and characterized in the 1930s by Pavel

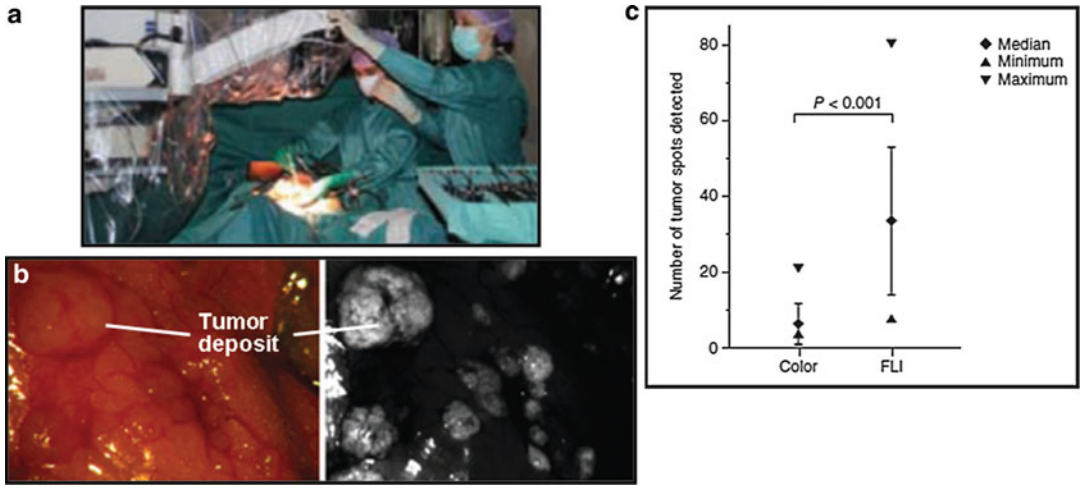

Fig. 11 (**a**) Photograph of intraoperative use of fluorescence imaging system developed by Ntziachristos and colleagues. (**b**) Conventional color image (*left panel*) and fluorescence *gray*-scale image (*right panel*) following systemic administration of FITC-conjugated folate (0.3 mg/kg) of intra-abdominal resection site of ovarian cancer. The tumor deposits are more clearly visualized on the fluorescence image than on the color image. (**c**) Graphical presentation of the results of conventional versus fluorescence imaging-assisted resection of ovarian cancer, demonstrating that intraoperative fluorescence imaging (*FLI*) visualized significantly more ovarian cancer deposits than conventional imaging (Adapted from [91] with permission)

Cherenkov [65]. In 1958, Cerenkov shared the Nobel Prize in Physics with colleagues Ilya Frank and Igor Tamm for the discovery and explanation of the effect which now bears his name. Cerenkov radiation is perhaps familiar to some readers as the bluish "glow" observed in the water pools containing spent, but still radioactive, fuel rods at nuclear reactors. It arises when charged particles such as beta particles travel through an optically transparent, insulating medium at a speed greater than that of light in that medium. The Cerenkov effect, often analogized to the sonic boom that occurs at the instant a supersonic plane exceeds the speed of sound in air, occurs as the charged particles dissipate their kinetic energy by polarizing the electrons in the insulating medium (most commonly, water) as they travel through the medium. As these polarized electrons then relax

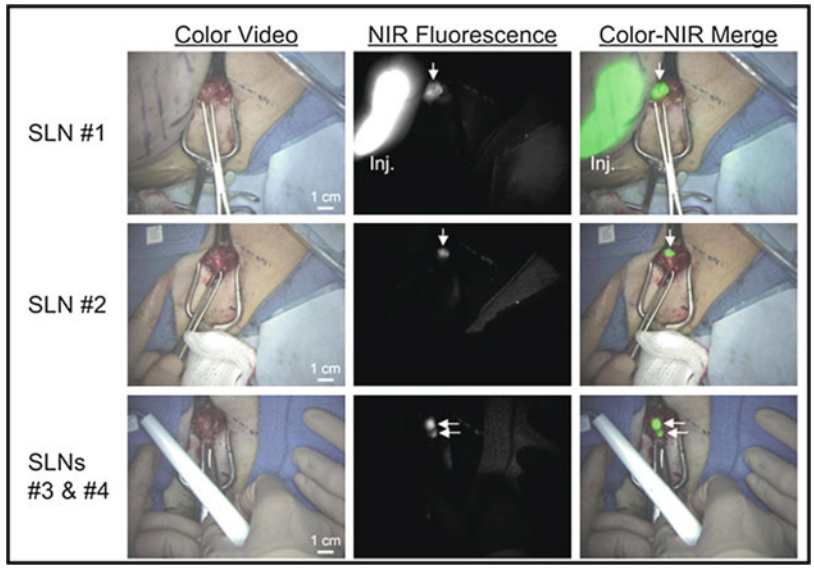

Fig. 13 Use of the FLARE™ system in intraoperative localization and resection of sentinel lymph nodes (*SLNs*) in breast cancer surgery. Four peri-tumoral injections were performed of indocyanine green (*ICG*) conjugated to human serum albumen (10 μg of ICG in 0.2 mL per injection). The conventional color video images in the *left panels* show the surgical field and the incision in the proximity of four SLNs. The NIR fluorescence video images (100 ms per exposure) show the injection site (*top middle panel*) and the four ICG-albumen-concentrating SLNs (*middle panels*). For the images in the lower two *middle panels*, the injection site was covered with an opaque surgical drape. The *left panels* show the overlaid, or merged, color and fluorescence images. The SLNs are clearly far more apparent in the fluorescence than in the color images (Adapted from [60] with permission)

(or re-equilibrate), and if the charged particle is traveling faster than light, constructive interference of the light thus emitted occurs, producing the grossly visible Cerenkov radiation.

The application of Cerenkov radiation to in vivo radionuclide imaging is a recent development [64, 66–73]. Phantom studies by Ruggiero et al. have demonstrated, using a commercial optical imaging system (Ivis 200, Caliper Life Sciences) equipped with a cryo-cooled CCD, measurable emission of Cerenkov radiation associated with a number of clinically relevant radionuclides, including ^{18}F, copper-64 (^{64}Cu), zirconium-89 (^{89}Zr), iodine-124 (^{124}I), iodine-131 (^{131}I), and actinium-225 (^{225}Ac) [72] (Fig. 15a, b). Importantly, the optical Cerenkov signal is linearly related to activity concentrations (Fig. 15c), at least where the effects of attenuation and scatter are minimal. Ruggiero et al. have also produced planar Cerenkov images of the tumor localization of a ^{89}Zr-labeled antibody in prostate tumor xenografts in mice which compare favorably, both qualitatively and quantitatively, with the ^{89}Zr PET images [72] (Fig. 16). Using intradermal tail injections of [^{18}F]FDG, Thorek et al. subsequently performed both PET- and Cerenkov imaging-based lymphography in mice, with both modalities demonstrating excellent visualization of lymph nodes [73] (Fig. 17). Initial clinical trials of Cerenkov imaging are currently underway to delineate its potential clinical utility. As illustrated in Fig. 17, assisting the resection of sentinel lymph nodes appears to be one potential application. In a clinical pilot study, for example, Thorek et al. evaluated the feasibility of Cerenkov imaging of patients ($n = 4$) undergoing standard diagnostic [^{18}F]FDG scans to detect nodal disease [74]. Two 5-min scans were performed for each patient at ~70 min postinjection of [^{18}F]FDG (12 mCi), one over the site of the [^{18}F]FDG-avid axillary lymph node by PET scanning and one over the contralateral side of the patient without detectable nodal disease as a negative control. An intensified CCD camera (Mega10z, Stanford

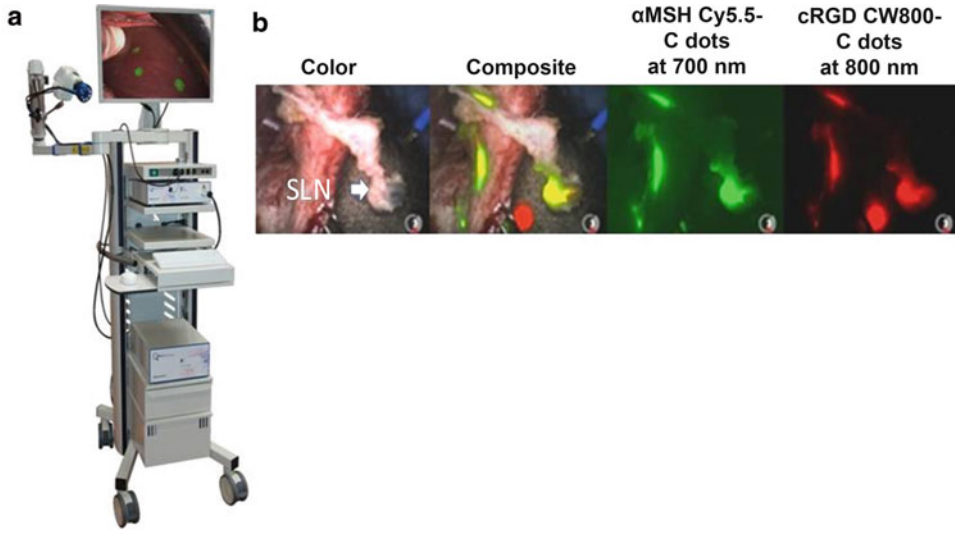

Fig. 14 (**a**) Photograph of the ArteMIS™ (now Spectrum™) handheld NIR fluorescence camera system. The compact form factor of this system makes it particularly suitable for the intraoperative setting (Courtesy of Quest Medical Imaging). (**b**) Preclinical sentinel lymph node study in a spontaneous melanoma miniswine model. The miniswine received percutaneous peri-lesional co-injections of ultrasmall (<10 nm) fluorescent Cornell-dot (C-dot) silica nanoparticles surface-functionalized with alpha-melanin-stimulating hormone (α-MSH) and with cyclic arginine-glycine-aspartic acid-tyrosine (cRGDY) for targeting the MSH receptors and integrin receptors, respectively, overexpressed on the surface of the melanoma cells (as confirmed by immunohistochemical staining of the excised node); the α-MSH- and the cRGDY-functionalized C dots were loaded with the Cy5.5 and the CW800 fluorophores, respectively. The real-time multiplexing capability of the ArteMIS™ (now Spectrum™) system provided clear visual discrimination of the two types of functionalized nanoparticles in the diseased sentinel lymph node. Such molecularly targeted nanoparticle probes thus are not only capable of highly sensitive visual detection of sentinel lymph nodes but also of phenotypic characterization of such nodes (Adapted from [63] with permission)

Photonics) was used. The single-photon-counting camera consisted of a dual-microchannel plate-intensifier system behind a photocathode read off a Peltier-cooled CCD (XX285, Sony Corp). The optics consisted of a quartz high-ultraviolet-transmission 50-mm f/0.8 lens and a long-pass filter with a cutoff at 605 nm (Chroma Technology). High-frame-rate acquisitions (120 frames per second) were integrated in the Piper Control software (Stanford Photonics), a background baseline was subtracted, and the images were processed and analyzed in *Image J* (National Institutes of Health) (13). The camera with lens and filter was mounted on a standard photography tripod, and the subjects imaged at a distance of ~8 cm. The patients were imaged with the room lights on for a white-light photograph and then with the lights off, the light-sealed door to the room closed, and an optical drape used to eliminate any remaining ambient light. A representative patient study is shown in Fig. 18. Despite the low yield of Cerenkov light and the suboptimal Cerenkov light spectrum for in vivo imaging (primarily in the highly attenuated blue-green range), based on this and other studies [74, 75], Cerenkov imaging of patients is feasible, though its ultimate clinical utility remains to be determined.

Photoacoustic imaging. In photoacoustic imaging [76–78], tissues are illuminated with laser light. When radiofrequency (RF) pulses are used, the technology is termed, "thermoacoustic imaging." Some of the delivered energy will be absorbed and converted into heat, leading to transient thermoelastic expansion of the illuminated tissue and thus ultrasonic (i.e., MHz-frequency) emissions. The ultrasonic waves thus emitted are then detected by ultrasonic transducers to form images. Image contrast is provided by the differential absorption among tissues of the incident excitation light. In contrast to fluorescence imaging, in which scattering

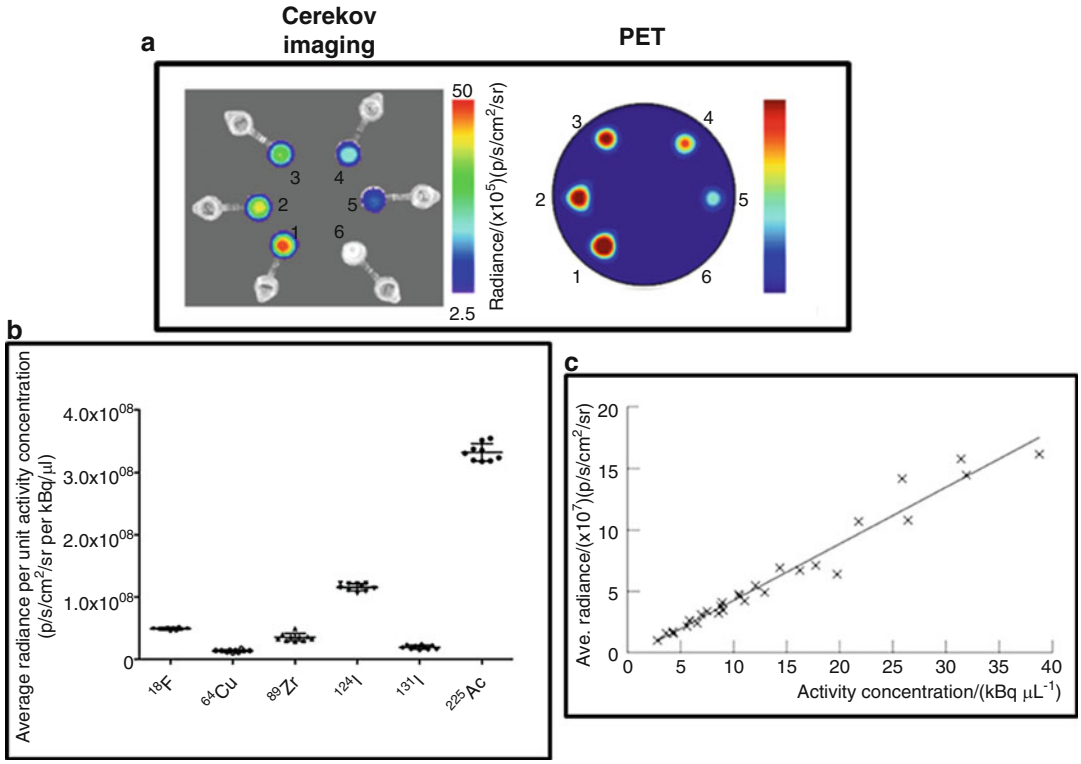

Fig. 15 (**a**) Phantom for evaluation of Cerenkov imaging of positron-emitting radionuclides, comprised of a circular arrangement of six 1-ml Eppendorf tubes filled with increasing activity concentrations. *Left panel*: Cerenkov image superimposed on a photograph of the phantom acquired with an Ivis 200 optical imaging system (Caliper Life Sciences). *Right panel*: PET image of the phantom acquired with a Focus 120 microPET scanner (Concorde Microsystems). (**b**) Average radiance per unit activity concentration (in photons (p)/second (s)/cm^2/steradian (sr) per kBq/μL) for different radionuclides as measured using the phantom arrangement and instrumentation described in (**a**). (**c**) Linear correlation ($r = 0.98$) between average radiance (in p/s/cm^2/sr) and activity concentration (in kBq/μL) for ^{89}Zr evaluated again using the phantom arrangement and instrumentation described in (**a**) (Adapted from [72] with permission)

in tissue degrades spatial resolution with increasing depth, photoacoustic imaging provides better spatial resolution (of the order of 100 μm) and deeper imaging depth (of the order of 1 cm or greater) because there is far less absorption and scattering in tissue of the ultrasonic signal compared to the emitted light signal in fluorescence imaging. When compared with ultrasound imaging, in which the contrast is limited because of the similarity in acoustical properties among tissues, photoacoustic imaging provides better tissue contrast as a result of the wider range of tissue optical properties. The optical absorption in biological tissues can be due to endogenous molecules such as hemoglobin or melanin or exogenously administered contrast agents. Since blood exhibits orders of magnitude higher light absorption than other tissues, there is sufficient endogenous contrast provided by oxygenated hemoglobin (HbO_2) and deoxygenated hemoglobin (Hb) for photoacoustic imaging to visualize blood vessels.

Most commonly, photoacoustic scanners use either a tomographic geometry (with an array of up to several hundred US transducers partially surrounding the subject) [76] or a planar geometry employing a linear transducer array [79, 80]. The tomographic approach offers a large effective aperture for data collection, but suffers from a low frame rate (>10 min per frame), due to the need for hundreds to thousands of laser pulses per

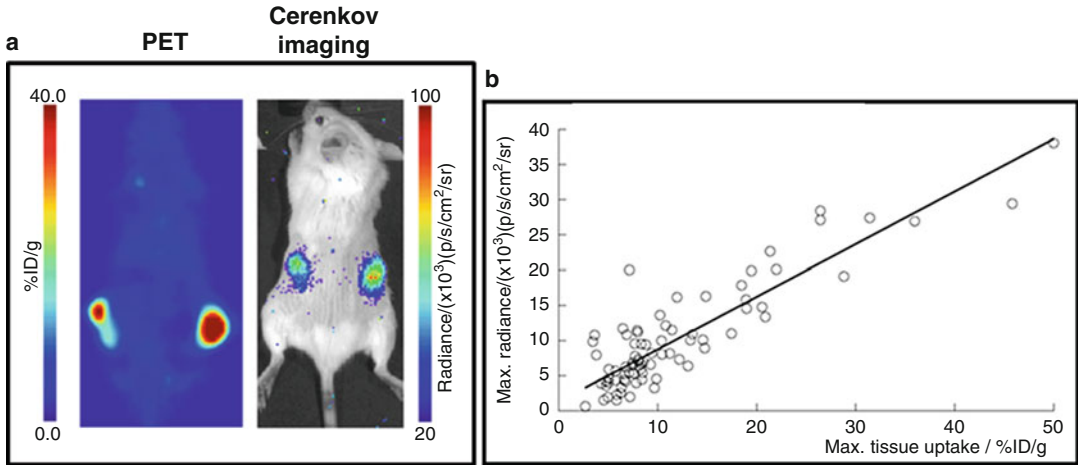

Fig. 16 (**a**) PET image (*left panel*) and Cerenkov image (*right panel*) of a ^{89}Zr-anti-PSMA (prostate-specific membrane antigen) antibody (J591) in a mouse with bilateral flank LNCaP prostate tumor xenografts at 96 h post-injection. The Cerenkov image is superimposed on a photograph of the mouse. The two xenografts are clearly visible in both images. (**b**) Linear correlation ($r = 0.89$) between the Cerenkov image-derived average radiance (in p/s/cm^2/sr) and the PET image-derived maximum tissue uptake (in percent of the injected dose per gram,%ID/g) (Adapted from [72] with permission)

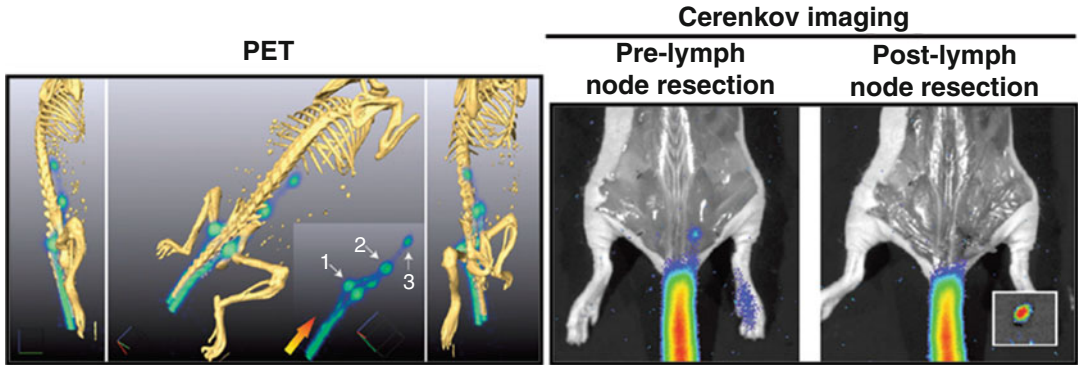

Fig. 17 Cerenkov imaging-guided lymph node resection in a normal mouse following intradermal tail injection of [^{18}F]FDG (30 μCi). *Left panel*: Volume rendering of fused CT image (*yellow* color table) and PET image (*green* color table) showing lymphatics and lymph nodes in relation to the skeleton. *Right panel*: Cerenkov image superimposed on a photograph of the mouse following removal post-sacrifice of the dorsal skin before (*left* image) and after (*right* image) resection of a luminescent inguinal lymph node. frame. The use of a linear array eliminates the need for scanning, and thus a two-dimensional frame can be acquired with many fewer laser pulses, providing much higher frame rates. In addition, in the tomographic geometry, the surface of the transducers is of the order of 1 cm from the surface of the subject (up to now, rodents) to accommodate an array of transducers encircling the subject. As a result, the mouse or rat must be immersed in water to provide the necessary acoustical coupling to the transducer; in the multispectral optoacoustic tomography (MSOT) system marketed by iThera Medical, the animal is suspended in a very thin membrane and then immersed in the water, thereby keeping the animal completely dry (Fig. 19a). Another preclinical

(**c**) Negative Cerenkov scan in light-protected environment of right axilla without [^{18}F]FDG-positive lymph node overlaid with white-light photograph. No significant Cerenkov emission associated with [^{18}F]FDG is seen. (**d**) White-light photograph from left axilla, overlaid with significant Cerenkov signal (shown in *red*-hue pseudocolor). (**e**) Transverse section of [^{18}F]FDG PET/CT scan through the patient's axillae, demonstrating that the Cerenkov signal co-localized (at least grossly) with the nodal focus of [^{18}F]FDG activity. There was no focus of [^{18}F]FDG activity in the contralateral disease-free axilla, consistent with the corresponding Cerenkov scan (From [74] with permission)

photoacoustic imaging system, employing a linear transducer array, is marketed by VisualSonics.

Photoacoustic imaging has been used successfully in preclinical models for tumor perfusion angiogenesis monitoring (see Fig. 19 [77]), blood oxygenation mapping, functional brain imaging, and melanoma detection, among other applications. The resulting functional images can be superimposed on high-resolution B-mode anatomic images.

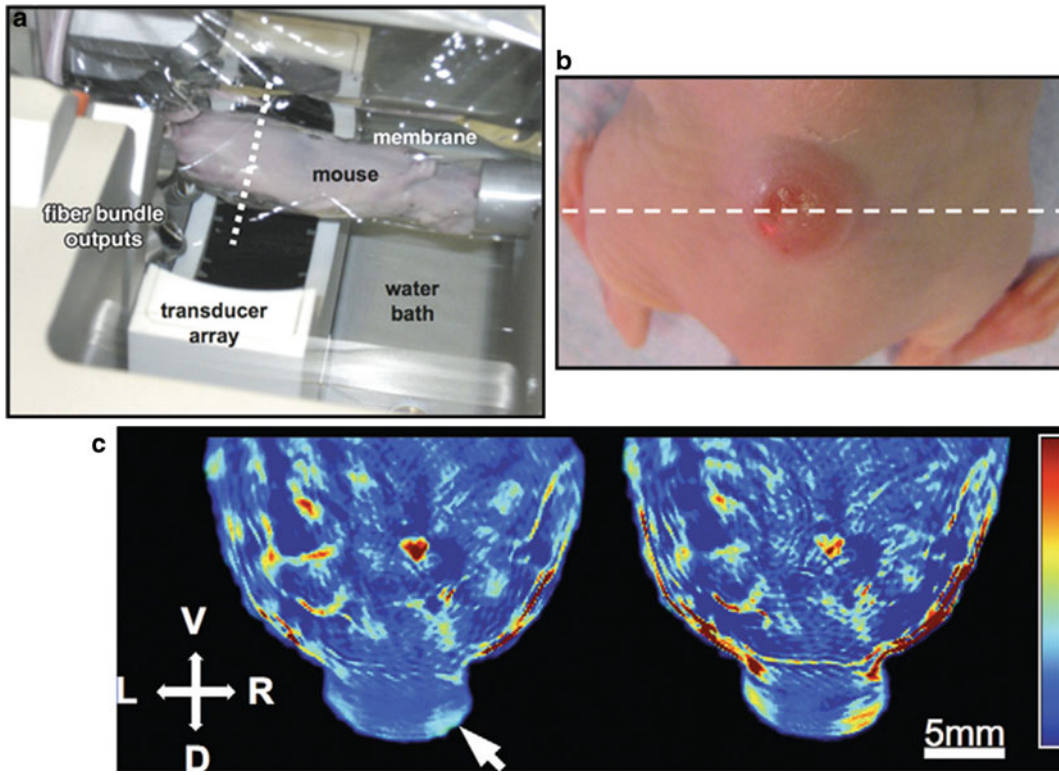

Fig. 19 (**a**) Setup for photoacoustic imaging of regional perfusion in a tumor xenograft on the dorsal surface of a nude mouse. Note that the tumor (on the dorsal surface of the animal and therefore not seen) is "immersed" in water. The animal remains dry, however, because of the presence of a thin membrane between the animal and the water. (**b**) Photograph of the 4T1 xenograft on the dorsal surface of the mouse. In (**a**, **b**), the *dashed line* indicates the approximate position of the transverse tissue section being imaged. (**c**) Images (acquired at 790 nm) before (*left panel*) and 30 s after (*right panel*) intravenous injection of IGC (*V* ventral, *D* dorsal, *L* left, *R* right). Note the increase in image contrast in and around the tumor (*arrow*) after injection, identifying the more highly perfused portions of the tumor (Adapted from [77] with permission)

While the clinical implementation of MSOT is still progressing and its clinical impact remains to be determined, the ability of this technology to visualize in real time the distribution and concentration of intrinsic and exogenous chromophores (including currently approved chromophores such as ICG and methylene blue) is such that it merits clinical evaluation. The Acuity™, marketed by iThera, is one of the very first clinical MSOT systems [81, 82] and appears adaptable to intraoperative imaging (Fig. 20). It is equipped with a fast-tunable 50-Hz laser and 2D or 3D detectors (128–512 elements, 2.5–10 MHz) and provides cross-sectional in-plane spatial resolution of 80–250 μm.

Diffuse optical tomography. Diffuse optical tomography (DOT) utilizes NIR light to generate quantitative functional images of tissue with a spatial resolution of 1–5 mm at depths up to several centimeters [83, 84]. Propagation of NIR light through a medium is dominated by scattering rather than absorption – tissue absorption path lengths are ~10 cm while scattering path lengths are less than 50 μm – and can be modeled as a diffusion process where photons behave stochastically (in a manner analogous to that of particles in random-walk modeling of diffusion). Quantitative measurements can be obtained by separating light absorption from scattering using spatial or temporal modulation techniques. Tissue molecular composition,

Fig. 20 Photograph of the iThera Acuity™ clinical MSOT system (Courtesy of iThera)

including the determination of the concentrations of oxy- and deoxyhemoglobin, water, lipid, and exogenous probes, and tissue structure can be determined from absorption and scattering measurements, respectively. Time modulation systems use picosecond optical pulses and time-gated photon-counting detectors; frequency modulation systems use a RF-modulated light source, PMTs or fast photodiodes, and RF phase detectors. DOT has been applied to breast cancer diagnostics, joint imaging, and blood oximetry (i.e., activation studies) in the human muscle and brain tissue as well as to cerebral ischemia and cancer studies in small animals and is adaptable to intraoperative imaging. Commercial instruments are now available that yield tomographic and volumetric image sets. These devices are compact, portable, and relatively inexpensive (~$150 K).

Optical coherence tomography. Optical coherence tomography (OCT) is an interferometric technique, typically employing low-coherence NIR light, to produce two-dimensional images of tissue surface layers and structure [85]. The principle of OCT is analogous to that of pulse-echo (i.e., B-mode) ultrasound imaging except OCT uses light instead of acoustic waves to delineate tissue structure by measuring reflectance of light rather than sound waves and thus achieves far better spatial resolution but with less depth penetration. The technique has been described as "an optical biopsy," since OCT can produce near-histologic images (spatial resolution, 1–15 μm) without excision. Due to photon absorption and scattering, its sampled depth is limited to within several millimeters of the tissue surface. The two-dimensional images can be assembled to construct a volumetric image set. In OCT, the axial resolution is proportional to the center wavelength and inversely proportional to the bandwidth of the light source and improves with the index of refraction of the sample. Originally developed for and still most commonly applied to ophthalmology (to obtain detailed images of retinal structure), OCT is being applied for cancer diagnosis, evaluation of coronary artery disease and tissue characterization.

Raman spectroscopic imaging. When light interacts with matter, most of the light is elastically scattered, retaining its original energy, frequency, and wavelength; this phenomenon is also known as Rayleigh scattering (Fig. 21a). However, a small fraction of light is inelastically scattered, with the scattered light having a lower energy and frequency and longer wavelength than the incident light. The process leading to this inelastic scatter is termed the Raman effect [86], and the difference in wavelength between the incident and scattered light is called the Raman shift. Because photons with optical energies interact with outer-shell, or valence, atomic electrons, which are responsible for the intramolecular chemical bonds among atoms, materials having different molecular

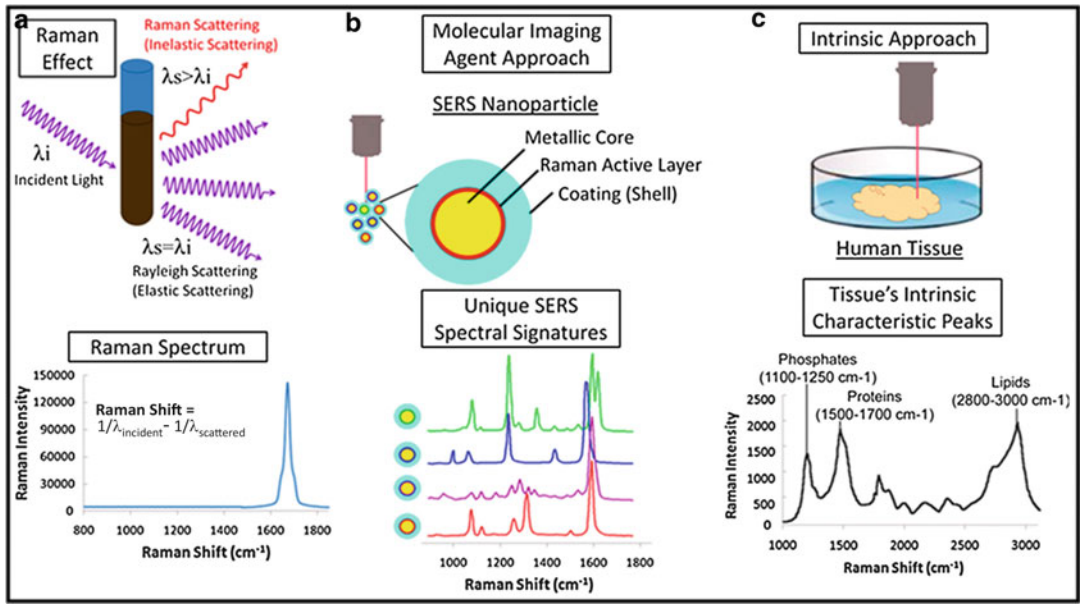

Fig. 21 (**a**) Raman effect, showing sample being illuminated with incident photons of wavelength (λi). Most of the incident photons are scattered elastically (Rayleigh scattering) and resulting scattered photons have same wavelength (λs) as the incident photons (i.e., $\lambda s = \lambda i$). A few photons are inelastically scattered (Raman scattering) at wavelengths longer than incident photons (i.e., $\lambda s > \lambda i$). The relative proportion of inelastically scattered photons is typically depicted using a Raman spectrum, which is a plot of scattered photon intensity versus the Raman shift (i.e., the wave number difference between the incident and scattered photons). Multiple different wavelengths of inelastically scattered light can occur, and a spectrum plot can therefore include multiple peaks, although a single primary peak, as shown, is also possible. (**b**) Molecular imaging agent approach showing SERS nanoparticles, which consist of a metallic core, a Raman-active layer adsorbed onto the metal surface, and a shell coating the entire particle. An array of unique spectral signatures can be obtained by modifying the Raman-active layer of the nanoparticle. These unique Raman nanoparticles can serve as molecular imaging agents for in vitro and in vivo procedures. (**c**) The intrinsic approach, showing a human tissue specimen being illuminated with a laser. The intrinsic Raman spectral signature of tissue can reveal important information about phosphate, protein, and lipid content of cells or tissue of interest (From [86] with permission)

compositions will inelastically scatter light differently. Every molecule therefore has a distinct Raman spectrum (or "signature"), that is, a different Raman shift-dependent intensity of the scattered light; this is the basis of using Raman spectroscopy to identify the molecular constituents of various materials [86]. By illuminating a sample with a highly collimated beam of light and at the same time either translating a scattered light detector or the sample in two dimensions, spatial indexing of the Raman spectrum can be performed and a Raman spectrum image created. Though they may appear similar, the Raman effect is distinct from fluorescence in that the former represents a light-scattering phenomenon and the latter light absorption and reemission. Like fluorescence imaging, Raman spectroscopic imaging has been applied to endogenous (or intrinsic) molecules naturally present in tissue and to exogenously administered materials (as in surface-enhanced Raman scattering (SERS) (see below)).

A drawback of the Raman effect as an analytical tool is that it is a very weak phenomenon, producing only one inelastically scattered photon for every ten million elastically scattered photons. Technical advances, such as the introduction of lasers and of resonance-based enhancements, have greatly expanded the practical applications of the Raman effect. For years now, the Raman effect has been used in a variety of analytical applications and, more recently, in various in vitro cell assays and microscopy. The most

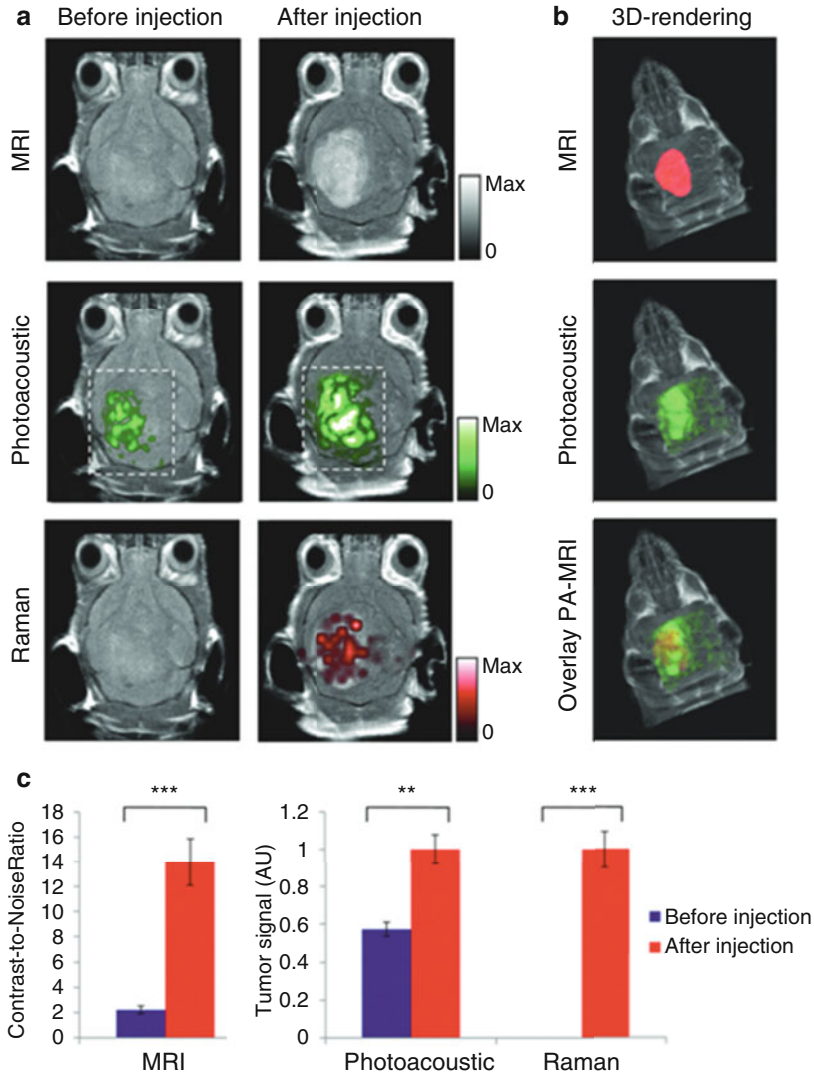

Fig. 22 Triple-modality detection with nanoparticle probes of brain tumors in mice. Three weeks after orthotopic implantation with U87MG glioblastoma cells, the brain tumor-bearing mouse was injected intravenously with the nanoparticles, which localized in the tumor due to the EPR (enhanced permeability and retention) effect. Photoacoustic (*PA*), Raman, and MR images of the brain (skin and skull intact) were acquired before and 2, 3, and 4 h postinjection, respectively. Raman imaging was performed using a commercial Raman microscope (inVia, Renishaw) with a computer-controlled x, y-translation stage. (**a**) Axial MR, PA, and Raman images. The postinjection images of all three modalities demonstrated clear tumor visualization. The PA and Raman images were co-registered with the MR image, demonstrating good concordance within the tumor of the nanoparticle distribution among the three modalities. (**b**) Volumetric rendering of MR images with the tumor segmented (*red*, *top panel*); overlay of the 3D PA image (*green*) over the MR image (*middle panel*); and overlay of the tumor-segmented MR and PA images (*bottom panel*) showing good co-localization of the PA signal within the tumor. (**c**) Quantification of the imaging signals in the tumor shows a significant increase in the MRI, PA, and Raman signals after versus before the nanoparticle injection ("***" indicates $p < 0.001$, "**" indicates $p < 0.01$). Error bars represent the standard error of the mean, AU, arbitrary units (From [87] with permission)

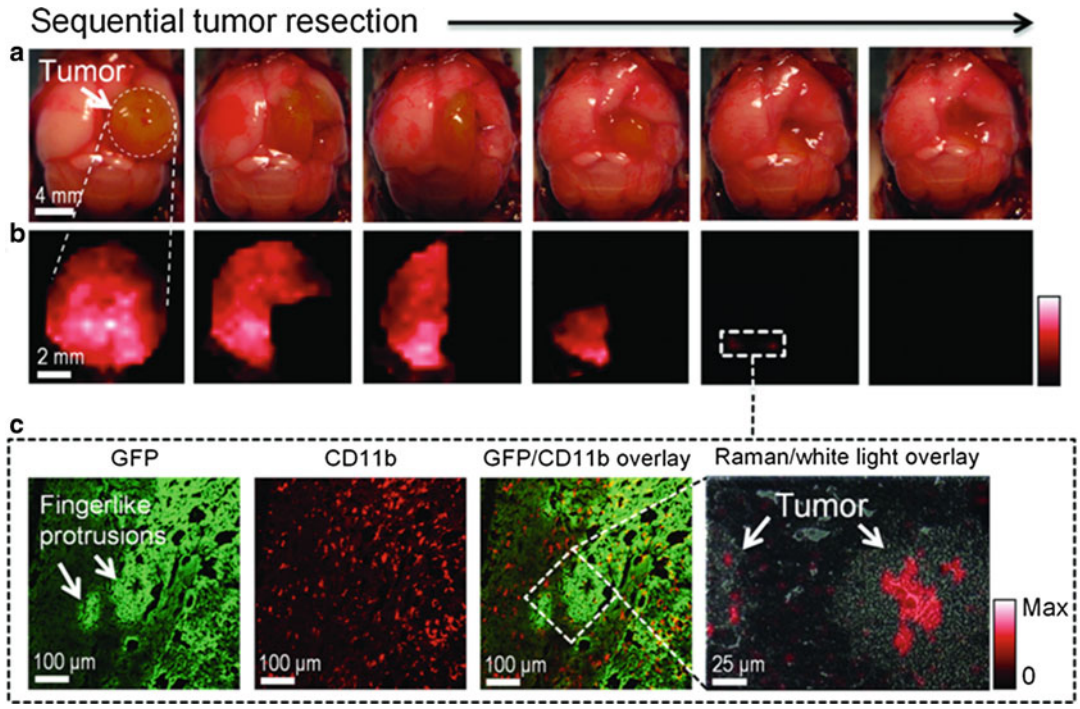

Fig. 23 Preclinical model of Raman-guided surgery. (**a**) Following orthotopic implantation with GFP-transduced U87MG glioblastoma cells, the brain tumor-bearing mouse underwent craniotomy under general anesthesia. Quarters of the tumor were then sequentially removed (as illustrated in the photographs). (**b**) Intraoperative Raman imaging was performed after each resection step, until the entire tumor had been removed by visual inspection. After the gross removal of the tumor, several small foci of Raman signal were found in the resection bed (outlined by the *dashed white square*). (**c**) Subsequent immunohistochemical analysis of sections from these foci demonstrated an infiltrative pattern of the tumor in this location, forming fingerlike protrusions extending into the surrounding brain tissue. CD11b (second panel from *left*) is a widely used microglial immunohistochemical marker. As shown in the Raman microscopy image (*right panel*), the Raman signal was observed within these protrusions, indicating the selective presence of MPRs in these protrusions. The *white dashed box* not drawn to scale. Raman signal in linear *red* color table (From [87] with permission)

commonly used enhancement methods are surface-enhanced Raman scattering (SERS) and coherence anti-Stokes Raman scattering (CARS); both SERS and CARS enhance the Raman signal by orders of magnitude. SERS involves adding metal (e.g., gold) nanoparticles which absorb the optical energy and yield an enhanced Raman signal by virtue of the metal surface transferring energy to nearby molecules (Fig. 21b). The resulting Raman signal provides picomolar sensitivity, which is compatible with tissue tracer concentrations achievable in vivo. Furthermore, labeling SERS nanoparticles with several different molecular ligands can provide simultaneous assay of multiple molecular components. CARS involves illumination with photons of different energies, with one photon energizing a molecule of interest from its ground state to an initial excited state and a second photon energizing the molecule from a "relaxed" state (i.e., at an energy level after releasing energy during the "laser-off" time interval following absorption of the first photon) to a different higher-energy level; this second (or higher) tier of vibrational energy is ~fivefold more intense than the Raman signal after the original pulse (Fig. 21c). The CARS technique is often used for high-

resolution, three-dimensional microscopy. Its advantages are that there is no need for administered probes (as in SERS) and rapid acquisition of images. Several preclinical studies have utilized the SERS or CARS techniques for in vivo molecular imaging of cell receptors (e.g., RGD-carbon nanotubes that bind to $\alpha_5\beta_3$ integrin-expressing tumors), tumor microvessels, enzyme activity, pH, lipid composition, and myelin composition (Fig. 22).

Over the last decade, the biomedical applications of Raman spectroscopic imaging have grown dramatically. Because it is essentially a surface imaging technique (like most optical imaging techniques), Raman spectroscopic imaging has been applied mainly to examination of skin and of pathological specimens as well as to small animals. For example, Raman mapping has enabled accurate identification of malignant from benign lesions and normal tissue in the skin, brain, larynx, parathyroids, breast, and urinary bladder. Raman spectroscopic imaging has also been applied endoscopically in the colon. Recently, Kircher et al. have reported a molecular imaging strategy using a novel triple-modality MRI-photoacoustic-Raman nanoparticle probe [87] clinically translatable to the intraoperative setting (Fig. 23).

Concluding Remarks

The last decade has featured remarkable technical advances in intraoperative imaging and techniques potentially adaptable to intraoperative imaging. While intraoperative nuclear counting using handheld probes is now routine, intraoperative nuclear imaging remains largely investigational. While certain applications of intraoperative and endoscopic optical imaging (such as optical cystoscopy) are also now fairly routine, more exotic forms of optical imaging such as Cerenkov imaging and photoacoustic imaging have only recently been translated to the clinic. Other promising forms of optical imaging such as Raman spectroscopic imaging have not yet been clinically translated to any significant extent. Multimodality intraoperative probes capable of simultaneously detecting both nuclear and optical signals are being developed as well. The ultimate clinical impact of these new imaging modalities in intraoperative and endoscopic settings remains to be determined.

Abstract

Radionuclide therapy (RNT) uses systemically administered radiopharmaceuticals directed to a specific cancer-associated target to provide low-dose-rate (LDR) treatment. The radiation dose is delivered to the tumor cells by continuous, but declining, exposure that is a function of the initial uptake and the variable half-life. The average dose rate for RNT is typically of the order of 2–8 Gy/day, and the maximum absorbed dose may be up to 50 Gy delivered over a period of many days. This is in marked contrast to the situation with external beam radiotherapy (EBRT), where the dose is delivered at a high-dose rate (HDR), typically 1–5 Gy/min, and also in contradistinction to the dose rate at which brachytherapy is delivered, typically 1–5 Gy/h. The mechanisms by which cells respond to LDR exposures are fundamentally different from those occurring at HDR. LDR exposures tend to promote loss of clonogenic potential in some cell types (e.g., lymphomas) by activating apoptotic responses, whereas high doses tend to cause necrosis as their primary mechanism of cytotoxicity. The ability to induce apoptosis varies inversely with dose rate. Many cell types exhibit an initial hypersensitive response at doses below ~25 cGy followed by a region of increasing radioresistance up to ~50 cGy. This phenomenon probably involves an alteration in the cellular processing of DNA damage as a function of dose. Radiation damage to cells is due primarily to indirect effects such as formation of free radicals in water (with their diffusion and subsequent interaction with cellular

components, mostly DNA) and to some degree direct damage to DNA. Different tissues and different individuals have different abilities to respond to and repair this damage. The value of LDR therapy with radionuclides in patients with differentiated thyroid carcinoma, somatostatin receptor-expressing tumors, neuroendocrine tumors, lymphoma, liver tumors, and treatment of metastatic bone pain is discussed.

Radionuclide therapy • Radiobiology • Radiation dosimetry • Therapeutic radiopharmaceuticals • DNA damage and radiation dose

Glossary

3D-ID	3D-internal
[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
ASCT	Autologous stem cell transplantation
BED	Biologic effective dose
BSA	Body surface area
CRPC	Castration-resistant prostate cancer
CT	X-ray computed tomography
CTDI	CT dose index
DMSA	Dimercaptosuccinic acid
DOTA	1,4,7,10-Tetra-azacyclododecane-1,4,7,10-tetraacetic acid
DOTANOC	DOTA-1-Nal^3-octreotide
DOTATATE	DOTA- Tyr^3-octreotate
DSB	Double-strand breaks
DTC	Differentiated thyroid cancer
DTPA	Diethylenetriaminepentaacetic acid
DVH	Dose–volume histograms
EANM	European Association of Nuclear Medicine
EBRT	External beam radiation therapy
ECD	Ethyl cysteinate dimer
ED	Effective dose
EU	European Union
FDA	United States Food and Drug Administration
FISH	Fluorescence in situ hybridization
FSH	Follicle-stimulating hormone
GBE	*Ginkgo biloba* extract
GI	Gastrointestinal
Gy	Gray unit (ionizing radiation dose in the International System of Units, corresponding to the absorption of one joule of radiation energy per kilogram of matter)
HCC	Hepatocellular carcinoma
HDR	High-dose rate
HMPAO	Hexamethylpropylenamine oxine
ICRU	International Commission on Radiological Units
LDH–IRR	Low-dose hyper-radiosensitivity–increased radioresistance
LDR	Low-dose-rate
LET	Linear energy transfer
LPL	Lethal–potentially lethal
LQ	Linearquadratic
LSF	Lung shunt fraction
LSS	Life span study
MAA	Macroaggregated albumin
MAG3	Mercaptoacetyltriglycine
MDP	Methylene diphosphonate
MIBG	Meta-iodobenzylguanidine
MIRD	Medical internal radiation dose
MRI	Magnetic resonance imaging
MN	Micronuclei
NAT	Noradrenaline transporter
NHL	Non-Hodgkin's lymphoma
NSCLC	Non-small cell lung cancer
NT	Non-tumor tissue
NTCP	Normal tissue complication probability
OLINDA	Organ level internal dose assessment
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PET/MRI	Positron emission tomography/Magnetic resonance imaging

PRRT	Peptide receptor radionuclide therapy
RBE	Relative biological effectiveness
RE	Relative effectiveness per unit dose
RILD	Radio induced liver disease
RIT	Radioimmunotherapy
ROI	Region of interest
ROS	Reactive oxygen species
SF	Surviving fraction
SNM	Society of Nuclear Medicine
SPECT	Single-photon emission computed tomography
SPECT/CT	Single-photon emission computed tomography/Computed tomography
STASIS	Stress or aberrant signaling-induced senescence
SUV	Standardized uptake values
Sv	Unit of radiation absorption in the International System of Units (SI), which takes into account the relative biological effectiveness (RBE) of ionizing radiation
TACE	Transarterial chemoembolization
TARE	Trans-arterial radioembolization
TBA	Total-body absorbed
TCP	Tumor control probability
TNF	Tumor necrosis factor
TRAIL	TNF-related apoptosis-inducing ligand
VOI	Volume of interest
WBD	Whole-body radiation dose
WBS	Whole-body scan
γ-H2AX	Phosphorylated member X of the H2A histone family

New radiopharmaceuticals have led to increasing success of radionuclide therapy (RNT) [1, 2]. To plan treatment with RNT requires understanding dosimetry to both the target organ and other sites of tracer localization [3, 4]. However, despite the fact that maximizing radiation-absorbed dose to tumor while minimizing damage to normal tissues is the central objective of RNT, up till now RNT dosimetry has not gained wide acceptance as a necessary clinical tool. The need for dosimetry to individually optimize the therapeutic activity to be administered

has been far from self-evident, and efforts in this direction are in an infancy stage [4].

This chapter describes the progress that has been achieved in the fields of dosimetry and radiobiology, including a brief overview of the techniques used in biological dosimetry.

Radiobiology

There are three major approaches to the delivery of radiation therapy to treat patients with cancer: (1) locoregional delivery, such as in external beam radiotherapy (EBRT), (2) sealed-source interstitial/intracavitary radiotherapy (brachytherapy), and (3) RNT which include the use of receptor-directed ligands, metabolic precursors, or monoclonal antibodies (i.e., radioimmunotherapy) [5].

The key clinical and basic characteristics of RNT are the systemic administration of a radiopharmaceutical directed to a specific cancer-associated target and the rate at which the radiation dose is delivered to that target [5].

According to the principle of very low-dose rate (LDR), in RNT the radiation dose is delivered to the tumor cells by continuous, but declining, exposure that is a function of the initial uptake and the variable half-life. The average dose rate for RNT is typically of the order of 2–8 Gy/day, and the maximum absorbed dose may be up to 50 Gy delivered over a period of many days. This is in marked contrast to the situation with EBRT, where the dose is delivered at a constant high dose rate (HDR), typically 1–5 Gy/min, and also at variance with the dose rate brachytherapy is delivered, 1–5 Gy/h [5].

To date, most radiobiological models of RNT have been based on the extrapolation of data obtained following homogeneous exposures to acute single or fractionated doses of EBRT and have assumed that EBRT and RNT administered are substantially equivalent from the biological point of view. However, emerging evidence suggests that the mechanisms of cellular response to LDR exposures are fundamentally different from those occurring at HDR with either EBRT or brachytherapy [3, 6].

The combination of prolonged response, limited toxicity, and the ability to treat on multiple occasions suggests that the mechanism of action of LDR therapies is different from that seen with HDR exposures. Accordingly, treatment plans, clinical trials, and outcome assessment should be designed to consider this difference. Current radiobiological research points to a way in which RNT can be more effectively administered to patients by taking into account the biology of the mechanism of action of therapy as well as the physical characteristics of the radionuclide [5].

Conventional Radiobiological Models

A number of basic principles, emerged from early studies describing the effects of acute single or fractionated doses of EBRT on the clonogenic survival of cells, generally held that a cell must be "hit" by a radiation track in order to be killed, that genomic DNA was the principal "target" for killing, and that double-strand breaks (DSBs)/clustered lesions/multiply damaged sites were the principal DNA lesions leading to cell death [3].

Early models focused largely on the mechanical or metabolic challenges that DSBs might pose to a cell when it attempts to replicate its DNA (in S-phase) or divide (in mitosis). The linear-quadratic (LQ) model of fitting and interpreting clonogenic cell survival curves became a cornerstone of experimental radiation oncology and indeed is still widely used for predicting the clinical impact of changes in dose fractionation or dose rate on biological effect [5].

This model assumes two components of cell killing, one proportional to the dose D (αD) and the other is a quadratic term (βD^2) in which two sublesions are presumed to interact to produce a lethal event. The relationship between cell survival (surviving fraction, SF) and dose is then described by: $-\ln[\mathrm{SF}] = \alpha\mathrm{D} + \beta\mathrm{D}^2$. The two-hit/quadratic (β) term represents the fraction of cell killing caused by damage that can be spared either by dose fractionation or by decreasing the dose rate. In contrast, the one-hit/linear α-type lethal events

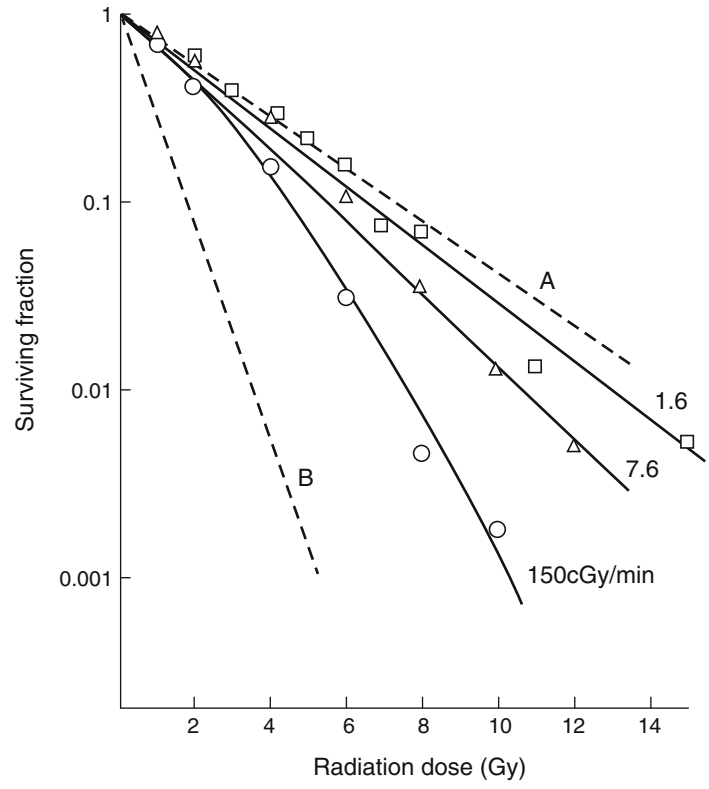

Fig. 1 Conventional dose-rate effect for cell killing as the dose rate is lowered from 150 to 1.6 cGy/min. The *dashed curves* represent the best fit to the data set obtained using the lethal–potentially lethal (LPL) model assuming either full repair (**a**) or no repair (**b**), respectively

are independent of time and thus of fractionation or dose rate [3, 5].

Application of the LQ model to HDR exposures indicates that cell killing generally decreases as the dose is fractionated, and this sparing would reflect the repair that takes place between fractions of the individual "sublethal" lesions that, in combination, would otherwise have contributed to β-type cell killing. Survival curves for large numbers of small fractions ultimately approximate the initial slope (α) of the HDR curve.

The typical dose rates used for both clinical EBRT and radiobiological studies are of the order of minutes (~1–5 Gy/min), exposure times not long enough for DNA repair to occur during the irradiation process. As the dose rate is lowered, the time taken to deliver a given dose increases, and it is then possible for DNA repair to take place during irradiation and for radiosensitivity to gradually decline [3, 5].

Survival curves at decreasing LDR become straighter and ultimately extrapolate the initial slope (α) of the HDR curve, with a sparing effect that would be attributed to the repair of sublethal lesions occurring during the protracted exposure (Fig. 1).

At very LDRs (≤2 cGy/min), cell proliferation can occur during the irradiation, thus leading to repopulation of the pool of clonogenic cells. Clearly, based on this assumption, RNT should be ineffective, although this expectation is not consistent with many clinical observations. Such phenomenon, in which decreasing the dose rate results in increased cell killing, has been defined "inverse dose-rate effect." The effect has been attributed both to the lower-dose rate (permitting the cells to progress through the cell cycle into more radiosensitive phases) and to some hypersensitivity of cells to low-dose/LDR exposures, as will be discussed below [3, 5].

Cell Death Mechanisms

Most cellular responses to ionizing radiation-induced DNA damage are genetically regulated and involve specialized DNA damage-recognition factors that trigger a cascade of signaling events that alter the expression and/or activity of specific genes/proteins involved in cell cycle arrest, DNA repair, accelerated senescence, and apoptosis at the cellular level and in tissue repair at the tissue level [5].

Necrosis, a form of cell death that has been variously described as generalized, nonspecific, accidental, or passive (i.e., it is not a genetically regulated process), generally occurs after high doses in cells that enter mitosis carrying high levels of unrepaired DNA damage [5].

In contrast, apoptosis is an energy-dependent, genetically controlled "suicide" process that involves the activation of degradative proteolytic enzymes called caspases and tends to occur at low doses of radiation. Apoptotic postirradiation cell death is mediated by two pathways, both resulting in activation of the cascade of caspases that function as cell executioners. Firstly, signals from the nucleus or cell membrane can activate the "intrinsic" pathway of apoptosis with a series of sequential events that cause final activation of caspases 3,6,7, and 8. Secondly, the "extrinsic" pathway of apoptosis is mediated by death receptors that are activated by ligands, such as the Fas ligand, tumor necrosis factor-α (TNF-α), and TNF-related apoptosis-inducing ligand (TRAIL). TRAIL induces apoptosis in response to ionizing radiation through the clustering of DR4 and DR5 receptors in the cell membrane [7].

Other modes of cell death are the "accelerated" or "premature" senescence or "STASIS" (stress or aberrant signaling-induced senescence), a genetically programmed response to DNA damage [8], and the mitotic catastrophe, generally defined as the failure of a cell to properly undergo mitosis after DNA damage. It has recently been recognized that mitotic catastrophe is not a mode of cell death per se, but a death that generally occurs secondarily to mitotic catastrophe, apoptosis, or accelerated senescence [9]. Death secondary to mitotic catastrophe has been suggested to account for a significant proportion of the cytotoxicity observed after radiation exposure.

Possible Contributing Mechanisms to RNT Tumor Responses

Low-Dose/Dose-Rate Apoptosis

Different mechanisms of cytotoxicity appear to operate in different dose and dose-rate ranges for a given cell type. Indeed, several experimental studies support the tenet that LDR exposures tend to promote loss of clonogenic potential in some cell types (e.g., lymphomas) by activating apoptotic responses, whereas high doses tend to cause necrosis as their primary mechanism of cytotoxicity [10]. For example, low doses of EBRT induce substantial apoptosis in tumor cells and that the dose–response curve for apoptosis plateaus above ~7.5 Gy [11]. Furthermore, multiple small fractions of EBRT were found to produce a higher level of apoptosis than a large single dose. Clinical effectiveness of lower doses of RNT and other LDR therapies could be related to their ability to optimize such effects, such as apoptosis exhibiting an inverse dose-rate effect [5].

Low-Dose Hyper-radiosensitivity–Increased Radioresistance

Many cell types exhibit an initial hypersensitive response at doses below ~25 cGy, followed by a region of increasing radioresistance up to ~50 cGy, the survival curve above 1 Gy closely following the expected LQ response [12]. This phenomenon, illustrated in Fig. 2, has become known as the "low-dose hyper-radiosensitivity–increased radioresistance" (LDH–IRR) response. The mechanism of LDH–IRR probably involves an alteration in the cellular processing of DNA damage as a function of dose. One possibility is that the transition from LDH to IRR may involve the activation of

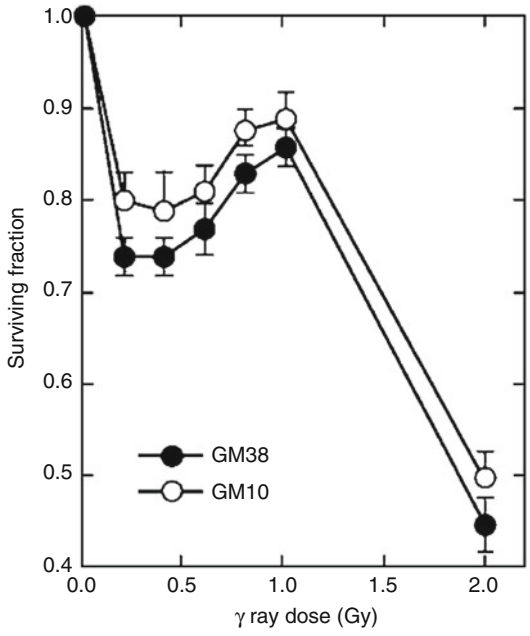

Fig. 2 Cellular survival responses of two normal human fibroblast strains, GM38 and GM10, following exposure to ^{60}Co γ-radiation

radioprotective DNA-repair pathways that are triggered by a certain threshold level of DNA damage. Cells would then be hypersensitive to low doses of radiation that produce insufficient DNA damage to trigger this protective process.

LDH–IRR seems to be preferential and possibly limited to a fraction of cells in the G2 phase of the cell cycle, and an important consequence of the LDH–IRR response is that the conventional LQ model greatly underestimates cellular radiosensitivity after acute low doses. This limitation was addressed by Joiner et al. [12] in a modified LQ model that incorporates the impact of an induced repair threshold.

If the LDH–IRR response occurs also during LDR therapies, the latter could exert much greater cytotoxicity per unit of absorbed dose than would be predicted by the conventional LQ model. The LDH–IRR model leads to the prediction that DNA-repair processes should be less efficient after doses below the IRR threshold (i.e., typically ≤40 cGy) if this response is related to induced DNA repair.

G2 Synchronization, Bystander, and Cross-Fire Effects

In some tumor cell lines, LDR exposures in the range of 10–300 cGy/h have been shown to cause the partial synchronization of cells in the G2/M phase as a result of the prolonged activation of the G2 checkpoint [13]. This effect could have two consequences for LDR therapies. Firstly, it might abrogate the competitive effects of proliferation on the elimination of clonogenic tumor cells. Secondly, it might enhance the relative effectiveness of LDR radiation by holding the cells in G2, which is a relatively radiosensitive phase of the cell cycle, a mechanism that was invoked to explain the inverse dose-rate effect seen in some cell lines at LDR.

The "bystander" effect refers to the phenomenon whereby manifestations of damage (such as cell death) are observed in cells adjacent to those that are traversed by an ionizing particle but that are not themselves "hit" [5]. This means that a cytotoxic response in the presence of the bystander effect will be greater than that predicted on the basis of classical dosimetric estimates. The biological bystander effect appears to reflect the generation of a "damage signal" emanating from irradiated cells that is communicated to the non-irradiated adjacent cells through a variety of signaling mechanisms. These include intercellular cross talk, the release of reactive oxygen species (ROS) or of clastogenic factors, and intracellular signal transduction pathways. The contribution from these mechanisms probably varies among different model systems, leading to some controversy as to their relative importance.

The bystander effect is quite distinct from the *cross-fire effect*, another mechanism of RNT, in which an ionizing particle emanating from a source radionuclide in one cell deposits its energy in a distant target volume represented by a neighboring or distant cell [13]. Cross-fire effects depend predictably on the particle range and play a major role in the effectiveness of RNT using β-emitting isotopes such as those generated by ^{131}I that have a range of millimeters in tissue. Such cross-fire

effects with β-emitters are also important for therapeutic responses, because they should help to overcome the limitations imposed on RNT by heterogeneity in the distribution of the radiopharmaceutical within the tumor mass, which is especially important in solid tumor.

Adaptive Responses

The in vitro *adaptive response* is the phenomenon whereby exposure of cells to a low "priming" dose of radiation induces resistance to a subsequent higher-dose exposure [14]. Like LDH–IRR, the adaptive response has been suggested to involve inducible radioprotective mechanisms, such as DNA-repair pathways, although not all studies are consistent with such a mechanism. A possible explanation for these diverse findings is the broad range of cell types, assays, priming treatments, and times of observation employed in different studies; furthermore, adaptive responses typically occur only within a narrow dose range of ~0.5–20 cGy. With respect to the potential role of adaptive responses in RNT, it has been noted that LDR irradiation can be regarded as a series of priming doses briefly separated in time; the adaptive response could, therefore, have a negative influence on the efficacy of LDR therapies, unless, of course, it is not activated under these conditions.

Fractionated RNT and Hypoxia

Fractionated delivery of RNT is designed mostly to compensate for the anticipated heterogeneity of RNT dose distribution, which determines absent or suboptimal intratumoral radionuclide deposition, an event that is especially important in large, poorly vascularized tumors that contain regions of hypoxia [10]. The development of hypoxia in tumors is believed to represent a major barrier to successful EBRT, in part because hypoxic cells are ~threefold resistant to acute exposures to ionizing radiation with respect to normoxygenated cells [15]. Conventional dose fractionation partially overcomes the negative effect of hypoxia, by allowing for the reoxygenation of hypoxic cells between fractions, and it is reasonable to assume that the same would be true for protracted LDR therapies. Under some conditions, fractionated delivery of radiolabeled antibodies and peptides has shown efficacy, with fractionated delivery causing less toxicity than a single administration. In general, both preclinical models and clinical radioimmunotherapy (RIT) evidence suggest that RNT fractionation results in a beneficial effect and in a more uniform radiation dose distribution. This has certainly proved to be an effective strategy with ^{131}I-metaiodobenzylguanidine (^{131}I-MIBG), with obvious increases in clinical effectiveness, and there are now data to support the use of fractionated treatment with radiopeptides as a way of reducing toxicity.

Future Directions

There is no doubt that a better understanding of the radiobiology and mechanisms of action of RNT will facilitate the development of newer radiopharmaceuticals and the design of prospective phase III and IV clinical trials [5]. Although our understanding of the low-dose-related phenomena has increased dramatically in the last few years, it is important to validate these effects in the clinical setting. In particular, validation of a role for the bystander effect in RNT in vivo will impact the assessment of therapeutic response to RNT, as well as risk estimates for therapeutic and diagnostic radiopharmaceuticals. In addition, application of high-throughput genomic/proteomic screening methods (DNA arrays, single nucleotide polymorphism analysis, and protein arrays) will allow a rapid and accurate prediction of patient response, both in the tumor and in normal tissues [5]. Other issues, such as the role of metabolic markers in selecting therapies and dosage schedules, and the potential interactions between low-dose chemotherapy and RNT, constitute additional important areas for clinical development.

Dosimetry: Overview on Methods

The basic goal of RNT is to deliver enough radiation-absorbed dose to the tumor while

minimizing the risk of toxicity to the bone marrow and to other normal tissues. For RNT, many physicians administer approximately the same activity to all patients, while ideally administered activity should be adjusted using a patient-specific treatment planning strategy based on radiation-absorbed dose. With a patient-specific approach, activity administration is optimized to maximize treatment efficacy while minimizing deleterious side effects to normal organs.

In RNT the absorbed dose is the energy deposited (E) per unit mass of matter (m) (with units of J/kg, 1 J/kg = 1 Gy). In RNT, E is the number of radionuclide disintegrations in a particular volume multiplied by the energy emitted per disintegration of the radionuclide and the fraction of emitted energy that is absorbed by a particular mass (m).

To improve the correlation between dose and the exposure effect, other quantities must be defined, such as relative biological effectiveness (RBE), radiation weighting factors, and tissue weighting factors. This suggests that energy absorbed per unit mass does not predict response at all levels, and some other factors must be considered.

Damage to cells is due primarily to indirect effects of radiation (formation of free radicals in water that diffuse and subsequently interact with cellular components, mostly DNA) and to some degree to direct effects (direct damage to DNA from radiation interaction). Also, different tissues and different individuals have different abilities to respond to and repair this damage. Thus, physical quantities such as the absorbed dose must be linked to radiobiological quantities to completely understand and be able to predict effects in a system.

Internal dose can be calculated by the following simple equation from the medical internal radiation dose (MIRD) Committee of the Society of Nuclear Medicine (SNM) [16, 17]:

$$D_{T-S} = \frac{\vec{A} \times \Delta \times \phi_{T-S}}{M_T} = \vec{A} \times S = A_0 \times \tau \times S \tag{1}$$

where D is the absorbed dose in a target organ (Gy), $\tilde{A}$ is the cumulated activity in source region S, Δ is the energy emitted by the radionuclide per disintegration, $\phi_{T \to S}$ is the fraction of energy emitted by the radionuclide in source region S that is absorbed in the target region, and M_T is the mass of region T. Furthermore, τ is the residence time, which is simply equal to $\tilde{A}$ /A_0, the cumulated activity divided by the patient's administered activity (A_0). S is the absorbed dose per unit cumulated activity and it is given by

$$S = \frac{\Delta \times \phi_{T-S}}{M_T} \tag{2}$$

Equation 1 means that the absorbed dose depends on the half-life of the radionuclide and its spatial and temporal distribution in the target. The latter are typically obtained by images collected at different times after administration of the radiopharmaceutical and used to estimate the amount or concentration of radioactivity in a specific region. The level of activity obtained at different times after injection, plotted against time, gives a time–activity curve for a particular target, such as an organ or tissue. The integral of this curve gives the total number of disintegrations or the cumulated activity ($\tilde{A}$) for the region. Therefore, the main input data needed for evaluation of radiation dose are the biokinetic data that characterize the distribution and retention of the radiopharmaceutical throughout the biological system.

This absorbed dose could be used to estimate the biologic effective dose (BED) [18]:

$$\text{BED} = D \times \text{RE} \,\text{where}\, \text{RE} = \left[1 + \frac{D\lambda}{(\alpha/\beta)(\mu + \lambda)}\right] \tag{3}$$

where D is the absorbed dose, μ is the exponential repair rate constant that quantifies the rate of sublethal damage repair, and λ is the effective clearance rate constant (given by the sum of the physical decay and the biological clearance rate constants). It means that the BED may be defined as the product of the total physical dose D and a modifying factor named the *relative effectiveness per unit dose*, RE, that quantifies dose-rate effects with respect to radiosensitivity and repair of radiation damage.

The BED equation is derived from the linear-quadratic (LQ) model that describes the surviving fraction (S_f) of target cells after a radiation dose (D):

$$S_f = \exp\left(-\alpha D - \beta D^2\right)$$

where the linear component αD describes the DSBs induced by a single ionizing event, and the quadratic component βD^2 describes the same effect induced by two separate ionizing events; α and β are the tissue-specific coefficients for radiation damage, α being proportional to dose (one single event is lethal) and β being proportional to squared dose (two sublethal events required for lethal damage). The α/β ratio is also named "repair capacity" and quantifies the sensitivity of a given tissue to changes in fractionation. Typical values for the α/β ratio are about 5–25 Gy for early-reacting normal tissues and tumors and about 2–5 Gy for late-responding normal tissues.

Also with the biological effective dose, the focus in radionuclide dosimetry study is to calculate the absolute amount of energy delivered per mass unit of tissue, i.e., the absorbed dose D.

In order to plan and design an appropriate dosimetric study, it is necessary to know approximately how the compound will be taken up and cleared from various organs and the whole body, by collecting multiple samples. Most therapeutic agents have a relatively fast phase of organ uptake and initial clearance, followed by more general systemic removal that lasts for many days. Therefore, a typical sampling scheme is to collect several samples in the first hours after administration and then about once or twice a day for a few days to several weeks.

To calculate the cumulated activity, the integral of the time–activity curve for each source organ may be obtained by (1) direct integration of data, for example, with the trapezoidal method, (2) a fit of the data to yield a mathematical expression of the uptake and retention in the target organ, and (3) using compartmental models, if the pharmacokinetics inside the target tissue is available.

Specific quantification techniques have been summarized for 2D and 3D imaging in the MIRD16 and MIRD 17 [19, 20]. Using planar data (2D imaging), the most accepted technique is to obtain images from the posterior and anterior projections and then correct the projected data in each region of interest (ROI) for attenuation and scatter. The most popular technique for attenuation correction involves the use of a Cobalt-57 (or other appropriate radionuclide) projection source imaged with and without the patient in the view, the attenuation coefficient for the system having been characterized in advance. For scatter correction, the two- or three-energy window method is widely accepted and applied when gamma camera software permits simultaneous acquisition in multiple energy windows. One of the best known packages able to offer mean absorbed doses in the organs, based on uniform activity distribution in organs/tissues, was the MIRDOSE3.1 package that implemented the use of whole-body MIRD-stylized mathematical phantoms representing adult males and females, children, and pregnant women [21]. The MIRDOSE3.1 software could be used for calculating internal dose for a large number of radiopharmaceuticals, the rapid comparison of calculations for different cases, examination of dose contributions to different organs, and regional marrow dose calculations.

MIRDOSE3.1 has been updated to a new generation code, Organ Level Internal Dose Assessment (OLINDA), employing the Java programming language and the Java Development Kit environment [22]. The entire code was rewritten, but all of the basic functions of the MIRDOSE code were retained, while others were extended. More individual organ phantoms were included, the number of radionuclides was significantly increased (including alpha emitters), and the ability to perform minor patient-specific adjustments to doses reported for the standard phantoms was made possible.

Quantitative 3D imaging using single-photon emission computed tomography (SPECT) methods is considerably more complex. The essential requirements for 3D imaging-based dosimetry are the availability of 3D anatomic imaging studies, such as CT or MRI, at least one 3D imaging study of the radioactivity distribution (e.g., PET or SPECT), and software that implements a point-kernel or Monte Carlo calculation methodology to

estimate the spatial distribution of absorbed dose. Two fully developed packages are 3D-Internal Dosimetry (3D-ID) and DOSIMG [23, 24].

Clinical Experience

Clinical applications of dosimetry are not widely adopted in RNT, mainly because data from prospective randomized clinical trials that may prove the effectiveness of dosimetry in predicting clinical outcome after treatment are lacking. In order to prove that dosimetry-based RNT is of additional benefit over administration of fixed empirical activities or activities per body weight, prospective randomized phase III trials with appropriate endpoints should be undertaken [25]. So far, the lack of standardized methodology for calculating the absorbed doses and the continued use of approaches based on administrations of fixed empirical activities irrespective of personalized radiation dose estimates has hampered efforts to compare clinical outcomes in different patient populations and has led to significant difficulty in comparing results among different trials [4].

^{131}I-Iodide Therapy of Differentiated Thyroid Carcinoma

Radioiodide therapy has largely been proven to be a safe and effective method in the treatment of patients with DTC after total or near-total thyroidectomy [26]. Nevertheless, although it has been shown to be useful for ablation of thyroid remnants and for treatment of locoregional or distant metastases, at present there is no consensus on the activity of ^{131}I-iodide to administer, because of the lack of prospective, randomized data [27]. Many excellent reviews of empiric fixed prescribed activity have been previously published, and the most frequently used sets of empiric fixed prescribed activities range from 1.1 to 5.5 GBq for ablation to 5.5–11.0 GBq for treatment of metastases [28].

The advantages of using the empiric fixed prescribed activity are convenience, a long history of use, an acceptable rate and severity of complications, and the possibility to avoid the "stunning" phenomenon due to the diagnostic ^{131}I-iodide activity [27].

However, the persistence of disease in a significant proportion of patients and the possibility for multiple small empiric activities to have less therapeutic benefit than the same total activity given at one time have led to attempts to improve such empiric approach to therapy [28].

Efforts to meet this goal have led to two basic dosimetrically determined prescribed activity approaches, each one addressing a different aspect of this problem. Benua et al. developed an approach to define the maximum activity of radioiodide that can be administered without significant bone marrow suppression [29]. Maxon developed a method to evaluate the activity of radioiodide needed to adequately treat metastatic lymph nodes [30].

The limited bone marrow toxicity method (Benua approach) was developed at the Memorial Sloan Kettering Cancer Center, by setting an upper limit for the radiation dose to the patient's blood, which is considered as a surrogate for the critical organ, i.e., the red bone marrow [29].

Since radioiodide concentration is almost identical in blood as in inner organs including the red bone marrow, assessing the blood absorbed dose allows to estimate the radiation-absorbed dose that will be delivered to the hematopoietic system of the individual patient during therapy [30]. A summary of the methodologies used can be found in the review article by van Nostrand [28] and in the guidelines of the Dosimetry Committee of the European Association of Nuclear Medicine (EANM) for pre-therapeutic dosimetry [31].

The method allows estimation of the radiation dose that will be delivered to the hematopoietic system per unit activity administered to a given patient and restricts such dose to no more than 2 Gy to the blood [29, 31]. Therefore, the maximum activity for treatment is calculated as the amount of ^{131}I-iodide that would deliver an absorbed dose of 2 Gy to the blood compartment [32].

This method requires evaluation of the kinetics of activity in the blood and in the whole body, obtained by conjugate views of a whole-body scan (WBS) acquired with a dual-head gamma camera equipped with high-energy collimators [28].

To evaluate the blood kinetics, five blood samples should be obtained over 1 week (e.g., at 2, 6, 24, 96, and 144 h) after administration of ^{131}I-iodide, and the blood activity should be measured in a calibrated well counter from aliquots of blood samples [28].

The first WBS measurement obtained 2 h after tracer administration represents 100% of administered activity, while measurements are repeated at 24, 48, 72, and 96 h (or later if uptake and/or renal clearance is delayed). As an alternative to WBS conjugate-view imaging obtained with a gamma camera, measurements with an external probe can be used [28].

To calculate the whole-body activity as a function of time and circulating activity per mL of blood, the geometric mean of corresponding net counts obtained by conjugate views and all blood activities are normalized to the first data point and to the administered activity, respectively [28, 31].

The curves, $A(t)$, describing the activity in the blood and in the total body as a function of time after the administration are usually multi-exponential, and bi-exponential fitting is usually appropriate to determine the function describing time–activity curves in the blood and in the total body, respectively.

The residence times in the whole body and activity concentration in blood, $\tau_{\mathrm{TotalBody}}[\mathrm{h}]$ and $\tau_{\mathrm{Blood}}[h]$, are calculated by integrating the corresponding retention function $R(t) = A(t)/A_0$.

According to the generally accepted MIRD formalism, the mean absorbed dose to the blood per unit administered activity is determined by the sum of contributions of blood self-irradiation and of penetrating radiation from the whole body.

The mean blood absorbed dose per unit administered tracer activity can therefore be calculated as

$$\frac{\bar{D}_{\mathrm{Blood}}}{A_0}\left[\frac{\mathrm{Gy}}{\mathrm{GB_q}}\right] = 108 \times \tau_{\mathrm{Blood}}[h] + \frac{0.0188}{\mathrm{wt[kg]}} \times \tau_{\mathrm{TotalBody}}[\mathrm{h}]$$

The activity to be administered for a blood absorbed dose of 2 Gy is

Table 1 Problems and difficulties of limited bone marrow dosimetry (Benua approach)

No valid clinical data or outcome rates yet exist on a benefit of the strategy
The approach does not estimate the absorbed dose to the thyroid remnant or metastasis
"Stunning effect" due to diagnostic activity of ^{131}I could alter lesion biokinetics and the absorbed dose in a subsequent ^{131}I therapy
Increased cost and practical inconvenience

$$A_{\mathrm{Adm}}\left[\mathrm{GB_q}\right] = \frac{2 \times A_0[\mathrm{Gy/GBq}]}{D_{\mathrm{Blood}}}$$

Under the conservative assumption that the activity concentrations within the hematopoietic tissue and the blood are identical [33], a red marrow-based approach for the determination of the maximum activity to be administered has been proposed [33]. Although this method seems to be accurate, no systematic clinical validation of the red marrow absorbed dose versus toxic effect has yet been undertaken.

The limited bone marrow dosimetry is easy to perform both pre-therapeutically and peri-therapeutically, thus allowing administration of additional activity for selected patients without risk of severe side effects. However, the original method might not to be applied in the presence of extended metastatic bone involvement, as the blood-based absorbed dose calculation could underestimate the absorbed dose to the red marrow. Similarly, it should be carefully applied also in the case of patients with diffuse lung micrometastases, because the critical organ could be the lung itself instead of the hematopoietic red marrow [34, 35]. The main limitations of this method are reported in Table 1.

The goal of the lesion-based dosimetry (Maxon approach) is to individualize radioiodide activity that delivers the recommended absorbed doses to ablate thyroid remnant or to treat metastatic disease while minimizing the risk to the patient [36]. These absorbed doses are traditionally considered to be $\geq$300 Gy to ablate thyroid remnant and $\geq$80 Gy to successfully treat metastatic disease [36].

In order to determine the activity required to deliver the absorbed doses, it is necessary to measure the uptake, clearance, and concentration of ^{131}I contained in the identifiable thyroid remnants and/or metastases. One way to ascertain these parameters is through an analysis of selected regions of interest (ROIs) on conjugate-view gamma camera images or on SPECT images, obtained at sequential time points after administration of a tracer activity. Typically, these images should be acquired at 24, 48,72, and 96 h after tracer administration, but later time sampling might be necessary if the uptake and clearance are delayed. In addition, transmission images to correct for attenuation in the lesion area, scatter images, as well as calibration procedures are necessary. A curve-fitting procedure is then employed to determine the assumed single-exponential half-life value and to extrapolate the curve to zero time to determine the initial activity in the lesion [28].

Pre-therapeutic dosimetric assessments of the activity required to achieve a certain prescribed absorbed dose to a remnant or lesion are often based on adaptations of the generic MIRD equation for absorbed dose, as previously described:

$$\bar{D} = \vec{A} \times S$$

where $\bar{D}$ denotes the mean absorbed dose to the remnant/lesion, $\tilde{A}$ is the cumulative activity, and S is the "S factor" of the MIRD scheme depending on the lesion/remnant mass.

For dosimetry of metastases, CT, MRI, or US can be used for attenuation correction and to determine the mass, while no thoroughly validated method is yet available for ablative treatments to exactly calculate the thyroid remnant volume after surgery.

If the lesions are small, the "nodule module" of the OLINDA/EXM software might be useful to generate a spherical model of the remnant and/or tumor. Furthermore, if the size of the lesion is smaller than 5.0 mm (assuming that such small size can actually be accurately determined), then the tissue range of the beta particles can no longer be neglected in the dose calculation. This as well as other limitations of the lesion-based method is reported in Table 2.

Table 2 Problems and difficulties of lesion-based dosimetry (Maxon approach)

Non uniform absorbed doses within each lesion
An accurate estimate of the lesion mass is not always possible
Low uptake in lesions and, therefore, low count rates may cause statistical errors in the measurements
The biological effectiveness of dosimetry-guided ^{131}I therapy is not proven yet
"Stunning effect" due to diagnostic activity of ^{131}I could alter lesion biokinetics and the absorbed dose in a subsequent ^{131}I therapy

Conventional radiopharmaceuticals that allow quantitation of radioiodide uptake in thyroid remnants and metastases, such as 123I-iodide or ^{131}I-iodide, have limitations; in fact, there are problems regarding cost and the logistics of supply for ^{123}I-iodide, while ^{131}I-iodide has poor imaging properties (that translate into relatively low sensitivity) and its use can cause the so-called "stunning" phenomenon [27]. In contrast, with the introduction of hybrid positron emission tomography/computed tomography (PET/CT) devices to the clinic, ^{124}I PET/CT is becoming an emerging and attractive methodology for lesion dosimetry in the management of patients with DTC [37]. With its ability to determine the concentration of ^{124}I-iodide at anatomical sites of interest, PET/CT provides quantitative images and provides higher spatial resolution and imaging sensitivity than gamma camera-based devices [37].

Using the PET data as input to a fully three-dimensional dose planning program, Sgouros et al. [38] calculated spatial distributions of absorbed doses, isodose contours, dose–volume histograms, and mean absorbed dose estimates for a total of 56 tumors. The mean tumor-absorbed dose for each patient ranged widely, from 1.2 to 540 Gy, while distribution of values for the absorbed dose in individual tumor voxels was even more dispersed, ranging from 0.3 to 4,000 Gy.

Median per patient tumor radiation-absorbed doses between 1.3 and 368 Gy were reported by de Keizer et al. [39], who performed tumor dosimetry after rhTSH stimulated ^{131}I-iodide treatment. Dosimetric calculations were performed using tumor radioiodide uptake measurements from

posttreatment ^{131}I scans, while tumor volumes were estimated from radiological images.

In general, a ^{124}I-iodide PET/CT dosimetry protocol involves estimating the absorbed dose per administered ^{131}I activity for each radioiodine-positive lesion, allowing the calculation and the choice of the actual recommended ^{131}I activity. However, pre-therapeutic ^{124}I PET/CT dosimetry requires the knowledge of lesion volumes in order to adequately correct for partial volume effects. Such effects can reduce measured activity concentrations in lesions by up to ~three times the spatial system resolution, i.e., up to ~2 cm in diameter.

Often no morphological CT correlates can be assigned to ^{124}I-iodide PET foci. This can be partially attributed to the fact that CT examinations prior to radioiodine therapy need to be performed without contrast media to avoid iodine contamination. If no CT correlates exist, the target volumes must then be assessed from PET images alone by applying various threshold methods. The original ^{124}I PET dosimetry protocol entailed five PET measurements at 4, 24, 48, 72, and 96 h after ^{124}I-iodide administration, although simplified models by using four, three or two points (24 h/96 h) have been proposed [40].

There are only a few published studies that have examined the absorbed dose in thyroid remnants and metastases using ^{124}I PET/CT. Freudenberg et al. [41] determined a median LDpA of 95 Gy/GBq for bone metastases ($n = 73$), 113 Gy/GBq for lymph node metastases ($n = 32$), and 86 Gy/GBq ($n = 14$) for lung metastases in those patients who were eligible for RIT.

At the moment, considering the slow progression disease and long follow-up period, it is difficult both to evaluate the long-term benefits and to design classical blinded and randomized studies in DTC patients submitted to pre-therapy ^{124}I PET/CT dosimetry. However, pre-therapy ^{124}I PET/CT dosimetry seems to be very useful in selected patients with locoregional or distant metastases who may benefit from radioiodine therapy with an individually tailored escalated activity or to abandon the therapy because of insufficient obtainable dose in the lesions.

Besides being a promising method to obtain accurate dosimetry in patients with metastases, ^{124}I PET/CT imaging is a useful diagnostic tool for accurate pre-radioiodine therapy staging, with a diagnostic accuracy similar to the WBS obtained after high therapeutic activities of radioiodine.

Peptide Receptor Radionuclide Therapy

Peptide receptor radionuclide therapy (PRRT) represents a promising option for patients with somatostatin receptor-expressing tumors. Several clinical trials have proven its efficacy, especially for neuroendocrine tumors [42, 43]. However, possible radiation-induced renal damage and large inter-patients' variability in biodistribution and tumor uptake require accurate dosimetry-based therapy planning. Recent improvements in dosimetry methods [44–51] and radiobiological models [18, 52, 53] have resulted in promising results and correlations that constitute challenging perspectives for optimized PRRT and for other radionuclide therapies as well [53–57].

^{90}Y-DOTATOC, ^{90}Y-DOTATATE, and ^{177}Lu-DOTATATE are the most widely employed radiopharmaceuticals for PRRT. Pilot trials also considered ^{111}In-octreotide for therapy, due to the high LET of its Auger-electron emission. However, since tumor response was seldom achieved, ^{111}In-based PRRT protocols have virtually been abandoned [42].

The physical half-life of ^{90}Y is compatible with the peptide kinetics, while the high energy of the β-particles confers high probability of killing all neoplastic cells in a certain volume around the uptake site through the cross-fire effect. Conversely, ^{90}Y is not easily suitable for imaging due to the lack of γ-emission, even if promising results have been shown for planar and SPECT bremsstrahlung ^{90}Y-images corrected for scatter and detector response, either based on Monte Carlo simulations or obtained by new-generation equipments (SPECT/CT) [58–60]. The possibility to obtain ^{90}Y-PET images due to the low incidence of pair production of ^{90}Y (branching ratio of 32×10^{-6}) is also challenging. It has already found application in the radioembolization of

liver lesions using ^{90}Y-microspheres [61, 62] and has been recently studied to be applied in ^{90}Y-PRRT [63].

^{111}In-octreotide, ^{86}Y-octreotide, and ^{68}Ga-peptides have been proposed as alternative options to ^{90}Y-imaging. Due to their similar chemical characteristics, the assumption of comparable behavior in vivo of ^{111}In- and ^{90}Y-derivatives has been widely accepted [64]. Thus, several authors have used the identical molecule labeled with either ^{111}In or ^{90}Y for imaging or for therapy, respectively (e.g., ^{111}In-DOTATOC and ^{90}Y-DOTATOC). Since the physical $T_{1/2}$ of ^{111}In is almost identical to that of ^{90}Y and is compatible with the distribution kinetics of peptides, the diagnostic activities usually administered (~185 MBq) allow one to obtain serial images (planar, SPECT) over 3–4 days, although some difference in the chemical structure of ^{111}In-octreotide cannot offer identical biokinetics of the corresponding ^{90}Y-conjugate. A fortiori, even less recommendable is a dosimetry plan based on the distribution of ^{111}In-octreotide (Octreoscan©), even though some authors claim its use for a "practical" dosimetry [65, 66]. The same compound labeled with ^{86}Y (^{86}Y-DOTATOC) represents a further option, since it totally preserves the chemical nature of ^{90}Y-derivatives and offers PET resolution. However, limitations of this approach are due to the physical $T_{1/2}$ of ^{86}Y (14.7 h, too short to follow the kinetics of uptake peptide and retention), complex image quantification, cost, and poor availability [64]. Similarly, ^{68}Ga-peptides are not suitable for dosimetry purposes, despite the high-quality PET images provided, because of the extremely short $T_{1/2}$ of ^{68}Ga (68 min) as compared to the kinetic pattern of peptide distribution. Furthermore, the chemical properties of ^{68}Ga might slightly alter the biodistribution kinetics of the radiolabeled peptide as compared to the therapeutic agent [64].

In comparison with ^{90}Y, ^{177}Lu induces less damage by cross-fire effect, but releases higher energy in smaller tissues. Moreover, the γ-rays emitted by ^{177}Lu are suitable for imaging and dosimetry, although for proper scintigraphic imaging, diagnostic/dosimetric activities of at least of 370–740 MBq should be administered. Most often dosimetry is evaluated after administering therapeutic activities of ^{177}Lu-DOTATATE (i.e., 3.7–7.4 GBq), as treatment is usually given in multiple cycles. So, the activity to be administered in cycles after dosimetry can, in case, be adjusted based on the dosimetry results.

^{90}Y- and ^{177}Lu-peptides have shown similar biological half-lives for organs and lesions, with varying uptakes depending on the different expressions of somatostatin receptors with respect to the peptide affinity. The same dosimetry methods and time schedules for data recording can be used for ^{90}Y- and ^{177}Lu-PRRT, but dosimetry must be assessed specifically for every used radiopeptide, and for the single patient, due to wide intra-patient variations as well as frequent inter-patient differences on tumor uptake.

The absorbed doses per unit activity for ^{177}Lu-peptides are much lower (two- to fourfold) than for ^{90}Y-peptides [64]. The activities administered in ^{177}Lu- or ^{90}Y-PRRT should vary accordingly, although the therapeutic protocols most commonly employed in clinical studies are not yet uniformly established with respect to activities administered and number of cycles [67–69].

Table 3 reports a summary of the dosimetric results for the most commonly used ^{90}Y- and ^{177}Lu-peptides (^{90}Y-DOTATOC and ^{177}Lu-DOTATATE), which share some properties: (1) the pharmacokinetics are characterized by very fast blood clearance and urinary elimination, leading to low exposure of the whole body (Fig. 3); (2) the spleen, kidneys, and liver receive the highest absorbed doses; (3) the kidneys are the dose-limiting organs; and (4) no significant uptake in bone or red marrow is typically reported.

To reduce renal radiation burden, preclinical and clinical studies showed that the infusion of protective agents (negatively charged amino acids) allows 25–65% reduction of the kidney uptake [70]. Despite such protection, the cumulative dose to the kidneys could still be borderline with the limits considered for nephropathy induction, especially with ^{90}Y-peptides.

Increased application of PRRT has stimulated interest in improving calculation of the radiation burden to organs at risk. There are two remarkable studies by Sandstrom et al. that focus on individualized kidney and bone marrow dosimetry and

on the method dependence, observer variability, and kidney volumes of dosimetry for ^{177}Lu-PRRT [48, 49]. Some papers use SPECT/CT-based renal dosimetry in ^{177}Lu-PRRT [50, 51], while an accurate method for planar image activity quantification and absorbed dose assessment in general is described by the group of Sjögreen et al. The clinical value of the absorbed dose to the kidney is the topic discussed by Swärd et al. [45].

Table 3 Absorbed dose estimates for the principle PRRT trials with ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE

	Absorbed doses per unit activity (Gy/GBq) mean values among patients published by different authors	
	^{90}Y-DOTATOC	^{177}Lu-DOTATATE
Red marrow	0.03; 0.06; 0.09; 0.17	0.02; 0.04; 0.07
Kidneys[a]	1.71; 2.44; 2.73; 3.84	0.62; 0.81; 0.88; 0.97
Liver	0.27; 0.66; 0.75; 0.86; 0.92	0.13; 0.18; 0.21
Spleen	2.19; 4.74; 5.36; 7.20	0.64; 1.2; 2.15
Bladder	1.04; 1.59; 2.61	0.31
Total body	0.10; 0.15; 0.28	0.05

[a]Absorbed dose values reported include renal protection
[b]For tumors, instead of the mean values, the ranges of variability are presented

Two papers compared planar and SPECT images of ^{177}Lu-PRRT, both considering planar images corrected for scatter, background, attenuation, and response of the system, and SPECT images corrected for attenuation and response of the system. The first, by Garkavij [44], observed ~10% difference in the dosimetric results for the kidneys when comparing planar images using two different background corrections, ~20% difference when comparing planar with SPECT images, and ~10% difference when comparing the hybrid method using SPECT combined to planar images with the 3D SPECT method. The second, by Sandström [67], obtained a difference within 14% for the kidneys when comparing SPECT vs. planar images, while a difference within 10% for kidneys up to 23% for the liver when comparing two different 3D methods to draw the volumes of interest.

Other comparisons were made by Larsson et al. who focused on different planar dosimetric methods for the kidneys and studied the influence of the number of time points and the use of standard organ sizes. The authors found a large interindividual variation – which increased in case of the lack of late acquisition on day 7 – and demonstrated the need of personalized dosimetry and treatment planning [47]. Guerriero et al. further increased the accuracy of the biokinetics of kidneys and tumors in both, ^{177}Lu- and ^{90}Y-peptide

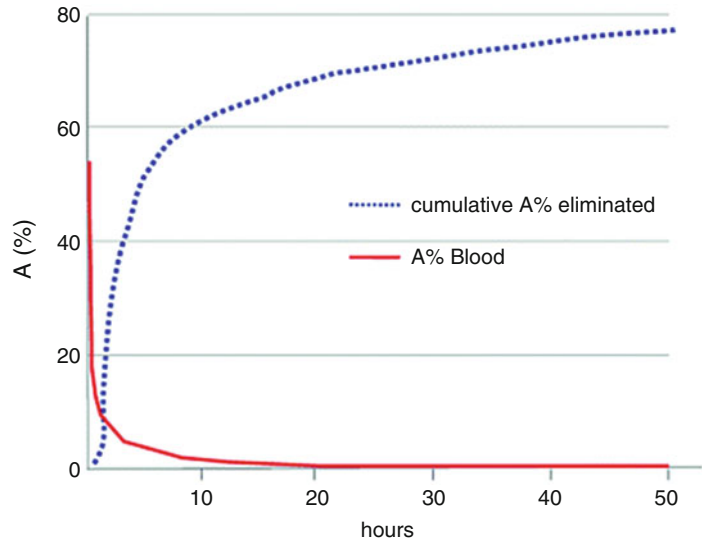

Fig. 3 Radiopeptides blood clearance (*red curve*) and urine excretion (*blue dotted curve*)

therapy. They investigated the most adequate timing for imaging and interpolation of the time–activity curve, the performance of a simplified dosimetry by means of only one to two scans, and the influence of renal risk factors and different peptides (DOTATOC vs. DOTATATE) [71]. The trapezoidal method followed by physical or biological decay after experimental data was compared with mono- and bi-exponential fits, skipping or not the 6 h and the 3-day time points. The authors found that data should be collected at least up to ~100 h for ^{177}Lu therapy and ~70 h for 90Y therapy in order to minimize dose uncertainties.

Another important issue for biokinetics is the possible variation among cycles. The study by Garkavij et al. compared dosimetry to the same patients in different cycles and showed that the first two of the four planned therapy cycles make the major contribution to the tumor-absorbed dose, possibly due to a saturation of the peptide receptors, while the different cycles contribute on average equally, within 10%, to the absorbed dose to the kidneys [44]. These findings apply in general and have been confirmed by other investigations [57], but there is a minority of cases in which the tumor is so avid of radiopeptides that it sequesters a very high percentage of the injected activity, leading to a so-called sink effect that decreases the activity concentration in healthy organs including the kidneys. In such cases, if the tumor is responsive during the course of therapy, the biokinetics in subsequent cycles may vary consistently, and dosimetry at a certain cycle is no more representative of the other cycles and not useful to estimate the cumulative doses to organs at risk and tumor [72].

In the attempt to improve accuracy of renal dosimetry estimates, the standard methods that assume uniform activity distribution in kidneys have been shifted to the multi-region MIRD model for a sub-organ kidney dosimetry and dose-rate effects [22, 55, 73, 74]. Some authors proposed the analysis of SPECT images to assign activity to the cortex or to the medulla for a patient-specific dosimetry [66]. In truth, the resolution of SPECT images is unable to provide a reliable activity distribution within the kidney substructures, being too low as compared to the 1–3 mm thickness of the cortex, for instance. More detailed information on intrarenal distribution has been derived instead from experimental results of renal autoradiograms [75].

The impact of the physical characteristics of the radionuclides with respect to inhomogeneous activity distribution (also within sub-organ regions) is a further issue concerning potential nephrotoxicity [69]. A threshold biologically effective dose (BED) of 33 Gy for kidney radiation damage and a BED50 (defined as the BED value derived from the TD50 value derived from the EBRT) of 44 Gy were found for ^{90}Y-PRRT [55]. Besides the most relevant impact on PRRT, these findings have shown the great potential of sharing information from different radiation release modalities. As a further support for the radiobiological model, clinical experience has shown that multiple-cycle protocols lower the nephrotoxicity, while patients with higher BED values and more serious side effects to the kidneys received the treatment in a few cycles [69, 76, 77]. This observation perfectly matches with the theoretical expectation from the BED concept: for a given cumulative dose, the higher the number of cycles, the lower the total BED, thus the lower the damage [69, 78]. Clinical results on ^{90}Y-PRRT have provided evidence of the safety up to a BED of about 40 Gy to the kidneys, cumulatively, and that risk factors (such as hypertension and diabetes) lower the tolerability to a BED of about 28 Gy [55, 76].

Treatment protocols based on multiple therapy cycles represent a useful modality to lower toxicity for a same cumulative activity, and/or improve the therapeutic outcome for a same fixed BED to the kidneys, owing to the different radiosensitivity of most tumors versus the kidney tissue. Cycles seemed especially effective in ^{90}Y-PRRT, where frequent occurrence of renal impairment has been clinically confirmed [69, 76, 79].

^{90}Y-peptides appear to be less nephrotoxic [43, 80, 81]. Possible reasons for these different outcomes are the different particle ranges in tissues and different peptide localizations. The short-range β-particles of ^{177}Lu-peptides, or the Auger electrons of ^{177}Lu-peptides, might irradiate the tubuli (radioresistant cells) more selectively while the long-range β-particles of ^{90}Y-peptides may increase the irradiation of the more radiosensitive

glomeruli, with consequent higher toxicity [69, 75, 78]. On the other hand, the advantage of cycling PRRT with ^{177}Lu is not as important with ^{90}Y. This is clear when considering that the contribution to the cumulative absorbed dose to the tumor after each therapy cycle gradually decreases [44] and that the absorbed dose to the kidneys with ^{177}Lu-PRRT is much lower at the activities usually administered in clinical trials, leading to a lower risk of nephrotoxicity. Overall, the use of too many cycles is not recommendable for ^{177}Lu-PRRT, while four cycles or possibly less seem to offer a better chance to avoid repair of sublethal cell damage and repopulation without dramatically alter the renal risks.

Despite long-term data analysis of ^{90}Y-trials and ^{177}Lu-trials, the intrinsic toxicity of the two radiopeptides is still to uncertain [64, 77, 82, 83]. Because the ^{177}Lu-based and the ^{90}Y-based clinical protocols use fixed total activities (e.g., ^{177}Lu, four cycles of 7.4 GBq; ^{90}Y, three cycles of 3.7 GBq) that lead to lower kidney absorbed dose and BED values for ^{177}Lu-schemes as compared with ^{90}Y. A reliable comparison of ^{177}Lu- vs. ^{90}Y-peptide therapy would require randomized trials conceived to release the same absorbed dose or BED using different radiopeptides. The choice of the most suitable radiopharmaceutical can be made based on individual differences in tumor mass and location, adjacent tissues, and targeting compound affinity. In principle, the physical characteristics of ^{177}Lu, with lower tissue penetration, make it more suitable for small tumors and micrometastases, while the cross-fire effect ^{90}Y might have the advantage of a higher radiation burden to larger lesions [64]. This hypothesis has been supported by preclinical findings and is the basis for new clinical rationales proposing cocktails of ^{177}Lu- and ^{90}Y-radiopeptides. New interesting approaches propose tandem treatments with ^{90}Y- and ^{177}Lu-peptides, with equal or different administered activities of the two radiopharmaceuticals [84, 85].

For tumor response, a first remarkable correlation has been observed between tumor-absorbed dose and tumor reduction with ^{90}Y-DOTATOC [65]. Responding tumors could be identified as those receiving much higher doses compared to nonresponding (up to sixfold, ~230 vs. ~40 Gy). Moreover, when correlating tumor-absorbed dose versus lesion mass reduction, a trend versus a dose–effect relationship was found, although not statistically significant, with a correlation coefficient of 0.5.

Excellent correlations were obtained between absorbed doses and tumor volume reduction after ^{177}Lu therapy, with a correlation coefficient of 0.6 for tumors bigger than 2.2 cm and a correlation coefficient of 0.9 in tumors bigger than 4 cm. These results were obtained by the improvement of dosimetry methods, namely, by correcting for the partial volume of the lesions identified in SPECT images [57].

Many parameters may influence the response of tumors – such as tumor dimension, vascularization, radiosensitivity, and activity distribution. Larger series of data with specific radiobiological parameters for different tumor characteristics are to be collected and will certainly improve outcome prediction.

Studies have measured circulating NET tumor transcripts (NETest), based on several marker genes to monitor tumor gene activity levels. The results confirmed that this test provides assessment of disease status and treatment effectiveness with significantly higher accuracy and earlier time points as compared with other biomarkers (such as cromogranine A) and morphological/functional imaging [86, 87]. It is quite clear that interdisciplinarity including dosimetry and genetic profile will play a crucial role in radionuclide therapies, allowing identification of patients that are not likely to be responsive and/or patients with a low risk of adverse sequelae, guiding trials, and tailoring therapies.

Radioimmunotherapy of Lymphoma

Radioimmunotherapy (RIT) offers an important option for the treatment of follicular low-grade non-Hodgkin's lymphoma (NHL) refractory or relapsed after treatment with the current best practice [88]. Two radiolabeled antibodies are

commercially available for treatment, tositumomab and ibritumomab, that are the radiolabeled immunoglobulin components of Bexxar and Zevalin, respectively [88, 89].

Bexxar is the ^{131}I-labeled anti-CD20 antibody tositumomab, while Zevalin is the ^{90}Y-labeled anti-CD20 antibody ibritumomab. Although both tositumomab and ibritumomab recognize a partially overlapping epitope on antigen CD20 (one of many epitopes expressed on the mature B cell), they have slightly different binding characteristics [88].

For both radiopharmaceuticals, an unlabeled antibody is infused before administration of the radiolabeled murine anti-CD20 antibody component. In the Bexxar regimen, both the labeled and unlabeled antibody are tositumomab. In the Zevalin regimen, the unlabeled antibody is rituximab (the chimeric antibody used as an immunotherapeutic and marketed as Rituxan), while the labeled antibody is ibritumomab [88, 89].

In Europe only Zevalin is commercially available, while in the USA and Canada, both Zevalin and Bexxar have been approved for clinical use [88].

No direct comparison in a randomized blinded trial has been performed to assess whether the difference in physical characteristics of the two radionuclides, ^{131}I and ^{90}Y, have different therapeutic effects or toxicity.

In principle, the greater energy of the β emitted by ^{90}Y is thought to be advantageous in the therapy of larger tumor masses, whereas the lower energy of the ^{131}I-particle emission is thought to be an advantage for treating patients with small tumor foci and marrow involvement. In the non-myeloablative setting, the use of either agent is contraindicated for patients with lymphomatous infiltration exceeding 25% of the bone marrow [90].

For Bexxar and Zevalin, different protocols and dose determinations have been reported, also due to the different approval requirements by regulatory agencies in the USA and Europe. However, for both radiopharmaceuticals, the red bone marrow is the dose-limiting organ due to its intrinsic radiosensitivity, to the rapid equilibration of the radiolabeled antibodies within its extracellular fluid volume, and to the long retention kinetics in the bone marrow [88].

When using Bexxar, dosimetry is estimated to determine the whole-body radiation-absorbed dose, since hematological toxicity and the dose–clinical response relationship depend on the whole-body radiation-absorbed dose rather than on a MBq/kg dosing schedule [91].

The optimal clinical benefit with acceptable hematological toxicity has been observed at 65–75-cGy whole-body radiation-absorbed dose, considering 65 cGy for patients with platelet counts between 100,000 and 150,000 and 75 cGy for patients with platelet counts greater than 150,000 [88].

The whole-body radiation-absorbed dose is determined from three WBS acquisitions after the administration of 185 MBq of ^{131}I-tositumomab (with prior infusion of 450 mg of unlabeled tositumomab), administered for determining the residence time which is necessary for dosimetric estimates.

The purpose of the scan is simply to evaluate the whole-body total counts rather than to produce a diagnostic image, because the parameters involved in visualizing a tumor (dose administered, tumor size, and location) are different from those involved in radiobiological response evaluations [88].

Whole-body counts are determined from the total counts on the anterior and posterior WBS acquired 1 h postinjection (day 0), then 2 days (day 2) and 5 days (day 5) later, to determine the radiopharmaceutical residence time (τ) and cumulated activity ($\tilde{A}$) in the body.

To calculate the desired therapeutic activity, the following equation can be used:

$$\text{Theraputic dose} = \frac{\vec{A}}{\tau}\frac{\text{Desired TBD(cGy)}}{75\text{cGY}}$$

The calculation simply divides a cumulated activity, $\tilde{A}$ (tabulated for several patient's weight), that would result in the patient receiving a 75-cGy whole-body radiation-absorbed dose, by the patient-specific residence time, τ. This would result in the activity associated to a 75-cGy whole-body absorbed dose that could be also rescaled by an

absorbed dose ratio if a value of total-body absorbed (TBD) dose different from 75 cGy is desired.

Seven to 9 days after the initial "dosimetric" study, the infusion sequence (unlabeled tositumomab followed by ^{131}I-tositumomab) is repeated with the ^{131}I-tositumomab therapeutic activity (1.85–5.5 GBq) that had been determined by dosimetry (Table 4).

In the USA and EU countries, biodistribution studies are not required because of the lack of correlation between red marrow dose and toxicity and considering that red marrow toxicity is reversible. This choice (which seems to be dictated mainly by practical/economical reasons) is arguable, as cases in which only the scintigraphic images were able to predict toxicity of the treatment are not so rare [92]. However, when using larger activities in clinical trials involving myeloablative doses with stem cell transplantation, personalized dosimetry estimates are required to avoid unpredictable toxicity. In fact, with bone marrow rescue, it is not possible to identify a priori a "safe" maximal activity or a unique critical organ for all patients, because of the wide intra-patient variability in doses to the vital organs.

At present, neither ^{90}Y-ibritumomab tiuxetan dosimetry outcomes in favor of its predictivity have been found nor correlation between red marrow dose and hematological toxicity has been demonstrated [91, 93–96]. This consideration has discouraged the practice of red marrow dosimetry for Zevalin. In this regard, toxicity in these patients is most likely linked to involvement of bone marrow by the disease and to reduced bone marrow reserve due to previous aggressive chemotherapy regimens [97].

Table 4 Organ radiation absorbed doses (mGy/MBq) for ^{90}Y-ibritumomab tiuxetan (Zevalin®), based on pre-therapeutic ^{111}In imaging

Organ	Number of patients	Median and range (mGy/MBq)
Spleen	166	7.35 (0.37–29.7)
Liver	179	4.32 (0.85–17.5)
Lungs	179	2.05 (0.59–4.86)
Red marrow (blood derived)	179	0.59 (0.09–1.84)
Red marrow (sacrum derived)	179	0.97
Kidneys	179	0.22 (0–0.95)
Bone surfaces	179	0.53 (0.09–1.31)
Urinary bladder wall	179	0.89 (0.38–2.32)
Other organs	179	0.41 (0.06–0.62)
Total body	179	0.54 (0.27–0.78)

The therapeutic activity of Zevalin for the non-myeloablative therapy of rituximab-refractory or relapsed patients with low-grade follicular non-Hodgkin's lymphoma is prescribed proportionally to the patient's weight, with recommended administered activity of 15 MBq/kg up to a maximum limit of 1,200 MBq [94]. Patients with platelet counts between 100,000 and 150,000 should receive 11 MBq/kg [94]. Much higher activities, ranging from 29 to 55 MBq/kg, have been used under myeloablative regimens, followed by autologous stem cell transplantation (ASCT) [98].

Radioembolization of Liver Tumors

Trans-arterial radioembolization (TARE) is a loco-regional treatment developed in order to release high radiation doses to malignant hepatic lesions by intra-arterial administration of a radiation vehicle. The rationale is the same as for trans-arterial chemoembolization (TACE): liver tumors are mainly fed by arterial blood, while normal tissue by portal blood. TARE consists of the intra-arterial administration of a radioactive agent. This is permanently trapped in the microcapillaries where it delivers its radiation until complete physical decay. In the last decade, significant response rates have been achieved with this approach in patients with unresectable primary hepatocarcinoma (HCC) [99] or secondary hepatic malignancies [100].

Several techniques have been tested in research trials, including the administration of radiolabeled molecules (such as ^{90}Y-,^{131}I-,^{188}Re-,^{166}Ho-Lipiodol) or of microspheres loaded with radionuclides (e.g., ^{90}Y, ^{166}Ho), differing in size, material, and specific radioactivity. However, the impressive increase in the number of treated patients in the last decade follows the registration of only two medical devices, i.e., microspheres loaded with ^{90}Y: (1) SIR-Spheres made in plastic resin (Sirtex Medical, Lane Cove, Australia) and (2) TheraSphere made in

glass (MDS Nordion, Ottawa, Canada). The main difference between the two products is the number of administered particles, which is ten times higher for resin particles. This implies a truly embolic behavior, never observed in glass microspheres. The second difference is the approved indication in the USA versus Europe. The FDA approved the use of resin spheres in patients with colorectal carcinoma metastatic to the liver, while glass spheres in HCC patients with or without portal vein thrombosis. In Europe and in various countries worldwide, both agents have regulatory approval for liver neoplasms in general.

The amount of activity to be administered should generally be established taking into account the clinical and dosimetric factors which affect the outcome: basal liver function (Child-Pugh score, presence of portal vein thrombosis, previous or concomitant treatment), tumor burden, targeted organ fraction, predicted absorbed dose to normal tissue, and absorbed dose to lesions. Actually in Europe, the Council Directive 2013/59 in Article 56 prescribes that any radiation treatment be optimized using dosimetry. In practice, the choice of the injected activity has been based on empirical approaches or on rough dosimetric evaluations, as summarized hereinafter.

For both devices, therapy is generally simulated by intra-arterially administered ^{99m}Tc-albumin macroaggregates (^{99m}Tc-MAA), in order to evaluate possible shunting to the lungs (lung shunt fraction, LSF), which limits the administrable activity, or avoid gastrointestinal (GI) shunt, which is an absolute contraindication to treatment. A planar trunk scintigram and a liver SPECT scan are usually accomplished. A major advantage deriving from the permanent trapping is that, differently from all other radiopharmaceuticals, images can be quantitatively analyzed to perform dosimetric evaluation though taken at only one time point. The adequacy of ^{99m}Tc-MAA for simulation is under discussion. Although similar distribution patterns of ^{99m}Tc-MAA and bremsstrahlung ^{90}Y-microsphere images have been generally reported, some dissimilarities have also been observed, possibly due to the different size and number of MAA versus microspheres or to occasional alterations of the original vascular anatomy produced by angiography [101]. Nevertheless, the acquisition of pre-therapeutic images represents a suitable source of clinical and dosimetric information for risk/benefit evaluation, through a treatment planning session similar to that ordinarily performed in external beam radiotherapy. Post-therapy images can be obtained either as bremsstrahlung SPECT or as ^{90}Y-PET. The latter are by far more accurate from the quantitative point of view. Post-therapy imaging has almost the same level of importance as the ^{99m}Tc-MAA scan, since it demonstrates the real therapeutic biodistribution.

Patient-specific dosimetry requires a detailed slice-by-slice volume of interest (VOI) drawing around tumor (T) and non-tumor tissue (NT). Using the mean dose approach, values of the absorbed doses per unit activity can easily be derived from two simple equations. The first is the way to convert counts in the image in 90Y activity:

$$A_{\mathrm{VOI}}\left({}^{90}Y\right) : A_{\mathrm{total}({}^{90}Y)} = \mathrm{VOI}_{\mathrm{counts}} : \mathrm{total}_{\mathrm{counts}}$$

$$D[\mathrm{Gy}] = 50 \cdot \frac{A_{\mathrm{VOI}}[{}^{90}Y]}{M_{\mathrm{VOI}}[\mathrm{kg}]}$$

A more sophisticated evaluation can be made by the voxel dosimetry approach or by Monte Carlo modeling that provides information on dose distribution and expected radiobiologic effects at the voxel level [102].

Producers indicate different approaches to choose the amount of activity to be injected for the two radiopharmaceuticals [101]. Three main methods are suggested [101] for resin spheres: the empirical method, the body surface area (BSA)-based method, and the partition method.

The empirical method does not personalize the treatment for different liver dimensions or tumor avidity, but it takes into account the tumor involvement and attempts to lower the radiation risks to the lungs and the NT tissues. With this, method activities range from 1.2 to 3.0 GBq, and the doses received by the lungs and by the NT are within 18 and 83 Gy, at most. According to Kennedy et al. [100]. "The Radio Induced Liver Disease (RILD) was diagnosed in 28 of 680 treatments (4%), with 21 of 28 cases (75%) from one center, which used the empiric method."

The BSA method, probably the most widely employed for resin microspheres, has been proposed since in normal patients, liver mass correlates with BSA. The basic equation, empirical, includes the patient body surface area: $[\mathrm{BSA}(\mathrm{m}^2) = 0.20247 \times \mathrm{H}0.725 \times \mathrm{W}\ 0.425, \text{with}\ \mathrm{H} = \text{height}(\mathrm{m})\ \text{and}\ \mathrm{W} = \text{weight}(\mathrm{kg})]$ and provides a maximum activity supposed to be safe for NT and lungs, once applying the same restrictions for lung shunt as above:

$$A = (\mathrm{BSA} - 0.2) + \frac{M_\mathrm{T}}{M_\mathrm{T} + M_\mathrm{L}}$$

where A = activity (GBq), M_T = tumor mass, and M_L (g) = total liver mass. In general, the activities calculated by the BSA method are more conservative than those derived from the empiric method, never exceeding 2.5 GBq. Although including some individual parameters, the reliability of this method in terms of tailored evaluation should not be overemphasized. In fact, direct measurements in patients have provided evidence that the BSA-based estimates do not correlate with liver mass nor with tumor involvement. Comparison between the BSA-based and the dosimetry methods showed discrepancies in activities to be administered ranging from −30% to 35% [103].

In the partition method [104], the activity to be administered is calculated within the MIRD equations, once a limit dose is prescribed for NT; lung safety is also considered. Liver involvement, tumor avidity as compared to the NTL, and the possible occurrence of lung shunt are taken into account by the following equation:

$$A = D_\mathrm{nL} = \frac{A_\mathrm{T} \times M_\mathrm{nL} + A_\mathrm{L} \times M_\mathrm{nL}}{49,670 \times A_L(1 - \mathrm{LSF})}$$

where A = activity, D_nL(Gy) = absorbed dose (Gy) limit for NTL, A = tumor activity (GBq), A = liver activity (GBq), M (g) = NTL mass, and LSF = lung counts/(lung + liver counts).

Although this model was originally designed for single or discrete nodules, appropriate modification by a weighted T/NT ratio makes it easily applicable also to multiple lesions [105]. The review paper by Cremonesi et al. [101] provides the absorbed dose limits applied by several authors, including the most common recommendations [106] and more conservative approaches [105].

The model proposed for RE with glass spheres relies on a simplified dosimetry equation, in which the dose averaged on the injected liver (D_L) is prescribed:

$$A = D_\mathrm{L} \times \frac{V_\mathrm{L} \times 1.03}{50(1 - \mathrm{LSF})}$$

where A = activity, D_L(Gy) = prescribed liver dose, V_L = total liver volume, and LSF = lung shunt fraction.

Absorbed doses to tumor and NT are not separately calculated, so no distinction is made for different tumor involvement or uptake ratios. Several studies [106] have indicated prescribed radiation doses (DL) of at least 100 Gy for a maximal effect on tumors, based on the fact that no dose-limiting organ toxicity has been observed in patients who had received nominal absorbed doses of up to 150 Gy. Mean cumulative doses to the treated liver as high as 200 Gy or even 390 Gy have been described as tolerated in patients affected by HCC with Okuda stage II and stage I who received multiple treatments [107]. Overall, these doses are apparently quite far from the limits recommended in the ^{90}Y-resin approaches and much farther than the tolerance doses set by external beam radiotherapy (30–35 Gy) to avoid excessive risk of radiation hepatitis [105]. This is explained with the nonuniformity of absorbed dose deposition at the microscopic level, which is markedly higher for the less numerous glass microspheres [108]. Another basic point is the usually different administration technique. From the US experience following the split registration, glass spheres against HCC have been injected lobarly, while resin spheres against metastases were administered in the common hepatic artery. These are two completely different situations, since the lobar approach exploits the organ reserve and the regeneration capability of the liver [109].

The possibility of performing a real treatment planning in radioembolization is emphasized by the result of three studies, which applied radiobiological models to analyze response and toxicity after standard administration of microspheres.

Strigari et al. [110] derived the normal tissue complication probability (NTCP) and tumor control probability (TCP) for HCC treated with resin spheres using post-therapy bremsstrahlung SPECT. TCP (50%) was at 150 Gy, while a dose above 200 Gy demonstrated response in all cases. Liver toxicity higher than G2 had a NTCP (50%) value of 52 Gy. Flamen et al. [111] found a good ^{99m}Tc-MAA dose - [^{18}F]FDG response correlation in colorectal metastases treated with resin spheres. Chiesa et al. [112] determined retrospectively with ^{99m}Tc-MAA SPECT the NTCP curve for Child A patients treated lobarly with glass microspheres, with a risk of radioinduced liver decompensation at 70 Gy if averaged over the whole non-tumoral parenchyma, including the non-injected lobe. This mean inclusive on the non-treated tissue is the simplest way to include the well-known liver volume effect (the smaller the irradiated fraction, the higher the tolerance). TCP was dramatically dependent upon the lesion size, being TCP (50%) = 250 Gy for masses less than 10 g and around 1,300 Gy for larger tumors. Garin et al. [113] were able to demonstrate a correlation between lesion absorbed dose and overall survival in HCC patient treated with glass spheres, with a cutoff of 205 Gy. Compared to Chiesa et al.'s results, this means that glass spheres require at least 205 Gy to stabilize the disease, while objective response requires higher dose. Individualized dosimetry-based administrations with increase of administered activity with respect to the producer indication were also safe and successful [114]. The unexplored way toward treatment planning in radionuclide treatment is open, thanks to dosimetry in radioembolization, which is the less demanding and that with higher impact among all kinds of radiopharmaceutical type of dosimetry. As a confirmation, for the first time in the history of nuclear medicine therapy, both ^{90}Y-microsphere producers made investment in multicenter research about dosimetry [62].

Therapy of Neuroendocrine Malignancy

In the late 1980s, ^{131}I-meta-iodobenzylguanidine (^{131}I-MIBG) started to be used as a radiotherapeutic metabolic agent in neuroectodermal tumors, i.e., those tumors derived from the primitive neural crest (which develops to form the sympathetic nervous system). Malignant neuroectodermal tumors include pheochromocytoma, paraganglioma, carcinoid tumors, medullary thyroid cancer, and neuroblastoma.

As an analog of noradrenaline, at low concentrations ^{131}I-MIBG is taken up into cells of neuroectodermal origin by the noradrenaline transporter (NAT). Once internalized, it is stored in intracellular storage granules. Transfer of MIBG from the cytoplasm into neurosecretory granules is mediated by an ATPase-dependent proton pump, and MIBG is not metabolized but excreted unchanged [115].

Treatment with ^{131}I-MIBG is indicated for tumors showing adequate uptake and retention of radiolabeled MIBG on the basis of a pre-therapy diagnostic scan, which is performed using ^{123}I-MIBG in children and either ^{123}I-MIBG or ^{131}I-MIBG in adults [116].

Most treatments regard neuroblastoma, the most common extracranial solid tumor affecting children (approximately 1 per 10,000 live births), most of the cases being diagnosed before the age of 4. Most of these malignancies originate in the nervous system, although about two-thirds of the cases arise in the abdomen near the adrenal glands. Distant metastases at diagnosis are frequent, and treatment of high-risk neuroblastoma includes surgery, chemotherapy, and ^{131}I-MIBG [117].

In high-stage neuroblastoma, treatment with ^{131}I-MIBG may be either palliative therapy, first-line therapy as a single agent or combined with chemotherapy, or consolidation therapy after induction of partial remission. More recently, this treatment has been used as second-line therapy after failed induction chemotherapy, combined with topotecan and stem cell rescue in children with metastatic neuroblastoma or with myeloablative chemotherapy and autologous stem cell transplantation in refractory neuroblastoma [118].

In addition to uptake in the tumor, ^{131}I-MIBG accumulates in the liver, heart, lungs, and adrenal glands, while the bladder is irradiated by the urine-excreted metabolites of ^{131}I-MIBG.

Thyroid uptake of free radioiodide is prevented using oral stable iodine. Since many drugs can interfere with MIBG uptake and storage, these drugs should be withdrawn for adequate periods before treatment, and patients should be stabilized on alternative medication.

High-specific activity (up to 1.48 GBq/mg) is recommended for therapy, and single-administered activities range between 3.7 and 11.2 GBq, according to tumor burden or local legislation. Since several cycles of therapy with ^{131}I-MIBG may be required to achieve objective response, these treatments are often repeated at widely different intervals, depending on blood count recovery; treatment is continued until the maximum clinical response is achieved.

Red bone marrow is the dose-limiting organ for ^{131}I-MIBG therapy, and activity reduction should be considered in patients with myelosuppression or with impaired renal function. In patients with neuroblastoma who had received prior intensive chemotherapy, the dose-limiting toxicity of ^{131}I-MIBG therapy is myelotoxicity at 2-Gy whole-body dose, according to the pre-therapeutic ^{131}I-MIBG scans. This threshold can be circumvented if bone marrow stem cell support is available. A total of 4.0-Gy whole-body dose with stem cell rescue has been given with good tolerance and no other short-term, dose-limiting organ toxicity [119].

The approach to administer fixed activity "fractions" of 3.7–11.1 GBq offers the advantages of simplicity and shorter isolation and hospitalization period required for radioprotection; this feature in non-negligible when treating very sick children with poor prognosis.

Administration of high activities of ^{131}I-MIBG based on body weight (555–777 MBq/kg), with stem cell support if necessary, has also been reported. A maximum tolerated activity of 444 MBq/kg is reported, combined with myeloablative chemotherapy and autologous stem cell transplantation [120].

However, when using fixed activities, no dose–response assessment or optimization on the basis of absorbed radiation dose is possible. Furthermore, the relatively LDR of radiation compared with (ultra)high doses may be viewed as radiobiologically suboptimal.

The results obtained over more than two decades demonstrate that whole-body absorbed doses correlate both with administered ^{131}I-MIBG activity and with the subsequent development of hematological toxicity [121, 122].

An administered activity of 444–666 MBq/kg of ^{131}I-MIBG may deliver 50–700 cGy of whole-body absorbed dose; 80% of patients with advanced chemorefractory stage III/IV neuroblastoma can develop grade 3 or 4 hematotoxicity at a whole-body absorbed dose of 2.5 Gy established from a pre-therapy ^{131}I-MIBG scan.

In relapsed or refractory neuroblastoma, the whole-body absorbed dose calculated according to the standard MIRD schema can be prescribed accurately and allows higher activities of ^{131}I-MIBG to be administered within the safety limits for bone marrow toxicity [123].

The mean absorbed dose, D, is given by the product of the cumulated activity and the MIRD whole-body-to-whole-body S value, that is [124]:

$$\bar{D}_{(\mathrm{WB}\leftarrow\mathrm{WB})} = \vec{A} \times S_{(\mathrm{WB}\leftarrow\mathrm{WB})}$$

Value $S_{(\mathrm{WB}\leftarrow\mathrm{WB})}$ is often obtained using the following equation (correction for body weight):

$$S_{(\mathrm{WB}\leftarrow\mathrm{WB})} = 1.34 \times 10^{-4} m_{\mathrm{p}}^{-0.921}$$

where m_{P} is the patient's mass in kilograms. This equation was generated by interpolating the S(WB ← WB)values from the MIRD phantoms for a newborn as well as for 1-year, 5-year, 10-year, and 15-year-old children, and finally for an adult, each of which has a specific mass. Table 5 reports the absorbed doses to the organs calculated for unit of ^{131}I-MIBG activity administered.

An experimental MIBG protocol has been proposed in which the aim was to deliver a total whole-body absorbed dose of 4.0 Gy in two fractions, in combination with topotecan, after failure of induction chemotherapy [125]. Post-therapy dosimetry is performed after a first fixed fraction

Table 5 Median and range organs absorbed doses values (Gy) for ^{131}I-MIBG, per unit of activity administered (MBq/kg)

	Fielding [74]	Matthay [79]	Gaze [81]	Koral [82]	DuBois [78]
^{131}I-MIBG activities (MBq/kg, range)		555 (93–770)	444	572 (431–683)	666 (599–770)
Organ	Absorbed doses (Gy, range)				
Whole body	1.9 (0.7–2.6)	2.28 (0.57–6.50)	2.19 (1.7–2.9)		2.92 (1.73–4.18)
Red marrow	2.0 (0.9–2.6)	2.20 (0.44–3.29)			3.47 (2.06–5.02)
Blood	0.8 (0.2–1.9)	1.77 (0.79–3.53)			
Liver	5.3 (1.6–11.3)			13.1 (7–19)	

of 444 MBq/kg, with calculation of the activity dose to be administered with the subsequent second fraction in order to achieve the desired total whole-body absorbed dose of 4 Gy [126].

Recent studies analyzed the whole-body radiation dose (WBD) and tumor-absorbed doses from ^{131}I-MIBG therapy in relation to tumor response and toxicities. Trieu et al. [127] retrospectively evaluated a cohort including 213 patients with high-risk neuroblastoma treated with ^{131}I-MIBG between 1996 and 2015 to correlate WBD from ^{131}I-MIBG with tumor response, toxicities, and other clinical factors. The WBD was calculated for every patient using radiation exposure rate measurements obtained by a ceiling-mounted ionization chamber or by a handheld ionization chamber. They found that WBD correlated with ^{131}I-MIBG activity, particularly with ^{131}I-MIBG administered per kilogram suggesting that activity prescriptions for ^{131}I-MIBG therapies should be made based on patient weight as opposed to a predetermined total activity dose in order to achieve a targeted WBD. A recent study by Minguez et al. proposed an equation, which describes whole-body absorbed dose per unit of administered activity as a function of patient mass, as an alternative for prescriptions of activity on first administration when dosimetry data for the individual patient are unknown [128]. However, Trieu et al. [127] found no relationship between WBD and overall response, and they were unable to establish any relationship between hematologic or thyroid toxicity and WBD. This unexpected finding prompts future studies to evaluate tumor dosimetry, rather than just WBD, as a tool for predicting response following therapy with ^{131}I-MIBG.

A study like this has been made by George et al. [129] who evaluated the response, toxicity, and long-term outcome of ^{131}I-MIBG therapy in the treatment of refractory or relapsed neuroblastoma following a dosimetry-based 3D individualized approach performed in 8 of the 25 patients.

To calculate tumor-absorbed doses, image data were obtained by 38 SPECT acquisitions performed on consecutive days following the treatment. Reconstructed SPECT scans for each patient were sequentially coregistered to allow 3D voxelized dosimetry to be performed using an in-house dosimetry software package (Qrius). The image-based 3D dosimetry application provided an absorbed dose map of consecutive therapies from which dose–volume histograms (DVH) were derived.

To date, there is no clearly defined methodology to incorporate DVHs in patient-specific planning or to compare DVHs for individual therapies or to relate to outcome. However, it is clear that dose heterogeneity could affect the outcome of subsequent therapies and may partially explain the variation in responses. In light of this, a 3D dosimetry approach where DVHs are taken together with tumor-absorbed dose as well as dose-limiting criteria provides a reasonable method to help plan patient-specific treatment and should be used as a guideline to inform subsequent therapies.

A dosimetry-based approach on the basis of patient pharmacokinetics may often result in the administration of higher activities with excellent response rates while keeping toxicity within acceptable limits. However, to date, there are currently no published randomized controlled trials of ^{131}I-MIBG therapy for neuroblastoma at any stage of treatment [21]. To maximize the therapeutic potential of ^{131}I-MIBG therapy and to determine its place within the patient pathway, well-designed clinical trials incorporating dosimetry are needed.

Future studies, including more accurate tumor dosimetry such as ^{124}I-MIBG with PET/CT technology, could improve the assessment of the relationship between WBD, tumor-absorbed doses, and overall response [130, 131]. Seo et al. [130] estimated expected radiation dose in tumors from ^{131}I-MIBG therapy using ^{124}I-MIBG micro-PET/CT imaging data in a murine xenograft model of neuroblastoma transduced to express high levels of the human norepinephrine transporter. The three-dimensional tool used for estimating the radiation dose that evaluated a range of activity of 52.8–206 MBq could deliver about 20 Gy to tumors.

Patient-specific dosimetry, using quantitative ^{124}I-MIBG PET/CT with a GEometry ANd Tracking 4 (Geant4)-based Monte Carlo method, was used by Huang et al. [131] in a 10-year-old girl with relapsed neuroblastoma. Organ-absorbed dose for the salivary glands was 98.0 Gy, heart wall 36.5 Gy, and liver 34.3 Gy, while tumor-absorbed dose ranged from 143.9 to 1,641.3 Gy in different sites.

Finally, the use of ^{124}I-MIBG PET/magnetic resonance imaging (MRI), performed with an integrated PET/MRI system, could be a promising technique in dosimetry as it improves tumor delineation because of the high soft tissue contrast in MRI. In a case reported by Hartung-Knemeyer et al. [132], PET/MRI allowed a more accurate volumetry in comparison to PET/CT, resulting in a reduction of the calculated lesion dose in abdominal muscle lesions up to 70%.

Treatment of Metastatic Bone Pain

Bone pain due to osseous metastases constitutes the most frequent type of pain among all cancer patients, with different prevalence among the various types of cancers. In general, oncological practice, breast and prostate cancers are responsible for more than 80% of the cases with bone metastases [133].

The pathophysiology is not well understood, and multiple mechanisms are postulated, including tumor-induced cytokines, stimulating factors released by tumor cells, direct nerve injury, and infiltration of the bone trabeculae and matrix by tumor cells causing osteolysis [134]. The appropriate management of painful skeletal metastasis includes the use of systemic analgesics, hormones, chemotherapeutic agents, steroids, external beam radiation therapy (EBRT), radiofrequency ablation, local surgery, and radiopharmaceuticals.

Curative options for multiple skeletal metastases unfortunately, do not exist, and most of the described treatments are palliative [133]. Systemic RNT has shown its value in the management of painful bone metastasis in clinical practice, although it remains an infrequently used treatment modality for many physicians, even those working in the fields of oncology and nuclear medicine [133, 135].

Phosphorus-32 (^{32}P-ortophosphate) and strontium-89 (^{89}Sr-chloride) were the first bone-seeking radiopharmaceuticals approved for the treatment of painful bone metastases [136], while bisphosphonates labeled with either ^{153}Sm [137], ^{186}Re [138], or ^{188}Re [139] are newer among the traditional bone-seeking radionuclides [140].

Although there are some differences in the physical half-life, beta energy, penetration range, and biochemical characteristics among the various bone-seeking radiopharmaceuticals, no clear advantage in terms of increased response rate has emerged. A uniform response rate of approximately 70% has been reported with all bone-seeking radiopharmaceuticals, and the response appears to be inversely proportional to disease extent and Karnofsky index [133, 135].

Several detailed dosimetric studies have been reported for bone-seeking radioisotopes. All the radiopharmaceuticals have shown an approximate tenfold therapeutic ratio between the metastasis and bone, although there is an order of magnitude difference in absorbed dose calculations (5–50 Gy) between individual metastases [133, 135, 140].

Table 6 Radiation dosimetry of radiopharmaceuticals used for treatment of refractory metastatic bone pain

Organ	^{89}Sr-chloride (mGy/MBq)	^{153}Sm-EDTMP (mGy/MBq)	^{186}Re-HEDP (mGy/MBq)
Bone surface	17.0	6.8	1.4
Bone marrow	11.0	1.5	1.3
Lower bowel wall	4.7	0.01	0.57
Bladder wall	1.3	1.0	0.54
Testes	0.8	0.005	0.008
Ovaries	0.8	0.009	0.019
Kidneys	0.8	0.02	1.5

From Bodei et al. [141], with permission

Radiation dosimetries for ^{89}Sr-chloride, ^{153}Sm-lexidronam (^{153}Sm-EDTMP), and ^{186}Re-etidronate (^{186}Re-HEDP) are reported in Table 6 [141].

Hematological toxicity is the dose-limiting factor, usually presenting as thrombocytopenia. Although there is a clear relationship between metastatic burden and toxicity, the correlation between thrombocytopenia and absorbed dose calculations is difficult to be noticed [133] even though there have been some exceptions [142].

The bone-seeking agent of choice has not yet been determined. Since all the commonly used radiopharmaceuticals have similar efficacy profiles, the agent should be selected in a case-based fashion taking into consideration the availability, toxicity, and goal of therapy.

It is intriguing that all studies that have searched for a dose–response relationship have failed to show a correlation between absorbed dose to metastasis and clinical response. Some of these calculations have shown clinical responses at absorbed doses for which classical radiobiological paradigms would predict no likelihood of response. Furthermore, no correlations have been found with primary endpoints, such as overall survival.

Recently, many clinical trials have shown the safety and efficacy of the ^{223}Ra-dichloride for patients affected by metastatic castration-resistant (hormone-refractory) prostate cancer (CRPC), leading to approve the ^{223}Ra-based drug (Xofigo©) for the treatment of adults with CRPC, symptomatic bone metastases, and no known visceral metastases. For the first time, therapy with a bone-seeking agent showed a life expectancy longer than that of patients in the placebo group, delaying the start of bone fractures and pain [143]. ^{223}Ra is a calcium mimetic (half-life 11.4 days) alpha emitter. The high linear energy transfer (LET) of alpha radiation gives rise to a greater biological effectiveness than beta radiation and to cytotoxicity that is independent of dose rate, cell cycle growth phase, and oxygen concentration [144]. The range of alpha particles (<100 μm) is much shorter than that of beta radiation, causing less hematological toxicity for a given absorbed dose to the bone surface than beta emitters [145]. Actually, several trials are ongoing for dose escalation and combination therapy (e.g., with hormone therapy). ^{223}Ra emits also a small number of photons useful for imaging, so in vivo image-based dosimetry is feasible (even though challenging), allowing investigations on a macrodosimetric scale [146–148], as well as the traditional microdosimetric approach to study the mechanisms of action of the alpha radiation [144].

Biological Dosimetry

Study of the biological effect induced by ionizing radiation on living organisms has systematically relied on the analysis of cytogenetic indicators, requiring the definition of several theoretical approaches to be interpreted [149]. Biological dosimetry, based on the investigation of biophysical and biological endpoints to estimate absorbed dose, is usually employed in cases of actual or suspected radiation overexposure. Although several biological samples can be considered representative of individual exposure, dose assessment is usually performed on peripheral lymphocytes. This cell population represents a suitable biological model to investigate radiation-induced effects, since it circulates in the body and remains quiescent in the G0 stage of the cell cycle for a relatively long time.

Chromosomal aberrations induced by ionizing radiation can be classified as stable or unstable

abnormalities. Stable anomalies, being consistent with cell survival, can persist for many years and involve reciprocal, nonreciprocal, and interstitial translocations. Unstable anomalies, inducing mitotic cell death, decrease with time and include dicentrics, centric rings, and acentric aberrations. Chromosomal aberrations scored in lymphocytes represent a suitable long-term biomarker of whole-body exposure and provide a fairly accurate index of bone marrow dose [149]. The estimate of individual exposure is obtained comparing the dose–effect relationships of aberrations measured by scoring with the dose–response relationships observed in in vitro models.

Biological dosimetry may be particularly useful in the assessment of individual response to radiation, providing an important contribution to the development of personalized therapy planning and radiation protection, as well as to establish radiation-induced risk and drugs effects, meant to decrease the radiation-induced side effects.

Although the efficacy of biological dosimetry is established in many cases, the method has some limitations. Accurate dose assessment in case of RNT can be very complex, because of the inhomogeneities in body irradiation and the LDR of irradiation. Correction for inhomogeneous irradiations can be performed, employing contaminated Poisson distribution method. The distribution of observed aberrations among cells is compared with that expected from a normal Poisson distribution. Nevertheless, a large number of aberrations, not always achievable, are required [150]. In case of LDR of exposure, the comparison with in vitro exposure can be hazardous. Indeed, repair can occur during exposure, reducing the quadratic component with dose rate decreasing as exposure is spread over a longer period of time [150]. No valid solution for this problem has yet been developed.

Furthermore, biological dosimetry assessment is complex when long retrospective dosimetry is needed, because of disappearance of lymphocytes carrying unstable aberrations [150]. Several years after exposure, scoring of stable aberrations might appear more appropriate, although involving more laborious and expensive techniques (G-banding, FISH). The sensitivity of biological dosimetry is reduced when doses are very low (e.g., below 0.1–0.2 Gy), because of the relevant contribution from environmental factors (light, chemicals, oxidative species originated by metabolism, smoking, and aging) to DNA damage. Moreover, individual variability in repair of radiation damage can affect dosimetry outcome. Finally, the biological effects on circulating lymphocytes due to exposure of low radiation doses are sparse and difficult to measure, so cumulative radiation exposure can be slightly underestimated.

Assays in Biological Dosimetry

Dicentrics

One of the most commonly used biology dosimetry assay is the count of dicentric chromosomes, selected as suitable biomarkers because of their rare spontaneous occurrence and their specificity for ionizing radiation [149].

Despite the high specificity observed for acute exposure radiation damage, the method appears cumbersome and unsuitable for dose assessment with prolonged delayed blood sampling. Even if lymphocytes with aberrations continue to circulate in peripheral blood for many years after irradiation, a delay longer than 6 weeks between irradiation and sampling can cause reduction in aberration yield, with a consequent dose underestimation.

Chronic exposures may not be easily determined by dicentric aberration scoring. It would be reasonable to postulate that repair must play a significant role in the effects of LDR. A study by M'Kacher et al. [151] described the use of biological dosimetry in patients receiving repeated treatments with 131I-iodide for differentiated thyroid cancer (DTC), resulting in cumulative doses from 1.0 to 3.5 Gy. A reliable retrospective dosimetry based on chromosomal aberration analysis (number of dicentric and chromosome 4 painting) was achieved only for samples collected following the first two treatment cycles but not from the third treatment and onward. At this stage, estimated doses were considerably lower than those delivered, suggesting that apoptosis occurring in lymphocytes with multiple chromosomal anomalies could affect the dosimetry outcome following repeated irradiations [151].

Micronuclei

Micronuclei (MN) can be the result of small acentric chromosome fragments that are not incorporated into the daughter nuclei during cell division. They are enveloped by a nuclear membrane and appear as small nuclei – micronuclei – in the cytoplasm outside the main daughter nuclei. They arise during exposure to various clastogenic agents and are the result of non- or misrepaired DNA double-strand breaks. Because of its high reliability and reproducibility, the MN assay has become one of the standard cytogenetic techniques for genetic toxicology testing in human and for mammalian cells in general [149].

The baseline, spontaneous frequency of MN is quite variable and can be affected by factors related to diet, age, and gender. Such variability clearly poses limitations on using MN as a biological dosimeter, particularly for low doses where pre-existing individual background frequencies are not known.

The MN assay in peripheral blood lymphocytes is an appropriate biological dosimetry tool to evaluate in vivo radiation exposure and to assess in vitro radiosensitivity and radiation risk. Many studies showed that the number of radiation-induced MN is strongly correlated with radiation dose and radiation quality, but sensitivity of the assay is limited to 0.2 Gy. This is due to the relatively high and variable spontaneous MN yield that is an inherent limitation of the assay for low-dose estimation. The spontaneous MN yield increases systematically with age, and MN disappearance is very similar to that observed for dicentrics. This result is in agreement with the decline in the MN frequency following irradiation (around 60%, 1-year post-treatment), observed in patients undergoing radiotherapy.

In a study by Monsieurs et al. [152], the MN assay was used to estimate the radiation-associated risk in patients receiving ^{131}I-iodide treatment for hyperthyroidism and thyroid remnant ablation after surgery for thyroid carcinoma. Surprisingly, the number of micronuclei induced by the different procedures, although the activity of ^{131}I-iodide was much higher in the thyroid cancer group, was similar. When this was compared to MN induction by EBRT in patients with cervical carcinoma or with Hodgkin's lymphoma, it was seen that EBRT was associated with a much higher degree of radiation toxicity. The author concluded that this might have been a suitable explanation of the different rates of induction of secondary cancer observed in the two therapeutic approaches.

A recent study employed the MN assay to evaluate the radioprotective effect of ginkgo biloba extract (GBE). It was demonstrated that the use of GME significantly reduced the number of MN after ^{131}I-iodide ablation therapy in thyroid cancer patients [153].

Chromosome Painting

Fluorescence in situ hybridization (FISH) allows a rapid and accurate characterization of chromosome or chromatid region by using specific DNA sequences labeled with fluorescent molecular probes. FISH painting is a single rapid method, allowing simultaneous evaluation of many types of aberration (dicentrics and single or complex translocations) [149]. Accuracy in translocation detection can be improved by using multiple color painting. Although dicentrics are less stable than translocations, they have background frequencies that are lower in unexposed people. This makes it easier to detect the effects of lower exposure doses, provided that exposure was recent and acute. In contrast, the relative stability of translocations makes them more suitable for analysis of chronic or temporally displaced exposures. Although translocation frequencies were initially thought by some investigators to be fully persistent, many studies have observed their decline with time following exposure, in some cases reaching a dose-related plateau [153].

Comet Assay

The comet assay (single-cell gel electrophoresis) is a fast, sensitive, and not expensive technique to measure DNA damage in a single cell [154]. At variance with the cytogenic assays previously described, the comet assay can be performed in any phase of the cell cycle, cells do not need to be

cultured, and sterile conditions are not required. It can be applied to all cell types, only a few hundreds are needed, and by this technique it is possible to measure single- or double-strand DNA breaks and the apoptotic index.

In the comet assay, cells are mixed with agarose and layered on microscope slides, where they are lysed and subjected to electrophoresis; staining with fluorescent dyes such as DAPI or ethidium bromide permits microscopic visualization of the "comets." DNA containing breaks unwinds and migrates away from the "head" (the nucleus), forming a "tail"; quantification of the amount of DNA in tails and in heads of comets provides an estimate of the frequency of strand breaks. Chromosomal aberrations measured by comet assay do not last long, since they can either be repaired or lead to cell death [155].

Gutierrez et al. [156] used the comet assay to measure the radiation damage in patients treated with ^{131}I-iodide for hyperthyroidism, reporting only a slight increase in DNA breaks 1 month after treatment. These results, however, were less clear to interpret compared to the MN assay, owing to the high sensitivity of the test, but the poor specificity that may affect the results especially in longitudinal studies.

γ-H2AX

The nucleosomal core histone variant γ-H2AX forms part of the cellular DNA damage response. Exposure to ionizing radiation triggers the large-scale activation of specific DNA damage signaling and repair mechanisms. This includes the phosphorylation of H2AX in the vicinity of a DSB. Foci of phospho-H2AX (γ-H2AX) form over large chromatin domains surrounding DSBs. The formation and loss of γ-H2AX foci have been measured following exposure to radiation doses as low as 1 mGy, and foci yields have been shown to increase linearly with dose [157]. Moreover, the initial number of γ-H2AX foci formed per cell nucleus following ionizing irradiation agrees with the yield of induced DSBs. Foci disappearance over time follows DSB rejoining in repair-competent cells; there is a close one-to-one relationship between initial and residual radiation-induced DSBs and γ-H2AX foci. These include rapid and potentially automatable processing and analysis, sensitivity to doses of a few milligrays, linear dose response across a broad dose range, ability to use unstimulated lymphocytes obtained by minimally invasive procedures, and potential to reveal partial body exposures. A recent article described the use of γ-H2AX in thyroid cancer patients undergoing thyroid remnant ablation therapy. The technique was used to assess double-strand breaks starting 0.5–120 h after treatment, and it was possible to demonstrate the early start of DNA damage by a linear dose-dependent increase and a bi-exponential response function describing a fast and a slow repair component [158].

However, severe limitations associated mainly with the rapid loss of the γ-H2AX signal following irradiation have to be considered. They are likely to restrict the use of the γ-H2AX to very recent radiation exposures – less than 2 days before blood sampling. Since the yield of γ-H2AX per unit dose changes rapidly over time, dose–effect curves for calibration of the assay are required for multiple time points.

Conclusions

Although dosimetry has been of great value in the preclinical phase of radiopharmaceutical development, its clinical use to optimize administered activity on an individual patient basis has been less evident. Similarly, little attention has been paid to radiobiology in therapeutic nuclear medicine, which exhibits significant differences with respect to the biologic effects of EBRT. However, data in the literature which underscore the potential of dosimetry to avoid under- and overdosing and the importance of radiobiology in RNT are increasing.

The recent proliferation of PET/CT and SPECT/CT cameras, the development of patient-specific 3D imaging-based dosimetry, and the availability of faster computers and improved Monte Carlo methods will offer more and more major scientific and clinical opportunities in RNT dosimetry improving the physics of absorbed dose estimation. Furthermore, the increasing scientific interest in the radiobiological features specific to radionuclides

will improve our knowledge in nuclear medicine therapy and will advance our ability to administer this treatment modality optimally.

As stated by Edith Quimby in 1969 "Radionuclide dosimetry is not a finished product, but it has come a long way from the early empiric days. We must be grateful to the patient people who have spent untold hours on these developments" [158].

Diagnosis

By incorporating adequately large activities of appropriate radionuclides into target tissue-avid radiopharmaceuticals, a sufficiently high radiation dose can be delivered to produce a therapeutic response in tumors or other tissues. However, such high administered activities can also ensue some radiation injury in normal tissues. Nevertheless, nuclear medicine remains largely a diagnostic specialty, where relatively low administered activities are administered to yield important clinical information whose benefit far outweighs the small potential risk associated with the attendant low normal tissue radiation doses. The radiation doses associated with diagnostic administration of radiopharmaceuticals are typically of the order of 1 cSv [159], well below the threshold doses associated with the deterministic effects of radiation described in the prior section. Average normal tissue doses are received by the "standard" patient, found in package inserts for approved radiopharmaceuticals and in reports issued by authoritative bodies such as the International Commission on Radiological Units (ICRU), even though the actual doses received by a particular patient may deviate significantly from these average values. For such procedures, the radiation effects of practical concern are stochastic (or statistical) effects, i.e., possible germ-cell mutagenesis and, in particular, carcinogenesis.

Medical Radiation Exposures: Societal Concerns

The clinical applications of diagnostic nuclear medicine, particularly PET and nuclear cardiology, as well as computed tomography (CT), have grown dramatically over the last several decades. In the USA, for example, the annual number of nuclear medicine procedures has increased threefold (from 7 to 20 million) and the annual number of CT procedures 20-fold (from 3 to 60 million) between 1985 and 2005 [160], much of the increase in the latter being related to the use of CT in children (up to $\sim$ 10% of all such procedures). As a result of this increased medical exposure of the population, the average (i.e., per capita) annual background dose in the USA has nearly doubled, from 3.0 to 5.6 mSv [161]. There has been increasing concern in the medical profession and in the popular press over the potential public health impact – namely, an increased risk of cancer – associated with this dramatic growth in exposure from diagnostic radiology and nuclear medicine. Brenner and Hall, for example, have estimated that as much as 2% of all cancers in the USA may be attributable to CT irradiation [162]. While nuclear medicine diagnostic procedures are not performed as frequently as CT scans and the radiation doses are generally not as high, the radiogenic cancer risk per procedure is comparable. For all the diagnostic procedures, the relevant parameters should always be judiciously selected to deliver the minimum radiation dose consistent with yielding the clinical information being sought, according to a commonsense approach as emphasized in the "Image Gently" campaign [163–166] promoted by many agencies and professional organizations.

Nuclear medicine practitioners must be prepared to rationally address the "cancer-risk" concerns of patients, referring physicians, regulators, and other stakeholders.

Radiation Doses in Diagnostic Nuclear Medicine

Radiopharmaceuticals

Table 7 is a compilation of radiation doses for common diagnostic nuclear medicine procedures in terms of the effective dose (ED) for the 70-kg standard adult anatomic model [159, 167, 168]. Effective dose is used in radiation protection to compare the stochastic risk of a nonuniform

Table 7 Radiation doses for diagnostic nuclear medicine procedures for the 70-kg standard man anatomic model

Procedure	Radiopharmaceutical[a]	Administered activity (MBq)	Effective dose cSv/MBq	cSv total

exposure to ionizing radiation with the risk associated with a uniform whole-body exposure. It is a weighted sum of the doses to the individual tissues/organs of the body, where the tissue weighting factor reflects the relative susceptibility of that tissue to stochastic damage (i.e., carcinogenesis or, in the case of germ cells, germ-cell mutagenesis). EDs for such procedures are usually of the order of 1 cSv

for typical administered activities, meaning that the overall risk of carcinogenesis (and germ-cell mutagenesis) is roughly equivalent to that of a uniform whole-body dose of 1 cGy. Anatomic models and relevant dosimetric quantities such as absorbed fractions are now available [168], and radiopharmaceutical doses have thus been estimated for newborns, 1-year-olds, 5-year-olds, 10-year-olds, and 15-year-olds as well as adults [168–170]. There is typically a several-fold or greater difference in doses among organs for a particular radiopharmaceutical and anatomic model [171] for fluorine-18-labeled fluorodeoxyglucose ([^{18}F]FDG) in the Standard Adult anatomic model. Furthermore, as emphasized by several authors [172–174], one should use organ-, age-, and gender-specific doses and risk factors, rather than the ED and the overall risk factor, to estimate the cancer risk(s) associated with a particular procedure.

Multimodality Studies: PET/CT and SPECT/CT

As noted, there has been growing concern regarding the radiation dose associated with CT studies, particularly for the pediatric patient population [162, 172]. When CT is performed as part of a SPECT/CT or a PET/CT study, the axial field of view may be much larger than that of conventional CT studies, routinely extending from the base of the skull to the mid-thigh and thus potentially yielding an ED considerably greater than that of conventional, limited field-of-view CT studies [175]. Accordingly, when the CT component of a PET/CT study is used for attenuation correction and anatomic localization rather than for radiologic diagnosis, the CT scan parameters can, and should, be adjusted to appropriately reduce the CT dose. X-ray beams are characterized by (1) the current (expressed in units of milliampere (mA)) between the anode and cathode and (2) the maximum or peak (p) voltage (expressed in thousands of volts (V), or kilovolts (kV), and represented as "kVp") between the filament and the metallic target, where the electrons accelerated across this potential difference are stopped and the bremsstrahlung X-rays produced. Helical, or spiral, CT scans are also characterized by the pitch, the distance of travel of the patient table per rotation of the X-ray tube, and detector assemblies. The X-ray intensity and therefore the radiation dose are proportional to the mA and approximately proportional to the square of the kVp value. The dose is inversely related to the pitch. To determine the minimum-dose CT acquisition parameters that are compatible with accurate attenuation correction, investigators have systematically evaluated the impact of such parameters and therefore patient dose on both CT and PET image quality. Kamel et al. [176], for example, found no significant effect of tube current (10, 40, 80, and 120 mA) on [^{18}F]FDG standard uptake values (SUVs) and measured lesion sizes, with no significant difference in SUVs and lesion sizes between ^{68}Ge- and CT (80 mA)-attenuation-corrected PET scans. The authors concluded that CT scans using tube currents as low as 10 mA yield adequate attenuation correction for PET. Fahey et al. [175] subsequently evaluated the dose from the CT component of PET/CT studies to determine minimum-dose CT acquisition parameters (10, 20, 40, 80, 160 mA; 80, 100, 120, 140 kVp; 0.5 and 0.8 s per rotation; 1.5 pitch) that provide adequate attenuation correction for a range of patient sizes (i.e., anatomic phantoms) from newborns to adults. The CT dose index (CTDI), a commonly used CT dosimetry parameter indicative of the ED, varied by two orders of magnitude for each phantom over the range of acquisition parameters (e.g., for the 10-year-old-sized phantom, the CTDIs were 0.030 and 2.1 cSv for 80 kVp, 10 mAs, and 0.8 s and for 140 kVp, 160 mAs, and 0.8 s, respectively). The CTDI for the newborn phantom was twice that for the adult phantom for the same CT acquisition parameters. The ^{68}Ge rod source dose was only 0.003 cSv (3-min scan). Although CT statistical uncertainty (i.e., mottle or "noise") varied substantially among acquisition parameters, its contribution to PET noise was minimal ($<\sim$2%). In a pediatric phantom, PET images generated using CT performed with 80 kVp and 10 mA for attenuation correction were qualitatively and quantitatively indistinguishable from

those generated using CT performed with 140 kVp and 160 mA. Importantly, however, with very low-dose CT (80 kVp, 10 mA) for the adult phantom (i.e., for the combination of both low kVp and low mA), systematic undercorrection of the PET data for attenuation resulted. The impact on dose of these different CT acquisition parameters is significant. A diagnostic-quality CT (e.g., with "standard" kVp of 140, mAs of 190, and pitch of 1.25) delivers an ED of 2.2 cSv [175, 177–179] and therefore a total ED of 3.3 rem. However, for attenuation correction of an [^{18}F]FDG PET scan in an adult, a quantitatively accurate but non-diagnostic CT scan (e.g., with a kVp of 120, mAs of 60, and pitch of 1.5) delivers an ED of only 0.60 cSv [175, 177–179] and therefore a total ED of 1.7 cSv. For smaller patients a tube current as low as 60 mA can be used (with a kVp of 120 and a pitch of 1.5); the CT ED is only 0.1 cSv [175, 177–179]. Thus, if the purpose of the CT component of a SPECT/CT or PET/CT study is attenuation correction and anatomic registration and not radiologic diagnosis, appropriately judicious selection of the CT parameters can reduce the total ED by over 50% without compromising the diagnostic information content and quantitative accuracy of the PET study.

Dose–Response Relationships in Radiation Carcinogenesis

The largest and best characterized human cohort exposed to significant amounts of ionizing radiation remains the A-bomb survivors in Hiroshima and Nagasaki. Not surprisingly, A-bomb dosimetry had long been uncertain and plagued by a number of unresolved issues, including the yield of the Hiroshima bomb, the dose contribution of activation products, and the RBE and magnitude of the neutron dose. The latest A-bomb dosimetry system, Dosimetry System 2002 (DS02), improves on the Dosimetry System 1986 (DS86) and earlier A-bomb dosimetry systems in many important details, including the specifics of the radiation released by the bombs, addition of significant numbers of survivors to the so-called Life Span Study (LSS), and the effects of shielding by structures and terrain, and has thus resolved many of the outstanding dosimetric issues [180].

Choice of the correct model (i.e., mathematical relationship) between the excess cancer risk and radiation dose for extrapolation of the A-bomb dose–response data from its historical "high-dose" (>100 cSv) range to the diagnostic or "low-dose" (<10 cSv) range has long been controversial. The basic choices for such a mathematical extrapolation model are the supralinear model, the sublinear (i.e., linear-quadratic) model, and the linear, no-threshold model (Fig. 4). A supralinear model implies that the cancer risk per cSv is actually higher at low doses than at high doses; there are no data or biophysical evidence to support such a model that has never been creditably considered. The sublinear (i.e., linear-quadratic) model has for many years been the generally accepted dose–response model. The available human data are generally consistent with such a model, as are certain biophysical models of radiation action at the molecular level. Importantly, the sublinear model implies that the risk per cSv is lower at lower doses than at the higher doses (at which data are actually available). With the publication of the BEIR V and BEIR VII Reports [181, 182], however, the linear, non-threshold model is now the prevailing model for solid tumors, while the linear-quadratic model is the model of choice for leukemias [181, 182]. The linear, non-threshold model implies that the risk per cSv is constant at all doses, and it further implies that any excess radiation dose (i.e., above background), no matter how small, carries with it a finite (i.e., nonzero) excess risk of cancer and genetic damage. The available A-bomb survivor data for solid tumors – now including significant numbers of survivors receiving doses as low as 5 cSv on the basis of DS02 [180, 183] – are consistent with the linear, non-threshold model as well as with the linear-quadratic model. That is, on the basis of statistical considerations such as goodness-of-fit, one cannot actually distinguish between the sublinear (i.e., linear-quadratic) and the linear, non-threshold models. The linear, non-threshold model is more conservative (i.e., predicts a higher risk

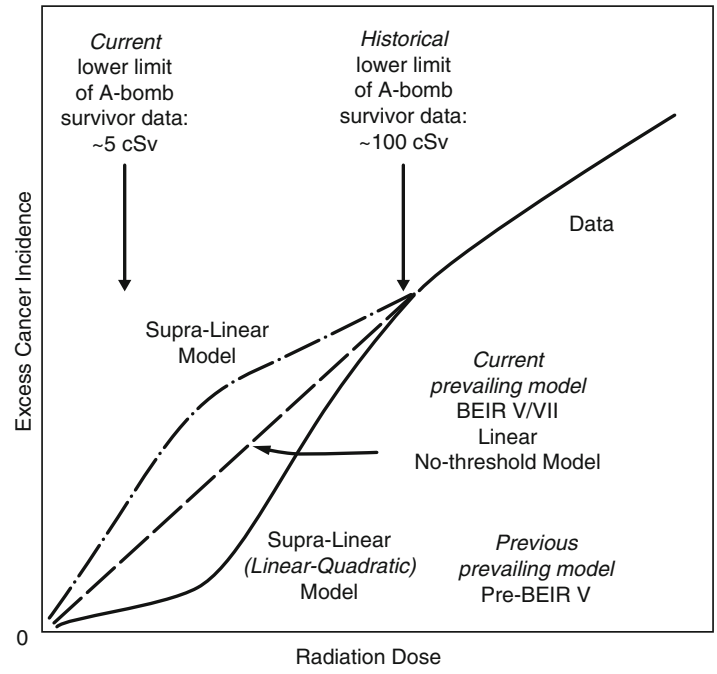

Fig. 4 Schematic representation of the basic choices for mathematical extrapolation of the A-bomb dose–response (i.e., excess cancer risk vs. radiation dose) data from its historical "high-dose" (>100 cSv) range to the diagnostic or "low-dose" (<10 cSv) range

per cSv at low doses) than the sublinear model and is therefore considered "safer" and thus more appropriate by some for radiation protection purposes. As noted, however, this issue remains controversial.

The BEIR VII age at exposure- and gender-specific risk factors for solid tumor and leukemia incidence and mortality shows pronounced differences in radiogenic cancer risk (in terms of both incidence and mortality) depending on age at exposure and gender (especially at younger ages); there are large differences depending on the cancer site, with female breast, lung, colon, and urinary bladder being the most susceptible to radiation-induced cancer [182]. The risk factors incorporate a so-called dose-rate effective factor of 1.5, meaning that HDR ($> \sim 10$ cSv/min or higher) radiation has a 50% higher risk factor than LDR ($<\sim 1$ cSv/min or lower) [182]. It is possible, however, that the dose-rate effectiveness factor may actually be higher than 1.5 and that the risk factors may therefore overestimate somewhat the cancer risk associated with the LDRs typical of diagnostic radiopharmaceuticals. Moreover, although stratified by age and gender, the risk factors within each stratum represent population-averaged values and thus do not account for individual differences in radiation sensitivity related to any preexisting condition, genetic susceptibility to radiogenic damage, etc. [174]. Importantly, as noted by Brenner and colleagues [162, 184], the risk factors they employed to estimate the numbers of radiogenic cancers associated with CT scanning are based on A-bomb incidence data at doses as low as 5 cSv – comparable to cumulative doses actually received by patients undergoing multiple CT procedures (as is often the case clinically) [4] – and not model-based extrapolation from higher (i.e., "supra-clinical")-dose data.

Risk–Benefit Considerations

Our discussion thus far has focused on the risks, most notably, the risk of cancer, associated with low (i.e., diagnostic)-level radiation – to the exclusion of any concrete consideration of its medical benefit. This is rather typical in the scientific literature: other than a perfunctory acknowledgment that the benefits of diagnostic procedures far outweigh any radiogenic risks,

such benefits are rarely, if ever, quantitated in a manner comparable to that of quantitation of risk. An unintended consequence of such "unbalanced" analyses – that is, quantitation of risk without comparable consideration of benefit – may be the mistaken perception that the medical benefit of a diagnostic procedure does not far outweigh radiogenic risk. Alternatively, the lack of quantitation of benefit may result in procedures in which risk outweighs benefit unjustifiably persisting in clinical practice. As illustrated by the case study which follows, risk–benefit analyses should thus quantitatively incorporate both the medical benefit and the radiogenic risk of diagnostic procedures.

Van Tinteren et al. [185] compared the management and clinical of suspected non-small cell lung cancer (NSCLC) with and without preoperative [^{18}F]FDG PET. With the conventional preoperative evaluation of NSCLC, that is, without [^{18}F]FDG PET, 81% of patients underwent thoracotomy, and 41% of those thoracotomies were futile, that is, non-potentially curative, because of the progression of disease disclosed at surgery. In series of Van Tinteren et al. [185], the surgery-related mortality was 6.5%. Adding [^{18}F]FDG PET to the preoperative evaluation reduced the proportion of NSCLC patients undergoing thoracotomy to 65%, with only 21% being futile. Thus, a non-curative operation was avoided in 20% of patients with the addition of [^{18}F]FDG PET. If one extrapolates the foregoing data to the US population, with 174,470 new lungs per year, the conventional preoperative evaluation will result in $174,470 \times 0.81 \times 0.41 \times 0.065 = 3,766$ futile surgical deaths each year; the addition of [^{18}F]FDG PET to the preoperative evaluation reduces the number of futile surgical deaths per year to $174,470 \times 0.65 \times 0.21 \times 0.065 = 1,547$ – a gross benefit of [^{18}F]FDG PET $3,766 - 1,547 = 2,219$ lives saved per year. However, for a 370-MBq administered activity of [^{18}F]FDG, the ED is 1.4 cSv [159] and the number of radiogenic cancer-related deaths therefore $174,470 \times 1.4\ \text{cSv} \times 0.0005/\text{cSv} = 122$, where 0.0005/cSv is the mean cancer risk factor (i.e., the lifetime age- and gender-averaged fractional increase in excess cancer mortality) [182]. Thus, the addition of [^{18}F]FDG PET to the preoperative evaluation of suspected lung cancer results in a net benefit of $2,219 - 122 = 2,097$ lives saved per year. Such a balanced quantitative analysis thus provides some perspective for objective consideration of radiogenic risks and medical benefits.

Considerations for Sensitive Populations: Prospective Parents, Pregnant Women, and Nursing Mothers

Prospective Parents

Experimental studies in a number of nonhuman systems have established that gonadal irradiation at sufficiently high doses can result in demonstrable abnormalities in subsequently (i.e., postirradiation) conceived offspring of the irradiated parent(s). Importantly, however, despite comprehensive studies of well over 10,000 children born to the atomic bomb survivors in Hiroshima and Nagasaki receiving mean gonadal doses of over 30 cGy and individual gonadal doses of up to several hundred cGy, there remains no evidence for heritable radiation effects in man [182, 186]. Specifically, in children born to A-bomb survivors at least several years after the bombings, there was no statistically significant increase in any radiogenic heritable effect. This implies that for diagnostic nuclear medicine procedures, where the gonadal doses are of the order of only 1 cSv (an order of magnitude less the 30-cSv mean gonadal dose received by the A-bomb survivors), there is no significant risk of heritable adverse effects among the offspring of patients who undergo such procedures. The estimation of human genetic risks is thus based largely on data derived from laboratory studies in animals, introducing the considerable uncertainty of extrapolation from nonhuman systems to humans [187]. The estimated absolute and relative risk factors are approximately 50 additional genetic effects/million live births/cSv and approximately 0.01%/cSv, respectively, in the F1 generation [182].

Not surprisingly perhaps, the absence of germ-cell damage in diagnostic nuclear medicine does not extend to therapeutic applications of radionuclides. Although a number of patients are small, demonstrable gonadal damage, such as reduced

sperm counts and impaired fertility, may occur among ^{131}I-iodide therapy patients over the first year posttreatment [182]. However, even among thyroid cancer patients treated with large (GBq) amounts of ^{131}I-iodide and receiving gonadal doses of the order of 100 cSv, such damage is transient [188, 189]. For example, follow-up studies of such patients indicate that among male patients there is a time-dependent recovery of sperm count and serum follicle-stimulating hormone (FSH) to control levels by 2 years posttreatment [190]. Long-term studies (i.e., 10 years or longer posttreatment) among both male and female patients indicate that fertility and the frequencies of miscarriages and congenital abnormalities among their offspring are comparable to control values [190].

Pregnant Women

It is an established radiobiological principle that the conceptus is particularly sensitive to radiation effects. Radiation doses to the conceptus associated with diagnostic procedures – generally of the order of or less than 0.1 cSv per 37 mBq administered to the mother [191–198] – are nonetheless well below the threshold doses for deterministic effects such as radiogenic fetal death or congenital malformations. Although modification of the standard anthropomorphic adult anatomic model [168] has yielded reasonably accurate dosimetric models of the conceptus–pregnant woman [191, 197, 198], radiopharmaceutical kinetic data in utero and therefore fetal dose estimates remain quite limited. For such procedures and at such in utero doses, the practical concern is the increased risk of childhood cancer. Published data, including the seminal Oxford Survey of Childhood Cancers [182, 199], indicate an excess risk of childhood cancer as high as 20% per Sv received in utero, with a linear response down to doses as low as 1 cSv. Signs alerting female patients and containing wording similar to, "If you are pregnant or if it is possible you may be pregnant, please notify the staff before the beginning of any procedure," should therefore be prominently posted throughout a nuclear medicine department, particularly in waiting and/or dressing areas. Once informed that a female patient of childbearing age is pregnant or may be pregnant, the nuclear medicine physician should confer with the referring physician to arrive at a medically informed, documented decision that the planned procedure is or is not justified. In particular, because RNT typically involves the administration of high (typically GBq) activities, such therapy is generally contraindicated in pregnant women, unless there is no viable alternative. A serum pregnancy test should be performed before RNT in any female patient of childbearing age. Assertions by the patient and/or her family regarding the impossibility of a pregnancy because of medical condition, sexual inactivity, use of birth control measures, or recent menstrual history should not preclude performing a serum pregnancy test prior to RNT.

The use of ^{131}I-iodide therapy for thyroid diseases in pregnant or potentially pregnant women is particularly problematic because radiogenic destruction of the iodine-avid fetal thyroid may result from such treatment and may result in hypothyroidism in utero with consequent cretinism [200]. The fetal thyroid begins concentrating iodine at the 12th–15th week of gestation, and fetal absorbed doses can be over 1,000 cSv per 3.7 GBq administered to the mother, depending on gestational age and maternal thyroid uptake. Therapeutic administered activities of 0.37–3.7 GBq of iodine would therefore result in fetal thyroid absorbed doses from 10,000 to 100,000 cSv, respectively. Case reports that include administered activity, gestational age, and follow-up of pregnant women treated with radioiodide for hyperthyroidism or thyroid cancer indicate that the outcome of pregnancy with regard to fetal thyroid function at birth did not appear to be compromised in the cases when radioiodide was given before the tenth week of pregnancy. However, there was essentially a 100% risk for congenital hypothyroidism and/or cretinism when radioiodine was administered thereafter, even in amounts less than 5 GBq [200]. Pregnancy is thus a contraindication to radioiodide therapy, and as stated above, a serum pregnancy test should be performed before administration of such therapy in any female patient of childbearing age.

Nursing Mothers

Virtually any systemically administered material, including a radiopharmaceutical, will appear to some extent in the breast milk of a lactating female, producing high activity concentrations in breast milk and potentially delivering significant radiation doses to nursing infants [201–206]. In one study, for example, the cumulative breast milk activity ranged from 0.03% to 27% of 131I-iodide administered for thyroid uptake studies [206]. Because of an infant's small size and the inverse relationship between absorbed dose and mass, ingestion of even a relatively small amount of activity will result in proportionately large total-body and organ absorbed doses. Furthermore, because of proximity of the infant to the mother when nursing, there is a potentially significant external absorbed dose to the infant. Signs alerting women with language such as, "If you are breast-feeding, please notify the staff before the beginning of any procedure," should therefore be prominently posted throughout a nuclear medicine department. Using a variety of dosimetric criteria (e.g., an effective dose equivalent to the nursing infant of 0.1 cSv), a number of authors have recommended different interruption periods prior to resuming breast-feeding following administration of radiopharmaceuticals [201–206]. The duration of the cessation of nursing will depend on the radionuclide and its effective half-life in vivo, the administered activity, and the extent to which radioactivity is concentrated in breast milk. While there is no absolute consensus, the following are representative of the published recommendations: 24 h following any administration of ^{99m}Tc, 2–4 weeks following administration of ^{67}Ga-citrate, and permanently for the current nursing infant following any administration of ^{131}I-iodide, especially for administration of therapeutic amounts of ^{131}I.

Abstract

Hodgkin and non-Hodgkin lymphomas are lymphoid neoplasms arising from B cells, T cells, or NK (natural killer) cells. [^{18}F]FDG PET/CT is more accurate for the primary staging of lymphoma, particularly because it can detect disease in normal-sized lymph nodes, liver, spleen, and bone marrow. A major advantage of [^{18}F]FDG PET in determining the outcome of therapy is distinguishing active lymphoma from fibrosis/necrosis in residual masses. Posttherapy [^{18}F]FDG PET provides important prognostic information and has been incorporated into the currently used criteria for evaluating response to therapy in lymphoma (Lugano/Lyric Classifications). Interim [^{18}F]FDG PET/CT also provides prognostic information and is being evaluated for "risk-adapted therapy" in setting of clinical trials.

Keywords

Lymphoma • [^{18}F]FDG-PET/CT • [^{18}F]FDG • Hodgkin • non-Hodgkin • Staging • Response to therapy

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FLT	3′-^{18}F-fluoro-3′-deoxythymidine
ABVD	Therapy with adriamycin, bleomycin, vinblastine, and dacarbazine
ASCT	Autologous stem cell transplantation
BEACOPP	Therapy with bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and procarbazine

Summary 380

References 381

Lymphoma is a hematologic malignancy characterized by abnormal proliferation of lymphoid cells (i.e., lymphocytes, histiocytes), most commonly arising in lymph nodes, but potentially involving any organ or tissue in the body. There are two major classifications of lymphomas that are determined by distinct morphologic features: Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). Diagnostic nuclear medicine procedures, in particular 2-deoxy-2-[^{18}F]fluoro-D-glucose positron emission tomography/computed tomography ([^{18}F]FDG-PET/CT), have emerged in the past two decades as an integral component in the evaluation of many patients with lymphoma to optimize therapeutic strategies.

Investigators began studying the use of [^{18}F]FDG-PET in patients with lymphoma in the late 1980s [1]. Initial studies showed great benefit and promise from metabolic tumor imaging, but the lack of anatomic information was a limitation. [^{18}F]FDG-PET detected more lesions than CT [2]. In 2001, combined PET/CT scanners were introduced for widespread clinical use, and the power of the hybrid imaging technique was soon realized. Current roles of [^{18}F]FDG-PET and PET/CT for patients with lymphoma include determining if disease is present, staging, restaging, evaluating response to therapy, identifying transformation and guiding biopsy, and offering prognostic information. PET is sometimes used to diagnose infections in patients with lymphoma, as well. PET-based "risk-adapted" therapy is currently the subject of numerous ongoing investigations.

This chapter will provide a brief clinical overview of the lymphoma subtypes as well as a review of the current and possible future roles of nuclear medicine imaging in patients with lymphoma.

Hodgkin Lymphoma

Epidemiology and Etiology

Hodgkin lymphoma represents approximately 10% of all lymphomas. In the United States, there were an estimated 9,050 new cases of HL and 1,150 deaths due to HL in 2015 [3]. The number of deaths due to HL has been decreasing over the past four decades due to better treatments [3].

HL has bimodal age peaks in the third and seventh decades of life and a slight male predominance. The exact etiology of HL is uncertain. Factors associated with higher risk of HL vary depending on geographic location (i.e., the industrial development of a country), socioeconomic status, immune suppression, and even age. Epstein-Barr herpesvirus (EBV) has been implicated in the pathogenesis of EBV-positive HL (about 40% of HL cases [4]), but is less likely to have role in EBV-negative HL [5]. Close family members of patients with HL, particularly identical twins [6, 7], are at higher risk for developing HL. One hypothesis for the etiology of HL based on the socioeconomic and genetic epidemiologic data is delayed exposure to a common (infectious) antigen in genetically susceptible individuals [8].

Pathology and HL Subtypes

There are two major subclasses of HL, classical and lymphocyte-predominant HL (cHL and lpHL). HL tumor is characterized by the presence of

distinctive, large, malignant cells (Reed-Sternberg (RS) cells in cHL and lymphocytic and histiocytic cells in lpHL) which represent only a minority, 1–5%, of the tumor in cHL. Background infiltrates consisting of a mixture of lymphocytes, histiocytes, eosinophils, plasma cells, and fibroblasts comprise the rest of the tumor [9]. There are four variants of cHL: nodular sclerosing, mixed cellularity, lymphocyte–rich, and lymphocyte–depleted. The variants are determined based on the morphology of the malignant cells and the composition and pattern of the background infiltrate [9].

Sufficient tissue is needed to make the diagnosis of HL because of the composition of the tumors, and excisional biopsy is recommended [10]. Immunohistochemistry is a helpful adjunct to morphology for establishing the diagnosis of HL. cHL and lpHL are both monoclonal B-cell disorders arising from germinal centers, although surface antigen expression between the two subclasses is different [11, 12]. Typically, the Reed-Sternberg (RS) cell in cHL expresses CD30 and in about 80–90% of cases also expresses CD15 [13, 14]. The malignant lymphocytic and histiocytic cells in lpHL express the B-cell antigen CD20, but varying frequencies (20–35%) of CD20 expression on malignant RS cells in cHL have been reported [15, 16]. Additional immunohistochemistry stains are also useful for differentiating cHL from lpHL as well as from T-cell-rich B-cell NHL and anaplastic large cell NHL which are often in the differential diagnosis [8]. An excellent review of the biologic classifications of HL is provided by Mani and Jaffe [17].

Genetic Features

Most cHL shows clonal, somatically mutated rearrangement of V, D, and J segments of immunoglobulin heavy-chain locus in RS cells on sensitive polymerase chain reaction (PCR) techniques indicative of mature B lymphocytes [18]. Clonal cytogenetic abnormalities with marked intraclonal variability are common in cHL [19, 20]. Abnormalities of 14q [20] and amplifications of PDL1 and PDL2 genes on chromosome 9 [21] are frequent. EBV is frequently associated with lymphocyte-depleted and mixed cellularity cHL, less common in lymphocyte-rich cHL and infrequent in nodular sclerosis subtypes [22, 23]. Molecular genetics of RS cells have shown an inactivating mutation of TNFAIP3 gene which encodes negative regulator of NF-kappaB [24]. Gene expression profiling (GEP) studies of RS cells have shown distinct expression profiles in cHL [25].

Clinical Presentation, Evaluation, Staging, and Prognosis

HL often presents as painless adenopathy, most commonly supradiaphragmatic in the supraclavicular and low neck lymph nodes. The pattern of nodal involvement varies depending on the histologic subtype. Thirty percent of patients also have systemic "B" symptoms (fevers, night sweats, and/or weight loss) [8] probably due to the production of cytokines by the malignant and background infiltrative cells [26].

History and physical exam, laboratory tests, and imaging are routinely performed at the initial diagnosis of HL for staging and assessing organ function prior to treatment. As will be discussed below, HL is typically [^{18}F]FDG-avid and [^{18}F]FDG-PET/CT is now the preferred noninvasive imaging modality for staging HL [27, 28]. According to the most recent recommendations for staging HL and NCCN guidelines, bone marrow biopsy for staging HL is no longer required if [^{18}F]FDG-PET/CT is performed, but may be warranted for further evaluation of cytopenias if the [^{18}F]FDG-PET/CT is negative [8, 10, 28].

The modified Ann Arbor staging system is used for staging HL (Table 1) [29, 30]. HL typically spreads to contiguous nodal groups. Stage is based on the number of nodal groups involved and is based on involvement in nodes above and/or below the diaphragm, extra-nodal organ involvement, and the presence or absence of "B" symptoms. Accurate staging is critical because along with several prognostic factors, staging guides the initial treatment plan.

Patients with early-stage HL (stage I/II) are subdivided into favorable and unfavorable risk groups for overall management. The grouping definitions differ between Europe and North

Table 1 Revised staging of primary nodal lymphomas: Lugano Classification

Limited Disease	
Stage I	1 LN region or lymphoid structure
Stage II	≥2 LN regions on same side of diaphragm
Advanced Disease	
Stage III	LN regions on both sides of the diaphragm or above diaphragm with splenic involvement
Stage IV	LN regions and noncontiguous extra-nodal sites
All stages (only HL)	A – no symptoms B – Fever (>38°C), night sweats, 10% body weight loss
Stages 1,2	E – involvement of extra-nodal site
Designation E is used for only patients with limited disease and not for advanced disease	
For bulky disease, documenting the diameter is recommended and not the designation X	

Table 2 International Prognostic Score (IPS) and Indices (IPI) for HL and NHL

	Factors[a]	Risk Group
IPS	Male gender Age >45 Stage IV Hemoglobin <10.5 g/L WBC count >15 x 10^9/L Lymphocyte count <0.6 x 10^9/L or <8% WBC Serum albumin <40 g/L	Risk increasing with each increase in number of adverse factors
IPI	Age >60 Elevated serum LDH ECOG performance status ≥2 Ann Arbor clinical stage III or IV >1 involved extra-nodal disease sites	Low: 0–1 Low intermediate: 2 High intermediate: 3 High: 4–5
Revised IPI	same as IPI	Very good: 0 Good: 1–2 Poor: ≥3
FLIPI	Age >60 Elevated serum LDH Ann Arbor clinical stage III or IV >4 involved nodal disease sites Hemoglobin level <12.0 g/dL	Low: 0–1 Intermediate: 2 High: ≥3

WBC – white blood cell; LDH – lactate dehydrogenase; FLIPI – IPI for follicular NHL
[a]One point given for each factor present

America. Generally, unfavorable disease is considered with larger tumor burden (either bulky mediastinal adenopathy, more nodal groups involved), older age, and "B" symptoms [31, 32]. Approximately 65% of patients with early-stage HL have unfavorable disease [10].

Additional prognostic risk factors have been validated for patients with HL and are used to guide therapy and interpret clinical trials. The International Prognostic Score (IPS) is most commonly used (Table 2) [33], predominantly for patients with advanced-stage III/IV disease. Freedom from progression for 5 years decreases from 84% for those with an IPS of 0 to 42% for those with a score of 5–7 [33]. Gallamini et al. showed that the results of interim [^{18}F]FDG-PET after two cycles of chemotherapy were better than IPS alone for predicting progression-free survival (PFS) in those with advanced HL [34]. This is probably because the results of interim [^{18}F]FDG-PET scan reveal patient-specific chemosensitivity of the tumor, an obvious important factor for good outcome.

Treatment and Follow-Up

The advent of multi-agent chemotherapy in the 1960s beginning with mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) has led to excellent overall response rates and cure of disease in many patients [35–38]. Cure rates are >90% for patients with early-stage and favorable disease, but they are in the 65–70% range for advanced disease. A complete discussion of the evolution of therapy for HL is beyond the scope of this chapter, but general management strategies are presented to place the role of imaging into the therapeutic context.

The treatment choice for early-stage HL aims to achieve cure while balancing the risks of recurrence and late toxicity (i.e., cardiac disease and secondary malignancy). For favorable early-stage HL, either combined chemotherapy and involved-field/involved-site radiation or chemotherapy alone may be appropriate [39–42]. Combined modality therapy improves disease control compared to chemotherapy alone, but studies have not shown differences in overall survival [43, 44]. Shorter courses of chemotherapy may be given and smaller radiation fields applied with combined modality therapy [32, 45]. In the population with favorable early-stage HL, individual patient characteristics, such as age and specific tumor location, guide the decision-making process. For example, in young women sparing radiation to breast tissue is an important consideration.

For unfavorable early-stage HL, combined chemotherapy and radiation is favored over chemotherapy alone, especially for bulky disease [10]. While disease-free survival is also better with combined therapy in this population, the effects on overall survival are less clear. The course of chemotherapy is typically longer (six cycles) for unfavorable, early-stage HL vs. favorable disease [10, 46].

For both early-stage favorable and unfavorable HL, adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) is the most commonly used initial chemotherapy regimen based on efficacy and toxicity profiles [8, 46–50]. Other initial chemotherapy options are Stanford V and bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and procarbazine (BEACOPP). BEACOPP has similar efficacy compared to ABVD, but significantly more toxicity, so it has not been recommended for early-stage disease [46, 51, 52].

Radiation field size has been reduced in recent years to avoid toxicity to normal organs. Many patients now receive involved-site or involved-nodal radiation therapy, which targets the sites of originally involved lymph nodes and considers tumor regression after chemotherapy to spare normal organs. Details are provided in the Guidelines from the International Lymphoma Radiation Oncology Group [45]. Imaging (and increasingly [^{18}F]FDG-PET/CT) is used to optimize these radiation fields. Another goal is lower radiation dose and dose is adjusted based on stage and tumor bulk.

For advanced HL, ABVD has been shown to be superior to MOPP and hybrid regimens [48–50] and is typically given for six cycles. More intensive regimens have been compared to ABVD. The German Hodgkin Study Group trials demonstrated better outcomes with escalated BEACOPP than with ABVD [53], but more acute toxicity and secondary leukemias were seen. Escalated BEACOPP is more widely used in Europe, and NCCN guidelines recommend escalated BEACOPP as an option for advanced HL with IPS >4 [10]. It is not recommended for elderly patients with advanced HL due to acute toxicity [54]. Randomized phase III studies comparing BEACOPP and Stanford V have not shown beneficial results. Initial results from European Organisation for Research and Treatment of Cancer (EORTC) trial number 20012 comparing eight cycles of ABVD ($n = 275$) to four escalated + four standard cycles of BEACOPP ($n = 274$) were presented in 2012 [55]. More relapses were found in the ABVD group and more early discontinuations in the BEACOPP group, but no differences in event-free or overall survival were found between the treatment groups. The randomized Eastern Cooperative Oncology Group (ECOG) trial comparing ABVD to the Stanford V did not show a benefit of Stanford V [56]. The role of radiation therapy to areas of bulky disease in advanced HL is also still uncertain and under investigation.

About one-third of patients with HL are refractory to or relapse after initial therapy and often receive high-dose chemotherapy and stem cell transplant [57]. Despite high response rates post-transplant [58–61], a significant number, 26–65%, of these patients relapse [57, 60–64]. Relapse or decreased survival posttransplant has been associated with a number of risk factors including poor performance status at transplant, chemotherapy-resistant disease, increasing number of failed chemotherapy regimens, more than minimal or bulky disease at transplant, B symptoms at relapse, and extra-nodal disease at relapse [57, 60–64]. Post-transplant, therapy options are limited due to patients' decreased bone marrow reserve. Single-agent chemotherapy, local irradiation, or reduced intensity of chemotherapy followed by allogeneic stem cell transplant can be considered, but therapy is most often given with palliative intent.

Several drugs like bendamustine, lenalidomide, and everolimus have shown activity in relapsed/refractory HL and are being evaluated as second- and third-line therapies [65–67]. The antibody-drug conjugate brentuximab vedotin, which targets CD30, has been approved for treatment of refractory/relapsed HL patients who do not respond to or are not candidates for transplant [68]. Other novel agents such as immune checkpoint inhibitors like anti-programmed death receptor-1 (PD-1) (nivolumab and pembrolizumab) monoclonal antibodies [69] are promising and under investigation.

lpHL has a different, more indolent natural history, and late relapses are more likely to occur compared to cHL [70]. Non-bulky, early-stage (I/II) lpHL without B symptoms is typically treated with radiation alone. Other early and advanced stages may be treated with combinations of chemotherapy, radiation, and/or rituximab. There is no standard chemotherapy regimen for lpHL due to a lack of randomized controlled trials comparing different regimens [10]. Because lpHL routinely expresses the CD20 antigen, rituximab used as a single agent has been studied, and very encouraging response rates have been reported [71–73]. Additional follow-up is needed to further assess the durability of the responses.

Data are limited regarding optimal follow-up of patients with HL after therapy. Generally, history, physical exam, and laboratory evaluations are performed at increasingly spaced intervals up to 5 years after completion of initial treatment. The NCCN guidelines recommend very limited imaging – CT once during the first 12 months and then as clinically needed. The use of [^{18}F]FDG-PET/CT in follow-up is discussed further below. Additional careful follow-up is needed to monitor for late effects of treatment.

Very important considerations in treating patients with HL are the long-term side effects of external beam radiation (e.g., hypothyroidism, premature menopause, carotid and coronary artery stenosis, and secondary breast cancer) and chemotherapy (e.g., infertility, cardiomyopathy, secondary leukemia, and osteoporosis) [8]. Increased risk of death persists for more than 25 years in patients with HL due to late-term treatment complications rather than HL itself [74, 75]. Strategies using interim PET for risk-adapted therapy may be advantageous for this purpose and for guiding dose intensification for those patients who are more likely to relapse and dose de-intensification in those responding well. This is discussed in the section on PET and risk-adapted therapy.

Non-Hodgkin Lymphoma

Epidemiology and Etiology

In 2015, the estimated number of new cases of NHL in the United States was 71,850, and NHL is the sixth most common cancer in men and the fifth most common in women [3]. NHL resulted in about 19,790 deaths from the disease in 2015 – ranking as the ninth and sixth most common cause of cancer deaths for men and women, respectively [3]. The incidence of NHL has been rising since the 1970s, most markedly in the elderly population. The overall increase in incidence is out of proportion to that expected due to the aging population alone, and the reasons for this are mostly unclear. Despite this, the death rate from NHL has been decreasing since 1997 due to improvements in therapy [76]. Most cases of NHL occur in individuals greater than 60 years of age.

Alterations of the immune system, certain viruses, and environmental exposures have been implicated in the etiology of NHL, with varying degrees of evidence. For example, both immune suppression (e.g., posttransplant) and immune stimulation (e.g., Sjogren's syndrome, rheumatoid arthritis) have been associated with increased risk of NHL [77–79]. Viral-lymphoma associations have also been suggested. Environmental exposures linked to NHL include organochlorine-based pesticides, organic solvents, and wood products.

Pathology and NHL Subtypes

NHL consists of a heterogeneous group of diseases that arise from malignant transformation of lymphoid tissues. Initial classification schemes were based primarily on morphology. Advancements in immunologic, molecular, and genetic laboratory techniques have led to several updates and revisions of classification systems for NHL [80–82]. The ability to identify cell surface markers, cytogenetic markers, and molecular markers led to the recognition that subtypes of NHL depend on the stage of maturation when malignant transformation of the lymphocyte occurs as well as the location of the "normal lymphocyte counterpart" within the lymph node.

The currently used World Health Organization classification uses morphologic, immunophenotypic, genetic, and clinical features to define distinct NHL subtypes and was revised in 2008 [81, 82]. The revision further defined and refined definitions of early/in situ lesions, the relevant distinctions in subtypes based on age, and borderline diagnoses (hard to classify as one subtype versus another due to atypical or overlapping features). This is nicely reviewed by Jaffe [81]. The NHL subtypes are grouped by lineage (B-cell or T-cell/natural killer (NK) cell) and the maturity of the cell from which the malignancy is derived (Table 3). Most (80–85%) are B-cell neoplasms [9]. NHL may behave in a manner that, if left untreated, is indolent, aggressive, or very aggressive, and the aggressiveness of a tumor within a histologic subtype can be variable between patients so it is not included in the official classification scheme. Diffuse large B-cell lymphoma (DLBCL) and follicular lymphoma are the most common NHL subtypes in the United States.

Genetic Features

Gene expression profiling (GEP) studies are used to diagnose and classify NHL. Based on GEP, DLBCL is classified into germinal center B-cell type and activated B-cell type [83, 84]. The activated B-cell type has been shown to have inferior 5-year survival rates compared to the germinal center B-cell type [85]. DLBCL has chromosomal translocations, the three most common involving

Table 3 World Health Organization Classification of NHL

B-cell lymphomas	T/NK-cell lymphoma
Precursor B lymphoblastic lymphoma/leukemia	Precursor T-cell lymphoblastic lymphoma
Mature B-cell lymphoma	Mature T-cell lymphoma
Chronic lymphocytic leukemia/small cell lymphoma	Adult T-cell lymphoma/leukemia
Lymphoplasmacitic lymphoma	Mycosis fungoides (Sezary syndrome)
Splenic marginal zone lymphoma	Primary cutaneous anaplastic large cell lymphoma
MALT-lymphoma	Anaplastic large cell lymphoma
Normal marginal zone lymphoma	Peripheral T cell lymphoma, unspecified
Follicular lymphoma	Angioimmunoblastic T-cell lymphoma
Mantle cell lymphoma	Extranodal NK/T cell lymphoma, nasal type
Diffuse large B-cell lymphoma	Enteropathy-type T-cell lymphoma
Mediastinal (thymic) large B-cell lymphoma	Hepatosplenic T-cell lymphoma
Intravascular large B-cell lymphoma	Subcutaneous panniulitis-like T cell lymphoma
Primary effusion lymphoma	Blastic NK cell lymphoma
Burkitt's lymphoma/leukemia	

the oncogenes BCL-2, BCL-6, and c-MYC. Double-hit lymphomas refer to DLBCL with translocations of both c-MYC and BCL-2 or BCL-6 and carry a worse prognosis compared to other types of DLBCL [86]. Double-expressor lymphoma refers to amplification of c-MYC and BCL-2 by mechanisms other than translocation [86].

Clinical Presentation, Evaluation and Staging, and Prognosis

NHL most commonly presents as painless adenopathy, similar to HL, but the rapidity of tumor growth and the exact presentation varies with histologic subtype and aggressiveness of the tumor. NHL spreads in a manner less predictable than HL (more hematogenously than by contiguous nodal spread) and is more likely to involve extra-nodal sites than HL. Systemic "B" symptoms are found in 40% of patients, more common in the aggressive than indolent NHL subtypes [87]. Lymphomatous infiltration of the bone marrow may result in cytopenias, and the presentation of infiltration of other organs may be site specific.

A core or excisional biopsy is usually needed for diagnosis in order to provide sufficient tissue. Fine needle aspiration alone and cytology often do not provide enough tissue for morphologic, immunologic, and genetic assessment. After diagnosis, the initial work-up is similar to that of HL. History and physical exam, laboratory tests, and imaging are performed for staging and assessing organ function prior to treatment. Staging is best performed with PET for NHL subtypes that are typically [^{18}F]FDG avid (i.e., DLBCL). Indolent NHL may sometimes have low metabolic activity, and PET for staging may be less helpful in some of these instances. Variability of [^{18}F]FDG uptake and staging with PET in NHL are discussed further below. Bone marrow biopsy is no longer required for all patients with NHL for staging, but is reserved for those with DLBCL and a negative [^{18}F]FDG-PET/CT in the marrow or those with low-[^{18}F]FDG-avidity lymphomas [28]. Laboratory testing is primarily used for prognostic scoring and to test baseline organ function prior to treatment.

Currently, NHL is also staged according to the modified Ann Arbor staging system (Table 1) [28, 88]. In the Lugano classification, four stages remain, but the subscript E is used for only when there is limited extra-nodal disease and it is not relevant for patients with advanced-stage disease. The designation "X" is replaced by largest tumor diameter for describing bulky disease, and the subdivision of patients based on constitutional symptoms is not incorporated for staging NHL (Table 1). The Lugano classification is discussed later with more detail.

The histopathologic subtype primarily determines the prognosis for patients with NHL. Within each subtype of NHL, disease-specific genetic alterations and molecular markers may provide additional information for predicting outcomes and guiding management. The International Prognostic Index (IPI) was developed in patients with aggressive NHL (Table 2) [89]. Four risk groups were identified (low = IPI 0–1, low intermediate = IPI 2, high intermediate = IPI 3, and high = IPI 4–5) with decreasing 5-year overall survival with increasing IPI score (73%, 51%, 43%, 26%, respectively) [89]. The original IPI was developed and validated prior to the routine use of rituximab in regimens to treat NHL. Sehn et al. [90] retrospectively evaluated the use of the IPI in 365 patients with DLBCL treated with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone (R-CHOP). Using the original IPI groupings, only two (not four) risk groups were identified. The revised IPI redistributed the risk groups (very good = IPI 0, good = IPI 1–2, poor IPI 3–5), and this model was felt to better predict outcome. In the rituximab era, the risk group with 4-year survival $<$50% was no longer identified [90].

Additional variations of the IPI have been developed, including age- and stage-adjusted IPIs to account for the variability of prognoses within these groups [89, 91]. The enhanced IPI (NCCN-IPI) was reported recently in a study of 1,650 patients to discriminate low- and high-risk subgroups better than IPI, a finding validated in another independent cohort of 1,138 patients [92]. The usefulness of the IPI also has been shown to provide prognostic information at the time of relapse [93–96].

There are two versions of the IPI for patients with indolent follicular NHL (FLIPI 1 and 2). Using the first FLIPI version, overall survival decreases with increasing FLIPI score based on three risk groups (low, intermediate, and high) and provides prognostic information for this population, even in the setting of rituximab [97, 98]. Validation of FLIPI 2 is ongoing.

Treatment and Follow-Up

As with the natural history and prognosis of NHL, treatment varies and depends on the specific NHL subtype. Recommendations for detailed management strategies are provided by a panel of experts in the NCCN guidelines [99]. Excellent review articles are available for specific questions and agents for the treatment of NHL, including new biologic agents and treatment strategies [100–105]. We will review overall management strategies for the most common NHLs – DLBCL and follicular NHL. These are also probably the most commonly encountered by the nuclear medicine physician or radiologist. Discussion of treatment for the other subtypes is beyond the scope of this chapter and can be found elsewhere [99, 106].

Indolent NHL is generally considered incurable at present. Patients respond to therapy, but may have multiple relapses and long disease-free or progression-free periods. A major question for those with indolent NHL is when to initiate therapy. Several studies have shown that "wait and watch" is a valid strategy even in the rituximab era outside of clinical trials in patients with advanced-stage low-tumor burden follicular lymphoma [107, 108].

General indications for treatment of indolent NHL are symptoms, organ compromise, rapid or steady progression of tumor, bulky disease, cytopenias due to lymphoma, and patient preference or eligibility for a clinical trial [99]. The treatment plan and aggressiveness of the regimen used are usually tailored for the patient's disease and clinical status. Common regimens include purine analogs, alkylators, anthracyclines, and rituximab alone or in combination with chemotherapy. Selected patients with bulky early-stage disease may be treated with radiotherapy alone.

Sousou and Friedberg nicely reviewed the pivotal studies that investigated the role of rituximab in patients with indolent lymphoma [109]. Treatment with rituximab alone [110–112] and with chemotherapy [113–116] has improved overall response rates and PFS for patients with indolent NHL in both the front line and maintenance settings [117]. There is a suggestion toward improved overall survival [118, 119], which has been confirmed in long-term follow-up data [113]. Patients who respond to first-line therapy can be treated with maintenance rituximab up to 2 years [120]. Consolidation with radioimmunoconjugates in patients initially treated with chemotherapy alone has been shown to improve the quality of remission but not better than initial chemoimmunotherapy alone [121–123]. Areas of continued study for rituximab are use with immune stimulators to improve efficacy, optimal schedule for maintenance dosing, and resistance mechanisms. Other monoclonal antibodies to CD20 are also being developed and investigated [124].

In the relapsed setting, indolent NHL may be treated in a similar manner to initially untreated disease. Overall response rates to rituximab in the relapse setting range from 40% to 60% with complete responses in 10–20% and median progression-free survival (PFS) of 8–24 months [112, 125, 126]. Radioimmunotherapy is more active and produces better results than unlabeled antibody alone, and its use in relapsed (as well as the front line) indolent NHL is discussed in a separate chapter [121–123, 127, 128]. Autologous and allogeneic transplants have been performed safely and with antitumor activity prolonging the overall survival and progression-free survival [129, 130]. If there is a role for transplant in indolent lymphoma, the optimal role is still being defined.

For aggressive B-cell NHL, systemic chemotherapy is the mainstay of treatment. Diffuse large B-cell NHL is the most common aggressive NHL and is discussed as an example. The present regimen of choice is R-CHOP [131–133]. For non-bulky early-stage disease, the NCCN

guidelines recommend three cycles of R-CHOP with IFRT or six cycles of R-CHOP with or without IFRT [88]. Higher doses of IFRT (30–40 Gy) are added to six cycles of chemotherapy for early-stage, bulky disease. The preference at major centers is to treat patients with advanced disease on a clinical trial; otherwise, a full course of chemotherapy is recommended [99, 131]. For germinal center B-cell type DLBCL patients treated outside the setting of a clinical trial, the choice of treatment is R-CHOP-21 (R-CHOP given every 21 days). Two randomized phase III trials have shown that dose-dense R-CHOP-14 does not improve the outcome compared to R-CHOP-21 [134, 135]. Clinical trials of R-CHOP with novel agents like lenalidomide, ibrutinib, and bortezomib are available for patients with advanced activated B-cell-type DLBCL [136–138]. For patients with double-hit DLBCL, dose-adjusted EPOCH-R has been shown to be associated with better outcome than R-CHOP [139, 140]. The NCCN recommends several alternate first-line regimens for frail patients [88].

The role of high-dose therapy and transplant for initial therapy of aggressive NHL is controversial and the subject of clinical trials. Currently, autologous hematopoietic cell transplantation (HCT) is not recommended after initial treatment of DLBCL as there is no survival advantage with HCT [141]. FDG-PET/CT is being used as a prognostic indicator in several of these risk-adapted therapy trials, and these studies are discussed in the section on risk-adapted therapy. In the relapsed setting, there are several salvage chemotherapy regimens that may be used with the ultimate goal of transplant in those patients who respond.

T-cell NHL accounts for ~15% of all lymphomas. Most T-cell lymphomas are clinically aggressive, and with a few exceptions (anaplastic large cell, early-stage T-/NK cell, nasal), most are incurable. CHOP and CHOP-based therapy may be used for initial treatment in these settings with or without radiotherapy [142–144]. Certain subtypes of T-cell NHL can be treated with consolidation radiation or HCT [88]. The optimal regimen for treatment of adult T-cell leukemia/lymphoma is yet to be established. Other approaches have been investigated for T-cell NHL subtypes including investigations of biologic agents (bevacizumab [145] and histone deacetylase inhibitors [146]) and agents against other lymphocyte surface antigens (alemtuzumab [147], mogamulizumab [148], brentuximab [149]).

Follow-up for patients with NHL also depends on the subtype of NHL, treatment intent, and the patient's clinical symptoms. For those treated with curative intent, history and physical exam, laboratory testing, and imaging occur with decreasing frequency over the first 5 years and then annually. Patients must be monitored for late complications of therapy, which are similar to those discussed for HL.

Nuclear Medicine Imaging for Lymphoma

Nuclear medicine imaging has had a role in the evaluation of patients with lymphoma since the 1970s [150]. Gallium-67 imaging preceded [^{18}F]FDG-PET/CT as the functional imaging technique for staging, monitoring response to therapy, and providing prognostic information [151–157]. A negative gallium-67 scan favored a better outcome after treatment and as soon as after one cycle of chemotherapy in both HL and NHL [153–157]. Other agents were also evaluated, for example, indium-111 bleomycin, but they were not shown to be more efficacious than gallium-67 [158, 159].

Today, gallium scanning has been replaced with [^{18}F]FDG-PET/CT imaging, which offers higher-resolution images; higher sensitivity for disease detection, particularly for lower-grade lymphomas; lower radiation doses; and a shorter time from injection until imaging is performed [159–164]. Bone scanning has also been used for detection of lymphomatous involvement in bone; however, these typically marrow-based lesions may be falsely negative on bone scan. In the PET era, bone scanning is considered if patients present with bone pain and a PET scan is not available [8]. [^{18}F]FDG-PET/CT is now well integrated into management strategies for lymphoma. The current roles of PET (disease

detection, staging, and posttreatment assessment) are reviewed. Numerous ongoing clinical trials investigating the role of interim PET, obtained after one to four cycles of chemotherapy, for risk-adapted therapy will be discussed.

[^{18}F]FDG-PET for Detecting and Histologic Grading of Lymphoma

Most lymphomas accumulate [^{18}F]FDG [2]. Weiler-Sagie et al. [165] readdressed this issue in a large retrospective study of 766 patients with newly diagnosed lymphoma referred for initial staging with [^{18}F]FDG-PET/CT. [^{18}F]FDG-avid disease was found in all patients with HL, 94% with aggressive NHL and 83% with indolent NHL. The histologic subtypes of lymphoma less likely to be [^{18}F]FDG-avid were small lymphocytic lymphoma (% [^{18}F]FDG avid – 83%), enteropathy-type T-cell lymphoma (67%), extranodal marginal zone lymphoma (67%), MALT marginal zone lymphoma (54%), lymphomatoid papulosis (50%), and primary cutaneous anaplastic large T-cell lymphoma (40%) [165].

To some extent, the location of lymphomatous involvement may also hinder its detection regardless of histopathologic subtype. The cutaneous location accounted for one-third of the 48 non-[^{18}F]FDG-avid cases in Weiler-Sagie et al.'s study [165], including two with DLBCL. The other most common locations of non-[^{18}F]FDG-avid disease were bowel, bone marrow, effusions, and mucosal surfaces [165]. Clearly tumor burden has an effect, and low tumor burden can be falsely negative.

Weiler-Sagie et al. did not address the degree of [^{18}F]FDG uptake in the histologic subtypes of lymphoma, but this has been done previously [165]. Broadly speaking, low-grade lymphomas take up less [^{18}F]FDG than high-grade lymphomas [166–168]. Standardized uptake values (SUVs – a semiquantitative measure of tumor metabolism) of greater than 10 had a high likelihood of being aggressive and excluded low-grade lymphoma with a specificity of 81% in one study of patients with non-Hodgkin lymphoma [168]. Despite this, there is substantial overlap of [^{18}F]FDG uptake between lymphoma grades with some low-grade tumors exhibiting high levels of [^{18}F]FDG uptake. The level of [^{18}F]FDG uptake likely lies along a continuum based on the histologic grade of the lymphoma, but in an individual patient, the level of [^{18}F]FDG uptake is probably not an adequate single surrogate marker for histologic grading of lymphoma.

One exception may be when a disproportionately high accumulation of [^{18}F]FDG is seen in a single lesion compared to the others in a given patient (Fig. 1). This may be indicative of transformation of a low-grade lymphoma to a high-grade lymphoma in the same patient, and [^{18}F]FDG-PET and PET/CT could help guide biopsies of these lesions [168]. Bruzzi et al. [169] retrospectively evaluated 37 patients with chronic lymphocytic leukemia (CLL), with and without signs

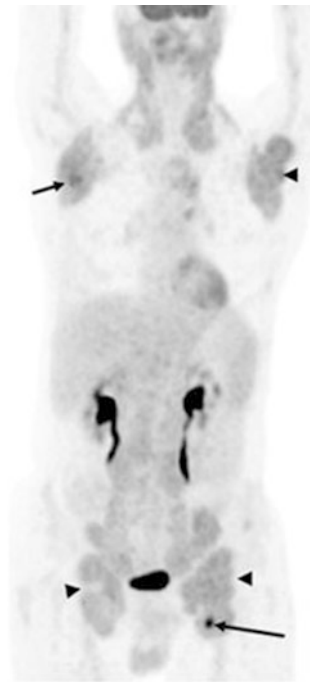

Fig. 1 A 65-year-old man with a history of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL). There is mild to moderate [^{18}F]FDG uptake in bilateral cervical, axillary, para-aortic, iliac, and inguinal lymph nodes consistent with indolent NHL (*arrowheads*). Within the left inguinal adenopathy, there is a focus of more intense [^{18}F]FDG uptake (arrow, $SUV_{lbm\text{-}max} = 10.6$). Biopsy of the more intense focus in the inguinal region revealed Richter's transformation. Another area of more moderate uptake suspicious for early transformation can be seen in the right axilla (*arrow*)

and symptoms of transformation, with PET/CT. Using an SUV_{max} cutoff of 5, the negative predictive value of PET for detecting transformation was high (97%); however, the specificity and positive predictive value were low (80% and 53%, respectively) [169].

Bodet-Milin et al. [170] used PET/CT to prospectively guide biopsy in 38 patients with indolent NHL ($n = 23$ follicular, $n = 10$ CLL, $n = 2$ Waldenstrom macroglobulinemia, $n = 3$ marginal zone NHL) and clinical suspicion for transformation. Biopsy was obtained at the most accessible site with the highest SUV_{max}, and 17 patients had histologic transformation on biopsy. The median SUV_{max} and gradient SUV_{max} (highest SUV_{max}-lowest SUV_{max}) were higher for those with histologic transformation. Using receiver operator curve analysis, an SUV_{max} threshold of 14 was optimal for identifying transformation (sensitivity/PPV ~ 94%, specificity/NPV ~95%) [170]. As expected, sensitivity or specificity could be improved one way or the other with higher and lower thresholds. Bodet-Milin's study differed from Bruzzi's in several regards; all patients had a clinical suspicion of transformation, and higher threshold values for transformation likely decreased the false-positive rate. They suggest that a higher threshold may be reasonable for patients with follicular versus chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), as CLL/SLL typically has less [^{18}F]FDG uptake at baseline [170]. These data together suggest that PET may be useful for detecting transformation, but tissue confirmation is still required for confirmation at the present time. It should be noted that SUV in all nonfat tissues can be elevated in obese patients; thus, the SUV of 10 is a rough guideline, only.

[^{18}F]FDG-PET for Initial Staging of Lymphoma

It is well established that [^{18}F]FDG-PET is superior to Ga^{67} scintigraphy [160–164] and improves primary staging of lymphoma as compared to CT [171–175]. For nodal status, this is primarily due to the ability of [^{18}F]FDG-PET to detect lymphoma in normal-sized lymph nodes that would be considered benign by CT size criteria. [^{18}F]FDG-PET also detects more extra-nodal lesions, for example, in the liver, spleen, bone, and lung, than CT does (Fig. 2), with less radiation exposure to the patient.

The Lugano classification recommends [^{18}F]FDG-PET/CT as the imaging test of choice for staging all [^{18}F]FDG-avid nodal lymphomas. Contrast-enhanced CT is recommended for the staging of all non-[^{18}F]FDG-avid lymphomas. The modified Ann Arbor staging is still used in the Lugano classification [28] (Table 1). The suffixes A and B for constitutional symptoms are recommended only for HL. The designation E is used for only patients with limited disease and not for advanced disease. For bulky disease, documenting the diameter is recommended and not the designation X (Table 1).

Although biopsy is the gold standard to detect lymphomatous involvement in the bone marrow, bone marrow biopsy and [^{18}F]FDG-PET have been reported to be approximately 80% concordant [173, 176, 177]. The Lugano classification does not recommend bone marrow biopsy in HL if [^{18}F]FDG-PET/CT is performed [28]. This recommendation is based on several studies showing that [^{18}F]FDG-PET/CT is sensitive for detecting involvement of bone marrow in HL [178, 179]. Sampling error on biopsy may result in a "false-positive" PET study, which is actually true positive (Fig. 3). El-Galaly et al. showed that only one-third of 454 HL patients with focal skeletal lesions on [^{18}F]FDG-PET/CT were positive on bone marrow biopsy [178].

In another study, bone marrow involvement could be confirmed in seven of ten patients with negative iliac crest biopsies by [^{18}F]FDG-PET-directed re-biopsy ($N = 4$) or anatomic imaging ($N = 3$) [177]. A meta-analysis investigating the use of [^{18}F]FDG-PET for detecting bone marrow disease revealed sensitivities in the 54–74% range and specificities in the 91–95% range [180]. Only a small number of studies evaluating Hodgkin lymphoma were included. In the case of DLBCL, Lugano classification recommends bone marrow biopsy only in patients without marrow involvement on [^{18}F]FDG-PET/CT. Though [^{18}F]FDG-PET/CT can underdiagnose low-volume disease in DLBCL, several studies have consistently

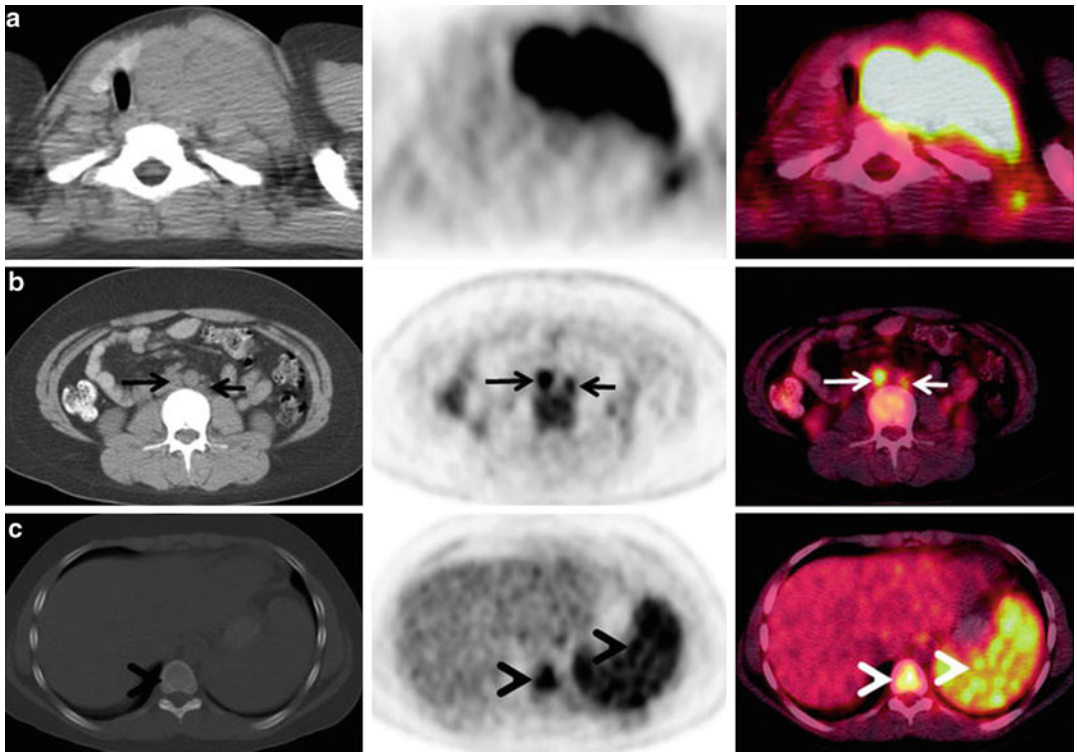

Fig. 2 A 34-year-old woman with Hodgkin lymphoma presented for staging with a PET/CT scan. The diagnostic CT scan with intravenous contrast was done prior to the PET scan and showed enlarged lymph nodes in the mediastinum extending to but not below the aortic arch (not shown). This was consistent with stage II disease. The PET/CT scan shows that the mediastinal mass has intense [^{18}F]FDG uptake (**a**). The PET scan also showed numerous [^{18}F]FDG-avid lymph nodes below the diaphragm (**b**, *arrows*) and in the bone marrow and spleen (**b**, **c**, *arrowheads*). The patient was upstaged to stage IV and received systemic chemotherapy (for **a**, **b**, and **c** – left, CT; center, PET; right, fused PET/CT)

shown that [^{18}F]FDG-PET or PET/CT has better diagnostic performance than bone marrow biopsy for diagnosing marrow involvement [181–183]. In a study of 133 patients with newly diagnosed DLBCL, [^{18}F]FDG-PET/CT was more sensitive (94% vs. 24%) and accurate (98% vs. 81%) than bone marrow biopsy [182]. Bone marrow biopsy is recommended in all other lymphoma histologies [28].

When evaluating an abnormal focus of increased [^{18}F]FDG uptake in the bone, it is important to note that the concurrent CT scan may appear normal up to 50% of the time [184] and the context and entire distribution of uptake must be considered. In the lymphoma population in the study by Nakamoto et al., none of the marrow lesions were seen on CT, but the population was small [184]. [^{18}F]FDG-PET is more likely to detect bone marrow disease when greater than 30% of the marrow is involved. False-negative [^{18}F]FDG-PET scans for bone marrow disease (PET negative, biopsy positive) occur if less bone marrow is involved, in lower-grade histologies, or if the primary nodal disease is not [^{18}F]FDG-avid. Misinterpretation of diffuse [^{18}F]FDG uptake in the marrow due to concurrent systemic illness or recent administration of hematopoietic growth factors can potentially lead to false-positive [^{18}F]FDG-PET scans. This can be avoided by a carefully elicited clinical history.

The addition of [^{18}F]FDG-PET to lymphoma staging procedures correctly alters stage and leads to changes in management in 8–48% of cases [171, 173, 175, 185, 186]. Patients are upstaged more often and consequently receive more

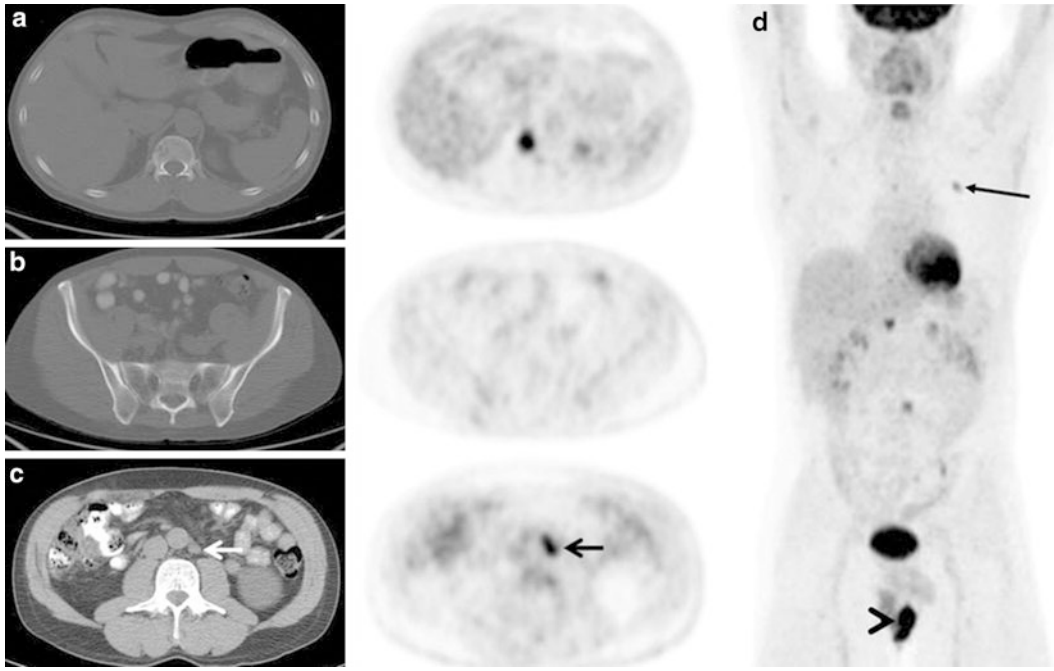

Fig. 3 A 55-year-old man with diffuse large B-cell lymphoma presented for a staging PET/CT scan. A focus of intense [^{18}F]FDG uptake fusing to lytic changes in the right T11 vertebral body is seen (**a**). Biopsy of this lesion confirmed diffuse large B-cell lymphoma. Bone marrow biopsy was negative for lymphomatous involvement. Not surprisingly, the PET scan in the region of standard iliac crest biopsies showed normal marrow uptake. The PET and marrow biopsy were discordant in this case for lymphomatous involvement. Other sites of disease in the marrow were also found in the left rib (**d**, maximum intensity projection image, *arrow*). Additional extra-nodal disease was found in a scrotal mass (**d**, maximum intensity projection image, *arrowhead*), and the only nodal disease was a 1.5 × 1.2 cm left para-aortic lymph node with intense [^{18}F]FDG uptake (**c**, *arrows*). Overall, the findings were consistent with stage IV disease (**a**, *top row*; **b**, *middle row*; **c**, *bottom row*. For **a**, **b**, and **c** – left, CT; right, PET)

aggressive initial therapy; however, downstaging also occurs (Fig. 4). The inclusion of [^{18}F]FDG-PET in the primary staging of lymphoma has substantial impact on patient care. Although this has also been shown to be true for low-grade follicular NHL, the role of [^{18}F]FDG-PET in the staging of other indolent NHLs (i.e., CLL/SLL) may be more limited [187–190].

[^{18}F]FDG-PET/CT Versus PET Alone

A majority of studies investigating the use of metabolic imaging in lymphoma have evaluated [^{18}F]FDG-PET alone. Tatsumi et al. [191] reported that combined [^{18}F]FDG-PET/CT imaging may be better than either modality alone. In 53 patients with lymphoma, 48 of 1,537 findings were discrepant between PET and CT; 40 were correct PET findings, 5 were correct CT findings, and 3 remained uncertain. Nine patients were only staged correctly with PET/CT versus CT alone [191]. Allen-Auerbach et al. [192] found that PET/CT was more accurate than PET alone for the detection of lymphoma (94% versus 84%, respectively). PET/CT improves lesion localization, allows detection of lesions that might be missed by either modality alone, and provides more reliable tumor measurements. Though contrast-enhanced CT with PET can help in improving the sensitivity of detecting nodes and other clinically relevant findings, the impact on patient management is very minimal [193–195]. However, the Lugano classification still recommends contrast-enhanced CT for accurate nodal assessment in the setting of clinical trials, radiotherapy planning, and vascular thrombosis [28].

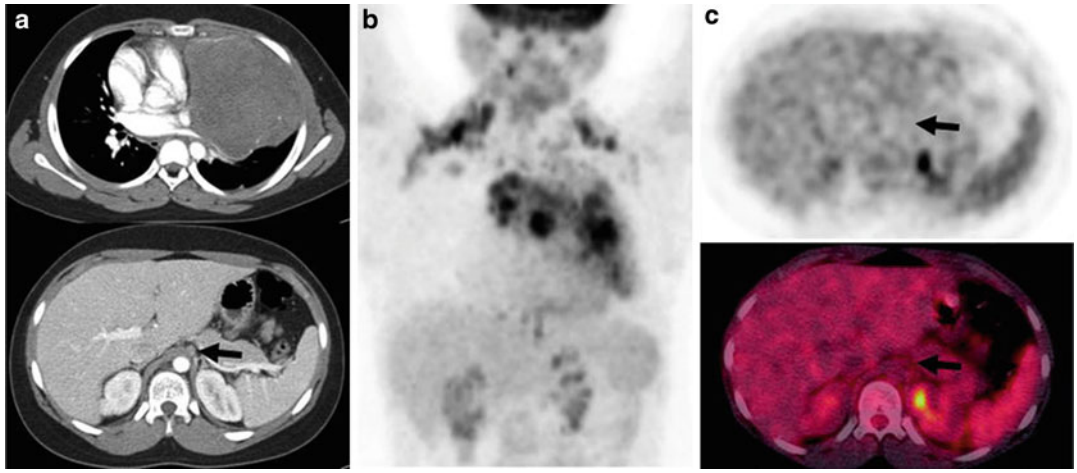

Fig. 4 A 26-year-old man with Hodgkin lymphoma underwent staging procedures. A diagnostic CT scan with intravenous contrast shows the large mediastinal mass (**a** – *right top* and *bottom rows*). There was a borderline abnormal size celiac axis lymph node suspicious for stage III disease (**a** – *bottom row*, *arrow*). The PET/CT scan shows abnormal uptake in the mass and nodes above the diaphragm (**b**), but no abnormal uptake in the celiac axis node below the diaphragm (**c**, *left top* and *bottom rows*, *arrows*). Physiologic renal excretion of [^{18}F]FDG is also seen in the posterior and medial left upper quadrant. The PET downstaged the patient from stage III to stage II, and he received a short course of chemotherapy and radiotherapy (**a**, left column – transaxial IV contrast CT scan slices; **b**, center column – coronal PET image; **c**, right column – transaxial PET (*top*) and fused PET/CT (*bottom*) images)

Post-Therapy Response Assessment by [^{18}F]FDG-PET and PET/CT

Residual masses on anatomic imaging in patients with lymphoma are common post-therapy, but do not always indicate the presence of active malignancy [196]. A major advantage of [^{18}F]FDG-PET is its ability to detect functionally viable tumor cells within the mass, distinguishing active lymphoma from fibrosis/necrosis. The information gained from post-therapy [^{18}F]FDG-PET also provides prognostic information [175, 197–201]. Patients with PET-positive disease post-therapy (Fig. 5) have lower 1- and 2-year progression-free and overall survival rates (0–54%) than those who are PET negative (83–95%) (Fig. 6), regardless of the presence of a residual mass on CT. PET positivity post-therapy predicts subsequent relapse. Therefore, the results of post-therapy [^{18}F]FDG-PET scan have important therapeutic implications.

Despite its improved prognostic implications, a negative post-therapy PET scan does not exclude the presence of residual microscopic disease that falls below the resolution of the PET scanner [175, 197–201]. The resolution of modern PET scanners falls between 0.5 and 1.0 cm [202] which converts to about 10^8–10^9 tumor cells [203]. Patients who are PET negative with a residual mass are more likely to recur than those who are PET negative without residual mass [175, 197–201].

The optimal time to obtain a post-therapy PET is a frequent question of referring oncologists, but the answer is not completely resolved. A minimum of 10 days post-chemotherapy has been recommended to avoid false-negative scans due to the early treatment effect of "stunning" [204]. Longer and more variable times post-external beam radiation have been suggested [205], and optimal interval times post-radioimmunotherapy are beginning to be investigated and discussed in the chapter on radioimmunotherapy [206, 207].

Integration of [^{18}F]FDG-PET and PET/CT into Tumor Response Criteria

[^{18}F]FDG-PET/CT is now an integral component of assessing lymphoma response to therapy. Historically, the first major criteria for assessment of

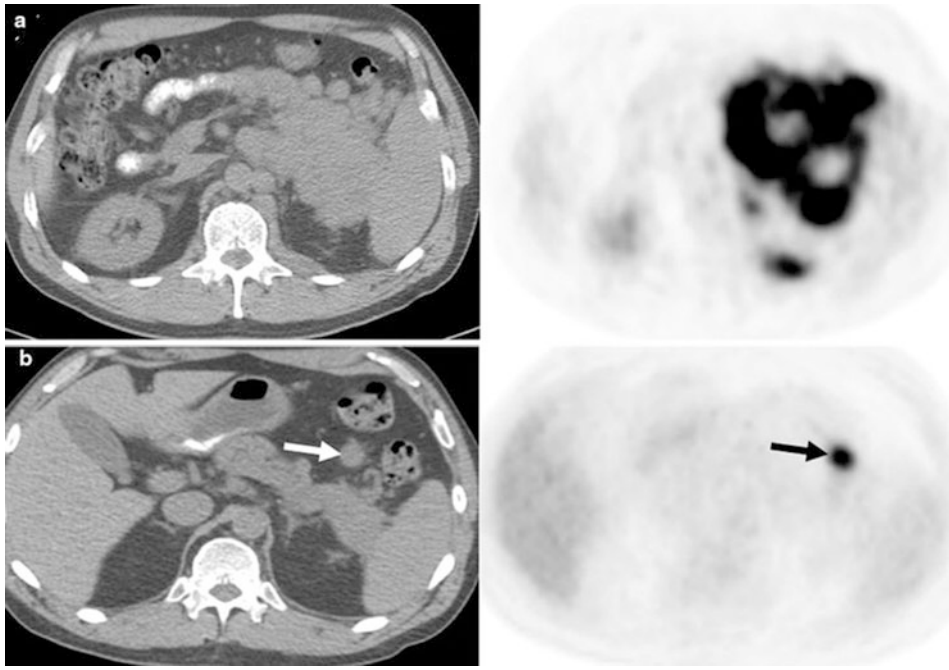

Fig. 5 Pre- and post-therapy PET scans in a patient with diffuse large B-cell lymphoma. The pre-therapy PET scan shows intense [^{18}F]FDG uptake in a left upper quadrant mass, adjacent nodules, and left paravertebral regions (**a**, *top row*). After six cycles of R-CHOP, a 2.3 cm nodule remained in the left upper quadrant with intense [^{18}F]FDG uptake (**b**, *bottom row*, *arrows*) consistent with residual active lymphoma (positive post-therapy PET scan). A positive post-therapy PET scan is associated with a poor prognosis (for **a** and **b** – left, CT; right, PET). In the new Lugano classification and Deauville 5-point scale, this would be rated at score of 5

treatment response in lymphoma were proposed by the International Working Group (IWG) in 1999. Five categories of response were defined based on CT including the category of "complete remission – unconfirmed" for cases with post-therapy residual masses. These IWG criteria [208] were revised in 2007 to include a post-therapy assessment by [^{18}F]FDG-PET [209] based on the numerous studies showing the predictive value of the post-therapy [^{18}F]FDG-PET scan and a retrospective, but pivotal, study in 54 patients with aggressive NHL [210]. In this study, the integrated PET and IWG response criteria more accurately classified lymphoma response by identifying a subset of partial responders by IWG criteria who had a complete metabolic response by [^{18}F]FDG-PET (i.e., PET negative) and a more favorable prognosis [210]. The integrated criteria were subsequently found to be applicable to indolent NHL and HL [211, 212]. At the time of this writing, the most current version of the criteria is the Lugano classification [28].

The Lugano classification was developed to improve both the staging and response criteria for HL and NHL following a workshop held at the 11th International Conference on Malignant Lymphoma in Lugano, Switzerland, in June 2011 and a subsequent workshop at the 12th International Conference on Malignant Lymphoma in 2013 [28].

Although several studies showed the predictive value of interim [^{18}F]FDG-PET/CT (after two to three cycles of chemotherapy) [213–215], it was increasingly realized that the interobserver variability in interpreting the scans and the use of the revised IWG criteria, which were originally designed for end-of-therapy evaluation, resulted in suboptimal evaluation of interim PET/CT. The Deauville criteria were proposed in 2009 for assessment of response on interim [^{18}F]FDG-PET/CT [216, 217]. The Deauville criteria provide a qualitative 5-point scale with uptake in

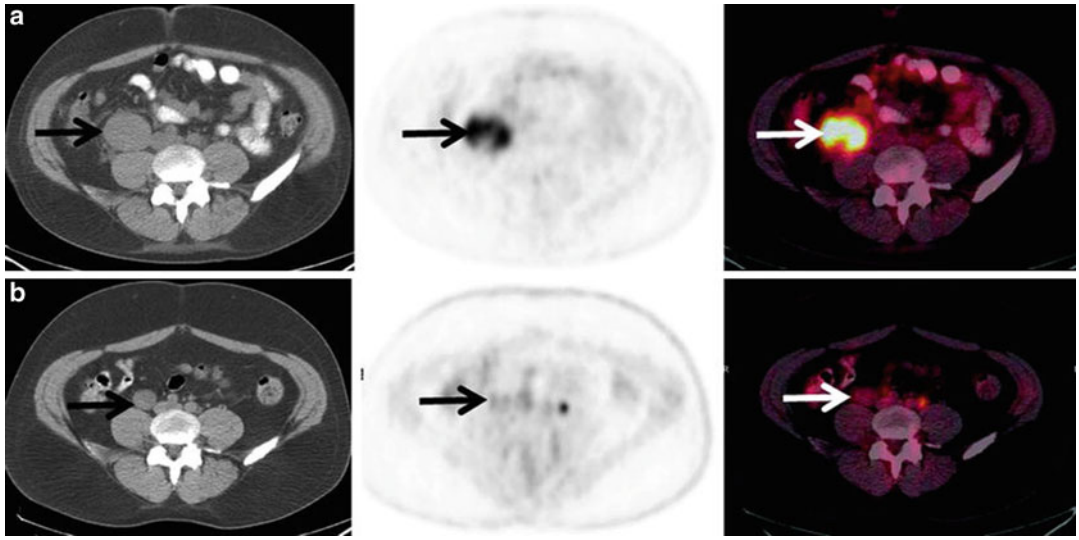

Fig. 6 Pre- and post-therapy PET scans in a patient with diffuse large B-cell lymphoma. The pre-therapy PET scan shows intense [^{18}F]FDG uptake in a right psoas mass (**a**, *top row*). After six cycles of R-CHOP, the PET scan was negative for active lymphoma with tumor uptake equal to background (**b**, *bottom row*). Although residual microscopic disease is not excluded, a negative post-therapy PET scan is associated with a good prognosis even if a residual mass remains on a CT scan. The residual [^{18}F]FDG uptake may be due to post-therapy inflammation (for **a** and **b** – left, CT; center, PET; right, fused PET/CT). In the new Lugano classification and Deauville 5-point scale, this would be rated at score of 2 (Wahl RL, editor. Categorical course in diagnostic radiology: clinical PET and PET/CT imaging, 2007, The Radiological Society of North America [RSNA])

Table 4 Deauville 5-point scale

1	No uptake
2	Uptake $\leq$ mediastinal blood pool
3	Uptake $>$ mediastinal blood pool but $\leq$ liver
4	Uptake moderate $>$ liver
5	Uptake markedly $>$ liver and/or new lesions
X	New areas of uptake unlikely to be related to lymphoma

tumor scored in comparison to mediastinal blood pool and/or liver uptake (Table 4). The prognostic value of Deauville criteria for interim [^{18}F]FDG-PET/CT assessment has been shown in both HL and NHL [218, 219].

In the Lugano classification, the Deauville 5-point scale is the basis for interpretation of both post-therapy and interim [^{18}F]FDG-PET/CT, and there are four categories of response using [^{18}F]FDG-PET/CT for [^{18}F]FDG-avid lymphomas and CT for non-[^{18}F]FDG-avid lymphomas (Table 5). The interpretation of the score depends on the timing of the scan and the clinical scenario. A score of 1 or 2 is interpreted as complete response on both interim and end-of-therapy scans. A score of 4 or 5 is considered a partial response on interim scans if the uptake is less than baseline or as progressive disease if the uptake is greater than baseline. On end-of-therapy PET, a score of 4 or 5 is considered as failure of treatment irrespective of the intensity of uptake compared to baseline. Similarly, a score of 3 is usually considered negative on both interim and end-of-therapy scans, but as an inadequate response in risk-adapted trials evaluating de-escalation strategies. Classification of response based on CT for non-[^{18}F]FDG-avid lymphomas is not significantly different compared to the original IWG criteria in 1999 or the revised IWG criteria in 2007 (Table 5).

Concurrent with the publication of the Lugano classification, the consensus report from the imaging subcommittee of the International Harmonization Project in Lymphoma on the acquisition and interpretation of PET scans that accompanied the revised IWC [220] in 2007 was also updated

Table 5 Lugano Criteria for Response Assessment in Lymphoma

Response	PET/CT[a]	CT
Complete response	Score 1,2,3 with or without residual mass in nodes or extra-nodal sites	Complete disappearance of all sites of disease or decrease in size of nodes to ≤1.5 cm in LDi
Partial response	Score 4 or 5 with decreased uptake compared to baseline and residual masses of any size	≥50% decrease in PPD (single lesion) or SPD of six measurable target nodes and/or extra-nodal sites (multiple lesions); decrease in spleen size >50% in length beyond normal
No response/ stable disease	Score 4 or 5 with no obvious change in [^{18}F]FDG uptake compared to baseline	<50% decrease in PPD (single lesion) or SPD of six measurable target nodes and/or extra-nodal sites (multiple lesions) and no criteria for progressive disease
Progressive disease	Score 4 or 5 with increase in intensity of [^{18}F]FDG uptake compared to baseline or new foci of [^{18}F]FDG uptake compatible with lymphoma	New or increased adenopathy (nodes 1.5 cm > LDi, PPD ≥ 50% from nadir, LDi or SDi increase from nadir by 0.5 cm for lesions ≤2cm and by >1.0 cm for lesions > 2.0 cm), increase in splenic length by >50% of its prior increase from baseline, or by at least 2cm from baseline if no prior splenomegaly, new or recurrent splenomegaly, new nodal or extranodal sites or increase of preexisting nonmeasurable lesions

Notes
[a]Deauville 5-point scale
PET/CT: The interpretation of the score depends on the timing of the scan and the clinical scenario. A score of 1 or 2 is interpreted as complete response on both interim and end of therapy scans. A score of 4 or 5 is considered a partial response on interim scans if the uptake is less than baseline or as progressive disease if the uptake is greater than baseline. On end of therapy PET, a score of 4 or 5 is considered as failure of treatment irrespective of the intensity of uptake compared to baseline. Similarly, a score of 3 is usually considered negative on both interim and end of therapy scans, but as an inadequate response in risk-adapted trials evaluating de-escalation strategies
CT: A measurable node should be 1.5 cm in longest transverse diameter (LDi) and a measurable extranodal site should be 1.0 cm in longest diameter. The longest and shortest (SDi) diameters on the transverse plane of each lesion are multiplied to obtain product of the perpendicular diameters (PPD). Six largest nodes as well as extra-nodal sites which are measurable in two dimensions should be identified from different body regions. The overall disease burden at baseline is quantified by adding the product of the diameters of these six lesions to obtain the sum of the product of the diameter (SPD)

[27]. The general recommendations and major changes from 2007 are summarized in Table 5.

Multiple consensus reports using PET for response assessment (interim and post-therapy) in lymphoma and other tumors stress the importance of obtaining high-quality, standardized PET and CT scans on dedicated PET systems. Detailed discussions on obtaining such scans are found in reports by the National Cancer Institute [221] and the Netherlands multicenter trial group [222] and reviewed in the revised IWC [220] and PET Response Criteria in Solid Tumors (PERCIST) [223].

The use of [^{18}F]FDG-PET for routinely monitoring the response of low-grade follicular and other indolent lymphomas is debatable, but given that the method is more sensitive and specific than CT, it is gaining greater acceptance in clinical practice. Assessments of lower-grade/ indolent lymphomas that are [^{18}F]FDG avid with PET/CT are now included in the new Lugano classification [27, 28].

Interim PET and Risk-Adapted Therapy

Theory and Biologic Basis

Chemotherapy of tumors begins to affect tumor metabolism soon after it is started. In 1993, PET was used sequentially to assess breast cancer response to chemohormonotherapy, and decreases in the amount of [^{18}F]FDG uptake in responding tumors were seen by 8 days into treatment [224]. The clear predictive value of PET in the post-

therapy setting for patients with lymphoma has led investigators to evaluate its usefulness earlier during the course of chemotherapy, and numerous studies have upheld PET's prognostic value in the interim therapy setting [225–231]. Event-free survival (EFS) is consistently lower in patients with positive interim PET scans (0–46%) compared to those with negative interim scans (62–98%), despite variability in the study designs (prospective vs. retrospective, chemotherapy cycles, qualitative vs. quantitative PET assessments), tumor histologies, and treatments employed. This body of work, including a landmark study by Gallamini et al. [34] (discussed below), is the premise for risk-adapted therapy for patients with lymphoma.

Importantly, Gallamini et al. [34] showed that in 190 patients with advanced HL, the results of early interim PET after two cycles of ABVD chemotherapy were more predictive than the widely used and validated IPS. As previously discussed, the IPS for HL and IPI for NHL are both currently used to guide management decisions. Both indices are based solely on pretreatment parameters and do not consider the inherent "chemosensitivity" of the tumor or the rate of tumor kill which are both related to outcome, but PET can assess both of these factors [203].

The conceptual framework for PET providing an early readout on "chemosensitivity" is nicely discussed by Kasamon, Jones, and Wahl, and two underlying points are summarized [203, 232]. First, chemotherapy is expected to kill the same percentage of cells during each cycle (first-order kinetics) [233]. For example, 11 cycles of chemotherapy are needed for cure with 10^{10}–10^{11} cancer cells. Second, due to the lower limit of resolution for current scanners, PET can only detect the initial logs of cell kill. A negative scan after therapy either means cure or residual microscopic disease. A true-negative interim therapy (or soon post-therapy) scan implies that the rate of kill is fast enough to achieve cure by the end of therapy, whereas a positive interim therapy scan does not [203, 232].

The logical question follows, "Can the prognostic information from an interim therapy PET scan be used to improve therapeutic strategies for patients based on their individual risk, hence risk-adapted therapy?" And this can be considered in two ways. First, should therapy be intensified to improve the chance of cure in a patient with a positive interim PET scan as cure is unlikely with the initial therapy? On the other hand, is it safe to omit or decrease therapy in a patient with a negative interim scan? As alluded to in the section above on treatment for early-stage HL, this second option is particularly attractive to reduce the long-term toxicities from therapy in this otherwise curable population.

To date, there are a small number of published trials, but an even larger number of ongoing trials that are investigating these questions. These trials are reviewed and limitations of the use of interim therapy PET for risk-adapted therapy discussed. Until the results of these trials are available and more mature, interim PET scanning and risk-adapted therapy should be performed in the clinical trial setting [209].

Clinical Trials of Risk-Adapted Therapy for Aggressive NHL

A negative interim PET/CT performed after two to three cycles of chemotherapy has been shown to predict a favorable outcome. Kasamon et al. [234] published a phase II study in 59 patients with aggressive NHL, hypothesizing that suboptimal response on interim PET (PET positive) was a sign of chemoresistance and that intensifying therapy in this group of patients would improve their outcome. After two to three cycles, R-CHOP chemotherapy was continued for a negative interim PET (tumor uptake $\leq$ mediastinal blood pool) or intensified to high-dose therapy and autologous stem cell transplant (ASCT) for a positive interim scan (tumor uptake $>$ mediastinal blood pool). On an intent-to-treat basis and at median follow-up time of 34 months, 2-year event-free survival (EFS) was 67% (95% CI 53–86%) in patients with positive interim PET versus 89% (95% confidence interval 77–100%) for negative interim PET. The IPI was not associated with the interim PET result. The outcome of the PET-positive group compared very favorably to historical controls where $<$20% PFS was expected[174]. In another study of 103 patients

with untreated DLBCL who were treated with CHOP with or without rituximab, a negative PET after four cycles of treatment was associated with 5-year EFS of 80% compared to 36% for patient with positive PET [235].

The predictive value of interim PET in DLBCL is, however, less clear as few studies have shown that interim PET can be falsely positive and associated with favorable outcome [236, 237]. Moskowitz et al. [236] performed a phase II study of risk-adapted therapy in advanced DLBCL, but with a slightly different strategy. The treatment scheme was dose-dense R-CHOP followed by PET after four cycles. PET-negative patients received ifosfamide, carboplatin, etoposide (ICE) alone for three more cycles. All PET-positive patients underwent biopsy, contrary to Kasamon's study, and received two cycles of ICE. If the biopsy was negative, an additional cycle of ICE was given, but if positive, therapy was intensified to R-ICE, high-dose therapy, and ASCT. Interim PET scans were positive in 38 of 97 patients. Five of these 38 patients had a positive biopsy for tumor and proceeded to ASCT. The remaining biopsies showed inflammation. At a median of 44 months of follow-up, EFS was not significantly different between interim PET-negative patients and PET-positive/biopsy-negative patients. Three of the five patients who underwent ASCT were alive and progression free at the time of publication.

Possible explanations offered for the high "false-positive" rate on PET were dose-dense initial therapy, increased inflammation due to greater use of rituximab than in prior studies, interim scan occurring relatively soon, a median of 12 days after last therapy (although longer than minimal recommendation of 10 days [220, 221]), the reader threshold for determining "positivity" of a scan, and consolidation to ICE for all patients [236]. The authors concluded and recommended that biopsy be performed to confirm interim-positive PET scan findings prior to treatment intensification to ASCT [236]. It is also possible that false-negative biopsies occurred. It should be noted there is little data on the predictive value of biopsy in this setting. In another study of 88 patients with newly diagnosed DLBCL treated with R-CHOP, there was no significant difference in the 2-year PFS between patients with negative and positive interim PET. The end-of-therapy PET was highly predictive of the 2-year PFS [237].

Clinical trials in aggressive NHL have primarily focused on intensification of therapy if the interim scan is positive and exploring findings of the previous risk-adapted trials. The results of the ECOG 3404 study were recently published [238]. This study evaluated interim PET response-based strategy of switching patients to R-ICE chemotherapy after three cycles of R-CHOP. The interim PET was scored as positive or negative by central review. A 2-year PFS of $\geq$45% was the target response in the interim PET-positive group. The scans were interpreted using customized binary criteria (ECOG criteria). The study enrolled 74 patients and only 16% of patients had a positive interim PET. A rereview of the interim scans by an expert panel was performed due to the low number of the positive scans. Nearly 30% of the interpretations were discrepant among the readers highlighting the need for more accurate scoring system or possibly precise quantitation of the images. The 2-year PFS was 76% in the interim PET-negative group and 42% in the interim PET-positive group treated with R-ICE. The authors concluded that the poor outcome of patients with interim PET positivity despite intensification of therapy indicates innate resistance to treatment and that until further evidence is available, treatment modification in DLBCL patients based on early PET should remain restricted to clinical trials [238].

The current NCCN guidelines also state that treatment modification of DLBCL patients should not be guided by interim PET scan results. Any modifications should be performed only after conforming real positivity on repeat biopsy of residual masses [88]. The demonstration of true benefit of therapy intensification for those with a positive interim PET scan is limited by comparison to historical controls and the lack of randomization to standard versus experimental therapy in the above phase II trials. An ongoing study in Germany, Positron Emission Tomography Guided Therapy for Aggressive Non-Hodgkin's Lymphomas (PETAL), attempts to address this [239]. In this study, patients with positive PET scans are

randomized to either six additional cycles of R-CHOP or a more intense Burkitt's lymphoma regimen. For those randomized to R-CHOP, two additional cycles are given (total eight cycles) compared to those who have a negative interim PET scan (total six cycles). The interim results of this trial have shown relapses more often in patient with positive interim PET than patients with negative interim PET [240]. Recruitment into this trial is ongoing, and the results should provide further insight into the usefulness of PET in the interim setting for aggressive NHL.

Clinical Trials of Risk-Adapted Therapy for Hodgkin Lymphoma

Risk-adapted therapy is also a major focus of research trials for patients with HL. For those with early, unfavorable, or advanced disease, the approach is generally similar to NHL, intensification of therapy based on a positive interim scan. For those with early-stage disease, therapy de-intensification after a negative interim PET is undergoing ongoing evaluation in attempt to reduce the risk of late-term complications from potentially excessive therapy.

There are several trials evaluating risk-adapted strategies in early-stage favorable HL. The interim results of the EORTC/LYSA/FIL H10 trial evaluating the non-inferiority of omitting radiotherapy in early interim PET-negative patients with early HL have been published [42]. A total of 1,137 patients were recruited in the study and assigned to standard and experimental arms. Nine hundred patients (favorable = 381 and unfavorable = 519) had interim PET-negative disease. Interim futility analysis showed that in both favorable and unfavorable groups, the experimental arm (chemotherapy alone) had a greater number of relapses or early progression compared to the standard arm (standard chemotherapy and radiotherapy). Based on these results, the independent data monitoring committee recommended closure of accrual to the PET-negative experimental arm. The UK RAPID trial was a phase III trial which also evaluated the non-inferiority of no further treatment versus involved-field radiotherapy in patients with a negative interim PET [241]. Of the 571 patients who underwent PET scanning in the study, 74.6% patients had negative PET. The 3-year PFS and OS in the no further treatment group ($n = 211$) were 90.8% and 99.0%, respectively, compared to 94.6% and 97.1%, respectively, in the radiotherapy group ($n = 209$). Overall, the study concluded that the strategy of no further treatment was not non-inferior to consolidation radiotherapy although the prognosis was very good in both arms with or without radiotherapy. That said, it appears that the possible benefits of radiotherapy were quite modest relative to the number of patients that needed to receive the treatment.

Dann et al. [242] performed a prospective study of risk-adapted BEACOPP therapy in 108 patients with intermediate- and high-risk HL. Treatment was adapted based on pretreatment risk factors (standard BEACOPP for intermediate-risk disease or escalated BEACOPP for high-risk (IPS $\geq$ 3) disease) and then escalated or de-escalated based on interim functional imaging with gallium-67 or PET after two cycles. With this schema, 5-year EFS and OS were not different between the intermediate- and high-risk groups at a median of 47 months of follow-up. In the high-risk group ($n = 39$), 31 (79%) had therapy de-escalated for negative interim scintigraphy, and the negative predictive value of interim PET was 93%. The authors suggested that it may be feasible to de-escalate therapy in a high-risk group based on negative interim PET. Only 4 of 19 patients (21%) with a positive interim PET scan had progressed at last follow-up (median 47 months). Several additional ongoing trials of risk-adapted therapy for advanced-stage HL, mostly therapy intensification with positive interim PET, are in references [243–245].

The interim data of the response adapted therapy in advanced HL (RATHL) have been recently published [246]. The results of the study indicate good agreement between readers while using the 5-point scale for interim PET assessment. The final results on the role of interim PET in treatment adaptation are awaited.

In the yet-to-be-published GITIL/FIL HD0607 trial, the role of early intensification of therapy in advanced-stage HL patients with positive interim PET has been evaluated [247]. Patients with positive PET after two cycles of ABVD were treated with BEACOPP escalated and BEACOPP baseline (4 + 4) without or with rituximab. On the other hand, patients with negative interim PET received four cycles of ABVD with or without RT. Of the 446 patients with interim PET, 20% had positive scans. Response to treatment was assessed in a cohort of 263 patients (15% with positive interim PET and 84% with negative interim PET). Complete response to treatment was seen in 73% of PET-positive patients and 95.5% of PET-negative patients [247]. The results of many other trials are awaited.

Interpretation of Interim Therapy PET Scans

Most risk-adapted therapy trials have employed qualitative analyses (i.e., visual scales) for interpreting interim PET scans as positive or negative. Several have been used (Juweid et al. [220], ECOG [248] and London criteria [249]), and these scales have evolved over the years. As indicated in the section above, the Deauville criteria are currently used in the interim setting (give Lugano reference).

Cases of [^{18}F]FDG uptake in tumor much less or much greater than background are clear-cut as negative or positive; however, [^{18}F]FDG uptake in tumor occurs along a continuum. Most of the difficulty arises in the concept of "minimal residual uptake" (MRU) and the optimal definition of "background" (and thus the cutoff point for a positive vs. negative scan) in the interim setting. MRU was first defined in 2000 as low-grade uptake on posttreatment PET within an area of previous disease, reported as likely inflammation but where a small volume of malignancy cannot be excluded [250]. The definition of MRU has been adapted slightly over recent years by different investigators, hence the variable criteria and interpretation of interim PET scans for studies of patients with NHL and HL.

In a study of aggressive NHL, Kasamon et al. [234] found that 56% of patients had a positive interim PET scan using mediastinal blood pool as a comparator. In the follow-up ECOG study (E3404), a centralized PET review by a single reader took place, and the rate of positive interim PET scans was lower than expected. As a result, evaluation of the reproducibility of interim PET interpretation took place [248]. Three expert PET readers scored baseline and interim PET scans from 38 patients on E3404 using the ECOG and London criteria without additional training. Only moderate reproducibility among the experts was found for interpreting the interim scans ($k = 0.44$ for ECOG criteria and $k = 0.50$ for London criteria).

The sources of disagreement were lesions in the para-aortic region, bone, and spleen [248]. These sites of disagreement are not completely unexpected as the spleen and bone marrow can have considerably heterogeneous uptake post-therapy due to treatment effects.

On the other hand, Barrington et al. have reported very good agreement among four centers in Europe for interpretation of interim PET using the London criteria (RATHL trial) [249]. The interim PET scans were read independently by the participating centers and then in consensus. The kappa values showed very good agreement for negative (uptake less than or equal to the liver) vs. positive (uptake moderate or markedly increased versus the liver) scans for both the independent ($k = 0.85$, 95% CI 0.74–0.96) and consensus readings ($k = 0.90$, 0.79–1.00) [249]. Agreement was slightly less for independent reads when the category of "uptake greater than mediastinal blood pool but less than liver" was considered separately (from negative or positive). The updated results of the RATHL study made similar conclusions. There was good agreement in the interpretation of the interim PET scans using the Deauville 5-point scale (5-PS) among experts ($k = 0.84$, 0.76–91) and between experts and local readers ($k = 0.77$, 0.68–0.86) [246].

Some uncertainty does remain in the optimal cutoff for altering therapy based on interim PET. Mikhaeel et al. showed that for patients with early-stage NHL, the MRU survival curve lies closer to those who have a negative interim PET, but in late-stage disease, the MRU curve lies closer to the PET-positive curve [230]. The significance may vary based on a combination of factors, including clinical stage, lymphoma subtype, and benefits and risks of the impending therapeutic decision. The use of semiquantitative parameters like the standardized uptake value (SUV) may be helpful in the interim setting to help reduce the variability if PET is performed using standardized methods.

Lin et al. [251] found that in patients with DLBCL, a decline in maximum SUV of >65.7% after two cycles of therapy better predicted outcomes versus visual assessment by reducing the number of false-positive scans. These results did not hold, however, in a subsequent study where PET was performed after four cycles of therapy [252]. Optimal methods for assessing PET may be also be dependent on timing of the scan.

Standardized response criteria for interim PET scanning and the results of the many ongoing trials will hopefully provide the necessary data to determine if risk-adapted therapy is possible and beneficial for individual patients. At the present time, most experts agree that changes in therapy based on interim therapy PET (except for progressive disease) should currently be kept in the context of clinical trials. The current NCCN guidelines recommend interim PET scan assessment with Deauville criteria in both early-stage favorable and advanced-stage disease [10]. In a large retrospective multicenter study published recently, the reproducibility of Deauville 5-PS for interpretation of interim PET was assessed [253]. The study included 260 patients with early-stage unfavorable or advanced-stage HL treated with chemotherapy with or without consolidation radiotherapy. The interim PET scans were positive as per Deauville criteria in 17.3% patients. A three-year PFS was 28% for interim PET-positive patients compared to 95% for PET-negative patients. Interim PET had sensitivity and specificity of 73% and 94% for predicting outcome. There was strong concordance among reviewers while using the Deauville criteria (Cohen's kappa 0.69–0.84) [253].

Full quantitation of images holds the potential to reduce variability among readers, but will require further study.

Surveillance PET for Lymphoma

In HL and aggressive NHL, early detection of relapse is desirable in order to initiate treatment when tumor burden is low. This may increase the chance of successful disease eradication, which ultimately may lead to better outcomes. Several studies have shown that recurrence of lymphoma is often diagnosed by the presence of clinical symptoms before detection or confirmation by imaging [254–256]. PET offers a potential benefit over anatomic imaging for earlier disease detection, but this must be balanced with considerations of radiation exposure to the patient and cost from the increased number of scans obtained during surveillance.

The current literature on the use of [^{18}F]FDG PET for follow-up of patients with lymphoma is limited. However, it does confirm the ability of PET to detect relapse before the patient becomes symptomatic and before anatomic imaging becomes positive, by up to 9 months in one study [257]. PET is also useful for detecting relapse in the setting of a persistent, unchanging residual mass on CT in the follow-up period [258]. For patients who achieve a complete remission after therapy, the negative predictive value of PET for excluding relapse in the follow-up period is high (99–100%) [257–259].

The major limitation of surveillance PET has been a high false-positive rate (low positive predictive value, 11–53%) in several studies [257–259]. This is particularly true in the pediatric population of patients where cure rates are high and the incidence of recurrent disease is low. In the study by Rhodes et al. [258], false-positive results occurred due to reactive neck lymph nodes. Another contributing factor to these high false-positive rates was that PET alone was used, and conditions such as rebound thymic hyperplasia or brown fat were recorded as positive for disease recurrence. This is

much less likely to occur in the current era of PET/CT and as we have gained knowledge in interpretation of post-therapy PET in patients with lymphoma.

Zinzani et al. [260] prospectively performed follow-up PET scans (every 6 months for 2 years and then yearly) in 421 adult patients with lymphoma who achieved a complete response by PET after therapy (160 with HL, 183 with aggressive NHL, 78 with indolent NHL). For HL and aggressive NHL, the number of true-positive scans decreased and true-negative scans increased with time. The incidence of relapse was stable over time for those with indolent NHL, as might be expected. Compared to the prior studies in pediatrics, the false-positive scan rate was low (~1% of 1,789 scans). However, eight percent of patients had inconclusive-positive PET scans, two-thirds with concurrent negative CT scans, and biopsy was important to confirm disease presence in these patients. Most patients with inconclusive negative scans did not relapse [260].

The early studies did show that there may be a subgroup of patients for whom PET might be useful for surveillance. Rhodes et al. [258] suggested that those children with residual masses or unchanging abnormal CT scans might benefit the most from surveillance PET scanning. Zinzani et al. [260] also found that PET positivity was more common in groups with a higher risk of recurrence by prognostic factors for all lymphoma types. These findings are further supported by a more recent study by Petrausch et al. who found that the usefulness of PET for surveillance may be related to risk factors at the time of scanning [261, 262].

Petrausch et al. [262] evaluated 134 patients with HL in remission after first-line therapy that had at least one follow-up PET scan. The predictive value of follow-up PET for detecting recurrence was 98%, all with histologic confirmation. Symptoms at the time of PET, residual mass on CT, and advance stage of disease were risk factors for recurrence. Median recurrence-free survival decreased with the presence of an increasing number of these three risk factors, and importantly, no asymptomatic patient with early-stage disease and no residual mass on CT had evidence of recurrence on PET at a mean follow-up of 38 months. Interestingly, patients with a residual mass were more likely to show recurrence on a PET scan done in the first 24 months of follow-up, whereas after 24 months, the presence of symptoms at the time of PET scanning was more predictive of recurrence. The authors concluded that while PET reliably detects recurrent HL, follow-up with PET/CT may best be based on risk factors. This approach would consider the important concerns of increasing radiation exposure due to medical imaging as well as economic cost.

In summary, the current evidence does not support the routine use of PET for follow-up of patients with lymphoma, and PET is not included as part of routine follow-up in current clinical guidelines [10, 99]. The Lugano criteria accordingly do not recommend routine surveillance imaging especially in patients with HL and DLBCL [28]. In patients with clinical signs and in the setting of clinical trials, a CT scan can be performed for follow-up. For indolent lymphomas, the Lugano criteria recommend judicious use of follow-up scans [28]. Emerging data suggests that PET for surveillance is possibly beneficial for a subset of patients as discussed above. More studies are needed to further define this subset and to evaluate the effects of follow-up PET on patient management, outcomes, and cost-effectiveness. Additionally, since CT surveillance is commonly applied and since PET/CT is more accurate than CT in nearly all studies, logical widespread clinical practice includes using PET/CT for follow-up of patients with NHL, especially those at high risk for recurrence.

Tracers Beyond [^{18}F]FDG

Although [^{18}F]FDG is the only current PET tracer approved and routinely used in the evaluation of patients with lymphoma, several radiolabeled amino acid tracers have also been investigated. Carbon-11 methionine ([^{11}C]methionine), an essential amino acid needed for protein and polyamine synthesis and transsulfuration and transamination reactions, has also been evaluated in a limited number of studies [167, 263–266]. [^{11}C]Methionine is taken

up by all grades of lymphoma (HL and NHL) with a reported sensitivity of 97% for disease detection in a single study of 32 patients [265]. The continuum of uptake between low- and high-grade NHL seen with [^{18}F]FDG is not as apparent with [^{11}C] methionine using semiquantitative measures like SUV, but can be found with more intensive kinetic analysis [265]. [^{11}C]Methionine performed equally well compared to [^{18}F]FDG for staging lymphoma, and uptake in untreated patients was not associated with outcome [265, 266]. Other limitations of [^{11}C] methionine are the need for an on-site cyclotron due to the 20 min half-life of ^{11}C and normal biodistribution in abdominal organs obscuring tumor sites. A current study at St. Jude Children's Research Hospital, Memphis, TN, is investigating methionine PET in a variety of tumor types, including lymphoma [267].

More recently, the thymidine analog 3′-^{18}F-3′-deoxythimidine (^{18}F-FLT) has been investigated [268–270]. ^{18}F-FLT uptake reflects thymidine kinase activity and the fraction of cells in S-phase and is an indirect measure of proliferation [269]. In the first human studies, ^{18}F-FLT uptake was observed in indolent and aggressive NHL which was slightly less than [^{18}F]FDG uptake in lymphoma lesions [268, 269]. ^{18}F-FLT discriminated indolent from aggressive NHL (area under the curve 0.98) better than [^{18}F]FDG (area under the curve 0.78) [269]. There was a high correlation between ^{18}F-FLT SUV and the proliferation index Ki67 [269]. One limitation of ^{18}F-FLT imaging in lymphoma is the high normal accumulation of the tracer in several normal organs (hematopoietic bone marrow, liver, spleen) but particularly the hematopoietic bone marrow (SUV 6–12 range) [268, 269] where disease may be missed [269].

Kasper et al. [271] prospectively evaluated 48 patients with HL ($n = 15$) and NHL ($n = 10$ indolent, $n = 23$ aggressive) at the end of chemotherapy to test the prognostic ability of ^{18}F-FLT PET and [^{18}F]FDG-PET in this setting. The authors reported that both tracers were predictive of outcome (PET positive = worse prognosis) and the combination of tracers did not provide additional information. However, the study is limited in that very heterogeneous treatment regimens were used.

Several preclinical models have shown that ^{18}F-FLT PET may be useful for evaluating early response of lymphoma to therapy [272–276]. Reduced proliferation was shown as soon as 24 h after cytotoxic therapy in one high-grade lymphoma xenograft mouse model [275]. The time course and extent of the anti-proliferation effect may be dependent on the agent employed [272, 273, 275]. For example, a transient rise in ^{18}F-FLT uptake (after a 2-day decline) was observed in a mantle cell mouse model of NHL after mTOR inhibition with rapamycin [272]. The pattern of ^{18}F-FLT uptake partially paralleled cyclin D1 expression. Larger declines in ^{18}F-FLT uptake were seen after cytotoxic therapy than after immunotherapy in animal models and in a single human study [272, 275].

These results are promising, and there are several ongoing clinical trials further evaluating the safety and role of ^{18}F-FLT PET in patients with lymphoma. Some are assessing the overall safety and usefulness of ^{18}F-FLT PET and include patients with lymphoma and other hematologic or solid tumors [277–279]. In a recent prospective study of 65 patients with aggressive lymphoma treated with four cycles of R-CHOP and three cycles of ICE, ^{18}F-FLT PET was performed at baseline and after one to two cycles of chemotherapy and [^{18}F]FDG-PET at baseline, after cycle 4 and at end of therapy. The study found that interim ^{18}F-FLT PET was predictive of PFS and OS. Interim ^{18}F-FLT PET had high negative predictive value for identifying patients with good prognosis. However, the positive predictive value though slightly better than [^{18}F]FDG-PET was still very low. Volumetric parameters were not associated with PFS and OS. The study concluded that ^{18}F-FLT PET could help design risk-adapted therapies due to the high negative predictive value [280].

Additional Challenges and Limitations in the Interpretation of [^{18}F]FDG-PET in Lymphoma

The [^{18}F]FDG-PET and PET/CT techniques have limitations, and confounding factors can make image interpretation challenging. As previously

stated, the system resolution of the scanner limits the ability of both [^{18}F]FDG-PET and PET/CT to detect small lesions. Most modern scanners have resolutions of about 0.5–1 cm [202]. Larger lesions are not only more readily detected, but quantification of tumor metabolism and tumor size is more reliable.

False-positive PET studies can occur due to inflammation or infection [281, 282]. In patients with lymphoma, this is of greatest concern post-therapy (chemotherapy or radiation). New [^{18}F]FDG-avid foci remote from sites of initial disease must be interpreted with caution, particularly if known tumor foci have responded to therapy (Fig. 7, lung infection from RSNA syllabus – copyright requested and pending). Comparison to a baseline study and attention to interval clinical history, for example, recent infections, trauma, and blood counts, are very helpful in the post-therapy evaluation for this purpose.

Adjunctive hematopoietic cytokines reduce the incidence of chemotherapy-induced neutropenia and its associated infectious complications in patients with nonmyeloid malignancies. Granulocyte colony-stimulating factor (G-CSF) administration before [^{18}F]FDG-PET scanning results in altered [^{18}F]FDG biodistribution, such as increased [^{18}F]FDG visualization in the bone marrow and spleen [283, 284]. Consequently, disease in or just adjacent to the bone marrow or spleen may be masked. In these cases, review of images at multiple intensity levels on the computer screen and anatomic images for abnormalities helps the reader to avoid misinterpretation. In addition, G-CSF may decrease the bioavailability of [^{18}F]FDG for (residual) tumor which could result in underestimation of the amount of residual disease post-therapy [283]. The effects of G-CSF are most pronounced closer to the time of administration, but can last up to 28 days [284]. As with chemotherapy, it is probably

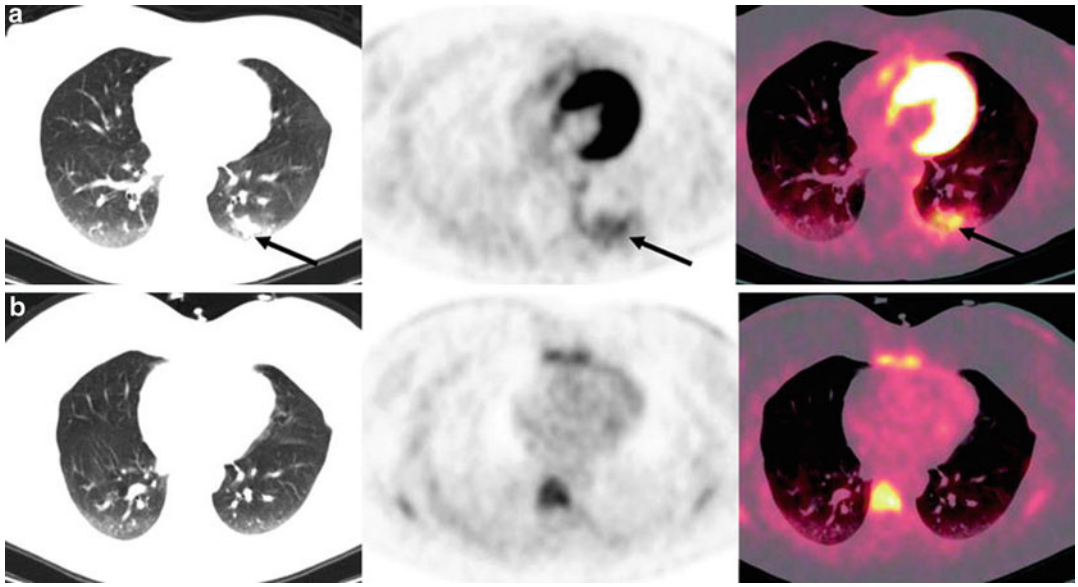

Fig. 7 Reprinted with permission from Jacene [288]. A 54-year-old female with a history of non-Hodgkin lymphoma status post six cycles of rituximab and chemotherapy presented for a post-therapy [^{18}F]FDG-PET/CT scan (**a**). The scan revealed complete resolution of all sites of disease seen on her baseline study; however, a new focus of activity fusing to left lower lobe opacity was identified (*arrow*). Because of the otherwise excellent response to chemotherapy and location of the new finding outside the initial sites of disease, an inflammatory etiology was suspected. The patient returned for a follow-up [^{18}F]FDG-PET/CT scan 3 months later (**b**). The [^{18}F]FDG activity and lung opacity resolved and no new foci of [^{18}F]FDG activity to suggest recurrent lymphoma were visualized, confirming the likely inflammatory etiology (left, CT; center, PET; right, fused PET/CT)

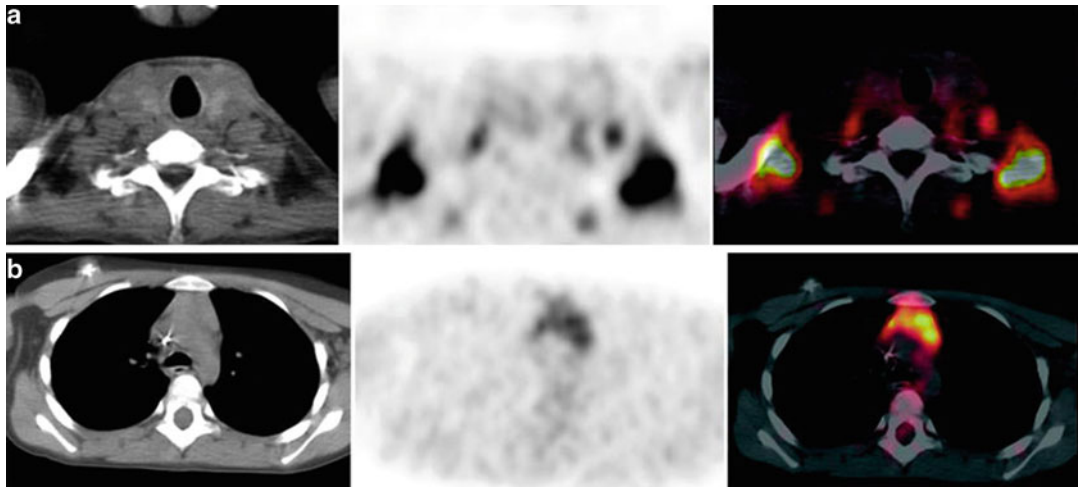

Fig. 8 Reprinted with permission from Jacene [288]. (**a**) Intense [^{18}F]FDG activity fusing to fat on the CT scan is a typical pattern for physiologic hypermetabolism in *brown* fat. (**b**) [^{18}F]FDG uptake in the anterior mediastinum in a triangular shape and fusing to thymic tissue is a typical pattern of thymic hyperplasia (*left*, CT; *center*, PET; *right*, fused PET/CT) (Wahl RL, editor. Categorical course in diagnostic radiology: clinical PET and PET/CT imaging, 2007, The Radiological Society of North America [RSNA])

ideal to wait a minimum of 7–10 days after G-CSF administration before obtaining a post-therapy PET, but the therapeutic schedule should be considered and not delayed. Erythropoietin also increases [^{18}F]FDG uptake in the bone if administered just prior to scanning [285].

Other common causes of false-positive PET scans include physiologic [^{18}F]FDG uptake in thymic hyperplasia [286] and brown adipose tissue (brown fat) [287] (Fig. 8, from RSNA syllabus – copyright requested and pending). Experience, pattern recognition and/or combined PET/CT imaging aids image interpretation in both instances. Typically, thymic uptake is visualized in the anterior mediastinum and has a triangular shape. On combined PET/CT imaging, the [^{18}F]FDG uptake fuses to thymic tissue in the anterior mediastinum. Brown fat was first identified in the head, neck, and supraclavicular regions as foci of intense [^{18}F]FDG uptake that fuse to fat on CT [287]. It has also been visualized in the mediastinum and abdomen. In patients with lymphoma, hypermetabolism in brown fat and involved lymph nodes can coexist, and combined [^{18}F]FDG-PET/CT imaging is essential for proper interpretation.

Summary

[^{18}F]FDG-PET is a useful noninvasive imaging modality for the evaluation of patients with both HL and NHL. A baseline PET/CT scan is more accurate for primary lymphoma staging than anatomic imaging, and obtaining one often facilitates future interpretation of post-therapy scans by defining the initial sites of disease. Post-therapy PET provides valuable functional and prognostic information and is probably most beneficial in patients with initially [^{18}F]FDG-avid tumor. Post-therapy scan results can help define future management decisions as curative or palliative. Knowledge of lymphoma type and clinical history (interval therapy, surgery, concurrent illness, and drug administrations) is critical for accurate image interpretation.

Currently, interim PET scans are best utilized in the clinical trial setting where results can influence decisions along a management tree. Numerous clinical trials are ongoing evaluating interim PET scanning, and the results of these studies should provide further insight into the optimal use of PET/CT for "risk-adapted" therapy. Work on standardization of PET response criteria is ongoing.

Abstract

Multiple myeloma represents about 1.8% of all cancers and 10% of all hematologic malignancies.

Multiple myeloma (MM) is the most common primary bone cancer. The clonal proliferation of malignant plasma cells in the bone marrow may result both in local growth and in systemic effects due to the overproduction of a monoclonal protein (M-protein). Plasma cell proliferation is linked to a variety of clinical presentations of the disease, ranging from simple monoclonal gammopathy of undetermined significance (MGUS) to smoldering myeloma (SMM) to full-blown "malignant" MM. MM differs from MGUS and SMM by the presence of the end-organ damage associated with a complex syndrome named CRAB. However, in the updated version of the criteria for the diagnosis of plasma cell proliferative disorders established by the International Myeloma Working Group (IMWG), more specific criteria have been established to define MM, MGUS, and SMM. Excess bone marrow plasmacells, M-protein, osteolytic bone lesions, renal disease, and immunodeficiency constitute the pathophysiologic bases of the clinical manifestations of MM. Severe bone pain, pathologic fractures, spinal cord compression, and hypercalcemia are caused by lytic bone lesions. The course of MM is highly variable, and the clinical behavior is remarkably heterogeneous. Many studies have identified prognostic factors capable of predicting this heterogeneity in survival (serum β2-microglobulin, albumin, C-reactive protein, and lactate dehydrogenase). The standard workup of MM is based on a number of laboratory tests that are utilized for risk stratification. The International Staging System (ISS) is a powerful and reproducible three-stage classification in which the ISS3 class is associated with the poorest outcome. Imaging studies demonstrate the extent and severity of bone involvement (intramedullary/extramedullary, site and number of lesions) at baseline, including disease-related complications, such as pathologic fractures; they also serve to assess response to treatment and provide follow-up surveillance. The ISS introduced over 25 years ago is mainly based on serum β_2-microglobulin and albumin levels, without any reference to the presence of bone lesions or to the methodology employed

for their evaluation. Although the ISS serves as a prognostic indicator rather than as an accurate scoring system, it adequately estimates tumor burden and risk stratification, allowing differentiation of MGUS and SMM from MM. In 1975 Durie and Salmon introduced a clinical staging system based on the presence of bone lesions to grade the severity of the disease. While the original Durie and Salmon system was essentially based on the use of planar x-ray for evaluating bones, a newer version, the PLUS system was released in 2005 to improve the accuracy of staging with advanced imaging modalities such as [^{18}F]FDG-PET/CT, and MRI.

Keywords

Multiple myeloma • Bone tumor • Multimodality imgaging • Hematological malignancy

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-d-glucose
^{68}Ga-DOTATOC	^{68}Ga-DOTA-octreotide
^{99m}Tc-HMPAO	^{99m}Tc-Hexamethylpropyleneamine oxime
^{99m}Tc-MDP	^{99m}Tc-Hydroxymethylene diphosphonate
^{99m}Tc(V)-DMSA	^{99m}Tc-Labeled pentavalent dimercaptosuccinic acid
ABCB 1	Member 1 of the adenosine triphosphate binding cassette superfamily B, also known as multidrug resistance protein 1
ASH	American Society of Hematology
ASCT	Autologous stem-cell bone marrow transplantation
BM	Bone marrow
CR	Complete response
CRAB	Hypercalcemia (C), renal failure (R), anemia (A), and bone lesions (B)
CT	X-ray computed tomography
DCE	Dynamic contrast-enhanced sequences
DEXA	Dual-energy X-ray absorptiometry
DKK1	Dickkopf 1, an inhibitor of osteoblast precursor cells
DMSA	Dimercaptosuccinic acid
DOTA	1,4,7,10-Tetra-azacyclododecane-1,4,7,10-tetraacetic acid
DWI	Diffusion-weighted imaging
ECOG	Eastern Cooperative Oncology Group
FDA	United States Food and Drug Administration
FISH	Fluorescent in situ hybridization
FLC	Free light chain
HDT	High-dose therapy
IMWG	International Myeloma Working Group
Ig	Immunoglobulin
Igh	Immunoglobulin heavy chain
IL	Interleukin
IMPeTUs	Italian Myeloma criteria for PET USe
ISS	International Staging System
LC	Laterocervical
LDCT	low-dose X-ray computed tomography
LDH	Lactate dehydrogenase
MDCT	Multidetector computed tomography
MDEs	Myeloma-defining events
MDR	Multidrug resistance
MGUS	Monoclonal gammopathy of undetermined significance
MIP-1α	Macrophage inflammatory protein 1-alpha
MIP	Maximum intensity projection
MM	Multiple myeloma
MR	Minor response
MRI	Magnetic resonance imaging
n-CR	No complete response
NOPR	National Oncologic PET Registry
OPG	Osteoprogeterin
OS	Overall survival

PAMP	Pathogen-associated myeloma cell proliferation
PCLI	Plasma cell-labeling index
PD	Progressive disease
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PET/MRI	Positron emission tomography/Magnetic resonance imaging
PFS	Progression-free survival
Pgp	P-glycoprotein, also known as multidrug resistance protein 1, or ABCB 1 (member 1 of the adenosine triphosphate binding cassette superfamily B)
POEMS	Syndrome characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell proliferative disorder, and skin changes
PR	Partial response
PTHrP	Parathyroid hormone-related protein
RANK	Receptor activator of nuclear factor kappa B
SAP	Serum amyloid P
sCR	Stringent complete response
SD	Stable disease
SMM	Smoldering myeloma
SPECT	Single-photon emission computed tomography
SSTR	Somatostatin receptor
STIR	Short tau inversion recovery sequence, a modality of magnetic resonance imaging
SUV_{max}	Standardized uptake value at point of maximum
SUV	Standardized uptake value
Sv	Unit of ionizing radiation dose in the International System of Units based on the health effect of ionizing radiation on the human body
SWOG	Southwest Oncology Group
TLRs	Toll-like receptors
TNFalpha	Tumor necrosis factor alpha
TRANCE	Tumor necrosis factor-related activation induced cytokine
TTP	Time to progression
VDT-PACE	Intensive induction chemotherapy based on a combination of bortezomib, dexamethasone, thalidomide, plus a 4-day continuous infusion of cisplatin, adriamycin, cyclophosphamide, and etoposide
VDT	Chemotherapy based on bortezomib, thalidomide, and pegylated liposomal doxorubicin
VEGF	Vascular endothelial growth factor
VGPR	Very good partial response
VRD	Chemotherapy regimen based on the combination of Revlimid®, Velcade®, and dexamethasone
VRD	Bortezoib-lenalidomide-dexamethasone
WBCs	White blood cells
WBLD-CT	Whole-body low-dose computed tomography
WB-MRI	Whole-body magnetic resonance imaging
WB-MDCT	Whole-body multiple detector computed tomography
WBXR	Whole-body X-ray
Wnt	Wingless gene encoding for the proto-oncogene Int-1 homolog, also known as wingless-type MMTV integration site family

Overview of the Disease

Multiple myeloma represents about 1.8% of all cancers and about 10% of all hematologic malignancies. Multiple myeloma (MM) is the most common primary bone cancer. The number of new cases estimated in 2016 is more than 30,300 with over 12,650 deaths. Its incidence is higher in men (61%) and in african-americans; some categories of workers (i.e., farmers, workers in wood mills, paper mills, and furniture manufacturing plants) seem to be more prone to develop the disease. The peak of incidence occurs between 45 and 85 years of age, with a median of 69 years, and rarely patients are younger than 40 years (<2%) [1, 2].

Multiple myeloma was first described by Solly [3] in 1844. Solly described an inflammatory process that began with a "morbid action" of the blood vessels in which the "earthy matter of the bone is absorbed and thrown out by the kidneys in the urine." In the early 1900s, Wright recognized plasma cells as the tumor cells present in MM [4].

The clonal proliferation of malignant plasma cells in the bone marrow (Fig. 1) may result both in local growth and in systemic effects due to the overproduction of a monoclonal protein (M protein), first described by Waldenstrom in 1961 as a narrow band of hypergammaglobulinemia on electrophoresis [5]. Most commonly, M protein is IgG (52%) or IgA (21%), rarely IgD or IgE. Biclonal plasma proteins can also be detected, such as IgG and IgA (33%) or IgG and IgM (24%); on the other hand, non-secretive (negative both serum and urine immunofixations) and light chain only subtypes have been described (1%) [6]. Almost all patients evolve from an asymptomatic premalignant stage termed monoclonal gammopathy of undetermined significance (MGUS); through the smoldering myeloma (SMM), to the "malignant" MM [1, 7].

Historically, MM differs from MGUS and SMM by the presence of the end-organ damage associated with a complex syndrome named CRAB [8]: hypercalcemia (C), renal failure (R), anemia (A), and

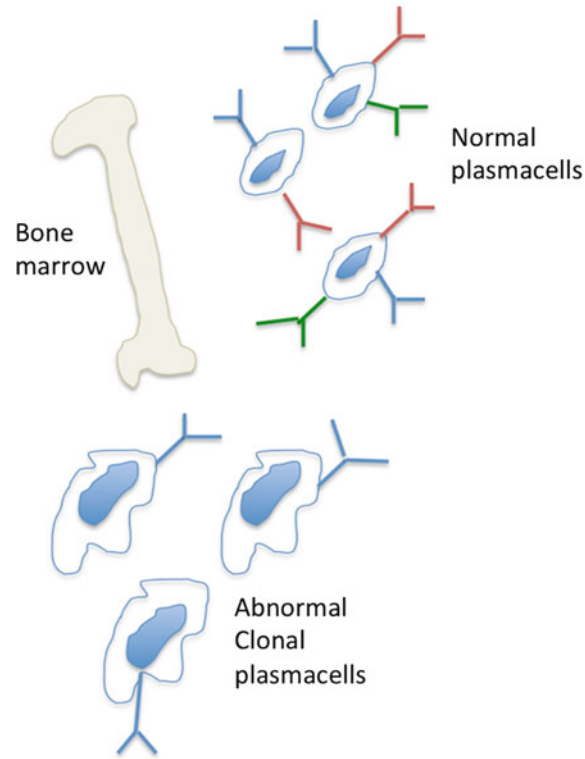

Fig. 1 Plasma cells originate in bone marrow. Normal polyclonal plasma cells secrete different antibodies (*blue*, *red*, *green*). Atypical clonal plasma cells secrete only one type of immunoglobulin, with the same rearrangement of IgH

bone lesions (B). However, in the updated version of the criteria for the diagnosis of plasma cell proliferative disorders established by the International Myeloma Working Group (IMWG), more specific criteria have been established to define MM, MGUS, and SMM [8, 9] (Table 1).

MGUS is distinguished in: (i) non-IgM MGUS (progression rate of 1%/year in MM, solitary plasmacytoma, or immunoglobulin-related amyloidosis), (ii) IgM-MGUS (progression rate of 1.5%/year in Waldenström macroglobulinemia or immunoglobulin-related amyloidosis), and (iii) light-chain MGUS (progression rate of 0.3%/year in light-chain MM or immunoglobulin light-chain amyloidosis).

Smoldering myeloma is defined as serum monoclonal protein (IgG or IgA) $\geq$30 g/L or urinary monoclonal protein $\geq$500 mg per 24 h and/or clonal bone marrow plasma cells 10–60% associated to the absence of myeloma-defining events or amyloidosis. On the other hand, MM is defined as clonal bone marrow plasma cells $\geq$10% or biopsy-proven bony or extramedullary plasmacytoma (clonality should be established by showing k/λ-light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence; bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen) and any one or more of the following myeloma events defined as end-organ damage that can be attributed to the underlying plasma cell proliferative disorder (hypercalcemia, renal insufficiency, anemia, bone lesion).

The same revision stated that the patients with high-risk smoldering myeloma (free light-chain involved/uninvolved ratio >100, more than two focal lesions in the spine or pelvis after MRI evaluation, and more than 60% of clonal atypical plasma cells in the bone marrow, defined as "myeloma-defining events or MDEs) have to receive treatment, because of the very high probability (about 80%) of developing a CRAB sign in a short period [9].

A free light-chain ratio >100 has been described in about 15% of patients with smoldering myeloma; their risk of progression within 2 years was 64–72% [10, 11].

The micro-environment of the bone marrow appears to be crucial for the development, maintenance, and progression of the disease [12]. A proliferative trigger for plasma cells consequent to antigenic stimuli is responsible for plasma cell activation. Toll-like receptors (TLRs), pathogen-associated myeloma cell proliferation (PAMP), and CD126 are important key molecules in the process of plasma cells malignant transformation. Myeloma plasma cells are typically characterized by a very long life (with low thymidine-labeling index, 1–2%), while the other differentiation steps are maintained.

Primary translocations involving the immunoglobulin heavy chain locus on chromosome 14q32 are detectable in about 50% of MGUSs, while in symptomatic MM, several molecular abnormalities are present, such as *Ras* and/or *TP53* and/or *myc* family mutations, p16 methylations, or secondary translocations [13]. High-matrix metalloproteinase-2 levels and enhanced neoangiogenesis are also detectable in MM with increased vascular density typical of active disease, thus suggesting a strong relationship between the progression of myeloma and neovascularisation [14].

Moreover, patients affected by smoldering myeloma but carrying t(4:14), 1q gain, or del(17p) showed a median time to progression (TTP) of 24 months and are considered as "at high risk." Trisomies are associated to a TTP of 34 months, so defining a "intermediate risk" population, whereas other cytogenetic abnormalities and t(11;14) are considered as "at standard risk" (TTP 54 months) [15].

Excess bone marrow plasma cells, M protein, osteolytic bone lesions (present in >90% of patients), renal disease, and immunodeficiency [12] constitute the pathophysiologic bases of the clinical manifestations of MM. Severe bone pain, pathologic fractures (>70%), spinal cord compression (2–3%), and hypercalcemia (15%) are caused by lytic bone lesions (although spinal cord compression is sometimes caused by collapse of a vertebral body due to the disappearance of a lesion in response to therapy) [16].

Although bone lesions in MM can occur in any bone, lesions are found in the spine (49%), skull (35%), pelvis (34%), ribs (33%), and proximal portions of the arms and legs (22% and 13%, respectively) as well as in the mandible (10%). At diagnosis almost 10% of the patients present

Table 1 Criteria for the diagnosis of plasma cell proliferative disorders established by the International Myeloma Working Group [8, 9]

Disease	Diagnostic criteria	
	IMWG	Updated
Monoclonal gammopathy of undetermined significance (MGUS)	All three criteria must be met:	Non-IgM MGUS
	• Serum monoclonal protein <3 g/dL	• Serum monoclonal protein (non-IgM type) <30 g/L
	• Clonal BM plasma cells <10%	• Clonal BM plasma cells <10%*
	• Absence of end-organ damage attributable to the plasma cell proliferative disorder	• Absence of end-organ damage (CRAB) or amyloidosis attributable to the plasma cell proliferative disorder
		IgM MGUS
		• Serum IgM monoclonal protein <30 g/L
		• BM lymphoplasmacytic infiltration <10%
		• No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, hepatosplenomegaly, or other end-organ damage attributable to the underlying lymphoproliferative disorder
		Light-chain MGUS
		• Abnormal FLC ratio (<0.26 or >1.65)
		• Increased level of the appropriately involved light chain (increased kFLC in patients with ratio >1.65 and increased λ FLC in patients with ratio <0.26)
		• No immunoglobulin heavy chain expression on immunofixation
		• Absence of end-organ damage (CRAB) or amyloidosis attributable to the plasma cell proliferative disorder clonal BM plasma cells <10%
		Urinary monoclonal protein <500 mg/24 h
Smoldering multiple myeloma (also referred to as asymptomatic multiple myeloma)	Both criteria must be met:	Both criteria must be met:
	• Serum monoclonal protein (IgG or IgA) ≥3 g/dl and/or clonal BM plasma cells ≥10%	• Serum monoclonal protein (IgG or IgA) ≥30 g/L or urinary monoclonal protein ≥ 500 mg per 24 h and/or clonal bone marrow plasma cells 10–60%
	• Absence of end-organ damage attributable to a plasma cell proliferative disorder	• Absence of myeloma-defining events or amyloidosis

(*continued*)

Table 1 (continued)

Disease	Diagnostic criteria	
	IMWG	Updated
Multiple myeloma (MM)	All criteria must be met:	Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma (clonality should be established by showing k/λ-light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence) and any one or more of the following myeloma-defining events:
	• Clonal BM plasma cells ≥ 10% or biopsy-proven plasmacytoma	
	• Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically	
	Hypercalcemia: serum calcium >11.5 mg/dL	• Evidence of end-organ damage attributable to the underlying plasma cell proliferative disorder, specifically:
	Renal insufficiency: serum creatinine >1.73 μmol/L (or >2 mg/dL) or estimated creatinine clearance <40 mL/min	1. Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or > 2.75 mmol/L (>11 mg/dL)
	Anemia: normochromic, normocytic with a hemoglobin value of ≥2 g/dL below the lower limit of normal or a hemoglobin value <10 g/dL	2. Renal insufficiency: creatinine clearance <40 mL per min† or serum creatinine >177 μmol/L (>2 mg/dL)
	Bone lesions: lytic lesions, severe osteopenia, or pathologic fractures	3. Anemia: hemoglobin value of >20 g/L below the lower limit of normal or a hemoglobin value <100 g/L
		4. Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or [^{18}F]FDG PET/CT (if BM has <10% clonal plasma cells, >1 bone lesion is required to distinguish from solitary plasmacytoma with minimal marrow involvement)
		• Any one or more of the following biomarkers of malignancy:
		1. Clonal BM plasma cell percentage ≥60% (clonality should be established by showing k/λ-light-chain restriction on flow cytometry, immunohistochemistry, or immunofluorescence; bone marrow plasma cell percentage should preferably be estimated from a core biopsy specimen)
		2. Involved: uninvolved serum free light-chain ratio ≥100 (values based on the serum Freelite assay; the involved free light chain must be ≥100 mg/L)
		3. >1 focal lesions on MRI studies (size ≥5 mm)

*Bone marrow can be deferred in patients with low-risk monoclonal gammopathy of undetermined significance (IgG type, monoclonal protein <15 g/L, normal free light-chain ratio) in whom there are no clinical features concerning for myeloma.

diffuse osteopenia or osteoporosis. MM bone disease involves more than 50% of a bone surface, and osteoblastic activity is drastically depressed or absent [17].

Transformed malignant plasma cells are responsible, both directly and indirectly, for local bone resorption, through activation of osteoclast activity and inhibition of the osteoblasts. In fact, myeloma cells secrete several osteoclast-activating factors (IL-1, IL-6, TNF-alpha) that stimulate the secretion of the so-called tumor necrosis factor-related activation induced cytokine (TRANCE); this compound interferes with osteoblast differentiation. Furthermore, IL-1, IL-6, and TNF-alpha stimulate the secretion of dickkopf 1 (DKK1), a potent inhibitor of osteoblast precursor cells. The myeloma cells frequently release also the parathyroid hormone-related protein (PTHrP). Figure 2 diagrammatically depicts some of those complex interactions.

The local proliferation of myeloma cells may lead to the appearance of a solid lesion that involves the soft tissue primarily arising outside the bone or extending from a preexistent bone lesion. In the absence of systemic spread (normal BM without evidence of clonal plasma cells, normal skeletal survey, and MRI/CT of spine and pelvis except for the primary solitary lesion), this situation is named solitary plasmacytoma [9, 18].

Excess protein produced by myeloma can increase the viscosity of plasma. Hyperviscosity is associated with impairment of the microcirculation, particularly in the eye and central nervous system causing visual impairment, dizziness, headache, and hearing loss. Rarely there is spontaneous bleeding [19] due to platelet dysfunction. Patients with myeloma are at increased risk of infection due to reduction of normal plasma cell function. Infections are potentially fatal complications that can occur during chemotherapy, at relapse or following bone marrow transplantation, and are most frequently caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Herpes zoster* virus [20]. Other complications include myocardial ischemia or congestive heart failure due to deposition of light-chain protein (amyloid)

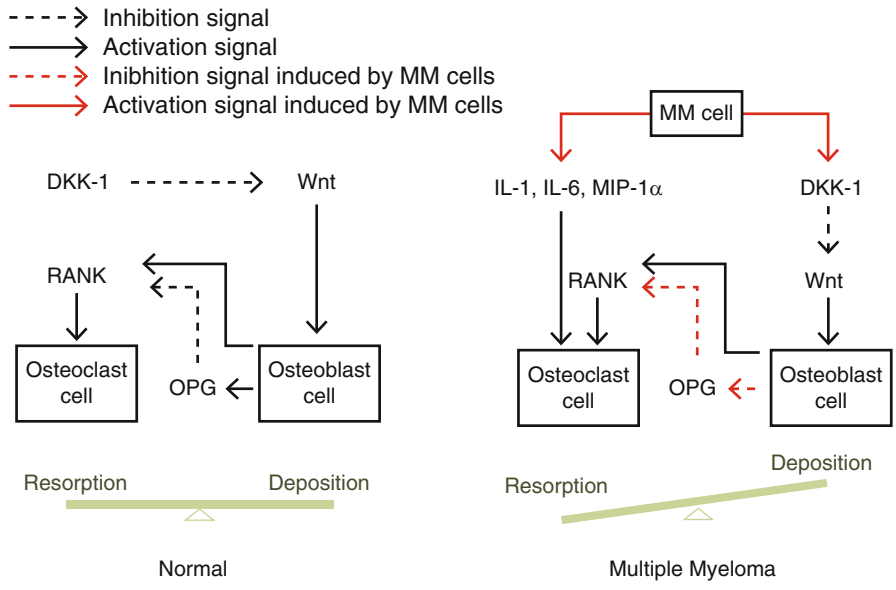

Fig. 2 Schematic representation of interactions between MM cells and bone microenvironment (*left panel*) as compared to the physiological balance (*right panel*). Dickkopf 1, a potent inhibitor of osteoblast precursor cells (DKK1), over-inhibited in normal condition via *wingless* gene (Wnt), is activated by MM cells promoting osteoblasts activity and decreasing osteoprogeterin (OPG) circulating levels. Furthermore, cytokine (IL-1, IL-6, and MIP-1α) and RANK promoting osteoclasts tip the balance toward bone resorption resulting in the typical lytic bone appearance of MM lesions

in the myocardium causing dilated or restrictive cardiomyopathy, as well as a hypersensitivity syndrome and/or anemia [21].

Neuropathy in patients with myeloma is usually symmetric, distal sensory or sensory motor with axonal degeneration, often associated with amyloid deposits, or antibodies against peripheral myelinated fibers [22]. In 1% of the cases, myeloma occurs in a rare syndrome (POEMS syndrome) [12]: this syndrome is characterized by polyneuropathy, monoclonal plasma cell proliferative disorder (almost always λ) associated to one or more major criteria (sclerotic bone lesions, Castleman's disease, or elevated levels of VEGF), and one or more minor criteria (organomegaly, extravascular volume overload, endocrinopathy, skin changes, papilledema thrombocytosis/polycythemia) [9].

Although the presence of lytic bone lesions is highly suggestive for MM, it is not by itself sufficient to establish the diagnosis. The minimum criteria for MM diagnosis are either the detection of at least 10% abnormal plasma cells in the bone marrow (after biopsy) or of M-protein levels >30 g/L in serum or >1 g excreted in the 24-h urine [8].

Initial investigation of a patient with suspected multiple myeloma should include family history (focus on first-degree relatives with the diagnosis of hematologic malignancies, especially lymphoma, chronic lymphocytic leukemia, and plasma cell dyscrasias), past medical history (focus on comorbid conditions, such as coronary artery disease, congestive heart failure, hypertension, renal disorders, liver disorders, and lung diseases), a complete blood count with differential, and a complete biochemistry (including liver function tests, renal function tests, electrolytes, calcium, and albumin) [23].

The clinical course of MM is highly variable, and the clinical behavior is remarkably heterogeneous. Many studies have identified prognostic factors capable of predicting this heterogeneity in survival (serum β2-microglobulin, albumin, C-reactive protein, and lactate dehydrogenase) [1].

The standard workup of MM is based on a number of laboratory tests that are utilized for risk stratification. The international staging system (ISS) is a powerful and reproducible three-stage classification (Table 2), in which ISS3 class is associated with the poorest outcome [8]. Such assessments include complete blood count, routine biochemistry and urine analysis, serum and urine protein electrophoresis (preferably on an aliquot of the 24-h collection), lactate dehydrogenase and β_2-microglobulin levels, immunofixation of serum or urine sample for the detection of M component, nephelometry (for measuring the free light chains employed to monitor also patients with oligo- or nonsecretory myeloma), and cytogenetics or FISH analysis.

Table 2 Mayo risk stratification for high-risk myeloma (From Kyle et al. [8])

High-risk characteristic
Conventional cytogenetics
Deletion of chromosome 13 (monosomy)
Hypodiploidy
Either hypodiploidy or deletion of chromosome 13
Fluorescent in situ hybridization (FISH)
t(4;14)
t(14:16)
17p–
Plasma cell-labeling index (PCLI) studies: PCLI ≥3%

Cytogenetics includes conventional karyotyping and FISH for t(4;14), t(14;16), chromosome 17, and chromosome 1. Indeed, t(4;14), t(4:16), deletion(17p), and (1q) are mostly associated with a poorer outcome. It has recently been demonstrated that combining both t(4;14) and del (17p), along with the ISS stage, could significantly improve the prognostic assessment [24]. Gene-expression profiling may segregate patients with standard or high-risk disease, but this is not yet established in routine practice [1].

The fraction of plasma cells infiltrating the bone marrow is evaluated based on May-Grünwald Giemsa-stained smears. MM plasma cells typically stain positive for CD38, CD56, and CD138 and are usually negative for surface immunoglobulin and CD19. The number of plasma cells in the bone marrow is an important

criterion for distinguishing MM from MGUS and from solitary plasmacytoma. MM is usually characterized by more than 10% plasma cells in the bone marrow, although, due to the heterogeneous distribution of plasma cells in the bone marrow, this fraction may vary substantially depending on the site of sample aspiration; this parameter is therefore not a consistent prognostic factor. Nevertheless, cytology of bone marrow aspirates remains the standard method for quantitating plasma cells infiltration. The bone marrow plasma cell labeling index (PCLI), a parameter of the DNA synthesis rate derived from in vitro incubation with tritiated thymidine, represents an additional predictor of survival [12]. This index is usually low at diagnosis (<1%) in MGUS and SMM, but it increases at relapse since it correlates with neoangiogenesis, therefore with active disease, as well as inversely with survival regardless of the tumor mass. However, 40% of patients with symptomatic MM have normal PCLI [25].

Imaging studies demonstrate the extent and severity of bone involvement (intramedullary/extramedullary, site, and number of lesions) at baseline, including disease-related complications, such as pathologic fractures; they also serve to assess response to treatment and provide follow-up surveillance [7]. The standard skeletal survey reveals punched-out lytic lesions, osteopenia, or fractures in approximately 80% of patients at the time of diagnosis. Due to the lack of the osteoblastic response, the bone scan is insensitive for the detection of many bone lesions in myeloma patients.

The clinical staging system for MM (international staging system, ISS, Table 3), introduced over 25 years ago, is mainly based on serum β_2-microglobulin and albumin levels, without any reference to the presence of bone lesions nor to the methodology employed for their evaluation. Although the ISS serves as prognostic indicator rather than as an accurate scoring system, it has proven to adequately estimate tumor burden and risk stratification, also enabling to distinguish MGUS and SMM from MM [8]. The CRAB criteria are preferred to establish MM-related organ dysfunction [26]. In 1975 Durie and Salmon introduced a clinical staging system

Table 3 International staging system (ISS) for MM (From Kyle et al. [8])

Stage	Criteria
Stage I	Serum $\boldsymbol{\beta_2}$-microglobulin <3.5 mg/L and albumin ≥3.5 g/dL
Stage II	No stage I or III
	There are two categories:
	Serum $\boldsymbol{\beta_2}$-microglobulin < 3.5 mg/L but serum albumin< 3.5 g/dL
	Serum $\boldsymbol{\beta_2}$-microglobulin ranging from 3.5 to <5.5 mg/L irrespective of the serum albumin level
Stage III	Serum $\boldsymbol{\beta_2}$-microglobulin ≥5.5 mg/L

based on the presence of bone lesions to grade the severity of the disease: a normal bone structure or plasmacytoma characterized as stage 1 and advanced lytic bone lesions characterized as stage 3, while stage 2 corresponded to patients who did not fit either stage 1 or stage 3 features (see Table 4a) [27]. While the original Durie and Salmon system was essentially based on the use of planar X-ray for evaluating bones, a newer version, the PLUS system, was released in 2005 (see Table 4b) with the aim of improving the accuracy of staging by the use of advanced imaging modalities such as [^{18}F]FDG-PET, [^{18}F]FDG-PET/CT, and MRI (Table 4b) [28]. These techniques enable to evaluate the total number of bone lesions, to distinguish MGUS or SMM from active myeloma, as well as to better discriminate between stage II and III disease. Nevertheless, the original system based on conventional X-ray only is still employed in areas where access to advanced imaging modalities is limited.

A detailed staging system is crucial, since MM has extremely heterogeneous outcomes, and treatment is strongly dependent on the disease onset. Based on the stage and risk factors, risk-adapted therapeutic strategies can therefore be defined. While MGUS does not require any treatment (except long-term observation), there is no evidence that early treatment of patients with SMM prolongs their survival. The diagnosis of active symptomatic MM requiring therapy is based on end-organ effects of the disease.

Despite all treatment options, MM is still considered an incurable disorder with a median survival of about 2–3 years in high-risk patients

Table 4 Overview of Durie and Salmon staging system (A) and the Durie and Salmon PLUS staging system (B) [26]

	A: Durie/Salmon staging system		B: Durie and Salmon PLUS staging system	
Disease	Criteria	Measured myeloma cell mass in whole body (myeloma cells in billions/m^2)	Classification	MRI and/or [^{18}F] FDG-PET
MGUS	Stage I (low cell mass)	600 billion		All negative
	All of the following:			
	Hemoglobin value >10 g/dL			
	Serum calcium value normal or <10.5 mg/dL			
	Normal bone structure (scale 0) or solitary bone plasmacytoma only at bone X-ray			
	Low M-protein production rates:			
	IgG value <5.0 g/dL			
	IgA value <3.0 g/dL			
	Urine light-chain M protein on electrophoresis <4 g/24 h			
Smoldering or indolent myeloma	Stage II (intermediate cell mass)	600–1200 billion	Stage I A	Can have single plasmacytoma and/or limited disease on imaging
	No Stage I or Stage III			
MM	Stage III (high cell mass)	1200 billion	Stage I B	<5 focal lesions
	One or more of the following:			
	Hemoglobin value <8.5 g/dL			Mild diffuse disease
	Serum calcium value >12 mg/dL			
	Advanced lytic bone lesions at bone X-ray (scale 3)			
	High M-protein production rates			
	IgG value >7.0 g/dL		Stage II A/B	5–20 focal lesions
	IgA value >5.0 g/dL			Moderate diffuse disease
	Urine light-chain M protein on electrophoresis >12 g/24 h		Stage III A/B	20 focal lesions
				Severe diffuse disease
Sub classification (either A or B)				
A: relatively normal renal function (serum creatinine value) <2.0 mg/dL and no extramedullary disease				
B: abnormal renal function (serum creatinine value) ≥ 2.0 mg/dL and extramedullary disease				

compared to 5–7 years with high-dose therapy followed by autologous stem-cell bone marrow transplantation (ASCT) in standard-risk patients. Cytogenetic and FISH studies reveal chromosome abnormalities of prognostic significance in 33% and in 90%, respectively, of the patients with MM [12]. Translocations such as t(4;14), t(14;16), or 17p– are associated with poor prognosis (median survival 25 months), as also is the presence of hypodiploidy 21 or the deletion of chromosome

Table 5 Potential future biomarkers for diagnosis of multiple myeloma (From Rajkumar et al. [9])

	2-year probability of progression
High level of circulating plasma cells	80%
Abnormal plasma cell immunophenotype ≥95% plus immunopairs	50%
Cytogenetics subtypes t(4;14), 1q amp, or del17p	65%
High bone marrow plasma cell proliferative rate (increase in serum monoclonal protein by ≥10% on each of two successive evaluations within a 6-month period)	50%
Unexplained decrease in creatinine clearance by ≥25% accompanied by a rise in urinary monoclonal protein or serum-free light-chain concentration	Unknown

Table 6 5-year survival rate of MM patients accordingly to the stage of disease (Modified from Rajkumar [29])

Stage	5-year survival rate
Stage I	82%
ISS stage I (serum albumin > 3.5 g/dL, serum β_2-microglobulin < 3.5 mg/L)	
No high-risk cytogenetics	
Normal LDH	
Stage II	62%
Neither stage I or III	
Stage III	40%
ISS stage III (serum β_2-microglobulin > 5.5 mg/L)	
High-risk cytogenetics [t(4;14), t(14;16) or del(17p)] or elevated LDH	

13. The concomitant presence of monosomy and/or deletion of chromosome 13 and serum β_2-microglobulin levels greater than 2.5 mg/L are linked to reduced survival. An elevated PCLI also confers a negative prognosis [8]. Potential future biomarkers for diagnosis of multiple myeloma are reported in Table 5 [9]. Table 6 reports the 5-year survival rate of MM patients accordingly to the stage of disease [29].

Evaluation of Disease Burden with Imaging Modalities

In addition to the previous discussion on the incorporation of additional biomarker-defined myeloma-defining events to the standard CRAB features, updates are also needed that take into account the substantial changes to laboratory testing and imaging (e.g., low-dose whole-body CT and [^{18}F]FDG-PET/CT) used in the diagnosis of MM that have happened since the initial publication of the IMWG diagnostic criteria [9, 16, 30, 31]. Appropriate use of imaging techniques is essential both for determining the severity of bone involvement and for identifying and characterizing the skeletal complications. Imaging is also critical for detecting extramedullary foci, for diagnosing infection and other complications, and for evaluating progression of the disease. Recently, the European Myeloma Network provided recommendations for the management of the most common complications of MM [32].

For staging purpose, the detection of osteolytic lesions is generally based on conventional planar X-ray (Fig. 3) which is currently considered to be the standard technique and is recommended for the detection of bone disease in the CRAB criteria that are used for the definition of myeloma-defining events [16, 31, 33]. Lytic lesions on plain X-rays are typically holes, punched-out lesions with absent reactive sclerosis of the surrounding bone, typically localized in the flat bones of the skull and pelvis. In the long bones, lesions may appear as endosteal scalloping, small lytic lesions (<1 cm), mottled areas of multiple small lesions, or large destructive lesions [34]. These lesions are the consequence of nodular replacement of marrow by plasma cells with destruction of the entire bone [35]. Conventional X-ray may also reveal diffuse osteoporosis, which is best recognized in the spine [36]. Radiological and clinical findings (presence of pain) are used in the scoring system (Table 7a) to predict the risk of fracture of long bones and to identify optimal treatment (Table 7b): patients with a high score benefit from internal fixation, whereas patients

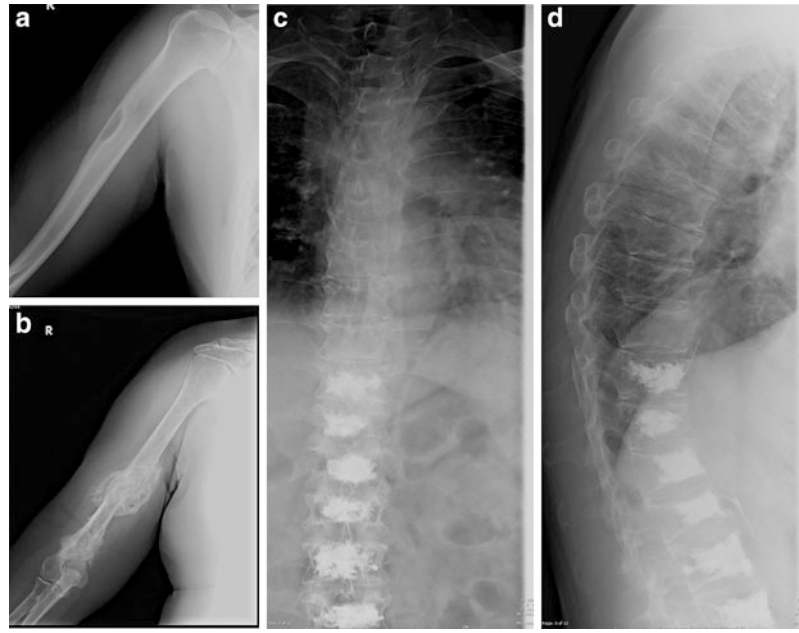

Fig. 3 X-ray appearance of lytic lesions in MM localized at the right humerus and vertebral bodies. Single lytic lesion (**a**) and two lytic lesions with osteoblastic reaction (**b**). Multiple lytic lesions of the dorsal spine (D6–D9) in patient treated with D10-L5 vertebroplasty (**c** anteroposterior view, **d** latero-lateral view)

Table 7 Scoring system for diagnosing impending pathological fractures (Adapted from Winterbottom et al. [20])

A			
	Score		
Variable	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size	<1/3 diameter	1/3–1/2 diameter	>2/3 diameter
B			
Total score	Risk of impending fracture	Management	
≤7	Low (5%)	Conservative (chemo-/radiotherapy)	
8	Suggestive (15%)	Conservative or surgery (to be evaluated case by case)	
≥9	Diagnostic (33%)	Prophylactic bone fixation	

with a low score can be treated with radiotherapy alone. Asymptomatic patients with X-ray evidence of disease (at least one lytic lesion) have a high risk of progression, with a median time to progression of 8 months.

Whole-body skeletal survey, traditionally used in the Durie and Salmon staging system, is burdened with a relatively high rate of false negatives (30–70%), thus resulting in a significant underestimation of the severity of disease. In fact, conventional X-ray cannot always identify the presence of bone lesions, especially in the early stages of the disease, since lytic lesions become apparent when as much as 30–50% of the bone mineral density is lost. Furthermore, in plain X-rays some areas are not well visualized (i.e., lateral and anteroposterior views of the spine are needed for better visualizing of the vertebral bodies), and it is not possible to distinguish myeloma-related osteoporosis from osteoporosis due to other causes (i.e., steroid-induced or postmenopausal osteoporosis) [37]. Conventional X-ray examinations are also somewhat operator- and technology-dependent, thus increasing the risk of underdiagnosing lytic disease.

A major disadvantage of conventional X-ray is the relatively long imaging time and the necessity of maintaining different positions that not all patients (often elderly and suffering pain for previous pathological fractures) are able to maintain. The potential of low-dose whole-body radiographic

system (Statscan, a radiographic system that records high quality films of the skeleton in a short time) for detecting focal myeloma lesions has been explored; preliminary results are very promising, but clinical experience with this technique (which was originally developed for trauma and emergency patients) is still limited.

However, novel techniques can detect more lytic lesions compared to conventional radiography [32]. Whole-body multidetector computed tomography (WBMD-CT) is more sensitive for the detection of lytic lesions in myeloma compared to conventional radiography (between 70% and 89% for MDCT, depending on stage of the disease), as it can detect more lesions with an extremely high resolution (very small lesions can be detected, even <5 mm) and better performance when evaluating areas that are critical for planar X-ray; it is very quick to perform (2 min or less), it is more accurate for diagnosis and helpful for planning radiotherapy or surgical interventions; furthermore, it can be employed in cases of suspected spinal cord compression when MRI is contraindicated [31, 32, 38–42]. However, specificity of MDCT for assessing certain skeletal changes often associated with myeloma, such as osteopenia, is low. To reduce the radiation burden, whole-body low-dose CT (WBLD-CT) may be used [20, 26]. Also whole-body LDCT was found to be superior to whole-body X-ray for the detection of osteolytic lesions (Table 8) [43].

Since the administration of iodinated contrast agent is not required for evaluating the skeleton with CT, it is useful even in patients with Bence-Jones proteinuria, who are at risk of cast nephropathy and renal failure. However, actual bone destruction must occur for CT imaging to become positive, since focal tumor infiltration confined to the bone marrow remains undetectable. In fact, diffuse interstitial infiltration of the bone marrow is not invariably associated with trabecular/cortical bone destruction, so that the rate of false-negative CT scans is relatively high [44].

Whole-body LDCT advantages over whole-body X-ray include:

1. Superior diagnostic sensitivity for depiction of osteolytic lesions, especially in areas where the whole-body X-ray detection rate is low (i.e., pelvis and spine).
2. Superiority in estimating fracture risk and bone instability.
3. Duration of the examination, which is 5 min or less, an important issue for patients in extreme pain.
4. Production of higher-quality 3D high-resolution images for planning biopsies and therapeutic interventions.

Table 8 Comparison between whole-body LDCT and whole-body X-ray in the detection of osteolytic lesions in MM (Modified from Terpos et al. [43])

References	Study design	Patients, n	Reference test	Key findings
Gleeson et al. [47]	Prospective	39	WBXR, WB-MRI, BM biopsy	WBLD-CT > WBXR, higher detection rate comparable to WB-MRI
Kropil et al. [48]	Prospective	29	WBXR	WBLD-CT > WBXR, detection ratio for lytic lesion WBLD-CT/WBXR = 2.06 (7 for the skull, 2.07 for the thoracic cage, 4.6 for the spine, and 2.54 for the pelvis)
Princewill et al. [46]	Retrospective	51	WBXR	WBLD-CT > WBXR, detection ratio for lytic lesion WBLD-CT/WBXR = 3.9 (1.09 for the skull, 74 for the thoracic cage, 4.92 for the spine, 6.67 for the pelvis and the fat bones, and 2.31 for the long bone); 61% of cases upstaged with WBLD-CT
Wolf et al. [45]	Prospective	52	WBXR	WBLD-CT > WBXR, particularly in the axial skeleton; 63% of cases upstaged with WBLD-CT; 23% of cases negative at WBXR and positive at WBLD-CT

WBXR whole-body X-ray (conventional skeletal survey), *WBLD-CT* whole-body low-dose computed tomography

5. Demonstration of unsuspected manifestations of myeloma or other disease, especially in the lungs and kidneys (33% in the study by Wolf et al. [45]) [38, 45–50].

Major disadvantages of whole-body LDCT include lack of availability in several centers [9, 38], and lack of specificity for the differential diagnosis between malignant and osteoporotic fractures, despite improvements during recent years [51]. Furthermore, although exposure to radiation is much lower compared with standard CT, it continues to be higher than whole-body X-ray: mean dose of whole-body LDCT is approximately 3.6 and 2.8 mSv for females and males, respectively, compared with 1.2 mSv for whole-body X-ray [52]. Nevertheless, the higher diagnostic accuracy of whole-body LDCT and patient comfort, which is particularly important for older patients, renders the dose/quality ratio favorable for whole-body LDCT [43].

Figure 4 represents typical CT examples of lytic lesions of the spine and of a solitary plasmacytoma.

Similarly, positron emission tomography in combination with CT (PET/CT) is superior to conventional radiography in the detection of lytic disease, while whole-body magnetic resonance imaging (WB-MRI) accurately depicts the marrow involvement in MM patients.

MRI identifies bone marrow involvement, based on the loss of the fatty bone marrow component consequent to replacement by plasma cells. MRI has high sensitivity in distinguishing focal or diffuse infiltration of the bone (especially in the spine), as well as detecting destruction of the mineral bone. Myeloma lesions in the marrow appear typically hypointense in T1-weighted sequences and hyperintense in T2-weighted and STIR sequences (Fig. 5).

Five MRI patterns of marrow involvement have been recognized in multiple myeloma:

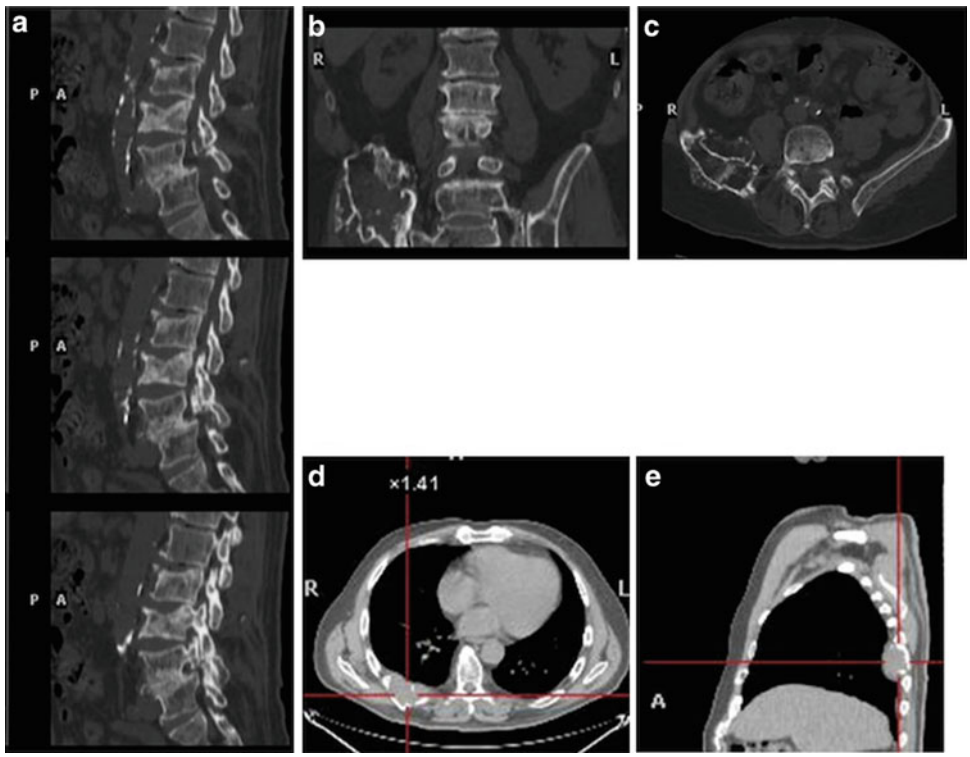

Fig. 4 Typical CT example of lytic lesions of the spine (**a**, sagittal view) and iliac bone (**b** and **c** in coronal and transaxial view, respectively) with the bone window. Panel on the *bottom* shows the transaxial (**d**) and sagittal (**e**) views of a posterior tract of right rib plasmacytoma

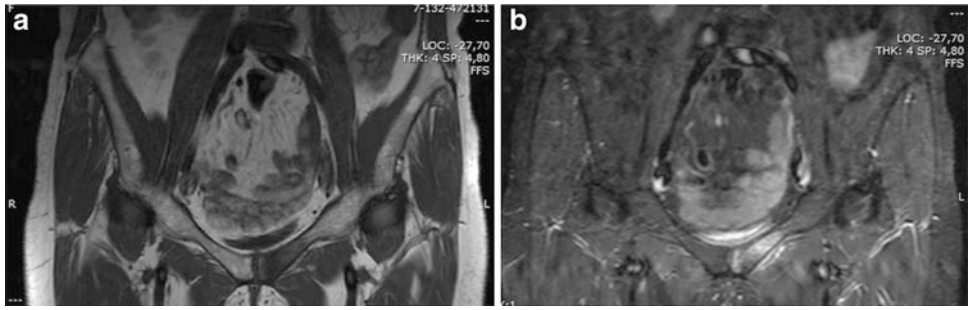

Fig. 5 STIR (**a**) and T2 (**b**) images of a lytic bone lesion of the left pubis. Hyperintense in T2-weighted and STIR sequences

1. A focal pattern that consists of localized areas of myeloma cell infiltration 5 mm or greater in diameter (in 30–50% of patients with advanced MM but also in high-risk smoldering myeloma).
2. A diffuse pattern, characterized by almost complete replacement of normal marrow by myeloma cells (in 25–40% of patients with MM).
3. A combined diffuse and focal pattern (in 10% of patients with MM).
4. A normal bone marrow pattern (in 15–25% of patients with MM).
5. A variegated or "salt and pepper" pattern, with innumerable small bone marrow focal lesions (in 1–5% of patients with MM) [16, 33, 43, 53].

MRI findings reflect pathophysiological processes such as iron overload, amyloid deposition, or reactive marrow hyperplasia. Patients with MM may exhibit normal MRI appearance when the tumor burden is low, while focal or diffuse bone marrow infiltration exhibit variable patterns. At diagnosis, bone marrow infiltration is detected by MRI in 29–50% of the patients with Durie-Salmon stage I disease and negative plain radiographs. Furthermore, MRI offers prognostic information, as the number of lesions detected correlates with response to treatment and with overall survival. Patients with advanced disease and normal MRI respond better to conventional chemotherapy and have better survival than patients with focal/diffuse bone marrow infiltration. Nevertheless, patients with positive MRI do not always require immediate treatment. In fact, in stage I, treatment is not indicated until symptoms appear. The detection of $\geq$10 spine lesions in patients with advanced stage is associated with an increased risk (6–11-fold) of fracture than patients with normal MRI or with less than ten lesions. MRI can distinguish osteoporotic from malignant fractures and is the technique of choice when cord compression is suspected MRI provides accurate information about the epidural space, the level and extension of cord or nerve root compression, and size of the lesion. The main disadvantage of MRI is long scan duration (about 45 min). Moreover, claustrophobic patients or patients with metallic implant/device cannot undergo the exam. The typical MRI protocol for evaluating MM patients does not include some skeletal segments (i.e., the sternum, clavicles, and ribs) and therefore may underestimate the disease burden. Whole-body MRI (WB-MRI, Fig. 6) may overcome those limitations; in fact WB-MRI is more sensitive than WB-MDCT for assessing bone marrow infiltration (both focal and diffuse) and is recommended immediately after the X-ray survey. It allows identifying lesions early in their course (before osteolysis occurs) as well as non-secretory and macrofocal myeloma (especially in the spine and pelvis), which is characterized by lesions with low metabolism and activity.

MRI may also be improved with the use of dynamic contrast-enhanced sequences (DCE-MRI) that evaluate the bone marrow microcirculation caused by myeloma-induced angiogenesis. The DCE-MRI-derived "A" variable describes intensity of the signal (therefore angiogenesis) and is found to be significantly increased in MM patients, in whom it correlates with the presence of osteolytic lesions, with

Fig. 6 A 65-year-old patient with multiple myeloma. WB-MRI demonstrates multifocal osteolysis in the cranial vault, sternum, and ribs (*a* +*b*) and in the lower extremities (*d*). Diffuse infiltration of the lumbar spine and pelvis is shown by the homogeneous signal decrease in bone marrow and demonstrated emanated spinal involvement, particularly in the superior segment

the degree of bone destruction and with the presence of local complications. The amplitude of "A" is a negative prognostic factor for event-free survival and for overall survival in MM [20, 26, 54, 55].

Diffusion-weighted imaging (DWI), which is based on contrast deriving mainly from differences in the diffusivity of water molecules in the tissue environment, is a novel and promising MRI technique. DWI-MRI uses the calculation of apparent diffusion coefficient values to better evaluate myeloma burden and MRI infiltration patterns [56, 57]. Apparent diffusion coefficient values are higher in patients with MM at diagnosis, compared with patients in remission 20 weeks after initiation of treatment [58]. DWI-MRI was found superior to whole-body X-ray for the detection of bone involvement in patients with relapsed/refractory MM in all areas of the skeleton except the skull, where both examinations had equal sensitivity [59]. In a small study, DWI-MRI was found more sensitive than [^{18}F]FDG-PET/CT in detecting myeloma lesions (77% and 47%, respectively) in both newly diagnosed ($n = 15$) and pretreated ($n = 9$) MM patients [60]. In a recent study, 17 patients were evaluated using DWI-MRI, and [^{18}F]FDG-PET/CT and imaging results were compared to bone marrow biopsy. In all studied regions whole-body DWI scores were higher than those produced by [^{18}F]FDG-PET/CT. DWI-MRI was particularly accurate in diagnosing diffuse disease (37% of regions imaged on whole-body DWI scans compared with only 7% on [^{18}F]FDG-PET/CT). Both techniques were equally sensitive in the detection of focal lesions [61].

Bone scintigraphy with ^{99m}Tc-labeled disphosphonate is not useful for diagnosis nor for staging of MM, as the detection of bone lesions is about 35–60% [20, 54] (Fig. 7), with sensitivities

generally lower than that of conventional X-rays. In a comparison of the X-ray skeletal survey versus bone scintigraphy [62], increased uptake of the radiopharmaceutical in radiographically abnormal regions occurred in only 44% of the cases, while normal uptake was seen in 48%, and reduced uptake in 8% of the cases. Lesions that are well defined on the bone scan are the result of complications in MM, mainly osteoblastic response to a compression fracture of a vertebral body or pelvic insufficiency fracture, soft-tissue calcifications within a plasmacytoma [63], or tumor-associated amyloidosis [64]. This pattern is consistent with the prevalent loss of bone mass not associated with osteoblastic activation, which is typical of the myeloma bone lesions. Thus, in MM, bone scintigraphy is generally nearly normal, or it may demonstrate areas with decreased radiopharmaceutical accumulation or the typical osteoporotic pattern (see example in Fig. 8a). On the other hand, bone scintigraphy may be helpful for evaluating some specific skeletal segments such as the sternum and ribs that can hardly be explored with plain X-rays (Fig. 8b).

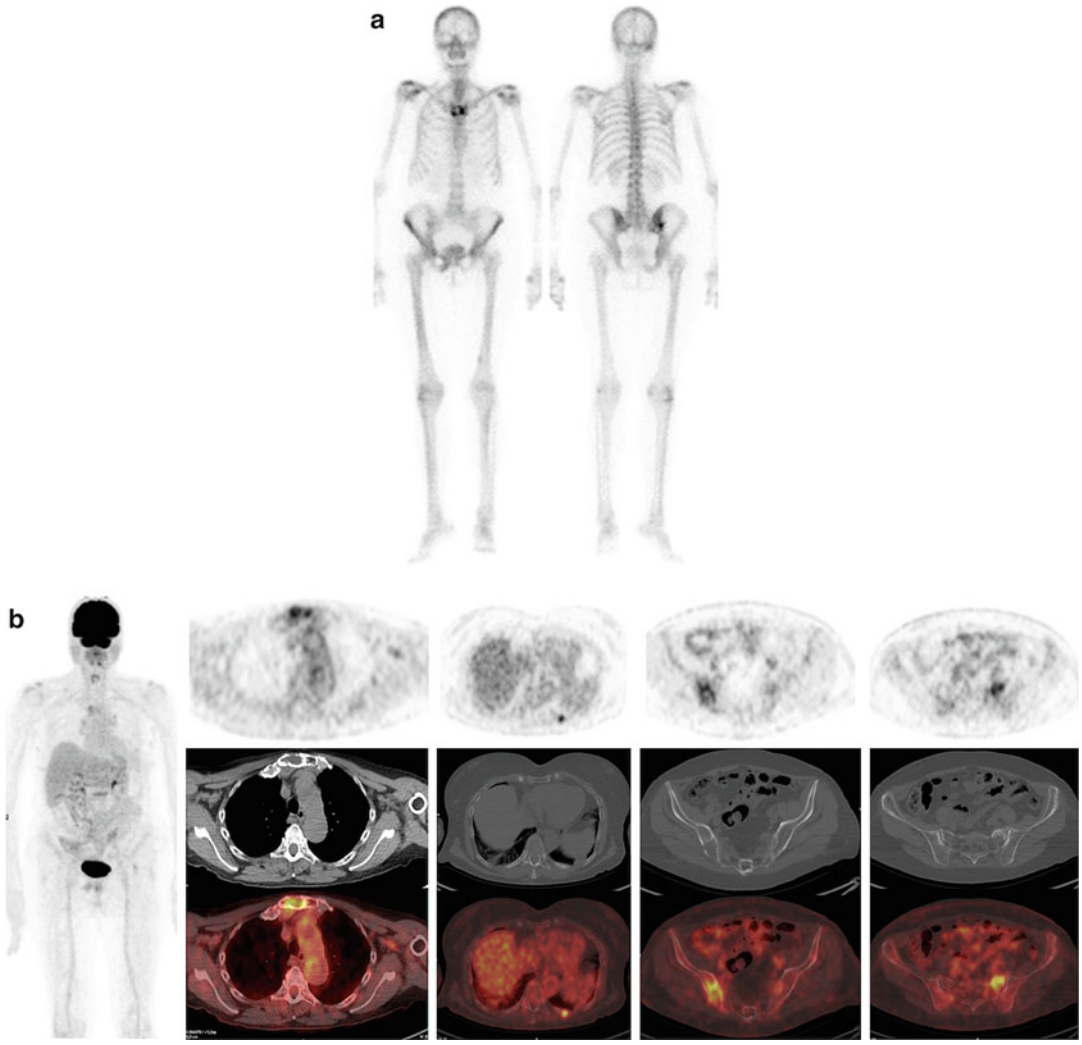

Fig. 7 Bone scintigraphy (**a**) and [^{18}F]FDG-PET/CT (**b**) in a patient with MM IgG. Bone scintigraphy missed lesions in a left rib and in the left sacrum

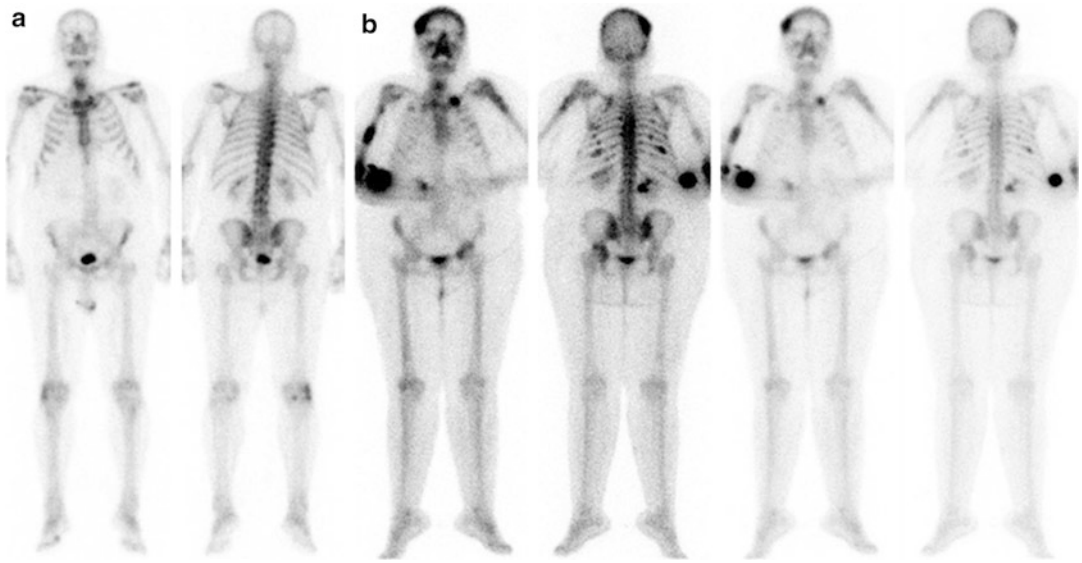

Fig. 8 (**a**) Typical pattern of mild and diffuse ^{99m}Tc-MDP uptake in a patients with MM. (**b**) Atypical appearance of multiple myeloma at bone scan: multiple lesions are evident as in the area of radiopharmaceutical uptake at the skull, left clavicula, humeri, ribs, spine, left iliac bone, and left femur

Nuclear medicine imaging with nonspecific oncotropic radiopharmaceuticals, such as ^{67}Ga-citrate, ^{99m}Tc(V)-DMSA, ^{201}Tl-chloride, ^{99m}Tc-Sestamibi, or [^{18}F]FDG have all met greater success in imaging MM than typical bone-scanning agents. ^{67}Ga-citrate localizes in areas of active tumor either through primary localization within the tumor cells or because of the presence of mononuclear cell and lymphocytic infiltrates observed along with the plasma cells and characterizing the tumor-induced secondary "inflammatory response." Whether these mechanisms act singly or in combination remains unknown [65–67]. ^{67}Ga-citrate is rarely used for tumor detection in MM because increased uptake may be observed in some abnormal soft-tissue sites and in solitary myelomas of bone [62, 68–70], although with variable degrees. Furthermore, the use of ^{67}Ga is hampered by certain disadvantages versus ^{99m}Tc-Sestamibi or [^{18}F]FDG imaging, such as multiday scanning and low resolution. When infection is suspected in MM patients, ^{67}Ga-citrate may be used if ^{99m}Tc-HMPAO/^{111}In-oxine-labeled autologous WBCs are not available. ^{99m}Tc(V)-DMSA has been reported to accumulate in plasmacytoma, irrespective of the presence of amyloidosis [71, 72].

^{201}Tl-chloride has been used for the detection of MM, based on uptake mediated by either increased metabolic demand of the tumor or secondary inflammatory response induced in the marrow [73]. In a study comparing ^{201}Tl-chloride and ^{99m}Tc-labeled bone-seeking agents in patients with MM, ^{201}Tl-chloride was shown to be a promising agent for detecting disease [74]; however, in the clinical routine based on single-photon radiopharmaceuticals for characterizing MM patients, this agent is currently replaced by ^{99m}Tc-Sestamibi, which shows similar localization properties, associated, however, with images of higher quality and lower cost.

^{99m}Tc-Sestamibi accumulates in cells with high metabolic requirements and can therefore be employed to assess in a semiquantitative manner the degree of bone marrow infiltration by plasma cells; this technique is both highly sensitive (92%) and specific (96%). The patterns of ^{99m}Tc-Sestamibi uptake typical of MM can be described as normal (N), focal (F), diffuse (D), and mixed (F+D). Another semiquantitative score (similar to that originally described by Pace et al. [75]) is based on extension (E) and intensity (I) of ^{99m}Tc-Sestamibi uptake, as follows (Fig. 9):

- E0 = no evidence of bone marrow uptake
- E1 = uptake confined to the spine and pelvis
- E2 = uptake in the spine, pelvis and ribs, or in the proximal humeral and femoral epiphyses
- E3 = uptake in the spine, pelvis, ribs, and in distal humeral and femoral epiphyses
- I0 = no evidence of bone marrow uptake
- I1 = bone marrow uptake < uptake in the myocardium
- I2 = bone marrow uptake = uptake in the myocardium
- I3 = bone marrow uptake > uptake in the myocardium

The degree of radiopharmaceutical uptake correlates well with the degree of plasma cell infiltration, with the amount of a monoclonal component, with the clinical status and with stage of the disease. In some studies good correlation was also found between ^{99m}Tc-Sestamibi uptake and other parameters of disease activity, such as the serum levels of lactate dehydrogenase, C-reactive protein, and β_2-microglobulin. Diffuse moderate or intense ^{99m}Tc-Sestamibi uptake, or focal uptake, correlates with poor prognosis. However, ^{99m}Tc-Sestamibi imaging is less sensitive than MRI (50.5% vs. 100%) [76] for evaluating focal lesions localized in the spine (especially in patients with early disease stage), because scintigraphic assessment of such segment is hampered by the high physiologic uptake in the liver and bowel. SPECT imaging has been shown to overcome the relatively poor spatial resolution of planar ^{99m}Tc-Sestamibi scintigraphy. It is important to emphasize that the ^{99m}Tc-Sestamibi scan is always negative in case of MGUS, while false negative results have been described in case of overexpression of P-glycoprotein, associated with multidrug-resistant myeloma [20, 26, 75, 77, 78].

Agool et al. [79] have more recently proposed the use of somatostatin receptor (SSTR) imaging as an alternative method to visualize malignant plasma cells. In fact, in vitro studies have demonstrated that MM cell lines express functional

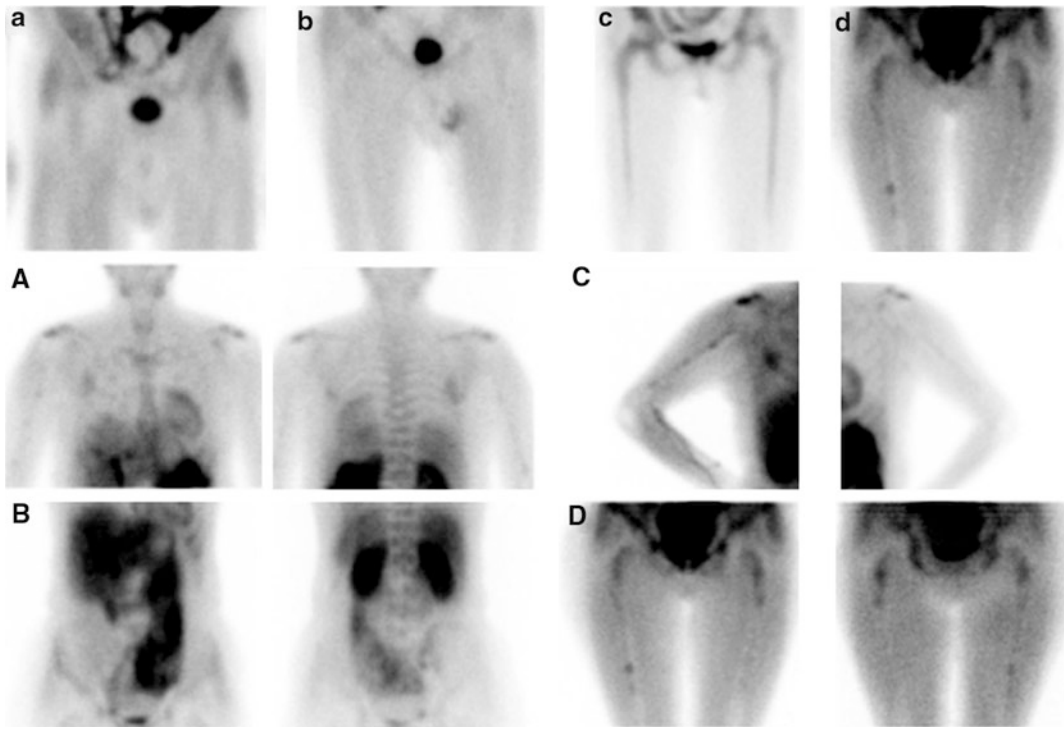

Fig. 9 ^{99m}Tc-Sestamibi scintigraphy demonstrating different degree on bone marrow involvement: focal (**a**, **b**, **d**) and diffuse (**c**) or I3E3 (**a**–**d**)

SSTR2, SSTR3, and SSTR5, the latter being the most represented. Additionally, in vitro growth of myeloma cells can be inhibited by somatostatin and octreotide. Preliminary data in patients with relapsing MM indicate that SSTR imaging is very sensitive, demonstrating abnormal accumulation in 82% of patients compared to a 33% detection rate with whole-body X-ray. Partial or total normalization of the scintigraphic pattern has also been observed in patients responding to treatment. The expression of SSTR could be related to aggressiveness of the disease. However, the limitation represented by poor spatial resolution of planar images (used in this trial) can be overcome either by employing SPECT/CT or by using PET/CT with a positron emitting SSTR analogue (i.e., ^{68}Ga-DOTATOC).

Scintigraphy with the serum amyloid P (SAP) labeled with either ^{99m}Tc or ^{123}I has been proposed to confirm the diagnosis [20, 54, 80] and to quantify the extent of the deposits of light-chain (AL) amyloidosis.

[^{18}F]FDG PET/CT is today the standard for radionuclide imaging in patients with MM, because it identifies early bone marrow infiltration in patients with apparent solitary plasmacytoma and demonstrates the extent of extramedullary involvement. [^{18}F]FDG-PET shows both high sensitivity (86%) and high specificity (92%) [81], with the additional advantage of distinguishing between metabolically active disease ([^{18}F]FDG positive) and clinical conditions characterized by very low burden, such as MGUS or smoldering disease ([^{18}F]FDG negative). Active transformed plasma cells are extremely glucose avid; therefore, [^{18}F]FDG-PET shows focal or diffuse pattern of uptake reflecting the distribution of bone marrow disease. While patients with MGUS generally have a negative [^{18}F]FDG-PET scan (although diffuse low-grade bone marrow uptake can occasionally be observed), the appearance of [^{18}F]FDG focal uptake in a patient with MGUS indicates transformation into an active myeloma. Identification of extramedullary disease on a [^{18}F]FDG-PET scan performed at diagnosis correlates with poor prognosis (see Figs. 10 and 11 for different representative patterns of [^{18}F]FDG uptake in patients with plasmacytoma and MM, respectively). An early clinical investigation on the performance of [^{18}F]FDG-PET in MM (66 patients followed serially) showed the capability of the technique to identify patients with high-risk disease and to monitor patients either in non-secretory myeloma or in complete remission without measurable M component [82]. Such initial observations were subsequently confirmed by other studies, also demonstrating that [^{18}F]FDG-PET could lead to upstaging of the disease in 31–37.5% of patients (depending on the series) and to changes in treatment management in up to 56% of the cases [83]. These results stimulated larger studies with [^{18}F]FDG-PET in patients with myeloma [84, 85]. Data derived from The National Oncologic PET Registry (NOPR), a large prospective program aiming at recording changes of the intended clinical management of cancer patients on the basis of the [^{18}F]FDG-PET/CT findings, have further confirmed this trend. The registry has so far included over 1300 myeloma patients (13.1% scan/incidence in 2007), showing a definite impact on management in about 52% of patients when the scan was requested for staging purpose, 46% in case of restaging, and 51% in presence of suspected recurrence.

In MM the 2.5 threshold for the standardized uptake value (SUV, often considered as the cutoff for other forms of cancer) may not be applicable. In fact, many lesions $<$10 mm (that are obvious on MRI or using dedicated CT) cannot be detected on the [^{18}F]FDG scan using this threshold if one does not take into account the recovery coefficient, whereby SUV decreases along with decreasing lesion size. Figure 12 shows an example of faint pathological [^{18}F]FDG uptake (SUV_{max} under the 2.5 threshold) in a bone lesion and a concomitant larger bone lesion characterized by higher uptake. Therefore, the complementary imaging information provided by the CT component of a [^{18}F]FDG-PET/CT examination is very effective, even if CT is performed in most cases in the low-dose mode (Fig. 13). With all these considerations in mind when interpreting [^{18}F]FDG-PET/CT scans, this imaging modality has reported in this study to be more sensitive than both plain X-ray (89.2% vs. 47.4%) and CT alone (89.2% vs. 70.4%) [86]. In addition to demonstrating persistent or recurrent osseous disease,

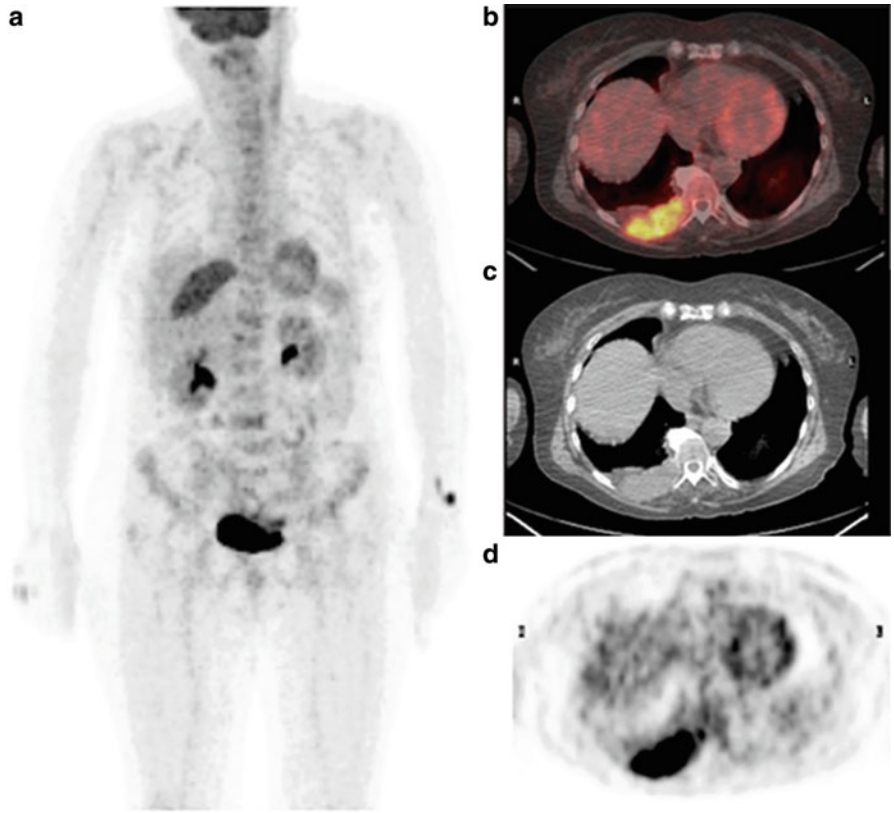

Fig. 10 The typical representative patterns of [^{18}F]FDG uptake in patients with solitary plasmacytoma. MIP images (**a**) and the relative transaxial sections on fused images (**b**), CT (**c**) and PET (**d**), demonstrating an intense area of radiopharmaceutical uptake corresponding to a large lesion developing from the posterior trait of the right rib. No additional lesions are present in any other bone segments

[^{18}F]FDG-PET/CT is more sensitive than other imaging modalities for localizing extramedullary sites of disease, thus revealing additional lesions in almost 30% of the patients who had been diagnosed with solitary plasmacytoma by MRI [87, 88]; this results in upstaging extent of the disease and has therefore a relevant impact on the choice of therapeutic strategies [89–91]. However, sensitivity of [^{18}F]FDG-PET for assessing diffuse disease in the spine and pelvis remains almost half than that of MRI [78].

Thus, while [^{18}F]FDG-PET/CT performs better than either ^{99m}Tc-Sestamibi scintigraphy or MRI in detecting focal bone and bone marrow lesions, MRI remains the method of choice for evaluating diffuse bone marrow infiltration in the spine, considering that diffusely increased non-specific [^{18}F]FDG uptake is frequently observed in the bone marrow of young people or in patients with anemia [78, 83, 92]. [^{18}F]FDG-PET/CT should be preferred for an accurate initial staging of patients with MM (Fig. 14), while MRI is to be preferred when assessing the degree of bone marrow infiltration by plasma cells in the early phase of the disease. By combining MRI of the spine/pelvis and whole-body PET/CT, the ability to detect sites of active MM, both medullary and extramedullary, can be as high as 92%. Although rarely, active disease demonstrated by bone marrow assessment may be missed by both [^{18}F]FDG-PET/CT and MRI (false-negative cases); however, when [^{18}F]FDG-PET/CT and MRI are concordantly positive, no false-positive results are generally observed, thus yielding specificity and positive predictive values close to 100%. This consideration is of value in aiding clinicians to

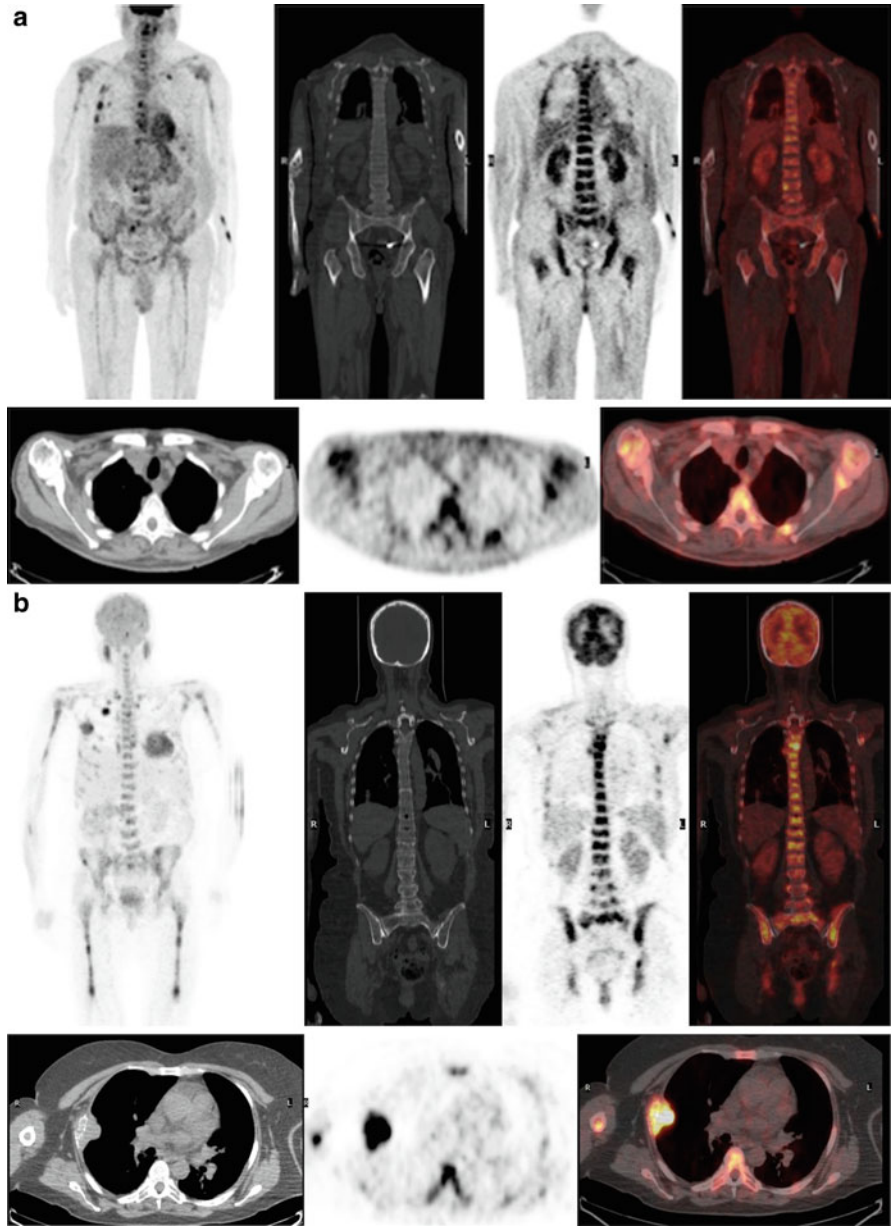

Fig. 11 Different patterns of [^{18}F]FDG uptake in patients with MM. Panel (**a**) diffuse and moderate [^{18}F]FDG uptake in bone (as intense as the liver uptake) with focal area of major accumulation corresponding to multiple bone sites of active myeloma. *Top right* MIP images, coronal view (CT with bone window, PET, and fused images) on *top left*, and transaxial view showing humeral, scapular, spine, and rib involvement on the bottom (CT with mediastinal window, PET, and fused images). Panel (**b**) diffuse and intense [^{18}F]FDG uptake in bone (more intense than the liver) with focal area of major accumulation corresponding to multiple bone and soft-tissue site disease. *Top right* MIP images, coronal view (CT with bone window, PET, and fused images) on *top left*, and transaxial view showing humeral, spine, sternum, and rib involvement with a judge lesion of the lateral right rib involving the chest wall (CT with mediastinal window, PET, and fused images). Of notice, [^{18}F]FDG reproduces the pattern of homogeneous and diffuse uptake along the humeri and femora which is typical of ^{99m}Tc-Sestamibi in advanced myeloma with better spatial resolution

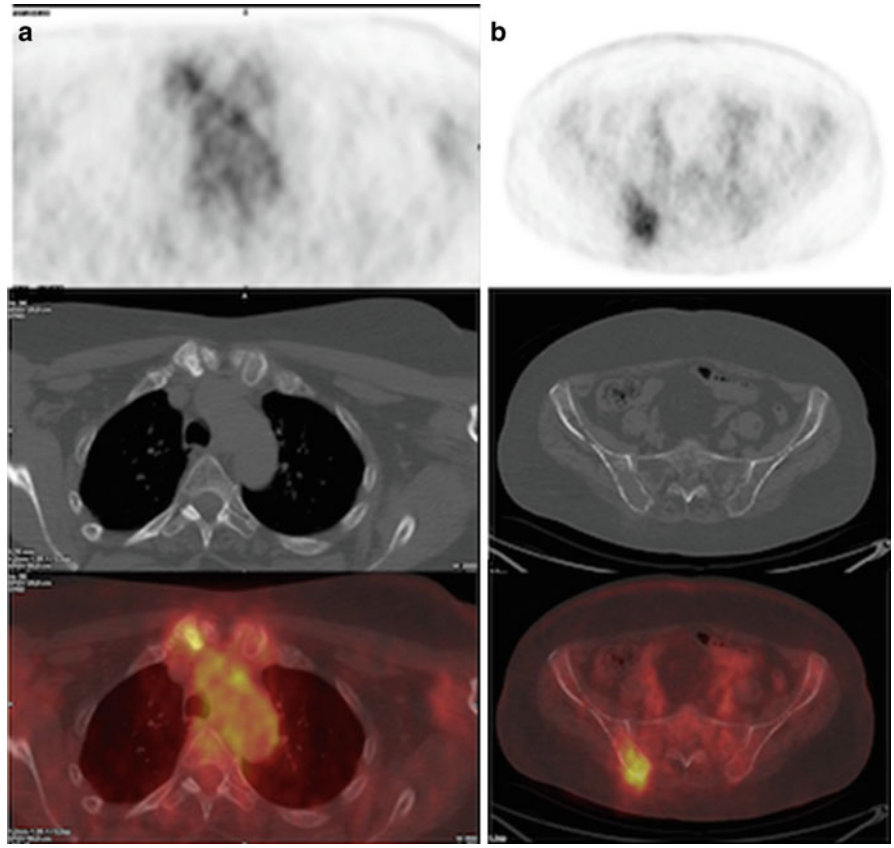

Fig. 12 Example in the same patient of MM lesions characterized by different patterns of [^{18}F]FDG uptake with an SUV_{max} of 2.2 in the right clavicle (**a**) and SUV_{max} of 4 in the right ileum (**b**)

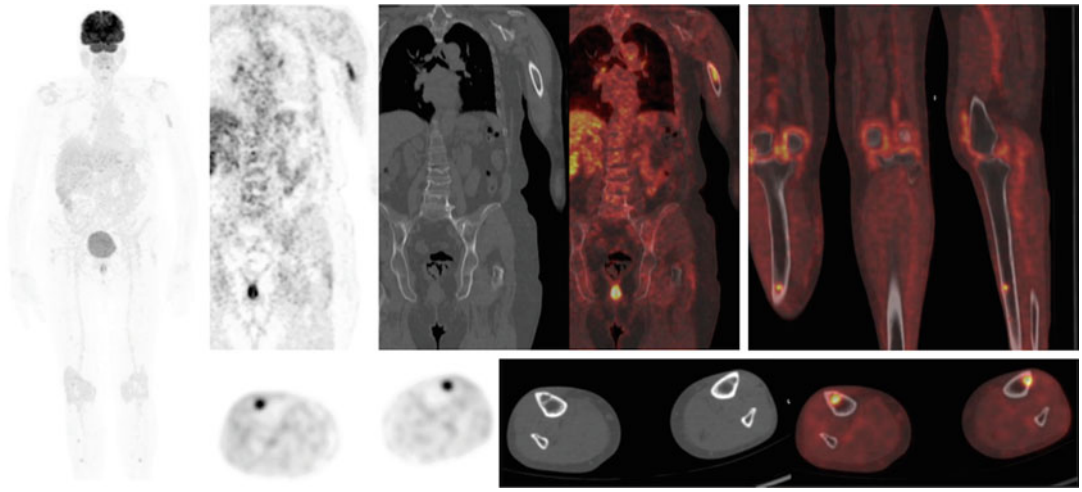

Fig. 13 Example of the complementarity of PET and CT images in a patient with MM

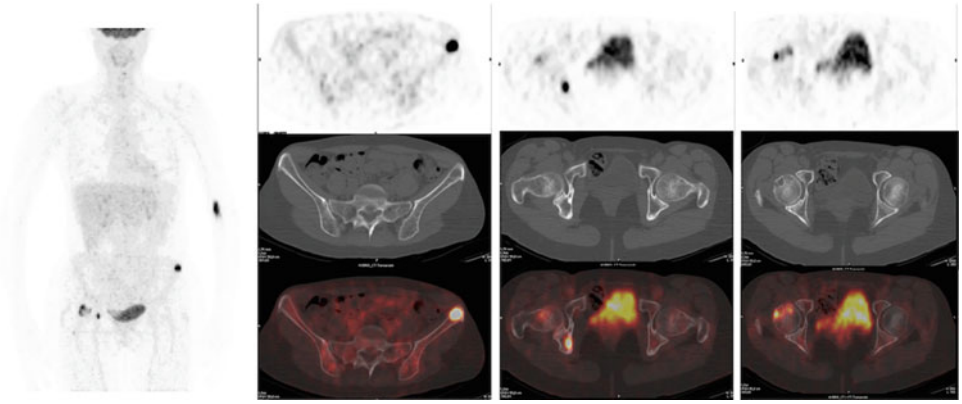

Fig. 14 Staging in a patient with MM IgG k (stage IIIA, ISS1). MIP and axial images show [^{18}F]FDG uptake in the pelvis and right femora

either continue with or change chemotherapy regimens on the basis of persistently positive findings on imaging studies. The low negative predictive values of [^{18}F]FDG-PET/CT (50%) and MRI (59%) and also of the combination of the two (64%) suggest that negative results should always be considered with caution and correlated to other markers of disease activity [93].

The prognostic significance of [^{18}F]FDG-PET/CT is not yet well established. Bartel et al. [94] evaluated the prognostic value of [^{18}F]FDG-PET/CT in patients with newly diagnosed MM. By applying tertile-derived cut-points, several imaging parameters affected overall survival and event-free survival adversely, in particular, the presence of extramedullary disease and the number of lytic lesions detected by metastatic bone survey and the number of focal sites of [^{18}F]FDG uptake. Abnormal MRI findings and high SUV of focal [^{18}F]FDG uptake were associated with shorter event-free survival, while having borderline effects on overall survival. The number of lesions detected by PET/CT was the parameter most closely correlated with other prognostic variables, such as β_2-microglobulin, lactate dehydrogenase, and C-reactive protein and gene expression profiling-derived indices: positive correlation with high risk and two proliferation parameters and inverse correlation with low bone disease subgroup. The PET/CT findings also maintained an independent adverse prognostic value, if combined with positive cytogenetic abnormalities and elevated lactate dehydrogenase levels. [^{18}F]FDG-PET/CT identified 30% of patients who had poorer prognosis despite having low-risk disease as defined by gene expression profiling analysis. Based on logistic regression analysis, the PET findings were independently positively correlated to both MRI and metastatic bone survey. Among the non-imaging parameters, the results of PET correlated positively with C-reactive protein and negatively with gene array-defined low bone disease.

[^{18}F]FDG-PET also offers the advantage of identifying superimposed infection. On the other hand, such high sensitivity can increase the false positive results when the scan is performed within a short interval after radiotherapy or surgery; it is therefore recommended to perform the scan at least 4 weeks after a surgical procedure or 2–3 months after completion of radiotherapy [83, 95].

Limitations of [^{18}F]FDG-PET/CT include the lack of sensitivity for detecting diffuse bone marrow involvement (in this case MRI remains the gold standard) and low-density plasmacyte infiltration. Moreover, physiological [^{18}F]FDG uptake in the brain reduces the sensitivity for small skull lesions [96]. One of the major limitations of [^{18}F]FDG-PET/CT lies in the lack of standardized interpretation criteria and the controversies regarding the use of SUV_{max} to define its positivity. Recently, an Italian panel of experts introduced novel criteria (IMPeTUs) [97] for the

interpretation of PET/CT images in MM. The final version of the criteria (Table 9) includes the description, using 5-point scales, of metabolic state of the bone marrow, number and site of focal PET-positive lesions with or without osteolytic characteristics, presence and site of extramedullary disease, presence of paramedullary disease, and presence of fractures. The visual degree of uptake is defined for bone marrow, the target lesion (i.e., the hottest area), and extramedullary lesions according to the schema proposed in the Deauville criteria for the evaluation of lymphoma patients. The IMPeTUs criteria must be validated in prospective studies to evaluate their clinical value.

The diagnostic potential of non-[^{18}F]FDG positron-emitting radiopharmaceuticals has been investigated in patients with MM. In particular, radiolabled choline (a precursor of phospholipid synthesis whose uptake is increased in proliferating cells) has been compared to [^{18}F]FDG [98, 99]. Authors suggest that the superior sensitivity of radiolabeled choline-PET/CT over [^{18}F]FDG-PET/CT for detecting bone lesions is due to the high phospholipid metabolic rate of myelomatous cells, as these compounds are involved in the modulation of intracellular growth signal transduction pathways. The main clinical disadvantage in the use of radiolabeled choline is its high physiological liver uptake that may prevent the detection of hepatic lesions.

Results of in vitro experiments showing that the radiolabeled amino acid [^{11}C]methionine is incorporated into immunoglobulins produced by the malignant plasma cells have prompted a clinical study performed with [^{11}C]methionine-PET/CT in MM patients by Dankerl et al. [100]. Consistently with the underlying hypothesis, osteolytic lesions exhibited a high uptake of [^{11}C]methionine, similar to that of [^{18}F]FDG. Furthermore, newly diagnosed osteolytic lesions in untreated patients were strongly [^{11}C]methionine positive, while recurring osteolytic lesions were [^{11}C]methionine negative. Although the series evaluated in this study was relatively small, the substantial mismatch between the number of lesions identified by [^{11}C]methionine-PET and those identified by CT represented an important added value of metabolic imaging for

Table 9 The IMPeTUs criteria for the interpretation of PET/CT images in MM (Modified from Nanni et al. [97])

Lesion type	Site	Number of lesion (x)	Grading
Diffuse	Bone marrow[a]		Deauville 5-point scale[b]
Focal	Skull	x = 1 (no lesions)	Deauville 5-point scale[b]
	Spine	x = 2 (1–3 lesions)	
	Extraspinal (all the rest)	x = 3 (4–10 lesions)	
		x = 4 (>10 lesions)	
Lytic		x = 1 (no lesions)	
		x = 2 (1–3 lesions)	
		x = 3 (4–10 lesions)	
		x = 4 (>10 lesions)	
Fracture		At least one at CT	
Paramedullary[c]		At least one	
Extramedullary	Nodal (n = 7)/extranodal (n = 5)[d,]	At least one	Deauville 5-point scale[b]

[a]Appended if increased uptake in limbs and ribs
[b]Deauville 5-point scale
1 = No uptake at all
2 ≤ Mediastinal blood pool uptake (SUV_{max})
3 > Mediastinal blood pool uptake, ≤ liver uptake
4 > Liver uptake more than 10%
5 > Liver uptake (twice)
[c]Bone lesion involving surrounding soft tissues with bone cortical interruption
[d]Nodal disease (*N*) plus site: laterocervical (*LC*), supraclavicular (*SC*), mediastinal (*M*), axillary (*Ax*), retroperitoneal (*Rp*), mesentery (*Mes*), inguinal (*In*); extranodal disease (*EN*) plus site: liver (*Li*), muscle (*Mus*), spleen (*Spl*), skin (*Sk*), other (*Oth*)

early detection of lesions not yet obvious as macroscopic bone changes; these findings would therefore provide an accurate estimate of tumor burden, particularly for clinically silent and unexpected localizations. Very recently, Lapa et al. [101] performed a head-to-head comparison of [^{11}C] methionine and [^{18}F]FDG-PET/CT scans in 43 patients referred for staging or restaging of MM.

PET/CT with 3′-^{18}F-fluoro-3′-deoxy-L-thymidine (^{18}F-FLT, whose uptake mirrors DNA synthesis via thymidine kinase-1) has been proposed to distinguish hematological malignancies from other clinical conditions causing pancytopenia. Although the exact mechanism of ^{18}F-FLT uptake in bone marrow remains unclear, several studies suggest that it is linked to the cycling activity of hematopoietic cells, thus reflecting the state of the entire bone marrow compartment [26]. Bone marrow uptake of ^{18}F-FLT is intense in patients with myelodysplasia and myeloproliferative disorders, while it is lower-to-absent in patients with MM, myelofibrosis, or aplastic anemia. Patients with MM may present variable degrees of ^{18}F-FLT uptake in response to bone marrow expansion into the peripheral bones.

Extensive skeletal involvement has also been incidentally detected during PET with [^{11}C]Acetate [102]. It is not entirely clear why myelomatous lesions would exhibit such high uptake of [^{11}C]Acetate, although this observation is consistent with a much earlier in vitro study with plasma cells obtained from patients with MM, showing enhanced uptake of acetate as a substrate for the Krebs cycle [103]. On the other hand, it is well known that malignant cells (including MM cells) typically have increased glycolysis versus their normal counterparts, as also confirmed by a correspondingly increased [^{18}F]FDG consumption; since the Krebs cycle (whose metabolic substrate is acetate) constitutes a component of overall glycolysis, it is not surprising that uptake of both [^{18}F]FDG and [^{11}C]Acetate occurs in MM.

Although there are some issues that need to be clarified when using sensitive techniques such as WBLD-CT, PET/CT, or MRI (e.g., what the difference is between an MM patient with 4 lytic lesions detected by conventional radiography and another patient with 14 lytic lesions detected by WBLD-CT), data so far support the use of WBLD-CT as standard procedure for the diagnosis of lytic disease in patients with MM (grade 1A) as pointed out by the "European Myeloma Network Guidelines for the Management of Multiple Myeloma-related Complications" [32] (Fig. 15).

Positive lesions in WBLD-CT are considered those with a diameter of 5 mm or more. Conventional radiography can also be used if WBLD-CT is not available. In asymptomatic patients with no lytic disease in WBLD-CT, MRI and [^{18}F]FDG PET/CT are not recommended. In the presence of more than 1 focal lesion, the patients are characterized as having symptomatic disease that needs therapy (grade 1A) [32].

However, in the "Revised International Myeloma Working Group diagnostic criteria for multiple myeloma and smoldering multiple myeloma," the detection of one or more osteolytic lesions on skeletal radiography, CT, or [^{18}F]FDG-PET/CT has been reported. Therefore, the IMWG recommends either [^{18}F]FDG-PET/CT, low-dose whole-body CT, or MRI of the whole-body or spine in all patients with suspected smoldering multiple myeloma. Increased [^{18}F]FDG uptake alone is not adequate for the diagnosis of MM; evidence of underlying osteolytic bone destruction is needed on the CT portion of the examination.

Assessing Response to Treatment

Although there are several studies evaluating the role of imaging at diagnosis, there are limited data for the value of imaging during treatment and follow-up of patients with myeloma [43]. Many criteria can be employed to assess response to therapy in MM patients, including those set by the European Group for Blood and Bone Marrow Transplant/International Bone Marrow Transplant Registry/American Bone Marrow Transplant Registry, by the Chronic Leukemia-Myeloma Task Force, by the Southwest Oncology Group (SWOG), and by the Eastern Cooperative Oncology Group (ECOG). In 2006, the International Myeloma Working

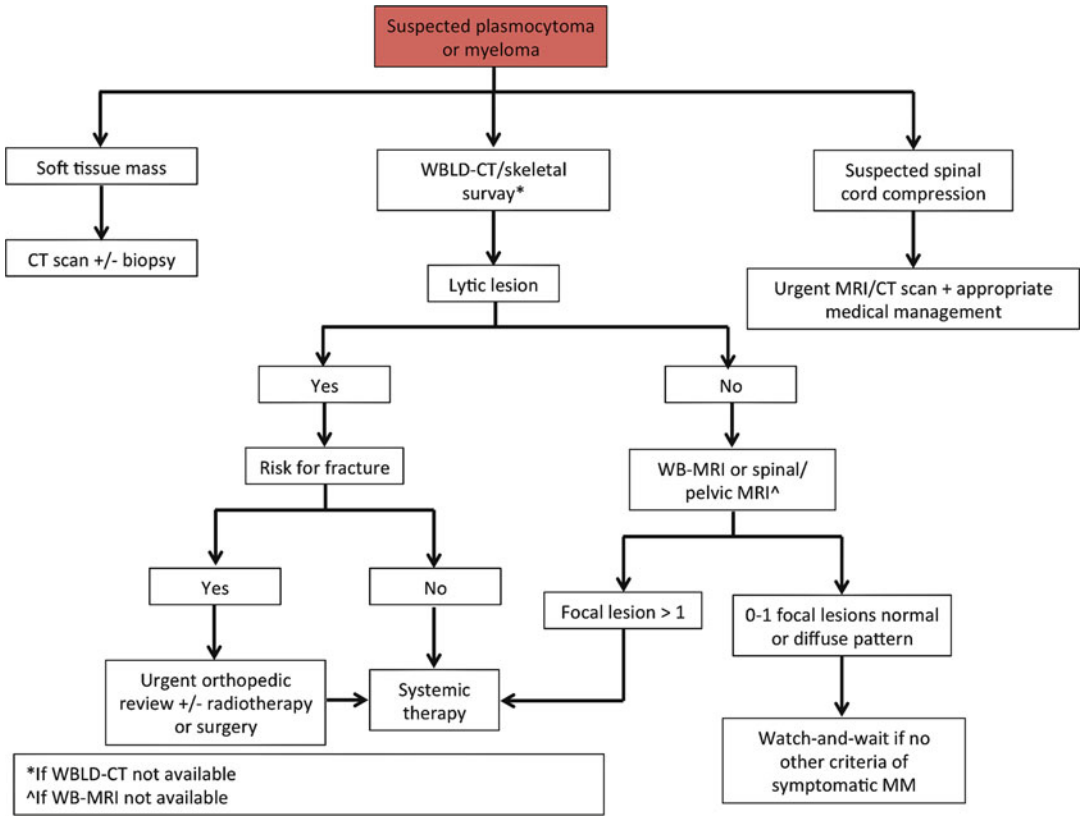

Fig. 15 Algorithm for imaging in multiple myeloma (Modified fromTerpos et al. [32])

group (IMWG) recognized the importance of standardizing such criteria and elaborated the so-called uniform response criteria (Table 10). While adopting the classical categories of Complete Response (CR), Partial Response (PR), Stable Disease (SD) and Progressive Disease (PD), the system introduced the new category of "positive response of additional clinical significance" following treatment. Although the IMWG response criteria deleted the category "minor response" (considered to be somewhat vague and therefore unreliable), more recently this category has been reintroduced by the ASH-FDA in patients with relapsed refractory myeloma, while specific criteria for progression have been defined for SMM (Table 11) [8].

Although changes in BM infiltration are not employed as a guiding criterion for assessing response to treatment, finding <5% plasma cells is one of the requisites for complete remission. Furthermore, in patients without measurable disease, it is possible to monitor the disease by the serum-free, light-chain assay. Irrespective of the specific system employed to classify response to treatment, the main pitfall of these systems is represented by the method used to assess bone marrow and bone lesions. In fact, plain radiography is of limited value for evaluating the response to treatment; in particular, even if the appearance of new bone lesions clearly indicates disease progression, lytic bone lesions rarely show radiologic signs of recovery. Furthermore, new compression vertebral fractures may occur either in case of disease progression or in case of bone loss or in case of reduction of the tumor mass that supports the bone cortex [3, 8, 26, 78]. MDCT is not generally used for assessing response to treatment, since osteolytic lesions rarely recover. In selected cases,

Table 10 International Myeloma Working Group uniform response criteria for MM (From Kyle et al. [8])

Category	Criteria
Complete response (CR)	Negative immunofixation of serum and urine **and** disappearance of any soft-tissue plasmacytomas **and** <5% plasma cells in bone marrow
	Patients with only measurable disease by serum FLC levels: CR is defined as normal FLC ratio (0.26–1.65) in addition to CR criteria listed above
Stringent complete response (sCR)	Negative immunofixation of serum and urine **and** disappearance of any soft-tissue plasmacytomas **and** <5% plasma cells in bone marrow **and** normal FLC ratio **and** absence of clonal cells in bone marrow by immunohistochemistry or immunofluorescence
Very good partial response (VGPR)	Serum and urine M protein detectable by immunofixation but not on electrophoresis or ≥90% or greater reduction in serum M protein plus urine M protein <100 mg/24 h
	Note: Patients with only measurable disease by serum FLC levels, VGPR is defined as a >90% decrease in the difference between involved and uninvolved FLC levels
Partial response (PR)	≥50% reduction of serum M protein **and** reduction in 24 h urinary M protein by ≥90% or to <200 mg/24 h **and** ≥50% reduction in the size of soft-tissue plasmacytomas if present at baseline
	Note: If the serum and urine M protein are unmeasurable, ≥50% decrease in the difference between involved and uninvolved FLC levels
	If serum and urine M protein and serum FLC are unmeasurable, ≥50% reduction in bone marrow plasma cells, provided baseline percentage was ≥30%
Stable disease (SD)	Not meeting criteria for CR, VGPR, PR, or PD
Progressive disease (PD)	>25% from lowest response value in any one or more of the following:
	Serum M protein (absolute increase must be ≥0.5 g/100 mL)[a]
	Urine M protein (absolute increase must be ≥200 mg/24 h)
	Only in patients without measurable serum and urine M-protein levels: the difference between involved and uninvolved
	FLC levels (absolute increase must be >10 mg/L)
	Bone marrow plasma cell percentage (absolute% must be ≥10%)
	Definite development of new bone lesions/soft-tissue plasmacytomas or definite increase in size of existing bone lesions/soft-tissue plasmacytomas
	Development of hypercalcemia (corrected serum calcium >11.5 mg/100 mL) ascribable solely to the plasma cell proliferative disorder

All response categories (CR, sCR, VGPR, and PR) require two consecutive assessments made at any time before the institution of any new therapy; complete PR and SD categories also require no known evidence of progressive or new bone lesions if radiographic studies were performed. Radiographic studies are not required to satisfy these response requirements. Bone marrow assessments need not be confirmed

[a]For PD serum M protein increases of ≥1 gm/100 mL are sufficient to define relapse if starting M protein is ≥5 gm/100 mL

mainly those characterized by significant soft-tissue component (i.e., plasmacytoma), response to therapy can instead be demonstrated by reduction in tumor size as assessed with CT. Moreover, CT may be of value in patients with persistent unexplained symptoms despite therapy or with risk of impending fracture or when no clinico-biochemical response to treatment is observed. The disappearance of any MRI-detectable bone marrow lesion typically represents complete response, while a partial response to therapy is associated with changes of the MRI pattern from diffuse to focal/variegate or with the reduction of the signal on the T2-weighted spin echo images. Nevertheless, MRI has limited value for the early assessment of response to treatment, since complete resolution of bone marrow lesions may take as long as 9–12 months from the completion of the therapy. DCE-MRI is superior to standard MRI for this purpose; in particular, favorable response is indicated by the disappearance of gadolinium enhancement or by the absence of contrast-induced enhancement in a follow-up study as compared to the baseline scan. DCE-MRI derives parameters correlated with microvascular density in the bone marrow both before and after therapy [104, 105]. However, the real added value

Table 11 Additional response criteria for specific disease stages. International Myeloma Working Group uniform response criteria for MM (From Kyle et al. [8])

Category	Criteria
Relapsed MM	At least one prior regimen and not meeting criteria for relapsed and refractory MM
Relapsed and refractory MM	Relapse of disease while on salvage therapy or progression within 60 days of most recent therapy
Minor response (MR) in patients with relapsed refractory MM	≥25% but <49% reduction of serum M protein **and** reduction in 24 h urine M protein by 50–89%, which still exceeds 200 mg/24 h **and** reduction in size (25–49%) of any soft-tissue plasmacytoma **and** no increase in size/number of lytic bone lesions (development of compression fracture does not exclude response)
Progression to active MM in patients with smoldering MM	Evidence of PD based on the IMWG criteria (Table 9) **and** any one or more of the following:
	Development of new lesion (soft-tissue plasmacytoma/bone lesions)
	Hypercalcemia (>11 mg/100 mL)
	Decrease in hemoglobin of ≥2 g/100 mL
	Serum creatinine level ≥2 mg/100 mL

of this technique seems to lie in the possibility to predict which patients might benefit from therapy with anti-angiogenetic drugs, i.e., bevacizumab (a monoclonal antibody that inhibits VEGF). Nevertheless, this approach has not yet gained a definite role in the evaluation of the course of the disease and of activity of the myeloma lesions. Preliminary reports suggest that DWI-MRI may be used for the better definition of response to therapy, but this has to be confirmed in larger studies and in comparison with [^{18}F]FDG-PET/CT results [50, 57]. The combination of DWI and DCE-MRI produced a score with a high agreement (76%) with the IMWG criteria of response in 27 patients with myeloma under treatment [106]; however, more data are needed to evaluate such score in larger studies [43].

Given the heterogeneous nature of the disease and inconsistent response to treatment, along with the relatively small number of published studies in this field, MRI currently has a limited role in response assessment. In general, MRI findings of response to therapy (CR or PR) include resolution or decrease of the extent of focal lesions or diffuse patterns in conventional chemotherapy or novel anti-myeloma agents [107–109]. In a small study with 33 patients who underwent an ASCT, MRI resulted in high specificity and accuracy (86% and 79%, respectively) but only 64% sensitivity for the detection of remission because of false-positive results of nonviable lesions [109]. Thus, for better evaluation of remission, functional imaging techniques (e.g., PET/CT or possibly DWI-MRI) seem to be more appropriate. Nonetheless, in a retrospective study which compared MRI and [^{18}F]FDG-PET/CT in 210 patients with MM, MRI achieved better results than PET/CT for the detection of myeloma at diagnosis and at progression, while PET/CT detected findings of response to anti-myeloma therapy earlier than MRI [110].

Regarding patients with smoldering multiple myeloma with a negative MRI study at diagnosis, the timing of follow-up with MRI and the significance of any findings on these studies have not yet been established. Merz et al. [111] evaluated the role of repeated MRI in 63 patients with smoldering multiple myeloma. The second examination was performed 3–6 months after the first. Approximately one-half of the patients showed progression on MRI, while 40% developed symptomatic disease, according to CRAB criteria.

Other studies [78, 112] have found a close correlation between the results of ^{99m}Tc-Sestamibi scintigraphy (i.e., disappearance of any area of uptake) and the conventional criteria used for defining clinical response to therapy (i.e., measurement of the M-protein component). Overall, these findings support the hypothesis that bone marrow uptake is an indicator of myeloma activity in the bone marrow, even in the absence of focal

areas of increased uptake. This procedure has shown high specificity (86%) in patients in CR, whereas sensitivity was 45% in presence of PR; these findings emphasize the high performance of ^{99m}Tc-Sestamibi scintigraphy for identifying absent disease, whereas its sensitivity is lower for the definition of residual disease when response is not complete. Multivariate analysis also showed that the sensitivity of ^{99m}Tc-Sestamibi scintigraphy was low in the presence of bone marrow infiltration $<30\%$.

The prognostic value of ^{99m}Tc-Sestamibi imaging for predicting recurrence of the disease has been extensively investigated by Pace et al. [75]. In a group of patients evaluated both at baseline and after chemotherapy, they demonstrated a significant association between pretreatment scintigraphic pattern and clinical status at follow-up. In particular, none of the patients responding to therapy had a posttreatment ^{99m}Tc-Sestamibi scan showing focal uptake or diffuse uptake with a summed score higher than 2; by contrast, the nonresponders showed either diffuse bone marrow uptake or areas of focal uptake with summed score higher than 2. A negative baseline ^{99m}Tc-Sestamibi imaging showed high prognostic value for clinicobiochemical remission, and multivariate analysis demonstrated the added value of the ^{99m}Tc-Sestamibi uptake pattern with respect to known prognostic variables, such as C-reactive protein. Furthermore, ^{99m}Tc-Sestamibi imaging patterns at follow-up were significantly associated with the clinical status evaluated after chemotherapy.

In an independent study, a semiquantitative parameter of ^{99m}Tc-Sestamibi washout derived from dual point scintigraphic acquisitions as the counts/pixel at early imaging (10 min) minus counts/pixel at delayed imaging (60 min) divided by counts/pixel at 10 min (corrected for decay) has been also employed to distinguish patients responding to treatment from nonresponders. A fast clearance of ^{99m}Tc-Sestamibi from the bone marrow of patients with MM is associated with poor response to subsequent chemotherapy.

Moreover, ^{99m}Tc-Sestamibi washout reflects the degree of expression of the P-glycoprotein (Pgp), a transmembrane protein encoded by the ABCB1 gene that mediates the outward transport of many cytotoxic compounds including a variety of anticancer agents and confers tumor cells the capability to escape the lethal effect of many cytotoxic compounds, thus causing multidrug resistance (MDR). Overexpression of Pgp in resistant-cultured tumor cells causes a reduced net uptake of ^{99m}Tc-Sestamibi as a consequence of an enhanced Pgp-dependent outward transport of the tracer [113]. Thus, since overexpression of Pgp is one of the primary mechanisms of MDR in MM as well as in other malignancies [114, 115], it can be hypothesized that the ^{99m}Tc-Sestamibi washout rate could serve to predict response to chemotherapy in MM patients.

However, all these studies have included small groups of patients, and none of them evaluated the impact of ^{99m}Tc-Sestamibi scintigraphy on progression-free survival and overall survival.

In case of effective response to therapy, [^{18}F]FDG uptake declines rapidly (within hours). The persistence of a positive [^{18}F]FDG-PET has high prognostic value, as it correlates with early recurrence. Furthermore, [^{18}F]FDG-PET/CT represents the most sensitive imaging technique to evaluate response of the bone lesions to treatment, particularly for distinguishing treated bone marrow lesions from viable neoplastic tissues [8, 26, 92] (Figs. 16 and 17).

[^{18}F]FDG-PET/CT has been employed in patients with newly diagnosed MM as part of the "Total Therapy 3" study, characterized by four distinct phases of induction therapy (two cycles of VDT-PACE with peripheral blood stem cell collection after the first cycle + tandem transplantation with melphalan 200 mg/m^2, consolidation with two cycles of dose-reduced VDT-PACE, and maintenance therapy for 3 years, with monthly cycles of VTD for the first year and thalidomide plus dexamethasone in years 2 and 3) [94]. The exam was performed at baseline (together with metastatic bone survey and MRI) and within 10 days from starting the first induction cycle of VDT-PACE. The follow-up studies included annual metastatic bone survey, while MRI scans were performed before each of two transplantations, before consolidation and maintenance phases, and semiannually thereafter. All imaging studies were also repeated at relapse,

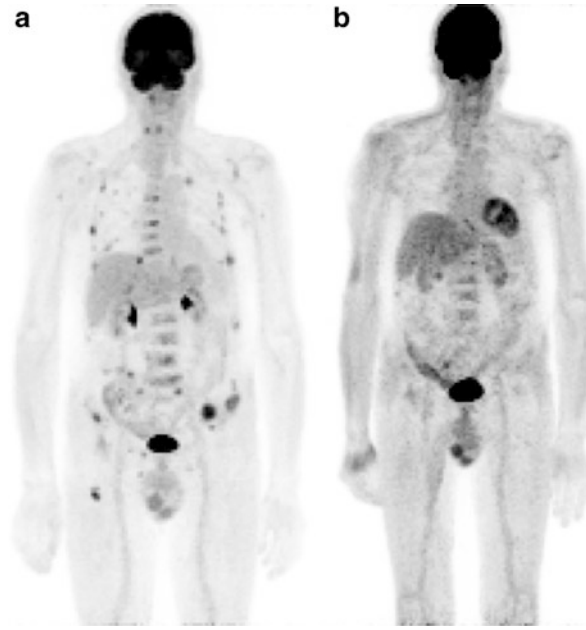

Fig. 16 Treatment response evaluation assessed by [^{18}F]FDG-PET/CT in a patient with MM IgG K (stage IIIb, ISS2). Baseline MIP (**a**) shows many areas of [^{18}F]FDG uptake disappeared (**b**) after chemotherapy (VelDexMyo regimen)

Fig. 17 [^{18}F]FDG-PET/CT of the same patient shown in Fig. 16 after recurrence

defined by M-protein and bone marrow criteria and by any of the imaging procedures. Similarly as in the case of other malignancies such as lymphoma, disappearance of [^{18}F]FDG uptake before transplantation proved to be an independent favorable prognostic factor, thus demonstrating the importance of complete suppression of tumor metabolism in myeloma. Using the [^{18}F]FDG-PET/CT criteria (absence of [^{18}F]FDG focal uptake in bone segments and extramedullary disease), the authors were able to define CR status in 92% at 18 months, which became obvious earlier than the median onset of clinical n-CR (87%) and CR status (56%) by 4 and 12 months, respectively. The cumulative proportion of patients qualifying for MRI-defined CR was 29% at 18 months and reached 59% at 48 months. In patients without focal lesions, MRI-defined CR (hypointensity on STIR images) was reached in 62% at 18 months, similar to 56% of the patients attaining clinical CR status. While very early [^{18}F]FDG-PET/CT changes (at 10 days) did not affect outcome, complete [^{18}F]FDG suppression and extramedullary disease before transplantation conferred

superior overall and event-free survival; in fact, 30 months after the first autotransplantation, 92% and 89% of the patients were alive and event-free compared with 71% and 63% among those with less than 100% disappearance of [^{18}F]FDG uptake. Complete [^{18}F]FDG suppression before the first transplantation correlated with superior outcomes in both low-risk and high-risk gene array-defined risk groups, reaching statistical significance for overall survival in low-risk and for event-free survival in high-risk myeloma. Normalization of the PET findings before transplantation was associated with improved outcomes, whereas gene array-defined high-risk designation conferred poor overall and event-free survival. In the absence of molecular genetic data, the favorable implications of pre-transplantation [^{18}F]FDG suppression were canceled by elevated serum levels of lactate dehydrogenase and β_2-microglobulin. Clinical CR or n-CR status before transplantation did not impact post-transplantation survival outcomes. The prognosis of high-risk patients not achieving complete [^{18}F]FDG suppression was especially poor.

More recently, 700 patients with symptomatic MM eligible for high-dose therapy (HDT) have been randomized to receive either eight cycles of bortezomib-lenalidomide-dexamethasone followed by 1-year maintenance with lenalidomide or three cycles of VRD followed by high-dose therapy and autologous transplantation then VRD consolidation and 1-year lenalidomide maintenance (the IFM-DFCI 2009 study). Spine and pelvis MRI and whole-body PET-CT at diagnosis, after three cycles of VRD, and prior to maintenance were performed. At diagnosis, MRI was positive in 94.7% of patients and PET/CT 91%. Following three cycles, MRI remained positive in 93% and PET/CT in 55% of patients. Normalization of MRI after 3 months of induction therapy was not predictive neither for progression-free survival nor for overall survival, whereas normalization of PET/CT was associated with a significant improvement in PFS but not OS. Prior to maintenance, MRI remained positive in 83%, and PET/CT in 21% of the patients. Normalization of MRI before maintenance was not predictive for survivals, whereas normalization of PET/CT was associated with a prolonged PFS and OS, thus suggesting that PET/CT should be incorporated in the follow-up of MM patients who undergo to high-dose treatment [116].

Quantitative data on kinetics and distribution patterns of [^{18}F]FDG obtained from dynamic PET/CT in 40 patients with MM correlated significantly with percentage of bone marrow infiltration by plasma cells [117]. Furthermore, PET/CT efficiently detected extramedullary disease in patients both at diagnosis and at relapse [118]. PET/CT was tested for better definition of CR in 282 MM patients. The examination was performed at diagnosis and every 12–18 months afterward. At diagnosis, 42% of patients with MM had more than three focal lesions (SUV_{max} >4.2 in 50% of cases). After treatment, PET/CT was negative for 70% of patients, while 53% of patients achieved CR according to IMWG criteria. Approximately 30% of patients at CR had a positive PET/CT. A negative PET/CT was an independent predictor for prolonged PFS and OS in patients with CR. In addition, for patients with CR, median PFS was 50 months for patients with a positive PET/CT and 90 months for patients with negative PET/CT [119].

In smoldering multiple myeloma, 16% of patients with normal whole-body X-ray had positive PET/CT results [120]. The median time to progression (TTP) for patients with positive PET/CT was shorter than patients with negative PET/CT (1.1 years vs. 4.5 year), while the probability of progression at 2 years for patients with positive PET/CT results was 58% [121]. The largest study in the field involved 188 patients with smoldering myeloma: [^{18}F]FDG-PET/CT was positive in 39% of patients. The probability of progression to symptomatic MM within 2 years was 75% for patients with positive PET/CT under observation and 30% for patients with negative PET/CT. This probability was higher if hypermetabolic activity was combined with underlying osteolysis (2-year progression rate of 87%). The median TTP was 21 months compared with 60 months for patients

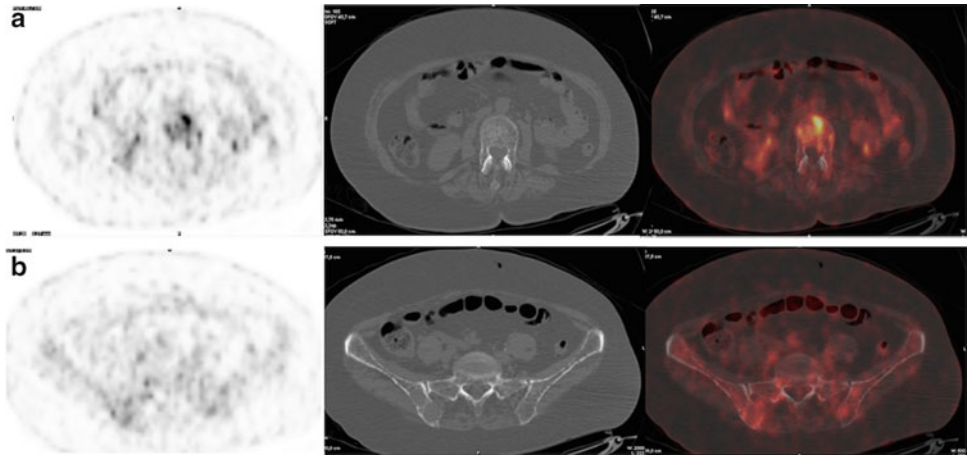

Fig. 18 Different pattern of [18F]FDG-PET/CT in a patient with oligosecretory/nonsecretory MM. Images show an area of focal [^{18}F]FDG uptake in L3 (**a**) while no uptake in the pelvis (**b**)

with positive PET/CT and those with negative PET/CT, respectively [122].

PET/CT has also a role in nonsecretory or oligosecretory myeloma for the detection of active lesions in the body [123] (Fig. 18). In this setting it may be useful also to monitoring treatment response.

PET/MRI represents a novel imaging modality with attractive potential clinical applications. In MM, there is only one prospective study comparing PET/MRI with PET/CT in 30 patients with MM with both techniques performed sequentially. There was high correlation between the two techniques, regarding the number of active lesions and the degree of uptake (SUV) [43, 124].

DEXA Scanning

The World Health Organization has identified dual-energy X-ray absorptiometry (DEXA) as the gold standard for measuring the severity of osteoporosis, for defining the risk of fractures, and for assessing changes in bone mineral density over time. This method is fast, noninvasive, and implies a low radiation burden to patients (between 0.001 and 0.01 mSv). However, bone mineral density can be affected by pathological conditions, such as vertebral collapse and spinal osteophytes that are often concomitant in patients with MM. At present, DEXA scanning cannot distinguish benign osteoporosis from osteoporosis induced by MM. Furthermore, the reduction in bone mineral density in patients with MM usually is not diffuse but is rather confined to the hematopoietically active portions of the skeleton; consequently, bone densitometry studies are not still sufficient to determine the presence of MM bone disease [9].

Diagnostic Applications of Nuclear Medicine: Leukemias

16

Martina Sollini, Sara Galimberti, Roberto Boni, and Paola Anna Erba

Abstract

Leukemias are a group of acute and chronic hematological neoplasias characterized by the dissemination of the cancer cells originating in the bone marrow via the bloodstream. In 2016 the estimated number of new leukemia cases was more than 110,000 in all of Europe and 47,000 in the USA. Leukemias, cause of 4% of all cancer deaths and account for 3.6% of all cancers. Historically, leukemias have been divided into four major categories further classified into subtypes based on specific features of cells: acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL), acute myelogenous leukemia (AML), and chronic myelogenous leukemia (CML). A revised classification of myeloid/lymphoid neoplasms and leukemias has recently been published to better characterize each disease. This updated classification incorporated new scientific and clinical information to refine diagnostic criteria for previously described neoplasms and introduced newly recognized disease entities. In this chapter the main entities of leukemia, with specific regard to imaging for diagnosis, treatment response assessment, and follow-up, will be treated according to what reported in the clinical guidelines.

Keywords

Leukemia • Imaging • Bone cancer • Hematological malignancies

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FLT	3'-^{18}F-Fluoro-3'-deoxythymidine
aCGH	Array comparative genomic hybridization
aCML	Atypical chronic myeloid leukemia
ALK	Anaplastic large-cell lymphoma
ALL	Acute lymphoblastic leukemia, also defined as "acute lymphocytic leukemia"
AML	Acute myeloid leukemia, also defined as "acute myelogenous leukemia"
B-ALL	B-cell acute lymphoblastic leukemia
BCL2	Gene encoding for the B-cell lymphoma 2 protein

https://doi.org/10.1007/978-3-319-26236-9_39

BCL6	Gene encoding for the B-cell lymphoma 6 protein
BCR-ABL1	Fusion gene formed by a translocation between chromosomes 9 and 22 [t(9;22)]
BM	Bone marrow
CBFB-MYH11	Chimeric transcript created by the inversion (16)(p13;q22)
CEBPA	Gene encoding for the protein CCAAT/enhancer-binding protein alpha
CHOP	Chemotherapy based on cyclophosphamide, vincristine, doxorubicin, and dexamethasone
CLL	Chronic lymphocytic leukemia, also defined as "chronic lymphocytic leukemia"
CML	Chronic myeloid leukemia, also defined as "chronic myelogenous leukemia"
CMML	Chronic myelomonocytic leukemia
CNL	Chronic neutrophilic leukemia
CNS	Central nervous system
CR	Complete response
CRLF2	Cytokine receptor-like factor 2
CT	X-ray computed tomography
DEK-NUP214	Gene fusion created by the t (6;9)(p23;q34) translocation
DLBCL	Diffuse large B-cell lymphoma
EBV	Epstein-Barr virus
ESMO	European Society of Medical Oncology
ET	Essential thrombocythemia
EUTOS	European Treatment and Outcome Study
FGFR	Receptor tyrosine kinase for the fibroblast growth factor family
FISH	Fluorescence in situ hybridization
GATA2	Gene encoding for a protein called GATA binding protein 2, a transcription factor
GEP	Gene expression profiling
HCL	Hairy cell leukemia
HHV8	Human herpesvirus-8
HL	Hodgkin's lymphoma
HLA	Human leukocyte antigen
iAMP21	Intrachromosomal amplification of chromosome 21
IgG	Immunoglobulin G
Igh	Immunoglobulin heavy chain
IGH/IL3	Fusion gene created by the t (5;14)(q31;q32) translocation
IGHV	Immunoglobulin heavy chain
IWCLL	International Working Group on CLL
JAK-STAT	Signaling pathway that transmits information from extracellular chemical signals to the nucleus resulting in DNA transcription and expression of genes involved in immunity, proliferation, differentiation, apoptosis, and oncogenesis
JAK2	Gene encoding for Janus kinase 2, a non-receptor tyrosine kinase
JMML	Juvenile myelomonocytic leukemia
KMT2A	Gene encoding for histone-lysine (K)-specific N-methyltransferase 2A
KMT2C	Gene encoding for lysine (K)-specific methyltransferase 2C
LAIP	Leukemia-associated immunophenotype
MALT	Mucosa-associated lymphoid tissue
MBL	Monoclonal B lymphocytosis
MCL	Mantle cell lymphoma
MDS-RS	Myelodysplastic syndrome with ring sideroblasts
MDS	Myelodysplastic syndrome
MDS/MPN	Myelodysplastic/Myeloproliferative neoplasms
MECOM	Gene econding for the protein MDS1 and EVI1 complex locus protein EVI1, also known as ecotropic virus integration site 1 protein homolog, or positive regulatory domain zinc finger protein 3

MGUS	Monoclonal gammopathy of undetermined significance
MLL-MLLT3	Gene fusion created by the t (9;11)(p22;q23) translocation
MPAL	Mixed phenotype acute leukemia
MR	Molecular response
MRD	Minimal residual disease
MRI	Magnetic resonance imaging
MYC	Avian myelocytomatosis viral oncogene homolog
NGS	Next-generation sequencing
NK	Natural killer
NMP1	Gene encoding for the protein nucleophosmin
NOS	Not otherwise specified
NOTCH1	Notch homolog 1, translocation-associated (Drosophila), a human gene encoding for a single-pass transmembrane receptor
NSCLC	Non-small-cell lung cancer
PB	Peripheral blood
PCM1-JAK2	Gene fusion created by the t (8;9)(p22;p24) translocation which leads to the activation of the Janus kinase 2PCM1 gene encoding for the pericentriolar material 1
PD	Progressive disease
PDGFR	Platelet-derived growth factor receptor
PDGFRA	Gene encoding for the platelet-derived growth factor receptor alpha
PDGFRB	Gene encoding for the platelet-derived growth factor receptor beta
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PI3K/AKT/mTOR	Intracellular signaling pathway important in regulating the cell cycle
PMF	Primary myelofibrosis
PML-RARA	Gene fusion created by the t (15;17)(q22;q12) translocation
PMN	Myeloproliferative neoplasms
PR	Partial response
PTLD	Posttransplant lymphoproliferative disorders
PV	Polycythemia vera
RT-PCR	Reverse transcriptase polymerase chain reaction
RUNX1-RUNX1T1	Gene fusion created by the t (8;21)(q22;q22) translocation
RUNX1	Runt-related transcription factor 1
SBB	Sudan Black B, a non-fluorescent lysochrome (fat-soluble) diazo dye used for tissue staining
SCT	Stem cell transplantation
SEER	Surveillance, Epidemiology, and End Results Program of the National Cancer Institute (National Institutes of Health of the United States)
SLL	Small lymphocytic lymphoma
SNP	Single-nucleotide polymorphism
T-ALL	T-cell acute lymphoblastic leukemia
TAM	Transient abnormal myelopoiesis
TKI	Tyrosine kinase inhibitor
T-ALL	T-cell acute lymphoblastic leukemia
TCF3-PBX1	Chimeric gene created by the t (1;19)(q23;p13) translocation
TFH	T follicular helper
WHO	World Health Organization

Leukemias are a group of acute and chronic hematological neoplasias characterized by the dissemination in the bloodstream of the cancer cells originating in the bone marrow. The incidence of acute leukemia in adult (either myeloid – AML or lymphoblastic – ALL) is about 4/100,000/year, that of the chronic myeloid leukemia (CML) 1.5/100,000/year, and that of the chronic lymphocytic leukemia (CLL) of 5/100,000/year. Thus, in 2016 the estimated number of new leukemia cases is more than 110,000 in all of Europe and 47,000 in the USA. Leukemias, cause of 4% of all cancer deaths and account for 3.6% of all cancers, with CLL being the most frequent type (60%), followed by AML (25%). Leukemias are most frequently diagnosed among people aged 65–74 years, but all age groups can be affected. ALL are the most common pediatric tumor (about 35% of cancers in children aged 0–14 years), but all age groups can be affected. Approximately 9% were diagnosed before age 20, 9% between 20 and 44, 10% between 45 and 54, 18% between 55 and 64, 22% between 65 and 74, 21% between 75 and 84, and 11% after 85 years of age [1].

A leukemia is considered lymphocytic or lymphoblastic if it occurs in a marrow cell that forms lymphocytes, while it is "myelogenous" or "myeloid" if it occurs in a marrow cell that forms red cells, some kinds of white cells, and platelets (Fig. 1).

Historically, leukemias have been divided into four major categories further classified into subtypes based on specific features of cells [2]:

- Acute lymphocytic leukemia (ALL)
- Chronic lymphocytic leukemia (CLL)
- Acute myelogenous leukemia (AML)
- Chronic myelogenous leukemia (CML)

A revised classification of myeloid/lymphoid neoplasms and leukemias has been recently published in order to better characterize each disease accurately reflecting the specific neoplastic nature. This updated classification incorporated new scientific and clinical information to refine diagnostic criteria for previously described neoplasms and introduced newly recognized disease entities. Table 1 shows the new classification [3, 4].

Acute Lymphocytic Leukemia (ALL) in Adult

In 2016, the estimated number of new cases of ALL was about 6,500, accounting for 0.4% of all new cases of cancer. The number of new cases of ALL was 1.7 per 100,000 per year based on 2009–2013 cases, according to the SEER database. ALL is most frequently diagnosed among people aged <20 (57%); it is most common in children, adolescents, and young adults, with a median age at diagnosis of 15 years. ALL is most common in Hispanics and Whites [1]. ALL occurs both in children and adults. Predisposing risk factors for adult ALL are not known, contrary to childhood ALL [5]. In adults, the age of appearance is one of the most important prognostic determinants. Although the two forms share some common features, fundamental biologic differences may account for the striking variation in outcome. However, although survival in adult patients (>19 years old) remains inferior to that achieved for children with ALL [6], recent advances in molecular testing, the development of new targeted agents, and an improved understanding of the importance of minimal residual disease (MRD) could soon translate into improved prognosis [7]. Recurrent numerical and/or structural cytogenetic abnormalities are found in 70% of adults and 90% of children with ALL and provide important prognostic and certain drug resistance information [8]. Literature data [9, 10] suggest that routine characterization of ALL can aid in the design of more tailored treatment plan.

Furthermore, many chromosomal abnormalities identified in adult ALL have also been found to

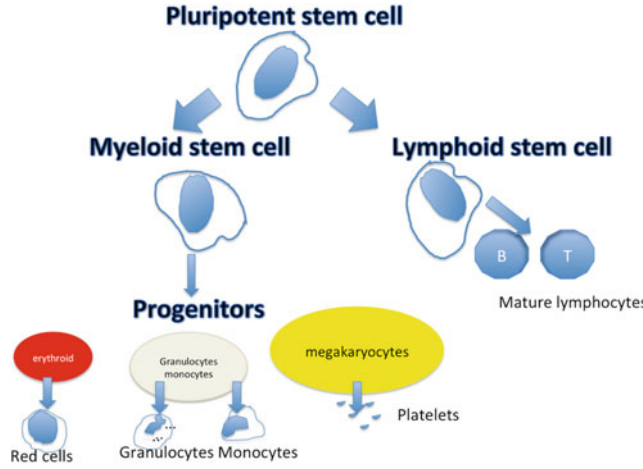

Fig. 1 Schematic representation of leukemias

correlate with prognosis [11–14]. The most important cytogenetic abnormality in adult ALL (found in 15–30%) is the Philadelphia (Ph') chromosome. Ph' chromosome is defined as t(9;22)(q34;q11.2), which results in the BCR-ABL1 fusion gene, with a constitutive and uncontrolled tyrosine kinase activity [15]. A novel subtype of ALL was recently identified by gene expression profiling which clusters with BCR-ABL1 positive ALL. This entity is now referred to as "Ph'-like" disease and represents 15–20% of the adolescent and young adult ALL. These patients have an unfavorable outcome and 5-year disease-free survival of only 25.8% [16]; this subtype has high frequency of kinase-activating alterations providing the lymphoblasts with proliferation advantage. Some of these fusions are sensitive in vitro to tyrosine kinase inhibitors (TKIs), leading to clinical trials assessing their integration into ALL armamentarium [7]. Some advances have been made in the identification of molecular markers of T-cell leukemogenesis. Activating mutations of NOTCH1 (a class I transmembrane heterodimeric glycoprotein that is normally involved in T-cell development and regulation) have been detected in almost 60% of human T-ALL [17]. These activating mutations led to clinical testing of gamma-secretase inhibitors that prevent NOTCH1 activation [18–20].

Epigenetic changes including hypermethylation of tumor suppressor genes or microRNAs and hypomethylation of oncogenes have also been studied in ALL. It represents a novel area of investigation for targeted drugs, such as DNA methyltransferase inhibitors [21–23].

CRLF2 is located in the pseudoautosomal region at Xp22.3/Yp11.3; it is rearranged in 50% of Down syndrome-related ALL and also in Ph'-like ALL [16]. Cells with CRLF2 mutations exhibit activation of the JAK/STAT and of the downstream PI3K/mTOR pathway; thus, in these subtypes, everolimus, temsirolimus, and ruxolitinib could be useful targeted treatments [24]. Other possible targets of interest in ALL include the 22q11.22 deletion and platelet-derived growth factor receptor alpha (PDGFR-alpha) gains that are associated with poor outcome and could predict therapeutic responses to TKIs able to inhibit PDGFR-alpha, such as imatinib [25].

Imaging for Diagnosis and Staging of ALL

A comprehensive diagnostic approach requires the study of cell morphology, immunophenotype, genetics/cytogenetics, and genomics, as detailed in the 2008 World Health Organization (WHO) classification [26] and recently reviewed [4, 27] (Table 1). The initial diagnostic work-up must confirm ALL diagnosis, distinguishing leukemia originating from the B or T lymphocytes, from precursors or more mature cells, and those Ph'

Table 1 Revised classification of myeloid/lymphoid neoplasms and leukemias according to the 2016 WHO classification.

2016 WHO classification	
Myeloid neoplasm and acute leukemia classification	Mature lymphoid, histiocytic, and dendritic neoplasms
Myeloproliferative neoplasms (MPN)	***Mature B-cell neoplasms***
Chronic myeloid leukemia (CML), BCR-ABL1	Chronic lymphocytic leukemia/small lymphocytic lymphoma
Chronic neutrophilic leukemia (CNL)	Monoclonal B-cell lymphocytosis[a]
Polycythemia vera (PV)	B-cell prolymphocytic leukemia
Primary myelofibrosis (PMF)	Splenic marginal zone lymphoma
PMF, prefibrotic/early stage	Hairy cell leukemia
PMF, overt fibrotic stage	Splenic B-cell lymphoma/leukemia, unclassifiable
Essential thrombocythemia (ET)	Splenic diffuse red pulp small B-cell lymphoma
Chronic eosinophilic leukemia, not otherwise specified (NOS)	Hairy cell leukemia variant
MPN, unclassifiable	Lymphoplasmacytic lymphoma
Mastocytosis	Waldenström macroglobulinemia
Myeloid/lymphoid neoplasms with eosinophilia and rearrangement of PDGFRA, PDGFRB, or FGFR1 or with PCM1-JAK2	Monoclonal gammopathy of undetermined significance (MGUS), IgM[a]
Myeloid/lymphoid neoplasms with PDGFRA rearrangement	μ heavy-chain disease
Myeloid/lymphoid neoplasms with PDGFRB rearrangement	γ heavy-chain disease
Myeloid/lymphoid neoplasms with FGFR1 rearrangement	α heavy-chain disease
Provisional entity: myeloid/lymphoid neoplasms with PCM1-JAK2	Monoclonal gammopathy of undetermined significance (MGUS), IgG/A[a] plasma cell myeloma solitary plasmacytoma of bone
Myelodysplastic/myeloproliferative neoplasms (MDS/MPN)	Extraosseous plasmacytoma
Chronic myelomonocytic leukemia (CMML)	Monoclonal immunoglobulin deposition diseases[a]
Atypical chronic myeloid leukemia (aCML), BCR-ABL1	Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
Juvenile myelomonocytic leukemia (JMML)	Nodal marginal zone lymphoma
MDS/MPN with ring sideroblasts and thrombocytosis (MDS/MPN-RS-T)	Pediatric nodal marginal zone lymphoma
MDS/MPN, unclassifiable	Follicular lymphoma
Myelodysplastic syndromes (MDS)	In situ follicular neoplasia[a]
MDS with single-lineage dysplasia	Duodenal-type follicular lymphoma[a]
MDS with ring sideroblasts (MDS-RS)	Pediatric-type follicular lymphoma[a]
MDS-RS and single-lineage dysplasia	Large B-cell lymphoma with IRF4 rearrangement[a]
MDS-RS and multilineage dysplasia	Primary cutaneous follicle center lymphoma
MDS with multilineage dysplasia	Mantle cell lymphoma
MDS with excess blasts	In situ mantle cell neoplasia[a]
MDS with isolated del(5q)	Diffuse large B-cell lymphoma (DLBCL), NOS
MDS, unclassifiable	Germinal center B-cell type[a]
Provisional entity: refractory cytopenia of childhood	Activated B-cell type[a]
Acute myeloid leukemia (AML) and related neoplasms	T-cell/histiocyte-rich large B-cell lymphoma
AML with recurrent genetic abnormalities	Primary DLBCL of the central nervous system (CNS)
AML with t(8;21)(q22;q22.1);RUNX1-RUNX1T1	Primary cutaneous DLBCL, leg type

Table 1 (continued)

2016 WHO classification	
Myeloid neoplasm and acute leukemia classification	Mature lymphoid, histiocytic, and dendritic neoplasms
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFB-MYH1	EBV^+ DLBCL, NOS[a]
APL with PML-RARA	EBV^+ mucocutaneous ulcer[a]
AML with t(9;11)(p21.3;q23.3);MLLT3-KMT2A	DLBCL associated with chronic inflammation
AML with t(6;9)(p23;q34.1);DEK-NUP214	Lymphomatoid granulomatosis
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM	Primary mediastinal (thymic) large B-cell lymphoma
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3); RBM15-MKL1	Intravascular large B-cell lymphoma
Provisional entity: AML with BCR-ABL1	ALK^+ large B-cell lymphoma
AML with mutated NPM1	Plasmablastic lymphoma
AML with biallelic mutations of CEBPA	Primary effusion lymphoma
Provisional entity: AML with mutated RUNX1	$HHV8^+$ DLBCL, NOS[a]
AML with myelodysplasia-related changes	Burkitt lymphoma
Therapy-related myeloid neoplasms	Burkitt-like lymphoma with 11q aberration[a]
AML, NOS	High-grade B-cell lymphoma, with MYC and BCL2 and/or BCL6 rearrangements[a]
AML with minimal differentiation	High-grade B-cell lymphoma, NOS[a]
AML without maturation	B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma mature
AML with maturation	***Mature T and NK neoplasms***
Acute myelomonocytic leukemia	T-cell prolymphocytic leukemia
Acute monoblastic/monocytic leukemia	T-cell large granular lymphocytic leukemia
Pure erythroid leukemia	Chronic lymphoproliferative disorder of NK cells
Acute megakaryoblastic leukemia	Aggressive NK-cell leukemia
Acute basophilic leukemia	Systemic EBV^+ T-cell lymphoma of childhood[a]
Acute panmyelosis with myelofibrosis	Hydroa vacciniforme-like lymphoproliferative disorder[a]
Myeloid sarcoma	Adult T-cell leukemia/lymphoma
Myeloid proliferations related to Down syndrome	Extranodal NK-/T-cell lymphoma, nasal type
Transient abnormal myelopoiesis (TAM)	Enteropathy-associated T-cell lymphoma
Myeloid leukemia associated with Down syndrome	Monomorphic epitheliotropic intestinal T-cell lymphoma[a]
Blastic plasmacytoid dendritic cell neoplasm	Indolent T-cell lymphoproliferative disorder of the GI tract[a]
Acute leukemias of ambiguous lineage	Hepatosplenic T-cell lymphoma
Acute undifferentiated leukemia	Subcutaneous panniculitis-like T-cell lymphoma
Mixed phenotype acute leukemia (MPAL) with t(9;22)(q34.1;q11.2); BCR-ABL1	Mycosis fungoides
MPAL with t(v;11q23.3); KMT2A rearranged	Sézary syndrome
MPAL, B/myeloid, NOS	Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
MPAL, T/myeloid, NOS	Lymphomatoid papulosis
B-lymphoblastic leukemia/lymphoma	Primary cutaneous anaplastic large-cell lymphoma
B-lymphoblastic leukemia/lymphoma, NOS	Primary cutaneous γδ T-cell lymphoma
B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities	Primary cutaneous $CD8^+$ aggressive epidermotropic cytotoxic T-cell lymphoma
B-lymphoblastic leukemia/lymphoma with t(9;22)(q34.1;q11.2);BCR-ABL1	Primary cutaneous acral $CD8^+$ T-cell lymphoma[a]

Table 1 (continued)

2016 WHO classification	
Myeloid neoplasm and acute leukemia classification	Mature lymphoid, histiocytic, and dendritic neoplasms
B-lymphoblastic leukemia/lymphoma with t (v;11q23.3);KMT2A rearranged	Primary cutaneous $CD4^+$ small/medium T-cell lymphoproliferative disorder[a] peripheral T-cell lymphoma, NOS
B-lymphoblastic leukemia/lymphoma with t(12;21) (p13.2;q22.1); ETV6-RUNX1	Angioimmunoblastic T-cell lymphoma, follicular T-cell lymphoma[a]
B-lymphoblastic leukemia/lymphoma with hyperdiploidy	Nodal peripheral T-cell lymphoma with TFH phenotype[a]
B-lymphoblastic leukemia/lymphoma with t(5;14) (q31.1;q32.3) IL3-IGH	Anaplastic large-cell lymphoma, ALK^+
B-lymphoblastic leukemia/lymphoma with t(1;19) (q23;p13.3);TCF3-PBX1	Anaplastic large-cell lymphoma, ALK^-[a]
Provisional entity: B-lymphoblastic leukemia/ lymphoma, BCR-ABL1–like	Breast implant-associated anaplastic large-cell lymphoma[a]
T-lymphoblastic leukemia/lymphoma	***Hodgkin lymphoma***
Provisional entity: natural killer (NK) cell lymphoblastic leukemia/lymphoma	Nodular lymphocyte predominant Hodgkin lymphoma
Provisional entity: B-lymphoblastic leukemia/ lymphoma with iAMP21	Classical Hodgkin lymphoma
T-lymphoblastic leukemia/lymphoma	Nodular sclerosis classical Hodgkin lymphoma
Provisional entity: early T-cell precursor lymphoblastic leukemia	Lymphocyte-rich classical Hodgkin lymphoma
Provisional entity: natural killer (NK) cell lymphoblastic leukemia/lymphoma	Mixed cellularity classical Hodgkin lymphoma
	Lymphocyte-depleted classical Hodgkin lymphoma
	Posttransplant lymphoproliferative disorders (PTLD)
	Plasmacytic hyperplasia PTLD
	Infectious mononucleosis PTLD
	Florid follicular hyperplasia PTLD[a]
	Polymorphic PTLD
	Monomorphic PTLD (B- and T-/NK-cell types)
	Classical Hodgkin lymphoma PTLD
	Histiocytic and dendritic cell neoplasms
	Histiocytic sarcoma
	Langerhans cell histiocytosis
	Langerhans cell sarcoma
	Indeterminate dendritic cell tumor
	Interdigitating dendritic cell sarcoma
	Follicular dendritic cell sarcoma
	Fibroblastic reticular cell tumor
	Disseminated juvenile xanthogranuloma
	Erdheim-Chester disease[a]

[a]Changes from the 2008 classification

positive, allowing the most appropriate treatment (anti-CD20, anti-CD19, anti-CD22 antibodies, tyrosine kinase inhibitors) [28].

Aspiration of bone marrow and bone marrow biopsy represent the standard procedure; the bone marrow must contain at least 20% blast cells, as a criterion to differentiate ALL from lymphoblastic lymphoma, but the proportion of circulating blasts is highly variable. ALL blasts are atypical lymphoid or undifferentiated cells. The immunophenotype study plays the key diagnostic role, demonstrating commitment of the blast cell

population to the B- or T-cell lineage. The European Group for the Immunological Characterization of Leukemias recognized distinct BCP/T-ALL subsets, providing a rational immunological classification along with criteria for differential diagnosis [29] subsequently updated and improved [30–32]. The early diagnostic step is completed by a rapid molecular screening by means of reverse transcriptase polymerase chain reaction (RT-PCR) or fluorescence in situ hybridization (FISH) assays, primarily for the detection of BCR-ABL1 rearrangement, sensitive to tyrosine kinase inhibitors (TKIs) [33]. Results from cytogenetics, genetics, and genomics are available at a later stage, allowing the recognition of several ALL syndromes with prognostic and/or therapeutic implications. The more prognostically favorable cytogenetic/genetic subsets are represented by t(12;21)(p13;q22)/TEL-AML1 (rare in adults), the hyperdiploid ALL, and T-ALL with NOTCH-1/FBXW7 mutations. The integration of the conventional studies (karyotype, FISH, qualitative, and quantitative PCR) with the new ones [array comparative genomic hybridization (aCGH), gene expression profiling (GEP), single-nucleotide polymorphism (SNP) array analysis, next-generation sequencing (NGS)] led to the recognition of highly specific poor-risk conditions, whose global incidence is 30%. These assays are not still regularly carried out in clinical practice, but are recommended to improve the risk classification and support targeted therapies [28].

The diagnostic phase is completed by the search for a sensitive molecular marker or an aberrant leukemia-associated immunophenotype (LAIP) for the detection and monitoring of minimal residual disease (MRD) [34]. Human leukocyte antigen (HLA) typing of patients and relatives is recommended at this stage, to facilitate subsequent application of the allogeneic stem cell transplantation (SCT) when necessary [28].

Patients with ALL typically present with constitutional symptoms, bleeding, infections, and/or bone pain, with less than 10% of individuals having symptomatic central nervous system (CNS) involvement at diagnosis. Mature B-ALL can also present as extramedullary (gastrointestinal or testicular) diseases. Mediastinal mass with wheezing and stridor can be a presenting feature of T-cell ALL [35].

Symptomatic CNS involvement is more frequent in patients with mature B-ALL; these patients may present with cranial nerve deficiencies (especially cranial nerves VI, III, IV, and VII), leading to double vision, abnormal ocular movements, facial dysesthesia, and facial droop [36]. Patients with T-ALL frequently present with a mediastinal mass on chest X-ray. If the mass is sufficiently large, it results in stridor, wheezing, pericardial effusions, and superior vena cava syndrome [37]. Involvement of the skin, testicles, kidneys, joints, and bones is uncommon in adults [38, 39]. Approximately 15–25% of ALL patients of all ages have leukemia with a T-cell phenotype, which is associated with higher initial WBC counts, mediastinal mass, male gender, and higher incidence of CNS involvement. In children, the frequency of T-lineage ALL increases with age.

Physical examination may reveal pallor, ecchymoses, or petechiae. Lymphadenopathy and hepatosplenomegaly are infrequent; patients present with signs and symptoms of metabolic hyperactivity, including profound constitutional symptoms, weight loss, and often large abdominal and (especially in children) testicular masses [40]. Involvement of the gastrointestinal tract is also frequent and may cause bleeding or rupture.

Microscopy and cytochemical stains are still essential in the initial work-up: bone marrow is usually hypercellular and replaced with a homogenous population of leukemic blasts [41].

In contrast to lymphoma, leukemia is not staged because it involves the bone marrow, and leukemic cells circulate throughout the bloodstream to all parts of the body.

In patients with atypical presentations or complications, particularly in the presence of bone pain, osteopathy and hypercalcemia, CNS involvement or infectious complications or to detect extramedullary disease, imaging may be helpful [42] (Fig. 2). In the American Cancer Society of Childhood Leukemia Report (2002), several radiological (X-rays, ultrasound, CT, and MRI) and nuclear medicine imaging modalities are useful to assess the disease. However, the recent ESMO guideline does not recommend any radiologic imaging in ALL

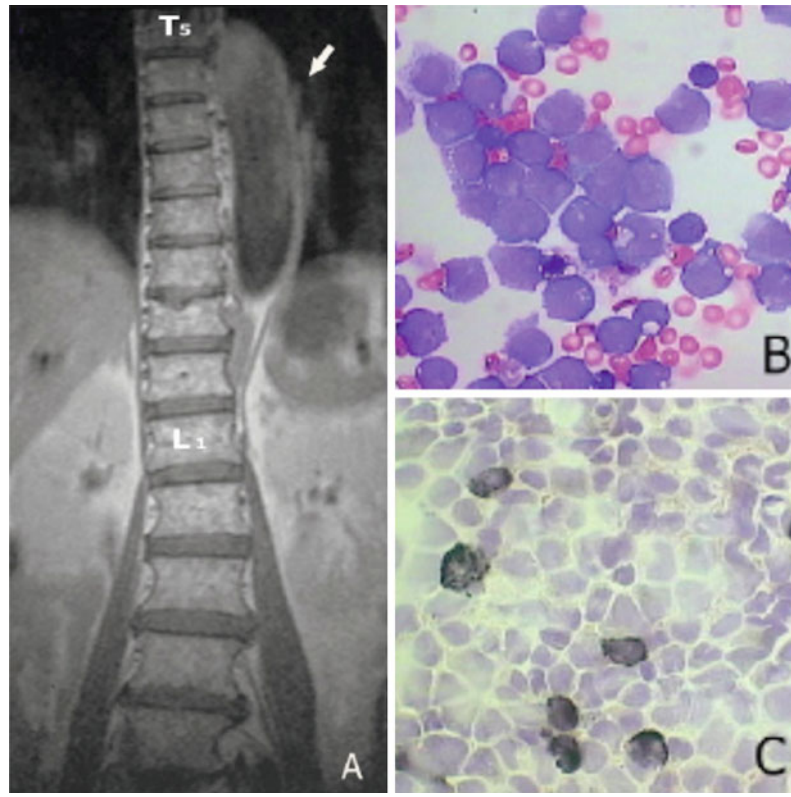

Fig. 2 Sagittal T1-weighted MR image (**a**) showing the spinal cord wrapped by hypointense tissue extending from T5 to T12 (*arrow*). Cerebral spinal fluid smear showing myeloblasts with a high nucleocytoplasmic ratio, monoblasts with more plentiful cytoplasm, and a folded nucleus with a lacy chromatin pattern (May-Grünwald-Giemsa, original magnification 960, (**b**)). Cerebral spinal fluid smear stained with SBB showing few myeloblasts with strong positive granular reaction (*black*) and monoblasts with weaker or absent granular reaction (original magnification 960, (**c**)) (Modified from Potenza et al. [161])

diagnosis or for the initial staging [28]. In clinical practice many patients with ALL present with constitutional symptoms, e.g., fever, and then imaging is part of the diagnostic work-up to identify the cause of fever.

Osteopathy, including bone pain and pathologic fracture, is one of the initial symptoms of ALL, with an incidence of about 20% in childhood ALL [43]. Bone scintigraphy may be helpful to elucidate the etiology of bone pain: in fact, pain localized at joints may be the first presentation of ALL. The knee is the most frequently affected site, followed by the ankle. Bone scintigraphy is able to demonstrate abnormalities in the majority of leukemic patients with bone lesions occurring even in sites without pain. Focal intense uptake in one or several metaphyses as well as in diaphyses represents the typical scintigraphic findings, and the most common affected sites are metaphyses, diaphyses, and epiphyses of long bones, the pelvis, and ribs. Lower limbs are involved more frequently than upper extremities (Fig. 3). Moreover, diffuse uptake in the pelvis and spine may suggest marrow infiltrative disease [44], and bone X-ray may be helpful to detect leukemic changes in bone or joint in the presence of bone pain [45].

Ultrasound and CT scan are generally used to assess extramedullary involvement in the abdomen, and MRI is indicated to assess the CNS for leukemic infiltration, infections or multifocal leukoencephalopathy.

Renal involvement does not necessarily imply a significant organ impairment, because elevated creatinine may occur due to lymphadenopathy compressing renal vessels and/or ureter. Nephromegaly is a common finding in children [46]. Additionally causes of renal parenchymal abnormalities in childhood ALL include infection, lymphoma transformation, nephroblastomatosis, cysts, angiomyolipomas, and metastases. Furthermore, atypical infection with microabscesses in the liver, spleen, and kidneys appear as focal small non-enhancing areas of parenchymal abnormality [47] on CT, especially in children. In patients with

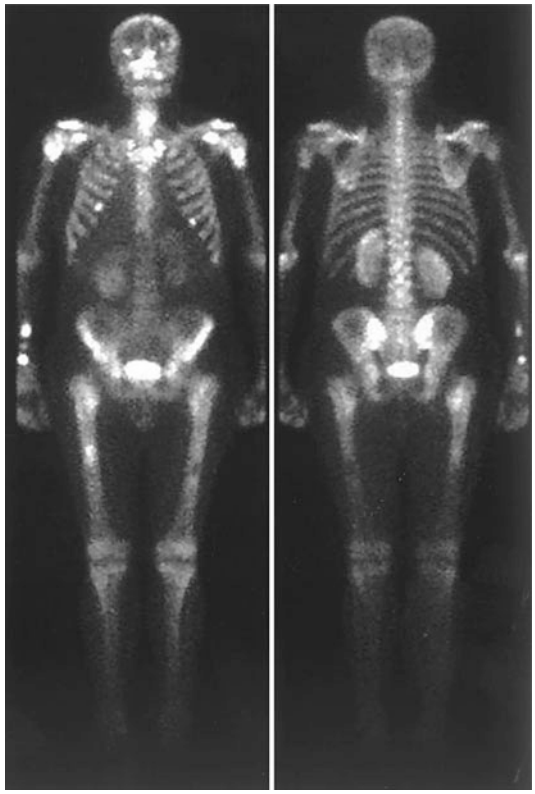

Fig. 3 Bone scintigraphy of a 43-year-old men with a ALL showing increased radiopharmaceutical uptake in all long bone diaphysis, as suggestive of bone marrow expansion (Modified from Benitez et al. [162])

possible CNS infection and negative cultures, MRI may be helpful in revealing the presence of the disease and in the assessment to response to treatment. Early diagnosis of neurologic involvement is essential to insure effective therapy and for detection of treatment-related neurotoxicity, secondary brain tumors, infections, and cerebrovascular disease [48–50]. MRI abnormal enhancement of the meninges and/or nerve roots may result from leptomeningeal or subarachnoid disease/relapse or infection, rarely, both. Other causes of nerve root enhancement on MRI include postsurgical arachnoiditis, mechanical root compression associated with inflammation, cytomegalovirus polyradiculopathy or inflammatory demyelinating polyradiculoneuropathy (Guillain-Barrè syndrome), and rarely spontaneous spinal hematomas [48]. Promising results have been reported in the identification of the extramedullary involvement, specially in recurrent disease, using [^{18}F]FDG-PET/CT [51, 52].

Imaging for the Evaluation of Treatment Response of ALL

The definition of treatment response in ALL does not require any imaging. However, imaging plays an important role for detecting and monitoring treatment.

Treatment-related CNS complications include white matter lesions, small-vessel calcifications, cerebrovascular disorders, treatment-induced tumors, infections, and enlargement of ventricles and/or widening of sulci (sign of cortical atrophy). Leukoencephalopathy is the most common neurotoxicity, usually due to methotrexate in ALL patients. It appears as white matter hyperintensities on T2-weighted MRI, and it may be persistent or transient [53]. Mineralizing microangiopathy is a delayed form of neurotoxicity typically detectable as dystrophic calcifications in the basal ganglia and subcortical white matter.

The detection of iron overload, particularly in myocardium in patients receiving chronic red cell transfusions, is mandatory to prevent ventricular dysfunction. MRI-T2*-weighted images using gradient-echo MRI-T2* allow the determination of myocardial iron amount and may be used both for diagnosis and monitoring myocardial iron overload during and after antileukemic treatment with blood transfusions [54].

Chronic Lymphocytic Leukemia (CLL)

CLL is characterized by a progressive accumulation of monoclonal B lymphocytes and is part of a spectrum of diseases grouped as low-grade lymphoproliferative disorders. CLL is the most common form of all leukemias among adult populations of the Western world and is more common in men. Since this disease is characterized by relatively longer survival rate, its prevalence rate is the highest among all leukemias. In 2016, the estimated number of new cases of CLL is about 19,000,

accounting for 1.2% of all new cases of cancer. CLL is rare in people younger than 50 years, but after this age a fairly rapid rise in incidence takes especially after 55 years. Approximately 9% of cases are diagnosed between 45 and 54 years, 22% between 55 and 64, 28% between 65 and 74, 26% between 75 and 84, and 13% after 85 years of age (about 2% in patients <44 years) [1].

Genetic, rather than environmental, factors are the most likely explanation for the geographic and ethnic differences in incidence. There is an inherited genetic susceptibility for CLL, with a six to ninefold increased risk for family members of CLL patients. There are no clearly identified etiologic factors known in CLL [55].

The diagnosis of CLL is established by the presence in the peripheral blood of $\geq 5 \times 10^9$/L monoclonal B lymphocytes (clonality of the circulating B lymphocytes needs to be confirmed by flow cytometry or assessment of the immunoglobulin heavy chain (IgH) clonal rearrangement by PCR). In the peripheral blood smear, the leukemic cells appear as small, mature lymphocytes with a narrow border of cytoplasm and a dense nucleus lacking discernible nucleoli and with partially aggregated chromatin. Larger, atypical lymphocytes or prolymphocytes may be seen, but they must not exceed 55% [56].

Immunophenotype is useful for distinguishing CLL from other indolent lymphomas, such as the marginal zone, the lymphoplasmacytic, and the mantle cell (MCL) [55]: indeed, in addition to the B markers (CD20, CD19), common to all B lymphomas, the co-expression of CD5 (that occurs also in MCL); the CD79, CD11c, CD103, and FMC7 negativity; and the CD200 and CD23 positivity characterize the B-CLL.

In the WHO classification, small lymphocytic lymphoma (SLL) and CLL are considered as a single entity (Table 1).

The diagnosis of SLL requires the presence of lymphadenopathy and/or splenomegaly with a number of B lymphocytes in the peripheral blood not exceeding 5×10^9/L. SLL cells show the same immunophenotype as CLL. The diagnosis of SLL should be confirmed by histopathological evaluation of a lymph node or tumor mass biopsy, whenever possible. In the absence of lymphadenopathy, organomegaly, cytopenia, and clinical symptoms, the presence of fewer than 5×10^9/L monoclonal B lymphocytes is defined as "monoclonal B lymphocytosis" (MBL) [55–57] which can be detected in 5% of subjects with normal blood count. As described for monoclonal gammopathies and multiple myeloma, progression to CLL occurs in 1–2% of MBL cases per year [57].

CLL cells co-express the CD5 antigen and B-cell surface antigens CD19, CD20, and CD23. The levels of surface immunoglobulin, CD20, and CD79b are characteristically low compared with normal B cells. Each clone of leukemia cells is restricted to expression of either kappa or lambda immunoglobulin light chains [55].

The pathophysiology of CLL involves inhibition of apoptosis [58]. Accumulation of mature B cells that have escaped programmed cell death and undergone cell cycle arrest in the G0/G1 phase is the hallmark of CLL [59]. These cells have a low proliferative activity, and data lend support to the hypothesis that in vivo defective apoptosis accounts for accumulation of B cells.

CLL is generally considered an indolent disease associated with a prolonged chronic course; more than one-third of patients die for other causes and the natural history is very heterogeneous: some patients die within 2–3 years from the diagnosis, mainly because of complications or causes directly related to CLL. Nevertheless, the majority of cases present relatively benign initial course (5–10 years), followed by a terminal phase lasting 1–2 years with considerable morbidity, both from the disease itself and from complications of therapy. The most frequent causes of death are severe systemic infections (especially pneumonia and septicemia), bleeding, and inanition with cachexia. In about 3% of CLL patients, a diffuse large-cell immunoblastic lymphoma supervenes terminally (Richter's transformation), associated with a rapidly progressive course, refractoriness to all chemotherapy, and death within 6 months [60]. Another possible terminal event is the morphologic transformation of blood lymphocytes from the typical small, mature-appearing cell to larger cells with distinct nucleoli and less dense chromatin in the nucleus, called *prolymphocytoid transformation*. Acute leukemia

is rarely observed as a terminal event; it occurs independently by treatment with alkylating agents, and when it does occur, it is myeloid in origin (myelocytic, myelomonocytic, or acute erythroleukemia). There is no widely accepted effective therapy for these terminal transformations of CLL. Patients with CLL are considered to be at a somewhat higher risk than the general population of developing another cancer, usually of lung or gastrointestinal tract. Skin cancers occur with considerably greater frequency among CLL patients than among the general population, but these do not result in higher mortality.

Several systems of clinical staging have been proposed by investigators around the world, but just the Rai system [61] and the Binet system [62] (Table 2a, b) are in wide use in clinical practice as well as in research. In Europe, the Binet staging system is more widely used, whereas in the USA, the Rai system is more commonly applied. Both Binet and Rai staging systems separate three groups of patients with different prognoses [55].

The Rai staging system [61] is based on the concept that in CLL there is a gradual and progressive increase in the burden of leukemic lymphocytes, resulting in sequential clinical manifestations of the disease starting in the blood and bone marrow and then involving the lymph nodes, spleen, and liver or other lymphoid sites. The earliest stage (stage 0) is characterized by no stigmata of disease other than the minimum diagnostic requirements of CLL. About 20–25% of patients at the time of initial diagnosis of CLL are in the earliest clinical stage (stage 0, median survival from the time of diagnosis = 150 months), 25% are in the advanced stages (stages III and IV, median survival = 19 months), and the remaining 50% are in stage I or II (median survival = 101 and 71, respectively). In 1987, however, the system was simplified to consist of only three groups: low (Rai stage 0), intermediate (Rai stages I and II combined), and high (Rai stages III and IV combined) (140). Binet's method [62] classifies all patients with anemia (defined as hemoglobin below 100 g/L) and/or thrombocytopenia (platelets less than 100×10^9/L) as stage C. All of the remaining patients are divided into two groups. This staging takes into consideration five areas: cervical, axillary, and inguinal lymph nodes (whether unilateral or bilateral, each area is counted as one) and the spleen and liver. The International Working Group on CLL (IWCLL) recommended that, in practice, an integrated system using both methods should be used [63]. According to this recommendation, each Binet stage is to be further identified by the appropriate Rai stage (i.e., A-0, A-I, A-II, B-I, B-II, C-III, C-IV). However, this integrated system has not been widely accepted, and most clinicians today use either the Rai's or Binet's method for patient management and therapeutic investigation.

Table 2 Rai (2A) and Binet (2B) staging systems

2A

Rai stage	High levels of lymphocytes	Swollen lymph nodes	Enlarged spleen or liver	Anemia	Low levels of platelets
0	Yes	No	No	No	No
I	Yes	Yes	No	No	No
II	Yes	Yes or no	Yes	No	No
III	Yes	Yes or no	Yes or no	Yes	No
IV	Yes	Yes or no	Yes or no	Yes or no	Yes

2B

Binet stage	Number of lymph node areas	Anemia	Low levels of platelets
A	<3	No	No
B	3 or more	No	No
C	Any number	Yes (or low platelets)	Yes (or anemia)

Both the Rai's or Binet's staging systems rely solely on a physical examination and standard laboratory tests, whereas the role of various imaging procedures (ultrasound, computed tomographic scan, or magnetic resonance imaging [MRI]) has not been validated for staging of CCL. The Binet's method may require some modification in the future, since CT has become a routine part of initial investigations and may reveal enlargement of retroperitoneal or mediastinal nodes that are currently not included among the five sites of palpably enlarged lymphoid areas.

The Rai's or Binet's clinical staging systems alone are not sufficient to estimate the individual prognosis reliably, particularly for patients with early-stage disease. Therefore, additional parameters have been sought to more accurately assess the prognosis of patients with CLL. This search has provided a steadily increasing number of laboratory tests, which predict the response to treatment, progression-free survival, or overall survival of patients with CLL. Several prognostic factors have been tested, including extent of blood lymphocytosis, morphologic features of blood lymphocytes (i.e., the relative proportion of prolymphocytes), presence of normal or abnormal chromosomal karyotype, phenotypic profile of B lymphocytes, age, sex and levels of serum immunoglobulins, molecular genetics makers, beta-2 microglobulin, and adhesion molecules [64]. The mutational status of IgH genes on CLL lymphocytes seems promising: VH gene mutations correlate with significantly longer survival and a relatively more benign disease course than unmutated genes. Testing for gene mutations, however, is not routinely done in hospitals, but perhaps CD38 expression, a readily available test, holds the promise of being useful as a surrogate marker. Patients with mutated VH genes showed a strong correlation with low expression of CD38 and ZAP70 on CLL lymphocytes [65]. These findings were especially strong prognostic indicators for patients in the intermediate-risk category patients, but at the moment these molecular features don't really lead the therapeutic strategy. In fact, CLL cells with unmutated IGVH status have a higher genetic instability with a higher risk of gaining unfavorable genetic mutations. OS and time to treatment intervention are significantly shorter in this patient group. The expression of CD38 and ZAP70 correlates to some extent with the IGHV mutational status, but has no therapeutic impact and is therefore not required.

Imaging for Diagnosis and Staging of CLL

Diagnosis of CLL is essentially based on symptoms, laboratory tests, and physical examination. Before any treatment, history, and physical examination including a careful palpation of all lymph node areas, the spleen, and the liver, a complete blood cell count and differential count, serum chemistry including lactate dehydrogenase, bilirubin, serum immunoglobulins, and direct antiglobulin, should be performed. Particular attention should be paid to the history and status of relevant infections (i.e., hepatitis B and C, cytomegalovirus, human immunodeficiency virus) in order to avoid virus reactivation during chemoimmunotherapy or allogeneic stem cell transplantation (alloSCT) [55]. The diagnostic work-up should include FISH analysis for the detection of deletion of the chromosome 17 [del (17p)] affecting the tumor protein p53 expression and in the absence of del(17p) molecular genetics for the detection of TP53 gene mutation (at least exons 4–10, eventually exons 2–11) [66].

Although a bone marrow biopsy is not really necessary for diagnosis, nevertheless it is recommended for assessing the pattern of bone marrow infiltration and for the diagnostic evaluation of unclear cytopenias. An extended FISH analysis (for chromosome 11, 12, 13, 17) is recommended before the start of therapy because the detection of additional cytogenetic abnormalities [del(11q) or trisomy 12] may have therapeutic consequences. In particular, deletion of chromosome 17 and/or of TP53 is indicative of a worse prognosis or for the possibility of employing the Bruton kinase inhibitor ibrutinib in first line of therapy. CT scans may be helpful to assess the tumor load or to determine the cause of unclear symptoms, but they should not generally be used in asymptomatic patients or for clinical staging. In addition, CT scans may be useful for baseline and final assessment in clinical trials. In elderly

patients, abdominal ultrasound might be considered instead [55, 56].

Abdominal ultrasound and CT may be helpful to detect splenomegaly or bulky disease, findings that may influence therapy planning [56, 67]. Muntanola et al. [68] suggested that the presence of abdominal involvement (splenomegaly or lymphadenopathy) in patients with Rai stage 0 predicts a more aggressive clinical course of the disease with shorter time to progression compared to patients with normal CT findings. Furthermore, abnormal abdominal CT findings correlate with severity of bone marrow infiltration, ZAP-70 expression, and shorter lymphocyte doubling time.

MRI does not provide significant information for CLL management, except in rare cases of central nervous system localization of the disease, as typical for cases of childhood leukemia.

No other nuclear medicine modalities, including [^{18}F]FDG-PET and [^{18}F]FDG-PET/CT, are at the present recommended for patient management. Nevertheless, in case of suspected Richter's transformation (the transformation of CLL cells into aggressive type of lymphoma, most commonly diffuse large B-cell lymphoma, DLBCL), [^{18}F]FDG-PET/CT is considered the method of choice for early assessment. The pattern of [^{18}F]FDG uptake and the PET-derived parameters may help in choosing the site of biopsy [69], and discern Richter's transformation [70]. In fact, in the majority of patients during the indolent course of CLL over many years, cells are characterized by a low metabolic rate and low-grade [^{18}F]FDG uptake into lymphoadenopathies (Fig. 4). The appearance of intense [^{18}F]FDG uptake correlates with increased numbers of large B cells in the bone marrow and/or lymph nodes (CLL acceleration), with the appearance of both localized and/or diffuse pattern of increase [^{18}F]FDG uptake.

The value of [^{18}F]FDG-PET/CT for the detection of Richter's transformation has been reported in 37 CLL patients with very high sensitivity (91%) and negative predictive values (97%) [69]. False-

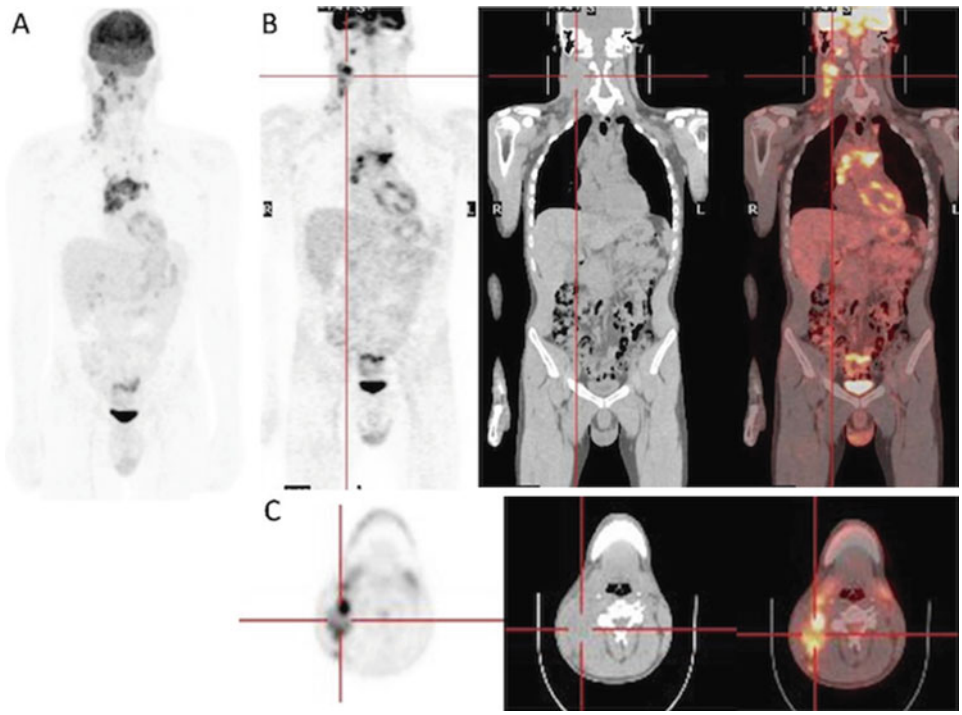

Fig. 4 [^{18}F]FDG PET/CT in patient with CLL and Richter's transformation. Images demonstrate multiple site of lymph node uptake in the neck and mediastinum. (**a**) MIP image. (**b**) Coronal view and (**c**) transaxial view of PET, CT, and PET/CT fused images

positive results in this series were caused by other malignancies (i.e., Hodgkin disease or NSCLC), as frequently observed in CLL patients. The accelerated phase of CLL, an early transition to lymphomatous transformation characterized by increased numbers of more immature cells within the bone marrow and by lymphoid tissue with a higher rate of cell turnover, may represent an additional false-positive [^{18}F]FDG-PET/CT. Finally, infection can also cause false-positive findings on [^{18}F]FDG-PET/CT; the CT component of the PET/CT exam may be employed to improve accuracy in this specific setting. When [^{18}F]FDG-PET/CT is used to guide biopsies, histological analysis remains the gold standard. The prognostic role of [^{18}F]FDG-PET/CT in CLL should be confirmed by histopathology [71].

Treatment Evaluation of CLL

Response evaluation includes a physical examination and complete blood cell count. A bone marrow biopsy may be carried out to define CR. Chest X-ray and an abdominal ultrasound or CT for response evaluation may be carried out, if abnormal before therapy [55]. Table 3 shows CT scan parameters required to assess the treatment response in clinical trials according to Hallek et al. [56]. Detection of minimal residual disease (MRD) by flow cytometry has strong prognostic impact [72, 73]. Patients who are MRD negative after therapy show a longer response duration and survival. Additional clinical consequences of MRD positivity post-therapy remain unclear, except for patients after an allogeneic transplantation, where a positive MRD signal may trigger the reduction of immunosuppressive therapies or the start of antileukemic maintenance therapy. Therefore, MRD assessment is not generally recommended for monitoring post-therapy outside clinical studies [55].

Recently, the next-generation sequencing (NGS) techniques allowed the possibility of recognizing a disease-specific B clone and following it after treatment. The new therapies (rituximab plus bendamustine, ibrutinib, obinutuzumab plus chlorambucil, idelalisib) seem to offer higher rates of molecular remission and correlate with longer disease-free survivals [74–77].

Follow-Up and Long-Term Implications in CLL

CLL is an incurable disease. Therefore, lifelong observation and follow-up is recommended for all patients in order to identify the moment when re-treatment will be necessary. Follow-up of asymptomatic patients should include a blood cell count and clinical evaluation (palpation of the lymph nodes, liver, and spleen) every 3–6 months, depending on the dynamics of the leukemic development. Special attention should be paid to the appearance of autoimmune cytopenias. Moreover, CLL patients have a two

Table 3 CT scan parameters required to assess the treatment response in clinical trials according to Hallek et al. Guidelines for the diagnosis and treatment of chronic lymphocytic leukemia: a report from the International Workshop on Chronic Lymphocytic Leukemia updating the National Cancer Institute–Working Group 1996 guidelines [56]

Complete remission (CR)	Partial remission (PR)	Progressive disease (PD)
Lymph nodes should not be >1.5 cm in diameter and no hepatomegaly or splenomegaly	Reduction in lymphadenopathy defined as: decrease in lymph node size ≥50% either in the sum products of up to 6 lymph nodes or in the largest diameter of the enlarged lymph node(s) detected prior to therapy and no increase in any lymph node and no new enlarged lymph node. In small lymph nodes (<2 cm), an increase <25% is not considered to be significant and a reduction in the noted pretreatment enlargement of the spleen or liver ≥50%	Appearance of any new lesion (such as enlarged lymph nodes >1.5 cm or other organ infiltrates) or increase in the previously noted enlargement of lymph nodes ≥50% or an increase in the previously noted enlargement of the liver or spleen ≥50% or the de novo appearance of hepatomegaly or splenomegaly

to sevenfold increased risk of developing secondary malignancies (mostly solid cancers, but also secondary myelodysplastic syndromes or acute myeloblastic leukemia). The transformation into a diffuse large B-cell lymphoma (DLBCL) or Hodgkin's lymphoma (HL) occurs in 2–15% of CLL during the course of disease [55]. The transformation into DLBCL (Richter's transformation) usually has a very poor prognosis that required therapies used in DLBCL, such as rituximab plus CHOP (cyclophosphamide, vincristine, doxorubicin, and dexamethasone), but response duration is typically short, and an allogeneic HSCT should be recommended in case of available donor and sufficient fitness. The transformation of CLL into Hodgkin's disease represents a separate entity, where conventional chemotherapy against HL often achieves long-lasting remissions [55].

Hairy Cell Leukemia (HCL)

Classical hairy cell leukemia (HCL) is a B-cell chronic lymphoproliferative disorder characterized by splenomegaly, pancytopenia, and bone marrow involvement with fibrosis. HCL represents 2% of all adult leukemias [78]. Approximately 1,600 new cases per year are diagnosed in Europe, with a median age of 52 years at the time of diagnosis [79]. In the USA, a higher frequency of HCL is observed among White Americans than among African-Americans or Asians, as well as in patients following exposure to the herbicide "Agent Orange," used during the Vietnam War [80]. HCL variant (HCL-V) is classified among mature B-cell neoplasias [4]. HCL-V is an uncommon disorder, accounting for approximately 0.4% of chronic lymphoid malignancies and 10% of all HCL cases, without sexual predominance and a median age at diagnosis of 71 years.

The examination of peripheral blood films and immunophenotyping are usually sufficient the diagnosis in the majority of cases. The neoplastic cells are twice the size of small lymphocytes and have a round or kidney-shaped nucleus with excess chromatin and abundant pale cytoplasm with projections. Monocytopenia and macrocytosis are very common; other cytopenias may be present. A diagnosis of HCL based on cytology can be effectively confirmed by flow cytometry studies using anti-B-cell monoclonal antibodies such as CD19, CD20, or CD22, together with a panel of antibodies such as CD11c, CD25, CD103, and CD123, which are more specific to HCL; this combination will allow the differentiation of HCL from other B-cell leukemias and lymphomas with circulating villous cells, such as the marginal lymphoma [78, 81, 82]. In addition, strong expression of CD200 is characteristic of HCL and may be useful as distinctive feature in difficult cases [83]. HCL-V typically presents with high lymphocyte counts, with the cells being nucleolated and lacking monocytopenia. Flow cytometry will indicate the cells to be CD11c+ and often CD103+ but very rarely CD25+ and CD123+. As the bone marrow can rarely be aspirated ("dry tap") in classical HCL, diagnosis is typically performed by a bone marrow trephine biopsy. The degree and pattern of infiltration varies from mild interstitial to diffuse, and the lymphoid cells are surrounded by a clear halo due to the abundant cytoplasm, giving the characteristic "fried egg" pattern. In difficult cases, BRAF V600E mutation of exon 15 may be useful to diagnose classical HCL and MDR [84]. This mutation has been described in 100% of classical HCL, but is absent in HCL-V and in cases with VH4-34 rearrangement [78, 85, 86]. It has also a clinical impact, because the anti-RAF compounds, such as vemurafenib, have been shown to be very effective in relapsed patients [87]. In HCL-V, the infiltration is either intrasinusoidal or interstitial. Immunohistochemistry with the monoclonal antibodies CD20, CD72 (DBA44), CD11c, CD25, CD103, annexin A1, and tartrate-resistant acid phosphatase stain will highlight the lymphoid infiltrates and support the diagnosis of classical HCL [82]. However, annexin A1 is not suitable for detecting residual disease after treatment as it stains myeloid cells. Cyclin D1 may be weakly positive but differential diagnosis with mantle cell lymphoma rarely arises. HCL does not have a distinct chromosomal abnormality. The majority of the cases have mutations of the immunoglobulin heavy chain (IGHV) gene, suggesting that the disease arises on a memory B cell. Unlike other splenomegalic disorders such as

splenic marginal zone lymphoma or HCL-V, there is no evidence of specific IGHV, IGHD, and IGHJ repertoires or stereotypes in HCL [88–90]. Although HCL-V patients lack the BRAF mutation, TP53mutations are present in one-third of cases [91]. There is no worldwide accepted staging system for HCL. In addition to the diagnostic tests on the blood and bone marrow trephine biopsy, a staging work-up should include full blood cell counts with differential and reticulocytes, renal and liver biochemistry, serum immunoglobulins, β2 microglobulin, direct antiglobulin test, Coombs test, and hepatitis virus B and C and human immunodeficiency virus screening. Computed tomography (CT) imaging is desirable at the time of diagnosis (as around 10% of HCL patients have abdominal lymphadenopathy) and should be performed at relapse [78, 92]. MRI is being evaluated as a means for assessing total body burden of disease in the marrow [93].

Imaging During Follow-Up of HCL

A follow-up of asymptomatic patients should include a complete history, physical examination, the blood cell count, and routine chemistry every 3–12 months. CT scan is not necessary outside clinical trials [78]. The frequency of second malignancies is increased in HCL patients, whether treated or untreated. Solid and hematological malignancies develop in 10% of HCL patients, particularly chronic lymphoproliferative diseases (multiple myeloma, Hodgkin's and non-Hodgkin's lymphoma), melanoma, and thyroid cancer [94, 95].

Acute Myeloid Leukemia (AML)

In 2016, the estimated number of new cases of AML is about 20,000, accounting for 1.1% of all new cases of cancer. The number of new cases of AML was 4.1 per 100,000 per year based on 2009–2013 cases according to the SEER database [1]. AML affects adults of all ages, but is especially common among people aged 65–74.

Currently, thanks to advances in transfusion and infectious disease supportive care [96] as well as serial evaluations of different chemotherapeutic approaches, more than 80% of young adults and 60% of all patients can achieve complete remission. Varying with patient age and other factors, from 15% to 50% of these complete responders can be expected to achieve long-term survival with the likelihood that most of these individuals are cured of their disease. Acquired genetic changes in bone marrow stem cells that cause a complete or partial block in normal hematopoietic stem cell maturation are the basis of the development of the disease. The genetic changes may involve mutations that lead to activation of growth-promoting proto-oncogenes, inactivation of tumor suppressor genes, or alterations in transcription factors. Mutations in codons 12, 13, or 61 of the N-*ras* gene encoding a 21 kd guanosine nucleotide-binding protein involved in signal transduction have been noted in a consistent patients with AML. The greatest insight regarding AML pathogenesis has been provided by the identification of genes at cytogenetic breakpoints involved in balanced translocation. The fusion proteins generated by the translocation generally result in disruption of transcription factors believed to be critical in myeloid differentiation [97]. Many of these chromosomal abnormalities [e.g., t(8;21), t(15;17), inv16] are associated with specific AML subtypes and carry prognostic importance. Although the acquired genetic lesions that lead to leukemia are being rapidly defined, DNA damage from a known cause accounts for a small fraction of patients with AML. There have been a number of epidemiologic studies that have attempted to link environmental exposures to leukemia [98]. There may be a small increased risk associated with cigarette smoking [99], whereas exposure to electromagnetic radiation [100] seems an unlikely cause of AML. Occupational exposures, particularly to benzene [101] or petrochemicals [102], have been implicated in the development of AML. Alkylating agents have been associated with deletions of chromosome 5 and 7, whereas etoposide (used in childhood ALL) and high-dose anthracycline/

cyclophosphamide combinations may cause 11q23-associated disease. With these few exceptions, however, there is no clear relationship between environmental exposures and the occurrence of acute leukemia.

AML can present either as a de novo leukemia, without an apparent antecedent illness, or as an evolution from previous marrow disorders, such as myelodysplasia, aplastic anemia, chronic myeloid leukemia (CML), and Fanconi's anemia [103], or after the administration of therapy for other types of cancers or nonmalignant disorders.

The natural history of AML arising de novo in young adults is believed to be a disease of the committed stem cell that is vastly different from the same disease arising from the pluripotent stem cell, as occurs in secondary AML [104].

The diagnosis of AML requires the examination of peripheral blood and bone marrow specimens. The work-up of these specimens should include morphology, cytochemistry, immunophenotyping, cytogenetics, and molecular genetics (PCR, FISH) [105]. In most patients, it is relatively simple to distinguish between AML and ALL on morphologic grounds. In general, the blasts from patients with AML are larger, with more abundant cytoplasm and more prominent, often multiple nucleoli. The definitive diagnosis depends, however, on the presence of Auer rods, on concentrations of myeloid-containing granules (present in 50% of those with AML), or on demonstration of at least 3% granulated precursors [106]. The cells are often reactive with antibodies directed against CD34. Terminal deoxynucleotidyl transferase (TdT) is generally absent, but can sometimes be detected in a minority of blasts. While historically sorted by the largely descriptive French-American-British (FAB) criteria [107], AML are now classified according to the WHO classification [3]. The FAB morphologic classification names the AML according to the normal marrow elements that they most closely resemble [107]. The WHO classification incorporates, in addition to morphological criteria, cytogenetic data, molecular genetics, immunophenotype data, and clinical information into a diagnostic algorithm to delineate clinically significant disease entities. In the WHO classification, the term "myeloid" includes all cells belonging to the granulocytic, monocyte/macrophage, erythroid, megakaryocytic, and mast cell lineage. Despite the dilemma and controversy regarding how to incorporate recently described and clinically important genetic lesions into the revised scheme, the framework of the classification proved flexible enough so that new, well-defined entities could be incorporated as provisional entities, those for which more data need to be collected so that they can be better characterized. One of the major challenges in the revision of the WHO classification is how to incorporate important and/or recently described genetic aberrations into a classification scheme of AML and yet adhere to the WHO principle of defining homogeneous, biologically relevant, and mutually exclusive entities based not only on the prognostic value of a genetic abnormality, but on morphologic, clinical, phenotypic, and/or other unique biologic properties. According to the last version of the WHO classification, different subgroups of AML and related neoplasm may be identified (Table 1): the AML with recurrent genetic abnormalities, the AML with myelodysplasia-related changes, the therapy-related myeloid neoplasms, the AML not otherwise specified, the myeloid sarcoma, the myeloid proliferations related to Down syndrome, and the blastic plasmacytoid dendritic cell neoplasm. A specific section is reserved for acute leukemias of ambiguous lineage.

Recently, a meta-analysis of 9 studies including 4,509 patients affected by AML was performed: the frequency of NPM1 mutations ranged from 7% to 56%. Nevertheless, all data confirmed the positive prognostic value of this mutation, with a double probability of achieving complete remission compared with NPM1 wild type and a significant advantage also on disease-free survival and overall survival [108].

In the subgroup of AML with recurrent genetic abnormalities, variant *RARA* translocations should be diagnosed as AML with the variant partner specifically designated [109]. For all other entities within the category of AML with recurrent genetic abnormalities, 20% or more blasts must be present

in the PB or BM to establish the diagnosis of AML [26, 105]. Although these leukemias are recognized as unique entities, it is important to realize that additional genetic abnormalities may coexist and influence their biologic and clinical behavior, including response to therapy and the overall survival. Studies of AML associated with the chromosomal rearrangements t(6;9)(p23;q34); *DEK*-NUP21, inv(3)(q21q26.2), or t(3; 3)(q21;q26,2); *RPN1-EVI1* and t(1;22)(p13;q13); and *RBM15-MKL1* have provided evidence that these genetic rearrangements, although uncommon, are associated with distinctive morphologic and clinical features that argue for their incorporation in the revised listing of AML with recurrent genetic abnormalities [110–112]. A more controversial issue is whether leukemia initially demonstrating a blastic myeloid proliferation associated with the Ph' chromosome or *BCR-ABL1* is a distinct and easily defined entity. Although *BCR-ABL1*-positive AML has been reported [113–115], criteria for its distinction from CML initially manifesting in a blast phase are not entirely convincing, and for this reason, *BCR-ABL1*-positive AML is not recognized in this classification. Many cases of *BCR-ABL1*-related acute leukemia will meet the criteria for ALL or mixed phenotype acute leukemia, provided that a blast phase of a previously unrecognized CML can be excluded. In addition to the newly listed leukemias associated with cytogenetically detectable rearrangements, AML with mutated *NPM1* or *CEBPA* have been added to the classification as "provisional entities." Mutated *FLT3* frequently accompanies other genetic lesions, and although it is not included as a defining criterion for any distinct entity in the revised WHO classification, the mutational status of *FLT3* should always be ascertained in AML, particularly in cytogenetically normal AML, because of its prognostic importance.

The **AML with myelodysplasia-related changes** is diagnosed when patients have 20% or more blasts in the PB or BM and (1) evolve from previously documented MDS or MDS/MPN, (2) have specific myelodysplasia-related cytogenetic abnormalities, or (3) exhibit dysplasia in 50% or more of the cells in two or more myeloid lineages [26].

The **therapy-related myeloid neoplasms** included t-AML/t-MDS and t-AML/t-MDS/MPN. Most patients who develop therapy-related myeloid neoplasms have received alkylating agents and/or radiation as well as topoisomerase II inhibitors. It has been argued that 90% of patients with therapy-related neoplasms have cytogenetic abnormalities identical to those observed in AML with myelodysplasia-related features or in AML with recurrent cytogenetic abnormalities; therefore, such cases would be more appropriately classified in those categories rather than in a separate, therapy-related category. However, the majority of patients with therapy-related myeloid neoplasms have a worse outcome than do their de novo counterparts with the same genetic abnormalities [3, 26, 116–120].

The group of **AML not otherwise specified** (AML NOS) encompasses those cases that do not fulfill the criteria for any of the other AML categories. The AML NOS will continue to diminish as more genetic subgroups are recognized.

The **myeloid sarcoma** is a pathologic diagnosis for an extramedullary proliferation of blasts of one or more of the myeloid lineages that disrupts the normal architecture of the tissue (any, particularly the skin, gastrointestinal tract, lymph nodes, and bone) in which it is found [121]. Most often, myeloid sarcoma is found concurrently in a patient with previously or recently recognized AML, but it may also precede the appearance of blood or bone marrow disease. In this latter case, the diagnosis of myeloid sarcoma should be considered as synonymous with AML, and the tumor should be evaluated for morphologic, phenotypic, and genetic features that would allow it to be classified further into one of the subgroups of AML. A myeloid sarcoma is evidence of relapse in a patient thought to be in remission of a previously diagnosed AML, is evidence of evolution to AML in a patient with a previously diagnosed MDS or MDS/MPN, and is blast transformation in a patient with MPN [26].

The **myeloid proliferations related to the Down syndrome**, which include transient abnormal myelopoiesis and myeloid leukemia, have unique morphologic, immunophenotypic, clinical, and molecular features, including *GATA1*

mutation, that justify their separation from other myeloid neoplasms [122–125].

The **blastic plasmacytoid dendritic cell neoplasm** recognizes virtually all cases of a tumor that is derived from precursors of a specialized subset of dendritic cells, plasmacytoid dendritic cells, and hence is a myeloid-related neoplasm. This subgroup includes most cases previously designated as "blastic natural killer cell leukemia/lymphoma" [26]. It is a clinically aggressive neoplasm that is usually characterized at its onset by solitary or multiple skin lesions, often with associated regional lymphadenopathy. Many cases will ultimately progress to involve the PB and BM as well. The blasts in such cases do not express myeloperoxidase or cases of AML with minimal differentiation that do not show any lymphoid-associated antigens [126–129].

Imaging for Diagnosis and Staging of AML

AML patients generally present with anemia (median hemoglobin 8 g/dL), thrombocytopenia (median platelet count 40–50 $\times$ 10^9/L), and leukocytosis (median white blood cell count 10–20 $\times$ 10^9/L). Most patients are neutropenic, and morphologic abnormalities (hypogranulation, nuclear hyperlobulation, Pelger-Huët anomaly) are often noted in the remaining neutrophils. Careful examination will detect blasts in most patients, although it can be difficult to distinguish among leukemia subtypes (or occasionally even to be confident of the diagnosis of acute leukemia) in patients with a low number of circulating blasts.

Initial symptoms are typically related to complications of pancytopenia including weakness, easy fatigability, infections of variable severity, or hemorrhagic findings, such as gingival bleeding, ecchymoses, epistaxis, or menorrhagia. Combinations of these symptoms are common. Occasionally patients present because of prominent extramedullary sites of leukemia usually related to either cutaneous or gingival infiltration by leukemia cells. Bone pain is infrequent in adults with AML, although some individuals describe sternal discomfort or tenderness, occasionally with aching in the long bones, particularly of the lower extremities. Most patients have had more subtle evidence of leukemia for weeks, to perhaps months, before diagnosis. The findings on physical examination are variable and generally nonspecific. If fever is present, it is almost always related to infection, and an infectious site must be vigorously sought and generally treated empirically with broad-spectrum antibiotics. Examination of the skin can reveal pallor. Infiltrative skin lesions are suggestive of leukemic involvement. Other coutaneous manifestations may be infection either primary or embolic, or, most commonly, petechiae or ecchymoses related to thrombocytopenia and/or coagulopathy. Examination of the fundus reveals hemorrhages and/or exudates in the majority of patients. Careful examination of the oropharynx and teeth is important because of the occasional occurrence of leukemia involvement and the value of applying effective dental prophylaxis, if time permits, prior to chemotherapy. Palpable adenopathy is uncommon; significant lymph node enlargement is rare as well as hepatomegaly and splenomegaly. None of these findings is diagnostic of acute leukemia, and the final diagnosis and categorization depends on appropriate evaluation of peripheral blood and bone marrow. Routine chemistry including liver and kidney parameters and coagulation profile, as well as blood group and HLA typing of patient and family members, are required as part of the initial work-up of AML. Radiological diagnostic examinations must include dental survey and chest/abdomen CT scan or chest X-ray and abdominal ultrasound [26].

Extramedullary disease in lymph nodes, the CNS, or soft tissue is observed particularly in case of relapse after allogeneic stem cell transplantation or bone marrow transplantation [130].

Due to the increasing value of PET/CT in solid tumors and hematological malignancies, interest has grown in AML. Data on [^{18}F]FDG in AML mainly concern extramedullary involvement, specially in recurrent disease [51, 52], and require further validation before its use in clinical practice. Promising results of [^{18}F]FDG-PET/CT have also been reported in the management of granulocytic sarcomas [131]. In AML another positron emitting radiopharmaceutical, 3′-^{18}F-fluoro-3′-deoxy-L-thymidine

(^{18}F-FLT) has been used to detect extramedullary sites of active disease [132] and for the early assessment of treatment response [133]. The rate of ^{18}F-FLT uptake into lesions is directly proportional to DNA. Published data show that ^{18}F-FLT uptake is significantly increased in patients with myelodysplastic syndromes and myeloproliferative neoplasias [134]. There is intense uptake of ^{18}F-FLT in bone marrow and spleen (Fig. 5), but extramedullary lesions may also be seen.

Response Evaluation and Follow-Up in AML

AML response to treatment is monitored with serial peripheral blood counts and repeated bone marrow examinations. To design the best regimen, the first bone marrow exam is performed at the day +30. Cytogenetic/molecular abnormalities detected at diagnosis and morphological/immunophenotypical response, patients should continue conventional chemotherapy or should be switched to a more intensive treatment, such as autologous or allogeneic transplantation. During intensive chemotherapy, bone marrow should be examined in the aplastic phase to monitor blast clearance, persistence, or early relapse. The usual criteria of response are blast clearance in the bone marrow to <5% of all nucleated cells, a recovered normal hematopoiesis, and return of the peripheral blood cell count to normal levels. Although sensitive PCR methods as well as immunophenotyping are available, permitting molecular follow-up and detection of minimal residual disease in patients with suitable markers (mostly

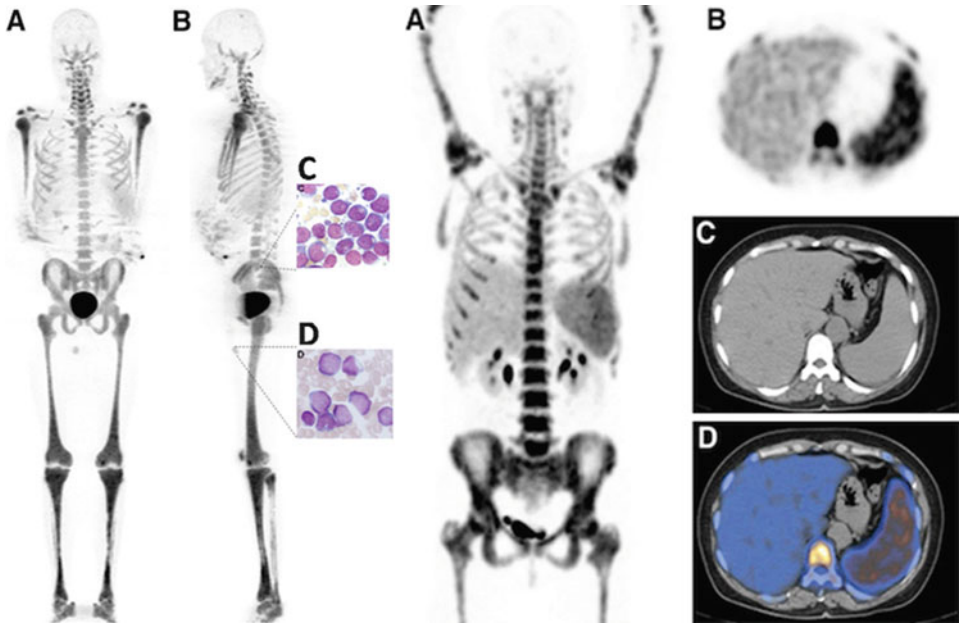

Fig. 5 In vivo biodistribution of ^{18}F-FLT in patient with refractory AML 60 min after injection of radiotracer (whole-body MIP (**a**) and (**b**) *right panel*). Intense uptake of the radiopharmaceutical is evident in hematopoietic bone marrow of central bones and extensive bone marrow expansion with intense tracer uptake. Tracer uptake is absent from bones not containing hematopoietic marrow (forearms and skull). Scans also indicate intense focal extramedullary ^{18}F-FLT uptake in projection of right testicle. Hematoxylin staining of peripheral blood demonstrating 99% leukemic blasts (**c**) and biopsy verification of testicular leukemia manifestation (**d**). ^{18}F-FLT PET demonstrate intense tracer uptake in bone marrow and spleen as typical in patient with initial diagnosis of AML. MIP (**a** *left panel*) and transaxial section of PET (**b**), CT (**c**), and fused images PET/CT (**d**). Other organs are normal, as observed in controls

specific chromosomal translocations or typical antigen expression profiles, respectively), the early detection of molecular relapse in the absence of morphological evidence for recurrent AML is of uncertain therapeutic consequence. Specifically, evidence that early re-induction treatment of such patients still in hematological remission would be of any benefit is lacking [105].

Chronic Myeloid Leukemia (CML)

In 2016, the estimated number of new cases of CML is about 8,200, accounting for 0.5% of all new cases of cancer. The number of new cases of AML was 1.8 per 100,000 per year based on 2009–2013 cases according to the SEER database [1].

CML is a clonal myeloproliferative disorder of a pluripotent stem cell [135] with a specific cytogenetic abnormality, the Philadelphia chromosome that identifies the chromosome (22q-) resulting from the balanced translocation between the long arm of chromosome 9 and 22.

In the great majority of patients, a causative factor cannot be identified. Nevertheless, it is well known that ionizing radiations are leukemogenic, although the most common type of leukemia following radiations is AML [136]. The median age of onset of CML is 64 years; the peak incidence occurs during the ages of 65–74 years [1]. The first phase of the disease, the chronic phase, could terminate, trough an accelerated phase, in acute leukemia (blastic phase), characterized by a short survival [137].

The translocation of the ABL1 gene from chromosome 9–22 t(9;22)(q3.4;q1.1) leads to the formation of a new, hybrid, fusion gene (BCR-ABL1) that codes for an oncoprotein (P210, more rarely P190 or P230) that is located in the cytoplasm and has a strong, constitutively activated tyrosine kinase activity, resulting in the activation of several downstream signals that transform hematopoietic stem cells [138]. Cells carrying the BCR-ABL1 gene show an abnormal interaction with the actin and the stroma, an increased proliferation, and a reduced apoptosis rate due to the activation of the RAS/ERK and PI3K/AKT pathways [139].

Moreover, BCR-ABL-positive cells are genetically unstable and are prone to develop multiple and heterogeneous genomic abnormalities, resulting in the transformation of the leukemic phenotype from chronic to acute, hence leading to the progression from chronic to accelerated and blastic phase [140]. One important event associated with progression is the development of point mutations in the kinase domain (KD) of the ABL1 gene, leading to resistance to the tyrosine kinase inhibitors (TKI), such as imatinib, dasatinib, nilotinib, and bosutinib [141, 142]. Ponatinib is the unique TKI able to bypass the gatekeeper mutation T315I, except in the cases when it is associated with other ABL1 mutations (compound mutations) [143, 144]. BM biopsies taken from untreated patients at diagnosis show increased cellularity due to proliferation of the granulocytic series that turns in different stages of maturation, although myelocytes and segmented forms predominate [26]. No substantial features of dysplasia are found. Eosinophils may be prominent. Blasts must account for $<5\%$ of the whole examined population. Megakaryocytes are smaller than normal with hypolobulated nuclei. Although their number may be normal or slightly decreased, in about 50% of cases there is a moderate to extensive megakaryocytic proliferation. Moderate to marked reticulin fibrosis is encountered in 30% of cases. Pseudo-Gaucher cells and sea-blue histiocytes are usually observed. Notably, the BM picture undergoes important changes (e.g., reduction of the granulocytic cellularity, normalization of megakaryopoiesis, regression of fibrosis, and increase in apoptosis associated with decrease in proliferative activity), particularly following long-term treatment with TKIs [145].

According to the European Leukemia Net guidelines [146], CML patients have to be carefully monitored by cytogenetic and molecular tests: the achievement of a BCR-ABL1/ABL1 ratio lower than 10% at 3 months of therapy (early molecular response), of 1% at 6 months, and of 0.1% at 12 months (MR3) and the achievement of the complete cytogenetic response at 12 months in the absence of additional chromosome abnormalities characterize the optimal responder subject. On the contrary, cases with a BCR-ABL1/ABL1 ratio

higher than 10% at 6 months or 1% at 12 months are categorized as failed patients and so for a different treatment. Nevertheless, TKIs allowed prolong long-term survival up to 90%.

The recognition of disease progression from CP to BP is relevant for prognosis and treatment.

Many studies tempted to characterize the genomic alteration characterizing the transition to the blastic phase: the myeloid one is characterized by the TP53, WT1, RAS, NPM1, IDH1/2, and RB1 mutations, while the lymphoblastic transformation shows acquired mutations of IKZF1, IDH1/2, and CDKN2A [143].

Nevertheless, it is important to remember that the probability of developing a blastic phase is about 6% with imatinib and 2% with nilotinib [147].

Imaging for Diagnosis and Staging of CML

CML symptoms are not specific, including weight loss, asthenia, small fever, sweats, and malaise, and are not frequent, since in more than 40% of cases, the diagnosis is fortuitous, being based on abnormal blood counts. In most cases, diagnosis is based on blood counts (leukocytosis and frequently also thrombocytosis) and differential (immature granulocytes, from the metamyelocytes to the myeloblasts, and basophilia). Splenomegaly is present in half of the cases in the initial chronic phase, but the majority of these patients are asymptomatic [145]. Symptoms and signs usually develop insidiously and include fatigue, anemia, progressive splenomegaly, and leukocytosis. In the chronic phase, the white blood cell count approximates $2{,}000 \times 10^9$/L. The myeloid cells in the peripheral blood show all stages of differentiation, but the myelocytes predominate. More than half of the patients have platelet counts above $1{,}000 \times 10^9$/L, but thrombotic phenomena are unusual. A slight degree of anemia is common. The striking biochemical abnormality in CML is the reduction of leukocyte alkaline phosphatase activity, both in intensity and in the number of neutrophil band forms that stain positively for the enzyme. As the disease evolves, varying degrees of fibrosis occur [148]. Clinically, the most reliable finding is the presence in the peripheral blood, bone marrow, or both of myeloblasts and promyelocytes exceeding 30% of the differential distribution (70% of the cases) [149]. In the absence of frank blast crisis, other criteria include the development of fever of undetermined origin, increasing splenomegaly, a rising white blood cell count, basophilia, an increasing degree of anemia, and thrombocytopenia and refractoriness to previously effective therapy. High blast cell counts may lead to pulmonary and/or cerebral leukostasis and hemorrhage. The median survival after blastic transformation is approximately 3–6 months.

Currently, no imaging modalities are used for CML diagnosis or staging. [^{18}F]FDG-PET in the chronic phase of CML has diffuse increased uptake in the bone marrow [150]. The appearance of [^{18}F]FDG is very similar to the hematopoietic cytokine-mediated [^{18}F]FDG bone marrow uptake [151]. When patients with CML are evaluated under treatment or after cessation of treatment, reduced FDG uptake has been observed in the bone marrow. [^{18}F]FDG-PET/CT may be useful for the diagnosis of granulocytic sarcomas, rare extramedullary manifestations of myeloid (or lymphoblastic leukemia) that may develop anywhere, but most commonly arise in the skull, orbits, and sinuses [152]. Preclinical studies suggested a potential role of [^{18}F]FLT as quantitative and semiquantitative uptake measurement for metabolic imaging [153].

Many prognostic scoring systems have been proposed, including the Sokal [154], the Euro [155], and the EUTOS [156] scores. The first and the second have been developed in the interferon era, based on age and on the percentage of circulating blasts, basophils, and eosinophils and of spleen size weighted as continuous variables. The EUTOS has been proposed after the introduction of imatinib and is based on the spleen dimensions and the basophil count. These risk scores distinguish among three categories the Sokal and Euro and between two categories the EUTOS risk score. The introduction in the clinical practice of the second-generation TKIs reduced the impact of the risk categories on survival. These prognostic classifications are important

because case selection and the results of interferon treatment may influence the presumed therapeutic effect of interferon or other forms of nontransplant treatment.

Imaging for Monitoring Treatment of CML

In CML, responses are classified as hematological (complete if the spleen dimension and blood count is normal), cytogenetic (complete if Ph' metaphases are absent), and molecular. The molecular responses are defined as logarithmic reduction of BCR-ABL1/ABL1 ratio in respect of 100% of diagnosis. MR3 (0.1%) is now considered the goal of treatment at 12 months; nevertheless, today the major attention has been taken to the deep molecular response (4, 4.5, 5 logarithms reduction); indeed, patients treated for more than 5 years with imatinib and with a deep molecular response lasting more than 2 years have a 50% likelihood of remaning in remission after TKI discontinuation [157, 158]. More rapid and deeper molecular responses can be achieved by second-generation TKIs used as first line of treatment [159, 160].

No imaging techniques exist that would be used as surrogate for the molecular response categorization.

Monitoring is essential for treatment optimization and for a cost-effective outcome: at the beginning and during the first 3 months, biochemical and hematological monitoring is recommended every 2 weeks, to ensure the compliance of the patient and exclude relevant toxicities. From the third month on, cytogenetics is recommended every 6 months until the confirmed complete cytogenetic response, and quantitative PCR is recommended every 3–6 months. Screening for ABL1 mutations is recommended only in the case of failure or suboptimal response; ultra-deep sequencing techniques significantly increased the possibility of detecting mutations in cases resulting unmutated after conventional sequencing. This item is clinically relevant because some mutations are TKI specific and induce to change the drug.

As reported at diagnosis, also in the monitoring of responses, no role for imaging modalities is recognized by the current ESMO Clinical Practice Guidelines [145].

Abstract

PET/CT and PET/MR can be used with various radiopharmaceuticals to assess the mechanisms underlying biochemical changes and physiopathology of brain tumors.

Amino acid tracers are frequently used for most clinical questions. These tracers include, among others, [^{11}C]methionine, *L*-3,4-dihydroxy-6[^{18}F]fluorophenylalanine ([^{18}F]FDOPA and O-(2-^{18}F-fluoroethyl)-L-tyrosine (^{18}F-FLT). Amino acid tracers are particularly accurate to distinguish tumor recurrence and radiation necrosis. The role of [^{18}F]FDG, the earliest PET tracer used for diagnosis and monitoring of brain tumors, is being redefined, due to the availability of amino acid tracers. For in vivo prediction of tumor grade, however, [^{18}F]FDG is still more accurate than most amino acid tracers.

Higher baseline values of tracer uptake as well as lower percent changes after therapy in treated patients predict shorter survival – this has been shown for several tracers.

PET/CT and PET/MR can be used after surgery to assess the presence of residual tumor. PET, in combination with MR, is increasingly used for the definition of the tumor volume that has to be irradiated. Identification of the part of the tumor that displays highest metabolic activity can also be used to direct stereotaxic biopsy.

Other tracers have been synthetized to explore different biochemical processes, for example, hypoxia (e.g., [^{18}F]-fluoromisonidazole), DNA synthesis (3-deoxy-3-[^{18}F]-fluorothymidine), and membrane proliferation (radiolabeled choline). However, these tracers have a less established role in clinical practice.

Keywords

Brain tumor • Positron emission tomography/computed tomography (PET/CT) • Positron emission tomography/magnetic resonance (PET/MR)

Glossary

[^{11}C]MET	[^{11}C]methionine
[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
[^{18}F]FDOPA	*L*-3,4-dihydroxy-6-[^{18}F]fluorophenylalanine
^{123}I-IAZA	^{123}I-iodoazomycin arabinoside
^{123}I-IMT	^{123}I-alpha-methyltyrosine, a tyrosine analog transported as L-tyrosine by the neutral amino acid transporter
^{18}F-FAZA	^{18}F-azomycin arabinoside
^{18}F-FES	16α-^{18}F-fluoro-17β-oestradiol

^{18}F-FET	*O*-(2-^{18}F-Fluoroethyl)-L-Tyrosine, a tyrosine analog
^{18}F-FLT	^{18}F-fluorothymidine
^{18}F-FMAU	^{18}F-2-fluoro-5-methyl-1-beta-d-arabinofuranosyluracil
^{18}F-MISO	^{18}F-fluoromisonidazole
^{64}Cu-ATSM	^{64}Cu-diacetyl-bis(N_4-methylsemicarbazone)
^{99m}Tc-ECD	^{99m}Tc-ethylcisteinate dimer
^{99m}Tc-HMPAO	^{99m}Tc-hexamethylpropyleneamine oxime
ADC	Apparent diffusion coefficient, a parameter of MR imaging
AJCC	American Joint Committee on Cancer
BBB	Blood–brain barrier
BTV	Biological tumor volume (the extent of tumor based on PET imaging); the combination of GTV and BTV provides the planning target volume for radiation therapy
CBF	Cerebral blood flow
CI	Confidence interval
CMR_{glc}	Cerebral metabolic rate for glucose
CNS	Central nervous system
CSF	Cerebrospinal fluid
CT	X-ray computed tomography
DG	2-Deoxyglucose
DOTA	1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid
DOTANOC	DOTA-1-Nal^3-octreotide
DOTATATE	DOTA- Tyr^3-octreotate
DOTATOC	DOTA-octreotate
DTPA	Diethylenetriaminepentaacetic acid
DWI	Diffusion-weighted imaging, an MR imaging technique
EGFR	Epidermal growth factor receptor; the mutated form EGFRvIII plays a prominent role in tumorigenesis and pro-angiogenic signaling
FLAIR	Fluid-attenuated inversion recovery, an MR imaging technique
GBM	Glioblastoma multiforme
GTV	Gross tumor voume (the extent of the tumor on morphologic imaging)
IDH	Isocitrate dehydrogenase; mutations of this enzyme occur more frequently in oligodendroglial and astrocytic tumors
KPS	Karnofsky performance score
LAT1	L-type amino acid transporter 1
M	Metastasis status according to the AJCC/UICC TNM staging system
MDR1	Multidrug resistance gene 1, a characteristic associated with aggressive tumors; this gene encodes for P-glyoprotein
MGMT	Methyl guanine DNA methyl transferase, a DNA repair enzyme; methylation of MGMT promoter is associated with increased overall survival
MIB-1	Marker of cell proliferation used for stratification of grades of brain tumors
MoAb	Monoclonal antibody
MPNST	Malignant peripheral nerve sheath tumor
MR	Magnetic resonance
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
PET	Positron emission tomography
PET/CT	Positron emission tomography/computed tomography
PET/MR	Positron emission tomography/magnetic resonance
PI3K	Phosphatidylinositol 3-kinase
PNET	Primitive neuroectodermic tumor
pRIT	Pretargeting radioimmunotherapy
PTEN	Phosphatase and tensin homolog is a tumor suppressor; PTEN deletions indicate a poor prognosis
RIT	Radioimmunotherapy

ROC	Receiver operating characteristic, a statistical analysis to assess the performance of a binary classifier
ROI	Region of interest
SPECT	Single photon emission computed tomography
SPECT/CT	Single photon emission computed tomography/computed tomography
SST	Somatostatin
SSTR	Somatostatin receptors
SUV	Standardized uptake value
T	Tumor status according to the AJCC/UICC TNM staging system
T/N	Ratio of tumor uptake to normal brain uptake
TBR	Tumor-to-background ratio
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status), and "M" (distant metastasis status)
TP53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
VEGF	Vascular endothelial growth factor
VOI	Volume of interest
WHO	World Health Organization

Primary brain tumors are a heterogeneous group of neoplasms, each with its own biology, prognosis, and treatment. Among primary brain tumors, gliomas constitute the most frequent pathologic finding, being characterized by distinct histologic patterns and grades that are predictive of tumor invasiveness and patient survival. In this chapter we will review the main features of neoplasms of the central nervous system (CNS), and we will focus on the use of positron emission tomography (PET) and single-photon emission computed tomography (SPECT) as well as of hybrid techniques, particularly PET with computed tomography (PET/CT) and PET with magnetic resonance (PET/MR) with various radiopharmaceuticals for the diagnosis, treatment, and follow-up of brain tumors. Even though nowadays all PET tomographs are either PET/CT or PET/MR tomographs, the term PET will be used often either to contrast CT or MR studies or to refer to old studies that were performed with stand-alone PET tomographs.

Epidemiology of Brain Tumors

Many different organizations track the incidence of gliomas. This can be done using data collected through government cancer surveillance

(i.e., statewide or countrywide cancer registries) [1] or through the use of health system records [2]. Incidence rates of glioma vary significantly by histologic type, age at diagnosis, gender, race, and country. Overall age-adjusted incidence rates range from 4.67 to 5.73 per 100,000 persons. Age-adjusted incidence of glioblastoma, the most common and most deadly glioma subtype in adults, ranges from 0.59 to 3.69 per 100,000 persons [3, 4]. Although brain tumors are more frequent in adult subjects, they can occur in pediatric patients and adolescents as well. However, age and gender distribution vary accordingly to histotype. Meningiomas are more common in females than in males with a 3:2 ratio, while gliomas are slightly more common in men. The age-adjusted incidence rates of brain tumors tend to be highest in developed, industrial countries. However, the lower incidence of brain tumors in developing countries may also be attributed to decreased diagnosis [5].

Staging and Prognostic Stratification

The American Joint Committee on Cancer (AJCC) in agreement with the World Health Organization (WHO) classification of tumors of the CNS was updated a few years ago [6]. On the basis of histological origin, the WHO classification identifies six types of CNS neoplasms (Table 1): (1) tumors of the neuroepithelial tissue, (2) tumors of the cranial and paraspinal nerves, (3) tumors of the meninges (meningiomas), (4) lymphomas and hematopoietic neoplasms, (5) germ cell tumors, and (6) tumors of the sellar region. In addition to these primary CNS tumors, metastatic tumors need to be considered as well. Most neuroepithelial tumors are derived from glial cells and therefore are termed gliomas. There are three types of gliomas, namely, astrocytomas, oligodendrogliomas, and ependymomas. The category of astrocytomas is included in the glioblastoma. However, some tumors, such as the medulloblastoma, derive from neurons. In this chapter, we will focus particular attention to the distinction between low-grade and high-grade gliomas and briefly mention meningiomas.

CNS tumors do not currently have TNM designation [6]. Attempts at developing a TNM-based classification and staging system for CNS tumors have been disappointing. There are multiple reasons for this. (1) Tumor size is significantly less relevant than tumor histology and tumor grading (Table 2). Thus, the T classification is less pertinent than the biologic nature of the tumor itself. (2) Because the brain and spinal cord have no lymphatics, the N classification does not apply. (3) An M classification is not pertinent to the majority of CNS tumors, because they have the tendency to recur locally and they virtually never disseminate at distance.

Based on the histological features, CNS tumors are divided into low-grade and high-grade tumors. Grading is based on the degree of nuclear atypia, mitosis, microvascular proliferation, and necrosis. Grading is clinically important because prognosis worsens as tumor grading increases. Tumor grade is determined by multiple histological sampling of tumor tissue. Grading becomes unreliable in treated tumors because blood–brain barrier (BBB) damage and necrosis also can result from the formation of reactive tissue after therapy [7].

Low-grade gliomas are grade I and II, while high-grade gliomas are grade III and IV. Since histological features may vary within different areas of the same tumors, the most malignant region determines the grade of the tumor. Grade III astrocytomas are commonly referred to as anaplastic astrocytomas. Glioblastoma, a grade IV glioma, is the most malignant as well as the most common form of gliomas, accounting for about 50% of all gliomas [8]. All glioblastomas can be divided into two subtypes based on the presence or absence of a precursor lesion of a lower grade. Primary high-grade glioblastomas develop more commonly in subjects younger than 45 years, while secondary glioblastomas that progressed from low-grade gliomas occur more frequently in older subjects (>60 years). Primary glioblastoma is the most common type (>90%) and diagnosed as a de novo lesion without progression from a lower-grade tumor in older patients. Secondary glioblastomas develop through progression from a low-grade diffuse astrocytoma or anaplastic astrocytoma and present in younger patients [9].

Table 1 The 2010 AJCC classification of tumors of the CNS (Adapted from Ref. [6])

(1) *Tumors of neuroepithelial tissue*	
Astrocytic tumors	
Pilocytic astrocytoma	9421/1[a]
Pilomyxoid astrocytoma	*9425/3*[b]
Subependymal giant cell astrocytoma	9384/1
Pleomorphic xanthoastrocytoma	9424/3
Diffuse astrocytoma	9400/3
Fibrillary astrocytoma	9420/3
Gemistocytic astrocytoma	9411/3
Protoplasmic astrocytoma	9410/3
Anaplastic astrocytoma	9401/3
Glioblastoma	9440/3
Giant cell glioblastoma	9441/3
Gliosarcoma	9442/3
Gliomatosis cerebri	9381/3
Oligodendroglial tumors	
Oligodendroglioma	9450/3
Anaplastic oligodendroglioma	9451/3
Oligoastrocytic tumors	
Oligoastrocytoma	9382/3
Anaplastic oligoastrocytoma	9382/3
Ependymal tumors	
Subependymoma	9383/1
Myxopapillary ependymoma	9394/1
Ependymoma	9391/3
Cellular	9391/3
Papillary	9393/3

[a]Morphology code of the International Classification of Diseases for Oncology (ICO-O) (614A) and the Systematized Nomenclature of Medicine (http://snomed.org). Behavior is coded /0 for benign tumors, /3 for malignant tumors, and /1 for borderline or uncertain behavior

[b]The italicized numbers are provisional codes proposed for the fourth edition of ICD-O. While they are expected to be incorporated into the next ICD-O edition, they currently remain subject to change

Glioblastomas are highly aggressive tumors that are generally resistant to treatment. Average survival is less than 1 year from diagnosis. Glioblastomas are characterized by hypercellular anaplastic glioma cells with marked mitotic activity as well as necrosis and endothelial proliferation. Neoplastic cells frequently reveal pleomorphism showing different histologic features such as small homogeneous cells with scant cytoplasm, fibrillary-shaped cells, multinucleated giant cells, and cells with pleomorphic nuclei and cytoplasm [10]. Because of such cellular pleomorphism, the tumor is often referred to as glioblastoma multiforme (GBM) [10]. Histologic features in glioblastomas are associated with clinical outcome: greater necrotic component is associated with poor survival, while greater oligodendroglial component is predictive of longer survival [11].

Genetic Predisposition and Underlying Molecular Biology Changes

The traditional classification of brain tumors of the WHO grades II–IV is based on histological features of a heterogeneous population of tumors with varying prognoses and treatments. Histologic visual criteria may be prone to errors, and interpreting

Adapted from Ref. [6]

cellularity is not always possible due to the histological heterogeneity of the tumor. Over the last decade, research efforts have resulted in a better understanding of the molecular basis of glioma formation as well as the genetic alterations commonly identified in gliomas [9].

The discovery and characterization of the isocitrate dehydrogenase (IDH) 1 and 2 mutations in brain tumors that occurred in the last 6 years is a major achievement. IDH1 and IDH2 mutations occur more frequently in oligodendroglial and astrocytic tumors and less frequently in GBMs. IDH mutant gliomas have indeed a better prognosis in comparison to IDH wild-type gliomas [12]. Whether mutations in IDH result in a loss of tumor suppressor function or act as an oncogene remains a source of debate. It has been hypothesized that the effects of the IDH mutant enzyme's product, 2-hydroxyglutarate, change a cell's methylation profile and alter cell telomere length and gene expression. The effects of IDH mutations also produce decreased cytoplasmic levels of alpha-ketoglutarate and nicotinamide adenine dinucleotide phosphate oxidase that may in turn stabilize hypoxia-inducible factor 1-α facilitating cellular proliferation [13].

The evolution of a recurrent high-grade glioblastoma is more rapid than a primary high-grade glioblastoma. In the pathway to secondary high-grade glioblastoma, TP53 mutations are the most frequent and earliest detectable genetic alterations, already present in 60% of precursor low-grade astrocytomas [14]. On the contrary, unbalanced translocation of chromosomes 1 and 19 with deletion of the 1p arm and the 19q arm is found in almost 70% of histologically defined oligodendrogliomas. 1p/19q codeletions and TP53 mutations are relatively exclusive of one another, supporting the argument of two separate lineages that can be identified on a molecular basis to supplement histological diagnosis. A 1p/19q codeletion is associated with improved prognosis in low-grade gliomas and it is predictive of improved outcomes with chemotherapy and radiation [15].

The DNA repair enzyme O_6-methyl-guanine-DNA methyltransferase (MGMT) status repairs O^6 alkyl guanine adducts. The repair enzyme mechanism interferes with the overlapping effect of drug, which alkylates at the O_6 position of guanine. Methylation of the promoter of the MGMT gene results in silencing of gene transcription, so that the effect of temozolomide is enhanced. MGMT promoter methylation was identified in 36% of the overall population of glioma series studied, which demonstrated the presence of the mutation improves the effect of temozolomide and ultimately increases overall survival regardless of treatment arm [9, 16]. Numerous trials have shown that MGMT promoter methylation is a prognostic marker associated with improved survival. MGMT promoter methylation can be associated with 1p19q codeletions as well as IDH mutations suggesting it may be an epiphenomenon related to these or other factors that result in improved survival [9, 16].

The epidermal growth factor receptor (EGFR) is a transmembrane receptor in the receptor tyrosine kinase (RTK), phosphatase and tensin homolog, and phosphatidylinositol 3-kinnase (PI3K) cell proliferation pathway. EGFR*vIII*, a mutated form of EGFR, plays a prominent role in tumorigenesis of glioblastoma, but the underlying mechanisms have remained elusive. EGFR*vIII* amplification can lead to increased downstream activity resulting in proangiogenic signaling, increased proliferation, increased tumor cell survival, and migration [17]. EGFR*vIII* amplifications have been reported in approximately 40% of primary glioblastomas. EGFR*vIII* amplification has been reported to be a predictor of poor survival; however, other studies have failed to show this effect. Studies have reported that EGFR*vIII* amplification can predict response to tyrosine kinase inhibitors, especially when PTEN expression is preserved [17, 18].

Phosphatase and tensin homolog (PTEN) is a tumor suppressor gene expressing a protein involved in the same RTK/PTEN/PI3K cell proliferation pathway as EGFR. PTEN mutations are estimated to occur in 15–40% of primary glioblastomas, but up to 80% of glioblastomas have loss of chromosome 10q in the region where PTEN is located (10q23). Chromosome 10q loss, PTEN mutations, and EGFR amplifications are frequently seen together in the small cell phenotype of glioblastoma. PTEN deletions have been

reported to be a poor prognostic factor for pediatric glioblastomas; however, this has not been found true in adult patients [17].

Contrary to other tumors, environmental factors do not play a major role in the development of brain tumors.

Clinical Presentation

Symptoms of brain tumors depend on the location, size, and rate of growth of the tumor. High-grade, fast-growing tumors have early symptom onset, while slow-growing, small-sized tumors may remain asymptomatic for many years, especially if they are located in cerebral mute areas, such as the frontal lobe. In these cases, brain neoplasms can be an incidental finding at CT or MR imaging.

Symptoms can be either focal or generalized and appear in a late phase. Generalized symptoms reflect increased intracranial pressure. The most common symptom is headache. Typically, the headache is diffuse, but it may affect only one side, frequently reflecting the site of the tumor. Generally, headache is more intense on awakening in the morning and responds poorly to analgesics; it wanes spontaneously after few hours. Rarely, headache is throbbing and mimicking migraine. Nausea, vomiting, and sixth-nerve palsy are less common.

Focal symptoms or signs take place when the neoplasm compresses the nearby cerebral parenchyma. They can be motor, sensory, or sensory motor. Aphasia is typical of frontal lobe involvement, ataxia is typical of cerebellar involvement, and diplopia occurs with optic nerve gliomas.

Seizures occur at variable degree in brain tumor patients, being more frequent in low-grade tumors. Typically, the seizures are focal but they may become generalized and cause loss of consciousness.

Prognosis

In addition to the previously mentioned genetic factors, there are other prognostic factors for brain tumors (Table 3).

Table 3 Prognostic factors in CNS tumors

Histology
Pathologic grade
Presence and extent of necrosis
Presence of gemistocytes
Proliferative fraction (Ki-67)
Presence of oligodendroglial component
Presence of cells in mitosis and endothelial proliferation
Age of patient
Functional neurological status
Karnofsky Performance Scale
Extent of resection
Biopsy, subtotal, radical removal
Tumor spread
Presence of local spread
Molecular aspects
Isocitrate dehydrogenase IDH1 and IDH2 mutations (protective factors)
1p/19q codeletion (protective factor)
O_6-methyl-guanine-DNA methyltransferase methylation (protective factor)
TP53 mutations (risk factors)
Epidermal growth factor receptor amplification (risk factor)
Phosphatase and tensin homolog mutations (risk factor)

Tumor histology. Histology is by far the most important variable affecting prognosis, and in many cases it determines the treatment modalities that are employed. Prognosis is worst with highest grade. The latest WHO classification system has combined tumor nomenclature with an associated grading system so that the actual histological diagnosis directly correlates with the histological grade of the tumor. The most common histologies for brain and spinal cord tumors are given in Tables 1 and 2, along with the tumor grade for each different diagnostic category.

Age. Most retrospective outcome studies of brain tumor therapy show that older age at the time of diagnosis is a powerful predictor of poor outcome [5, 19]. This fact holds true for the gliomas, which are the most common primary brain tumors, and for most other tumors that affect the adult population, including most metastatic tumors to the brain. There are, however, some childhood tumors that have a very poor prognosis,

are inherently high grade, and rapidly progress to a fatal outcome. Some metastatic tumors, such as melanoma, occur in younger patients and also violate this general statement with regard to the specific effect of age on prognosis.

Extent of tumor resection. In patients who are treated surgically for tumors of the CNS, the extent of resection is often closely correlated with the outcome. This is a less powerful predictor than tumor histology or age, but most retrospective studies confirm that the extent of removal is positively correlated with survival. For this reason, the documentation of whether a surgical tumor removal is "gross total," "subtotal," or "biopsy only" is useful in determining future therapy and prognosis.

Tumor location. Because of the differential importance of various areas of the brain, the location of a given tumor affecting the brain can have a major impact on the functional outcome, survival, and type of therapy.

Functional neurologic status. Another important prognostic factor in most retrospective studies of CNS tumors is the functional neurologic status of the patient at the time of diagnosis [11]. This has been estimated traditionally using the Karnofsky Performance Scale, which is reproducible, it is well known by most clinicians, and it is in common use for stratification of patients entering clinical trials for the treatment of brain tumors. The outcome and prognosis of patients correlate well with functional neurological status.

Metastatic spread. Tumors affecting the CNS rarely develop extraneural metastases because of inherent biologic characteristics of these tumors and because the brain does not have a well-developed lymphatic drainage system. In addition, many patients with tumors of the CNS have a short life expectancy, which further limits the likelihood of metastatic spread. Certain tumors do spread through cerebrospinal fluid (CSF) pathways, and such spread has a major impact on survival. Dissemination through the CSF pathway is a hallmark of certain childhood tumors, e.g., primitive neuroectodermal tumors, many of which carry a poor prognosis; this event, however, is rarely seen in adult patients with the more common CNS tumors. Primary lymphomas of the CNS may spread along the craniospinal axis and sometimes exhibit intraocular dissemination.

Clinical Applications

Before entering into the issues of PET and SPECT imaging of brain tumors, the clinical situations in which PET/SPECT may be useful are described in Table 4:

1. *Diagnosis*. CNS masses may be incidental findings on MR or CT examinations performed as part of diagnostic staging for non-CNS pathology or following neuroradiological examinations performed for neurological or psychiatric symptoms. In most cases, morphologic assessment by MR imaging is often the first step toward diagnosis of primary brain tumor, allowing the precise assessment of tumor size, margins, mass effect, and the presence or absence of contrast enhancement. However, CT and MR lack specificity and do not allow determination of tumor metabolism and activity. PET may be useful to reinforce the diagnostic hypothesis and to address other issues that are important for presurgical evaluation.
2. In vivo *tumor grading*: Grading is obtained following histological analysis of stereotactic

Table 4 Clinical indications to SPECT or PET imaging in gliomas

Pre-therapy
1. Diagnosis
2. Noninvasive tumor grading
3. Guidance for stereotactic biopsy
4. Surgical planning
5. Identification of metabolically active tumor (or biological target volume, BTV) for radiotherapy planning
6. Evaluation of multidrug resistance
Post-therapy
1. Identification of residual tumor
2. Differential diagnosis between tumor recurrence and radiation necrosis
3. Evaluation of response to therapy
4. Prediction of survival

biopsy or of the surgical specimen, if biopsy is not possible. Thus, it would be desirable to predict tumor grade noninvasively with brain imaging or to use an imaging technique to guide biopsy to the areas that are more likely to be of higher grade.

3. *Guidance for stereotactic biopsy.* A typical feature of gliomas is the variability in histological grade that can occur within the same tumor. This is particularly common in high-grade tumors, which generally evolve from low-grade forms. More than 60% of tumors contain both low-grade and high-grade features. As a consequence, sampling errors on stereotactic biopsy are a matter of particular concern. MR and CT do not provide sufficiently accurate information for distinguishing low-grade from high-grade areas. Whether or not PET can be used for guiding biopsy sampling has been addressed in various studies.
4. *Surgical planning*. MR imaging may underestimate the tumor extent in cerebral gliomas. In fact, margins of the abnormal MR lesion in the autopsy specimens of brains affected by gliomas may have viable tumor cells on histopathological examination. Accurate delineation of tumor extent is critical for a complete resection and for localizing metabolically active areas within the tumor in case of a partial resection.
5. *Radiotherapy planning*. Tumor delineation is also important to define the tumor volume that must be irradiated for therapeutic purposes. Adjuvant radiation therapy improves tumor control and is therefore carried out in all tumor patients. Inaccurate tumor delineation with persistence of viable tumor cells beyond the target area (i.e., geographic misses) is a major cause of treatment failure.

   Radiotherapy planning volume is traditionally based on MR. The target volume defined on the basis of morphological imaging is referred to as gross tumor volume (GTV). One of the most important limitations in the application of image-guided radiotherapy consists in the failure to define the tumor extension precisely, which can be attributed to nonspecific changes of MR after surgery or radiation therapy. Thus, PET has been used to identify the metabolically active brain areas. The metabolically active volume, as identified by PET, is referred to as biological target volume (BTV). The combination of GTV and BTV provides the ultimate planning target volume (PTV).
6. *Differentiation of tumor recurrence* versus *radiation injury.* This is currently the most common indication for a PET study. Radiotherapy is associated with a risk of radiation necrosis, especially in the case of tridimensional, conformal treatments that deliver high local doses to small volumes. The occurrence of necrosis is difficult to predict, and it is necessary to differentiate it from tumor recurrence. Radiotherapy-induced injury of the BBB and brain tissue causes edema, so that contrast enhancement may be evident on both CT and MR. This is a potentially confounding factor, because tumor recurrence is also characterized by contrast enhancement. This typically occurs for high-grade gliomas that invade cerebral vessels, thereby increasing BBB permeability. Thus, the observation of contrast enhancement on CT and MR requires further differential diagnosis.
7. *Assessment of response to therapy.* The majority of non-CNS cancers are responsive to some lines of chemotherapy, and the evaluation of response to therapy is a cornerstone of imaging in oncology. Instead, CNS tumors respond poorly to traditional chemotherapies, and metabolic changes induced by chemotherapy are not routinely evaluated. SPECT and PET studies were performed to assess the biological basis of the poor chemosensitivity of gliomas to most common chemotherapy drugs. Nevertheless, the development of some effective CNS chemotherapy agents, such as temozolomide, and, more recently, of antiangiogenic drugs, such as bevacizumab, has renewed interest in assessing the response to treatment. PET was also used in the past to address the effect on cerebral blood flow and glucose metabolism in response to dexamethasone, which is used to reduce edema and to alleviate neurological symptoms.

8. *Prognostic stratification*. Metabolic pattern as assessed by PET may be useful to predict the behavior of brain tumors. Such prognostic information may be obtained at any time point, i.e., initial staging, response to therapy, and restaging.

This classification of clinical indications for brain tumor imaging is "problem oriented." Not always is a PET scan requested to address all these issues, and some of them are strictly correlated. Using temporal criteria in relation to the main therapeutic events and very similarly to what is done in general oncology, PET scans are indicated in patients with brain tumors:

1. For initial staging
2. After surgery for the evaluation of residual mass
3. For restaging, when suspicious of recurrence or for differential diagnosis from radiation necrosis
4. For the evaluation of response to therapy

Prognostic information can be obtained with appropriate study designs at any time point.

However, tumor recurrence versus radiation necrosis is the typical restaging situation.

Overall Performance of Diagnostic Imaging Other Than Nuclear Medicine

CT is often the first modality employed in a patient presenting with a brain tumor, but MR is the reference imaging modality in brain tumor patients. The role of CT is largely confined to emergent imaging in the detection of hemorrhage, herniation, and hydrocephalus; however, the detection of mass effect from brain tumors and calcification within brain tumors, such as oligodendrogliomas or meningiomas, can have diagnostic relevance [17].

MR sequences exploring morphological features play a major role in the evaluation of and treatment planning of brain tumors. Standard sequences performed utilizing spin-echo techniques include T2 fluid-attenuated inversion recovery (FLAIR), pre-gadolinium T1, and post-gadolinium T1. These sequences are preferably performed in at least two orthogonal planes or obtained with a three-dimensional (3D) sequence that is reformatted into orthogonal planes (i.e., 3D T2 FLAIR). High-resolution isovolumetric sequences such as high-resolution 3D T2 sequences and post-gadolinium T1 spoiled gradient recalled acquisition or similar sequences are generally performed preoperatively with fiducials in place for use with intraoperative navigational software. Similarly, post-gadolinium T1 sequences are performed with a stereotactic head frame in place prior to stereotactic radiosurgery [20]. High-resolution 3D T2* gradient echo sequences, such as susceptibility weighted imaging, are also routinely performed. These susceptibility sensitive sequences are very sensitive to blood degradation products and calcification and may be helpful to depict post-radiotherapy micro-hemorrhages [17].

The primary roles of structural MR in initial brain tumor evaluation include determining the location of the lesion (i.e., intra-axial vs. extra-axial); establishing the specific location within the brain for treatment/biopsy planning; evaluating mass effect on the brain, ventricular system, and vasculature; and suggesting a possible diagnosis. Establishing the diagnosis of a specific tumor type can be challenging, but often the correct diagnosis can be limited to a short list of likely possibilities. Contrast enhancement indicates local breakdown of the blood–brain barrier and is a key feature seen in many brain tumors and other mass lesions. Within gliomas, contrast enhancement is generally considered to be associated with a high-grade tumor although certain low-grade gliomas, such as pilocytic astrocytomas in children, generally show contrast enhancement and certain high-grade gliomas may not enhance. Peritumoral edema is generally T2/FLAIR hyperintense signal abnormality surrounding the main mass lesion. This may in some instances, such as with metastasis, represent predominately vasogenic edema surrounding the lesion. However, with gliomas the peritumoral edema generally also represents infiltrative edema caused by tumor cells infiltrating into the regions of non-enhancing T2/FLAIR signal abnormality. The number of lesions is an important factor to consider

as a large number of lesions may signify certain pathologies, such as metastases. However, metastasis can be solitary, and demyelinating lesions or cerebral abscesses can also mimic tumor. Other potentially discriminating features to note include a cyst and mural nodule morphology (seen with the lower-grade tumor hemangioblastoma, pilocytic astrocytoma, ganglioglioma, and pleomorphic xanthoastrocytoma), calcification (generally seen with oligodendrogliomas), and necrosis and hemorrhage (generally seen in high-grade gliomas and hemorrhage also in certain metastases). Many of the same features are important in the ongoing evaluation of patients with known brain tumors. The updated version of the Response Assessment in Neuro-Oncology working group developed criteria based on MR to define response to treatment [21]. Diffusion-weighted imaging (DWI) offers insight into the diffusion of water molecules in tissues and can be used to calculate the apparent diffusion coefficient (ADC). ADC values derived from DWI have been shown to be reduced in highly cellular tumors, such as high-grade glioma. With regard to gliomas, lower ADC values have been reported in higher-grade gliomas than lower-grade gliomas, and lower ADC values have been reported to have a poorer prognosis independent of tumor grade [22].

Nuclear Imaging for Staging/Prognosis

Historical perspective. Several tracers have been used for imaging brain tumors (Table 5), and there are multiple mechanisms responsible for tracer uptake (Table 6). For several years, nuclear medicine techniques held a primary role for diagnosing brain tumors because CT entered into clinical practice in 1973 and MR a few years later. Pioneering studies with radiopharmaceuticals to detect brain tumors were carried out with ^{131}I-labeled serum albumin and, subsequently, with ^{203}Hg- or ^{197}Hg. Images were recorded with the rectilinear scanner developed by Benedict Cassen in 1950. Subsequently, with the advent of the scintillation camera (1959) [23], ^{99m}Tc-pertechnetate (^{99m}Tc), was primarily used for nuclear brain scanning. The advent of CT scanning, with markedly improved anatomic resolution, resulted in replacement of pertechnetate and ^{99m}Tc-DTPA brain scans. These radiopharmaceuticals display limited transport across the BBB in normal conditions, and the rationale to their use stemmed from altered BBB permeability in CNS pathologies. Dynamic acquisition allowed studying the perfusion of brain vessels, a procedure referred to as nuclear cerebral angiography [24].

Although thallium-201 chloride (^{201}Tl-chloride) and ^{99m}Tc-methoxyisobutylisonitrile (^{99m}Tc-sestamibi) were introduced later, both of them are no longer used today for CNS scintigraphy. ^{201}Tl ionic thallium is a substrate for the Na^+/K^+ ATPase pump, and thus ^{201}Tl uptake

Table 5 Most common current radiotracers for brain tumor imaging

Biological process	Radiotracer
Glucose transport across BBB and metabolism	[^{18}F]fluorodeoxyglucose ([^{18}F]FDG)
Amino acid transport and protein synthesis	[^{11}C]leucine
	[^{11}C]methionine ([^{11}C]MET)
	^{123}I-alpha-methyltyrosine (^{123}I-IMT)
	[^{11}C]tyrosine
	^{18}F-fluoroethyltyrosine (^{18}F-FET)
	alpha-[^{11}C]methyltryptophan
	[^{18}F]proline
Amino acid transport and dopamine metabolism	[^{18}F]fluoro-L-3,4-dihydroxyphenylalanine ([^{18}F]FDOPA)
Cellular proliferation	^{18}F-fluorothymidine (^{18}F-FLT)
	^{18}F-2-fluoro-5-methyl-1-beta-D-arabinofuranosyluracil (^{18}F-FMAU)
Somatostatin receptor imaging	^{111}In-DTPA-octreotide
	^{68}Ga-DOTANOC, ^{68}Ga-DOTATOC
Lipid metabolism	[^{11}C]choline/^{18}F-fluorocholine
Hypoxia	^{18}F-fluoromisonidazole (^{18}F-MISO)
	^{123}I-iodoazomycin arabinoside (^{123}I-IAZA)
	^{18}F-azomycin arabinoside (^{18}F-FAZA)
	^{64}Cu-methylthiosemicarbazone (^{64}Cu-ATSM)

Table 6 Factors affecting uptake of radiopharmaceuticals in gliomas

1. Perfusion and blood–brain barrier integrity
2. Histological grade
3. Glucose metabolic rate
4. DNA proliferation rate
5. Protein synthesis rate
6. Membrane (phospholipid) proliferation rate
7. Expression of membrane transporters
8. Oxygen tissue concentration (hypoxia)
9. Dimension of the lesion (partial volume effect)
10. Necrotic areas
11. Treatment with steroids
12. Radiotherapy treatment
13. Multidrug resistant phenotype
14. Expression of Na^+/K^+ ATPase
15. Expression of catecholamine binding sites
16. Glutathione content and redox potential
17. Intracytoplasmic and transmembrane esterase activity

reflects increased metabolic activity. The detection rate was reported as high as 85% [25–27], but it is important to consider that such figure was obtained with larger tumors than those investigated nowadays. False negatives were typically patients with small tumor size or tumors located in deep structures (basal ganglia and thalamus). Poor spatial resolution was the most important limiting factor for imaging. Investigators often failed to find a correlation between ^{201}Tl uptake and either tumor histology or cellular proliferation rate [28].

^{99m}Tc-sestamibi is a cationic lipophilic compound that accumulates in the cytoplasm and mitochondria as a result of passive diffusion across the negative cellular membranes. Cellular uptake is also dependent on the integrity of the mitochondrial membrane potential. Moreover, ^{99m}Tc-sestamibi kinetics is related to the multidrug resistance system (MDR1) and P-glycoprotein activity, and it may provide prognostic information about disease [29]. Thus, it was of interest to assess whether the tumor's response to chemotherapy can be predicted by ^{99m}Tc-sestamibi SPECT and whether ^{99m}Tc-sestamibi could be used for investigating the poor chemosensitivity of gliomas [30]. ^{99m}Tc-sestamibi findings were compared to the expression of the MDR1 gene and its product P-glycoprotein. SPECT in brain tumor patients showed increased uptake in patients who deteriorated clinically and negligible uptake in patients that did not recur, and MDR1 gene expression was inversely related to grade of malignancy [31]. The recent development of PET tracers for the evaluation of the MDR system drastically reduced the applications of ^{99m}Tc-sestamibi [32].

Brain Perfusion Imaging

^{99m}Tc-hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO) and ^{99m}Tc-ethylcisteinate dimer (^{99m}Tc-ECD) rapidly diffuse across the BBB and distribute in the brain according to cerebral blood flow (CBF). The intracellular trapping mechanisms are different. ^{99m}Tc-HMPAO is reduced by glutathione-enriched molecules to a more hydrophilic compound that is not able to retrodiffuse. However, the redox potential of the cell also plays an important role for intracellular retention of ^{99m}Tc-HMPAO [33]. ^{99m}Tc-ECD enters the neurons and it is hydrolyzed to more hydrophilic forms by an intracellular esterase [34].

The most frequent pattern of the appearance of brain tumors is increased activity compared to the normal parenchyma [35]. Increased vascularity (i.e., blood volume) as well as increased CBF accounts for this finding. Moreover, some metabolic trapping related to glutathione activity and esterase activity has been shown for ^{99m}Tc-HMPAO and ^{99m}Tc-ECD [36]. The mean reported positive detection rate for the detection of brain tumors was around 70% with noteworthy differences among various studies attributed to the tracer (higher for ^{99m}Tc-HMPAO) and size of the lesions [35–37]. Brain tumor perfusion, measured with any of these tracers, did not correlate with tumor histology [36]. Brain tumors may also appear as a hypoactive (cold) area rather than a hot area. Cold tumors on ^{99m}Tc-HMPAO have been related to low glutathione content. Finally, heterogeneous appearance with cold areas mixed to hot areas can be found. This typically occurs in high-grade, large-sized tumors that display necrosis in their core. Similarly to other SPECT tracers, ^{99m}Tc-HMPAO and ^{99m}Tc-ECD dynamic

acquisitions and absolute measurements are not possible, and images have poorer spatial resolution than PET images. Therefore, these tracers should not be considered today of routine clinical use to study brain tumors.

2-Deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG)

[^{18}F]FDG allows measurements of tumor glucose metabolism. [^{18}F]FDG was the first PET tracer used for imaging brain tumors and it is still widely used nowadays, after more than 30 years [38]. The rationale for the use of [^{18}F]FDG is that tumor glucose consumption is increased and thus tumor metabolic activity relates to the biological behavior. Warburg first observed that, in contrast to normal differentiated cells, which rely primarily on mitochondrial oxidative phosphorylation to generate the energy needed for cellular processes, most cancer cells rely instead on anaerobic glycolysis, a phenomenon termed "the Warburg effect."

The 2-deoxyglucose (DG) model for quantifying the cerebral metabolic rate for glucose (CMR_{glc}) was defined by Sokoloff following autoradiographic experiments in rats [39]. DG is a glucose analog that differs from glucose by the substitution of fluoride atom for the hydroxyl group on the second carbon atom. It is transported across the BBB by the same transporter as that for glucose. Within the neuron, DG is phosphorylated to DG-6-P by hexokinase. Because of the lack of the hydroxyl group, [^{14}C]DG is not further metabolized and is therefore irreversibly trapped into neurons within the time frame of the experiment [39].

Patients are invited to fast for at least 6 h before tracer injection and hydrated. All modern tomographs are acquired today in 3D mode, which enable increased sensitivity and better signal-to-noise ratio. Between 125 and 250 MBq, [^{18}F]FDG is injected depending on the body weight [40]. A 10-min static acquisition is performed about 45-min postinjection (uptake period). The patient is allowed to rest in a quiet dimly lit room with eyes closed in a condition of minimal audiosensory stimulation during the uptake phase, i.e., from tracer injection to the start of PET scanning. Images are corrected for attenuation, scatter, and random coincidences. Subsequent image reconstruction is performed using filtered back projection or, more frequently, iterative reconstruction [40].

Using arterial input function, dynamic scanning, and kinetic analysis, it is possible to obtain a quantitative measurement of the parameter of interest, e.g., the cerebral metabolic rate of glucose [39, 41]. Using noninvasive approaches and a single static acquisition, it is possible to obtain qualitative or semiquantitative measurements. The standardized uptake value (SUV) and the tumor-to-non-tumor activity ratio are the most common semiquantitative indices.

According to a 2-tissue compartment, irreversible model, cerebral metabolic rate of glucose (CMR_{glc}) can be computed as follows:

$$CMR_{glc} = \frac{C_p}{LC}\frac{K_1 k_3}{k_2 + k_3} \quad (1)$$

where C_p is the mean glucose concentration, LC is the lumped constant (a factor that accounts for kinetic differences between glucose and deoxyglucose), K_1 and k_2 reflect glucose transport from plasma to brain and vice versa, and k_3 reflects glucose phosphorylation by hexokinase. The rate of DG-6-P accumulation is related to neural activity. Physiological consumption of glucose for gray matter is two- to fourfold higher than in white matter. The 2-deoxyglucose model was subsequently adapted to human studies with [^{18}F] labeling for PET.

Diagnosis and grading. Early studies in brain tumor patients stressed the importance of the functional information provided by PET compared to morphologic neuroradiological techniques. Much of this early work is credited to the group headed by Di Chiro at the National Institutes of Health [38, 42, 43]. Di Chiro et al. first used PET with [^{18}F]FDG in 23 patients with cerebral gliomas. All ten high-grade gliomas demonstrated focal tracer uptake that was easily visible (Fig. 1). Cerebral glucose utilization was often depressed in adjacent areas. Mean CMR_{glc} in high-grade gliomas was 7.4 ± 3.5 mg/100 g min. The 13 low-grade

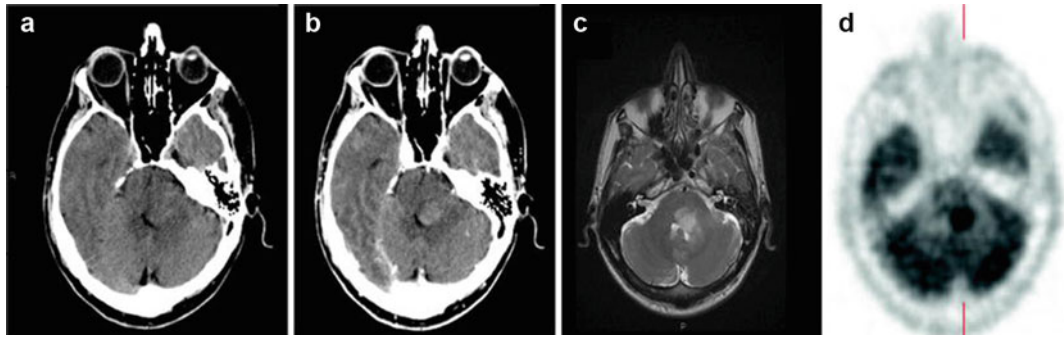

Fig. 1 A 42-year-old patient presented with headache and motor coordination impairment. Unenhanced CT (**a**), contrast enhancement CT (**b**), T2-weighted MR (**c**), and [^{18}F] FDG PET were performed. A focal area of increased glucose consumption in comparison to both *white matter* and *gray matter* is visible in the cerebellum. Visualization of the tumor is sharper on contrast enhancement CT compared to unenhanced CT. Biopsy revealed a high-grade glioma

gliomas had CMR_{glc} of 4.0 ± 1.8 mg/100 g min, with no distinctly visible hot spot. Thus, the rate of glucose metabolism was correlated to tumor malignancy [42]. This finding was considered as a major achievement because in those early times in vivo, noninvasive grading of neoplasms appeared much less intuitive as nowadays. The best cutoffs for the tumor-to-white matter ratio and the tumor-to-gray matter ratio for distinguishing high-grade gliomas and low-grade gliomas were 1.5 and 0.6, respectively. With these cutoffs, sensitivity and specificity were 94% and 77% [42]. Very similar results were obtained in a larger study 13 years later despite significant technological changes that had occurred meantime [44].

Brain tumors may induce suppression of metabolic activity in nearby normal and edematous tissue. Reduced glucose metabolism may occur also in normal brain tissue that is remote, but functionally linked to the site of the tumor (diaschisis) [45]. The cerebellum is a frequent site of metabolic reduction that is typically contralateral to the site of the tumor (crossed cerebellar diaschisis). Cerebellar hypometabolism is ascribed to functional interruption of the contralateral cerebropontine-cerebellar pathway [46].

Qualitative vs. *quantitative*. Which analysis method should be used for interpreting brain tumor images? Each analysis method has advantages and disadvantages (Table 7). PET was originally developed as a quantitative technique, and the first applications used arterial line input function for quantitative measurement of CMR_{glc}. However, for clinical purposes analysis did not always match histopathology results [47]. Moreover, a significant difference in glucose metabolism between high-grade and low-grade gliomas was not always detected [48]. This has noteworthy importance when passing from group analysis of research studies to single subject analysis of the clinical routine. Methodological considerations and technological factors cast into doubt the validity of the [^{18}F]FDG model in brain tumors. Sokoloff first noted that the lumped constant value in tumors was different from that in normal brain. Rate constants could also change as a consequence of altered metabolism [49]. Finally, tissue inhomogeneity, which is thought to introduce an overestimation of CMR_{glc} in normal cerebral tissue, is expected to have a greater effect with old scanners, because of poorer resolution [50]. By partial volume effect, measurements in a certain ROI reflect the spillover of activity into neighbor areas as well spill in of activity from neighbor areas [51]. Partial volume effect would artificially decrease CMR_{glc} in rim-shaped hypermetabolic areas for which ROI analysis would include significant amount of white matter. On the basis of these considerations, visual analysis has been advocated for clinical routine purposes, while PET quantitation with arterial line input function should be limited to restricted research protocols [52].

Table 7 Characteristics of quantitative and semiquantitative brain PET studies with [^{18}F]FDG

	Quantitative studies	Qualitative studies
Arterial input function	Necessary	Not necessary
Acquisition	Dynamic (frames ranging from 30 s to 5 min for a total of 60 min)	Static (10–15-min acquisition 45-min postinjection)
Glycemia	Necessary	Not necessary
Parameters	CMR_{glc} (mg/glc/100-g brain tissue)	SUV
		Tumor-to-non-tumor ratio
		Visual analysis
Data analysis	Time-consuming and technically challenging computer programming	None to simple (ROI analysis)
Diagnostic yield	Greater accuracy than semiquantitative analysis not proven	Sufficient for the vast majority of routine clinical tumor cases
Metabolic specificity	Not specific for tumor	Not specific for tumor
Pitfalls	Lumped constant assumed to be equal to normal brain	Visual analysis subject to subject bias
Application	Preferred for research studies	Preferred for clinical diagnostic routine

Subjectively, [^{18}F]FDG uptake within a tumor region is compared to the contralateral white matter region or, less frequently, to contralateral gray matter region. Accordingly, high-grade tumors have metabolism greater than white matter, and low-grade tumors have metabolism that is similar or lower than white matter. Semiquantitative measurements, such as SUV or tumor-to-white matter ratios, may be useful. Tumor-to-white matter ratios do not have some limits of SUV, because biases due to global factors are being canceled out as the ratio of the two ROIs is computed. Visual analysis is standard today in the clinical activity [48, 53–55].

Glucose loading. It is apparently paradoxical that, while patients are being asked to fast before a PET scan, glucose loading might have been used for increasing the diagnostic possibilities of [^{18}F]FDG PET in patients with brain tumors. Indeed, glucose loading has been used for enhancing detection of gliomas. Hyperglycemia reduces [^{18}F]FDG transport/uptake into the brain due to direct competition with the glucose transporter. This effect is less marked in brain tumors than in normal cortex because [^{18}F]FDG uptake in tumors occurs also through BBB breakdown. Thus, glucose loading resulted in an increased tumor-to-cortex ratio [56, 57]. Although this technique provided promising results and glucose loading is a relatively simple and safe procedure, this approach did not achieve widespread clinical use.

Late acquisition. Delayed or dual time point imaging is a successful approach used in oncological [^{18}F]FDG PET applications with the aim to increase sensitivity. The underlying rationale is that in many tumors, [^{18}F]FDG uptake continues beyond the usual 45-min uptake period, while at this time, the tracer has reached equilibrium between plasma and normal tissues. Because of the slower kinetic of the tracer in neoplasms compared to normal tissue, proportionally greater activity will be detected in tumor tissue compared to normal tissue as the interval from injection to imaging increases. Delayed imaging (90-min postinjection) increased the tumor-to-cortex contrast. This is due to both increased activity in the tumor as well as increased washout of the tracer from normal brain [58].

Tumor recurrence vs. *radiation necrosis*. The gold standard for distinguishing tumor recurrence from radiation necrosis is biopsy. The accuracy and specificity of biopsy can be as high as 95%, although biopsy of an edematous or gliotic site may be nondiagnostic [59]. Early studies showed that CMR_{glc} was increased in patients with tumor recurrence and low in patients with necrosis [60]. Even though these results were confirmed in study groups, false positives often occur on a patient-by-patient basis. Increased [^{18}F]FDG accumulation may occur following radiotherapy because of radiation-induced inflammation. The ratio between glucose metabolism in the tumor and in the contralateral remote white matter increases from 25% to 42% 1 day post-radiotherapy

and then decreases toward baseline values 7 days post-radiotherapy. Therefore, specificity may be as low as 40–60%, while sensitivity is generally high [61].

Stereotactic biopsy guidance. PET has the potential to increase the diagnostic yield of brain biopsy by selecting the areas that display highest tracer uptake and therefore are more likely to contain high-grade histotype. Specifically, stereotactic trajectories in areas of increased uptake are more often diagnostic and yield a higher proportion of high-grade gliomas. Based on these results, and similar findings obtained with other tracers, stereotactic PET-guided biopsy is now recommended [62].

Treatment planning. PET with [^{18}F]FDG showed promise for improving the accuracy of defining the target volume and for radiation dose escalation. An early study indicated that patients with glioblastoma multiforme can be treated with standard conformal fractionated radiotherapy if there is no [^{18}F]FDG uptake, while an additional boost is indicated in patients with increased [^{18}F]FDG uptake. [^{18}F]FDG PET volumes were predictive of survival and time to tumor progression [63]. These results, however, could not be replicated by the same group [64]. The use of [^{18}F]FDG for treatment planning remains a controversial issue considering the current more widespread use of amino acid tracers. [^{18}F]FDG might be of special interest in high-grade gliomas exhibiting marked intratumoral heterogeneity where hot spots could be possible targets for dose escalation [55].

Advantage and disadvantages of [^{18}F]FDG and of most common tracers used for brain tumor imaging are summarized in Tables 8 and 9.

Radiolabeled Amino Acids

Introduction. Neutral L-amino acids are essential amino acids; they cannot be synthesized by the brain, and, therefore, they must be supplied either by breakdown of endogenous proteins or by the diet. Since a single type of transport carrier mediates the transcapillary movement of structurally related amino acids, these compounds compete with each other for entry into the brain. After entering the neurons, amino acids may be used for protein synthesis or for other metabolic pathways.

Amino acids are the building blocks of proteins. The rate of protein synthesis is increased in proliferating brain tumors, which makes its measurement an important target for in vivo imaging. This measurement, however, held several

Table 8 Most important favorable and unfavorable characteristics of common current radiopharmaceuticals for brain tumor imaging

	Advantages	Disadvantages
[^{18}F]FDG	Easily available, overall good accuracy, good-quality images	High physiological uptake in normal brain
	Allows tumor grading	False positive by radiation necrosis and infection
	Correlates with prognosis	
Amino acid tracers	Available for PET as well as for SPECT	Tracer uptake is poorly affected by tumor grade
	Negligible uptake in normal brain	
	Optimal tumor delineation and contrast	
	Correlates with prognosis	
	Very high negative predictive value for distinguishing recurrence from necrosis	
	Useful for definition of radiotherapy plan	
^{18}F-FLT	Negligible uptake in normal brain	Uptake heavily affected by BBB integrity
	Optimal tumor delineation and contrast	Kinetic analysis with metabolite correction is required to distinguish BBB disruption from increased metabolism
	Superior to amino acid tracers for grading	
	Allows differential diagnosis between tumor recurrence and necrosis	

Table 9 Sensitivity and specificity for diagnosis of brain gliomas/gliomas recurrence for most common PET tracers[a]

Tracer	Sensitivity (95% CI)	Specificity (95% CI)	Indication	Reference	Study
[^{18}F]FDG	94%	77%	Diagnosis	[42]	Monocentric
[^{18}F]FDG	75%	81%	Necrosis versus tumor recurrence	[183]	Monocentric
[^{18}F]FDG	0.77 (0.66–0.85)	0.78 (0.54–0.91)	Necrosis versus tumor recurrence	[184]	Meta-analysis
[^{11}C]MET	0.70 (0.50–0.84)	0.93 (0.44–1.0)	Necrosis versus recurrence	[184]	Meta-analysis
[^{11}C]MET	75–95% (range)	87–100% (range)	Diagnosis	[7]	Review
^{18}F-FET	0.82 (0.74–0.88)	0.76 (0.44–0.92)	Diagnosis	[92]	Meta-analysis
^{18}F-FLT	79%	63%	Diagnosis	[185]	Monocentric

[a]Note that these values should be taken cautiously because they depend on several variables, including gold standard, clinical indication, tumor grade and dimension, sample size, analysis method, and type of study (single center, multicenter, or meta-analysis). Multitracer single studies are generally more informative for the comparison between two tracers. For these reasons, only some studies are cited

methodological restrictions. In the deoxyglucose method, intracytoplasmic trapping is the only active metabolic pathway, there are no radioactive metabolites, and computation of glucose metabolism is conceptually easy. For amino acids this is not the case. In addition to protein synthesis, amino acids can either be metabolized by transamination (rapidly followed by decarboxylation for CO_2 production) or enter other metabolic pathways. For some amino acids, typically ^{18}F-FET and ^{123}I-IMT, the intracellular metabolism is negligible and uptake is thought to reflect primarily transport across the BBB [65, 66]. Independently by the targeted biochemical process, amino acid tracers have shown to be useful for imaging brain tumors on several grounds.

[^{11}C]Methionine. Methionine (MET), an essential sulfur amino acid, is necessary for growth and development. At variance with [^{18}F]FDG, labeled amino acid uptake in normal cortex is very low. For this reason their uptake is not sensitive to visual and auditory stimulation enabling a simpler PET procedure. Most importantly, the role of amino acids in mediating an inflammatory tissue response is much less important than for glucose [67]. Thus, high specificity could be predicted. Soon after the publication of rapid high-yield procedures for labeling of methionine with ^{11}C ([^{11}C]MET), experiments were carried out to investigate the clinical role of [^{11}C]MET in various clinical settings.

Diagnostic accuracy. The overall sensitivity of [^{11}C]MET PET for distinguishing gliomas from nonmalignant lesions has been estimated to be around 75–95%, with somewhat lower values sometimes reported in low-grade gliomas, where uptake may occasionally be negligible. More interestingly, specificity of [^{11}C]MET PET ranged between 87% and 100% [68].

Grading. On the other hand, the predictive value of [^{11}C]MET PET for grading is limited. Several studies showed that [^{11}C]MET is taken up by gliomas irrespective of grade and that there is sizeable overlap in uptake values between low-grade and high-grade gliomas. Nevertheless semiquantitative analysis allows differentiating high-grade and low-grade gliomas better than visual analysis [68, 69].

Prognosis. In grades II and III gliomas, higher tumor to contralateral count ratios are associated with reduced survival. No such association was observed within the grade IV glioma group, most likely because of the overall poor prognosis in all these patients [70]. The prognostic value of [^{11}C]MET uptake has been consistently replicated in various studies [71].

Tumor extent determination. The critical factor in determining the edges of the tumors is the

method used for distinguishing significant from negligible tracer uptake. There is currently no consensus on the best method for this purpose. Visual qualitative and several semiquantitative methods have been adopted: fixed percent threshold value of tumor uptake, tumor-to-non-tumor ratios, absolute SUV values, and automatic software-based segmentation algorithm are some examples of such techniques. Irrespective of the method used, [^{11}C]MET PET delineates a larger volume in comparison to MR or [^{18}F]FDG PET. Integrating [^{11}C]MET PET with MR images is useful for planning surgery, with ensuing clinical impact in about 80% of the procedures [72–74]. The integration of [^{11}C]MET PET with morphological imaging was also useful for defining the radiotherapy plan [74, 75] (Fig. 2). PET guidance is considered necessary for defining the amount of tissue to be removed in brain tumors.

Tumor biopsy. Tumor biopsy is necessary before initiating any form of treatment. Although the poorer relation between [^{11}C]MET uptake and grading does not allow predicting the highest tumor grade, [^{11}C]MET PET has been advocated to reduce the number of required biopsy attempts and to reduce the risk of damaging functional areas in patients with brain tumors [72–74].

Therapy assessment and follow-up. Following surgical or radiation therapy, [^{11}C]MET PET can be repeated for assessing response to treatment, as well as for planning potential second-look surgeries. Prolonged survival in grades III and IV glioma patients with no [^{11}C]MET uptake after surgical resection as compared to those with residual [^{11}C]MET uptake has been reported [76].

Tumor recurrence vs. *radiation injury.* Because of limitations of [^{18}F]FDG for discriminating recurrent tumor from radiation injury, several authors investigated the usefulness of [^{11}C]MET PET (Fig. 3). Comparative evaluations show a greater accuracy of [^{11}C]MET PET than [^{18}F]FDG PET for the differential diagnosis. The use of semiquantitative binding provides a more robust tool to the differentiation of tumor recurrence from radiation injury [77].

3-^{123}I-Alpha-Methyltyrosine (^{123}I-IMT) and *O*-(2-^{18}F-Fluoroethyl)-L-Tyrosine (^{18}F-FET)

Several amino acid-derived radiopharmaceuticals can also be labeled with single-photon emitters, allowing a less expensive, more widely accessible

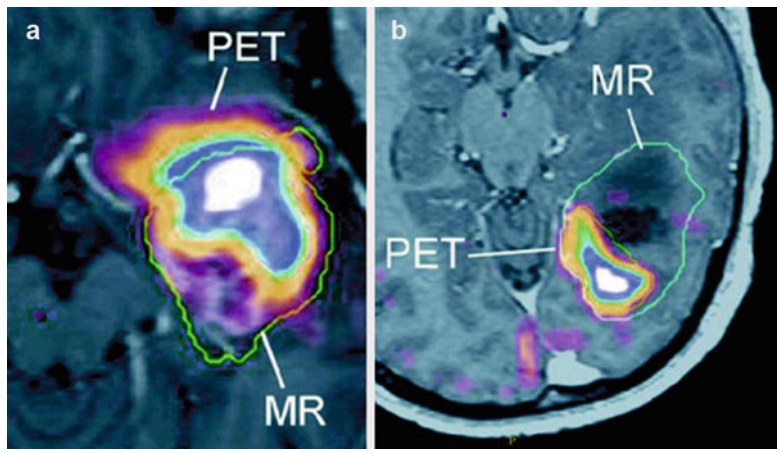

Fig. 2 Two examples of the use of PET in the definition of a radiotherapy plan. Tracer uptake on [^{11}C]MET PET is mapped with different colors according to its intensity. (**a**) Patient with left temporal anaplastic astrocytoma. PET contour projects out of the MR contour and some MR voxel extend out of the PET contour. The integration of both information will define the ultimate radiotherapy treatment plan. (**b**) Patient with left posterior temporal-occipital anaplastic oligoastrocytoma. In this case a greater discrepancy was found between the volume identified by [^{11}C]MET PET and the volume identified by MR (Reprinted with permission from Ref. [74])

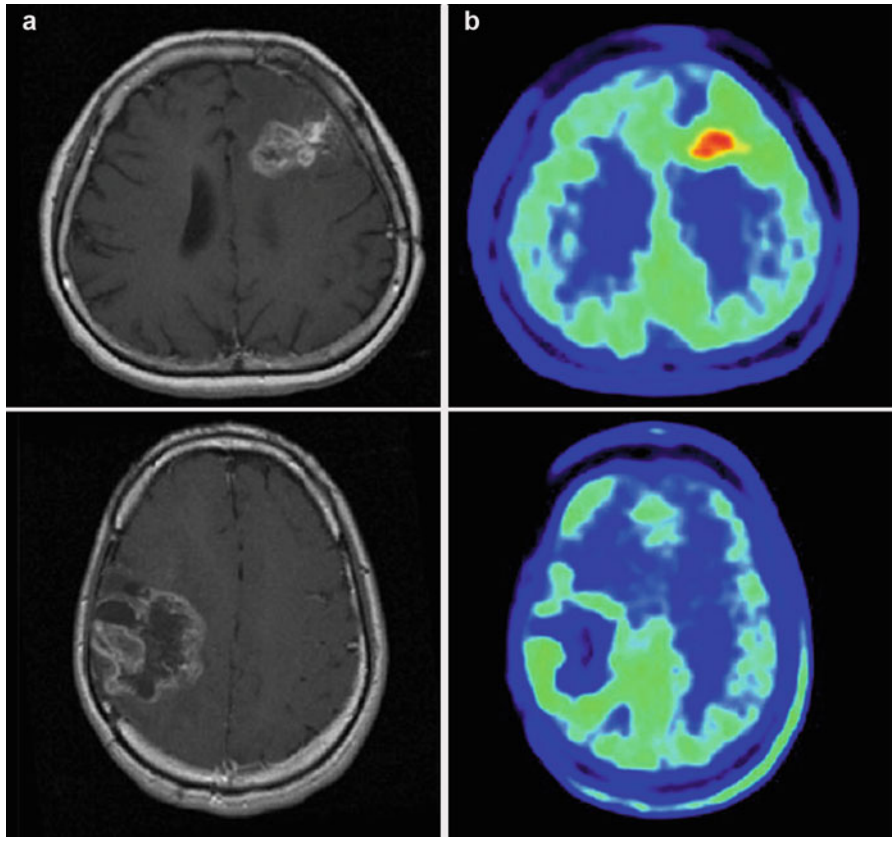

Fig. 3 (*Top*) Images of a 49-year-old woman who had been previously treated for glioblastoma multiforme with tumor resection and conventional radiotherapy at dose of 60 Gy. (**a**) T1-weighted MR image with contrast medium, obtained 13 months after initial surgery, showing contrast-enhanced lesion in the left frontal lobe. (**b**) [^{11}C]MET PET image showing focal accumulation of tracer corresponding to the abnormality on MR image. Recurrent tumor was pathologically confirmed by second surgery. (*Bottom*) Images of a 25-year-old man who had been previously treated for anaplastic astrocytoma with tumor resection and conventional radiotherapy at dose of 60 Gy. (**a**) T1-weighted MR image with contrast medium, obtained 21 months after initial surgery, showing ringlike enhancement of lesion in the right parietal cortex. (**b**) [^{11}C]MET PET image showing slight accumulation of tracer corresponding to abnormality on MR image. Gliosis without tumor was pathologically demonstrated by second surgery. Both images exemplify the primary role exerted by PET with ^{11}C-MET in distinguishing tumor recurrence from radiation necrosis (Reprinted with permission from Ref. [77])

technique for imaging protein synthesis in brain tumors. The interest has been twofold: (1) to develop and validate the clinical use of such tracers and (2) to compare the performance of SPECT tracers to PET tracers.

^{123}I-IMT may be considered the prototype of SPECT amino acid tracers. ^{123}I-IMT has a similar affinity to the neutral amino acid carrier at the BBB as L-tyrosine, but is not further metabolized and not incorporated into proteins [78]. BBB disruption and active transport through the natural amino acid carrier represent the mechanisms of tracer uptake [79]. Uptake in normal brain tissue is negligible, a feature that allows optimal contrast between tumor and surrounding normal cortex [78, 79].

The sensitivity and specificity for discriminating gliomas from nonneoplastic lesions is in about the same range as amino acid PET tracers. The accuracy is generally higher for high-grade gliomas compared to low-grade gliomas [80]. Low-grade gliomas are more difficult to

distinguish from nonneoplastic lesions owing to their lower uptake [81–83].

^{123}I-IMT SPECT has been compared to [^{18}F]FDG PET for studying tumor and non-tumor lesions. Tumor uptake ratios were higher for ^{123}I-IMT than [^{18}F]FDG. Despite the lower resolution and lower sensitivity of SPECT compared with PET, ^{123}I-IMT SPECT was superior to [^{18}F]FDG PET in the detection and delineation of tumor tissue. Better tumor delineation was obtained with PET and either [^{11}C]MET or ^{18}F-FET compared to ^{123}I-IMT SPECT [81, 84].

^{123}I-IMT SPECT may be used in radiotherapy planning. The tumor volume defined by ^{123}I-IMT uptake was compared with the volume of the hyperintensity areas of T2-weighted MR and with the volume of contrast enhancement on T1-weighted MR. ^{123}I-IMT-defined tumor volume increased the radiotherapy target volume based on T2 and T1 images by about 30–40% and led to an increase in boost volume by 20%. Current approaches recommend the use of radiolabeled amino acid SPECT or PET tracers for definition of the target volumes for radiotherapy planning [85].

The wider availability of PET/CT scanners led to an increase of the use of ^{18}F-FET [86]. After i.v. administration ^{18}F-FET is taken up by both tumor and normal brain tissue. ^{18}F-FET uptake increases in normal gray and white matter to reach a plateau 20-min postinjection and the value remains stable until 120-min postinjection [87, 88]. In brain tumors, ^{18}F-FET kinetics depends on histology and grade. ^{18}F-FET is taken up by neoplastic cells, but is not incorporated into proteins, in contrast to natural amino acids such as [^{11}C]MET, which has a 15% incorporation rate [89, 90]. The uptake mechanism of ^{18}F-FET tracer is complex and not fully understood, but it seems to involve multiple pathways, including the specific LAT1 subtype system and the ubiquitous Na-dependent system $B^{0,+}$ and B^0 [91, 92].

As to the imaging protocol, patients should be fasting for about 4 h before trace injection to avoid saturation with unlabeled L-amino acid modifying FET transport into tumor cells. After injection, PET images are dynamically acquired for about 40–60 min (8–12, 5-min frames, or 4–6, 10-min frames) [86, 93].

^{18}F-FET PET image analysis provides both qualitative and quantitative information. The use of last acquired averaged frames (40–50 or 50–60 min) allows the reduction of brain–blood noise and improves the signal-to-noise ratio. Lesion maximum and SUV_{mean} are usually determined by averaging later frames. Moreover, using a manually drawn or an automatic region of interest (ROI), the contralateral normal brain uptake and maximum and mean tumor-to-background ratios (TBR_{max}, TBR_{mean}) may be computed. By locating ROIs on all slices in which the tumor is represented, a volume of interest (VOI) around the tumor is generated, on each frame of the dynamic acquisition to compute time–activity curves [12],

Numerous, but usually small studies assessed ^{18}F-FET PET value in the diagnosis of primary brain tumors. ^{18}F-FET PET was shown to be more accurate than ^{123}I-IMT SPECT [84], [^{18}F]FDG [12, 94], ^{18}F-fluorothymidine PET [95], and ^{18}F-fluorocholine PET [96] to detect brain tumors.

A recent meta-analysis of 13 studies on the use of ^{18}F-FET PET in primary brain tumor including 462 patients showed sensitivity and specificity of 82% (95% confidence interval 74–88%) and 76% (44–92%), respectively [92]. Using ROC analysis TBR_{mean} and TBR_{max} higher than 1.6 and 2.1, respectively, provided the best diagnostic value for differentiating primary brain tumors from non-tumoral lesion. Moreover, TBR_{mean} and TBR_{max} were significantly lower in grade I–II gliomas as compared with grade III–IV gliomas.

Even though on a group basis, SUV and TBR allow identification of differences in ^{18}F-FET uptake and metabolism between gliomas and non-tumoral lesions, on a single subject basis, this discrimination is more difficult because of metabolic overlap found among the different WHO grades [92]. Analysis of time–activity curves allows improving the differentiation between low- and high-grade gliomas. Early (<15 min) maximal uptake followed by a decreasing curve has been related to high-grade glioma, and late (>15 min) maximal uptake followed by a steadily rising curve has been related to low-grade tumor [97–99].

L-3,4-dihydroxyphenylalanine ([^{18}F]fluorodopa, [^{18}F]FDOPA). Among other amino acid

tracers, a growing important role is being played by [^{18}F]FDOPA, which is also sensitive to dopamine metabolism. Other than in the striatum and the substantia nigra, where the uptake of the tracer is physiologically high, [^{18}F]FDOPA displays low uptake in all the remaining brain areas. Contrary to studies performed for the diagnosis of movement disorders, where a dynamic scan or a late scan acquisition at about 70 min are performed, for tumor imaging, an early scan at 20-min post-injection is preferred. With ongoing interval from injection, the specific uptake in the striatum increases, and it may mask either the visualization or tumor in the proximity of the basal ganglia or other tumors that have low [^{18}F]FDOPA uptake. At 20-min p.i., the uptake in tumor is on the contrary similar or higher than in the basal ganglia [100].

[^{18}F]FDOPA PET/CT is highly sensitive and specific for the detection of glioma recurrence, it is superior to [^{18}F]FDG, and it is especially advantageous in patients with low-grade gliomas [101, 102]. Tripathi et al. directly compared the performance of [^{18}F]FDOPA, [^{18}F]FDG, and ^{18}F-FLT in evaluating primary and recurrent low-grade gliomas. SUV_{max} for [^{18}F]FDOPA was two to three times higher than for ^{18}F-FLT, but it was lower than and for [^{18}F]FDG. This shows that ^{18}F-FLT uptake is generally low in gliomas. The authors concluded that [^{18}F]FDOPA is superior to ^{18}F-FLT and [^{18}F]FDG for low-grade gliomas [103].

It was also shown that PET/CT with [^{18}F]FDOPA has greater diagnostic power compared to MR for the differential diagnosis between tumor recurrence and radiation necrosis. Specifically, sensitivity, and accuracy were 92.3%, 44.4%, and 80% for MR and 100%, 88.9%, and 97.1% for [^{18}F]FDOPA [102].

A very interesting study [100] was performed to address the comparative value of [^{18}F]FDOPA versus [^{11}C]MET, which is the most widely used amino acid tracer for detecting tumor recurrence and generally considered as the gold standard. [^{11}C]MET and [^{18}F]FDOPA images matched in all patients and showed all lesions as hot spots with higher uptake than in the contralateral brain. SUVs and tumor/contralateral did not statistically differ between the two tracers. The authors concluded that [^{18}F]FDOPA is accurate as a surrogate for [^{11}C]MET in imaging amino acid transport in malignant cerebral lesions for the purpose of visualization of vital tumor tissue. It combines the good physical properties of ^{18}F with the pharmacological properties of [^{11}C]MET and might therefore be a valuable PET radiopharmaceutical that can be more widely used for brain tumor imaging in centers without a cyclotron [100].

Tumor proliferation. Increased cell proliferation rate is a well-known hallmark of cancer. The key step for cell proliferation is DNA synthesis. Thus, different radiotracers were developed to assess in vivo DNA synthesis. Thymidine is a pyrimidine used for DNA but not for RNA synthesis. This selectivity made this compound the first choice for assessing proliferation. Thymidine is incorporated into DNA through the exogenous (salvage) pathway for pyrimidines, through phosphorylation to thymidine triphosphate. The salvage pathway represents only a minor source for thymidine synthesis because the majority of thymidine is synthesized through the de novo pathway. Nevertheless, as the two pathways are competitive in physiological conditions, both are informative on DNA synthesis, while only the salvage pathway can be measured for the limited number of compartments involved and modeling assumptions. Imaging of DNA proliferation was expected to be superior to imaging of glucose metabolism for assessing response treatment, because cells may maintain their oxidative and glycolytic function in spite of impaired DNA synthesis [104].

Initial PET studies were performed with [^{11}C]thymidine. This tracer is rapidly metabolized producing several labeled compounds, primarily [^{11}C]CO_2, that retrodiffuses into the brain affecting the time–activity curve [105]. The exponentially growing complexity of metabolites correction combined to the low signal-to-noise ratio due to ^{11}C-labeling limited the use of this compound.

More recently, 3-deoxy-3-^{18}F-fluorothymidine (^{18}F-FLT, a thymidine analog) was developed. ^{18}F-FLT offers the advantages of ^{18}F-labeling and a more favorable radiometabolite profile [106]. However, the blood–brain barrier limits cellular uptake of ^{18}F-FLT [107]. ^{18}F-FLT uptake is a function of the plasma input function and the rate of its

transport across the blood–brain barrier; therefore, a complete kinetic model of ^{18}F-FLT uptake, transport, and metabolism is needed to accurately quantify DNA synthesis in brain tumors [108]. Without such a model, ^{18}F-FLT is unlikely to perform better than an inert contrast agent, such as gadolinium chelates, in brain tumor imaging. The assumption that ^{18}F-FLT standardized uptake value reflects primarily the uptake of the tracer into the DNA synthesis pathway is potentially misleading in CNS neoplasms [109].

Patients with brain tumors have increased tracer incorporation (K_i). In high-grade tumors where CBF is also increased, the increased tracer incorporation may partially be related to blood flow [107] (Fig. 4).

Probably owing to the difficult modeling strategy, findings differed among studies. For example, authors reported a significant correlation between ^{18}F-FLT K_i or k_3 and Ki-67 immunostaining, while no significant correlation was found for ^{18}F-FLT uptake ratios [108]. Others reported that uptake ratios have similar power as kinetic analysis to predict long-term survival [110]. ^{18}F-FLT (83%) had slightly lower sensitivity than [^{11}C]MET (88%), and both tracers have 100% specificity. SUV_{max} for [^{11}C]MET was significantly higher in high-grade gliomas compared to low grade, although there was a wide overlap. For ^{18}F-FLT, the difference was more relevant. ^{18}F-FLT was slightly superior to [^{11}C]MET for tumor grading. Although the two tracers explore two different biological processes, there is no substantial additional advantage by their sequential use [111].

Radiolabeled choline. Radiolabeled choline (either [^{11}C]choline or ^{18}F-fluorocholine), a phospholipid precursor, is a tumor-seeking radiopharmaceutical that has emerged because of its alleged potential to image membrane proliferation. While it is known that choline is a precursor of phospholipids (through the synthesis of phosphorylcholine), there are currently insufficient data to support the assumption that [^{11}C]choline labels uniquely membrane phospholipids. The rationale behind the clinical use of this PET tracer derived from in vivo studies with proton magnetic resonance spectroscopy showing elevated signal of choline-containing compounds (i.e., phosphorylcholine and glycerophosphocholine) in brain tumors [69]. Other metabolic pathways include the synthesis of acetylcholine and conversion to

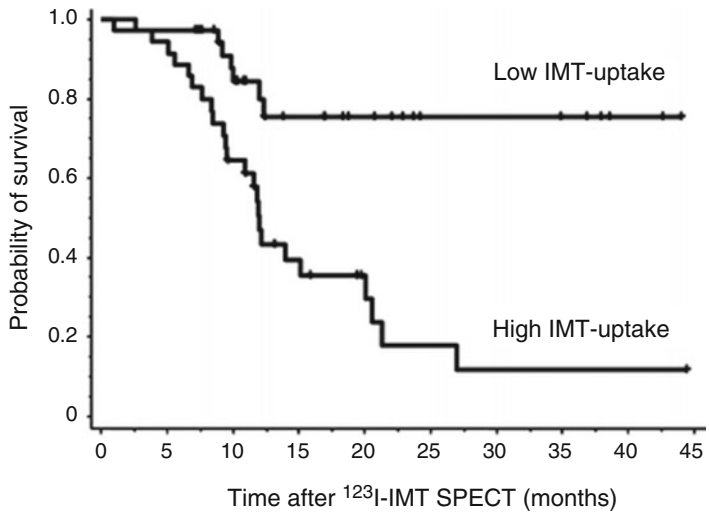

Fig. 4 Kaplan–Meier curves of overall survival among patients with postoperative low ^{123}I-IMT uptake and high ^{123}I-IMT uptake. Survival is significantly shorter in patients with ^{123}I-IMT uptake ratio >1.7 compared to patients with ^{123}I-IMT uptake ratio <1.7. The figure exemplifies the high prognostic power of functional nuclear medicine techniques, even in the case of SPECT (Reprinted with permission from Ref. [83])

betaine, while a significant amount of precursor remains unmetabolized in the cytoplasm [69]. However, regardless of the measured biochemical process, [^{11}C]choline did show to be useful for imaging and for assessing the response to therapy of gliomas and meningiomas.

The tracer displayed an excellent capability to delineate the tumor contours due to the negligible uptake by normal brain. As already noted for PET with amino acid tracers, this feature has been shown to be useful to guide biopsy and for radiotherapy planning [112]. Nevertheless, pitfalls may also occur. False positives are generally of greater concern than false negatives and are due to some accumulation of the tracer in inflammatory lesions [113]. Increased tracer uptake may occur also in brain metastases from other tumors and in meningiomas [114].

Higher [^{11}C]choline uptake has been reported in high-grade gliomas compared to low-grade gliomas [115]. Presently, there are discrepant findings on the issue whether [^{11}C]choline tumor metabolism, as measured by PET/CT, predicts [115–117] or does not predict tumor grade [69]. In a multitracer study, tracer uptake was significantly higher in high-grade gliomas than in low-grade gliomas for [^{11}C]choline, but not for [^{18}F]FDG [116]. However, [^{11}C]choline PET/CT could not differentiate between low-grade gliomas and benign lesions because of the relatively low uptake in low-grade tumors [116]. In a large study enrolling 94 patients with suspected brain tumor, [^{11}C]choline had greater accuracy than [^{18}F]FDG (84% vs. 71%). The authors concluded that, after accounting physiological variants and potential pitfalls of the tracer, [^{11}C]choline might have greater potential than [^{18}F]FDG for brain tumor PET imaging [113]. Another multitracer study compared [^{11}C]MET, [^{11}C]choline, and [^{18}F]FDG. The authors measured the ratio of tumor uptake to normal brain uptake (T/N ratio), using the frontal cortex as reference region, and analyzed the correlations between tracer uptake and tumor grade, type, and proliferation activity. Whereas all three tracers showed a similar correlation between the T/N ratio and tumor grade in astrocytic and oligodendroglial tumors, [^{11}C]MET enabled the most straightforward visual localization of hot lesions [118].

Until now, there have been few applications of [^{11}C]choline PET/CT for radiation therapy planning. [^{11}C]choline PET/CT could better delineate the boundaries between lesions and surrounding normal brain tissues compared with MR, and the standard radiotherapy target volume was changed in 31% of patients [117]. In posttreatment patients with high-grade gliomas, lower [^{11}C]choline uptake predicted longer survival [119]. [^{11}C]choline PET/CT can be used to distinguish brain tumor recurrence from necrosis after radiotherapy with sensitivities and specificity that might be higher than those of MR [120].

Imaging tumor hypoxia. Hypoxia is defined as reduced O_2 tissue concentration. Hypoxia in tumors is associated with progression, as well as resistance to radiotherapy and to some chemotherapy regimens. Several bioreductive radiopharmaceuticals have been evaluated as hypoxia tracers. These tracers include nitroimidazole compounds, e.g., ^{18}F-fluoromisonidazole (^{18}F-MISO), ^{123}I-iodoazomycin arabinoside (^{123}I-IAZA), ^{18}F-azomycin arabinoside (^{18}F-FAZA), and ^{64}Cu-labeled methylthiosemicarbazone (^{64}Cu-ATSM). The common feature of these different tracers is that tissue binding is sensitive to tissue oxygen concentration. Specifically, as the tissue oxygen level decreases, irreversible trapping increases. Different parameters are being used to quantify tissue binding, including tissue-to-plasma ratios, SUV_{max}, a percent threshold of SUV_{max} (hypoxic volume), distribution volume (derived from the plasma input function), and pixel-based maximum-intensity-projection plots obtained using statistical parametric mapping. The correlation of such parameters with tissue oxygen tension measured with fine needle oxygen electrodes (the gold standard for measuring hypoxia) is generally not performed in humans because such procedure is invasive [121].

PET studies of brain tumor hypoxia are relatively scant and mostly limited to the use of ^{18}F-MISO [122]. ^{18}F-MISO freely crosses the blood–brain barrier and rapidly equilibrates within tissues independently of perfusion [123]. Tracer uptake in glioblastomas multiforme is heterogeneous. Increased ^{18}F-MISO tumor uptake is generally found in the periphery but not in the

center of glioblastomas multiforme (Fig. 5). The latter finding is expected, because only viable cells are able to accumulate ^{18}F-MISO, and delivery to necrotic tissue is low. This pattern is also consistent with the spatial distribution of the hypoxia-inducible factor 1 that is more expressed in tumor areas adjacent to necrosis but not in necrosis per se [124].

No correlation was found between delayed ^{18}F-MISO uptake and [^{15}O]water distribution in brain tumors, thus indicating that hypoxia may occur also in cerebral areas with normal CBF. Hypoxic volume measured with ^{18}F-MISO is a significant prognostic factor for survival. ^{18}F-MISO uptake was greater in high-grade gliomas than in low-grade gliomas [125]. In a more recent prospective study of glioma patients who underwent both ^{18}F-MISO and [^{18}F]FDG PET examinations, ^{18}F-MISO PET showed an improved ability to distinguish glioblastoma from lower grades as compared to [^{18}F]FDG [126].

PET/MR

The development of magnetic field-insensitive PET detector technology paved the way from PET/CT to hybrid PET/MR systems, which have been commercially available since 2011. Due to the higher contrast between gray and white matter, MR provides a substantial advantage over CT for diagnosing CNS lesions [127]. For scanning neurological patients, the combination of both PET and MR has often proven to be superior to the single modality approach, with improved workflow and an increase in patient comfort. The ability to characterize different pathophysiological diseases features can be useful especially in research [128]. The acquisition of MR also allows correction for partial volume effect. PET or PET/CT studies vs. MR had shown that, irrespective of the tracer, PET provides more accurate information. PET/MR studies with dedicated PET/MR scanners are now similarly providing evidence of the additional information and synergistic effect of these two techniques.

Studies with PET/MR scanners in brain tumor patients have been so far limited; therefore, we will report about studies that compared PET to MR as well as studies that used dedicated PET/MR hybrid systems.

One study reported a greater accuracy of [^{18}F]FDG PET in comparison to MR for the prediction of survival in patients with high-grade glioma after therapy with temozolomide [129].

Ohtani et al. compared [^{11}C]choline PET, contrast-enhanced MR imaging, and [^{18}F]FDG PET in 22 patients with suspected brain tumors. They found a correlation between [^{11}C]choline and the histological tumor grade, with higher uptake in high-grade gliomas. The authors suggested that the combination of [^{11}C]choline PET and MR imaging could improve the detection of high-grade gliomas. However, [^{11}C]choline PET could not differentiate between low-grade gliomas and benign lesions [116].

Tan et al. used [^{18}F]FDG, [^{11}C]choline PET/CT, and MR to differentiate brain tumor recurrence from necrosis after radiotherapy in 55 patients. Sensitivities of MR, [^{18}F]FDG, and [^{11}C]choline PET/CT in lesion diagnosis were 87%, 77%, and 92%, respectively, and their specificities were 81%, 63%, and 88%, respectively. These results suggested that [^{11}C]choline PET/CT, having higher sensitivity and specificity, may perform better in distinguishing recurrent brain tumor from radionecrosis compared with [^{18}F]FDG PET/CT and MR [120].

Boss et al. reported that the MR and PET data acquired in ten patients was of high diagnostic quality and that there was a high level of concordance between tumor-to-background ratios derived from PET/CT and those derived subsequently from PET/MR [130]. The same group later used MR spectroscopy and [^{11}C]MET PET to classify inconclusive MR findings as either low-grade gliomas or high-grade gliomas and to identify the most malignant parts within tumors before surgery. They found that areas with maximum [^{11}C]MET uptake provided satisfactory tumor grading. The spatial overlap between cerebral areas of high PET uptake and highest metabolite concentrations determined by MR spectroscopy was limited, which suggests that the diagnostic gain provided by MR

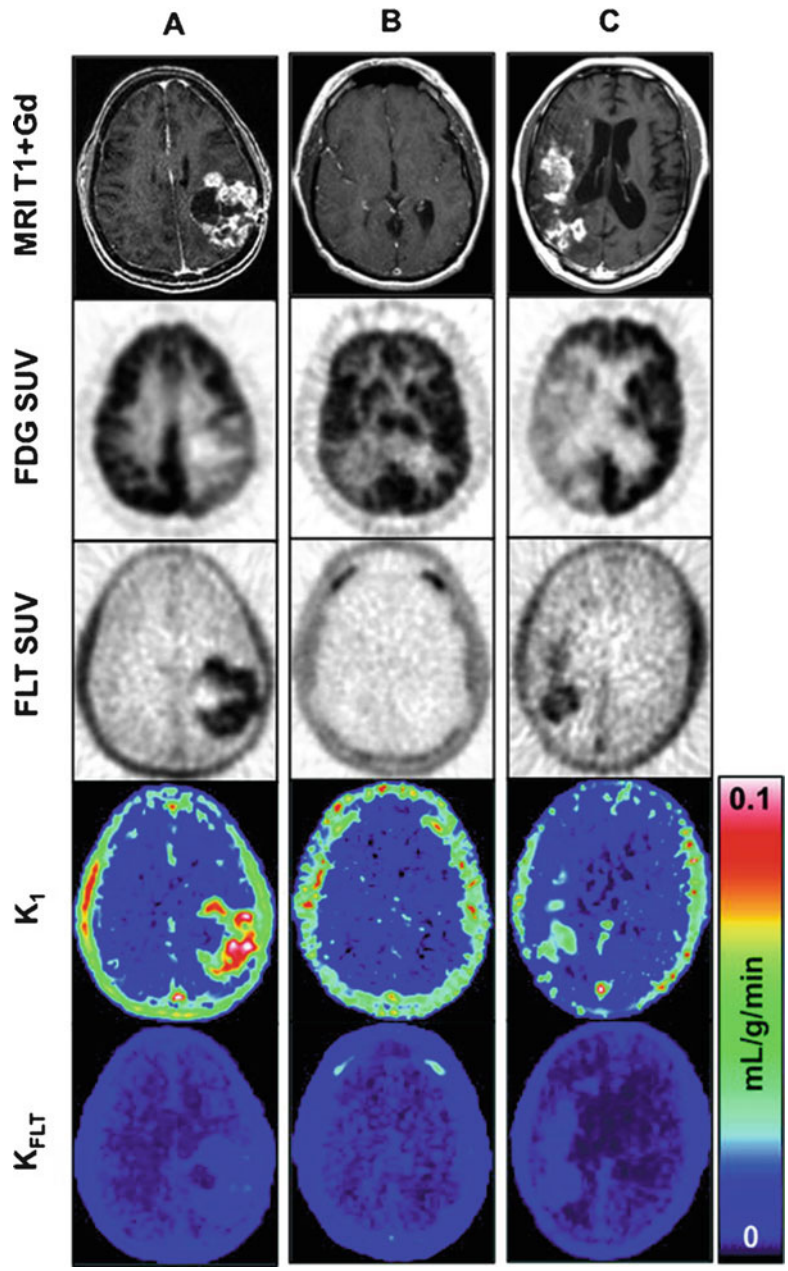

Fig. 5 Three scenarios with different aspects of ^{18}F-FLT and [^{18}F]FDG metabolism are presented. (**a**) A 44-year-old woman with recurrent grade III anaplastic astrocytoma of the left parietal cortex with BBB breakdown treated previously by radiotherapy (59 Gy). (**b**) A 56-year-old man with right parietal grade II oligodendroglioma with intact BBB treated previously by surgical resection followed by chemotherapy. (**c**) A 46-year-old man with recurrent grade II oligodendroglioma of the left temporal and parietal cortex with BBB breakdown treated with radiotherapy (54 Gy) and temozolomide before PET. Surgery and therapy occurred at least 2 years before PET for all three patients. Coregistered images are as follows: MR T1-contrast enhancement; [^{18}F]FDG SUV summed 30–60 min; ^{18}F-FLT SUV summed 30–60 min; parametric map of transport, K_1; and parametric image of metabolic flux, K ^{18}F-FLT. This figure exemplifies two different concepts: (1) the different patterns of various tracers in the same tumor depend on tumor metabolism and BBB integrity; (2) it shows how [^{18}F]FDG uptake is less influenced by BBB breakdown (it is reduced in (**a**) and (**c**) where BBB is disrupted), while ^{18}F-FLT uptake increases notably with BBB disruption (**a** and **c**), but ^{18}F-FLT does not enter the brain if BBB is normal (**b**) (Reprinted with permission from Ref. [107])

spectroscopy is limited [131]. A whole-body hybrid PET/MR system was used in another study by Preuss et al. to obtain [^{11}C]MET PET and MR imaging data necessary for biopsy planning and neuronavigation in a small series of pediatric patients with brain tumor. Representative histopathological specimens were obtained in all patients. Additional anesthesia as well as CT-related radiation exposure could also be avoided [132]. In another small PET/MR series mainly in patients with high-grade gliomas, both modalities provided sufficient diagnostic quality, and the ^{18}F-FET PET findings were in accordance with those of conventional MR [133]. All combined PET/MR imaging studies discussed above agree on the convenience of obtaining all necessary imaging parameters in one session with excellent spatial coregistration of MR and PET data. Moreover, Dunet et al. demonstrated the superiority of the combination of dynamic ^{18}F-FET PET and diffusion-weighted MR over the single modality approach for glioma grading and argued in favor of combined ^{18}F-FET PET/MR in the initial assessment of primary brain tumors [134]. They reported that tumor time–activity curve reached the best accuracy (67%) when considered alone to distinguish between low- and high-grade gliomas, followed closely by ADC histogram analysis (65%). The combination of time–activity curve and apparent diffusion coefficient (ADC) histogram analysis improved the sensitivity to 86% and the specificity to 100% [134].

Assessing the Efficacy of Treatment

The diagnostic value of MR and CT concerning changes in tumor size or contrast enhancement in response to therapy is limited because the known reactive transient BBB alterations with consequent contrast enhancement may mimic tumor progression. This phenomenon, the so-called pseudoprogression, is seen in 20–50% of cases and can lead to unnecessary overtreatment [135]. For this reason, the use of PET appears today as an ideal tool; in fact the efficacy of therapy has been assessed with different radiotracers across times.

Several studies indicate that glucose metabolism, at initial presentation, at recurrence, or in response to therapy, is predictive of survival.

In case of recurrent tumor, the mean survival time of patients with gliomas exhibiting high glucose utilization was shorter than in patients with low glucose utilization (5 vs. 19 months) [136]. Similar results were obtained by Alavi in a study that included mostly treated patients [137]. He reported estimated median survival of 33 months for hypometabolic lesions and 7 months for hypermetabolic lesions. Furthermore, in the subgroup of high-grade gliomas, it was possible to divide patients into a group with low and a group with high metabolic activity with 1-year survival rates of 78% and 29%, respectively [137]. In the setting of recurrence, these results were confirmed by Santra et al. [138]. In a more recent study, Colavolpe et al. retrospectively assessed pretreatment PET scans qualitatively and quantitatively in 41 patients with high-grade gliomas [139, 140]. The authors performed multivariate analysis including traditional prognostic factors (age, KPS, extent of surgery, and histological grade) in addition to either visual metabolic grade or the ratio between the tumor and contralateral SUV_{max}. The semiquantitative evaluation in the pretreatment of [^{18}F]FDG PET/CT provided significant additional prognostic information in newly diagnosed high-grade tumors, it was statistically more robust than the visual evaluation, and it was independent of traditional prognostic factors [139].

PET has been shown to be useful for monitoring the response to chemotherapy. Following treatment with temozolomide, the percentage of decline of CMR_{glc} versus baseline is greater in clinical responders than in nonresponders [141]. In another study, it was shown that early changes in glucose metabolism predicted response to temozolomide, but not temozolomide plus radiotherapy. In the first scenario, a greater metabolic reduction after therapy predicts longer survival [129]. One study reported the greater accuracy of [^{18}F]FDG PET in comparison to MR for predicting survival after therapy [129]. A recent publication based on the National Oncologic PET Registry examined retrospectively data from 479 patients with primary

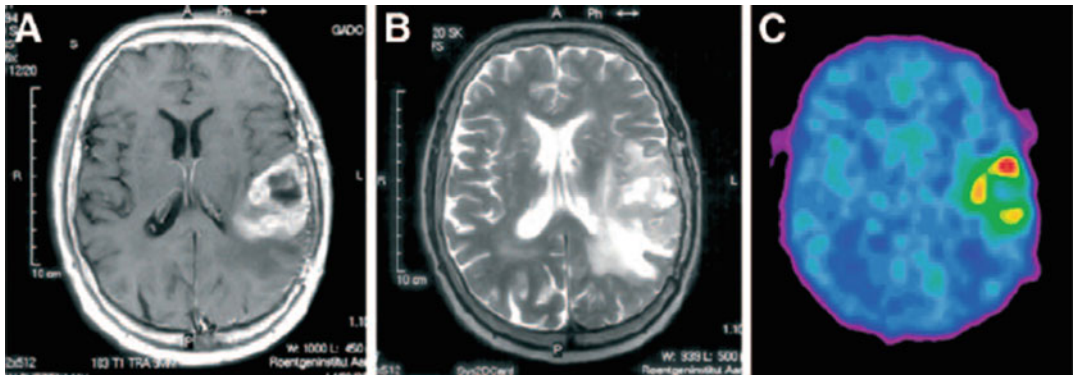

Fig. 6 Gadolinium contrast-enhanced T1- (**a**) and T2-weighted (**b**) MR images in a patient with glioblastoma multiforme in the left temporal lobe. (**c**) Late PET images show ^{18}F-MISO tumor uptake 150–170 min after injection. The figures typically identifies the behavior of a hypoxia tracer that accumulates less in the center of a lesion, where the tissue is hypoxic, and highly accumulates in the periphery of the lesion, where the tumor tissue is well oxygenated (Reprinted with permission from Ref. [124])

brain tumors (72%) or brain metastasis (28%) and found that overall, [^{18}F]FDG PET imaging changed the intended management in 38% of patients with primary brain tumors [142].

^{123}I-IMT uptake has prognostic implications. In patients who had undergone tumor resection 4–6 weeks before SPECT imaging, significant ^{123}I-IMT uptake after tumor resection was associated with shorter survival (Figs. 6 and 7). ^{123}I-IMT uptake ratio remains a significant prognostic factor when age and grading are included in a multivariate model [83].

^{18}F-FET imaging was also shown to have prognostic implications. In low-grade gliomas, baseline low ^{18}F-FET uptake predicted longer time to progression and time to malignant transformation; high uptake predicted conversion into a high-grade glioma [143]. ^{18}F-FET can be used to quantify residual tumor volume after surgery and postsurgical tumor volumes evaluated by PET predict progression-free and overall survivals [144]. Finally, patients with higher decrease in ^{18}F-FET uptake after antiangiogenic therapy with irinotecan–bevacizumab displayed longer survival [145]. Galldiks et al. compared changes in ^{18}F-FET TBR_{max} and TBR_{mean} as well as gadolinium contrast enhancement in 25 glioblastoma patients who underwent radiochemotherapy with temozolomide. Changes in TBR_{max} and TBR_{mean} between therapy and baseline predicted overall survival and progression-free survival, while gadolinium-volume changes did not [146].

Harris et al. created parametric response maps of ^{18}F-FLT and [^{18}F]FDOPA before and at two time points after bevacizumab treatment. They reported that an increase in [^{18}F]FDOPA or ^{18}F-FLT uptake on parametric response maps after bevacizumab treatment predicted shorter progression-free survival and that [^{18}F]FDOPA additionally predicted overall survival in recurrent gliomas [147].

[^{18}F]FDOPA was used at baseline, 2 and 6 weeks after the start of bevacizumab therapy for assessing response to therapy. [^{18}F]FDOPA metabolic tumor volume, but not SUV, predicted overall survival and progression-free survival. Interestingly, absolute metabolic tumor volume at 2 weeks after therapy was the strongest predictor of survival [148].

Additional Value of SPECT/CT and PET/CT vs Stand-Alone SPECT and PET

Radionuclide imaging has per se the capability of identifying disease at early stages, since it visualizes molecular targets that may change before structural tissue changes occur. Adding the CT component may improve correction for photon attenuation, but also allows for easier correlation of areas with

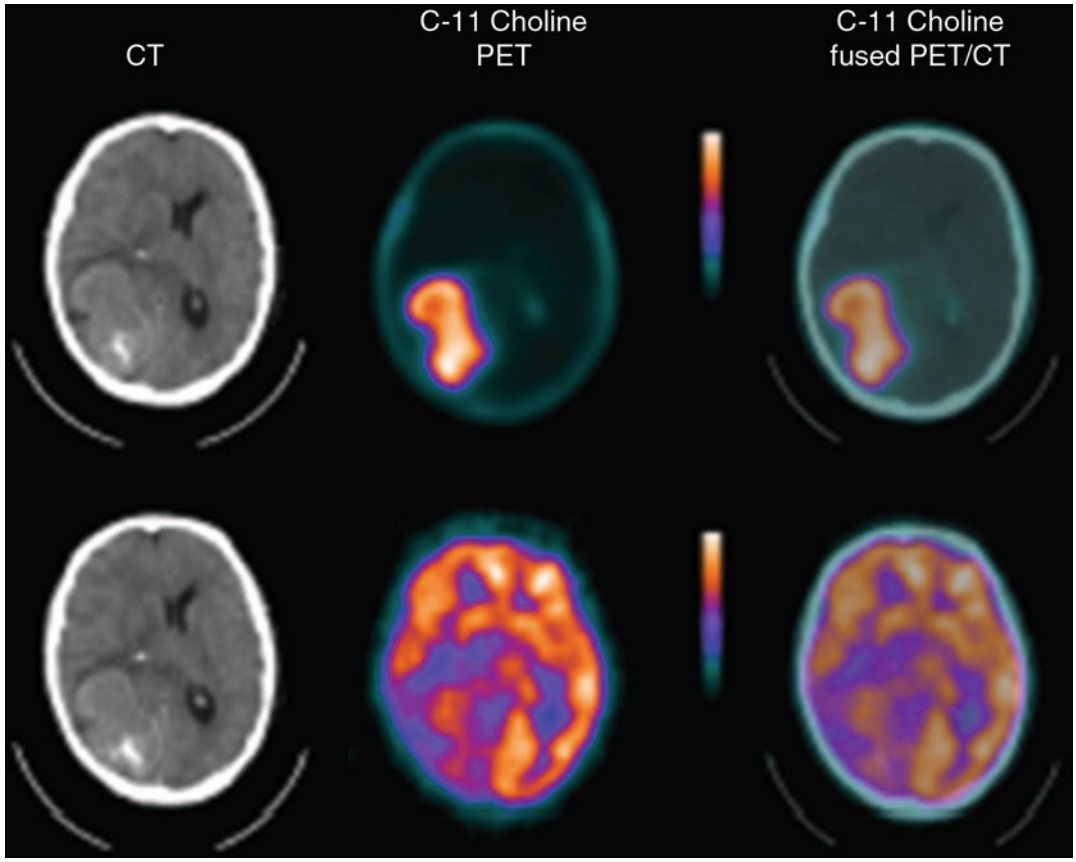

Fig. 7 CT, PET, and fused PET/CT images of a WHO grade II meningioma. CT shows a meningioma in the left temporo-occipital region that reaches medially the ipsilateral thalamus and striatum. There is high [^{11}C]choline uptake in the tumor (*top*), as well as heterogeneous increase in [^{18}F]FDG uptake (*bottom*). Note, however, the different location of the areas of increased [^{11}C]choline uptake (maximal in the posterolateral part of the tumor) and [^{18}F]FDG uptake (maximal in the anteromedial part of the tumor) (Reprinted with permission from Ref. [186])

physiological variants or abnormal tracer accumulation to anatomical landmarks [149].

So far, data on the added value of combined SPECT/CT and PET/CT examinations of the brain remain scanty. In principle, the diagnostic value of various cerebral SPECT examinations, such as cerebral perfusion or receptor studies, might be increased, to some extent, by additional CT examinations. However, considering that the morphological gold standard is represented by MR, the impact of the additional CT component on the diagnosis and clinical management of the patient is actually quite limited.

Low-dose CT is associated with relatively low radiation doses of 1–4 mSv and should be sufficient for anatomic referencing of SPECT lesions and attenuation correction. In clinical practice, if a recent enhanced CT scan is available, then another contrast-enhanced CT scan will not be repeated during SPECT/CT. For this reason, the use of low-dose, nonenhanced spiral CT is generally recommended when SPECT/CT is performed for anatomic referencing or attenuation correction [150]. This holds true also for brain tumor patients since virtually all patients referred to SPECT/CT or PET/CT will have already performed a diagnostic CT or MR. Low-dose CTs are generally acquired with a tube current of 20–40 mA and tube voltage of about 120–140 kV [150].

Usually, CT scan-based attenuation correction of brain SPECT data may lead to improved image quality and more accurate evaluation. In fact, it was shown that attenuation correction based on individual CT scans produces more accurate results than traditional methods based on the uniform linear attenuation coefficient [151].

Some studies have demonstrated the usefulness of SPECT/CT for accurate preoperative detection and localization, for radiotherapy planning, and for treatment monitoring of brain tumors [149]. SPECT/CT achieves precise anatomical localization of viable tumor lesions versus adjacent sites with physiological tracer uptake, such as the ventricles, choroid plexus, and venous sinuses [152, 153], with a proven clinical impact on management in 43% of patients [152].

Common Therapies

Primary brain tumors have a dismal prognosis. Five-year survival rates can be as low as <5% for glioblastoma, 30% for astrocytomas, but up to 100% for benign neoplasms as meningiomas. These rates have remained virtually unchanged over the last years, thus indicating the lack of substantial improvement in prognosis in spite of technological advances in diagnostic and surgical strategies [8].

Therapy is generally a combination of surgery, chemotherapy, and radiotherapy or radioimmunotherapy. Because of the limited efficacy and potentially severe side effects of each treatment, many studies are in progress to enhance the efficacy of this multimodality approach.

Surgery. Surgery remains the primary therapeutic approach for most brain tumors. The goal of surgery is twofold. First, it is necessary for definitive histological diagnosis of the tumor. Second, it allows tumor debulking, which is necessary for preventing or alleviating symptoms. Based on the extent, resections can be classified as either partial or complete. However, except for pilocytic astrocytomas, the necessary extent of surgical resection beyond obtaining a tissue for diagnosis remains controversial. Partial resections are performed for large, deeply infiltrating neoplasms for which only debulking is possible or for neoplasms located near difficult-to-access regions. Complete resection is otherwise preferred. Even normal astrocytes and oligodendrocytes can move preferentially along the preformed fiber paths in the brain, and neoplastic cells often exhibit that capacity even more. Even complete solid tumor removal (or any other local therapy) will not reach these cells, and they will likely cause tumor recurrences. Although a larger resection has greater curative potentials, the surgeon always faces a balanced compromise between the likelihood of increasing the local control and the risk of causing important side effects [4, 109].

Radiation therapy. Radiation therapy has been used extensively in the treatment of malignant and aggressive intracranial tumors, and its use has been associated with prolonged disease-free survival, but not with overall survival [4, 154]. Because of potential side effects, radiation therapy is often deferred until there are signs of progressive recurrence or malignant transformation [4, 154]. In the case of GBM, radiotherapy is complicated by the diffuse infiltrative nature of the disease and by its extreme radioresistance. However, a clear gain of median progression-free survival of GBM patients was also reported [4, 154].

Chemotherapy. The overall efficacy of chemotherapy in brain tumors is limited because the BBB limits access to the brain for molecules with low molecular weight and high lipophilicity, and the multidrug resistance system limits the efficacy of a wide range of drugs. Temozolomide is now the most effective drug and it is approved for refractory anaplastic astrocytoma or GBM [155]. The combination of radiotherapy, lomustine and temozolomide, yielded promising long-term survival data in patients with newly diagnosed glioblastoma, albeit with greater acute toxicity [156, 157].

Antiangiogenic therapy. Neoangiogenesis is another potential target for therapy of gliomas. High-grade gliomas demonstrate high levels of angiogenesis. Antiangiogenic drugs were developed to target vascular endothelial growth factor (VEGF) and VEGF receptor. Emerging literature suggests the efficacy of antiangiogenic therapy,

particularly bevacizumab, for recurrent high-grade gliomas [157, 158].

Radioimmunotherapy. Locoregional radioimmunotherapy (RIT) have been proposed for targeting brain tumors. Monoclonal antibodies (MoAb) conjugated with high-energy β^- emitters (^{131}I, ^{90}Y or ^{177}Lu) are used for this purpose. Tumor cells that do not express the antigen on their surface can be damaged by the "cross-fire effect" [159]. Different strategies have been proposed to improve the tumor-to-non-tumor uptake ratio, such as the three-step pre-targeting radioimmunotherapy (pRIT) ("sandwich" approach) based on the avidin–biotin system, which has been employed with some success [160]. Disease-free survival in the treated patients was significantly longer than in patients undergoing conventional therapy [161]. Patients treated with pRIT and temozolomide have a significantly longer disease-free survival compared to patients treated with pRIT alone [162].

Differently from low aggressive forms of some tumors, such as thyroid cancer and prostate cancer, active surveillance does not represent a valid therapeutic approach for either high-grade or low-grade gliomas.

Meningiomas

Meningiomas are the most common benign intracranial tumors. Their prognosis is excellent, except when they are located in surgically inaccessible anatomical sites. Grade I meningiomas (also commonly referred to as typical meningiomas) have low proliferative rate [163]. Grade II meningiomas (i.e., atypical or anaplastic meningiomas that constitute less than 5% of all meningiomas) have histological features consistent with greater proliferative activity [164]. The recurrence rate after surgery is higher in grade II than in grade I meningiomas. All meningiomas are highly vascularized. Meningiomas express a wide range of receptors, which makes them sensitive to different hormonal controls and potential target for various radioligands. The diagnosis of meningiomas is easily performed on CT. The distinction between typical and atypical meningiomas is not reliable on either CT or MR, and the capacity of PET to predict grading and recurrence of disease has been tested. However, meningiomas located near the base of the skull may be difficult to distinguish from other lesions, such as lymphomas, metastases, or neurinomas [165], and ^{68}Ga-DOTATOC-PET data can complement anatomical data from MR and CT to improve target volume definition, especially in cases with complex infiltration and recurrent disease after surgery [166, 167].

CMR_{glc} is significantly higher in atypical meningiomas than in typical meningiomas and correlates with tumor proliferation rate [168–170]. However, remarkable differences in CMR_{glc} are observed among different types of typical meningiomas [168, 169]. Less frequently [^{18}F]FDG PET did not predict histological or behavioral features [171]. Multivariate analysis showed that, in addition to MIB-1 labeling index, presence of brain invasion, and WHO grade, [^{18}F]FDG uptake in meningiomas predicts tumor recurrence [170].

In addition to [^{18}F]FDG, several other tracers have been shown to accumulate in meningiomas, including [^{11}C]MET, [^{11}C]choline, and ^{18}F-FET. SUV_{max} of [^{11}C]MET but not [^{18}F]FDG was correlated with Ki-67 in meningioma cells [171]. [^{11}C]MET PET/CT can be used for the definition of the GTV delineation in fractionated stereotactic radiotherapy of skull base meningiomas. [^{11}C]MET PET images incorporation into stereotactic radiotherapy plan allowed better definition of the GTV [172] and may lead to changes (both reductions and increases) of the GTV in a significant number of cases [173]. [^{11}C]MET PET was used in the evaluation of the response to therapy with interferon-alpha and be useful for predicting the clinical response, for determining the length of the therapy and for adjusting of drug dosage [174].

Giovacchini et al. described the uptake of [^{11}C]choline in a small group of seven meningioma patients that were also studied with [^{18}F]FDG. The uptake of [^{11}C]choline but not of [^{18}F]FDG was higher in patients with grade II than in grade I meningiomas [114]. Other case reports were subsequently published [175, 176].

SPECT somatostatin receptor scintigraphy, namely, ^{111}In-octreotide, has been used successfully

in the past owing to the frequent overexpression of somatostatin receptors (SSTR) $SSTR_2$ in meningiomas [177]. However, owing to the widespread development of generator-based ^{68}Ga-conjugates, PET has substantially substituted SPECT. The three compounds most commonly used for PET imaging are ^{68}Ga-DOTATOC (^{68}Ga-DOTA-Tyr^3-octreotide), ^{68}Ga-DOTANOC ([^{68}Ga]-DOTA-Nal^3-octreotide), and ^{68}Ga-DOTATATE (^{68}Ga-DOTA-Tyr^3-octreotate). ^{68}Ga-DOTATOC and ^{68}Ga-DOTATATE have high affinity for $SSTR_2$, which is the most common SSTR subtype found in meningiomas. ^{68}Ga-DOTANOC targets a broader range of somatostatin subtype receptors, including $SSTR_2$, $SSTR_3$, and $SSTR_5$ [178]. Initial studies were performed using ^{68}Ga-DOTANOC [179, 180]. Cumbersome kinetic analysis using the plasma input function was adopted [180]. An interesting study performed in an animal model kinetic analysis using the Logan graphical method was used to compute the distribution volume of the three tracers. Although the distribution volume was relatively similar with ^{68}Ga-DOTATATE and ^{68}Ga-DOTATOC, uptake was higher with ^{68}Ga-DOTATATE in the tumor than with ^{68}Ga-DOTANOC and ^{68}Ga-DOTATOC, suggesting a higher diagnostic value of ^{68}Ga-DOTATATE for detecting meningiomas [165]. Later studies have the visibility of qualitative and semiquantitative evaluation for routine clinical questions [181].

16α-^{18}F-fluoro-17β-oestradiol (^{18}F-FES) has been occasionally used to evaluate estrogenic receptors in meningiomas. The identification of meningiomas occurs in about 60% of cases [182].

Conclusion

Several traditional and new tracers have been developed for evaluating brain tumors. This abundance in radiopharmaceuticals together with the technical development of PET/CT tomographs first and then PET/MR has enabled a substantial deepening in the knowledge of morphological and functional properties of brain tumors. PET/MR scanners also have substantial logistic and technical advantages: one single imaging session can be performed for the individual patient ("one-stop-shop") and optimal technical conditions (minimization of movement, accurate coregistration) can be achieved.

Several studies on genetic predisposition and on the corresponding molecular pathology were also performed yielding important information on the pathophysiology and risk factors for brain tumors. Surgery still represents the cornerstone of therapy in gliomas, while the role of radiotherapy is increasing and combinations, with or without escalation, with temozolomide are being tested. Angiogenesis inhibitors, such as the monoclonal antibody bevacizumab, have been tested with promising results.

There are different clinical settings in which PET can be used in the clinical practice. The most frequent is the differential diagnosis between tumor recurrence and radiation injury, where radiological techniques including MR suffer substantially from both sensitivity and specificity. PET, especially in combination with MR, is increasingly more used for the definition of the gross tumor volume to be irradiated. The identification of the metabolically active volume can also be used to direct biopsy, for planning surgery, or can clarify an undetermined finding on MR. A unique capability of PET is to predict in vivo tumor grading better than any other technique. Generally, high metabolic activity is predictive of higher tumor grade, even though there is variable accuracy among tracers in such prediction; for example, [^{18}F]FDG is more accurate than amino acid tracers. Changes in cerebral tracer uptake can be monitored in response to therapy. Changes after therapy as well as baseline values in untreated patients have prognostic value.

Several radiopharmaceuticals have been developed to explore biochemical processes other than glucose metabolism that are associated to tumor growth. Amino acid tracers are sensitive to transport across the BBB and, to some extent, protein synthesis. Contrary to [^{18}F]FDG, amino acids are less involved in inflammation and therefore have higher specificity for differentiating tumor recurrence versus radiation necrosis. Among available tracers, [^{11}C]MET is the one that is nowadays more validated in the clinical setting and more

widely used. Other promising tracers include [^{18}F]FDOPA and ^{18}F-FET. However, the tumor uptake of [^{18}F]FDG has prognostic value. Other tracers, such as hypoxia tracers and radiolabeled choline, presently have a more uncertain role in the clinical routine, even though some interesting results derived from clinical research studies.

Diagnostic Applications of Nuclear Medicine: Head and Neck Cancer

18

Heiko Schöder

Abstract

Most head and neck cancers are squamous cell carcinomas (HNSCC) arising in the oral cavity, oropharynx, larynx, and hypopharynx. The incidence of HNSCC is rising in the industrialized world, and there is increasing recognition of the role of human papillomavirus (HPV) infection as an etiologic factor in the development of this disease. In the USA, about 48,330 new cases of head and neck cancer have been diagnosed in 2016, and approximately 9,600 patients died of the disease. CT or MRI is essential to define the extent of the primary tumor, assess lymph node size, and detect bone and bone marrow disease. [^{18}F]FDG PET/CT imaging from the skull base to the floor of the pelvis is essential in patients with locally advanced disease and in all patients who are candidates for definitive chemoradiotherapy to define N and M staging. Interpretation of head and neck PET/CT requires expertise in head and neck anatomy and an understanding of variations of physiologic [^{18}F]FDG uptake in normal tissues. Scan interpretation is primarily based on visual assessment, although SUV measurements may be helpful. However, SUV is related to lesion size and may be underestimated in small primary tumors. Most primary tumors originate in the palatine tonsil, base of tongue, pyriform sinus, nasopharynx, and larynx. HNSCC tends to spread locally with invasion of adjacent structures. T staging is routinely done by either CT or MRI, not PET. However, occasionally [^{18}F]FDG PET may visualize small submucosal primary tumors that are difficult to distinguish from adjacent normal tissues with anatomic imaging studies. The presence of nodal metastases is an independent prognostic factor for survival in patients with head and neck cancer and may affect the choice of surgical or radiation therapy. Early and complete removal of neck node metastases is a prerequisite for cure. PET provides added value in the initial nodal staging. However, false-positive [^{18}F]FDG uptake can occur in inflamed, reactive lymph nodes. False-negative [^{18}F]FDG PET studies may occur when nodes have a small tumor burden, cystic degeneration of metastatic nodes with a small rim of viable tumor tissue, or low tracer uptake in the metastatic node. Nodal metastases in close proximity to the primary tumor may not be detectable as separate hypermetabolic focus when the primary shows very intense tracer uptake. Distant metastases are rare in patients with head and neck cancers, but the frequency increases with higher T stage and size, number of tumor-involved lymph nodes, jugular vein invasion, and in primary tumors in the hypo- and oropharynx. The most common location is

the lung, followed by bone and liver. [^{18}F]FDG PET/CT is sensitive for the detection of distant metastases. In patients treated with definitive chemoradiotherapy, [^{18}F]FDG PET/CT should be done approximately 12 weeks after the end of therapy to assess response to treatment.

[^{18}F]FDG PET/CT imaging is particularly useful to detect residual disease in neck lymph nodes. Clinical parameters and structural imaging cannot reliably predict the presence of residual metastatic neck disease; "planned neck dissection" was usually performed in the past after the completion of chemoradiotherapy, especially in patients with initial N2–N3 disease. Recently, in light of the high negative predictive value of posttreatment [^{18}F]FDG PET, this approach seems no longer justified. In patients with suspected recurrence, [^{18}F]FDG PET/CT has the highest sensitivity and specificity regardless of the primary treatment modality. However, posttherapy inflammation remains a potential source for false positive interpretation. Carcinoma of unknown primary accounts for approximately 1–2% of head and neck cancers. Occurrence of nodal metastases in neck levels I–III increases the likelihood for a primary HNSCC. However, in 5–40% of cases a primary malignancy is not identified during diagnostic evaluation, and these patients undergo extensive work-up, including panendoscopy of the upper aerodigestive tract and [^{18}F]FDG PET/CT. The use of [^{18}F]FDG PET/CT may reduce the number of panendoscopies. Other imaging studies are usually not needed, because it is extremely unlikely that they may identify a primary tumor that cannot be detected by [18F]FDG imaging.

In view of its unique epidemiology, tumor biology, and prognosis, nasopharyngeal carcinoma (NPC) should be considered separately. The highest incidence is noted in southern Chinese (20 times more common than in Caucasians). NPC tends to spread submucosally, in parapharyngeal tissues, along the maxillary and the mandibular nerves. Neck lymph node metastases are seen in the vast majority of patients. The lateral retropharyngeal nodes are traditionally considered first echelon nodes. The rate of distant metastases is high, involving bone, lung, and liver. Local disease extent is best defined by MRI, in particular disease involvement of the skull base and intracranial spread. Neck lymph node involvement is probably best characterized by a combination of MRI and [^{18}F]FDG PET/CT. [^{18}F]FDG PET/CT is useful for detection of disease outside the neck. The combination of MRI and [^{18}F]FDG PET/CT also appears most appropriate for chemoradiotherapy response and recurrent disease assessment. Similar to other head and neck cancers, the intensity of [^{18}F]FDG uptake in NPC primary tumors provides prognostic information. The utility of PET for delineating the gross tumor volume (GTV) in radiotherapy has been investigated. Most studies agree that the incorporation of PET in the radiotherapy planning process clearly improves target design over CT-based planning.

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FAZA	^{18}F-azomycin arabinoside
^{18}F-FET	O-(2-^{18}F-fluoroethyl)-L-tyrosine
^{18}F-FLT	3′-Deoxy-3′-^{18}F-fluorothymidine
^{18}F-FMISO	^{18}F-fluoromisonidazole, 1-fluoro-3-(2-nitroimidazol-1-yl)-propan-2-ol
5-FU	5-Fluorouracil
AJCC	American Joint Committee on Cancer
AKT	Protein kinase B
BOLD	Blood oxygen level-dependent contrast imaging, a magnetic resonance technique
CRT	Chemoradiotherapy
CT	X-ray computed tomogaphy

DCE	Dynamic contrast-enhancement, a magnetic resonance technique
DFS	Disease-free survival
DWI	Diffusion-weighted imaging, a magnetic resonance technique
E2F	Group of genes that encode for a family of transcription factors
EGFR	Epidermal growth factor receptor
GTV	Gross tumor volume
Gy	Gray unit (ionizing radiation dose in the International System of Units, corresponding to the absorption of one joule of radiation energy per kilogram of matter)
HNSCC	Squamous cells carcinomas of the head and neck
HPV	Human papilloma virus
m-TOR	Mammalian target of rapamycin
M	Metastasis status according to the AJCC/UICC TNM staging system
MEK	Mitogen-activated protein kinase
MR	Magnetic resonance
MRI	Magnetic resonance imaging
MTV	Metabolic tumor volume
N	Lymph node status according to the AJCC/UICC TNM staging system
NPC	Nasopharyngeal carcinoma
OPC	Oropharynx cancer
OS	Overall survival
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PET/MRI	Positron emission tomography/Magnetic resonance imaging
PFS	Progression-free survival
PI3K	Phosphatidylinositol 3-kinase
PTEN	Gene encoding for the phosphatase and tensin homolog protein, a tumor suppressor; PTEN deletions indicate a poor prognosis
RAF	Rapidly accelerated fibrosarcoma, related to retroviral oncogenes
RAS	Oncogene regulating signaling cascades
RB	Retinoblastoma protein
ROC	Receiver operating characteristic, a statistical analysis to assess the performance of a binary classifier
RT	Radiotherapy
RTOG	Radiation Therapy Oncology Group
SUV	Standardized uptake value
T	Tumor status according to the AJCC/UICC TNM staging system
TLG	Total lesion glycolysis
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
USFNA	Ultrasound-guided fine needle aspiration
VGEF	Vascular endothelial growth factor

Epidemiology and Biology of HNSCC

In the Western world, more than 90% of head and neck cancers are squamous cell carcinomas (HNSCC). These tumors arise in the oral cavity, oropharynx, larynx, and hypopharynx (Figs. 1, 2, 3, and 4). In the United States, approximately 48,330 new cases were diagnosed in 2016 [1], and about 9,600 patients died of the disease. Only 40–50% of patients are expected to survive for 5 years. The worst prognosis is seen in patients with un-resectable advanced disease, with a 5-year survival rate of less than 10%, whereas patients presenting with tumors that are confined at the time of diagnosis (T1/2N0M0) have an excellent cure rate. Unfortunately, at the time of initial diagnosis many patients already have regional nodal metastases (~45%) or even distant metastases (Figs. 1, 2, 3, and 4). Also noteworthy is the high rate of second primary malignancies, mostly in the upper aerodigestive tract.

Traditionally, the most important risk factors for HNSCC were tobacco use and alcohol consumption, which seem to have a synergistic effect. In the past decade, a new disease entity has become more common: HNSCC of the oropharynx secondary to infection with human papilloma virus (HPV) [2]. HPV is a known cause of cervical cancer in females. Transmission to the oral cavity occurs through oral sex. In the United States, approximately 60% of patients with oropharynx cancers test positive for HPV-16. The overall incidence of HNSCC is still rising in the industrialized world because the substantial increase in HPV-positive cases (in particular males with carcinoma of the palatine tonsil and base of the tongue) exceeds the decline in HPV-negative cases. Most HPV-positive cases express the viral oncoproteins E6 and E7. E6 oncogene expression induces degradation of p53, and E7 induces inactivation of the retinoblastoma protein (RB). Under normal conditions, p53 induces cell cycle arrest in the G_2 phase to allow for repair of damaged DNA; it also is a master regulator for apoptosis [3]. RB normally binds to, and inactivates, the E2F transcription factors, which control the transition from the G_1 to the S phase of the cell cycle. Only under the influence of mitogen signals is this "brake" of RB on E2F released, thus permitting cell cycle progression. Binding of the viral oncoprotein E7 to RB therefore causes dis-inhibition and un-controlled cell cycle progression [3, 4]. Table 1 summarizes the epidemiologic and biologic features of HPV-positive and HPV-negative HNSCC [3, 5].

Patients with HPV-positive HNSCC have a better prognosis than patients with HPV-negative disease [6, 7]. This was initially shown in a phase II trial that employed induction chemotherapy followed by concurrent chemoradiotherapy in patients with stage III or IV HNSCC of the oropharynx or larynx. Response rates to induction chemotherapy were 82% vs. 55%, 2-year overall survival (OS) was 95% vs. 62%, and the 2-year progression-free survival (PFS) was 86% vs. 53% [7]. Similarly, in a large retrospective analysis [6] the 3-year OS was 82% for the 206 patients with HPV-positive tumors compared with 57% for the 117 patients with HPV-negative tumors. Corresponding rates for PFS were 74% and 38%, respectively. Even after adjusting for age, race, T and N stage, tobacco exposure, and treatment modality (standard fractionation vs. accelerated fractionation radiotherapy), patients with HPV-positive tumors still showed a 58% reduction in the risk of cancer death. Using a risk classification that considered HPV status, T and N stage, and smoking status, patients could be characterized as low, intermediate, or high risk. Whereas the 3-year survival was 93% in the low-risk group (HPV+ tumor and <10 pack years smoking history), it was only 46% in the

high-risk group (HPV-negative, $\leq$ 10 pack years and T4 or >10 pack years and any TN). Collectively these data, and those reported from other groups, suggest increased sensitivity to chemo- and radiotherapy in HPV-positive tumors. The prognostic value of HPV status was again confirmed in the more recent RTOG 0522 trial [8], in which patients with p16-positive oropharynx cancer (OPC) showed better 3-year PFS and OS than those with p16-negative oropharynx cancer (73% vs. 49%, and 86% vs. 60%, respectively). By contrast, epidermal growth factor receptor (EGFR) expression of thee primary tumor did not predict patient outcome. The mounting evidence on the prognostic value of the p-16 status in oropharynx cancer has led to efforts to perform better risk stratification of patients with HPV-positive tumors. Accordingly, a new staging system has been proposed for patients with HPV-positive disease, in which even patients with the most locally advanced disease (i.e., T4 N3) will be assigned to clinical stage III, and only those with documented distant disease to stage IV, reflecting differences in OS between these groups [9]. In addition, there is growing interest in (a) developing new treatment paradigms for HNSCC that may decrease the amount and duration of standard chemoradiotherapy in low-risk patients (to maintain high cure rates but reduce potential treatment associated long-term side effects, such as dysphagia, xerostomia, feeding tube dependency, or chronic aspiration) and (b) finding more successful therapies for high-risk patients, including early participation in clinical trials [10, 11]. Patients with persistent HPV expression after completion of therapy may require closer surveillance [12]. The potential role of an HPV vaccine for men and the role of an "oral Pap smear" for early detection of oropharynx cancer are under study.

An important consideration in head and neck cancer is the concept of field cancerization. The

occurrence of multiple synchronous or metachronous primary tumors in the upper aerodigestive tract was first described by Theodor Billroth more than 100 years ago. Over the past few decades knowledge has expanded, and a recent study showed that at least 35% of cases of oral and oropharynx cancers demonstrate genetic abnormalities in the surrounding (histopathologically normal) mucosa [13]. This is often addressed by the clinical term "biologically positive margins," suggesting that local recurrence is likely even though standard histopathology shows no cancer cells at or near the surgical margins of the tumor specimen [14].

As for many other malignancies, genetic alterations and activation or inhibition of cellular signaling pathways are important for the development and progression of many HNSCC. Some signaling factors are of particular interest because they are potential targets for drug therapy, including the EGFR, vascular endothelial growth factor (VEGF), and molecules involved in regulating the PI3K–PTEN/AKT pathway as well as the RAS-RAF-MEK pathway.

Treatment Strategies

The treatment approach varies with the disease stage and site(s) of disease in the head and neck [15]. Approximately one third of patients with HNSCC present with early-stage disease. Depending on tumor location and institutional preferences, they are treated surgically or with radiotherapy, and approximately 80% are cured. Patients with locoregional advanced disease, which is surgically unresectable, and patients in whom definitive treatment is administered with an attempt at organ preservation (e.g., oropharyngeal and laryngeal

Table 1 Epidemiology of HNSCC circa 2011

Incidence	HPV-positive HNSCC	HPV-negative HNSCC
	Increasing	Decreasing
Anatomical site	Oropharynx (tonsil, tongue)	All sites
Histology	Non-keratinized	Keratinized
Age	Younger; < 60 years	Older; > 60 years
Sex ratio	3:1 men	3:1 men
T stage	Tx, T1, T2	Any
N stage	Advanced, often cystic-necrotic, multilevel	Any
Risk factors	Sexual behavior	Alcohol, tobacco
Etiology	HPV virus	
Prognosis	Favorable	Unfavorable
New approaches	De-escalation of standard therapy?, vaccination?; oral Pap smear?	Early identification of nonresponders to standard therapy > clinical trials

Adopted from Leemans, Nat Rev. Cancer 2011 [3] and Marur et al., Lancet Oncol 2010 [5]
HPV human papilloma virus, *HNSCC* head and neck squamous cell carcinoma

carcinomas), undergo treatment with concurrent chemoradiotherapy [16, 17]. Cisplatinum is the medication with the most randomized clinical trial data to support its use as a drug enhancing the effects of radiotherapy in this setting. The larynx-preservation paradigm is supported by the results of a study that randomized 547 patients with stage III–IV supraglottic and glottic larynx cancer into three treatment arms: concurrent chemoradiotherapy, induction chemotherapy consisting of cisplatinum and 5-fluorouracil (5-FU) followed by radiotherapy, or radiotherapy alone. After a median follow-up of 3.5 years, the rates of locoregional control were 78%, 61%, and 56% for the three treatment arms, respectively. The fraction of patients who maintained an intact larynx at 2 years (and thus

the ability to speak and swallow after the end of therapy) was also better with the concurrent regimen (88%, 75%, and 70% for the three treatment arms, respectively) [17]. OS rates were similar in all three groups. The utility of concurrent high-dose cisplatinum for other subsites was established in a randomized study of 295 patients with unresectable head and neck cancer [18]. Concurrent chemoradiotherapy is therefore now widely applied as the definitive treatment of choice for locoregional advanced HNSCC. If residual disease is detected after the end of therapy or during follow-up, salvage surgery (e.g., laryngectomy) may be offered.

The management of the neck when using an organ-preservation approach has remained somewhat controversial. Complete response rates in irradiated cervical lymph nodes vary between 59% and 83% and to some degree are related to nodal size, radiotherapy dose, as well as the time point when response is determined: Complete response rates are almost 100% in N1 disease, higher in N2 than in N3 disease, and better when the largest metastatic node is smaller than 3 cm [19]. In N2–N3 disease, residual cancer in neck nodes has been reported in 16–39% of patients achieving a clinical complete response (no overt residual neck mass) [19–21]. Over the past decade, locoregional control rates with concurrent chemoradiotherapy have improved. It is now widely accepted that routine neck dissection is not appropriate in this setting. Instead, fluorodeoxyglucose positron emission tomography/computed tomography ([^{18}F]FDG PET/CT) has emerged as a gatekeeper for the management of the neck in this setting [15] (see next section).

Newer biologic therapies in HNSCC include angiogenesis inhibitors and drugs targeting the EGFR. EGFR is over-expressed and/or activated in the majority of HNSCC relative to normal tissue, and high expression is associated with poor disease control [22, 23]. While these data suggest HNSCC as an ideal malignancy for treatment with EGFR inhibitors, the selection of appropriate patients remains challenging. In studies of anti-EGFR agents in patients with advanced HNSCC, the objective response rates were approximately 10%, depending on the specific agent [24]. Cetuximab, a chimeric IgG_1 antibody against the extracellular domain of EGFR, is the most widely studied agent and has been tested in a number of clinical trials in patients with advanced disease. Cetuximab also enhances the efficacy of radiotherapy. In a randomized study of 420 patients [25], the addition of cetuximab to radiotherapy improved locoregional tumor control and OS without increasing mucositis and dysphagia when compared with radiotherapy alone. The corresponding median PFS was 24 months vs. 15 months, and the median OS was 49 months vs. 29 months. This study showed that concurrent radiotherapy plus cetuximab is a viable treatment option in locoregional advanced HNSCC. Whether this alternate regimen improves outcome vis-à-vis the standard approach with cisplatinum-based chemotherapy and concurrent radiotherapy is under investigation. Other trials investigated the role of adjuvant cetuximab in patients with recurrent or metastatic HNSCC undergoing platinum-based chemotherapy. Preliminary data showed a survival benefit over chemotherapy alone (reviewed in [26]). However, more recently published multicenter studies did not confirm this: In the RTOG trial 0522 [8], which included 981 patients, the addition of cetuximab to concurrent chemoradiotherapy with cisplatin did not improve patient outcome, with 3-year PFS rates of 61% and 59%, and 3-year OS of 73% and 76%, respectively, for those treated without vs. with the addition of cetuximab. The locoregional failure rate and rate of distant metastases were also similar between groups. Recent data have also raised concerns regarding cetuximab-associated side effects leading to lower patient compliance in chemoradiotherapy regimens [27].

Antiangiogenic therapy has mainly been studied using bevacizumab, a recombinant humanized, monoclonal IgG antibody against VEGF-A, usually in combination with chemotherapy or in combination with cetuximab. Preliminary data suggest that partial responses or disease stabilization can be achieved in more than 75% of patients [28]. Other drugs under study include various tyrosine kinase inhibitors. Recent improved understanding of relevant signaling pathways may open up new avenues for targeted drug therapies in HNSCC. For instance, down-regulation of the transforming growth factor beta receptor is frequently found, and the PI3K/PTEN/AKT/m-TOR pathway (important for increased proliferation, evasion of

apoptosis, and increased survival) is frequently up-regulated. A number of drugs interfering with these tumor pathways are under study [26].

Imaging of Head and Neck Cancer

Standard imaging studies for the staging and follow-up of head and neck cancer include contrast-enhanced CT, magnetic resonance imaging (MRI), and [^{18}F]FDG PET/CT. CT or MRI is essential for characterizing the primary tumor and in defining its extent. Bone involvement is better detected with CT, while early bone marrow disease is better detected with MRI. MRI can better define the interface between normal muscle and tumor. It is essential in staging nasopharyngeal carcinoma, and also has particular advantages for detecting intracranial tumor spread and perineural spread and for differentiating entrapped secretions in paranasal sinuses from adjacent tumor.

Lymph node staging is done equally well with either CT or MRI. Traditionally, both imaging tests have relied on the assessment of lymph node size in order to identify metastatic disease. In general, lymph nodes $\geq$1.5 cm in levels I and highest level II, as well as lymph nodes $\geq$1.0 cm in all other locations, are considered abnormal. This approach is suboptimal because metastasis can be present in normal-sized lymph nodes and enlarged nodes may not contain tumor. Depending on the chosen cut-off for lymph node size, one can achieve high sensitivity at the expense of specificity or vice versa [29]. Secondary criteria are the presence of grouped lymph nodes (usually >3 nodes in one location), heterogeneous nodal enhancement, stranding of surrounding fat indicating extracapsular spread, and demonstration of central necrosis (the most reliable criterion for nodal metastasis). Special MRI sequences, such as diffusion-weighted imaging (DWI), or newer MR contrast agents (including ultrasmall superparamagnetic iron oxide particles, or more recently various nanoparticles), may improve the characterization of nodes. However, they are not yet routinely employed and all available data are preliminary.

The vast majority of head and neck cancers show intense [^{18}F]FDG uptake; however, uptake in salivary gland tumors may be variable (high [^{18}F]FDG uptake in some benign tumors, low uptake in some malignant tumors). Combined PET/CT is more accurate than PET alone and has beneficial effects on patient management [30, 31]. We perform [^{18}F]FDG PET/CT imaging from the skull base to the floor of the pelvis for appropriate N and M staging in patients with head and neck cancer. Both distant metastases and potential synchronous primaries in the aerodigestive tract are hypermetabolic and therefore easily detectable. In order to save costs and potentially radiation dose, some investigators have proposed a limited field of view scan (e.g., ending at the level of the diaphragm) for patients with head and neck cancer. We, however, believe that a different approach should be taken: Rather than using [^{18}F]FDG PET in all patients, the test should be used in subsets of patients where imaging findings are most likely to alter management. For instance, it is essential in surgical patients with locally advanced disease. In addition, we use [^{18}F]FDG PET/CT in all patients who are candidates for definitive chemoradiotherapy for the purpose of staging and radiotherapy planning; these scans are performed in the radiotherapy position with a mask. PET/CT is also used for response assessment in patients with advanced disease undergoing chemotherapy, concurrent chemoradiotherapy, or enrolled in experimental protocols.

Interpretation of head and neck PET/CT requires special expertise in head and neck anatomy as well as an understanding of physiologic [^{18}F]FDG uptake in normal tissues and awareness of the many potential normal variants. Scan interpretation is primarily based on visual assessment, although standardized uptake value (SUV) numbers may be helpful in estimating biologic aggressiveness and for response assessment. SUV is related to lesion size and may be underestimated in small primary tumors. Physiologic [^{18}F]FDG uptake is nearly always noted in lymphoid tissues (tonsils) composing "Waldeyer's ring," including the pharyngeal tonsil (upper nasopharynx), symmetrical uptake in the palatine tonsils (unless the patient status is posttonsillectomy or suffers from unilateral tonsillitis or tonsillar carcinoma), and the lingual tonsil at the base of the tongue.

Variable uptake is noted in the tongue and floor of the mouth muscles, and is usually more intense if the patient was moving the tongue or swallowing during the uptake phase. Asymmetrical uptake in a normal tongue can be noted after hemiglossectomy or even resection of smaller unilateral tongue lesions, leading to increased muscle activity and [^{18}F]FDG uptake in the contralateral tongue. This is also noted after unilateral denervation, e.g., after hemimandibulectomy or due to hypoglossal nerve paralysis, where fatty atrophy and lack of [^{18}F]FDG uptake in the denervated hemitongue is associated with relatively intense uptake in the contralateral normal tongue. Asymmetrical uptake, due to spasm, can sometimes be observed in the pterygoid or temporalis muscles. Uptake along the scalene muscles is frequently seen, either symmetrical or asymmetrical, and is easily characterized as a normal variant on fusion images. Retained mucous in paranasal sinuses shows no [^{18}F]FDG uptake unless there is severe inflammation, infection, or tumor. Similar to MRI (but not CT), [^{18}F]FDG PET/CT differentiates well between tumor and entrapped secretions due to sinus outflow obstruction. While mucous retention or small polyps are fairly common in the paranasal sinuses, fluid retention in mastoid air cells should prompt careful assessment of the oropharynx to identify possible reasons for obstruction of the Eustachian tube.

Normally, symmetrical [^{18}F]FDG uptake is seen in the vocal cords and other laryngeal muscles (mild uptake is usually noted even if the patient does not vocalize during the uptake phase). Asymmetrical vocal cord uptake suggests vocal cord paralysis, usually due to damage of the ipsilateral recurrent laryngeal nerve. Secondary CT signs are sometimes helpful in confirming suspected vocal cord paralysis, including a paramedian position of the paralyzed vocal cord, tilting of the thyroid cartilage, displacement of the ipsilateral arytenoid cartilage, dilatation of the ipsilateral piriform sinus, and prominent laryngeal ventricle. Longstanding vocal cord paralysis may lead to atrophy of the posterior cricoarytenoid and thyroarytenoid muscles [32, 33]. In searching for possible reasons for vocal cord paralysis, attention should focus on the upper mediastinum as well as the lower neck to identify possible tumors or metastasis. Other reasons for vocal cord paralysis include nerve damage due to fibrosis (e.g., after radiotherapy) and chemotherapy (vinca alkaloids can cause transient vocal cord paralysis [34]). Asymmetrical or unusual focal [^{18}F]FDG uptake can be observed in patients who received instillation of foreign material (e.g., Radiesse) for attempted medialization of a paralyzed cord. In this case the [^{18}F]FDG uptake occurs on the treated site, likely due to foreign body reaction and inflammation. The instilled dense material is easily identified on the CT images. Large salivary glands usually show symmetrical [^{18}F]FDG uptake (submandibular gland > parotid gland). A common cause for unilateral focal [^{18}F]FDG uptake in parotid glands are pleomorphic adenomas (the most common benign tumor in the parotid gland), or "Warthin's tumors" (which are entrapped normal lymphoid tissue). The submandibular gland is usually removed as part of neck dissections. Asymmetrical uptake in the contralateral remaining normal gland should not be confused with lymph node metastases. Postsurgical muscle flaps can show (physiologic) very intense [^{18}F]FDG uptake, in particular at the flap pedicle, presumably related to hyperemia. This should not be confused with tumor recurrence. Some of the aforementioned normal findings and normal variations are described in detail in several review articles [35, 36].

Neck Metastases from an Unknown Primary Tumor

This condition, also known as carcinoma of unknown primary, accounts for 3–15% of all cancer diagnoses and for approximately 1–2% of head and neck cancers. For practical purposes this entity should be defined as the combination of no history of previous malignancy, no clinical or laboratory evidence of primary neoplasm, and a neck mass that is histologically or cytologically proven to be carcinoma. Occurrence of nodal metastases in neck levels I–III increases the likelihood of a primary HNSCC. However, in 5–40% of cases a primary malignancy is not identified during diagnostic evaluation and long-term follow-up. Provided a primary tumor cannot be

identified, in many institutions these patients are treated with extensive radiotherapy fields that cover the entire pharyngeal mucosa, the larynx, and bilateral necks. This is obviously associated with considerable morbidity. Identification of a primary tumor will direct rational therapy to a single mucosal site and the ipsilateral neck (unless the primary tumor is in, or close to, the midline). Detection of the primary tumor, in general, also allows for less extensive treatment (e.g., smaller radiation fields) and may potentially improve locoregional control. Therefore, these patients undergo extensive work-up. In some cases, the "unknown primary" is already identified in a thorough clinical examination by an experienced head and neck surgeon or oncologist; all other patients should undergo panendoscopy of the upper aerodigestive tract and [^{18}F]FDG PET/CT.

The literature is replete with studies of patients with unknown primary. Unfortunately, most study populations are very heterogeneous, and the definition of unknown primary and methods of verification vary considerably. For this chapter, we have only considered studies in which patients had at least undergone clinical examination, CT or MRI, and office endoscopy prior to PET (Table 2). The percentage of primary tumors detected is quoted as 14–37% [37–48]. When reviewing the literature, it should be noted that the sensitivity of PET is oftentimes stated incorrectly: Since all neck metastases must have an underlying primary tumor, the denominator for calculating sensitivity should be the total number of patients studied (not the much smaller number of patients in whom the primary is eventually detected by imaging and panendoscopy). Therefore, it appears overall less controversial and more meaningful to simply state the rate of primary tumors that were only detected by PET (see Table 2). Depending on the interpretation criteria, some studies report a high number of false-positive findings. It is therefore necessary to strike a reasonable balance between the wish to identify the location of the unknown primary on PET and the danger of calling every little variant suspicious. Potential reasons for false-negative PET studies include a small primary tumor (although lesions as small as 4 mm can be detected as long as there is intense [^{18}F]FDG uptake), low metabolic activity (cystic/necrotic tumor or lymph nodes), or the primary tumor was accidentally removed at the time of neck dissection.

In our institution, patients with unknown primary and negative results from clinical examination and office endoscopy first undergo [^{18}F]FDG PET/CT (Fig. 5), before panendoscopy; panendoscopy is defined as naso-pharyngoscopy, direct laryngoscopy, and upper esophagoscopy (in the absence of specific symptoms or imaging findings, a bronchoscopy is no longer done routinely because the yield is exceedingly low). This approach may reduce the number of necessary panendoscopies and avoid false-positive [^{18}F]FDG uptake after manipulation during endoscopy and biopsy (Fig. 1). Of note, other imaging studies are usually not needed, because it is extremely unlikely that they may identify a primary tumor that cannot be detected by PET. Statistically, most primary tumors originate in the ipsilateral palatine tonsil, base of the tongue, piriform sinus, nasopharynx (more commonly in East Asian populations), and larynx. Particular attention should therefore be focused during PET/CT interpretation to these sites. If the PET study is positive, biopsies should be obtained from the suggested location. If the PET study is negative, panendoscopy with biopsy sampling from suspected locations (based on the location of the lymph node and statistical considerations) should be performed. Depending on the results of these biopsies, the patient may proceed to surgery or radiation therapy.

Primary Tumor Staging

Most HNSCC are diagnosed clinically. The primary goal of imaging studies is therefore not tumor detection, but rather to define the extent of the primary tumor, in particular with regard to structures whose involvement may alter the surgical approach (e.g., depth of soft tissue infiltration, bone invasion, orbital invasion, skull base invasion, tumor "tracking" along nerves and blood vessels).

Head and neck cancers tend to spread locally with invasion of adjacent structures. For instance, many cancers of the oral tongue tend to extend into

Table 2 [^{18}F]FDG PET and PET/CT for the detection of unknown primary tumors in patients with neck lymph node metastases

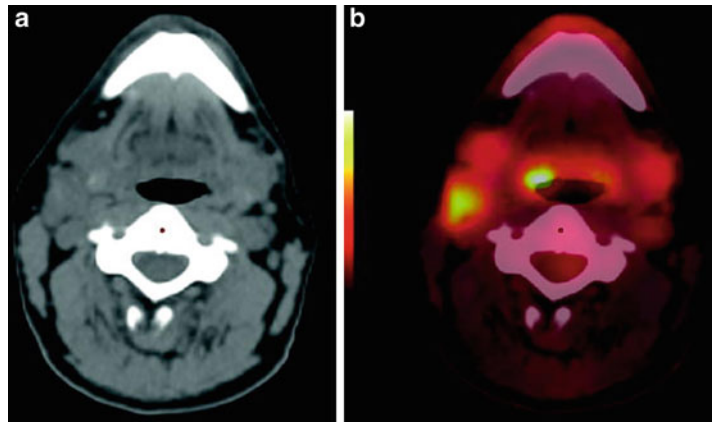

Fig. 5 Carcinoma of unknown primary in a 46-year-old man who presented with a right neck mass from an unknown primary squamous cell carcinoma. Clinical exam and office endoscopy were negative. [^{18}F]FDG PET was performed for localization of primary tumor. Non-contrast CT shows enlarged right neck node (**a**); PET/CT fusion image shows abnormal [^{18}F]FDG uptake in right level two node and at the right base of tongue primary (**b**)

the floor of the mouth. Staging of HNSCC is routinely done using either CT or MRI, not PET. However, occasionally [^{18}F]FDG PET may depict small submucosal primary tumors that are difficult to distinguish from adjacent normal tissues with anatomic imaging studies. In a study of 48 patients with HNSCC (mostly tumors of the oral cavity), [^{18}F]FDG PET detected 35 of 40 primaries known or still present at that time (88%), whereas contrast-enhanced CT of the neck identified a primary tumor only in 18 of the 35 patients (51%) with known or present primary tumors. Of the 17 primaries not detected by CT, 11 were clearly visualized with [^{18}F]FDG PET [49]. PET/CT readers should pay attention to secondary tumor signs. For instance, cancers at the anterior floor of the mouth can cause obstruction of Wharton's duct, through which the submandibular gland empties into the oral cavity. Ductal dilatation and enlargement of the gland, sometimes associated with increased [^{18}F]FDG uptake, may be noted. Perineural spread can occur in various locations in the head and neck, but is particularly common with adenoid cystic carcinoma (submucosal cancers that are common in the hard palate). Therefore, PET/CT readers should also be familiar with the normal branching patterns of cranial nerves relevant for innervation of the head and neck, in particular the facial nerve and trigeminal branches V2 and V3.

Lymph Node Staging

The risk of lymph node metastases is related to the anatomic location of the primary tumor. Tumors originating in sites that are rich in lymphatics, such as the tongue and floor of mouth, metastasize earlier and more often than those in other locations, including the hard palate or upper gum. The presence of nodal metastases is an independent prognostic factor for survival in patients with head and neck cancer; it decreases OS by approximately one half [50]. These historical data were corroborated by a larger retrospective study of 3,800 patients, in which the presence of neck node metastases lowered the 5-year disease-specific survival rate by approximately 30% [51]. The prognosis worsens additionally with the number of lymph nodes involved [52], with extracapsular spread of nodal disease [53], and with metastases located in the lower neck [54, 55]. The presence and extent of nodal metastases may affect the surgical or radiotherapy approach. Early and complete removal of neck node metastases is a prerequisite for cure. Accurate nodal staging of the neck is therefore particularly important.

The clinical neck examination and anatomic imaging studies suffer from a lack of sensitivity and specificity in assessing the extent of nodal

disease [29, 56]. Numerous studies have compared the accuracy of anatomic imaging modalities and [^{18}F]FDG PET for the detection of nodal metastases in the neck [49, 57–62] (Fig. 6). In most studies, PET had a higher sensitivity and/or specificity than CT, MRI, or ultrasound. In 124 patients with oral cavity cancer, the authors compared [^{18}F]FDG PET and neck CT or MRI with surgical histopathology of each dissected neck level; metastatic nodes were found in 95 of 493 dissected neck levels. Overall, and for each neck level, [^{18}F]FDG PET showed a higher accuracy then CT or MRI. The overall sensitivity, specificity, and accuracy for PET vs. CT/MR were 75% vs. 53%, 93% vs. 94%, and 89% vs. 86%, respectively [62]. However, these numbers may be somewhat optimistic, because the same authors later published data from 471 patients with oral cavity cancer, and found a suboptimal sensitivity and specificity of 73% and 58% on a per-patient basis [63]. In a meta-analysis of 35 studies comparing the diagnostic performance of [^{18}F]FDG PET or PET/CT with that of neck CT, MRI, or ultrasound-guided fine needle aspiration (USFNA), [^{18}F]FDG PET had a combined sensitivity and specificity in the range of 73–82% and 86–89%, compared with 74%/76% for CT, and 78%/80% for MRI. For unclear reasons, four studies comparing PET and USFNA showed a surprisingly low sensitivity of ~45% for both modalities (probably due to methodological issues or selection bias); as expected USFNA had a near perfect 96% specificity because it is based on cytology of aspirates [64].

It is important to understand that the sensitivity and specificity of [^{18}F]FDG PET were probably overestimated in earlier studies, when the technique had just been introduced. This is a common phenomenon applicable to any new imaging technique. In addition, CT and MRI techniques have vastly improved over the past 15 years. Readers are encouraged to review the Methods sections of published studies carefully; the most rigorous assessment would require analysis for each neck level (rather than analysis per patient or per neck), comparison with surgical histopathology of neck dissection, and at least 6–12 months of follow-up for non-dissected neck sites. Nevertheless, PET probably provides some (difficult to quantify) added value in the initial nodal staging of HNSCC.

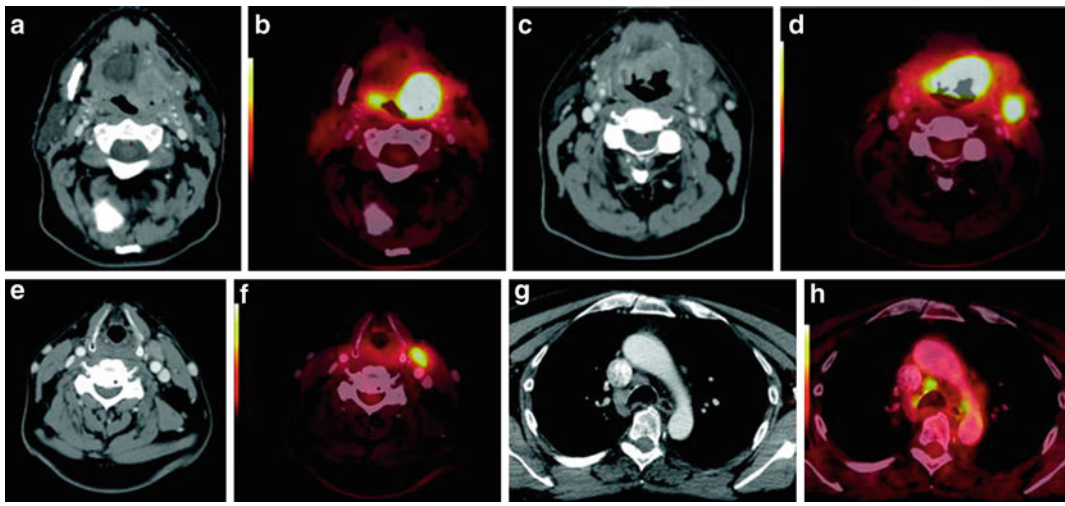

Fig. 6 Staging studies in a 57-year-old man with base of tongue cancer. Contrast-enhanced CT of the neck shows a large enhancing mass at the left base of tongue (**a**), which is intensely hypermetabolic on PET/CT fusion image (**b**). Intense [^{18}F]FDG uptake in lymph node metastases in the left neck level I (**c**, **d**) and level III (**e**, **f**). In addition, the staging scan showed enlarged hypermetabolic nodes in the mediastinum (**g**, **h**). Because of a potential change in management, these mediastinal nodes were biopsied: histopathology showed granulomatous disease (i.e., false-positive [^{18}F]FDG uptake)

False-positive [^{18}F]FDG uptake can occur in inflamed, reactive lymph nodes, a common phenomenon in the "classic" (HPV-negative) patient with HNSCC, secondary to poor oral and dental hygiene. Other reasons for false-positive [^{18}F]FDG uptake include granulomatous disease (Fig. 6) and uptake in the inflamed wall of branchial cleft cysts. The latter may be difficult to distinguish from cystic/necrotic lymph nodes, in particular since these nodal metastases often originate from small, indolent, and clinically occult primary tumors in the oropharynx [65]. Although various SUV cut-offs have been proposed, in clinical reality no single SUV number can reliably distinguish between metastatic and benign lymph nodes. Reasons for false-negative [^{18}F]FDG PET studies may include a small tumor burden in metastatic nodes, cystic degeneration of metastatic nodes only surrounded by a small rim of viable tumor tissue, low tracer uptake in the metastatic node, and imaging artifacts. Nodal metastases in close proximity to the primary tumor may not be detectable as separate hypermetabolic focus when the primary tumor shows very intense tracer uptake.

Detection of Distant Metastases and Synchronous Second Primary Malignancies

Distant metastases are rare in patients with head and neck cancers, but the frequency increases with higher T stage and size and number of tumor-involved lymph nodes and with jugular vein invasion. The risk for distant disease also increases with nodal metastases in the lower neck or supraclavicular region, in primary tumors in the hypo- and oropharynx, and in the setting of locoregional recurrence. The most common location is the lung, followed by bone and liver (with an estimated frequency of 66%, 20%, and 10%, respectively [66]). In contrast to most squamous cell cancers, adenoid cystic and neuroendocrine carcinomas tend to metastasize early and widely, even in the absence of advanced local disease. Although the lung is the most common site of distant disease, a chest CT is insufficient for comprehensive staging if the probability for distant disease is reasonably high, because potential metastases at other sites, including bone and liver, remain undetected [67]. [^{18}F]FDG PET/CT clearly improves the detection rates.

Patients with HNSCC have a higher propensity for synchronous (within 6 months of primary diagnosis) or metachronous (>6 month after primary diagnosis) second primaries compared with many other malignant tumors. This is likely related to synergistic effects from exposure to carcinogens in tobacco and alcohol. In a retrospective study of 1,100 patients, synchronous second primaries were noted in 7% of patients, and metachronous second primaries in another 9% of patients (at a median of 3.5 years after detection of the first head and neck cancer) [68]. However, in other analyses the reported rates for second primary malignancies in patients with HNSCC vary widely, from 7% up to 30%, probably related to selection bias [69–73]. Rather than recording the rate of second primaries, it may be more informative to record a standardized incidence ratio (the ratio between the number of observed to expected primary cancers in patients with prior HNSCC, using a cohort of similar age, sex, and ethnicity as standard of reference) [74]. In a recent analysis of the SEER database [74], the highest standardized incidence ratio was found for primary HNSCC in the hypopharynx, the lowest for primaries in the larynx. Patients with oral cavity or oropharynx index cancer most commonly develop a second primary at other subsites of the head and neck. Interestingly, the rate of second primaries in patients with an index tumor in the oropharynx has declined over the past decade, presumably related to the increasing number of HPV-positive tumors (which carry a better prognosis in general, and apparently also a lower risk for a second primary). Indeed, in a study of 746 patients with oropharynx primary cancer [6], the rate of second primaries at 3 years was 8.9% in total, but it was only 5.9% in patients with HPV-positive tumors compared with 14.6% in patients with HPV-negative tumors. By contrast, the 3-year rate of distant metastases overall was 10%, without significant differences in rates between patients with HPV-negative and those

with HPV-positive tumors (8.7% vs. 14.6%). As discussed earlier, patients with HPV-positive tumors experience higher initial and long-term cure rates for disease in the neck, and for this reason the distribution of any recurrent disease differs in that distant metastases outside the neck are becoming *relatively* more common, and may present later, than in historical controls.

Based on our own experience, a second primary or distant metastases outside the neck will be detected in less than 10% of cases in the staging scan, depending on the location, size, and histology of the primary tumor, as well as presence of bulky lymphadenopathy. Similar data (8–11% prevalence) were reported by other groups [71–73]. The vast majority of second primary tumors are observed in the upper aerodigestive tract and can be identified easily and efficiently with [^{18}F]FDG PET/CT. In a study of 350 patients, second primaries and distant metastases were detected with a sensitivity of 97% and a specificity of 93% [73]. In another study, including 589 patients, [^{18}F]FDG PET/CT identified 56 synchronous primary tumors in 44 patients (as many as three primary tumors in some patients) and missed another nine lesions [72]. Panendoscopy is often performed as part of the initial staging in patients with locoregional advanced HNSCC. A recent study of 311 patients showed, however, that [^{18}F]FDG PET/CT has in fact a higher sensitivity than panendoscopy, although at the expense of slightly lower specificity (100% vs. 74% and 95% vs. 99%, respectively) [71]. However, depending on reader expertise and interpretation criteria, up to 50% of suspected second primaries may be false positive in some studies. Typical sites of false-positive interpretations may include benign lymphoid hyperplasia in the nasopharynx, tonsils, and base of the tongue, as well as granulomatous nodal (Fig. 6) and lung infections. This highlights the need to temper vigilance with reason when interpreting PET scans in patients with HNSCC. Superficial, small-volume lesions in the esophagus and stomach may be missed.

In summary, PET/CT with [^{18}F]FDG is probably the single best test for the evaluation of second primaries and distant metastases; sensitivity in the range of 90–95% has been reported [73, 75]. The specificity, and in particular positive predictive value, may vary depending on reader experience. In patients with elevated risk for distant metastases based on clinical staging parameters (e.g., $\geq$3 lymph node levels involved, level IV and/or bilateral neck involvement, nodal size >5 cm, CT or MR evidence of extracapsular spread, and local recurrence), whole-body PET/CT is cost-effective in the search for distant metastases [76].

Change in Patient Management

Detection of heretofore unknown lymph node metastases or distant disease may change patient management. Patients with distant disease no longer qualify for treatment with curative intent. Additional disease sites in the neck may alter the surgical or radiotherapy approach. This was convincingly demonstrated in a recent study of 71 patients with untreated HNSCC. Referring physicians formulated a management plan prior to PET, which was then adjusted based on PET findings. A change in management occurred in 33% of patients. The referring clinicians rated the impact of PET on patient management as high in 18%, medium in 15%, and low in 66% of the 71 cases. Management changes included a switch from surgery to radiotherapy, changes in the course of radiotherapy or chemotherapy, and adjustments of the radiation field. [77].

Response Assessment After (Chemo-) Radiotherapy

Structural imaging with contrast-enhanced CT or MRI and functional imaging with [^{18}F]FDG PET/CT are now considered standard imaging tests for assessing the response to therapy in HNSCC. To determine the utility of [^{18}F]FDG PET as an indicator of response, we shall focus on studies in which [^{18}F]FDG PET was employed for patients treated with curative intent. Response rates at the site of primary disease are generally very high with concurrent chemoradiotherapy. Therefore, the main focus of posttherapy PET imaging is the detection of residual disease in neck lymph nodes [78–86] (Table 3). Of note, most studies included

heterogeneous patient populations, and the treatment strategies varied. Nonsurgical definitive therapy is now usually performed with concurrent chemoradiotherapy; with this approach, a greater extent and degree of inflammation is expected than with radiotherapy alone. Chemotherapy alone is only used for induction therapy or for patients with metastatic disease. In patients undergoing chemoradiotherapy, responses should be assessed with [^{18}F]FDG PET/CT approximately 12 weeks after the end of therapy to avoid false-negative and false-positive findings. The rate of false-positive cases declines with the length of the time interval between end of therapy and PET. A higher rate of false-negative [^{18}F]FDG PET has been observed for scans performed less than 4–6 weeks after the end of therapy [80, 87, 88]. The majority of irradiated cells do not die instantaneously but instead can still undergo several cycles of cell division (only cells irradiated in the mid-to-late S phase show instantaneous cell cycle blockade). The subsequent fate of such cells varies: Some cells may remain dormant for a protracted time and die eventually, but some cells may recover and start dividing again [89, 90]. Indeed, experimental studies in irradiated cell cultures show a rapid decline in [^{18}F]FDG uptake but the tracer uptake is not instantaneously abolished. Dormant cancer cells maintain their capability for glucose uptake and retention as long as their cell membrane is intact and basic metabolic processes continue. Some of these cells eventually die, whereas other cells may recover their full metabolic and proliferative potential. With increasing volume, the residual viable tumor cell nests may eventually become detectable on [^{18}F]FDG PET images.

In three of the larger studies investigating the role of [^{18}F]FDG PET for response assessment after concurrent chemoradiotherapy, [78, 79, 83] the sensitivity and specificity for detection of residual disease in neck lymph nodes were 100% and 94% [79], 83% and 93% [78], and 71% and 89%, respectively [83]. Of note, in all three studies the negative predictive value was 97%–100%. A patient example is shown in Fig. 7. False-positive lymph nodes are secondary to inflammation or granulomatous disease; false-positive uptake at other sites can occur due to inflammation, abscess formation, osteoradionecrosis, etc. Combined PET/CT reduces the fraction of false-positive cases. A prospective study of 121 patients confirmed the aforementioned observations, which largely stemmed from retrospective analyses [86]. Of the 121 patients, 62 achieved a complete response in neck nodes by CT criteria, and 50 did not. In the group of 62 patients, all PET studies were correctly negative (specificity and negative predictive value, 100%). More interestingly, of the 50 patients with residual enlarged nodes on CT, PET was correctly negative in 41 and correctly positive in two cases.

The test performance of PET can probably be refined further when clinical risk parameters are considered. In a study of 92 patients with stage I–IV primary cancer in the oropharynx, larynx, or hypopharynx, who underwent definitive radio- or chemoradiotherapy, both sensitivity and specificity were higher in high-risk patients than in low-risk patients (high risk was defined as stage III–IV, N2b and N3, non-oropharyngeal primary site, smoking history, and HPV-negative status) [85]. This observation re-emphasizes a basic rationale applicable to all imaging tests: The greatest impact on disease detection and patient management is generally observed in patients with intermediate pretest probability.

It needs to be emphasized that the true value of posttherapy [^{18}F]FDG PET in patients treated with current radio- or chemoradiotherapy protocols is the negative predictive value in the range of 95–100% (Fig. 7). This means that many patients who might otherwise proceed to biopsy or “planned neck dissection” can in fact be observed with clinical follow-up and periodic imaging studies. While the positive predictive value of PET after chemoradiotherapy is relatively low, most scans will in fact be negative when interpreted properly. However, true prolonged intense [^{18}F]FDG uptake after definitive therapy indicates a poor treatment outcome or treatment-related complications: A study in patients with larynx cancer treated with intensity-modulated radiation therapy [91] showed an inverse relationship between the intensity of (persistent) [^{18}F]FDG uptake at 12 months after treatment and

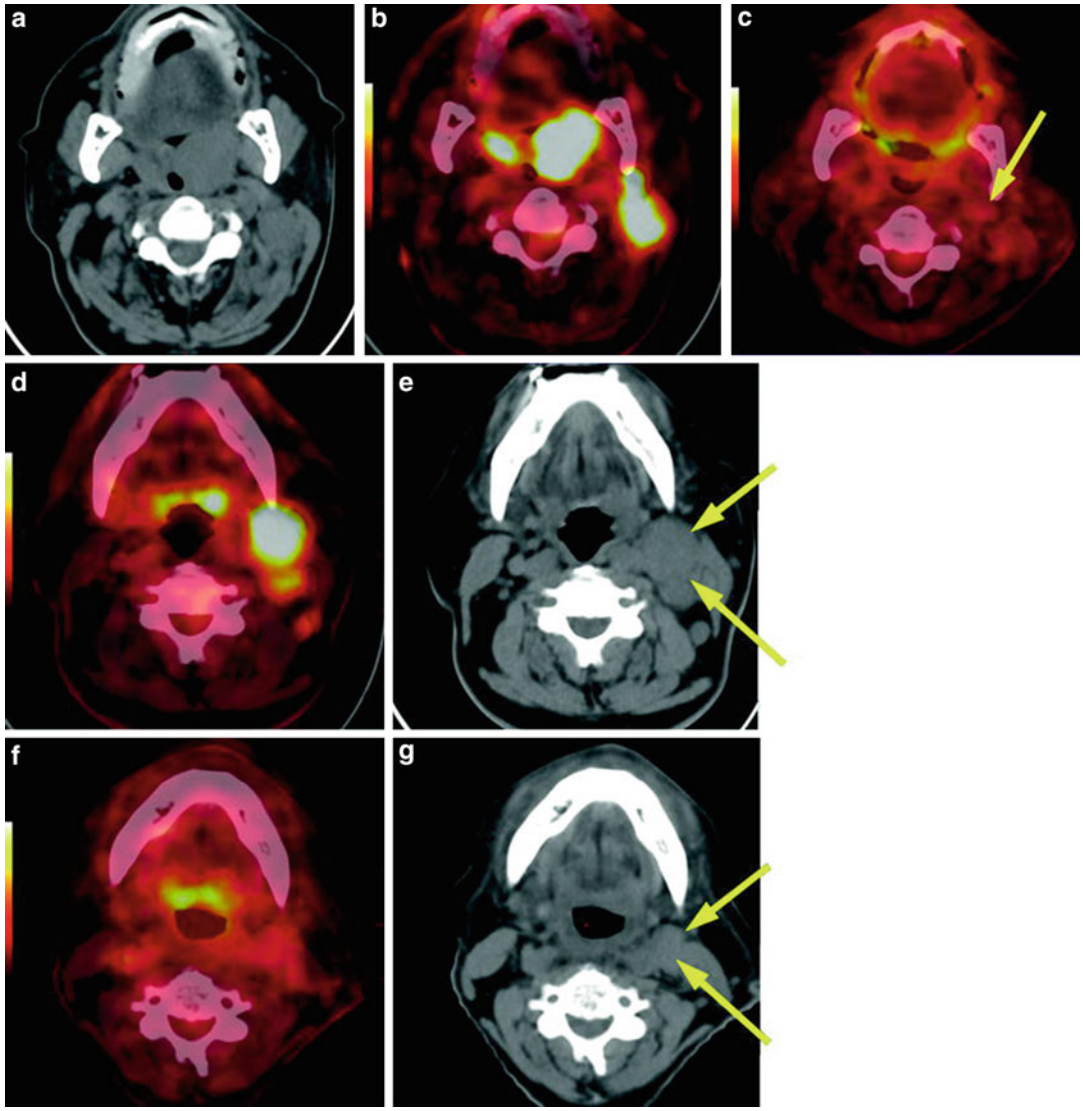

Fig. 7 Response assessment after chemoradiotherapy in a 62-year old male with primary tumor in left tonsillar fossa and left neck node metastases, staged as T3N2B. The patient was treated with concurrent chemoradiotherapy. The baseline staging scan shows the hypermetabolic left tonsillar primary, as well as metastatic neck nodes (**a**, **b**). [^{18}F]FDG PET/CT performed 3 months after the end of treatment shows nonspecific inflammation at the base of tongue and mild nonspecific uptake in a residual level II node (**c**). Another hypermetabolic node in level II measured 2.6 x 2.5 cm on the staging scan (**d**, **e**). After chemoradiotherapy, a residual node measured 1.9 x 1.5 cm (**f**, **g**). Scan findings were interpreted as absence of residual viable tumor in lymph nodes. Nevertheless, because of the large extent of initial nodal metastatic disease this patient underwent left modified neck dissection. The specimen showed only necrotic tumor foci but no viable cells

quality of life, as well as the ability to speak and swallow solid foods. In other words, persistently high [^{18}F]FDG uptake indicates either persistent disease or persistent treatment-induced structural and functional damage to the larynx.

Suggested PET Interpretation Criteria for Response Assessment

In general, focal and asymmetric [^{18}F]FDG with intensity greater than that in surrounding normal

tissues (in particular muscle) and blood vessels should be considered suspicious for residual disease. On PET/CT, such abnormalities should fuse to the site of the primary disease or lymph nodes (rather than blood vessels, fat tissue, skeletal muscle, etc.). By contrast, diffuse (nonfocal) [^{18}F]FDG uptake within the radiation field is usually an indicator of postradiation inflammation. With concurrent chemoradiotherapy, high-grade toxic effects are observed in up to 80% of patients, including grade 3 or 4 mucositis in 41% and laryngeal toxicity in 14% of patients [17]. This has obvious implications for imaging studies: Laryngeal edema and treatment-induced infiltrative changes in perilaryngeal soft tissues are commonly observed on posttreatment CT, along with nonspecific contrast enhancement patterns. Likewise, increased laryngeal or oropharyngeal [^{18}F]FDG uptake may be observed for a prolonged period after chemoradiotherapy. In most cases, this will be of mild-to-moderate intensity and diffuse throughout the larynx or along the oropharynx walls. Again, focal uptake should raise the suspicion of ulceration or persistent disease. In view of the relatively high response rates, persistent disease is uncommon, and this should be considered when interpreting PET scans in this setting. SUV numbers cannot differentiate reliably between residual cancer and inflammation. In clinical practice, scans are usually interpreted as positive or negative, or using a five-point scale (positive, probably positive, equivocal, probably negative, negative), considering focality, intensity, and pattern of residual [^{18}F]FDG uptake in relation to findings on the pretherapy scan.

Impact on Patient Management

Because clinical parameters and structural imaging cannot reliably predict the presence of residual metastatic neck disease, "planned neck dissection" was usually performed in the past after the completion of chemoradiotherapy, especially in patients with initial N2–N3 disease. Historically, the risk for residual cancer in such nodes exceeded 20%. In light of the high negative predictive value of posttreatment [^{18}F]FDG PET, this approach seems no longer justified [92, 93]. In one of the previously cited studies, [83] "planned neck dissection" would have been considered in 51 patients owing to the presence of residual enlarged lymph nodes, but disease was in fact only present in seven of them. Implementing a treatment strategy based on posttherapy PET/CT findings could have reduced the number of planned neck dissections by 75% (from 51 to 13) while missing disease in 2% (two of 84 hemi-necks). Based on our experience over the past decade, we have proposed a clinical algorithm for the management of patients with HNSCC after chemoradiotherapy (Fig. 8). A dedicated neck CT with intravenous contrast and [^{18}F]FDG PET/CT (potentially in one imaging session) should be performed about 10–12 weeks after the end of therapy, unless clinical management requires imaging at an earlier time. This time point strikes a balance between the clinical wish for early yet accurate response assessment and the surgeon's wish not to perform a neck dissection in tissues that have developed extensive fibrosis and scar tissue as the result of chemoradiotherapy. Management of patients with residual enlarged nodes and negative PET findings should be individualized according to the following considerations (Fig 9): Since response rates are high and PET has a high negative predictive value, "planned neck dissection" is unnecessary in the majority of cases. Nevertheless, close follow-up of these patients is required. Only if close clinical follow-up cannot be guaranteed, or if there are extenuating circumstances that indicate a higher likelihood for local recurrence (e.g., extranodal tumor extension), may a neck dissection be indicated. The rationale for this data-driven approach should be discussed with the patient.

Imaging During Chemoradiotherapy or After Induction Chemotherapy

The potential clinical utility of PET for *early response assessment* during chemo- or combined chemoradiotherapy has not been studied systematically in HNSCC. Data from other malignancies [94, 95] suggest that a significant decline in [^{18}F]FDG uptake between baseline and interim PET

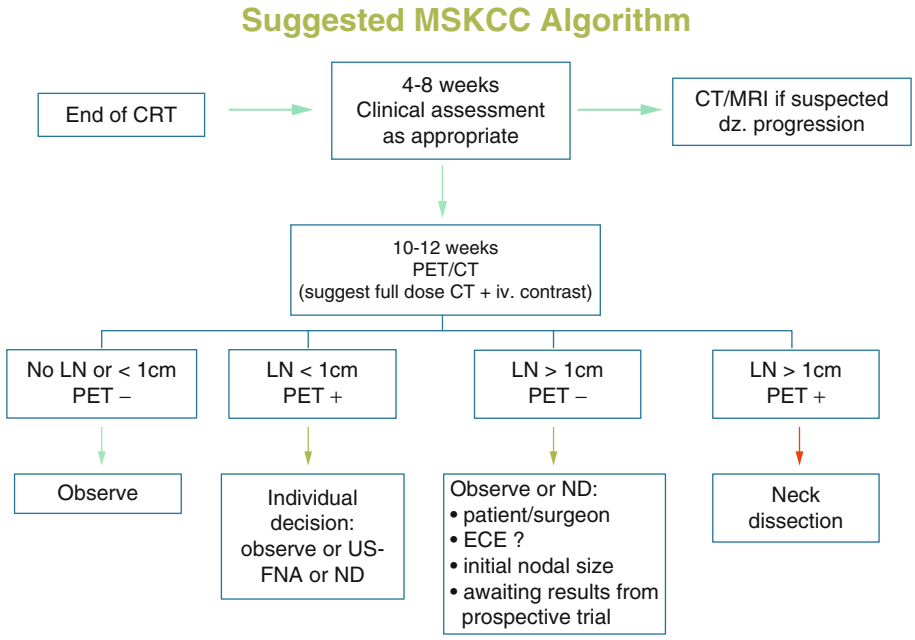

Fig. 8 Suggested algorithm for management of HNSCC patients after chemoradiotherapy. This algorithm is based on our experience at MSKCC; PET/CT is obtained approximately 10–12 weeks after the end of therapy. (Modified from Schoeder et al. J Nucl Med. 2009;50 suppl 1:74S–88S; reprinted by permission of the Society of Nuclear Medicine)

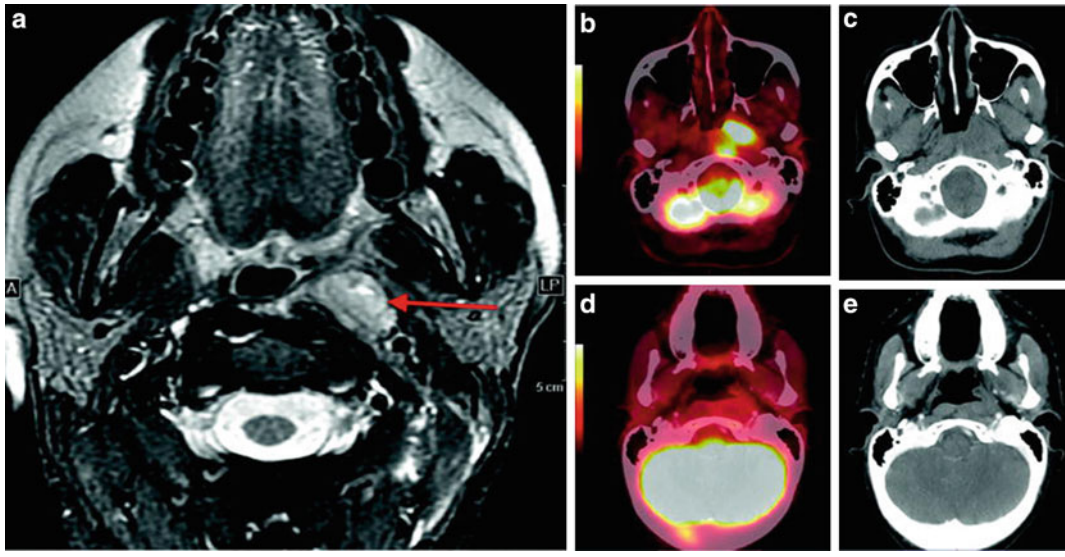

Fig. 9 Nasopharyngeal carcinoma in a 34-year-old female presented with left neck mass. Clinical exam and MRI showed nasopharyngeal mass and left neck nodes. MRI T2-weighted fat suppressed image shows the high signal (white) mass in the left posterolateral nasopharynx (**a**). Staging [^{18}F]FDG PET/CT shows the mass as well as an adjacent retropharyngeal metastatic node (**b**, **c**). After induction chemotherapy, there is mild nonspecific residual [^{18}F]FDG uptake in the nasopharynx (**d**, **e**). The patient subsequently underwent concurrent chemoradiotherapy. (Note the different position of the head for the two scans; the second PET/CT (**d**, **e**) was obtained in the radiotherapy mask and with intravenous contrast)

after a few cycles of chemo- or chemoradiotherapy may indicate a better prognosis and high likelihood of achieving a complete response. Few studies have attempted to address this question in HNSCC [96, 97, 98–100], often including patients with a variety of primary sites (all sites, pharynx only, or focused on oral cavity tumors). One of the earlier studies used coincidence camera imaging and noted an early and significant decline in [^{18}F]FDG uptake in 47 patients with locally advanced disease after one cycle of chemotherapy or 24 Gy of radiotherapy. When dichotomized by the median SUV, individuals with lower ^{18}F-FDG uptake showed a better rate of locoregional control. However, a closer analysis of this study reveals that similar prognostic information could also be derived from the baseline scan alone [96]. Recent studies confirmed that persistent high [^{18}F]FDG uptake on interim PET is associated with worse patient outcome; similarly, a greater and faster decline in SUV or metabolic tumor volume (MTV) may indicate better prognosis after completion of therapy [100]. On the contrary, persistent [^{18}F]FDG uptake and slow decline in SUV or MTV have a low positive predictive value (as low as 30% in one recent study) [101], i.e., even many patients with slow decline in [^{18}F]FDG uptake under therapy may achieve reasonable outcome once the full course of therapy is completed. Currently, the exact role, most meaningful time point, and optimal interpretation criteria for interim PET in patients with HNSCC remain unclear. It is also unclear how interim PET findings might alter patient management (good local control rates with current concurrent chemoradiotherapy, lack of an established alternate therapy). One meaningful approach would be a prospective study investigating the potential utility of treatment de-escalation in low-risk (usually p-16 positive) patients who show rapid response on interim [^{18}F]FDG PET scan.

There are limited data on the role of PET imaging for assessing the response to induction chemotherapy, prior to subsequent concurrent chemoradiotherapy. This is a topic of persistent interest among medical oncologists. Proponents of this approach believe that it may improve clinical outcome (lower rate of distant metastases and better survival) in locoregional advanced HNSCC. However, two recently completed randomized clinical trials (DeCIDE and Paradigm) were not able to prove this hypothesis. Induction chemotherapy did not improve outcome in nonselected patients [102, 103]. If induction chemotherapy is to play a role in the management of head and neck cancer, future studies will need to focus on high-risk patients, using tumor biologic parameters and imaging studies. For instance, if a patient showed very little or no metabolic response after induction chemotherapy, this might indicate a low likelihood for cure with subsequent chemoradiotherapy; perhaps such patients would benefit from immediate salvage surgery after induction therapy, or should be enrolled in more aggressive chemoradiotherapy and posttreatment surveillance protocols. Conversely, patients with good response to induction therapy may perhaps benefit from de-escalation of standard chemoradiotherapy by applying lower radiation doses (e.g., ongoing clinical trial such as NCT01706939).

Imaging After Surgery Prior to Adjuvant Therapy

A few studies [104–106] investigated the role of [^{18}F]FDG PET/CT early after surgical resection and prior to planned adjuvant radiotherapy. Usually these scans are performed relatively early after surgery in order not to delay necessary adjuvant radiotherapy. While early postsurgical imaging is associated with a higher risk for false-positive [^{18}F]FDG findings, these studies nevertheless detected residual [^{18}F]FDG-avid disease in 13–30% of patients, leading to changes in management, such as adjustment of radiation field or dose and abandonment of adjuvant radiotherapy or a switch to palliative chemotherapy, in 15%–30%. Patients with positive surgical margins, perineural spread of disease, or extracapsular extension of nodal disease in the surgical specimen may particularly benefit from pre-radiotherapy PET/CT. Because of the low positive predictive value of [^{18}F]FDG PET in this setting, all suspicious findings should be confirmed by biopsy before changing patient management.

Recurrent Disease

The early detection of recurrent head and neck cancer is important in determining the ability to perform salvage surgery, which can improve the clinical outcome of these patients. For instance, patients with recurrent early-stage HNSCC who undergo salvage surgery have a 70% 2-year relapse-free survival, whereas those with recurrent advanced-stage HNSCC undergoing salvage surgery have a 22% 2-year recurrence-free survival [107]. It is therefore critical to detect potential recurrences early in the course of events. An imaging modality used for this purpose should have a high sensitivity for the detection of disease, but at the same time not yield too many false-positive findings.

CT and MRI, which rely on structural changes, are notoriously unreliable in this setting because of treatment-related alterations of tissue planes, nonspecific contrast enhancement, etc. However, the PET/CT interpretation may also be complicated because postsurgical changes can involve distortions of the normal anatomy related to resection and surgical reconstruction, involving various soft tissue flaps, bone grafts, bone plates, surgical obturators, etc.

It is now clearly established that [^{18}F]FDG PET/CT has a high sensitivity and specificity for the detection of recurrent HNSCC, regardless of the primary treatment modality used [108–115]. In a retrospective study of 143 patients with HNSCC at any site, including 72 patients in whom recurrent disease was ultimately proven, Wong et al. [111] found a sensitivity of 96% for [^{18}F]FDG PET. The specificity varied with the anatomic subsite in the neck that was studied and tended to be lower at sites that showed post-treatment inflammation, whereas it was highest in the nontreated neck or outside the neck (where false-positive uptake would be less likely). This was also confirmed in other studies [109].

As a rule, clinically detectable recurrent disease is extremely unlikely in the setting of an entirely negative PET scan. With adequate patient preparation and combined PET/CT, certain sources of nontumor-related [^{18}F]FDG uptake can be eliminated or at least correctly identified (e.g., laryngeal muscle uptake, radioactive saliva in the throat or vallecula epiglottica, nonspecific [^{18}F]FDG uptake in brown fat tissue of the neck or scalene muscles), but posttherapy inflammation remains a potential source for false-positive interpretation. Accordingly, the sensitivity for the detection of recurrent head and neck cancer is very high, but specificity in the treated (after surgery or radiotherapy) area is lower than elsewhere in the neck or at remote sites, such as lung or bone [109, 111] (Table 4). Since the negative predictive value of [^{18}F]FDG PET/CT is very high, these patients in general do not require any further evaluation. By contrast, the positive predictive value is lower, depending on the location and time interval since treatment, so that sites of [^{18}F]FDG uptake require careful assessment and histologic confirmation before embarking on therapy. If biopsies from the site of [^{18}F]FDG uptake are negative for recurrent disease, close clinical follow-up may be sufficient. Potential reasons for false-positive [^{18}F]FDG uptake include inflammation, infection, and radionecrosis.

SUV numbers or other quantitative and semiquantitative parameters cannot reliably distinguish between recurrence and inflammation or infection. For instance, Lapela et al. [108] reported a wide overlap in SUVs for disease recurrence (range 2.1–36.9) vs. nontumor-related [^{18}F]FDG accumulation (range 1.5–9.3). Using ROC analysis, Wong et al. [111] suggested an SUV of 3.2 to distinguish between recurrent disease and benign conditions, providing a sensitivity of 92% and specificity of 70%. If the SUV decreases in serial scans, malignancy is unlikely and no further intervention is needed. If a high SUV persist or rises further, repeat biopsy may be required, unless there is another obvious explanation, such as infection, fistula, or radionecrosis. However, it should be noted that SUV numbers are affected by [^{18}F]FDG uptake time and technical parameters. Therefore, SUV should be used judiciously: While it may sometimes aid in study interpretation, it is not a surrogate for clinical experience. Indeed, visual interpretation by an experienced reader appears as at least as accurate as SUV-based assessment [111].

Imaging studies should not be ordered "routinely," i.e., in the absence of clinical signs or

symptoms and without abnormalities on clinical examination. However, there may be a small subgroup of patients at high risk for locoregional recurrence, in whom PET/CT at predefined time intervals may be appropriate, even in the absence of clear abnormalities on the clinical examination: In a prospective study of 44 patients with stage III or IV HNSCC and high risk for recurrence, [^{18}F]FDG PET was performed at 2 and 10 months, thereafter as considered necessary by the treating physician [116]. During the first year of follow-up, PET detected recurrent disease with a sensitivity of 100% and specificity of 93%. Notably, five of the 16 recurrences were only detected with PET. One of the clinically meaningful parameters for risk stratification is the patient's HPV status, since patients with HPV-negative oropharynx tumors are at higher risk for recurrence after completion of chemoradiotherapy, even when reaching a complete clinical and metabolic response [117]. Efforts to study the role of surveillance imaging should therefore be focused on this group of patients.

Prognostic Value of [^{18}F]FDG PET

Several studies have shown that [^{18}F]FDG PET alone can assess the aggressiveness and proliferation rate of HNSCC [118–120]. The intensity of

[^{18}F]FDG uptake at the primary site or neck node metastases correlates with prognosis in patients both with primary and recurrent disease, and regardless of the treatment modality used [63, 77, 109, 111, 121–132], [133–136] (Table 5). In patients with recurrent disease, clinical PET interpretation and SUV are independent prognostic markers for relapse-free survival and OS [109, 111]. More recently, the volume of [^{18}F]FDG-avid disease (MTV) and the combination of SUV and MTV (expressed as total lesion glycolysis) have also been suggested as a prognostic indicator (Table 5). Although high [^{18}F]FDG uptake and a large MTV thus indicate a poor prognosis, no uniform cut-off values have been established. In fact, while most studies confirm that patients with higher SUV, MTV, or total lesion glycolysis have a worse outcome, the cut-off values, methods for separation of prognostic groups (e.g., by median or by lowest p-value), as well as the clinical end points (e.g., 2-year vs. 5-year outcome; local control, disease-free survival or OS) vary remarkably. It also remains to be seen how this important information can be integrated into treatment or follow-up algorithms. For instance, in conjunction with other prognostic markers, a high tumor or nodal SUV or MTV might prompt consideration of induction chemotherapy prior to concurrent chemoradiotherapy or surgery, as well as consideration of postoperative chemoradiotherapy instead of radiotherapy alone, or shorter follow-up intervals.

Nasopharyngeal Cancer

In view of its unique epidemiology, tumor biology, and prognosis, nasopharyngeal carcinoma (NPC) should be considered separately from other head and neck squamous cell carcinomas. This tumor shows a distinct racial and geographical distribution. The highest incidence is noted in southern Chinese, in whom it is more than 20 times more common than among Caucasian people [137]. Of note, the risk for NPC persists in individuals who have emigrated to other parts of the world.

NPC tends to spread submucosally with early infiltration of parapharyngeal tissues. The tumor can spread in all dimensions; intracranial spread can occur along the maxillary nerve, following initial invasion of the pterygopalatine fossa and along the mandibular nerve via the foramen ovale. Neck lymph node metastases, also including level V nodes, are seen in the vast majority of patients. The lateral retropharyngeal nodes are traditionally considered first echelon nodes, but can be bypassed in up to 30% of cases. The rate of distant metastases is higher than for HNSCC, involving bone, lung, and liver.

Standard imaging tests for staging NPC include brain and neck MRI and, at a minimum, [^{18}F]FDG PET/CT. Local disease extent is best defined by MRI, in particular disease involvement of the skull base and intracranial spread. Neck lymph node involvement is probably best characterized by a combination of MRI and [^{18}F]FDG PET/CT (Fig. 9); small retropharyngeal nodes may be detected better with MRI. [^{18}F]FDG PET/CT appears sufficient as the single imaging test for the detection of distant disease outside the neck [138, 139]. A bone scan is no longer part of the staging studies. Although liver involvement can be determined with contrast CT or ultrasound, these additional studies do not appear necessary; instead, it may be advisable to simply perform the CT of the PET/CT at diagnostic dose settings and with intravenous contrast material. With modern treatment techniques, including intensity-modulated radiotherapy, proton beam therapy, and concurrent chemoradiotherapy, the majority of patients can be cured. However, accurate staging and early detection of recurrence are prerequisites to reach this goal. The combination of MRI and [^{18}F]FDG PET/CT also appears most appropriate for response assessment, although it may be possible in many situations to employ PET/CT as the only imaging test for this purpose [140]; outside the nasopharynx (where MR performs better than CT), it may be appropriate to perform the CT component of the PET/CT as a true diagnostic study (rather than low dose CT) with intravenous contrast material. Recurrent disease is best detected by the combination of MRI and [^{18}F]FDG PET/CT [141–143]. In a study of 63 patients with treated NPC, the accuracy for detecting local recurrence was 75% with

MRI and 73% with [^{18}F]FDG PET/CT; however, importantly, the combination of both tests increased the accuracy to 95% [141]. Nevertheless, occasionally both imaging tests may have difficulties in differentiating between posttreatment inflammation, early fibrosis, and recurrent disease. Radiotherapy-related treatment complications include temporal lobe necrosis, cranial nerve palsy, and osteoradionecrosis of the skull base (with or without superimposed infection). Of note, the latter may show contrast enhancement on MRI as well as [^{18}F]FDG uptake on PET scan. Similar to other head and neck cancers, the intensity of [^{18}F]FDG uptake, as well as the volume of [^{18}F]FDG-avid disease, in NPC primary tumors provides prognostic information [144]. [134].

Radiotracers Other than [^{18}F]FDG for Imaging of HNSCC

A number of non-[^{18}F]FDG radiotracers have been explored for imaging of head and neck cancers, with potential applications for the study of cancer biology, staging and radiotherapy planning, and response assessment. Imaging with amino acid tracers does not appear to provide any advantage over [^{18}F]FDG. The intense uptake in salivary glands interferes with the detection of metastatic neck nodes [145]. Although initially proposed as more specific than [^{18}F]FDG, false-positive amino acid uptake does occur in inflamed lymph nodes as well. Another amino acid tracer, ^{18}F-fluoroethyl-tyrosine (^{18}F-FET), showed inferior sensitivity

compared with [^{18}F]FDG [146, 147]. Similarly, imaging with [^{11}C]choline was not superior to [^{18}F]FDG PET/CT for response assessment in the head and neck [148]. Several groups are focusing on developing and refining imaging techniques for hypoxia in HNSCC. Hypoxic tumors are resistant to radio- and chemotherapy. It is conceivable that the poor prognosis of patients with hypoxic primary HNSCC or nodal metastases could be improved with modern aggressive treatment strategies. Radiotracers under investigation for hypoxia imaging in the head and neck include ^{18}F-fluoromisonidazole (^{18}F-MISO), ^{18}F-fluoroazomycin (^{18}F-FAZA), and $^{64/60}$Cu-ATSM [149–151]. Ongoing clinical trials are investigating the prognostic value of tumor hypoxia as imaged by PET, and how the hypoxia PET signal can be used for dose escalation in patients with hypoxic tumors (NCT01212354, NCT02352792), or for dose de-escalation in patients with early resolution of hypoxia during chemoradiotherapy (NCT00606294), in an effort at biology-driven modern radiotherapy. Tumor cell proliferation can be imaged with ^{18}F-fluorothymidine (^{18}F-FLT) [152]. ^{18}F-FLT, in general, is not a diagnostic radiotracer; in most disease sites it shows less uptake than [^{18}F]FDG, and false-positive uptake in inflamed lymph nodes can occur [153]. It is conceivable that tumors with high FLT uptake benefit from more intense therapy. However, predominantly ^{18}F-FLT may be a good imaging test for response assessment [154]. Based on limited data from recent studies, ^{18}F-FLT uptake in HNSCC declines earlier and faster than [^{18}F]FDG uptake does and such early decline is associated with better patient outcome [155, 156]. Finally, a number of radiotracers for imaging EGFR and the response to EGFR inhibitors, as well as angiogenesis and the response to angiogenesis inhibitors (both of potential clinical interest in head and neck cancer), are under study and in early clinical investigations.

PET for Radiotherapy Planning

[^{18}F]FDG PET/CT is now an established and essential imaging technique for the staging and planning of patients undergoing definitive (chemo-)radiotherapy (mostly for tumors of the oropharynx, nasopharynx, and larynx) or for post-surgical irradiation. The utility of PET for delineating the gross tumor volume (GTV) has been investigated. Most studies agree that the incorporation of PET in the planning process clearly improves target design over CT-based planning. In the single study of head and neck cancer patients in which data were correlated with histopathology (of laryngectomy specimens), pre-surgical PET was more accurate than CT or MRI in outlining the presumed tumor margins [157]. Nevertheless, in clinical practice, the combination of contrast enhanced CT or MRI and PET is usually applied for treatment planning. Of note, simple physical exam remains necessary and in case of small superficial primary tumors, may be more accurate than any imaging [158]. Several other studies have shown the incorporation of PET in treatment planning improves interobserver agreement. Often the PET-derived GTV is smaller than CT-based volumes, whereas simultaneously tumor extension was shown outside the CT-based GTV. Considerable time and effort have been spent in trying to define a mathematically and biologically correct approach when outlining tumor margins on PET. For instance, [^{18}F]FDG-avid volumes may appear larger or smaller depending on the window setting at the display. To improve objectivity, a number of segmentation algorithms have been proposed; unfortunately all have limitations in daily practice [159]. Therefore, most clinicians rely on visual assessment (and ideally close cooperation between radiation oncologist and nuclear medicine physician) for outlining PET-based tumor volumes. Beyond these clinical applications, there is growing interest in defining a “biologic” target volume. It is hoped that this will help in identifying patients with better or worse prognosis in whom radiotherapy could be escalated (dose, time, fractionation) or de-escalated. Dose escalation to highly metabolically active subvolumes has been proposed by several authors, and was shown to be technically feasible [160, 161]. Modeling studies suggest that hypermetabolic tumors may require 10–30% more dose than tumors with lower [^{18}F]FDG uptake [162]. This concept is supported by studies

showing that a majority of recurrences originate within the site of the original [^{18}F]FDG-avid tumor volumes, and recurrence becomes more likely with increasing tumor avidity [163, 164]. In addition to [^{18}F]FDG, other radiotracers, such as hypoxia imaging agents [149, 165, 166], some amino acids, and proliferation markers are of growing interest in radiation oncology [167].

Emerging Role for PET/MRI

PET/MRI is an emerging imaging technology. It has been applied in head and neck cancer and, depending on the primary tumor site and clinical question, may serve as a surrogate for PET/CT for staging purposes, detection of recurrence, and possibly also response assessment. Various imaging protocols have been proposed and generally attempt to strike a balance between acceptable imaging time and the number and type of MRI sequences that can be acquired in a reasonable time and are clinically necessary. Imaging times are generally longer with PET/MRI than with PET/CT, increasing the likelihood for patient motion [168]. Readers of PET/MRI need to be familiar with a number of technique-specific artifacts, including artifacts in the attenuation map, in order to avoid misinterpretation of imaging findings. There is currently no evidence that PET/MRI is broadly superior to PET/CT for imaging of head and neck cancer. Of course, MRI per se provides better information than does CT for certain clinical questions (e.g., skull base invasion, perineural spread of disease), and in these scenarios combined PET/MRI is likely to offer the most clinical benefit. The role of special MRI techniques, such as dynamic contrast-enhanced (DCE) imaging, diffusion-weighted imaging (DWI) and blood oxygen level-dependent (BOLD) imaging, is under investigation. These techniques may provide valuable (and in some instances prognostic [169, 170]) information as part of an MRI-only protocol, but when obtained as part of an PET/MRI protocol this may be redundant with the information that is already derived from the PET component of the integrated scan, such as pattern, intensity, and volume of radiotracer uptake. In practice, PET/MRI will be applied most appropriately for selected patients with head and neck cancer and for specific clinical questions (Figs. 6, 7, 8, and 9).

Diagnostic Applications of Nuclear Medicine: Thyroid Tumors

19

Rossella Elisei, Laura Agate, Sara Mazzarri, Valeria Bottici, Federica Guidoccio, Eleonora Molinaro, Giuseppe Boni, Marco Ferdeghini, and Giuliano Mariani

Abstract

Thyroid cancer (TC) is the most frequent endocrine malignancy. Its incidency has been growing in the last three decades reaching a mean of 12/100,000 women and 4/100,000 men. Since the mortality is low (0.5%), the prevalence is very high especially among women who have a higher rate compared to men (3:1). TCs are distinguished into well-differentiated thyroid cancer (DTC) (i.e., papillary and follicular), poorly differentiated thyroid cancer (PDTC), anaplastic (ATC), and medullary cancer (MTC). Other very rare TC accounts for non-epithelial tumors, lymphoma, and carcinomas characterized by the presence of mucin-producing cells and keratin.

TC usually presents as a thyroid nodule. Thyroid ultrasonography (US) is useful to detect thyroid nodules, but since only 5% of thyroid nodules are malignant, the diagnosis of malignancy is done by fine-needle aspiration cytology (FNAC). Radioiodide or ^{99m}Tc-pertechnetate thyroid scan has a low diagnostic specificity and sensitivity for characterizing thyroid nodules. X-ray of the neck is useful to disclose a deviation of the trachea or lumen restriction, in large nodules and in multinodular goiter. CT and MRI are generally reserved for mediastinal thyroid masses or the identification of regional or distant metastasis.

The most widely used staging system for TC is the TNM classification that has been defined jointly by the Union Internationale Contre le Cancer (UICC) and by the American Joint Committee on Cancer (AJCC). Thyroid remnant ablation with ^{131}I-iodide is indicated in DTC patients with a moderate to high risk of recurrence. Patients are prepared with rhTSH and low iodine diet.

ATC is a rare tumor (<3% of all TCs) derived from follicular cells with a very poor prognosis and almost invariably lethal. The most common clinical presentation of ATC is a new, large, firm thyroid mass, often associated with signs/symptoms of local compression/invasion. Multimodality treatment of ATC includes surgery, EBRT, and combination of chemotherapies. Therapy with ^{131}I-iodide is not useful, since these tumors do not concentrate radioiodide. Preoperative imaging with US, CT, and MRI plays an important role, and [^{18}F]FDG PET is useful to plan the therapeutic strategy.

MTC is a well-differentiated TC arising from the parafollicular, calcitonin-producing C cells. Its prevalence is 5–10% in all TCs. Sporadic and familial forms are recognized. Elevated baseline serum levels of calcitonin (Ct) are suspicious for MTC. Following surgery, MTC patients are monitored with serum Ct and CEA levels, and serial neck US examinations are performed. Ct doubling time in serum is the most sensitive biomarker for MTC progression. Scintigraphy with ^{123}I-MIBG has very high sensitivity for staging patients with MEN II and familial MTC. However, it has a low sensitivity in patients with increased serum Ct but no clinical site of disease. ^{68}Ga-DOTATATE PET/CT is now the best imaging modality in the detection of metastatic MTC lesions in the presence of high levels of serum Ct. Radionuclide therapy with the radiolabeled somatostatin analogue ^{90}Y-DOTA-Tyr^{3}-octreotide (^{90}Y-DOTA-TOC) has been tested in metastatic MTC. The two TKIs, vandetanib and cabozantinib, represent nowadays the best therapy of metastatic and progressive MTC.

Keywords

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{123}I-MIBG	^{123}I-*meta*-Iodobenzylguanidine
^{18}F-DOPA	2-^{18}F-Fluoro-L-3,4-dihydroxyphenylalanine
AJCC	American Joint Committee on Cancer
ATC	Anaplastic thyroid cancer
BRAF	Gene encoding for the B-Raf protein, a serine/threonine-protein kinase; the gene is also known as the proto-oncogene B-Raf and v-Raf murine sarcoma viral oncogene homolog B
CEA	Carcinoembryonic antigen, a tumor-associated serum marker
CI	Confidence interval
Ct	Calcitonin
CT	X-ray computed tomography
DMSA	Dimercaptosuccinic acid, a metal-chelating agent
DOTA-TOC	DOTA-octreotide
DOTA	1,4,7,10-Tetra-azacyclododecane-1,4,7,10-tetraacetic acid
DOTATATE	DOTA-octreotate
DTC	Well-differentiated thyroid cancer
EBRT	External beam radiation therapy
EFVPTC	Encapsulated follicular variant of papillary thyroid tumor
FNAC	Fine-needle aspiration cytology
FT3	Free circulating form of the thyroid hormone tri-iodothyronine
FT4	Free circulating form of the thyroid hormone tetra-iodothyronine
FTC	Follicular thyroid tumor
FVPTC	Follicular variant of papillary thyroid tumor
GLUT	Glucose transporter family
Gy	Gray unit (ionizing radiation dose in the International System of Units, corresponding to the absorption of one joule of radiation energy per kilogram of matter)
MAP	Mitogen-activated protein
MEN	Multiple endocrine neoplasia
MET	Gene encoding for a protein of the receptor tyrosine kinase family
MIBG	*meta*-Iodobenzylguanidine
MIP	Maximum intensity projection
MRI	Magnetic resonance imaging
MTC	Medullary thyroid cancer

mTOR	Mammalian target of rapamycin
NEFVPTC	Non-encapsulated follicular variant of papillary thyroid tumor
NIFTP	Noninvasive follicular variant of papillary thyroid carcinoma
NIS	Na^+/I^- symporter
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PAX8	A member of the paired box (PAX) family of transcription factors
PDTC	Poorly differentiated thyroid cancer
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
PI3K/AKT	Intracellular signalling pathway regulating the cell cycle
PPA Rγ	Gene encoding for the peroxisome proliferator-activated receptor gamma (or PPARG, a nuclear receptor), also known as the glitazone receptor, or NR1C3 (nuclear receptor subfamily 1, group C, member 3)
PTC	Papillary thyroid tumor
RAS	Oncogene regulating signalling intracellular cascades
RET	A proto-oncogene encoding for a receptor tyrosine kinase for extracellular signalling molecules (from "rearranged during transfection")
rhTSH	Recombinant human TSH
SWI/SNF	A nucleosome remodeling complex (from "SWItch/Sucrose Non-Fermentable")
TC	Thyroid cancer
TERT	Gene encoding for telomerase reverse transcriptase, a catalytic subunit of the enzyme telomerase
Tg	Thyroglobulin
TKI	Thymidine kinase inhibitor
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status), and "M" (distant metastasis status)
TRK	Gene encoding for a receptor tyrosine kinase for extracellular signalling molecules
TSH	Thyroid stimulating hormone or thyrotropin
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
US	Ultrasonography

Introduction and General Background

Although constituting only about 3.5% of all human cancers, thus being considered a rare tumor, thyroid cancer (TC) is the most common endocrine malignancy. TC comprises different histologic subtypes arising from follicular cell and less frequently from the neural crest-derived parafollicular C cells. Other rare primary TCs include non-epithelial tumors (sarcomas and hemangiosarcomas), thyroid lymphoma, and an extremely rare group of carcinomas characterized by the presence of mucin- and keratin-producing cells.

According to the World Health Organization (WHO) [1], primary thyroid tumors are classified as follows:

1. Papillary thyroid tumors (PTC)
2. Follicular thyroid tumors (FTC)
3. Poorly differentiated thyroid tumors (PDTC)
4. Anaplastic thyroid carcinoma (ATC)
5. Medullary thyroid carcinoma (MTC)
6. Other rare thyroid tumors

The prevalence of thyroid tumors according to histology as observed in a large consecutive series from a single referral center is reported in Fig. 1.

Differentiated Thyroid Cancer Derived from Follicular Cells

Although also MTC is one of the differentiated thyroid cancers, the term "differentiated thyroid carcinoma" (DTC) is routinely employed to define those cancers that originate from thyroid follicular cells. The most frequent type of DTC is PTC, which constitutes about 80% of all cases and is the most prominent malignancy of the endocrine organs.

Histopathologic Classification and Features

PTC and FTC are defined as "differentiated thyroid carcinomas" because they maintain the most important specific features of the follicular normal cells, such as the ability to take up and accumulate iodine, to produce thyroglobulin (Tg), and to respond to the thyroid-stimulating hormone (TSH).

The histologic diagnosis of PTC is based on the typical features of the cell nuclei, which are typically larger than in normal thyroid cells, transparent at the center, and containing hypodense chromatin (so-called ground glass nuclei); furthermore, their shape is irregular and may reveal fissures (thus resembling "coffee beans"). Large, circular, well-delimited intranuclear inclusions, corresponding to cytoplasmic invaginations, may also be present [2]. About 50% of PTCs are also characterized by the presence of calcium deposits named "psammoma bodies" [3]. PTCs are also characterized by the presence of a focal or diffuse pattern of papillae, i.e., fibrovascular structures covered by a single layer of neoplastic cells sometimes associated with follicles filled with colloid; trabecular or lobular patterns, areas of sclerosis, and squamous metaplasia can also be present.

When PTCs show a follicular-like structure, differential diagnosis with FTC is based on the peculiar features of their cell nuclei. In fact, FTCs exhibit frank follicular differentiation, without however the typical nuclei and papillary architecture of PTC [4].

Several variants of PTC have been distinguished (see Fig. 2):

- The "classical" variant of PTC with the papillary architecture
- The "follicular" variant in which the cells are organized in colloid-containing follicles, but are characterized by the typical PTC nuclei [5, 6]

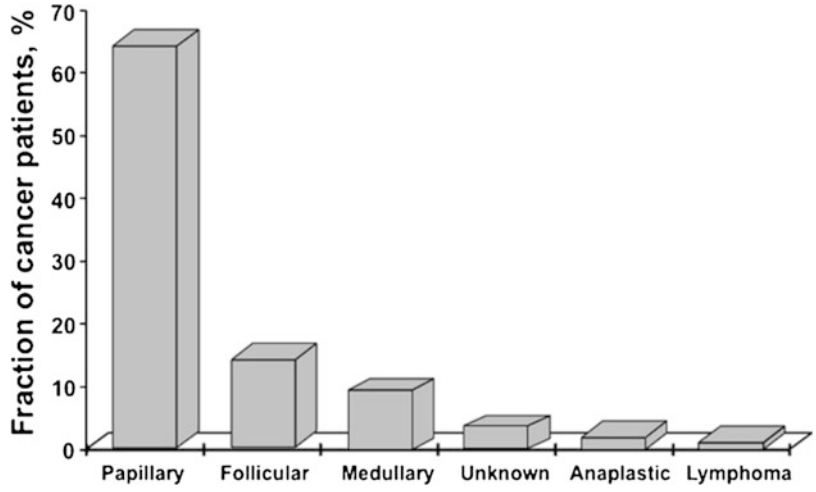

Fig. 1 Prevalence of different histotypes of thyroid cancers in a consecutive series over 8,000 patients followed at the Department of Endocrinology of the University of Pisa Medical School (Pisa, Italy) in the period 1969–2005

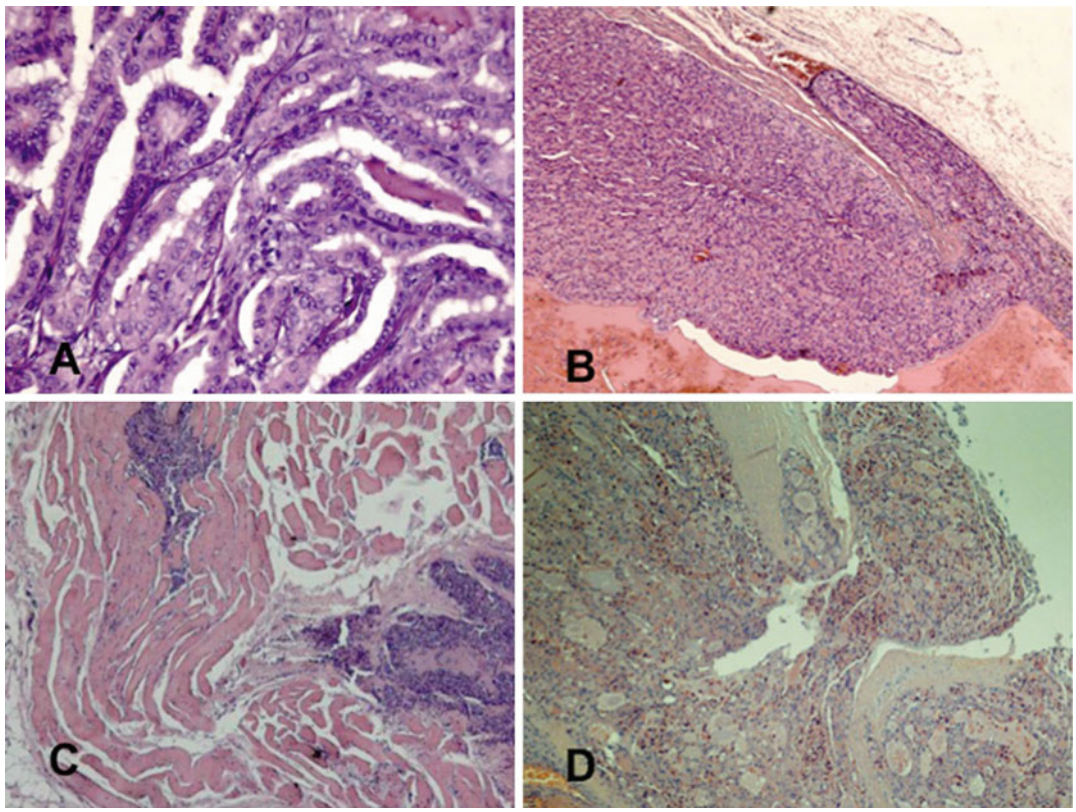

Fig. 2 Examples of different histologic types and variants of DTC. (**a**) Classical variant of papillary thyroid cancer (*PTC*), showing typical papillary pattern. (**b**) Low-magnification image of a follicular thyroid cancer (*FTC*) with minimally invasive pattern; infiltration through the thyroid capsule is shown in the right lower corner of the section. - The "diffuse sclerosing" variant, characterized by the following morphologic findings: (a) diffuse involvement of one or both lobes, (b) numerous micropapillary formations located within cleft-like spaces consistent with lymph vessels, (c) extensive squamous metaplasia, (d) large number of psammoma bodies, (e) marked lymphocytic infiltration, and (f) prominent fibrosis [7]
- The "tall cell" and the "columnar cell" variants [8, 9], which have a typical papillary pattern but are constituted by elongated cells containing a granular and eosinophilic cytoplasm

The follicular variant of PTC (FVPTC, see example in Fig. 3) was recognized as a new histologic presentation almost 30 years ago [5], and its incidence has increased by 173% in the last decades [10, 11]. FVPTC is actually a heterogeneous disease that includes two distinct subgroups: (1) an infiltrative/diffuse (nonencapsulated) subvariant (NEFVPTC), which resembles classic PTC in its metastatic lymph node pattern and invasive growth, and (2) an encapsulated form (EFVPTC) with a pattern similar as that of follicular adenomas/carcinomas (FTA/FTC).

A different molecular profile has been demonstrated between the "encapsulated" and the "infiltrative" FVPTC; in fact, the former is much more similar to FTA/FTC (high rate of RAS and absence of BRAF mutations), while the latter is much more similar to the classical variant of PTC (concerning especially BRAF mutations). Moreover, the molecular profiles of "encapsulated" and "infiltrative" FVPTCs parallel their different biological patterns of growth [12]. Very recently, a group of pathologists considered as the most expert in the world for the diagnosis of TC published a consensus about the idea that thyroid tumors currently diagnosed as noninvasive encapsulated follicular variant of PTC (EFVPTC), which have a very low risk of adverse outcome, can be now named noninvasive follicular variant of papillary thyroid carcinoma (NIFTP). This reclassification will impact on a large series of patients worldwide and result in a great reduction in psychological and clinical consequences associated with the diagnosis of cancer [13].

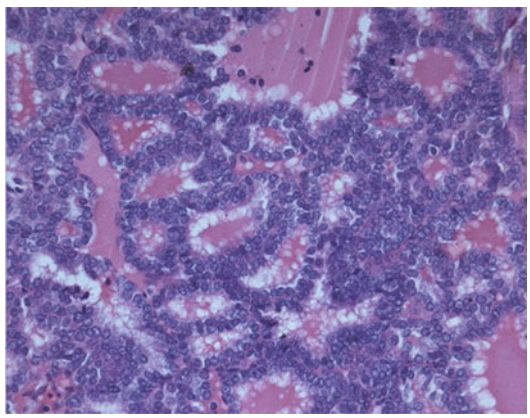

Fig. 3 High-magnification image of a follicular variant of PTC (*FVPTC*): follicular atypical cells with nuclear features typical of PTC lining follicle-like structures (Courtesy of Prof. Fulvio Basolo, Division of Pathology, Department of Surgery, University of Pisa, Pisa, Italy)

While the classical and follicular variants are the most common and the less aggressive PTC variants, both the sclerosing and the tall/columnar variants have a less favorable prognosis. The prognostic value of the different variants has been recently explored in a study in which a very large number of cases were collected and analyzed, thus clearly confirming that the prognosis, especially for recurrence, worsens from follicular to classical to tall cell variant [14].

Tumors with size less than 1 cm in diameter are defined as microcarcinomas [15]. They may exhibit features of a classic, small PTC or may appear as nonencapsulated sclerotic nodules that, although only few mm in size, infiltrate the surrounding thyroid tissue. The large-scale application of high-resolution neck US has led to an increase in the number of microcarcinomas detected more or less incidentally [16]. Since microcarcinomas usually have a good prognosis, their real clinical significance is debated, especially when considering that autopsy studies have found microcarcinomas in up to 35% of subjects who have died for reasons other than TC [17–19]. Nevertheless, when there is extrathyroidal and/or lymph nodal extension, the prognosis of microcarcinomas is the same as for cancers greater than 1 cm in size [20].

About 50% of PTCs exhibit lymphocyte infiltrates resembling those of chronic lymphocytic thyroiditis; such infiltrates can surround the tumor foci or spread in the adjacent normal thyroid tissue [21]. A higher prevalence of thyroid autoantibody positivity has been reported in TC patients than in the general population [22].

Upon accurate histologic analysis, about 50–60% of PTCs are multifocal, affecting both thyroid lobes in more than 30% of the cases. In contrast, FTC is usually unifocal and well encapsulated; invasion of the capsule and vascular invasion distinguish follicular carcinoma from benign follicular adenoma. For this reason, the diagnosis of FTC cannot be made on the basis of cytological findings, as it requires adequate tissue sampling of the capsule for definitive diagnosis; even intraoperative frozen-section histology can be incorrect in this respect. Depending on the degree of invasiveness, FTC is classified as minimally or widely invasive [15], the latter having a worse prognosis. While aggressive PTCs mainly spread through the lymphatics to produce locoregional lymph node metastases, FTCs generally invade the blood vessels and metastasize to the lung or bones and, less frequently, to the brain and liver.

The "oncocytic or oxyphilic" cell type (or Hürthle cell type), belonging to the FTC group, is composed of cells derived from the follicular epithelium, typically large with an abundant granular, eosinophilic cytoplasm, large nuclei, and a prominent nucleolus. The granular appearance of the cytoplasm is conferred by the abundant mitochondria [23]. Macroscopically, the oncocytic variant generally presents as a solitary thyroid nodule with complete or partial encapsulation. It should be noted that Hürthle cells can be found also in a number of benign conditions, including nodular goiter, hyperthyroidism, and Hashimoto's thyroiditis. A nodule can be defined as oncocytic tumor only if >75% of cells exhibit oncocytic features [15]. The same criteria of malignancy as for follicular tumors (i.e., vascular and capsular invasion) also apply to oncocytic cell tumors. Hürthle cell carcinomas with papillary structures but without the specific nuclear features of PTC have been reported in a significant proportion of patients [24]. Furthermore, oncocytic carcinomas are associated with extrathyroid extension and with both distant and lymph node metastases more frequently than are typical FTCs. In several series, the prognosis of Hürthle cell carcinoma is reported to be less favorable than that of the classical FTC [24].

Epidemiology

Despite relevant differences in the rates of incidence among different countries, the incidence of DTC, and particularly PTC, has the highest rate of increase worldwide [16]. However, there are epidemiological evidences that this increasing pattern has reached a plateau, and a trend to a decline is now observed [25]. DTC is more common in women than in men; the annual incidence rates range from 8 to 12 per 100,000 women and between 3 and 6 per 100,000 men. This gender difference declines after menopausal age, but still the majority of cases arise in women.

Although the incidence has increased by about 10% every 5 years in both sexes, mortality has declined by 8% every 5 years for men and by 17% for women. Similar patterns have been observed in a number of developed countries and are well documented in the USA [16]. This discrepancy between the increasing incidence and the declining mortality strongly supports the hypothesis that the rising incidence is most likely due to the increased ability to detect microcarcinomas, which generally have an excellent prognosis [26]. Since the rise in incidence started with the introduction and wide diffusion of neck ultrasound, which is able to detect thyroid nodules even smaller than 0.5 cm, it is conceivable that this diagnostic technique greatly contributed to detection of small DTCs that in the past were found only at autopsy. However, there are also some reports claiming that advanced cases are similarly increasing [27].

DTC is very rare in children and the peak age of incidence is 40–50 years, both in men and in women. The unique big series of childhood DTC was the one reported after the Chernobyl nuclear accident. A few years after the nuclear reactor explosion, an >80-fold of increase in DTC was

observed in children who were living in the regions exposed to the radioactive fallout [28] and in particular in those who were <5 years of age at the time of the accident [29]. When diagnosed in children and adolescents, DTC is usually more aggressive than in adults, but it is still curable if appropriately treated. On the other hand, an older age at diagnosis, especially >60 years, constitutes one of the worst prognostic factors [30].

More than 95% of the patients with DTC survive 30–40 years after diagnosis. Unfavorable prognostic factors for survival include follicular histotype, male gender, advanced age, larger size of the primary tumor, and the presence of local and distant metastases (especially multiorgan distant metastases at the time of diagnosis) [30].

Risk Factors

The most well-established risk factor for DTC, and in particular PTC, is exposure to ionizing radiation. This association has long been known, after observing a significant increase of DTC incidence in subjects who in their childhood/adolescence had been submitted to external beam radiation therapy (EBRT, mostly roentgen therapy) targeted to the neck and/or head or to the upper chest to treat benign diseases such as tonsillitis, tinea capitis, acne, thymic enlargement, and others [31–36]. Several studies have strongly supported the causative role of ionizing radiation exposure in the development of PTC [31, 37–41]. Although a latent period of 5–9 years from exposure is necessary for the tumor to develop (the highest risk being reported between 15 and 29 years), the risk continues to be elevated for 40 or more years after the exposure. Although the risk decreases significantly with increasing age at exposure, still some excess risk exists after age 20. Further confirmation of the relationship between radiation exposure and PTC emerged after the Chernobyl nuclear reactor accident of April 1986, with a huge increase in the incidence of childhood TC in the contaminated areas [42]. The Chernobyl accident also showed that the adult thyroid is less radiosensitive than that of a child. Cardis et al. investigated the role of contamination from radioactive iodine in children with a case-controlled study. An approximately sevenfold excess risk for thyroid cancer was estimated for a dose of 1 Gy, and a linear dose–risk relationship was observed at least up to 2 Gy [43]. Moreover, in vitro studies clearly demonstrated a cause–effect relationship between radiation exposure and in vitro induction of RET/PTC rearrangements [44], which were present at a very high prevalence in post-Chernobyl childhood thyroid cancer [45].

Genetic susceptibility should also be considered among the possible risk factors for DTC. Although the familial cases represent no more than 5–10% of all DTCs, the risk for PTC appears to be from three- to sixfold greater when a TC is diagnosed in a parent or in a sibling, respectively [46]. Furthermore, population studies demonstrated that the risk for DTC is approximately fivefold higher in first-degree relatives of TC patients compared with the general population.

The presence of a benign thyroid disease can influence the development of DTC, goiter, and benign nodules constituting the strongest risk factors with relative risks of approximately 3 and 30, respectively. The role of hypothyroidism and hyperthyroidism is less clear [47]. Considering that DTC occurs approximately three to four times more frequently in women than in men, hormonal factors are hypothesized to play a role in its etiology. A pooled analysis of case–control studies showed that the association between DTC and menstrual or reproductive factors was relatively weak, although stronger among women diagnosed with DTC at a young age [48]. Other studies have demonstrated that therapy-induced menopause is positively associated with DTC, as is the continuous use of oral contraceptives; in this latter regard, the association declines with increasing time since stopping oral contraception [49]. On the other hand, other studies have shown that hormonal and reproductive factors are only weakly associated with DTC [50, 51]. In this regard, the greatest difference in DTC incidence between genders is observed during the reproductive life period, while both in children and in elderly patients, this difference disappears; this observation supports the hypothesis that estrogens possibly favor the

development of DTC, but no clear scientific evidences have been reported so far.

The reduced levels of thyroid hormones due to iodine deficiency cause a rise in TSH secretion. Although the role of TSH in favoring the development of DTC has been known for many years, it is still a matter of ongoing discussion [52]. While endemic iodine deficiency is well established as a risk factor for goiter and FTC [53], other studies suggest that iodine supplementation programs could increase the incidence of PTC, by inducing iodine excess [54]. However, iodine deficiency was associated with a threefold increase of PTC in children exposed to the Chernobyl radioactive fallout, thus representing the most important risk factor in developing radiation-induced childhood thyroid cancer in Belarus [43]. On the other hand, increased surveillance and growing application of improved diagnostic procedures (especially neck US) are most likely responsible for the changing proportion of PTC versus FTC in the iodine-sufficient areas. Concerning other dietary risk factors, no definite relationships between food or drugs and DTC have been reported. A significantly reduced incidence of DTC has been shown with increased consumption of fish/seafood in areas of endemic iodine deficiency, but not in areas where iodine intake is high [54–56]. Seafood is an important natural source of iodine in the diet of different populations; therefore an association between fish intake and TC risk may be mediated by iodine. A panel of experts of the World Cancer Research Fund identified both iodine deficiency and iodine excess as probable and possible risk factors for TC, respectively, whereas vegetables and fruits might have a protective role [57]. On the other hand, even greater body weight and/or height has been found to be significantly associated with increased incidence of TC in both women and men [58]. A possible explanation for this relationship is that body size affects iodine requirement, therefore indirectly associated with TC risk. Alternatively, the association with body oversize might indicate a potential influence of some growth factor or hormone during childhood or adolescence, although the potential role of growth factors on thyroid carcinogenesis is still poorly defined.

Additional environmental factors, such as those associated with volcanic areas, cannot be excluded as risk factors. It is known that the incidence of TC is increased in volcanic islands such as Hawaii and Iceland [59]. A recent study performed in Sicily clearly demonstrated that residents of the Catania province, which includes the Etna volcano, have a higher incidence of PTC than elsewhere in Sicily. It is also interesting to note that the drinking water of the Catania province has much higher levels of vanadium, manganese, boron, and iron than water used in the rest of Sicily. The role of these elements in the pathogenesis of TC remains to be established [60].

Pathogenesis

Several genetic abnormalities, either determining activation of oncogenes or inactivation of tumor suppressor genes, have been described in different types of DTC (Table 1). In particular, H-, N-, and K-RAS gene-activating point mutations have been reported both in follicular adenomas and in FTC, while RET/PTC and TRK rearrangements, BRAF point mutations, and MET overexpression have been detected in PTC. It is of interest that RAS, RET, TRK, MET, and BRAF genes are all involved in the activation of the intracellular MAP kinase cascade whose activation leads to cell proliferation. Abnormal activation of this cascade is one of the best-recognized mechanisms of thyroid tumorigenesis. It is known that RAS gene activation induces cell division and inhibits cell differentiation. RAS oncogenes are activated by point mutations mainly found in three hot spots located in codons 12, 13, and 61. RAS oncogene point

Table 1 Most common genetic alterations in DTC

Gene alteration	FTC (%)	PTC (%)
BRAF^{V600E} point mutation	0	45
H, K, N *Ras* point mutations	40–50	10–20
RET/PTC rearrangements	0	20
PAX8-PPA Rγ rearrangements	35	0
PI3K/Akt mutations	6–13	0

FTC follicular thyroid carcinoma, *PTC* papillary thyroid carcinoma

mutations have been found in nearly 40% of benign and malignant follicular thyroid tumors, while they are much less frequent, although not completely absent, in PTC [61–63]. Interestingly, RAS mutations are more frequent in thyroid tumors of subjects living in countries where iodine intake is inadequate [64].

The RET proto-oncogene, which is located in chromosome 10q11.2, encodes a tyrosine kinase transmembrane receptor involved in the activation of the MAP kinase cascade. This proto-oncogene is normally expressed in a variety of neural cell lineages including thyroid C cells and adrenal medulla, but it is not expressed, or at very low levels, in normal thyroid follicular cells [65]. RET oncogene activation may be determined either by a rearrangement generating the fusion, at the chromosomal level, of the tyrosine kinase domain of RET gene and the 5 domain of different genes [66] or by activating point mutations [67]. RET/PTC rearrangements have been reported almost exclusively in PTC [68] and in few cases of benign follicular adenomas [69]. Recently, few cases of other human tumors have been found to harbor some peculiar RET/PTC rearrangements [70]. RET/PTC rearrangements are related to ionizing radiation exposure, a well-recognized risk factor for PTC. The increased prevalence of RET/PTC rearrangements in childhood post-Chernobyl TC [45] and the possibility of determining RET/PTC rearrangements in vitro in thyroid cells experimentally exposed to ionizing radiation [44] suggest a causative connection between radiation exposure and these chromosomal alterations. Despite this evidence, RET/PTC rearrangements have also been reported in sporadic PTC [69]. The prevalence of RET/PTC rearrangements in thyroid tumors of patients who had no history of neck irradiation ranges from 2.5% to 35% among different series [66, 70–74], while it is much higher (up to 75%) in post-Chernobyl childhood TC [70]. The fact that RET/PTC rearrangements can be found also in micro-PTCs suggests that this is an early event in thyroid carcinogenesis [73, 75]. On the other hand, there is evidence that RET/PTC-positive tumors do not progress to ATC [75], thus suggesting that the presence of RET/PTC rearrangement is a good prognostic factor.

An activating mutation of the B isoform of the Raf kinase gene, which is located in exon 15 and results in a valine to glutamic acid substitution at amino acid 600 (BRAF V600E mutation), is the most common mutation in PTC, with a prevalence ranging from 29% to 83% in different published series [76, 77]. The BRAF V600E mutation, which constitutively activates and promotes tumorigenesis through the MAP kinase pathway, is highly specific for PTC, and it is also present in those ATCs with a PTC component [78]. This mutation has never been described in other malignant thyroid histotypes or in benign tumors [78]. The relationship between the BRAF V600E mutation and the clinical and pathologic features of PTC is still controversial. Some authors demonstrated that BRAF V600E mutations are more frequent in PTCs with an advanced tumor stage at diagnosis [79, 80]. However, in other studies this association has not been or has only partially been confirmed [77]. The BRAF V600E mutation signals a worse prognosis with decreased survival for patients with PTC [81]. Recently, a new oncogene, TERT, has been demonstrated to play a role in thyroid carcinogenesis and in particular in the aggressiveness of TC. The presence of TERT mutation, especially if associated with BRAF V600E mutation, represents a well-established prognostic factor of poor outcome, both in terms of recurrences and survival [82, 83].

A very comprehensive study analyzing more than 400 PTC cases by next-generation sequencing techniques showed that, on the basis of genetic profile and of clinical behavior, PTCs can be distinguished into two different subtypes: the BRAF-like and the RAS-like PTC [84]. On the basis of this evidence, the question of whether PTC should be classified according to the molecular profile more than to the histotype has been raised.

Clinical Presentation

Thyroid tumors usually present as a thyroid nodule, either isolated or within a multinodular goiter. Although thyroid nodules are common, especially in subjects older than 50 years, TC represents only 4–5% of all thyroid nodules. Diagnostic workup

of thyroid nodules to distinguish benign and malignant lesions is therefore necessary. Complete medical history and physical examination of the neck are important steps in this process. A history of familial thyroid cancer and/or of exposure to radiation during childhood increases the risk of malignancy, while accurate palpation yields information on location and size of the nodules, their consistency and motility during swallowing, and on any extra-nodular thyroid tissue. Neck examination can also clarify the presence and extent of lymph node involvement, which is frequently found in PTC [85].

Although not specific for malignancy, the following signs indicate the need for diagnostic workup: nodules that are firm in consistency and irregular or fixed to local tissues, palpable neck lymph nodes, rapid increase in size of the nodules over weeks or months, and dysphagia or hoarseness.

Diagnosis

Although the serum levels of TSH, FT3, and FT4 are routinely measured to assess thyroid function, these parameters are not helpful to distinguish benign from malignant nodules. Also the serum level of thyroglobulin (Tg), which is usually elevated in case of nodular goiter, is not informative as to the nature of the nodule. Only elevated levels of serum Ct can preoperatively suggest the possibility that we are facing with an MTC, and further analysis to confirm this suspicious are required.

Ultrasonography

Thyroid ultrasonography (US) is the most accurate imaging technique for the detection of thyroid nodules, and it is mandatory when a nodule is discovered on palpation. In fact, US is the most accurate means for determining the volume of the gland; for defining the size, number, and structure (cystic, solid, or mixed) of thyroid nodules; for distinguishing thyroidal from extrathyroidal masses; for evaluating lymph node metastasis; and for guiding fine-needle aspiration cytology (FNAC). Furthermore, some US features are more frequent in malignant thyroid nodules [86]. In particular hypoechogenicity, the absence of a peripheral halo, irregular borders, microcalcifications, and hyper-vascularization are strongly suggestive of malignancy, especially when combined [86, 87]. No differences have been observed in the neck US features for PTC, FTC or MTC. Neck US is so relevant in the evaluation of thyroid nodules that in the last international guidelines for the management of thyroid nodules and cancer, it plays a leading role in the choice of the nodules to be submitted to FNAC [88].

Elastosonography is a recently developed dynamic US technique that estimates tissue stiffness by measuring the degree of distortion of the nodule under evaluation when applying an external mechanical force. In fact, under mechanical compression, the softer tissues deform easier than the harder tissues, to define an objective parameter of tissue consistency [89]. Elastosonography has been employed to assess the hardness/elasticity of thyroid nodules as a modality to distinguish malignant from benign lesions [90–92]. More recently, it has been reported that the highest elasticity scores, that indicate greater nodular consistency, are strongly correlated with malignancy, yet with minimal loss of sensitivity, especially in cytologically indeterminate thyroid nodules [93, 94]. On the other hand, conventional US evaluation maintains a pivotal role in identifying those thyroid nodules that are most suitable candidates for elastosonographic characterization. Nodules with a calcified shell and cystic nodules can be excluded from elastosonography evaluation.

Fine-Needle Aspiration Cytology

Fine-needle aspiration cytology is currently the method of choice for presurgical diagnosis of TC, as it can reliably screen the nature of a thyroid nodule, therefore identify those cases requiring thyroid surgery, either because of a diagnosis of PTC or because of findings requiring histologic elucidation (as is the case, e.g., cytology with a microfollicular pattern) [95]. FNAC is best performed using US guidance that improves its

diagnostic accuracy by decreasing the number of inadequate specimens and false-negative results; in fact, the acellular or nondiagnostic aspirate is reduced from 14% to 8% in US-guided FNAC [96], especially if the needle is passed more than once in the nodule under evaluation. This method is a rapid, accurate, and inexpensive means of evaluating thyroid nodules, with sensitivity ranging from 65% to 95%, specificity up to 96%, accuracy 98% [97], and negative predictive value up to 99% [98, 99]. Performing two separate aspirates on separate occasions decreases the false-negative rate to 1.2% [100].

Solid thyroid nodules over 1 cm in size, either solitary or in the context of a multinodular goiter, should be evaluated by FNAC, especially if appearing as "cold" at thyroid scintigraphy and with certain US features (see above). Nodules smaller than 1 cm should be followed with periodic thyroid US but not submitted to FNAC, according to the most recent American Thyroid Association guidelines for the management of thyroid nodules [88]. Cytology of the material obtained by FNA can be classified into five diagnostic categories (see examples in Fig. 4), each one carrying a specific risk of malignancy, therefore different indications for patients' management [101]. These five categories are denominated "Thy 1" to "Thy 5" [102], as follows:

- Thy 1: nondiagnostic aspirate due to inadequate sample or due to the presence of technical artifacts. Aspirates that contain only cyst fluid, histiocytes, and erythrocytes are considered inadequate. A minimum of six clusters of at least ten follicular cells assures the adequacy of cytological sampling [103, 104].
- Thy 2: benign, nonneoplastic lesion consistent with nodular goiter or thyroiditis.
- Thy 3: cytology is not diagnostic (it represents 10–15% of all FNACs) [105, 106]. This category includes all follicular lesions, for which the differential diagnosis between benign follicular lesion and FTC or follicular variant of PTC should be considered. A further subclassification of this category into Thy 3A and Thy 3B has been recognized to identify groups with a lower (10–15%) and higher (40%) risk of malignancy, respectively [107].
- Thy 4: lesion suspicious for malignant carcinoma.
- Thy 5: diagnosis of malignancy.

Immunohistochemical analysis (e.g., HBME-1, galectin-3, and CXCR4) and molecular analysis for genetic biomarkers involved in DTC (such as RET/PTC, PAX-8-PPARγ, and BRAF mutations) could be useful for evaluating indeterminate category cytologies (mostly Thy 3) and also for prognostic purposes in case of malignancy [108]. Very advanced methods of analysis to rule in or rule out the malignancy of these Thy 3 indeterminate nodules [109, 110] have been developed significantly improving the presurgical diagnosis of these nodules. The major concern is the cost of these methods and the fact that they are available only in specific centers and cannot be routinely used.

Thyroid Scintigraphy and Other Diagnostic Imaging Procedures

While thyroid scintigraphy with either radioiodide or ^{99m}Tc-pertechnetate can distinguish nodules as "hot" (i.e., functioning and usually benign) or "cold" (i.e., nonfunctioning), it cannot however distinguish the benign or malignant nature of cold nodules. In fact, the expression of the Na^+/I^- symporter (NIS) gene in DTC is markedly reduced (10- to 1,200-fold) with respect to normal thyroid follicular cells [111], thus resulting in a "cold" appearance on conventional thyroid scintigraphy with either radioiodide or ^{99m}Tc-pertechnetate. However, equally "cold" appears on thyroid scintigraphy as any benign nonfunctioning adenomas, where the expression of the NIS gene is decreased by 2- to 700-fold. Therefore, because of its low specificity, the thyroid scan is employed as an adjunctive rather than as a first-line diagnostic test. In particular, a thyroid scan is helpful when a hyperfunctioning nodule is considered in the differential diagnosis

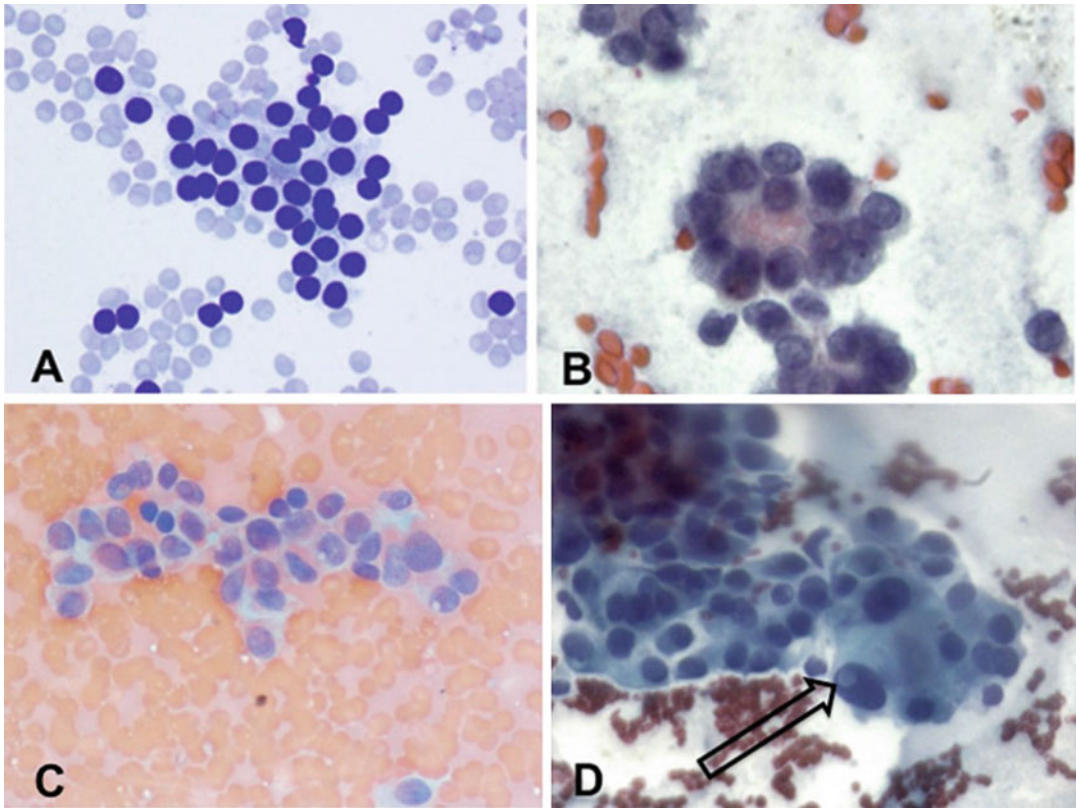

Fig. 4 Examples of different patterns observed in fine-needle aspiration cytology from thyroid nodules. (**a**) Thy 2 (benign lesion): thyroid cells isolated or in clusters, all with regular shape and monomorphous nuclei (erythrocytes in the background serve as a reference for size of thyroid cells and nuclei). (**b**) Thy 3 (indeterminate lesion): clusters of cells in follicle-like structures, with enlarged nuclei and occasional nuclear atypias. (**c**) Thy 4 (suspicious for papillary cancer): cluster of thyroid cells, some of which with enlarged, obviously atypical nuclei. (**d**) Thy 5 (papillary cancer): cluster of thyroid cells with markedly enlarged and polimorphous nuclei; at least one pseudonucleole, typical feature for PTC, is clearly visible (indicated by *black open arrow*) (Courtesy of Prof. Fulvio Basolo, Division of Pathology, Department of Surgery, University of Pisa, Pisa, Italy)

because of a suppressed TSH level [101]. Furthermore, thyroid scintigraphy may be considered as a possible additional diagnostic aid in those cases with indeterminate FNAC (class Thy 3) associated with serum TSH levels seemingly within normal limits or borderline with suppressed levels.

Despite their high sensitivity, all the scintigraphic approaches with tumor-seeking radiopharmaceuticals (such as ^{99m}Tc-sestamibi, see Fig. 5) that have been proposed for diagnosing DTC in patients with nodular goiter have failed because of their very low specificity. In fact, these agents accumulate both in TC and in benign adenomas; considering that DTC only constitutes no more than 5% of all thyroid nodules (very low pre-test probability), this feature translates into an alarmingly low specificity that only triggers further diagnostic testing without appreciably restricting the population of patients with suspected lesions.

The above consideration is also true for the nonspecific tumor-imaging agent [^{18}F]FDG, that has, however, a high negative predictive value for thyroid cancer. Giovanella et al. evaluated [^{18}F]FDG in 88 euthyroid patients with a solitary thyroid nodule and nondiagnostic FNAC (Thy 3 category); in their series, none of the 44 patients with a negative [^{18}F]FDG scan had malignancy, while all 21 patients with DTC had a positive [^{18}F]FDG scan

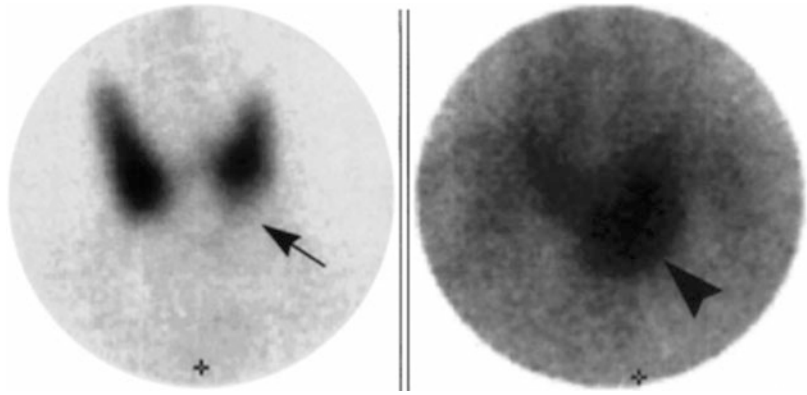

Fig. 5 Thyroid scintigraphy with ^{99m}Tc-pertechnetate (*left*) and with ^{99m}Tc-sestamibi (*right*) in a patient with a solitary nodule at the base of the left lobe, measuring 34 mm on US examination. The nodule appears as "cold" on the ^{99m}Tc-pertechnetate scan (*arrow*), while its uptake of ^{99m}Tc-sestamibi is greater than in the surrounding parenchyma (*arrowhead*). FNAC and definitive histology after thyroidectomy revealed a papillary carcinoma (Reproduced with permission from Földes I, Lévay A, Stotz G. Comparative scanning of thyroid nodules with technetium-99m pertechnetate and technetium-99m methoxy-isobutylisonitrile. Eur J Nucl Med. 1993;20:330–3)

18 out of the 67 patients with a benign thyroid nodule also had a positive scan. These findings result in 100% sensitivity and 100% negative predictive value for [^{18}F]FDG PET/CT, although with lower specificity (69%), overall accuracy (79%), and positive predictive value (62%) [112]. Another prospective study investigated the diagnostic performance of [^{18}F]FDG PET/CT, ^{99m}Tc-sestamibi scintigraphy, and multiparametric neck US in a similar group of 87 patients with Thy 3 FNAC. [^{18}F]FDG PET/CT had significantly greater sensitivity (94%), diagnostic accuracy (66%), and negative predictive value (98%) than either ^{99m}Tc-sestamibi scintigraphy or neck US. The association of PET/CT with US significantly increased specificity, but decreased sensitivity [113].

On the other hand, increased uptake of [^{18}F]FDG in the thyroid gland is detected in a certain fraction (up to 4%) of patients undergoing an [^{18}F]FDG PET/CT scan for thyroid-unrelated reasons, an occurrence defined as "incidentaloma" that can predict thyroid malignancy especially when tracer uptake is focal rather than diffuse (see Figs. 6 and 7) [114, 115]. A meta-analysis of 31 articles reporting the results of 197,296 PET studies and 3,659 focal thyroid incidentalomas concluded that the pooled proportion of malignancy in patients with incidentalomas is 19.8% (95% CI, 15.3%–24.7%) [116]. Based on these results, further diagnostic investigation (e.g., with image-guided FNAC) is recommended in all patients with thyroid incidentaloma detected in the [^{18}F]FDG PET/CT scan performed for any reason, because of the relatively high proportion of thyroid malignancy in these patients – as also confirmed by more recent large cohort studies [117, 118].

X-ray of the neck is only useful to disclose a deviation or lumen restriction of the trachea, as it can be observed in patients with large nodules and multinodular goiter. Computed tomography (CT) or magnetic resonance imaging (MRI) may be useful in identifying the extent and location of advanced thyroid tumors. These imaging studies are generally reserved for characterizing mediastinal thyroid masses and for identifying regional or distant metastases [119].

Staging

The most widely used staging system for TC is the tumor–node–metastasis (TNM) classification system defined jointly by the Union Internationale Contre le Cancer (UICC) and by the American Joint Committee on Cancer (AJCC). It is based on the histopathologic description of the tumor size, local lymph node metastases) and of distant

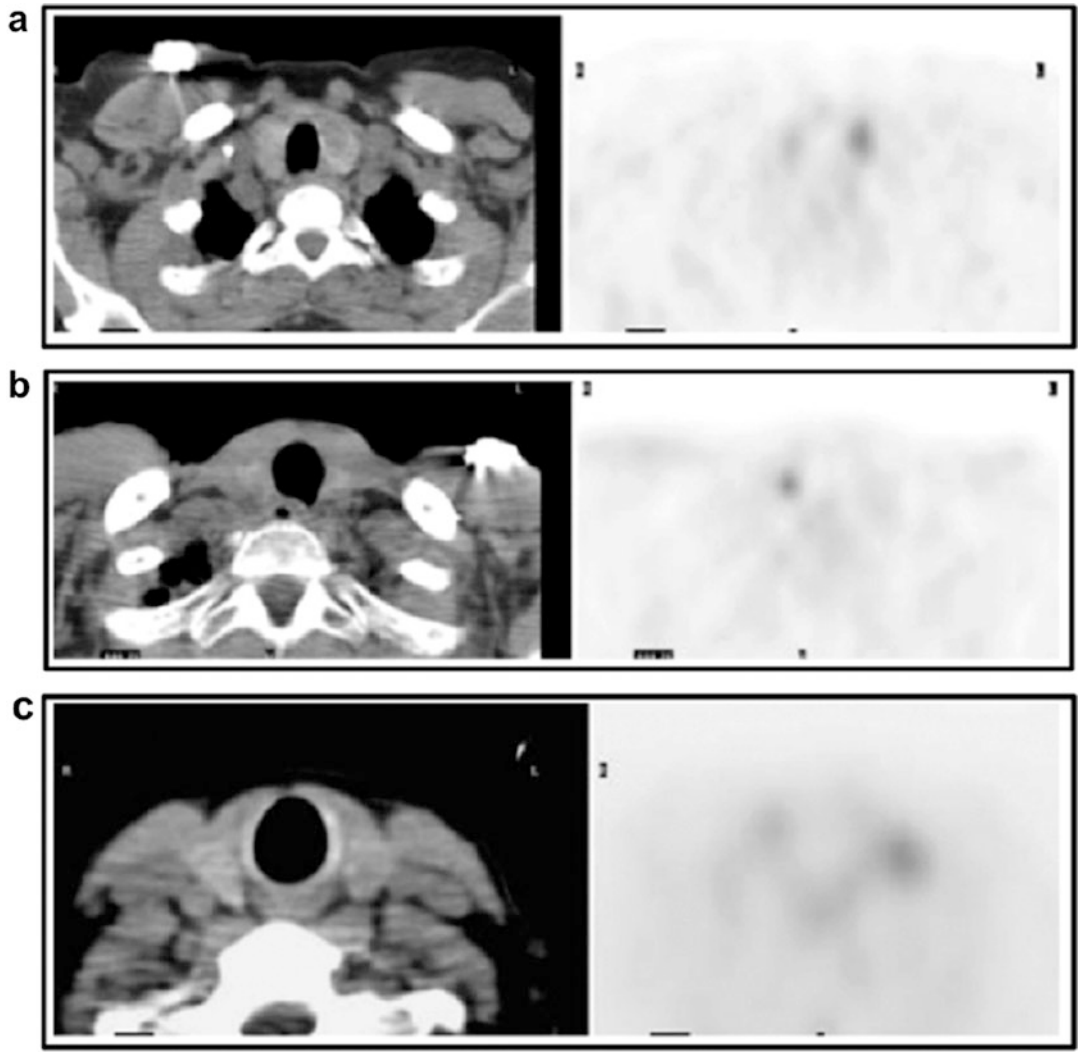

Fig. 6 Examples of thyroid incidentalomas found on whole-body [^{18}F]FDG PET/CT performed for non-thyroid-related indications; although with similar patterns of increased tracer uptake in the thyroid bed, final diagnosis ascertained by FNAC and/or histology can be quite different. For all cases: axial CT image in left panel, corresponding axial [^{18}F]FDG PET image in *right panel*. (**a**) Patient with cervical cancer: mildly increased [^{18}F]FDG uptake in the thyroid with a diffuse pattern, more evident in left lobe. Final diagnosis: chronic thyroiditis. (**b**) Patient with gastric cancer: focal increased [^{18}F]FDG uptake in right thyroid lobe. Final diagnosis: adenomatous goiter. (**c**) Patient with cervical cancer: focal increased [^{18}F]FDG uptake in the left thyroid lobe. Final diagnosis: papillary thyroid cancer (Modified and reproduced with permission from Liu Y. Clinical significance of thyroid uptake on F18-fluorodeoxyglucose positron emission tomography. Ann Nucl Med. 2009;23:17–23)

metastases (M). Age (<45 or >45 years at diagnosis) is also important in this classification. The latest (seventh edition) TNM classification appeared in 2010 and is shown in Table 2. The corresponding prognostic implications in terms of observed 5-year survival for patients with PTC and with FTC are shown in Fig. 8.

If the TNM classification is relevant to indicate the risk of survival, it is not very useful in predicting the risk of recurrence. A new classification based on the risk of recurrence after initial treatment has been proposed, and then widely accepted, by the American Thyroid Association [101]. This risk-based classification distinguishes

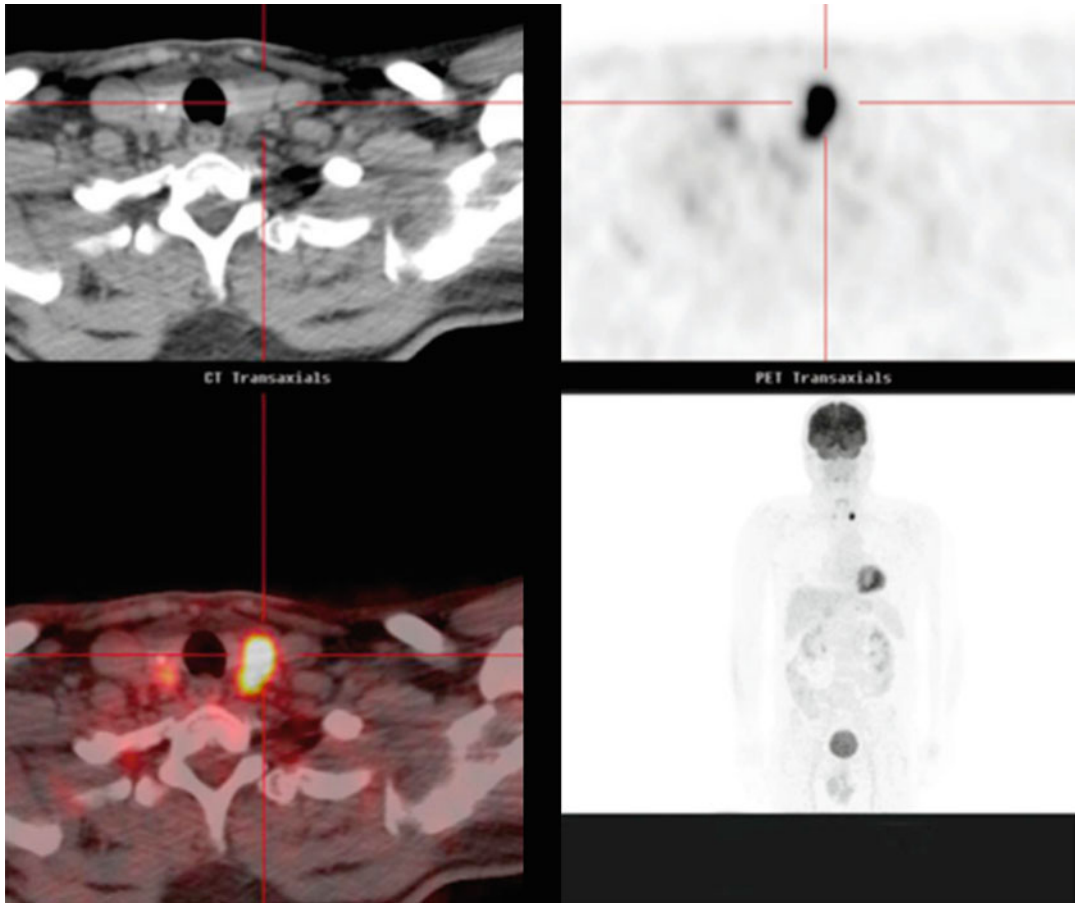

Fig. 7 Incidental detection of PTC in a patient undergoing [^{18}F]FDG PET/CT during follow-up after primary treatment for malignant melanoma. FNAC from the focal lesion in the left thyroid lobe showing markedly increased [^{18}F]FDG uptake (with SUV_{max} >14) showed a Thy 4 pattern. The patient underwent then total thyroidectomy and remnant ablation with ^{131}I-iodide; histology revealed a well-differentiated PTC (>2 cm in maximum diameter). Radioiodide remnant ablation was successful, and subsequent long-term follow-up was characterized by a favorable clinical outcome (From Volterrani D, Erba PA, Mariani G. Fondamenti di Medicina Nucleare - Tecniche e Applicazioni. Milan: Springer, 2010, with permission from Springer Science + Business Media)

three levels of risk (low, intermediate, and high) to develop recurrence during follow-up, and it is very useful from a practical point of view to plan the therapeutic strategy and the follow-up schedule. The possibility to change the level of risk after therapy and during follow-up, the so-called "ongoing" risk re-stratification, has been also demonstrated of clinical usefulness [120].

Most of the information contributing to TNM staging of DTC derives from postsurgical histologic findings regarding either the primary tumor and/or cervical lymph nodes. Radionuclide imaging has little role in the preoperative phase. This consideration includes whole-body PET/CT with [^{18}F]FDG [121], although recent reports highlight the value of contrast-enhanced [^{18}F]FDG PET/CT for preoperatively staging neck lymph nodes in patients with DTC [122].

Prognostic Factors

About 80% of patients with DTC can be cured with initial treatment, and 95–97% of them are still alive after 30 years of follow-up [123]. Despite this good prognosis, some patients are at

high risk of developing local recurrence and/or distant metastases, which can end up with death. These patients should be identified at the time of diagnosis to adapt their treatment to their risk, by analyzing the following prognostic factors (especially in combination) [30].

Age

Age at diagnosis is one of the most important independent prognostic factors for both PTC and FTC, as advanced age represents a negative prognostic factor for both recurrence and death. The prognostic significance of age persists when the total death rate is corrected for the overall mortality of a control population of the same sex, age, and year of birth when only cancer-related deaths are considered. The risk of recurrence and death increases linearly with age, particularly after age 40 [30]. Although it is still unclear why they have a worse prognosis, elderly patients tend to have locally invasive tumors at presentation, a higher incidence of distant metastases at diagnosis, and aggressive histological variants; all these factors may signal a worse prognosis.

Thyroid tumors tend to have shorter doubling times in older patients. Furthermore, these tumors are often not well differentiated, so that they are less likely to concentrate radioiodine. On the other hand, children and adolescents, despite frequently displaying locally extensive disease at diagnosis, have an excellent long-term prognosis [124, 125].

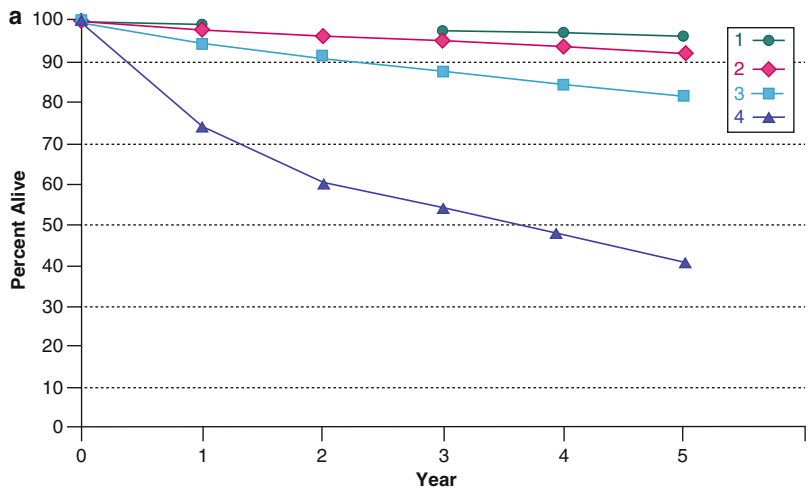
Gender

Male gender has been reported to be a risk factor in some series but not in others [126–128]. While it is usually a negative prognostic factor on univariate analysis, it loses its prognostic value on multivariate analysis. The question of whether male sex truly is a negative prognostic factor is therefore still not elucidated.

Histologic Types and Variants

The prognosis of PTC is better than that of FTC. The less favorable prognosis of FTC is more likely related to the patient's older age and to the extent of the tumor at the time of diagnosis than to histology alone. In fact, survival rates for patients with PTC and FTC are similar among patients of comparable age and stage of disease [129–131]. Furthermore, within these two main histological entities, the prognosis may differ among their respective variants [5].

In PTC, the tall cell variant [131], the columnar cell variant [8], the oxyphilic variant [24], and the solid/trabecular variant [132] have a worse prognosis. Prognosis is good when the cancer is well encapsulated [13] and in cases of FVPTC [14], although some tumors are more aggressive [5]. Intermediate prognosis is reported for the diffuse sclerosing variant [7]. While the minimally invasive FTC shows a good prognosis, the widely invasive FTC has a less favorable prognosis; in particular, advanced vascular invasion is a negative prognostic factor



Observed Survival	1	2	3	4	5	95% CIs	Cases
1	99.4	98.8	98.4	97.8	97.1	96.7–97.4	14124

[133], while the degree of capsular invasion is of limited prognostic relevance [128]. Some FTC variants, such as Hürthle cell carcinoma, poorly differentiated and insular histotypes, have frequently been associated with an unfavorable prognosis [127, 128, 134].

The insular histotype identifies a subtype of PTC, although no consensus has been reached

on this definition. Thus, although it is not listed in the WHO classification as a distinct histological entity by itself [1], it is sometimes considered an independent histological type.

It is of interest that the degree of invasion and the degree of differentiation are not related to each other; therefore, both parameters must be taken into account for overall prognosis. When microscopic foci of undifferentiated cells are found within a DTC, the tumor must be regarded and treated as an ATC, with very poor prognosis; extrathyroidal infiltration and local invasiveness are additional prognostic factors that make the prognosis of thyroid cancer even worse.

Tumor Size

The size of the primary tumor may vary from less than 1 cm in diameter (the most frequent occurrence at present) to a quite large tumor. When they are unifocal and lymph node negative, tumors less than 1 cm (the so-called microcarcinomas) have an excellent prognosis for both overall survival and relapse-free survival [26]. The risk of recurrence and tumor-specific mortality gradually rises as primary tumors increase in size. Nevertheless, this parameter seems to be more predictive for PTCs than for FTCs, in which the prognostic significance of the degree of differentiation and magnitude of invasion prevails over tumor size [30].

Multifocality

Whereas FTC is usually unifocal, PTC is multifocal in about 50% of the cases (from 20% to 80% depending on the number of tissue sections examined) [85]. Multifocal PTCs are more frequently accompanied by lymph node metastases at diagnosis [26] and exhibit more frequently local disease persistence, regional recurrences, and distant metastases. Controversial data have been reported about the relationship between multifocality and mortality [30, 128, 135]. In this regard, it is worthwhile noting that multifocality in one lobe is associated with a higher aggressiveness than when the other lobe is involved as well. This finding can, at least in part, explain why recurrences and cancer-related deaths are less frequent with total thyroidectomy than with less radical surgical procedures.

Extrathyroidal Invasion

Tumor extension beyond the thyroid capsule is an independent predictor of worse prognosis for both PTC and FTC. It is observed in 5–10% of PTCs and in 3–5% of FTCs and is associated with higher rates of local recurrence, distant metastases, and tumor-related death [136, 137]. However, microscopic invasion of the thyroid capsule should be distinguished from macroscopic invasion involving other structures in the neck. The latter occurrence has a bleaker prognosis, especially because of the difficulty of clearing the disease locally from the surgical point of view [138].

Lymph Node Metastases

While lymph node metastases are frequent in PTC (30–60%), they are not so frequent in FTC (15–20%) [139]. They are more common in children, occurring in up to 80% of the cases. Local lymph nodes may be involved even in the event of micro-PTC [26]. While in some series regional lymph node metastases have been found to be associated with higher rates of tumor recurrence and cancer-specific mortality [101, 130, 132, 140], no significant difference in survival was found in other series [141, 142]. Lymph node involvement is associated with a significantly poorer outcome even in patients without extrathyroid invasion.

In the series from the Mayo Clinic, bilateral cervical and mediastinal lymph node metastases were independent prognostic factors predictive of tumor recurrence and cancer-related mortality [128]. Similarly, palpable node metastases represented an independent risk factor for cancer-related death also in the experience at the Institute Gustave-Roussy [129]. We observed a 3.6% cancer-related mortality in patients with lymph node metastases at diagnosis; this value is

extremely high for a disease commonly considered to carry an excellent prognosis [30].

Other than the presence or absence of lymph node metastases, the site, size, number, and extension of metastasis beyond the lymph node capsule probably also impact on prognosis, even though these parameters have not been taken into account in most series.

Distant Metastases

The presence of distant metastases at the time of diagnosis is a negative prognostic factor in patients with either PTC or FTC. Tumor-specific mortality in patients with distant metastases varies from 36% to 47% at 5 years, rising even further to approximately 70% at 15 years [143]. Univariate analysis for distant metastases shows that younger age, well-differentiated histologic type, localization in the lung rather in the bone, the presence of small lesions, and ^{131}I-iodide uptake are associated with better prognosis. Nevertheless, in multivariate analysis extensive metastatic disease has greater prognostic impact than anatomic location (lung or bone). The best outcome is seen in younger patients with micronodular metastases responsive to radioiodine therapy that are not visible on standard x-rays [85].

Molecular Prognostic Factors

Poor outcome is associated with loss of expression of thyroid-specific differentiation genes, such as those for the TSH receptor, the Na^+/I^- symporter, thyroglobulin (Tg), and thyroperoxidase; the expression of these genes is low in poorly differentiated tumors and absent at all in ATCs [144]. Among the oncogenes involved in the pathogenesis of PTC, there are controversial evidences of the negative impact of BRAF V600E on outcome [81, 145], while no prognostic significance has been shown for RET/PTC rearrangements [146]. The copresence of BRAF V600E mutation and the mutation of TERT promoter is now recognized as the most unfavorable prognostic factor for both survival and recurrence in PTC [83]. Somatic mutations of the p53 tumor suppressor gene or overexpression of its encoded protein carry a worse prognosis for ATC, which is a highly lethal tumor [147]. The coexistence of several mutations is an even worse poor prognostic factor [148]. Similarly, overexpression of the p21 protein, which is encoded by the RAS oncogene, has been associated with more aggressive TC [149]. The above findings open new avenues to oncogene products that may constitute novel prognostic factors for thyroid tumors.

Role of Nuclear Medicine in the Management and Follow-Up of DTC After Surgery

While radionuclide imaging has a limited role in the initial diagnostic phase and preoperative staging of DTC, nuclear medicine procedures altogether (both therapy and imaging) take on important roles in the management and follow-up of patients with DTC after surgery, which is the modality of choice for primary treatment of any patient with newly diagnosed DTC. In fact, thyroid remnant ablation with ^{131}I-iodide is indicated in DTC patients with a moderate to high risk of recurrence. The major diagnostic modalities employed to follow patients with DTC treated with remnant ablation are measurement of serum Tg, ^{131}I-WBS, and neck US. In case of cancers with aggressive patterns of tumor growth, PET/CT with [^{18}F]FDG provides information which is important both from the prognostic point of view and for defining the overall burden of disease, as well as for assessing the efficacy of therapies. All these radionuclide-based procedures will be extensively presented in ▶ Chap. 42, "Radionuclide Therapy of Thyroid Tumors" of this book.

Anaplastic Thyroid Cancer

The term "anaplastic thyroid carcinoma" (ATC) includes a small subset of thyroid tumors derived from follicular cells that are however associated with poor prognosis and differ from well-differentiated follicular cell cancers for histopathologic features, biologic behavior, and

treatment. ATC is an uncommon, usually lethal malignancy of older adults that accounts for 2–3% of all TCs [150]. Although in the majority of cases it affects older adults, cases in young adults have been reported with increasing frequency. No major difference is observed in incidence between women and men. Generally, ATC is rapidly fatal with a median overall survival frequently less than 6 months after diagnosis. Long-term survivors are so rare that the diagnosis is questioned in reports that describe the few 5-year survivors [151]. An overall decline in in the incidence of ATC. Several possible explanations have been proposed to justify this decline, such as the fact that several tumors previously diagnosed as ATC have been reclassified as lymphomas or as PDTC. It is also likely that the early diagnosis and treatment of DTC has reduced the incidence of ATC by reducing the risk of dedifferentiation of DTCs into an ATC. Finally, considering that ATC is twice as common in areas with endemic goiter than in areas without, the decline in the incidence of ATC might also be due to a more efficient iodine prophylaxis. Although ATC derives from follicular thyroid cells, the typical cytological and histological features are completely lost and the thyroidal origin of the tumor is recognized only because it grows within the thyroid.

Histopathologic Features and Pathogenesis

The histologic patterns of ATC include giant-cell, spindle-cell, and squamoid-cell tumors (Fig. 9). These subtypes frequently coexist and are not predictive of patients' outcome. Areas of necrosis and hemorrhage are common, and mitotic activity is high. The paucicellular variant (which may be confused with Riedel's struma) and the carcinosarcoma variant (which includes large regions of osteosarcomatous differentiation) are two uncommon variants of ATC [151, 152].

No risk factors are known for the development of ATC, except perhaps a long-standing multinodular goiter [153]. While it is generally accepted that ATC develops from a preexisting DTC that dedifferentiates, it is also possible that it arises de novo; furthermore, it is likely that two types of ATC coexist, as suggested by different molecular features observed between pure ATCs and ATCs including areas of well-differentiated TC. The progression of DTC to ATC is documented by the simultaneous presence of BRAF V600E mutation (that is typical of almost 50% of PTC) or RAS mutation (more frequent in FTC) and the loss of the p53 tumor suppressor gene (which is involved in the control of the cell cycle and apoptosis) [148]. However, p53 mutation is very common (73%) in ATCs, and it is not necessarily associated with BRAF V600E or RAS mutation, thus suggesting that a subgroup of ATCs is likely "pure" and not deriving from DTC through a dedifferentiation process [78]. Another oncogene very frequently mutated in ATC (73%), and to a lower extent (8%) in PDTC is TERT. However, the real genomic hallmark of ATC is that when compared to PDTC and even more to DTC, ATCs show a greater number of multiple mutations, including a higher frequency of mutations in p53, TERT promoter, PI3K/AKT/mTOR pathway effectors, SWI/SNF subunits, and histone methyltransferases [148].

Clinical Presentation and Diagnosis

The clinical presentation of an ATC is usually more impressive than that of a DTC: a big and firm thyroid nodule, recently developed, is the most common presentation often associated with dysphonia or other signs/symptoms of local compression/invasion, such as dysphagia or dyspnea (Fig. 10). The common clinical history reported by patients is the rapidity of growth of a neck lesion either in the thyroid bed or in the lateral part of the neck. The average size of the mass at the time of initial diagnosis is 8 cm (maximum diameter), ranging from 3 to 15 cm [150, 154]. Regional lymph node metastases and vocal cord paralysis are present in 30–40% of the cases [154]. Systemic hematogenous metastases occur in up to 75% of the patients, the lung being the most common site (80%), followed by the bone, skin, and brain [155]. Cardiac and intra-

[150], with permission)

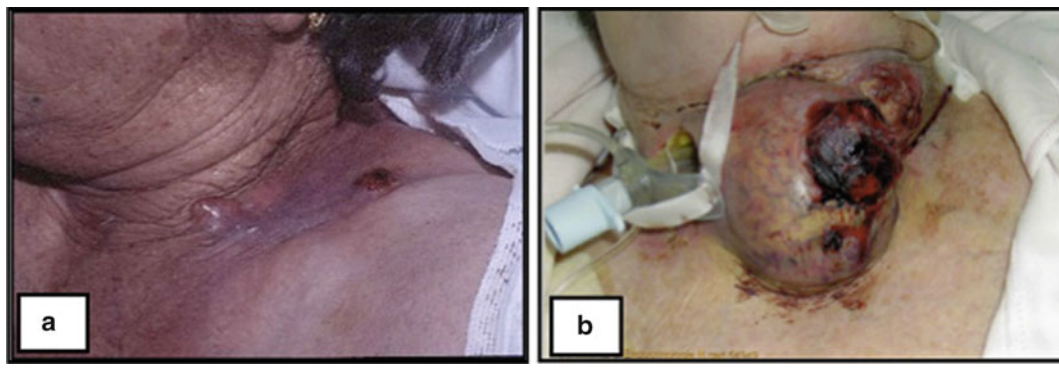

Fig. 10 Patients with very advanced anaplastic thyroid carcinoma. (**a**) Cutaneous metastases in the region of the neck. (**b**) Local infiltration requiring tracheostomy; note the lateral position of tracheostomy due to severe dislocation of the upper airways (From Chiacchio et al. [150], with permission)

abdominal metastases have also been described [155]. Death is usually related to extensive local disease with ultimate airway obstruction rather than to distant metastases. Although ATC can show some typical cytological features [156] (see Fig. 11), histologic confirmation is usually recommended, especially in order to exclude tumors with better prognosis or that require different therapy; such tumors include PDTC, MTC, primary thyroid lymphoma, poorly differentiated metastasis to the thyroid, primary squamous cell carcinoma, and angiomatoid thyroid neoplasms.

Radionuclide Imaging of ATC

ATC cells typically have lost several features of the original thyroid follicular cells, most notably their response to stimulation by TSH and the ability to concentrate iodine. Therefore, the radionuclide techniques employed for staging and monitoring patients with ATC cannot be based on the use of radioiodide. Instead, ATC cells express high levels of glucose transporters and in particular of GLUT1 and GLUT3 [157]. Therefore, PET/CT with [^{18}F]FDG PET constitutes the only radionuclide imaging technique potentially useful in ATC patients, both for initial staging and during follow-up [158–161] (see Fig. 12). On the other hand, morphologic imaging techniques such as US, CT, or MRI also play an important role for defining the local extent of disease in patients with ATC, especially to assess infiltration of the anatomic structures surrounding the thyroid.

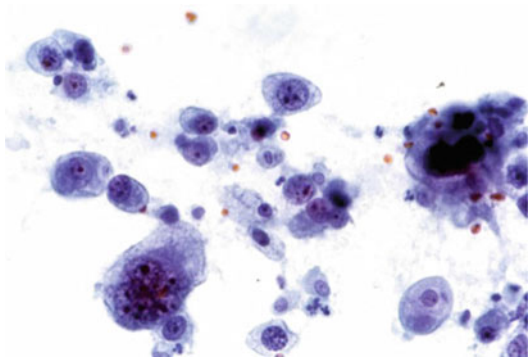

Fig. 11 Cytology from fine-needle aspiration of a thyroid nodule. Obvious abnormal pattern with clearly neoplastic cells varying in shape and size from isolated single-nucleated to giant, multinucleated cells; macronucleoli can also be seen, as well as irregular chromatin. This pattern is typical for anaplastic thyroid cancer (From Chiacchio et al. [150], with permission)

Medullary Thyroid Cancer

MTC is a well-differentiated thyroid tumor maintaining the biochemical and pathological features of the parafollicular, calcitonin-producing C cells from which it derives. Its origin makes it a separate entity from the other DTCs. The parafollicular C cells represent about 1% of all thyroid cells and are located at the basal layer of the follicle. C cells originate from the neural crest and migrate to their final location along with the ultimobranchial body, during embryonic development. There are at least four features that make the C cells a separate entity from follicular cells: (a) the peculiar distribution in the thyroid gland, which is prevalent at the junction of the upper third and the lower two-thirds and along the central vertical axis of each thyroid lobe; (b) the total growth and functional independence from TSH; (c) the inability to concentrate and retain iodide; and (d) the production and secretion of Ct, a biogenic amine which is almost exclusively produced by both normal and malignant C cells.

MTC shows macroscopically as either chalky white or red in color on cross section, with hard and firm consistency. Histologically, MTC is pleomorphic with spindle-shaped or rounded cells characteristically organized in a nested pattern (Fig. 13). Mitoses are not very frequent, nuclei are usually uniform, and the eosinophilic cytoplasm is characterized by the presence of secretory granules. Deposits of amyloid substance are frequently (60–80%) observed between the tumor cells. Sometimes an MTC is difficult to be distinguished from an ATC, or a Hürthle cell or an insular DTC, especially when pseudopapillary elements or giant cells are present. Positive immunohistochemistry for Ct is diagnostic of MTC, although positivity for chromogranin A and

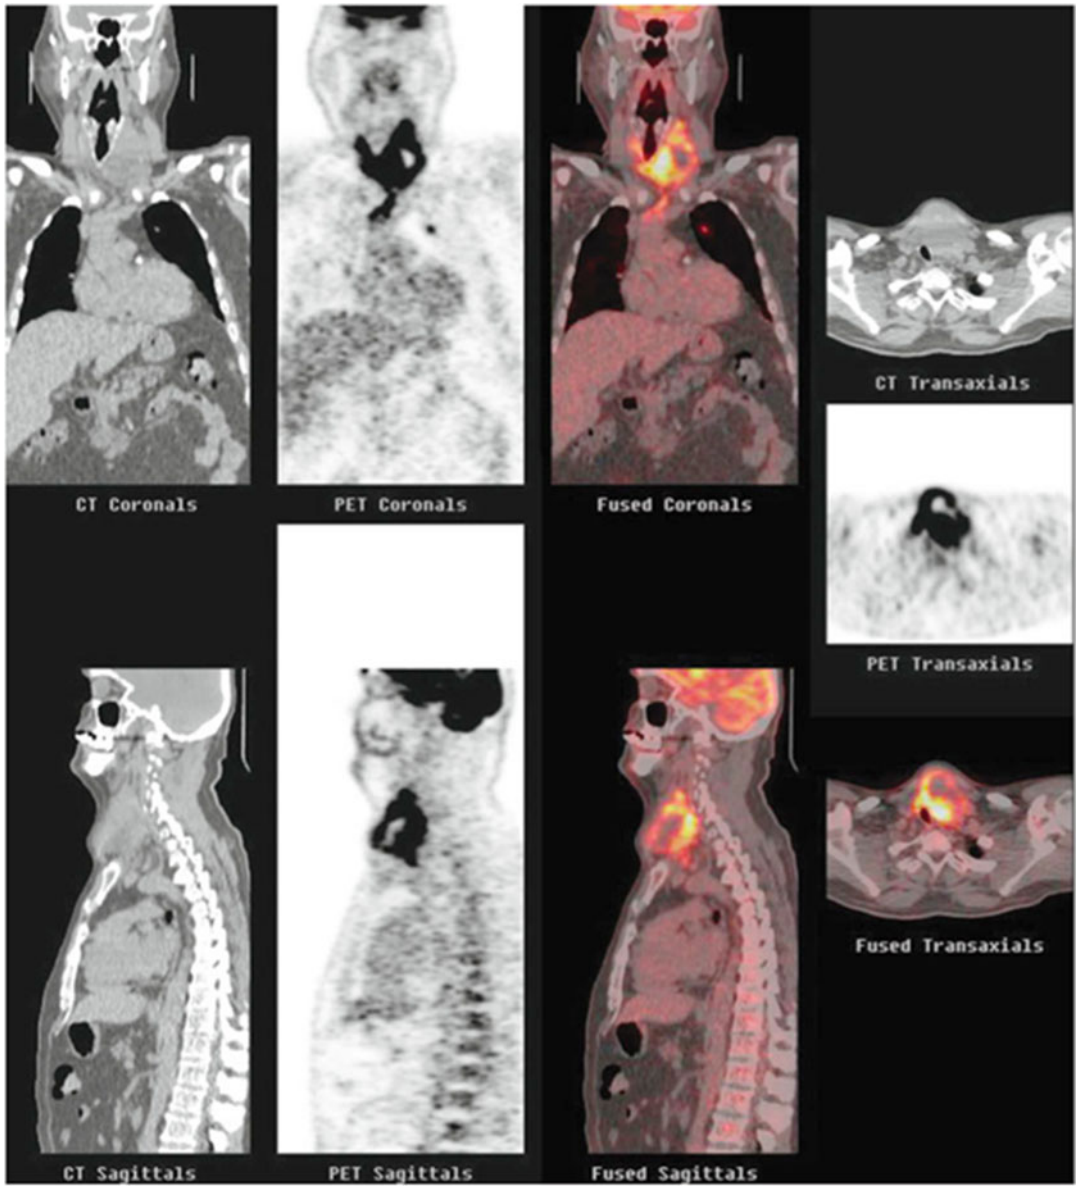

Fig. 12 [^{18}F]FDG PET/CT performed for primary staging in a patient with anaplastic thyroid cancer affecting predominantly the left lobe. Coronal, transaxial, and sagittal sections (CT, PET, and fused PET/CT) define well the local extent of disease, showing a large lesion that dislocates and restricts the trachea. A lung metastasis in the left parahilar region is also detected (Modified from Volterrani D, Erba PA, Mariani G. Fondamenti di Medicina Nucleare — Tecniche e Applicazioni. Milan: Springer, 2010, with permission from Springer Science + Business Media)

carcinoembryonic antigen (CEA) may also be useful [162]. Histopathologic description of MTC must include the number and distribution of tumoral foci as well as the simultaneous presence of C cell hyperplasia. This information is especially important also from the practical point of view, because bilaterality, multicentricity, and C cell hyperplasia are considered the histologic hallmarks of the hereditary forms [163]. No other major differences have been observed in the histologic features between the sporadic and the hereditary forms of MTC.

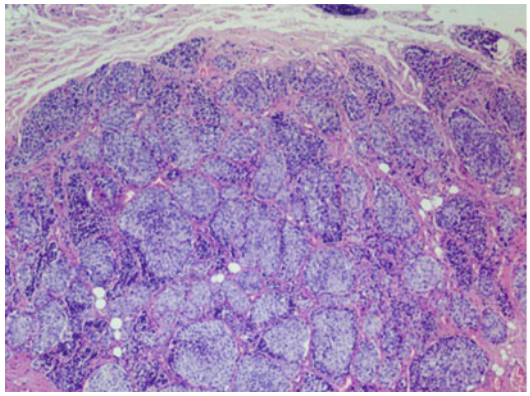

Fig. 13 Histologic pattern of medullary thyroid cancer: nests of neoplastic cells with amyloid stroma in between; immunohistochemical analysis using anti-calcitonin and/or anti-chromogranin antibodies is required to confirm the diagnosis (Courtesy of Prof. Fulvio Basolo, Division of Pathology, Department of Surgery, University of Pisa, Pisa, Italy)

The overall frequency of MTC is not well established, while its prevalence is about 5% in all thyroid malignancies, 0.4–1.4% in all thyroid nodules, and less than 1% in thyroids of subjects submitted to autopsy. Contrary to PTC and FTC, no difference in distribution between women and men is observed. Although occurring mostly in individuals in their fourth and fifth decades of life, a wide range in age at onset is present but children are affected only in the hereditary form.

The biological behavior of MTC is much less favorable when compared with that of the other DTCs, even though it is not as unfavorable as that of ATC. A 10-year survival of about 50% for patients with MTC is reported in several series, both the cure and survival of these patients being positively affected by an early diagnosis [164].
