Two different forms of MTC are recognized: the sporadic form, which accounts for about 75% of all the cases, and the hereditary or familial form, which accounts for the remaining 25% and in which MTC is only one component of a hereditary syndrome, since other endocrine glands can also be involved. The three different phenotypes, their prevalence, and the prevalence of involvement of the other glands are reported in Table 3.

No significant environmental factors or ethnical differences associated with the development of sporadic MTC have been identified, so far. Nevertheless, associations with prior thyroid diseases and other disorders such as hypertension, allergies, and gallbladder disease have been reported in a pooled analysis of epidemiological studies [165].

Table 3 Prevalence of different endocrine neoplasms and other clinical manifestations in the type II multiple endocrine neoplasia (MEN) syndromes

Syndrome	Manifestations	Prevalence (%)
MEN IIA	MTC	100
	Pheochromocytoma	40
	Parathyroid adenomas	20
	Cutaneous lichen amyloidosis	<10
MEN IIB	MTC	100
	Mucosal neuromas	100
	Marfanoid habitus	95
	Pheochromocytoma	45
Familial MTC	MTC	100

Activating single nucleotide RET point mutations are typically found in 98% of hereditary MTCs at the germinal level and in about 40% of sporadic MTCs at the somatic level [166]. Germline RET point mutations are mainly localized in exons 10–11 and 13–16, but other rare mutations have been reported also in other exons such as 5 and 8. Somatic RET mutations are mainly concentrated in exon 16, while only few cases have been reported in exons 10 and 11. Moreover, RET somatic mutation prevalence is significantly higher in bigger MTC tumors than in smaller and particularly high in advanced and progressive MTC [167]. A close correlation between genotype and phenotype has been recognized, as well as between certain point mutations and higher or lower aggressiveness of MTC [168]. Four risk levels have been suggested in the recently published "American Thyroid Association guidelines for the diagnosis and treatment of MTC" to classify the different RET mutations and to time surgical treatment of RET gene carriers [169]. Although not yet introduced in the routine clinical practice, it would be worth to know if a patient with sporadic MTC is carrying a RET somatic mutation, since the mutated cases have worse prognosis [170]; thus, a

more aggressive therapeutic strategy or a more stringent follow-up could be reserved to these patients. Moreover, all cases of apparently sporadic MTC should be screened for a germline RET mutation, since about 5–10% of them are misdiagnosed hereditary forms [166].

Role of Nuclear Medicine in the Management of MTC

Derivation of parafollicular C cells from the neural crest makes MTC a member of the so-called neuroendocrine tumors (more recently defined as "neuroendocrine neoplasms"). The molecular targets upon which radionuclide-based imaging and therapy are based are therefore different from those utilized in the diagnostic and therapeutic approach to DTC as defined above. In particular, MTC shares with other neuroendocrine neoplasms the modalities of uptake and intracellular processing of some amines, as well as expression on cell surface of receptors for some regulatory peptides, most notably somatostatin. Besides the production of the hormone Ct (which is specific for the C cells), a somewhat peculiar feature of MTC in the scenario of neuroendocrine neoplasms is that MTC cells express sizable amounts of the tumor-associated carcinoembryonic antigen (CEA) [171].

Despite high diagnostic sensitivity especially in the postoperative workup, at present the use of DMSA labeled with pentavalent technetium-99m (^{99m}Tc(V)-DMSA) as an MTC imaging agent [172, 173] is interesting only from the historical point of view, although this radiopharmaceutical is occasionally still employed as a reference in multiple agent comparative studies [174].

Based on the production of CEA by MTC cells, considerable efforts have been devoted to develop novel approaches to imaging, and possibly therapy, with the use of anti-CEA monoclonal preparations labeled with either indium-111, radioiodine [175–179], technetium-99m [180], or gallium-68 for PET imaging [181].

Furthermore, following promising results in early clinical trials [182], considerable efforts have been devoted to explore the use of monoclonal anti-CEA preparations labeled with iodine-131 for radioimmunotherapy of patients with metastatic MTC; the more recent investigations in this field adopt a pre-targeting approach rather than the direct use of the radiolabeled monoclonal preparation per se [183–186].

Nevertheless, the most intensely investigated nuclear medicine applications for the management of patients with MTC, from both the imaging and the therapeutic viewpoints, are based on two biological features expressed by several types of neuroendocrine neoplasms, namely, the ability to take up and concentrate biological amines and the enhanced expression of membrane-associated receptors for a variety of biological peptides, most notably somatostatin. The first feature is the basis for tumor targeting with radioiodinated MIBG for either imaging purposes and/or therapeutic purposes [187–191] and for PET imaging with ^{18}F-DOPA [192, 193]. The second feature (expression of receptors for regulatory peptides) constitutes the basis for either single-photon [194–196] or PET imaging [193] as well as for possible therapy using properly designed and radiolabeled somatostatin analogues [197, 198].

The issues pertaining to radionuclide imaging and therapy of MTC as a neuroendocrine neoplasm will be discussed more extensively in ▶ Chaps. 29, "Diagnostic Applications of Nuclear Medicine: Neuroendocrine Tumors", and ▶ 43, "Neuroendocrine Tumors: Therapy with Radiolabeled Peptides" of this book. As in the case of other neuroendocrine neoplasms with a somewhat indolent pattern of tumor growth, the diagnostic performance of the most widely used PET tracer in oncology, [^{18}F]FDG, is suboptimal in patients with MTC, unless the disease progresses toward a more aggressive pattern of tumor growth. Therefore, the first-line approach to radionuclide imaging for these tumors is represented by the use of radiopharmaceuticals addressing the specific neuroendocrine features mentioned above rather than by the use of [^{18}F]FDG. Conversely, as neuroendocrine neoplasms take on a biologically aggressive pattern of growth, they tend to lose some of the biological features specific of the tumor of origin; in these cases, PET

with [^{18}F]FDG performs better than imaging with the more neuroendocrine-specific tracers. The examples reported in Figs. 14, 15, 16, and 17 have been chosen to epitomize this variable imaging pattern.

Other Thyroid Cancers

This category comprises a group of extremely rare primary thyroid tumors that include epithelial carcinomas (i.e., mucinous, squamous cell and mucoepidermoid carcinomas, characterized by the presence of keratin- and mucin-producing cells), as well as non-epithelial tumors (e.g., malignant lymphoma) and tumors arising from mesenchymal elements such as sarcomas. On the other hand, the thyroid can be the site of metastasis of cancers originating in other organs, such as the lung, kidney, and breast cancers [199, 200]. Sometimes it can be difficult to distinguish if the thyroid lesion is a primary tumor or a metastasis of another tumor originating in another organ. However, nowadays the molecular profiles of several human tumors are known and their specificity can enable to clearly identify the origin of the tumor [201].

Concerning the primary thyroid tumors, squamous cell thyroid carcinoma should be distinguished both from local involvement caused by a primary squamous cell carcinoma of the neck and from an ATC containing squamous components [202]. Mucinous carcinoma of the thyroid is similar to mucinous carcinomas originating at other sites, and areas of PTC or FTC are not evident. In the case of mucinous adenocarcinoma, the first option to consider is the possibility of secondary thyroid involvement from a tumor originating at another site, since primary thyroid mucinous adenocarcinomas are extremely rare (only six cases reported in literature) [203]. Mucoepidermoid carcinoma most commonly

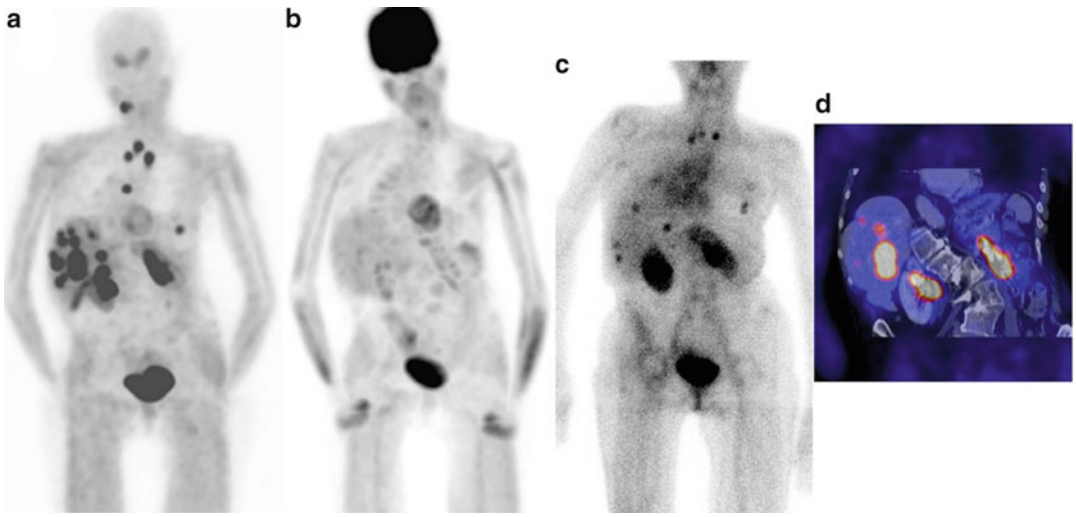

Fig. 14 Imaging with different radiopharmaceuticals in a 68-year-old patient with a MEN 2a-related metastatic MTC; serum calcitonin was 27,190 ng/L and CEA 1,460 μg/L. (**a**) ^{18}F-DOPA PET (anterior MIP) shows lesions located in the neck, upper mediastinum, left thorax, liver, and skeleton. (**b**) [^{18}F]FDG PET (anterior MIP) shows only physiologic uptake but no tumor lesions. (**c**) Whole-body ^{99m}Tc(V)-DMSA (anterior view) shows lesions in upper mediastinum, left thorax, liver, and skeleton, although with much smaller number of lesions than detected by ^{18}F-DOPA PET. (**d**) ^{18}F-DOPA PET/CT coronal fusion slice shows liver lesions (Reproduced from Koopmans KP, de Groot JWB, Plukker JTM, de Vries EGE, Kema IP, Sluiter WJ, et al. ^{18}F-Dihydroxyphenylalanine PET in patients with biochemical evidence of medullary thyroid cancer: relation to tumor differentiation. J Nucl Med. 2008;49:524–31 (permission requested))

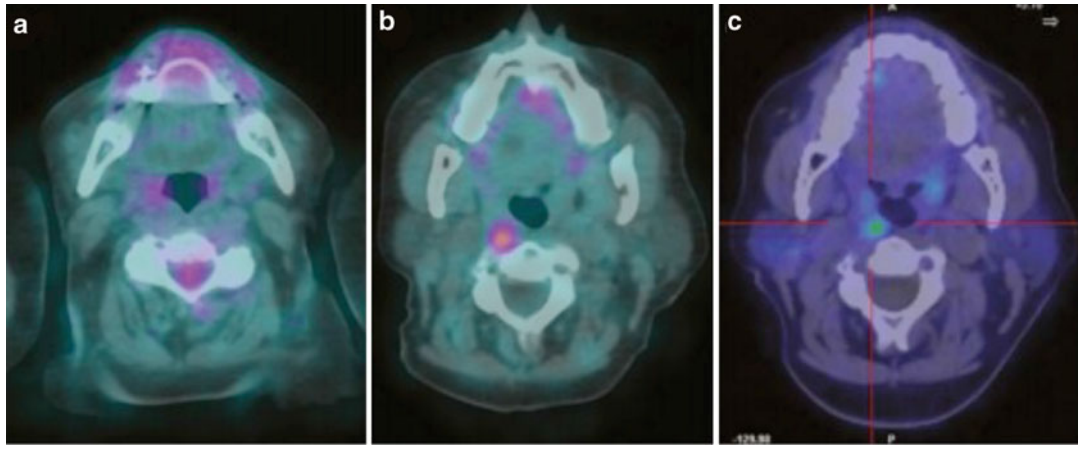

Fig. 15 PET/CT (axial fused images) with [^{18}F]FDG (**a**), ^{18}F-DOPA (**b**), and ^{68}Ga-somatostatin analogue in a 62-year-old patient with rising Ct and CEA levels after surgery for MTC. Increased uptake in a right retropharyngeal lymph node is clearly visible on both the ^{18}F-DOPA and ^{68}Ga-somatostatin analogue scans, but not in the [^{18}F]FDG scan. Recurrent MTC in the lymph node was confirmed by FNAC (Reproduced with permission from Treglia G, Castaldi P, Villani MF, Perotti G, de Waure C, Filice A, et al. Comparison of ^{18}F-DOPA, ^{18}F-FDG and ^{68}Ga-somatostatin analogue PET/CT in patients with recurrent medullary thyroid carcinoma. Eur J Nucl Med Mol Imaging. 2012;39:569–80)

occurs in the salivary glands and shows ductal structures lined with ciliated columnar cells with low-grade malignant potential [204]. Its origin remains unclear, as it can arise from solid cell nests of the ultimobranchial apparatus or from the follicular thyroid epithelium [205]. Malignant mesenchymoma of the thyroid is extremely rare, and it can show chondrosarcomatous, osteosarcomatous, fibrosarcomatous, and rhabdomyosarcomatous patterns. These histologic subtypes are high-grade malignant tumors with poor prognosis [206]. Sarcomas of the thyroid are similar as those arising in other organs, and it is often difficult (if not just impossible) to distinguish a primary thyroid sarcoma from the ATC variant with sarcomatous differentiation.

Malignant lymphomas of the thyroid account for 1–5% of all thyroid malignancies and less than 2% of extranodal lymphomas; they can constitute the only manifestation of the disease or be part of systemic disease [207]. Thyroid lymphomas are almost exclusively derived from B cells of mucosa-associated lymphoid tissue (MALT) [208] and frequently coexist with autoimmune thyroiditis; as for other localizations, optimal imaging of thyroid lymphomas is based on [^{18}F] FDG PET (Fig. 18). Peripheral T-cell lymphoma or primary plasmacytomas of the thyroid are uncommon. Combined chemo-radiation therapy is recommended for all diffuse B-cell or mixed lymphomas. Single-modality therapy with surgery or EBRT alone may be considered for early-stage intrathyroidal MALT lymphomas [209].

Primary paraganglioma of the thyroid is a very rare neuroendocrine tumor the histologic diagnosis of which can be very difficult, as it requires differential diagnosis with the hyalinizing trabecular adenoma and with MTC. The prognosis is favorable with complete surgical excision [210].

Clinically obvious, secondary metastatic carcinomas account for 2–3% of malignant tumors of the thyroid; thyroid involvement does not per se modify overall prognosis of these patients. The occurrence of thyroidal metastases from other primary tumors, mainly from the renal, lung, breast, and colon carcinomas [199–201], is instead much more frequent on autopsy-based surveys, although varying between 1.2% and 24% for different cancers [211]; nevertheless, this condition is usually devoid of any thyroid-specific symptoms. If the thyroid represents the only site of metastasis (as it can be observed especially in patients with clear cell renal carcinoma), total thyroidectomy is recommended.

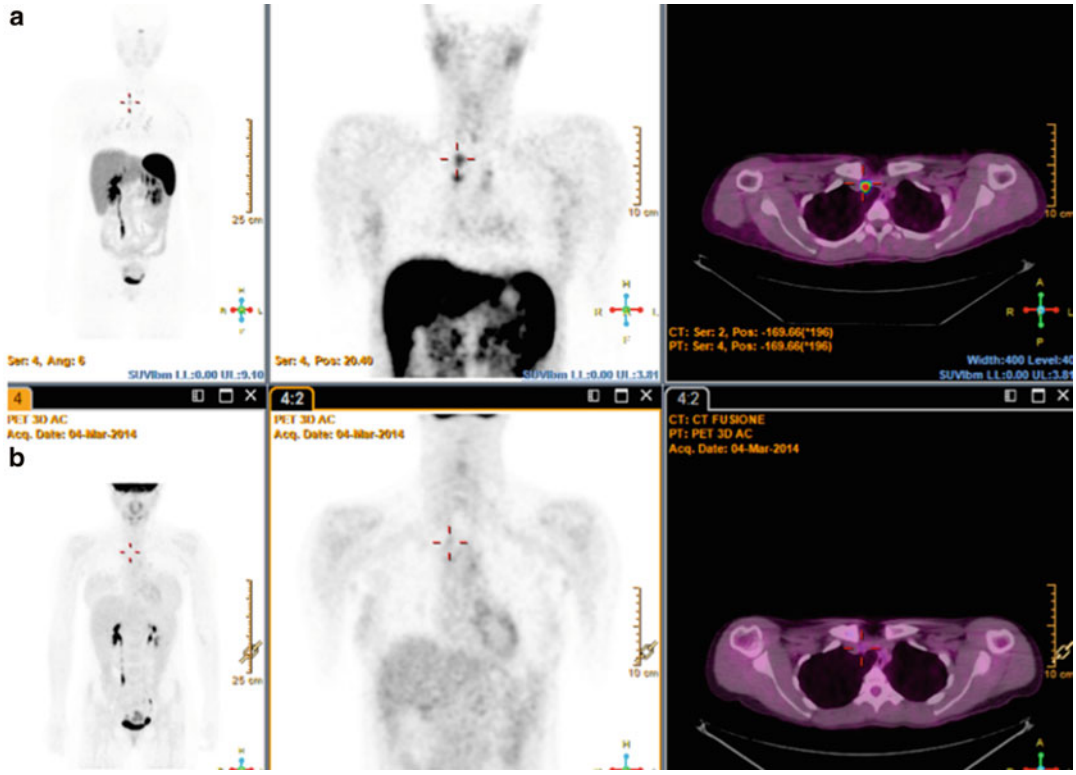

Fig. 16 PET/CT with ^{68}Ga-DOTA-TOC (**a**) and with [^{18}F]FDG (**b**) in a patient previously treated with thyroidectomy because of MTC; MIP image in the *left panel*, coronal PET slice in the *center panel*, axial fused PET/CT slice in the *right panel*. Recurrence of disease was suspected on the basis of slowly rising serum Ct levels. Metastatic disease in mediastinal lymph nodes is clearly depicted by frankly increased uptake of ^{68}Ga-DOTA-TOC, while there is only faint uptake of the glycometabolic tracer [^{18}F]FDG (Supplied by courtesy of Dr. Annibale Versari, Nuclear Medicine Service, "Arcispedale S. Maria Nuova", Reggio Emilia, Italy)

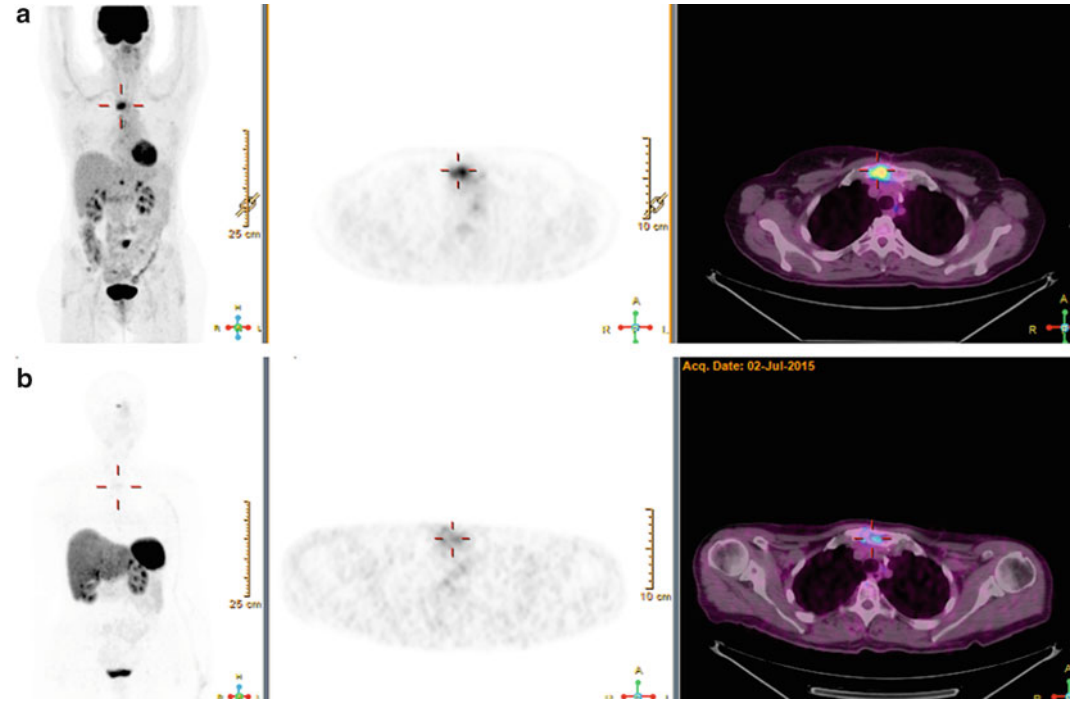

Fig. 17 PET/CT with [^{18}F]FDG (**a**) and with ^{68}Ga-DOTA-TOC (**b**) in a patient previously treated with thyroidectomy because of MTC; MIP image in the *left panel*, coronal PET slice in the *center panel*, axial fused PET/CT slice in the *right panel*. Early after surgery recurrence of disease was suspected on the basis of steeply rising serum Ct levels and painful sternal lesion. Metastatic bone disease in the sternum is clearly depicted by frankly increased uptake of the glycometabolic tracer [^{18}F]FDG, while there is only faint uptake of ^{68}Ga-DOTA-TOC (Supplied by courtesy of Dr. Annibale Versari, Nuclear Medicine Service, "Arcispedale S. Maria Nuova", Reggio Emilia, Italy)

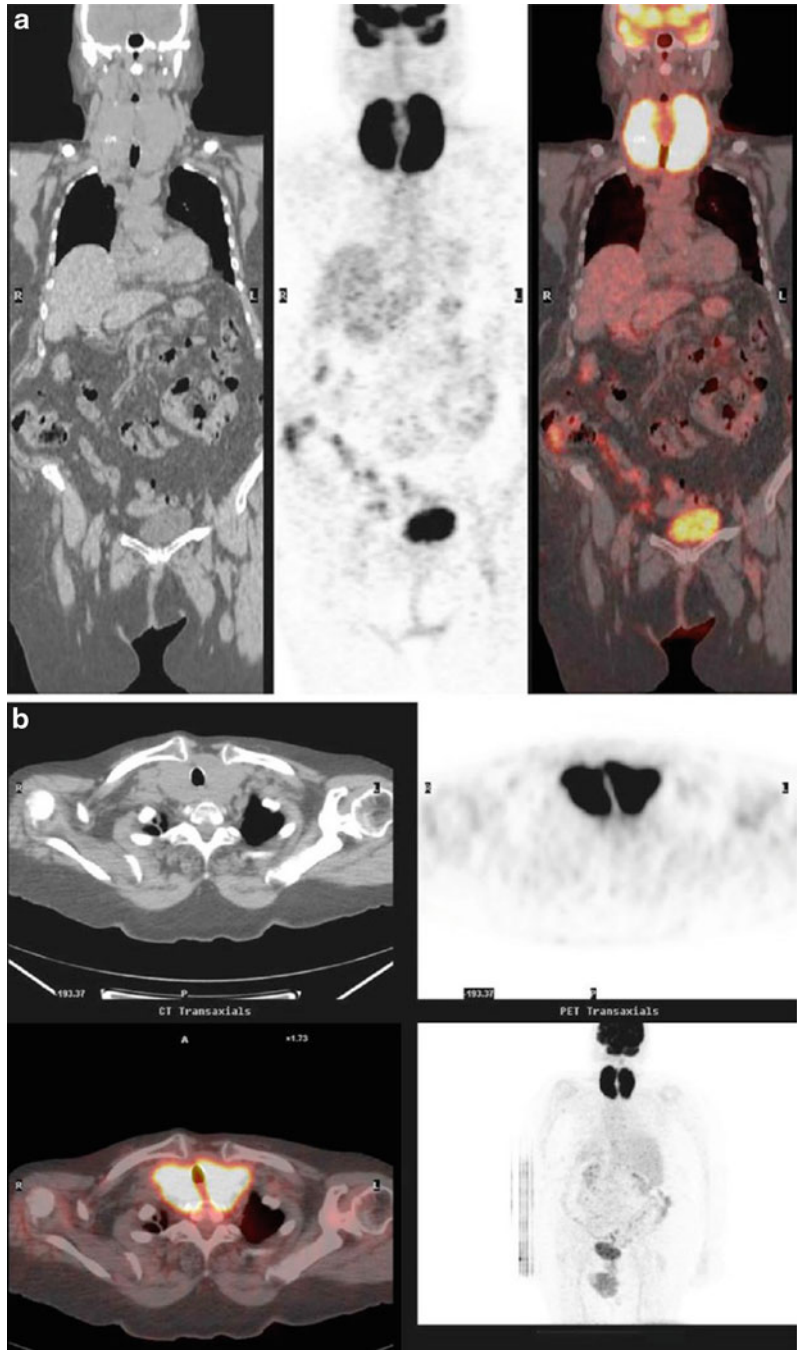

Fig. 18 PET/CT with [^{18}F]FDG in an 87-year-old patient with thyroid B-cell lymphoma as the sole site of disease (primary thyroid lymphoma). (**a**) Coronal CT (*left panel*), PET (*center panel*), and fused imaging sections (*right panel*), showing diffuse involvement and marked enlargement of the entire thyroid gland that extends from the upper cervical region to the upper mediastinum. (**b**) Transaxial CT (*upper left panel*), PET (*upper right panel*), and fused imaging (*lower left panel*), at the level of lower neck (the clavicles are clearly identified); the MIP image is shown in the *lower right panel*. Virtually all the trachea is surrounded by the abnormal tissue, with initial lumen constriction

Diagnostic Applications of Nuclear Medicine: Parathyroid Tumors

20

Federica Guidoccio, Sara Mazzarri, Salvatore Mazzeo, and Giuliano Mariani

Abstract

The most common causes of hyperparathyroidism (HPTH) are of a benign nature, for either primary or secondary HPTH (as well as the tertiary form). Diagnosis of HPTH is based on clinical and biochemical findings, without any role for diagnostic imaging per se. Imaging is instead important for characterizing the disease, regarding especially number and sites of the hyperfunctioning parathyroid glands, which can be in their classical anatomic location or in ectopic locations. This information is crucial for planning surgery with a minimally invasive approach, associated or not with intraoperative guidance with the help of a handheld gamma-detecting probe – an approach that is common to other applications of radioguided surgery.

In addition to high-resolution ultrasound (US) and Magnetic resonance imaging (MRI) (and ceCT for selected applications), SPECT/CT with ^{99m}Tc-sestamibi has excellent performance for preoperative imaging of hyperfunctioning parathyroid glands. The PET tracer [^{11}C]methionine has also been shown to possess excellent localization properties in patients with HPTH.

Parathyroid carcinoma is a very rare endocrine malignancy that occurs in <1% of primary HPTH. The initial clinical manifestations of parathyroid carcinoma are primarily linked to the effects of markedly elevated serum PTH levels. At initial presentation, very few patients have metastasis at regional lymph nodes or at distant sites. Parathyroid carcinoma tends to infiltrate adjacent structures in the neck. US, CT, and MRI have been used to localize parathyroid carcinomas and to detect mediastinal and thoracic recurrences or distant metastases. ^{99m}Tc-sestamibi scintigraphy can be successful for preoperative localization of the neoplasia and can identify metastases in lymph nodes and at distant sites. PET with [^{18}F]FDG can also detect metastatic parathyroid cancers. Parathyroid carcinoma recurs in more than 50% of the cases and imaging studies should be performed in all patients before reoperation.

Anatomy, Physiology, and Pathophysiology

There are normally two pairs of parathyroid glands in adult humans, each one measuring approximately 6 × 4 × 2 mm and weighing 30–50 mg (for a total weight of approximately 130–140 mg). Supernumerary parathyroid glands can be found in 2–5% of the general population, while it is very rare to find less than four glands. The parathyroid glands are endodermal in nature and originate embryologically from the third and fourth pharyngeal pouches. From the point of view of their final anatomical location, it is important to notice that their relative position is inverted during their migration in fetal life (Fig. 1). In fact, the two glands that are originally positioned more cranially (in the third pharyngeal pouch) follow in part the descent of the thymus, to reach their final location at the posterolateral surface of the lower lobes of the thyroid; nevertheless, they can also detach from their connection to the thymus and remain located somewhere along their path of descent. The glands that are originally positioned in the fourth pharyngeal pouch (more caudally) are instead closely associated with the embryologic

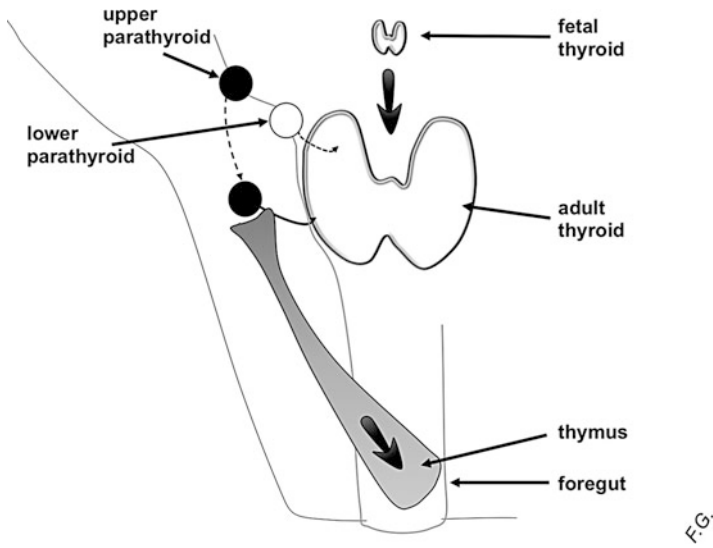

Fig. 1 Embryological origin and routes of descent of the thymus and parathyroid glands during fetal life. The parathyroid glands that originate more cranially (in the third pharyngeal pouch) migrate initially in association with the thymus, to reach their final position more caudally with respect to the parathyroid glands that originate in a lower location (fourth pharyngeal pouch). Therefore, the lower parathyroid glands follow a much longer path of descent, a feature that probably explains the greater frequency of ectopic location in adult life of these glands with respect to the upper parathyroid glands (Modified from: Sadler [171])

structure of the thyroid gland; they maintain a close association with the fetal thyroid until the descent of both structures to their final location in the neck. These parathyroid glands are positioned at the posterolateral surface of the upper poles of the thyroid lobes. The most frequent anatomo-topographic location of the upper glands is posterior to the middle and upper third of the thyroid lobe, cranially to the inferior thyroid artery and posterior to the recurrent laryngeal nerves. The inferior parathyroid glands are located in a more variable position, most likely due to their more complicated pattern of migration from and initial cranial position to a final caudal position [1]. From the surgical point of view, in approximately 50% of the cases, the lower parathyroid glands are located posteriorly or laterally to the lower pole of the thyroid lobe, within a 20 cm radius. Other less frequent locations include within the thyrothymic ligament, within the thymus in the mediastinum, or intrathyroidal [2] (Fig. 2). Enlarged adenomatous or hyperplastic parathyroid glands may change somewhat their location.

The predominant type of cells that constitute adult parathyroid tissue is constituted by the so-called chief cells, followed by the oxyphilic cells (whose histologic appearance is linked to their abundance in mitochondria) and by the intermediate stage of transitional oxyphilic cells [3]. The parathyroid hormone (PTH) acts on different tissues and apparatuses with multifaceted functions, the combined effect of which is to increase calcium concentration in blood. In order to achieve this effect, PTH stimulates bone resorption (thereby mobilizing calcium from bone to circulating fluids) and promotes calcium resorption in the kidneys; at the same time, it decreases tubular resorption of phosphate. Moreover, PTH stimulates the synthesis of the active form of vitamin D, which in turn stimulates calcium absorption in the gastrointestinal tract [4].

Benign Causes of Hyperparathyroidism

Primary hyperparathyroidism (*HPTH*) is characterized by inappropriate PTH production, i.e., not as a response to reduced calcium concentration in circulating blood as it would be the physiologic function of the parathyroid glands; therefore, this inappropriate PTH secretion results in

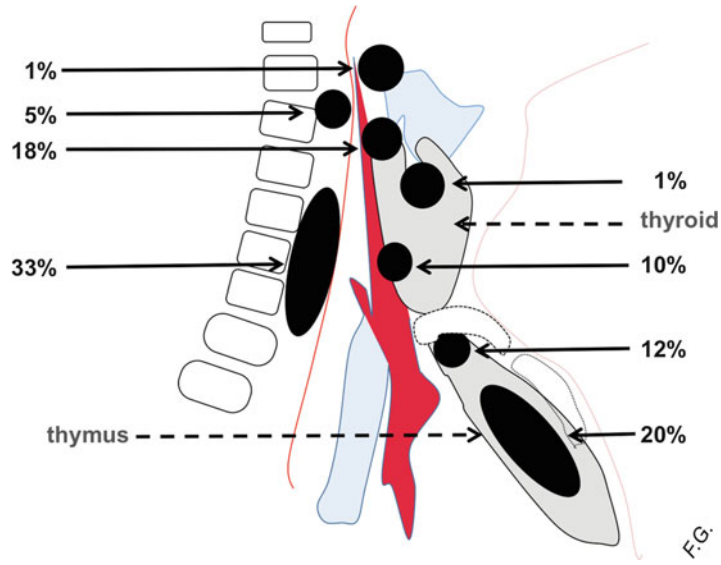

Fig. 2 Diagrammatic representation of the variability in anatomic location of hyperfunctioning parathyroid glands. This data refers to a total of 104 adenomas found at reoperation over a quite long time span (1930–1975) at the Massachusetts General Hospital (Harvard Medical School, Boston, MA); patients underwent second surgery because of recurrent PHPT after prior conventional four-gland exploration surgery. About 65% of all ectopic locations mirror the route of descent of the lower parathyroid glands (longer migration path) (Modified from: Wang [172])

hypercalcemia [5]. The causes of primary HPTH are either a single parathyroid adenoma (80–85% of the cases), hyperplasia or multiple adenomas (10–15% of the cases), or parathyroid carcinoma (0.5–1% of the cases) [6]. Familial forms of primary HPTH include multiple endocrine neoplasia type I (MEN I) and type II (MEN II), the HPTH-jaw tumor syndrome, familial hypocalciuric hypercalcemia, and familial isolated HPTH [7].

The characteristic abnormality in hyperparathyroidism is the downregulated response of parathyroid cells to reduce PTH secretion in response to elevated calcium. In vitro and in vivo studies have focused on the receptor for calcium ions expressed by parathyroid cells (CaR) to explore the role of the calcium sensor in the development of hyperparathyroidism. Abnormalities in CaR expression or function as a consequence of some as yet unidentified genetic mutation(s) may contribute to the failure of PTH secretory regulation [4].

Also genetically linked variations of vitamin D metabolism can be associated with some forms of hyperparathyroidism. In fact, some allelic variants of vitamin D receptors (VDR) are overexpressed in patients with PHPT, combined with a reduced expression of VDR mRNA; as a consequence, the parathyroid cells are less susceptible to inhibition by active vitamin D, a condition that favors hyperplastic or adenomatous changes [4, 8, 9].

Prior irradiation of the neck and upper chest for benign diseases, including treatment of Grave's disease with ^{131}I-iodide, is an additional risk factor for the development of HPTH [10, 11]. Interestingly, this association has not been demonstrated after treatment with radioiodide for thyroid cancer, a condition that is usually treated with much greater amounts of radioactivity than Graves' disease. The genetic alterations found in radiation-associated parathyroid tumors most commonly involve losses in 11q and 1p, similarly as in parathyroid adenomas linked to MEN-1 gene abnormalities; these observations suggest a certain degree of vulnerability of this gene to irradiation.

Secondary HPTH is the result of long-standing hypocalcemia, as a physiologic or pathophysiologic parathyroid response to maintain calcium homeostasis. The most frequent cause of secondary HPTH is chronic renal failure, developing in about 90% of the patients undergoing hemodialysis [12, 13]. Other causes of secondary HPTH include osteomalacia, rickets, and malabsorption.

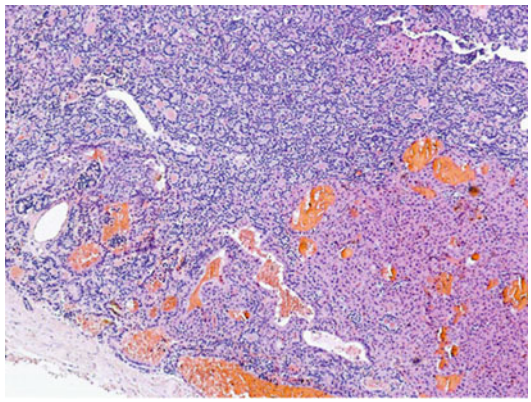

Fig. 3 Histologic pattern of a parathyroid adenoma (low magnification): nests of densely packed cells arranged in follicular and colloid-like structures mimicking the thyroid; scattered lymphocytic infiltrates are also present (Courtesy of Prof. Fulvio Basolo, Division of Pathology, Department of Surgery, University of Pisa, Pisa, Italy)

Tertiary HPTH is referred to the condition of persisting HPTH after successfully treating the cause of a secondary form of HPTH, as it can happen following, e.g., correction of chronic renal failure with kidney transplantation. Tertiary HPTH is usually sustained by hyperplasia of all four glands, but in over 20% of the patients, single or double adenomas are present [12].

Parathyroid adenomas include several histologic patterns, the most frequent of which are the oncocytic variant (constituted of cells with abundant granular eosinophilic cytoplasm) (Fig. 3), the lipoadenoma variant (composed of abundant stromal cells), and the water-clear cell variant. These variants represent clonal expansions, and several molecular abnormalities have been described such as rearrangement of the cyclin-D1/PRAD1 oncogene and mutation of the tumor suppressor MEN1 gene (11q13). Loss of the chromosome 11q locus is the most frequent abnormality found in parathyroid adenomas [14, 15].

Diagnosis and Treatment of Benign Hyperparathyroidism

Besides hypercalcemia, manifestations of symptomatic primary HPTH include overt bone disease, kidney disease, as well as nonspecific gastrointestinal, cardiovascular, and neuromuscular dysfunction. The main renal manifestations include nephrolithiasis (due to hypercalciuria), nephrocalcinosis, and renal dysfunction. Bone disease includes osteopenia (with pathologic fractures) and osteitis fibrosa cystica, while altered neurologic function can manifest with obtundation and delirium [16]. Nevertheless, over 80% of the cases of primary HPTH are today asymptomatic, being only discovered during general check-up evaluations (that now routinely include measurement of the serum calcium levels); there are no clinical factors that predict prognosis of these patients [17, 18]. Diagnosis of primary HPTH is based on persistent hypercalcemia and elevated serum PTH levels. Serum phosphorus is typically low, due to decreased resorption in the kidneys.

Secondary HPTH is characterized by hypocalcemia or normocalcemia (despite increased serum PTH levels) and hyperphosphatemia, associated with decreased vitamin D levels [12]. In tertiary HPTH, there are normal or elevated serum calcium concentrations in combination with moderately elevated PTH levels, decreased vitamin D and phosphate levels, and elevated alkaline phosphatase [12].

Currently, the only promising medical therapy available for primary HPTH is based on the use of the drug "cinacalcet" [19, 20], a novel member of the family of calcimimetics; its mechanism of action is based on direct modulation of the CaR expressed by the chief parathyroid cells, thereby the drug increases the sensitivity of the calcium sensor to extracellular calcium and thus reduces the secretion of PTH [21–23]. Management of patients with secondary HPTH is predominantly medical, and it includes calcitriol, vitamin D, calcimimetics (such as cinacalcet and new phosphate binders) [24, 25]. In tertiary HPTH, medical treatment is generally not indicated, although supplementation with vitamin D can be beneficial.

About 1–2% of patients with secondary HPTH require parathyroidectomy because of calciphylaxis, failure of medical management of hypercalcemia, hypercalciuria, serum PTH >800 pg/mL, hyperphosphatemia (with "calcium × phosphorus" product greater than 70), and associated symptoms [26, 27]. The main

form of treatment for tertiary HPTH is surgery, which is indicated in case of severe or persistent hypercalcemia, severe osteopenia, and clinical symptoms [28].

Complete resection of any hyperfunctioning parathyroid tissue is crucial for surgical treatment with curative intents. Persistent or recurrent HPTH generally results from inadequate initial resection and/or from the presence of an ectopic hyperfunctioning gland that had not been recognized at surgery; this condition requires reoperation. Bilateral neck exploration, based on surgical visualization of all four parathyroid glands, achieves a high success rate with minimal morbidity, if performed by experienced endocrine surgeons [29]. During parathyroid surgery, distinguishing an adenoma from hyperplasia can be problematic, not only on visual analysis but also upon intraoperative frozen section histology.

Preoperative imaging techniques play an important role in the surgical management of patients with HPTH, in order to localize and identify abnormal glands [30]. This approach has been crucial for the development of minimally invasive parathyroidectomy [31, 32], a procedure that can be video-assisted, endoscopic, radioguided, or image-guided unilateral exploration [33–35]. Several imaging techniques are available for preoperative localization of hyperfunctioning parathyroid glands, as detailed further below.

Persistent and Recurrent Hyperparathyroidism

In 5–10% of patients who undergo surgery for primary HPTH, persistent or recurrent HPTH can occur. Hyperparathyroidism presenting after a period of >6 months of normocalcemia following surgery is defined as "recurrent hyperparathyroidism" and is usually linked to regrowth of the remaining parathyroid tissue.

Causes of the immediate failure of surgical treatment failure (inducing persistent HPTH) include inaccurate/incomplete localization of adenoma(s), the insufficient resection of easily recognized multigland disease, and (even though a rare occurrence) the presence of metastatic parathyroid carcinoma. Persistent HPTH is characterized by abnormalities in calcium metabolism in the immediate postoperative period. Surgical failure may be due to either inexperience of the surgeon or interpretation errors during intraoperative frozen section histology. Persistent HPTH is more frequent in patients with familial forms of hyperparathyroidism, especially the MEN-1 syndrome (generally in less than 25% of patients, but up to 40–60% for less-experienced surgeons [36].

Another rare situation of recurrent or persistent hyperparathyroidism is called "parathyromatosis" which is defined as multiple remnants of hyperfunctioning parathyroid tissue scattered throughout the neck or upper mediastinum. This condition may be due either to growth of nests of parathyroid tissue left along the route of descent during embryologic development of the parathyroid glands or to accidental implantation of parathyroid tissue in the surgical bed at the time of parathyroidectomy.

Role of Preoperative Imaging

Preoperative imaging of the parathyroid glands is important to identify the parathyroid glands that are enlarged/hyperfunctioning because of hyperplasia and/or adenoma. Visualization of normal parathyroid glands using conventional imaging is virtually impossible; because of their tissue characteristics and small size and weight (less than 40 mg), they cannot be distinguished from the adjacent thyroid parenchyma. Adequate presurgical imaging not only reduces the surgical time by limiting surgical exploration to the affected side but, above all, allows the detection of parathyroid adenomas in ectopic sites. While approximately 80–85% of parathyroid adenomas are found in their normal location adjacent to the thyroid gland, 15–20% are ectopic [37]; when parathyroid adenomas are located in the mediastinum, into the thyroid gland, in or lateral to the cervical neurovascular bundle, or high in the neck, the term "major ectopy" is employed to describe the condition. Overall ectopic locations include:

- Anterior–superior mediastinum (either within the thymus or in a juxta-thymic position)
- Posterior–superior mediastinum along the esophagus
- Lower thyroid lobe (2–3% of all parathyroid adenomas)
- The middle mediastinum (very rarely)

Other ectopic locations include the carotid sheath (within or even lateral to this anatomic structure), while an undescended lower parathyroid gland is rarely found in the upper neck, anterior to the carotid bifurcation.

Hyperplasia and adenoma(s) of parathyroid glands produce increased cellularity, increased metabolic activity, and increased arterial vascular supply. These features are the basis for visualization using different imaging approaches. Imaging protocol for hyperplastic/adenomatous parathyroid glands usually consists of high-resolution ultrasound, radionuclide imaging, contrast-enhanced computed tomography (CT), and magnetic resonance imaging (MRI) [30, 38–40], used in variable combinations depending on certain patient-specific features as well as on local availability, logistics, cost, and radiation dosimetry considerations. In a recent review [39], the most frequently cited average values of sensitivity for correct localization of the adenoma are 76.1% (95% CI 70.4–81.4%) for ultrasound examination, 78.9% (70.4–90.6%) for scintigraphy with ^{99m}Tc-sestamibi, and 89.4% for CT. The corresponding average positive predictive values are 93.2% (95% CI 90.7–95.3%) for ultrasound, 90.7% (83.5–96%) for scintigraphy, and 93.5% for CT.

Non-radionuclide Imaging Techniques

High-resolution ultrasound (*US*) currently constitutes, in association with nuclear medicine imaging, a reliable first-line modality for preoperative localization of a parathyroid lesion. The main advantages of US are low cost, wide availability, and the noninvasive nature of the technique; furthermore, US has an important role to select patients for other imaging modalities (for instance, in case of negative US studies due to ectopic parathyroid glands located in deep cervical sites or in the mediastinum).

Optimal parameters for best diagnostic performance of US include the use of a high-frequency (7.5–13 MHz) linear array probe. The entire region of the neck including the thyroid gland, the paratracheal groves, and the carotid–jugular axis from the carotid bifurcation superiorly to the sternal notch inferiorly should be carefully explored by transverse and longitudinal scans. In patients with a large thyroid goiter and/or when the thyroid gland is partially plunging in the upper mediastinum, the use of a lower frequency US probe, with deeper penetration, can be helpful to explore the neck. The patient is lying supine and with the neck hyperextended during the US scan; right or left lateral rotation of the head is useful to better visualize the deep sites of the neck, in particular the paraesophageal or paravertebral regions (possible sites of an ectopic parathyroid adenoma/mass) are better visualized with right or left lateral rotation of the head.

A parathyroid mass typically appears on gray-scale US imaging as a rather homogeneous hypoechoic mass adjacent and posterior to the thyroid gland (Fig. 4). Topographically, the mass is usually located anteriorly to the longus colli muscles, medially to the common carotid artery; occasionally the mass is located more inferiorly in the paratracheal and paraesophageal groves. It is not infrequent to detect a clear hyperechoic interface line separating the thyroid gland from the parathyroid lesion (Fig. 5). Structure of an adenomatous/hyperplasic parathyroid gland is mostly frequently constituted by a hypercellular tissue with absent or scarce fluid or stromal components, a feature that explains the hypoechoic pattern of these lesions. Nevertheless, fatty deposition and/or internal calcifications occasionally occur in adenomas, causing the appearance of nontypical inhomogeneous echographic patterns, some of which are characterized by lobulation and/or cystic changes.

On the other hand, it is difficult in most instances to distinguish the US pattern of a hyperplasic parathyroid gland from that of a parathyroid and adenoma. In general, hyperplasic parathyroid glands most frequently have a spherical shape than adenomas and occasionally contain intraparenchymal

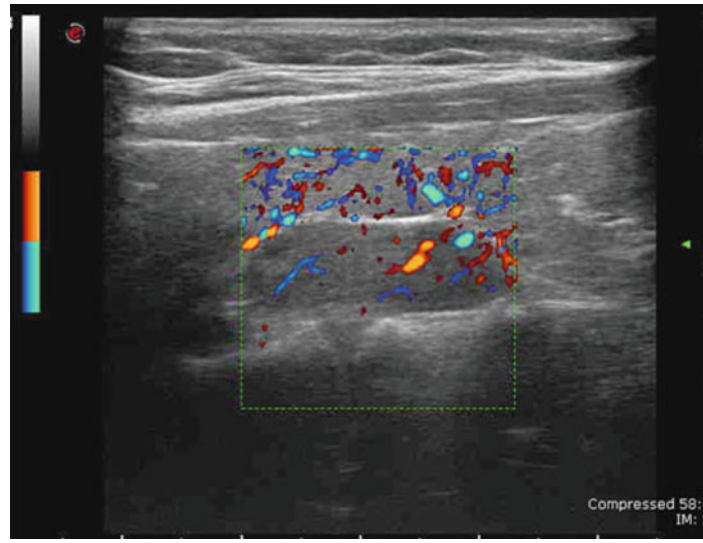

Fig. 4 Ultrasound pattern of a parathyroid adenoma located behind the right thyroid. The thyroid parenchyma is well recognized in the middle part of the image, just below the superficial layers (skin and subcutaneous muscle). The parathyroid adenoma is located just beneath the thyroid tissue, well separated by a hyperechoic capsule and appearing slightly hypoechoic with respect to the thyroid parenchyma; color Doppler evaluation reveals some hypervascularization within the parathyroid adenoma

calcifications. Furthermore, when multiple parathyroid glands are involved in a patient with chronic renal failure, it is easy to diagnose parathyroid hyperplasia. Finally, although the US appearance of a parathyroid carcinoma mimics that of an adenoma, malignancy can be recognized by an irregular shape concomitant with infiltration of the adjacent anatomic structures [41, 42].

The color Doppler pattern is also useful to correctly identify parathyroid lesions that are in general characterized by diffuse intranodular color signals or focal peripheral flow associated with variable degrees of intranodular vascularization. These features are especially useful to distinguish a parathyroid mass from a typical thyroid nodule that generally displays a regular peripheral flow pattern [43–45]. A recent addition to the imaging armamentarium for enlarged parathyroid glands is contrast-enhanced US (CEUS), based on the use of microbubble contrast and contrast-specific imaging software [46]; the underlying rationale is that the blood pool contrast so induced can depict the micro- and macro-circulation of the organ/tissue under evaluation. Both parathyroid adenomas and hyperplastic glands exhibit strong enhancement in the arterial phase, a feature related to the hyperfunctioning nature of these lesions; parathyroid lesions usually display faster washout than lesions pertaining to the thyroid gland. On the other hand, lymph nodes (whose basic US structure can be misinterpreted as a parathyroid mass) display an early central arterial and late parenchymal enhancement without early washout.

The accuracy of parathyroid's localization with US varies as a function of the size and location of the adenoma, being lowest in the evaluation of the substernal, retrotracheal, and retroesophageal spaces [47]. Furthermore, in about 40% of the patients who have undergone prior surgery, US examination does not allow to detect the presence of parathyroid glands because of distorted anatomy and/or the presence of fibrous scar tissue. Notwithstanding these limitations, US still constitutes a reliable first-line imaging approach, in conjunction with radionuclide imaging, for preoperative localization of enlarged parathyroid glands.

CT imaging is less commonly used for preoperative localization and is usually reserved (similarly as for MRI) for detecting suspected ectopic glands in patients in whom prior parathyroidectomy has failed to cure HPTH [48]. CT should also be considered for patients in whom the first-line imaging steps (US and scintigraphy) are negative [39, 49] or for patients in whom the US examination is negative, but scintigraphy suggests an ectopic lesion [50].

CT localizes parathyroid adenomas in the retrotracheal, retroesophageal, and mediastinal spaces better than US. On the other hand,

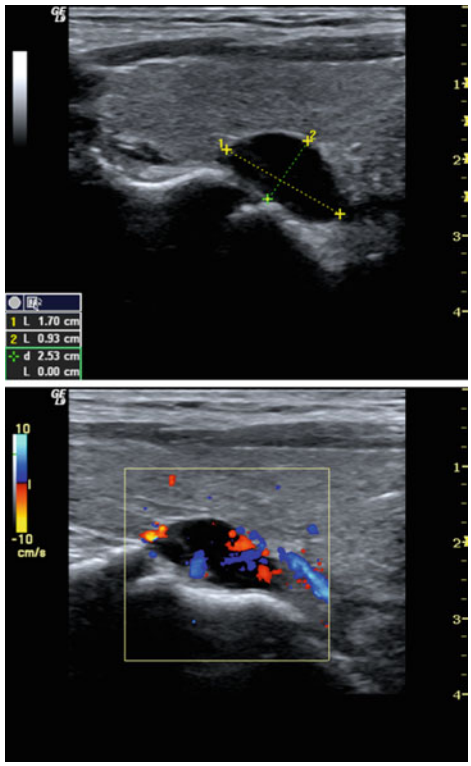

Fig. 5 Ultrasound pattern of a parathyroid adenoma more hypoechoic than the case presented in Fig. 4. Also in this case, the adenoma is located behind the right thyroid lobe of the thyroid, which is well recognized below the skin and subcutaneous muscle and separated from the parathyroid adenoma by a thin hyperechoic capsule (better detected in the *upper panel*). The more hyperechoic structure beneath the thyroid and the parathyroid adenoma is the transverse process of a vertebra in the cervical spine (C4–C5). Color Doppler evaluation (*lower panel*) reveals multiple vessels within the adenoma (Courtesy of Dr. Mario Meola, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy)

parathyroid glands located in the lower neck or close to the thyroid gland are not easily detectable by CT. The overall sensitivity of CT for preoperative identification of hyperplastic parathyroid glands ranges between 46% and 80%. Because of frequent hypervascularization of abnormal parathyroid glands, CT with contrast enhancement results in sensitivity consistently close to 80%. In fact, in patients with multigland disease, CT has high sensitivity and high positive predictive value, especially if performed with the so-called 4D modality [40, 51, 52]. When compared to ^{99m}Tc-sestamibi scintigraphy, CT has the advantage of a shorter examination time, associated with a comparable overall cost; on the other hand, dedicated acquisition protocols should be adopted in order to keep to a minimum the relatively high radiation burden of CT. Although local availability and logistics frequently dictate the sequence of imaging steps for preoperative localization of hyperfunctioning parathyroid lesions, there are some proponents for the use of CT imaging (either alone, combined with US, or combined with ^{99m}Tc-sestamibi scintigraphy) as the first-line approach rather than the combination of US with ^{99m}Tc-sestamibi scintigraphy [53–57].

Obvious disadvantages of CT imaging include a relatively high radiation burden to patients and the need to use an iodinated contrast to be administered i.v.; the latter feature has some associated risks and strict contraindications, for instance, in patients with prior allergic reactions to iodinated contrast agents or in patients with reduced renal function.

MRI is currently less used than CT as a second-line imaging procedure for preoperative localization of parathyroid lesions, mostly due to difficult access to this imaging modality [58]. Nevertheless, MRI is used in patients with negative or discordant localization studies, those with persistent or recurrent disease after prior surgery, or when contrast CT is contraindicated. In general, the sensitivity of MRI for localizing hyperfunctioning parathyroid glands ranges from 43% to 71%, higher when it is employed for detecting ectopic glands (88–96%) [59, 60]. Recent study showed that high-resolution MRI using a 3.0 T magnet could detect adenomas in 57% of patients with PHPT in whom both contrast CT and ^{99m}Tc-sestamibi scintigraphy failed to localize the adenoma [61].

MRI protocols involve the acquisition of multiplanar images of the neck and upper mediastinum. The standard images are obtained from the hyoid bone to the sternal notch; when a mediastinal ectopic parathyroid gland is suspected, additional ECG-gated axial images of the mediastinum are acquired. MRI scans are commonly acquired with standard T1–T2-weighted spin-echo sequences.

On MRI, enlarged parathyroid glands have considerably increased intensity on T2-weighted

and proton density images, but it is not possible to distinguish parathyroid adenomas from either simple hyperplasia or carcinoma.

Parathyroid Scintigraphy

Although there are no radiopharmaceuticals concentrating specifically only in the parathyroid glands, parathyroid scintigraphy plays an important role in the preoperative localization of hyperfunctioning parathyroid glands as a guide to minimally invasive parathyroidectomy. Early radionuclide techniques were based on the subtraction scan using two imaging agents, one accumulating both in the thyroid and parathyroid parenchyma and one exclusively in the thyroid gland, respectively. The two historical approaches to parathyroid imaging with radionuclides are the use of ^{75}Se-methionine (a radiolabeled amino acid accumulating in both tissues) coupled with ^{131}I-iodide (accumulating solely in the thyroid gland) [62–64], and the use of ^{201}Tl-chloride (imaging both parenchymas, similarly as ^{75}Se-methionine) coupled with ^{99m}Tc-pertechnetate (imaging the thyroid only) [65].

However, since its first introduction for parathyroid imaging in 1989 [66], ^{99m}Tc-sestamibi has rapidly become the radiopharmaceutical of choice for parathyroid imaging, with an overall 85–95% accuracy in primary HPTH. Localization of ^{99m}Tc-sestamibi in the parathyroid tissue is a function of metabolic activity, since this agent accumulates preferentially in mitochondria-rich tissues, as typically is a hyperfunctioning parathyroid gland. Although ^{99m}Tc-sestamibi accumulates also in the normal thyroid parenchyma, its washout rate from the parathyroid glands is different from that of the thyroid tissue [67]; in fact, this radiopharmaceutical is released much faster from the thyroid than from the parathyroid tissue. This differential retention kinetics seems to be related to downregulation in the parathyroid tissue of the P-glycoprotein system, which is responsible for the efflux of various compounds (including ^{99m}Tc-sestamibi) from the intracellular to the extracellular space [68]. The so-called single-tracer, double-phase scintigraphy is based on this difference in washout rate; it is performed by acquiring early images of the neck and thorax (about 15 min postinjection) and then imaging again at 2–3 h. A hyperfunctioning parathyroid adenoma appears as an area of early radiopharmaceutical uptake that persists on late imaging [69] (Fig. 6). Thyroid nodules that concentrate ^{99m}Tc-sestamibi avidly can cause difficulties in the interpretation of images [70]. To avoid this drawback, ^{99m}Tc-pertechnetate or ^{123}I-iodide scintigraphy can be performed in patients with thyroid nodular goiter [71]. Furthermore, some

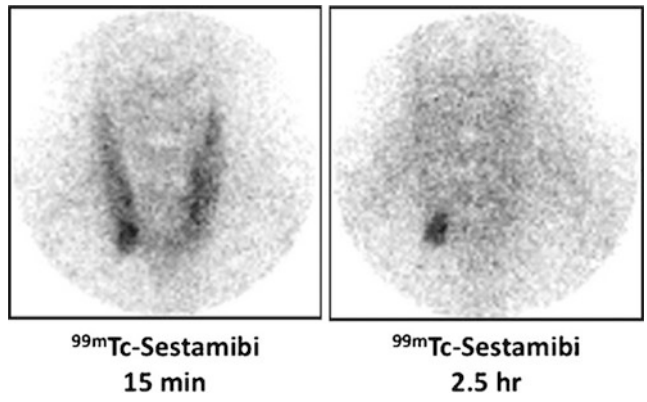

Fig. 6 Planar, single-tracer, dual-phase parathyroid scintigraphy with ^{99m}Tc-sestamibi in a patient with primary hyperparathyroidism, showing early uptake at the base of the right lobe (slightly greater than in the thyroid parenchyma), and selective retention in the delayed imaging. This area corresponded to a parathyroid adenoma that was subsequently removed with radioguided, minimally invasive surgery

parathyroid adenomas exhibit a rapid washout of ^{99m}Tc-sestamibi, thus possibly resulting in false-negative results.

Differently from earlier approaches based on the use of a single tracer, the current version of *dual-tracer subtraction parathyroid scintigraphy* is based on the use of ^{99m}Tc-sestamibi coupled with a second radiopharmaceutical that accumulates specifically in the thyroid gland, either ^{123}I-iodide or ^{99m}Tc-pertechnetate [71]. The thyroid images are subtracted from the ^{99m}Tc-sestamibi image, so that residual focal uptake indicates the presence of hyperfunctioning parathyroid tissue. Due to high cost and limited availability of ^{123}I-iodide (as well as to the relatively long acquisition time with this radionuclide), ^{99m}Tc-pertechnetate is most frequently employed as the pure thyroid imaging agent in the routine clinical practice. The ^{99m}Tc-pertechnetate image (standard activity of 185 MBq) is acquired 20 min after injection; thereafter potassium perchlorate can be administered to induce rapid washout of this agent from the thyroid gland, after which ^{99m}Tc-sestamibi is administered [72]. The $^{99m}TcO_4^-$/^{99m}Tc-sestamibi technique has sensitivity around 90% and specificity close to 100%. Alternatively, administration of ^{99m}Tc-pertechnetate after the delayed ^{99m}Tc-sestamibi acquisition allows to improve the definition of equivocal area of ^{99m}Tc-sestamibi uptake [48] (Fig. 7).

As an alternative to ^{99m}Tc-sestamibi, ^{99m}Tc-tetrofosmin is employed in some centers for parathyroid scintigraphy, although this agent exhibits slower washout from the thyroid gland than washout of ^{99m}Tc-sestamibi [73].

Parathyroid scintigraphy, either with the single-tracer, dual-phase technique or with the dual-tracer subtraction method, shows a sensitivity higher than 90% in primary PHPT, higher than that obtained with the other imaging techniques [31]. Nevertheless, sensitivity to detect hyperplastic glands in secondary HPTH is not higher than 55% [12]. ^{99m}Tc-sestamibi scintigraphy is critical in persistent or recurrent HPTH, with successful identification of the parathyroid remnant in 85% of the patients. SPECT, and especially SPECT/CT imaging, is useful especially in the detection of small or ectopic adenomas and in patients with multinodular goiter or with recurrent HPTH [74, 75] (Fig. 8).

By combining the three-dimensional functional information of SPECT with the anatomic information of CT, hybrid SPECT/CT allows optimal preoperative localization of the enlarged parathyroid glands (Fig. 9), thus complementing and sometimes even clarifying negative/equivocal US findings (Fig. 10). In this regard, it has clearly been demonstrated that SPECT/CT is more accurate than SPECT alone in patients with HPTH and nodular goiter and that the combination of early SPECT/CT with any delayed imaging method (SPECT/CT, SPECT, or planar imaging) is superior to double-phase planar imaging or double-phase SPECT [76–78]. This procedure should therefore be routinely used in the preoperative evaluation of patients with HPTH in whom minimally invasive parathyroidectomy is planned.

Similarly as has been successfully done for planar imaging, attempts have been made to apply subtraction protocols to SPECT acquisitions. In particular, Neumann et al. described a technique based on acquisition of SPECT/CT images with a dual-energy window after administration of ^{123}I-iodide and ^{99m}Tc-sestamibi. Then, the attenuation-corrected SPECT sections were utilized to obtain SPECT subtraction images (^{99m}Tc-sestamibi SPECT subtracted of the ^{123}I-iodide SPECT). In the authors' experience, SPECT/CT was significantly more specific than dual-isotope subtraction SPECT for preoperative localization of parathyroid adenomas [79].

In addition to single-photon imaging with conventional gamma cameras, the use of PET/CT with different tracers has also been proposed for localizing hyperfunctioning parathyroid tissue, particularly in the setting of recurrent HPTH and/or failure of conventional radionuclide imaging. Although the performance of these newer techniques is reported to be highly promising, clinical experience is still limited to a few specialized centers. The PET tracers employed in this scenario include [^{18}F]FDG, [^{11}C]methionine, ^{18}F-fluorocholine, and ^{18}F-DOPA as the most widely employed agents [80–84]. On the basis of recent systematic reviews and meta-analyses, the most promising PET tracers

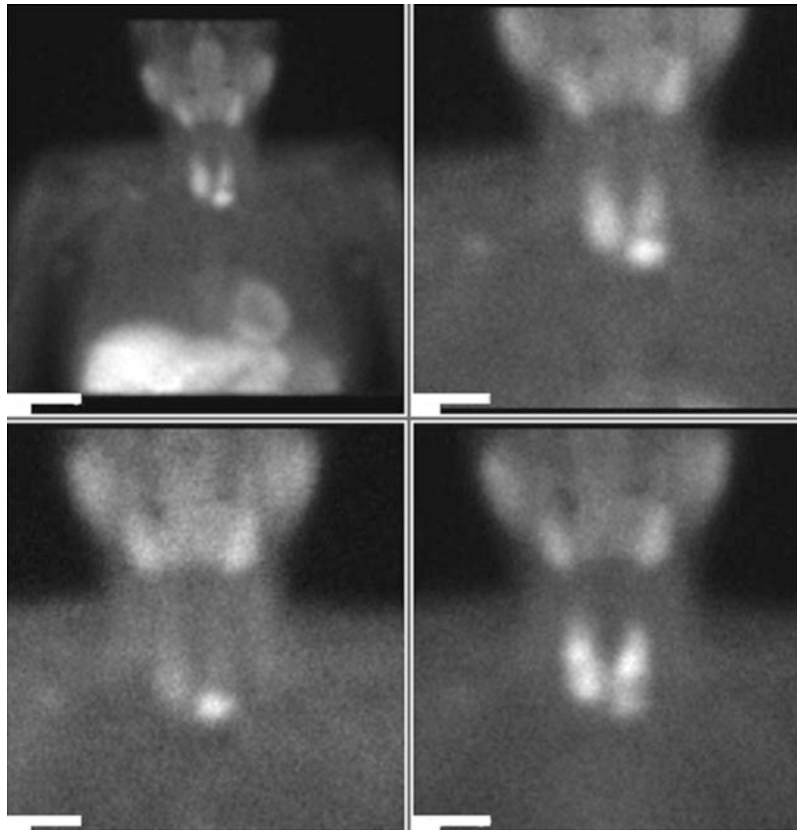

Fig. 7 Dual-tracer parathyroid scintigraphy with ^{99m}Tc-sestamibi and ^{99m}Tc-pertechnetate in a patient with hyperparathyroidism and multinodular goiter. *Upper left panel*: planar image acquired early after injection of ^{99m}Tc-sestamibi (about 10 min), with a field of view including the neck and the whole chest as a preliminary exploration for possible ectopic locations of the adenoma. *Upper right panel*: image acquired about 15 min postinjection, with zoom on the neck and upper chest; there is a suspicious area of abnormal accumulation corresponding to the base of the left thyroid lobe. *Lower left panel*: image acquired about 2.5 h postinjection of ^{99m}Tc-sestamibi, showing partial washout from the thyroid parenchyma and persistent uptake corresponding to the base of the left thyroid lobe. *Lower right panel*: image acquired about 20 min after administering ^{99m}Tc-pertechnetate (digitally subtracted from residual activity in the delayed ^{99m}Tc-sestamibi acquisition), showing selective visualization of the thyroid parenchyma with inhomogeneous uptake throughout the gland due to multinodular goiter. The parathyroid adenoma was located in the area showing slow washout of ^{99m}Tc-sestamibi in the delayed acquisition

appear to be [^{11}C]methionine and ^{18}F-fluorocholine. Although with a high degree of etherogeneity, the currently available clinical evidence for [^{11}C]methionine shows an 81% pooled sensitivity (95% CI 74–86%) with 70% detection rate (95% CI 62–77%) [83]; according to these data, another analysis obtained a pooled 69% sensitivity (95% CI 60–78%) for detecting a lesion in the correct quadrant, with very high specificity (98% pooled estimate for the positive predictive value; 95% CI 96–100%) [84].

Minimally Invasive Parathyroidectomy and Radioguided Surgery

Minimally invasive parathyroidectomy has been facilitated by the introduction of the intraoperative rapid PTH test, which can be performed with the purpose of detecting any remaining abnormal glands. Since the biological half-life of PTH in the circulation is approximately 2 min, serum PTH levels reduced by more than 50% about 15–30 min

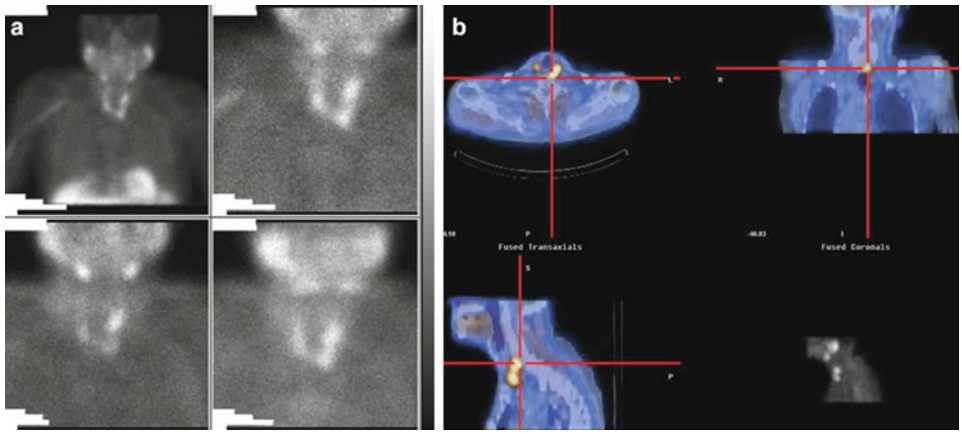

Fig. 8 Dual-tracer parathyroid scintigraphy with ^{99m}Tc-sestamibi and ^{99m}Tc-pertechnetate in a patient with hyperparathyroidism and multinodular goiter. (**a**) *Upper left panel*: planar image acquired early after injection of ^{99m}Tc-sestamibi (about 10 min), with a field of view including the neck and the whole chest as a preliminary exploration for possible ectopic locations of the adenoma. *Upper right panel*: image acquired about 15 min postinjection, with zoom on the neck and upper chest; there is a suspicious area of abnormal accumulation corresponding to the apex of the left thyroid lobe. *Lower left panel*: image acquired about 2.5 h postinjection of ^{99m}Tc-sestamibi, showing partial washout from the thyroid parenchyma and persistent uptake corresponding to the apex of the left thyroid lobe. *Lower right panel*: image acquired about 20 min after administering ^{99m}Tc-pertechnetate (digitally subtracted from residual activity in the delayed ^{99m}Tc-sestamibi acquisition), showing selective visualization of the thyroid parenchyma with inhomogeneous uptake especially at the left thyroid lobe due to multinodular goiter. (**b**) Transaxial, coronal, and sagittal fused SPECT/CT sections defining location of the parathyroid adenoma at the apex of the left thyroid lobe

after removal of a suspected parathyroid adenoma indicate that the source of abnormal production of PTH has actually been removed.

The key to success for focused parathyroidectomy employing minimally invasive approaches relies on preoperative imaging for accurate localization of the adenoma(s) and/or hyperplasia. In addition to preoperative imaging, the surgeon can rely on intraoperative procedures that can help to find the hyperfunctioning parathyroid tissue and/or to assess completeness of surgical resection of the lesion (such as, e.g., the intraoperative serum PTH assay) [85]. One of such procedures is represented by radioguided parathyroid surgery, which is performed with a handheld "gamma probe" for continuous, real-time measurements in the surgical bed after administration of ^{99m}Tc-sestamibi.

The success of radioguided surgery in HPTH patients (especially in case of primary HPTH) is based on the following considerations: (1) in most of the cases (80%) this condition is caused by a single hyperfunctioning adenoma, which is usually located adjacent to the thyroid gland [86–89]; (2) avid uptake of ^{99m}Tc-sestamibi in parathyroid adenomas is the basis for their efficient identification and preoperative localization, thus making it easier to detect intraoperatively the adenoma using the gamma probe [90]. However, there are some well-defined indications for radioguided parathyroid surgery. In particular, this procedure is to be considered only in case of clear identification and localization of a solitary parathyroid adenoma in the ^{99m}Tc-sestamibi scan, as it occurs in 60–70% of the patients with primary HPTH [90]. Indications for a minimally invasive approach can be summarized as follows:

- Both US and scintigraphy have identified only a single adenoma.
- Uptake of ^{99m}Tc-sestamibi in the enlarged parathyroid gland is clear and unequivocal.
- The ^{99m}Tc-sestamibi scan does not show thyroid nodules with persistent tracer uptake.
- A familial form of the disease has been excluded.

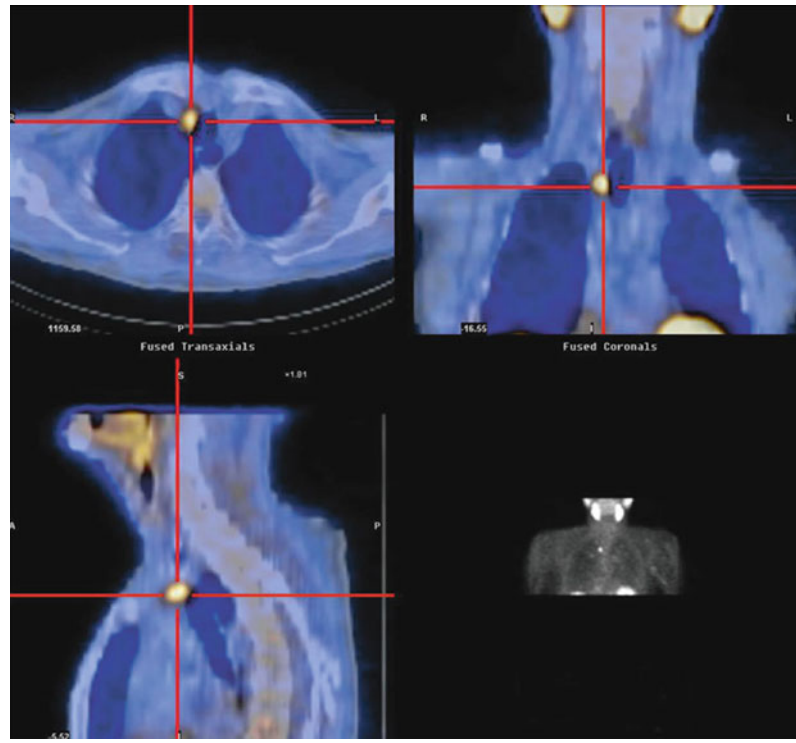

Fig. 9 ^{99m}Tc-sestamibi SPECT/CT (fused transaxial, coronal, and sagittal sections) in patient with persistent HPTH after prior parathyroidectomy (during which thyroidectomy was also performed because of concomitant multinodular goiter). Hybrid imaging defines the exact anatomic coordinates of the ectopic parathyroid adenoma located in the upper mediastinum

- The patient had not been submitted to prior irradiation of the neck.

Whereas, minimally invasive radioguided parathyroidectomy is not contraindicated in patients submitted to prior neck surgery. On the other hand, the open surgery procedure becomes mandatory in case of concomitant presence of a nodular thyroid goiter or of multigland parathyroid disease. Similarly, bilateral neck exploration is recommended when a parathyroid malignancy is suspected [90].

Norman and Chheda described the first protocol for minimally invasive radioguided parathyroidectomy in 1997 [91]. In their "single day" approach, ^{99m}Tc-sestamibi parathyroid scintigraphy was combined with radioguided surgery in the same day. In particular, radioguided surgery is performed 2–3 h after administration of 740–925 MBq of ^{99m}Tc-sestamibi and acquisition of a single-tracer, dual-phase parathyroid scintigraphy. This protocol has two main advantages: (1) the technique is cost-effective in patients with primary or recurrent hyperfunctioning parathyroid adenoma, and (2) the entire procedure (preoperative scintigraphic localization and radioguided surgery) is concentrated in a rather short time window of approximately 3–4 h.

Soon after the first reports by Norman and colleagues, the Padua group proposed a "low-dose" multiple day protocol [92, 93], which consists in performing parathyroid scintigraphy and radioguided surgery in two different days. In particular, the patient is first submitted to a classical dual-tracer parathyroid scintigraphy using full diagnostic activities; surgery is planned based on the findings of this scan. Thereafter, on the day of surgery (which is scheduled according to general logistic and organizational needs), the patient is injected with only 37 MBq of ^{99m}Tc-sestamibi just before starting the radioguided surgery procedure. At variance with the Norman's protocol, the radiation exposure for personnel in the operating room derived from such low radioactivity amount is minimal; furthermore, the surgical approach can be planned and optimized in advance based on the results of the prior full-dose parathyroid scintigraphy [48, 94, 95].

The intraoperative detection rate of parathyroid adenomas is very high with both protocols

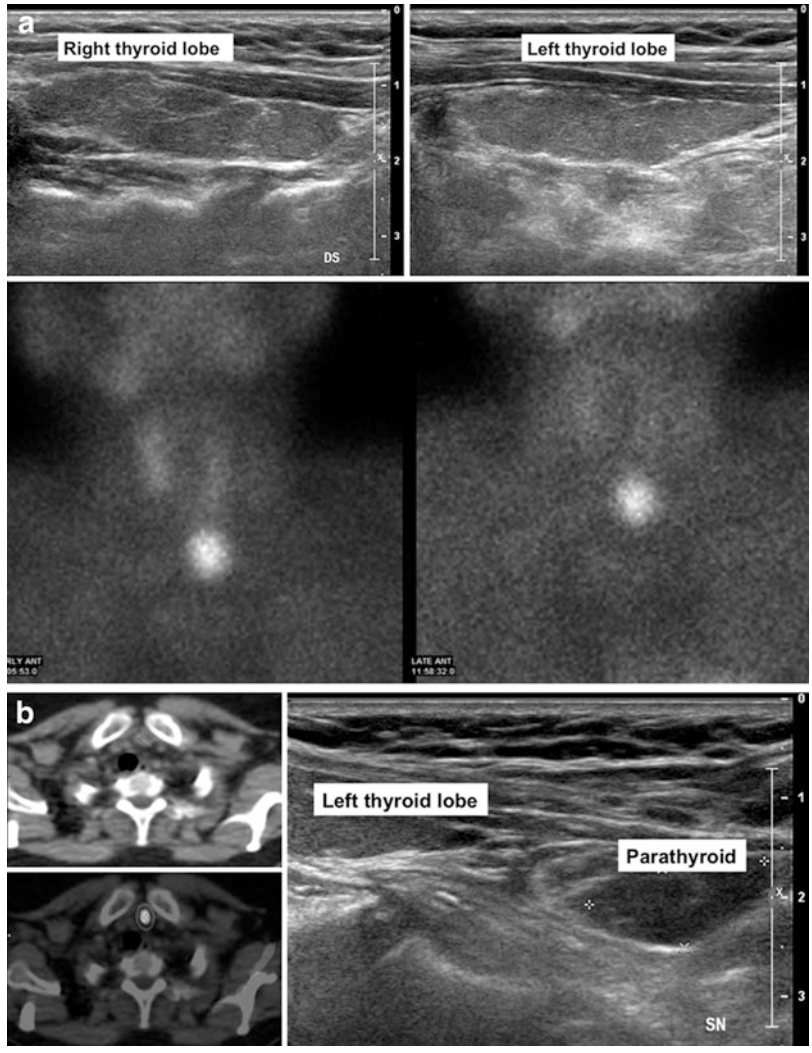

Fig. 10 A 62-year-old woman with clear diagnosis of primary HPTH (serum calcium 11 mg/dL, serum phosphorous 1.9 mg/dL, serum PTH 996 pg/mL). (**a**) An initial US scan of the neck could not reveal abnormal parathyroid lesions in the expected locations (*upper panel*); the *lower panel* shows the early and delayed ^{99m}Tc-sestamibi planar scans, with clear positivity for a hyperfunctioning parathyroid mass located below the left lower thyroid lobe. A SPECT/CT acquisition was additionally performed. (**b**) The *left panels* show the axial sections obtained with hybrid SPECT/CT imaging, confirming prolonged retention of ^{99m}Tc-sestamibi in a mass which was detectable also on the low-definition CT component of the scan (CT image above, fused SPECT/CT image below). A focused US scan was therefore repeated and confirmed the presence of a parathyroid adenoma in an unexpected location, well below the lower end of the left thyroid lobe (Courtesy of Drs. Maria Luisa De Rimini and Pietro Muto, Nuclear Medicine Service, "Monaldi" Hospital, Naples, Italy)

(over 95%); thus, choice of the method depends on local logistic/organizational considerations. However, the "low-dose protocol" is more suited for patient populations in iodine-deficient geographic areas, where there is a high prevalence of nodular goiter. In fact, thyroid nodules can occasionally be ^{99m}Tc-sestamibi avid and with slow tracer washout, an occurrence that could cause false-positive scintigraphic results if relying solely on a single-tracer, dual-phase imaging protocol. In these conditions, dual-tracer parathyroid scintigraphy has better specificity than the dual-

phase scintigraphy adopted in the Norman protocol, therefore allowing better selection of patients meeting for radioguided surgery [96]. More recently, the low-dose protocol has been shown to be highly effective also in patients with secondary HPTH, with clear advantages versus the high-dose protocol [97].

Despite the excellent performance of radioguided surgery reported by several groups around the world, there seems to be a prevailing trend within the USA for parathyroid surgery to shift away from intraoperative radioguidance [98], despite the fact that the fear of exposure to significant levels of radiation for the personnel involved in the procedure has been cleared by recent careful dosimetric measurements demonstrating that the maximum allowed radiation exposure to the surgeon would not be reached until over 5,600 radioguided parathyroidectomies are performed by the same personnel per year [99]. In fact, in most centers surgeons tend to rely on accurate preoperative localization imaging alone, especially if combined with the intraoperative PTH assay. Nevertheless, considerable interest is continuing to focus on radioguided parathyroid surgery [32, 100–102], thanks also to the introduction of newer intraoperative detection/imaging techniques [103, 104], as reported in better details in ▶ Chap. 50, "Radioguided Surgery: Novel Applications" of this book. In addition to primary and secondary HPTH (including primary multigland disease [105]), radioguidance continues to show particular clinical usefulness in diverse additional clinical conditions such as tertiary HPTH [106] and in pediatric patients [107].

Parathyroid Carcinoma

Pathology

Less than 1% of the cases of primary HPTH are sustained by a parathyroid carcinoma [108], a very rare endocrine malignancy (no more than 400 cases had been reported in the literature up to 1997) [109]. Since histology of parathyroid tumors can be equivocal or frankly misleading,

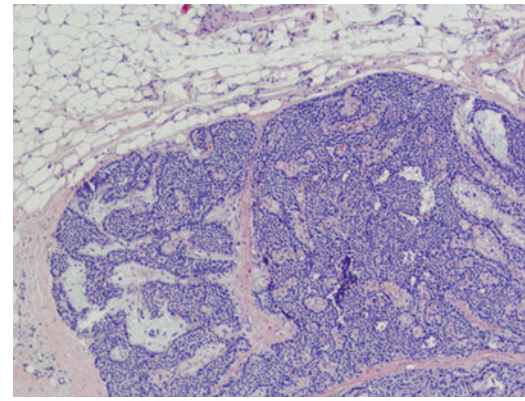

Fig. 11 Histologic pattern of a parathyroid carcinoma (low magnification): nests of densely packed cancer cells with trabecular arrangement (also occasionally arranged in follicular-like structures) separated by fibrous bands incompletely dividing the tumor into lobules. Initial invasion of the tumor capsule is seen at the *upper edge* of the tumor (Courtesy of Prof. Fulvio Basolo, Division of Pathology, Department of Surgery, University of Pisa, Pisa, Italy)

the differential diagnosis between a parathyroid carcinoma and an adenoma is often made only when local recurrence or metastases occur [110, 111]. The histologic features of parathyroid carcinoma are not very specific and difficult to be defined. Generally, neoplastic cells (usually chief cells) are arranged in a lobular pattern partitioned by dense trabeculae (Fig. 11). The more typical features are a high mitotic activity, vascular and capsular invasion, and the presence of thick fibrous bands. Gross infiltration of adjacent structures also strongly suggests the diagnosis of carcinoma; from the clinical point of view, this feature corresponds to a firm mass adherent to surrounding tissues and with very irregular margins. Mean size of the primary tumor at presentation is usually >2–3 cm, and color of the cutting surface is grayish-white [112, 113]. However, many of these features are not specific for malignancy, since they can also be found in parathyroid adenomas. Only the detection of metastatic lesions makes the diagnosis of malignancy certain, but metastasis is rare at presentation [114, 115]. For all these reasons, distinguishing a benign from a malignant parathyroid tumor is very difficult and rarely made at initial histologic evaluation. Immunohistochemistry makes diagnosis of parathyroid

carcinoma easier. Since parathyroid carcinoma usually has an elevated mitotic activity, increased expression of cell cycle-associated antigens, such as Ki-67 and cyclin D1, can make the diagnosis of parathyroid carcinoma more likely than that of adenoma [116, 117]; nevertheless, there is some overlap between benign and malignant forms. Decreased expression of p27, an inhibitor of cyclin-dependent kinase, and abnormal galectine-3 expression have also been demonstrated in parathyroid carcinomas, while evaluation of HRPT2 gene abnormalities constitutes a promising diagnostic tool as well [118]. Finally, loss of heterozygosity and loss (total or focal) of parafibromin expression have been reported in the large majority of parathyroid carcinomas but very rarely in adenomas [119–122].

Epidemiology

In contrast to parathyroid adenomas, where women predominate over men by a ratio of 3–4:1, parathyroid cancer occurs with equal frequency in the two sexes. The mean age at diagnosis is 40 years, which is 10 years earlier than the typical age of onset age for parathyroid adenomas.

Etiology

The etiology of parathyroid carcinoma remains largely unknown. Neck irradiation and a long-standing secondary HPTH might be considered as risk factors for parathyroid carcinoma, but, indeed, this relationship has been demonstrated only for parathyroid adenomas [10, 11]. Most parathyroid carcinomas are sporadic, although a few cases have also been reported in familial isolated HPTH [123] and in the HPTH-jaw tumor syndrome [124], a rare autosomal disorder where a parathyroid malignancy has been reported in as many as 15% of the patients. Parathyroid carcinoma has been reported also in MEN1 syndrome and with somatic MEN1 mutations [125], while only one case of parathyroid carcinoma has been reported in the MEN2A syndrome [126].

Pathogenesis

Several oncogenes and tumor suppressor genes, especially those involved in the control of the cell cycle, such as retinoblastoma (Rb), p53, breast carcinoma susceptibility (BRCA2), and the cyclin Dl/parathyroid adenomatosis gene 1 oncogene (PRAD1) genes [127], have been linked to parathyroid carcinomas. However, none of these genes play a primary role in the pathogenesis of parathyroid carcinoma.

Instead, a strong correlation has been demonstrated between the HPTH-jaw tumor syndrome and mutation of the HRPT2 gene (alias CDC73 and Clorf 28). This gene encodes a 531-amino acid protein called parafibromin which plays a central role in the control of the cell cycle, and subsequently in determining cell fate and promoting tumorigenesis [128]. HRPT2 is frequently mutated both in HPTH-jaw tumor syndromes and in many parathyroid carcinomas [129, 130]. In particular, parathyroid carcinoma occurs with higher frequency in the HPTH-jaw tumor syndrome than in sporadic PHPT (15% versus less than 1%). Similar germline mutations occur in a subset of kindreds with familial isolated HPTH [128, 129]. Most of these mutations are "nonsense" point mutations and result in lack of or reduced protein expression of the encoded parafibromin protein. The prevalence of HRPT2 mutations in sporadic parathyroid carcinomas may be as high as 76.6%. Therefore, HRPT2 mutations are considered one of the most significant molecular events involved in the pathogenesis of most sporadic parathyroid carcinomas. Another mechanism of HRPT2 gene inactivation, methylation of the promoter, has been reported in 2 out of 11 parathyroid carcinomas [131]. Controversial data have instead been reported about the presence of HRPT2 mutations in sporadic benign parathyroid adenomas [108, 130, 132].

Clinical Presentation

The initial clinical manifestations of parathyroid carcinoma are primarily linked to the effects of markedly elevated serum PTH levels

(i.e., hypercalcemia) rather than to local infiltration or distant metastases. From the clinical point of view, parathyroid carcinomas are usually indolent, though progressive. At initial presentation, very few patients have metastasis at regional lymph nodes (<5%) or at distant sites (<2%) [108, 133]. Parathyroid carcinoma tends to recur locally and to infiltrate adjacent structures in the neck. Metastases occur late in the course of the disease, involving cervical lymph nodes (30%) and/or lungs (40%) and/or liver (10%). Distant metastases in the bone, pleura, pericardium, and pancreas are more rare. Severe hypercalcemia with renal involvement (nephrocalcinosis and nephrolithiasis) is present in up to 80% of the patients, while bone involvement (osteitis fibrosa cystica, subperiosteal resorption, "salt and pepper" skull, and diffuse osteopenia) occurs in up to 90% of the patients. In about 80% of the patients with parathyroid carcinoma, a palpable neck mass is present at physical examination. Besides symptoms linked to nephrolithiasis, patients may complain of muscle weakness, fatigue, depression, nausea, polydipsia and polyuria, bone pain, and fractures. Recurrent severe pancreatitis, peptic ulcer disease, and anemia can also occur. However, none of these features are specific for malignancy. A few parathyroid carcinomas do not produce excess PTH [134] and can therefore be confused with thyroid or thymic carcinoma because of locally advanced disease (palpable neck mass, dysphagia, hoarseness due to laryngeal nerve palsy). The correct diagnosis can be defined by immunohistochemistry for PTH (positive staining), while staining for thyroglobulin, thyroid transcription factor 1, and calcitonin is negative. The features that might raise the suspicion of a parathyroid carcinoma in a patient with PHPT include male gender, age <50 years, serum calcium >14–15 mg/dL, markedly elevated serum PTH levels, bone and renal clinical involvement, and tumor size >3 cm.

The identification of HRPT2 gene mutations in patients with apparently sporadic parathyroid cancers as germline events suggests that a subset of these patients might have the HPT-JT syndrome or variant thereof [135]. In these cases, the surveillance for renal and jaw lesions is recommended [130]. Moreover, the relatives of a patient carrying a germline HRPT2 mutation are susceptible to develop a parathyroid cancer or other manifestation of the HPT-JT syndrome. Monitoring of family members with serum calcium determinations and neck US is therefore warranted.

Imaging of Parathyroid Carcinoma

Although not extensively discussed in the literature because of the relative rarity of this tumor, the same imaging techniques as those used for localizing benign parathyroid disease are helpful also for imaging parathyroid cancers. They include US evaluation of the neck, ^{99m}Tc-sestamibi scintigraphy, CT, and MRI, as well as PET [136, 137]. The accuracy of imaging depends on the size and site of the parathyroid carcinoma, while the suspected tissue always requires histologic confirmation [138, 139].

US examination of the neck is useful especially for detecting a space-occupying lesion, while it can also help to distinguish a parathyroid carcinoma from an adenoma, as well as invasion in the surrounding tissue and metastasis in local lymph nodes [140]. Although the US findings are not exquisitely specific for parathyroid cancer, large size, inhomogeneous appearance, and/or irregular borders with a depth/width (DW) ratio >1 are observed in 94% of the cases [141]. During follow-up, US evaluation is useful for detecting local recurrence of parathyroid carcinoma.

CT and MRI have been variously used to localize parathyroid carcinomas and to detect mediastinal and thoracic recurrences or distant metastases [142]. Nevertheless, in the postoperative status artifacts due to surgical clips may make the interpretation of cervical CT scans difficult; in this condition, T1-weighted MRI with gadolinium contrast may be more useful to detect residual locoregional parathyroid carcinoma [143]. Invasive diagnostic procedures, such as selective venous catheterization with measurement of PTH concentration in the effluent blood, may also be used to localize lesions when noninvasive imaging studies have been noncontributory [144]. ^{99m}Tc-sestamibi scintigraphy can be successful for preoperative localization of a parathyroid malignancy (with 80–90% sensitivity). However, it cannot distinguish

a parathyroid adenoma from a carcinoma [145, 146], since ^{99m}Tc-sestamibi localizes in both parathyroid adenomas and parathyroid carcinoma as well as in any other non-tumor hyperfunctioning tissue(s) and in different types of malignancy. The National Cancer Database Report by the American Cancer Society estimates that 15–17% of parathyroid carcinomas, which look identical to parathyroid adenomas on ^{99m}Tc-sestamibi scintigraphy, have concomitant lymph node metastasis at the time of diagnosis [113]. Once parathyroid carcinoma has been diagnosed and resected, ^{99m}Tc-sestamibi scintigraphy can identify recurrences in the surgical bed, as well as metastases in the contralateral neck lymph nodes (Fig. 12) and metastasis at distant sites such as the lung and bone [147]. The evaluation of bone lesions can be challenging from the diagnostic point of view, because skeletal brown tumors (a possible consequence of HPTH) accumulate ^{99m}Tc-sestamibi as well, thus mimicking metastatic parathyroid carcinoma [148]. When performed for surgical planning in patients with recurrent disease, ^{99m}Tc-sestamibi scintigraphy correctly identifies 67% of the recurrences; this compares well with 53% for CT imaging. Although discordant results between the two techniques are reported in 78% of the cases [149], both imaging studies are recommended for optimal preoperative planning [150].

PET with [^{18}F]FDG has also shown to be very helpful for detecting metastatic parathyroid cancers [151], although brown tumors can be [^{18}F]FDG avid as well, thus being possibly incorrectly interpreted as metastatic bone lesion [152]. Overexpression of the P-glycoprotein, a plasma membrane mechanism involved in multidrug resistance through an ATP-dependent drug efflux pump, seems to be involved in the false-negative results at either ^{99m}Tc-sestamibi scintigraphy or [^{18}F]FDG PET [153]. Due to the rarity of parathyroid carcinoma, there is very limited experience with the use of PET agents other than [^{18}F]FDG, occasional reports being usually included in case study populations of HPTH patients in general. Similarly as for benign forms of HPTH, the performance of [^{11}C]methionine PET/CT is expected to be especially promising in patients with parathyroid carcinoma.

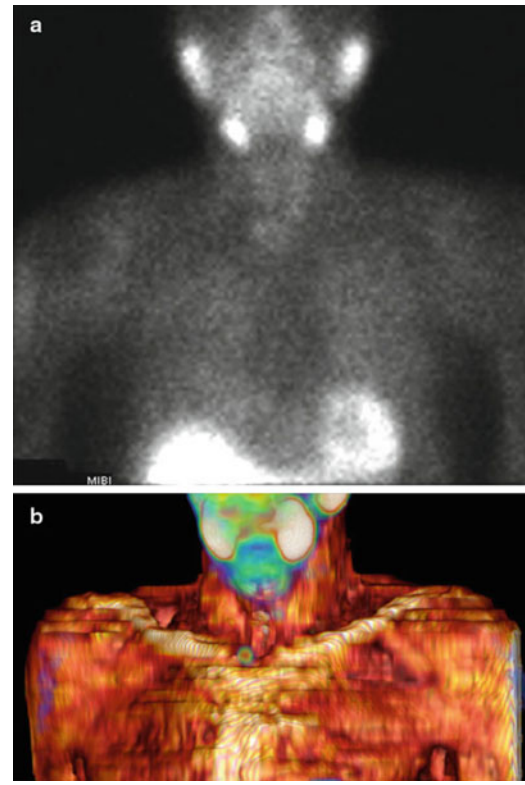

Fig. 12 A 75-year-old patient previously submitted to surgery because of primary HPTH initially thought to be caused by an adenoma of the lower right parathyroid gland. Histology revealed instead parathyroid carcinoma. About 18 months later, local recurrence was treated with a second surgery, after which the PTH levels in blood normalized for several months then started to rise again. (**a**) Planar scan of the neck and chest obtained about 10 min after administration of ^{99m}Tc-sestamibi, suggesting some ill-defined abnormal uptake of the radiopharmaceutical at the base of the neck (*slightly right sided*). (**b**) Tridimensional volume rendering of fused SPECT/CT of the neck and upper chest clearly identifies the site of abnormal ^{99m}Tc-sestamibi uptake in the right paramedian suprasternal space; the lesion corresponds to a previously unrecognized metastasis in a lymph node, as subsequently confirmed histologically

Management of Parathyroid Carcinoma

Surgery

Complete resection of the primary lesion at the time of initial operation is the only curative treatment for parathyroid carcinoma; this is possible

when the cancer is diagnosed at an early stage, when the tumor is small and intraparathyroidal. Patients who present with features suggestive of parathyroid carcinoma warrant thorough exploration of all four parathyroid glands, as parathyroid carcinoma has been reported to coexist along with benign adenomas or hyperplasia.

The most effective surgical approach is en bloc resection with curative intents [154]. Tracheoesophageal, paratracheal, and upper mediastinal lymph nodes should be excised, but extensive lateral neck dissection is indicated only when there is metastasis in the anterior cervical lymph nodes. Despite early diagnosis and a potentially curative resection, parathyroid carcinoma recurs in more than 50% of the cases. Most recurrences occur 2–3 years after the initial operation, although disease-free intervals as long as 20 years have been reported [155].

Imaging studies should be performed in all patients before reoperation. FNA of a suspicious lesion (with measurement of PTH in the needle washing) should be used with caution, if at all, to avoid seeding of malignant cells along the needle track [156]. If noninvasive imaging is negative, arteriography and selective venous sampling for PTH measurement may be useful. The management of recurrent or metastatic lesions is primarily surgical. Recurrences in the neck should be treated with wide resections, including the regional lymph nodes and other involved structures. Accessible distant metastases, particularly in the presence of localized metastatic disease, should also be excised, if possible. Even a small tumor may produce a sufficient amount of PTH to cause hypercalcemia. Although resection of a single metastasis or other foci of malignant tissue is rarely curative, their removal may result in periods of normocalcemia ranging from months to years. Decreasing the tumor burden may also render the patient's hypercalcemia more amenable to medical treatment.

Chemotherapy

Although several chemotherapy regimens have been tried (such as nitrogen mustard, vincristine, cyclophosphamide, actinomycin D, and adriamycin alone or in combination with cyclophosphamide and 5-fluorouracil), none of them has proved to be effective either by themselves or combined [157, 158]. Therefore, chemotherapy has currently no role in the management of patients with parathyroid carcinoma.

External Beam Radiation Therapy

With the exception of a single report of apparent cure (10 years) in a patient with infiltration of the trachea [157], external beam radiation therapy (EBRT) has little, if any, effect in invasive parathyroid cancers [155]. Nevertheless, recent reports suggest the benefit of EBRT as adjuvant therapy. In fact, a median disease-free survival of 60 months has been reported in four patients who received postoperative adjuvant EBRT [159]. Furthermore, a reduced rate of local recurrence has been observed when adjuvant EBRT is given after surgery, irrespective of the type of surgery and stage of the disease [160].

Management of Hypercalcemia

When parathyroid carcinoma has become widely metastatic and no surgical options are available, the control of hypercalcemia becomes the primary medical objective. Hydration with i.v. infusion of saline and loop diuretics is often beneficial in the short term, although drugs that inhibit bone resorption are needed in the longer run. Intravenous bisphosphonates (pamidronate and zoledronate) can be used for transient control of hypercalcemia. Also plicamycin is effective, but the response is transient, and repeated courses may be associated with toxicity. New promising therapies include anti-PTH immunotherapy and dendritic cell immunotherapy [161, 162]. Calcimimetics and allosteric modulators of the calcium receptors reduce PTH secretion by enhancing sensitivity of the parathyroid cells to extracellular calcium [163]. A first generation calciomimetic, R-568, was used for 2 years in a patient with metastatic parathyroid carcinoma, resulting in effective control of

hypercalcemia [164]. Cinacalcet, a more potent second-generation agent with a longer half-life and more predictable hepatic metabolism, has recently replaced R-568. In benign PHPT, cinacalcet normalizes serum calcium and partially reduces PTH levels for up to 3 years [165]. Cinacalcet therefore represents an important new option for managing severe hypercalcemia, especially in patients with inoperable disease. A highly effective approach to the treatment of severe hypercalcemia (that represents the primary cause of mortality in these patients) is based on the use of the monoclonal antibody denosumab against the RANK ligand, with a mechanism involving inhibition of receptor activation of the nuclear factor kB ligand [166–169].

Prognosis

The prognosis of parathyroid carcinoma is quite variable and, although complete cure is unlikely, prolonged survival is common with palliative surgery and medical therapy. The mean time to recurrence is usually 3 years, although periods as long as 20 years have been reported [170]. Once the tumor recurs, 5-year survival rates vary from 40% to 86%. The most favorable prognostic factor is early diagnosis and the complete excision of the tumor at initial surgery.

Concluding Remarks on Preoperative Parathyroid Imaging When Planning Minimally Invasive Parathyroidectomy

There are advantages and limitations in each of the imaging modalities described in this chapter, and various combinations are used to achieve accurate and reliable preoperative localization of the parathyroid lesion(s) for which surgery is planned. Final choice of the patient-specific imaging sequence often depends on local availability and attitudes rather than on strictly designed algorithms.

A practical algorithm has recently been proposed as a guide to imaging in patients with primary HPTH [30] (Fig. 13). The underlying condition is that the diagnosis of primary HPTH has been firmly established on the basis of biochemical parameters, that is, increased serum calcium levels with inappropriately increased PTH levels. High-resolution US examination of the neck is generally the first imaging test in these conditions, since this procedure is widely available, easy to perform and, in experienced hands, frequently enables to identify an orthotopically located parathyroid adenoma (i.e., adjacent to thyroid tissue); furthermore, US-guided FNA cytology can be performed in equivocal/inconclusive cases. On the other hand, the mediastinum and the para-tracheoesophageal space (possible sites of ectopy) cannot be explored with US, and the diagnostic performance is reduced in patients previously submitted to surgery; furthermore, US examination is a highly operator-dependent technique.

Unequivocal identification/localization of a parathyroid adenoma by high-resolution US would in principle be sufficient to guide a minimally invasive surgical approach, possibly associated with intraoperative quick PTH assay for assessing correct resection of the parathyroid lesion (see dotted path in the upper left portion of Fig. 13). Nevertheless, localization of the adenoma is generally confirmed in these patients with ^{99m}Tc-sestamibi scintigraphy, which is useful also to exclude and possible additional, ectopic hyperfunctioning glands (especially if performed with hybrid SPECT/CT imaging). Fused SPECT/CT images yield extremely useful functional and anatomic information for preoperative planning. Furthermore, in case of a positive ^{99m}Tc-sestamibi scan, radioguided surgery can be performed, as indicated by the RGS-MIRP acronym in Fig. 13 (RGS, "radioguided surgery"; MIRP, "minimally invasive radioguided parathyroidectomy").

^{99m}Tc-sestamibi scintigraphy (which entails a much smaller radiation burden than contrast-enhanced CT) is mandatory as a second-line imaging procedure in patients with a negative or inconclusive US examination. Patients with negative US but with positive scintigraphy may undergo a focused surgical approach, especially if radioguided surgery is to be employed. Nevertheless, such discordant findings should be clarified with third-line imaging, such as CT and/or MRI).

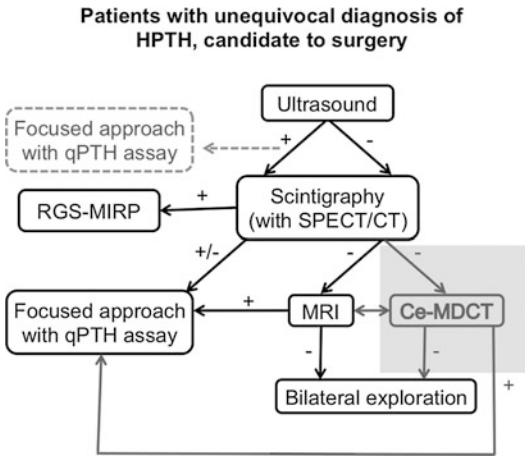

Fig. 13 Flowchart diagram showing an algorithm proposed for noninvasive preoperative imaging of patients with PHPT. The *gray-shaded* path in the *right lower* portion indicates the goal of reducing the use of contrast-enhanced CT in favor of MRI. The *dotted gray* path in the *upper right* portion demonstrates the patient who undergoes focused surgery directly on the basis of unequivocal localization of a parathyroid lesion by US, as in the case of a negative ^{99m}Tc-sestamibi scintigraphy after unequivocal US localization of parathyroid lesion(s). *Ce-MDCT* contrast-enhanced multi-detector computed tomography, *qPTH* intraoperative quick PTH assay, *RGS-MIRP* radioguided surgery minimally invasive radioguided parathyroidectomy

Further investigation with either CT or MRI is recommended for patients in whom both US and ^{99m}Tc-sestamibi scintigraphy are negative. To this purpose, the current practice in most centers is to rely on contrast-enhanced CT, unless there are clear contraindications to administration of the iodinated contrast medium. Since access to MRI is generally more limited than that to CT imaging, MRI is currently reserved for selected cases only, although the use of MRI is to be recommended in the perspective of reducing the radiation burden to patients (especially to the thyroid); this is the reason why the CT path in Fig. 13 is shaded in gray.

In patients with unequivocal localization of parathyroid lesion(s) by either CT or MRI, a minimally invasive procedure (combined with intraoperative PTH assay for) can safely be performed. Finally, a classical bilateral surgical exploration is justified when all the imaging techniques employed have failed to identify the hyperfunctioning parathyroid gland(s) or have provided inconclusive findings.

Diagnostic Applications of Nuclear Medicine: Breast Cancer

21

Marsha Camilla Lynch, Jean H. Lee, and David A. Mankoff

Abstract

This chapter details the use of radiotracer methods in application to breast cancer. We provide a background on breast cancer incidence and clinical features, followed by an overview of current treatment approaches. We then review the use of radionuclide methods applied to major diagnostic tasks for breast cancer that include detection, staging (locoregional and distant), response to therapy, and surveillance.

Keywords

Breast cancer • Diagnosis • Staging • Restaging • Nuclear medicine • [^{18}F]FDG PET/CT • Prognosis

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FES	16-Alpha-^{18}F-fluoro-17 beta-estradiol
^{18}F-FFNP	21-^{18}F-fluoro-16α,17α-[(R)-(10-α-furylmethylidene)dioxy]-19-norpregn-4-Ene-3,20-dione
^{18}F-FLT	^{18}F-fluorothymidine
^{99m}Tc-HDP or ^{99m}Tc-HMDP	^{99m}Tc-hydroxymethylene diphosphonate
^{99m}Tc-MDP	^{99m}Tc-methylene diphosphonate

BRCAPRO	BRCA mutation carrier prediction model
BS	Bone scintigraphy
BSGI	Breast-specific gamma imaging, also known as molecular breast imaging
CHEK2	Checkpoint kinase 2
CR	Complete response
CT	X-ray computed tomography
DCIS	Ductal carcinoma in situ
DFS	Disease-free survival
ENE	Extranodal extension
ER	Estrogen receptor
ERBB2	Gene for the HER2 receptor
FISH	Fluorescent in situ hybridization
HER2	Human epidermal growth factor receptor 2, also known as receptor tyrosine-protein kinase erbB-2, or HER2/neu
IM	Internal mammary
LABC	Locally advanced breast cancer
MBC	Metastatic breast cancer
MHT	Menopausal hormone therapy
MRI	Magnetic resonance imaging
mTOR	Mammalian target of rapamycin
$Na^{18}F$	Sodium [^{18}F]fluoride
NAT	Neo-adjuvant therapy
NCCN	National Comprehensive Cancer Network
NPV	Negative predictive value
OS	Overall survival
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PALB2	Partner and localizer of BRCA2, also known as FANCN
pCR	Pathologic complete response
PEM	Positron emission mammography
PET	Positron emission tomography
PET/CT	Positron emission tomography/computed tomography
PR	Progesterone receptor
PTEN	Phosphatase and tensin homolog
RECIST	Response evaluation criteria in solid tumors
SBI	Society of Breast Imaging
SERM	Selective estrogen receptor modulator
SLN	Sentinel lymph node
SNP	Single nucleotide polymorphism
SPECT	Single-photon emission computed tomography
SPECT/CT	Single-photon emission computed tomography/computed tomography
SUV	Standardized uptake value
TNBC	Triple-negative breast cancer
TNM	AJCC staging system based on parameters “T” (tumor status), “N” (lymph node status) and “M” (distant metastasis status)
US	Ultrasonography

Epidemiology of the Tumor

Breast cancer is the most common non-skin cancer and the second leading cause of cancer mortality in women [1, 2]. Breast cancer is largely a disease of women (one in eight lifetime risk) with an estimated 231,840 new cases expected to be diagnosed in the USA in 2015 [1]. The incidence of breast cancer in men is ~100 times less than in women, with approximately 2,350 new cases expected in 2015. A sharp 7% decline in incidence of breast cancer occurred among white women between 2002 and 2003 attributable to a decline in the use of menopausal hormone therapy (MHT) after a 2002 report linked the use of combined estrogen plus progestin MHT with an increased risk of breast cancer and coronary heart disease [3]. More recently (data from 2007 to 2011), the incidence rates have been stable in white women and increased slightly to 0.3% in black women [2].

There has been a steady decrease in mortality from breast cancer since 1989, attributed to both improvements in early detection, screening programs initiated in the USA in the early 1980s, and treatment [4, 5]. Despite several randomized control trials demonstrating the mortality benefit of screening, there remains controversy on screening guidelines for average-risk women. New 2015 recommendations from the American Cancer Society (ACS) now suggest yearly screening beginning from 45 through 54 and biennial screening from age 55 to age 74 or expected lifetime of less than 10 years [6]. Other organizations including the Society of Breast Imaging (SBI), American College of Obstetricians and Gynecologists (ACOG), and American College of Radiology (ACR) continue to recommend annual screening beginning at age 40. Just over 40,000 women and 400 men are expected to succumb to the disease in 2015. Mortality rates from the most recent data have slightly favored younger more than older women and white more than black women in recent times [2].

Risk Factors

Risk factors for development of breast cancer are due to one or a combination of genetic/familial, reproductive/hormonal, lifestyle, and environmental factors. Further, some of these factors may be classified as modifiable/external or non-modifiable/internal. The most well-established risk factors for female breast cancer include age, family history and genetics, late first pregnancy, and obesity [7]. Besides obesity, other modifiable factors that contribute to breast cancer risk include physical inactivity, use of MHT, long-term heavy smoking, and alcohol consumption [8, 9]. Other well-established non-modifiable risk factors include long menstrual history (early menarche, late menopause), mantle radiation for Hodgkin's lymphoma, and inherited gene mutations (e.g., BRCA1/BRCA 2). Factors shown to decrease the risk of breast cancer include breastfeeding for at least a year, increased physical activity, and, in high-risk women, decreasing endogenous estrogens by either inhibition of the estrogen receptor using selective estrogen receptor modulators (SERMs) or blocking estrogen synthesis using aromatase inhibitors (AIs). It is estimated that in some populations of average-risk women, lifestyle risk reduction measures may contribute to up to a 30% decrease in overall risk and chemopreventive measures using SERMS and AIs may reduce breast cancer risk by up to 50% [9–12].

Age is an important risk factor. The highest risk of developing invasive breast cancer by age group occurs in women 70 and over (1 in 15), while the

risk in women 39 years and younger is only 1 in 208. The majority of women who develop breast cancer are postmenopausal; however, breast cancer is not uncommon in premenopausal women. Breast cancer in younger women tends to be more aggressive than breast cancer diagnosed for older women and is an important cause of mortality in younger patients. Breast cancer is the leading cause of cancer death in women age 20–59, accounting for over 12,000 deaths annually [2].

Genetic Predisposition

Approximately 30% of breast cancer cases are familial and associated with mutations in breast cancer susceptibility genes. Of these, up to 30% are due to high-penetrance mutations in the BRCA1, BRCA2, PTEN, and p53 genes, and these patients face substantially increased lifetime risk of breast cancer, between 40% and 85% over the average-risk women (~12%). Mutations in genes related to DNA repair, such as PALB2 and CHEK2, have also been shown to be associated with moderate risk [13–15]. Several risk assessment models have been developed to estimate the breast cancer risk or probability of carrying a susceptibility genetic mutation, most notably the Gail, Claus, BRCAPRO, Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BODAICEA), and Tyrer-Cuzick models [16–20]. These models take into account various sets of risk factors to estimate an individual's risk, including genetic mutations, family history, history of chest irradiation and personal history of ductal carcinoma in situ, ovarian cancer, lobular neoplasia, or atypical ductal hyperplasia, which are used to inform provider and patient decision-making regarding an appropriate screening timetable. The ACR/SBI recommends annual screening with mammography and breast MRI for women with a lifetime risk of greater than 20% for developing breast cancer beginning by age 30, for known high-penetrance gene mutations, 10 years earlier than the youngest affected relative or 8 years after chest radiation [21].

There are other common genetic variants, single nucleotide polymorphisms (SNPs), that confer a much smaller increased risk, but may in combination account for a more substantially increased risk of development of breast cancer in the remainder of familial breast cancer patients who do not have an identifiable high-risk or moderate-risk genetic mutation. Currently, there are more than 90 risk loci identified through genome-wide-associated studies, a technique used to identify genetic variations associated with breast cancer, with estimated hundreds more yet to be discovered that might explain significant proportion of familial and sporadic breast cancer risk [22, 23].

Underlying Breast Cancer Biology Changes

Breast cancers arise from the epithelial cells in the breast cancer ducts [24]. The most important histologic feature in the primary tumor is the presence or absence of tumor invasion beyond the ductal architecture. Tumors that have not broken through the outer boundaries of ductal structures are termed noninvasive (ductal carcinoma in situ, DCIS) and rarely metastasize [24]. Invasive cancers are those that have broken through tissue boundaries at the time of diagnosis and have the potential to metastasize both through lymphatic and hematologic spread. Other histologic features of note include the architectural pattern (ductal, lobular, or mixed), nuclear grade (low, intermediate, or high), and the presence or absence of lymphovascular invasion [24]. In addition to morphological analyses, biopsy material is routinely assayed for phenotypic features that include the expression of hormone receptors (estrogen receptor [ER] and progesterone receptor [PR]) and HER2/neu (also known as cerbB2), typically by immunohistochemistry or fluorescent in situ hybridization (FISH).

The use of gene expression profiling methods has yielded further insights into breast cancer phenotype [25] establishing the current understanding of breast cancer, not as a single entity but as a heterogeneous disease with a number of subtypes defined by distinct molecular signatures [26–32]. Perou et al. proposed four breast cancer subtypes: (1) luminal A, typically hormone receptor positive

Table 1 Four major subtypes of invasive breast cancer used clinically (Adapted from [27])

Subtype	Standard immunochemical results and cancer grade	Frequency (%)	Comments
Luminal A	ER^+ PR^+ HER^+, usually low grade	50–55	Best prognosis, low Ki-67 level
Luminal B	ER^+ PR^+ HER^-, usually intermediate to high grade	15	Generally more proliferative (high Ki-67 levels) with less marked hormonal receptor expression than luminal A tumors, approximately 30% are HER2 positive
HER2 enriched	ER^- PR^- HER^+, usually midgrade to high grade	15	Prognosis much improved with directed therapy (e.g., trastuzumab); 30–40% of tumors also express ERs and PRs
Basal-like	ER^- PR^- HER^-, high grade	10–20	Often synonymous with triple negative

and histologically low grade; (2) luminal B, typically hormone receptor positive and histologically medium to high grade; (3) HER2 enriched, which show increased expression of the ERBB2 gene; and (4) basal-like, which express neither the ER/PR receptors nor HER2 ("triple negative") and typically express high levels of genes favoring cellular proliferation. Basal cancers represent the most aggressive tumors (see Table 1).

Measuring levels of certain cellular biomarkers within tumors, e.g., Ki-67, a marker of cellular proliferation, can clarify the molecular portrait of a particular tumor and also aid in prediction of tumor aggressiveness and behavior. Molecules and receptors may also serve as targets for specific therapy, e.g., the HER2 receptor is targeted with the drug trastuzumab [33]. Some predictive expression panels are now approved and used in clinical practice [34]. For example, the 21-gene assay used in the Oncotype DX (Genomic Health Inc.) panel is now routinely used to determine which patients with early-stage ER-positive breast cancer may benefit from adjuvant chemotherapy in addition to endocrine therapy [27, 35, 36].

Staging Categories and Prognostic Stratification

Breast cancer stage at presentation is an important factor in prognosis and treatment. Stages are defined in Table 2. The most widely accepted (AJCC) system uses a TNM approach [37]. There is also a stage classification, which includes groups of TNM categories ranging from early-stage disease (stage I) to late-stage, metastatic disease (stage IV). Improved diagnosis, staging, and especially sentinel lymph node (SLN) biopsy resulted in significant changes in breast cancer staging definitions in the 6th edition of the AJCC staging manual, reviewed in Singletary et al. [37] with no major changes [38] to the breast cancer staging definitions in the currently used 7th edition of the AJCC guidelines [39] published in 2010.

Breast Cancer Detection and Diagnosis, Modalities Other Than Nuclear Medicine for the Tumor

Mammography is the primary imaging modality for breast cancer screening, detection, and diagnosis [40]. The average earlier stage and smaller size of lesions detected by mammographic screening, versus symptomatic and/or palpable lesions, reflects the success of mammographic screening, which has been shown to reduce breast cancer mortality [40]. Full-field digital mammography has largely replaced screen-film mammography. And the recent addition of digital breast tomosynthesis has been shown to reduce false-positive rates and increase cancer detection [41, 42]. Both ultrasound and MRI are important adjuncts to x-ray mammography for detection, diagnosis, characterization, and determination of the extent of breast cancer and are routinely utilized in these roles [43, 44].

MRI has been shown to be useful for screening in high-risk patients, i.e., women with greater than 20% lifetime risk of breast cancer.

Table 2 Summary of the AJCC staging system for breast cancer (Adapted from [37–39])

Tumor (T)
T0 – no primary tumor found
Tis – carcinoma in situ
T1 – invasive cancer <2 cm in greatest dimension
T1mic – microinvasion ≦0.1 cm in greatest dimension
T1a – tumor >0.1 cm but ≦0.5 cm in greatest dimension
T1b – tumor >0.5 cm but ≦1 cm in greatest dimension
T1c – tumor >1 cm but ≦2 cm in greatest dimension
T2 – tumor >2 cm but ≦5 cm in greatest dimension
T3 – tumor >5 cm in greatest dimension
T4 – tumor of any size with direct extension to chest wall or skin
Regional lymph nodes (N) (clinical staging)[a]
N0 – no regional nodal metastases
N1 – metastasis in mobile ipsilateral axillary nodes
N2 – metastasis to fixed ipsilateral axillary nodes (N2a) or ipsilateral internal mammary nodes in the absence of ipsilateral axillary lymph node metastasis (N2b)
N3 – metastases in ipsilateral infraclavicular nodes and axillary nodes (N3a) or ipsilateral internal mammary nodes and axillary nodes (N3b) or metastases to ipsilateral supraclavicular nodes (N3c)
Regional lymph nodes (N) (pathologic staging)[b]
pNX – regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
pN0 – no regional lymph node metastasis histologically, no additional examination for isolated tumor cells
pN0(i−) – no regional lymph node metastasis histologically, negative immunohistochemical staining
pN0(i+) – isolated tumor cells identified histologically or by positive immunohistochemical staining, no cluster >0.2 mm
pN0(mol−) – no regional lymph node metastasis histologically, negative molecular findings
pN0(mol+) – no regional lymph node metastasis histologically, positive molecular findings
pN1 – metastasis in one to three axillary lymph nodes and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[a]
pN1mi – micrometastasis (>0.2 mm, none >2.0 mm)
pN1a – metastasis in one to three axillary lymph nodes
pN1b – metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[a]
pN1c – metastasis in one to three axillary lymph nodes and in internal mammary lymph nodes[c] with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[a]
pN2 – metastasis in four to nine axillary lymph nodes or in clinically apparent[a] internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN2a – metastasis in four to nine axillary lymph nodes (at least one tumor deposit >2.0 mm)
pN2b – metastasis in clinically apparent[a] internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN3 – metastasis in ten or more axillary lymph nodes or in infraclavicular lymph nodes or in clinically apparent[a] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes or in more than three axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes or in ipsilateral supraclavicular lymph nodes
pN3a – metastasis in ten or more axillary lymph nodes (at least one tumor deposit >2.0 mm) or metastasis to the infraclavicular lymph nodes
pN3b – metastasis in clinically apparent[a] ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes or in more than three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent[a]
pN3c – metastasis in ipsilateral supraclavicular lymph nodes
Distant metastases (M)
MX – distant metastases cannot be assessed

(*continued*)

Table 2 (continued)

M0 – no distant metastases			
M1 – distant metastases			
Alternate staging system for invasive breast cancer			
Stage I	Stage II	Stage III	Stage IV
T1N0M0	Stage IIA	Stage IIIA	Any T, any N, M1
	T0N1M0	T3N1M0	
	T1N1M0	T1-3N2M0	
	T2N0M0	Stage IIIB	
	Stage IIB	T4N0-2 M0	
	T2N1M0	Stage IIIC	
	T3N0M0	Any T, N3M0	

[a]This system is for clinical staging based upon imaging and physical examination
[b]Pathologic staging for nodal metastases is further classified for sentinel lymph nodes, for detection on the basis of immunohistochemistry assays, and for detection on the basis of molecular assays. Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," such as pN0(i_)(sn)
[c]If associated with more than three positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden

In a meta-analysis of 14 studies of high-risk women conducted between 2000 and 2011, MRI was shown to have higher sensitivity for malignancy (84.6%) than mammography (38.6%) or ultrasound (39.6%) [45].

The American Cancer Society recommendations have incorporated MRI for screening in high-risk patients [46]. Mammography, ultrasound, and breast MRI can all be used to direct tissue sampling by needle biopsy for breast cancer diagnosis.

Randomized control trials have shown no survival or quality of life benefit when annual mammography has been compared with intensive imaging or laboratory surveillance in asymptomatic women with early-stage breast cancer [47].

With regard to staging and metastatic workup for asymptomatic women with a history of early-stage breast cancer, stage I, IIA, and IIB, no further imaging is indicated beyond diagnostic mammography (with adjunct use of US and MRI) given the low chance of distant metastases and the higher chance of false-positive findings [48]. For later stage breast cancer patients, stage III and above current guidelines recommend chest CT, abdomen +/− pelvis CT or MR, bone imaging (bone scintigraphy (BS) or $Na^{18}F$ PET/CT), and optional [^{18}F]FDG PET/CT. Bone scan and [^{18}F]FDG PET/CT are the most common nuclear imaging methods used in staging and metastatic workup. These will be discussed later. Again, anatomic imaging modalities are considered the gold standard with chest and abdominopelvic CT, breast MR, and brain MR performed as directed by physical examination and clinical assessment.

Nuclear Imaging for Primary Detection and Diagnosis

Radiotracer methods for primary breast cancer detection and diagnosis have not as yet found widespread use despite some important advantages over anatomic imaging, namely, the potential for more specific targeting of breast cancer tissue, good tumor to background contrast, and uptake independent of breast density [49–53]. ^{99m}Tc-sestamibi is the most common single-photon radiopharmaceutical used in both scintimammography, imaging of the breast using traditional nuclear medicine gamma cameras, and breast-specific gamma imaging (BSGI, also called molecular breast imaging), imaging with dedicated breast small field-of-view gamma cameras. The radiopharmaceutical is taken up and retained differentially in breast tumors from normal breast tissue. The specific mechanism is unknown, but appears to depend on factors relating to regional blood flow, plasma and mitochondrial membrane potential, angiogenesis, and tissue

metabolism [54–56]. Scintimammography, however, has a limited ability to detect lesions less than 1 cm and also has lower sensitivity for non-palpable lesions. BSGI can overcome some of these limitations using dedicated devices that provide high spatial resolution using dedicated breast imaging devices [49, 51, 57]. The disadvantage of both techniques is that they require relatively long imaging times and subject the patient to a substantially increased radiation dose (15–30 times) compared with mammography [57, 58]. At present, they are not indicated for routine screening/primary detection.

PET has also been tested in application to breast cancer detection and diagnosis, spurred by the finding of increased 2-Deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) uptake in cancer compared to normal breast tissue. [^{18}F]FDG uptake in tumors reflects the rate of glucose metabolism and correlates somewhat with histologic type (higher uptake in ductal vs. lobular), tumor histologic grade, and indices of cellular proliferation (higher uptake with higher levels of proliferation) [59, 60]. Overall, the sensitivity of whole-body [^{18}F]FDG PET in the detection of primary breast cancer ranges 64–96%, specificity of 73–100%, positive predictive value of 81–100%, and negative predictive value of 52–89% [61]. Whole-body [^{18}F]FDG PET however has low sensitivity for small, well-differentiated, and in situ cancers [62]. As with ^{99m}Tc-sestamibi scintimammography, this has severely limited its use for primary tumor diagnosis.

Dedicated breast positron emission mammography (PEM) units have been developed [63], and advantages include higher spatial resolution, shorter imaging time, and reduced attenuation compared with whole-body imaging. PEM units allow a co-registration of anatomic and molecular information similar to PET/CT and have biopsy capability [64]. In a large trial of patients with newly diagnosed early breast cancer, PEM showed improvement in specificity over MRI, and the performance of PEM plus conventional imaging is similar to MRI with regard to cancer detection [65].

However, PEM limitations include difficulty in imaging posterior lesions, variable [^{18}F]FDG uptake in small tumors, and false-positive findings from prior biopsy [66, 67]. In addition, similar to single-photon techniques, radiation doses are significantly higher than mammography [57].

Nuclear Imaging for Regional Nodal Staging

Staging is typically divided into regional lymph nodes, especially axillary nodes, and distant or systemic staging of sites beyond regional lymph nodes, especially to visceral organs (lung and liver) and bone. Almost all patients with invasive breast cancer will undergo axillary nodal staging, since the presence or absence of axillary lymph nodes is an important consideration for further treatment after surgery [68].

The traditional approach to axillary nodal staging was the axillary nodal dissection, where axillary contents were removed and examined; however, the morbidity of this process, including a significant incidence of lymphedema, led to the search for a less morbid but equally accurate approach [68]. This consideration motivated sentinel lymph node (SLN) methods, designed to identify and sample the node(s) that are the first draining nodes, i.e., "sentinels" in the axillary drainage basin for the breast lesion. SLN biopsy is a shorter surgical procedure than full axillary nodal dissection with much less morbidity [68]. If sentinel nodes are negative, then the chance of "downstream" nodal metastases is quite small, and the patient can be spared the full dissection. If the sentinel node shows evidence of metastasis, then an axillary dissection may be needed to determine the extent of axillary spread. SLN biopsy has been shown to be highly accurate compared to axillary dissection [69–71] and has emerged as the standard of care for axillary nodal sampling in patients with clinically negative axillae [72]. SLN biopsy has been thoroughly tested in large clinical trials and shown to be safe and accurate, with comparable relapse and survival compared to axillary nodal dissection [73, 74]. Further, a large randomized clinical trial showed that completion axillary dissection is not useful for improved locoregional control or survival in women with smaller (T1/T2) tumors, no palpable adenopathy, and one or two positive nodes positive by SLNB without gross ENE [75].

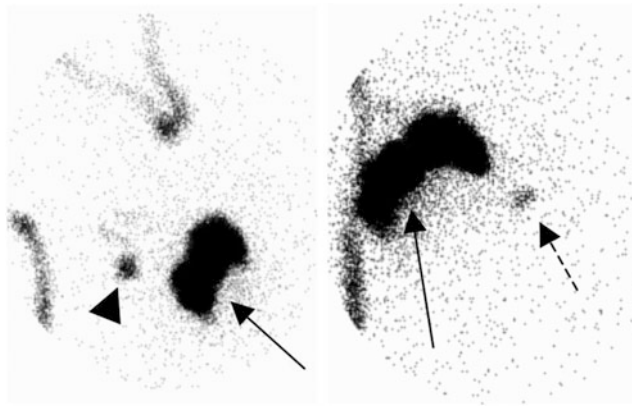

Fig. 1 Lymphoscintigraphy for breast cancer sentinel lymph node mapping. Images (oblique, *left*, and anterior, *right*), with the body contour outline drawn using a radioactive marker, show a peri-lesional injection (*solid arrows*), an axillary sentinel lymph node (*arrowhead*), and drainage to an internal mammary lymph node (*dashed arrow*)

Radionuclide methods play a key role in SLN biopsy (see also ▶ Chap. 47, "Radioguided Surgery for Breast Cancer" of this book). Typically, for SLN mapping, a colloidal radiopharmaceutical (^{99m}Tc-sulfur colloid in the USA, ^{99m}Tc-nanocolloidal albumin or ^{99m}Tc-antimony in Europe) is injected, and sentinel nodes are identified through imaging (lymphoscintigraphy, Fig. 1), gamma probes, or both [76]. Other, more specific agents have been developed and are undergoing testing [77]. Some centers use both radiocolloid and visible blue dye to guide SLN sampling, while some centers use one of the methods without the other [68].

The importance of sampling internal mammary (IM) nodes has been a point of considerable debate [78]. Studies using SLN mapping and lymphoscintigraphy to sample IM lymph have demonstrated the feasibility of this approach [79–81]; however, the overall percentage of positive IM nodes is on the order of 5% or less. And although a significant proportion of breast cancers have primary drainage to the IM nodes, approximately 30% of medial tumors and 15% of lateral tumors, it is rare to have IM lymph node metastasis in the absence of axillary nodal metastases [82]. As a result, most practices in the USA do not routinely sample IM nodes. Yao et al. [83] found that patients with positive axillary nodes and IM nodal drainage, even in the absence of IM nodal sampling, were significantly more likely to relapse and die of breast cancer than those without drainage. Another study found a higher rate of nodal relapse outside the axilla, versus in the axilla, after SLN biopsy [84]. Such studies prompt careful consideration of the approach to SLN mapping in breast cancer and the potential benefit of peri-lesional injection, which have a higher likelihood of drainage demonstrating IM nodal drainage, and lymphoscintigraphy in selected patients to identify extra-axillary drainage [85].

There was considerable interest in [^{18}F]FDG PET as a noninvasive imaging method to detect axillary nodal spread in newly diagnosed breast cancer and avoid the need for invasive biopsy. However, although early studies showed high sensitivity of increased uptake in axillary nodes in breast cancer, multiple subsequent studies including larger multicenter trials have failed to show sufficient sensitivity of PET in the staging of the axilla in patients with early-stage breast cancer [86, 87] to obviate the need for tissue sampling with SLN mapping and biopsy [88–90]. Early-stage breast cancer patients, i.e., those with small tumors less than 2–3 cm with clinically negative axillary nodes, represent the majority of breast cancer patients, many clinically silent and diagnosed by screening mammography. Given the low probability of metastatic disease in this population

and the risk of false positives with whole-body PET/CT, there is no recommended role for [^{18}F]FDG PET in axillary or clinical staging in patients with early-stage disease [21, 91].

Nuclear Methods for Staging of Distant Metastases

Systemic evaluation for metastatic disease is recommended in the initial workup for high-risk and later clinical stage (≥stage III) breast cancer as well as for patients with recurrent breast cancer and known metastatic disease [48]. High-risk disease is commonly defined as locally advanced breast cancer (LABC) [48], including primary tumor larger than 5 cm, skin or chest wall involvement, fixed axillary nodes, positive supraclavicular/infraclavicular/IM nodes, and inflammatory cancer. Patients with LABC have a poor prognosis because of the high incidence of distant metastases during follow-up [92, 93]. In these patients detection of distant metastases is crucial to determine the initial goals of therapy, i.e., curative versus palliative and/or local control, and thus systemic staging is recommended as part of initial evaluation [48]. The bone scan and PET/CT play significant roles in systemic staging in breast cancer patients. Important areas of more distant spread for breast cancer include nodal beds outside the axillary and IM chain, for example, in the mediastinum, the lungs, the liver, and the bones [94].

The skeleton is the most common site for breast cancer metastases, affecting approximately 50–70% of patients, and is the sole site of metastatic disease in almost one half of patients [95–99]. For decades, the bone scan (BS) has been the primary method for staging breast cancer bone metastases despite well-known limitations with respect to sensitivity and specificity (Fig. 2). The most commonly used radiopharmaceuticals are ^{99m}Tc-hydroxymethylene diphosphonate (^{99m}Tc-HMDP or ^{99m}Tc-HDP) and ^{99m}Tc-methylene diphosphonate (^{99m}Tc-MDP) with accumulation within bone metastases related to changes in local blood flow and abnormally increased activity of osteoclasts.

The reported sensitivity ranges from 62% to 100% and specificity ranges from 78% to 100% [100, 101]. False positives can be caused by trauma, degenerative changes, and other benign conditions, while false negatives can occur in the presence of predominantly osteolytic metastases, low bone turnover, or in avascular regions (such as necrosis) [101]. Single-photon emission computed tomography (SPECT) has been shown to improve sensitivity and specificity [102–104], with further improvement in diagnostic confidence shown with SPECT/CT [105–108], likely due to the reduction of false positives through the morphological appearance CT. SPECT is particularly helpful to characterize solitary lesions in the spine and/or to differentiate bone metastases from degenerative lesions. Salvelli et al. reported the sensitivity and specificity of SPECT to be over 90% [102].

Sodium-[^{18}F]fluoride (Na^{18}F) is a bone-seeking positron-emitting agent with a similar mechanism of skeletal uptake as ^{99m}Tc-labeled bone scan agents. Both have uptake related to blood flow and osteoblastic activity; however, Na^{18}F has practical advantages over the single-photon bone scan agents that include faster clearance and higher contrast [109]. The now widespread availability of hybrid PET/CT systems has renewed interest in the relatively higher spatial resolution of Na^{18}F PET/CT for bone imaging, as there has been demonstrated higher diagnostic accuracy over BS (with or without SPECT) and CT for breast cancer and number of other malignancies [110–121] (Fig. 3). Several prospective trials and registries are ongoing which seek to more robustly address issues regarding time needed for interpretation, radiation dose, cost, and clinical impact compared to the BS [115, 122–126].

[^{18}F]FDG PET has also been shown to be complimentary, and in some studies superior to BS in the detection of skeletal metastases in most studies [127–131] (Fig. 4). There is however an important difference compared to bone scans and fluoride imaging. The increased uptake detected on [^{18}F]FDG PET is thought to be within the breast cancer tumor cells thus reflecting tumor activity within the bone rather the osteogenic (blastic) response of the bone architecture to the metastases, as is the case with BS and Na^{18}F uptake. Several studies demonstrated that [^{18}F]FDG PET is superior to bone scanning in the detection of lytic and

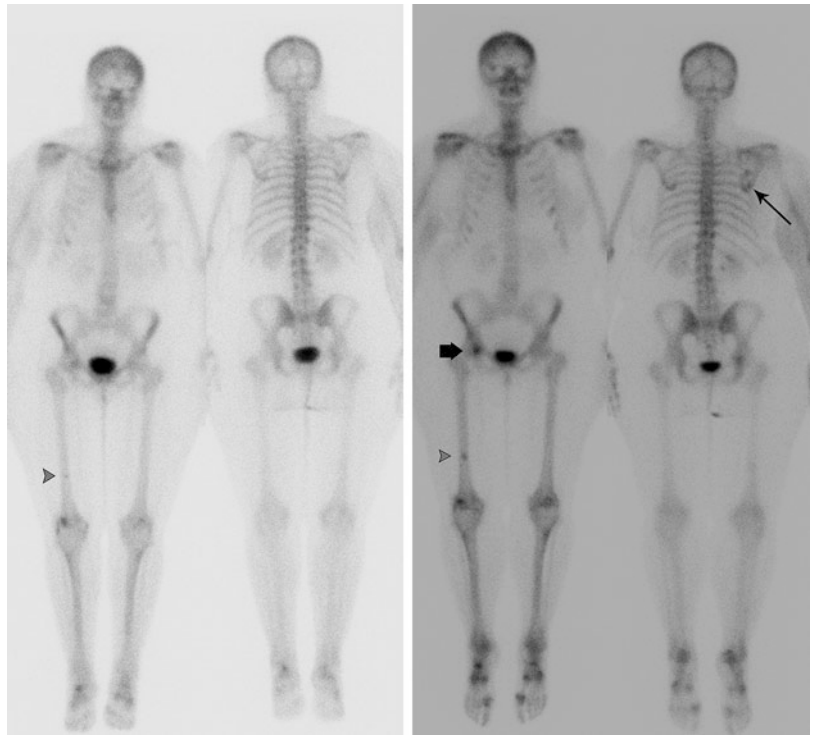

Fig. 2 Bone metastases identified by bone on two subsequent occasions during follow-up. ^{99m}Tc-methylene diphosphonate bone scan shows progression of osseous metastatic disease, for example, radiotracer uptake in the right femoral lesion (*arrowhead*) and new uptake in the right femoral head (*thick arrow*) and right scapula (*thin arrow*)

intramedullary metastases, but inferior for detecting primarily osteoblastic lesions. Cook and colleagues showed that [^{18}F]FDG PET detected the lytic metastases often missed by bone scan, while [^{18}F]FDG PET often missed osteoblastic metastases, for which bone scan is superior [132]. Subsequent studies confirmed these findings (reviewed in Fogelman et al. [63, 109]), showing that [^{18}F]FDG PET is complementary to bone scan and Na^{18}F imaging. Some of the increased sensitivity over BS is likely due to earlier detection of active tumor in bone prior to osteoblastic response [133]. Again, as with hybrid imaging with SPECT/CT and Na^{18}F PET/CT, specificity is gained through reduction of false positives with correlative CT aiding in improved differentiation between benign and malignant lesions. And though [^{18}F]FDG PET has been shown to have lower sensitivity for purely osteoblastic or sclerotic lesions [132, 134, 135], with many demonstrating no uptake, these may be detected by the changes on the accompanying CT [135]. Given reported high concordance between BS and [^{18}F]FDG PET/CT [136], and the known advantages over BS, the question of the necessity of the BS in the era of hybrid PET imaging is being raised. NCCN guidelines still recommend BS for staging in symptomatic patients with early-stage/operable breast cancer, and Na^{18}F PET/CT is now included in current NCCN guidelines as an alternative to BS [48]. In addition, a recent amendment suggests PET/CT may be helpful for problem solving in equivocal cases and that bone scanning/Na^{18}F PET/CT may not be necessary in cases where [^{18}F]FDG PET clearly demonstrate bone metastases [48].

Besides bony metastatic disease, [^{18}F]FDG PET has proven useful in the general detection of distant metastases for initial staging and restaging of breast cancer patients [95, 137–141]. A 48-patient pilot study by van der Hoeven et al. suggested that PET was more sensitive than conventional imaging in detecting distant metastases [138]. Recently, a prospective cohort study by Groheux et al. compared conventional imaging staging (bone scan, chest radiography or dedicated CT, liver ultrasound, enhanced CT abdomen and pelvis) with a single session of

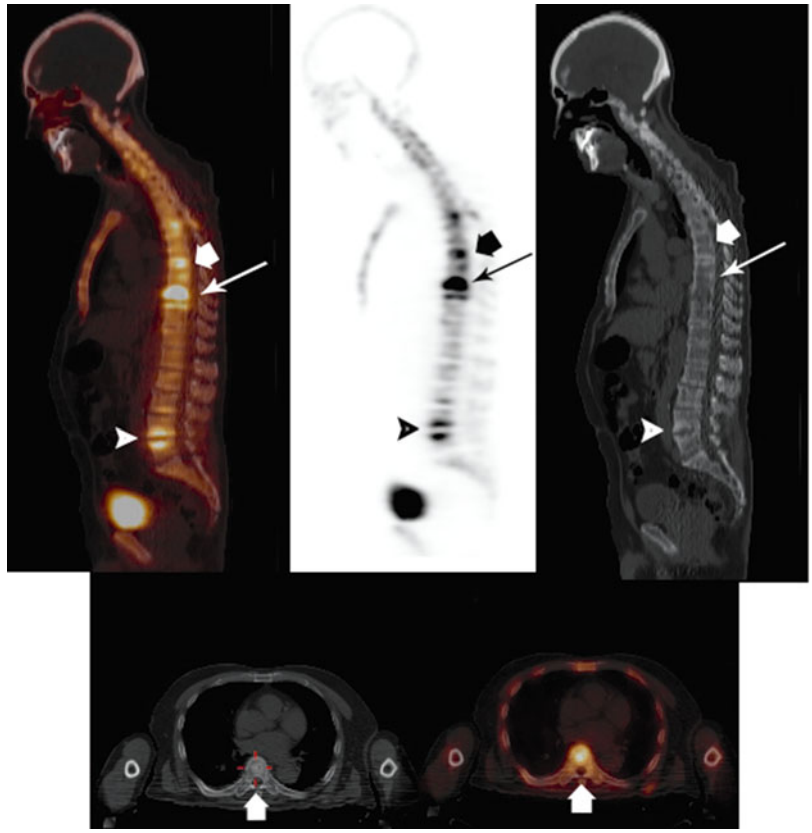

Fig. 3 Bone metastases identified by $Na^{18}F$ PET. Fluoride PET images (sagittal low-dose CT, emission, and fused images (*top*); low-dose CT and fused images (*bottom*)) of a patient with multiple bone metastases demonstrate the increased detail and tomographic information by PET. Sagittal images demonstrate radiotracer uptake in the cervical and thoracic spine compatible with osseous metastases, for example, at the T8 (*fat arrows*) and T10 (*thin arrows*). Axial images at the T8 level demonstrate increased tracer uptake associated with an osseous sclerosis (*fat arrow*). Note linear tracer uptake at the L4/L5 (*arrowhead*) level involving the inferior endplate of L4 and superior endplate of L5 corresponds to degenerate uptake

staging with [^{18}F]FDG PET [95] in 117 patients with LABC. The study found that not only did PET change the clinical stage in 61 patients (52%), PET identified more distant metastases compared to the conventional imaging (43 vs. 28 patients). In addition, PET/CT was found to outperform conventional imaging in detecting bone, distant lymph node, and liver metastases. Diagnostic chest CT outperformed PET/CT, owing to respiratory motion and partial volume effect reducing the sensitivity of PET for sub-centimeter lung nodules, and relatively more difficult visualization of sub-centimeter lung nodules on the lower dose acquisition CT obtained as part of the PET/CT.

There is ongoing study of the utility of PET/CT in staging intermediate risk breast cancer patients, i.e., patients with large breast cancers (T2) or clinical N1 disease [142, 143]. In a recent prospective study of 254 patients with clinical stage IIA through IIIC (as determined by clinical examination, mammography, breast MRI, and locoregional ultrasound), Groheux et al. found that imaging with [^{18}F]FDG PET/CT revealed distant metastatic disease in 2.3% of patients with clinical stage IIA disease (1/44), 10.7% of patients with stage IIB disease (6/56), 17.5% of patients with stage IIIA disease (11/63), 36.5% of patients with stage IIIB disease (27/74), and 47.1% of patients with stage IIIC disease (8/17) [143]. As expected the yield of metastatic disease increases with increasing clinical stage. Further studies are needed to determine clinical impact and cost-effectiveness of staging evaluation with PET/CT of patients in the intermediate risk category.

Approaches to Breast Cancer Therapy

With exception of very early- and late-stage disease, almost all breast cancer care involves a combination of locoregional and systemic treatments.

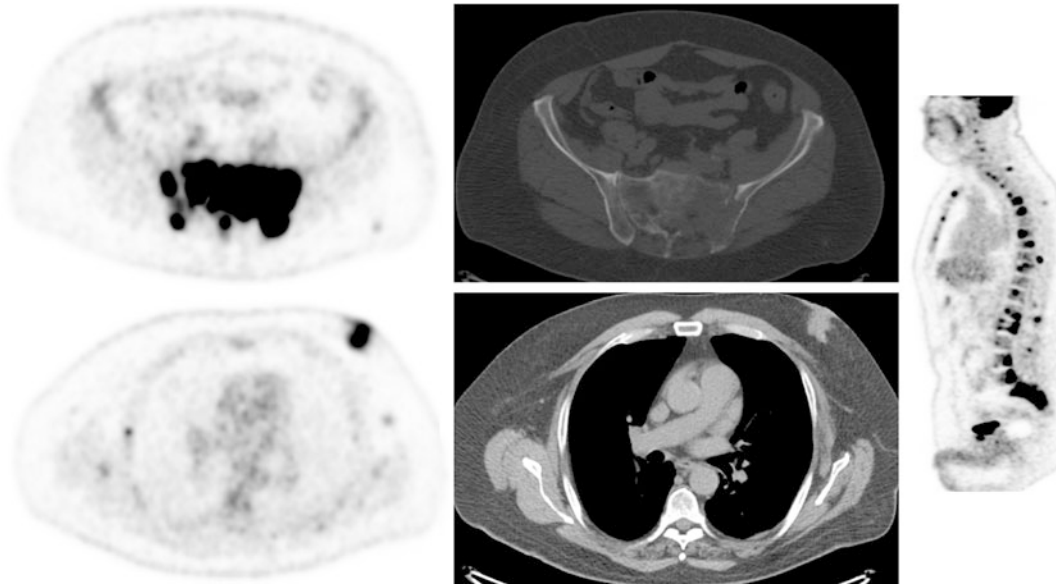

Fig. 4 Breast cancer distant metastases identified by [^{18}F] FDG PET/CT in a male patient presenting with back pain. Axial PET and low-dose CT images (*left* and *middle* columns) demonstrate increased [^{18}F]FDG uptake associated with destructive osseous metastatic lesion involving the sacrum. Sagittal PET (*right*) demonstrates multifocal osseous involvement of the spine and sternum. Axial PET and CT images on the *bottom row* demonstrate intense radiotracer uptake in a left breast nodule, corresponding to the primary invasive ductal carcinoma tumor

Locoregional therapy includes surgery and radiotherapy, and systemic therapy includes chemotherapy (e.g., taxanes), endocrine (hormonal, e.g., aromatase inhibitors) therapy, and/or targeted (biologic, e.g., anti-HER2 drugs) therapy.

Primary tumor excision remains a key component of the treatment of newly diagnosed breast cancer [144]. This includes mastectomy, removal of the entire breast, and breast-conserving surgery (BCS), also known as "lumpectomy" of the cancer [144]. Lumpectomy followed by adjuvant radiotherapy provides low rates of local recurrence and survival similar to mastectomy, but with preservation of the breast [145]. For invasive disease, axillary nodal staging is routinely performed at the time of surgery. The purpose of axillary sampling is largely for diagnosis; the therapeutic value of lymph node removal remains largely unproven [146]. For this purpose, sentinel lymph node has emerged as the preferred method for patients with clinically negative axillae [68], sparing the patient most of the morbidity, principally lymphedema, of full axillary dissection [147].

Breast cancer is one of the solid tumors that is often responsive to systemic therapy. Systemic therapy can be cytotoxic chemotherapy and can also involve more targeted and selective treatments. In all but the earliest cancers, adjuvant systemic therapy is used in addition to locoregional therapy to treat residual microscopic disease [145] and has contributed significantly to reduced breast cancer mortality. Systemic cytotoxic chemotherapy is used in more advanced or aggressive tumors, typically ER- or PR-negative tumors [148], triple-negative tumors, HER2-positive tumors, and large tumors [41, 48].

In ER-expressing tumors, adjuvant endocrine therapy is used, typically an aromatase inhibitor or tamoxifen [149]. In higher-risk ER-expressing tumors, both chemotherapy and endocrine therapy can be used [148]. RNA-based genomic testing can be used to aid in estimating the risk of distant recurrence and identify patients in this group who may benefit from chemotherapy [35]. Both types of treatment are also primary therapy for metastatic disease [150]. For HER2-positive breast cancer, trastuzumab, a HER2-specific monoclonal

antibody has been shown to substantially improve survival [151]. Directed therapy has become a key component of both adjuvant and metastatic systemic therapy for patients with HER2-overexpressing tumors [152, 153]. Pertuzumab, a monoclonal antibody directed against a different epitope than trastuzumab on the HER2 receptor, and lapatinib, a tyrosine kinase inhibitor targeting the HER2 pathway, are both routinely used in therapy regimes for higher-risk HER2-positive disease [48].

New breast cancer targets and therapy combinations continue to be investigated [154, 155]. Improvement in progression-free survival in women with hormone receptor-positive metastatic breast cancer has been demonstrated with the addition of the mTOR inhibitor everolimus [156] and more recently with the addition of the drug palbociclib, an inhibitor of cyclin-dependent kinases 4 and 6 [157].

In ER-negative tumors, chemotherapy is typically an important component of systemic therapy. This is typically combined with HER2-directed therapy in HER2-overexpressing tumors. On the other hand, tumors that are ER/PR/HER2 negative (triple negative, TNBC) are treated primarily using chemotherapy. The ongoing study is particularly important in triple-negative patients where therapies effective in other breast cancer subtypes (endocrine and HER2-targeted therapies) are unlikely to work [158, 159].

For patients with LABC, or those with large tumors who have smaller breasts and/or desire breast conservation, neoadjuvant therapy is considered. The primary purpose of this therapy is to reduce the size to the tumor to better facilitate BCS and local control. However, response to neoadjuvant therapy also provides valuable assessment of the tumor's response to therapy prior to definitive treatment.

Radiotherapy is commonly used as an adjunct to surgery in locoregional breast cancer treatment [160]. Lumpectomy in the absence of breast radiotherapy leads to unacceptably high rates of local recurrence [145]; therefore breast radiotherapy is an integral part of breast conservation treatment. In addition to radiation of the breast in patients undergoing breast conservation, adjuvant irradiation can also be used for the chest wall in mastectomy patients, but it is usually reserved for patients with larger tumors or documented chest wall invasion [160]. Adjuvant radiotherapy is also used in the treatment of involved nodal basins and has been shown to enhance survival in those patients with multiple axillary nodal metastases [161].

Assessing the Efficacy of Treatment(s)

Evaluating the efficacy of systemic treatment is an important diagnostic need for breast cancer. The largest population of patients undergoing systemic therapy for breast cancer receives treatment as adjuvant therapy, after completion of primary surgery. Since there should be no residual macroscopic disease after definitive surgery, imaging is not helpful for response monitoring for adjuvant therapy, except for re-staging upon suspicion of recurrence. Imaging however plays an important role in response evaluation of systemic neoadjuvant therapy (NAT), given prior to definitive surgery primarily in LABC, as well as systemic therapy given as the primary treatment for metastatic, stage IV disease.

In the neoadjuvant setting, studies have demonstrated that the extent of residual breast and axillary disease after treatment is prognostic for both disease-free survival (DFS) and overall survival (OS) [162–164]. Patients demonstrating complete pathologic response (pCR), defined as no residual invasive tumor at post-therapy surgery histopathology, have improved long-term outcome compared to patients without pCR [162, 164]. NAT offers both the opportunity to assess tumor responsiveness while improving surgical options for patients with locally advanced disease by down-staging the primary tumor.

Sized-based approaches such as physical exam and mammography that rely on changes in size for response evaluation (e.g., RECIST criteria [165]) do not reflect early changes at the molecular level that may occur prior to changes in tumor size. Functional imaging therefore may be particularly helpful in determining treatment efficacy earlier in the course, allowing for earlier change of therapeutic strategy, thus avoiding unnecessary toxic systemic side effects of ineffective treatments.

One of the earliest studies showing the use of [^{18}F]FDG PET in the assessment of treatment response was performed by Wahl and colleagues in 1993 [166]. The investigators observed significant quantitative differences in the [^{18}F]FDG uptake measured before and after 2 months of therapy (mid-therapy) for responders versus nonresponders. While nonresponders had no significant change, patients who went on to a good response had declines in [^{18}F]FDG SUV of 50% or more. Most subsequent studies evaluating response at mid-therapy found similar quantitative findings (reviewed in [63, 167, 168]. A meta-analysis of 19 studies including over 900 patients by Wang et al. [169] underscored that imaging earlier in the course of treatment (after the first or second cycle) with cutoffs between 55% and 65% declines from baseline as response criteria offered better correlation with pathologic response of primary tumors.

The knowledge that breast cancer is a molecularly heterogeneous disease has prompted response evaluation studies within the various molecular subsets of breast cancer [170]. Groheux et al. [171] and Humbert et al. [172], in prospective studies including women with HER2-positive breast cancer treated with trastuzumab-containing regimens showed that low residual metabolism post-NAT (SUV $<=3.0$ after two cycles and <2.1 after one cycle, respectively) strongly correlated with pCR. Similar studies in patients with ER-positive/HER2-negative tumors and triple-negative tumors have also been conducted [173–175]. ER-positive/HER2-negative tumor type is somewhat less [^{18}F]FDG avid at baseline and less sensitive to chemotherapy than more aggressive subtypes (e.g., TNBC) [170], and pCR is rarely achieved. Studies have found that for this subtype baseline SUV and changes after one or two cycles of NAT may offer prognostic value in the form of survival rather than pCR [174, 175]. For triple-negative tumors, change in SUV from baseline has been shown to correlate with pCR, which is more closely associated with survival [173]. These studies indicate that assessment of serial PET data to infer breast cancer response to therapy should be considered in light of breast cancer subtype, supported by studies showing that [^{18}F]FDG kinetics may vary by breast cancer subtype [170].

Although some researchers have shown advantages of obtaining specific kinetic parameters of the tumor over the static SUV measurements [176], measuring percentage change in SUV from baseline and measuring absolute SUVs at baseline and follow-up time points are the most commonly used parameters in response assessment studies, likely due to ease of calculation and reproducibility. These studies highlight the need for standardization of the timing of interim [^{18}F]FDG PET evaluation, cutoff points, and criteria used in assessing response to therapy for different subtypes of breast cancer [177, 178]. Further, study outcomes may also be influenced by the specific treatment regimes.

Studies of [^{18}F]FDG PET performed after the completion of chemotherapy have shown reduced sensitivity for residual disease – i.e., that the absence of [^{18}F]FDG uptake is not a reliable indicator of complete pathologic response [167, 179–181]. This is especially true for axillary nodal disease since the sensitivity for residual microscopic disease post-therapy is low. However, recent studies have shown that the presence of [^{18}F]FDG uptake post-therapy is specific and highly predictive of relapse [182]. Therefore, even though [^{18}F]FDG PET may miss small-volume disease post-therapy, the presence or absence of [^{18}F]FDG uptake carries prognostic significance that may be important in directing follow-up.

In the metastatic setting, timely determination of the efficacy of systemic and/or targeted therapy is critical to the overall goal of maximizing survival and minimizing symptoms and side effects. Achieving and correlating with pCR is no longer the aim in this setting, and clinicians rely on clinical evaluation as well as anatomic and functional imaging in their assessment. Again, molecular imaging with [^{18}F]FDG PET can offer more and earlier insight into treatment response, particularly in cases where the regimen may produce an overall cytostatic (reflected in the tumor metabolism) rather than cytotoxic (reflected in tumor size) effect (Figs. 5 and 6). A number of small studies showed, similar to neoadjuvant therapy, that response of metastatic breast cancer (MBC) to

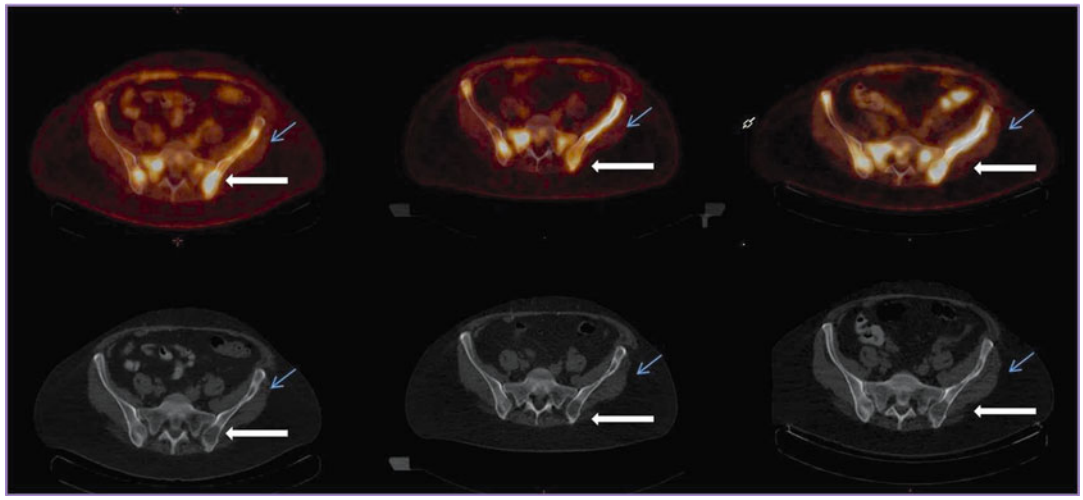

Fig. 5 Evolution of metabolic involvement in the pelvic bones of patient with bone-dominant metastatic at baseline, 4 weeks and 12 weeks post-endocrine therapy. Grossly unchanged lytic osseous change on CT images within the left iliac bone over the interval, however variable metabolic activity, with overall progression. Posterior left iliac bone involvement (*thick arrows*) demonstrates mild decline in metabolic activity at 4 weeks post initiation of therapy (SUV from 7.4 to 4.1) but however increased above baseline (7.9) at 12 weeks. Left iliac wing (*thin arrows*) demonstrates increase in [^{18}F]FDG uptake at 4 weeks, from 5.7 to 8.6, and persistent increase, to 10.8, at 12 weeks, with much more extensive changes. Later clinical follow-up revealed progression of osseous and new visceral metastases, indicating the ability of the serial [^{18}F]FDG PET/CT to indicate early disease progression

therapy is accompanied by substantial drops in [^{18}F]FDG uptake, typically 40–50% or more from the pre-therapy baselines [183–185]. Mortazavi-Jehanno et al. [186] showed that [^{18}F]FDG PET was predictive of progression-free survival in patients with ER-positive MBC tumors undergoing endocrine therapy, and more recently Lin et al. [187] found in a prospective studying including 82 patients with HER2-positive MBC undergoing early-line trastuzumab and lapatinib therapy that [^{18}F]FDG PET was useful for predicting response to therapy by RECIST.

A particularly difficult clinical problem is the evaluation of response for bone metastases [101]. Given that many bone lesions do not demonstrate a measurable soft tissue component, anatomic imaging using RECIST 1.1 is limited particularly with respect to evaluation of osseous metastases. Just as with detection, PET/CT has shown superiority to bone scan in assessment of treatment efficacy with regard to osseous metastases. Though excellent for detection, BS is problematic for response evaluation as changes will significantly lag behind the bone metastasis response and may even transiently worsen or "flare" in response to successful therapy [188, 189]. This flare phenomenon has also been shown with Na^{18}F PET/CT given the similarity in mechanism [190, 191] and thus has implications for the timing of Na^{18}F PET in response evaluations. In addition, given that [^{18}F]FDG PET is not as sensitive for sclerotic lesions and breast cancer bone metastases may be mixed lytic/sclerotic or sclerotic, Na^{18}F PET may provide a complementary role in assessment of response to therapy and has been shown to impact decision-making in treatment monitoring [192].

The observed differences between bone scintigraphy and [^{18}F]FDG PET for visualizing bone metastases [132] led some investigators to hypothesize that [^{18}F]FDG PET might provide a useful and accurate means for assessing bone metastasis response. Stafford and colleagues [193] showed that changes in [^{18}F]FDG uptake correlated with the clinical assessment of response in bone-dominant MBC as well as with changes in breast cancer tumor markers, which are used clinically to assess bone metastasis response. A follow-up

Fig. 6 Breast cancer response to treatment by serial [^{18}F]FDG PET. Sagittal PET and fused images from a patient with ≥30% decline in average lesion SUV_{max} after 4 weeks of endocrine therapy. For example, sternal involvement (*black* and *white arrows*) decreased from SUV_{max} of 16.0 at baseline to 7.2 after 4 weeks. The patient sustained a response with decline in average SUV at 12 weeks and was without progression for 15 months from initiation of this line of endocrine therapy. This was the third-line endocrine therapy for this patient. This case illustrates the ability of serial [^{18}F]FDG PET/CT to predict response of metastatic disease to systemic therapy in disease sites like bone that are challenging to follow by standard imaging such as CT and bone scan

study [194] by Specht et al. showed that changes in [^{18}F]FDG uptake predicted time to progression, and Tateishi et al. [195] showed that both metabolic and structural changes by [^{18}F]FDG PET/CT predicted bone metastasis time to progression.

These studies show the significant role [^{18}F]FDG PET may play in assessing treatment response for bone-dominant MBC.

Future Directions

As breast cancer treatment becomes increasingly targeted and individualized, there are increasing demands upon breast cancer diagnosis to help direct the therapeutic approach. The imaging approaches in current clinical use for diagnosing and staging breast cancer – mammography, ultrasound, contrast-enhanced MRI, CT, bone scan, and [^{18}F]FDG PET/CT – provide important information on disease extent and response to treatment, but are relatively nonspecific. Advances are more specific and quantitative, and molecular imaging methods are poised to help provide the kind of diagnostic data that are needed to help take advantage of new therapeutic options for breast cancer. We highlight some selected examples below. These include imaging tumor receptor expression and imaging tumor proliferation to assess early response to treatment.

The expression of tumor receptors and other proteins involved in cellular signaling is particularly relevant to breast cancer treatment. Targets of interest include the estrogen and progesterone receptors (ER, PR), targets for endocrine therapy, and HER2, the target for HER2-directed therapy. These biomarkers have been traditionally measured by in vitro assay of biopsy material [196]; however, the development of vivo molecular imaging of these targets is setting the stage for more specific guidance on treatment and management of breast cancer. Complementary advantages of imaging to measure receptor expression include its non-invasiveness, the ability to measure receptor expression in the entire disease burden and thus the ability to avoid sampling

error that can occur with heterogeneous receptor expression, and the potential for serial studies of in vivo drug effects on the target [197, 198].

PET imaging of the ER using the radiopharmaceutical 16-alpha-^{18}F-fluoro-17-beta-estradiol (^{18}F-FES) [199] has been validated as a measure of ER expression in breast tumors against ER expression assays of tissue samples by radioligand binding [200] and immunohistochemistry [201]. Higher ^{18}F-FES SUV has been correlated with response to endocrine therapy [197, 202, 203]. A majority of breast cancers express ER (approximately 70%) and ER status is an initial key determinant in therapeutic strategy [204]. Given that there may be substantial heterogeneity of ER expression across tumor sites [205, 206], functional imaging of the ER receptor with PET/CT appears positioned to provide valuable insights into tumor burden characterization and pharmacodynamic response to targeted therapy at different stages of the disease [198]. Interest in imaging of the progesterone receptor (PR) in vivo using 21-^{18}F-fluoro-16α,17α-[(*R*)-(1′-α-furylmethylidene)dioxy]-19-norpregn-4-ene-3,20-dione (^{18}F-FFNP) has been increasing [207] as tumors with ER/PR co-positivity are shown to be more re sponsive to endocrine therapy [208].

HER2 expression in breast cancer has become an important indicator of prognosis and an increasingly important target for therapy, and imaging probes using both single-photon radionuclides (e.g., ^{111}In-labeled-trastuzumab and ^{99m}Tc-ICR12) and positron-emitting radionuclides (e.g., ^{64}Cu-trastuzumab, ^{64}Cu-DOTA-$Z_{HER2:477}$, ^{68}Ga-trastuzumab F(ab′)$_2$ fragments, ^{68}Ga-ABY-002, and ^{89}Zr-trastuzumab) have been developed and validated [209, 210]. ^{89}Zr-trastuzumab PET/CT has emerged as one of the more favorable HER2 imaging methods due to advantageous radionuclide properties, biodistribution characteristics, and straightforward quantification capabilities of PET compared to single-photon techniques [210, 211]. A recent multicenter trial (ZEPHIR study) including patients with HER2-positive MBC who had progressed after prior trastuzumab therapy and were due to receive trastuzumab emtansine – a recently approved antibody-drug conjugate [212] – has shown that pretreatment HER2 and metabolic imaging with ^{89}Zr-trastuzumab PET/CT and [^{18}F]FDG PET, followed by metabolic assessment with [^{18}F]FDG PET after one cycle of therapy, had a 100% NPV for therapeutic response after three cycles of therapy and also predicted time to treatment failure [213]. This study paves the way for other studies to assess the utility of combination imaging using PET and other modalities not only in determination of treatment efficacy in a number of clinical settings, such as the neoadjuvant and first-line metastatic settings, but also as a predictive tool in the pre-therapy setting [214].

Although studies of [^{18}F]FDG PET have shown that tumor glycolysis declines early in the course of treatment [215–217], it is likely that other pathways more closely tied to cellular growth and death may provide even earlier and more specific indications of therapeutic response. Imaging cellular proliferation in breast tumors is becoming increasingly enticing, especially given the recent approval of a new drug palbociclib, which inhibits cell cycle progression into S phase [218].

A number of PET tracers are being developed and studied [219] with much attention focused on thymidine analogs, since thymidine is a substrate for activity of the thymidine salvage pathway for DNA synthesis. ^{18}F has largely replaced the short half-life ^{11}C [220] for radiolabeling proliferation analogs (new ref see comments), with the most promise shown with ^{18}F-fluorothymidine (FLT). A recent phase II study showed some promise for its use in predicting pCR in the neoadjuvant setting [221]. Work on other proliferation targets such as the sigma-2 receptor ligand is ongoing [222, 223].

Abstract

While CT and MRI provide high-resolution anatomic assessment of lung and mediastinal malignancies, [^{18}F]FDG imaging is superior in differentiating benign from malignant lymphadenopathy and in the detection of distant metastases. Pre-therapy assessment with [^{18}F]FDG can provide important prognostic information. In addition [^{18}F]FDG PET/CT can eliminate about half of futile thoracotomies and is therefore recommended for staging of lung and mediastinal tumors. [^{18}F]FDG imaging is also indicated in the diagnosis of recurrent disease and in monitoring treatment. [^{18}F]FDG PET/CT has been introduced for radiation planning, enabling refining treatment volumes to allow increased dose in target volume and reduced toxicity to nontarget tissues. Although [^{18}F]FDG is the most widely used tracer in oncology, other PET tracers are evaluated with specific clinical and research goals and may have a future role in the management of lung malignancies.

Epidemiology

Lung cancer is the leading cause of cancer death accounting for 29% of all cancer deaths in the USA [1]. It is estimated that in 2012, there were 58.7 new cases per 100,000 and 47.2 deaths per 100,000 per year from this disease in men and women [1]. Approximately 6.6% of men and women will be diagnosed with lung cancer at some point during their lifetime, based on 2010–2012 data [1]. Non-small cell lung cancers (NSCLC) are responsible for 85% of lung cancers. Major histologic types of NSCLC include squamous cell carcinoma (which typically arises in the bronchus), adenocarcinoma (originating in the periphery of the lung), and large-cell undifferentiated carcinoma. Small-cell lung carcinoma (SCLC) accounts for 15% of lung malignancies and typically arises centrally in association with a bronchus [1]. In the USA, adenocarcinoma is the most common histologic type of lung cancer, accounting for more than 40% of lung cancers, and has the worst prognosis among NSCLCs.

About 90% of lung cancer cases occur between the ages of 40 and 80, with a peak incidence in the fifth and sixth decades. Only 2% of cases are detected before the age of 40. At the time of diagnosis, 16% of patients have localized disease, 22% have regional spread, and approximately 57% have distant metastases.

Environmental and Genetic Factors

While approximately 10–15% of smokers develop lung cancer, cigarette smoking is linked to the majority of lung cancers in more than eight

out of ten cases (86%). About 15% of lung cancers occur in nonsmokers, but many of these patients have been exposed to secondhand smoke. The amount of smoking as well as the duration of being a smoker is directly correlated to the risk of developing lung cancer. Starting smoking at a young age is more harmful. Stopping smoking reduces the risk of lung cancer. Passive smoking increases the risk of lung cancer, but to a much lesser extent.

Additional factors which increase cancer risk include exposure to asbestos, radon gas, hydrocarbons, and metals such as chromium, nickel, and inorganic arsenic.

It is estimated that 8–14% of lung cancers are due to inherited factors. Relatives of lung cancer patients have a 2.4 times increased risk in developing lung cancers due to combination of genes.

Underlying Molecular Biology Changes

Lung cancer may arise from differentiated or undifferentiated cells, from either the central (SCLC and squamous cell carcinoma) or the peripheral (adenocarcinoma) airway compartment. The interaction between inhaled carcinogens and the epithelium of upper and lower airways leads to the formation of DNA adducts: pieces of DNA covalently bound to a cancer-causing chemical. In 2004, a locus on chromosome 6q23–25 was reported as conferring familial lung cancer susceptibility by family members affected by cancer [2].

The evidence for activated or inactivated carcinogens found in tobacco smoke is strongest in CYP1A1 polymorphisms and GST mu null [3].

Histological types depend on causative factors as well as cell origin. Smoking is linked with small cell, squamous cell, and adenocarcinoma. Nonsmokers usually develop adenocarcinoma. Lung cancers unrelated and related to smoking have different mutation profiles.

There are several signaling pathways in lung cancer. The main signaling pathways that may provide roadmaps for therapy include growth-promoting pathways (epidermal growth factor receptor/Ras/phosphatidylinositol 3-kinase), growth inhibitory pathways (p53/Rb/P14^{ARF}, STK11), apoptotic pathways (Bcl-2/Bax/Fas/FasL), DNA repair, and immortalization genes [4].

Staging and Prognostic Stratification

Only 15% of all lung cancer cases are diagnosed at an early stage, with a 5-year survival rate higher than 50%. Most of lung cancer cases are diagnosed at an advanced stage with distant metastases and a 5-year survival rate of about 4%. The overall 5-year survival rate for lung cancer is 17.4% [1]. Therefore, prognosis mainly depends on staging at the time of diagnosis.

To provide appropriate therapy, the histology of the lesion and determining whether the disease is localized, has regional involvement, or distant metastases are necessary. Staging of lung cancer uses the American Joint Committee on Cancer (AJCC) classification: T (tumor), N (lymph node involvement), and M (metastasis) staging system (Tables 1 and 2).

Prognostic Stratification

Although tumor stage is the main prognostic indicator, there are several additional factors affecting prognosis, including tumor histology, molecular genetics, comorbidity, socioeconomic background, age, gender, tumor heterogeneity, textural analysis, and standard uptake value (SUV) measured intensity of [^{18}F]FDG uptake [5–12]. In 554 patients with post-surgical follow-up, squamous cell carcinoma had the most favorable outcome and anaplastic small cell the least favorable [6]. However, in the subgroup of tumors <4 cm confined to the lung, SCLC had the highest percentage of 5-year survivors. In larger tumors, or in those with spread to the neighboring structures or lymph nodes, squamous cell was significantly more favorable. Histology did not affect survival in stage IV disease [6].

In a population-based cohort study in 5,683 first-time diagnosed lung cancer patients, the most common comorbid conditions included chronic pulmonary disease (52.5%), diabetes

(15.7%), and congestive heart failure (12.9%). The presence of comorbid conditions was associated with worse survival [7]. Socioeconomic differences in survival are partly explained by social inequality in staging, treatment, and the presence of comorbidities [8].

Lung cancer mortality is strongly related to age, rising sharply from 45 to 49 years, with the highest mortality rates in men older than 85 years and women 80–84 years. Mortality rates are similar between men and women until the age of 50–54 and higher in men afterward up to a ratio of 21 men:10 women above 85 years [9]. Women had a higher incidence of adenocarcinoma and a higher incidence of stage IA disease as well as significantly better survival when compared to men (5-year survival 77.7% vs. 61.9% in adenocarcinoma and 59.3% vs. 53% in other lung tumors). No significant gender-related prognostic differences were found in non-adenocarcinoma [10].

Tumor heterogeneity, assessed by CT texture analysis (CTTA), and disease stage as determined by [^{18}F]FDG-PET are significant independent predictors of survival [11, 12].

Conventional Imaging Methods

Imaging plays an essential role in the detection, staging, and response assessment. CT is the modality of choice for lung cancer imaging,

Table 2 The AJCC definition of TNM for lung

TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1a	Tumor 2 cm or less in greatest dimension
T1b	Tumor more than 2 cm but 3 cm or less in greatest dimension
T2	Tumor more than 3 cm but 7 cm or less or tumor with any of the following features (T2 tumors with these features are classified T2a if 5 cm or less)
	Involves main bronchus, 2 cm or more distal to the carina
	Invades visceral pleura (PL1 or PL2)
	Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumor more than 3 cm but 5 cm or less in greatest dimension
T2b	Tumor more than 5 cm but 7 cm or less in greatest dimension
T3	Tumor more than 7 cm or one that directly invades any of the following: parietal pleural (PL3), chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in the main bronchus less than 2 cm distal to the carina[a] but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, separate tumor nodule(s) in a different ipsilateral lobe
	Regional lymph nodes (N)
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
	Distant metastasis (M)
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion[b]
M1b	Distant metastasis

[a]The uncommon superficial spreading tumor of any size with its invasive component Limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1a

[b]Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as M0

whereas magnetic resonance imaging (MRI) is used for resolving specific questions, i.e., chest wall or mediastinal invasion, adrenal mass characterization, or differentiation between tumor recurrence and radiation fibrosis [13].

Multi-detector computed tomography (MDCT) devices provide high-quality images with short acquisition times [14]. Thin slices help avoid volume averaging and improve the display of anatomic structures. MDCT data can be reconstructed as

axial, sagittal, coronal, and oblique images, as well as multi-planar reformations (MPR), maximum and minimum intensity projections (MIP or MinIP), virtual bronchoscopy, and volume rendering. Low-dose CT can detect stage I lung tumors four to six times more frequent than conventional radiology [15]. Annual screening with low-dose CT can find lung cancers in their earliest stage, when the tumor is most easily treated. The National Lung Screening Trial (NLST) showed that screening with low-dose CT reduced the risk of death from lung cancer by 20% among persons 55–74 years of age who had a smoking history of at least 30 pack years. Recently this strategy is being adopted by several health systems [16, 17]. However, some lung cancers presenting as pulmonary nodules can be missed on CT [18] due to error in perception or misinterpretation. Subcentimeter nodules and low-density nodules, also known as ground-glass opacity (GGO), can be missed [19, 20].

Detection of a new solitary pulmonary nodule (SPN) in a patient with a history of lung cancer raises the possibility of recurrent disease. Features such as lesion size, location, contour, edge, and density (including the presence or absence of calcifications or fat) should be evaluated [21–23]. Unfortunately, none of these features alone establish benignity or malignancy. Specific combinations of features are more likely to be associated with either malignant or benign disease. For example, spiculated borders, ill-defined contours, the presence of bubble-like lucency, eccentric calcification, semisolid lesion, or GGOs are suggestive of malignancy, whereas a completely solid lesion with smooth and well-defined contours; total, central, or popcorn calcification; or inclusions of fat is indicative for benignity [24]. Because of the lack of specificity, more than 20% of SPNs are classified as indeterminate or suspicious after performing CT, and further investigation is required, either a repeat CT to evaluate change in size, PET/CT, or biopsy [23].

Evaluation of the growth rate is based on measurements of the nodule diameters on two consecutive examinations and calculating the doubling time. It can aid in the characterization, especially of indeterminate nodules. Inter- and intra-observer reproducibility of 2D diameter measurements is low [25–27]. Automated computation of the size of an SPN on 3D reconstruction has been shown to improve the ability to assess its growth [27], with the exception of nodules that are abutting the chest wall or vessels, where errors can occur [28]. Recently, the evaluation of the mass of an SPN, calculated by multiplying nodule volume and density, was proposed as a more accurate method. Mass measurements allow growth to be detected earlier and are subject to less variability [29, 30]. In solid SPNs the risk for malignancy can be evaluated by determining the degree of enhancement, which correlates with the degree of vascularity. Typically, malignant nodules enhance more than 20 HU, whereas benign nodules enhance less than 15 HU after intravenous administration of contrast media [31]. Dynamic perfusion CT can further evaluate features including blood volume, blood flow, permeability, mean transit time, and peak enhancement that can help assess the degree of vascularity of the nodule which correlates with malignancy [32]. Dual-energy CT has been suggested as a method of assessing the degree of enhancement with a single scan performed after the administration of contrast material and creating a virtual unenhanced image from the same dataset. Therefore, a single enhanced dual-energy CT scan allows measurement of the degree of enhancement as well as detection of calcifications. It may reduce radiation exposure to patients by avoiding baseline unenhanced scans and may also reduce measurement error due to different regions of interest during the subtraction of an unenhanced image from an enhanced one [33].

Staging (TNM)

Once the diagnosis of lung cancer has been established, the next important work-up step is the assessment of the anatomic extent of the tumor. Staging separates patients who are candidates for surgical resection from those with inoperable disease who should be treated with

chemotherapy and/or radiation. Staging is performed according to the recommendations of the International Staging System, and previously described evidence-based guidelines are used for clinical purposes [19] (Tables 1 and 2).

T Stage

Selection of the appropriate therapeutic approach requires measurement of tumor size and local extent (T stage) of the lesion. CT is an excellent tool for this purpose. The size of the lesion is easily measured, and its edges can be identified in most cases. However, the presence of atelectasis or consolidation distal to the tumor can complicate the identification of tumor margins. In the case of an intraluminal lesion, CT can be useful in identifying its proximal part, but another marker, such as the extent of hypermetabolism, is required to define the distal extent of the lesion. When the suspected lesion is surrounded by lung parenchyma, thin-section CT is crucial to determine whether the tumor invades the pleura [34]. In the presence of pleural invasion, the surgical approach cannot be modified. CT or MRI can be used to detect chest wall invasion but is not helpful in distinguishing chest wall invasion from fibrous adhesions. Reliable diagnosis of chest wall invasion can be made in the presence of rib destruction or of an obvious chest wall mass [35, 36]. The problem remains unresolved in the presence of contiguity of the tumor with the parietal pleura or of pleural thickening. The accuracy of CT for diagnosis of chest wall invasion is 39–87% [37–45]. Although MRI has superior soft tissue contrast resolution compared to CT, its sensitivity of 63–90% and specificity of 84–86% for diagnosis of chest wall invasion are low and similar to CT [46]. Respiratory dynamic MRI may potentially improve the accuracy of this modality [47]. MRI is superior to CT in the evaluation of chest wall involvement by superior sulcus or Pancoast tumors which almost invariably invade the extrathoracic soft tissue (subclavian vessels, brachial plexus, and vertebrae) [48–50]. Brachial plexus involvement and tumor extension into the spinal canal are contraindications to surgical resection, unlike vertebral body invasion. Invasion of the subclavian vessels, the common carotid, or the vertebral artery represents a relative contraindication to surgery. These vessels may need to be ligated, and CT and MRI can reveal significant atherosclerotic disease of the contralateral vessels, in which case the resection and ligation may not be feasible [51–53].

Nodularity of the pleura or pleural thickening associated with enhancement on CT is consistent with metastatic involvement. Thin-section CT is more sensitive in diagnosing pleural involvement [54–55].

In patients with bronchogenic carcinoma, CT allows accurate differentiation of potentially resectable T1–T3 lesions from unresectable T4 tumors. Mediastinal invasion cannot always be diagnosed on CT. MRI has inherent advantages including the fact that the delineation of mediastinal and hilar vessels does not require the administration of intravenous contrast. Improved soft-tissue characterization by MRI may be helpful in differentiating the tumor from other processes. However, MRI is costly and time consuming, and its spatial resolution is inferior to that provided by CT. Although neither MRI nor CT is capable of demonstrating minimal invasion of either the mediastinal pleura or mediastinal fat, significant obliteration of fat planes or compression or encasement of vessels in the mediastinum appears to be better demonstrated by MRI than CT [3, 54]. When using cardiac-gated T1-weighted MRI, the motion artifacts of the heart are reduced, and visualization of tumor invasion of the pericardium or heart is superior to CT [55]. The addition of contrast material in ECG-gated or breath-hold MR angiography improves the accuracy with higher sensitivity and specificity than contrast-enhanced CT and T1-weighted MR [54, 55].

N Stage

The most widely used diagnostic criterion of nodal metastases is lymph node size (short axis diameter). Other characteristics, such as shape, density, or contour, do not determine nodal

involvement. However, lymph node enlargement may also be due to reactive hyperplasia, and metastatic nodes are not necessarily enlarged. In a meta-analysis CT had a sensitivity of 57%, a specificity of 82%, and positive and negative predictive values (PPV and NPV) of only 56% and 83%, respectively, for mediastinal staging [55]. CT findings can exclude more than 40% of patients from potentially curative surgery and, on the other hand, lead to another almost 20% of patients will undergo unnecessary or non-curative surgery. CT should be seen as a tool pinpointing to suspicious enlarged nodes for histological confirmation. MRI is not sensitive for assessment of calcifications and is therefore not routinely used in the evaluation of lymph nodes although novel MRI sequences, including STIR turbo spin echo (SE) and diffusion-weighted imaging (DWI), have been used to differentiate metastatic from non-metastatic lymph nodes with a sensitivity and specificity that are superior to CT and comparable to [^{18}F]FDG-PET/CT [54, 55].

M Stage

Although in patients with early stage NSCLC the incidence of occult distant metastases is $<1\%$ [56], most clinicians prefer to conduct a metastatic survey in all patients [57]. The adrenals are currently evaluated by chest CT extended below the diaphragm, considering any adrenal mass with an attenuation value of <10 HU on non-enhanced CT to be consistent with an adenoma [58]. If an adrenal lesion remains indeterminate on a non-enhanced CT, MRI can be helpful [58]. The liver is often included in the chest CT. If a suspicious lesion is detected, dedicated CT, US, or MRI is required for its further characterization. Contrast-enhanced CT is the most commonly performed procedure in search of brain metastases in spite of the fact that MRI with contrast injection has a greater sensitivity than CT [59]. The utility of whole body MRI in the staging algorithm of lung cancer patients is considered, especially with advanced stage patients, due to the superiority in detecting brain metastases, determining mediastinal and chest wall invasion and lymph node metastases [60, 61].

TNM staging has a very important role in managing patients with lung cancer. Treatment options as well as prognosis vary for the different stages of disease. Tumor (T) staging is best accessed by either CT or MRI as these techniques offer better resolution and anatomical details. T stage depends on tumor size, location, and relationship to nearby structures. Five-year survival rates differ in relationship to the tumor size from 77% in T1a ($\leq$2 cm), 71% in T1b (2–3 cm), 58% in T2a (3–5 cm), 49% in T2b (5–7 cm), and 35% in T3 tumors ($>$7 cm) [34]. Data are now available showing the importance of [^{18}F]FDG imaging in TNM staging [35–37]. [^{18}F]FDG imaging also has a significant role in assessing involvement of the pleura. While pleural fluid cytology can be falsely negative in 30–40% of patients, [^{18}F]FDG imaging has a sensitivity of 89–95%, specificity of 67–94%, and accuracy of 91–92% for the detection of malignant pleural involvement [38, 39].

Locoregional lymph node spread represents an important factor in lung cancer management, especially in the absence of distant metastases. Patients with either negative or positive N1 (bronchopulmonary or hilar) nodes are considered for lung resection without further testing. Mediastinal lymph node-positive (ipsilateral [N2] or contralateral [N3]) patients are usually referred to confirmation biopsy either by mediastinoscopy, endoscopic ultrasound (EUS), or endobronchial ultrasound (EBUS). If positive on further tests, management is changed from surgery alone to a combined approach of surgery with chemo-/radiotherapy or combined chemo-/radiotherapy without surgery. [^{18}F]FDG imaging has an established high accuracy for nodal staging. The NICE study [40] suggested that [^{18}F]FDG-negative or a chain of [^{18}F]FDG-positive nodes would not necessarily need confirmation by other diagnostic testing.

The management of N2 disease varies. Most patients are regarded as not suitable for radical surgery alone, and neoadjuvant chemotherapy can be considered in a trial setting. Depending on the nodal station, some patients are better

Table 3 Treatment recommendations for non-small cell lung cancer

Stage	Standard management	Future directions	Survival
IA and B	Surgical resection	Adjuvant therapy (chemotherapy/radiation or combination); chemoprevention	75% (IA)
			55% (IB)
IIA and B	Surgical resection	Same as stage I	50% (IIA)
			40% (IIB)
IIIA	Chemoradiotherapy, surgical resection in selected patients	Neoadjuvant combined-modality therapy to downstage primary tumor	10–35%
IIIB	Chemoradiotherapy	Same as stage IIIA	5%
IV	Ciplatin-based chemotherapy, surgical resection if solitary metastatic lesion with resectable primary tumor	More efficacious single-agent and combination chemotherapy	<5%

served with radical radiotherapy. In other countries combined modality management is recommended for N2 disease. Proven N3 disease patients are usually not considered for radical treatment procedures. As indicated in the seventh edition of TNM classification, patients with single N1 disease have a 5-year survival of 48% as compared to 35% in patients with multiple N1, 34% for single N2, and 20% in patients with multiple N2 nodes [41].

In addition to T- and N staging, [^{18}F]FDG PET/CT imaging is useful for M staging where M0 = no metastasis and M1 = distant metastases. The presence of distant metastases usually changes patient management drastically with stage IV patients typically treated symptomatically and for palliation. Patients with good performance status (e.g., Zubrod/ECOG 0–2) are offered palliative chemotherapy, radiotherapy, and/or active supportive care. The 5-year survival rates in patients with involvement of ipsilateral nodes, pleural effusion, contralateral nodes, and distant metastases are 16%, 6%, 3%, and 1%, respectively [42].

Changes in lung cancer stage grouping were implemented in 2009 (Tables 1 and 2). The major changes include: stage T2 large size was upgraded from IB to IIA, and small T2 N1 was downgraded from IIB to IIA. According to this new TNM staging, the 5-year survival rates for NSCLC are 73% for stage IA, 58% for IB, 46% IIA, 36% IIB, 24% IIIA, 9% IIIB, and 13% for stage IV [42].

The same TNM classification is also suggested for SCLC. The 5-year survival rates for small-cell lung cancer are 38% for stage IA, 21% for IB, 38% IIA, 18% IIB, 13% IIIA, 9% IIIB, and 1% for stage IV [43].

Table 3 summarizes the treatment recommendations for non-small cell lung cancer.

Follow-Up Imaging

Lung cancer is usually followed up by serial CT scans. For patients receiving chemotherapy, assessment of treatment effectiveness is crucial. CT is the method of choice for measuring lesions before and after treatment. The World Health Organization (WHO) criteria and the Response Evaluation Criteria in Solid Tumors (RECIST) have created guidelines for the evaluation of tumor response to therapy. These guidelines provide a standard reporting system using uni- or bidimensional evaluation of tumor size to define its response to therapy as "complete response," "partial response," or "progressive disease" [62–64]. In recent years the introduction of molecular-targeted therapies, immunological agents, and stereotactic radiotherapy has necessitated the use of a new approach. There is growing evidence that target therapies induce effects that differ from those related to the classic cytotoxic treatment including intratumoral hemorrhage, changes in vascularity, or cavitation. More advanced imaging techniques such as DWI,

MR, and PET/CT that represent more adequately tumor biology and function are considered to evaluate response, including tumor volume, attenuation, or perfusion [65].

In patients treated with radiotherapy, CT can reveal postradiation pneumonitis and fibrosis and monitor tumor recurrence. In patients with nonspecific CT findings suspicious for recurrent cancer, sometimes difficult to differentiate from fibrosis, MRI using T2-weighted images or contrast-enhanced imaging can be helpful [66, 67].

Mediastinal Tumors

Mediastinal abnormalities are caused by a large number of processes that can involve various compartments of the mediastinum. Up to 50% of these processes are asymptomatic and discovered incidentally [68, 69]. The radiological armamentarium for evaluation of the mediastinum includes a wide variety of imaging modalities.

The standard posterior-anterior and lateral chest X-ray remains the initial diagnostic imaging tool [70]. It can reveal widening of the mediastinum, deformation of its contours, displacement of adjacent organs, and the presence and type of calcification. However, its ability to delineate the extent of mediastinal processes and their relationship to specific anatomic structure is limited.

CT plays a crucial role in the detection and, in particular, in the characterization of mediastinal abnormalities. Due to its excellent density resolution, CT is not only able to distinguish normal structures from pathological processes in the mediastinum but it can also characterize the latter based on their attenuation pattern and to accurately determine their origin and extent [71, 72]. Following the detection of a mediastinal abnormality on chest X-rays, CT should be the next step in the diagnostic work-up. A second common indication for CT is the detection of mediastinal pathology which is clinically suspected such as a suspected thymoma in patients with myasthenia gravis, thymic carcinoid in patients with ectopic corticotropin production, or an ectopic mediastinal parathyroid adenoma in patients with hypersecretion of parathyroid hormone production [73]. CT is also one of the main imaging modalities used for percutaneous biopsy guidance.

MRI is usually reserved for cases that need further clarification of CT findings and provides additional information regarding the nature, location, and extent of mediastinal disease. Based on its ability to distinguish between different tissues, MRI can confirm the cystic nature of a lesion that appears solid on CT. It can reveal small amounts of fat, favoring the diagnosis of fat-containing masses such as teratoma, hemangioma, or extramedullary hematopoiesis [74], and, in some cases, it can differentiate fibrosis from viable, recurrent tumor [71, 73]. Due to its ability to image vessels, MRI is used for the investigation of mediastinal pathology suspected to be of benign vascular origin, as well as for the assessment of invasion of a large artery or vein or their narrowing by a mediastinal tumor [74, 75]. MRI is helpful to evaluate mediastinal abnormalities, particularly in patients in whom administration of iodinated intravenous contrast medium is contraindicated. However, MRI is limited by reduced spatial resolution as compared with that of CT and by its inability to accurately detect calcifications [72, 74, 75]. In summary, CT is the modality of choice for evaluating suspected mediastinal pathology, whereas MRI is used as a problem-solving tool. Each modality has its own particular strengths; therefore CT and MRI do not compete, but are complementary in many clinical scenarios [71, 76, 77].

Differentiating malignant from benign tumors and grading of malignancy are essential for treatment planning as well as for defining patient prognosis. Unfortunately, the malignant or benign nature of a lesion cannot be confirmed using imaging criteria alone. Findings of irregular contours, necrotic or cystic component, heterogeneous enhancement, lymphadenopathy, and invasion of the great vessels are strongly suggestive of a malignant thymic tumor [78], whereas a unilocular, thin-walled, water-density lesion most probably represents a “true” cyst [78]. Nevertheless, further investigations are often required, including noninvasive tests, such as diffusion-weighted single-shot echo-planar MRI [79–81] or functional and metabolic nuclear medicine procedures, or invasive tests such as percutaneous or

video-assisted thoracoscopic biopsy, to obtain a definite diagnosis.

Thymomas, germ cell tumors, lymphomas, and neurogenic tumors account for the overwhelming majority of primary malignant mediastinal tumors in adults. Approximately 30–35% of thymomas, 20% of germ cell tumors, and 15% of nerve sheath tumors are invasive [68, 70, 71]. Radical excision is the standard of care for malignant thymic diseases and for lesions of neurogenic origin, whereas radiotherapy is the treatment of choice for seminoma. Non-seminomatous germ cell tumors are treated with a combination of surgery and chemotherapy, while a combination of chemo- and radiotherapy is administered in most cases of lymphoma [82–84].

Thymoma is the most common primary neoplasm located in the anterior mediastinum [85, 86]. It affects predominantly adults, with equal incidence in men and women, and is very rare in children [86]. Up to 50% of patients with thymoma suffer from myasthenia gravis, but some may also present with other thoracic complaints or can be entirely asymptomatic [86–88].

Thymoma is usually well defined, but it can be aggressive, penetrating the capsule and extending into the mediastinal fat, pleura, pericardium, lung, and great vessels [88, 89], and it can also cross the diaphragm, reaching the retroperitoneum [70]. Its size varies, ranging from small nodules to large masses [87]. Invasive thymoma can send drop metastases to the ipsilateral pleura and the pericardium [69]. Hematogenous metastases and lymphadenopathy are rare [87]. The presence of enlarged mediastinal lymph nodes in association with a dominant anterior mediastinal mass suggests the diagnosis of lymphoma or of thymic carcinoma rather than thymoma [86, 90].

Thymoma is not always detectable on chest X-rays. Contrast-enhanced MDCT is used for precise assessment of a mediastinal mass and its local invasion, aiding in the preoperative planning. Staging of thymoma is based on the widely accepted clinicopathological classification of Masaoca et al. [91] as well as on the WHO histological classification [92].

Although thymoma typically rises in the anterior-superior mediastinum, it can occur anywhere from the thoracic inlet to the cardiophrenic angle [93, 94]. Most tumors are unilateral [95], spherical or ovoid, and usually encapsulated soft tissue lesions outlined by adjacent mediastinal fat [96]. Up to 60% of thymomas demonstrate various degrees of invasion of adjacent structures [96] or encasement of vessels [97, 98]. While a lack of mediastinal fat obliteration does not necessarily exclude capsular penetration, when these planes are preserved, extensive invasion is unlikely [99]. Aggressive thymoma can present with pleural involvement even at diagnosis, and in cases with circumferential lung encasement, it may be indistinguishable from malignant mesothelioma [99]. Pleural effusion is not typical for patients with thymoma [89].

Thymoma can manifest heterogeneity on CT due to cystic degeneration, hemorrhage, or necrosis [98]. Calcifications can occur, are more frequent in aggressive subtypes, and exhibit a variety of patterns ranging from curvilinear calcification of tumor capsule or fibrous septa to punctuate or coarse calcifications within the tumor itself [87, 97–100].

Thymoma has no distinctive features on MRI, which only rarely provides additional important information to an optimally performed contrast-enhanced CT study [101]. MRI can be useful in the assessment of vascular involvement in patients who cannot tolerate intravenous iodine contrast injection or for clarifying equivocal CT findings. On dynamic MRI thymomas reach peak lesion enhancement earlier than other mediastinal neoplasms, earlier for lower stage as compared to higher-stage disease [102, 103]. Chemical shift MRI is lower in thymic hyperplasia as compared to thymoma. This is of significance in particular in patients with myasthenia gravis, who present with a homogeneous enlarged thymus on CT and MRI which can at times be indistinguishable from thymoma [103].

On T1-weighted MR images, thymoma has a similar signal intensity to muscle, while T2-weighted images show a high signal intensity. Thymomas showing a heterogeneous pattern and cystic changes present as areas of increase signal intensity on T2-weighted images [100, 103]. Hemorrhage is identified as an area of high signal

intensity on both T1- and T2-weighted or on STIR images [80]. Tumor capsule and fibrous septa show low signal intensity on both T1- and T2-weighted images [80]. The role of [^{18}F]FDG-PET/CT in thymoma is unclear. The majority of these lesions have SUVs <3 and a variable appearance on [^{18}F]FDG imaging. SUVs >5 suggest that the lesion may have a different etiology, such as lymphoma.

Differential Diagnosis Between Lung Cancer and Lymphoma

Although lymph node abnormalities depicted by CT are nonspecific, the patterns of thoracic lymphadenopathy can provide important clues in the differential diagnosis of their potential etiology. Nodal metastatic spread of lung cancer always follows a similar pathway. Tumors in the right lung involve initially almost exclusively ipsilateral mediastinal nodes, while left lung tumors have a higher propensity for contralateral spread [104]. Involvement of distal nodes may occur even when proximal nodes are spared. Nearly 30% of lung cancer patients have metastases to mediastinal lymph nodes without lobar or hilar lymph nodes being involved [105]. Lack of vessel invasion by enlarged lymph nodes may help in differentiating lymphoma from metastatic lung cancer [106].

Lymphoma is characterized by predominantly mediastinal nodal involvement. When present, hilar node involvement is usually asymmetric and accompanied by mediastinal disease [107]. Lymphoma tends to expand along or around, rather than invade adjacent structures.

Hodgkin's disease (HD) has a predilection for thoracic involvement found in up to 85% of patients, especially in the pre-vascular and paratracheal regions [108]. As a rule multiple sites show lymphomatous involvement although at times enlargement of a single nodal group can be encountered, usually indicating a nodular sclerosing histologic subtype [109]. HD typically spreads contiguously, involving adjacent lymph nodes, and only rarely skips nodal groups as described for lung cancer [109, 110]. HD also has a tendency to cause thymic involvement in association with mediastinal lymph node enlargement [111].

Thoracic disease is less common in non--Hodgkin's lymphoma (NHL) and is found in up to 50% of cases [112]. The pattern of nodal involvement is also somewhat different from other types of malignancy. Single-site lymph node enlargement is much more common in patients with NHL and occurs mainly in posterior or superior mediastinal or anterior diaphragmatic nodes [113]. Hilar node involvement is less common than for HD or lung cancer. Extranodal disease is frequently present and may involve the lungs, pleura, pericardium, and chest wall [112].

Sarcoidosis

Approximately 70% of patients with sarcoidosis present with a characteristic radiologic pattern including hilar and mediastinal lymphadenopathy with or without concomitant parenchymal abnormalities [114–116]. However, in up to one third of cases, radiological findings are nonspecific. The most frequent presentation is that of right paratracheal and bilateral hilar lymphadenopathy. The aortopulmonary, subcarinal, and retroazygous lymph nodes may be enlarged as well [117]. The posterior mediastinum is less commonly involved. Isolated lymphadenopathy in the anterior or posterior mediastinal compartments as well as unilateral hilar disease is more suggestive of lymphoma, metastatic lung cancer, or a granulomatous or infectious process rather than sarcoidosis. Lymph node calcification (occasionally with an eggshell pattern) can be found in up 25% of cases [118].

Parenchymal sarcoid can show a variety of radiographic patterns, including fine nodular, reticulo-nodular, or acinar lesions (poorly marginated, small to large nodules, or coalescent opacities), and only rarely focal lesions. Acinar opacities or interstitial granulomas may coalesce to give the appearance of the alveolar form of sarcoidosis, and an air bronchogram may be detected [118]. High-resolution CT (HRCT) findings include areas of ground-glass attenuation,

subpleural, or perivascular nodules, which appear as beading and irregular thickening of bronchovascular bundles and thickening of interlobular septa. The nodules, corresponding to coalescent interstitial granulomas, have irregular margins. The foci of ground-glass attenuation may represent areas of active alveolitis or diffuse microscopic interstitial granulomas [119–123]. Patients older than 50 years of age have a higher prevalence of solitary and multiple mass-like opacities in the lung at presentation [123]. In the presence of cavitation of parenchymal lesions, which occurs in less than 1% of patients with sarcoid, tuberculosis and fungal infections should be ruled out.

Histoplasmosis

Radiographic findings of thoracic histoplasmosis depend primarily on the clinical type of presentation and on the immune status of the host. A solitary pulmonary nodule is common in patients with an asymptomatic primary infection. The size of such nodules varies from a few millimeters to several centimeters. Most have well-defined margins and central, laminar, or diffuse calcification patterns. In some cases these nodules are slow growing, and in such cases histoplasmosis may be difficult to distinguish from malignancy.

Adenopathy is frequently seen in addition to parenchymal lung abnormalities, often with calcifications. The differential diagnosis of noncalcified mediastinal adenopathy includes sarcoidosis, lymphoma, and metastases. Enlarged lymph nodes may cause significant bronchial or tracheal compression or obstruction and may lead to esophageal obstruction as well [124].

In more severe cases, radiographs may show widely disseminated, diffuse, fairly discrete nodular shadows throughout the lungs, with individual lesions measuring 1–10 mm diameter. This form of disease is known as miliary histoplasmosis, and appearances are similar to miliary tuberculosis [125]. The infiltrates clear within 2–8 months; however, fibrotic lesions may calcify and persist for many years.

Lung cavitation is usually noted in patients with underlying obstructive lung disease and is similar to chronic active tuberculosis, with predominantly upper lobe disease, characterized by fibrosis, necrosis, cavitation, and granulomatous inflammation. Fibrosing mediastinitis can develop in some patients. It is important to define the extent of the fibrous mass in the mediastinum or hilum and to identify if it causes obstruction of the superior vena cava, pulmonary vessels, esophagus, trachea, or bronchi. Stippled or dense calcifications within the mass are present in most patients with fibrosing mediastinitis [126].

Coccidioidomycosis

Thoracic manifestations of primary coccidioidomycosis (CM) include parenchymal disease, lymphadenopathy, and pleural effusion [127]. Parenchymal consolidation, single or multiple, is the most common manifestation found in 75% of patients. It is segmental or subsegmental, usually unilateral and with a peri-hilar or basal distribution. It can resolve spontaneously within 1–2 weeks. Nodular lung disease is found in up to 20% of patients. The nodules are frequently well defined, simulating metastases, but may also present with ill-defined margins. They are 5–25 mm in diameter and have a parahilar and lower-lobe distribution. In approximately 20% of patients, hilar adenopathy is also present, usually unilateral and concomitant with parenchymal lesions. Mediastinal adenopathy is seen in the presence of severe and prolonged infection and is associated with a higher risk of dissemination. Pleural effusion occurs in less than 20% of patients, although pleuritic chest pain is more frequent, in 50–75% of cases [128].

Approximately 5% of patients may develop a persistent pulmonary disease such as pneumonia with or without adenopathy, nodules and cavities, bronchiectasis, empyema, or calcifications. Pulmonary nodules are the most common radiographic findings in persistent infection. They are, as a rule, single, well circumscribed and round, averaging 1.5–2 cm in diameter, and tend to occur

in the periphery of the middle and upper lobes of the lungs, in contrast to tuberculosis, when nodules develop mainly in the anterior segment of an upper lobe. CM-related nodules can remain stable for months and eventually regress. Only rarely is slow growth observed [128].

Calcification is much less frequent in CM than for tuberculosis and histoplasmosis. Therefore in the evaluation of these nodules, malignancy is a primary concern for the clinician. Cavitation may develop as a result of necrosis in an area of pneumonia or may be the result of the excavation of a nodule. Usually cavities appear as a single lesion, are located in the upper lobes, and can have thin or thick walls. Thin-walled cavities have a tendency to change in size, possibly reflecting check-valve communication with the bronchial tree. A rapid change in size of a cavity suggests coccidioidal infection rather than any other granulomatous process.

Disseminated CM may occur as a complication of the primary illness, a late complication of chronic disease, or may represent the reactivation of latent disease in susceptible individuals. Dissemination has a miliary pattern that resembles tuberculosis, although with less well-defined nodules. The differential diagnoses of this pattern also include other mycotic infections, silicosis, sarcoid, and metastatic disease. Hilar and mediastinal adenopathy is almost always associated with disseminated disease [128].

Tuberculosis

Primary lung tuberculosis (TB) has a nonspecific imaging presentation [129–132]. Common findings include segmental or lobar airspace consolidation, ipsilateral hilar and mediastinal lymphadenopathy, and/or pleural effusion.

Airspace consolidations tend to be homogeneous, with ill-defined margins, and usually occur in the lower and middle lobes and in the anterior segments of the upper lobes. Cavitation within parenchymal opacity is uncommon in primary infection. The lung opacity tends to become rounded with healing and continues to shrink until only a small nodule remains. Subsequently, the nodule may become calcified or ossified, resulting in a calcified granuloma.

Lymphadenopathy is a common manifestation of primary pulmonary TB. The presence of hilar and mediastinal lymphadenopathy helps in differentiating primary from postprimary TB where it is conspicuously absent. Lymphadenopathy may be the only manifestation of primary pulmonary TB without a concomitant parenchymal opacity. This is more common in patients with HIV infection. Adenopathy is mainly found in the ipsilateral hilar region in approximately 60% of children with primary TB, paratracheal adenopathy is found in 40%, and subcarinal lymphadenopathy in 80% of pediatric patients. In adults, lymphadenopathy is unusual in an immunocompetent host but is more frequent in blacks and Asians. Adenopathy is common in patients with an HIV infection. On contrast-enhanced CT involved lymph nodes demonstrate central hypoattenuation with peripheral rim enhancement. Sometimes the pattern of lymphadenopathy is indistinguishable from that of sarcoid or lymphoma. With an appropriate immune response or with adequate chemotherapy, enlarged necrotic lymph nodes may diminish in size and commonly calcify. Calcified lymph nodes and a granuloma represent the Ranke complex. Airway involvement is frequently present in primary TB due to bronchi compression by enlarged lymph nodes or endobronchial spread of infection, broncholithiasis, or bronchiectasis.

Parenchymal abnormalities of postprimary TB show a wide spectrum of findings [133], including patchy or confluent airspace opacities in the apical and posterior segments of the upper lobes and the superior segments of the lower lobes; cavities with a thick outer wall and a smooth inner contour and air-fluid levels [134]; tuberculomas appearing as discrete, sometimes calcified, nodules, typically within the upper lobes; and widespread ill-defined acinar shadows manifesting endobronchial spread, military (hematogenous) spread, appearing as circumscribed nodules less than 1–2 mm in diameter located diffusely throughout both lungs. In contrast to primary TB, lymphadenopathy is notably absent in patients with postprimary disease, with the exception of patients with HIV/AIDS infection.

Bronchiectasis may occur as well, as a consequence of fibrosis. Pleural involvement is more common in postprimary TB than in primary infection, including empyema or empyema necessitans.

PET and PET/CT for Evaluation of Lung Cancer

[^{18}F]FDG PET/CT has been used extensively in the differential diagnosis and characterization of single pulmonary lesions. While the overall performance of [^{18}F]FDG imaging for diagnosis of pulmonary malignancy is good, there are pitfalls and limitations that can lead to potential false-positive and false-negative findings. Inflammatory lesions such as sarcoid or tuberculosis can take up [^{18}F]FDG. While the pattern and, at times, intensity of uptake may be helpful to appropriately identify the etiology of the lesions, biopsy may be necessary to make a definitive diagnosis. False negatives may be due to small-size lesions or to the histological subtype of well-differentiated malignancies such as bronchioloalveolar carcinoma (BAC) or carcinoid [135], as well as sub-solid nodules, particularly GGOs, which often exhibit low glucose utilization rates and low-level metabolic activity and have therefore low or absent [^{18}F]FDG uptake. These are slow-growing tumors with less proliferative potential and longer mean doubling times as compared to NSCLC. The sensitivity of [^{18}F]FDG imaging for BAC is only around 50% [136]. On the other hand, multifocal BAC appearing as multiple nodules or GGOs is detected with a high sensitivity by [^{18}F]FDG imaging studies [137]. Indolent behavior, small size, and paucity of malignant cells all contribute to poor FDG avidity of sub-solid nodules [20]. Well-differentiated adenocarcinomas manifesting as GGOs can be falsely negative on [^{18}F]FDG PET/CT, whereas benign GGOs can be falsely positive [20, 138]. However, [^{18}F]FDG PET/CT is warranted in GGOs with a mixed solid component, more likely of being high-grade invasive tumors.

In spite of the abovementioned limitations, [^{18}F]FDG PET/CT has been reported to change management in 25–52% of patients with NSCLC and has a major role in reducing the number of futile thoracotomies [20, 139, 140]. Pretreatment [^{18}F]FDG PET/CT provides prognostic information. Pillot et al. have summarized the literature assessing the relationship between the SUV of the tumor and outcome [141], suggesting that the SUV is a powerful surrogate marker for outcome in NSCLC. Recently, Goodgame et al. retrospectively analyzed 136 patients with stage I NSCLC. Thirty-two patients had recurrence during a median follow-up of 46 months. In multivariate analysis a preoperative SUV_{max} of 5.5 or higher was an independent predictor of relapse and death in this group of patients [142]. Tann et al. conducted a retrospective study in 51 patients with stage I lung cancer, comparing [^{18}F]FDG PET/CT results to growth rates and tumor doubling times obtained from pretreatment chest CT examinations performed more than 25 days apart, and found that rapid, moderate, and slow doubling times correlated with SUV measurements [143]. Im et al. performed a meta-analysis of 13 studies and 1581 patients assessing the prognostic value of the volumetric parameters of [^{18}F]FDG PET/CT in patients with lung cancer [144]. Both the metabolic tumor volume (MTV) and total lesion glycolysis (TLG) were significant prognostic parameters in NSCLC. Patients with high MTV or high TLG had a poorer prognosis [145]. Recently it has been demonstrated in 102 NSCLC patients significantly higher [^{18}F]FDG uptake compared to EGFR and wild-type profiles [146]. If these preliminary results will be proven in large prospective trials, a single pretreatment [^{18}F]FDG PET/CT study may predict in future the rate of tumor growth and be used in an individualized approach to therapy.

Since most lung lesions are hypermetabolic (with the exception of low-grade BAC, carcinoid, and sub-solid nodules, as stated above), [^{18}F]FDG PET/CT imaging can provide important information for the management of patients with lung lesions. [^{18}F]FDG PET/CT is recommended as a component of initial evaluation in T1–T3 disease. [^{18}F]FDG imaging findings can play a pivotal role in determining whether a patient with T1 disease is resectable or whether patients with more advanced disease have metastases that may require specific therapy. In addition to defining whether pulmonary

nodules represent lung cancer, [^{18}F]FDG PET/CT can determine the number and location of hypermetabolic lesions in the chest and elsewhere and define tumor response to therapy.

A baseline study in patients with pulmonary nodules can help distinguish benign from malignant disease (Figs. 1 and 2). This is usually accomplished by evaluating a combination of the CT pattern of the lesion and its SUV (values >2 are suspicious, and values >4 require further evaluation, usually with biopsy). [^{18}F]FDG imaging studies can also detect other sites of hypermetabolism. If there are multiple hypermetabolic foci in addition to the nodule under investigation, the lesion is more likely to be neoplastic than inflammatory in etiology.

A baseline study in a patient with histologic evidence of lung cancer should evaluate the lung parenchyma, bronchus, lymph nodes (in the chest, neck, and abdomen), chest wall, pleura, liver, adrenal glands, and bone for hypermetabolic foci to stage the disease and address the question about the potential roles of surgery, radiotherapy, and chemotherapy in patient management.

Serial scans are helpful for surveillance, to detect recurrence, especially in patients with no clinical evidence of disease, and to determine the effectiveness of therapy, by detecting changes in lesion size and SUV, as well as detecting new lesions.

Characterization of the Solitary Pulmonary Nodule

A single pulmonary nodule is seen as an opacity in the lung parenchyma measuring <3 cm (larger lesions are masses) without associated adenopathy or atelectasis. Lung nodules can be caused by infection, inflammation, and neoplasms (about

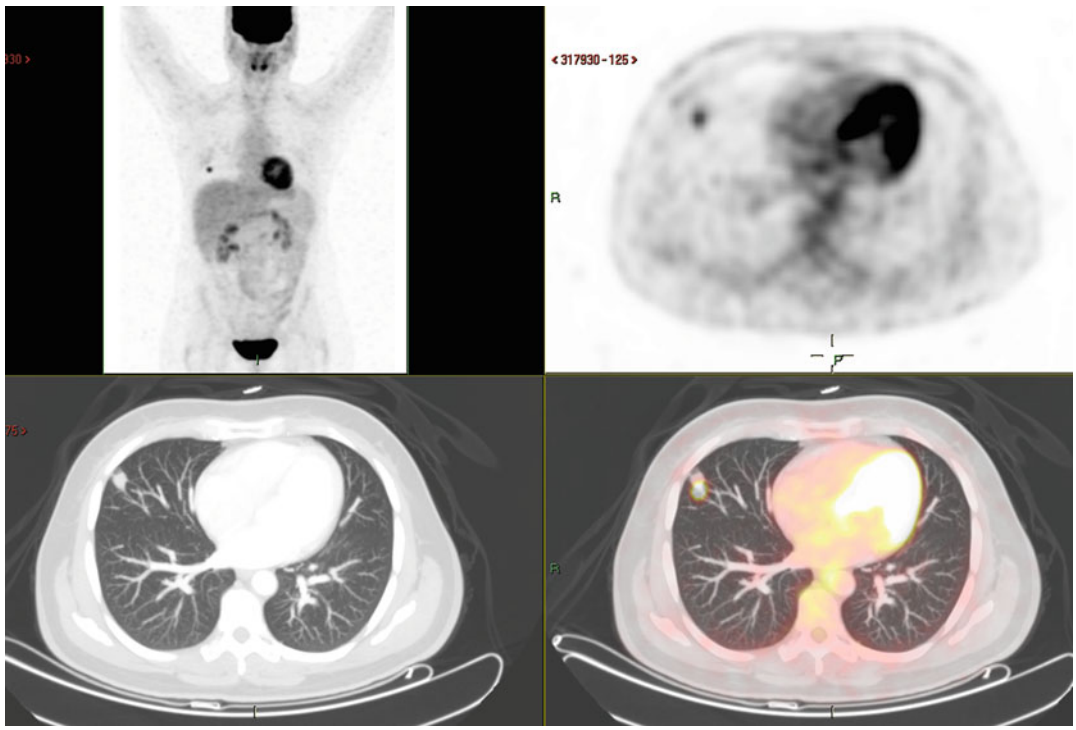

Fig. 1 A 54-year-old woman with a 1.1-cm RML nodule was referred to PET/CT for presurgical assessment. Selected transaxial CT, PET, and fused PET/CT slice and MIP image (*upper left*) show the [^{18}F]FDG-avid RML nodule (SUV_{max} 5.0). There is no hilar nor mediastinal [^{18}F]FDG-avid lymphadenopathy and no distant [^{18}F]FDG-avid disease, corresponding to T1aN0M0 disease by PET/CT. *RML* right middle lobe, *MIP* maximum intensity projection

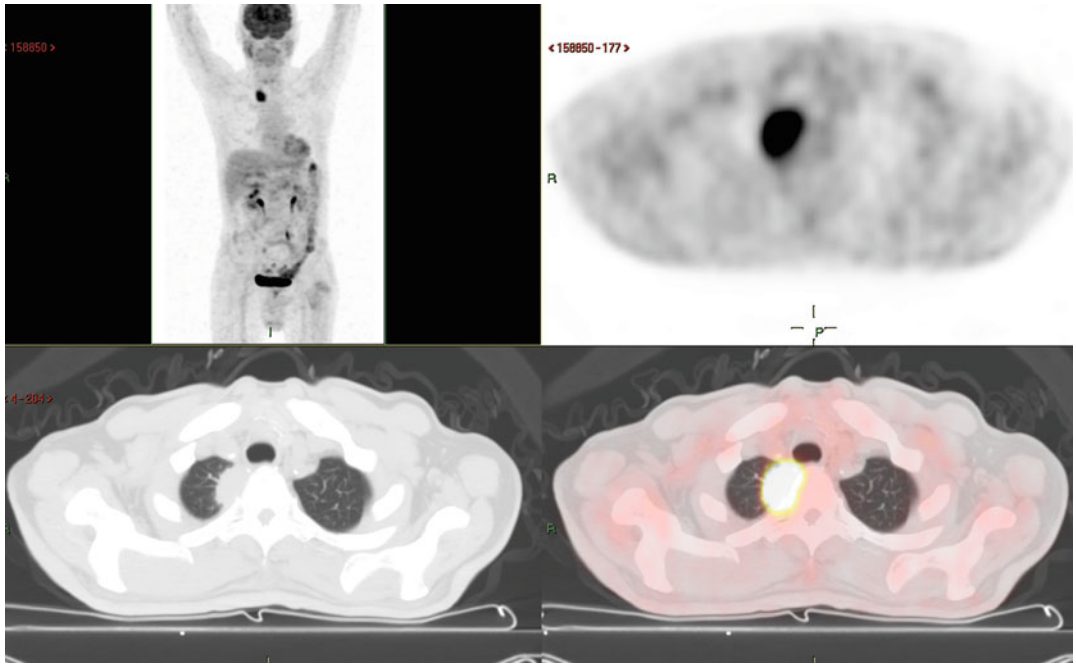

Fig. 2 A 73-year-old man with a 3-cm paravertebral RUL mass was referred to PET/CT for assessment prior to chemotherapy and radiotherapy. Selected transaxial CT, PET, and fused PET/CT slice and MIP image (*upper left*) show the [^{18}F]FDG-avid RUL mass (SUV_{max} 11.7), involving the intervertebral foramina of D2–D3. There is no hilar nor mediastinal [^{18}F]FDG-avid lymphadenopathy and no distant [^{18}F]FDG-avid disease, corresponding to T4N0M0 disease by PET/CT. *RUL* right upper lobe, *MIP* maximum intensity projection

80 different etiologies have been identified). CT alone, or with the addition of [^{18}F]FDG PET, allows the majority of pulmonary nodules to be categorized as benign or malignant. Lesions without spicules, with uniformly distributed dense calcification (>300 Hounsfield units, including the center of the nodule) and which have <15 HU enhancement with contrast administration, are radiographically benign. On the other hand, spiculated borders, indistinct margins, extension to pulmonary veins, focal retraction of adjacent pleura, heterogeneous composition, or enhancement of >25 HU following injection of intravenous contrast suggests malignancy. However, even after careful assessment by CT, distinguishing a malignant from a benign lesion is difficult. Lesions <7 mm diameter have <1% likelihood of malignancy [146]. Lesions 7–20 mm have a 15% incidence of malignancy, and lesions >20 mm have an 81% likelihood of malignancy. Determining the metabolic status of lesions >0.7 cm in diameter with FDG PET-CT can determine if these lesions are malignant or benign in ~90% of lesions. Lesions with SUV ≤2.0 have a low likelihood of malignancy, reducing the need for biopsy, lesions with SUV >4.0 are more likely malignant, and lesions between SUV 2.0 and SUV 4.0 are indeterminate. Nevertheless, an [^{18}F]FDG-negative lesion in a patient with high clinical suspicion for malignancy (e.g., history of smoking, exposure to asbestos, older age, and/or history of non-thoracic neoplasm) still needs to be biopsied to establish the etiology. In the presence of a low clinical suspicion in a patient who is at high risk for biopsy, follow-up by further imaging is usually indicated. If patients carry a high clinical risk, biopsy and histologic evaluation of the lesion are advisable if at all possible. While it could be argued that [^{18}F]FDG imaging is not indicated for diagnostic purposes in patients with a high clinical suspicion (as they would need biopsy or surgery), its main role in the management of these patients is to determine if disease is localized prior to possible surgical or radiation therapy.

In a meta-analysis of 1,474 pulmonary lesions of any size, Gould et al. [147] found a sensitivity of 96.8% and specificity of 77.8% for [^{18}F]FDG PET to distinguish malignant from benign etiologies. In another meta-analysis including five prospective studies, Hellwig et al. [148] reported a sensitivity of 93%, specificity of 87%, and PPV and NPV of 94% and 89%, respectively. The risk to miss malignancy was 11%. Cai et al. [149] showed that [^{18}F]FDG PET/CT is more accurate than helical dynamic CT for SPN characterization and therefore, where available, should be performed as a first-line evaluation. The semiquantitative criterion of a mean SUV $\geq$2.5 has been shown prospectively to have a sensitivity of 90–100% and specificity of 69–95% for diagnosis of malignancy [149, 150] (Fig. 1). In a prospective study in 585 patients, Bryant et al. [150] demonstrated that in nodules less than 2.5 cm in diameter, an SUV_{max} of 2.5 or less was associated in 24% of cases with malignancy, as compared to lesions with an SUV_{max} of 2.6–4 which have an 80% chance of malignancy, and lesions with an SUV above 4.1 with a 96% probability. In spite of these data, Hashimoto et al. [151] have recently shown that in SPNs with an SUV_{max} <2.5, visual analysis performs as well as semiquantitative measurements. The probability of malignancy in a visually evident lesion was 60%, but decreased significantly in lesions with no [^{18}F]FDG uptake.

Location

The location of the lesion is usually determined by CT or the CT component of PET/CT. The exact location of the tumor and its anatomical relationship to important structures such as the bronchi, pleura, pulmonary veins, and thoracic aorta, as well as defining the presence of mediastinal or chest wall invasion, are important in the decision-making process for further management.

Size

The size of the lesion is also determined by CT in most cases. However, in the presence of atelectasis distal to the tumor, the differential diagnosis between the tumor mass and the adjacent atelectasis may be difficult to determine on CT. The [^{18}F]FDG study can define which portion of the lesion is associated with metabolically active tumor, providing additional valuable information for staging. Precise measurement of tumor size is required for TNM classification (Table 1). Subclassification according to tumor size is a factor that has an impact on prognosis (Table 2). In addition, since in most patients there is an interval of few days to a few weeks between the initial staging CT and the [^{18}F]FDG study, exact measurement of the tumor size on the CT component of PET/CT study can help the clinician in determining the growth rate of the tumor.

Solitary Pulmonary Nodule (SPN)

SPN is defined as any nodule up to 3 cm in diameter. The majority of SPNs (60–70%) are benign in etiology. Lung cancer, however, is found in 20–30% of SPNs. [^{18}F]FDG imaging is a better predictor of malignancy in SPN than a combination of clinical and morphologic conventional imaging criteria [134, 144].

False-negative [^{18}F]FDG PET/CT (no uptake in a malignant SPN) is found in less than 5% of nodules 0.6–3 cm in diameter [38]. In the NY-ELCAP study, 378 nodules less than 5 mm in diameter were all nonmalignant on histopathology, therefore, suggesting the need for further follow-up only in nodules that are 5 mm in diameter or larger [152]. In nodules 5–10 mm in diameter, Bastarikka et al. [153] report a sensitivity of 69%, which increased to 95% in nodules of greater than 10 mm for the detection of malignancy by [^{18}F]FDG imaging. The authors also noted that uptake decreased when the size of the nodule was less than twice the system resolution (7–8 mm), and therefore different criteria may need to be applied for nodules less than 15 mm in diameter.

False-negative [^{18}F]FDG imaging results are usually due to the small size (less than 1 cm) of the SPN or the histology of a lesion [135] (Fig. 3). In a series of 36 patients with BAC, 50% of

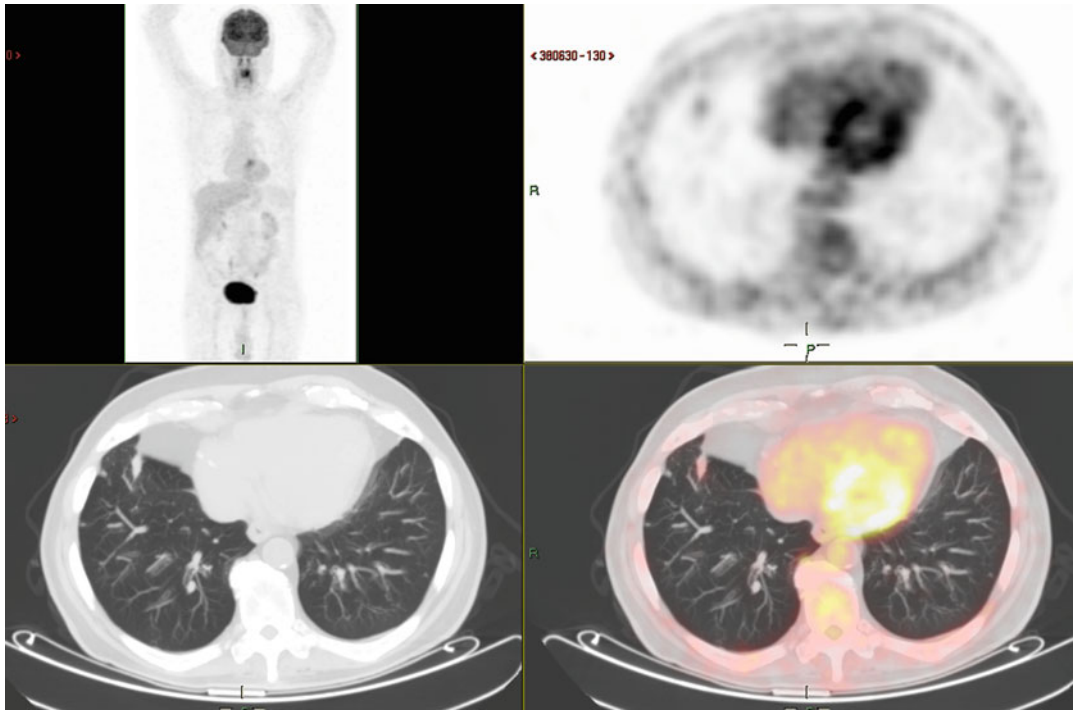

Fig. 3 A 73-year-old man with a 1.4-cm RUL nodule with a nonuniform border was referred to PET/CT for assessment. Selected transaxial CT, PET, and fused PET/CT slice and MIP image (*upper left*). Serial coronal PET slices and MIP image (lower right) show a low-grade [^{18}F]FDG-avid RUL nodule. CT showed additional subcentimeter nodules in RLL, RUL, and LLL, all below the resolution of PET. PET/CT findings are nonspecific, a tumor with low [^{18}F]FDG avidity could not be excluded, and further follow-up was recommended. *RUL* right upper lobe, *RLL* right lower lobe, *LLL* left lower lobe, *MIP* maximum intensity projection

patients had an SUV_{max} $\leq$2.5, and furthermore tumor FDG avidity predicted mortality [154].

Over 40% of SPNs are granulomas, including mycobacterial infection or histoplasmosis. The average SUV_{max} was 5.05 in patients with pulmonary mycobacterial infections (lesions >2 cm). Therapy resulted in a reduction of [^{18}F]FDG uptake to near negligible levels [155]. [^{18}F]FDG PET/CT has a promising role for evaluation of TB in high-risk immunocompromised patients with cancer [156, 157]. In an area with endemic histoplasmosis, inflammatory lesions were difficult to separate from NSCLC (mean SUV_{max} 3.2 in benign lesions vs. 8.5 in neoplastic lesions with significant overlap between groups) [158].

Nodal involvement with sarcoidosis can also be a confounding factor in evaluating the performance of [^{18}F]FDG imaging in SPNs. In one series, 95% of patients with sarcoidosis had pulmonary nodal uptake (SUV 8.6), and 66% of patients had parenchymal uptake (SUV 4.7) [159]. In cancer patients with biopsy-proven sarcoidosis, early metabolic response to systemic steroid treatment can help in the final differential diagnosis when both coexist [160]. Other inflammatory conditions such as pneumonia, pyogenic abscess, aspergillosis, Wegener's granulomatosis, and anthracosis may also need to be differentiated from lung cancer. In a patient with an [^{18}F]FDG-avid SPN and low clinical suspicion of malignancy, further investigation is indicated to determine the cause of tracer uptake.

Dual-phase [^{18}F]FDG studies at 1 and 2 h after tracer injection have been suggested to increase the sensitivity and specificity of [^{18}F]FDG imaging [161, 162]. Using an SUV cutoff of 2.5 and a

10% increase in SUV as a threshold of malignancy, Matthies et al. showed an improvement in sensitivity from 89% to 100%, associated however with a deterioration in specificity from 94% to 89% in single- and dual-phase PET studies, respectively, possibly due to differences in glucose-6 phosphatase and hexokinase levels within benign and malignant cells [161]. Chen et al. have assessed the increment in SUV (SUV_{inc}) from dual-phase [^{18}F]FDG PET in 187 consecutive patients with NSCLC and showed 3-year progression free survival (PFS) and overall survival of 61.6% and 87.8% in patients with $SUV_{inc} \leq 1$, compared to 21.1% and 46.2% in patients with $SUV_{inc} > 1$. The authors conclude that SUV_{inc} is a promising prognostic factor in NSCLC [162]. Of note, however, active granulomas, a frequent cause for false-positive [^{18}F]FDG studies, may also demonstrate the same increase in tracer uptake over time [155].

Other Lesions

[^{18}F]FDG PET/CT imaging can identify incidental lesions or entities such as inflammatory processes. However, it may be difficult to distinguish inflammation secondary to radiation therapy or recent interventional procedures from disease persistence or recurrence, especially if serial [^{18}F]FDG scans are used for surveillance (Fig. 4).

[^{18}F]FDG Imaging for Preoperative Staging of NSCLC

Accurate staging of NSCLC provides important prognostic information and determines the best treatment approach. Surgical resection is indicated for early stages of NSCLC and in N1 or N2 disease (ipsilateral mediastinal nodes), unless lymph node metastases are bulky, multilevel, or non-resectable. In N3 disease (contralateral mediastinal, scalene, or supraclavicular nodal metastases) as well as in patients with metastatic spread surgery is not indicated.

T Stage

Although CT can accurately detect tumor size and infiltration of adjacent structures, [^{18}F]FDG PET/CT predicts T stage in 82% of cases as compared to 68% and 76% for stand-alone CT and visually co-registered separately performed PET and CT, respectively [33–36, 163–166]. [^{18}F]FDG PET/CT may improve accuracy for detection of tumor invasion of the chest wall [163]. Changes in the therapeutic management due to PET/CT occur mainly in T3 and T4 tumors [164]. [^{18}F]FDG PET/CT has also an advantage in the assessment of tumor spread to the pleura. Pleural thickening and pleural nodularity can be detected on CT and MRI, but may also be encountered in benign disorders. However, [^{18}F]FDG PET/CT has a high PPV and NPV in the assessment of malignant pleural effusion [165]. In contrast to CT, [^{18}F]FDG PET/CT can help differentiate between tumor (usually avid) and peri-tumoral atelectasis (usually non-avid) and therefore has an impact on planning of surgical procedure or radiation therapy. The accurate information on tumor extent provided by [^{18}F]FDG PET/CT has been shown to cause changes in planning the radiation field in 30–40% of patients [167, 168].

N Stage

Based on the criterion that a node of $\geq$10 mm in the short axis diameter is metastatic, the sensitivity of CT has been reported in the range of 52–69% and the specificity between 69% and 82% [169]. Normal-size lymph nodes on CT have micrometastases in 15% of cases [170], while 30–40% of enlarged lymph nodes have no tumor cells [171]. [^{18}F]FDG imaging, on the other hand, has a sensitivity ranging between 79% and 85%, specificity of 89–92% [172], and a NPV above 90% [173] for the detection of metastatic mediastinal lymphadenopathy. False-negative results can occur in cases of micrometastases and false-positive findings in cases of inflammation. The PPV of [^{18}F]FDG imaging for evaluating the mediastinum ranges from 45% to 93% [174, 175]. Mediastinoscopy is therefore the standard of care for mediastinal staging. In cases of

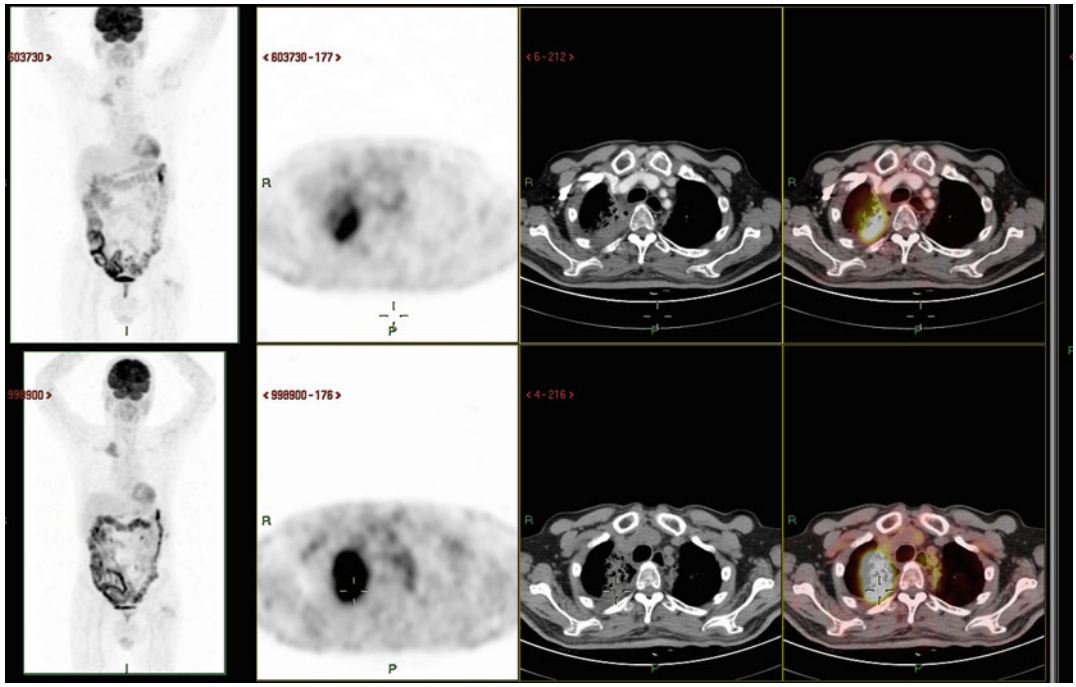

Fig. 4 A 73-year-old man with a paravertebral RUL adenocarcinoma, same patient as Fig. 5. Follow-up studies performed 2 months (*bottom row*) and 5 months (*upper row*) after completion of chemo- and radiation therapy. Selected transaxial CT, PET, and fused PET/CT slice and MIP image (*left*) show an [^{18}F]FDG-avid RUL mass which has reduced in size and in [^{18}F]FDG avidity compared to the first study. In addition there is a new [^{18}F]FDG-avid RUL infiltrate (SUV_{max} 4.8), reducing in size between the two studies, most likely representing post-radiotherapy pneumonitis, although a persistent residual and viable tumor within this infiltrate cannot be excluded. *RUL* right upper lobe, *MIP* maximum intensity projection

[^{18}F]FDG-positive mediastinal nodes, the study can further direct biopsy. Antoch et al. [33] assessed 27 NSCLC patients comparing CT and [^{18}F]FDG PET/CT with histopathology. PET/CT classified the tumor stage correctly in 26 patients, compared to 19 with CT. The accuracy for regional lymph node staging was 93% with PET/CT and 63% with CT. PET/CT also detected 17 distant metastases in four patients, compared to 14 metastases in four patients with CT [33]. Shim et al. prospectively recruited 106 patients with NSCLC who underwent tumor resection and lymph node dissection after [^{18}F]FDG PET/CT and CT. PET/CT correctly staged 86% of the primary tumors as compared to 79% by CT. PET/CT was more sensitive and more specific (85% vs. 70% and 84% vs. 69%, respectively) than CT for diagnosis of malignant regional nodes, with more false-positive findings and false-negative findings on CT [172].

M Stage

Distant metastases are found in 30–40% of patients with NSCLC at the time of presentation; most common sites are in the adrenal glands, liver, bones, and brain [176] (Fig. 5). Adrenal masses occur in about 10% of patients with bronchogenic cancer, and benign adenomas occur in 3–5% [58]. [^{18}F]FDG imaging is more sensitive than CT in the diagnosis of extrathoracic disease [176]. Sensitivities of 88–100% have been reported in characterizing adrenal lesions, with NPV and PPV of 98% and 94%, respectively [177, 178]. The sensitivity and specificity of [^{18}F]FDG imaging for detection of liver metastases from NSCLC are also high, reaching 100% [179]. Bone metastases are present in 20–30% of patients at the time of diagnosis. Although bone scintigraphy (BS) is highly sensitive, it has a less than optimal specificity [180]. In a recent meta-analysis, the sensitivity and specificity of [^{18}F]FDG PET/CT were

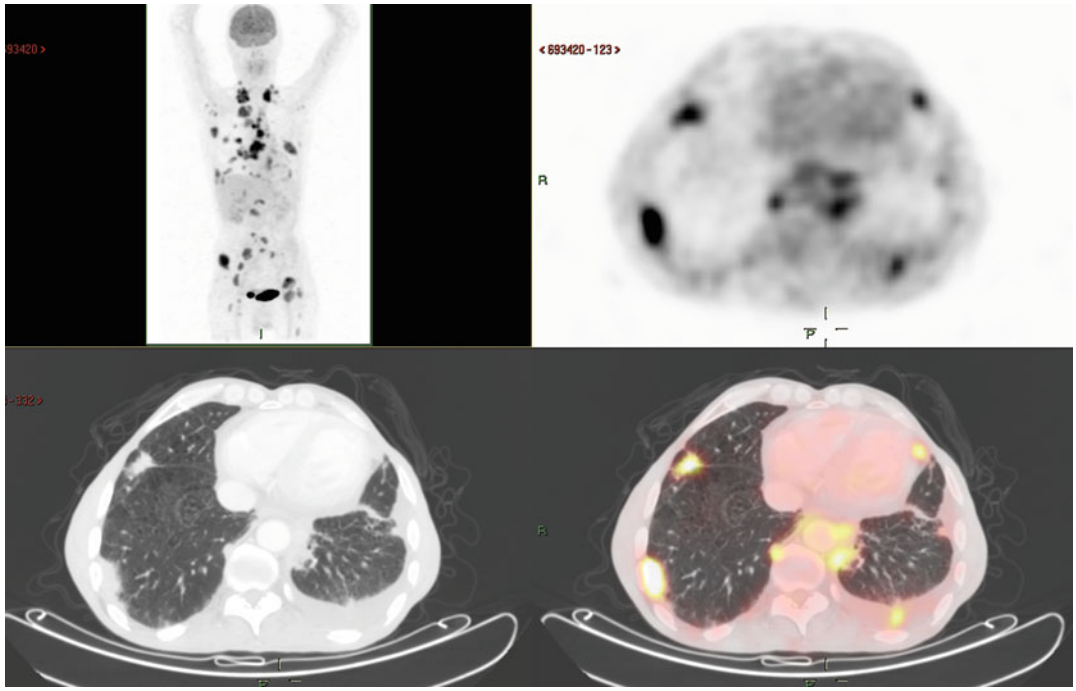

Fig. 5 A 65-year-old man was referred to [^{18}F]FDG PET/CT for evaluation of known metastatic lung cancer. Selected transaxial CT, PET, and fused PET/CT slice show 2.2-cm [^{18}F]FDG-avid RML nodules with spiculated margins, most likely the primary tumor (SUV_{max} 5.5). The MIP image (*upper left*) shows extensive [^{18}F]FDG-avid disease with involvement of the mediastinal and cervical lymph nodes, pleural plaques, pancreas, and extensive skeletal disease, consistent with stage IV disease. *RML* right middle lobe, *MIP* maximum intensity projection

92% and 98%, respectively, compared to 86% and 88% for BS [181]. Therefore, it has been suggested that BS can be eliminated in the staging workup of preoperative patients who undergo an [^{18}F]FDG PET/CT examination.

^{18}F-Fluoride-PET/CT was also assessed for the detection of bone metastases in NSCLC. In a prospective study [182] of 103 patients with lung cancer, receiver operator curve (ROC) analysis showed that the performance of ^{18}F-fluoride PET was better than that of the conventional BS. In 1,000 NSCLC patients with confirmed bone metastases, PET/CT had a better sensitivity (98.3% vs. 95.1%) and specificity (98.7% vs. 98.4%) as compared to planar BS [183]. Recently Kruger et al. [184] have correlated the findings on [^{18}F]FDG PET/CT to BS and ^{18}F-Fluoride studies in 126 patients with NSCLC including 34 patients with osteolytic metastatic bone lesions. [^{18}F]FDG PET/CT was superior to planar BS in the detection of these skeletal lesions, also leading to changes in patient management. ^{18}F-Fluoride detected more metastatic foci and was at least as sensitive as [^{18}F]FDG PET/CT [184].

[^{18}F]FDG imaging is less useful in the detection of brain metastases, due to high physiologic glucose utilization in normal brain tissue. [^{18}F]FDG PET/CT has an advantage in depicting unsuspected pancreatic metastases from lung cancer, particularly those that are not detected by CT alone [185]. Finally, [^{18}F]FDG imaging can also diagnose a synchronous second primary tumor, mainly of colorectal origin, detecting incidentalomas, unsuspected foci of increased tracer uptake in the gastrointestinal tract [185].

Value of [^{18}F]FDG PET/CT in Patient Management

Fisher et al. [186] assessed the clinical effect of [^{18}F]FDG PET/CT on preoperative staging of

NSCLC, comparing 98 patients who had PET/CT to 91 patients who had conventional staging. The primary end point was defined as the number of futile thoracotomies. There were 21/60 futile thoracotomies in the [^{18}F]FDG PET/CT group compared to 38/73 in the conventional imaging group. The number of justified thoracotomies and survival of patients were similar in the two groups. Therefore the use of [^{18}F]FDG PET/CT reduced the number of total and specifically of futile thoracotomies in these patients [186]. Similar findings were also reported by others, who have assessed the cost-effectiveness of lung cancer staging with [^{18}F]FDG PET/CT [139]. In a randomized prospective study, 188 patients had either conventional imaging including CT or had both conventional workup and [^{18}F]FDG imaging [187]. Patients who performed [^{18}F]FDG studies had a 51% reduction in unnecessary thoracotomies. Subedi et al. [188] assessed the clinical impact of [^{18}F]FDG PET/CT in 161 patients with suspected lung cancer. In this study the addition of PET/CT to the conventional evaluation of lung cancer excluded the presence of malignancy in 10% of patients with no uptake in the suspected lung lesion and revealed occult metastases in 16% of patients. [^{18}F]FDG PET/CT was a better predictor for T staging (64% vs. 58%) and N staging (78% vs. 65%) and influenced management decisions in 41% of patients, leading to a decrease in the number of thoracotomies performed for non-resectable disease [189].

[^{18}F]FDG Imaging for Radiation Treatment Planning in NSCLC

NSCLC patients with newly diagnosed stage IIIA or IIIB disease as well as patients with limited disease who are not suitable for surgery are candidates for radiation therapy [190]. It has been shown that [^{18}F]FDG imaging has a significant impact on defining the target volume in patients with lung cancer prior to radiation therapy [191]. Nestle et al. have reviewed the results in 661 patients with lung cancer in 18 trials that compared target volumes, gross tumor volume (GTV), clinical tumor volume (CTV), and planning target organ volume (PTV) using CT alone and [^{18}F]FDG PET/CT. All trials showed significant changes in target volumes when [^{18}F]FDG PET/CT was added due to better diagnosis of lymph node involvement and optimized differentiation between tumor and adjacent atelectasis [190]. In the past, due to diagnostic uncertainties, target volumes in lung cancer patients included large portions of unaffected tissue. High doses of irradiation were delivered with a high risk of irradiating normal lung and adjacent tissues. Due to the high NPV for the detection of mediastinal lymph nodes (>90%) and the delineation of the metabolically active tumor volume, [^{18}F]FDG PET/CT can influence the definition of the GTV for radiotherapy planning. The GTV can be reduced when [^{18}F]FDG-negative nodes or areas of atelectasis are excluded from the radiation treatment field or enlarged when previously unsuspected [^{18}F]FDG-avid nodes are detected. This can lead to a change in the GTV or dose to be delivered in up to two thirds of cases [192–198]. For example, omission of extensive nodal irradiation in patients with N2 disease with lower burden of nodal invasion resulted in a significant reduction of doses given to the lung, esophagus, heart, and spinal cord [195]. However, because of a false-positive rate that may reach 30%, depending on the patient population, ideally, pathological confirmation of [^{18}F]FDG-positive nodes should be obtained by mediastinoscopy or endoscopic ultrasound-guided fine-needle aspiration [197]. Importantly, the addition of [^{18}F]FDG imaging to CT reduces the inter-observer variability in definition of the GTV for NSCLC [199–204].

There are no large clinical trials assessing long-term consequences of [^{18}F]FDG-induced changes in the treatment plan. Isolated cases of nodal failure [205] and out-of-field recurrence [206] were reported. Large prospective trials of patient outcome are needed to assess the clinical impact of this strategy.

Is Radical Therapy Suitable for the Patient?

The outcome of the combined anatomic and metabolic data available from [^{18}F]FDG PET/CT imaging guides clinicians in the selection of the most suitable treatment modality. For example, an 80-year old patient with a single isolated [^{18}F]FDG-positive N2 node adjacent to a left upper lobe tumor would benefit more from radical radiotherapy rather than from neoadjuvant treatment followed by radical surgery.

[^{18}F]FDG imaging can also help in planning the surgical approach with respect to the extent of resection, by identifying [^{18}F]FDG-positive lesions in the mediastinum, chest wall invasion, peribronchial infiltration, or vascular invasion. [^{18}F]FDG imaging is also increasingly used for radiation treatment planning. It can help in decreasing the risk of radiation-related side effects such as pneumonitis and esophagitis by accurate definition of the tumor volume.

Prognostic Value of SUV

The importance of SUV measurements on the baseline [^{18}F]FDG study is very useful in lung tumors. SUV is a good prognostic indicator as well as a good indicator of response to treatment. In NSCLC patients an SUV_{max} of the primary tumor >7 [207] and >10 [208] had an independent prognostic impact, also showing that the median survival decreased with increasing mean SUV levels. Others also showed that the SUV_{max} was an independent predictor of disease free and overall survival [209, 210]. In a retrospective study in 100 patients, Downey et al. [211] showed that the 2-year survival rates were 68% for patients with a SUV_{max} above 9% and 96% in patients with SUV_{max} below 9. In patients with NSCLC, Cerfolio et al. [212] found the SUV_{max} to be an independent predictor of tumor aggressiveness and a more accurate predictor of tumor recurrence and survival as compared to TNM staging. Total lesion glycolysis (TLG) was also found to be a significant prognostic parameter in NSCLC [208].

[^{18}F]FDG Imaging for Assessment of Response to Therapy in NSCLC

Twenty to 40% of patients with NSCLC respond to treatment. Tumor progression after first-line chemotherapy occurs in up to one third of patients [154, 209]. Second-line treatment options can be offered to nonresponding patients if tumor response can be predicted early. Treatment response is mainly assessed with CT; however, there is evidence that [^{18}F]FDG PET/CT is more accurate, as volume reduction is often slower than metabolic response. [^{18}F]FDG imaging has been used to assess the changes in glucose metabolism occurring during treatment and thus for early prediction of tumor response [154, 155, 210, 211] (Fig. 6). The absolute SUV_{max} after treatment has been assessed as a predictor of overall survival. Patients with a posttreatment SUV_{max} of less than 4 survived for more than 56 months, as compared to only 19 months for a posttreatment $SUV_{max} \geq 4$ [212]. Changes in SUV may occur as early as 1 week after initiation of treatment [213]. Weber et al. assessed 57 patients with advanced NSCLC before and after the first cycle of platinum-based chemotherapy. Using a reduction of 20% in tumor SUV as a criterion for metabolic response, they found a close correlation between the change in SUV and tumor response to therapy. Median time to progression and overall survival were significantly longer for the 28 patients with a metabolic response (163 and 252 days) than for the metabolic nonresponders (54 and 151 days, respectively) [210]. In 56 patients with NSCLC who underwent [^{18}F]FDG imaging and CT before and after neoadjuvant chemotherapy followed by tumor resection, the change in SUV correlated much better with the percentage of nonviable tumor cells in the resected specimens than the change in size on CT. A decline of 80% or more in SUV predicted a complete pathological response with a sensitivity, specificity, and

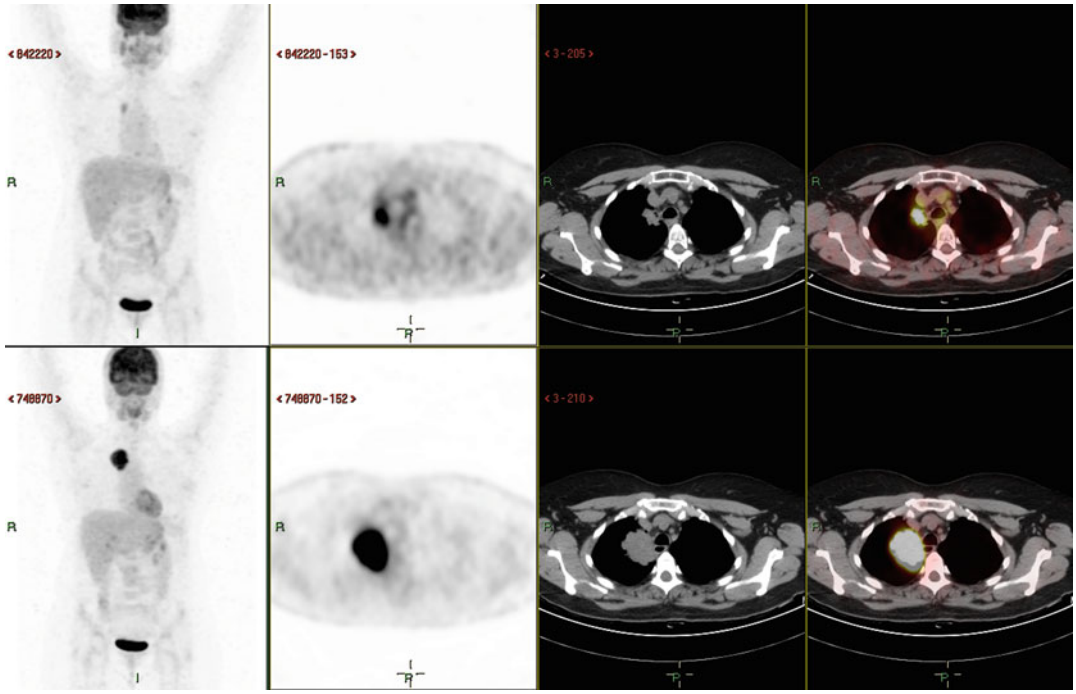

Fig. 6 A 52-year-old woman with a 5-cm RUL paramediastinal mass was referred to [^{18}F]FDG PET/CT for initial staging (*bottom row*) and for repeat PET/CT early after starting chemotherapy (*upper row*). Selected transaxial CT, PET, and fused PET/CT slices and MIP (*left*) show significant reduction in the size of the lesion (from 5 × 3 to 2.2 × 3 cm) and significantly reduced [^{18}F]FDG avidity during chemotherapy (SUV_{max} reduced from 13.5 to 5.6) consistent with a good partial metabolic response. *RUL* right upper lobe, *MIP* maximum intensity projection

accuracy of 90%, 100%, and 96%, respectively [211]. In a prospective study in 47 patients with stage III NSCLC, [18F]FDG imaging was performed before and after one and two cycles and at the end of induction chemotherapy [212]. At the end of therapy, nodal stage on CT was not predictive of outcome, but focal increase in [^{18}F]FDG uptake was associated with a twofold risk of death. A decline in SUV of 50% or more predicted survival. A similar trend was noted after one and two courses of chemotherapy [213]. Eschmann et al. performed [^{18}F]FDG imaging before and 2 weeks after completion of neoadjuvant radio- and chemotherapy and prior to resection in 70 patients with stage III NSCLC. A negative [^{18}F]FDG study or a reduction in SUV of more than 80% from baseline was the best predictors for good response to further treatment, whereas progressive disease on [^{18}F]FDG imaging studies correlated with an unfavorable outcome [214]. In 52 patients with advanced NSCLC who underwent baseline and follow-up [^{18}F]FDG PET/CT after four cycles of chemotherapy, a less than 50% decrease in TLG was identified as the optimal cutoff value to define disease progression, with 100% NPV for a 6 months of progression free survival (PFS). Almost all patients with a decrease in TLG less than 50% had early disease progression [215] (Fig. 7). A prospective multicenter study assessed 52 NSCLC patients who had a baseline and a second [^{18}F]FDG PET/CT during the fifth week of radio-chemotherapy or radiotherapy. SUV_{max} of 5.3 at the second study was the single predictive variable and had a sensitivity of 70% and specificity of 92% for predicting tumor progression or death at 1 year [216]. In 15 patients with stage I–III NSCLC requiring radiotherapy, [^{18}F]FDG PET/CT was performed at baseline, during, and after radiotherapy. There were 11 patients who achieved partial

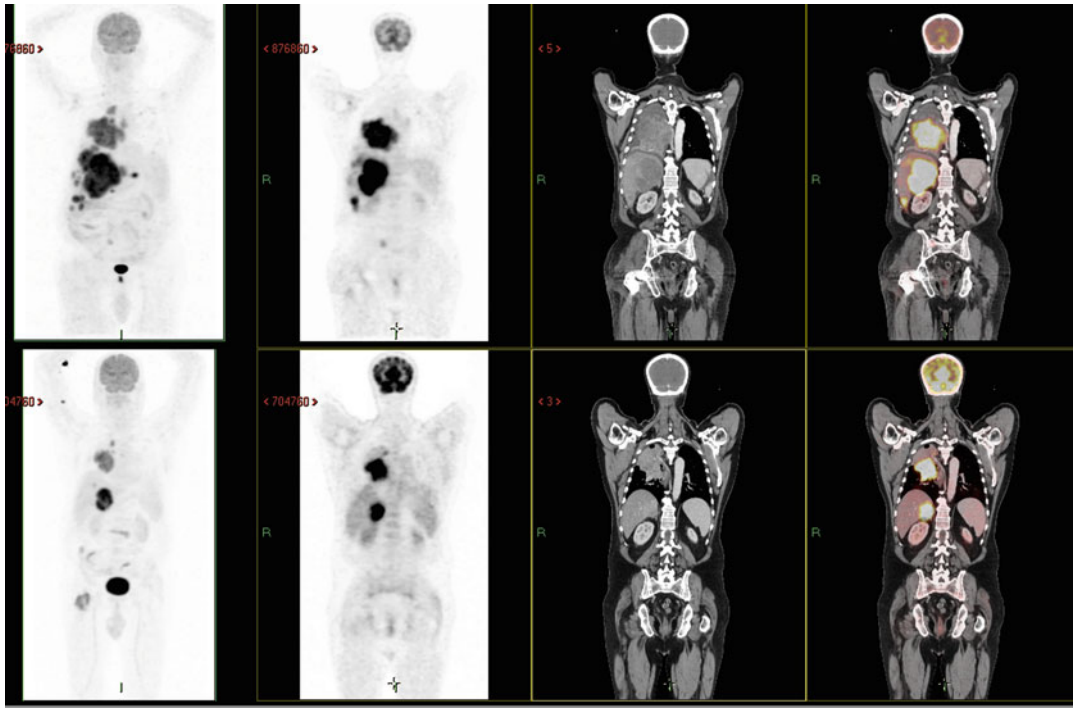

Fig. 7 A 74-year-old man with known metastatic NSCLC was referred to [^{18}F]FDG PET/CT for evaluation of right hip pain (*bottom row*) and for repeat PET/CT 4 months after completion of radiation therapy (*upper row*) due to increasing bone pain. Selected coronal PET, CT, and fused PET/CT slices and MIP (*left*) (*bottom row*) show the [^{18}F]FDG-avid right peri-hilar mass, mediastinal and right supraclavicular lymphadenopathy, liver metastases, and a right femoral lytic lesion. Following resection of right femoral lesion and radiotherapy (*upper row*), there is significant progression in [^{18}F]FDG-avid disease in the right lung, mediastinal nodes, left lung (not shown), and liver. *NSCLC* non-small cell lung cancer, *MIP* maximum intensity projection

response, two with complete response and two with stable disease. All [^{18}F]FDG-avid tumors showed a reduction in [^{18}F]FDG avidity from a mean SUV of 5.2 pre-therapy to 2.5 during radiation therapy and 1.7 post-radiotherapy [217] (Fig. 8). Increased [^{18}F]FDG due to posttreatment inflammation frequently occurs at 2–6 months after radiotherapy and may persist to about 12 months. It has to be considered when interpreting studies in patients treated with radiation [218].

Literature data thus indicate that a decrease in [^{18}F]FDG uptake usually correlates with the pathologic response and with improved survival. It needs to be emphasized, however, that there is not yet a consensus regarding the measurement of response and the degree of reduction in SUV that is required to define a metabolic response.

[^{18}F]FDG Imaging in the Follow-Up of Lung Cancer

After curative treatment follow-up is indicated to assure proper management of therapy-related complications or for early detection of tumor recurrence which is most likely to occur within the first 4 years with only 10% developing after 5 years or more [219]. A meta-analysis showed no significant benefits of follow-up of lung cancer after curative treatments. A nonsignificant trend for improved survival with intensive follow-up was identified in the curative-intent treatment subgroup [219]. The most recent guidelines published by the American College of Chest Physicians suggest that in patients who have undergone curative-intent surgical resection of NSCLC, chest CT should be

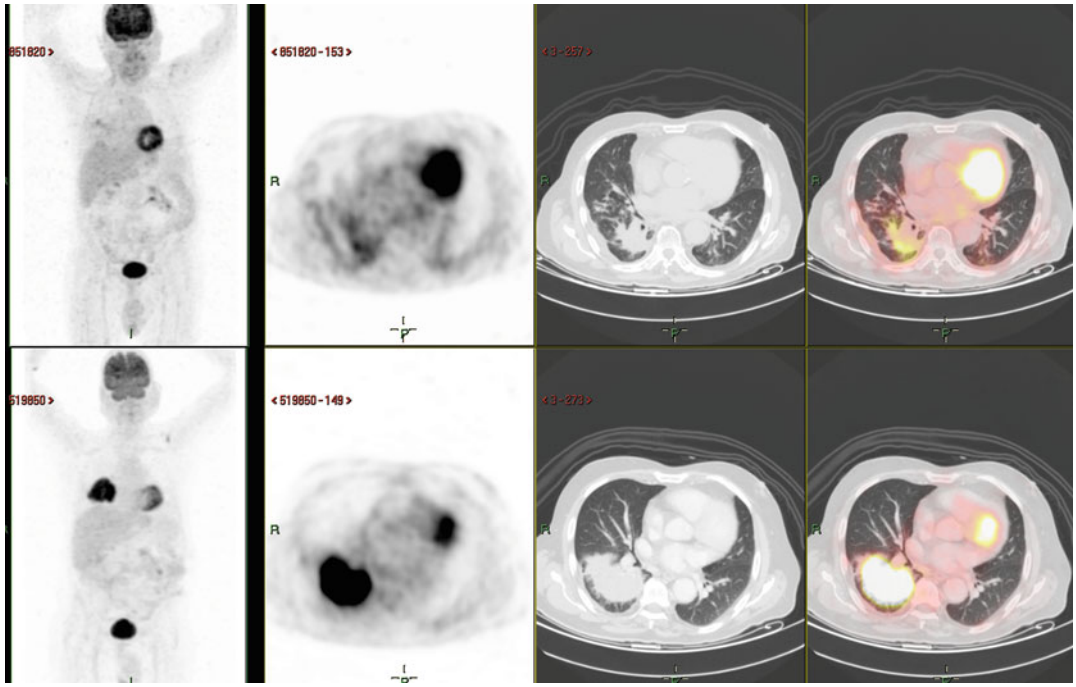

Fig. 8 A 82-year-old man with a 8-cm RLL mass was referred to [^{18}F]FDG PET/CT for initial staging (*bottom row*) and for repeat PET/CT 4 months after completion of radiation therapy (*upper row*). Selected transaxial CT, PET, and fused PET/CT slices and MIP (*left*) (*bottom row*) show the [^{18}F]FDG-avid RLL mass (SUV_{max} 19.7). There is no hilar nor mediastinal [^{18}F]FDG-avid lymphadenopathy and no distant [^{18}F]FDG-avid disease, corresponding to T3N0M0 disease by PET/CT. Following radiotherapy (*upper row*) there is significant reduction in the size of the lesion (from 8 to 4.8 cm) and significantly reduced [^{18}F]FDG avidity (SUV_{max} 3.0). Low-grade residual [^{18}F]FDG avidity is most likely due to post-radiotherapy inflammatory changes. *RLL* right lower lobe, *MIP* maximum intensity projection

performed every 6 months for the first 2 years after resection and every year thereafter [220]. It is further recommended that in NSCLC and carcinoid treated with curative intent, the original treating physicians participate in the decision-making process during follow-up. Routine surveillance with [^{18}F]FDG PET imaging, somatostatin receptor scintigraphy (SRS), or abdominal ultrasonography is not recommended [220].

[^{18}F]FDG PET-CT imaging is helpful in the management of advanced stage lung cancer. Advances in chemotherapy and availability of second- and third-line regimens (including less toxic drugs as well as oral chemotherapy) require a marker to define when these drugs are no longer effective and a change in therapy is necessary.

Changes in lesion size on CT and SUV on serial [^{18}F]FDG PET/CT studies provide information about the efficacy of therapy. Reduction in size and decrease in SUV suggest that therapy is effective. Increasing lesion size or failure of the SUV to decline by $\geq$25% after 6–8 weeks of treatment suggests failure of therapy. In patients who have a complete metabolic response, serial [^{18}F]FDG PET/CT surveillance imaging is very useful to detect recurrence and is more sensitive than stand-alone CT.

In a retrospective study of 261 lung cancer patients with 488 follow-up [^{18}F]FDG PET/CT studies performed $\geq$6 months after completion of initial treatment and followed for a median of 29.3 months, the median survival of [^{18}F]FDG-positive and [^{18}F]FDG-negative groups was 32.9 months and 81.6 months, respectively,

with similar differences in overall survival between the groups. Age and [^{18}F]FDG PET/CT results were the only factors associated with overall survival on multivariate analysis, regardless of the timing of the follow-up study [221]. The same group has assessed the value of the fourth and subsequent [^{18}F]FDG PET/CT studies performed during follow-up after completion of primary therapy in 1,171 patients. [^{18}F]FDG PET/CT identified recurrence or metastases in 43% of studies in patients with no previous evidence of disease and ruled out recurrence or metastases in 24% of studies with prior clinical suspicion of disease with an overall change in management in 28% of patients [222].

[^{18}F]FDG Imaging for Detection of NSCLC Recurrence

Early detection of recurrence can be difficult with CT. New findings can be related to tumor recurrence but can also be due to treatment. Differentiating treatment-induced fibrosis and necrosis from viable tumor may not be possible on CT [223, 224]. However, [^{18}F]FDG imaging can differentiate recurrent or persistent tumor from scar tissue with a sensitivity of 89–98% and specificity of 87–93% [225–227]. Since the results of [^{18}F]FDG studies performed less than 10 days after administration of chemotherapy may be misleading, it is advisable to perform the study at least 2 weeks after completion of therapy. Increased [^{18}F]FDG uptake in recent surgical scars, due to a healing inflammatory process, usually a linear pattern decreasing in intensity over time, can be differentiated from recurrence in the surgical field which has a more focal appearance with high intensity uptake [227].

Small-Cell Lung Cancer (SCLC)

SCLC which represents about 13% of all lung cancers is an aggressive malignancy with a rapid doubling time and early widespread metastases [228] (Fig. 9). Tumors are usually centrally located, often encasing mediastinal structures and compressing the tracheobronchial tree, presenting with large hilar and mediastinal nodes and often with distant metastases [43]. In the past patients with SCLC were staged as limited disease (tumor confined to the thorax) or extensive disease (contralateral lung and distant metastases) [229, 230]. Recently, however, the TNM staging has also been applied to SCLC [43] (Fig. 4). For accurate initial staging, NCCN guidelines suggest performing CT for assessment of the chest, liver, and adrenals and MRI for the brain. [^{18}F]FDG PET/CT is recommended only if limited disease is suspected.

The advantages of [18F]FDG PET-CT in SCLC appear to be similar to NSCLC. A prospective study of patients with extensive SCLC reported a sensitivity and specificity of 79% and 100% for standard staging, 93% and 83% for [^{18}F]FDG PET stand alone, and 93% and 100% respectively, for [^{18}F]FDG PET/CT. [^{18}F]FDG imaging is more accurate in nodal detection. [^{18}F]FDG-based selective nodal irradiation for limited disease SCLC resulted in a low rate of isolated nodal failures of 3% and low percentage of acute esophagitis [231]. These findings contradict results obtained using CT-based selective nodal irradiation, which showed isolated nodal failures in 11% of cases [231]. The low rate of isolated nodal failures and decreased esophageal toxicity supports the use of [^{18}F]FDG-based nodal irradiation for limited SCLC.

Response of SCLC to chemotherapy can be assessed as early as at the end of the first cycle of chemotherapy. Prognostic stratification was studied by Lee et al. [232] who reported that in patients with SCLC, high SUV_{max} was significantly related to poor prognostic factors and extensive disease. Furthermore, multivariate analysis indicated that high SUV_{max} was associated with poor survival outcomes compared with patients with low SUV_{max} (adjusted hazard ratio, 3.74). In a subgroup analysis, patients with limited disease and high SUV_{max} had a significantly shorter overall survival than patients with limited disease and low SUV_{max} (20.1 months vs. 35.3 months respectively; $p = 0.02$). Patients with extensive disease and high SUV_{max} had significantly shorter overall survival than patients

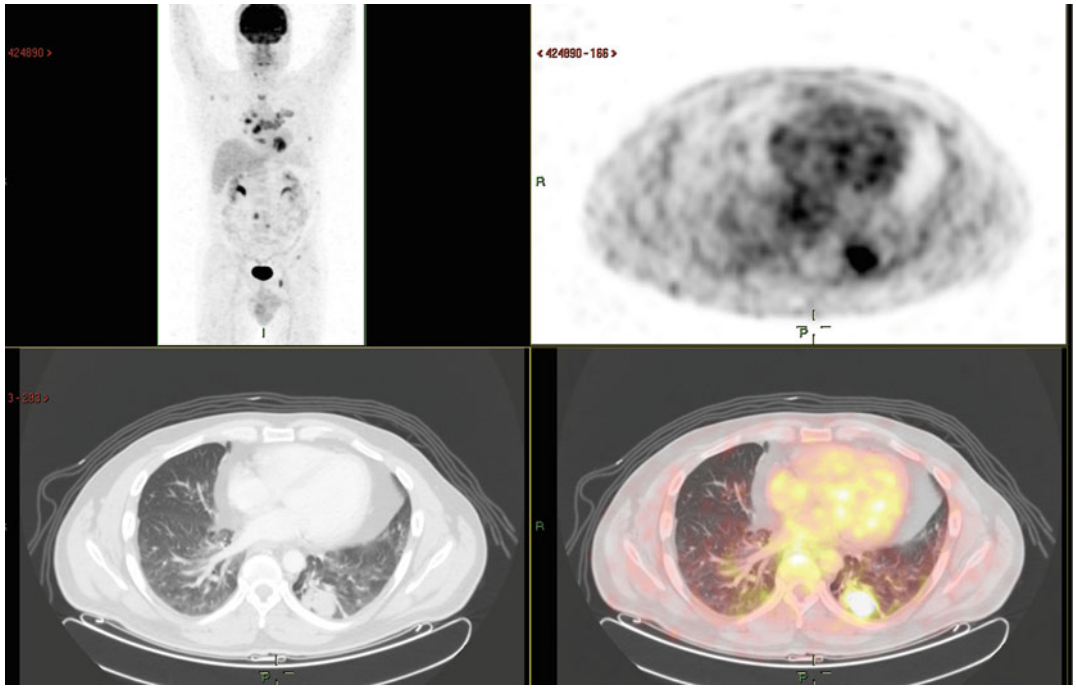

Fig. 9 A 52-year-old man was referred to [^{18}F]FDG PET/CT for staging of newly diagnosed small-cell lung cancer. Selected transaxial CT, PET, and fused PET/CT slice show a 4.5-cm [^{18}F]FDG-vid LLL mass. The MIP image (*upper left*) shows [^{18}F]FDG-avid mediastinal lymphadenopathy and skeletal involvement, consistent with stage IV disease. *LLL* left lower lobe, *MIP* maximum intensity projection

with extensive disease and low SUV_{max} (9.5 months vs. 17.7 months, respectively; $p = 0.007$). These findings were replicated in progression-free survival analysis. Therefore, it was concluded that in SCLC, metabolic tumor activity assessed by [^{18}F]FDG imaging is a significant prognostic factor and identifies subgroups of patients at higher risk of death in patients with both limited and extensive disease [232]. [^{18}F]FDG PET-CT also has a role in radiation treatment planning in patients with SCLC [233, 234]. In the current guidelines, [^{18}F]FDG PET-CT is not indicated for surveillance in SCLC.

[^{18}F]FDG and Other PET Tracers for Imaging in Neuroendocrine Tumors

Neuroendocrine tumors (NETs) vary in differentiation and glucose metabolism, and therefore [^{18}F]FDG imaging alone is unable to complete the phenotyping of this disease entity in individual patients [235]. [^{18}F]FDG imaging can detect NETs with a variable ability, even in the same patient [236]. Most NETs express a variety of somatostatin-subtype (STT) receptors, and the need for their thorough appreciation has guided the development of ligands successfully labelled with ^{68}Ga for specific imaging. Examples of such ligands are ^{68}Ga-DOTATATE and ^{68}Ga-DOTATOC, which target the SSTr2, SSTr4, and SSTr5 receptor subtypes [237–243]. Kayani et al. have recently compared ^{68}Ga-DOTATATE and [^{18}F]FDG using PET/CT in 18 patients with pulmonary NETs [243]. All typical carcinoids showed high ^{68}Ga-DOTATATE uptake (SUV_{max} 8.2 or higher) but 4 of 11 showed only minimal [^{18}F]FDG uptake (SUV_{max} 1.7–2.9), which could not discriminate tumor from distal atelectasis (Fig. 10). On the other hand, atypical carcinoids and high-grade tumors had less ^{68}Ga-DOTATATE uptake but were [^{18}F]FDG avid (SUV_{max} 11.7 or higher) [243].

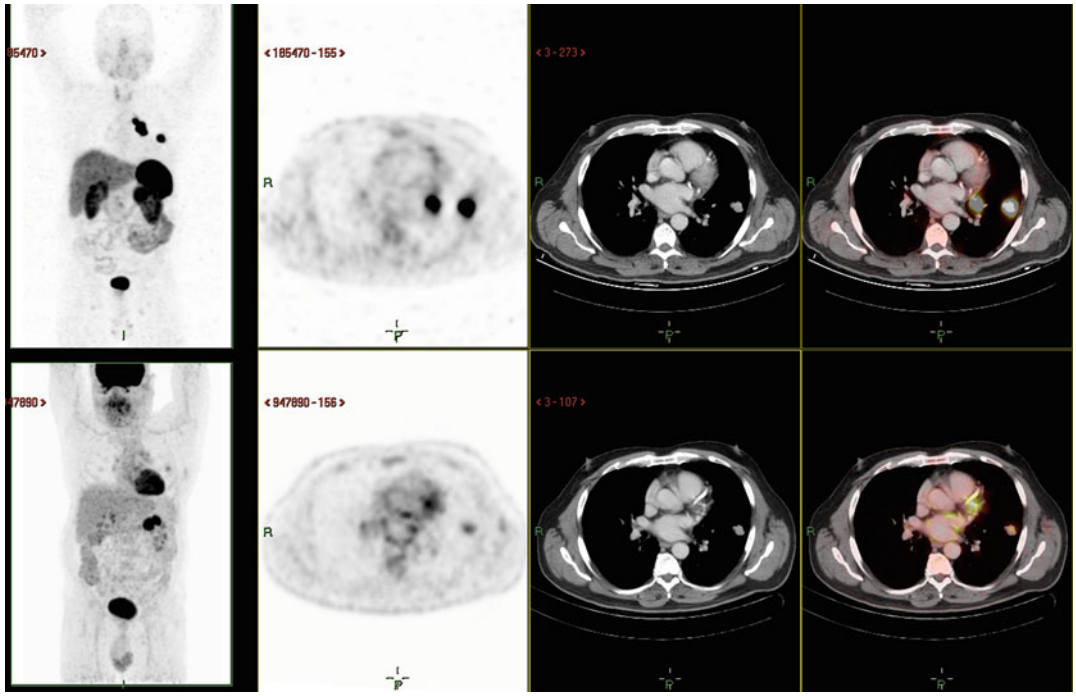

Fig. 10 A 61-year-old man was referred to PET/CT for evaluation of newly diagnosed carcinoid. PET/CT studies with [^{18}F]FDG (*bottom*) and with [^{68}Ga]DOTATATE (*top*) were performed. Selected transaxial CT, PET, fused PET/CT slice, and MIP (*left*) show non-[^{18}F]FDG-avid lingular, mediastinal, and left hilar lesions with somatostatin receptors. The patient underwent left upper lobectomy, confirming the diagnosis of carcinoid with lymph node involvement

[^{18}F]FDG Imaging of Malignant Pleural Disease

[^{18}F]FDG imaging has been used for the assessment of pleural masses and effusions. Pleural metastases of lung cancer are best diagnosed with CT, or the CT component of [^{18}F]FDG PET/CT study, since the lesions are as a rule below the resolution of PET [244]. In 25 patients with suspected malignant pleural effusions, Erasmus et al. found sensitivity, specificity, and PPV for [^{18}F]FDG PET/CT of 95%, 67%, and 95%, respectively [244]. Schaffler et al. have studied 92 patients and found a sensitivity, specificity, and PPV of 100%, 71%, and 63%, respectively [167].

Malignant pleural mesothelioma (MPM) is an aggressive tumor of mesothelial cell origin associated with asbestos exposure. Although it is a relatively rare neoplasm, its incidence is increasing worldwide due to widespread exposure to asbestos [245, 246]. Mesothelioma is seen more often in men (likely due to a higher incidence of exposure to asbestos) and occurs in the right hemithorax more often than the left. CT is the primary imaging modality [247–251]. Key findings include unilateral pleural effusion and nodular pleural and interlobar fissure thickening. Calcified pleural plaques are found in 20% of the patients, indicating previous asbestos exposure [251]. The invasion of adjacent structures, adenopathy, and the presence of bone, pulmonary, and distant metastases can occur in advanced stages of the disease [252, 253]. MRI provides detailed information in challenging cases [254] and can assist in differentiating malignant from benign pleural disease as well as in the assessment of chest wall and diaphragmatic involvement [255]. High signal intensity in relation to adjacent musculature on T2-WI, significantly enhancing on T1-WI, is suggestive of malignant disease. MRI has a 100% sensitivity

and 93% specificity for detection of pleural malignancy [256] and is superior to CT in delineating chest wall and diaphragm invasion, thus providing a better assessment of potential resectability [254, 255]. Dynamic contrast-enhanced MRI is a promising new technique that may reflect tumor histopathology [257] and may predict the therapeutic efficacy of chemotherapy in patients with MPM.

[^{18}F]FDG PET can provide additional diagnostic and prognostic information. SUVs are significantly higher in MPM as compared to benign diseases of the pleura such as inflammatory pleuritis and asbestos-related pleural thickening [258, 259] (Fig. 11). Not all areas of pleural thickening detected on CT correspond to areas of high metabolic activity, and [^{18}F]FDG imaging can be therefore a good guide to define the most appropriate sites for biopsy [260]. Benard et al. studied 28 patients with suspected and 22 with confirmed diagnosis of MPM. They found that the mean SUV measured on [^{18}F]FDG imaging studies correlated well with survival. Seven patients who died during follow-up had a mean SUV of 6.6 $\pm$ 2.9 as compared with 3.2 $\pm$ 1.6 in survivors [258].

Talc pleurodesis is a common palliative procedure since most patients develop pleural effusions. The inflammatory effect of pleurodesis affects both the CT and PET component where it is associated with higher SUV_{max} and TGV [261–263] (Fig. 12). Only few small studies were published with respect to response assessment in mesothelioma. Ceresoli et al. showed a decrease in 25% or more in tumor SUV_{max} correlated with time to progression and improved overall survival [264]. No correlation was observed between response on CT and time to tumor progression. Another small study showed that volume-based parameters on [^{18}F]FDG-PET, such as the metabolic tumor volume and TLG, were significantly correlated with patient outcome [265]. Recently Genenstreti et al. have assessed response to talc pleurodesis in eight patients with

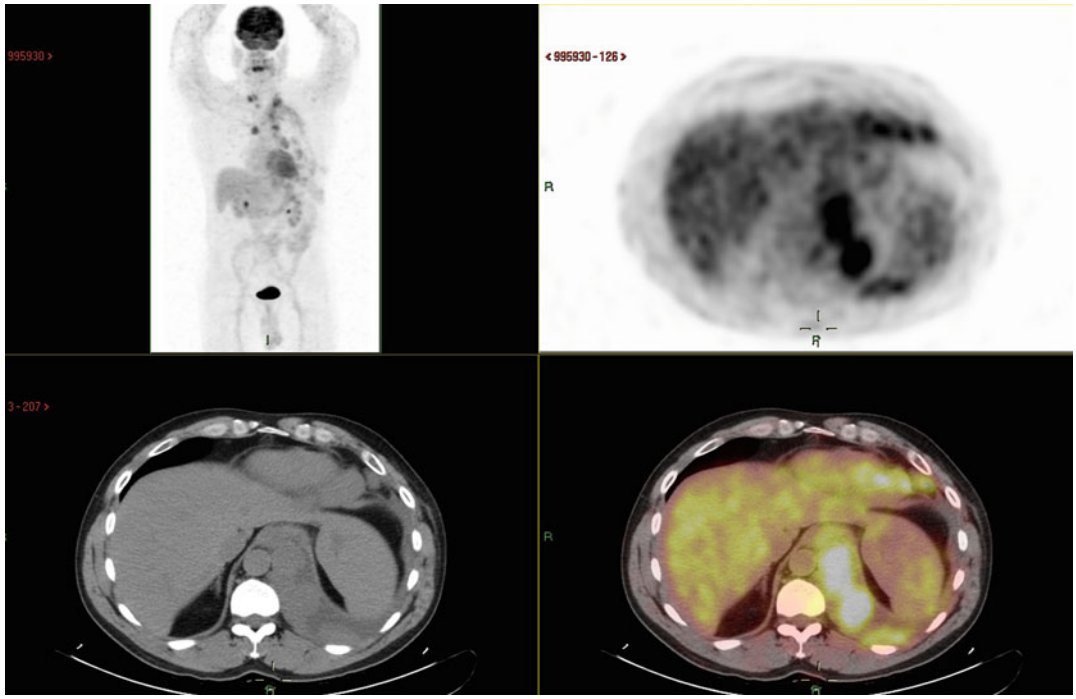

Fig. 11 A 45-year-old man with malignant pleural mesothelioma was referred to [^{18}F]FDG PET/CT for evaluation. Selected transaxial CT, PET, fused PET/CT slice, and MIP (*upper left*) show [^{18}F]FDG-avid soft tissue pleural masses and [^{18}F]FDG-avid mediastinal and right supraclavicular lymphadenopathy, consistent with metastatic involvement

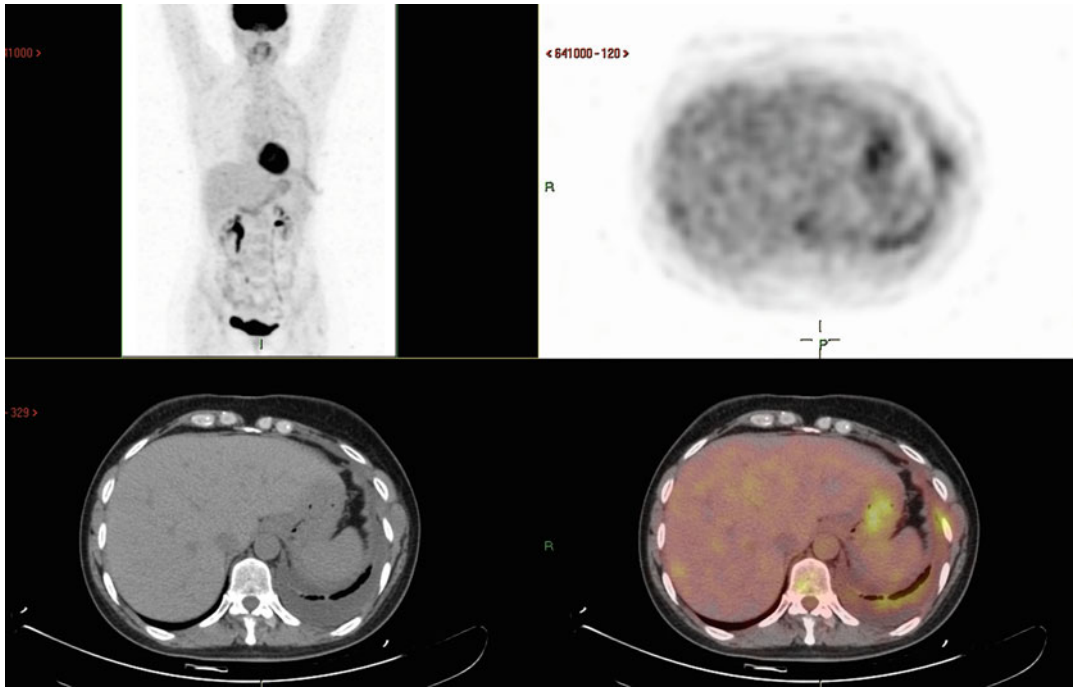

Fig. 12 A 57-year-old woman with malignant pleural mesothelioma after talc pleurodesis was referred to [^{18}F]FDG PET/CT for evaluation. Selected transaxial CT, PET, fused PET/CT slice, and MIP (*upper left*) show low-grade [^{18}F]FDG activity along the inner aspect of the left chest wall, corresponding to reactive changes after recent pleurodesis

MPM and showed that SUV mean corresponds better to modified RECIST and EORTC criteria as compared to SUV_{max} [266] (Fig. 13).

While [^{18}F]FDG imaging is at present under extensive investigation in patients with MPM, CT is the gold standard for response assessment in clinical trials in these patients. [^{18}F]FDG PET-CT was also assessed for radiation therapy planning in 13 patients with inoperable MPM, showing the usefulness of target volume delineation by PET/CT as compared to CT alone, which led to reducing the GTV, CTV, and PTVI by 47%, 39%, and 40%, respectively [267].

[^{18}F]FDG Imaging of Mediastinal Tumors

CT and MRI can identify mediastinal masses, show their extent, and diagnose correctly a variety of benign lesions. [^{18}F]FDG PET/CT may be helpful in the assessment of malignant as well as some of the benign masses. Luzzi et al. [268] evaluated [^{18}F]FDG PET/CT in the preoperative assessment of isolated anterior mediastinal lesions, especially for planning the operative strategy (biopsy or upfront resection), including 13 thymomas (six low grade and seven high grade), three lymphomas, and three with other primitive thymic tumors (one paraganglioma and two non-seminomatous germ cell tumors). The mean SUV of low-grade lesions was 3.3 ± 0.5 compared to 13.5 ± 7 in high-grade tumors ($p = 0.009$). The SUV in low-grade thymoma was significantly lower compared to lymphoma and to the other primitive anterior mediastinal tumors. Low SUV (less than 5) was associated with low-grade thymoma and minimal invasive thymoma. For lesions with an infiltrative pattern on CT and SUV above 5, open biopsy is mandatory to exclude mediastinal lymphomas or, in case of high-grade thymoma, to address neoadjuvant

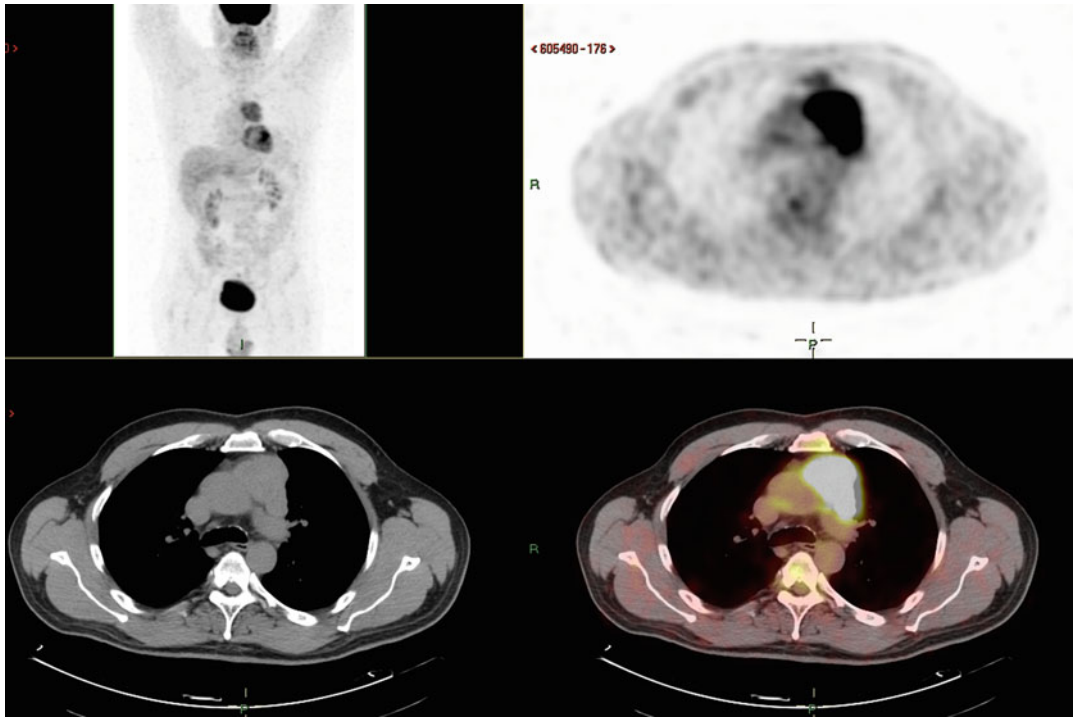

Fig. 13 A 62-year-old man with malignant invasive thymoma causing paresis of the left phrenic nerve was referred to [^{18}F]FDG PET/CT for evaluation before neoadjuvant chemotherapy and surgery. Selected transaxial CT, PET, fused PET/CT slice, and MIP (*upper left*) show a 6.7-cm [^{18}F]FDG-avid anterior mediastinal mass (SUV_{max} 4.0). B3 thymoma was confirmed at surgery

treatment [268]. Kumar et al. [269] reported on a mean SUV_{max} of 1.1 in thymic hyperplasia. Patients with low-risk thymoma had large tumors and a mean SUV_{max} of 3, while patients with high-risk thymoma had small tumors with a mean SUV_{max} of 2.1. The mean SUV_{max} in the entire group of thymomas was 2.3. All thymic carcinomas were large, with a mean SUV_{max} of 7. The difference between the mean SUV_{max} of thymic hyperplasia, thymoma, and thymic carcinoma was statistically significant, but not for high- and low-risk thymoma [269]. Sung et al. have assessed 33 patients with thymic epithelial tumors [270]. SUV_{max} of high- and low-risk thymomas were both significantly lower than that of thymic carcinomas. A homogenous [^{18}F]FDG uptake pattern was more common in thymic carcinomas, while thymomas showed heterogenous uptake [270]. Benveniste et al. have assessed whether [^{18}F]FDG PET/CT can assist in differentiating between early- (stage I–II) and advanced-stage (stages III and IV) thymoma before surgery, as patients with locally advanced tumors are treated with neoadjuvant chemotherapy before surgery [271]. [^{18}F]FDG uptake was significantly higher in patients with B3 thymoma compared to lower stages and was significantly higher in thymic carcinoma or carcinoid compared to thymoma [271]. Thomas et al. have evaluated 56 patients with unresectable advanced-stage thymic epithelial tumors who had [^{18}F]FDG PET/CT at baseline and after 6 weeks of treatment showing a close correlation between early response on [^{18}F]FDG PET/CT and subsequently diagnosed response by RECIST criteria. The authors conclude that [^{18}F]FDG PET/CT may be used for monitoring response to treatment in these patients [272].

Mediastinal sarcomas are rare, but can be [^{18}F]FDG avid [273]. The use of [^{18}F]FDG imaging in lymphoma is extensive and is covered in a separate chapter.

PET/MRI Imaging of Lung and Thoracic Malignancies

Increasing use of PET/MRI scanners in recent years does not expose the patient to the ionizing radiation of the CT scan, and provides new functional parameters, mainly lung perfusion, ventilation, blood flow, gas exchange, and respiratory motion. However, because of the low density of lung tissue artifacts at the air-tissue interfaces and because of respiratory and heart motion, MRI of the lungs is challenging.

The feasibility of PET/MRI in lung tumors has been confirmed in a pilot study in ten patients showing a similar overall performance with PET/CT [274]. While further recent studies showed an excellent agreement between PET/CT and PET/MRI in lung cancer patients with similar diagnostic accuracy, so far no specific advantage for PET/MRI was demonstrated [275–277]. The PET/MR protocol that has been used did not include specific brain and liver MR sequences which could have potentially improved the diagnostic value in some cases [277].

PET Imaging of Lung and Thoracic Malignancies with Other Tracers

While [^{18}F]FDG is the most widely used tracer in oncology, many biological targets can be imaged with other radiolabelled ligands. Uptake of [^{11}C]choline in tumors is an index of the rate of tumor-cell replication and has also been used to image lung cancer. Uptake of [^{18}F]FDG and [^{11}C]choline is similar in primary lung tumors [278, 279] but the latter can more accurately assess suspicious brain lesions, due to lower physiologic levels of tracer activity in the normal brain cortex.

Hypoxia is common in malignant tumors and influences the cell's ability to respond to therapy. The degree of hypoxia is therefore associated with tumor progression. Hypoxia also promotes angiogenesis by increasing the expression of growth factors such as the vascular endothelial growth factor. ^{60}Cu- or ^{64}Cu-labelled methylthiosemicarbazone (Cu-ATSM) has been used to assess tumor hypoxia [280]. This tracer is taken up and trapped in hypoxic cells but quickly washes out from normoxic cells. Dehdashti et al. [281] studied 14 patients with NSCLC before therapy with ^{60}Cu-ATSM-PET including eight who subsequently responded and six who had disease progression [281]. Pretreatment ^{60}Cu-ATSM uptake was predictive of response. The tumor/muscle uptake ratio was significantly lower in responders as compared to nonresponders. In the same group of patients, there was no significant difference in the degree of [^{18}F]FDG uptake between responders and nonresponders [278]. ^{18}F-fluoromisonidazole (^{18}F-MISO) is another specific tracer for hypoxia, with slower washout from normoxic cells compared to Cu-ATSM and was used in the initial studies of in vivo mapping of tumor hypoxia. Eschmann et al. [282] have assessed whether ^{18}F-MISO can predict tumor recurrence after radiation therapy in a group of patients including 14 with NSCLC. A tumor/muscle cutoff of 1.6 or a tumor/mediastinum cutoff of 2 differentiated patients with or without subsequent tumor recurrence.

Information on tumor cell proliferation can be obtained using the thymidine analog 3′-deoxy-3′-^{18}F-fluorothymidine (^{18}F-FLT). Thymidine incorporation into DNA is the gold standard for the assessment of proliferation, and ^{18}F-FLT has been therefore used to assess response to therapy. ^{18}F-FLT PET/CT in NSCLC correlated with tumor proliferation determined by Ki-67 labelling index and with tumor angiogenesis determined by tumor microvessel density (MVD) [283]. In 68 patients with known or suspected NSCLC who had ^{18}F-FLT PET/CT followed by surgery, ^{18}F-FLT SUV_{max} correlated with Ki-67 labelling index and with MVD. Survival of patients correlated with ^{18}F-FLT uptake and with Ki-67-labelling index, and both parameters correlated with MVD [283]. Everitt et al. studied 20 patients with stage I–III NSCLC at baseline and at weeks 2 and 4 during radical chemoradiotherapy with both FLT and [^{18}F]FDG PET/CT [284]. FLT was more sensitive for early treatment response. At the study performed at week 2, there was marked partial proliferative response in almost all tumors, whereas the metabolic tumor volume on [^{18}F]FDG PET-CT was

stable or showing only a moderate response in most patients, suggesting that chemoradiotherapy affects tumor cell proliferation more rapidly than cellular metabolism [284]. The prognostic significance of these differences is still unclear at present.

Integrin $\alpha_v\beta_3$ has a major role in angiogenesis and tumor growth. A recent pilot feasibility study in 17 lung cancer patients imaged with ^{18}F-Al-NOTA-PRGD2 (^{18}F-alfatide) showed that this tracer can successfully differentiate lung tumors from hamartoma but not from inflammatory changes [285]. Zheng et al. have recently assessed another integrin imaging tracer, ^{68}Ga-NOTA-PRGD2, in 91 patients with lung cancer and have reported sensitivity, specificity, and accuracy of 84%, 91%, and 86%, respectively, for the diagnosis of lung cancer. In addition, ^{68}Ga-NOTA-PRGD2 was more specific than [^{18}F]FDG PET-CT in the assessment of lymph node metastases, with positive and negative predictive values of 90% and 94% compared to 30% and 91% [286].

Conclusion

Although CT and MRI provide high-resolution anatomic assessment, [^{18}F]FDG imaging is superior in differentiating benign from malignant mediastinal lymphadenopathy and in the detection of distant metastases. Pre-therapy [^{18}F]FDG studies can provide important prognostic information. [^{18}F]FDG PET/CT can eliminate about half of futile thoracotomies and is therefore recommended for staging of lung and mediastinal tumors. [^{18}F]FDG imaging is also indicated in the diagnosis of recurrent disease and in monitoring treatment response. [^{18}F]FDG PET/CT has been introduced for radiation planning; optimizing delineation of treatment volumes, thus increasing the dose in target volumes; and reducing toxicity to nontarget tissues. Although [^{18}F]FDG is the most widely used tracer in oncology, other PET tracers are currently evaluated with specific clinical and mainly research goals and may have a role in future in the management of lung malignancies. PET/MRI has an overall similar performance to PET/CT in patients with lung cancer.

Diagnostic Applications of Nuclear Medicine: Esophageal Cancers

23

Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

Abstract

Esophageal cancer is the eighth most commonly diagnosed malignancy worldwide. This chapter will review the epidemiology, environmental factors, genetic predisposition, and underlying biomolecular changes of the disease. The staging of esophageal cancer will be reviewed as well as the roles of conventional diagnostic imaging and nuclear imaging in this staging. Finally, the efficacy of these modalities in assessing response to the various treatments described in the chapter and in the long term surveillance for disease recurrence will be addressed.

Keywords

Esophageal cancer • Conventional diagnostic imaging • [^{18}F]FDG-PET/CT • [^{18}F]FDG-PET/MRI • Staging • Assessment of therapeutic response • Surveillance

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
AJCC	American Joint Committee on Cancer
APC	Gene encoding for adenomatous polyposis coli
c-myc	Gene encoding for a transcription factor (a multifunctional, nuclear phosphoprotein involved in cell cycle progression, apoptosis, and cellular transformation)
CT	X-ray computed tomography
erb B-2	Gene encoding for the receptor tyrosine-protein kinase erbB-2 (also known as CD340 or proto-oncogene Neu)
EUS	Endoscopic ultrasonography
GERD	Gastrointestinal reflux disease
GI	Gastrointestinal
Gy	Gray unit (ionizing radiation dose in the International System of Units, corresponding to the absorption of one joule of radiation energy per kilogram of matter)
HPV	Human papillomavirus

Epidemiology and Environmental Factors

Esophageal cancer is the eighth most commonly diagnosed malignancy worldwide. It is also the sixth most common cause of cancer death, with a 5-year survival of approximately 15–20%. Over 16,000 new cases are estimated to be diagnosed in the United States in 2016, with over 15,000 deaths. Worldwide, over 450,000 new cases were diagnosed in 2012, with over 400,000 deaths. Esophageal cancer is three to four times more common among men than among women, with a lifetime risk in the United States of about 1 in 125 in men and about 1 in 435 in women [1, 2].

Over 95% of esophageal malignancies are squamous cell carcinoma (SCC) or adenocarcinoma, with lymphomas, sarcomas, neuroendocrine tumors, and metastatic disease largely accounting for the remainder. For most of the twentieth century, squamous cell carcinoma was the dominant histologic type, accounting for over 90% of cases and is still the dominant esophageal malignancy worldwide. However, over the past several decades in the Western world, the incidence of esophageal adenocarcinoma has risen significantly and now accounts for over 60% of esophageal cancers in the United States [3].

Esophageal SCC and adenocarcinoma differ in both typical tumor location and risk factors. Esophageal SCCs occur most frequently in the

mid to distal third of the esophagus, while adenocarcinomas are more prevalent in the distal third of the esophagus and gastroesophageal junction. Smoking and excessive alcohol intake are the major risk factors for esophageal SCC. The incidence of esophageal SCC increases with age, peaking in the seventh decade of life. Demographically, the incidence of esophageal SCC is three times higher in black people than in whites [4]. In the highest-risk region in the world for esophageal SCC, which stretches from Iran to China (the so-called esophageal cancer belt), major risk factors are poorly understood but are thought to include poor nutrition, diets lacking in fruits and vegetables, and the drinking of hot beverages [5]. Human papillomavirus (HPV), particularly subtypes 16 and 18, has also been implicated in the pathogenesis of esophageal SCC [6].

Esophageal adenocarcinomas arise from a region of metaplastic epithelium, commonly known as Barrett's esophagus, which replaces the squamous epithelium in the presence of gastrointestinal reflux disease (GERD) and progresses to dysplasia. Obesity and smoking are also known risk factors for esophageal adenocarcinoma [7]. The dramatic increase in incidence rates of esophageal adenocarcinoma in Western countries is in part tied to increases in the known risk factor of obesity. With regard to demographics, white people develop esophageal adenocarcinoma five times more often than black people, while men are affected eight times more often than women [8].

Genetic Predisposition

The role that hereditary factors play in the development of esophageal cancer remains unclear. However, familial aggregations have been described in regions with a high incidence of esophageal SCC, such as China [9]. Familial aggregations of Barrett's esophagus have also been described with regard to development of esophageal adenocarcinoma [10].

Genetic analysis of esophageal cancers has revealed frequent chromosomal losses, chromosomal gains, and occasional gene amplifications [11]. Gene polymorphism has also been studied. For example, polymorphisms of the epidermal growth factor gene have been found to be associated with a higher risk of esophageal adenocarcinoma, especially in patients with Barrett's esophagus [12].

Underlying Biomolecular Changes

A large number of molecular events have been implicated in the development and progression of both esophageal SCC and adenocarcinoma. Studies have indicated that activation of cyclin D1, erb B-2, and c-myc oncogenes and inactivation of p53, Rb, APC, and p16 tumor suppressor genes are frequently involved [13].

Barrett's esophagus develops when stratified squamous epithelium that normally lines the distal esophagus is replaced by metaplastic columnar epithelium as a result of chronic inflammation from GERD. Carcinogenesis in these metaplastic cells begins with genetic alterations that either activate some of the oncogenes and/or disable some of the tumor suppressor genes described above. It is thought that the first genetic changes that lead to adenocarcinoma in regions of Barrett's esophagus are abnormalities in p53 and p16 that permit proliferation of clones of premalignant and/or malignant cells [14].

Staging and Prognostic Classification

The TNM staging system of the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) is universally used. The most recent TNM staging system implemented in 2010 created separate histological stage groupings for esophageal SCCs and adenocarcinomas while maintaining similar definitions for tumor, nodal, and metastatic categories. For esophageal SCCs, staging is in part determined by the location of the superior edge of the primary tumor, with upper and middle esophageal malignancies arising above the lower border of the inferior pulmonary vein and lower esophageal malignancies arising below that level. Tumors

arising in the gastroesophageal junction and in the proximal 5 cm of the gastric cardia that extend to the gastroesophageal junction or esophagus (which includes almost all esophageal adenocarcinomas) are classified and staged as esophageal cancers.

Tumor (T) staging relates to the depth of invasion of the tumor in the esophageal wall and correlates with prognosis. While patients with disease limited to the mucosa/submucosa (T1) have a relatively high cure rate, patients with disease that has spread through the esophageal wall to the adventitia (T3) or to structures surrounding the esophagus (T4) have a much poorer prognosis. The T4 stage is further classified to indicate whether the cancer is invading adjacent structures such as the pleura, pericardium, or diaphragm (T4a) where surgical resection may still be possible or if it invades structures such as the aorta, carotid vessels, azygos vein, trachea, left main bronchus, or a vertebral body, which would preclude surgical resection (T4b).

Local lymph node invasion occurs relatively early in esophageal cancers because the esophageal lymphatics are located in the lamina propria, as opposed to being located beneath the muscularis mucosa elsewhere in the gastrointestinal tract [15]. For the nodal (N) staging system, regional lymph nodes for all esophageal cancers include the supraclavicular, upper paraesophageal, mediastinal, lower paraesophageal, diaphragmatic, pericardial, left gastric, and celiac stations. Data has demonstrated that the number of regional lymph nodes containing metastatic disease (positive nodes) is more important than the location of these positive nodes. N0 indicates no positive nodes, N1 indicates one to two positive nodes, N2 indicates three to six positive nodes, and N3 indicates seven or more positive nodes. These groupings are relatively arbitrary, and the presence of each additional positive lymph node is thought to increase risk and worsen prognosis.

Distant metastatic disease (M1) includes sites of malignancy not in direct contact with the esophagus and includes parenchymal (e.g., liver or lung) involvement and non-regional lymph node involvement, including the hilar and pulmonary lymph node stations.

Conventional Diagnostic Imaging Staging

Both esophageal SCC and adenocarcinoma have similar clinical presentations, with early esophageal cancer often presenting with nonspecific symptoms such as weight loss, hoarseness, and/or coughing. Dysphagia is usually described in more locally advanced cases.

The initial workup of these nonspecific symptoms suggesting esophageal disease usually consists of a barium swallow fluoroscopic examination and/or an upper GI endoscopy. While infiltrating or ulcerated mucosal masses visualized on endoscopy are nearly pathognomonic of esophageal cancer, biopsy is needed to confirm the diagnosis.

Once the diagnosis of a primary esophageal cancer is established via biopsy, the initial staging usually starts with a contrast-enhanced diagnostic CT scan of the chest and abdomen in order to evaluate the region of the primary tumor for local invasion of mediastinal structures and peritumoral lymph node metastases and to search for any distant metastases.

With regard to T staging, diagnostic CT scan is significantly limited in the identification of esophageal wall layers and is thus unable to accurately assess more superficial tumors (T1–T3). However, CT can provide important information on more invasive tumors, either by excluding the presence of T4 disease or by characterizing any adjacent mediastinal structures the tumor may invade and thus determining potential resectability (T4a vs. T4b disease). Regarding nodal metastases, CT scans have relatively poor diagnostic performance as they rely mostly on size criteria. Enlarged lymph nodes on CT may be reactive in nature, while normal-sized nodes may be positive for metastases [16]. Finally, while diagnostic CT can readily identify large distant metastases, it has limited sensitivity for smaller ones, particularly in the lungs, liver, and peritoneum.

Endoscopic ultrasonography (EUS) is also part of the initial staging workup for esophageal cancers. EUS uses high-frequency ultrasound to provide detailed images of the five layers of the

esophageal wall and the paraesophageal environment. EUS is still regarded as the most accurate imaging technique for locoregional staging of esophageal cancer. The overall accuracy of EUS for T staging is 80–90%, and it can accurately delineate both superficial (T1, T2) and invasive (T3, T4) tumors [17]. EUS is also effective in demonstrating peritumoral and paraesophageal metastatic lymph nodes. Findings suggestive of malignant lymph nodes include width greater than 10 mm, round shape, smooth border, and hypoechoic appearance. Of these, hypoechoic appearance and width greater than 10 mm appear to be the most specific for malignancy. When all four suspicious features are present in a visualized lymph node, there is an 80–100% chance of metastatic involvement [18]. Fine needle aspiration, which can be performed in conjunction with EUS, further increases the accuracy of diagnosing lymph node involvement. However, aspiration is only possible when the nodes are accessible and where the primary tumor does not block the path of the aspiration needle. EUS does have its limitations, most notably when there is a tumor-related stenosis in the esophagus that the ultrasound transducer cannot traverse. Since the entire tumor and more distal nodal stations are not visualized, EUS may understage the malignancy in these cases.

Nuclear Imaging Staging

Fluorodeoxyglucose-positron emission tomography/computed tomography ([^{18}F]FDG-PET/CT) has been shown to be of great value in the primary staging of esophageal cancer in conjunction with EUS. [^{18}F]FDG-PET/CT scanning has shown to add value to conventional staging methods consisting of both CT and EUS.

With regard to T staging, [^{18}F]FDG-PET/CT cannot accurately assess depth of tumor invasion. In fact, the sensitivity of [^{18}F]FDG-PET/CT in detecting biopsy-proven T1 tumors involving the mucosa and/or submucosa ranges approximately between 40% and 60%, likely due to the smaller size of the tumors and/or lower malignant cellularity (Fig. 1). [^{18}F]FDG-PET sensitivity for detection of more invasive tumors progressively rises from 83% in T2 tumors (involving the muscularis propria), to 97% in T3 tumors, to 100% in T4 tumors [19].

[^{18}F]FDG-PET/CT has demonstrated some advantages over traditional imaging in the staging of nodal metastases. Regional lymph nodes that are equivocal in size on diagnostic CT scan will be suspicious for metastatic sites of involvement if metabolically active on [^{18}F]FDG-PET/CT scan (Fig. 2). EUS does not evaluate for distal metastatic nodal disease. A meta-analysis performed by van Vliet et al. suggested that [^{18}F]FDG-PET/CT scanning is more sensitive for the detection of distant metastatic nodal disease than diagnostic CT alone [20]. However, with regard to regional nodal disease, [^{18}F]FDG-PET/CT has shown a similar, but slightly decreased, sensitivity when compared with EUS. This may be in part due to the [^{18}F]FDG uptake of lymph nodes in the immediate vicinity of the primary tumor being obscured by the primary tumor's uptake or by limitations in the spatial resolution of PET leading to false-negative results in small regional nodes (Fig. 3). Also, the [^{18}F]FDG uptake of the primary esophageal cancer has been shown to affect the detectability of nodal metastases, as they have similar histologies. Thus, if the primary lesion presents with a low baseline [^{18}F]FDG uptake, nodal metastases will have relatively low [^{18}F]FDG uptake as well, potentially resulting in a false-negative appearance [21].

The primary advantage [^{18}F]FDG-PET/CT demonstrates over EUS and diagnostic CT evaluation is in the detection of distant metastatic disease (M1). In addition to non-regional nodal metastases, distant metastatic disease includes parenchymal spread to the lungs and liver but may also include spread to more atypical sites difficult to evaluate on anatomic imaging such as the pleura, musculature, and skeleton (Fig. 4). Several studies have demonstrated that [^{18}F]FDG-PET and PET/CT have significantly higher sensitivities for the detection of distant metastatic disease than CT scans alone. [^{18}F]FDG-PET has been shown to upstage the disease in approximately 20% of patients first evaluated with CT/EUS, with the benefit of preventing unnecessary surgery [20, 22]. Another study

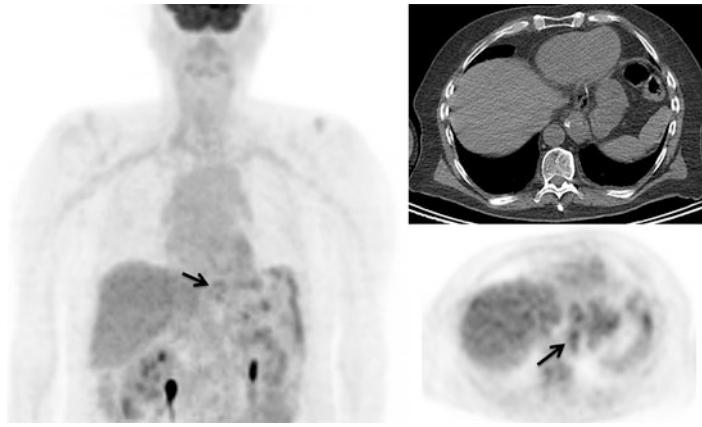

Fig. 1 [^{18}F]FDG-PET/CT of a 73 year old man with history of gastric bypass surgery presenting with recently diagnosed intramucosal adenocarcinoma of the distal esophagus in the background of Barrett's esophagus. The relatively mild associated uptake in the distal esophagus may relate to the primary tumor's small size and could even reflect inflammation in the setting of Barrett's esophagus. There is no evidence of regional or distant metastatic disease

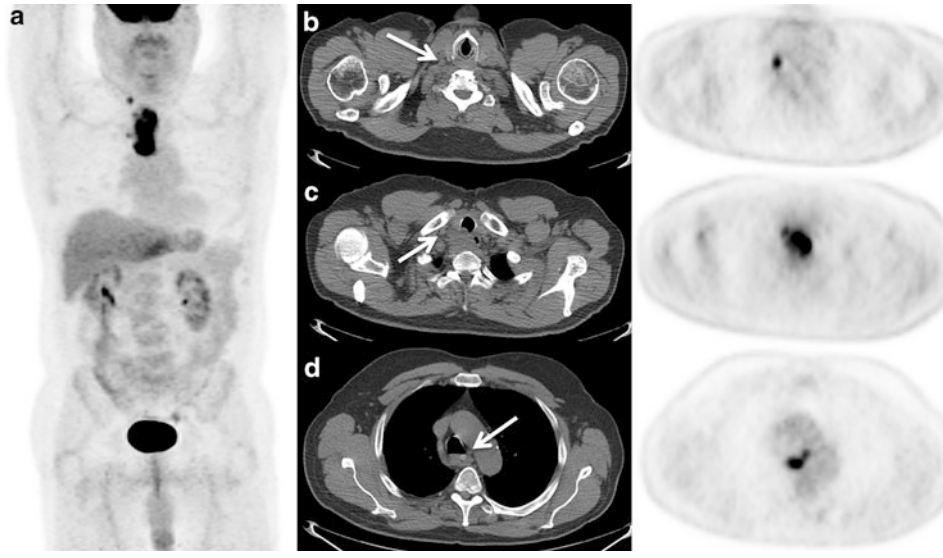

Fig. 2 (**a**) [^{18}F]FDG-PET/CT maximum intensity projection (MIP) image of a 67 year old man with newly diagnosed upper esophageal adenocarcinoma, represented by contiguous intense [^{18}F]FDG uptake in the upper thorax (*arrow*). (**b**) CT and PET images of an associated subcentimeter right supraclavicular lymph node (*arrow*). (**c**) CT and PET images of the primary tumor at the thoracic inlet and an associated subcentimeter node (*arrow*). (**d**) CT and PET images showing the more inferior extent of the primary tumor and an associated subcentimeter left paratracheal lymph node (*arrow*). The small [^{18}F]FDG-avid lymph nodes described in **b**, **c**, and **d** could all be considered equivocal on CT scan alone. The relatively intense [^{18}F]FDG uptake of these nodes on PET scan is strongly suggestive of regional nodal metastatic disease

demonstrated that staging with [^{18}F]FDG-PET significantly changed management in 38% of patients [23]. Given its superior sensitivity in detecting metastatic disease (and precluding expensive curative surgery), [^{18}F]FDG-PET combined with EUS, despite being more expensive, appears to be the more cost-effective method of staging patients compared to CT and EUS [24].

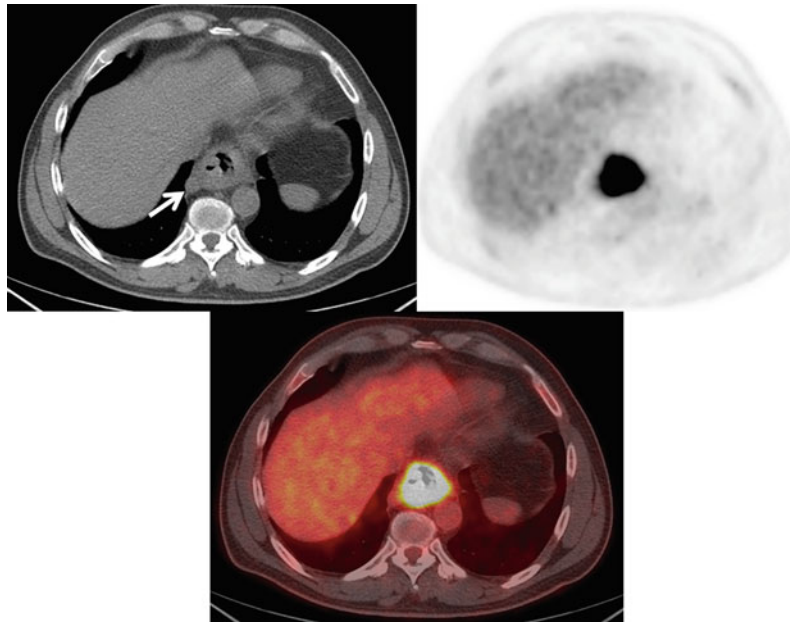

Fig. 3 [^{18}F]FDG-PET/CT scan of a 56 year old man with newly diagnosed distal esophageal adenocarcinoma. There is an enlarged paraesophageal lymph node immediately adjacent to the [^{18}F]FDG-avid primary tumor. This lymph node is likely a site of regional metastatic spread but is not significantly [^{18}F]FDG-avid, likely due to the dominance of the intense uptake (SUV_{max} 22) of the adjacent tumor

The potential prognostic value of the staging [^{18}F]FDG-PET/CT has been explored. Studies have suggested that patients with [^{18}F]FDG-avid nodal disease at baseline have a worse prognosis than those with undetectable nodal disease on [^{18}F]FDG-PET, suggesting that the PET N stage may be an appropriate parameter for determining whether to start a more aggressive treatment regimen than would be normally considered [25]. Several studies have investigated whether a relationship exists between the degree of [^{18}F]FDG uptake of the primary tumor, as measured by maximum standardized uptake value (SUV_{max}), and prognosis, with inconclusive results. A recent study reported that [^{18}F]FDG-PET provides independent prognostic information for overall survival and distant metastasis-free survival based on the staging tumor-to-blood standardized uptake ratio (SUR), a ratio of the tumor SUV and blood pool SUV. However, this parameter was not found to be prognostic with regard to locoregional tumor control [26]. Finally, studies evaluating intratumoral [^{18}F]FDG uptake heterogeneity, or "textural feature analysis," have suggested that baseline regional tumor uptake heterogeneity may predict poorer responses to traditional therapy. It is postulated that tumors exhibiting a heterogeneous, as opposed to a homogeneous, [^{18}F]FDG distribution may respond less favorably to uniformly distributed radiotherapy. Likewise, baseline tumor [^{18}F]FDG heterogeneity could also reflect underlying tumor neoangiogenesis, which if present, could reduce the effectiveness of conventional chemotherapy [27].

Although [^{18}F]FDG-PET/CT scanning is the mainstay of nuclear imaging for staging of esophageal cancer, initial investigations have been made into the utility of the newer and rapidly evolving hybrid modality of PET/MR. In one such study, EUS was once again found to demonstrate the highest accuracy in T staging, followed by PET/MR using [^{18}F]FDG, followed by diagnostic CT. While EUS appears to remain the gold standard for T staging, [^{18}F]FDG-PET/MR was somewhat

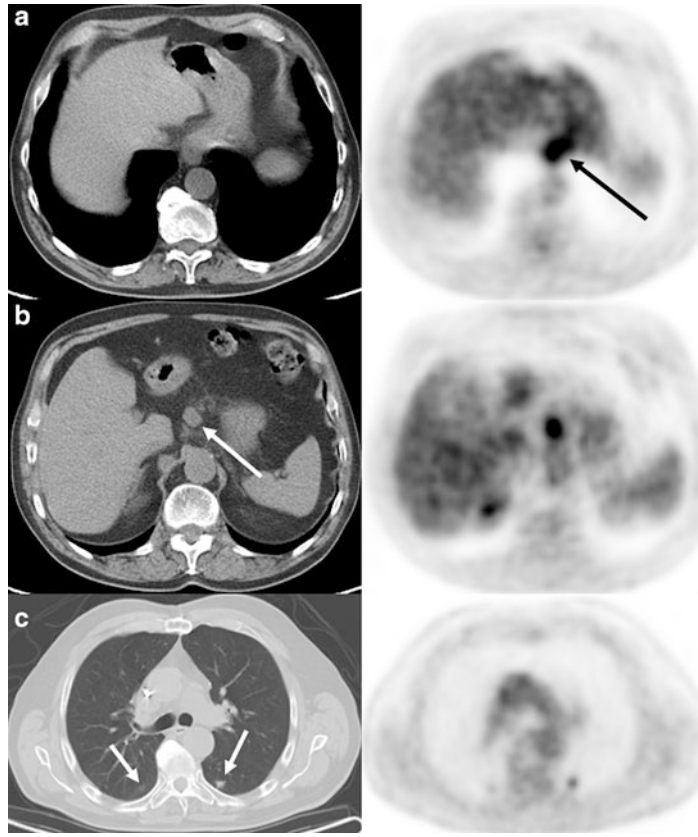

Fig. 4 (**a**) CT and PET images from an [^{18}F]FDG-PET/CT demonstrate a primary esophageal adenocarcinoma (*arrow*) arising at the gastroesophageal junction in a 74 year old man. (**b**) There is a single associated [^{18}F]FDG-avid celiac axis lymph node (*arrow*), which is considered regional disease. (**c**) There are bilateral [^{18}F]FDG-avid pulmonary nodules present (*arrows*) which are considered distant metastases (M1)

accurate in characterizing higher T stage lesions, and the MR images were able to identify esophageal wall layers, which are poorly evaluated on diagnostic CT scan and unable to be evaluated on non-contrast-enhanced [^{18}F]FDG-PET/CT. Furthermore, [^{18}F]FDG-PET/MR demonstrated the highest efficacy in diagnosing regional nodal metastases, followed by EUS, [^{18}F]FDG-PET/CT, and diagnostic CT, thought to be related to the excellent soft-tissue contrast of MR combined with the ability to quantitatively measure metabolic activity of the nodes. The diagnostic efficacy of M staging was not evaluated in this study, due to the time and cost involved in performing whole-body MR imaging over a large area comparable to [^{18}F]FDG-PET/CT imaging [28].

Common Therapies

The best option for curative treatment for patients with esophageal cancer is radical surgery consisting of esophagectomy with en bloc lymphadenectomy. The main contraindication for surgery is distant metastatic disease (M1) in which there are parenchymal metastases and/or distant metastatic lymph nodes or nodules. Unresectable invasive disease extending into the mediastinum (T4b) is also a contraindication for surgery. Despite improvements in perioperative care, esophagectomy carries significant morbidity and mortality risks and is thus contraindicated in patients with severe associated comorbid conditions (e.g., cardiovascular disease,

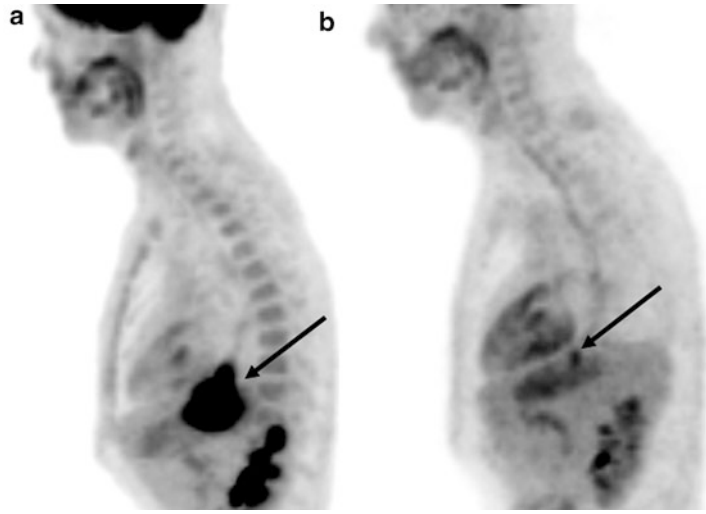

Fig. 5 (**a**) MIP images of [^{18}F]FDG-PET/CT scans performed on a patient with localized esophageal adenocarcinoma involving the gastroesophageal junction and gastric cardia. Baseline images prior to therapy show an intensely [^{18}F]FDG-avid mass with SUV_{max} 22. (**b**) Following completion of neoadjvant chemoradiotherapy, there is still some mild [^{18}F]FDG uptake at the gastroesophageal junction with SUV_{max} 3, but there has been a greater than 80% drop in uptake which has been shown to correlate with a more favorable long-term outcome. The patient went on to have an esophagectomy, and continued to be followed up with diagnostic CT. He is currently disease-free 6 years after the completion of trimodal therapy

respiratory disease). Medical care is reserved for nonsurgical candidates, with the main goal being the palliation of dysphagia, allowing patients to eat. Options include chemotherapy and/or radiotherapy, laser therapy, manual dilatation, metallic stenting, and photodynamic therapy.

After exclusion of distant metastases and/or unresectable locally invasive disease, the selection of the therapeutic regimen depends on the T stage. Localized tumors (T1/T2) have a high likelihood of curative resection, and primary esophagectomy is the most frequent treatment. In locally advanced tumors (T3/T4a, N^+), surgery is also the mainstay of therapy, but it has been shown that preoperative chemotherapy or chemoradiotherapy provides a survival benefit of 7–13% over surgery alone [29]. Neoadjuvant therapy typically consists of a combination of radiotherapy (approximately 45 Gy) and chemotherapy (commonly cisplatin and 5-fluorouracil). This combination therapy is usually administered over a 45-day period and is followed by esophageal resection after an interval of approximately 4 weeks. The goal of neoadjuvant therapy is to improve survival results related to surgery alone. Neoadjuvant chemotherapy is aimed at the eradication of lymphatic and/or hematogenous micrometastases and metastases, with improvement of survival. Neoadjuvant radiotherapy is aimed at shrinkage of the primary tumor, leading to an improved resectability rate.

Assessing Efficacy of Treatment

Many studies have shown that significant decrease in [^{18}F]FDG uptake of the primary tumor as well as resolution of [^{18}F]FDG-avid regional lymph nodes following neoadjuvant therapy correlates with favorable long-term prognosis following surgery. Complete metabolic response (defined as a reduction of SUV_{max} greater than 80%) after completion of preoperative chemotherapy has been shown to predict favorable long-term outcome (Figs. 5 and 6) [30].

PET response criteria in solid tumors (PERCIST) represent a standardized method for evaluation of metabolic tumor response. Under these criteria, progression on [^{18}F]FDG-PET scan is defined as an increase in [^{18}F]FDG uptake (as measured by SUV) of greater than 20% in a region 1 cm or larger

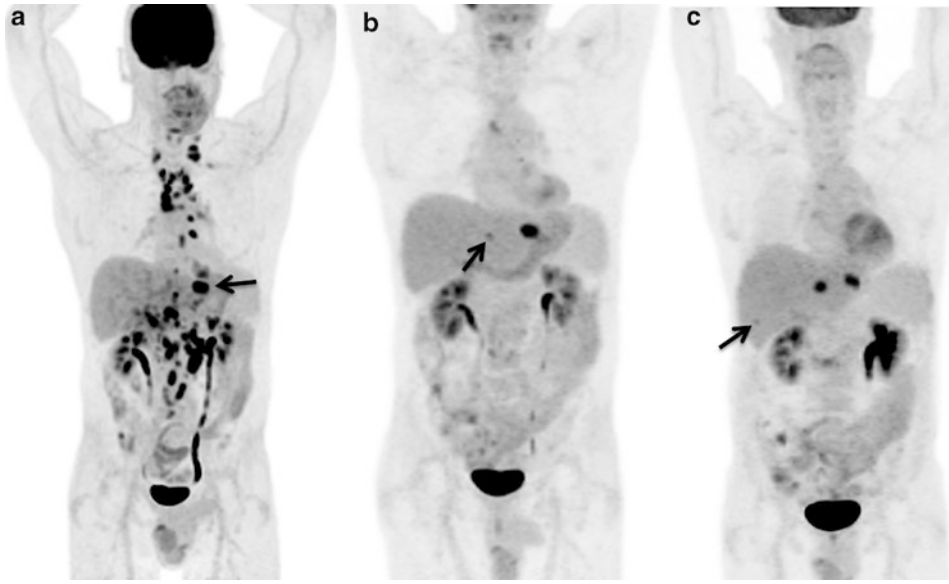

Fig. 6 [^{18}F]FDG-PET/CT MIP images of a 55 year old man who presented with metastatic gastroesophageal junction adenocarcinoma. (**a**) Baseline PET scan demonstrates the [^{18}F]FDG-avid primary tumor (*arrow*) along with extensive [^{18}F]FDG-avid metastatic lymphadenopathy above and below the diaphragm, in addition to liver metastases. (**b**) A follow up scan was performed two months after starting chemotherapy. There had been some response to treatment with significant decrease in size and uptake of the widespread lymphadenopathy and resolution of most of the liver metastases. The [^{18}F]FDG uptake of the primary tumor only decreased about 30% (from SUV_{max} 14.2 to 9.8), and there was persistent mild [^{18}F]FDG uptake in a single lesion in the caudate lobe of the liver (*arrow*), findings which did not suggest a favorable prognosis. (**c**) A follow up scan performed two months later demonstrated that the metabolic activity of the primary tumor had continued to slightly decrease but was still quite significant. There was also an increase in size and [^{18}F]FDG uptake of the caudate lesion as well as a new [^{18}F]FDG-avid lesion in the right hepatic lobe (*arrow*). These findings were consistent with progression of disease

in diameter, while response to treatment is defined as a decrease in uptake of greater than or equal to 30% [31]. Studies evaluating therapeutic response have compared PERCIST to RECIST (Response Evaluation Criteria in Solid Tumors), the more widely used solid tumor response metric based on changes in morphologic size [32]. One such study evaluating response to neoadjuvant therapy for locally advanced esophageal cancer demonstrated that PERCIST was found to be the strongest independent predictor of outcomes [33].

Surveillance

Even in those patients with esophageal cancer treated with curative intent, 5-year survival rates remain relatively poor, ranging from 34% to 47% [34]. Most recurrences occur within the first 2 years after surgery, with a median time to recurrence of slightly less than a year. Isolated distant systemic recurrences are diagnosed in about 50% of these patients, mainly involving the liver, lung, or bone. Locoregional recurrence (14%) or locoregional recurrence along with distant recurrence (35%) occurs less frequently [35]. After esophageal cancer recurs, very poor median survival rates of 3–9 months have been reported [36].

Because recurrences of esophageal cancer tend to occur at distant sites, [^{18}F]FDG-PET/CT may be useful in the postoperative surveillance period. In one recent meta-analysis, pooled estimates for [^{18}F]FDG-PET and [^{18}F]FDG-PET/CT scans calculated a high sensitivity (96%) and moderate specificity (78%) for detection of recurrent esophageal cancer after primary treatment with curative intent, indicating that [^{18}F]FDG-PET/CT is a valuable test in clinical

practice for surveillance of patients with esophageal cancer after surgery [37].

Endoscopic ultrasound is effective for the detection of locoregional recurrence with high sensitivity, but both endoscopy and ultrasound do not evaluate for the distant metastases that are of the most concern in this setting. Diagnostic CT scans can detect distant metastases but are limited in evaluating for recurrence at the site of resection due to anatomic distortion related to surgery and any prior radiotherapy. [^{18}F]FDG-PET/CT itself is somewhat limited in evaluating the resection site due to the possible presence of chronic inflammation associated with fibrotic scar tissue. As the false-positive rate on [^{18}F]FDG-PET/CT surveillance scans is not insignificant, histopathologic confirmation of suspected [^{18}F]FDG-avid lesions remains required.

Due to the limited amount of adequate treatment options after recurrent esophageal cancer is detected, presymptomatic surveillance with imaging is not universally performed. However, newer salvage chemotherapy regimens and surgical resection of isolated recurrent metastases have been associated with improved survival rates [38]. In this setting, [^{18}F]FDG-PET/CT may prove to be a reliable imaging modality for routine surveillance of treated esophageal cancer patients prior to development of symptoms given its high sensitivity.

Diagnostic Applications of Nuclear Medicine: Gastric Cancers

24

Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

Abstract

Gastric cancer is the fifth most common cancer worldwide. For the purposes of this chapter, gastric cancer will refer to gastric adenocarcinoma. The epidemiology, environmental factors, genetic predisposition, and underlying biomolecular changes of the disease will be reviewed. The staging of gastric cancer as well as the roles of conventional diagnostic imaging and nuclear imaging in this staging will be reviewed.

Finally, the efficacy of these modalities in assessing response to the various treatments described in the chapter and in the long-term surveillance for disease recurrence will be addressed.

Keywords

Gastric cancer • Gastric adenocarcinoma • Conventional diagnostic imaging • [^{18}F]FDG-PET/CT • ^{18}F-FLT-PET/CT • Staging • Assessment of therapeutic response • Surveillance

Glossary

[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
^{18}F-FLT	3′-deoxy-3′-[^{18}F]fluorothymidine
AJCC	American Joint Committee on Cancer
APC	Gene encoding for adenomatous polyposis coli
c-met	Gene encoding for tyrosine-protein kinase Met, also known as hepatocyte growth factor receptor (HGFR)
CA 19–9	Carbohydrate antigen 19–9, a tumor-associated serum marker
CA 72–4	Tumor-associated glycoprotein 72 (TAG-72), a tumor-associated marker
CDH1	Gene encoding for cadherin, an adhesion molecule
CEA	Carcinoembryonic antigen, a tumor-associated marker
CT	X-ray computed tomography
EBV	Epstein-Barr virus
EUS	Endoscopic ultrasound
FDA	United States Food and Drug Administration
FIGC	Familial interstitial gastric cancer

Epidemiology

Gastric cancer is the fifth most common cancer worldwide and the third leading cause of cancer deaths [1]. For the purposes of this chapter, gastric cancer will refer to gastric adenocarcinoma and not the lymphomas, sarcomas, and carcinoid tumors that can also primarily arise in the stomach. Gastric cancer rates are highest in Eastern Asia, Latin America, and Eastern Europe. The American Cancer Society estimates about 26,000 new cases and about 11,000 deaths from the disease in the United States in 2016. Overall, gastric cancer affects older people (average age of diagnosis is 69), men more than women, and the average person has about a 1 in 111 risk of developing the disease in their lifetime [2].

The worldwide incidence of gastric cancer has declined over the past few decades, and this is thought to be related to several factors including increased use of refrigeration for food and increased use of antibiotics to treat infections.

The incidence of gastric cancer varies throughout different geographic regions and can even vary in incidence among different ethnic groups in the same region. Over 70% of gastric cancers arise in developing countries, and overall there is a higher gastric cancer risk associated with living at higher geographic latitudes [3].

There are two main histologic types of gastric adenocarcinoma which have different epidemiologies, pathogenesis, morphology, and genetics. The most common is called the "intestinal type" because it has morphology similar to adenocarcinomas arising elsewhere throughout the gastrointestinal tract. The other "diffuse" or infiltrative type is less differentiated than the intestinal type. Intestinal-type gastric cancer is more common in males and older age groups and is likely related to

environmental factors, as it is more prevalent in higher-risk areas. The diffuse type affects men and women equally, is more common in younger age groups, and has a worse prognosis [4]. While there has been a worldwide decrease in the incidence of intestinal-type cancers that parallels the overall decrease in gastric cancers, the decrease in the diffuse type has been slower, and it now accounts for approximately 30% of gastric cancers [5].

Environmental Factors

Geographic and ethnic differences in the incidence of gastric cancer around the world as well as trends in gastric cancer in certain populations over time suggest that environmental factors play a key role in its development. The fact that the generations born to people migrating from high-risk to low-risk countries subsequently develop a lower incidence of gastric cancer suggests that exposures to these environmental risk factors occur early in life [6].

Substantial evidence exists that the risk of gastric cancer increases with a high intake of salt and salt-preserved foods such as salted fish and cured meat. The declining incidence of gastric cancer over the past century has at least in part been attributed to the increase in availability of refrigeration, which precludes the use of salting to preserve foods. Refrigeration has also allowed for fresh fruits and vegetables to be more readily available to the public at large, providing an increased source of antioxidants which aid in cancer prevention. Dietary nitrates, obesity, low socioeconomic status, prior gastric surgery, and smoking are also associated with increased risk of gastric cancer.

Helicobacter pylori (*H. pylori*) has been characterized by the World Health Organization as a Group 1, or definite, carcinogen. If left untreated, *H. pylori* infection leads to chronic active gastritis, which is a risk factor for both the intestinal and diffuse types of gastric adenocarcinoma. In the development of intestinal-type tumors, it is thought that a cascade of histopathologic events occurs over the course of four or more decades from chronic active gastritis to atrophic gastritis to intestinal metaplasia to dysplasia and finally to invasive carcinoma [7].

Epstein-Barr virus (EBV) is also detected in 2–16% of gastric adenocarcinomas worldwide, but in contrast to *H. pylori* infection, its role in carcinogenesis is not understood [8].

Genetic Predisposition

The majority of genetic changes associated with gastric cancer are acquired, some of which are linked to *H. pylori* infection. Aggregation of gastric cancer within families occurs in approximately 10% of cases. However, true hereditary gastric cancer only accounts for 1–3% of total cases and is comprised of at least three syndromes: hereditary diffuse gastric cancer (HDGC), gastric adenocarcinoma and proximal polyposis of the stomach (GAPPS), and familial interstitial gastric cancer (FIGC) [9]. At this time, only HDGC is understood genetically. HDGC is associated with truncating mutations in the CDH1 gene which codes for the cell adhesion protein E-cadherin. These mutations have a high penetrance and are inherited in an autosomal dominant pattern [10].

Underlying Biomolecular Changes

With regard to the development of intestinal-type gastric carcinomas, many studies have implicated *H. pylori* in the multistage carcinogenic cascade from chronic active gastritis to adenocarcinoma. Initiation of this carcinogenesis process has been linked to mutagenic nitric oxides produced by inflammatory cells responding to the *H. pylori* infection which in turn induce abnormalities in the DNA of gastric epithelial cells [11]. In the various stages of gastric carcinogenesis, studies have described overexpression of oncogenes such as K-ras and c-met, as well as loss of tumor suppressor genes such as p53, p73, and APC [12].

The human epidermal growth factor receptor 2 gene (HER2) codes for a transmembrane tyrosine kinase receptor protein. Mutations which result in overexpression of HER2 have been linked with gastric cancer. HER2 overexpression has been found in approximately 20–30% of gastric cancers [13, 14].

Unlike the complex and poorly understood molecular pathways leading to the development of intestinal-type gastric cancers, diffuse-type carcinomas have the characteristic molecular abnormality of defective intracellular adhesions. In most cases, these result from loss of expression of the cell adhesion protein E-cadherin, which is coded by the same gene (CDH1) which is mutated in the HDGC syndrome described above [15].

Staging and Prognostic Classification

The TNM staging system of the American Joint Committee on Cancer (AJCC and the International Union Against Cancer (UICC) is the staging system for gastric cancer most often used in the Western hemisphere and now commonly in Asia as well.

Tumors arising in the proximal 5 cm of the stomach (gastric cardia) that extend to the gastroesophageal junction or esophagus are staged by the AJCC TNM system for esophageal adenocarcinoma. All other gastric cancers with a midpoint lying more than 5 cm distal to the gastroesophageal junction or within the gastric cardia but which do not extend into the gastroesophageal junction or esophagus are staged using the gastric staging system.

Tumor (T) staging is dependent on depth of tumor invasion and not its size. The T1 designation is divided into T1a (invasion of the lamina propria or muscularis mucosae) and T1b (invasion of the submucosa). T2 denotes invasion of the muscularis propria. T3 denotes invasion of the subserosal tissue without invasion of adjacent structures. T4 stage tumors are divided into those that extend beyond the serosa into the peritoneum (T4a) and those that extend into the peritoneum and invade adjacent structures (T4b). The adjacent structures of the stomach which can be involved in local extension include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum. Extensive T4b invasion of adjacent structures can make surgical resection of the tumor difficult and thus significantly decreases prognosis.

Nodal (N) staging is based on the number of regional lymph nodes containing metastatic disease (positive nodes). N0 refers to no regional positive nodes, N1 refers to one to two positive nodes, N2 refers to three to six positive nodes, and N3 refers to seven or more positive nodes. The more regional lymph nodes involved with metastatic disease, the worse the prognosis. The groups of lymph nodes which drain the wall of the stomach consist of stations along the greater curvature of the stomach, in the peripancreatic and splenic area, and along the lesser curvature of the stomach. These constitute the array of regional lymph nodes related to primary gastric cancers.

The presence of metastatic disease (M1) precludes surgical resection and has a dismal prognosis with a 5-year survival of only about 4–5% [3]. Distant nodal sites which constitute metastatic disease include the retropancreatic, portal, paraaortic, retroperitoneal, and mesenteric stations. Hematogenous metastases from gastric carcinoma most commonly involve the liver because the stomach is drained by the portal vein. Other less common sites of hematogenous spread include the lungs, adrenal glands, central nervous system, and skeleton. Ovarian metastases (Krukenberg tumor, Fig. 1) are thought to be due to hematogenous, peritoneal, and/or lymphatic spread [16]. Peritoneal metastases are an extremely unfavorable prognostic factor and are indicative of incurable disease. Positive peritoneal cytology is also classified as metastatic (M1) disease.

Tumor location, though not a part of the TNM staging, does influence prognosis, with more favorable outcomes for tumors located more distally in the stomach.

Conventional Diagnostic Imaging Staging

Gastric cancers most commonly present clinically with weight loss and persistent abdominal pain. In tumors arising in the proximal stomach, dysphagia is a common presenting symptom. Occult gastrointestinal bleeding with or without iron deficiency anemia is also observed.

The initial workup of patients suspected of having gastric disease is usually an upper gastrointestinal endoscopy, which can best obtain

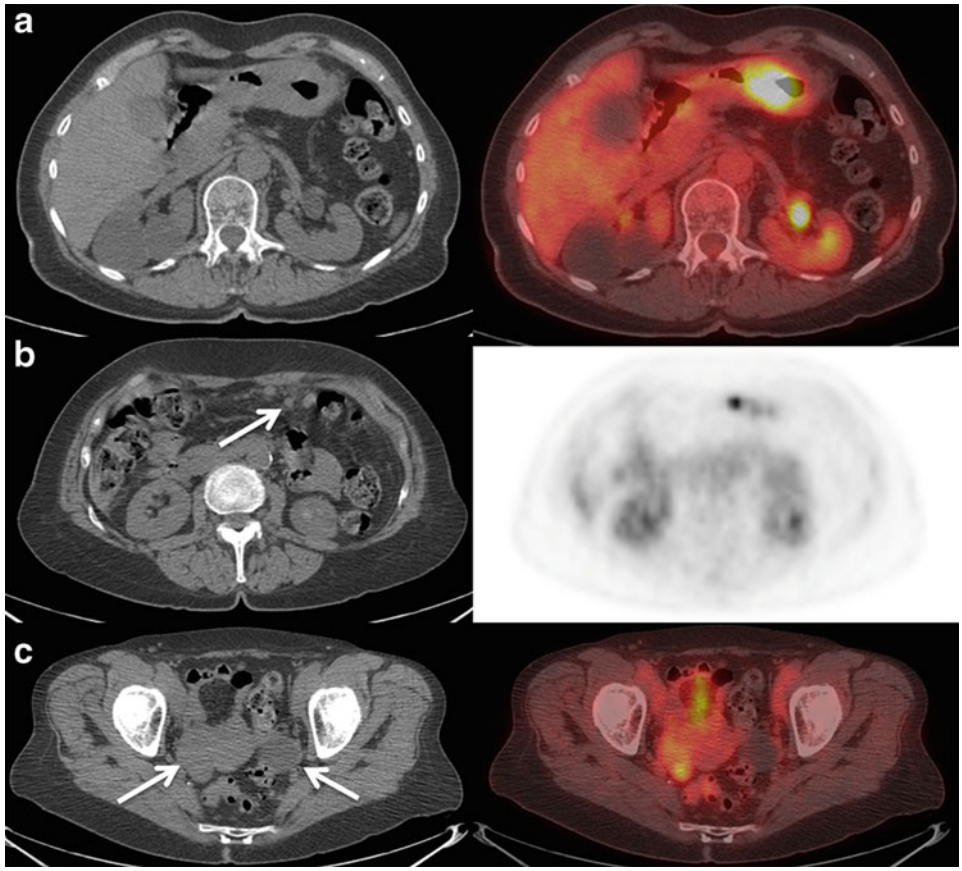

Fig. 1 (**a**) CT and fused images from an [^{18}F]FDG-PET/CT in a 65 year old woman with newly diagnosed gastric adenocarcinoma. The [^{18}F]FDG-avid primary tumor in the gastric body is demonstrated here. (**b**) CT and PET images of the mid-abdomen demonstrate [^{18}F]FDG-avid mesenteric nodules just to the *left* of midline (*arrow*) consistent with metastatic disease. (**c**) CT and fused images demonstrate large bilateral adnexal structures, solid and [^{18}F]FDG-avid on the *right* and more cystic with mild peripheral [^{18}F]FDG uptake associated with a more solid rim on the *left*. These findings were consistent with metastases to the ovaries (Krukenberg tumor)

anatomic location and tissue diagnosis of a gastric malignancy. Fluoroscopic barium studies are less often used due to false-negative results in up to 50% of cases and a low sensitivity for detection of early gastric cancers [17, 18]. However, barium studies may be more sensitive in detecting diffuse-type adenocarcinomas, which may present with widespread decreased distensibility of a "leather-flask" appearing stomach, termed linitis plastica, which is infiltrated by tumor. This appearance may be obvious radiographically but may look relatively normal on endoscopy.

Determination of the invasiveness of a gastric cancer is crucial to determine the ease of surgical resectability or if surgery is even feasible. Endoscopic ultrasound (EUS) is usually performed early in the preoperative evaluation after the diagnosis of gastric cancer is made. In a recent systemic review of studies comparing EUS staging with pathology, the sensitivity and specificity for EUS distinguishing T1 from T2 tumors were 85% and 90% respectively, while the sensitivity and specificity for EUS distinguishing T1/2 tumors from T3/4 tumors were 86% and 90%. For metastatic involvement of regional lymph nodes, the sensitivity and specificity were 83% and 67% respectively, findings which neither exclude nor confirm nodal positivity [19]. However, the ability to perform EUS-guided fine needle aspiration of suspicious nodes adds to the accuracy of nodal staging. Due

to the limited field of view of the ultrasound transducer, the utility of EUS in detecting metastatic disease is relatively poor.

Diagnostic contrast-enhanced CT scan of the chest, abdomen, and pelvis is usually also performed after diagnosis of a gastric cancer. CT is limited in assessing the depth of invasion, particularly with less invasive tumors (T1–T3). CT has been found to accurately assess T stage in only 50–70% of cases [20]. However, diagnostic CT is helpful in determining the extent of invasion of T4 lesions. A gastric mass that abuts an adjacent organ without evidence of an intervening fat plane is suggestive of parenchymal invasion. Coronal and sagittal reformatted CT images may help identify clear organ invasion that is equivocal when viewed in other imaging planes. On CT, positive nodes tend to be larger than 8–10 mm in short axis, have a round shape, are centrally necrotic, and have marked or heterogeneous enhancement. In addition, CT is helpful in identifying distant M1 nodes. However, CT is limited in that it has a low sensitivity in detecting normal-sized nodal metastases and distinguishing positive nodes from inflammatory lymphadenopathy. That being said, nodal staging is only slightly more accurate with EUS compared to CT [21].

MRI, though not routinely used in initial staging of gastric cancers, has demonstrated similar T staging accuracy as EUS [22].

Nuclear Imaging Staging

2-deoxy-2-[^{18}F]fluoro-D-glucose-positron emission tomography/computed tomography ([^{18}F]FDG-PET/CT) scans have been shown to be of some value in primary staging of gastric cancers. The [^{18}F]FDG-PET portion of the examination evaluates the metabolic activity of the primary malignancy and sites of metastasis, while the CT portion provides anatomic data.

While [^{18}F]FDG-PET/CT may demonstrate [^{18}F]FDG uptake associated with a primary gastric tumor, it is ultimately not very helpful in T staging due to its inability to accurately assess depth of tumor invasion and definitively identify adjacent organ invasion. In addition, primary gastric tumors, no matter the size, demonstrate variable levels of [^{18}F]FDG uptake. Large diffuse-type tumors with mucinous or signet ring histologies are relatively acellular and may only be minimally [^{18}F]FDG-avid (Fig. 2). In addition to low cellularity, these particular tumors also demonstrate low expression of glucose transporter 1 (GLUT1) protein that may further account for their relatively mild [^{18}F]FDG uptake [23].

[^{18}F]FDG-PET/CT is somewhat less sensitive than CT in the detection of regional lymph node metastases due to its relatively poor spatial resolution which makes discrimination of [^{18}F]FDG uptake associated with regional lymph nodes from the nearby primary tumor [^{18}F]FDG uptake difficult [24]. However, accurate characterization of these nodes may ultimately be unimportant in clinical planning, as they would all likely be removed at the time of surgery if the patient is a surgical candidate.

The major advantage of [^{18}F]FDG-PET/CT) over other anatomic imaging modalities is its ability to detect distant solid organ, peritoneal, and nodal metastases that would change the treatment strategy from curative to palliative (Fig. 3). A meta-analysis by Kinkel et al. designated [^{18}F]FDG-PET as the most sensitive imaging modality for this purpose [25]. For example, a small liver metastasis not identified on diagnostic CT may be visualized on [^{18}F]FDG-PET scan due to a high target-to-background ratio. Distant lymph nodes constituting M1 disease which may be equivocal in size and appearance on CT scan can be considered suspicious if [^{18}F]FDG-avid on PET scan.

Knowledge of the existence of peritoneal metastases at baseline associated with gastric cancer is important to avoid performing an unnecessary laparotomy. The ability of diagnostic CT to successfully identify peritoneal metastases can be limited by the small size of the tumor deposit(s), the presence of ascites, a paucity of intra-abdominal fat, and inadequate adjacent bowel enhancement. A few studies have reported that [^{18}F]FDG-PET has greater sensitivity than diagnostic CT in the evaluation of

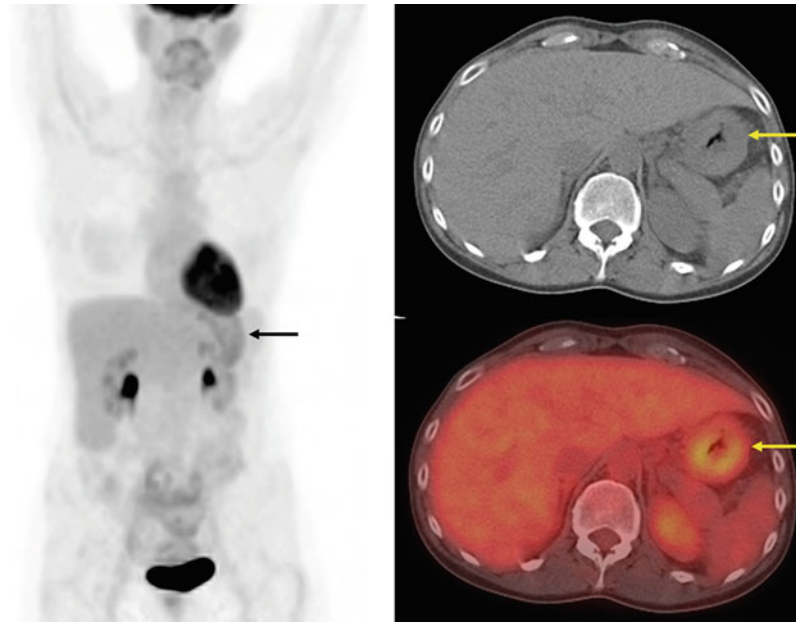

Fig. 2 [^{18}F]FDG-PET/CT scan of a 61 year old woman with recently diagnosed poorly differentiated signet ring gastric carcinoma (*arrows*). The tumor diffusely infiltrates the stomach, resulting in gastric wall thickening. Due to its relatively low cellularity, it demonstrates relatively mild FDG uptake

peritoneal carcinomatosis [26]. Indicators of peritoneal metastasis without definite associated CT correlates on [^{18}F]FDG-PET/CT include a pattern of diffuse uptake spreading throughout the abdomen and pelvis along the small and large bowel walls and/or discrete foci of [^{18}F]FDG uptake located randomly throughout the peritoneum, anteriorly in the mesentery, or dependently in the pelvis which are unrelated to solid viscera and may correlate with subtle ill-defined soft tissue density. However, the sensitivity of [^{18}F]FDG-PET scan for detection of peritoneal carcinomatosis was only calculated at around 50% [27] and is likely not significantly higher using [^{18}F]FDG-PET/CT due to the already low sensitivity for detecting small volume peritoneal carcinomatosis on CT alone as described above.

The intensity of [^{18}F]FDG uptake of primary gastric tumors has been found to correlate with HER2 status. Specifically, gastric adenocarcinomas that overexpress HER2 demonstrate relatively decreased [^{18}F]FDG uptake [28]. In this regard, the baseline [^{18}F]FDG-PET may be useful as a noninvasive means of determining HER2 status of gastric cancers and whether anti-HER2 therapies would be useful.

Common Therapies

Surgical resection of gastric cancers with regional lymphadenectomy offers the best chance for long-term survival for patients with localized disease. Early, minimally invasive (T1) gastric cancers can be cured by complete resection. The main contraindication for surgery is the presence of distant (M1) metastatic disease. Locally invasive disease (T4b) involving a major vascular structure such as the aorta or encasement and/or occlusion of the hepatic, celiac, or proximal splenic artery is also almost always a contraindication. Distal splenic artery involvement is not an absolute contraindication as the vessel can potentially be resected en bloc with the stomach, spleen, and distal pancreas. Diffuse-type infiltrative adenocarcinoma (linitis plastica) has an extremely poor prognosis and is considered a contraindication to curative resection by many surgeons.

Patients that are not candidates for curative resection may need palliative treatment for control of local symptoms such as nausea, pain, obstruction, perforation, or bleeding from the primary tumor. Nonsurgical palliation in these cases

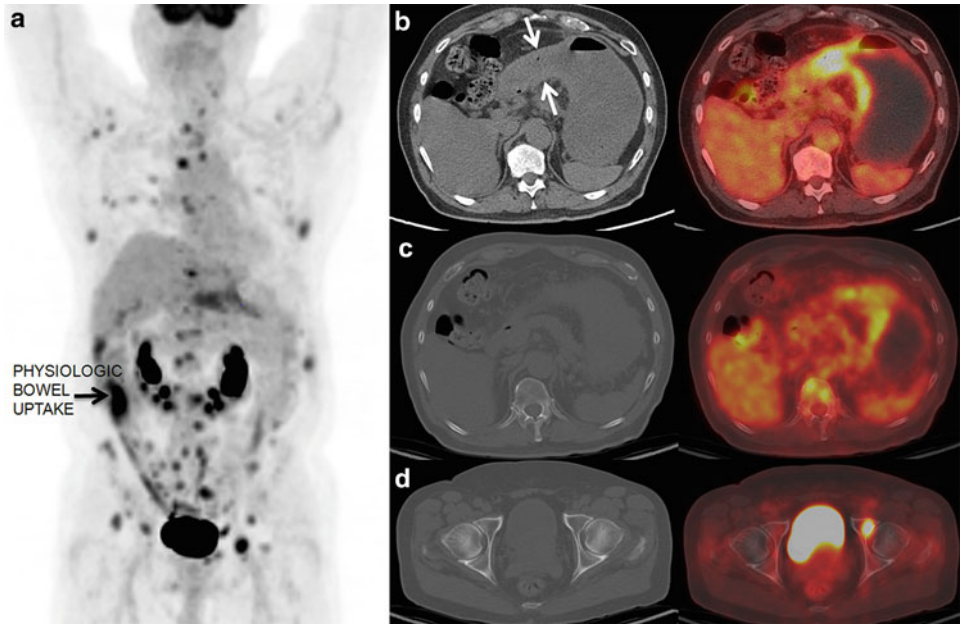

Fig. 3 (**a**) [^{18}F]FDG-PET/CT maximum intensity projection (MIP) image of a 75 year old man with a recently diagnosed infiltrative gastric adenocarcinoma. In addition to the uptake associated with the primary tumor (to be further described), there are innumerable [^{18}F]FDG-avid osseous metastases throughout the entire skeleton. There is no [^{18}F]FDG-avid lymphadenopathy or parenchymal metastatic disease. Of note, there was no mention of osseous metastases on the report of the diagnostic CT scan performed two weeks earlier. (Incidental note is made of a horseshoe kidney.) (**b**) CT and fused images of the stomach demonstrate [^{18}F]FDG-avid wall thickening involving a portion of the distal gastric body/proximal antrum consistent with the infiltrative primary malignancy. (**c**) There are two foci of [^{18}F]FDG uptake in the T12 vertebra. On CT, there may be some mild lucency associated with the sites of uptake. (**d**) There is an intense focus of uptake associated with the anterior left acetabulum associated with a tiny subtle lucency on CT. This PET/CT served to change the treatment strategy for this patient (from curative to palliative) due to the presence of widespread osseous metastatic disease which was obvious on the PET images but poorly appreciated on CT

includes stent placement, radiotherapy, and endoscopic laser therapy. In extreme cases which are highly symptomatic, palliative surgery is often performed.

Neoadjuvant chemotherapy or chemoradiotherapy is often recommended for patients with a more invasive primary tumor (T2 or higher) and/or with a high suspicion of regional nodal involvement on baseline imaging studies (N1+). Patients with bulky adenopathy suspicious for regional metastatic involvement which appears affixed to neighboring organs (such as the pancreatic head) may benefit from initial chemotherapy or chemoradiotherapy to shrink these findings and avoid a more complicated surgery (such as a Whipple procedure). The benefit of neoadjuvant therapy in patients determined to be unresectable at baseline but without distant metastatic disease (M0) is uncertain at this time.

Newer treatment options for inoperable gastric cancer include targeted therapies. In 2010, the monoclonal antibody trastuzumab (Herceptin) was approved by the FDA as a first-line treatment of HER2-overexpressing metastatic gastric cancers. Trastuzumab targets the extracellular domain of the HER2 protein and inhibits HER2 downstream cell signaling.

Assessing Efficacy of Treatment

[^{18}F]FDG-PET/CT may offer information on prognosis in patients with gastric cancer treated with preoperative chemotherapy. Patients responding

to preoperative chemotherapy per [^{18}F]FDG-PET/CT criteria have shown significantly improved survival compared with nonresponders [29]. Ott et al. demonstrated that a 35% decrease in [^{18}F]FDG uptake on PET scan performed 2 weeks after the start of preoperative chemotherapy predicted a favorable response with an accuracy of 85%. Two-year survival rate for those that responded using this criteria was 90% and was only 25% in nonresponders [30].

Wahl et al. delineated the [^{18}F]FDG-PET response criteria in solid tumors (PERCIST) which represent a standardized method for evaluation of metabolic tumor response. Under these criteria, progression on [^{18}F]FDG-PET scan is defined as an increase in [^{18}F]FDG uptake (as measured by standardized uptake value) of greater than 20% in a region 1 cm or larger in diameter, while response to treatment is defined as a decrease in uptake of greater than or equal to 30% [31].

As imaging of gastric cancers with [^{18}F]FDG-PET is somewhat limited because of the relative high number of primary tumors which are not significantly [^{18}F]FDG-avid, early evaluation of response to treatment is difficult [32]. Other PET radiotracers that may complement the information provided by [^{18}F]FDG have been investigated, including 3′-deoxy-3′-[^{18}F] fluorothymidine (^{18}F-FLT). ^{18}F-FLT is phosphorylated to fluorothymidine monophosphate by thymidine kinase I, leading to intracellular trapping. Thymidine kinase I concentration increases almost tenfold during DNA synthesis. Thus, ^{18}F-FLT uptake may accurately reflect cellular proliferation. In one such study, [^{18}F]FDG-PET imaging of pretreatment gastric cancer was compared to ^{18}F-FLT-PET imaging. In contrast to the standard [^{18}F]FDG-PET, FLT-PET was able to definitively detect all locally advanced gastric cancers. Even gastric tumors with histologies that typically demonstrate little to no [^{18}F]FDG uptake at baseline such as mucinous or signet ring adenocarcinomas demonstrated significant ^{18}F-FLT uptake [33].

Because many gastric cancers are not [^{18}F]FDG-avid on staging PET scans, repeat imaging following adjuvant treatment will likely not provide any additional useful information. Wahl et al. recommended the use of RECIST (Response Evaluation Criteria in Solid Tumors), the more widely used solid tumor response metric based on changes in morphologic size, to evaluate gastric cancers which are not significantly [^{18}F]FDG-avid at baseline [34]. After ^{18}F-FLT-PET showed promise in detection of gastric tumors which are typically not significantly [^{18}F]FDG-avid (as described above), Ott et al. [35] subsequently evaluated the performance of ^{18}F-FLT-PET versus [^{18}F]FDG-PET with regard to early response and prognosis in locally advanced gastric cancer treated with neoadjuvant chemotherapy. The only imaging parameter found to have a significant prognostic impact on survival was the ^{18}F-FLT uptake measured 2 weeks after the start of therapy [35]. However, caution was recommended in interpreting this result due to the small patient population and poor response rates. Further investigation is warranted at this time, but ^{18}F-FLT, in its role as a biomarker of cellular proliferation, may prove to be a predictive parameter and provide the molecular quantitative assessment of response to treatment that [^{18}F]FDG cannot provide in these particular gastric tumor subtypes.

Surveillance

As most deaths following surgical resection of gastric cancer are a result of distant recurrence, surveillance for recurrent disease is a key part of postsurgical management [36]. Although gastric tumor recurrence following surgery has a poor prognosis, early detection may be helpful in patients with minimal lymphadenopathy or small metastatic lesions who could have a more favorable response to subsequent salvage chemotherapy or radiotherapy. To detect gastric cancer recurrence following surgery, tumor markers (CEA, CA 19–9, CA 72–4) and endoscopy are commonly utilized. However, tumor markers cannot localize or quantify the recurrent disease, while endoscopy cannot detect extraluminal recurrence.

At present, the most frequently used method for detection of gastric cancer recurrence following surgery is a diagnostic CT scan. However, CT has several limitations. CT cannot reliably

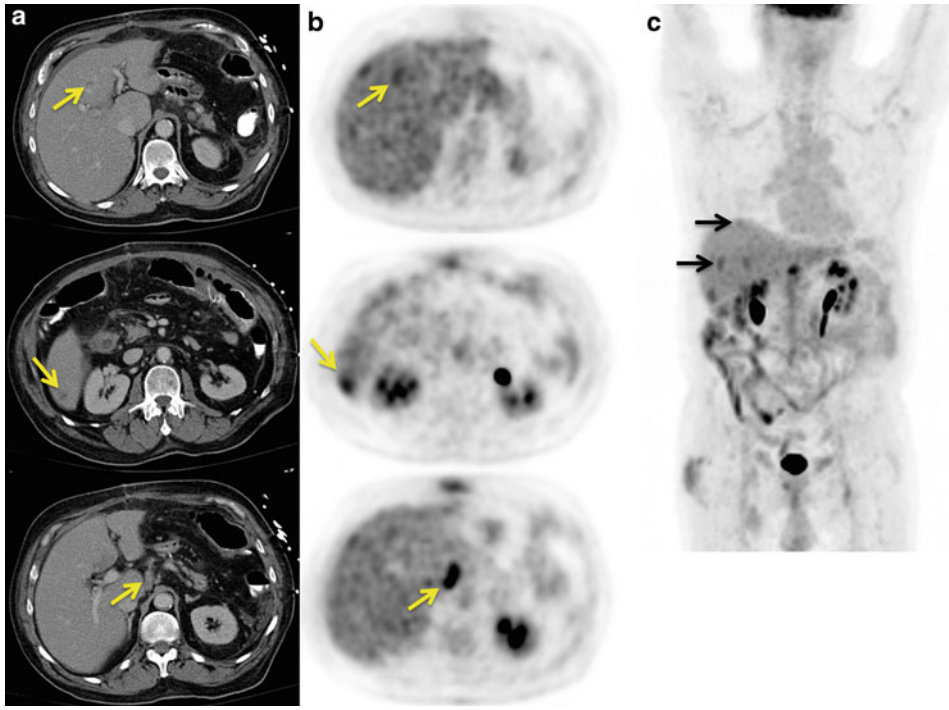

Fig. 4 (**a**) Diagnostic abdominal CT images of a 76 year old man with a history of gastric cancer treated with gastrectomy. There were two small new hypodense lesions observed in the liver and a gastrohepatic lymph node had slightly increased in size (*arrows*). (**b**) [^{18}F]FDG-PET/CT was ordered to further evaluate the somewhat equivocal findings on the CT scan. There was increased [^{18}F]FDG uptake associated with both liver lesions and the gastrohepatic lymph node was intensely [^{18}F]FDG-avid, findings consistent with new metastatic disease (*arrows*). (**c**) [^{18}F]FDG-PET/CT maximum intensity projection (MIP) image also demonstrates two additional foci of [^{18}F]FDG uptake in the liver without CT correlates which are also suspicious for metastatic disease (*arrows*)

differentiate treatment-induced morphologic changes from recurrent malignancy. Recurrence at the surgical anastomosis will look similar to nonspecific bowel wall thickening. [^{18}F]FDG-PET/CT) may help clarify equivocal CT findings in these cases, as recurrent tumor should have more conspicuous and focal [^{18}F]FDG uptake, while postoperative scar tissue should have only mild diffuse [^{18}F]FDG uptake. [^{18}F]FDG-PET/CT may also be more sensitive than CT alone in detecting distant recurrent metastatic disease following surgery, as it has shown to be in detecting distant disease prior to surgery (Fig. 4).

Postoperative surveillance of asymptomatic gastric cancer patients with [^{18}F]FDG-PET/CT has proven useful in detecting recurrent and/or metastatic disease, with a sensitivity of 84% and a specificity of 88% per a recent retrospective study conducted by Lee et al. [37]. Finally, as another recent study has demonstrated that sensitivity for detection of recurrent gastric cancer following surgical resection is greater in patients with initially [^{18}F]FDG-avid gastric cancers [38], surveillance FDG-PET/CT scans may be best utilized in patients with relatively high [^{18}F]FDG uptake associated with the primary tumor at baseline.

Diagnostic Applications of Nuclear Medicine: Gastrointestinal Stromal Tumors

25

Christopher G. Sakellis, Heather A. Jacene, and Annick D. Van den Abbeele

Abstract

Gastrointestinal stromal tumor (GIST), although rare, is the most common mesenchymal gastrointestinal neoplasm. This chapter will review the epidemiology, environmental factors, genetic predisposition, and underlying biomolecular changes of the disease. The staging of GIST as well as the roles of conventional diagnostic imaging and nuclear imaging in this staging will be reviewed. Finally, the efficacy of these modalities in assessing response to the various treatments described in the chapter and in the long-term surveillance for disease recurrence will be addressed.

Keywords

Gastrointestinal stromal tumor (GIST) • Conventional diagnostic imaging • [^{18}F]FDG-PET/CT • Staging • Tyrosine kinase inhibitors • Assessment of therapeutic response • Surveillance

Glossary

[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
ADC	Apparent diffusion coefficient
AFIP	Armed Forces Institute of Pathology
AJCC	American Joint Committee on Cancer
BRAF	Gene encoding for the B-Raf protein, a serine/threonine-protein kinase; the gene is also known as the proto-oncogene B-Raf and v-Raf murine sarcoma viral oncogene homolog B
CSF-1R	Colony-stimulating factor 1R
CT	X-ray computed tomography
DECT	Dual-energy CT
EORTC	European Organization for Research and Treatment of Cancer
EUS	Endoscopic ultrasound
FDA	United States Food and Drug Administration
GIST	Gastrointestinal stromal tumor
GLUT4	Glucose transporter 4
HPF	High-power fields

HU	Hounsfield units
IRA	Iodine-related attenuation
KIT	A proto-oncogene encoding for tyrosine-protein kinase Kit (or CD117), also known as mast/stem cell growth factor receptor (SCFR)
M	Metastasis status according to the AJCC/UICC TNM staging system
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
NCCN	National Comprehensive Cancer Network
NF1	Neurofibromatosis type 1
PDGFR	Platelet-derived growth factor receptor
PDGFRA	Platelet-derived growth factor receptor alpha
PET	Positron emission tomography
PET/CT	Positron emission tomography/ Computed tomography
RECIST	Response evaluation criteria in solid tumors
RET	A proto-oncogene encoding for a receptor tyrosine kinase for extracellular signalling molecules (from "rearranged during transfection")
RTK	Receptor tyrosine kinases
SCF	Stem cell factor
SDH	Succinate dehydrogenase
SURE	Sunitinib alternating with regorafenib
SUV_{max}	Standardized uptake value at point of maximum
SUV	Standardized uptake value
TKI	Tyrosine kinase inhibitor
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status) and "M" (distant metastasis status)
UICC	International Union Against Cancer (Union Internationale Contre le Cancer)
T	Tumor status according to the AJCC/UICC TNM staging system
TEK	Receptor tyrosine kinase
VEGFR	Vascular endothelial growth factor receptor

Epidemiology

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal gastrointestinal neoplasm but is still a rare tumor, only accounting for about 1% of all gastrointestinal neoplasms [1, 2]. The incidence of the tumor in the United States is estimated to be 4,000–6,000 new cases per year [3].

GISTs are distinct from other mesenchymal gastrointestinal tumors like liposarcomas or leiomyosarcomas, as they are derived from cells in the myenteric plexus of the lamina propria within the gastrointestinal wall [4]. They can arise anywhere throughout the gastrointestinal tract, most commonly in the stomach (60%) and jejunum/ileum (30%), followed by the duodenum, rectum, colon, and esophagus in descending order [5]. Rarely, GISTs have been found to arise in the mesentery or retroperitoneum.

The majority of GISTs are sporadic, and in these cases, men and women are affected equally. There is no racial preference, and they rarely arise before 40 years of age, with a mean age at diagnosis in the seventh decade of life [6].

Environmental Factors and Genetic Predisposition

At this time, there are no known environmental or lifestyle-related causes of GIST. However, almost all GISTs have been found to be associated with sporadic activating mutations which promote tumor survival and growth.

Approximately 85% of GISTs have oncogenic gain-of-function mutations in one of two receptor tyrosine kinases (RTK): KIT or PDGFRA (platelet-derived growth factor receptor alpha) which play a central role in the pathogenesis of GIST [7–9]. KIT encodes for CD117, a transmembrane receptor tyrosine kinase protein. The most common mutation in KIT in GIST involves exon 11 (about 70% of cases), while other mutations have been found in exons 9 (10–20% of cases), 13, and 17 [10]. Various types of mutations have been described, most commonly in-frame deletions involving exon 11 and duplications in exon 9.

The activating mutations involving the PDGFRA gene which is homologous to KIT and also encodes a transmembrane receptor tyrosine kinase have been found in 5–10% of GISTs [8]. Single nucleotide substitutions are the most common mutations described in these PDGFRA-positive tumors. KIT-negative GISTs are more likely to have PDGFRA mutations than KIT-positive GISTs [11]. Approximately 10–15% of GISTs are considered wild type and are both KIT- and PDGFRA-negative [10].

Although rare, inherited predispositions have been found to account for 5% or less of all GISTs. Patients with neurofibromatosis type 1 (NF1) have a high incidence of GISTs, which are typically multiple, arise in the small intestine, and are both KIT- and PDGFRA-negative [12]. Overexpression of KIT can occur in these wild-type NF1-related GISTs, though the mechanism is unclear.

Pediatric GIST is rare, tends to arise in the setting of heritable syndromes, has a female predilection, and commonly presents with chronic gastrointestinal bleeding and multifocal gastric involvement. Unlike adult GISTs, pediatric GISTs lack KIT or PDGFRA mutations, commonly metastasize to the lymph nodes, and have a more indolent course. The Carney-Stratakis syndrome results from germline mutations in succinate dehydrogenase (SDH) genes and presents in children who go on to develop GISTs and paragangliomas [13]. Primary familial GIST syndrome is a very rare autosomal dominant phenomenon and involves a germline mutation in KIT with high penetrance. These patients tend to be younger, develop multiple tumors in the stomach and/or small bowel, and may display extra-gastrointestinal traits such as skin hyperpigmentation [14].

A subset (3–13%) of wild-type GISTs has also been found to possess mutations in the serine-threonine kinase BRAF [15].

Underlying Biomolecular Changes

CD117, a transmembrane receptor tyrosine kinase protein, is encoded for by the KIT gene and functions as a receptor for stem cell factor (SCF). In normal cells, CD117 is enzymatically inactive until it binds SCF, whereby it initiates a signaling cascade within the cell. When there is a "gain-of-function" mutation in the KIT gene, as seen in most GISTs, the mutated CD117 protein remains activated without the presence of its ligand SCF, and thus the signaling cascade continues unabated. The most common mutations of the KIT gene which occur in exon 11 specifically affect the intracellular juxtamembrane portion of CD117, which plays a role in inhibiting signal transduction in the absence of SCF [16]. Mutations in other exons of the KIT gene as well as mutations seen in GIST in the PDGFRA gene all result in constitutive kinase activation and unchecked cell signaling, which ultimately affects cell proliferation, apoptosis, chemotaxis, and metabolism, resulting in tumorigenesis.

Staging and Prognostic Stratification

The TNM (tumor-node-metastasis) staging system developed by the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) is used for GIST. Although the T, N, and M definitions are similar for all tumors, there are separate stage groups based on the location of the primary tumor.

Primary gastric and omental GISTs are grouped together in one scheme, while primary small bowel, esophageal, colorectal, and peritoneal GISTs are grouped in another. Based on the data of two large retrospective Armed Forces Institute of Pathology (AFIP) studies of GISTs with long-term follow-up, tumor-related mortality of small bowel GISTs was more than twice that of gastric GISTs [17, 18].

Tumor (T) staging includes an assessment of both tumor size and mitotic rate. As most GISTs are roughly ovoid, the greatest tumor diameter is relatively easy to assess. The size thresholds in assigning a T designation are 2, 5, and 10 cm. Depth of tumor invasion is not utilized as most GISTs have transmural extension at presentation. The mitotic rate of GIST is evaluated pathologically by determining the number of mitoses observed per 50 high-power fields (HPF) on microscopy. A low mitotic rate is defined as 5 or fewer mitoses per 50 HPF, while a high mitotic rate is over 5.

Based on AFIP data, GISTs smaller than 2 cm in size with low mitotic rates were found to have very low risk of recurrence but were still considered to have metastatic potential. In both gastric and small bowel GISTs, less than 3% of tumors less than 10 cm and with fewer than 5 mitoses per 50 HPF metastasized, while over 80% of tumors larger than 10 cm and with 5 or more mitoses per HPF metastasized. The more intermediate-risk gastric GISTs (greater than 10 cm with low mitotic rate/less than 10 cm with high mitotic rate) had relatively low metastatic potential (10–15%), while the intermediate-risk small bowel GISTs with the same characteristics had a much higher metastatic rate (greater than 50%) [17, 18]. The National Comprehensive Cancer Network (NCCN) guidelines stratify the risk of malignancy of GISTs as high, moderate, low, or very low based on the site of primary tumor, size, and anatomic location [19].

Nodal (N) staging evaluates for the presence of regional lymph node metastases, which are rarely seen outside of rare pediatric familial cases. The presence of no regional nodal metastases or an unknown nodal status is designated as N0.

Distant metastatic disease (M1) in GIST is tumor involvement outside the main tumor mass, most commonly in the mesentery or liver within the abdomen. Extra-abdominal metastases are rare, but can occur in the bone, subcutaneous tissue, and lung. Multiple synchronous gastrointestinal GISTs, usually seen in the setting of hereditary syndromes, should not be considered as metastatic disease, as all could be separate primary tumors.

The histology of GIST may affect prognosis. The three major histopathologic types are spindle cell (70%), epithelioid type (20%), and mixed cellularity (10%). Early data suggested that 5-year recurrence-free survival was significantly higher with spindle cell histology compared to epithelioid or mixed histology [20]. However, subsequent studies implied that the degree of cellularity of the GIST was a more important prognostic factor than histologic type [21].

At this time, it is not clear whether the presence or absence of KIT mutations affects the prognosis of a particular GIST. Specific types of KIT mutations, including those in exon 9, have been shown to be associated with more aggressive tumor behavior [22]. Specific mutations are not factored into the current TNM staging system.

Conventional Diagnostic Imaging Staging

Contrast-enhanced CT is the current imaging of choice for the initial diagnosis and staging of GISTs. Although tissue sampling is required to definitively diagnose a GIST, CT not only characterizes the size and extent of the primary tumor but also evaluates for any peritoneal seeding and/or more distant metastatic disease. With the aid of oral and intravenous contrast, features associated with the primary tumor such as ulceration and fistulization with the gastrointestinal lumen can be characterized.

Typically, at the time of presentation, primary GISTs appear as smoothly contoured, heterogeneously enhancing masses. Larger tumors may display internal heterogeneity due to associated necrosis, cystic degeneration, or hemorrhage. It is important that multiphasic CT imaging with

unenhanced, arterial phase, and portal venous phase images is performed when imaging the liver, as the surrounding hepatic parenchyma on delayed portal venous phase images performed alone may mask hypervascular hepatic metastases.

Though CT is better at globally evaluating the patient for metastatic disease, MRI has shown utility in evaluating disease, especially in specific fixed structures such as the liver or rectum. The higher soft-tissue contrast of MRI compared to CT often provides an advantage in determining the organ of origin of primary GISTs and in evaluating invasion or involvement of adjacent viscera and/or blood vessels.

Some MRI features of primary GISTs at baseline may be predictive of malignancy risk. The presence of intratumoral cystic change, which is more accurately assessed on MRI than CT, has been found to correlate with high-risk GISTs, as defined by the NCCN guidelines [23]. A similar correlation between the presence of low attenuation findings on CT and malignant potential has not been found, possibly because these findings can be more nonspecific on CT [24, 25]. On MRI, lower mean apparent diffusion coefficient (ADC) values have also been found to correlate with a higher malignant risk, possibly due to the higher cellularity (and associated diffusion restriction) of high-risk tumors [23].

Endoscopic ultrasound (EUS) has been considered for the diagnosis and management of very small GISTs (less than 2 cm). EUS-guided biopsy of the lesion can be performed at the time of evaluation. Certain high-risk EUS features of these very small GISTs have been described including irregular border, cystic spaces, ulceration, echogenic foci, and overall heterogeneity, which may prompt their surgical resection [26].

Nuclear Imaging Staging

2-deoxy-2-[^{18}F]fluoro-D-glucose-positron emission tomography/computed tomography ([^{18}F]FDG-PET/CT) scans are now commonly used in the baseline evaluation of biopsy-proven GIST. CT and [^{18}F]FDG-PET scans were initially shown to have comparable high sensitivity and positive predictive value in initial staging of GIST [27], while subsequent studies have demonstrated [^{18}F]FDG-PET/CT is slightly more sensitive than CT alone [28]. While contrast-enhanced CT provides superior anatomic definition compared to the nondiagnostic CT portion of a PET/CT exam, the PET portion of a [^{18}F]FDG-PET/CT may be more sensitive in detecting an unknown primary GIST and may more definitively characterize small findings on CT scan as sites of metastatic disease. [^{18}F]FDG-PET/CT scans may also better evaluate patients at baseline who have an allergy to intravenous contrast.

[^{18}F]FDG-PET allows for quantitation of tumor metabolism using measurements such as the maximum standardized uptake value (SUV_{max}). As PET has been shown to be superior in many ways to diagnostic CT in monitoring and quantifying therapeutic response to tyrosine kinase inhibitor (TKI) therapy (described below), especially early in the course of treatment, a baseline [^{18}F]FDG-PET scan should be obtained before starting any TKI administration to assess the baseline tumor metabolic activity and extent of tumor burden.

Traditional Therapies and GIST

Complete surgical resection is the treatment of choice for any patient with surgically resectable GIST and no metastases and offers the best chance for long-term disease-free survival. The goal of surgery is complete resection of the primary tumor with an intact pseudocapsule and negative microscopic margins on pathology. The resected tumor needs to be handled with care during removal, as tumor rupture will negatively impact survival due to the risk that it results in new intra-abdominal microscopic seeding of tumor.

The current consensus is that conventional cytotoxic chemotherapy is not useful for managing GIST. Several trials evaluating chemotherapeutic regimens in advanced GIST have reported very low response rates (0–5%) [29, 30].

Radiotherapy has been reported in the past to show no advantage in disease-free survival in several studies. A retrospective study analyzing patients treated at Massachusetts General Hospital

between 1973 and 1998 with incompletely resected GIST, some of whom were also treated with radiotherapy, concluded there was no support for its use [31]. GISTs are also commonly associated with mobile structures such as loops of small bowel and are more difficult to accurately target with radiotherapy.

Molecular Therapy and GIST

Until the early 2000s, the outcome for patients presenting with GISTs which were either advanced (surgically unresectable or marginally resectable) or who presented with metastatic disease was relatively bleak. After the discovery of the key role mutations in receptor tyrosine kinase genes, most notably KIT, played in GIST tumorogenesis, molecularly targeted agents known as tyrosine kinase inhibitors (TKIs) were developed to specifically treat GIST.

The first of these tyrosine kinase inhibitors used to treat GIST in clinical trials, and later the first to be approved by the FDA for treatment of advanced or metastatic GIST in 2002, was the small molecule imatinib mesylate. Imatinib inhibits the reaction that starts the cell signaling cascade of the KIT protein by competing with ATP for a binding site on its surface, thus inhibiting tumor progression. The drug is not cytotoxic like conventional chemotherapies. Instead it is cytostatic, and the NCCN guidelines recommend continuous administration of imatinib for metastatic GIST until there is evidence of progression [19]. The standard dose of imatinib is 400 mg, and it is able to be administered only once daily orally due to its circulating half-life of about 20 h.

In a large multicenter trial evaluating imatinib in the treatment of advanced and/or metastatic GISTs, tumors that were KIT-positive showed significant long-lasting response to the drug, with 85% surviving at 76 weeks after starting therapy [32]. However, in the same trial, 14% of the patients were found to have tumors resistant to imatinib, likely due to mutations in different proteins or in parts of the KIT protein structure that do not respond to imatinib binding. GIST patients with the most commonly observed KIT mutations in exon 11 have been found to respond to imatinib more favorably than those with KIT mutations involving exon 9 or wild-type GISTs [10]. This better response may be related to the fact that the binding site of imatinib is in close proximity to the portion of the KIT protein encoded by exon 11.

Dose escalation to 800 mg per day is the recommended first step in patients with unresectable or metastatic GIST that shows early evidence of progression on imatinib. GISTs with KIT mutations in exon 9 have also demonstrated a higher response rate and longer progression-free survival with this higher dose [10].

Preoperative imatinib therapy is recommended as a first-line therapy to reduce the size of large tumors. It is also recommended to reduce the size of tumors at sites where they may become adherent to adjacent tissue or organs and would initially require an extensive en bloc surgery with higher associated morbidity. For example, a duodenal GIST may initially require a pancreaticoduodenectomy, while a rectal GIST might require an abdominoperineal resection in which the rectal sphincter is unable to be spared. In cases like these, preoperative imatinib has been shown to lead to initially unresectable but localized GISTs becoming resectable and to less morbid organ- and function-preserving surgeries for initially marginally resectable tumors. Preoperative imatinib treatment has also been shown to reduce the risk of tumor rupture before or during surgery, which thus improves prognosis [33]. According to NCCN guidelines, preoperative imatinib should be monitored by imaging and continued until two consecutive restaging scans fail to demonstrate interval improvement in tumor burden [19].

Imatinib has been used as an adjuvant treatment following surgery. Even with complete surgical resection of GIST, it has high recurrence rate in the first 2 years after surgery. Imatinib was approved by the FDA in 2008 for treatment of GIST after complete surgical resection, as it was shown to significantly prolong survival in this setting. For patients who did not receive preoperative imatinib, imatinib following complete surgical resection is recommended for at least 36 months per the NCCN guidelines in patients who presented with higher-risk primary GISTs, namely, tumors

larger than 5 cm with more than 5 mitoses per 50 HPF [19]. For patients who did receive preoperative imatinib, the NCCN guidelines recommend that imatinib therapy is considered following complete surgical resection if there had been an objective response to preoperative therapy. However, the duration of this treatment is uncertain, although there have been single- and multicenter trials that have shown benefit in continuing imatinib treatment for 2 years after surgery [19].

Sunitinib was the second receptor TKI approved by the FDA for the treatment of GIST in 2006. It is indicated in patients who have developed resistance to imatinib or have progression of disease following escalation of the daily imatinib dose from 400 to 800 mg. Sunitinib is a less specific inhibitory drug than imatinib and is structurally distinct. It inhibits KIT and PDGFR like imatinib, but also acts to inhibit vascular endothelial growth factor receptors 1–3 (VEGFR1–3), Fms-related tyrosine kinase 3, colony-stimulating factor 1R (CSF-1R), and the RET receptor [34]. Sunitinib thus possesses an antiangiogenic effect in addition to an antitumoral effect. Patients either receive a continuous daily oral 37.5 mg dose of sunitinib or 4 weeks of a continuous 50 mg dose followed by 2 weeks off treatment [35]. There is evidence suggesting that GISTs with KIT exon 9 mutations, wild-type GISTs, and pediatric GISTs, tumors which are typically less responsive to imatinib, are more sensitive to sunitinib [36]. Sunitinib has been considered as a first-line therapy for these particular tumors.

Regorafenib is an oral multikinase inhibitor that was approved by the FDA in 2013 for the treatment of imatinib- and sunitinib-resistant GIST. Regorafenib inihibits the activity of several protein kinases including KIT, RET, BRAF, and PDGFR and has an antiangiogenic effect with inhibition of VEGFR1-3 and TEK. Regorafenib was shown to increase progression-free survival in a phase 3 trial of GIST patients who had progressed on imatinib and sunitinib [37].

In patients with wild-type GISTs, which lack both KIT and PDGRA mutations, but who do exhibit mutations in the BRAF kinase, treatment with BRAF inhibitors has shown some success. Falchook et al. reported the first case study of treatment of one such patient using a BRAF inhibitor, dabrafenib [38]. Other novel drugs have been investigated in the treatment of metastatic GIST resistant to imatinib and sunitinib. Sorafenib is a TKI that exhibits inhibitory action against several kinases and has demonstrated significant disease control rates in several studies [39].

In addition to treatment with novel drugs, regimens of two complementary TKIs given daily in a rapidly alternating regimen are currently under investigation (e.g., NCT02164240 Phase Ib Study of SUnitinib Alternating With REgorafenib in Patients With Metastatic and/or Unresectable GIST (SURE) at clinicaltrials.gov) in patients with metastatic GIST resistant to imatinib. It is hoped that these regimens provide a broader spectrum of activity with better tolerated side effects than treatment with a single agent.

Assessing Response to Treatment

The standard imaging modality used to assess response to treatment in GIST is a contrast-enhanced CT scan. Tumor size is not a useful metric for CT evaluation of response of GIST to imatinib therapy, as it is for monitoring response to conventional cytocidal therapy used in most other tumors. Imatinib is a cytostatic therapy, and a significant decrease in size of GIST metastases may take months to develop, even if the tumor is responding to the drug. In fact, there may be a paradoxical increase in size of tumors responding to treatment due to development of intratumoral hemorrhage and/or cystic changes (Fig. 1). The common way of assessing tumor response to therapy has been change in unidimensional size measurements using Response Evaluation Criteria in Solid Tumors (RECIST), where a partial response is defined as a 30% reduction in unidimensional measurements and progressive disease is defined as a 20% increase or the appearance of new lesions [40]. These definitions are obviously limited in the case of response of GIST to imatinib.

[^{18}F]FDG-PET and [^{18}F]FDG-PET/CT have proven valuable in assessing early response to

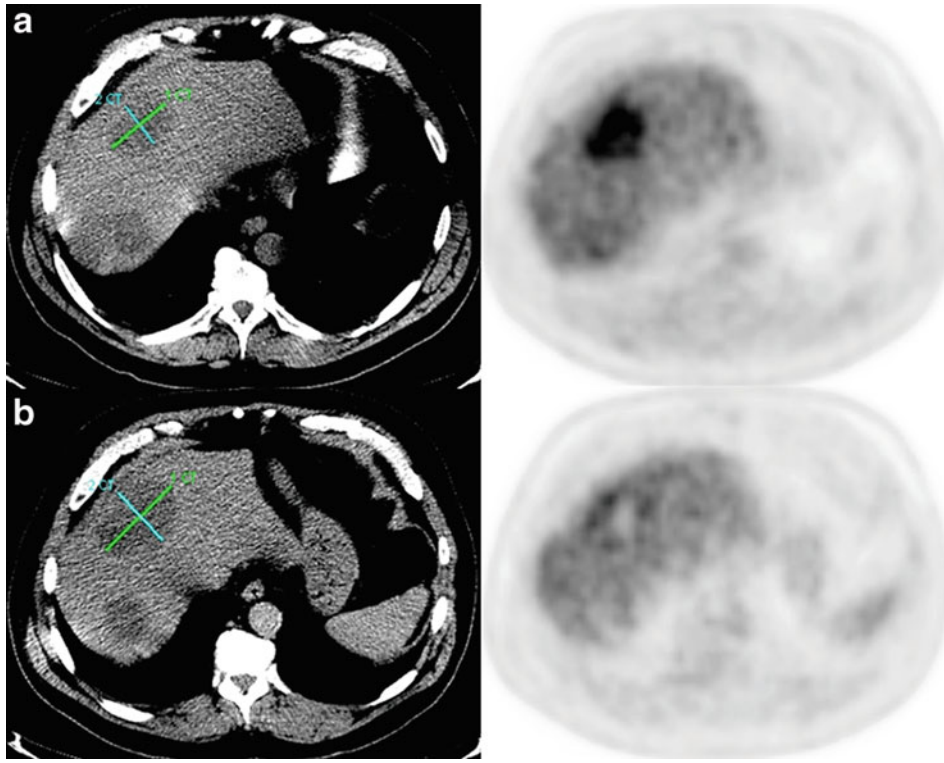

Fig. 1 (**a**) Baseline [^{18}F]FDG-PET/CT of 67 year old man with GIST demonstrating the dominant [^{18}F]FDG-avid hepatic metastasis. (**b**) PET/CT scan performed 2 months after start of imatinib demonstrates a slight increase in size of the dominant hepatic lesion, but a significant decrease in uptake and a decrease in associated density on CT scan. These findings are consistent with a significant metabolic response to therapy, despite the apparent increase in size of the dominant lesion

both neoadjuvant and systemic treatment in GIST, especially in the time before changes in size are demonstrated on CT. In one of the earliest trials assessing response to imatinib in GIST, [^{18}F]FDG-PET showed dramatic early decrease in [^{18}F]FDG uptake, and thus metabolic activity, in tumors which preceded anatomic changes by weeks or months (Fig. 2) [41]. A significant change in metabolic response can be observed on [^{18}F]FDG-PET in as little as hours after the start of imatinib therapy. This rapid response in metabolism was found to correspond at least in part with a decrease in glucose transporter 4 (GLUT4) expression in tumors on pathology prior to and following surgery in a study of patients receiving preoperative neoadjuvant imatinib [42].

The first phase 2 trial of imatinib [32] and many trials following it used criteria developed to assess metabolic response to treatment on [^{18}F]FDG-PET scans developed by the European Organization for Research and Treatment of Cancer (EORTC). Semiquantitative assessment of [^{18}F]FDG uptake is made using the maximum standardized uptake value (SUV_{max}) of tumor sites. The EORTC guidelines defined partial response as a greater than 25% decrease in SUV of tumor on a scan compared to the pretreatment baseline scan, with progressive disease demonstrating a greater than 25% increase in SUV or new [^{18}F]FDG-avid lesions [43]. The SUV_{max} is the most commonly used semiquantitative parameter for assessing response. When the EORTC guidelines for partial response to therapy have been met on early scans performed anywhere between 3 and 16 weeks after the start of imatinib therapy, several studies have demonstrated a correlation with more favorable outcome as defined

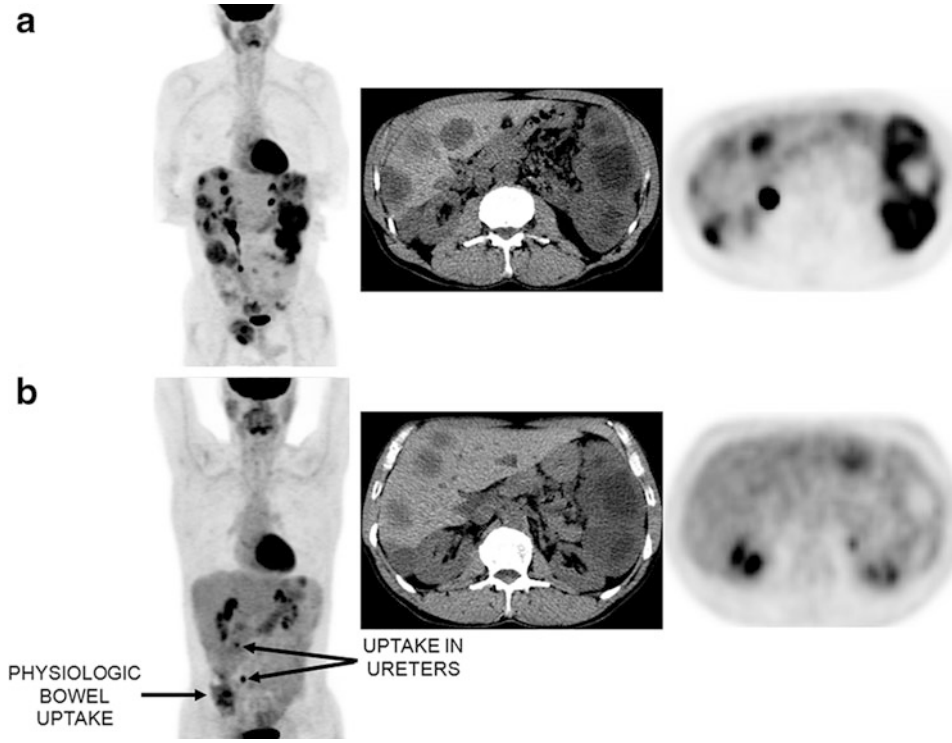

Fig. 2 (**a**) Baseline [^{18}F]FDG-PET/CT of 63 year old man with recently diagnosed metastatic gastrointestinal stromal tumor (GIST). There are multiple hepatic and peritoneal [^{18}F]FDG-avid lesions. (**b**) PET/CT scan performed 1 week later after the start of treatment with imatinib. Marked reduction of [^{18}F]FDG uptake is demonstrated in all lesions

by a longer time to treatment failure [44, 45]. Using a threshold of 40% reduction in baseline SUV_{max} on the first early PET scan has shown to be predictive of even longer time to treatment failure [46].

[^{18}F]FDG-PET has shown advantages over diagnostic CT in certain cases in assessing for treatment response in metastatic GIST. Imprecise timing of the administered intravenous contrast may cause a liver lesion to be inconspicuous on the baseline scan, while an enhancing mesenteric lesion at baseline associated with bowel loops may also be similarly obscured. If these lesions respond to treatment on follow-up CT scans, their resulting decrease in attenuation may make them newly conspicuous and may lead to them being misinterpreted as new lesions. An [^{18}F]FDG-PET/CT obtained at the same time as the follow-up diagnostic CT could help to properly characterize them as responding non-metabolically active lesions.

GIST has been found to have a characteristic pattern of response to imatinib treatment on CT scan. Heterogeneous high attenuation of tumor at baseline transitions to a more homogeneous pattern of lower attenuation (20–25 HU) during a response to treatment. These changes correlate histologically with a decrease in tumor vascularity and associated cystic and/or myxoid degeneration [47]. This change in attenuation usually occurs within 1–2 months [48]. Calcification and/or intratumoral hemorrhage can also occur, which leads to increased density and may mask response to therapy [49].

Alternative tumor response criteria on diagnostic CT proposed by Choi et al. (2007) incorporate change in tumor attenuation along with change in size and have been shown to have a similar

correlation to metabolic response to imatinib as [^{18}F]FDG uptake on [^{18}F]FDG-PET. The Choi criteria define treatment response as a decrease in tumor attenuation on CT of 15% and/or a reduction of tumor unidimensional diameter of 10%. While both the Choi and RECIST criteria were found to have a 100% specificity in identifying patients demonstrating metabolic response on [^{18}F]FDG-PET scan, the Choi criteria had a significantly higher sensitivity than the RECIST criteria, 97% versus 52% [50].

Dual-energy CT (DECT) allows for quantification of intratumoral intravenous iodinated contrast. DECT response criteria have been proposed and have been compared with the Choi CT criteria to determine whether they demonstrate better correlation with survival. DECT can quantify iodine-related attenuation (IRA), which can be considered a surrogate marker for perfusion and tumor vascularity. Meyer et al. compared DECT criteria to the Choi criteria in evaluating the response of GIST on tyrosine kinase inhibitor treatment [51]. The DECT criteria defined nonresponders as those with tumors that demonstrated an increase of 20% in both tumor size and IRA or a 50% increase in either tumor size or IRA, while responders were defined as all other patients. Those defined as responders by the DECT and Choi criteria demonstrated significantly longer progression-free survival than those defined as nonresponders. Of note, the DECT criteria, but not the Choi criteria, provided a statistically significant prediction of overall survival. One reason for this result was thought to be that intratumoral hemorrhage does not affect the quantification performed by DECT.

MRI has also been utilized in assessing the response of GIST to therapy. Some of the changes on MRI described in responding tumors are minimal to no contrast enhancement and T2 hyperintensity that may mimic that of cysts. Intratumoral hemorrhage can be more accurately differentiated from viable tumor on MRI than CT. Diffusion-weighted MRI images have also shown promise in characterizing early response to treatment. Diffusion-weighted MRI images demonstrate an increase ADC values compared to baseline values in tumors that are responding to treatment. Marked increase in the ADC values of lesions has been demonstrated on MRI just a week after the start of therapy and correlates with a favorable prognosis [52]. While early prognostic information provided by diffusion-weighted MRI may be on par with [^{18}F]FDG-PET/CT in localized GIST involvement, [^{18}F]FDG-PET/CT is better suited to evaluate the response of diffuse metastatic disease.

On all imaging modalities, the response of GIST to sunitinib and other TKIs is similar to the response seen on these modalities to imatinib. It should be kept in mind that sunitinib and certain other TKIs, unlike imatinib, have antiangiogenic effects on GIST which may result in intratumoral bleeding which may cause difficulty in CT interpretation. In these cases, [^{18}F]FDG-PET/CT may be helpful to rule out the presence of any metabolically active tumor, while MRI would better characterize any blood products.

[^{18}F]FDG-PET/CT continues to be utilized in trials involving novel TKIs due to its ability to identify early response to therapy and the positive prognostic significance of this early drop in metabolic activity.

Assessing Resistance to Treatment

Almost all patients treated with imatinib for metastatic or advanced GIST will inevitably develop resistance to the drug. This resistance can either develop early or late. Primary resistance is progression of disease within the first 6 months of imatinib treatment and has been found to occur in about 14% of patients [32]. There are several associations that have been described with primary resistance to imatinib including exon 9 KIT mutations, PDGFRA mutations, wild-type GISTs, and pediatric GISTs [53]. Response to initial imatinib therapy has been demonstrated consistently earlier on [^{18}F]FDG-PET/CT than on diagnostic CT, with decreases in metabolic

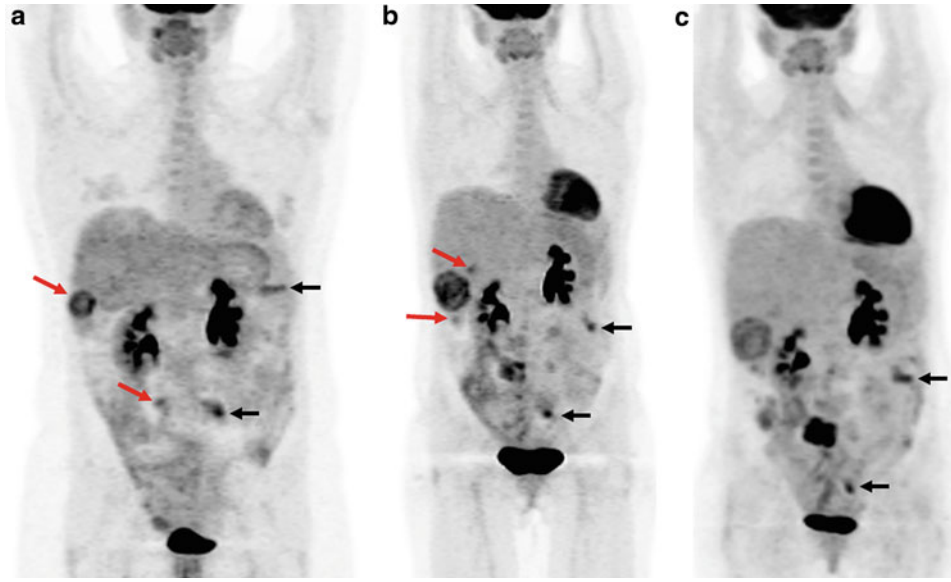

Fig. 3 (**a**) 44 year old man with metastatic GIST being treated with imatinib. [^{18}F]FDG uptake is demonstrated on PET scan in hepatic and mesenteric lesions (*red arrows*). *Black arrows* represent sites of colonic uptake unrelated to GIST without CT correlates. (**b**) Follow up PET scan after 6 weeks demonstrates an increase in size and uptake of the hepatic and mesenteric lesions, as well as two newly [^{18}F]FDG-avid hepatic metastases (*red arrow*), findings consistent with progression of disease. It was decided clinically to escalate the dose of imatinib. (**c**) Follow up PET scan after 3 weeks demonstrates a decrease in [^{18}F]FDG uptake in hepatic lesions, but an increase in uptake of the mesenteric lesion (*red arrow*). Although the hepatic disease did show response to the higher dose of imatinib, the mesenteric lesion continued to progress, indicating that this lesion had developed resistance to imatinib. (Of note, the focal sites of colonic uptake unrelated to GIST without CT correlates persist, and are highly suspicious for underlying adenomatous polyps)

activity often evident within the first week of treatment, while CT changes suggestive of response, including decrease in attenuation, may take up to a month or more to clearly develop. Therefore, [^{18}F]FDG-PET/CT may be of particular value in determining if a GIST has primary resistance to imatinib compared to other modalities. Lack of significant decrease in [^{18}F]FDG uptake from baseline of tumor on a [^{18}F]FDG-PET/CT scan performed during the first month of therapy is highly predictive of primary resistance, and this result should prompt clinicians to escalate the dose of imatinib [54]. If there is continued resistance demonstrated on scans after dose escalation, treatment with the second-line TKI sunitinib would be considered (Fig. 3).

Secondary resistance to imatinib occurs in patients who initially demonstrated a good response to treatment for at least 6 months. Secondary resistance to imatinib usually develops after a median of 2 years [55]. Usually secondary KIT mutations are responsible, often in exons [13, 14, 17] that code for portions of the intracytoplasmic portions of the KIT protein [36].

Findings of secondary resistance described on CT include new metastatic lesions and increase of size and/or attenuation of preexisting lesions. A characteristic pattern of tumor recurrence on CT or MRI is the so-called new "nodule-within-a-mass" appearance [56]. Here, recurrent tumor is defined as a new enhancing soft-tissue nodule or nodules on CT or MRI or within a cystic mass.

[^{18}F]FDG-PET/CT can identify secondary resistance by the reappearance of [^{18}F]FDG uptake within a previous lesion which was not

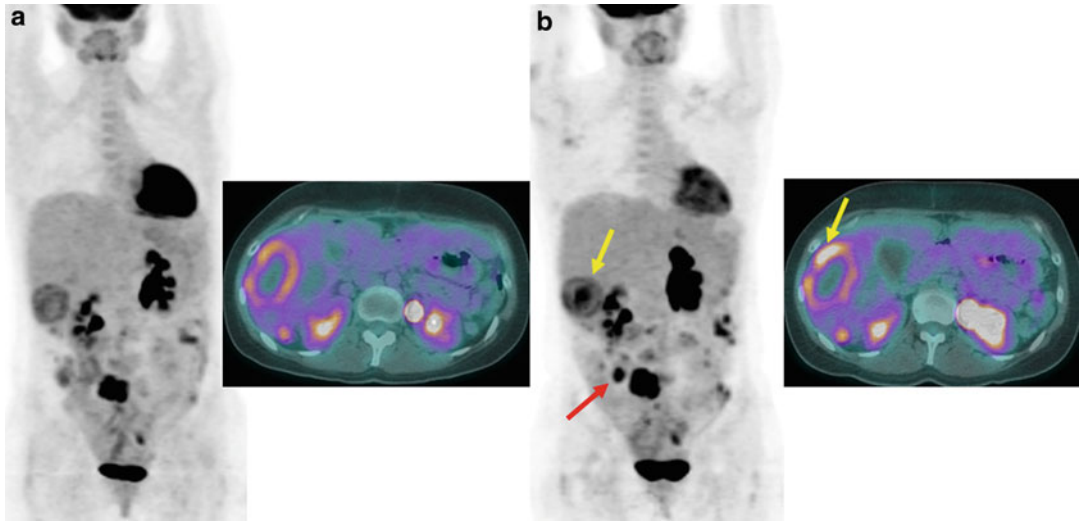

Fig. 4 (**a**) Same patient as in Fig. 3, undergoing treatment with escalated dose of imatinib. (**b**) Three week follow up PET scan not only demonstrates new [^{18}F]FDG uptake in another mesenteric lesion (*red arrow*) suggesting resistance to imatinib, but there is new increased [^{18}F]FDG uptake in the anterior aspect of the dominant hepatic lesion (*yellow arrow*), consistent with resistance to imatinib within a subpopulation of cells within an otherwise treated lesion. The clinical decision was made at this point to discontinue imatinib in anticipation of starting treatment with sunitinib

[^{18}F]FDG-avid on treatment. In patients with a large number of metastases, only a few lesions may demonstrate new [^{18}F]FDG uptake, yet this appearance would still be consistent with development of resistance. [^{18}F]FDG-PET/CT has the ability to demonstrate that resistance does not just arise throughout the entirety of discrete lesions. A small new focus of uptake within an otherwise photopenic lesion can suggest resistance developing within a subpopulation of cells within a single lesion (Fig. 4). These findings on [^{18}F]FDG-PET scans suggest that patients who develop secondary resistance have two biologically distinct populations of tumor, one that is still responding to imatinib and one which has developed mutations granting them resistance to the drug. This phenomenon was illustrated during a phase I/II clinical trial for sunitinib, where the trial protocol required patients to be off imatinib for a period of time (up to 3 weeks) before starting sunitinib. New baseline [^{18}F]FDG-PET scans were obtained with the patients taking neither drug. In addition to an increase in [^{18}F]FDG uptake seen in the lesions already determined to have imatinib-resistant GIST, a "flare" of new uptake was observed in many of the other previously non-[^{18}F]FDG-avid lesions (Fig. 5) [54]. Discontinuation of imatinib had lead to reactivation of glycolytic metabolism in the population of tumor cells that continued to respond to the drug.

Surveillance

GIST has a recurrence rate as high as 90% in the first 2 years, even after a successful complete surgical resection. GIST typically recurs in the liver or peritoneum. The current NCCN guidelines recommend contrast-enhanced CT for surveillance of GIST, especially in those initially characterized as high risk [19]. Patients are typically scanned in 3- to 6-month intervals. [^{18}F]FDG-PET/CT is usually only utilized when there is an ambiguous finding on CT or when treatment with a new TKI is considered and a baseline [^{18}F]FDG-PET scan is warranted.

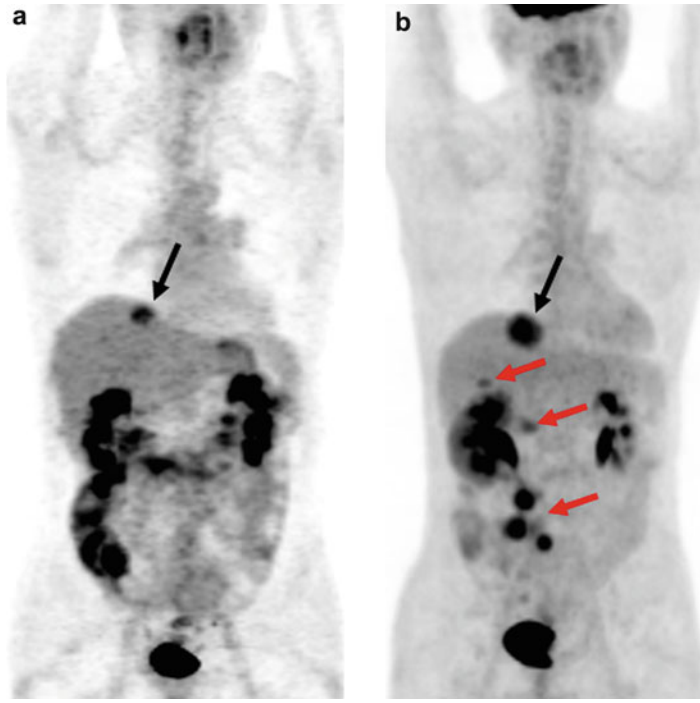

Fig. 5 (**a**) 48 year old man with metastatic GIST with development of a hepatic lesion resistant to imatinib (*black arrow*). (**b**) PET scan performed 3 weeks later prior to the start of sunitinib. Not only has the resistant lesion within the liver increased in [^{18}F]FDG uptake (*black arrow*), but there has been reactivation of metabolic activity in hepatic and mesenteric lesions which were previously responding to imatinib (*red arrows*)

In addition to detecting recurrent or progressive disease, surveillance scans can also identify side effects of TKI therapy. One of the more common side effects of imatinib seen on imaging is the third spacing of fluid within the body which can manifest as pleural effusions, pulmonary edema, ascites, and/or anasarca. As development of ascites would normally raise suspicion for the presence of new peritoneal disease, care must be taken in determining whether this is just a fluid overload-related side effect of the treatment. Other side effects of the various TKIs that may manifest on imaging include hepatic steatosis, hepatitis, pancreatitis, ischemic colitis, pneumatosis, and bowel perforation [57, 58].

Diagnostic Applications of Nuclear Medicine: Tumors of the Liver and Biliary Tract

26

Mustafa Raoof, Steven M. Larson, and Yuman Fong

Abstract

In liver and biliary tumors, modern imaging techniques play an important role in therapeutic decision-making. Whether the decision involves determining if the tumor is resectable or how it is responding to treatment, nuclear imaging has the potential to facilitate the decision-making process. Here we cover various studies that investigate the comparative effectiveness of cross-sectional morphologic imaging alone and in combination with functional nuclear medicine imaging. Specifically, we discuss the role of nuclear imaging in the diagnosis, characterization, and treatment of patients with primary and secondary liver or biliary tract malignancies.

Keywords

Primary tumors • Hepatocellular carcinoma • Hepatoma • Gallbladder carcinoma • Cholangiocarcinoma • Biliary cancer • Colorectal metastases • Neuroendocrine metastases • [^{11}C]Acetate • 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) • PET/CT • MRI • CT scan • Staging • Resectability • Recurrence • Nuclear imaging • Diagnostic

Glossary

[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
ACS	American Cancer Society
AFP	Alpha Fetoprotein
AI	Arterial infusion
CA	Cancer antigen
CA 19–9	Carbohydrate antigen 19–9, a tumor-associated marker
CEA	Carcinoembryonic antigen, a tumor-associated marker
CRC	Colorectal cancer
CT	X-ray computed tomography
DOTA	2-(4-Isothiocyanatobenzyl-1,4,7,10-tetra-azacyclododecane-1,4,7,10-tetraacetic acid (macrocyclic coupling agent to label compounds of biological interest with metal radionuclides)
DOTANOC	DOTA-1-Nal^3-octreotide
DOTATATE	DOTA-Tyr^3-octreotate
DOTATOC	DOTA-octreotide
FOLFOX	Chemotherapy regimen based on FOL– Folinic acid F – Fluorouracil OX – Oxaliplatin

Introduction

The tumors arising from the liver are among some of the most frequent and lethal human tumors worldwide. The liver is also the most common site of metastases from gastrointestinal tumors via portal circulation and is thought to be a barrier to the disseminated spread of cancer to other organs. Multimodality treatment of liver tumors necessitates accurate imaging to guide management decisions. Traditionally, a high-resolution cross-sectional imaging study with a multidetector CT scan or an MRI with triple-phase contrast has been considered the gold standard. Several advances in imaging technologies specifically nuclear imaging of these tumors have significantly improved our ability to evaluate the true extent of disease. In this chapter we review the role of nuclear imaging in the complex and often challenging treatment of primary and secondary liver and biliary malignancies.

Metastatic Tumors

Colorectal Metastases

Colorectal cancer metastases are the most common malignant lesions of the liver. Approximately half of the patients diagnosed with colorectal cancer (CRC) will develop liver metastases. Historically, these patients were treated with chemotherapy that resulted in suboptimal response, and none of the patients survived beyond five years (Fig. 1). The management of CRC liver metastases has undergone a paradigm shift over the last two decades. Surgical resection of CRC metastases has resulted in overall survival that approaches 30% at five years for a selected group of patients. Improvements in the quality and safety of hepatic resections, combined with the widespread use of ablative technologies as well as with arterial infusion pump placement, have broadened the selection criteria for patients who can benefit from potentially curative therapies. [^{18}F]FDG-PET/CT scans can play an important role at every stage of the management of these complex patients.

a. Operative Planning and Resectability
   The role of PET/CT in staging of the primary lesion in colorectal cancer has been studied extensively. PET/CT scan is neither sufficient nor accurate for clinical staging of the primary lesion, and without evidence of distant metastases on contrast-enhanced cross-sectional imaging,

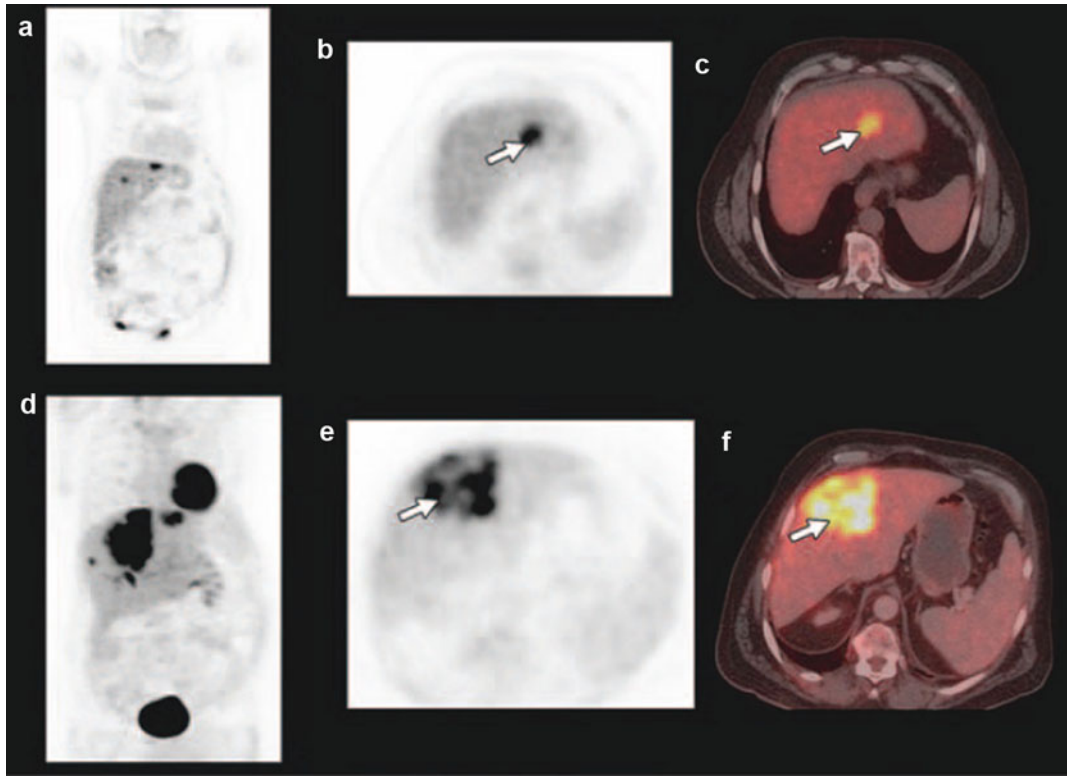

Fig. 1 71-year-old man with history of sigmoid colon cancer with surgical resection and chemotherapy for 6 months. (**a**) Patient's carcinoembryonic antigen levels started increasing after 6 months, and [^{18}F]FDG-PET/CT revealed hepatic metastasis. (**b**) Coronal PET shows two lesions (*arrow*) in segments 2 and 8. (**c**) Axial-fused PET/CT shows hypermetabolic lesion (*arrow*) in segment 2. (**d–f**) Patient underwent eight cycles of chemotherapy with FOLFOX-folinic acid, fluorouracil and oxaliplatin, and avastin, and subsequent PET-CT scans revealed progressive hepatic lesions (*arrow*, **e** and **f**) (Reprint with permission from Sacks A. et al. Value of PET-CT in the Management of Liver Metastases, Part 1. AJR Am J Roentgenol. 2011, Fig. 2, p. W259) [75]

the routine use of PET/CT is not justified. However, [^{18}F]FDG-PET scans are very accurate in detection of hepatic and extrahepatic disease. Pooled analysis from multiple studies demonstrates that the overall sensitivities of nonhelical CT, helical CT, 1.5-T MRI, and [^{18}F]FDG-PET in detecting liver metastases were 60.2%, 64.7%, 75.8%, and 94.6%, respectively [1]. Similar results were noted on a more recent analysis by Niekel et al., whereby the sensitivities of CT, MRI, and [^{18}F]FDG-PET were 83.6%, 88.2%, and 94.1%, respectively [2]. Similar sensitivity is noted for extrahepatic disease. A study by Kuehl et al. demonstrated an overall sensitivity of 95% for intrahepatic disease and 97% for extrahepatic disease [3].

Accurate staging of intrahepatic and extrahepatic disease is crucial in decision-making for these complex patients. A prospective study of patients with colorectal cancer metastatic to the liver demonstrated that a contrast-enhanced CT missed extrahepatic disease in one-third of the patients [4]. This number was reduced to 11% with the use of [^{18}F]FDG-PET scans. Similarly, another study reported that approximately one-third of the patients with a negative contrast-enhanced CT scan will have a positive finding on PET/CT scan [5]. [^{18}F]FDG-PET scans can be falsely positive in the setting of recent surgical resection or infection, and therefore, clinical correlation is vital when interpreting data from [^{18}F]FDG-PET scans.

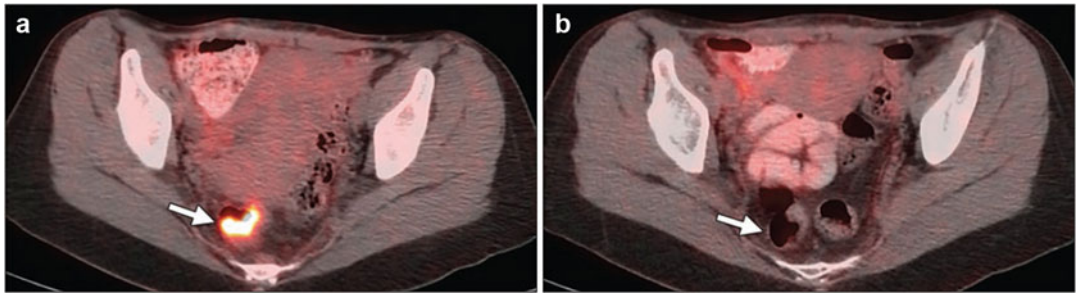

Fig. 2 [^{18}F]FDG PET/CT for initial staging and assessment of response to neoadjuvant therapy in 40-year-old woman with rectal adenocarcinoma. (**a**) Axial-fused PET/CT image obtained for initial staging shows metabolically active (standardized uptake value, 6.8) mass (*arrow*) in rectal wall. (**b**) Axial [^{18}F]FDG-PET/CT image obtained 3 months after staging PET/CT study (**a**) and after patient had undergone neoadjuvant chemotherapy shows lack of tracer uptake within rectal tumor (*arrow*), which suggests favorable response to therapy (Reprint with permission from Agarwal A. et al. FDG-PET-CT in the Management of Colorectal and Anal Cancers. AJR Am J Roentgenol. 2014, Fig. 2, p. 1116) [76]

In summary, PET/CT scans change the management choices in 30–40% of patients with colorectal liver metastases. The decision to obtain PET/CT scan preoperatively should be individualized. Patients with suspicious findings on contrast-enhanced CT or MRI or with extensive intrahepatic disease or those requiring extensive surgical resections with curative intent should be considered for an [^{18}F]FDG-PET scan.

b. Response to Therapies

Initial evidence supports the feasibility of PET scans in determining tumor response (Fig. 2). A study by Findlay et al. demonstrated that responsive lesions tend to grow slower at 5-week imaging intervals [6]. A recent meta-analysis of 15 studies with 867 patients demonstrated that a reduction in standardized uptake value (SUV) predicted overall survival. However, post-treatment SUV did not predict overall survival [7]. Additionally, [^{18}F]FDG-PET scans have been utilized increasingly to evaluate response to tumor-selective therapies such as radiofrequency or microwave ablation and selective radio- or trans-arterial chemoembolization.

[^{18}F]FDG-PET scans have the advantage of detecting metabolic response in a tumor that appears to be otherwise stable on cross-sectional imaging (Fig. 3). While several studies report the feasibility of this approach, whether a metabolic response is prognostic in these patients remains to be determined. Furthermore, neoadjuvant therapy lowers the sensitivity of [^{18}F]FDG-PET scans. A recent study reported a sensitivity of 65% for contrast-enhanced CT compared to 49% for [^{18}F]FDG-PET scan in detecting liver lesions after neoadjuvant chemotherapy [8]. For the same reason, there is no added value of [^{18}F]FDG-PET scan in detecting disappearing or vanishing liver metastases over a high-resolution contrast-enhanced CT or MRI.

c. Detecting Recurrence

Currently, National Comprehensive Cancer Network (NCCN) guidelines do not recommend routine use of PET/CT scans for surveillance, even in high-risk stage IV disease. This is likely the result of the lack of prospective studies that demonstrate the benefit of early detection of recurrence [9]. Theoretically, early detection would allow salvage curative resections, improving oncologic outcomes [10, 11]. A meta-analysis of 15 studies that included 510 patients demonstrated a 94% sensitivity and a 77.2% specificity of [^{18}F]FDG-PET scan in detecting recurrence for patients with rising CEA. This is more favorable than the sensitivity and specificity of contrast-enhanced CT scan at 51.3% and 90.2%, respectively [12], or that of plasma CEA levels alone, at 80% and 70%, respectively, in detecting recurrence [13]. Due to the unclear benefit of early

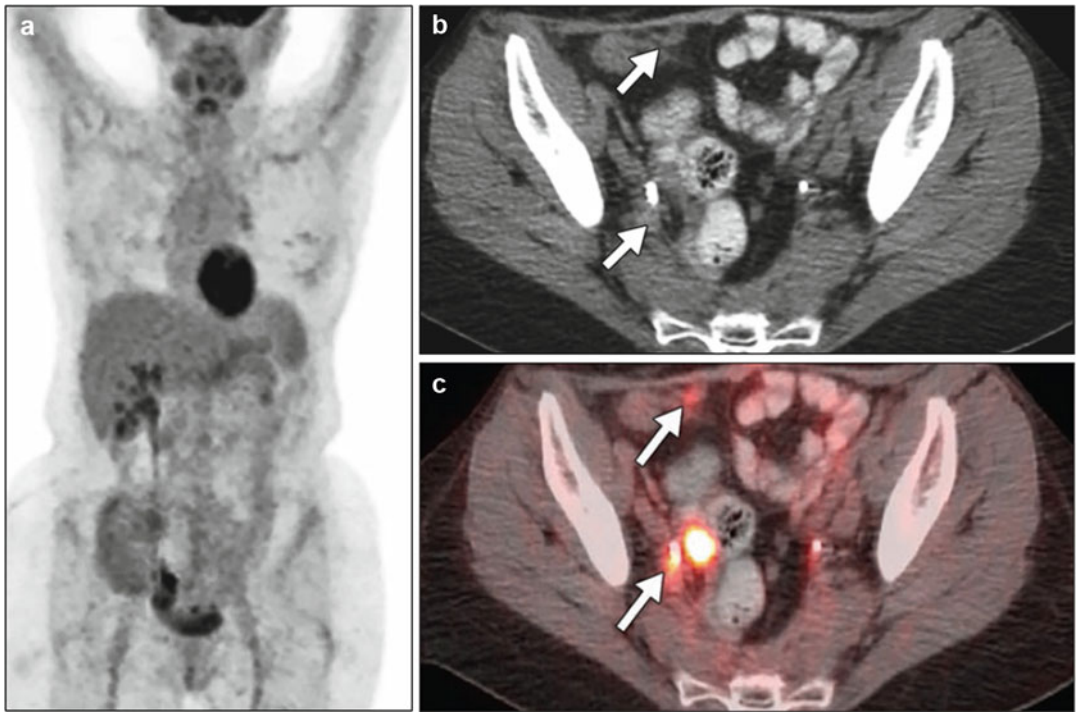

Fig. 3 Recurrence in 50-year-old woman with very low carcinoembryonic antigen (CEA) level who had undergone surgery and chemoradiation for treatment of adenocarcinoma of rectum. Patient underwent [^{18}F]FDG-PET/CT for restaging. (**a–c**) Anterior maximum intensity projection (**a**), axial CT (**b**), and fused PET/CT (**c**) images. Fused PET/CT image shows metabolically active (standardized uptake value, 10.02) malignant pelvic implants (*arrows*, **c**), whereas CT image shows ill-defined nonspecific soft tissue (*arrows*, **b**). CEA value at time of study was 1.8 ng/mL (Reprint with permission from Agarwal A. et al. FDG-PET-CT in the Management of Colorectal and Anal Cancers. AJR Am J Roentgenol. 2014, Fig. 5, p. 1117) [76]

detection on long-term survival and to the high cost of PET/CT scans, current consensus advises against the use of [^{18}F]FDG-PET scans for determining recurrence. However, an [^{18}F]FDG-PET scan should be considered in patients with continuously rising CEA over a 3-month interval with no visible disease on contrast-enhanced CT scan. We also consider [^{18}F]FDG-PET scan in CEA nonproducers who have suspicious findings for metastases on routine cross-sectional imaging.

Neuroendocrine Metastases

Neuroendocrine tumors (NETs) are rare with an incidence of 1.9–5.7 cases per 100,000 [14]. The majority of gastric, appendiceal, and rectal NETs are local. However, 65–95% of enteropancreatic NETs present with liver metastases [15, 16]. Liver metastases are the single most important prognostic determinant for patients with NETs. Morphologic combined with functional imaging plays an important role in diagnosis, determining resectability, and monitoring response to therapy and recurrence of liver metastases from NETs. However, the rarity of NETs makes it challenging to perform large prospective studies.

^{123}I-labeled noradrenalin analog metaiodobenzylguanidine (MIBG), ^{111}In-diethylenetriaminepentaacetic acid-octreotide somatostatin receptor scintigraphy (^{111}In-SRS), and [^{18}F]FDG-PET remain the most commonly used modalities for evaluating liver metastases from NETs. In a head-to-head comparison of the three modalities in a large prospective study of 96 patients, the overall sensitivity of ^{111}In-SRS, ^{123}I-MIBG scintigraphy, and [^{18}F]FDG-PET was 89%, 52%, and 58%,

respectively [17]. ^{111}In-SRS also exceeded ^{123}I-MIBG scintigraphy and [^{18}F]FDG-PET based on the number of lesions detected (393, 185, and 225, respectively). However, the sensitivity of [^{18}F]FDG-PET (92%) exceeded that of both ^{111}In-SRS (69%) and ^{123}I-MIBG scintigraphy (46%) for tumors with a proliferation index above 15%.

^{111}In-SRS relies on somatostatin receptor expression in NETs, which is seen in 60–90% of these tumors. Of these, 85% of NETs express somatostatin receptor subtype 2. There have been several attempts to improve on the ^{111}In-SRS introduced in 1990s, and the true benefit of these newer agents remains to be seen. Early experience with ^{68}Ga-labeled somatostatin analogues (DOTATOC, DOTATATE, or DOTANOC) suggests a lower cost and higher sensitivity in comparison to ^{111}In-SRS. Similarly, ^{64}Cu-DOTATATE somatostatin receptor scintigraphy was noted to be more sensitive than ^{111}In-SRS detecting additional lesions in 43% of the patients evaluated. Other radiotracers that have been used for functional imaging include ^{18}F-DOPA PET and [^{11}C]5-hydroxy-tryptophan ([^{11}C]5-HTP) PET. The role of these tracers and their comparative effectiveness remains to be studied [18].

In summary, we recommend that additional imaging should be strongly considered in patients with liver metastases from NETs on cross-sectional imaging to evaluate the true burden of disease and to determine resectability. ^{68}Ga-SRS appears to be more sensitive and cheaper than ^{111}In-SRS and should be utilized whenever available for low Ki67 (<15%) tumors. [^{18}F]FDG-PET should be preferred in evaluating tumors with high Ki67 (≥15%). Whether nuclear medicine imaging changes management over conventional morphologic imaging with high-resolution CT or MRI remains to be evaluated.

Primary Tumors

Hepatocellular Carcinoma

Hepatoma, also commonly referred to as hepatocellular carcinoma (HCC), is a neoplasm that arises from hepatic cells. Being one of the most common tumors worldwide, HCC is the fifth most frequent type of cancer, and it is the third most lethal [19, 20]. Due to the prevalence of hepatitis B or C infections in Asia compared to other world regions and to the expansion of hepatitis C infection in the USA, HCC cases are on the rise [21, 22]. Some patients with HCC still present normal liver function and may have a localized lesion when diagnosed; although those may be treated with partial resection, the 5-year survival rate is only 60–70% [23, 24]. Therapy for unresectable patients may require liver transplantation, although the majority of patients with HCC resort to nonoperative approaches, due to high-risk factors, including nonlocalized multiple intrahepatic lesions, extensive vascular invasion, or extrahepatic metastasis [25]. These therapeutic options include transcatheter arterial chemoembolization (TACE) and transcatheter arterial infusion chemotherapy (TAI) (Fig. 4).

Due to the complexity of HCC management, accurate staging of HCC is crucial in order to define treatment strategy. Conventional imaging modalities, including multiphase contrast-enhanced CT or MR imaging, are the current gold standard, with HCC tumors classically demonstrating late arterial enhancement with portal venous washout, obviating the need for tissue diagnosis. However, CT and MR scans frequently detect lesions that cannot be further defined, introducing uncertainty about the diagnosis or disease extent. Similarly, the therapeutic response of HCC to nonoperative therapy is usually assessed by conventional imaging modalities on the basis of changes in tumor size [26].

However, such criteria based on conventional imaging modalities have inherent limitation for accurate assessment of therapeutic response and tumor viability. Radiotracer imaging with or without concurrent high-resolution cross-sectional imaging provides a promising strategy to (i) improve our ability to detect subclinical disease, (ii) provide a functional insight into the behavior of tumors (i.e., glucose utilization), and (iii) probe molecular characteristics by utilizing targeted radiotracers. Each of these applications is reviewed below.

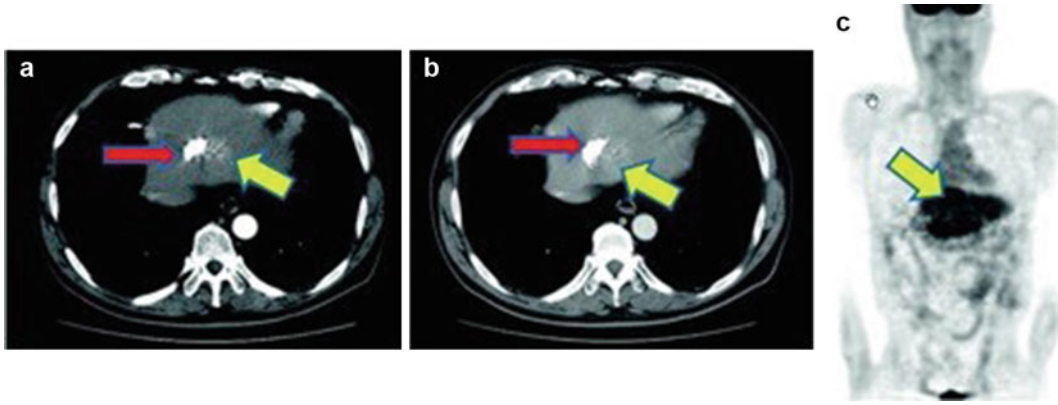

Fig. 4 A hepatoma recurrence after arterial chemoembolization. Contrast-enhanced CT at both arterial and portal phase shows a slight enhancement as suspected viable recurrent hepatoma, and a high [^{18}F]FDG accumulation is coincident with this stain (**a**–**c**; *large arrows*). [^{18}F]FDG-PET is to easily visualize viable hepatoma if the high-density area at CT image is difficult to distinguish with post-hemoembolized change (**a**, **b**; *small arrows*) [77]

a. 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG)
The most common and widely available radiotracer for imaging [^{18}F]FDG has been investigated in patients with hepatocellular carcinomas [27, 28]. While [^{18}F]FDG-PET is considered as a sensitive modality to assess tumor viability and tumor detection for a multitude of histologies, its ability to detect hepatocellular carcinoma lesions within the liver is low [28–33]. Relatively low [^{18}F]FDG accumulation in liver cells is due to the presence of cytosolic glucose-6-phosphatase (G-6-Pase) which converts [^{18}F]FDG-6-P back to [^{18}F]FDG, which allows the tracer to diffuse out of liver cells [34, 35]. Moreover, well-differentiated HCCs demonstrate similar metabolic characteristics as adjacent liver tissue, making it very difficult to identify tumor lesions within the liver (Figs. 5 and 6) [34–36].

At present, the use of [^{18}F]FDG-PET scans for routine local staging and surveillance is not recommended. The overall sensitivity of [^{18}F]FDG-PET/CT in detecting HCC within the liver suffers, with a reported range of 50–65%. For this reason, [^{18}F]FDG-PET has been determined to be insufficiently sensitive to diagnose primary HCC. A study by Khan et al. found that the sensitivity of [^{18}F]FDG-PET in the diagnosis of HCC was 55%, compared with 90% for contrast-enhanced CT [31]. Another report, by Wudel et al. involving one of the largest series of [^{18}F]FDG-PET for HCC ($n = 91$), reported that the sensitivity of [^{18}F]FDG-PET for detection of HCC was 64% [37]. To improve the sensitivity of [^{18}F]FDG-PET to detect HCC, investigators have suggested a 2–3-h delay between [^{18}F]FDG injection and imaging instead of the conventional 1-h delay between injection and imaging [38]. The delayed [^{18}F]FDG-PET may differentiate HCC lesions showing persistent [^{18}F]FDG uptake from normal liver tissue with gradual washout of [^{18}F]FDG [38].

Seminal work by Torizuka et al. demonstrated that [^{18}F]FDG uptake in HCC directly correlates with the degree of differentiation of these tumors, with higher grade tumors demonstrating on average a twofold uptake increase compared to low-grade tumors [39]. Further, a recent study demonstrated that SUV ratios (SUV ratio of hepatoma to adjacent liver) directly correlates with tumor doubling time, providing important prognostic information that allows prediction of overall survival when adjusted for tumor size [40]. The role of [^{18}F]FDG-PET scans as a component of clinical prognostication tool remains to be further tested and validated.

With growing experience in the utilization of [^{18}F]FDG-PET scans in patients with HCC, another application has come to light. Limited, small sample studies demonstrate the superiority

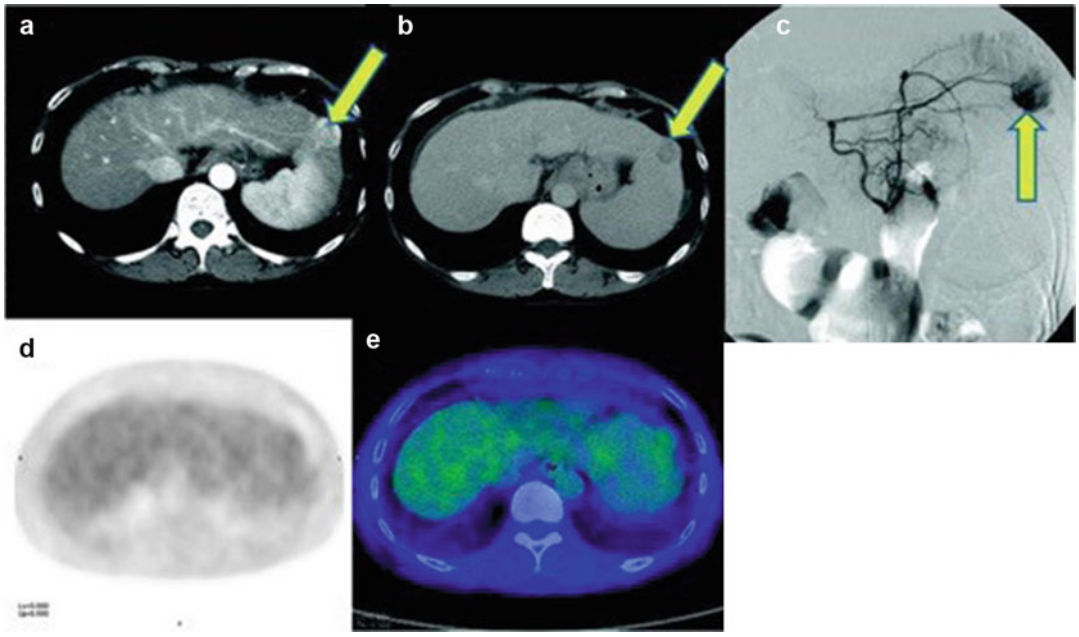

Fig. 5 *Normoglycolytic hepatoma*. Multiphase contrast-enhanced CT shows a tumor lesion, which has rich arterial perfusion but poor portal perfusion in left lobe (**a**, **b**; *yellow arrows*). Arterial angiography also shows early intense stain at same point (**c**; *yellow arrow*). These findings mean a typical classical hepatoma. However, PET/CT images do show only a normal [^{18}F]FDG accumulation on hepatoma (**d**, **e**) [77]

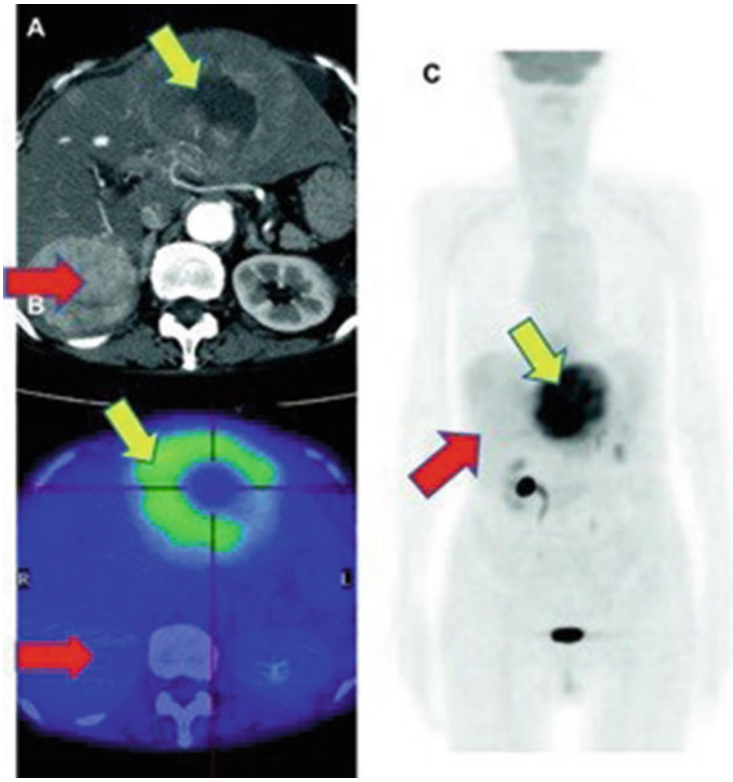

Fig. 6 *Synchronous double hepatomas*. Contrast-enhanced CT at arterial phase showed two of intrahepatic tumors. The heterogeneously stained tumor in the left lobe shows intense but heterogeneous accumulation of [^{18}F]FDG (**a**–**c**; *yellow arrows*). The other homogenously stained tumor in the right lobe shows [^{18}F]FDG normoaccumulation (**a**–**c**; *red arrows*). Both tumors were biopsied and proved that left-lobe hepatoma was poorly differentiated, but right-lobe one was well differentiated [77]

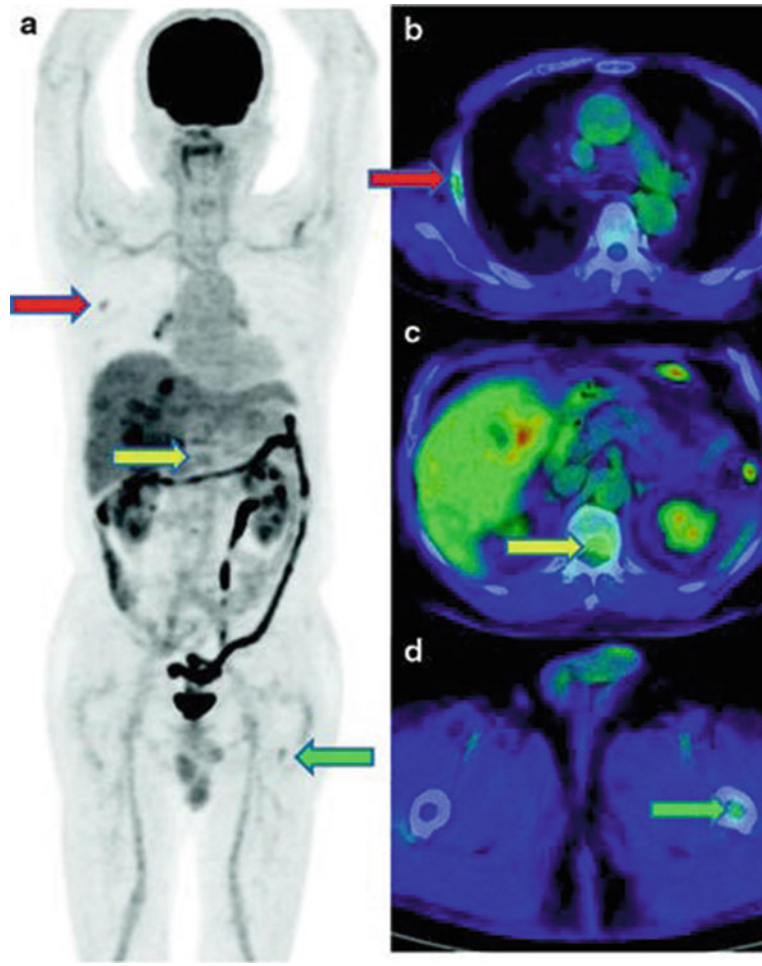

Fig. 7 *Multiple osseous metastases*. Slight [^{18}F]FDG accumulations are shown at the right thorax (**a**; *red arrow*), back (**a**; *yellow arrow*), and left femur (**c**; *green arrow*) on PET image. Fusion images disclose that these are, respectively, costal (**b**; *red arrow*), vertebral (**c**; *yellow arrow*), and femoral (**d**; *green arrow*) bone metastasis [77]

of detecting extrahepatic metastases with [^{18}F]FDG-PET scans in comparison to conventional MRI or CT (Figs. 7 and 8) [41]. In one study, 24 out of 87 patients with HCC had extrahepatic disease detectable by [^{18}F]FDG-PET [42]. Extrahepatic metastases in 10 out of the 24 patients were missed on conventional CT and MRI scans. The higher sensitivity of the [^{18}F]FDG-PET scan to detect metastatic disease versus localized disease is largely attributable to the higher grade of metastatic lesions. In particular, [^{18}F]FDG-PET scans are by far superior in the detection of bone metastases from HCC (sensitivity 83.3%, specificity 86.1%), in comparison to CT scan (sensitivity 41.6%, specificity 94.5%) and bone scintigraphy (sensitivity 52.7%, specificity 83.3%) [43].

Accurate assessment of treatment monitoring and outcome is another important role of [^{18}F]FDG-PET [29, 39, 44–46]. When the [^{18}F]FDG uptake in the lesion was higher or similar to the activity in the surrounding tissue, the presence of residual tumor was seen on histological confirmation. On the other hand, reduced [^{18}F]FDG uptake in the lesion makes it unlikely that there is residual tumor after TACE treatment [47, 48]. Similar findings have been reported in detecting local tumor progression following radiofrequency ablation of HCC. Kim et al. reported that, in HCC patients treated with

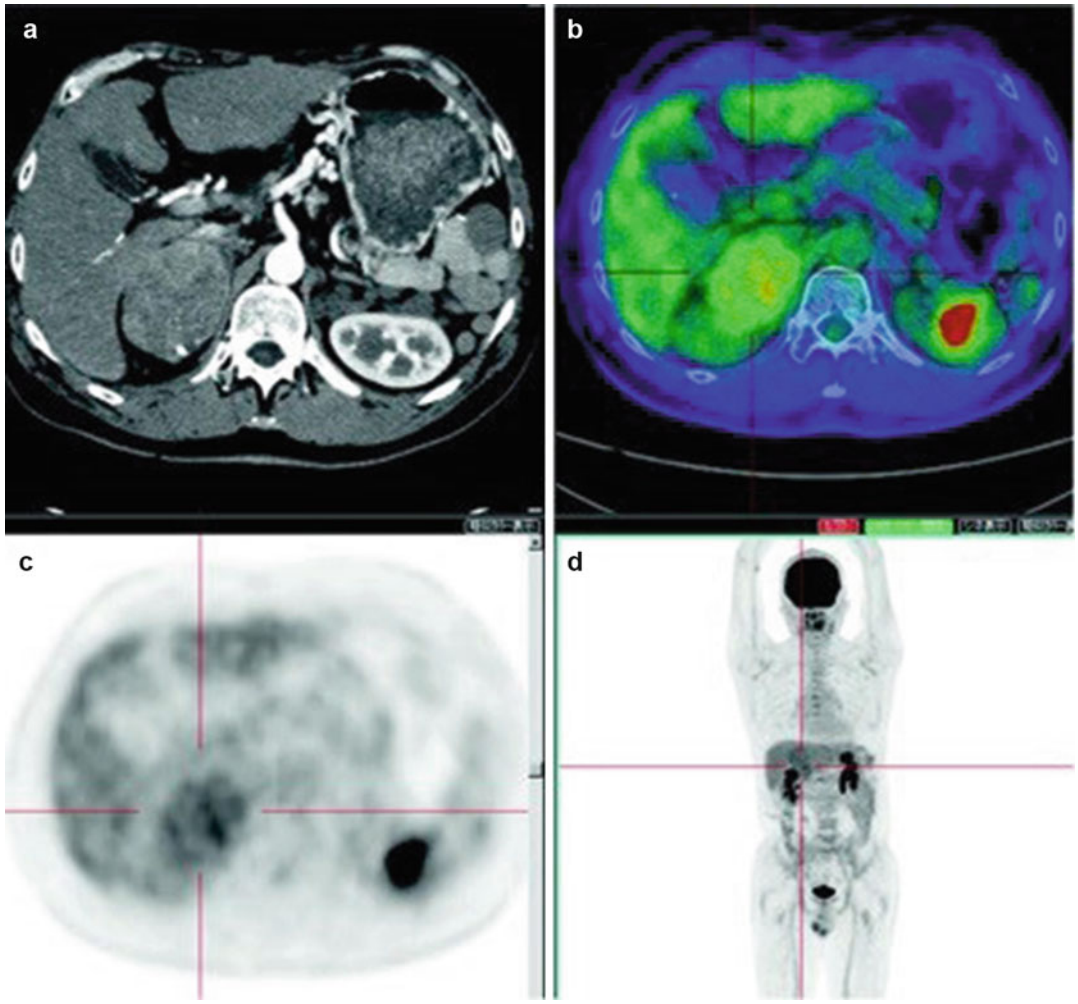

Fig. 8 *An adrenal metastasis of hepatoma*. A male with history of HCC therapy with AFP elevation but no intrahepatic recurrence. Contrast-enhanced CT at arterial phase shows early enhance on right enlarged adrenal gland (**a**). [^{18}F]FDG-PET/CT shows moderate hyperglycolysis at adrenal gland, so resection of this tumor disclosed metastatic hepatoma of adrenal gland (**b**). [^{18}F]FDG accumulation is slight and heterogeneous as well as general findings of hepatoma on PET (**c**, **d**) [77]

chemoradiation therapy, low [^{18}F]FDG uptake was associated with longer progression-free survival (PFS) and overall survival (OS) and that the high [^{18}F]FDG uptake group was more likely to have extrahepatic metastasis within 6 months [49].

b. [^{11}C]Acetate

To overcome the limited uptake and retention of [^{18}F]FDG in well-differentiated HCCs within the liver parenchyma, alternative radiotracers have been used. One such agent, [^{11}C]acetate, has been widely investigated with or without [^{18}F]FDG. Acetate, or acetic acid, is a molecule quickly picked up by cells and converted into acetyl-CoA by acetyl-CoA synthetase [50]. Acetyl-CoA feeds into the tricarboxylic acid cycle and it is utilized for cellular energy production. Alternatively, acetyl-CoA is an important substrate of anabolic pathways that lead to the synthesis of cholesterol, fatty acids, or amino acids. Tumor cells that overexpress fatty acid

synthetase or acetyl-CoA carboxylase generate [^{11}C]-labeled fatty acids and cholesterol, which are rapidly incorporated into the tumor cell membranes allowing for detection of tumor using [^{11}C]acetate-PET scans [50].

One of the first studies utilizing [^{11}C]acetate-PET scans in detecting HCC within the liver by Ho et al. included 39 patients with HCC [51]. Concurrent [^{18}F]FDG-PET scans were performed for comparison. Dual radiotracer imaging proved to be complimentary with a sensitivity of 98% and specificity of 86%. Well-differentiated lesions preferentially accumulate [^{11}C]acetate, whereas poorly differentiated lesions accumulate [^{18}F]FDG. A similar but considerably prospective study by Park et al. incorporated patients with localized as well as distant disease (n=90) [52]. [^{11}C]Acetate-PET offered superior sensitivity (75.4%) compared to [^{18}F]FDG-PET (60.9%). Dual-tracer imaging had a combined sensitivity of 82.7%. Of note, the ability to detect lesions by dual-tracer imaging is highly dependent on tumor size. For instance, tumors less than 2 cm are detected with a sensitivity of ~30% by combined radiotracer imaging.

The use of [^{11}C]acetate-PET in determining response to treatment remains to be studied. A feasibility study of [^{11}C]acetate in the monitoring of treatment response following Radiotherapy in patients with hepatocellular carcinoma is currently underway (NCT02549755). In conclusion, the early experience with dual-tracer PET imaging is very encouraging. More studies are needed to determine the utility of this modality in diagnosis, staging, surveillance, and response to therapy.

c. Tracers in Development

Targeted radiotracers hold the promise of enhanced sensitivity and specificity. Additionally, next-generation radiotracers could provide functional insight into the behavior of HCCs. This information can be crucial in selecting therapies as well as in assessing response to therapies. A recent study evaluated glypican 3-targeted [^{89}Zr] PET imaging for HCC [53]. Glypican 3 is expressed on the cell surface of up to 80% of HCCs, making it a suitable imaging target. Using this immune probe, tumors as small as 1 mm could be accurately identified in small animal studies with excellent specificity. Another study demonstrated that mouse extrahepatic hepatoma could be visualized by PET using copper-64 chloride as a tracer, based on increased copper uptake mediated by mouse copper transporter 1 (mCtr1). There was relatively less ^{64}Cu uptake in the hepatoma compared to the liver due to the presence of mCtr1 in normal liver cells. Choline is one of the components of phosphatidylcholine, an essential element of phospholipids in the cell membrane. HCC has significantly higher choline content than normal liver tissue. A prospective study aimed to compare the diagnostic performance of ^{18}F-fluorocholine and [^{18}F]FDG for detecting and staging hepatocellular carcinoma (HCC) in patients with chronic liver disease and suspected liver nodules [54]. This study demonstrated that ^{18}F-fluorocholine was significantly more sensitive (94%) than [^{18}F]FDG (59%) at detecting HCC, particularly in well-differentiated forms. The combined modality was thought to be superior.

In conclusion, [^{18}F]FDG-PET scan is inferior to multiphase CT or MRI in assessing true burden of hepatic disease. Liver HCC lesions that appear [^{18}F]FDG-avid tend to be poorly differentiated. Further, [^{18}F]FDG-PET can be considered in ruling out extrahepatic disease in patients undergoing transplantation or in analyzing burden of disease prior to systemic therapies. [^{11}C]Acetate scans are complimentary to [^{18}F]FDG-PET scans, and dual-tracer PET scans are expected to be more widely adapted in clinical practice as clinical experience accumulates. Development of targeted and functional radiotracers in proof-of-concept studies highlights the potential of these agents as promising tools in treatment of hepatocellular carcinomas.

Cholangiocarcinoma

Cholangiocarcinoma is a neoplasm that arises from cholangiocytes, the epithelial cells lining

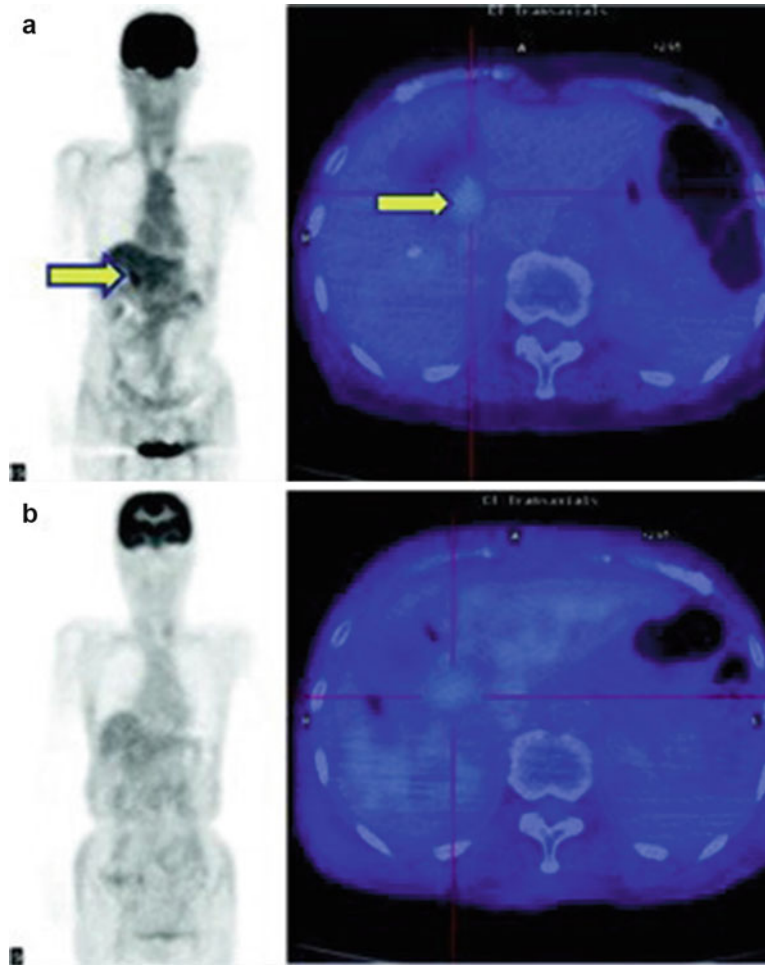

Fig. 9 Therapy monitor imaging of unresectable Klatskin tumor. [^{18}F]FDG abnormally accumulates primary tumor at hepatic hilum (**a**, **b**; *yellow arrows*). After external radiation (44 Gy) and brachytherapy (12 Gy) with concurrent hepatic arterial infusion (AI) together, [^{18}F]FDG accumulation became indistinct [77]

the bile ducts. The majority of lesions are adenocarcinoma. Carcinoma of the extrahepatic biliary tract is defined by the location of the tumor into Klatskin (hilar) tumor (Fig. 9), hepatic bile duct, common bile duct tumor, gallbladder cancer, and ampulla of Vater cancer [55]. Histopathological characterization of extrahepatic biliary cancer divides lesions into moderately differentiated, poorly differentiated, or undifferentiated adenocarcinoma [56]. Carcinoma of extrahepatic biliary tract is histopathologically divided into mass-forming (nodular), periductal-infiltrating (sclerosing), and intraductal (papillary) type (Fig. 10) [56]. These histopathological difference classifications give a great deal of influences at the situation using the radiological diagnosis. Although mass-forming types show vertical progression, while periductal-infiltrating lesions show horizontal progression, both of them progress invasively into surrounding structures. However, intraductal type including mucin-producing tumor progresses horizontally but noninvasively (Figs. 9 and 10) [56, 57].

In the USA, it is estimated that there have been 9760 new cases of cholangiocarcinoma in 2010 and 3320 deaths (ACS Cancer Facts 2010). Its incidence is annually 1–2 per 100,000 in the western world [58]. This rate is rising around the world, while in Japan the rate is decreasing in the twenty-first century. The annual number of deaths due to extrahepatic biliary cancer was

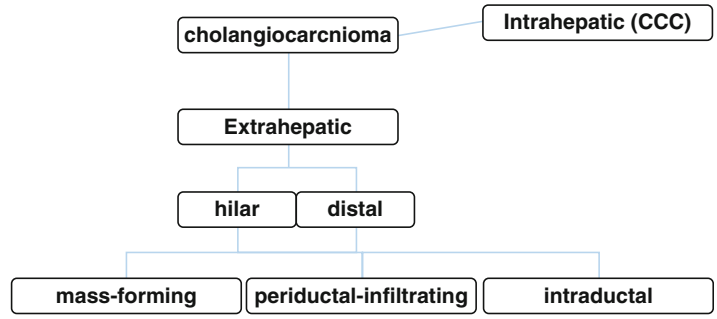

Fig. 10 Classification of cholangiocarcinoma [77]

about 3600 people in the USA. Statistics show that the 60s are the most frequent age, and the frequency in men is about twice than in women. Several known risk factors are described for cholangiocarcinoma, including primary sclerosing cholangitis [PSC, often associated with ulcerative colitis], Caroli's congenital abnormalities of the biliary tree (Caroli's disease syndrome, congenital hepatic fibrosis, and choledochal cysts), parasitic biliary infection (e.g., liver fluke, *Clonorchis*), and chronic typhoid fever [59]. It is thought that a long-term inflammation of the biliary tract or abnormal choledocholithiasis influences carcinogenesis, but there are a lot of unknown molecular carcinogenic processes [60].

The first clinical symptom is often painless jaundice, sometimes accompanied by pruritus, weight loss, and fever. Abdominal pain may occur in 30–50% of patients. Patients often have advanced disease at the time of diagnosis. In general, cholangiocarcinoma have a poor prognosis because complete resection is the only curative treatment. The 5-year survival rate after curative resection is still low (26–51%) [61]. For unresectable disease, chemotherapy with gemcitabine and cisplatin provides marginal benefit in overall survival [62].

Patients with cholangiocarcinoma typically present with painless jaundice that prompts an ultrasound (US) of the liver. Biliary dilation and elevated bilirubin necessitates multimodality imaging with endoscopic retrograde cholangiography, endoscopic US, and high-resolution triple-phase (arterial, venous, and delayed venous) contrast-enhanced cross-sectional imaging (CT or MRI). This provides adequate information to assess resectability of cholangiocarcinoma. Pathologic diagnosis is based on brushings and cytology. Often, surgical resection is warranted based on imaging findings in the absence of tissue diagnosis.

The role of [^{18}F]FDG-PET scan for imaging of biliary cancers is evolving (Figs. 11, 12, 13, and 14). Small, mostly retrospective series report a sensitivity ranging 91–95% for intrahepatic cholangiocarcinoma and 55–83% for extrahepatic cholangiocarcinoma [63–66]. Further, the diagnostic accuracy is higher for larger mass-forming lesions than periductal-infiltrating tumors. For instance, Anderson et al. reported that mass-forming or intraductally progressive (volume) type showed a higher proportion of patients with [^{18}F]FDG accumulation (17/20 patients) compared to the periductal-infiltrating (thin) type, which was found to be [^{18}F]FDG-positive in only 2/11 patients [63].

Obstructive jaundice typically leads to bactibilia, and some degree of cholangitis is usually present [57]. The utility of [^{18}F]FDG-PET scan is therefore limited by the high positive rates in the setting of acute cholangitis. It is also important to distinguish biliary cancer from autoimmune IgG_4-related cholangitis. As such, IgG_4-related disease is characterized by high serum IgG_4 concentrations and sclerosing inflammation (involving the parotid gland, pancreas, bile duct, and so on) with numerous IgG_4-positive plasma cells. However, [^{18}F]FDG-PET cannot help distinguish the two entities as autoimmune IgG_4-related cholangitis readily accumulates [^{18}F]FDG as well (Fig. 15). Involvement of multiple organs and elevated serum IgG_4

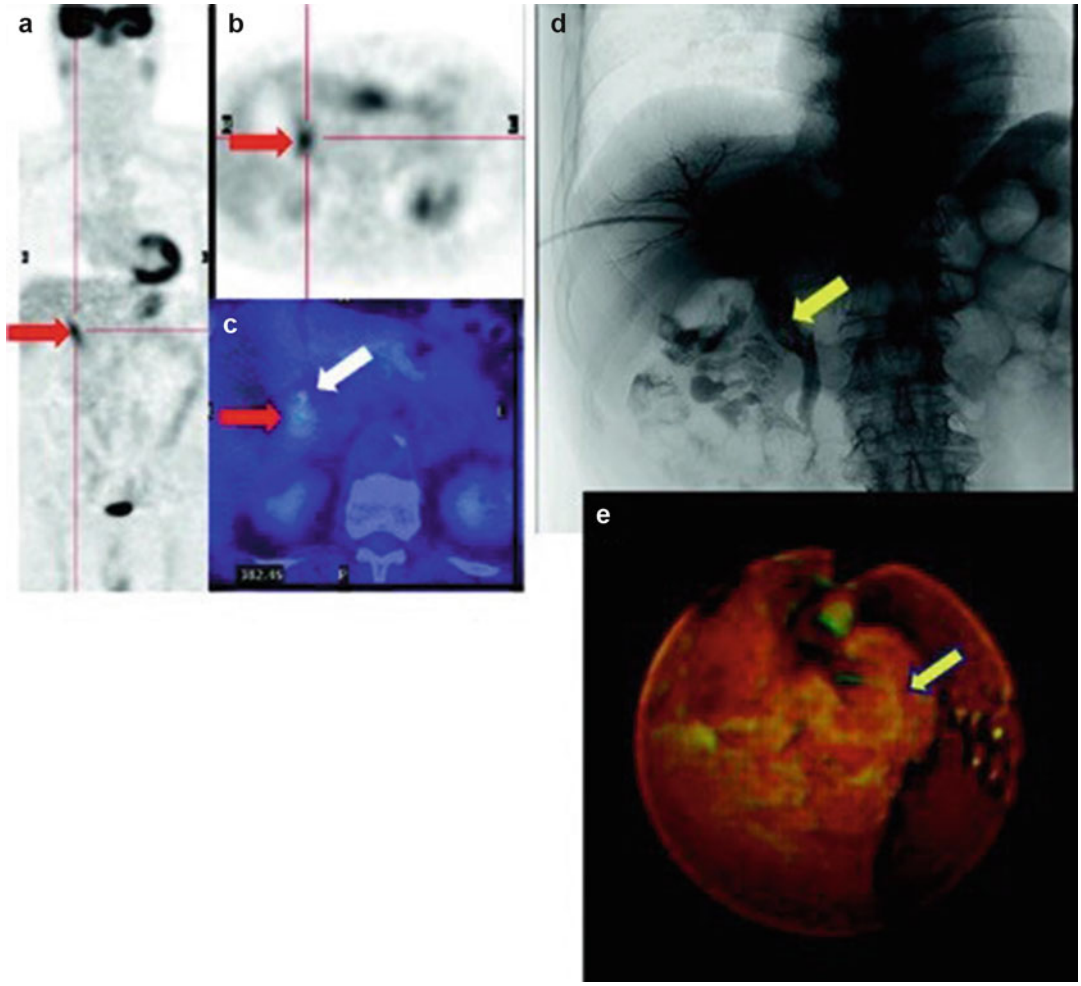

Fig. 11 Pretherapeutic extrahepatic bile duct (common bile duct) cancer. [^{18}F]FDG abnormally accumulates in the common bile duct (**a**–**c**; *red arrows*). And fusion image clearly discloses a local relationship between tumor and replaced drainage tube (**c**; *white arrow*). Cholangiography shows a filling defect on the dilated common bile duct (**d**; *yellow arrow*), and PTCS finding is mass-forming tumor (**e**; *yellow arrow*) [77]

should raise suspicion for autoimmune cholangitis rather than cholangiocarcinoma. Definitive diagnosis is only possible after surgical resection.

a. Preoperative Staging and Resectability
   Kim et al. analyzed their experience with 94 cholangiocarcinoma cases [65]. They reported a sensitivity of 95% for [^{18}F]FDG-PET/CT versus 100% for MRI/MRCP. High-resolution cross-sectional imaging provides vital information on the relationship of the tumor to the porta hepatic vasculature, allowing accurate assessment of resectability. [^{18}F]FDG-PET scan does not improve on this assessment given its low resolution. Accurate diagnosis of lymph node involvement is of clinical value for accurate staging in each patient. Again, [^{18}F]FDG-PET may have limited value for this purpose due to limited spatial resolution. One of the major limitations is that lymph node involvement is mainly seen in the adjacent areas of the primary tumor, therefore making it rather difficult to separate the lymph node lesion, without the use of PET/CT from the primary lesion by relatively low-resolution PET. In addition, it is rather difficult to

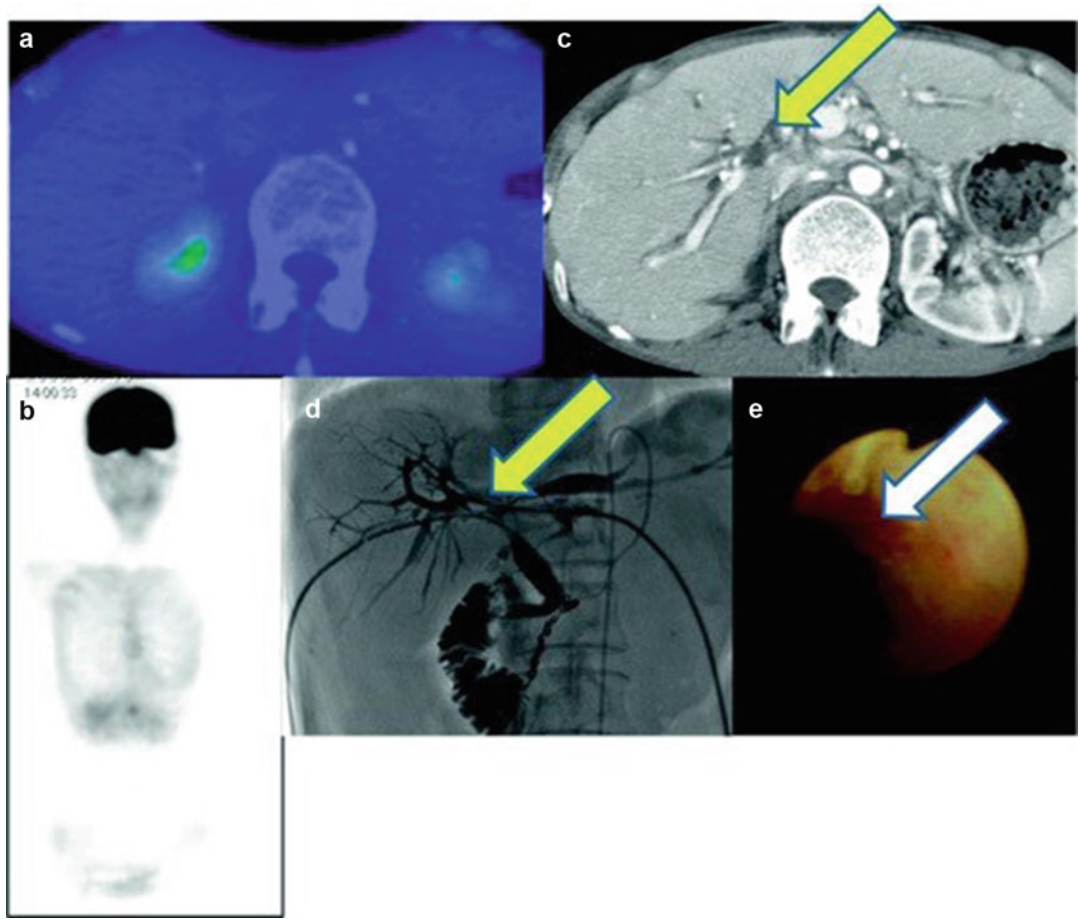

Fig. 12 Pretherapeutic Klatskin tumor. PET/CT does not show abnormal [^{18}F]FDG accumulation (**a**, **b**). Contrast-enhanced CT and cholangiography shows multiple filling defects (**c**, **d**; *yellow arrows*) because of tumor in hilum. PTCS shows focal mucosal redness (**e**; *white arrow*). Biopsy specimen proved periductal-infiltrating-type adenocarcinoma [77]

differentiate malignant invasion from the accompanied benign inflammatory lesions, which are often seen in biliary tracts. On the other hand, [^{18}F]FDG-PET has a high diagnostic value for detecting distant lymph node involvement, where previous reports showed a wide range of sensitivity (12–50%), specificity (80–100%), and overall accuracy (69–77%) [67]. However, among those, the relatively high specificity may prove to be of clinical value in identifying distant nodal involvement, as these patients are unlikely to benefit from aggressive surgical resection. It is estimated that [^{18}F]FDG-PET scans change patient management in 16–30% of patients with cholangiocarcinoma.

b. Detection of Recurrence

Patients with cholangiocarcinomas are currently evaluated by contrast-enhanced cross-sectional imaging for surveillance. A recent multicenter retrospective study in 50 patients with posttreatment surveillance of biliary cancer in Japan indicated that [^{18}F]FDG-PET provided high sensitivity (86%), specificity (91%), and overall accuracy (88%) for detecting tumor recurrence [68]. In addition, the [^{18}F]FDG-PET findings resulted in a change in management of 10 of the 50 patients

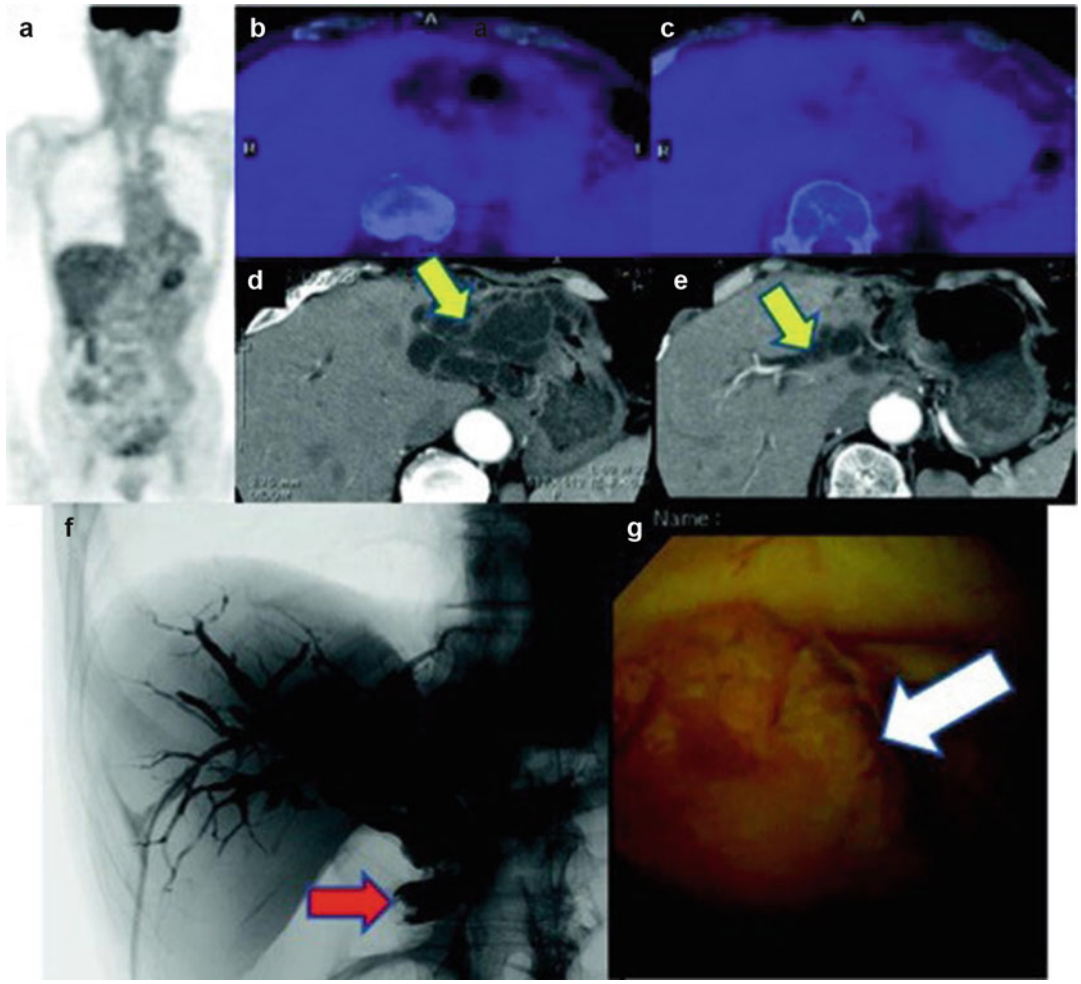

Fig. 13 Mucin-producing extrahepatic bile duct tumor. PET/CT does not show abnormal [^{18}F]FDG accumulation (**a**–**c**). Contrast-enhanced CT shows bile duct dilatation in bilateral lobe (**d**, **e**; *yellow arrows*). Cholangiography shows extra- and intrahepatic biliary dilatation and filling defect at lower common bile duct (**f**; *red arrow*). PTCS shows focal mucosal redness (**g**; *white arrow*). Biopsy specimen proved papillary-type, mucin-producing adenocarcinoma [77]

(20%) by initiating an unplanned treatment strategy ($n = 7$), by obviating the need for planned diagnostic procedures ($n = 2$), and by changing the treatment planning ($n = 1$) [68]. These multicenter studies confirmed the value of PET in patients with bile duct cancer after operation.

c. Risk Stratification

There are a number of established criteria for assessing prognosis of patients with bile duct cancer, including tumor histology and staging. Most of criteria may come from the findings during or after operation. PET and PET/CT may have a potential for selecting high-risk patients on the basis of tissue characterization. Furukawa et al. studied 69 patients with bile duct cancer [69]. These investigators found the [^{18}F]FDG uptake as a significant prognostic indicator. Those with SUV_{max} of higher than 6.3 on [^{18}F]FDG-PET were in the poor prognostic group, with a 3-year survival rate of 44.1%, whereas those with SUV_{max} of 6.3 or

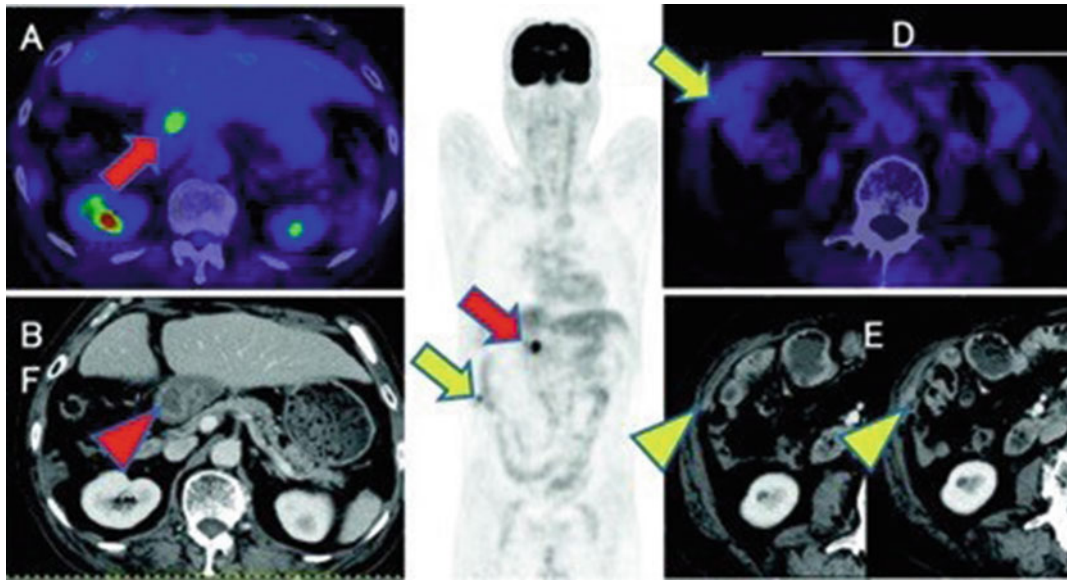

Fig. 14 Postoperative common bile duct cancer patient with CA19–9 elevation. Abnormal [^{18}F]FDG accumulations are shown at hepatic hilum (**a**, **c**; *red arrows*) and intra-abdominal space (**c**, **d**; *yellow arrows*). So these are highly suspected recurrent lesions including local recurrence and peritoneal dissemination. Coincidently, contrast-enhanced CT shows choledochojejunostomized wall (**b**; *red arrowhead*) and peritoneal small and increasing enhanced nodule (**e**, **f**; *yellow arrowheads*). But it is difficult to differentiate anastomosis and recurrence [77]

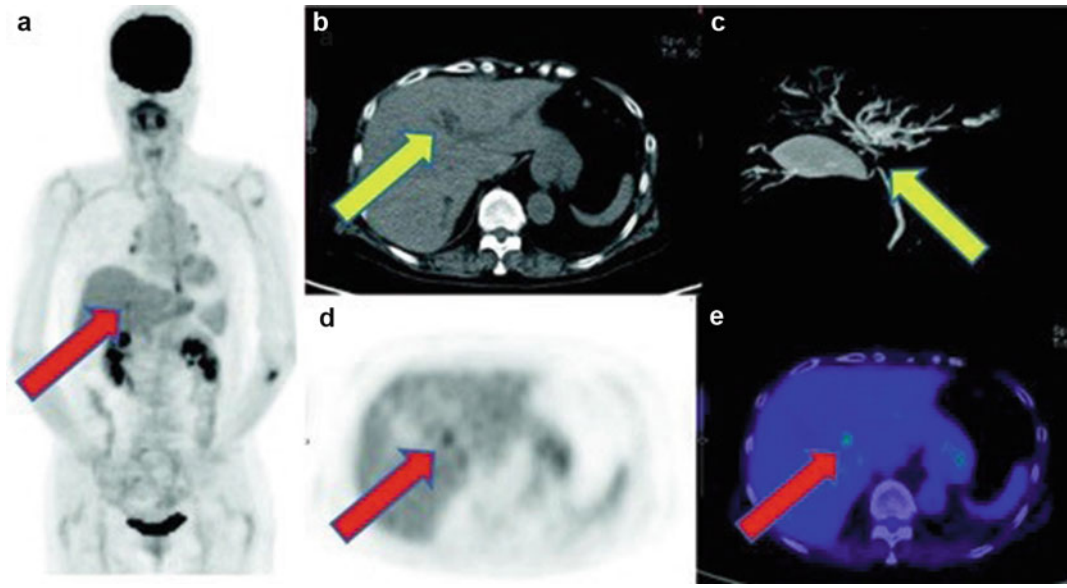

Fig. 15 IgG_4-related sclerosing cholangitis. Non-contrast CT and MRCP show intrahepatic bile duct dilatation due to hepatic hilar severe stenosis (**b**, **c**; *yellow arrows*). [^{18}F] FDG accumulates on the point of hepatic hilum (**a**, **d**, **e**; *red arrows*). But biopsy specimen proved no carcinoma cell but sclerosis cholangitis with plasmacyte and lymphocyte infiltration. His serum IgG_4 level was so high that IgG_4-related disease was confirmed [77]

less on [^{18}F]FDG-PET were in the better prognostic group, with a 3-year survival rate of 74.3% ($P = 0.012$). Kitamura et al. studied 73 patients with extrahepatic bile duct cancers to show SUV_{max} value of 5.7 as a significant cutoff point to differentiate poor prognosis from good prognosis subgroups [70]. They showed [^{18}F]FDG uptake value as an independent significant prognostic indicator on multivariate analysis.

Gallbladder Carcinoma

Gallbladder cancer (GBC) is a rare neoplasm that arises from the mucosal lining of the gallbladder. The American Cancer Society estimates approximately 10,000 cases of biliary origin cancers are diagnosed each year. Half of these originate in the gallbladder. Chronic inflammation is thought to be the main etiology in a majority of patients. For instance, the presence of gallstones increases the risk of GBC up to fivefold and predates the development of GBC in 75% of patients. Other causes of chronic inflammation predisposing to GBC can be autoimmune, i.e., primary sclerosing cholangitis and ulcerative colitis, or infectious, i.e., *Salmonella typhi* and *S. paratyphi*, liver flukes, and *Helicobacter pylori*. Genetic factors that may contribute are under active investigation. This hypothesis is based in the observation that the incidence of GBC is increased in certain genetic syndromes such as Gardner syndrome, neurofibromatosis type 1, and hereditary nonpolyposis colon cancer. The incidence of GBC in the USA has been decreasing since 1973. Internationally, a high incidence of GBC is noted in South America (Chile, Columbia, Peru, Bolivia, and Ecuador), South Asia (India), and East Asia (Korea and Japan).

Symptomatology occurs late in the course of the disease. Approximately 50% of patients have nodal disease at diagnosis. Increasingly, patients are incidentally discovered to have gallbladder cancer after a "routine" cholecystectomy for biliary colic or acute cholecystitis. Surgical resection is the only potentially curative treatment. Extent of surgical resection and resectability depends on accurate radiologic staging. A high-quality, contrast-enhanced cross-sectional imaging modality (CT or MRI) is the current standard. The role of PET scan is not clearly established for GBC and is not routinely recommended in the USA. However, mounting evidence from small studies may change this recommendation. The accuracy and utility of [^{18}F]FDG-PET in detecting regional and distant metastases in an otherwise resectable patient is discussed below. In addition, we discuss the role of [^{18}F]FDG-PET in the management of recurrent disease and the novel approaches being developed.

Preoperative PET/CT scans have been evaluated through small institutional experiences. The majority of these studies combine patients with GBC and cholangiocarcinoma, making it difficult to draw meaningful conclusions (Fig. 16). Butte et al. investigated 32 patients with incidental GBC following laparoscopic cholecystectomy [71]. While 13 patients had negative PET/CT results, 9 refused further resection, and only 1 of the 4 patients was resected, having residual disease on operative exploration. PET/CT changed management in 12 out of 32 patients (38%) demonstrating unexpected disseminated disease in 10 patients and localized resectable disease in 2 patients. Corvera et al. studied 31 patients with gallbladder cancer within their published series [66]. They demonstrated a sensitivity of 86% and a specificity of 50% for detection of the primary tumor, and a sensitivity of 87% and specificity of 89% for detection of nodal/distant disease, respectively. This resulted in a change in treatment for seven (23%) patients.

Shukla et al. evaluated the role of PET/CT in 24 patients with incidental gallbladder cancer prior to radical resection [72]. They demonstrated that PET/CT predicted resectability with a sensitivity of 100% but was not significantly superior to conventional CT. PET/CT demonstrated residual disease with a sensitivity of 28.5% and with a specificity of 80.9%. These results may have changed clinical management for two patients. One of the largest series analyzed data from 100 patients at a single institution [73]. Sixty-three patients were incidentally discovered to have GBC. In 73 patients, the PET/CT was concordant with contrast-enhanced imaging and did

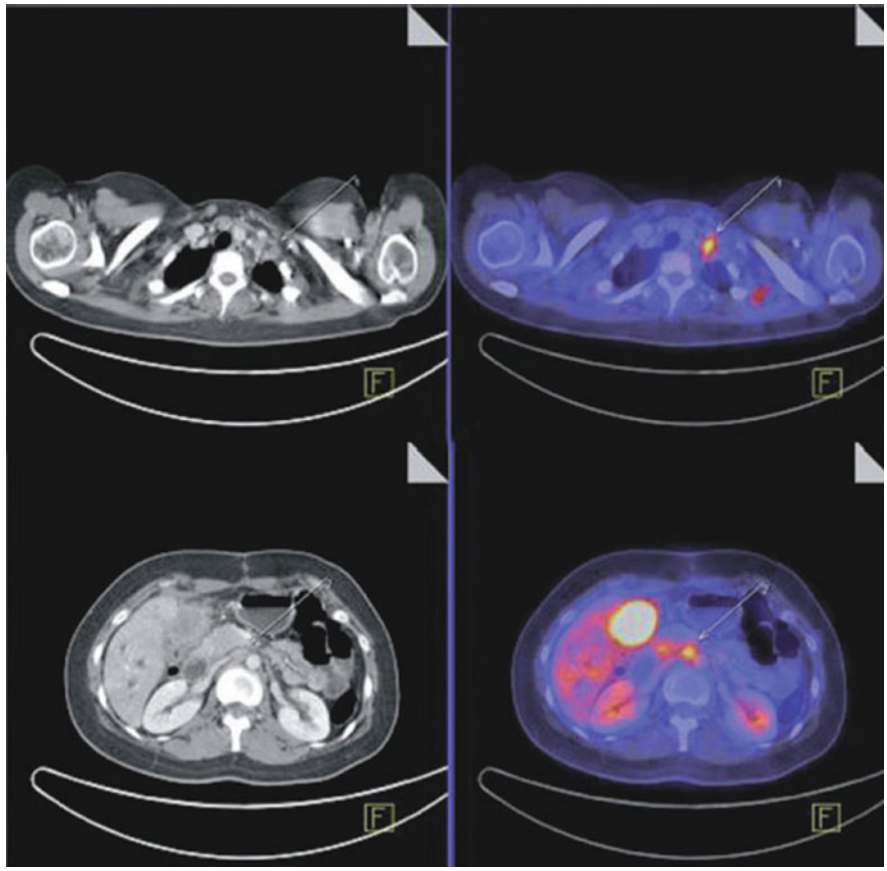

Fig. 16 An example of an [^{18}F]FDG PET/CT which showed evidence (positive finding) of disseminated disease (*arrow*) in a patient who was diagnosed with an incidental gallbladder carcinoma after cholecystectomy (Reprint with permission from Butte JM. et al. The role of PET/CT in patients with incidental gallbladder cancer. HPB. 2009, Fig. 3, p. 588) [71]

not add any information. In 3 patients, PET/CT detected metastatic disease not suspected on contrast-enhanced CT alone. In 12 patients, the CT scan was suspicious for locally advanced disease, and PET/CT helped confirm distant nodal disease (11 patients) or T4 disease (1 patient). Further, in two patients, CT was suspicious for distant metastases, but PET/CT ruled out that possibility, changing treatment choice. Taken together, PET/CT changed decision-making for 17 patients (17%). Improvement in conventional imaging has mitigated the benefit of PET/CT scans in recent years, with older studies reporting a higher proportion of patients where PET/CT appeared to change decision-making. The sensitivity of PET/CT in detecting distant metastases is 57%. This poor sensitivity is mainly because peritoneal disease tends to be less [^{18}F]FDG-avid (sensitivity 28%) versus nodal disease (70%). Given these results, routine preoperative [^{18}F]FDG-PET/CT is not recommended. A PET/CT scan may help prevent a potentially morbid operation in patients with suspicious nodal or distant lesions on cross-sectional imaging. False-positive result in these patients is thought to be low (specificity ~97–100%). Nonetheless, it must be kept in mind that equivocal or unexpected PET findings may prompt additional biopsies.

Kumar et al. evaluated the role of PET/CT in detecting recurrent GBC in 49 patients [74]. These investigators demonstrated a sensitivity and specificity of 97.6% and 90%, respectively, for

detecting recurrent disease. PET/CT was shown to be more specific than conventional imaging (100% vs. 50%) and resulted in a change in management for five patients (20%). More studies are needed to establish the role of PET/CT in recurrent GBC. The cost and resource utilization of unnecessary biopsies for false-positive findings needs to be investigated further.

In conclusion, [^{18}F]FDG-PET appears to be complimentary rather than definitive in many patients with GBC, and its role is limited in patients with negative CT/MRI and T1 disease. While the routine use of PET/CT in GBC is probably not cost effective, we believe that PET should be used when there are suspicious findings on CT/MRI, such as large tumors or questionable nodes. [^{18}F]FDG PET/CT should not be the imaging modality of choice when peritoneal-only disease is suspected as the sensitivity is low. Diagnostic laparoscopy has a higher yield in these patients.

Diagnostic Applications of Nuclear Medicine: Pancreatic Cancer

27

Elena Tabacchi, Cristina Nanni, Irene Bossert, Anna Margherita Maffione, and Stefano Fanti

Abstract

Pancreatic cancer can be assessed through a variety of imaging techniques including endoscopic ultrasonography (EUS), computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP), magnetic resonance imaging (MRI), and magnetic resonance cholangiopancreatography (MRCP).

These imaging modalities are often effective in the evaluation of pancreatic cancers although sometimes they require the use of radiopharmaceuticals with positron and single-photon emission CT (PET and SPECT) imaging techniques. In this chapter the role of nuclear medicine with various radiolabeled compounds and the rationale for their use in endocrine and nonendocrine pancreatic tumors are discussed.

Keywords

Pancreatic cancer • Neuroendocrine tumor • Gastroenteropancreatic tumor • SPECT/CT • PET/CT • Somatostatin receptor scintigraphy • Somatostatin analogues • ^{111}In-pentetreotide • [^{18}F]FDG • ^{123}I-MIBG • ^{131}I-MIBG • ^{18}F-DOPA • ^{68}Ga-DOTA-peptides • Peptide radioreceptor therapy

Glossary

[^{18}F]FDG	2-deoxy-2-[^{18}F]fluoro-D-glucose
[^{18}F]FDOPA	*L*-3,4-Dihydroxy-6-[^{18}F] fluorophenylalanine
^{18}F-DOPA	2-^{18}F-Fluoro-L-3,4-dihydroxyphenylalanine
[^{11}C]5-HTP	[^{11}C]5-Hydroxy-L-tryptophan
^{18}F-FLT	3'-^{18}F-fluoro-3'-deoxythymidine
^{123}I-MIBG	meta-[^{123}I] iodobenzylguanidine
^{131}I-MIBG	meta-[^{131}I] iodobenzylguanidine
ACTHoma	Neuroendocrine tumor producing adrenocorticopic hormone
AJCC	American Joint Committee on Cancer
BRCA1	Breast cancer type 1 susceptibility protein
BRCA2	Breast cancer type 2 susceptibility protein

Epidemiology of the Tumor

Pancreatic cancer (PC) is one of the five most lethal malignancies in the world [1], with an incidence rate equaling that of its mortality rate [2–4].

Its overall 5-year survival rate is 6%. Even after potentially curative surgery, survival rate does not increase significantly, with a 5-year survival rate raging from 10% to 25% [5–10].

Unfortunately, at the time of diagnosis, over 80% of all pancreatic tumors are unresectable [3].

Tumor detection at an earlier stage and development of effective therapies are the mainstay for reducing cancer death rate, even if the lack of a valid screening tool in terms of cost-efficacy makes this challenge difficult.

Environmental Factors and Genetic Predisposition

Less than 20% of familial pancreatic cancers can be attributed to a genetic syndrome [11], including hereditary cancer syndromes (like Peutz-Jeghers syndrome, familial atypical multiple mole melanoma, hereditary breast-ovarian cancer associated with BRCA1 and BRCA2 mutations, hereditary nonpolyposis colorectal carcinoma, and familial adenomatous polyposis) and syndromes related to inherited pancreatitis. Subjects presenting known familial adenomatous polyposis, BRCA1, or BRCA2 mutations have less than 5% increased relative risk [12] in comparison to the general population, while the risk in familial atypical multiple mole melanoma syndrome (FAMM) or Peutz-Jeghers is much greater [13]. The number of affected first-degree relatives and environmental factors can affect this genetic predisposition: some families with pancreatic cancer affecting at least two first-degree relatives and no association with genetic syndrome are currently defined as a "familial" pancreatic cancer kindred [14].

Hereditary pancreatitis and cystic fibrosis represent other syndromes that lead to an increased risk of pancreatic cancer. The remaining 80% of cases with an inherited predisposition remain under the generic term of familial pancreatic cancer with unclear genes identification.

Other epidemiological risk factors for pancreatic cancer include smoking [15], age (the risk increases with the age with a peak between 60 and 80 years) [1], race/ethnicity (more common in the African American population in comparison to the white population, probably as a result of socioeconomic factors and cigarette smoking) [1], gender (slightly more common in men than in women), chronic pancreatitis [16], long-standing

diabetes (long-standing DM is a modest risk factor for pancreatic cancer; conversely, new adult-onset diabetes mellitus can be a manifestation of pancreatic cancer [17]), partial gastrectomy [1], dietary risk factors (high meat intake, fried foods, nitrosamines) [1], and ABO blood groups (subjects with non-O-type blood are at modestly increased risk) [18].

Clinical Manifestations and Diagnosis

In the natural history of PC, symptoms at the time of diagnosis predict early death because symptoms are related to an advanced stage of disease: PC is diagnosed a median of 2 months after onset of symptoms, and death usually occurs 4–6 months following diagnosis. Delay in diagnosis is not uncommon due to nonspecific symptoms.

PC is considered a tumor with high propensity for metastatic dissemination so much that most patients with a history of resected PC subsequently die of metastatic disease [19].

To suspect PC on physical examination is a challenge for clinicians due to its retroperitoneal location. Disease-related symptoms depend on tumor location within the pancreas and on the degree of pancreatic involvement. First symptoms to appear include painless jaundice (in case of bile duct obstruction) and weight loss.

In advanced, metastatic disease, palpable lymph nodes, hepatomegaly, splenomegaly, ascites and peripheral edema (portal vein obstruction), palpable gallbladder (Courvoisier's sign), left supraclavicular lymphadenopathy (Virchow's node), or an abdominal mass might be appreciated [20].

Unfortunately, even laboratory findings in pancreatic cancer are nonspecific: raised liver enzymes and abnormalities in vitamin K-dependent clotting factors are related to biliary obstruction and malabsorption of fat-soluble vitamins, while impaired glucose tolerance or frank diabetes could be secondary to pancreatic duct obstruction and pancreatic atrophy (in as many as 70% of patients) [21].

Carbohydrate antigen 19-9 (CA 19-9) is the most commonly used serological marker in pancreatic cancer. Although it has a sensitivity of 80%, specificity is low (67.5%) because serum levels increase in many benign and malignant gastrointestinal conditions. For this reason, routine use as a diagnostic tool is not recommended, even if sequential evaluations may correlate with tumor growth. The presence of a normal CA 19-9, however, does not exclude recurrence [22–24].

Recent studies identified several promising biomarkers from saliva, stool, blood, and pancreatic juice, but their clinical utility must be validated [19].

Currently, available pancreatic imaging has a key-role in the characterization of pancreatic focal lesions, initial staging, surgical and therapeutic planning, and assessment of the treatment response using various imaging modalities, including ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and endoscopic ultrasonography (EUS) [25–35].

Multi-detector row computed tomography (MDCT) has a major role in the diagnosis and staging of pancreatic malignancies. MDCT of the pancreas is favorably complemented by EUS, which is more sensitive for the early detection of lesions, and allows relatively easy access to the pancreas for tissue diagnosis using fine-needle aspiration (FNA), as well as providing further important information for use in tumor staging [36]. MRI with magnetic resonance cholangiopancreatography (MRCP) and PET scanning can also contribute as secondary imaging modalities under selected circumstances, namely, when CT and EUS are not diagnostic.

Pancreatic epithelial neoplasms show a wide range of pathologic features: some of the entities are very uncommon or are regarded as variants of other entities from which they do not differ significantly in terms of treatment or prognosis. Thus, the wide and complex classification can be summarized into a shorter list of neoplasms which occur more frequently (Table 1) [37].

A particular group is represented by pancreatic neuroendocrine neoplasms (pNEN) which originate from neuroendocrine cells of the pancreas and account for less than 3% of all malignancies of the pancreas (increasing annual incidence in a range of 0.32–0.43/100,000) [38–40].

Table 1 List of pancreatic neoplasms which occur frequently

Exocrine neoplasms	Endocrine neoplasms	Epithelial neoplasms with multiple directions of differentiation	Epithelial neoplasms of uncertain direction of differentiation	Miscellaneous epithelial neoplasms
Serous cystic neoplasms	Microadenoma (<0.5 cm)	Mixed acinar-endocrine carcinoma	Solid-pseudopapillary neoplasm	Teratoma
Microcystic serous cystadenoma				
Macrocystic serous cystadenoma				
Solid serous adenoma				
von Hippel-Lindau-associated serous cystic neoplasm				
Serous cystadenocarcinoma				
Mucinous cystic neoplasms	Well-differentiated pancreatic endocrine neoplasm	Mixed acinar-ductal carcinoma		Lymphoepitelial cyst
With low-grade dysplasia				
With moderate dysplasia				
With high-grade dysplasia (carcinoma in situ)				
With an associated invasive carcinoma				
Intraductal neoplasms	Poorly differentiated endocrine carcinoma	Mixed ductal-endocrine carcinoma		Epidermoid cyst in intrapancreatic heterotopic spleen
Intraductal papillary mucinous neoplasms	Small cell carcinoma			
With low-grade dysplasia				
With moderate dysplasia	Large cell endocrine carcinoma			
With high-grade dysplasia (carcinoma in situ)				
With an associated invasive carcinoma				
Intraductal oncocytic papillary neoplasm				
Intraductal tubular neoplasms				
With low-grade dysplasia

Table 1 (continued)

Exocrine neoplasms	Endocrine neoplasms	Epithelial neoplasms with multiple directions of differentiation	Epithelial neoplasms of uncertain direction of differentiation	Miscellaneous epithelial neoplasms
With high-grade dysplasia (carcinoma in situ)				
With an associated invasive carcinoma				
Pancreatic intraepithelial neoplasia (PanIN)	Well-differentiated pancreatic endocrine neoplasm	Mixed acinar-ductal carcinoma		
PanIN-1A and PanIN-1B				
PanIN-2				
PanIN-3				
Invasive ductal adenocarcinoma		Pancreatoblastoma		
Tubular adenocarcinoma				
Adenosquamous carcinoma				
Colloid (mucinous noncystic) adenocarcinoma				
Hepatoid carcinoma				
Medullary carcinoma				
Signet ring cell carcinoma				
Undifferentiated carcinoma				
Anaplastic carcinoma				
Sarcomatoid carcinoma				
Carcinosarcoma				
Undifferentiated carcinoma with osteoclast-like giant cells				
Acinar cell neoplasms				
Acinar cell cystadenoma				
Acinar cell carcinoma				
Acinar cell cystadenocarcinoma				

Table 2 Clinical syndromes depending on the specific hormonal hypersecretion

Tumor subtype/ associated syndrome	Secretion products	Symptoms
Nonfunctional	Chromogranin A, pancreatic polypeptide, a-/β-human chorionic gonadotropin, calcitonin	Unspecific
Carcinoid syndrome	Serotonin	Diarrhea, flush, bronchial obstruction
Insulinoma	Insulin, proinsulin	Hypoglycemia
Gastrinoma/Zollinger-Ellison syndrome	Gastrin	Ulcerations, diarrhea
VIPoma	Vasoactive intestinal peptide	Diarrhea, hypokalemia
Glucagonoma	Glucagon	Necrolytic migratory erythema, diabetes mellitus
Somatostatinoma	Somatostatin	Diabetes mellitus, steatorrhea, cholelithiasis
GHRHoma	Growth hormone-releasing hormone	Acromegaly
CRHoma, ACTHoma	Corticotropin-releasing hormone, adrenocorticotropic hormone	Cushing's syndrome

For the most part, they are sporadic but they can also be part of rare hereditary syndromes like multiple endocrine neoplasia type 1 (with hyperparathyroidism and adenomas of the pituitary gland), von Hippel-Lindau syndrome, and tuberous sclerosis.

Pancreatic neuroendocrine neoplasms can be divided into functional and nonfunctional tumors. Functional tumors represent 10–55% of all pNEN with clinical syndromes depending on the specific hormonal hypersecretion [41, 42] (Table 2) and are most represented by insulinomas and gastrinomas. Carcinoid syndrome presenting with flush and/or diarrhea is only rarely seen (<5%) [41–44].

Nonfunctioning NETs may not present with clinical symptoms until they produce tumor mass effects at a late stage of tumor growth, so they are often diagnosed because of nonspecific abdominal symptoms or weight loss that leads the physician to make a referral for CT scanning of the abdomen.

Metastases are already present at the time of diagnosis in 60–70% of patients with the exception of insulinomas that are benign in 90% of the cases [45–48].

All pancreatic neuroendocrine tumors <2.0 cm in largest dimension with no evident local invasion or angioinvasion and no regional lymphatic or distant metastases are classified as "benign." Tumors confined to the pancreas and without metastases are said to be "uncertain" if the tumor size is >2.0 cm or local invasion has occurred (or both). Tumors with extended invasion of peripancreatic tissue or regional or distant tumor spread are classified as "malignant." These tumors can have heterogeneous microscopic findings, and immunohistochemical staining with markers (such as chromogranin A, synaptophysin, and neuron-specific enolase) can usually confirm the neuroendocrine origin [41].

Staging, Prognostic Classification, and Common Therapies

The staging system for pancreatic ductal adenocarcinoma is based on the AJCC/UICC TNM Staging System, 7th Edition (Tables 3 and 4) [49] which considers primary tumor extent (T stage), regional lymph node involvement (N stage), and presence of distant metastasis (M stage).

T stage includes: TX (primary tumor cannot be assessed), T0 (no evidence of primary tumor), Tis (carcinoma in situ, PanIN 3), T1 (tumor limited to the pancreas and no larger than 2 cm in greatest dimension), T2 (tumor limited to the pancreas but larger than 2 cm in greatest dimension), T3 (tumor

Table 3 TNM of the pancreatic ductal adenocarcinoma (From AJCC, 7th Edition)

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor limited to the pancreas, 2 cm or less in greatest dimension
T2	Tumor limited to the pancreas, more than 2 cm in greatest dimension
T3	Tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery
T4	Tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor)
Regional lymph nodes (N)	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Table 4 Staging of the pancreatic adenocarcinoma based on TNM classification

AJCC staging for pancreatic cancer			
Stage	T	N	M
Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T2	N0	M0
Stage IIA	T3	N0	M0
Stage IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage III	T4	Any N	M0
Stage IV	Any T	Any N	M1

Table 5 Overall survival in pancreatic adenocarcinoma

Median survival (Mo)			
Stage	All patients	Non-resected	Resected
IA	10.0	6.8	24.1
IB	9.1	6.1	20.6
IIA	8.1	6.2	15.4
IIB	9.7	6.7	12.7
III	7.7	7.2	10.6
IV	2.5	2.5	4.5
Total	4.4	3.5	12.6

Adapted from Bilimoria et al. [53].

extends beyond the pancreas but it doesn't involve the celiac axis or the superior mesenteric artery), and T4 (tumor extends beyond the pancreas and involves the celiac axis or the superior mesenteric artery).

N stage includes N0 (no regional lymph node metastasis) and N1 (presence of regional lymph node metastasis); the M stage includes M0 (absence of distant metastasis) and M1 (presence of distant metastasis).

The survival rate of patients with any stage of pancreatic exocrine cancer is poor. Clinical trials are appropriate alternatives for treatment of patients with any stage of disease and should be considered prior to selecting palliative approaches. Surgical resection remains the primary modality when feasible because it can lead to long-term survival and provides effective palliation [50–52].

Treatment guidelines of pancreatic ductal adenocarcinoma differ according to the stage: stage II cancers are generally treated by surgery and adjuvant chemotherapy (with or without adjuvant radiation therapy); stage III disease is treated by chemotherapy with or without adjuvant radiation therapy; stage IV is controlled with a chemotherapy-only approach (Table 4). TNM staging correlates with overall survival as shown in Table 5 [53].

Some important prognostic factors are the histological grade (poorly differentiated cancers have the worst overall survival compared to well- or moderately differentiated pancreatic ductal adenocarcinoma) [54, 55]. Also, features such as stromal content and lymphovascular invasion are associated with a poorer outcome [56, 57]. Despite the prognostic importance of TNM staging, the selection of patient candidates for resection is made through the use of a "surgical staging" defined by Varadhachary et al. from the MD Anderson Cancer Center and slightly modified by the National Comprehensive Cancer Network (NCCN) (Table 6) [58–60].

According to these, localized pancreatic ductal adenocarcinomas are separated into three categories based on the relationship to the major visceral vessels as well as the prospect of achieving an upfront or initial complete resection.

Table 6 Surgical staging

Surgical staging criteria based on the MD Anderson criteria and NCCN guidelines				
Abutment, ≤180° involvement of circumference of the vessel; encasement, >180° involvement of circumference of the vessel				
Stage	Superior mesenteric artery	Celiac axis	Hepatic artery	Superior mesenteric vein/portal vein
Resectable	No abutment	No abutment	No abutment	No distortion
Borderline resectable	Abutment	Abutment; involvement of hepatic artery without expansion to celiac (NCCN)	Abutment/short segment encasement with option for reconstruction	Short segment occlusion with option for reconstruction
Locally advanced	Encasement	Encasement; abutment for pancreatic ductal adenocarcinoma of the head (NCCN)	Encasement and no option for reconstruction	Occluded and no option for reconstruction

Adapted from surgical staging guidelines proposed by Varadhachary et al. [59]; Evans et al. [60] and NCCN guidelines

The *resectable tumors* are usually removed with R0 resection (negative microscopic resection margins); the *borderline resectable ones* are usually resected with R1 resection margins (microscopic positive resection margins), and *locally advanced* tumors will most likely achieve R2 resection margins (residual macroscopic disease). Resection margins refer to the surgical or transected resection margins and comprise the transected pancreatic neck, the uncinate margin, the duodenum, and the bile duct [61].

Radical pancreatic surgery includes the Whipple procedure (pancreaticoduodenal resection for the head and uncinate process masses) and distal pancreatectomy for tumors of the body and tail of the pancreas. To obtain negative margins of the surgical specimen, total pancreatectomy could be necessary (with or without splenectomy) [62, 63].

Patients with locally advanced or metastatic disease are not suitable for surgery, and a single therapy with gemcitabine is generally regarded as first-line therapy even if numerous patients do not respond due to chemoresistance [64]. The variation in chemoresistance between individuals is partly related to the human equilibrative nucleoside transporter-1 (hENT-1) responsible for the intracellular uptake of gemcitabine [65].

Few combinations of gemcitabine with other cytotoxic agents have yet provided any significantly prolonged overall survival rates with more toxic effects compared with gemcitabine as monotherapy [66, 67].

Some patients have palliation of symptoms when treated by chemotherapy with gemcitabine or 5-fluorouracil [68–70].

The use of capecitabine and erlotinib in patients with gemcitabine refractory first-line treatment of advanced pancreatic cancer is associated with modest improvements in overall survival [71].

Pain-relieving procedures such as celiac or intrapleural block and palliative biliary bypass or stent placement must be considered.

Radiologists commonly use language in reports that could lead inexperienced clinicians to falsely assume a pancreatic ductal adenocarcinoma as unresectable [72]; for this reason, a multidisciplinary approach or surgical consultation in the evaluation of all patients with localized tumors is important.

Less than 20% of patients with pancreatic ductal adenocarcinoma are candidates for resection, and the majority of patients who undergo resection will still recur [56].

This is most likely due to occult metastases that had already occurred at the time of diagnosis although patients presented with clinical stage I or II.

At the moment, there are no effective screening tests to detect pancreatic ductal adenocarcinoma at a curable stage, and ongoing studies focus on

innovative molecular markers in serum and gastrointestinal secretions that could lead to early detection. The staging system based on regional and distant disease spread seems relatively crude: some patients without lymph node spread have rapid recurrence after resection, while many with lymph node spread have long-term survival [73]. It appears likely that genomic, transcriptomic, proteomic, and metabolomic signatures associated with a more aggressive biology will emerge and these will complement or replace the current staging system.

Pancreatic neuroendocrine neoplasms are classified based on histopathology according to the World Health Organization (WHO) classification (2010) [74], and an important part of this classification is the tumor grading (proliferative activity evaluated by Ki-67 index or by counting mitoses) that correlates with prognosis [75].

Neuroendocrine tumors with a proliferation index <2% usually show a slow growth, while neuroendocrine carcinomas with a proliferation index >20% usually have an aggressive behavior [45]. Also the size of the tumor affects the likelihood of metastasis: primary tumors of <2 cm only rarely metastasize. When possible, surgical resection of primary tumors with radical intent is recommended and that is the mainstay of therapy in insulinoma. If the primary tumor is a G1/2 pNET, surgical approaches also include metastases. Systemic treatment can be used for palliative care or as neoadjuvant approach to reduce tumor size before surgical treatment. For symptom control, functional tumors are primarily treated with somatostatin analogues (SSA) with the exception of gastrinomas that can be treated using proton-pump inhibitors alone for long periods. In insulinomas diazoxide is used to inhibit the release of insulin from the pancreas.

Antiproliferative SSA-based treatment can be used in functional and nonfunctional pNET with a proliferation index <10% [76]; streptozotocin-based chemotherapy is recommended according to the guidelines of the European Neuroendocrine Tumor Society (ENETS) in patients with progressive disease.

In patients with progressive disease while on chemotherapy, targeted therapies are used such as the multi-targeted receptor tyrosine kinase inhibitor sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus. Other treatment options are peptide receptor radionuclide therapy (PRRT) and other kinds of chemotherapy like temozolomide [46]. Diagnostic imaging, beside clinical assessment, has a major role in therapeutic decision in this setting of multidisciplinary treatment options.

Diagnostic Imaging and Role of Nuclear Medicine

Early detection of pancreatic cancer is pivotal to improve the patient's survival rate. The standard imaging technique for the initial evaluation of pancreatic cancer is contrast-enhanced computed tomography (CT) and/or magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP). Endoscopic ultrasound (EUS) allows further local staging and allows histologic confirmation by means of EUS-guided biopsy or fine-needle aspiration on the detected lesion. Although CT currently has a major role in the evaluation of pancreatic cancer, MRI with MRCP allows better detection of tumors at an earlier stage through a comprehensive analysis of the morphological changes of the pancreatic parenchyma and ductal system. The diagnosis could be improved using positron emission tomography techniques (PET/CT) in selected scenarios where CT and EUS are equivocal. It is essential for clinicians to understand the advantages and disadvantages of each imaging modality in order to select the correct imaging workup and pursue optimal treatment [77].

2-Deoxy-2-[^{18}F]fluoro-D-glucose-based positron emission tomography ([^{18}F]FDG PET) imaging allows the assessment of in vivo tissue metabolism and defines malignant tumors as hypermetabolic lesions hence lesions with an increased tracer uptake. The rationale for its use is based on the increased expression of membrane glucose transporters subsequent to an enhanced anaerobial glycolytic activity in cancer cells, which leads to a higher glucose demand. [^{18}F]FDG is carried into the cell by glucose transporters, as the normal glucose to be rapidly phosphorylated in a

biochemical form that causes its virtual trapping into the cell.

The CT component of [^{18}F]FDG PET/CT can be either a noncontrast CT (for anatomical localization of the abnormalities seen on PET and further attenuation correction of PET images) or a contrast-enhanced CT (a true diagnostic adjunct to PET) [33, 35].

Integrated PET and MR (PET/MR) scanners have recently become available. As MR has the inherent strength of superior soft-tissue contrast resolution, multiplanar imaging acquisition, and functional imaging capability, such as that seen in DCE-MR, DWI, MR spectroscopy, or elastography, PET/MR may exhibit superior diagnostic performance compared with PET/CT [78].

Since [^{18}F]FDG mimics glucose metabolism, there is physiologially a diffuse accumulation of this tracer in tissues such as the brain and liver. [^{18}F]FDG uptake in both normal tissues and tumor is influenced by a variety of patient-related factors like blood glucose levels, diabetes, recent meals, administration of granulocyte colony-stimulating factor (G-CSF), etc. For this reason, a proper prescan protocol is essential for diagnostic accuracy and reproducibility, including fasting for at least 6 h prior to the study, administering a dose of [^{18}F]FDG based on the patients height and weight in an optimal blood glucose range (usually $<$200 mg/dL), voiding prior to the study to avoid mistaking [^{18}F]FDG in the urine for pathologic uptake, minimizing patient motion prior to the study to reduce [^{18}F]FDG uptake in the muscles and misregistration during the acquisition phase, and maintaining moderate room temperatures to avoid uptake in brown fat [33, 35, 79].

Primary Lesion Detection and Characterization

PET alone is not considered a first-line examination to identify a primary pancreatic malignancy although some studies reported a relatively high sensitivity for pancreatic cancer (84–95%) [80–83].

Despite some intensely [^{18}F]FDG-avid tumors, pancreatic cancers do not usually show high [^{18}F]FDG uptake, with a mean SUV of only 6.7 as described in a study by Izhuishi et al. This value is only slightly higher than the mean SUV of the pancreas itself (2.0) [80]. Another limitation of PET is the identification of lesions $<$1 cm in size, and for this reason, MDCT remains the primary diagnostic modality for identifying a suspected pancreatic malignancy with a sensitivity approaching 97% and with a rapid exam execution, wide availability, and diagnostic accuracy. In most cases, MRI or endoscopic ultrasound is a better second-line modality than PET or PET/CT, such as in cases with a dilated pancreatic duct on MDCT without a discrete identifiable mass or an equivocal lesion on CT [84].

On the other hand, an important role for PET or PET/CT in primary diagnosis of a pancreatic mass is the differentiation of a pancreatic cancer from a focal chronic pancreatitis: Van Kouwen et al. described that 87% of chronic pancreatitis did not have any [^{18}F]FDG uptake while 24/26 patients with pancreatic cancer had focal uptake [85]. There is also evidence that PET may have a role in distinguishing pancreatic cancer from autoimmune pancreatitis: Lee et al. suggested that autoimmune pancreatitis showed diffuse uptake throughout the gland in more than 50% of cases (without focality contrarily to what happens in pancreatic cancer) and tended to be associated with abnormal uptake in the salivary glands and kidneys [86]. An advantage of using [^{18}F]FDG PET has been observed in the characterization of pancreatic cystic lesions with a sufficient amount of [^{18}F]FDG-avid tumor cells [87–89].

Sperti et al. [90] studied the usefulness of [^{18}F]FDG PET in differentiating malignant from benign pancreatic cysts in 50 patients concluding that [^{18}F]FDG PET was more accurate than CT (94% vs. 80% respectively).

Intraductal papillary mucinous neoplasms (IPMNs), are tumors characterized by the intraductal proliferation of neoplastic mucinous cells in the main pancreatic duct or in major branches, represent a diagnostic challenge: an accurate differentiation between IPMN with low-grade or moderate-grade dysplasia and malignant lesions (IPMN with high-grade dysplasia and invasive carcinoma) is essential to an appropriate treatment planning [91], and in this scenario PET/CT seems to be useful [92, 93].

Pancreatic Cancer Staging

PET/CT can be a valid tool in staging patients with localized lesions on CT that are at high risk for metastatic disease, including patients with locally advanced disease, borderline resectable tumors, or a severe increase of CA 19-9 [58]. PET/CT does not currently add much staging information in most patients with resectable disease [94, 95] (Fig. 1).

False-negative PET results can be observed in hyperglycemic patients or in subcentimeter lesions, whereas false-positive PET results can occur in some inflammatory states like pancreatitis (Fig. 2), infection of a pseudocyst, or local inflammation due to the placement of a biliary stent and the resulting accumulation of leukocytes with high metabolic activity [96–98]. Some studies including a meta-analysis in 2001 by Gambhir et al., a study by Zafra et al., and another one by Topkan et al. found that PET/CT changed management of patients with pancreatic adenocarcinoma respectively in 36%, 34%, and 36.6% of the studied populations [99–102]. Despite these results, a study by Izuishi et al. conducted in 2010 on 65 patients with pancreatic cancer found that 61.5% of patients had metastatic disease to the liver that was already confirmed on CT: hence PET did not change a single patient's staging. However, in the same study, PET detected a considerable number of nodal and bone metastases not found on CT. Nonetheless in these patients, already judged inoperable due to vascular involvement or liver metastases, PET/CT did not change management [80]. Another study by Lytras et al. found no real benefit from PET compared to CT in identifying either liver metastases or peritoneal carcinomatosis [98]. Although literature remains equivocal on whether PET truly changes patient outcomes and management, the majority of available data suggest that PET identifies some metastases not detected on CT. Thus PET/CT has become an accepted part of the imaging algorithm for patients with a new diagnosis of pancreatic cancer.

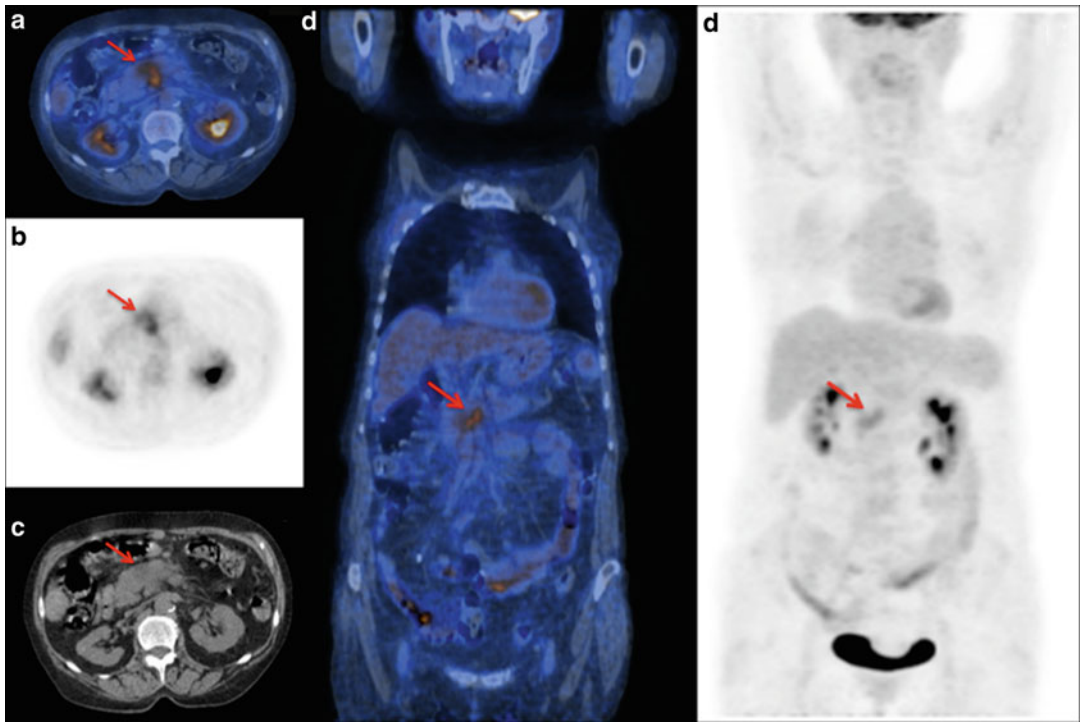

Fig. 1 Staging [^{18}F]FDG PET/CT. *Red flags*: pancreatic findings, pancreatic adenocarcinoma. (**a**) PET/CT, transaxial; (**b**) PET, transaxial; (**c**) CT, transaxial; (**d**) PET/CT, coronal; (**e**) MIP

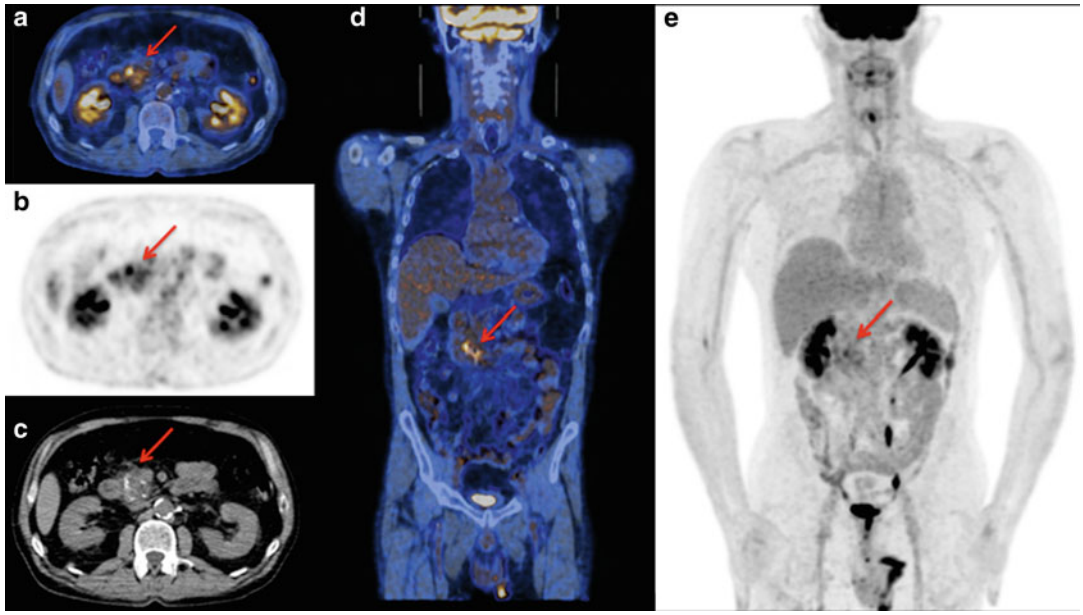

Fig. 2 False-positive [^{18}F]FDG PET/CT. *Red flags*: pancreatic findings, chronic pancreatitis. (**a**) PET/CT, transaxial; (**b**) PET, transaxial; (**c**) CT, transaxial; (**d**) PET/CT, coronal; (**e**) MIP

It should be emphasized that PET without a diagnostic contrast-enhanced CT is highly limited for staging, and a study by Imai et al. found that PET was as insensitive as CT for nodal metastases to the para-aortic chain (most likely due to PET's lack of sensitivity for lesions <1 cm) [103]. Furthermore, the role of PET in assessing local tumor spread and vascular involvement remains uncertain because the [^{18}F]FDG uptake within the primary mass can confound the assessment of the vascular margins where a degree of intrinsic [^{18}F]FDG blood activity is also present. For this reason, at the time, the resolution of PET is not considered sufficient to determine the vessels involvement, therefore the tumor resectability.

Therapy Response Evaluation

The identification of early responders to chemotherapy is important to avoid unnecessary toxicity in patients who will not respond (Fig. 3). Sometimes the metabolic response is not accompanied by changes in tumor size after chemoradiation therapy [104], and morphological response assessment by conventional imaging can be inaccurate (e.g., presence of fibrosis induced by treatments). In this scenario we can assume that the [^{18}F]FDG PET study can assess treatment response earlier and better compared with conventional imaging [105, 106].

In patients who are judged to be borderline resectable and are recommended to undergo neoadjuvant therapy, a baseline PET scan and CA 19-9 would allow the assessment of tumor metabolic response during therapy [107].

It is desirable to determine an appropriate time interval between end of treatment and time of posttherapy PET scan. Whereas oncologic therapies are expected to decrease the tumor metabolism, a treatment-induced inflammatory reaction can increase [^{18}F]FDG uptake. It has been demonstrated that also nonirradiated organs could show this inflammatory reaction probably via a cytokine interaction, and total [^{18}F]FDG uptake could fluctuate for more than 1 month [108].

However, perhaps because of its poor prognosis and short follow-up, there are no data on the right time interval between therapy and the PET study; therefore, we use the timing applied to other malignancies such as the head and neck (3 months from radiotherapy).

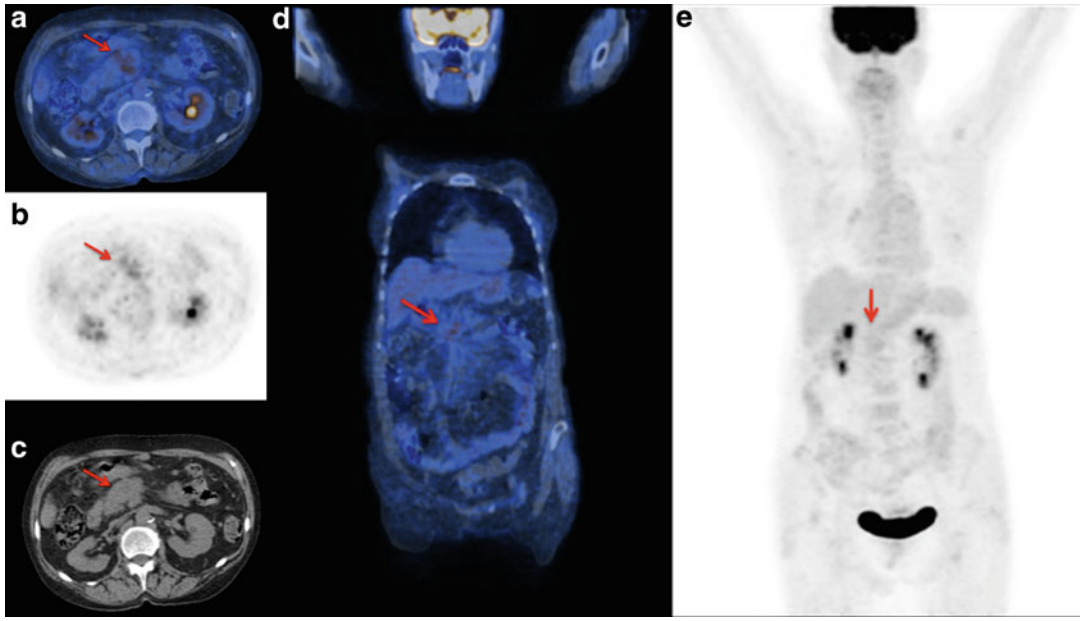

Fig. 3 Restaging [^{18}F]FDG PET/CT after 3 months from the end of radiotherapy in the same patient whose staging scan is represented in Fig. 1. *Red flags*: residual pancreatic cancer. (**a**) PET/CT, transaxial; (**b**) PET, transaxial; (**c**) CT, transaxial; (**d**) PET/CT, coronal; (**e**) MIP

[^{18}F]FDG PET/CT may predict survival by distinguishing between responders and nonresponders in order to plan the best treatment strategy [104, 105] and may be useful in differentiating recurrent disease from postsurgical/radiotherapy changes, especially if there is an increase in tumor marker levels with negative or equivocal conventional imaging findings [87, 109].

Prognostic Significance

Several studies have shown a correlation between higher metabolic activity of pancreatic carcinoma and poorer prognosis thus providing prognostic information [87].

Suspect of Relapse

An elevated CA 19-9 has a positive predictive value for pancreatobiliary malignancy of only 69%. This means that over 30% of those with an elevated CA 19-9 may have another tumor originating in another organ, or they may have no tumor at all. False-positive results have been associated with other pancreatobiliary disorders such as gallstones, pancreatitis, inflammatory bowel disease, other liver disorders, pulmonary diseases such as pneumonia, and hydronephrosis [110].

In this setting, when CA 19-9 is rising despite negative conventional imaging, [^{18}F]FDG PET could have a role in detecting sites of undetected recurrence, such as the local, liver, peritoneal dissemination, lung, distant lymph nodes metastasis (Fig. 4). [^{18}F]FDG PET could also exclude the presence of recurrence in cases of indeterminate findings by other imaging modalities [111].

Radiotherapy (RT) Planning

A well-established treatment option for patients with locally advanced pancreatic cancer is concurrent chemoradiotherapy, but, despite significant improvements in diagnostic imaging, chemotherapy, and radiotherapy, the outcome remains poor [112, 113].

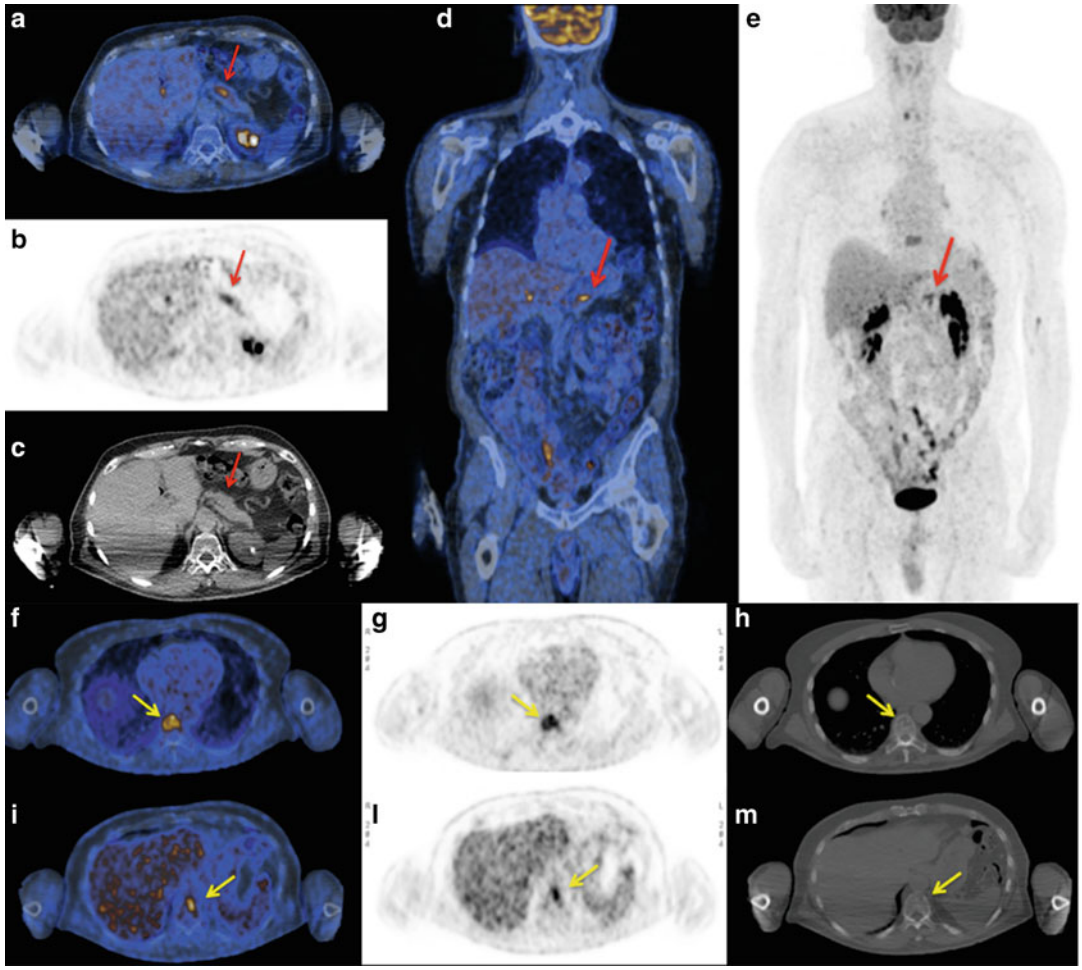

Fig. 4 (**a**) [^{18}F]FDG PET/CT in a patient with a history of pancreaticoduodenectomy and a suspect of relapse. *Red flags*: recurrence, pancreatic findings. *A* PET/CT, transaxial; *B* PET, transaxial; *C* CT, transaxial; *D* PET/CT, coronal; *E* MIP. (**b**) *Yellow flags*: bone recurrence. *F* I, PET/CT, transaxial; *G* L, PET, transaxial; *H* M, CT, transaxial

The accurate definition of target volumes and administration of appropriate radiation doses to these volumes represent a reasonable way to reduce local disease.

According to literature, the accuracy of target volume delineation, sometimes difficult with the use of conventional imaging alone (low accuracy on N and M staging), might be improved beyond the CT-based delineation by integrating PET and CT data. This integration allows an enlargement of the gross tumor volume (GTV) in 35.7% of cases due to detection of additional CT occult lymph node metastases and/or primary tumor extensions defined on the co-registered [^{18}F]FDG PET/CT with no evidence of increased toxicity [114].

Regarding resectable pancreatic cancer, in several surgical series, the outcome is proven to be affected by tumor size, status of resection margins, invasion of vascular and/or adjacent structures, degree of differentiation, performance status, CA 19-9, and C-reactive protein levels [115]. A few series indicate prognostic factors in locally advanced pancreatic cancer. A study by Parlak et al. [116] conducted on patients with locally advanced pancreatic cancer investigated the

potential prognostic value of the GTV delineated by co-registered contrast-enhanced CT and [^{18}F]FDG PET/CT-based RT on their outcome. This study suggests [^{18}F]FDG PET/CT-defined GTV may have a role in predicting outcome (in terms of overall survival, local regional progression free survival and progression free survival).

However, further evaluation in prospective clinical trials will be required to assess the real impact of change management induced by PET/CT on the overall survival of unresectable patients.

[^{18}F]FDG PET/CT-Guided Biopsy

PET/CT-guided biopsy combines the well-established value of anatomical information from CT with PET metabolic characterization [117] also in view of the fact that a lesion can present [^{18}F]FDG uptake with no anatomical alterations.

Malignant lesions can be heterogeneous and [^{18}F]FDG PET/CT is able to guide biopsy to the area of highest [^{18}F]FDG uptake [117, 118] (Fig. 5). The first studies on [^{18}F]FDG PET/CT-guided biopsy were published in 2008 by O'Sullivan et al. on musculoskeletal lesions [119] and subsequently other studies including that from Cerci et al. [120] in 2012 and Purandare et al. [121] in 2013 confirmed the value of PET/CT in guiding biopsy procedures.

When deciding on therapy, [^{18}F][^{18}F]FDG PET/CT-positive results should be confirmed by histology when possible: PET/CT-guided biopsy is feasible with reduced invasiveness, lower costs, and complication rate compared with surgical methods [122] and may optimize the diagnostic yield of image-guided interventions.

Neuroendocrine Tumors

Ultrasound, computed tomography, magnetic resonance, and nuclear medicine imaging play an important role also in the detection of clinically

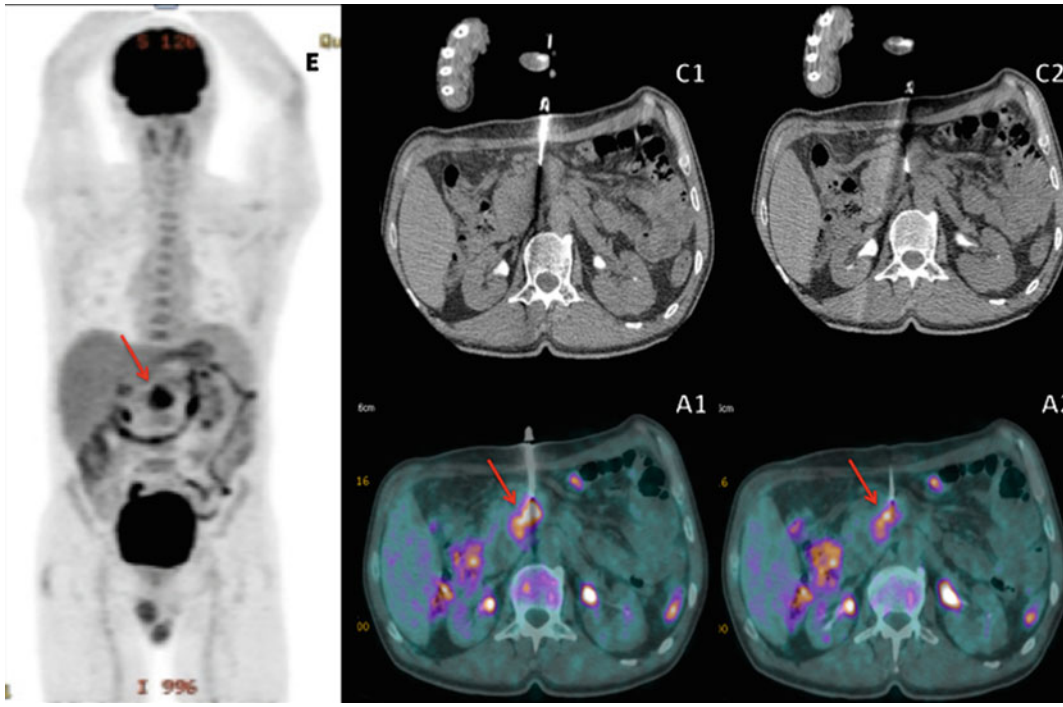

Fig. 5 [^{18}F]FDG PET/CT-guided biopsy. *Red flags*: pancreatic findings, site of biopsy. *A1* A2, PET/CT, transaxial; *C1* C2, CT, transaxial; *E* MIP (Images kindly provided by Juliano Cerci (Clinica Quanta, Curitiba, Brazil))

suspected or diagnosed pancreatic neuroendocrine tumors for staging.

Single photon and positron emitting radionuclides can be combined with various ligands (functionally active part) including somatostatin analogues [123]. Overexpression of subtypes of somatostatin receptors (SSTRs) in well- to moderately differentiated pNEN allows their in vivo characterization using single-photon emission computed tomography (SPECT) or positron emission tomography (PET) while for high-grade (more aggressive) pNEN, [^{18}F]FDG is preferred [124, 125].

The diagnosis of insulinomas poses a problem with somatostatin receptor analogues, and other tracers have been suggested as alternatives including ^{18}F-DOPA and GLP-1 (exendin labeled with either ^{111}In or ^{68}Ga) [126]. The major advantages of nuclear medicine imaging are the high sensitivity in detecting the primary tumor and metastases in unusual locations (whole body imaging), the high specificity in case of SSTR-positive lesions, and the assessment of SSTR positivity for therapeutic purposes. In order to add additional morphological informations, SPECT and PET should be combined with CT or MR imaging [127]. According to the ENETS guidelines, when initial SSTRs imaging is positive, patients should undergo SSTRs imaging for staging every 18–24 months [46].

Somatostatin Receptor Scintigraphy

Somatostatin is a peptide secreted by endocrine D cells in the gastrointestinal (GI) tract and pancreas, and it inhibits the release of endocrine and exocrine factors in the GI system itself [128].

Most GEP-NET cells have a high expression of high-affinity somatostatin receptors which are further classified into five subtypes (SSTR1, SSTR2, SSTR3, SSTR4, SSTR5) [129, 130]. More than 80% of GEP-NET express the subtype SSTR2 that binds the commercially available somatostatin analogues (SSAs) and the radiolabeled SSAs [129, 131].

^{111}In-DTPA-pentetreotide (Octreoscan®) is used for somatostatin receptor scintigraphy (SRS) [132]: it preferentially binds to SSTR2 with lower affinity to SSTR5 and SSTR3 [129, 133, 134]. Planar and single-photon emission computed tomography (SPECT) images are generally obtained 24 and 48 h after injection of this radiopharmaceutical. SRS has an overall sensitivity for well-differentiated GEP-NET of more than 80% and plays an important role in localization of primary GEP-NETs, their metastases and in monitoring treatment responses. SRS with ^{111}In-DTPA-pentetreotide can predict the clinical efficacy of current commercially available SSAs, and it is a useful tool to select patients for PRRT utilizing beta-radiation-emitting SSAs [135–138]. Physiological uptake of radiolabeled SSAs is shown in the pituitary gland, thyroid, kidneys, liver, and spleen [139]. False-positive results can derive from the presence of accessory spleen, infections, adrenal medullary tumors, and sometimes a specific uptake in the uncinate process of the pancreas [132]. The sensitivity is lower for small lesions (diameter <1 cm) due to insufficient tumor to background uptake ratio for nonmetastasized insulinomas due to low expression of SSTR2 [132, 140], and for NETs with high Ki-67 index [123].

Other radiolabeled SSAs (some still under investigation or already been used in few centers) are those labeled with ^{99m}Tc including ^{99m}Tc-depreotide (high affinity for SSTR2, SSTR3, and SSTR5) [141] and ^{99m}Tc-vapreotide (high affinity for SSTR2 and SSTR5 and low affinity for SSTR3 and SSTR4 [142]).

^{111}In-DOTA-lanreotide, ^{99m}Tc-HYNIC-TOC, and ^{99m}Tc-HYNIC-TATE are similar, in terms of SSTR affinity profile and results, to ^{111}In-pentetreotide [143–145].

Metaiodobenzylguanidine (MIBG) Scintigraphy

Radioiodinated MIBG, ^{123}I-MIBG (or ^{131}I-MIBG), is a guanethidine analogue with structural features similar to norepinephrine that at low concentrations is transported across the plasma membrane and accumulated in catecholamine-storing granules [146]. ^{123}I-MIBG (or ^{131}I-MIBG) scintigraphy has

a lower sensitivity than SRS for the imaging of NETs of the gastrointestinal tract (sensitivity about 50%) and pancreas (sensitivity <10%), but in patients with metastatic and inoperable GEP-NETs, high uptake on MIBG scintigraphy suggests a role for palliative treatment with ^{131}I-MIBG [147–150].

False-positive ^{123}I-MIBG scintigraphy is possible in adrenocortical adenoma, adrenocortical carcinoma, angiomyolipoma, and gastrointestinal stromal tumors [151].

Gastrin Receptor Scintigraphy

A high percentage of medullary thyroid carcinomas (MTCs) express the cholecystokinin 2 (CCK2) receptor, and many CCK2 receptor-binding radiopeptides have been developed for scintigraphy (^{111}In-DOTA-CCK, ^{99m}Tc-demogastrin, ^{111}In-DOTA-MG11), whereas for PET/CT imaging, ^{68}Ga-DOTA-minigastrin is used [152–154]. As GEP-NETs also express CCK2 receptors, this imaging modality was tested also in a variety of GEP-NETS (overall tumor detection reached 74% for ^{68}Ga-DOTA-minigastrin PET) [153].

Glucagon-Like Peptide 1 Receptor Imaging

Pancreatic beta-cells mainly express the glucagon-like peptide 1 receptor (GLP1R), and for this reason, it represents a target for imaging of insulinomas even if malignant insulinomas (unlike benign insulinomas) often lack GLP1R [155]. In many studies, GLP1R scintigraphy using ^{111}In-DOTA-exendin-4 successfully detected benign insulinomas, and this radiopharmaceutical is applied for the intraoperative localization of these benign tumors [155–159].

(Lys^{40}(Ahx-HYNIC-^{99m}Tc/EDDA)NH$_2$)-exendin-4 is another radiopeptide used for targeting the GLP1R and has been studied in medullary thyroid carcinomas (MTCs) and benign insulinomas [160, 161] [68].Ga-DOTA-exendin-3 is a promi sing tracer to visualize insulinomas on PET i maging [162].

Vasoactive Intestinal Peptide Receptor Scintigraphy

^{123}I-labeled vasoactive intestinal peptide (VIP) receptor scintigraphy generally shows lower sensitivity compared to SRS in GEP-NET localization, and for this reason, it is generally not recommended for the diagnostic workup of GEP-NETs [163–165].

PET/CT Using ^{68}Ga-DOTA-Labeled SSAs

^{68}Ga-DOTA-labeled SSAs (DOTANOC, DOTATATE, and DOTATOC) are used for the diagnostic workup of GEP-NETs (they allow for imaging 1–3 h within i.v. injection) and differ in their affinity spectrum toward the different SSTRs [132, 166–169]. ^{68}Ga-DOTATATE has high affinity for SSTR2, ^{68}Ga-DOTATOC for STTR2 and SSTR5, and ^{68}Ga-DOTANOC for SSTR2, SSTR3, and SSTR5 [132, 166–169] (Figs. 6 and 7). PET/CT with ^{68}Ga-DOTANOC, ^{68}Ga-DOTATATE, or ^{68}Ga-DOTATOC shows higher sensitivity for GEP-NET lesions in comparison with SRS SPECT-CT (more than 90%) due to better spatial resolution and SSTR binding affinity [132, 166–169].

There are new ^{68}Ga-DOTA-labeled SSAs for PET imaging that include ^{68}Ga-DOTAVAP and ^{68}Ga-DOTALAN [142].

[^{18}F]FDG PET/CT

High [^{18}F]FDG uptake is generally associated with more aggressive (poorly differentiated) GEP-NETs; thus, the use of this radiotracer can have an additional value in grade 3 neuroendocrine carcinomas (especially when SRS is negative) [123, 132, 170, 171].

[^{18}F]FDG PET has been used to predict the GEP-NET and lung-NET responses to PRRT with ^{177}Lu-octreotate: if [^{18}F]FDG PET after PRRT was negative, no tumor progression was found at follow-up. Patients with both a grade 2 NET and a positive [^{18}F]FDG PET finding showed a worse disease course after PRRT with subsequent changes in their therapeutic approach [172].

^{18}F-DOPA PET/CT

The use of ^{18}F-L-3,4-dihydroxyphenylalanine (^{18}F-DOPA) PET/CT is based on co-secretion of dopamine and hormones or peptides by GEP-NET cells. In these cells, L-DOPA is converted by the enzyme L-DOPA decarboxylase to dopamine.

In comparison with SRS and [^{11}C]5-hydroxy-L-tryptophan ([^{11}C]5-HTP) PET and ^{18}F-DOPA PET showed the highest sensitivity (98%) for the detection of NETs of the gastrointestinal tract but not for those of the pancreas [132, 173].

[^{11}C]5-HTP

[^{11}C]5-HTP is a radiolabeled precursor in the synthesis of serotonin. The short half-life of the ^{11}C radiolabel and the complex synthesis limits the clinical use and the availability of [^{11}C]5-HTP PET. Compared with CT, SRS, and ^{18}F-DOPA PET, [^{11}C]5-HTP PET showed the highest sensitivity (96%) for the detection of pancreatic NETs [132, 173–176], and it is particularly useful for detecting small pancreatic NETs and early recurrences.

Future Directions and Ongoing Studies

New tracers such as [^{11}C]thymidine or the thymidine analogue 3'-^{18}F-fluoro-3'-deoxythymidine (^{18}F-FLT) could be a potential alternative to [^{18}F]FDG in prognosticating and characterizing pancreatic cancer: some studies have demonstrated that the quantification of the nuclear antigen Ki-67, a proliferation indicator, enables reliable differentiation between benign and malignant pancreatic tumors [177]; therefore, compounds that indicate proliferative activity, such as ^{18}F-FLT [178], should be more suitable for differentiating between malignancy and inflammatory processes than nonspecific metabolic markers such as [^{18}F]FDG [179].

It is apparent that PET techniques will gradually replace SPECT. New somatostatin receptors radioligands are being developed for clinical imaging, not only are somatostatin receptor agonists being studied but also receptor antagonists [180]. Other peptide receptors might be interesting target for receptor imaging like gastrin-releasing peptide or bombesin receptors [181–183].

Diagnostic Applications of Nuclear Medicine: Colorectal Cancer

28

Ettore Pelosi, Désirée Deandreis, Laura Cassalia, and Daniele Penna

Abstract

Colorectal cancer is the fourth most common neoplastic disease (50–60% overall survival at 5 years); 90–95% of colorectal cancers are adenocarcinoma. Important prognostic factors include: whether the tumor is well differentiated, the extent of the primary tumor, and the presence of local and/or lymph node invasion. Two staging classifications for colorectal cancer are available: Dukes' classification and the TNM stage system by the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC).

Contrast-enhanced computed tomography (CECT) of the chest, abdomen, and pelvis is used in pretreatment staging. Because of the high incidence of disease recurrence (30–40%), morphological imaging (CT, abdominal ultrasound) and serial measurements of serum markers (carcinoembryonic antigen, or CEA) are used in the follow-up. The use of [^{18}F]FDG-PET for early detection of primary colorectal cancer is limited due to the low sensitivity for small tumors as well as for mucinous lesions. False-positive PET findings are also reported in patients with inflammatory bowel disease (IBD) or previous diagnostic polipectomy. Although [^{18}F]FDG PET is more sensitive than CT in detecting regional lymph node involvement, CT is better at detecting liver metastases. As a result, the role of [^{18}F]FDG PET-CT for presurgical staging is unclear. [^{18}F]FDG-PET is useful as a complementary exam in selected patients with a high metastatic potential.

During restaging and follow-up, whole-body [^{18}F]FDG-PET/CT is recommended to localize recurrent disease in cases of elevated serum CEA and negative morphological imaging findings or indeterminate lesions. Combined PET/CT tomography improves the accuracy of the evaluation of colorectal cancer, especially in the visualization of abdomino-pelvic extrahepatic disease.

[^{18}F]FDG-PET may be useful to evaluate response to chemotherapy, although the optimum timing of the assessment of metabolic response remains unsettled. Moreover, new drugs targeted to angiogenesis or tyrosine kinase have opened new frontiers to the use of [^{18}F]FDG-PET in evaluating response because of their cytostatic rather than cytoreductive effect. In rectal cancer it is often difficult to evaluate response to radiotherapy by anatomic imaging due to residual

tissue mass, but [^{18}F]FDG-PET/CT can detect residual tumor by the metabolic activity. Finally, [^{18}F]FDG-PET has been proposed in the evaluation of response to local treatment of liver and lung metastases by radiofrequency ablation (RFA). In patients with unresectable liver metastases and/or advanced burden of liver disease, transarterial radioembolization with microspheres labeled with ^{90}Y is becoming a valid therapeutic alternative to chemoembolization and RFA.

Overview of Colon-Rectal Cancer: Incidence and Mortality

Colorectal cancer is the fourth most common neoplastic disease, after prostate, lung, and breast cancer, and the second leading cause of death from cancer, with an estimated overall survival at 5 years of 50–60% in Western countries [1, 2]. There is considerable evidence for its correlation with saturated fat, low-fiber diet, obesity, and inflammatory bowel disease (IBD), as well as with genetic factors (familial adenomatous polyposis or the Lynch syndrome). Mortality rates have steadily decreased, particularly between 1980 and 2005, owing to improved surgical and adjuvant therapies (chemotherapy protocols and targeted molecular treatment) and more extensive screening programs with early diagnosis [3].

Despite improved prognosis and extensive primary and secondary prevention programs, about 150,000 new cases of colorectal cancer have been diagnosed in 2009 in the United States alone. Colorectal cancer remains a huge health problem [3].

Prognostic Factors

Some studies suggest a poorer prognosis in symptomatic patients due to local complications (e.g., locally extended cancer with obstruction and perforation) at diagnosis. Among patient characteristics, age less than 40 years at diagnosis is another factor of poor prognosis, because cancer is more aggressive in younger patients, with a high percentage of positive lymph nodes and aggressive histological features. As to histology, adenocarcinoma accounts for 90–95% of colorectal cancers. These tumors are classified into three groups according to the Dukes' grading system: grade 1, the most differentiated forms; grade 2, the intermediate forms; and grade 3, the less differentiated forms. The less differentiated forms carry a worse prognosis as they are locally more extensive, with a higher lymphatic affinity and metastatic potential. The remaining 5–10% of colorectal cancers include other histological variants such as colloid or mucinous adenocarcinomas, less frequently squamous cells, undifferentiated carcinomas, and carcinoid forms which usually arise in the rectum. The mucinous variant is also correlated with a more aggressive behavior and frequently with an advanced stage at diagnosis. Primary tumor extension at diagnosis expressed by local invasion and number of positive lymph nodes seems to be the most important prognostic factor, as curative treatment is possible only at the early stage of disease. Nearly 40% of patients present with a confined primary tumor at diagnosis, almost 40% with locally advanced disease, and the remaining 20% with metastatic spread. A localized tumor means that it is limited to the bowel wall, without lymphatic spread or peritoneal seeding when considering intraperitoneal sites (cecum, transverse colon, and sigmoid) or without extension to retroperitoneal lymph nodes, or to retroperitoneal tissue such as the kidneys, or to the ureter or the pelvis when considering extraperitoneal sites (ascending and descending colon and the majority of rectal localizations). Lymphatic spread usually occurs via the paracolic lymph node groups by the mesenteric the retroperitoneal lymph nodes in extraperitoneal localizations of colon cancer, and the perirectal lymph nodes in rectal cancer. Metastatic spread is often localized to the liver in colon cancer and in tumors of the upper rectum, whose venous system drains into the portal circulation. The distal rectum has a double drainage: to the portal system via the inferior mesenteric vein through the superior hemorrhoidal veins with metastatic spread to the liver, and to the inferior vena cava via the pelvic veins through the middle and inferior hemorrhoidal plexus; in the latter case case, lung metastases are more frequent. Bone lesions can be caused by metastatic spread through the vertebral venous

plexus and are more frequently located in the sacrum, coccyx, pelvis, and lumbar vertebrae.

Staging Classification and Prognosis

There are two different surgical staging classifications for colorectal cancer. Dukes' classification is a practical system that classifies tumors into three groups according to the extent of bowel wall penetration: (A) penetration into but not through the bowel wall, (B) penetration through the bowel wall, and (C) lymph node involvement regardless of bowel wall penetration. Stage D was later added to indicate disease extension beyond the limit of surgical resection and includes metastatic tumor. This system correlates easily with different prognoses for different stages. A 1984 meta-analysis by the Large Bowel Project, London, identified the number of positive lymph nodes as the most important factor [4]. A recent study by Fretwell et al. on 351 patients confirmed this result, showing that lymph node status is an independent prognostic factor [5].

The second system is the TNM classification, which has undergone several revisions with further modifications still in progress; the first unified and revised version was issued by the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) in 1987–1988 [6, 7]. This version takes into account tumor extension to the serosa and the number of positive lymph nodes calculated on at least 12 lymph nodes examined [8]. T is subdivided into T0 (absence of tumor in resected specimen), Tis (carcinoma in situ), T1 (submucosa invasion), T2 (muscolaris mucosa invasion), T3 (extension to subserosa or to nonperitoneal pericolic or perirectal tissue), and T4 (invasion of the peritoneal cavity or other organs). N is subdivided into N0 (tumor without lymph node involvement), N1 (tumor with one to three positive regional lymph nodes), N2 (tumor with four or more positive regional lymph nodes), and N3 (tumor with central positive lymph nodes). Based on the TNM classification, the AJCC/UICC identified a four-stage group (Table 1). Prognosis is closely correlated with stage: survival around 90% for Stage I, 80–70% for Stage II, 80–40% for Stage III, and around 10% for Stage IV (Table 2). The AJCC recommends recovering at least 12 lymph nodes for accurate analysis, where the number of lymph nodes recovered is itself a prognostic factor [9, 10]. Lymph node positivity at surgical resection is a known independent prognostic factor, and the cutoff of four lymph nodes in the TNM classification was based on statistical differences in prognosis between the two subgroups: overall 5-year survival of approximately 50% for patients with $\geq$4 metastatic lymph nodes at surgical staging versus approximately 70% for patients with less than four metastatic lymph nodes [4]. Furthermore, vascular or lymphatic invasion are adjunctive prognostic elements irrespective of the stage, since they increase the likelihood of lymph node or metastatic recurrence [11]. Other studies have demonstrated that peritoneal involvement could also be considered as a prognostic

Table 1 AJCC/UICC staging classification for colorectal cancer according to the TNM system

Stage I		Tis, N0, M0
Stage II	IIA	T3, N0, M0
	IIB	T4, N0, M0
Stage III	IIIA	T1-T2, N1, M0
	IIIB	T3-T4, N1, M0

[a]Uncertain result

factor independent of T and N stage [12]. Finally, other prognostic factors are molecular markers such as p53, p27, K-ras, thymidylate synthase, and mutations of mismatch repair genes, which can correlate with a more aggressive tumor. Furthermore, their abnormal expression can influence and predict tumor response to treatment [13–17]. Other cellular and tumor morphological parameters under study are the angiogenesis patterns, since anti-angiogenetic therapy constitutes a new chance of targeted treatment [18].

Clinical Objectives in Colorectal Cancer

The first objective in managing colorectal cancer patients is adequate and complete preoperative staging, which is routinely done by abdominal and thoracic contrast-enhanced computed tomography (CECT) to evaluate overall liver status. The purpose of primary tumor treatment is to be as curative and radical as possible, while exactly defining local disease extension. This is also important in cases with isolated metastatic spread. Surgery is usually the first choice treatment for localized disease and single and/or resectable metastases. In locally advanced disease, the use of neoadjuvant chemoradiation therapy appears to improve prognosis [19, 20]. Adjuvant treatment is indicated to limit tumor recurrence, based on initial tumor extension and prognostic factors (Stage III, lymph node metastases, poorly differentiated tumors, lymphovascular invasion). It ordinarily consists of systemic chemotherapy protocols based on 5-fluorouracil as first choice. On completion of treatment, close follow-up is essential because of the high percentage of disease recurrence after primary treatment (30–40%) [21]. Follow-up entails systematic evaluation by morphological imaging techniques (CT, abdominal ultrasounds) and systemic evaluation of serum markers (carcinoembryonic antigen, or CEA) to detect relapse or metastatic spread. Recurrence can be local, regional (lymph node localizations), peritoneal seeding, or metastatic liver/lung lesions, and it is closely correlated with primary tumor characteristics. The recurrence rate in locally advanced tumors is about 20% and rises to around 50% in the presence of initial lymph node involvement.

Current Role of Nuclear Medicine

Of the nuclear imaging modalities for managing patients with colorectal cancer, PET/CT with 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) is the most widely used. It is considered the most useful technique for achieving clinical objectives and has been added to standard imaging techniques as a new "strategic" tool in this scenario.

Several studies have demonstrated that whole-body [^{18}F]FDG-PET is an accurate noninvasive technique in staging/restaging several types of malignancies, and its usefulness has also been proved in the management of patients with colorectal cancer [22–24]. [^{18}F]FDG-PET is recognized as *appropriate* in restaging patients with suspected recurrence of colorectal cancer, elevated serum tumor markers such as CEA, and a negative or inconclusive standard diagnostic workup and in presurgical evaluation of patients with recurrence of disease and potentially resectable metastatic lesions.

In the preoperative initial staging of disease, [^{18}F]FDG-PET is considered *potentially useful* but not yet sufficiently demonstrated [25].

Finally, [^{18}F]FDG-PET in colorectal cancer holds promise for systematic follow-up and evaluation of response to therapy, especially in the evaluation of chemoradiation therapy in metastatic cancer (late and early response) or of local treatment efficacy such as radiofrequency ablation of liver metastases. Furthermore, because positivity and intensity of [^{18}F]FDG uptake are an expression of tumor aggressiveness, [^{18}F]FDG-PET is also considered as a prognostic tool [26].

Classic, standard nuclear imaging techniques such as ^{99m}Tc-HDP bone scan in disease staging and restaging are limited to the evaluation of secondary bone lesions. Finally, nuclear techniques such as treatment with intra-arterial ^{90}Y-microspheres for unresectable liver metastases are becoming increasingly available.

The current and potential uses of nuclear medicine techniques will be discussed in the following paragraphs.

Presurgical Staging of Primary Colorectal Cancer

Because few studies on a small number of patients are currently available, the role of [^{18}F]FDG-PET in the presurgical staging of primary disease remains controversial. Primary cancer is detected and studied by morphological imaging, oral contrast CT, and endo-ultrasonography which also allows for biopsy and histological confirmation [27, 28].

Several studies reported a high sensitivity of [^{18}F]FDG-PET (95–100%) in detecting the primary tumor, even when in situ [29–31]. The tumor's histopathological features and lesion diameter are closely correlated with these data. False-negative results have been reported in cases of mucinous carcinoma and of small tumor foci in tubulovillous polyps or villous adenoma [29, 30, 32]. Abdel-Nabi et al. reported false-positive PET findings (positive predictive value [PPV] 90%) in patients without colorectal cancer but with IBD or previous diagnostic polypectomy [29]. Although [^{18}F]FDG-PET appears to be more useful in detecting regional lymph node involvement and liver metastases, conflicting results have been reported. Abdel-Nabi and Kantorova both found higher sensitivity (78–88%) with PET than with contrast-enhanced abdominal/pelvic CT (38–67%) or ultrasonography (25%), with high specificity (96–100%) in detecting liver metastases [29, 30]. Furukawa reported that, when compared with multidetector helical CT for routine staging, [^{18}F]FDG-PET did not seem superior in terms of sensitivity and accuracy [31]. In this study, [^{18}F]FDG-PET accuracy in detecting lymph node involvement did not show a statistical difference in comparison with CECT accuracy (59% vs. 62%). Patel et al. in a systematic review reported that for extrahepatic lesions (three studies, 178 patients), PET/CT was more sensitive than CT, while specificity was similar (PET/CT sensitivity [SN] = 75–89% and specificity [SP] = 95–96% vs. CT SN = 58–64% and SP = 87–97%). For hepatic lesions (five studies; 316 patients), PET/CT had higher SN and SP than CT (PET/CT SN = 91–100% and SP = 75–100%; CT SN = 78–94% and SP = 25–98% [33].

Other studies confirmed low PET sensitivity (around 30%) primarily due to false-negative findings in cases of micrometastases or the presence of metastatic lymph nodes adjacent to the primary tumor [34]. In a review by Vriens et al., other more recent studies on a small group of patients showed that [^{18}F]FDG-PET can change patient management in 12–27% of cases when added to CT and/or pelvic magnetic resonance imaging (MRI) and ultrasonography, leading the bulk of cases to cancelation of surgery after unexpected metastatic lesions were detected, or to extension of the surgical plan or the radiotherapy field, or to neoadjuvant treatment after detection of pathological lymphadenopathy missed at morphological imaging [35–40].

In brief, the weighted mean change in the management of colorectal cancer calculated in the review was about 10.7% (95% confidence interval [CI] 7.6–14.5%) [41]. The discordant findings among the different studies can be explained by the patient selection bias, which showed a major impact of [^{18}F]FDG-PET in patients with a high metastatic potential, while in localized disease [^{18}F]FDG-PET added less additional information to the standard diagnostic workup (contrast-enhanced CT and colonoscopy).

What can be said at present is that the use of PET in staging primary colorectal cancer can lead to a change in clinical management when compared to standard diagnostic workup, but its systematic use in this application is not yet recognized.

We evaluated the role of [^{18}F]FDG-PET/CT in preoperative staging of rectal carcinoma and compared it to the conventional imaging techniques. With the collaboration of two PET centers and a total of four PET/CT scanners, 141 patients with diagnosis of rectal adenocarcinoma were studied from October 2006 to November 2014. For the evaluation of N stage, in 92/141 cases we found correlation between PET and conventional

imaging: 47/92 cases with evidence of lymph node metastases (N^+) and 45/92 without evidence of lymph node metastases (N^-). In the remaining 49 cases, PET and conventional imaging were discordant: in 38/49 PET did not identify small "mesorectal" lymph nodes (38/49); in 11 cases PET showed some "pelvic" unexpected lymph node metastases. In the M staging, in 106/141 patients (75%) we found correlation between PET and conventional imaging, with the same final stage of disease: in 46/106 patients without evidence of distant metastases (M^-) and in 60/106 with evidence of distant metastases (liver, lung, skeletal, peritoneal, adrenal). In the remaining 35/141 patients (25%), there was discordance between PET and conventional imaging in the M stage: in 9/35 cases PET identified unexpected metastases (three skeletal and six liver and/or lung; out of these we had one false positive case in the lung). In the remaining 26/35 patients, PET excluded distant metastases to the liver, spleen, and lung (out of these we had three lung false-negative findings and two liver false-negative findings). PET also identified seven cases of synchronous neoplasia (five in the colon, one gastric, and one thymoma). So, in our study PET showed high false-negative rate in the locoregional lymph nodes staging due to the spatial resolution limitations, but increased accuracy in the identification of lymph node metastases in less common areas; PET has also provided additional and/or complementary information regarding distant metastases; finally, PET identified unexpected neoplasia in 4% of patients. Considering the different and complementary information derived from PET and conventional imaging, at the moment we suggest the use of both techniques for rectal cancer staging [42, 43].

Recurrent Colorectal Cancer

The suspicion of colorectal cancer recurrence is oftentimes prompted by a rise in serum marker values (CEA) or abnormal findings at anatomical imaging (CECT, MRI) during follow-up and/or occurrence of new symptoms. [^{18}F]FDG-PET remains the mainstay of nuclear imaging in the follow-up of patients with colorectal cancer. In cases of elevated serum CEA values and negative morphological imaging findings, [^{18}F]FDG-PET is advised because of its ability to detect early disease and to reveal metabolic changes in normal-size structures before morphological findings appear. Literature data show that in about two out of three cases, whole-body [^{18}F]FDG-PET identifies recurrence of disease, making its use in an early phase of patient follow-up recommended [44]. Flamen et al. showed that [^{18}F]FDG-PET can detect disease recurrence in more than 80% of patients (43/50) [45]. In this study, disease recurrence missed at morphological imaging was located in the liver (27%), locally (20%), the lung (9%), other abdominal sites (36%), and other extra-abdominal non-pulmonary lesions (9%). These results were confirmed by both previous and more recent studies [46–48]. Lu et al. in a meta-analysis reported that 106 patients (106/510 = 20.8%) had true-negative [^{18}F]FDG-PET/CT results in detection of recurrent CRC when rising CEA. The pooled estimates of sensitivity and specificity and positive and negative likelihood ratios of [^{18}F]FDG-PET in the detection of tumor recurrence in CRC patients with elevated CEA were 90.3% (95% CI, 85.5–94.0%), 80.0% (95% CI, 67.0–89.6%), 2.88 (95% CI, 1.37–6.07%), and 0.12 (95% CI, 0.07–0.20%), respectively. The pooled estimates of sensitivity and specificity and positive and negative likelihood ratios of [^{18}F]FDG-PET/CT in the detection of tumor recurrence in CRC patients with elevated CEA were 94.1% (95% CI, 89.4–97.1%), 77.2% (95% CI, 66.4–85.9%), 4.70 (95% CI, 0.82–12.13%), and 0.06 (95% CI, 0.03–0.13%), respectively [49, 50]. Gade et al. showed in their study that PET/CT demonstrated recurrence with a sensitivity of 85.7%, a specificity of 94.7%, a positive predictive value of 93.8%, and a negative predictive value of 87.8% [51]. [^{18}F]FDG-PET is recommended when indeterminate lesions at conventional morphological imaging need to be characterized, in order to differentiate disease recurrence from scar tissue [52–55]. Identification of presacral recurrences in particular, which develop in a high percentage of patients, poses a considerable clinical challenge. Assessment with conventional pelvic imaging studies (CECT, transrectal ultrasound

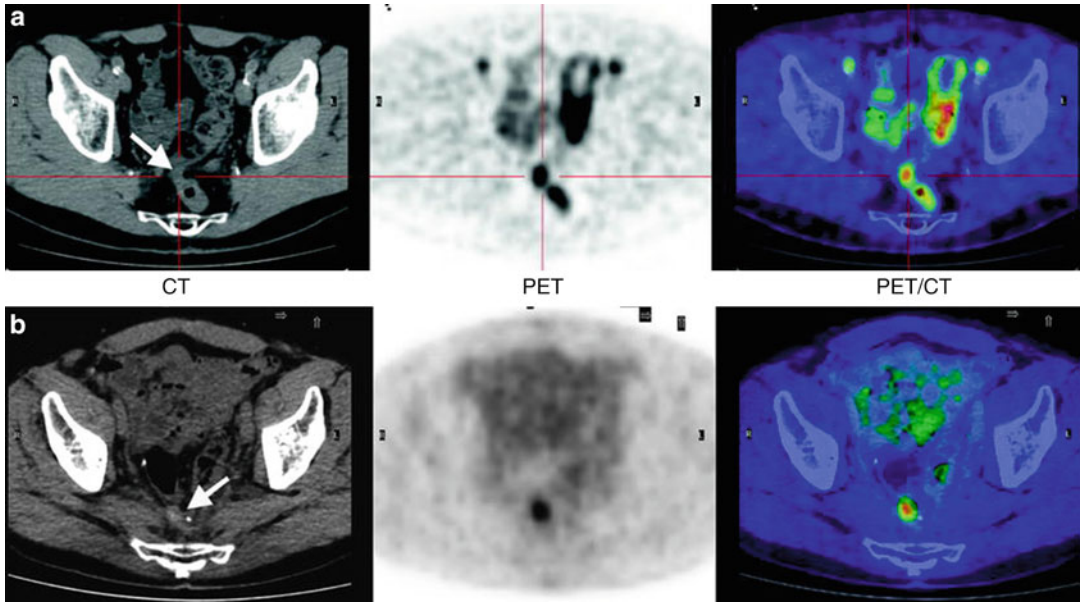

Fig. 1 Metabolic characterization of undetermined presacral lesions by [^{18}F]FDG-PET/CT. The nature of the lesions was confirmed by histological evaluation after the PET study. CT. (**a**, **b**) Suspected, undetermined presacral lesions at CT (*arrows*); PET. PET scan shows: (**a**, **b**) intense [^{18}F]FDG uptakes at the lesions level indicating disease recurrence; the fused PET/CT [^{18}F]FDG-PET images allows to easily localize and to characterize [^{18}F]FDG uptakes

[TREUS]) is problematic for differentiating post-surgical or radiotherapy residual fibrotic tissue from disease recurrence, which candidates the patient for further treatments (Fig. 1). Flamen et al. showed that [^{18}F]FDG-PET offers additional diagnostic value in 56% of cases compared to contrast-enhanced CT alone and in 20% of cases compared to contrast-enhanced CT in combination with TREUS [56]. Even-Sapir et al. demonstrated that PET/CT in patients with colorectal cancer who underwent abdominoperineal or anterior resection had 98% sensitivity, 96% specificity, 90% positive predictive value (PPV), 97% NPV, and 93% accuracy in distinguishing benign from malignant presacral abnormalities [57]. When recurrence is confirmed at morphological imaging, [^{18}F]FDG-PET is recommended to complete disease staging, because it can identify additional unexpected metastatic sites (upstaging) compared to CECT alone (Fig. 2). The general usefulness and the additional diagnostic value of [^{18}F]FDG-PET for this purpose were demonstrated in a meta-analysis by Huebner et al. showing that [^{18}F]FDG-PET leads to a change in clinical management in about 30% of patients with recurrent colorectal disease when added to standard imaging techniques in the evaluation of this patient subset [58]. In another study, Flamen et al. evaluated [^{18}F]FDG-PET and CECT performance in 103 patients with suspected recurrence of colorectal cancer [56]. [^{18}F]FDG-PET showed higher sensitivity than CECT in detecting metastatic lymph nodes in the abdominal cavity negative at CECT, especially those located in retroperitoneal and mesenteric sites. A statistically significant additional value of [^{18}F]FDG-PET was also found in the evaluation of extra-abdominal regions, where it identified unexpected metastases, most of which were located in the lung. Deleau et al. also reported a significant impact in the management of patients with CRC (40%) due to a higher sensitivity of PET than CT [59]. The literature reports discordant results for the evaluation of liver involvement. In the study by Flamen et al., no additional value of [^{18}F]FDG-PET in terms of sensitivity was found compared with normal CECT and/or MRI findings, but PET did allow to correctly classify anatomically

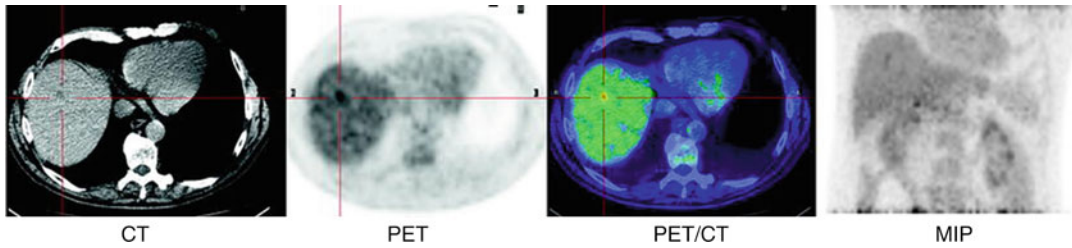

Fig. 2 Patient treated for primary colorectal cancer and referred for restaging. [^{18}F]FDG-PET/CT scan identified unexpected metastases in the liver not seen at CECT

undefined liver lesions [56]. Truant et al. showed that the sensitivity of [^{18}F]FDG-PET was equivalent to that of contrast-enhanced CT for hepatic sites (79% for both) and highly superior for extrahepatic abdominal sites (63% vs. 25%) [60]. A subsequent meta-analysis demonstrated that [^{18}F]FDG-PET can also be superior to conventional diagnostic techniques (CT, ultrasonography, MRI) in the detection of liver metastases (sensitivity around 90%) and that it can be considered as the most sensitive noninvasive imaging modality for the detection of hepatic metastases arising from gastrointestinal tract (GI) tumors, especially in colorectal cancer [61]. An interesting study by Sobhani et al. on 130 randomized patients undergoing complete follow-up (physical examination, biomarker assay, conventional imaging, and [^{18}F]FDG-PET) found that the time to recurrence detection was shorter for the patients studied by [^{18}F]FDG-PET than those who underwent conventional imaging (12.1 vs. 15.4 months), which led to the possibility to initiate a more curative treatment [62]. In a large group of patients ($n = 115$) presenting with recurrent colorectal cancer, Valk et al. reported that PET had a global sensitivity of 93% and a global specificity of 98% in detecting metastatic sites, compared with 69% and 96%, respectively, for CECT alone, confirming that [^{18}F]FDG-PET should be routinely performed in the follow-up of these patients. The most relevant finding emerging from this study was that PET identified unexpected metastases in 29% of patients presenting with only one site of recurrent disease at CECT, leading to an upstaging of disease [46]. Several studies later evaluated the impact of [^{18}F]FDG-PET or [^{18}F]FDG-PET/CT on the management of patients presenting with potentially curable liver metastases who underwent PET for complete restaging of disease [63–66]. McLeish et al. reported that hepatic metastases were identified on standard imaging in 232 (39.7%) patients, and [^{18}F]FDG-PET confirmed hepatic metastasis in 203 cases, including 22 cases with new lesions, and clarified presence of disease in 34/37 (92%) cases with equivocal standard imaging. In 54 patients, [^{18}F]FDG-PET was performed for disease assessment before hepatic resection. [^{18}F]FDG-PET had substantial management plan impact in 36/54 (66.7%) patients [67]. In this patient subset, PET allowed complete preoperative staging, determination of whether other neoplastic foci were present, and the choice of the most adequate treatment, thus avoiding unnecessary surgery. Lai et al. demonstrated that PET identified unexpected metastases in 25% of patients referred for presurgical staging to evaluate liver metastases resectability [63]. A 2005 review by Wiering et al. including all studies that had evaluated patients referred for presurgical staging for resectable liver metastases showed that [^{18}F]FDG-PET had sensitivity and specificity rates for liver lesions of 88% and 96.1%, respectively, and 91.5% and 95.4%, respectively, for extrahepatic lesions [68]. [^{18}F]FDG-PET resulted superior to CT in all cases but overall in detecting extrahepatic lesions. Patient management changed in about 32%, with cancelation of surgery and planning of systemic chemoradiation therapy in most cases. The review by Vriens et al. of 25 papers found a pooled mean management change of 22.3% in 1,060 patients [41]. With the introduction of combined PET/CT, the evaluation of many tumors and of colorectal cancer as well has improved even further, since it allows correlations between abnormal tissue metabolic changes detected at PET and anatomical

structures defined at CT, with accurate localization and characterization of lesions [69–71]. A review evaluating the potential of PET/CT in comparison with CECT, MRI, and PET alone suggested that, when available, [^{18}F]FDG-PET/CT appears to be the diagnostic tool of choice in early evaluation of recurrent colorectal disease [72]. Furthermore, the use of low-dose CT scanning to correct PET emission images for attenuation (instead of radioactive sources, as in the past) shortens the time needed to complete whole-body acquisition [73]. Still unclear is the influence of [^{18}F]FDG-PET on disease-free survival and overall survival in patients with recurrent colorectal cancer, owing to the difficulty of comparison between studies of different patient subgroups with different treatment plans; nonetheless, whole-body [^{18}F]FDG-PET has a key role in clinical practice and provides additional value to standard diagnostic workup and a high clinical impact [74].

In this subset of patients, [^{18}F]FDG-PET should be considered as an essential tool for better clinical management. Given its high NPV (around 95%), when a PET scan in this patient subgroup is negative, the presence of detectable disease recurrence could be excluded with [^{18}F]FDG-PET, though close clinical follow-up should still be undertaken. While there is considerable evidence for the usefulness of [^{18}F]FDG-PET, certain limitations to the technique deserve mention. [^{18}F]FDG-PET can produce false-positive findings at evaluation of abdominal recurrence when postsurgical inflammation and inflammatory disease are present (i.e., abscesses, colitis, rectal fistula). The physiological [^{18}F]FDG uptake in the GI and genitourinary tracts due to the excretion of the tracer itself can mimic but also hide pathological sites. The risk of false-negative findings is high in the presence of miliary liver metastatic spread, due to the physiological uptake of [^{18}F]FDG in the liver parenchyma and to a low lesion-to-background ratio or low [^{18}F]FDG uptake in diffuse peritoneal effusion. Besides anatomical sites, lesion size is another important factor affecting PET accuracy and may be responsible for false-negative results. This is true especially in lymph node or hepatic lesions <1 cm in diameter, near the technique's lower limit of effective spatial resolution. Finally, high patient blood glucose levels (>150 mg/dL) can deteriorate the [^{18}F]FDG-PET image quality, and some metastatic lesions, especially those in the liver, can be missed [75]. This is why blood glucose levels should be accurately kept under control with at least 6 h fasting before scanning. A meta-analysis by Huebner et al. evaluated the influence of false-positive and false-negative results on [^{18}F]FDG-PET sensitivity and specificity in patients with recurrent disease [58]. The final data showed that false positives had a greater impact than false negatives. In fact, the sensitivity of whole-body [^{18}F]FDG-PET resulted high (97%), with similar rates for the detection of liver (91–96%) and pelvic (94%) involvement. Specificity values in the evaluation of recurrence differed for total body (76%) and liver and pelvis (97–99%) due to the greater likelihood of false-positive results in extrahepatic and extrapelvic regions than in isolated organs. Furthermore, a study by Akhurst et al. [76] on a group of patients who underwent [^{18}F]FDG-PET for presurgical staging demonstrated that sensitivity was lower in those who received neoadjuvant chemotherapy due to the risk of the stunning phenomenon that leads to false-negative results when [^{18}F]FDG-PET is performed too early after the end of treatment.

Treatment Response Evaluation

The identification of responders to chemotherapy is of interest for selecting patients who may be expected to benefit from continued treatment and for selecting those who could be treated with other drugs. Evaluation of response to treatment is ordinarily based on morphological assessment of target lesions and of changes in lesion diameter over time. Currently, the Response Evaluation Criteria in Solid Tumors (RECIST) is the most widely used set of rules to define disease response to treatment: complete response is defined as disappearance of target lesions at morphological imaging; partial response, a minimum reduction of 30% in lesion diameter; disease progression, a minimum increase of 20% in lesion diameter or appearance of new lesions; and stable disease, neither partial response nor disease progression

[77]. With [^{18}F]FDG-PET came the need to have similar criteria for metabolic response, but consensus is still lacking. A significant decrease or increase in [^{18}F]FDG uptake in target lesions during treatment has always been considered as a sign of treatment response or disease progression, respectively; nevertheless, lacking standardized limits and standardized timing of response assessment, each study uses its own criteria. One limitation to [^{18}F]FDG-PET is its limited ability to detect minimal residual disease below the range of system spatial resolution. [^{18}F]FDG uptake is detectable in lesions measuring 5–10 mm in diameter, which correspond to about 10^8–10^9 tumor cells. But even with this limitation, a negative PET scan during or at the end of treatment is predictive of good prognosis since it indicates disease response. Furthermore, the interval required for a positive [^{18}F]FDG-PET/CT scan to become negative during treatment is a prognostic factor and a predictive element for final tumor response. If after 2 cycles of chemotherapy a PET scan is negative, as demonstrated in lymphomatous disease, the chances of obtaining remission at the end of the treatment are high, whereas the chances of remission with a few more chemotherapy cycles are lower if PET scans taken early at the beginning of treatment remain persistently positive [78–80]. Treatment response evaluated by [^{18}F]FDG-PET is clearly related to a better overall survival and disease-free survival in most types of tumors. Metabolic response to treatment is normally evaluated quantitatively by measuring variation in SUV_{max} (standardized uptake value), which is a more practical and reproducible way than with qualitative visual methods, even if many studies have employed the latter, with good stratification of subsequent prognosis [81–84].

Quantitative evaluation has to be reproducible, which means that pre-therapy and post-therapy scans have to be made in the same way, with the same scanner, similar injected activity, and the same patient preparation (body weight, blood glucose level) [85]. The problem is to determine which percentage in SUV_{max} reduction is considered significant for defining the clinical response. Many studies have proposed their own cutoff values (25–35%) for the drop in SUV_{max} [86, 87]. Recently, Wahl et al. have proposed the Positron Emission Tomography Response Criteria in Solid Tumors (PERCIST) as standardized criteria to define metabolic response to treatment. These criteria include standardized patient preparation: fasting at least 4–6 h before injection; serum glucose <200 mg/dL; insulin administration before [^{18}F]FDG-PET not indicated; image acquisition obtained 50–70 min after injection and reconstructed with the same software for baseline and post-therapeutic scan, with up to 15 min difference between the acquisition of the two scans; and SUV_{max} corrected for lean body mass as calculated by a region of interest (ROI) system of detection. Furthermore, it is recommended to choose up to five target lesions, two for organs with the highest [^{18}F]FDG uptake, better if about 2 cm in diameter. These target lesions will usually correspond to the target lesions considered by RECIST. Response to therapy is evaluated as a continuous variable expressed as the drop in the percentage of SUV_{max} between the pre- and post-therapeutic scans. Complete metabolic response is defined as the disappearance of all metabolic active tumor, with the target lesion showing the same uptake as the liver and indistinguishable from the surrounding background; a partial response, as a decrease of >30% in SUV_{max} of the most intense lesion; and progressive disease, an increase of >30% in SUV_{max} of the most intense lesion or a visible increase in the extent of [^{18}F]FDG uptake. Still debated is the number of chemotherapy cycles after which [^{18}F]FDG-PET has to be performed to evaluate the response and the delay in time between the last treatment and [^{18}F]FDG-PET; the PERCIST committee considers them as treatment-specific criteria. Several studies demonstrated that SUV_{max} begins to drop after only one cycle of chemotherapy, at which time early response can be detected [87, 88]. Based on previous studies, especially in lymphomatous disease, the suggested delay between the end of the treatment and the final [^{18}F]FDG-PET is around 10 days to 3 weeks for chemotherapy and 3 months after radiotherapy to avoid either the stunning risk or the occurrence of false-positive results, respectively [89]. [^{18}F]FDG-PET has been demonstrated to be a useful tool to evaluate

tumor response to treatment and to stratify patients for prognosis also in colorectal cancer [90]. Several studies have demonstrated the usefulness of performing [^{18}F]FDG-PET to evaluate response to neoadjuvant treatment, i.e., chemoradiation therapy with cytoreduction intent before surgery, during chemotherapy in advanced metastatic tumor, and after local treatment of liver metastases to detect complete/incomplete treatment [91, 92]. Maffione et al. correlated PERCIST criteria and a new criterion developed in their center that they named PET Residual Disease in Solid Tumor (PREDIST) with tumor regression grade (TRG) classification of pathologic response to neoadjuvant chemoradiotherapy (CRT) in patients affected by rectal cancer. [^{18}F]FDG-PET/CT scan is an accurate tool to preoperatively predict the response to CRT in patients with locally advanced rectal cancer. The novel proposed criterion (PREDIST) seems to be helpful to discriminate responders from nonresponders [93, 94]. Evaluation of response to radiotherapy is very difficult by anatomic imaging alone because residual tissue persists after irradiation, making it impossible for CT or MRI to distinguish persistent disease from fibrosis (accuracy 30–60%) [95–97]. A review by Wahl et al. of 19 studies published between 1992 and 2008 reported a NPV for [^{18}F]FDG-PET of 83–100% and a PPV of 77–100%, depending on the criteria used to define the response [77]. All these studies differed in the definition of response criteria, the delay between treatment and [^{18}F]FDG-PET acquisition, and clinical endpoints (metabolic response and histological verification vs. overall survival and disease-free survival). The studies considering histological confirmation of [^{18}F]FDG-PET findings as an endpoint demonstrated a significant correlation between [^{18}F]FDG-PET residual uptake and histological response (viable tumor cells). In the majority, a decrease in SUV_{max} after a median of 3–6 weeks after irradiation seemed to predict good response to radiotherapy. Most of the studies proposed quantitative evaluation of tumor response by using a decrease in SUV_{max} or SUV_{mean} after treatment, but with different cutoff values (30–60%); others proposed kinetic models which, although reproducible, are more difficult to perform in clinical practice. The study by Melton et al. in particular, which compared quantitative methods (decrease in SUV_{max} >70% and decrease in total lesion glycolysis [TLG]) versus qualitative visual methods, showed that for the evaluation of response to neoadjuvant treatment for colorectal cancer, the quantitative is more accurate than the qualitative method [98]. Of note, however, is the risk of false-positive results due to post-irradiation inflammatory processes and false-negative results due to minimal residual viable disease under the detection limits of [^{18}F]FDG-PET. A decrease in the SUV_{max} in patients undergoing treatment is not only the expression of tumor response, and the SUV_{max} itself is not only the expression of tumor absolute [^{18}F]FDG avidity: both need to be interpreted for their prognostic meaning. Some studies demonstrated that patients considered responders to [^{18}F]FDG-PET after chemoradiation therapy of the primary tumor had a better median overall survival and disease-free survival [84, 99–102]. Other studies demonstrated that the absolute SUV_{max} or SUV_{mean} can stratify patients with a better or worse overall survival, but at which cutoff is not yet clear. Calvo et al., for example, showed that patients with a pre-therapeutic tumor $SUV_{max} \leq 6$ had a better overall survival at 3 years after neoadjuvant and surgical treatment than those with a higher tumor SUV_{max} (92% vs. 60%) [103]. Riedl et al. proposed different ranges of SUV_{max} with different prognosis as expressed by median overall survival [104]. The role of [^{18}F]FDG-PET in the evaluation of systemic chemotherapy in advanced metastatic tumors is also under evaluation. A recent review by De Gesus Oei gives an overview of the results of five studies [105–110]. All such studies evaluated the response to treatment after a few cycles of chemotherapy in order to differentiate responder patients from nonresponders in order to optimize treatment. Maffione et al., also, reported that PET showed high accuracy in early prediction response during preoperative CRT. In the era of tailored treatment, early assessment of nonresponder patients allows modification of the subsequent strategy especially the timing and the type of surgical approach [111].

The problem is to define the correct timing for [^{18}F]FDG-PET so as to obtain a good correlation between global response and prognosis. These studies compared [^{18}F]FDG-PET findings at 1 or 2 weeks after the start of chemotherapy and then at 1–3 months. The majority demonstrated that the clinical correlation between metabolic response and treatment outcome was better detected at 1–3 months after the start of chemotherapy. Here, too, quantitative evaluation by SUV_{max} or SUV_{mean} is considered a better way to evaluate metabolic response than qualitative assessment. Furthermore, Dimitrakopoulou et al. demonstrated that the absolute SUV_{mean} of the most avid lesions at pre-therapeutic PET could predict response to treatment, a second-line chemotherapy in this study, thus supporting the concept that the higher the [^{18}F]FDG avidity as expressed by SUV_{max} or SUV_{mean}, the more resistant the lesions are to treatment [108]. The introduction of targeted therapy with anti-angiogenesis or anti-tyrosine kinase drugs for treating colorectal cancer has opened new frontiers to the use of [^{18}F]FDG-PET in evaluating response to treatment, given that this kind of therapy exhibits a cytostatic rather than a cytoreductive effect and that tumor metabolic change reflects response better than anatomic changes detectable by CT. Future, prospective studies are needed to elucidate this point [112, 113]. Skougaard et al. in their recent study compared European Organization for Research and Treatment of Cancer (EORTC) criteria with PET Response Criteria in Solid Tumors (PERCIST) for response evaluation of patients with metastatic colorectal cancer treated with a combination of the chemotherapeutic drug irinotecan and the monoclonal antibody cetuximab. A total of 61 patients and 203 PET/CT scans were eligible for response evaluation. With EORTC criteria, 38 had PMR, 16 had SMD, and 7 had PMD as their BOmR. With PERCIST, 34 had PMR, 20 had SMD, and 7 had PMD as their BOmR. There was agreement between EORTC criteria and PERCIST in 87% of the patients [114]. Finally, [^{18}F]FDG-PET has an important role in the evaluation of response to local treatment of liver and lung metastases by radiofrequency ablation (RFA), laser thermotherapy, or cryotherapy. [^{18}F]FDG-PET can detect incomplete treatment at a much earlier stage than CT and can better detect relapse of disease. After RFA, necrotic tissue and fibrotic scar formation in the treated lesion are frequently associated with inflammatory phenomena. Contrast enhanced CT does not reliably differentiate between persistent tumoral disease and inflammation. [^{18}F]FDG-PET shows different types of [^{18}F]FDG uptake in persistent active disease (focal and high [^{18}F]FDG uptake) versus inflammatory processes (more diffuse, circular, and mild uptake) (Fig. 3a–c). The review by De Gesus Oei looked at five studies [115–119]. All reported an NPV value for [^{18}F]FDG-PET of around 100% in an early stage (1–3 weeks after treatment), which means that [^{18}F]FDG-PET has to be performed early to define complete response to treatment. The wide range in PPV (80–97%) across the studies underlined again that, although [^{18}F]FDG-PET can detect relapse or persistent viable disease earlier than CT, there remains the risk of false-positive results due to inflammatory or infective phenomena.

New Prospects

PET/MRI

PET combined with magnetic resonance imaging (PET/MRI) seems to be a promising modality in different fields of tumor imaging. With the high soft tissue contrast of MRI and the superior ability of [^{18}F]FDG-PET to detect vital tumor tissue prior to morphological changes, the advent of combined PET/MRI will open new perspectives in noninvasive imaging. The combination of PET with MRI also opens up options to acquire multimodal molecular imaging parameters simultaneously. This may contribute to a more detailed characterization of molecular processes in vivo [120–122]. Some studies also report results for colorectal cancer. Paspulati et al. reported their initial experience showing a high diagnostic accuracy of PET/MRI in T staging of rectal cancer compared with PET/CT. In addition, PET/MRI shows at least comparable accuracy in N and M staging as well as restaging to PET/CT. However, the small sample size limits the possibility to

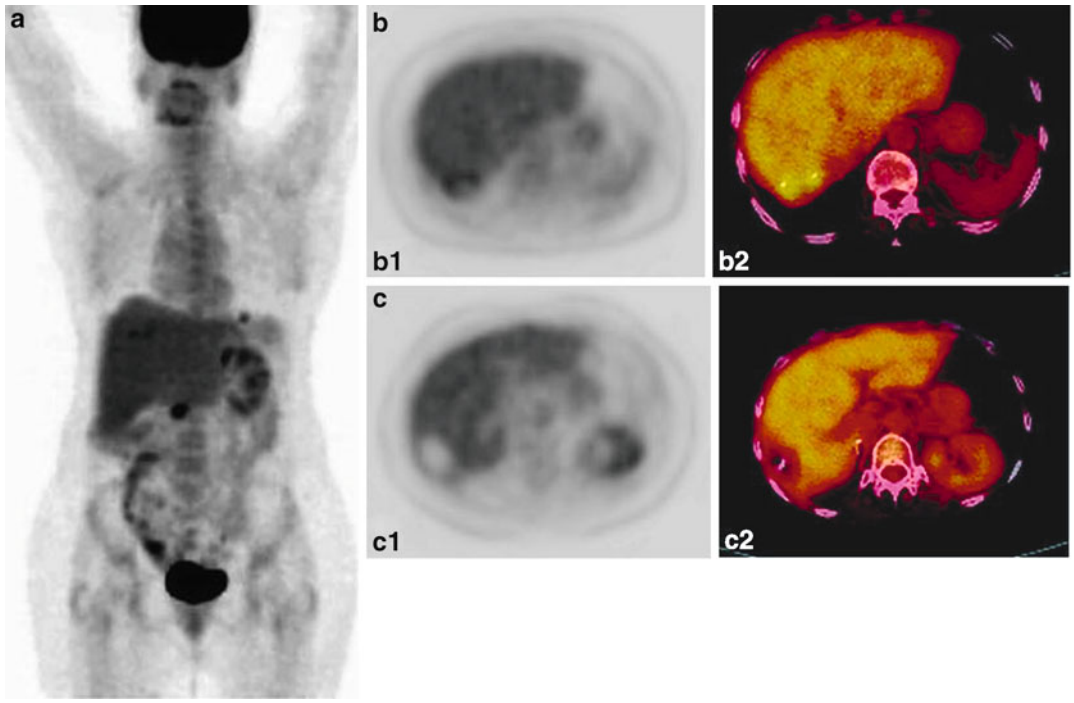

Fig. 3 Patient with colorectal cancer, liver metastases treated by RF, and abdominal lymphadenopathy. Evaluation of RF ablation efficacy by [^{18}F]FDG-PET. (**a**) MIP image, (**b1**) axial PET image showing physiological aspect of liver metastases after radiofrequency ablation (homogeneous and peripherical mild [^{18}F]FDG uptake), (**b2**) axial fusion image of the same lesion, (**c1**) axial PET image showing relapse of disease in liver metastases treated by RF ablation (heterogeneous and focal pattern of [^{18}F]FDG uptake), (**c2**) fusion axial image of the same lesion

assume these results as definitive. It is expected that PET/MRI would yield higher diagnostic accuracy than PET/CT considering the high soft tissue contrast provided by MRI compared with CT, but larger studies are necessary to fully assess the benefit of PET/MRI in colorectal cancer [123].

Radiotherapy Volume Planning

[^{18}F]FDG-PET is often used in clinical practice to identify target volume in radiotherapy treatment, especially in lung cancer [124–127]. Some studies also report results for colorectal cancer. Promising preliminary results in esophageal, pancreatic, and anorectal cancers and colorectal liver metastasis suggest that [^{18}F]FDG-PET might provide additional information useful in target volume delineation. Poor image resolution and a low sensitivity for lymph node detection currently limit its widespread implementation [128]. Ciernik et al. demonstrated that PET/CT-derived planning target volume (PTV) is as accurate as CT-derived PTV [129]. In the future, perhaps PET/CT alone will be sufficient for planning radiotherapy target volume.

Therapy with Transarterial ^{90}Y-Microspheres

In unresectable liver metastases and advanced liver metastases, radioembolization treatment with microspheres containing the beta emitter yttrium-90 is becoming a valid alternative to other treatments such as chemoembolization and radiofrequency. Microspheres are injected into an artery and, because of their diameter (20 to

60 μm), become entrapped by embolization in the microvascular tissues. The half-life of yttrium-90 is 64.1 h, and the administered dose is closely correlated with body surface area and tumor burden. Although few studies have evaluated its efficacy and feasibility to date, the results are promising in terms of tumor response and overall survival. A study by Whitney et al. evaluating application of this technique for liver metastases from different cancers, including colorectal cancer, demonstrated that it reduces tumor burden and can be followed by surgical resection of metastases [130]. In the bulk of studies, tumor response is based on CT according to RECIST, but there is also mounting evidence that [^{18}F]FDG-PET could be a useful tool and a more accurate technique even in this field to better characterize tumor response according to metabolic criteria. Necrosis, inflammatory, or fibrotic processes can lead to an increase in lesion size after treatment, which can be interpreted as disease progression at anatomic imaging [131–134]. Wong et al. showed that [^{18}F]FDG-PET detected more partial responses than CT, as clinically confirmed by the decrease in serum CEA levels [135]. In phase I–II studies, therapy with yttrium-90 microspheres can be combined with adjuvant chemotherapy to increase tumor radiosensitivity with good patient tolerability [136–139]. The most common side effects of this treatment are abdominal pain, transient hepatotoxicity with elevated transaminase, hyperbilirubinemia, and hypersplenism; occasional cases of important neutropenia possibly induced by bone marrow irradiation when combined with adjuvant chemotherapy have been reported [140]. Further studies on large-scale patient populations are needed to confirm these preliminary results.

Carcinoid Tumors

Endocrine tumors can be found in the GI tract and in the rectal tract in particular. Their management, treatment, and prognosis differ substantially from adenocarcinomas. Oftentimes, they are discovered after the onset of local symptoms such as rectorrhagy. Prognosis is closely correlated with tumor size and local extension. Frequently, a simple endoscopic resection is sufficient for obtaining complete remission; more complex surgery is chosen as first intention treatment for more advanced local tumors. Distant metastases are infrequent. Tumor extension is local in almost 70% of cases. Nuclear medicine offers an array of imaging techniques to study endocrine tumors, all of which are based on the affinity these tumors have for somatostatin receptors [141, 142]. Historically, ^{111}In-DTPA-octreotide scintigraphy is the most widely used technique to characterize the primary tumor and perform disease staging and follow-up of endocrine tumors. The sensitivity of this technique in endocrine tumor staging is between 60% and 100%, and it depends on tumor differentiation grade, somatostatin receptor density, origin, site, and size [143, 144]. Other approaches for evaluating intestinal endocrine tumor are now available: ^{18}F-DOPA-PET (^{18}F-6-fluoroDOPA), [^{11}C]HTP-PET ([^{11}C]5-hydroxytryptophane), ^{68}Ga-DOTA-TOC, and ^{68}Ga-DOTA-NOC, all tracers with an affinity for somatostatin receptors or that are involved in endogenous amine metabolism. Although several studies on small groups of patients have shown the superiority of these techniques over traditional somatostatin analog scintigraphy [145–147], further studies are needed to confirm their accuracy and to identify standard recommendations for their use [148–155].

Diagnostic Applications of Nuclear Medicine: Neuroendocrine Tumors

29

Lisa Bodei, Mark Kidd, Laura Gilardi, Duccio Volterrani, Giovanni Paganelli, Chiara M. Grana, and Irvin M. Modlin

Abstract

Neuroendocrine tumors (NETs) originate from neuroendocrine cells ubiquitously distributed throughout the body and occur mainly in the gastrointestinal and bronchopulmonary system. They are rare, are mostly sporadic, and comprise 0.66% of all neoplasia. Their incidence/prevalence is increasing based upon more sophisticated diagnostic strategies. Despite the majority being indolent, they are frequently metastatic at diagnosis. As a consequence their prognosis is often limited.

The European Neuroendocrine Tumor Society (ENETS) diagnostic and prognostic stratification criteria are based on histological typing, differentiation, grading (Ki67), and TNM staging. Although the general application of Ki67 is controversial, it remains embedded in therapeutic decision-making pending the implementation of molecular stratification systems.

Surgery is the only curative option. It is however effective in ~20% given the metastatic status of most lesions. Other therapeutic options include somatostatin analogs, interferon, "targeted" drugs, and peptide receptor radionuclide radiotherapy (PRRT).

NETs present a diagnostic and therapeutic challenge as their clinical presentation is protean, nonspecific, and late with hepatic metastases often present. Imaging plays a fundamental role in diagnosis, staging, treatment selection, and follow-up. Current modalities include morphologic techniques (CT, MRI), transabdominal ultrasound (US), and endoscopic (EUS) and intraoperative US (IOUS). Molecular imaging includes scintigraphy (^{111}In-pentetreotide or ^{99m}Tc-HYNIC-Tyr^3-octreotide), and, more

recently, PET with ^{68}Ga-labeled somatostatin analogs (SSA), ^{18}F-DOPA and [^{11}C]5-HTP; catecholamine metabolism is usually imaged with ^{123}I-metaiodobenzylguanidine. [^{18}F]FDG PET/CT has a prognostic role. A role for somatostatin receptor antagonists (better target/background ratio) as theranostics is currently proposed.

The major unmet needs are the development of more inclusive criteria for therapy monitoring, the validation of the recent PET techniques, and the integration of molecular biologic and metabolic information.

Glossary

[^{11}C]5-HTTP	[^{11}C]5-Hydroxytryptophan
^{18}F-DOPA	2-^{18}F-Fluoro-L-3,4-dihydroxyphenylalanine
[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
5-HIAA	5-Hydroxyindoleacetic acid, an end-metabolite of serotonin
5-HT	5-Hydroxytriptamin, also known as serotonin
AADC	Aromatic L-amino acid decarboxylase
AC	Atypical carcinoid
ACTH	Adrenocorticotropin hormone
AJCC	American Joint Committee on Cancer
APUD	Amine precursor uptake and decarboxylation
AUC	Area under the curve
BP	Bronchopulmonary
CEUS	Contrast-enhanced ultrasonography
CgA	Chromogranin A, a tumor-associated marker for neuroendocrine tumors
CT	X-ray computed tomography
CTC	Circulating tumor cell
CTGF	Connective tissue growth factor, also known as CCN2
DOTA	2-(4-Isothiocyanatobenzyl-1,4,7,10-tetra-azacyclododecane-1,4,7,10-tetraacetic acid (macrocyclic coupling agent to label compounds of biological interest with metal radionuclides)
DOTANOC	DOTA-Nal^3-octreotide
DOTATATE	DOTA-Tyr^3-Thr^8-octreotide
DOTATOC	DOTA-Tyr^3-octreotide
DTPA	Diethylenetriaminepentaacetic acid
DWI	Diffusion-weighted magnetic resonance imaging, an MR technique used to detect changes in the distribution of water molecules in selected regions
EANM	European Association of Nuclear Medicine
EC	Enterochromaffin
ECL	Enterochromaffin-like
EDDA	Ethylenediamine-N,N'-bis(2-hydroxyphenyl)acetic acid
ENETS	European Neuroendocrine Tumor Society
EPAS1	Gene encoding for the hypoxia-inducible factor 2-alpha (HIF-2α); the gene is also known as HIF2A
EUS	Endoscopic ultrasonography
FNAC	Fine needle aspiration cytology
FSH	Follicle-stimulating hormone
GEP	Originated in the gastroenteropancreatic tract
GH-RH	Growth-hormone releasing hormone
GH	Growth hormone
GIST	Gastrointestinal stromal tumor
GLP	Exendin, a glucagon-like protein
HPF	High-power field in optical microscopy
HYNIC	Hydrazidonicotinic acid/Hydrazinonicotinamide
IOUS	Intraoperative ultrasonography

LCNEC	Large-cell neuroendocrine carcinoma
LH	Luteinizing hormone
M	Metastasis status according to the AJCC/UICC TNM staging system
MAX	Gene encoding for the myc-associated factor X
MDCT	Multi-detector X-ray computed tomography
MEN	Multiple endocrine neoplasia
MIBG	*meta*-Iodobenzylguanidine
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
NE	Neuroendocrine
NEN	Neuroendocrine neoplasia
NET	Neuroendocrine tumor
NF1	Gene encoding for neurofibromin
NIH	United States National Institutes of Health
NKA	Gene encoding for Na^+/K^+ ATPase
NSE	Neuron-specific enolase
OS	Overall survival
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PCC	Pheochromocytoma
PCR	Polymerase chain reaction
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomograhy
PFS	Progression-free survival
PGL	Paraganglioma
PPGL	Pheochromocytoma and paraganglioma
PRRT	Peptide receptor radionuclide therapy
PTH-RP	Parathyroid-hormone related protein
PTH	Parathyroid hormone
qPCR	Quantitative PCR
RECIST	Response evaluation criteria in solid tumors
RET	Proto-oncogene encoding for a receptor tyrosine kinase
SCLC	Small-cell lung cancer
SDHB	Gene encoding for succinate dehydrogenase B
SDHD	Gene encoding for succinate dehydrogenase D
SEER	Surveillance, Epidemiology, and End Results, a tumor registry of the National Institutes of Health
SIADH	Syndrome of inappropriate antidiuretic hormone secretion
SNMMI	Society of Nuclear Medicine and Molecular Imaging
SPECT	Single-photon computed tomography
SPECT/CT	Single-photon computed tomography/Computed tomography
SRS	Somatostatin receptor scintigraphy
SSA	Somatostatin analog
SSTR	Somatostatin receptor
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
T	Tumor status according to the AJCC/UICC TNM staging system
TC	Typical carcinoid
TMEM127	Gene encoding for a protein that acts as a tumor suppressor
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status), and "M" (distant metastasis status)
TSC	Gene encoding for the tuberous sclerosis factor, also known as hamartin
TSH	Thyroid stimulating hormone

UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
US	Ultrasonography
VHL	von Hippel-Lindau
VIP	Vasoactive intestinal peptide
VMAT	Gene encoding for the vesicular monoamine transporter
WDHA	A syndrome characterized by watery diarrhea, hypokalemia, and achlorhydria
WHO	World Health Organization

Introduction

Neuroendocrine tumors (NETs) represent a major diagnostic challenge since their clinical presentation is variable, nonspecific, and usually late, often when hepatic metastases are already present [1, 2]. Critical issues in diagnosis are the identification of primary tumor location and of regional and distant metastases. Plasma biomarkers, histopathology, and imaging are used to define these areas. Imaging includes radiological and nuclear medicine techniques to acquire information on tumor site, extent, and functionality. These include delineation of somatostatin receptor expression (somatostatin receptor imaging), neuroendocrine tumor metabolism (^{18}F-DOPA), and metabolic status ([^{18}F]FDG-PET). Histopathological examination of tumor biopsies provides further information but is limited by tumor heterogeneity and a paucity of molecular markers that accurately demarcate tumor biology. Although Ki67 is widely used, it is a monoanalyte, and controversy exists in regard to its accuracy and precise clinical application [2]. Biomarkers such as plasma chromogranin A (CgA) and urinary 5-hydroxyindoleacetic acid (5-HIAA) are currently most used. They are monoanalytes; the assays are suboptimal in terms of sensitivity and specificity and do not meet the NIH performance metrics for accurate biomarkers [3]. The recent reports of the high accuracy of the measurement of circulating mRNA neuroendocrine transcripts suggest that this strategy may facilitate early diagnosis and detection of lesions and may provide an accurate basis for prognostic determination and therapeutic recommendation [4, 5].

Imaging plays a central role in diagnosis, staging, treatment selection, and follow-up of NETs. Current diagnostic modalities include radiological techniques such as multi-detector CT (MDCT), MRI, transabdominal ultrasound (US), and endoscopic (EUS) and intraoperative US (IOUS). Nuclear medicine strategies or molecular imaging includes scintigraphy (including single photon emission computed tomography, SPECT) with ^{111}In-pentetreotide or ^{99m}Tc-HYNIC-Tyr^3-octreotide and, more recently, PET with ^{68}Ga-labeled somatostatin analogs (SSA), ^{18}F-DOPA, and [^{11}C]5-HTP [2]. Recently somatostatin receptor (SSR) antagonists have been investigated in clinical trials, based upon their better targeting properties [6]. No modality alone is entirely effective, and the overall sensitivity and specificity of diagnostic imaging is ~80–90% [2, 7]. Regardless of imaging modalities utilized, about 50% of NETs remain with an unknown primary site [2]. In order to optimize sensitivity and specificity, anatomic and functional techniques are generally combined [8, 9]. The development of hybrid scanners (SPECT/CT, PET/CT), whereby molecular and anatomic details are superimposed, has facilitated an increase diagnostic accuracy. Somatostatin receptor imaging (either with conventional ^{111}In-pentetreotide scintigraphy or with ^{68}Ga-SSA-PET/CT) is a prerequisite to evaluate the eligibility and also putative efficacy of peptide

receptor radionuclide therapy (PRRT) and, to a lesser extent, systemic treatment with unlabeled somatostatin analogs.

Despite substantial advances in the fields of anatomic and functional imaging, a number of critical unmet needs remain in NET imaging. These are the development of more inclusive criteria for NET progression, the delineation of therapeutic responses that can be applied to slow-growing tumors, the validation of the more recent functional techniques (such as somatostatin receptor PET), and the integration of novel molecular genomic, biologic, and metabolic information [10, 11].

Neuroendocrine Tumors

Neuroendocrine tumors (NETs) are relatively rare tumors originating from ubiquitous neuroendocrine cells distributed throughout the body. The term "neuroendocrine" relates to the hybrid morphological and biological nature of these cells, which have both endocrine secretory properties. Such cells synthesize, store, and secrete a variety of classic (circulating) hormones as well as local chemical messengers which function as neurotransmitters or neuromodulators [12, 13].

In 1907, the pathologist Siegfried Oberndorfer was the first to describe small tumors of the intestine that he referred to using the German diminutive for cancer, "Karzinoide," thereby erroneously suggesting a benign tumor. Although he subsequently reversed this conclusion, the incorrect concept of a benign neoplasm has unfortunately remained enshrined in medical oncological dogma. In 1914, Pierre Masson suggested the endocrine origin of these tumors, and thereafter Friedrich Feyrter in 1938 introduced the concept of diffuse endocrine system. In 1966, Anthony Pearse sought to unify the origin of all neuroendocrine tumors by expanding Feyrter's concept. He ascribed a series of common biochemical characteristics to embrace all such neoplasia using the term APUDoma (amine precursor uptake decarboxylation) and concluded all had a neural crest origin. Further studies by Bloom and Polak linked the immunohistochemical and secretory characteristics of NETs with their symptoms and formed the basis for the contemporary understanding of neuroendocrine neoplasia [14].

Biomorphology

(a) NE cells

The neuroendocrine system is composed of three major compartments: (1) neurons in the central and peripheral nervous system; (2) epithelial endocrine cells (often with neuronal features), dispersed individually in the gastroenteric and respiratory tracts, thyroid, thymus, skin, breast, larynx, kidney, urinary bladder, and prostate and in some instances assembled in units, such as the pancreatic islets of Langerhans or the renal juxtaglomerular apparatus (*polkissen* cells); and (3) the classic endocrine organs, such as the anterior pituitary, parathyroid glands, and adrenals [15]. Neuroendocrine cells regulate activity systemically or locally via endocrine or autocrine/paracrine mechanisms and thereby modulate metabolic, chemoreceptor, motility, and secretion functions [16].

Neuroendocrine cells, depending on their degree of differentiation, produce, store, and exocytose a number of bioactive agents, including gastrin; insulin; serotonin; somatostatin; glucagon; pancreatic polypeptide; VIP in gastroenteropancreatic (GEP) tract; catecholamines in the adrenal medulla; ACTH, GH, prolactin, FSH, LH, and TSH in the anterior pituitary; and PTH in parathyroid glands. The majority of these cells contain chromogranins (a constitutive secretory proteins and/or synaptophysin), which have by default become utilized as nonspecific biomarkers of the neuroendocrine cell system or its neoplasia [17].

(b) Neoplastic spectrum

The majority of neuroendocrine neoplasia (NEN) (>95%) are sporadic. Others, particularly of gastric and pancreatic origin, may be related to genetic conditions including multiple endocrine neoplasia type 1 (MEN1), neurofibromatosis (NF1), von Hippel–Lindau

(VHL) disease, tuberous sclerosis complex (TSC), or Carney's syndrome [18]. Overall, there are at least 13 different neuroendocrine cell types in the gastrointestinal tract (EC, ECL, gastrin, δ, etc.) and four in the pancreas (α, β, δ, PP) with individual anatomical localization and defined neuroendocrine secretory products. Germline mutations in five genes have been recognized to be responsible for familial pheochromocytomas: the von Hippel–Lindau gene (VHL), causing VHL syndrome; the RET gene, leading to multiple endocrine neoplasia (MEN) type 2; the neurofibromatosis type 1 gene (NF1), associated with von Recklinghausen's disease; and the genes encoding the B and D subunits of mitochondrial succinate dehydrogenase (SDHB and SDHD), which are associated with familial paragangliomas and pheochromocytomas. Hereditary GEP or bronchial NET and pituitary adenomas occur in MEN type 1.

Tumors may arise from each of the neuroendocrine cell types and can exhibit a wide spectrum of clinical and pathological behavior, ranging from asymptomatic to florid (flushing/diarrhea) or from indolent (e.g., gastric type I tumor) to highly aggressive growth (e.g., glucagonomas). Their natural history varies from torpid local invasion and fibrosis in the peritoneal cavity or heart to diffuse metastatic spread, most commonly to the liver and lungs [2]. Metastases are present overall in ~35% of all gastroenteropancreatic (GEP) NETs at presentation, ranging from <5 for type I gastric tumors to 60–80% for those originating in the small bowel and colon [2, 19].

Incidence

The Surveillance, Epidemiology, and End Results (SEER) database, containing 48,195 NENs from 1973 to 2006 [20], indicates that NETs constitute 0.66% of all malignancies in the United States and the incidence is increasing at a rate of 3–10% per year depending on the subtype (Fig. 1). Thus in 2004 NETs comprised 1.25% of all malignancies, as compared to 0.75% in 1994 [19, 20]. This increment is related to the technical progress of more sensitive diagnostic tools and to an

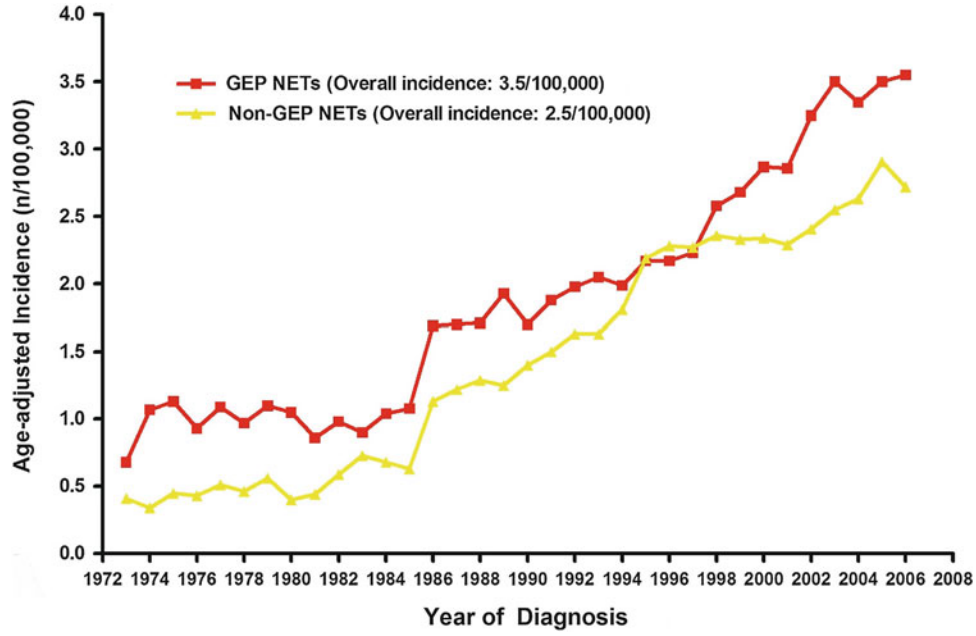

Fig. 1 Incidence of neuroendocrine neoplasms by anatomical location in the US population between 1973 and 2007

increased awareness among clinicians and pathologists [2, 21]. However, the greater frequency (1.22%) of NETs in a large autopsy series indicates that they are predominantly underdiagnosed [22]. It also suggests that there is a significant percentage that may have no clinical consequences during the lifetime of an individual. According to SEER, the most frequent site is the gastrointestinal tract (66%) followed by the bronchopulmonary system (25%). Other less frequent locations are the ovaries, testes, hepatobiliary, and pancreas (Fig. 2) [23].

The Rochester Epidemiology Project revealed that pheochromocytomas demonstrated an overall incidence in the white population of 0.8/100,000 cases per year over 30 years [24]. Of note was the observation that 0.5% of subjects with hypertension and 4% of those with an incidental adrenal mass harbor a pheochromocytoma [25].

Sporadic forms of pheochromocytoma are diagnosed in individuals aged 40–50 years, whereas hereditary forms are diagnosed at a younger age, often before 40. Pheochromocytoma is rare in children, but, when found, it is often extra-adrenal, multifocal, and associated with hereditary syndromes.

Histopathological Classification

NETs represent different pathological entities, depending on their organ and cell of origin, and have been considered as representing three categories: (a) those arising in neuroendocrine organs, such as medullary thyroid carcinomas, pancreatic endocrine tumors, pheochromocytomas, and paragangliomas; (b) those arising from dispersed neuroendocrine cells, such as bronchial or

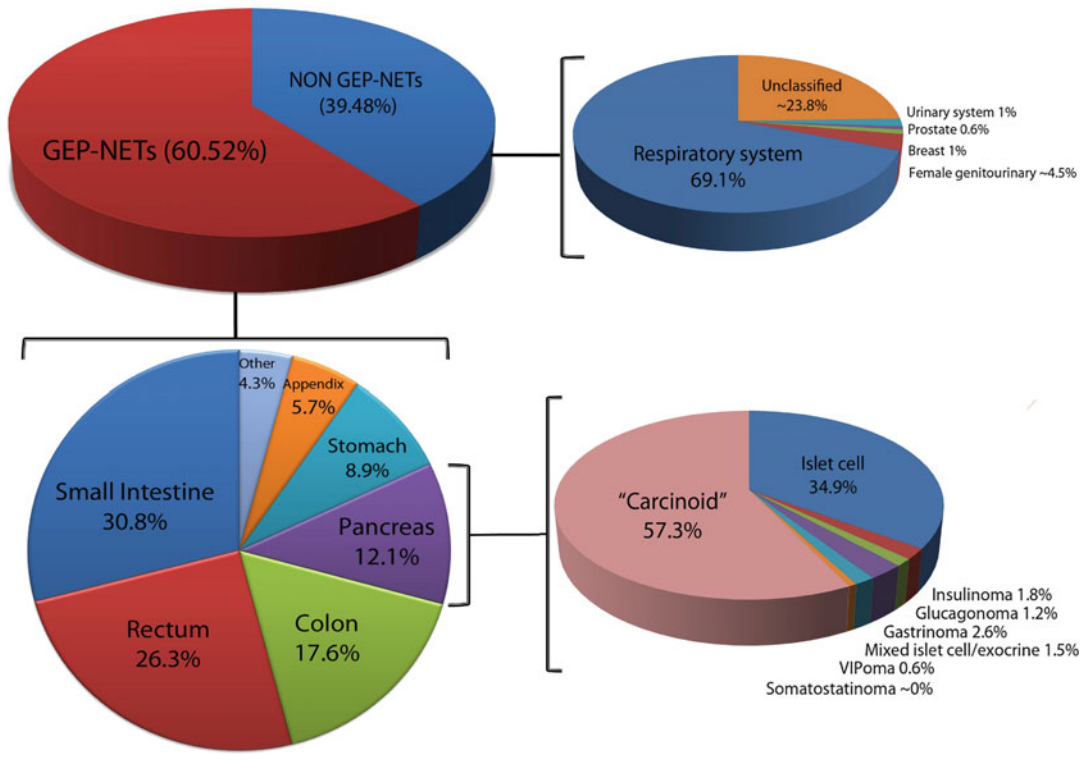

Fig. 2 Distribution of neuroendocrine tumors (n = 49,012) in the Surveillance, Epidemiology, and End Results (*SEER*) tumor registry database from 1973 to 2007, according to anatomical site and tumor type: total NETs (*top left*), gastroenteropancreatic (GEP)-NETs (*bottom left*), and pancreatic NETs (*bottom right*). Non-GEP-NETs are predominantly located in the respiratory system (~70 % are bronchopulmonary NETs; *top right*)

gastroenteric NETs; and (c) those arising from non-neuroendocrine organs, such as thymic carcinoids or cutaneous NETs.

NETs can be functioning or nonfunctioning, depending on the presence of a clinical symptomatology syndrome due to hypersecretion of bioactive amines or peptides. The 1963 classification of GEP-NETs, based on their embryologic origin (foregut, midgut, or hindgut) by Williams and Sandler [26], is used, though of minimal value, and has mostly been supplanted by the World Health Organization (WHO) classification system. The latter has defined these tumors based upon a number of morphological criteria including their degree of differentiation and site of origin [27]. The initial (2004) iteration identified well-differentiated neuroendocrine tumors (benign behavior or uncertain malignant potential), well-differentiated neuroendocrine carcinomas (low-grade malignancy), or poorly differentiated (small or large cell) neuroendocrine carcinomas of high-grade malignancy. The term "carcinoid" was reserved for "well-differentiated" tumors. Size, angioinvasion, proliferative activity, histologic differentiation, metastases, and hormonal activity (association with clinical syndromes or diseases) were included in the classification scheme. Histochemical indicators of prognosis include the degree of expression of the proliferation protein Ki-67 and the p53 tumor suppressor protein [28, 29]. ENETS and later WHO in 2010 further refined this classification to include the Ki-67 scoring index and the TNM classification system (Table 1) [30, 31]. The grading proposal stratifies tumors in G1, G2, and G3 and is based on the premise that *all* NETs are intrinsically malignant (Table 2) [32, 33]. The tumor grading, histopathology type and staging, reflects on the potential metastatic spread and, therefore, influences the choice of therapeutic options (surgery, biotherapy, and chemotherapy) [34]. Although the function of Ki-67 remains poorly characterized [35] and concerns remain regarding heterogeneity of expression and measurement techniques, it is used as a surrogate marker of proliferation [36]. In order to assure an optimal treatment of GEP-NETs, a standardized diagnostic procedure is required. The ENETS society has proposed diagnostic and prognostic stratification criteria, based on histological typing, differentiation, grading, and TNM staging. Immunostaining for the neuroendocrine markers synaptophysin and chromogranin and for the proliferation marker Ki67/MIB1 is considered mandatory, while immunostaining for hormones, receptors, and other markers is optional [34]. The recent development and introduction of a minimal data set for pathologists will add consistency and uniformity to the evaluation and classification of GEP-NENs [37].

This classification applies easily to GEP-NETs, while bronchopulmonary (BP) and thymic NETs

Table 1 WHO 2010 general neuroendocrine neoplasm categories: comparison with previous classifications

WHO 1980	WHO 2000	WHO 2010
I Carcinoid	1. Well-differentiated endocrine tumor (WDET)[a]	1. NET G1 (carcinoid)[b]
	2. Well-differentiated endocrine carcinoma (WDEC)[a]	2. NET G2[b]
	3. Poorly differentiated endocrine carcinoma/ small cell carcinoma (PDEC)	3. NEC (large cell or small cell type)[b, c]
II Mucocarcinoid	4. Mixed exocrine–endocrine carcinoma (MEEC)	4. Mixed adenoneuroendocrine carcinoma (MANEC)
III Mixed forms carcinoid – adenocarcinoma		
IV Pseudotumor lesions	5. Tumor-like lesions (TLL)	5. Hyperplastic and preneoplastic lesions

From Bosman et al. [151], with permission

[a]The difference between WDET and WDEC was defined according to staging features in the WHO 2000 classification. G2 NET does not necessarily translate into WDEC of the WHO 2000 classification

[b]Definition in parentheses for the International Classification of Diseases for Oncology (ICDO) coding

[c]"NET G3" has been used for this category but is not advised since NETs are by definition well differentiated

Table 2 WHO 2010 working principles for neuroendocrine neoplasms

Neoplasm definition to embrace all grades of endocrine tumors (low, intermediate, and high grade)
Neuroendocrine connotation recommended as description of shared neural–endocrine markers
Standard definition of neuroendocrine tumor (NET) for low- to intermediate-grade neoplasms and neuroendocrine carcinoma (NEC) for high grade
NET subdivision according to grade (ICDO codes 8240/3 and 8249/3); potential malignancy formalized
NEC subdivision in LCNEC and SC-NEC (ICDO codes 8013/3 and 8041/3)
Synonyms for NET: carcinoid, well-differentiated endocrine tumor/carcinoma; for NEC: poorly differentiated endocrine carcinoma, high-grade neuroendocrine carcinoma
TNM recommended (AJCC–UICC–WHO 2010)
For carcinoids only (excluded G3 neoplasms)
Blueprint from ENETS proposals 2006–2007 for the stomach, ileum, and colon but with significant differences for the appendix and pancreas (generate data)
Diagnosis by site according to the above uniform grading and staging parameters
Minimal histopathology report recommendation
Neoplasm definition as NET or NEC
Grade definition as G1–G3
pTNM definition (when possible)

From Bosman et al. [151], with permission

are still classified according to a proposal by Travis (Table 3). Travis recognized low-grade NETs – typical and atypical carcinoids – and high-grade NETs, large-cell neuroendocrine carcinoma (LCNEC) and small-cell lung cancer (SCLC). The most prevalent high-grade NET, accounting for 89% of cases according to the SEER database of National Cancer Institute, is SCLC [38–40].

A recent proposal of a three-tier grading system for BP-NETs has been published. It is based upon that currently utilized for GEP tumors and includes Ki67 index (with specific cut-offs) in addition to mitotic count and necrosis (Table 4) [41]. However, the utility of this new classification using Ki67 in BP-NETs requires prospective confirmation [42].

Pheochromocytomas and paragangliomas (PPGL) derive from sympathetic chromaffin tissue in the adrenal medulla and from the extra-adrenal paraganglial system of the thorax and abdomen. The frequency malignant propensity of chromaffin tumors, pheochromocytomas, and paragangliomas reflects the genetic background. Over 50% of PPGL can be attributed to genetic alterations [43]. These most frequently involve germline mutations of VHL or SDH genes (Table 5). The 2004 WHO classification recognized the common origin of PPGL from neuroectoderm and divided them into pheochromocytomas and paragangliomas, arising, respectively, in the adrenals or the extra-adrenal sympathetic tissue. Pheochromocytomas are usually considered as malignant only in the presence of metastases. These usually are found with decreasing frequency in the liver, lymph nodes, lung, and bone, either at diagnosis or during follow-up. This group has been colloquially defined by the so-called 10% rule, namely, 10% bilateral, 10% extra-adrenal, 10% familial, and 10% malignant [44]. Histopathological scoring criteria utilizing the presence of diffuse cellular growth, high cellularity, monotony, tumor cell spindling, atypical mitotic figures, high mitotic count, etc. failed to accurately assess the malignant potential due to inter- and intra-observer variation [45]. Malignant pheochromocytomas account for about 10% of all pheochromocytomas and are associated with capsular invasion and large tumor size (>5 cm in size and >80 g in weight) [46]. Genetically five autosomal dominant disorders are recognized: the paraganglioma (PGL) syndromes types 1–5 are characterized by a familial predisposition to PGLs, pheochromocytomas (PCCs), renal cell cancers, gastrointestinal stromal tumors and, rarely, pituitary adenomas. The different syndromes are based on five different/separate mutations of the SDH gene (SDHD=PGL1, SDHAF2=PGL2, SDHC=PGL3, SDHB=PGL4, and SDHA=PGL5) [47]. Malignant pheochromocytomas are evident in individuals with MEN2, > 90% of those in VHL disease, and ~90% of those in NF1 [48]. Malignant paragangliomas have a higher prevalence, 15–35% when associated with the SDHB gene mutations [49–51].

In addition to their hormonal profile, PPGL often exhibits neuroamine uptake mechanisms and/or specific receptors, such as cell membrane somatostatin receptors and norepinephrine

Table 3 The Travis 2004 classification of bronchopulmonary neuroendocrine tumors

Typical carcinoid
A tumor with carcinoid morphology and less than 2 mitoses per 2 mm^2 (10 high-power field (HPF)), lacking necrosis and 0.5 cm or larger
Atypical carcinoid
A tumor with carcinoid morphology with 2–10 mitoses per 2 mm2 (10 HPF*) OR necrosis (often punctate)
Large-cell neuroendocrine carcinoma
A tumor with a neuroendocrine morphology (organoid nesting, palisading, rosettes, trabeculae)
High mitotic rate: 11 or greater per 2 mm^2 (10 HPF), median of 70 per 2 mm^2 (10 HPF)
Necrosis (often large zones)
Cytologic features of a non-small cell carcinoma (NSCLC): large cell size, low nuclear to cytoplasmic ratio, vesicular or fine chromatin, and/or frequent nucleoli. Some tumors have fine nuclear chromatin and lack nucleoli, but qualify as NSCLC because of large cell size and abundant cytoplasm
Positive immunohistochemical staining for one or more neuroendocrine markers (other than neuron-specific enolase) and/or neuroendocrine granules by electron microscopy
Small cell carcinoma
Small size (generally less than the diameter of three small resting lymphocytes)
Scant cytoplasm
Nuclei: finely granular nuclear chromatin, absent or faint nucleoli
High mitotic rate (11 or greater per 2 mm^2 (10 HPF), median of 80 per 2 mm^2 (10 HPF)
Frequent necrosis often in large zones

From Travis et al. [152], with permission

Table 4 Proposed Grading system for bronchopulmonary neuroendocrine tumors

Grade	Mitotic count (10 HPF)[a]	Ki67 (%)[b]	Necrosis (%)[c]
G1	2	<4	No
G2	>2–47	4–<25	<10
G3	>47	≥25	>10

From Rindi et al. grading the neuroendocrine tumors of the lung: an evidence-based proposal. Endocr Relat Cancer. 2013, with permission

[a]10 HPF, ten high-power field=2 mm^2, to be assessed in at least 50 fields at 40× in areas of highest mitotic density

[b]Ki67%: MIB antibody, as percentage of 500–2,000 cells counted in areas of highest nuclear labeling

[c]Necrosis as % of sample: focal, presence of <10% of sample, diffuse, more than 10% of sample

transporter (vesicular monoamine transporter 1 and 2, VMAT 1 and 2), which are of critical relevance to their localization and treatment [52].

Clinical Symptomatology and Presentation

NETs, particularly those of GEP origin, exhibit protean symptomatology that is often overlooked. They may present with symptoms related to the inappropriate hypersecretion or paroxysmal bioactive peptide or amine. The large majority is nonfunctioning and such lesions are asymptomatic presenting late due to a mass effect (jaundice/pain). Thus, despite a sometime typical clinical scenario, such as the carcinoid syndrome, symptoms remain frequently unrecognized, and diagnosis is often tardy. Diagnostic delay is usually 5–7 years since the symptoms are considered as caused by other ubiquitous conditions (e.g., allergy, anxiety, menopause) as opposed to a tumor, or the paroxysmal nature of the symptoms leads to considerations of neurotic complaints or somatization [2]. NET is therefore often diagnosed late when metastasis (usually hepatic) has occurred; thus, curative surgery is no longer possible. Thus, despite the fact that the tumors tend to be well differentiated and slow growing, with a minority of aggressive forms, outcome is significantly diminished by delay in diagnosis.

Gastroenteropancreatic NETs

Gastric NETs (frequently referred to as gastric carcinoids) are typically multiple, small, and generally benign and derived from ECL cells. They are associated with hypergastrinemia and have

Table 5 Genetically related forms of pheochromocytoma and paraganglioma

Gene	Disease	Features
NF1	Neurofibromatosis type 1	Café-au-lait spots, neurofibromas, axillary and inguinal freckling, Lisch nodules, osseous lesions, optic gliomas, mainly pheochromocytomas
RET	Multiple endocrine neoplasia type 2	2A: Medullary thyroid cancer, primary hyperparathyroidism, PPGL
		2B: Medullary thyroid cancer, PPGL, Marfanoid habitus, mucocutaneous neuromas, gastrointestinal ganglioneuromatosis
VHL	von Hippel–Lindau disease	Central nervous system or retinal hemangioblastomas, renal cell carcinoma, PPGL, pancreatic neuroendocrine tumors and cysts, endolymphatic sac tumors, papillary cystadenoma of the epididymis and broad ligament
PGL1: SDHD	Hereditary paragangliomas	1. PGL5: SDHA
PGL2: SDHAF2		2. Head and neck paraganglioma
PGL3: SDHC		3. PPGL, rare renal cancers, GIST
PGL4: SDHB		4. PPGL, rare renal cancers, GIST
PGL5: SDHA		5. PPGL, GIST
1. TMEM127	Familial pheochromocytomas	1. Mainly pheochromocytomas, rare renal cancers
2. MAX		2. Mainly PPGL
EPAS1	Polycythemia paraganglioma	Polycythemia, PPGL, somatostatinoma
FH	Leiomyomatosis and renal cell	Cutaneous and uterine leiomyomas, type 2 papillary renal carcinoma, rare PPGL

GIST: gastrointestinal stromal tumors (Adapted from Favier et al. [43] with permission)

been classified as type I, associated with atrophic gastritis, or type II, in conjunction with MEN1 and/or the Zollinger–Ellison syndrome. Type I are very rarely malignant, whereas type II in 20–30% are malignant and metastatic. Type III gastric carcinoids not associated with hypergastrinemia and present as single, usually larger lesions often associated with metastatic disease.

Duodenal NETs frequently secrete gastrin and may be associated with Zollinger–Ellison syndrome, occasionally as part of MEN1. Intestinal NETs (the so-called classic "carcinoids," described by Oberndorfer) derive from enterochromaffin cells (EC cells). Symptoms are usually only evident after metastasis to the liver and are often paroxysmal and have been described as typical or atypical. Manifestations are protean and include cutaneous flushing, diarrhea, bronchospasm, tachycardia, and abdominal pain. Symptoms represent the overproduction and release in the systemic circulation of bioactive amines and peptides including mostly serotonin, histamine, and tachykinins. The classic carcinoid syndrome, however, is relatively uncommon (10–15%) [22]. A not insignificant percentage of carcinoids may be discovered when nonmetastatic due to emergency surgery for acute abdominal events relating to perforation, bleeding, or obstruction [53]. Colonic carcinoids are frequently large, nonfunctioning, and with a poor prognosis, while rectal lesions are small and rarely metastasize. Appendiceal carcinoids are usually identified early when they cause obstructive appendicitis and are mostly benign. A small percentage is malignant and metastatic usually manifesting with mucin producing diffuse peritoneal metastases and only occasionally functional [54].

NETs in the pancreas vary in size depending upon the time of identification and their symptomatology. Asymptomatic lesions usually present late unless identified by mass lesions obstructing the common bile duct or with bleeding and/or pain. Up

to 50% have synchronous local or liver metastatic disease. Functioning pancreatic islet cell tumors may present with syndromes related to the hyperproduction of insulin, gastrin, VIP, glucagon, or somatostatin. These tumors represent markedly different clinical and pathological entities depending upon their cell of origin and symptomatology. Insulinomas are often small and benign lesions causing hypoglycemia. Pancreatic gastrinomas are less common than in the duodenum but generally malignant, causing Zollinger–Ellison syndrome and in ~25% of cases are associated with MEN1. Glucagonomas present with mild diabetes and a characteristic rash (necrolytic migratory erythema). Finally, VIPomas may produce severe diarrhea, hypokalemia, and achlorhydria (WDHA syndrome). Rarely, a group of more malignant lesions may secrete ACTH, GH-RH, PTH-RP, and somatostatin [2].

Bronchopulmonary NETs

The majority of patients with BP-NETs have symptoms present with symptoms of cough, hemoptysis, and pneumonia (a classical triad), resulting from the lumen obstruction and ulceration of the tumor. Pathological classification predominantly divides the group into typical and atypical lesions although the criteria are sometimes difficult to ascertain. Typical carcinoids (TC) present characteristically as a central lesion, with signs and symptoms of bronchial obstruction, and exhibit a relatively benign/indolent biological behavior. Atypical carcinoids (AC) are frequently peripheral and functional. Their behavior may vary from indolent to aggressive, with lymphatic and hematogenous metastases. Less than 5% of BP-NETs exhibit hormonally related symptoms such as carcinoid syndrome, Cushing syndrome, acromegaly, or the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Large-cell neuroendocrine cancers are aggressive and rare form of NET, usually metastatic at diagnosis, causing rapid clinical deterioration. Paraneoplastic syndromes are sporadic. Small-cell lung cancers (SCLCs) are particularly aggressive and are associated with early hematogenous and lymphatic metastasis. SCLCs are extremely chemosensitive but usually relapse. Mediastinal syndrome, caused by lymph node metastases, is a relatively common clinical presentation and is often accompanied by distant metastases, typically to the brain or bones. In many instances, they are associated with paraneoplastic syndromes, particularly Cushing syndrome and the syndrome of inappropriate antidiuretic hormone secretion (SIADH) [55–57].

Chromaffin Cell NETs

Most PPGLs, except those arising from the head and neck region, are associated with catecholamine hypersecretion [58]. The majority (80–85%) of pheochromocytomas arise from the adrenal medulla, while about 15–20% are extra-adrenal. Catecholamine-producing paragangliomas are usually located in the abdomen [45, 58]. The most frequent signs of catecholamine hypersecretion (pheochromocytoma has been described as “the great mimic”) are hypertension, tachycardia, headache, pallor, sweating, and feelings of panic or anxiety. Hyperglycemia, lactic acidosis, weight loss, nausea, fever, and flushing may also occur. Hypertension is usually paroxysmal, sometimes severe, leading to hypertensive emergencies, superimposed on a state of normal blood pressure or of hypertension. Sometimes blood pressure may be normal, when tumor load is limited or when dopamine is preferentially secreted. In rare cases of prevalent epinephrine secretion, patients may even present with hypotension [58].

Biochemical Profile

Serum or blood hormone assays are currently used for diagnosis in conjunction with histopathology and clinical evaluation. Numerous different peptides and amines (secretory unianalytes) have been proposed as biomarkers to identify and monitor disease status of NETs. In the past, the most common markers of NETs have been chromogranins A and B, pancreatic polypeptide, pancreastatin, and NSE [59]. The majority of biomarkers proposed for the diagnosis of these lesions have proven to exhibit a low sensitivity

and specificity, are difficult to measure accurately or easily, and are therefore mostly of research use, with the exceptions of the specific peptides gastrin, insulin, VIP, and glucagon in pancreatic NETs, which proved to be of clinical utility.

Recently the development of molecular multianalyte markers (mRNA transcripts) has provided evidence that this strategy is more sensitive and specific [4]. Transcript analysis in the blood provides >90% accuracy in the identification of NETs and the ability to define disease progression [60].

In the past, plasma CgA levels have been widely utilized as the default biomarker for all NETs. Although they are relatively sensitive (60–90%), their specificity is poor (10–30%). This reflects elevated levels in other NETs and other malignancies, spurious increases in individuals with impaired renal function or during administration of proton pump inhibitors [61]. CgA has mostly been used as the default measurement to confirm diagnosis and obtain information as to tumor burden and possible location of the tumor. Its interpretation is limited however by the fact that it is a secretory product and does not represent the diverse biological activity of the tumor (proliferation, metabolic status, etc.). Circulating CgA is elevated in ~60% of individuals with GEP-NETs, most frequently in subjects with gastrinomas (100%), followed by small-bowel "carcinoid" tumors (80%) and nonfunctioning pancreatic NETs (70%) [62]. Plasma CgA levels are considered more frequently elevated in well-differentiated tumors compared to poorly differentiated tumors of the midgut reflecting the observation that it is a secretory marker and dedifferentiated lesions rarely secrete. It has been proposed that CgA possesses some utility in predicting survival and in providing information on the efficacy of therapy; however, this is likely a surrogate of the fact that secretory capacity is inversely related to tumor differentiation [4]. Measurement of CgA is substantially limited by a lack of standardization of assays and a relatively low sensitivity/specificity in some clinical situations. Thus, CgAs measured at different time points in the disease or using different commercial assays are not comparable or provide information that is difficult to interpret. Moreover, measurement of urinary 5-HIAA levels or plasma 5-HT levels is cumbersome, insensitive, and difficult to quantify.

A recent Delphic consensus unanimously established that common biomarkers used for GEP-NETs are inadequate for BP-NETs and concluded that mRNA transcript analysis (NETest) was provided a greater opportunity for clinical utility [63]. The multianalyte-derived NET gene signature encompasses the expression of 51 genes, measured by qPCR that are assessed by four different prediction algorithms scaled to a disease/tumor activity (0–100%) score [64] using expression that specifically capture the hallmarks of neoplasia [65]. The expression of 51 NET marker genes includes analysis of clusters of biologically relevant genes that constitute the different "omes" (proliferome, metabolome, secretome, epigenome, and plurome) [64] which define the NET "fingerprint." This can be used to provide direct information about the tumor, its pathophysiology, and its state of evolution from stability to progression [66]. The test has a sensitivity and specificity of greater than 90% and significantly outperforms CgA measurement in every assessable parameter [67]. Clinically, gene expression is decreased following surgery and can be used to identify residual/recurrent disease [68]; it can also effectively monitor treatment protocols, e.g., somatostatin analog therapy [69, 70], and can predict disease progression Fig. 3 [71].

If a secretory phenotype is present, the diagnosis of chromaffin cell tumors is based on syndromic presentation, which triggers the assessment of plasma and urinary catecholamines and genetic testing [43]. Functioning chromaffin cell tumors secrete catecholamines, namely, norepinephrine, epinephrine, and dopamine. These agents are catabolized to metanephrines, which may be identifiable in high concentration in the urine. Urinary and plasma catecholamines, urinary metanephrines (normetanephrine and metanephrine), and urinary vanillylmandelic acid are usually measured for diagnosis. Currently, the plasma and 24-h urinary measurement of free metanephrines is the most sensitive method to accurately diagnose a pheochromocytoma/paraganglioma (96–100% and 92–99% sensitivity, respectively, and 87–92%

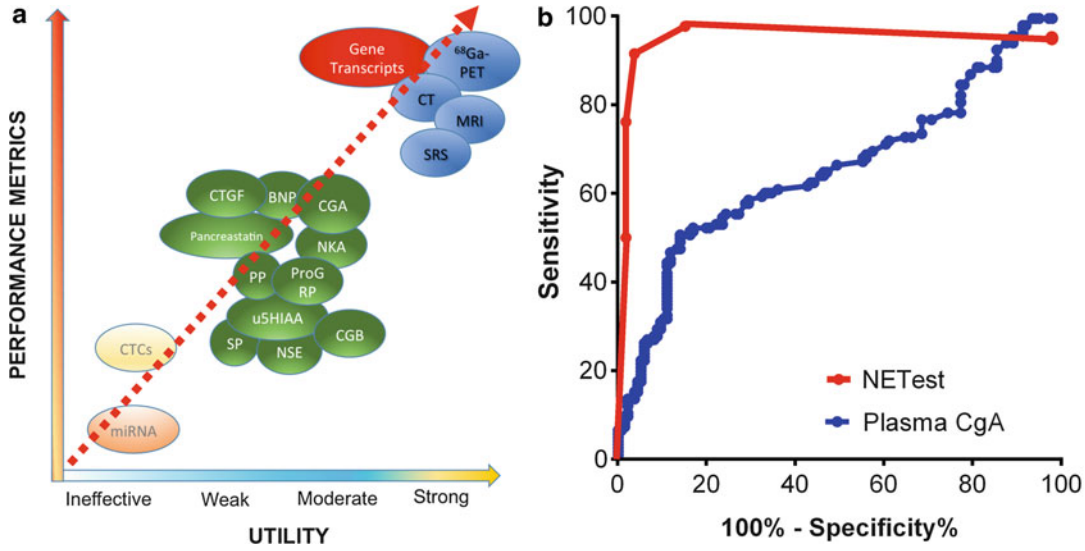

Fig. 3 Utility of biomarkers and imaging techniques in NET management. (**a**) The utility of current NET biomarkers and imaging based on published use and performance metrics. Overall clinical utility can be estimated by referencing the arrow (*red*) to the x any axes of metrics and utility. miRNA assessment (*orange*) has no rigorous utility or metrics available. CTC measurement (*yellow*) exhibits moderate metrics but has not been validated in NETs. Substance P, NSE, pancreatic polypeptide, NKA, pancreastatin, CTGF, and brain natriuretic peptide (*green*) all display variable performance metrics. Their overall utility is weak. Biomarkers including urinary 5-HIAA and CgA have moderate utility, but their metrics are highly variable. NET transcript analysis (*red*) exhibits high level metrics, and early clinical studies support its clinical utility. Imaging data derived from CT scan, MRI, somatostatin receptor scintigraphy, [^{18}F]FDG, and ^{68}Ga-SSA-PET/CT (*blue*) are included for comparison with current biomarkers. All imaging techniques have high utility, but the metrics exhibit a wide range from [^{18}F]FDG to ^{68}Ga-PET. *BNP* brain natriuretic peptide, *Ga-PET* ^{68}Ga-SSA-PET/CT, *PP* pancreatic polypeptide, *Pro-GRP* progastrin-releasing peptide, *SRS* somatostatin receptor scintigraphy, *u5-HIAA* urinary 5-HIAA. (**b**) Receiver operating characteristic curves for peripheral blood NET transcript analysis {polymerase chain reaction (PCR)} (*red*) compared to chromogranin A (CgA) (*blue*) for GEP-NETs. The NET transcript analysis area under the curve (AUC) was significantly more effective (AUC = 0.98, $p < 0.0001$) than CgA (AUC = 0.64, $p < 0.002$). In the efficacy analysis of NET, transcript analysis demonstrated that it was significantly more accurate than CgA ($p < 0.0001$)

and 64–72% specificity, respectively) [72]. Due to its low sensitivity and specificity, CgA is not used in chromaffin cell tumor assessment [73]. To avoid false-positive results, biochemical evaluation should not be performed if the patient is receiving drugs that can increase catecholamine levels. These agents include phenoxybenzamine and tricyclic antidepressants, monoaminooxidase inhibitors, calcium channel blockers, and caffeine. Biochemical evaluation of patients receiving these drugs is a major cause of false-positives. Dynamic tests, such as the clonidine test, are sometimes performed in norepinephrine-secreting tumors [74]. Head and neck paragangliomas are rarely hormonally active.

A key unmet need in the diagnostic assessment of NETs and chromaffin tumors is the availability of a blood test for early diagnosis or surveillance. The recent demonstration of specific NEN transcripts in plasma suggests that this strategy may enable early diagnosis and detection of lesions and even provide a basis for prognostic determination and therapeutic recommendation. Recent reports indicate that measurements of neuroendocrine blood transcripts are significantly more specific and reproducible than CgA measurement [5].

NET transcript analysis can identify PCC/PGL in 95–100%, and expression levels correlate with lesion extent, particularly extra-adrenal. Furthermore SDH mutations were associated with decreased expression of genes involved in metabolism providing a functional dimension to the assessment. In addition proliferation-associated

genes are elevated in progressive, metastatic disease; thus, measurement of circulating transcripts focusing on gene clusters has utility in identifying and differentiating disease activity in PGL/PCC tumors where other neuroendocrine biomarkers lack specificity [75].

Techniques

Radiological Techniques

Transabdominal ultrasonography (US) is usually the first examination to identify the location of the tumor. It is also used for needle guidance in case of fine needle aspiration cytology (FNAC) or core biopsy. To improve sensitivity, contrast-enhanced US (CEUS), endoscopic US (EUS), and intraoperative US (IOUS) are also used. Contrast-enhanced multi-detector CT (MDCT) and MRI are considered the fundamental methods for localizing the primary tumor and delineating its local extent, staging the locoregional and distant metastases, and restaging the patients after therapy [53]. Three-phase scans are performed to best delineate hypervascular and hypovascular lesions. Since NETs are typically hypervascular, CT and MRI are performed early after the bolus of contrast is injected (arterial phase) (Fig. 4). The sensitivity for pancreatic NETs ranges from 69% to 94% for CT and 74–94% for MRI and is >80% for EUS coupled with biopsy [53, 76–80]. The sensitivity for locating a primary small intestine NET is >90% for CT enteroclysis and 86–94% for MRI [81–83]. Although tumor arterial enhancement is homogeneous in small NETs, heterogeneous enhancement is more common in lesions larger than 3 cm. However, the degree, uniformity, and timing of enhancement can be highly variable, and other lesions, such as intrapancreatic accessory spleen, can be commonly mistaken for a NET. Vascular heterogeneity itself is considered to be a sign of malignancy since malignant lesions often have heterogeneous vascular structure, perfusion, and vascular permeability [84, 85].

Localization of GEP-NETs may be difficult since they often present as small lesions and their anatomic location is ubiquitous. EUS is mainly useful in the diagnosis and staging of small and intramural lesions of the duodenum, pancreas, stomach, and rectum and can detect up to 60% of duodenal and up to 100% of pancreatic lesions. EUS and IOUS have a detection rate of 92% for insulinomas. Although the diagnostic accuracy of US for the detection of pancreatic NETs is high, the best performance of US is for the diagnosis and follow-up of liver metastases (sensitivity and specificity are 88% and 95%, respectively) [27, 28].

GEP-NETs may metastasize systemically or locally into the bowel mesentery. Mesenteric disease can be identified on CT as a contrast-enhancing mass often containing calcifications [86]. Angio-CT has particular utility in the identification of the involvement of vascular structures (such as mesenteric arteries) that may preclude surgical resection [87]. However, CT and MR imaging cannot always differentiate tumors and mesenteric metastasis from intestinal structures. Lymphoma or retractile mesenteritis can also have a similar CT appearance [88].

The liver is the commonest site of NET metastases. The metastatic lesions are typically hypervascular, and most can be detected on CT or MR images acquired during the hepatic arterial phase. However, liver metastases may be hypovascular (Fig. 5). Moreover, larger metastases may show heterogeneous enhancement due to central necrosis. For liver metastases, MRI fast spin echo has a high sensitivity, while a single-shot sequence allows optimal distinction between hypervascular metastases from hemangiomas. Contrast-enhanced CT and MR imaging can also disclose occasional metastases to other intra-abdominal organs. Metastases to bone are easily missed on CT. Although MR imaging has a sensitivity of nearly 100%, the appearance of lesions may be identical to that of bone metastases from other primary tumors. Contrast-enhanced CT, MR imaging, and US are routinely used for monitoring lesions. Finally, video capsule and double-balloon enteroscopy can identify otherwise undetectable small intestine tumors [10].

Primary carcinoids of the lungs account for ~25–30% of all NETs. Most carcinoids (typical

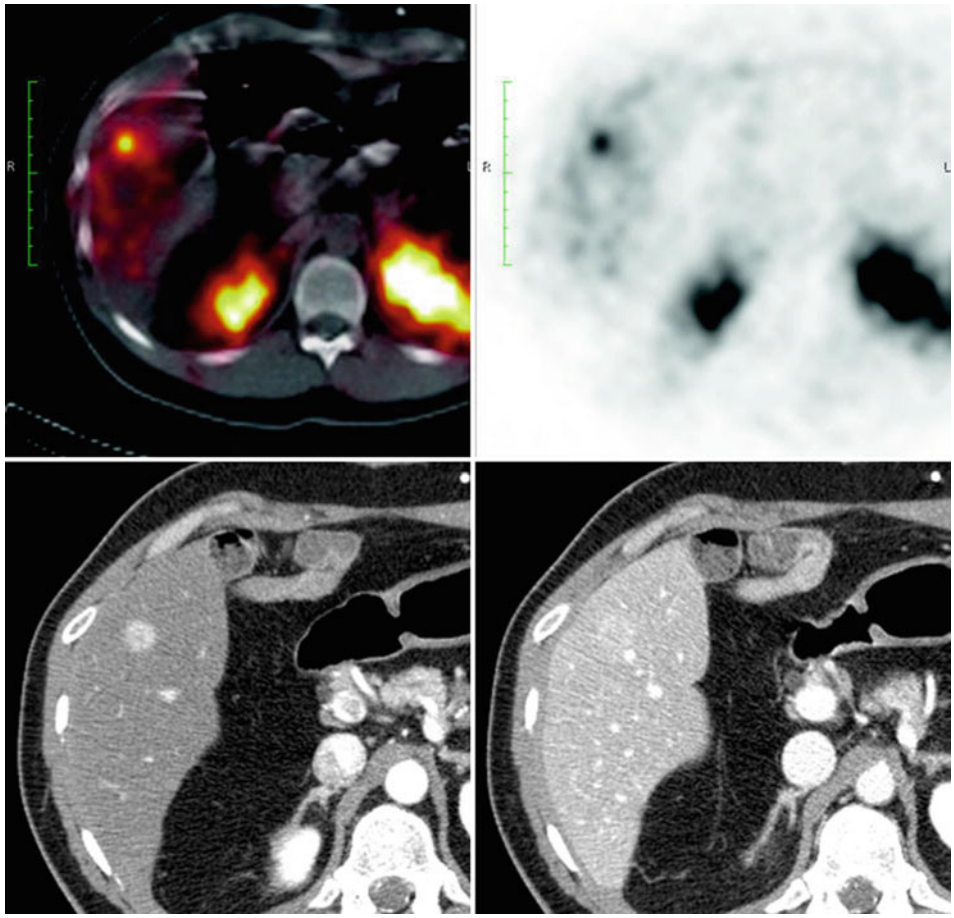

Fig. 4 Patient with a liver metastasis from an ileal neuroendocrine tumor. *Upper* images show SPECT/CT images demonstrating uptake of ^{111}In-pentetreotide within a liver metastasis. The *bottom left* image shows the metastasis with a typical contrast enhancement on CT during the arterial phase. The lesion enhancement decreases during the venous phase when compared to the liver parenchyma (*bottom right* image)

and atypical) are located close to central bronchi, although in about 16–40% (often atypical) are located in the peripheral lung. They typically show a spherical or ovoid shape with a well-defined border, but sometimes they develop along bronchi or pulmonary arteries. Punctate or diffuse calcifications are frequently observed on CT. Both typical and atypical carcinoids are usually hypervascular and demonstrate intense contrast enhancement (more than 30 HU). Atypical carcinoids are associated with hilar or mediastinal lymph node metastases. LCNEC, which is a poorly differentiated and high-grade NET, is morphologically intermediate between atypical carcinoid and SCLC. LCNEC and SCLC do not show any specific CT feature and can indistinguishable from the other common NSCLCs. However, CT plays a main role for staging and follow-up of all NETs of the lung.

CT and MRI are sensitive and specific for detecting adrenal pheochromocytomas (77–98% for CT and 95–100% for MRI). However, MRI and CT have a lower sensitivity (sensitivity of CT is 29%) for extra-adrenal lesions or metastases from malignant pheochromocytomas [46, 89]. In this setting, specificity may be decreased since

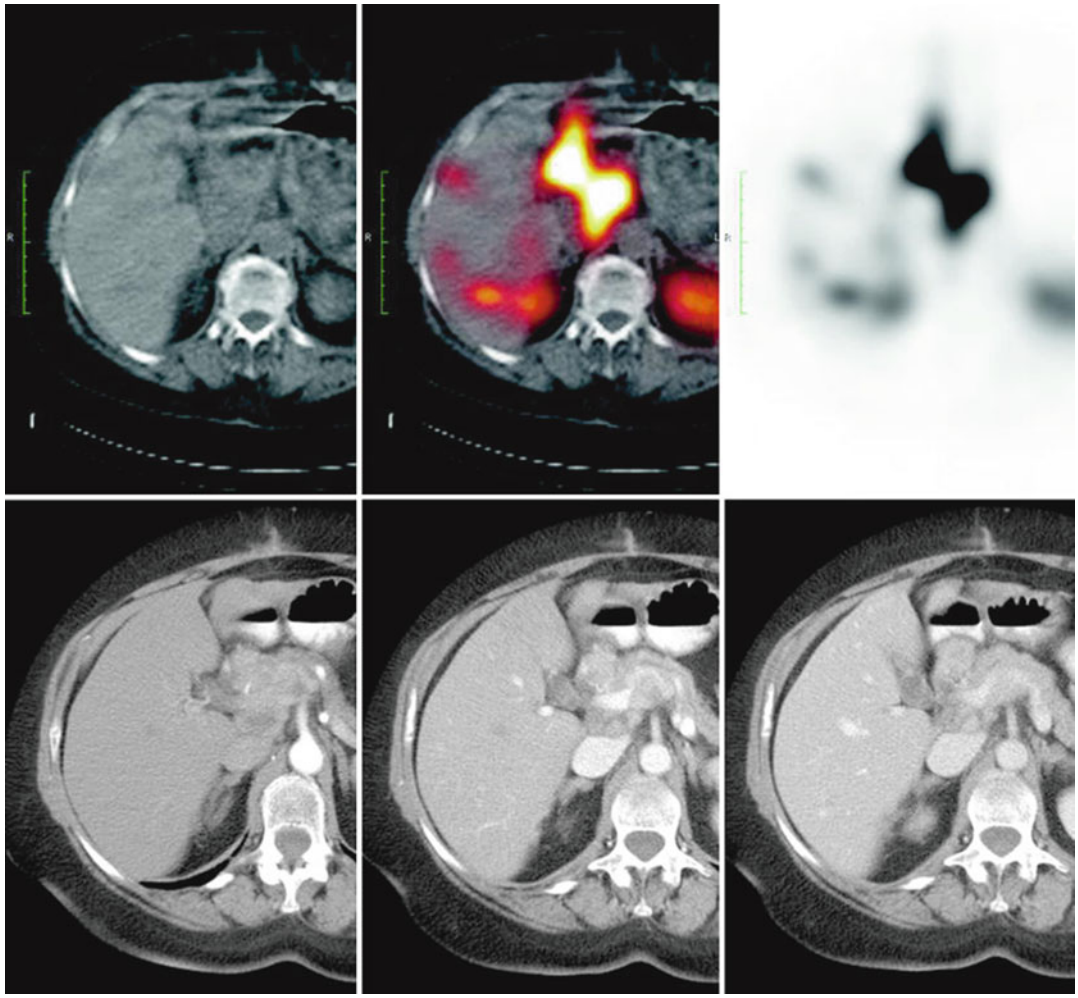

Fig. 5 Patient with a pancreatic NET and multiple liver metastases that result positive at SRS with ^{111}In-pentetreotide but negative at the three-phase contrast-enhanced CT

other tumors of neurogenic origin or mesodermal origin may resemble paragangliomas in both distribution and appearance [25] (Figs. 6 and 7).

Nuclear Medicine Techniques

Molecular imaging provides spectrum of information which includes somatostatin receptor status (e.g., ^{111}In-pentetreotide scintigraphy or ^{68}Ga-DOTA-SSA-PET/CT), metabolic activity ([^{18}F]FDG), and specific amine metabolism (e.g. ^{18}F-DOPA). As a result, further information regarding the biology of the lesion and the extent of disease may be generated, thus facilitating staging in molecular, metabolic, spatial, and functional dimensions.

Rationale of Nuclear Medicine Techniques

Somatostatin receptor imaging is used to obtain information as to the localization of disease and extent (staging and restaging) and to select patient for therapy with "cold" or radiolabeled somatostatin analogs [11, 90]. The rationale of somatostatin receptor imaging is the tumor cell receptor-mediated internalization of the receptor-radioanalog complex and its retention in the

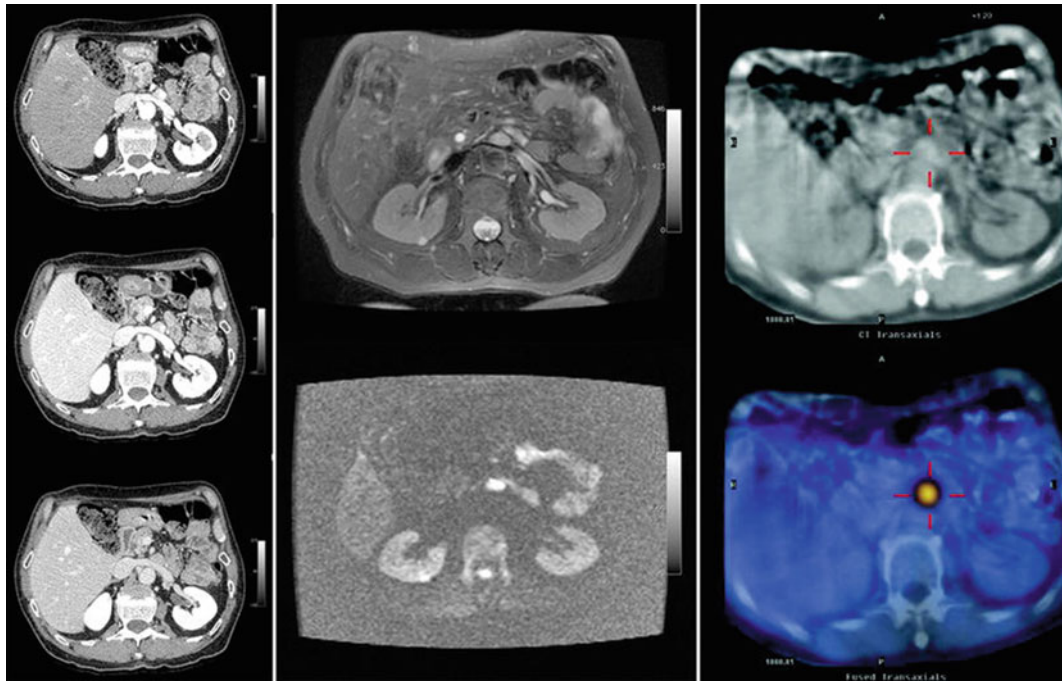

Fig. 6 Patient with an abdominal paraganglioma. The left images (from *top* to *bottom*) of a three-phase contrast-enhanced CT disclose a paraganglioma located in front of the left renal vein showing the typical contrast enhancement during the arterial phase (*top*). In the middle, MRI images show the same lesion hyperintense on T2-weighted image (*top*) and on DWI (*bottom*). The right images of a SPECT/CT study show the high uptake of ^{111}In-pentetreotide within the paraganglioma

cytoplasm. ^{111}In-pentetreotide or OctreoScan® represents the first approved radiopharmaceutical for NEN imaging and is the commonly used agent.

Somatostatin is a ubiquitous peptide that exists in either a 14-amino acid or a 28-amino acid form present in the hypothalamus, brainstem, gastrointestinal tract, and pancreas. SSTRs are found on cells of neuroendocrine origin as well as on activated lymphocytes. Six subtypes of SSTRs have been identified by molecular analysis (named sst1, sst2a, sst2b, sst3, sst4, and sst5), each exerting its action by inhibition of adenylyl cyclase activity. Each receptor subtype exhibits a different binding affinity for native somatostatin and for somatostatin analogs. Subtype 2 has the highest affinity (Kd 0.1–1 nM), whereas subtypes 3 and 5 are within the 10–100 nM range, and subtypes 1 and 4 exhibit a low affinity. Moreover, since SSTR2 is the most frequently expressed in NET tumors, it has proved to be the optimal target for imaging. A key advantage of somatostatin imaging efficacy is based upon the significant overexpression and hence high density of SSTRs in neuroendocrine neoplasia (80–2,000 fmol/mg protein compound) as compared to the relatively low expression within normal neuroendocrine tissue [91].

Currently, the majority of radiotracers used for SSTR imaging are based on octreotide, which is a long-acting analog of the human hormone, somatostatin. The presence of octreotide-binding sites (SSTRs) on tumors permits their in vivo visualization after injection of a radionuclide-labeled octreotide analog. Although ^{123}I-[Tyr^3]-octreotide was the initial imaging, radio compound utilized its relatively short effective half-life, and the high background of radioactivity within the abdomen limited its clinical application. The subsequent development of ^{111}In-[DTPA-D-Phe^1]-octreotide, or ^{111}In-pentetreotide, which exhibited greater stability and facilitated the acquisition of enhanced imaging characteristics in the delayed images. This compound is a registered trademark of Mallinckrodt Inc. with the name of OctreoScan®. Octreotide binds with high affinity to the SSTR2 and with moderate affinity to the SSTR3 and SSTR5 receptors. Subsequently since the early 2000s, the approach to the functional imaging of NENs has been substantially advanced by the introduction of octreotide derivatives, the DOTA-peptides, labeled with the positron emitter Gallium-68. The three most commonly used analogs are DOTA-Tyr^3-octreotide (DOTATOC), DOTA-Tyr^3-Thr^8-octreotide (DOTATATE), and DOTA-Nal^3-octreotide (DOTANOC). These analogs retain an octreotide-like affinity profile and, in particular, a high affinity for SSTR2. Only DOTANOC exhibits a substantial affinity for SSTR3 [91].

Initially NENs were referred to as APUD (amine precursor uptake and decarboxylation) tumors because of their ability to take up amino acids and transform them into biogenic amines by means of the enzyme aromatic amino acid decarboxylase. The terminology APUDoma was first used by Ilona Szij of Budapest and subsequently adopted by A. Pearse [13]. The amine uptake, decarboxylation characteristic remains a biological hallmark of chromaffin and neuroendocrine cells although the inelegant term for the tumors, APUDomas has over time evolved into the more commonly used acronym NETS. NET cells synthesize catecholamines in an enzymatic pathway, which initially converts the amino acid tyrosine into L-DOPA; thereafter, L-DOPA is decarboxylated to dopamine, oxidized to norepinephrine, and methylated to epinephrine, which is transported into synaptic vesicles. Reuptake of catecholamines occurs presynaptically by norepinephrine transporters present on the cell membrane [13]. Based upon this series of biochemical events, NETs can be imaged with ^{18}F-DOPA PET (6-L-^{18}F-dihydroxyphenylalanine) and [^{11}C]5-hydroxytryptophan ([^{11}C]5-HTP), which accumulate within cells due to the high activity of the aromatic amino acid L-DOPA decarboxylase. Thus, the tracer radioiodinated metaiodobenzylguanidine (MIBG) is internalized by the cell via the norepinephrine transporter and stored in neurosecretory vesicles by a catecholamine transporter (VMAT). ^{18}F-DOPA or ^{18}F-dopamine PET and ^{123}I/^{131}I-MIBG scintigraphy are highly sensitive for detecting tumors arising from the adrenal medulla. However, they can also be taken up by non-adrenomedullary NETs and paragangliomas [92, 93].

Metaiodobenzylguanidine (MIBG) is a norepinephrine analog that concentrates within secretory granules of catecholamine-producing cells. It is structurally similar to guanethidine. MIBG, like norepinephrine, is taken up by a cell membrane based active, sodium- and energy-dependent amine uptake mechanism (uptake-1), inserted into the cell membrane of chromaffin tissues, and then transported to the intracellular storage granules by an active uptake mechanism [94].

There are numerous drugs that reduce the sensitivity of the scintigraphy and frequently result in false negatives; this occurs through interference with the uptake, intracellular transport, granule storage, or the retention of MIBG [95]. To ensure optimal imaging, these pharmaceuticals should be temporarily withdrawn before the examination, for a time period of approximately five times longer their respective half-lives before imaging [58] (Table 6).

[^{18}F]FDG, a glucose analog, is transported into the cell via dedicated glucose transporters and thereafter phosphorylated by the cytoplasmic enzyme, hexokinase. The resulting compound cannot be further metabolized and is trapped within the cytoplasmic space. Since many tumors, particularly those of aggressive or accelerated proliferative nature, exhibit an increased glycolytic metabolism, they overexpress glucose transporters and have abundant hexokinase. This phenomenon provides the biological basis for the use of [^{18}F]FDG as a radiopharmaceutical to detect such tumors. The process of accelerated glycolytic metabolism is also however a common occurrence in activated inflammatory cells. Thus [^{18}F]FDG may also accumulate at sites of inflammation and constitute a potential cause of false positivity for malignancy [97].

Scintigraphy

Somatostatin Receptor Scintigraphy

Clinical Application

The radiolabeled somatostatin analog ^{111}In-pentetreotide (or ^{111}In-DTPA-D-Phe^{1}-octreotide or OctreoScan®) is the commonly used agent for somatostatin receptor scintigraphy (SRS) [98–101], although the ^{99m}Tc-labeled peptide ^{99m}Tc-EDDA-HYNIC-octreotide (Tektrotyd®) is used in several European countries [102]. The sensitivity of ^{111}In-pentetreotide scintigraphy has been well documented in the 1990s as >75% for gastroenteropancreatic (GEP-NETs) and bronchial tumors (BP-NETs, compared to other imaging modalities available (CT/MRI) [103]. Information from OctreoScan® images modified the therapeutic strategy in ~53% of cases by

Table 6 Pharmaceutical compounds that reduce the sensitivity of scintigraphy (Adapted with permission from [96])

Drugs	Mechanism of interference	Withdrawal before MIBG
Antiarrhythmics (e.g., amiodarone)	Uptake inhibition and depletion	Not easily feasible
Alpha–beta blockers (e.g., labetalol)	Uptake inhibition and depletion	3 days
Calcium channel blockers (e.g., amlodipine)	Increased uptake and retention	1–2 days
Alpha2 sympathomimetics (e.g., salbutamol)	Depletion of granules	1 day
Vasoconstrictor sympathomimetics (e.g., pseudoephedrine)	Uptake inhibition and depletion	1–2 days
Neuroleptics (e.g., haloperidol)	Uptake inhibition	1–15 days (short-acting formulations)
Antihistamine (e.g., promethazine)	Uptake inhibition	1 day
Opioid analgesics (e.g., tramadol)	Uptake inhibition	1 day
Tricyclic antidepressants (e.g., amitriptyline)	Uptake inhibition	2–8 days
Psychostimulants (amphetamines, cocaine)	Uptake inhibition and depletion	1–5 days

accurately staging NETs and especially by detection of metastatic disease [104, 105]. Currently, however the OctreoScan technique is regarded as suboptimal, with sensitivities <60%, compared with state-of-the-art morphological imaging (CT and MRI) [106]. Although MRI is considered to have the highest sensitivity for liver metastases, SRS is the most accurate imaging modality for "one-shot" detection of liver and extrahepatic metastases in patients with GEP-NETs [107] (Fig. 8). OctreoScan® is also utilized to monitor treatment efficacy. Changes in functional volume at scintigraphy are considered more useful than CT and RECIST (Response Evaluation Criteria in Solid Tumors) in monitoring tumor response after treatment and correlate well with later clinical response [108] (Fig. 9).

In BP-NETs, molecular imaging can help differentiate the etiology of bronchial masses [109]. Since most of thoracic NETs express somatostatin receptors, especially subtypes 2 and 5 (Fig. 10), ^{111}In-pentetreotide scintigraphy can detect most bronchial carcinoids >1 cm in diameter, including those associated with ectopic GH-RH secretion [110]. SRS is also helpful for radioguided surgery, allowing evaluation of the tumor bed after resection to detect any residual radioisotope uptake that might reflect the presence of residual tumor [111]. Since SSTRs are expressed on inflammatory cells, some degree of caution in the misinterpretation of early postsurgical changes should be considered.

Technique

The radiopharmaceutical should be prepared in accordance with the manufacturer's instructions and quality control performed with a calibrated ionization chamber. Radiochemical purity should be checked with thin-layer chromatography prior to patient administration. The amount of peptide injected in this preparation is 10 μg. To preserve diagnostic sensitivity, the recommended injected activity should be ~200 MBq (5.4 mCi). Lower activities can only be administered if acquisition parameters are adjusted accordingly [112]. At least two different sets of planar and/or whole body images should be acquired to facilitate the interpretation of the exam. Commonly adopted protocols include scans at 4 and 24 h or, optimally, 24 and 48 h postinjection and three-dimensional SPECT at 4, 24, and optionally at 48 h postinjection. Currently, the extensive use of SPECT/CT has reduced

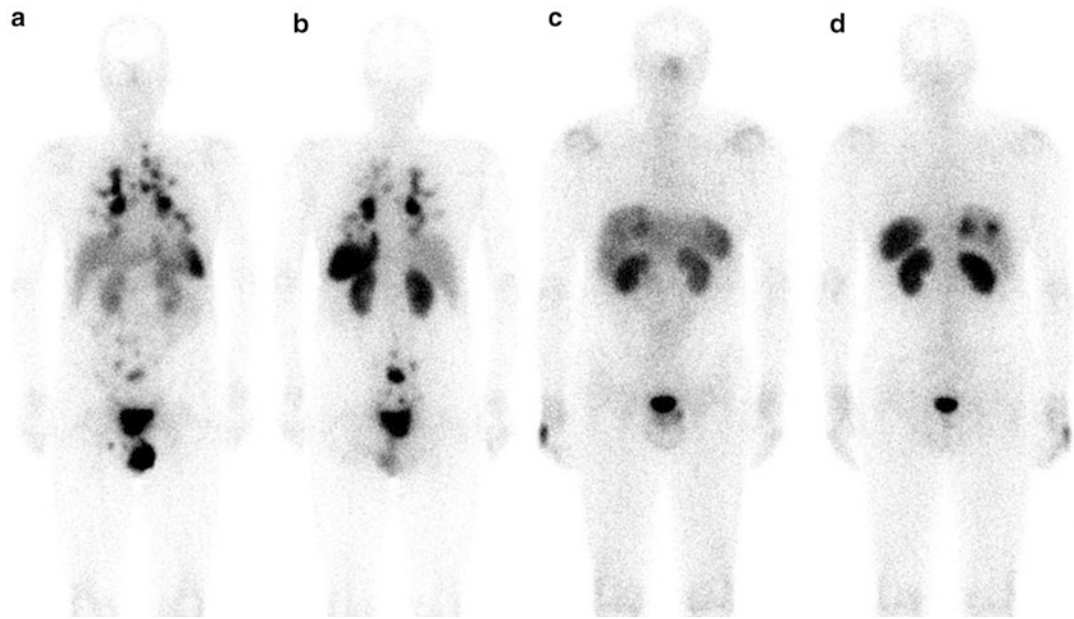

Fig. 8 SRS with ^{111}In-pentetreotide. On the *left* (**a**, **b**), a whole body scan shows a patient with an intestinal lesion, abdominal lymph nodes, and multiple lung metastases. On the *right* (**c**, **d**), a patient with liver metastases

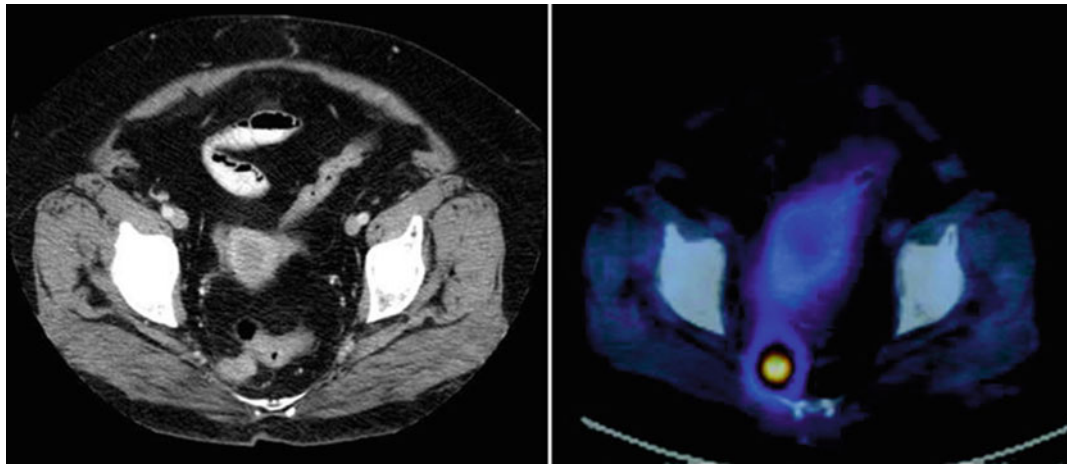

Fig. 9 SRS with ^{111}In-pentetreotide. Peritoneal relapse of a GEP-NET

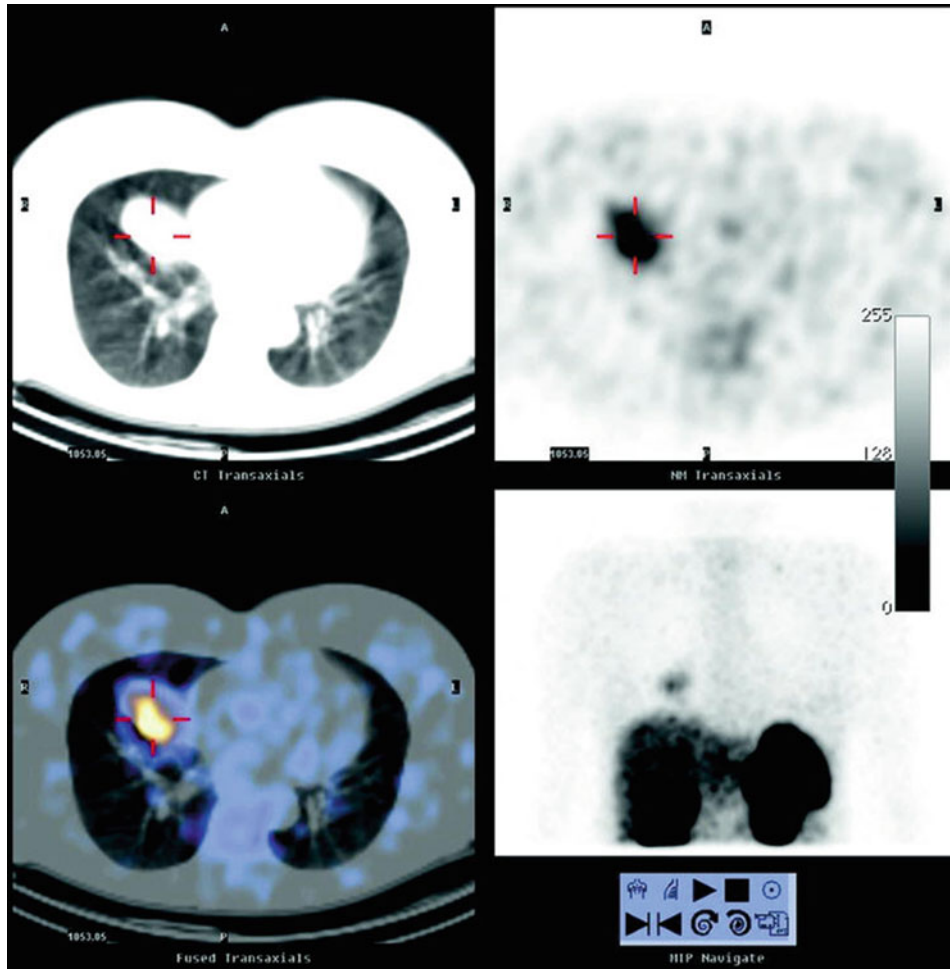

Fig. 10 Typical bronchial carcinoid. SRS with ^{111}In-pentetreotide shows an intense uptake of the tracer within a mass in the medium lobe

the need for the 4 and 48 h examinations, due to the increased specificity [100] (Fig. 11). Later images can also be acquired in case of equivocal findings. A gamma camera equipped with a medium-energy, parallel-hole collimator, with the window set for 20% on ^{111}In photopeaks (172 and 245 keV) should be used to acquire planar images, either spot or whole body. To achieve an acceptable

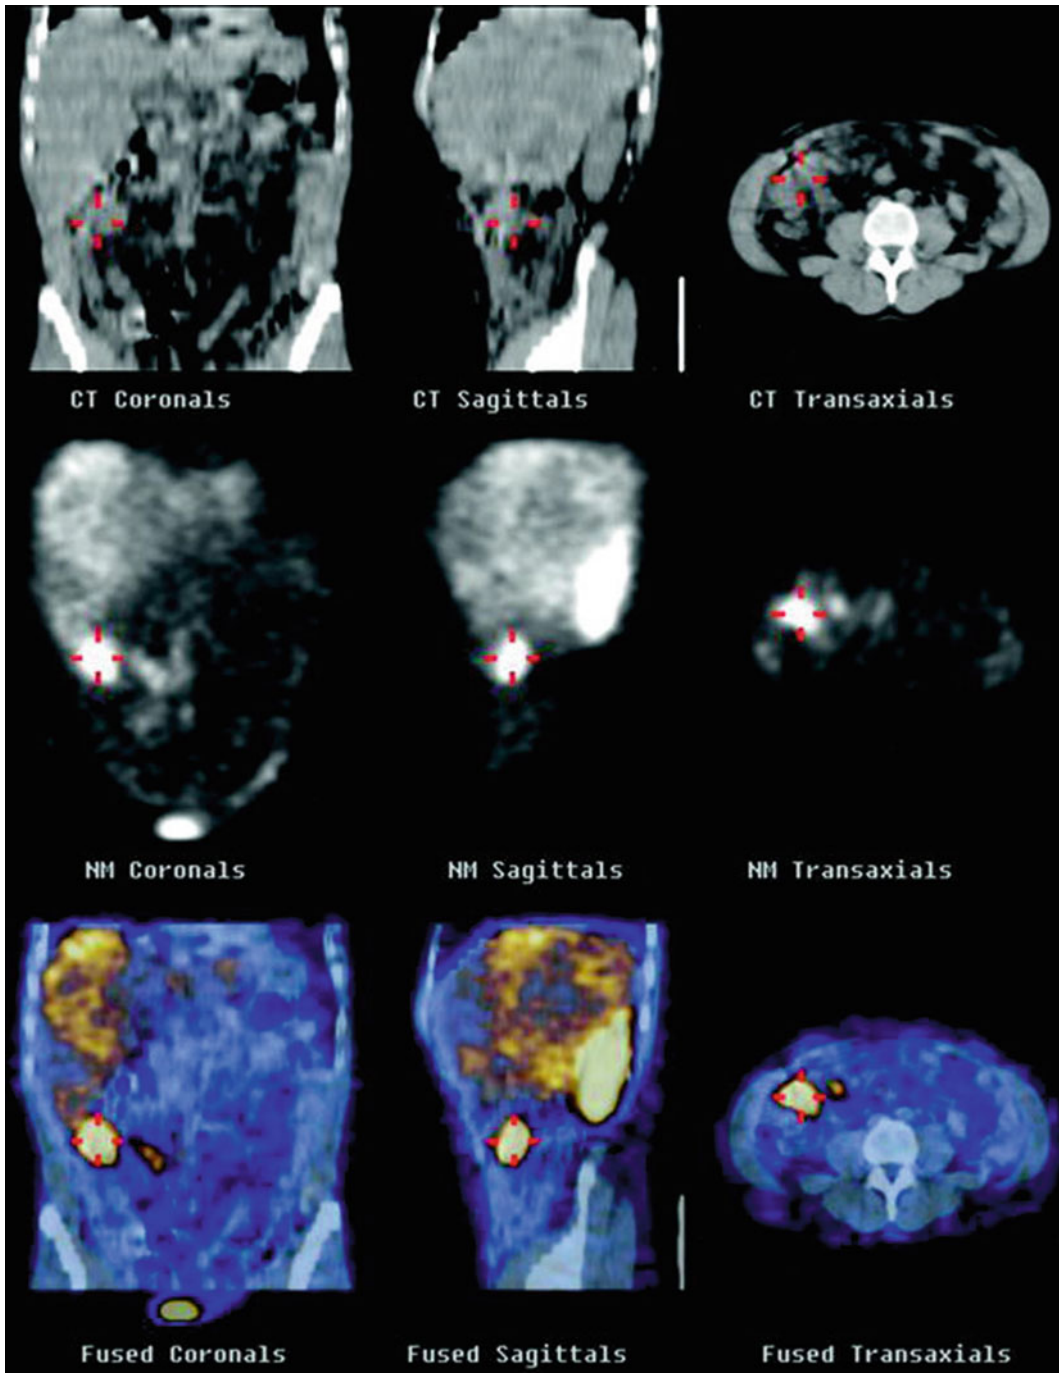

Fig. 11 SPECT/CT shows uptake of ^{111}In-pentetreotide within a NET of the ileum

sensitivity, planar images should be acquired for 10–15 min/image, using a 512 × 512 word matrix or 256 × 256 word matrix, whole body images into a 1,024 × 512 word matrix or 1,024 × 256 word matrix for a minimum of 30 min, corresponding to a maximum scanning speed of 3 cm/min. For precise details of the detailed scanning protocol, the SNMMI (Society of Nuclear Medicine and Molecular Imaging) or the EANM (European Association of Nuclear Medicine) procedure guidelines for ^{111}In-pentetreotide scintigraphy should be consulted [112].

After injection, plasma clearance is rapid, followed by a progressive accumulation in tissues. Elimination occurs mainly via the kidneys and, to a lesser extent, the hepatobiliary system. Physiologic areas of uptake are the spleen, the liver, and the kidneys. Normal scans also show variable uptake in the pituitary, thyroid, urinary bladder, and bowel [112]. The visualization of the kidneys is mainly due to filtration and proximal tubular reabsorption of the radiopeptide, while the uptake to the spleen, pituitary, and thyroid is receptor mediated (Fig. 12).

Preparation for the scan includes laxatives, to eliminate nonspecific activity in the bowel, and withdrawal of somatostatin analogs (short-acting analogs for at least 48 h, long-acting formulations for 4–6 weeks), although the latter point is still debated [112].

Interpretation

Assessment of images should be guided by clinical information. As a general rule, clearly outlined areas that show an isotope uptake higher than the normal liver distribution are classified as positive for receptor expression and thus considered to represent neuroendocrine malignancy. There are, however, alternative conditions that may be associated with increased somatostatin receptor expression and, hence, exhibit increased uptake. Possible sources of false positives include areas of chronic inflammation (such as radiation pneumonitis, sequelae of recent surgery), accessory spleens, gallbladder accumulation, focal stool aggregation, thyroid nodules, pulmonary granuloma, diffuse breast uptake, recent cerebrovascular infarction, arthritis, abscesses, and urine contamination [90].

False negatives imply the lack of visualization of NEN lesions, most commonly related to an incorrect methodology, such as low administered

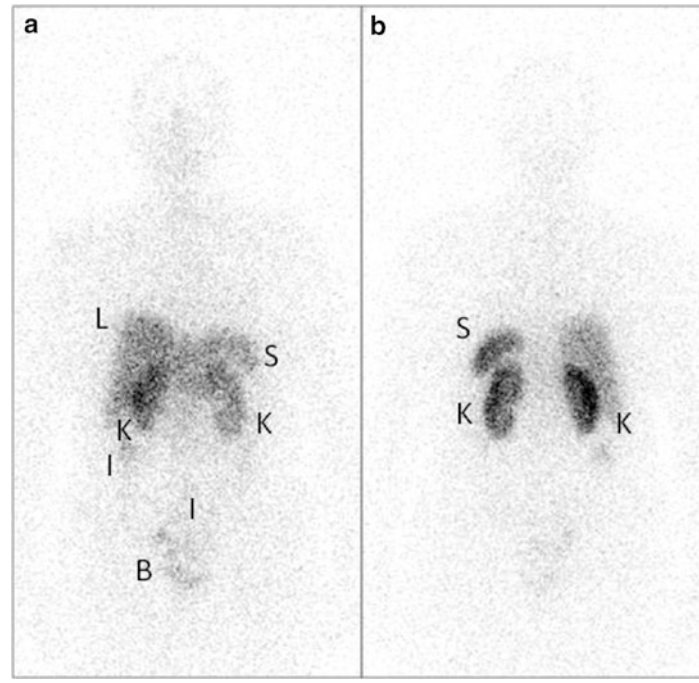

Fig. 12 Normal distribution of ^{111}In-pentetreotide, anterior (**a**) and posterior (**b**) whole body images, 24 h p.i., with physiological visualization of the liver (L), kidneys (K), and spleen (S) and of the activity eliminated in the urinary bladder (B) and the intestine (I)

activity, a too rapid (or too early) scan time, the absence of SPECT images, or lesions whose dimensions fall below the resolution limit of the gamma camera. Other possible causes may be competition for receptor uptake by recent analog therapy (although this issue is debated), alteration of receptor expression by recent chemotherapy, or truly receptor-negative disease (e.g., benign insulinomas, high-grade NETs). In some cases, normal accumulation in the liver may mask isointense metastases or those with a relatively low expression of somatostatin receptor density [101].

Metaiodobenzylguanidine

Clinical Application

Functional imaging with ^{123}I-MIBG is still the first choice among nuclear medicine methods available for chromaffin tumors although recent data suggest a superiority of ^{68}Ga-DOTA-SSA-PET/CT in pheochromocytomas and paragangliomas [113–117]. ^{123}I-MIBG has been used (labeled with ^{131}I or since 1980, with ^{123}I) for the specific imaging of tumors that originate from the neural crest (chromaffin tumors and NETs). Apart from its diagnostic utility, ^{131}I-MIBG has also been used (since 1984) for the therapy of chromaffin tumors and NETs [118]. In adrenal pheochromocytomas, ^{123}I-MIBG scintigraphy has sensitivity and specificity of 90% and 95%, respectively. Moreover, the combined sensitivity of catecholamine measurements and ^{123}I- MIBG scan approached 100% [119]. Thus a whole body scan ^{123}I-MIBG is particularly helpful in the preoperative identification of multiple primary lesions (relatively frequent in norepinephrine-secreting pheochromocytomas) or metastases from malignant tumors (Fig. 13).

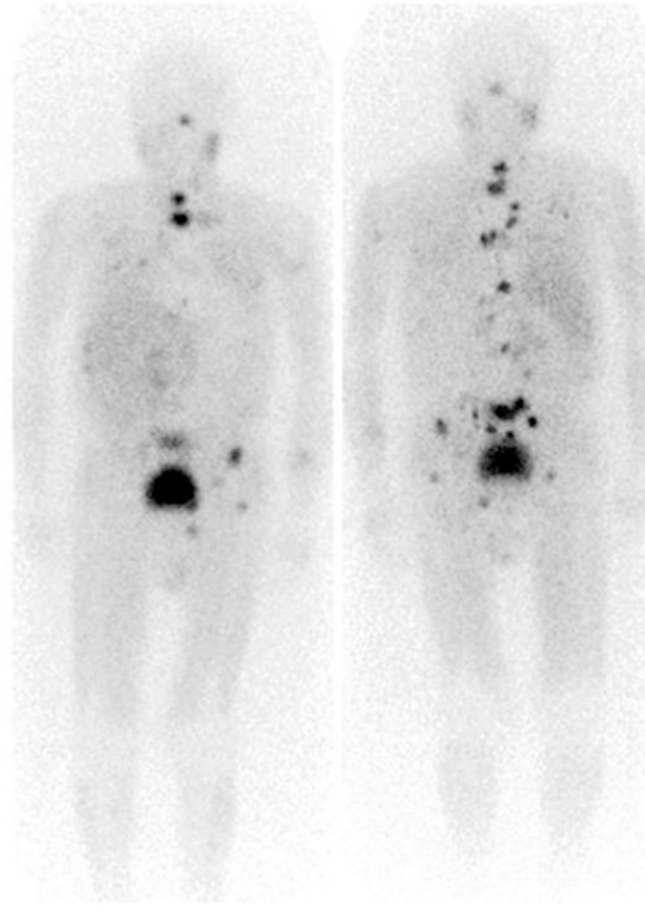

Fig. 13 ^{123}I-MIBG whole body scintigraphy. Multiple foci of tracer uptake indicating the presence of diffused bone metastases from a malignant pheochromocytoma

^{123}I-MIBG is of especial utility in the detection of recurrences since the radiotracer accumulates specifically within the tumor and is not affected by postsurgical or post-radiotherapy structural changes (Fig. 14). In extra-adrenal tumors, ^{123}I-MIBG imaging has a lower sensitivity (58%) than adrenal lesions (90–95%) [120]. Unlike abdominal and thoracic paragangliomas, ^{123}I-MIBG imaging has limited sensitivity for the detection of paragangliomas of the head and neck region (17–42%) [121].

Although both ^{131}I-MIBG and ^{123}I-MIBG are commercially available for diagnostic imaging, the former has been preferred since it is more widely available and economical. The physical characteristics of ^{131}I-MIBG, although not optimal for scintigraphic imaging (gamma energy 364 keV, half-life 8 days), facilitate delayed studies. Alternatively, the physical properties of ^{123}I (gamma energy 159 keV, half-life 13.3 h) provide better image quality, more favorable dosimetry, and the possibility of performing a SPECT study, rendering it the agent of choice. ^{123}I-MIBG has, however, been approved for US usage by the Food and Drug Administration [122].

Technique

Thyroid blockade with nonradioactive iodide or, alternatively, potassium perchlorate is necessary to avoid thyroid uptake of free radioiodine and consequent potential damage. A solution of saturated potassium iodide (1–2 mg/kg per day) is commonly used, beginning 1 day before injection and continuing for 3–5 days.

Administered activities are 37–74 MBq (1–2 mCi) for ^{131}I-MIBG and 370 MBq (10 mCi) for ^{123}I-MIBG. To avoid potential bioactive adverse events, ^{123}I- or ^{131}I-MIBG should be administered by slow intravenous injection.

^{131}I-MIBG scan is performed using a gamma camera equipped with a high-energy, parallel-hole collimator. Images are collected at 24 and 48 h after injection. If nonspecific activity is suspected in the kidneys or bowel, delayed images can be

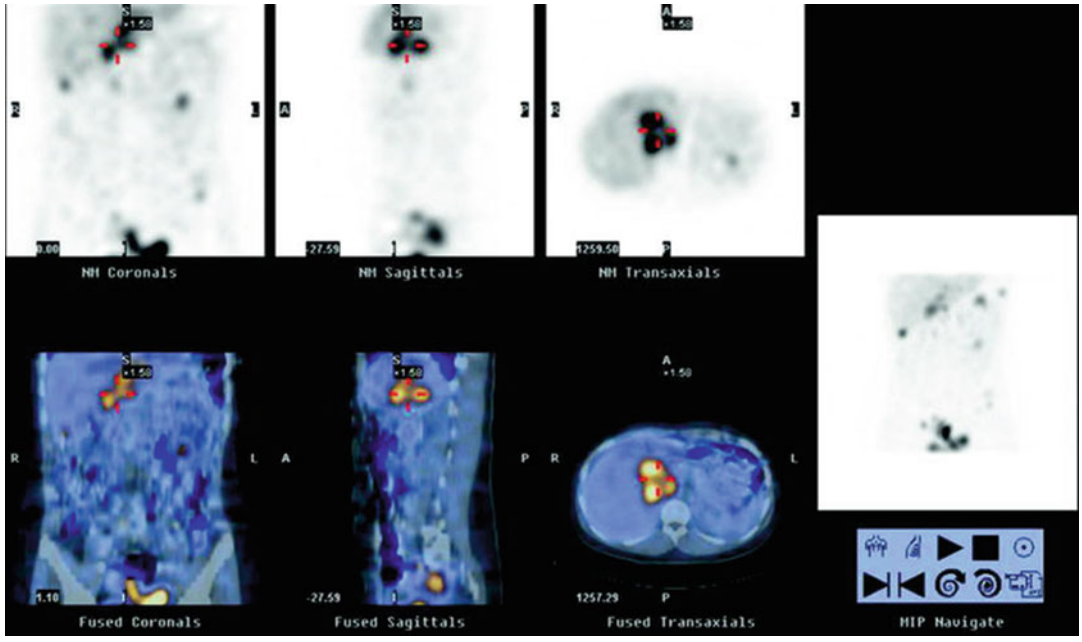

Fig. 14 Recurrence of adrenal pheochromocytoma. ^{123}I-MIBG SPECT/CT demonstrates a large lesion close to the site of the previous left adrenal resection. Patient history shows a laparoscopic surgery complicated by intense hemorrhage within the pheochromocytoma, producing the tumor seeding into the whole abdominal cavity (multiple other lesion are clearly shown in the MIP image on the *right*)

recorded after 72–120 h. Whole body and planar images of areas of interest are collected.

^{123}I-MIBG scan is performed with a medium-energy, collimator. Images are collected 6 and 24 h after injection and, if needed, 48 h post-injection. Whole body and spot images are recorded. The use of ^{123}I-MIBG allows SPECT imaging which is usually undertaken 24 h after administration. The use of hybrid SPECT/CT system further improves sensitivity [123]. Sub-optimal sensitivity can be caused by a small lesion size and and/or an extra-adrenal location. MIBG SPECT, evaluated side-by-side with contrast CT or MRI and/or hybrid imaging with SPECT/CT, provides an even more accurate anatomic localization of areas of MIBG uptake [120].

Interpretation

Normal findings, with either ^{123}I- or ^{131}I-MIBG, are the visualization of the lacrimal and salivary glands, heart, lungs, liver, spleen, urinary bladder, and, to some extent, bowel. Normal adrenal medulla is frequently visible with ^{123}I-MIBG but rarely with ^{131}I-MIBG. Any area of uptake located outside of these sites should be regarded as suspicious for malignancy (Fig. 15).

Physiologic accumulation of MIBG in the urinary tract or bowel can be a source of false-positive results. ^{123}I-MIBG SPECT evaluated with contrast CT or MRI or hybrid imaging with SPECT/CT allows more accurate anatomic localization of areas of uptake [124]. Rare causes of false-positive results such as the physiological accumulation of MIBG within the urinary tract or the bowel, which can mimic a tumor lesion, should also be considered. False negative results include lesions with dimensions below the spatial resolution of the gamma camera (~1 cm) or lesions whose uptake mechanisms have been altered by concomitant usage of drugs (Table 6).

PET/CT

Clinical Application

In the last 15 years, the approach to the molecular imaging of NETs has been revolutionized by the

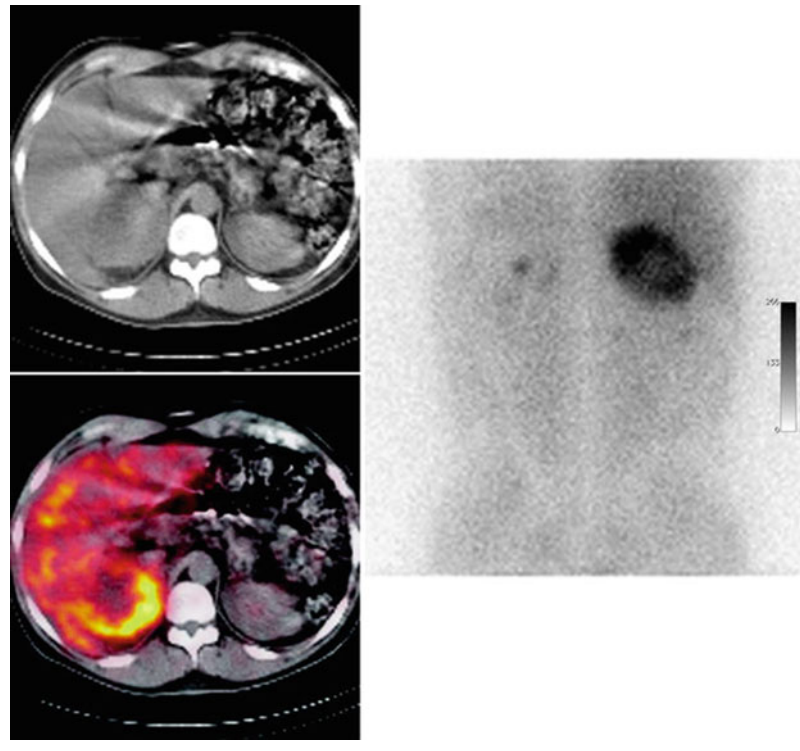

Fig. 15 ^{123}I-MIBG scintigraphy. The tracer uptake within a large tumor with central necrosis confirms the diagnosis of pheochromocytoma

introduction of PET with the Gallium-68 (^{68}Ga)-labeled octreotide derivatives, DOTATOC, DOTATATE, and DOTANOC (^{68}Ga-SSA-PET/CT) [125–127]. The overall sensitivity of ^{68}Ga-SSA-PET/CT for NETs is >90%, while the specificity ranges from 92% to 98% [106, 128, 129]. Copper-64 (^{64}Cu)-labeled SSA has also been evaluated for PET/CT of NETs with better imaging at later times (3–24 h p.i.) [130]. Compared to CT scan and receptor scintigraphy, PET exhibited the greatest sensitivity (97%) compared to CT (61%) and SRS (52%) for the detection of NET lesions, especially in patients with small tumors at a nodal or bone level. PET is also able to identify small lesions in unusual locations such as the breast, uterus, prostate, ovary, and kidney [106, 131]. PET with ^{68}Ga-DOTA-peptides is particularly useful in the early visualization of bone metastases, with a higher sensitivity, specificity, and accuracy than a CT scan. In a study of 84 patients (116 PET-positive lesions), only 84 (72.5%) were evident at conventional scintigraphy and only 58 (50%) at CT scan [106]. Recently, a study of 51 patients, 35 of which were GEP-NETs, among other SSTR2 positive tumors, demonstrated that PET/CT with ^{68}Ga-DOTATOC performed better than conventional somatostatin receptor scintigraphy or bone scintigraphy, resulting in a 97% sensitivity and 92% specificity [132].

Radiolabeled somatostatin receptor antagonists, characterized by a lack of internalization and a greater tumor uptake, were recently introduced in clinical trials due to their putative advantage of the much greater tumor-to-background ratio. Antagonists, such as ^{68}Ga-DOTA-JR11, have provided very interesting novel information in the largely explored SSR imaging [133].

Alternative PET tracers include ^{18}F-DOPA, which is a measure of neuroendocrine cell metabolism. This is a substrate utilized in the catecholamine synthesis pathway and is stored in the secretory granules [134]. The diagnostic performance of this compound appears however to be inferior to ^{68}Ga-DOTANOC [135]. [^{11}C]5-HTP, a serotonin precursor, which is the substrate for aromatic L-amino acid decarboxylase, is also utilized in research centers [92]. ^{18}F-DOPA PET was commonly used in the last decade, since it was the first PET modality to outperform ^{111}In-pentetreotide scintigraphy. In a variety of GEP-NETs, it exhibited high sensitivity and specificity for small-bowel carcinoid tumors (93% and 89%, respectively) compared to ^{111}In-pentetreotide [136]. In a prospective cohort of 53 patients with carcinoid tumors, ^{18}F-DOPA PET with carbidopa pretreatment demonstrated a per-patient sensitivity of 100%, detecting more lesions than conventional scintigraphy and CT scan [93]. The enthusiasm for the use of these alternative PET techniques has however been diminished by the increased availability of ^{68}Ga-DOTA-peptides and the demonstration of a superior sensitivity of somatostatin receptor PET with both ^{68}Ga-DOTANOC (71 vs. 45 lesions for ^{18}F-DOPA) and ^{68}Ga-DOTATATE (96% vs 56% for ^{18}F-DOPA) [135, 137]. A further limitation in their usage has been the fact that unlike somatostatin receptor imaging, these techniques do not possess a therapeutic counterpart.

[^{18}F]FDG-PET is usually not considered a primary diagnostic tool in well-differentiated NETs, because of its low sensitivity. Its optimal application is for imaging of high G2 NETs with Ki67 >15–20% for which SRS and ^{68}Ga-SSA-PET/CT may be less reliable [138]. [^{18}F]FDG-PET is generally recommended for neuroendocrine cancers (NEC) G3 tumors, although it has been reported as positive in 57% of G1 and 66% of G2 NETs [139]. The increased glucose metabolism, expressed as standardized uptake value (SUV), can provide predictive information in terms of overall survival (OS) and progression-free survival (PFS, SUV >3) [140]. Thus NETs that exhibit increased metabolic activity have a significantly lower disease control rate (100% vs 76%) and PFS (32 vs 20 months) after PRRT, compared to [^{18}F]FDG-negative tumors [139]. It has recently been proposed that [^{18}F]FDG can be used as an independent prognostic marker by applying a three-tier metabolic grading system based on the tumor-to-background ratio of uptake [141]. Finally, GLP1 receptor peptides for imaging of insulinomas (exendin analogs labeled with ^{68}Ga) are under investigation in clinical trials [142].

In bronchopulmonary NETs, ^{68}Ga-DOTA-SSA-PET/CT has surpassed OctreoScan in the

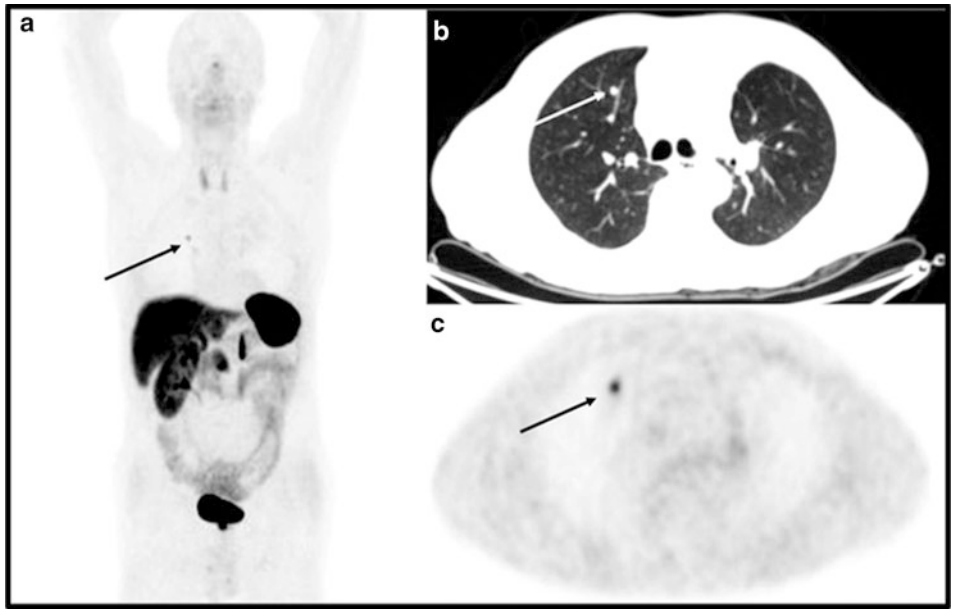

Fig. 16 ^{68}Ga-DOTATOC maximum intensity projection, CT, and PET images (**a**, **b,** and **c**, respectively) of a small typical bronchial carcinoid of the right upper lobe

assessment of small-volume disease, as well as mediastinal lymph node involvement and distant metastases (Fig. 16) [143].

[^{18}F]FDG-PET/CT in NETs of the lungs shows variable [^{18}F]FDG uptake according to tumor proliferation. A low [^{18}F]FDG uptake ($SUV_{max} < 2.5$) is evident in typical (low-grade) bronchial carcinoids [144]. Tumors of a higher grade than typical bronchial carcinoids can have high [^{18}F]FDG uptake. Atypical carcinoids can be more metabolically active and usually appear as a small pulmonary nodule with hilar or mediastinal lymph nodes showing high SUV. LCNECs usually exhibit high [^{18}F]FDG uptake, and PET/CT and stand-alone CT demonstrate high accuracy in prediction of the presence of hilar and mediastinal nodal involvement. However, PET/CT seems to be better than CT alone in detecting distant metastases and leading to the changes in the clinical management. An SUV_{max} greater than 13.7 predicts a short survival period, suggesting the use of PET/CT with [^{18}F]FDG not only in staging but also in assessing prognosis of LCNEC [145]. In SCLC, [^{18}F]FDG PET is valuable for initial staging to distinguish localized vs. metastatic disease, and [^{18}F]FDG PET/CT is also useful for prognosis, especially after treatment [146].

Early data addressing the combined use of [^{18}F]FDG and ^{68}Ga-DOTATOC appear to have clinical utility. Thus typical carcinoids, with high expression levels of SSRs, show high uptake on ^{68}Ga-DOTATOC PET/CT imaging but low [^{18}F]FDG uptake due to the low proliferative index. It has been proposed that increased avidity of [^{18}F]FDG and/or decreased avidity for ^{68}Ga-DOTATATE could identify aggressive tumors containing sites of possible dedifferentiation [144].

Data from a recent multi-center study of sporadic pheochromocytomas and paragangliomas indicate that PET/CT with ^{68}Ga-DOTATATE is superior to any other imaging modality, including [^{18}F]FDG PET/CT and CT/MRI, with a lesion-based detection rate of 97.6% versus 49.2% of [^{18}F]FDG PET/CT, 74.8% of ^{18}F-DOPA PET/CT, and 81.6% of CT/MRI [117]. In a group of 30 patients with pheochromocytomas and paragangliomas at initial diagnosis or relapse, ^{68}Ga-DOTATATE PET/CT exhibited the highest per lesion sensitivity (93% vs. 89% and 76%,

compared to ^{18}F-DOPA PET and conventional imaging). The highest sensitivity was identified in the detection of head and neck paragangliomas, especially in SDHD-related tumors [147]. Integration of this information with circulating mRNA from tumor may add further to the precise delineation of the biological behavior of these tumors.

Somatostatin Receptor PET/CT

Clinical Application

Somatostatin analogs labeled with ^{68}Ga (produced by a generator, therefore not requiring an in-house cyclotron) offer the advantage of both higher spatial resolution (about 4–5 mm) and signal-to-noise ratio as well as easier image quantification than SPECT (Fig. 17). Despite differences in receptor affinity, a clear clinical superiority of one of the three available compounds over the others has not been unambiguously demonstrated. A comparison of ^{68}Ga-DOTATOC versus ^{68}Ga-DOTATATE PET/CT in the same patients yielded comparable diagnostic accuracy for the two radiopeptides, with a potential advantage for ^{68}Ga-DOTATOC in the number of detected lesions and the higher SUV [148]. However, a recent comparison of ^{68}Ga-DOTATATE and ^{68}Ga-DOTANOC PET/CT imaging in the same patients with NETs showed higher SUV values and superiority of ^{68}Ga-DOTATATE on a lesion basis and a comparable diagnostic accuracy on a patient basis [149]. The inconclusive results on this issue may reflect the particular receptor configuration of the individual tumors. These novel radiopharmaceuticals are currently in use only as components of research projects, since none have yet been registered for use in routine clinical practice. The compound ^{68}Ga-DOTATATE was recently (2016) approved by FDA. It is of note that PET/CT with ^{68}Ga-DOTA-peptides offers several advantages over the

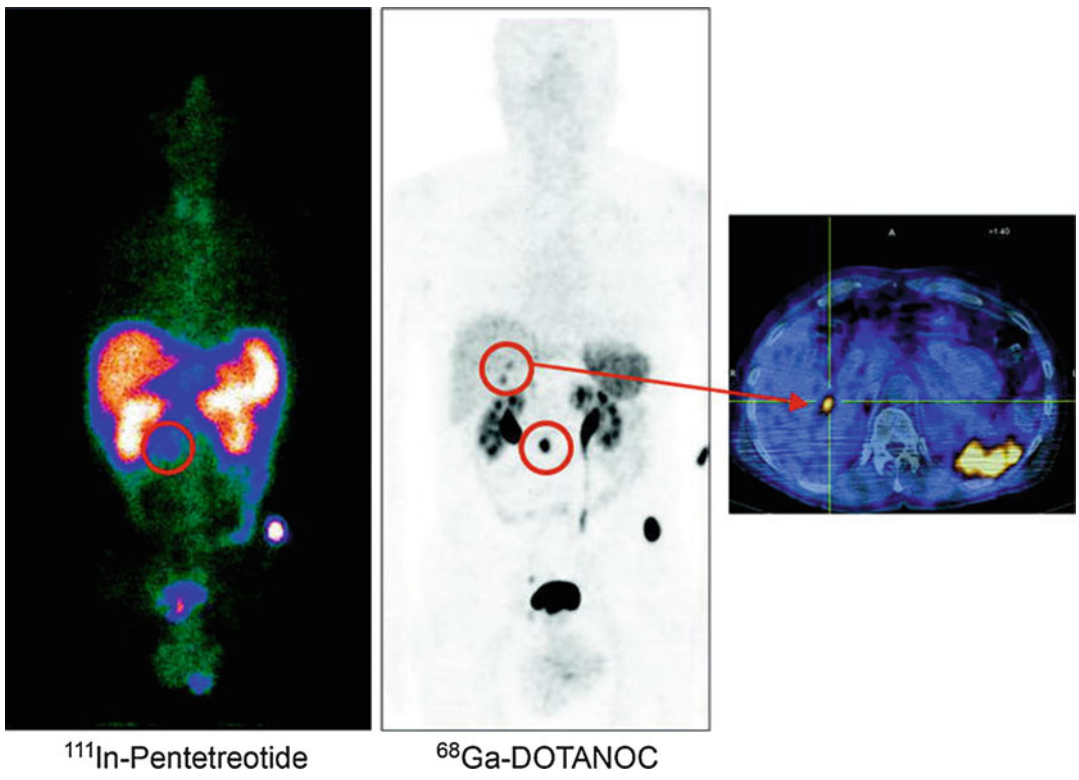

Fig. 17 Comparison between SRS with ^{111}In-pentetreotide and PET with ^{68}Ga-DOTANOC. The higher spatial resolution and signal-to-noise ratio of PET allow the identification of two small liver metastases which were not visualized by SRS

conventional scintigraphic technique. These include: the synthesis of the radiopeptide from the $^{68}Ge/^{68}Ga$ generator eluate is simple and economical and can also be undertaken in centers without an on-site cyclotron, the imaging can be performed as a single day procedure, the activity in a given region of interest can be semi-quantified as SUV, and the spatial resolution of the method is higher and allows an excellent quality of the images with the detection of small lesions <10 mm. A further potential advantage is the possibility of labeling the same peptide used for radionuclide therapy (whether DOTATOC, DOTATATE, or DOTANOC).

Technique

The recommended injected activity to obtain diagnostic quality images ranges from 100 to 300 MBq, depending on the tomographic characteristics and body weight. To avoid possible clinico-pharmacologic effects, the amount of the injected peptide should not exceed 50 μg [150]. The clearance of ^{68}Ga-DOTA-peptides from the blood is rapid. Arterial activity elimination is bi-exponential, and no radioactive metabolites are detected in serum and urine in the first 4 h. Maximal tumor activity accumulation is reached at 70 ± 20 min postinjection. Excretion occurs almost exclusively via the kidneys. The PET/CT acquisition begins 45–60 min after the intravenous administration of the radiopeptide, by means of a dedicated PET/CT scanner as a whole body image, preferably in a 3D mode. For a detailed description of the scanning protocol and image reconstruction, reference should be made to the EANM procedure guidelines for ^{68}Ga-DOTA-peptides [150]. The use of contrast media may further enhance detection. However, in standard usage, unenhanced PET/CT is considered sufficient. As for conventional scintigraphy, the normal findings include the visualization of the liver, the spleen, the pituitary, the thyroid, the kidneys, as well as the adrenal glands, salivary glands, the stomach wall, and the intestines (Fig. 18). Preparation is the same as for ^{111}In-pentetreotide.

Interpretation

The clinical interpretation of these images is easier than with single photon tomography, due to the better spatial resolution and the CT co-registration (Figs. 19 and 20). Criteria for defining areas of uptake as consistent with NET disease are the same as for ^{111}In-pentetreotide. In PET imaging, however, the head of the pancreas, in particular the uncinate process, may exhibit a variable physiologic uptake of ^{68}Ga-DOTA-peptides, related to the great concentration of pancreatic polypeptide cells [150]. This may represent a potential source of false-positive results that should not be ignored, since the pancreas and the duodenum are frequent sites of neuroendocrine malignancies. Other common non-NET-related sources of somatostatin receptor-mediated uptake (e.g., accessory spleens, sites of inflammation with lymphoid infiltrate, recent surgery, or urinary contamination) should be taken into consideration in the interpretation of the images (Fig. 21a–c).

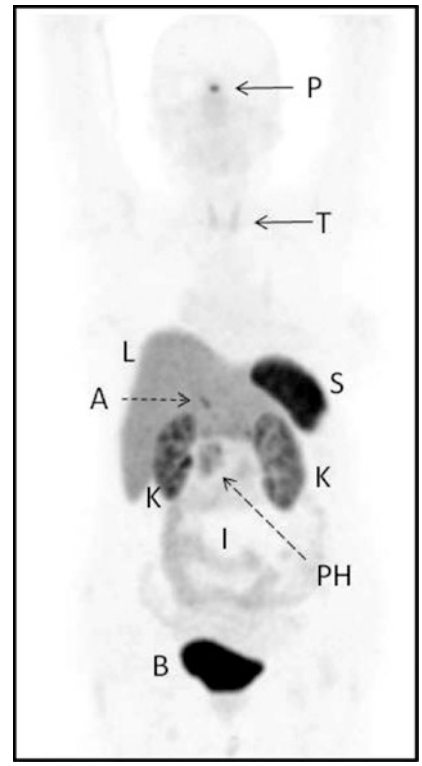

Fig. 18 Normal distribution of ^{68}Ga-DOTATOC (MIP, maximum intensity projection image) with physiological visualization of the pituitary (P), thyroid (T), liver (L), adrenals (A), kidneys (K), spleen (S), pancreatic head (PH) and of the elimination of the activity in the urinary bladder (B) and the intestine (I)

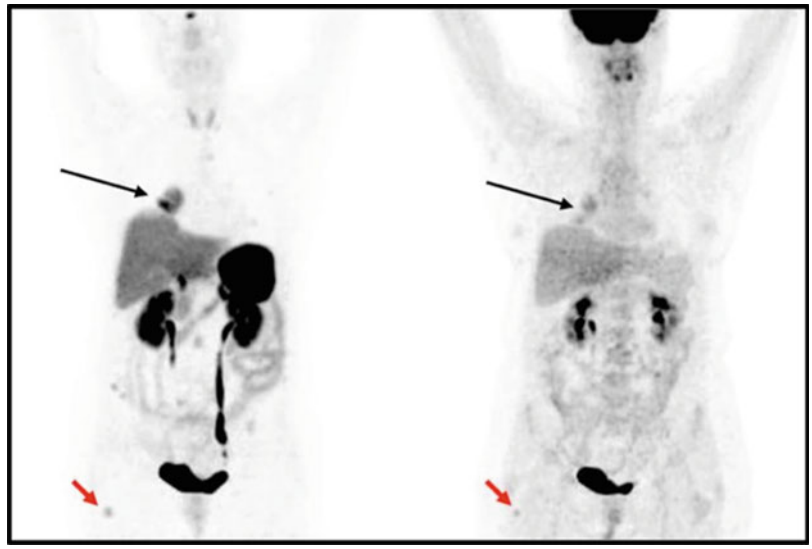

Fig. 19 ^{68}Ga-DOTATOC (*left*) and [^{18}F]FDG (*right*) PET/CT appearance of atypical bronchial carcinoid (*black arrows*). ^{68}Ga-DOTATOC maximum intensity projection image shows some bone metastases, while [^{18}F]FDG PET/CT detected only the one at the right femur (*red arrows*)

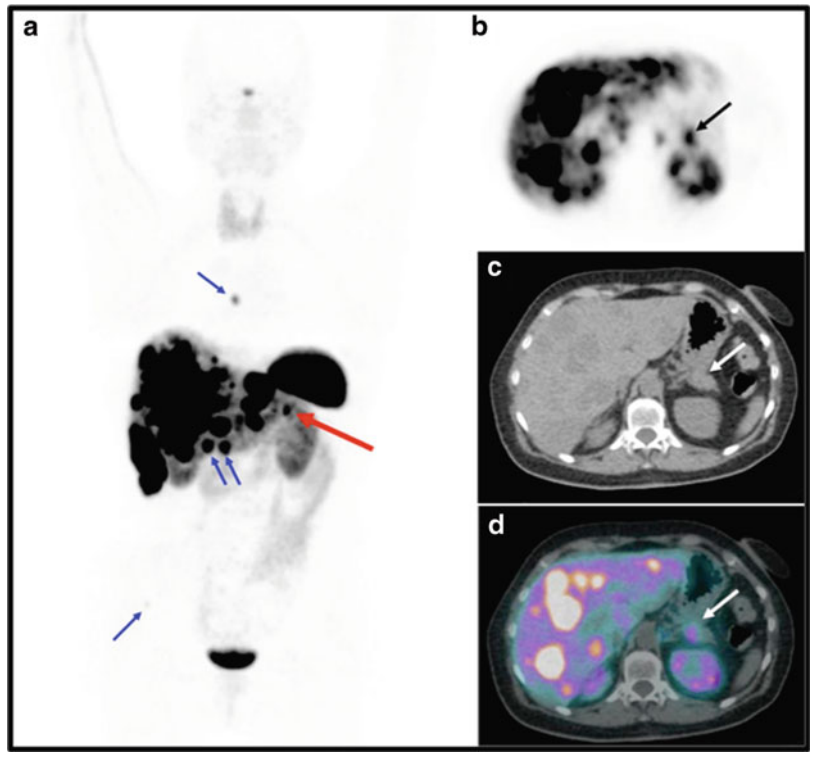

Fig. 20 Unknown primary NET with multiple liver lesions. ^{68}Ga-DOTATOC PET detected the primary tumor in the pancreatic tail (*red arrow* in **a**) and concomitant paracaval lymph nodes and bone metastases (*blue arrows* in **a**)

^{18}F-DOPA

NETs can be imaged with ^{18}F-DOPA PET/CT (Fig. 22). Oral co-administration of carbidopa, a peripheral inhibitor of AADC normally used in the treatment of Parkinson's disease, is routinely performed during ^{18}F-DOPA imaging to reduce the background activity, particularly in the pancreas, and to increase the tumor uptake and, ultimately, sensitivity [93]. Whole body imaging is initiated 30–90 min after injection of at least

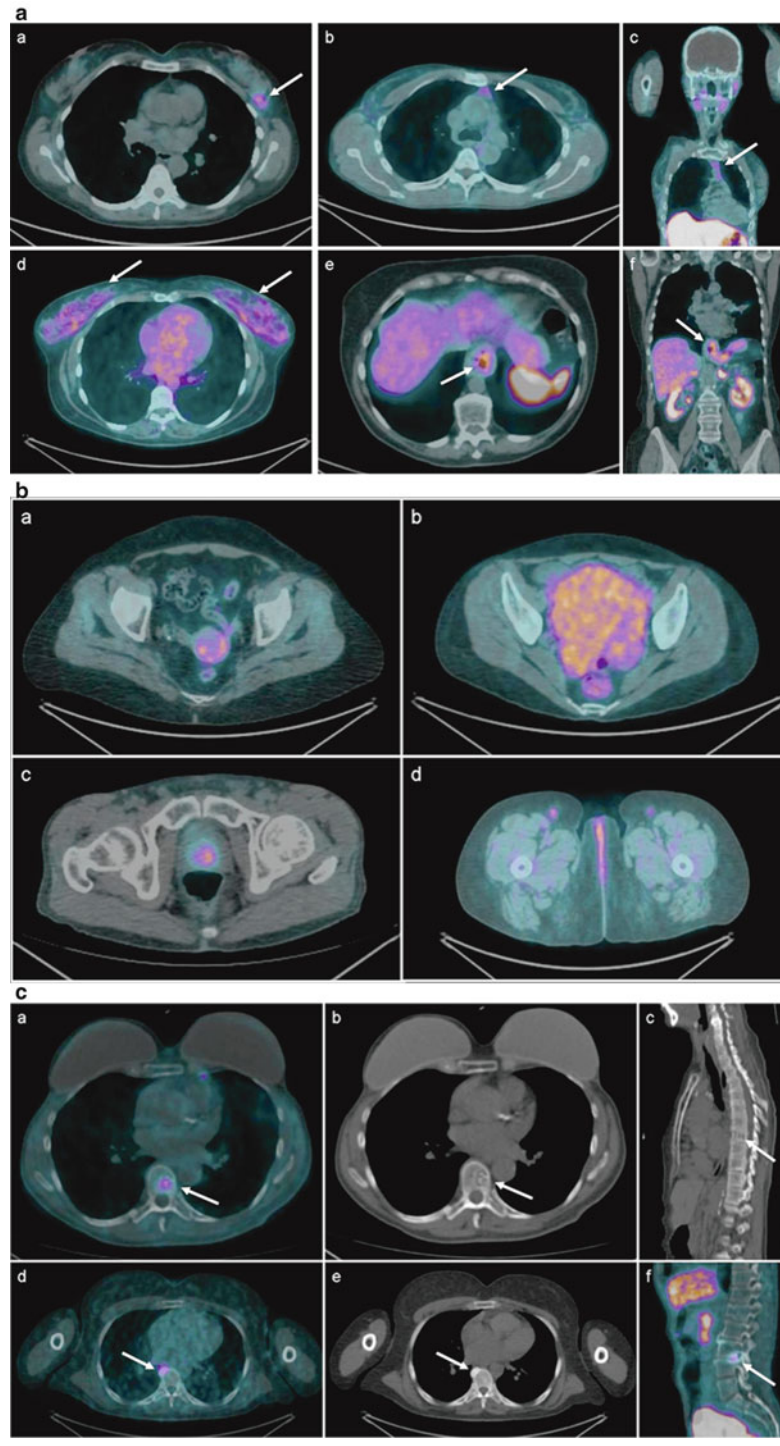

Fig. 21 Common non-NET-related findings at ^{68}Ga-DOTATOC PET/CT. **(A)** Common non-NET-related thoracic findings: Fused ^{68}Ga-DOTATOC PET/CT images of left breast fibroadenoma (*a*), breast physiologic radiotracer uptake (*d*), residual thymus (*b* and *c*), and hiatal hernia (*e* and *f*). **(B)** Common non-NET-related inguino-pelvic findings: fused ^{68}Ga-DOTATOC PET/CT images of physiologic radiotracer uptake in uterus and prostate (*a* and *c*, respectively), in uterus fibromatosis (*b*) and in reactive bilateral inguinal lymph nodes (*d*). **(C)** Common non-NET-related skeletal findings: ^{68}Ga-DOTATOC uptake in vertebral hemangioma (axial fused PET/CT, axial CT, and sagittal CT images *a*, *b*, and *c*, respectively), osteophyte (axial fused PET/CT and axial CT images *d* and *e*, respectively) and degenerative changes at L3–L4 passage (sagittal fused PET/CT image *f*)

100 MBq. Normal findings include the visualization of the kidneys, ureter, and bladder, with variable uptake in the gallbladder; intermediate uptake may be noted in the corpus striatum, myocardium, and liver and low uptake in the small intestine and muscles. There is also evidence of minimal uptake in the normal adrenal medulla [134].

[^{11}C]5-HTP

The serotonin precursor [^{11}C]5-HTP is used in some investigative centers to define the metabolism of the neuroendocrine cell and is thus considered a universal imaging method for NETs. Tomographic imaging is performed after intravenous injection of 370 MBq [92]. However, its widespread application is limited by the short half-life of ^{11}C, which requires an on-site cyclotron.

[^{18}F]FDG

For a detailed description of the scan methodology, reference should be made to the specific section on this subject.

Diagnostic Applications of Nuclear Medicine: Kidney and Bladder Cancer

30

Kirsten Bouchelouche

Abstract

Bladder cancer (BC) is the most common cancer in the urinary tract. It is a heterogeneous cancer, with 70% of patients presenting with superficial tumors which tend to recur but are generally not life threatening. Thirty percent present as muscle-invasive disease associated with a high risk of death from distant metastases. Renal cell carcinoma (RCC) is the most frequent type of kidney cancer in adults and the most lethal cancer in the urinary tract. It consists of three main histopathological RCC types, clear cell (65%), papillary (15–20%), and chromophobe (5%). There has been an important evolution in the understanding of the biology in both RCC and BC, which is important in cancer treatment strategies. Accurate imaging in both RCC and BC is still one of the mainstays of diagnosis, staging, and clinical management of the patients. The ability to identify metastatic disease preoperatively is of utmost importance in determining optimal treatment of the patient. The aim of this chapter, with focus on RCC and BC, is to give an overview of epidemiology of the tumors, environmental factors, genetic predisposition, underlying molecular biology changes, staging and prognostic stratification, overall performance of diagnostic imaging like computed tomography (CT) and magnetic resonance imaging (MRI) for the tumors, positron emission tomography (PET)/CT for staging/prognosis, and common therapies.

Introduction

In the urinary tract, bladder cancer (BC) is the most common cancer. Bladder cancer is a heterogeneous cancer, with 70% of patients presenting with superficial tumors, which tend to recur but are generally not life threatening, and 30% presenting as muscle-invasive disease associated with a high risk of death from distant metastases. A two-pathway model in BC has been proposed, taking into account both histopathological and molecular features. The main histological type in BC is urothelial carcinoma. Similar to BC, kidney cancer is not a single disease; it is made up of a number of different types of cancer, each with a different histology, a different clinical course, responding differently to therapy, and caused by a different gene. Renal cell carcinoma (RCC), the most frequent type of kidney cancer in adults and the most lethal cancer in the urinary tract, arises in the epithelium of the renal tubules and consists of three main histopathological entities. Clear cell RCC (ccRCC) is the dominant histology, accounting for approximately 65% of reported cases, followed by papillary and chromophobe RCC, accounting for approximately 15–20% and 5%, respectively [1]. Accurate imaging in both RCC and BC is one of the mainstays of diagnosis, staging, and therapeutic decision making. The ability to identify metastatic disease preoperatively is of utmost importance in determining treatment. The aim of this chapter, with focus on RCC and BC, is to give an overview of epidemiology of the tumors, environmental factors, genetic predisposition, underlying molecular biology changes, staging and prognostic stratification, overall performance of diagnostic imaging like computed tomography (CT) and magnetic resonance imaging (MRI) for the tumors, positron emission tomography (PET)/CT for staging/prognosis, and common therapies.

Kidney Cancer

Epidemiology

Kidney cancer was the 14th most frequently occurring cancer in women and the 9th most frequently occurring cancer in men worldwide in 2012 (Fig. 1). RCC is the most frequent type of kidney cancer in adults (>90% of cases) and accounts for 2–3% of all cancers in adults [2–4].

The incidence varies worldwide with the highest incidence in the developed countries (Fig. 2). Incidence worldwide is about 350,000 new cases per year and 140,000 deaths per year [3].

The incidence of RCC has steadily increased during the last three decades, with a trending

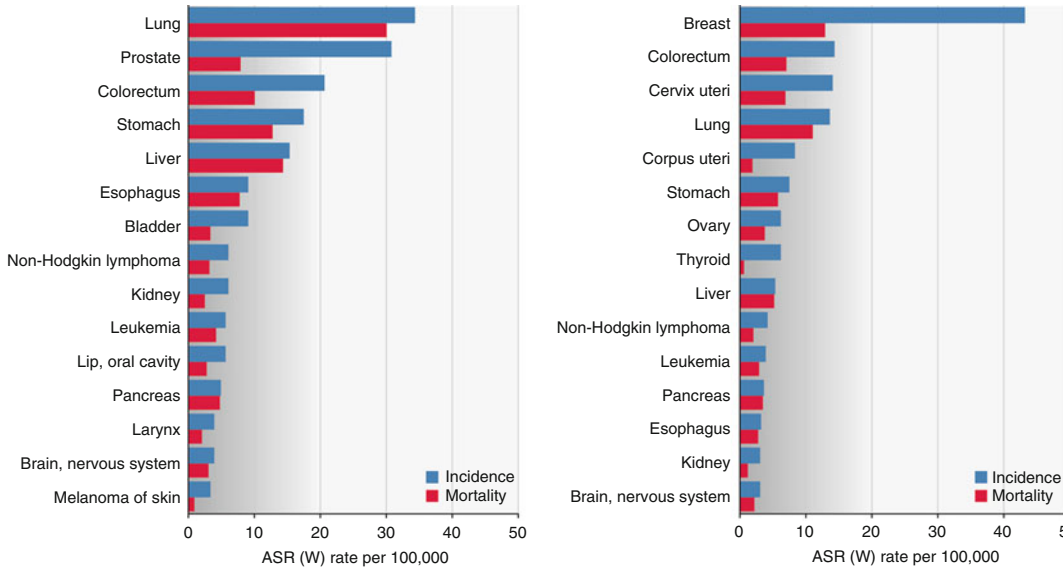

Fig. 1 Estimated age-standardized incidence and mortality rates in men (*left*) and women (*right*) (Reproduced from the public domain of the International Agency for Research on Cancer, GLOBOCAN database 2012, Cancer Incidence and Mortality Worldwide, available at http://globocan.iarc.fr)

increase in the incidence of this cancer by 2–3% per year [5]. However, in the same period, improvement in relative survival rates has been reported [3]. The factors contributing to this increase in incidence remain uncertain, but the widespread use of routine abdominal imaging and the detection of incidental, small solid renal tumors may contribute to this increase in incidence. Although most of the lesions in the kidneys detected incidentally are benign, up to 17% of the patients with RCC have distant metastases at the time of diagnosis [3]. RCC is a male-predominant (1.5:1.0 ratio) disease with a typical presentation in the sixth and seventh decades of life.

Environmental and Genetic Factors

Cigarette smoking and obesity are the strongest risk factors for RCC. Hypertension and family history also contribute to risk of disease [3]. As the world's population ages and the prevalence of risk factors (obesity, hypertension) increases, the burden of RCC is predicted to increase significantly. Classification of RCC has undergone dramatic changes over the past two decades. Improvements in these classification schemes are important, as pathologic variants differ not only in disease biology but also in clinical behavior, prognosis, and response to systemic therapy [6]. Each subtype harbors unique biology and thus responds differently to available treatment strategies. While RCC appears to arise from the nephron, different histological subtypes are believed to originate from different cells. Papillary and clear cell RCC (ccRCC) appear to arise from the proximal tubule, while oncocytoma and chromophobe tumors arise from the distal tubule [6]. The clear cell disease is so named because of the high lipid content in the cytoplasm which is dissolved during histological preparation methods leaving a clear cytoplasm. Clear cell RCC, papillary (types I and II), and chromophobe account for 85–90% of all renal malignancies (Fig. 3). The most common histological subtypes of RCC are clear cell (70–75%) and papillary (10–16%).

The International Society of Urological Pathology Vancouver Modification of WHO (2004) histological classification of kidney tumors is shown in Table 1.

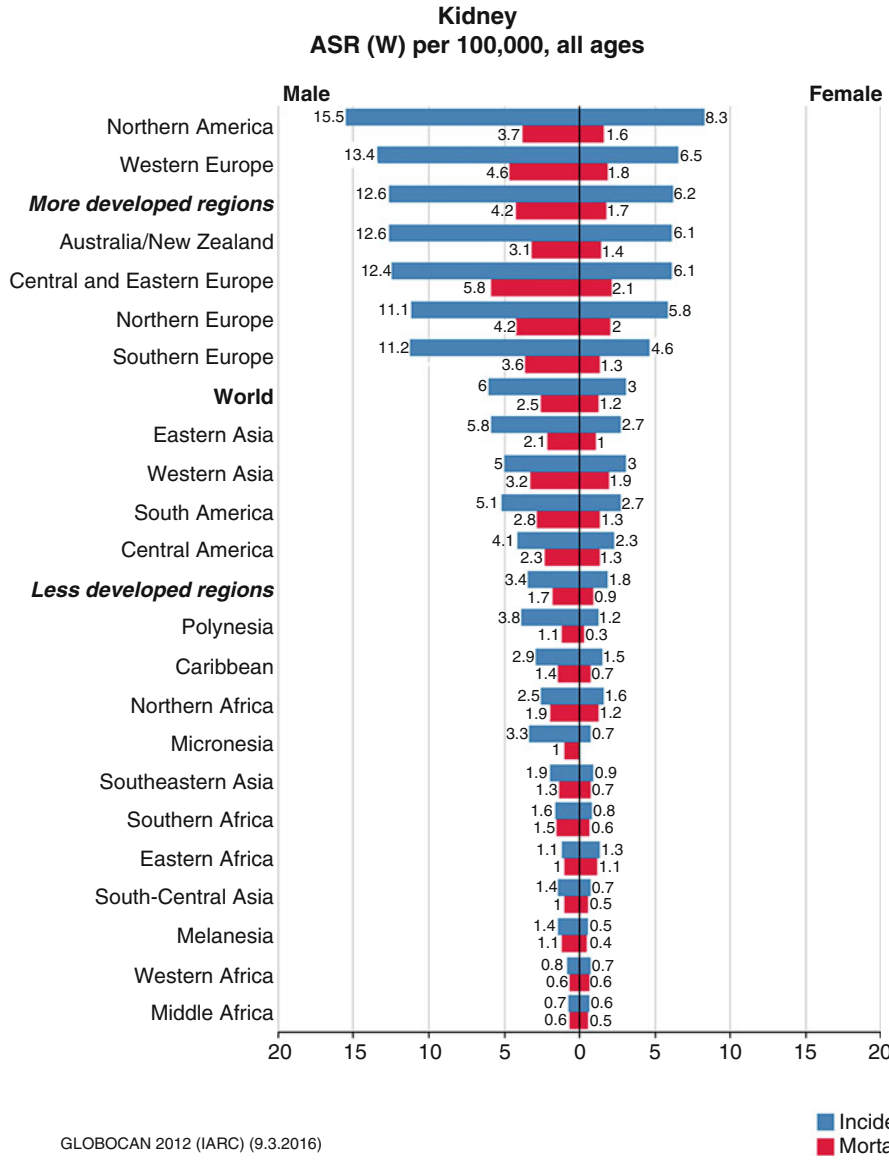

Fig. 2 Age-standardized incidence and mortality rates for kidney cancer by gender on different continents (Reproduced from the public domain of the International Agency for Research on Cancer, GLOBOCAN database 2012, Cancer Incidence and Mortality Worldwide, available at http://globocan.iarc.fr)

RCC can be sporadic or hereditary, and both types are often associated with structural alterations of chromosome 3 [3]. Familial RCC accounts for about 5% of cases of RCC. Most of these genetic conditions give rise to classic RCC subtypes, such as clear cell, papillary, and chromophobe tumors. Several autosomal dominant syndromes are described, each with a distinct genetic basis and phenotype [5]. Table 2 shows the hereditary RCC syndromes. The most common is von Hippel-Lindau (VHL) syndrome, which is characterized by the development of several vascular tumors, including ccRCC. The patients have a defect on one allele of the VHL

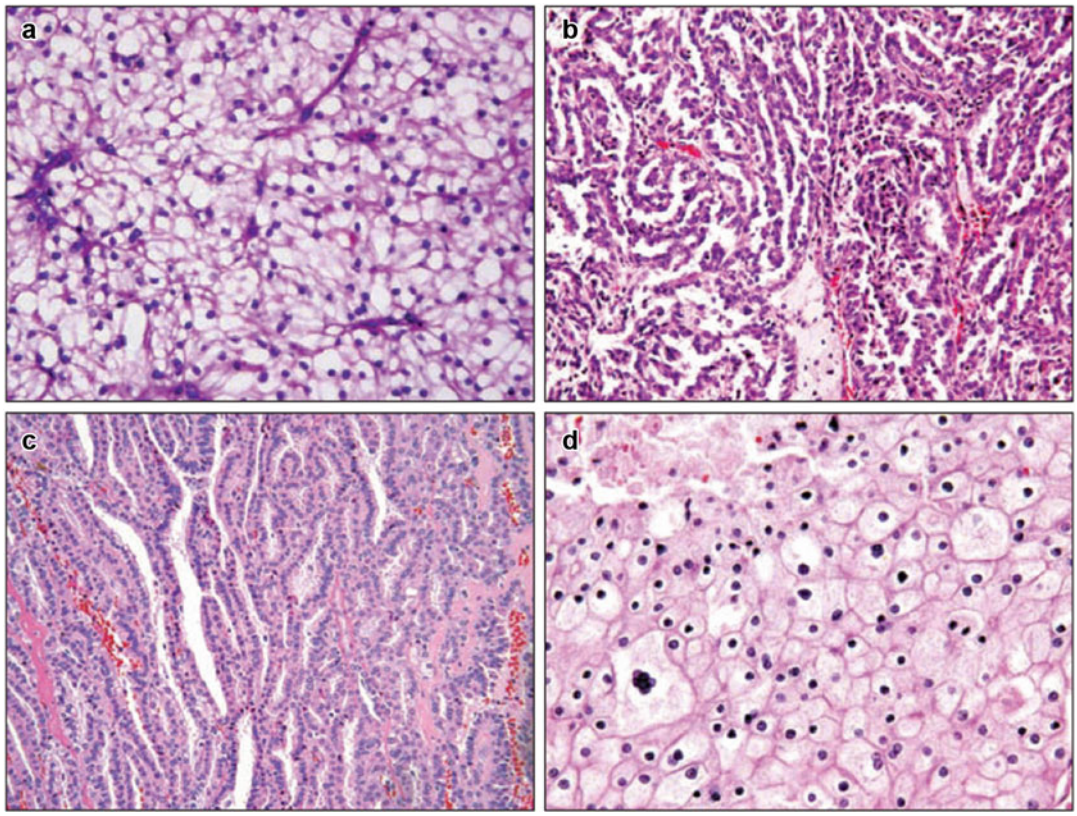

Fig. 3 Histopathological slides of renal cell carcinoma H&E staining. (**a**) Conventional ccRCC. Tumor shows large uniform cells with abundant cytoplasm that is rich in glycogen. (**b**) Papillary RCC type I. Tumor papillae are lined by short cuboidal cells with basophilic cytoplasm. Nuclei are small with few inconspicuous nucleoli. Collection of foamy histiocytes is present in middle of lower half of image. (**c**) Papillary RCC type II. Tumor shows papillae lined by columnar to pseudostratified cells that have striking eosinophilic cytoplasm. (**d**) Chromophobe RCC. Note sheet of tumor cells with focal necrosis (*upper left corner*). Tumor cells have abundant pale flocculent cytoplasm, prominent cell membranes, perinuclear halos, and wrinkled nuclei [7]

gene. Clear cell RCC in this syndrome tends to be early onset and multifocal. Most patients with sporadic (inherited) ccRCC have defects in both VHL alleles and dysfunction of the VHL protein [5]. In contrast, sporadic ccRCC tends to be late onset and unifocal. At least twelve well-studied genes are known to cause kidney cancer: VHL, MET, FLCN, fumarate hydratase, succinate dehydrogenase B, succinate dehydrogenase D, TFE3, TFEB, MITF, TSC1, TSC2, and PTEN. Each of these genes is involved in the cell's ability to sense oxygen, iron, nutrients, or energy; thus, it can be concluded that kidney cancer may fundamentally be a metabolic disease [8].

Symptoms and Diagnosis

RCC may remain clinically occult for most of its course. Symptoms usually do not appear until late, when the tumor may already be large and metastatic. The classic triad of flank pain, hematuria, and flank mass is uncommon (10%) and is indicative of advanced disease. Twenty-five to thirty percent of patients are asymptomatic, and their RCC is found on incidental imaging studies. The most common presentations are gross or microscopic hematuria (40%), flank pain (40%), and palpable mass in the flank or abdomen (25%). Only 30% of the patients are diagnosed on the basis of symptoms. RCC is a unique and

challenging tumor because of the frequent occurrence of paraneoplastic syndromes. The paraneoplastic events occur in 20% of patients and are largely related to secreted proteins, such as parathyroid hormone-related proteins (causing hypercalcemia), renin (causing hypertension), erythropoietin (causing erythrocytosis), and fever or wasting syndromes [5]. Prevalent use of ultrasonography and cross-sectional imaging is associated with increased incidental detection of many asymptomatic kidney tumors. Previously, biopsies of kidney tumors were not widely done due to concern about local tumor spread. The standard treatment was the removal of the kidney mass. The trend is now to perform a biopsy to establish the diagnosis of renal masses in patients that may be candidates for active surveillance and to select optimal targeted therapy in patients with metastatic disease [3]. Accuracy of biopsy for detecting malignancy is 38–100%. However, renal biopsies in the clinical management of renal masses are still underused.

Staging

As in other malignant tumors, prognosis in RCC depends on tumor extent and metastases at the time of primary diagnosis. Since surgery is currently the only curative treatment for RCC, the prognosis greatly depends on the presurgical tumor stage. Therefore, preoperative imaging is most important for the planning of the surgical approach and strategy. The aim of any preoperative imaging in RCC is to differentiate benign from malignant lesions; to adequately assess tumor size, location, and organ

Table 2 Listing of known hereditary renal cell cancer syndromes [6]

Syndrome	Gene(s)	Chromosome location	Histology
von Hippel-Lindau syndrome	*VHL*	3p25	Clear cell

confinement; to identify lymph node (LN) and/or visceral metastases; and to reliably predict the presence and extent of any thrombus of the vena cava. There are two staging systems for RCC, both based on the degree of tumor spread beyond the kidney. The 40-year-old Robinson system is still used but has in most centers been replaced by the TNM staging system (Table 3), developed by the American Joint Committee on Cancer (AJCC) [5, 7, 9]. Furthermore, a clinical staging of RCC is used (Table 4) [7, 9].

Table 3 TNM staging of renal cell carcinoma [7]

Stage	Description
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor <7 cm in greatest dimension, limited to kidney
T1a	Tumor <4 cm in greatest dimension, limited to kidney
T1b	Tumor >4 cm but <7 cm in greatest dimension, limited to kidney
T2	Tumor ≥7 cm in greatest dimension, limited to kidney
T3	Tumor extends into major veins or invades adrenal gland or perinephric tissues, but not beyond Gerota's fascia
T3a	Tumor invades adrenal gland or perinephric tissues but not beyond Gerota's fascia
T3b	Tumor grossly extends into renal vein(s) or vena cava below diaphragm
T3c	Tumor grossly extends into vena cava above diaphragm
T4	Tumor invades beyond Gerota's fascia
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single regional lymph node
N2	Metastasis in more than one regional lymph node
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Overall Performance of Diagnostic Imaging Other Than Nuclear Medicine for Kidney Cancer

The common utilization of abdominal ultrasound (US) or CT performed for other medical reasons has increased the number of incidentally detected renal tumors. Renal masses are classified as solid or cystic based on imaging findings. About 20% of masses are benign, 60% are probably indolent variants of RCC, and only 20% are potentially aggressive tumors [5, 9]. Important for differentiating malignant lesions is the presence of enhancement. US, CT, and MRI are used for detecting and characterizing renal masses, and most renal masses are diagnosed accurately by imaging alone. The aim of imaging is to characterize the renal mass and possible abdominal metastases, tumor extension, and venous involvement for staging. If malignant RCC is suspected, additional imaging is performed (i.e., CT of thorax, brain CT, total bone scan).

Ultrasound has been used for imaging of renal masses since it is easily repeatable, does not involve radiation exposure, and is cost-effective [10]. However, it requires operator experience, and the kidney cannot always be completely imaged, especially in large patients. Many RCCs are detected by abdominal US, but due to limitations in specificity and accuracy, it is necessary to use CT or MRI to confirm suspicious findings. US is inferior compared with CT, especially in smaller renal masses. The size of the lesions is an important factor. In lesions that are 0–5 mm, CT has a detection rate of 47%, as compared to US with a detection rate of 0 [11]. The detection rate increases with the size of the lesion. In lesions 10–35 mm, the detection rates are 80% and 82%, respectively [11]. US detection rate may be improved by the use of contrast-enhanced ultrasound (CEUS). A meta-analysis including 11 studies demonstrated that CEUS has a pooled

sensitivity of 88% and a pooled specificity of 80% for discriminating between malignant and benign renal masses [12]. However, microbubbles are not approved for use in the abdomen in many countries and thus are only of limited use. US may be used in patients undergoing radiofrequency ablation (RFA), and CEUS has demonstrated promising results in follow-up after RFA treatment [13].

Multislice CT has for many years been the gold standard for imaging of RCC and is widely used to differentiate benign from malignant lesions [14]. Renal oncocytoma and angiomyolipoma represent the most common benign lesions which have to be differentiated from RCC [14]. Imaging must be performed before and after administration of iodinated intravenous contrast medium to demonstrate enhancement. Enhancement with intravenous contrast correlates with malignant disease in about 80% of cases, although small renal tumors and those in young women are more likely to be benign [5]. Small ($\leq$4 cm) solid enhancing (becoming brighter on CT with contrast) renal masses must be considered highly suspicious for RCC [5]. Although RCC can appear as iso-, hyper-, or hypodense lesions on native CT scans, it usually demonstrates a significant contrast enhancement and intratumoral areas of necrosis following i.v. contrast application [14]. However, the management of these lesions has caused great controversy over the past decade. Benign lesions such as renal oncocytoma are most often homogeneous lesions exhibiting hypodensity compared to the normal renal parenchyma following i.v. contrast injection. The sensitivity and specificity of helical CT scans for differentiating conventional RCC from the other subtypes have been demonstrated to be 74% and 100% when 84 Hounsfield units (HU) is used as the cutoff value in the corticomedullary phase and 84% and 91% when 44 HU is used as the cutoff value in the excretory phase [15]. Triple-phase contrast abdominal CT is the current investigation of choice for the confirmation of diagnosis and staging in most instances [16]. In CT imaging, enhancement in renal masses is measured by comparing HU before and after contrast administration. To further increase diagnostic accuracy, evaluation should include images from the nephrographic phase, to discriminate between renal masses, which do not enhance to the same degree as the renal parenchyma. The nephrographic phase gives information about the glomeruli, the loop of Henle, and the collecting ducts. During this phase, medullary enhancement is similar to that of the cortex, so the kidney is seen more homogeneously on the images. Thus, this is the phase where it is easiest to detect lesions and characterize them in comparison with the arterial phase [10]. Multiphasic multidetector CT is able to distinguish ccRCC from oncocytoma, papillary RCC, and chromophobe RCC with accuracies of 77%, 85%, and 84%, respectively [17]. Figure 4 illustrates different RCCs on CT.

Venous tumor thrombus represents a significant problem in RCC, with 15–25% of patients having some degree of venous invasion [14]. Since an aggressive surgical approach is the mainstay in these patients, good presurgical planning depends on the preoperative evaluation of RCC with determination of tumor thrombus stage. Involvement of the renal vein and extension into the inferior vena cava below or above the diaphragm will change the surgery strategy [14]. Furthermore, the detection of visceral metastases appears to be crucial since it has been shown that even patients with metastatic disease might benefit from radical nephrectomy followed by systemic immunotherapy in the case of a good performance status and the presence of LN and pulmonary metastases only. Tumor staging is accomplished mainly with CT which allows for assessment of local invasiveness, LN involvement, or other metastases [5]. Abdominal CT provides information on: function and morphology of the contralateral kidney, primary tumor extension, venous involvement, enlargement of LNs, and conditions of the adrenal glands and other solid organs.

MRI. If the results of CT are indeterminate or in case of suspected pseudoenhancement, MRI may provide additional information on enhancement in renal masses, locally advanced malignancy, and venous involvement if the extent of the inferior vena cava tumor thrombus is poorly defined on CT. Exceptional circumstances where alternative imaging modalities would be preferred include contrast allergy, functional renal impairment, and pregnancy, where MRI may be used. The main

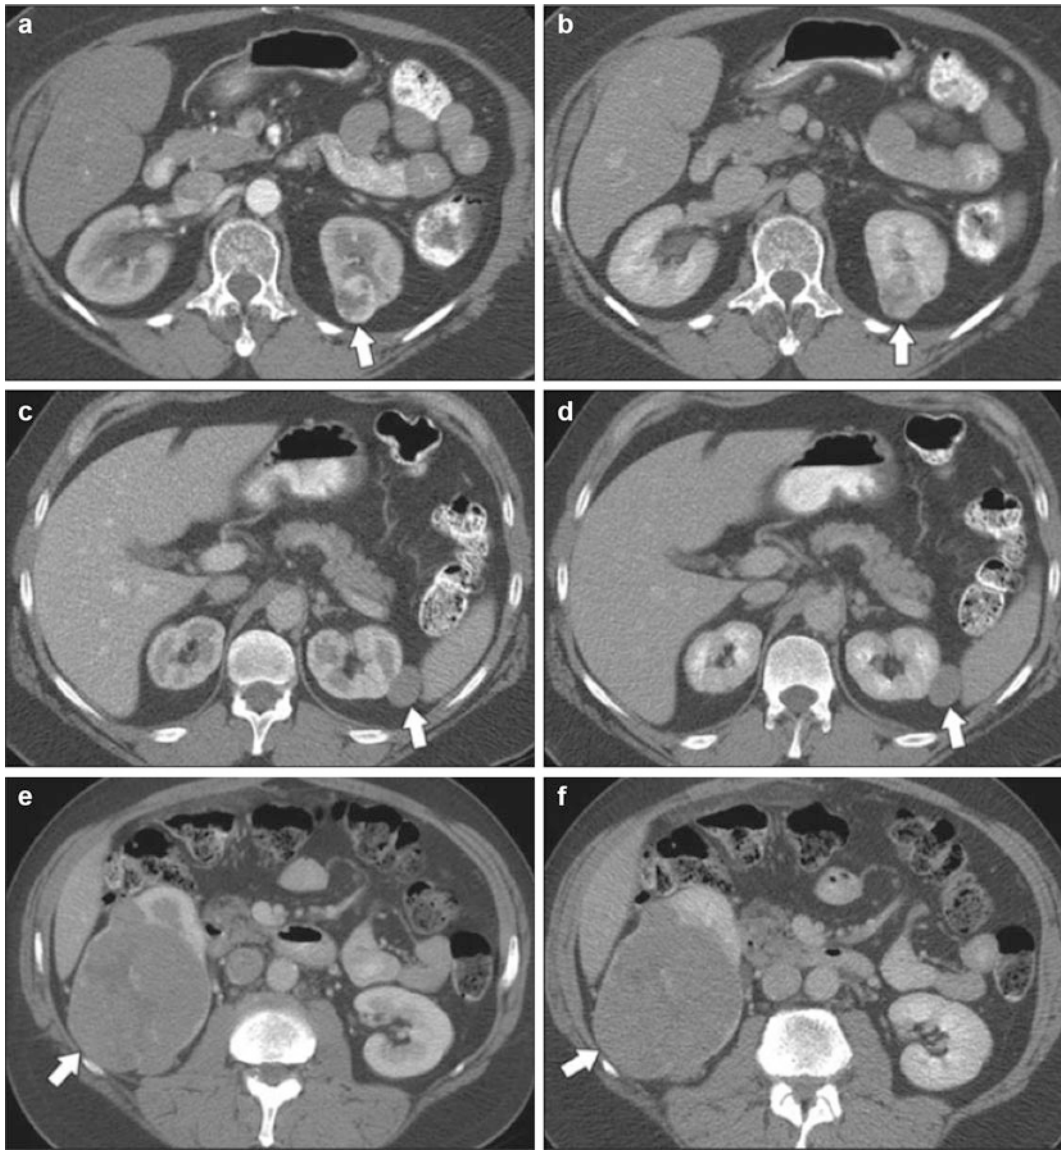

Fig. 4 CT appearances of various cell types of renal cell carcinoma. Conventional clear cell RCC (**a**, **b**). CT scans of TNM stage T1a tumor in corticomedullary and nephrogenic phases show typical hypervascularity of tumor (*arrow*, **a**) and subsequent washout (*arrow*, **b**). Papillary RCC (**c**, **d**). CT scans of TNM stage T1a tumor in corticomedullary (**c**) and nephrogenic (**d**) phases show typical hypovascularity of tumor (*arrow*). Chromophobe RCC (**e**, **f**). CT scans of TNM stage T2 tumor in corticomedullary (**e**) and nephrogenic (**f**) phases show hypovascularity of tumor (*arrow*) [7]

MRI feature indicating potential malignancy of a renal tumor is enhancement after i.v. gadolinium administration. However, enhancement at MRI cannot be measured as easily as enhancement at CT [18]. For the differentiation between thrombus and tumor thrombus in the renal vein and inferior vena cava, the use of gadolinium contrast is indicated, since the enhancement of the thrombus indicates a tumor [18]. Preoperative MRI accurately identifies the presence and nature of tumor thrombus with a sensitivity, specificity, and accuracy of 100%, 89%, and 92%, respectively [19]. The role of MRI in RCC imaging is still mainly in differentiating benign lesions versus malignant

lesion in patients who cannot undergo CT with i.v. iodinated contrast media or in cases with non-diagnostic CT results [18]. Both CT and MRI perform well in T staging of local tumor extent and M staging of distant metastases. However, both CT and MRI perform relatively poorly in N staging of lymphadenopathy [9, 14]. In patients with hereditary RCC who are worried about the radiation exposure of frequent CT scans, MRI may be offered as an alternative. Functional imaging with multiparametric MRI (mpMRI) is demonstrating promising results for discriminating RCC from benign lesions and for classifying RCC subtypes [20]. Especially, T2-weighted (T2W) MRI sequences have demonstrated promising results.

[^{18}F]FDG PET/CT for Staging/Prognosis

Primary diagnosis. Management of small renal tumors continues to change, and now urologists seek to incorporate new and important information as they plan surgery. For many years 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) PET/CT has been an important noninvasive imaging modality for the staging of many cancers. [^{18}F]FDG is a marker of increased glucose uptake. Many malignant neoplasms and their metastases are characterized by enhanced glucose utilization and therefore increased glucose uptake. As an analog of glucose, [^{18}F]FDG is taken up within tumor cells via GLUT and other transporters where it is phosphorylated by hexokinase but not further metabolized, leading to intracellular accumulation. PET imaging in combination with CT offers a high sensitivity scan for metabolic activity with precise anatomical localization. [^{18}F]FDG is excreted though the kidneys into the urine, and urine activity may mask tumors in urinary tract inclusive of the urinary bladder. The value of [^{18}F]FDG PET/CT in RCC is debated, especially for detecting primary renal tumors. Interference of excreted [^{18}F]FDG by the kidneys into the urinary tract accounts for the difficulty in identifying renal cancers that accumulate [^{18}F]FDG at levels that do not allow discrimination from normal urinary excretory tissue [21]. Forced diuresis coupled with parenteral hydration may improve the diagnostic accuracy of [^{18}F]FDG PET in various abdominopelvic malignancies, by enhancing urinary excretion of the tracer. However, the results from forced diuresis obtained in RCC are not convincing [22, 23]. Recently, early dynamic imaging and [^{18}F]FDG PET/CT have demonstrated promising results for evaluation of RCC [24]. In addition to the interference of background activity, the size and the [^{18}F]FDG avidity of the RCC may be partly responsible for the performance of [^{18}F]FDG PET/CT in RCC. Well-visualized tumors in kidneys on [^{18}F]FDG PET/CT are larger than non-visualized ones [22, 23]. In general RCCs have modest [^{18}F]FDG uptake due to lower metabolic state (Fig. 5). However, [^{18}F]FDG uptake is exquisitely seen in type II papillary RCC, especially when seen in the hereditary leiomyoma RCC syndrome [25]. Sarcomatoid tumors are also [^{18}F]FDG avid [25]. Benign renal tumors may also be FDG avid [25], and [^{18}F]FDG is not very useful on complex cystic renal masses, because of the low content of solid tissue in such lesions [26].

Various studies have confirmed that [^{18}F]FDG PET/CT offers little advantage over conventional imaging in the detection of primary RCC [21, 22, 28–32]. The sensitivity for detection of renal lesion is approx. 60% and the specificity approx. 90% [21, 22, 31, 33]. Contrast-enhanced CT and MRI have proven effective at detecting solid masses suspicious of RCC, but both modalities are nonspecific and cannot surely discriminate benign from malignant lesions. A negative [^{18}F]FDG PET/CT is not very useful clinically in these cases. Therefore, [^{18}F]FDG PET/CT only plays a minor role in the diagnosis of RCC. Diagnosis is generally made on CT and/or MRI and, if questions arise, a biopsy is usually recommended. [^{18}F]FDG may play an important role in particular subtypes of renal cancer, such as type II papillary and sarcomatoid (Fig. 6) [25, 34–36].

Primary staging. [^{18}F]FDG PET/CT is better to detect extrarenal rather than renal RCCs, as extrarenal lesions are not obscured by urinary [^{18}F]FDG activity [37]. In a meta-analysis, the pooled sensitivity and specificity were reported to be 79% and 90%, respectively, for detection of metastatic disease [33]. However, [^{18}F]FDG

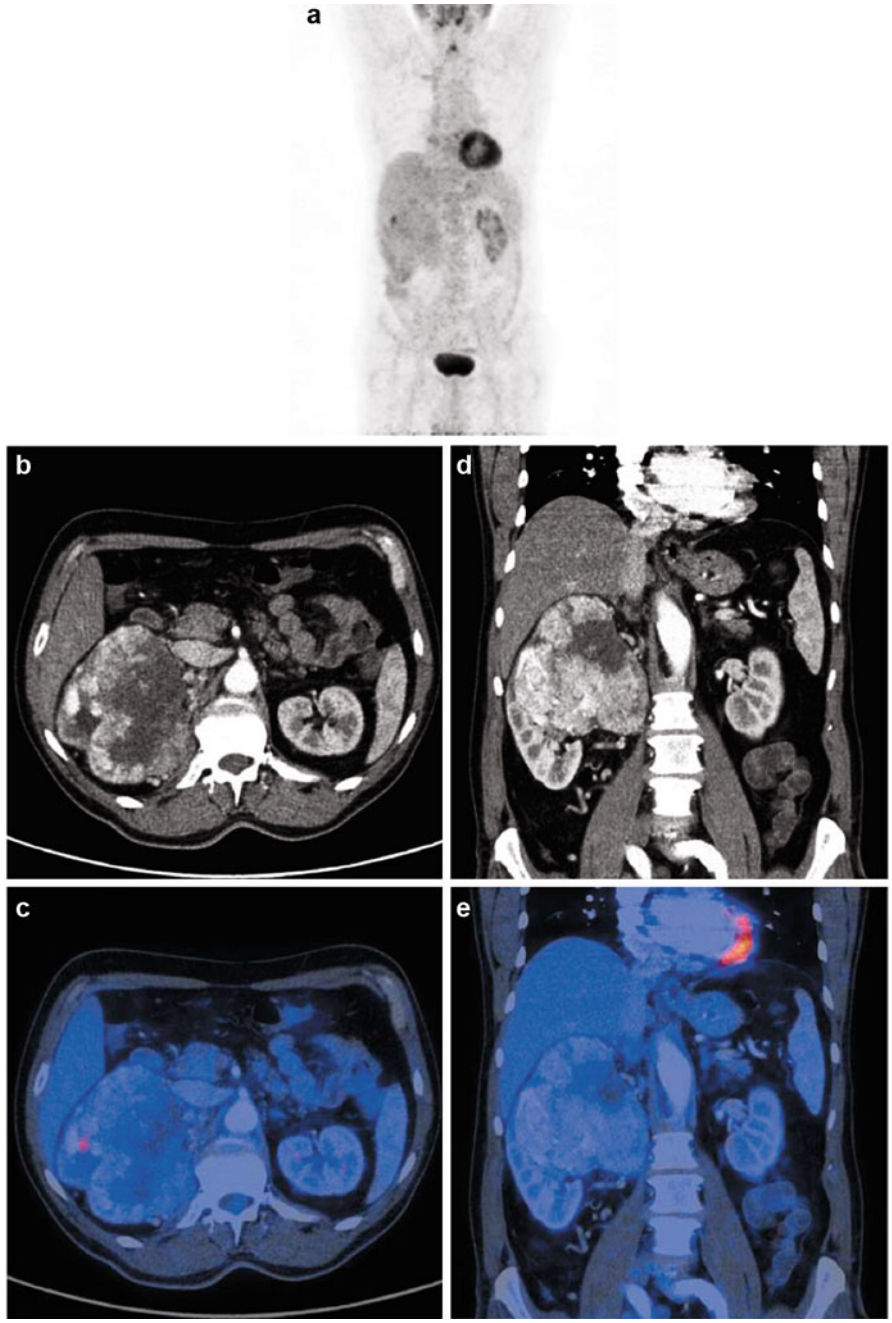

Fig. 5 Patient surviving more than 24 months after nephrectomy, classical RCC well differentiated with low level accumulation of [^{18}F]FDG (SUV_{max} 0–10). Whole-body MIP (**a**), CT images (**a**, **d**), and fused PET/CT images (**c**, **e**) [27]

PET/CT may not localize a small lesion as accurately as a larger one. In a study, the sensitivity of [^{18}F]FDG PET/CT increased from 76% to 92.9% when the lesion size increased from more than 1 to more than 2 cm [38]. In addition to lesion size, [^{18}F]FDG PET/CT may localize high-grade tumors more efficiently than low-grade ones [33]. In high-risk large tumors, [^{18}F]FDG

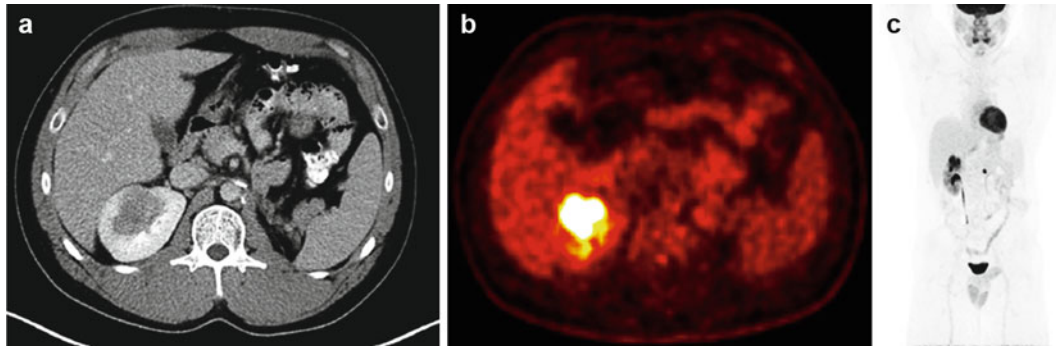

Fig. 6 Solitary renal cancer in the right upper pole. The patient had a type II papillary RCC in the right kidney (**a**) and was considered at high risk for metastatic disease. [^{18}F]FDG PET/CT demonstrates increased activity in the upper pole of the kidney corresponding to the mass on CT (**b**) and no evidence of metastatic disease elsewhere (**c**) [36]

PET/CT may be helpful for local staging in order to detect tumor thrombus in renal vein and inferior vena cava and discriminate between malignant or "bland" [39], which may help the surgeons in planning of the operation [40]. Furthermore, [^{18}F]FDG PET/CT may detect distant metastases with a higher accuracy than CT [22]. However, many of the primary RCCs detected by CT or MRI are small and with low risk of metastases. Thus, in general, [^{18}F]FDG PET/CT is not widely used for clinical primary staging of RCC.

Recurrent and metastatic disease. Early detection and management of metastatic disease have the potential to improve prognosis and quality of life. Several studies have used [^{18}F]FDG PET/CT for detection of recurrence and metastatic disease [21, 22, 37, 38, 41–44]. A meta-analysis found that [^{18}F]FDG PET can be useful in restaging and detection of metastatic disease, based on its acceptable sensitivity and specificity [45]. Similar results were demonstrated in another meta-analysis that only included studies using hybrid PET/CT scanners[33]. On a lesion-based analysis of three studies, the pooled sensitivity and specificity were 84% and 91%, respectively, for detection of extrarenal disease. On a scan-based analysis (n=7), the pooled sensitivity and specificity were 79% and 90%, respectively [33]. Figure 7 illustrates an example of [^{18}F]FDG PET/CT in BC and ccRCC.

Assessment of response to therapy. [^{18}F]FDG PET/CT in RCC is most often used in patients with metastatic disease treated with novel, targeted therapies [36]. Various molecular targeting therapies have become available for the treatment of advanced RCC. Agents targeting VEGF/PDGFR/mTOR pathway continue to be the mainstay of treatment in RCC [3]. Accurate prognostication is desirable for choosing the appropriate treatment for individual patients. Although tumor size measured according to the RECIST criteria have proven adequate for monitoring chemotherapy, for other cancers with modern targeted therapies, there is often little change in the size of the lesions, and some metastases even increase while the drug is prolonging survival [46]. Thus, [^{18}F]FDG activity may play a role in monitoring the efficacy of targeted therapies. Studies have demonstrated a correlation of sequential [^{18}F]FDG uptake on PET with the efficacy of VEGFR tyrosine kinase inhibitors [47–49]. In one study, time to progression in patients treated with the VEGFR inhibitor, sunitinib, was inversely correlated with [^{18}F]FDG uptake by the tumors [48]. Another study examined the relationship between [^{18}F]FDG uptake and the response in primary tumors to treatment with another VEGFR tyrosine kinase inhibitor, sorafenib, similarly demonstrating that those tumors with the highest avidity for [^{18}F]FDG tracer signal on PET were less likely to respond to therapy [49]. The decrease in [^{18}F]FDG accumulation of RCC lesions evaluated by PET/CT after treatment initiation with tyrosine kinase inhibitors is not influenced by the organs where the RCC metastasis is located [50]. Figure 8

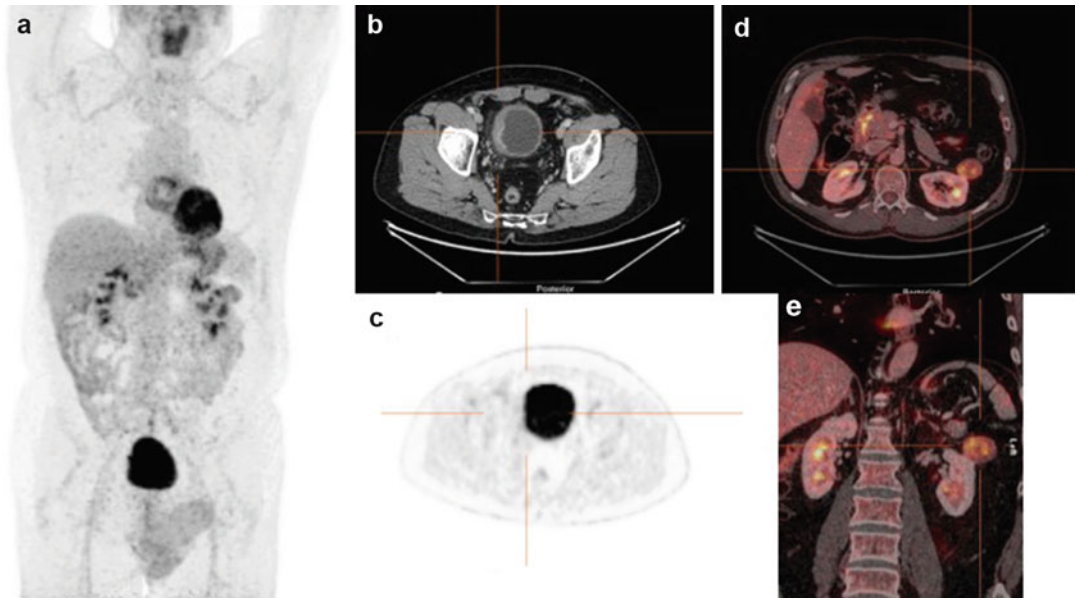

Fig. 7 Sixty-nine-year-old man with newly diagnosed muscle-invasive bladder cancer referred for primary staging with [^{18}F]FDG PET/CT. The bladder cancer is seen on CT in the right side of the bladder wall (**b**) but is not visible on PET (**a**, **c**) because of urinary excretion of [^{18}F]FDG that masks the tumor in the bladder. No lymph node metastases or distant metastases were seen (**a**). However, in the left kidney, a process measuring 3 × 4 cm with moderate [^{18}F]FDG uptake was seen on the fused PET/CT images (**d**, **e**). The patient was operated (laparoscopic cystectomy) for the bladder cancer. The process in the left kidney was removed with resection, and histology showed clear cell RCC. The case illustrates that tumor in the bladder often is masked on PET, because of urinary excretion of [^{18}F]FDG. Furthermore, some clear cell RCCs can be seen on PET/CT, most often with modest [^{18}F]FDG uptake, but not all clear cell RCCs are [^{18}F]FDG avid

demonstrates [^{18}F]FDG PET/CT in type II papillary RCC.

The prognosis for patients with RCC, where metastases are present at the time of diagnosis, is unfavorable. The median survival time given is between 10 and 21 months [51]. It is well known that prognoses for patients with RCC can vary, and the guidelines recommend risk-directed therapies using prognostic classifications based on a combination of clinical information and laboratory data. However, in this era of molecular targeting therapy, an index that expresses the biological activity of RCC directly, and prognosticates accurately, is desired for appropriate clinical decision making [52]. In one study the initial [^{18}F]FDG uptake in tumors correlated with prognosis, with patients whose renal tumors exhibit a SUV_{max} of greater than 10 having significantly worse survival than those with SUV_{max} less than 10 [27]. Recently, similar results were reported in a large study ($n = 101$), where pretreatment SUV_{max} assessed by [^{18}F]FDG PET was a useful prognostic marker for patients with advanced RCC, providing important information for clinical decision making [52]. Decreases in [^{18}F]FDG uptake on PET during therapy also correlate with prognosis [27, 46, 50].

Surveillance. In RCC, 20–40% of all patients relapse or develop metastases after radical nephrectomy with curative intent [53]. If this recurrence is diagnosed early, it can be treatable. Intensive surveillance imaging for recurrence of RCC following presumed curative surgical resection is driven by the widespread but unproven belief that early detection and treatment of asymptomatic disease may improve survival [54]. Defining the optimal surveillance regimen is challenging and must account for a number of complex patient and physician variables and interactions. The early detection of metastatic disease is the primary goal of postoperative surveillance for RCC. The imaging

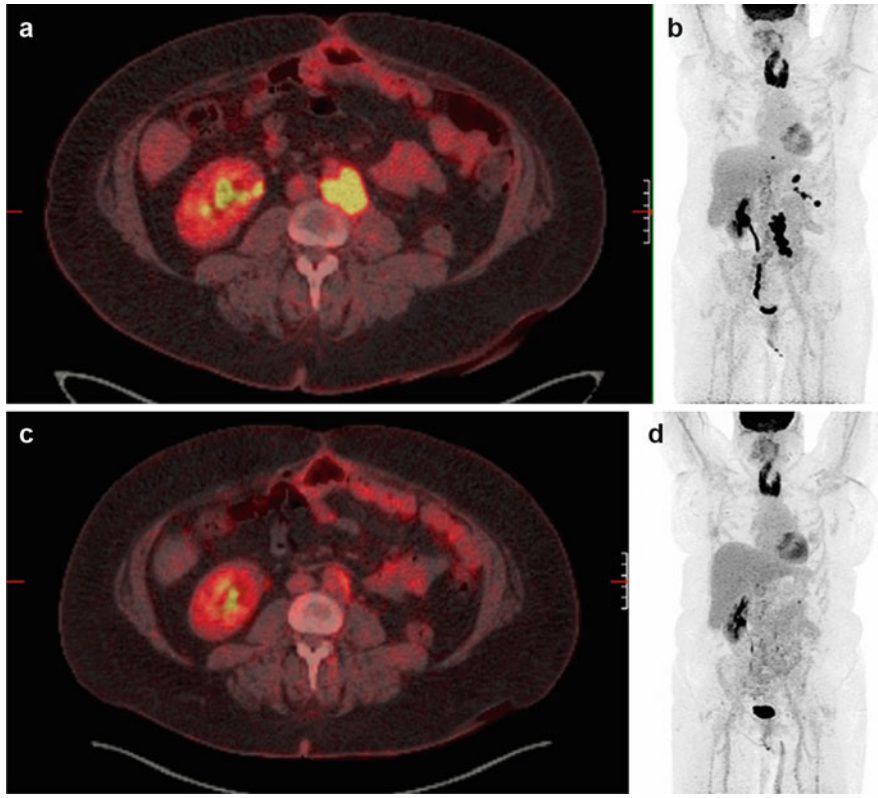

Fig. 8 Patient with type II papillary RCC associated with hereditary leiomyoma RCC syndrome, which has recurred after left nephrectomy. PET/CT with [^{18}F]FDG demonstrates intense uptake in the left para-aortic adenopathy on transverse PET/CT (**a**) and coronal projection image (**b**). After therapy with a combination of targeted therapies, the activity and size of the adenopathy have decreased dramatically (**c**, **d**). The patient has maintained a good response for 2 years [36]

methods used for follow-up can aid in the earlier detection of disease and in the appropriate administration of salvage therapy. A retrospective study assessed the efficacy of [^{18}F]FDG PET/CT for the surveillance of patients ($n = 63$) with a high risk of recurrence or metastasis after surgical treatment of RCC, compared to the conventional imaging methods [55]. The [^{18}F]FDG PET/CT accurately classified the presence of a recurrence or metastasis in 56 (89%) patients. [^{18}F]FDG PET/CT had an 89.5% sensitivity, 83.3% specificity, 77.3% positive predictive value, 92.6% negative predictive value, and 85.7% accuracy in detecting recurrence or metastasis, which was not significantly different from the results with conventional methods. Moreover, the accuracy of the [^{18}F]FDG PET/CT by nuclear grade and histological subtypes was not significantly different. The role of [^{18}F]FDG PET/CT in surveillance of RCC needs to be evaluated further in large prospective trials.

PET Radiopharmaceuticals Other Than [^{18}F]FDG

New radiotracers based upon compounds that are selectively accumulated by RCC or radiopharmaceuticals, which are not excreted in the urine, may be useful for imaging of RCC. Thus, other PET tracers than [^{18}F]FDG have been used in RCC in the past years including ^{18}F-fluoride (Na^{18}F), ^{124}I-eG250, [^{11}C]acetate, ^{18}F-MISO, and ^{18}F-fluorothymidine (^{18}F-FLT).

^{18}F-Fluoride. Bone is a common site of metastases in RCC, and bone metastases develop in more than 50% of patients with RCC during the

course of the disease [56]. About 80% of these bone metastases develop within 3 years of diagnosis [57]. For the moment, technetium ^{99m}Tc-methylene diphosphonate (^{99m}Tc-MDP) bone scan is the most commonly used modality for detection of bone metastases. However, as metastases from RCC are predominantly osteolytic, they may be missed on conventional ^{99m}Tc-MDP bone scan. Although Na^{18}F uptake, like ^{99m}Tc-MDP uptake, depends on the osteoblastic activity and the regional blood flow, the better spatial resolution with PET/CT may make Na^{18}F PET/CT more sensitive for detection of bone metastases. Yet, there has only been few reports using Na^{18}F PET/CT for detection of metastases in RCC. A recent report suggests that Na^{18}F PET is more sensitive than conventional ^{99m}Tc-MDP bone scan [58]. In the study, Na^{18}F PET/CT showed a sensitivity of 100%, specificity of 94.4%, positive predictive value (PPV) of 94.7%, negative predictive value (NPV) of 100%, and accuracy of 97.2% [58]. Na^{18}F PET/CT detected significant more lesions than bone scan. Na^{18}F is even able to detect lytic lesion [59]

^{124}I-cG250. Immuno-PET involves radiolabeling of monoclonal antibodies (mAbs) with positron emitters that bind to an antigen on tumor cells. In recent years, much focus has been on the chimeric antibody G250 (cG250), which reacts against carbonic anhydrase IX (CAIX). CAIX is overexpressed in ccRCC, and the G250 antigen is expressed on the cell surface of more than 90% of ccRCC whereas not expressed in normal kidney [60, 61]. CAIX is involved in cellular pH regulation and has been implicated in some pathogenic processes including tumor progression and is thought to play a role in regulating cell proliferation in response to hypoxic conditions [62]. High CAIX expression has been demonstrated in malignancies (renal, ovarian, colorectal, lung, brain, and bladder cancers). CAIX is associated with hypoxia and appears to be a marker of poor prognosis [63]. CAIX expression is regulated by the hypoxia-inducible factor 1α (HIF-1α). Mutation of the VHL genes leads to accumulation of HIF-1α and activation of downstream targets including CAIX [64]. Now CAIX is the best and most powerful diagnostic and predictive marker of ccRCC [63]. The half-life of common positron emitters, ^{11}C (20.4 min) and ^{18}F (109.7 min), is in general too short for use with a mAb in vivo. Positron emitters with longer half-lives, like ^{124}I (100 h) and ^{89}Zr (78 h), are better suited to the slow pharmacokinetics of radiolabeled mAbs. The optimal uptake of such antibody conjugates in tumors is normally several days post-injection for intact immunoglobulins [65]. In an ex vivo study, pairwise evaluation of ^{89}Zr-cG250 and ^{124}I-cG250 was performed. Superior PET images were obtained using ^{89}Zr-cG250, owing to the more prolonged trapping of the tracer in the tumor and simultaneous washout from normal tissues [66]. Recently, ^{124}I-cG250 PET/CT has been used to evaluate primary RCC [67, 68]. In the multicenter REDECT trial including 195 patients, ^{124}I-cG250 PET/CT showed a sensitivity of 86% and a specificity of 86% for ccRCC [68]. The results from the study were promising and demonstrated the potential use of ^{124}I-G250 PET as an imaging biomarker for malignancy. The PET agent may help noninvasively to distinguish ccRCC from other subtypes. Preoperative identification of tumor type could have important implications for the choice of treatment for RCC. Thus, ^{124}I-cG250 PET may be a useful diagnostic imaging tool in the future for clinical management of renal masses (Fig. 9). Imaging with ^{124}I-cG250 PET has the potential to change clinical management, in patients where a conservative approach (renal impairment, comorbid disease) may be appropriate in G250-negative tumors. These patients may be selected for nephron-sparing surgery or observed. Thus, ^{124}I-cG250 PET scan may be important value in risk stratification of patients with renal masses.

[^{11}C]Acetate, ^{18}F-MISO, and ^{18}F-FLT. The potential of [^{11}C]acetate as a metabolic tracer for RCC has been investigated in small studies [26, 69, 70]. Acetate is converted to acetyl coenzyme A in the mitochondria, followed by rapid clearance as carbon dioxide through the citric acid cycle. The results on [^{11}C]acetate PET are conflicting, and larger prospective studies are needed to clarify the role of [^{11}C]acetate PET/CT in RCC. However, the technical limitations of this agent (an on-site cyclotron is needed) are likely to inhibit its widespread

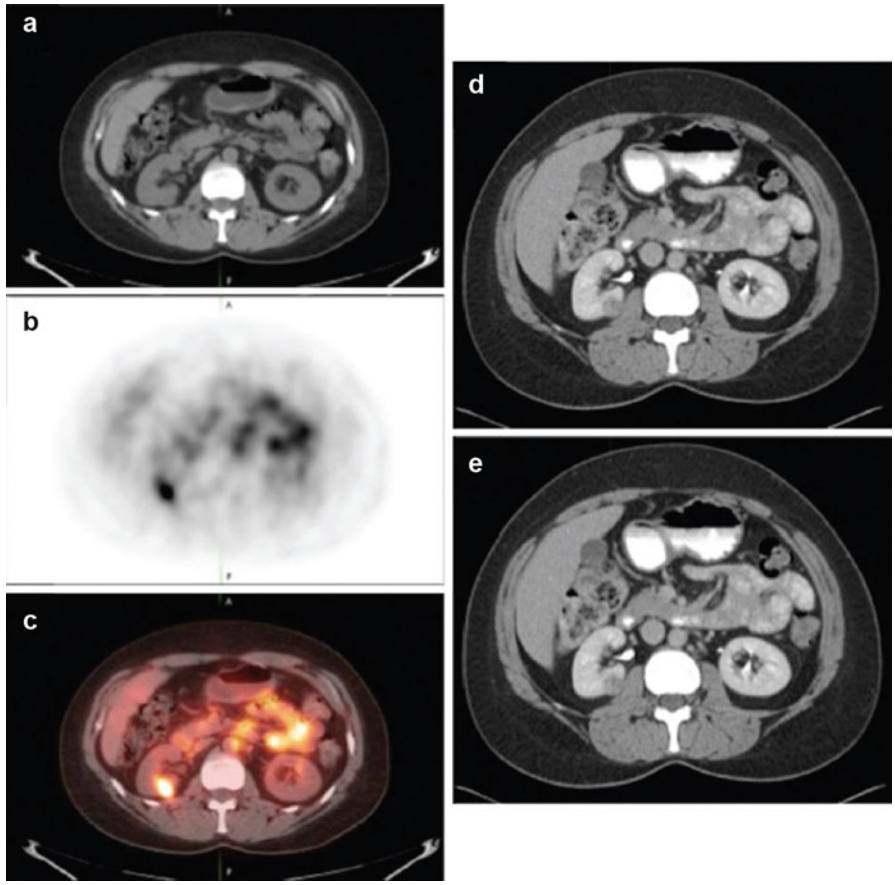

Fig. 9 Patient with a 1.0 cm right ccRCC (**a**). The mass is evident in the noncontrast CT image (**a**) from the PET/CT scan, positive on the ^{124}I-cG250 PET image, and is clearly evident on the fused PET/CT image (**c**). The mass was deemed to be positive on the contrast-enhanced CT scan of the parenchymal component (**d**) and excretory component (**e**) by Hounsfield criteria and qualitatively [68]

use. Radiolabeled nitroimidazole, ^{18}F-MISO, has emerged as noninvasive technique for assessing tumor hypoxia. Nitroimidazoles are effective against organisms thriving in hypoxic environments and are retained within hypoxic yet metabolically active cells. Thus, ^{18}F-MISO has been used in a number of malignant tumors, where hypoxia has been identified as a risk factor in the prognosis of the tumors. Because RCC is resistant to radiation and chemotherapy, it behaves like a tumor that contains hypoxic cell populations. A small study used ^{18}F-MISO PET in order to assess regional hypoxia in renal tumors [71]. A trend of increased ^{18}F-MISO uptake in RCC was demonstrated in RCC tumors as compared to normal tissue. However, although ^{18}F-MISO scans showed significant uptake in other solid tumors, there was only mild ^{18}F-MISO uptake in RCC. ^{18}F-FLT, which is radiopharmaceutical based on the nucleic acid thymidine and is able to measure cellular proliferation, has been used in few reports [72]. Larger studies are needed to evaluate the role of ^{18}F-FLT in RCC.

Common Therapies

The optimal treatment for RCC is surgery, especially when the tumor is located in the kidney with no LN involvement or metastasis. In advanced/metastatic RCC, most available treatments are palliative, and the patients usually die. In those cases,

the objective is to increase overall survival (OS), progression-free survival (PFS), response rate (RR), and quality of life (QF) of RCC patients [73]. Before target cell therapies became available, interleukin-2 (IL-2) and interferon-alpha (IFN-α) were the mainly used therapies for RCC, with low response, from 5% to 20% [73]. The treatment options for RCC include surgery, radiation therapy, chemotherapy, hormonal therapy, immunotherapy, targeted therapies, or combinations of these and some new approaches [74, 75]. Surgical treatment remains the mainstay of curative treatment for RCC and is recommended to achieve cure in localized RCC. In recent years, the explosion in laparoscopic and organ-sparing approaches has produced major shifts in the paradigm for surgical resection of RCC.

Surgical treatment. Operation may be performed as radical nephrectomy (RN) or as partial surgery (PN), i.e., nephron-sparing surgery. Radical nephrectomy includes the removal of the kidney, adrenal gland, perirenal fat, and Gerota's fascia and may be performed as open operation or as laparoscopic operation (standard laparoscopic or robot-assisted laparoscopic). Laparoscopic RN has a lower morbidity than open surgery [76]. Several studies have compared PN and RN for RCC (≤4 cm) and shown that RN was associated with increased mortality from any cause after adjusting for patient characteristics [77–79]. Thus, PN is recommended in patients with T1a tumors, and PN should be favored over RN in patients with T1b tumor when possible [80]. Ipsilateral adrenalectomy is only recommended when there is clinical evidence of invasion of the adrenal gland, and LN dissection is also only recommended if there is clinical evidence of LN invasion. PN is unsuitable in patients with locally advanced tumor growth and when PN is not feasible due to unfavorable tumor location. In these patients, the treatment is RN. Therapeutic alternatives to surgery include surveillance and ablative therapies. Two main ablative techniques, cryoablation (CA) and radiofrequency ablation (RFA), represent the currently available minimally invasive treatments for RCC. Other ablative techniques are used in experimental settings (microwave ablation, laser ablation, high-intensity focused ultrasound ablation). Population-based studies have compared the outcome of surgery (RN or PN) and nonsurgical management of renal tumors <4 cm and demonstrated a significant lower cancer-specific mortality for patients treated with surgery [81, 82]. However, this benefit is not seen in older patients (>75 years) in other studies [83, 84]. In active surveillance cohorts, the growth of small renal masses is low in most cases, and progression to metastatic disease is rare (1–2%) [85, 86]. Thus, in old patients and/or comorbid patients with small renal masses, active surveillance, RFA, and cryoablation can be offered.

Local advanced RCC is typically managed with radical nephrectomy, which will occasionally require en bloc resection of adjacent organs. Up to 40–60% of patients can be cured with such an aggressive approach [87]. Radical nephrectomy in the presence of metastatic disease (called debulking or cytoreductive nephrectomy) is often indicated as part of integrated management [75]. Lymph node dissection is performed in clinically positive LNs, for staging or local control. Tumor thrombus formation in inferior vena cava in RCC patients is an adverse prognostic factor [88]. These patients are operated with aggressive resection including the removal of the kidney and tumor thrombus if the patients have nonmetastatic disease. However, the best approach and management of these patients are still discussed [89].

Advanced/metastatic RCC is one of the most treatment-resistant malignancies [75].

The treatment may be local therapy (cytoreductive nephrectomy, embolization of the tumor), local therapy of metastases (bones, brain, etc.), or systemic therapy (immunotherapy, targeted therapies, monoclonal antibody against VEGF, mTOR inhibitors). Concerning local therapy of metastases, no general recommendation exists. The decision to resect metastases has to be decided in each patient and depends on the experience in the institution, risk profile, the patient's preference, etc. In some cases, stereotactic radiotherapy for bone metastases and stereotactic radiosurgery for brain metastases are offered for symptom relief. Chemotherapy is not considered effective in

patients with ccRCC. Chemotherapy is moderately effective only if 5-fluorouracil (5-FU) is combined with immunotherapeutic agents [90]. However, in one study IFN-α showed equivalent efficacy to IFN-α + IL-2 + 5-FU [91]. Overall, chemotherapy presently has little to no role in the treatment of metastatic RCC. Selected patients with metastatic disease may respond to immunotherapy, but many patients can be offered only palliative therapy for advanced disease. IL-2 and IFN-α have been used for more than 20 years. Despite this, the effectiveness of these two drugs is still controversial [75]. IFN-α monotherapy is inferior to targeted therapy in metastatic disease of RCC, but IL-2 monotherapy may be used in selected cases (ccRCC with only lung metastases). IL-2 has more side effects than IFN-α. Thus, immunotherapy is not routinely recommended as a first-line therapy in metastatic RCC.

New targeted therapies that have shown efficacy for advanced RCC include (1) tyrosine kinase inhibitors like sunitinib (Sutent®, Pfizer, New York, NY, USA), sorafenib (Nexavar®, Bayer, West Haven, CT, USA, and Onyx, Richmond, CA, USA), pazopanib (Votrient®, GlaxoSmithKline Pharma, London, UK), and axitinib (Inlyta®, Pfizer, New York, NY, USA); (2) monoclonal antibody against circulating VEGF like bevacizumab (Avastin®, Genentech, San Francisco, CA, USA); and (3) mTOR-inhibiting drug like temsirolimus (Torisel®, Wyeth, Collegeville, PA, USA) and everolimus (Afinitor®/Certican®/Votubia®, Novartis, Basel, Switzerland) [75, 92]. Other new treatments currently under investigations include stem cell transplantation, other interleukins, antiangiogenesis therapy, and vaccine therapy [93]. Sequential treatment with VEGF pathway-targeted therapies has become the standard treatment of metastatic RCC in many centers [75]. Figure 10 illustrates targeted therapies in RCC. Systemic treatment for metastatic RCC should be based on targeted agents, and sunitinib and pazopanib are recommended as a first-line therapy for advanced/metastatic ccRCC [80]. Bevacizumab + IFN-α is recommended as a first-line therapy for advanced/metastatic RCC in favorable-risk and intermediate-risk ccRCC and temsirolimus for first-line treatment in poor-risk RCC. Axitinib is second-line treatment for metastatic RCC. Everolimus is recommended for ccRCC patients who have failed VEGF-targeted therapy. Pazopanib and sorafenib are alternatives to axitinib as a second-line therapy. Sunitinib is a first-line therapy for non-clear cell metastatic RCC [80].

Bladder Cancer

Epidemiology of the Tumor

Bladder cancer (BC) is the ninth most commonly diagnosed cancer worldwide, with more than 380,000 new cases each year and more than 150,000 deaths per year. BC is the most common cancer in the urinary system [2] and is the sixth most common malignancy in men worldwide in 2012, following prostate, lung, colorectal, stomach, and liver cancer (Fig. 11). Recently, the overall and stage-specific age-adjusted 5-year survival and mortality rates of BC in the USA (period 1973–2009) were analyzed [94]. Although the analysis demonstrated statistically significant changes, the mortality rate associated with BC has not changed substantially in the last 30 years, indicating gaps between diagnosis and management of BC. Little or no change in BC control outcomes has been achieved during the study period [94]. Incidence of BC peaks in the sixth and seventh decades of life, although a trend toward presentation at younger ages has been suggested [95]. Because of long-term survival and the need for lifelong routine monitoring and treatment, the cost per patient of BC from diagnosis to death is the highest of all cancers in the USA [96]. Rates in males are three to four times those in females [97]. Incidence rates are high in many southern and eastern European countries, in parts of Africa and the Middle East, and in North America (Fig. 12) [97]. TCC accounts for over 90% of cases and is by far the most common epithelial tumor of the bladder [95]. The second most common cell type is squamous cell cancer (5%), and less than 2% are adenocarcinomas [95].

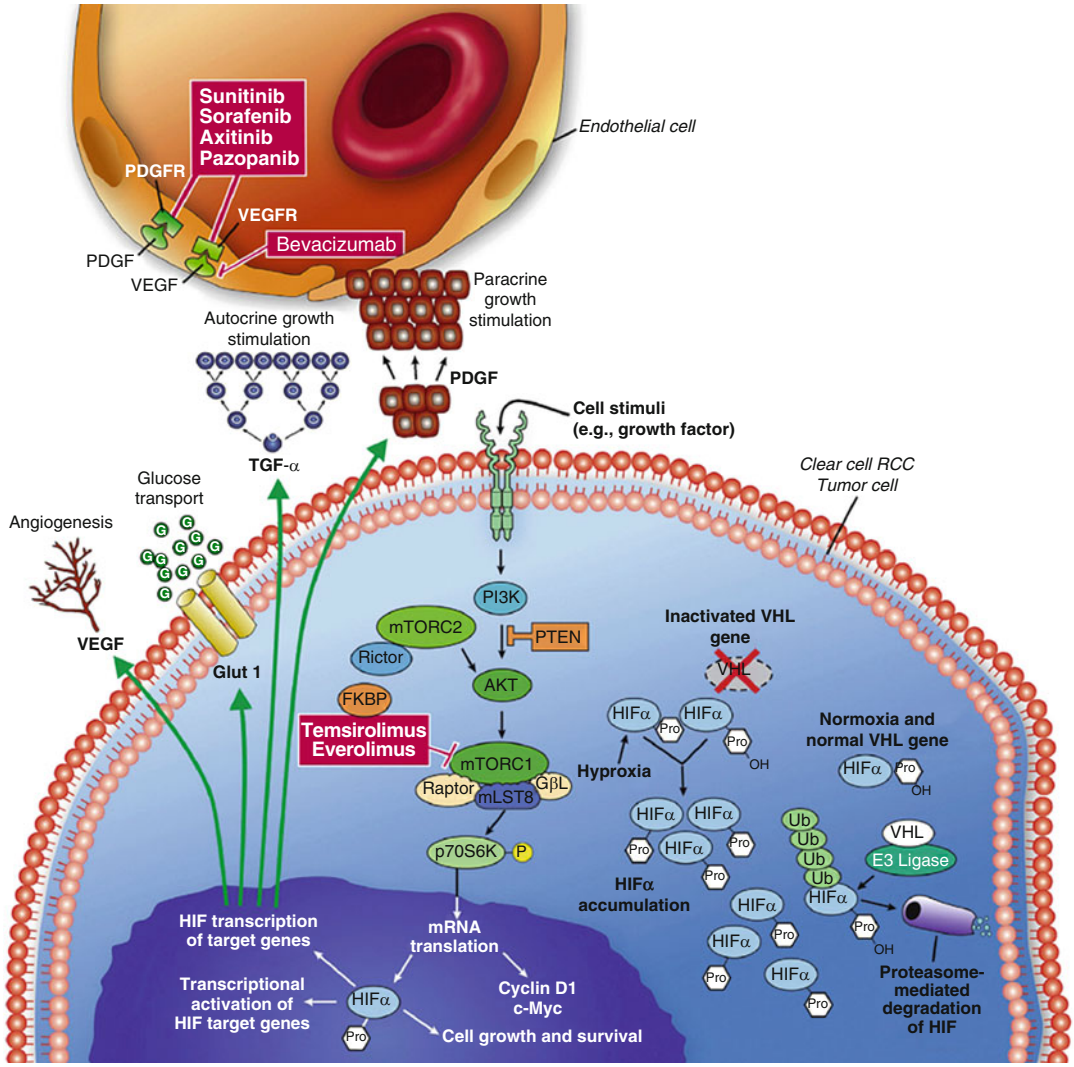

Fig. 10 The cellular pathways that are implicated in clear cell RCC carcinogenesis. Included are the seven US Food and Drug Administration-approved agents and where they act on this pathway [6]

Environmental and Genetic Factors

In bladder cancer, smoking is the most common risk factor and accounts for approximately half of all BCs [98]. Occupational exposure to aromatic amines and polycyclic aromatic hydrocarbons is an other important risk factor. The role of diet and environmental factors is less evident. In the recent years, there has been increasing evidence suggesting an influence of genetic predisposition on BC incidence.

Tobacco smoking. Several causative risk factors are associated with urothelial carcinoma (UC). Of these, smoking, especially cigarettes, is one of the most important factors and is consistently associated with the development of UC. While urothelial carcinoma of the bladder (UCB) and upper tract urothelial carcinoma (UTUC) are two distinct diseases [99], cigarette smoking is the most established risk factor for both [100]. Current smoking increases the risk of developing UCB and UTUC by as much as fourfold and sixfold,

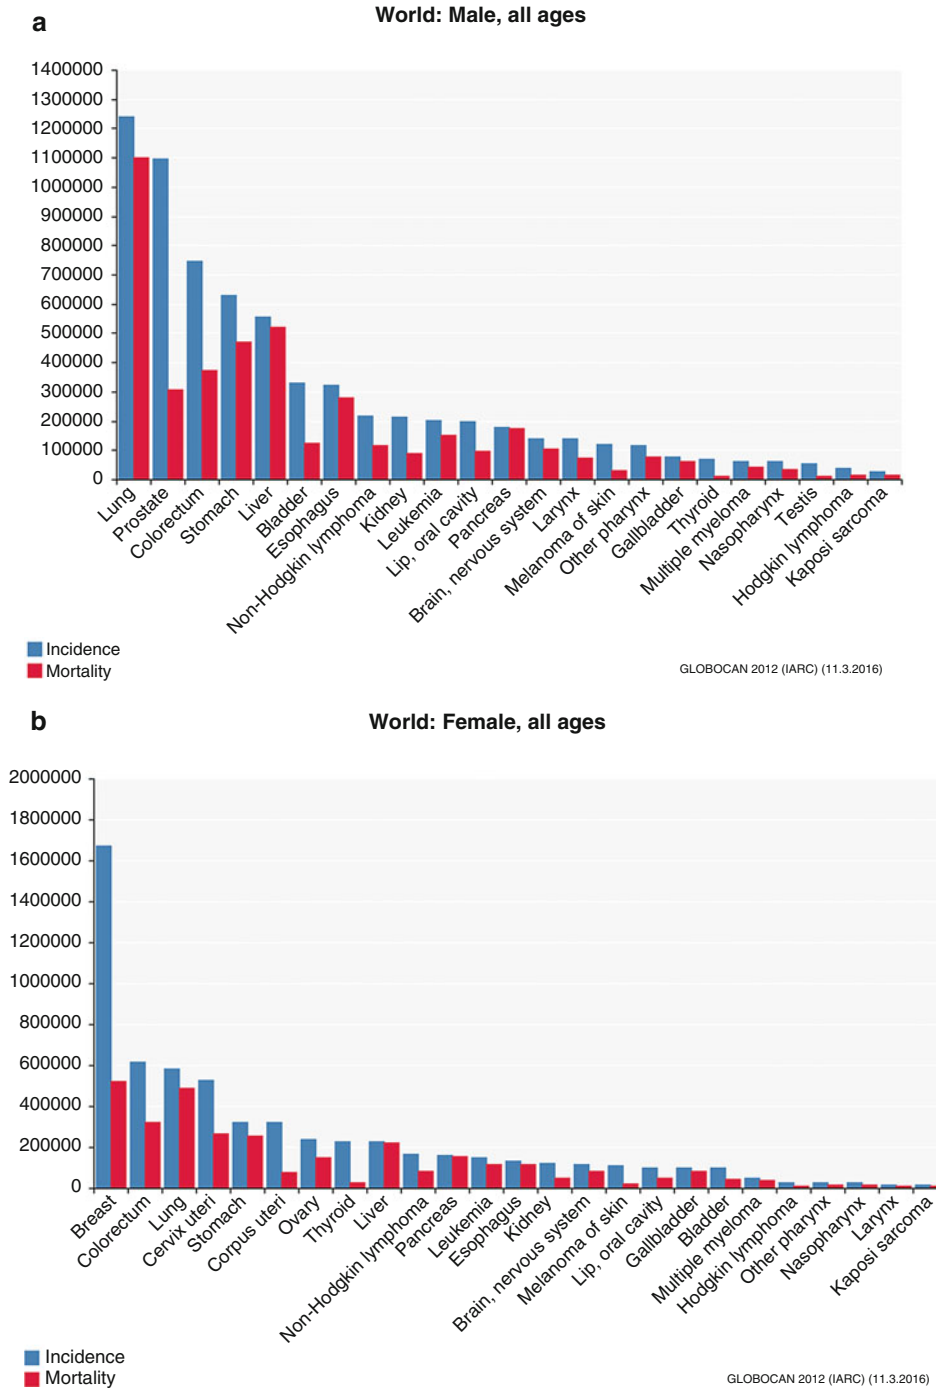

Fig. 11 Estimated age-standardized world incidence and mortality rates from different cancers in men (**a**) and women (**b**) (Reproduced from the public domain of the International Agency for Research on Cancer, GLOBOCAN database 2012, Cancer Incidence and Mortality Worldwide, available at http://globocan.iarc.fr)

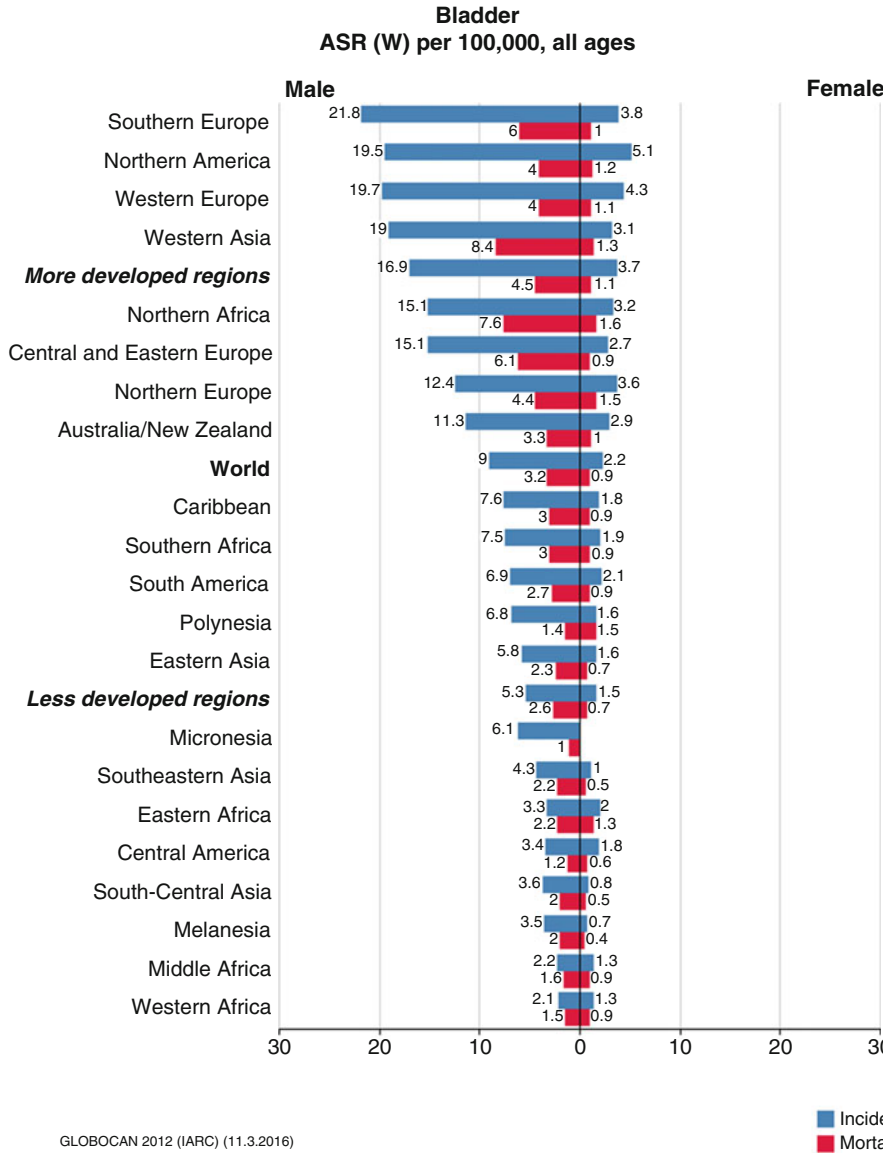

Fig. 12 Age-standardized incidence and mortality rates for bladder cancer by gender on different continents (Reproduced from the public domain of the International Agency for Research on Cancer, GLOBOCAN database 2012, Cancer Incidence and Mortality Worldwide, available at http://globocan.iarc.fr)

respectively [100], and 30–50% of all BC is caused by cigarette smoking [101]. The risk of developing UCB and UTUC increases with cumulative smoking exposure (i.e., number of smoked cigarettes/day and the duration of smoking), and it is independent of gender [100]. Tobacco smoking is causing 50–65% of male cases and 20–30% of female cases, and current cigarette smoking triples BC risk relative to never smoking [102]. A meta-analysis with 216 observational studies on cigarette smoking and BC demonstrated a significant association of BC for both current and former cigarette smokers [103]. The latency period is approximately 20–30 years. An increase in risk estimates for current smokers relative to never smokers has been demonstrated which may be due to changes in cigarette contents [102]. An immediate decrease in the risk of BC was observed

in those who stopped smoking [102]. The reduction was about 40% within 1–4 years of quitting cigarette smoking and 60% after 25 years of nonsmoking [104]. Thus, it is important to encourage people to stop smoking, since it would result in decreasing incidence of BC, both in men and women.

Exposure to chemicals. The second most important risk factor for BC is occupational exposure to chemicals, and work-related cases account for 20–25% of all BC [98]. The carcinogenic chemical compounds involved include aromatic amines (benzidine, 4-aminobiphenyl, 2-naphthylamine, 4-chloro-o-toluidine), polycyclic aromatic hydrocarbons, and chlorinated hydrocarbons, and it is likely to occur in occupations in which dyes, rubbers, textiles, paints, leathers, and chemicals are used [98, 105]. The risk of BC due to occupational exposure to carcinogenic aromatic amines is significantly greater after 10 years or more of exposure; the mean latency period normally exceeds 30 years. In recent years, the pattern extent and extent of occupational chemical exposure have changed because awareness has resulted in safety measurements in order to reduce carcinogenic chemical exposure [98]. Recent population-based studies demonstrated the occupational attribution for BC in men to be 7.1%, while no such attribution was discernible for women [106].

Genetic factors. There is growing evidence that genetic susceptibility factors and family associations may influence the incidence of BC. Genome-wide association studies of BC identified several susceptibility loci associated with BC risk. Several genetic changes have been related to risks of BC including *HRAS* mutation (Costello syndrome, facio-cutaneous-skeletal syndrome), *Rb1* mutation, *PTEN*/*MMAC1* mutation (Cowden syndrome), *NAT2* slow acetylator phenotype, and *GSTM1* null phenotype [107, 108]. With regard to gender, women have a lower BC incidence (up to fourfold) and a higher mortality rate than men [109].

Other factors. External beam radiotherapy for gynecologic cancer has been reported to increase rates of secondary bladder malignancies with relative risks of 2–4 [110]. Schistosoma haematobium bladder infections increase the risk of cancer (bilharzial bladder cancer) [111].

Exposure to arsenic in drinking water has also been recognized as a cause of BC [98]. Other dietary factors have been discussed, and many of these are still a topic of debate [98].

Molecular Biology

Improved treatment requires detailed understanding of UC pathogenesis and molecular biology. Expression-based analyses have identified distinct types of BC that have prognostic and therapeutic significance. Low-grade non-muscle-invasive BCs recur frequently but rarely progress to muscle invasion, whereas muscle-invasive BCs are usually diagnosed de novo and frequently metastasize [112]. Recent genome-wide expression and sequencing studies identify genes and pathways that are key drivers of UC and reveal a more complex picture with multiple molecular subclasses than through conventional grade and stage groupings. A two-pathway model has gained much attention, taking into account both histopathological and molecular features [112]. This model proposes that papillary noninvasive BC develops via epithelial hyperplasia and recruitment of a branching vasculature. Muscle-invasive BC is proposed to develop via flat dysplasia and CIS. The molecular characteristics of muscle-invasive BC and non-muscle-invasive BC are highly distinct. Figure 13 shows preneoplastic alterations in the bladder with tumor. These observations are leading to novel therapeutic approaches in BC [113]. This improved understanding of molecular features, disease pathogenesis, and heterogeneity provides new opportunities for prognostic application, disease monitoring, and personalized therapy of BC. Although noninvasive BC is not life threatening, its tendency to recur makes this disease more expensive to treat than other cancers, and disease monitoring and treatment are associated with considerable morbidity [112]. Key biomarker panels already are demonstrating promising results for application in noninvasive urine-based monitoring. For muscle-invasive BC, molecular profiling in the context of large clinical trials is required to confirm the ability of molecular signatures to stratify patients before treatment with conventional chemotherapy [112].

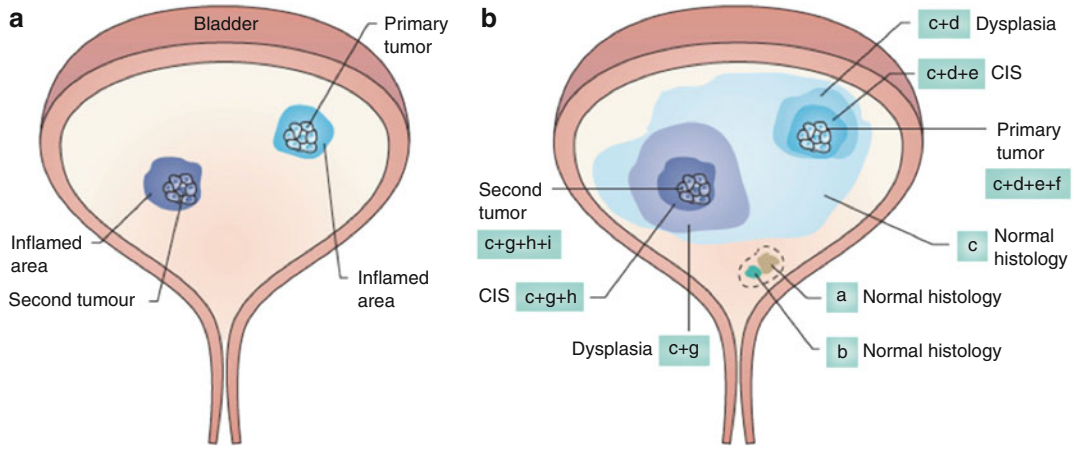

Fig. 13 Preneoplastic urothelial alterations in the tumor-bearing bladder. (**a**) A schematic of what the surgeon sees is shown. At presentation the primary tumor and an area of inflamed urothelium subsequently diagnosed as carcinoma in situ (CIS) are resected. During surveillance a second tumor and an associated area of CIS are visually identified and resected. (**b**) The molecular picture is shown. Large areas of urothelium have been replaced with altered cells. Different molecular events are indicated by letters. The primary tumor has developed within a large area of urothelium of normal appearance containing molecular alteration "c." Within this "field" of change, a dysplastic area (which also has normal appearance at cystoscopy) represents a subclone with "c + d" alterations; within this dysplastic area, a patch of CIS representing the immediate precursor to the overt tumor ("c + d + e + f") is recognized as an inflamed patch ("c + d + e"). A second tumor and CIS resected at a later date have also developed within the large altered field containing alteration "c" but differ in all other alterations (**g**–**i**). The possibility that tumors with independent initiating events may develop in some patients is indicated by patches "a" and "b," both of which may remain morphologically silent for many years. The dotted line indicates a urothelial patch as described by Gaisa et al. [124], which is putatively derived from a single stem cell. Despite independent tumor-initiating events, cells with alterations "a" and "b" are clonally related. The presence of large and clinically silent areas of preneoplastic urothelium emphasizes the need for novel approaches for local therapeutic targeting [112]

Symptoms and Diagnosis

Painless microscopic or gross hematuria is the initial symptom in over 80% of the patients with UC of the bladder, which is why UC needs to be excluded in patients presenting with these symptoms. The standard method of diagnosing papillary bladder cancer continues to be based on direct visualization of the bladder with cystoscopy and subsequent biopsy/resection [114, 115]. CIS is diagnosed by a combination of cystoscopy, urine cytology, and histological evaluation of multiple bladder biopsies [116]. Despite the development of several commercially available urinary markers for diagnosis and surveillance of BC, urinary cytology continues to play an important role in the diagnosis and surveillance of BC [117]. The specificity of cytology approaches 100%, whereas other markers generally outperform cytology with respect to sensitivity, especially for low-grade disease [114]. In an effort to improve the sensitivity of BC diagnosis, fluorescence cystoscopy continues to evolve. Several prospective randomized clinical trials have demonstrated increased detection of bladder tumors, particularly Ta tumors and CIS when using fluorescence cystoscopy [118–122].

Staging and Prognostic Stratification

Two different staging systems are used in classifying bladder tumors: the TNM and the Jewett-Strong-Marshall classification systems (Table 5) [123]. Until recently, the latter system was used extensively in the USA, but the TNM staging system (Table 6) has become the system of choice primarily because it has the advantage of distinguishing nodal involvement from locally advanced tumors and from distant metastatic spread

Table 5 The Jewett-Strong-Marshall classification of bladder cancer [123]

Class	Characteristic
O	Preinvasive
A	Submucosal invasion
B1	Superficial muscle
B2	Deep muscle
C	Extravesical spread
D1	Fixed to or invading prostate, uterus, vagina, or pelvic lymph nodes
D2	Spread to extrapelvic lymph nodes or distant metastases

Table 6 The TNM classification for bladder cancer [123]

Stage	Characteristic
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ: "flat tumor"
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscle
T2a	Tumor invades superficial muscle (inner half)
T2b	Tumor invades deep muscle (outer half)
T3	Tumor invades perivesical tissue
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumor invades prostate or uterus or vagina
T4b	Tumor invades pelvic wall or abdominal wall
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node $\leq$2 cm in greatest dimension
N2	Metastasis in a single lymph node >2 cm but $\leq$5 cm in greatest dimension or multiple lymph nodes
N3	Metastasis in a lymph node >5 cm in greatest dimension
M0	No distant metastasis
M1	Distant metastasis

[123, 124]. Furthermore, a clinical staging for bladder cancer is used [123, 124]. The prognosis and treatment of BC depend on tumor grade and stage [125]. The overall 5-year survival rate is 82%. It is 94% for localized and superficial cancers, but it is only 6% for metastatic cancers [124]. Proper and accurate staging of the tumor is essential for optimal treatment of the patients [126].

Overall Performance of Diagnostic Imaging Other Than Nuclear Medicine for the Tumor

T staging. After diagnosing BC, it is necessary to determine whether the patient has a superficial or a muscle-invasive tumor (T1 vs. T2) since infiltration beyond the lamina propria will require more aggressive treatment than transurethral resection. Cystoscopy and biopsy at the time of initial examination reveals the tumor's cell type, grade, and depth of invasion. The primary tumor in the bladder may be detected either as a thickening of the bladder wall or as an intraluminal mass. Both CT and MRI may be used for assessment of local invasion, but they are unable to accurately detect microscopic invasion of perivesical fat (T2 versus T3a) [127–130]. The role of CT and MRI is therefore to detect T3b disease or higher. MRI has superior soft tissue contrast resolution compared with CT, but poorer spatial resolution. CT has sensitivities in the range of 79–89.7% and specificities ranging from 91% to 94.7% in detecting BC [124, 131–133]. CT is unable to differentiate between stages from Ta to T3a tumors but is useful for detection of perivesical fat invasion (T3b) and adjacent organs. The accuracy of CT to detect extravesical tumor extension varies from 55% to 92% and increases with more advanced disease [134, 135]. MRI is superior to CT for determining depth of bladder wall infiltration, while CT and MRI yield similar results in demonstrating invasion of perivesical structures [125, 136]. Dynamic contrast-enhanced (DCE) MRI may help differentiate bladder tumor from surrounding tissues or post-biopsy resection, because enhancement of the tumor occurs earlier than that of the normal bladder wall, due to neovascularization [137]. MRI imaging is considered by some to be the modality of choice for primary staging of urinary BC [136]. On MRI, the tumors appear slightly hyperintense relative to muscle on T2-weighted sequences and isointense relative to muscle on T1-weighted sequences (Fig. 14). Assessing small bladder primary tumors on CT and MRI can be difficult because underdistention of the bladder causes the appearance of bladder wall thickening, which can be mistaken as a tumor, and because

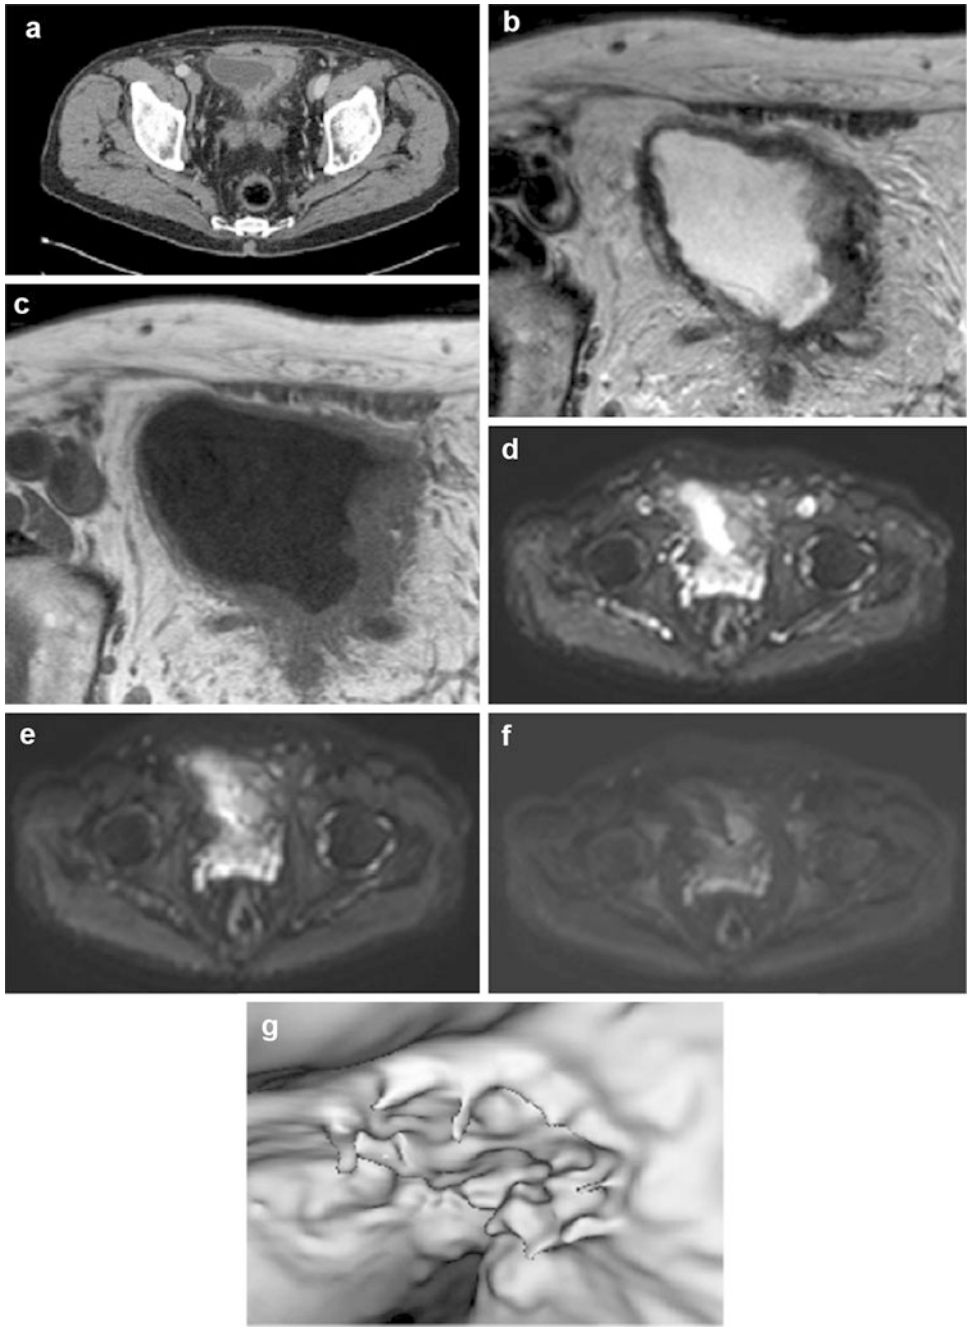

Fig. 14 Patient with known T2 N0 M0 bladder cancer (*left bladder wall*): (**a**) contrast-enhanced computed tomography (CT) scan, (**b**) axial T2-weighted image performed on a 3-T magnetic resonance imaging (MRI) unit showing a hypointense lesion, (**c**) corresponding T1 image, (**d**) axial diffusion-weighted (DW) MRI at b-value 0, (**e**) axial DW MRI at b-value 100, (**f**) axial DW MRI at b-value 750, and (**g**) magnetic resonance virtual cystoscopy (MRVC) of same tumor with three-dimensional reconstruction of tumor bed showing opening into adjacent diverticulum [130]

overdistension can flatten some tumors. Asymmetric wall thickening is often helpful in localizing the tumor. Currently, the most accurate method for differentiating T1 from T2 tumors is with a tissue specimen obtained from the muscularis propria of the tumor base during TUR [94, 126].

Excretory-phase CT urography is used for upper UTUC and has replaced conventional i.v. urography and ultrasound in high-risk patients. The sensitivity and specificity of CT urography for UTUC are 67–100% and 93–99%, respectively. For lesions detected on i.v. urography, biopsy is recommended to exclude false-positive results, to provide information about tumor grade, and for guiding therapy. Most often the biopsy is obtained endoscopically.

N staging. Accurate detection of LN metastases in BC is an essential component of the approach to treatment. Metastases are rarely associated with superficial disease. However, for muscle-invasive BC, additional imaging workup procedures are needed for accurate staging [125, 126]. CT and MRI reliably detect LN enlargement within the pelvis and abdomen in patients with BC. However, both techniques rely on size criteria. Metastases from BC frequently replace normal LNs, causing little if any enlargement, and high false-negative rates are recorded for both CT and MRI [123]. A commonly used criterion to diagnose pathologic adenopathy is a minimal axial diameter of 10 mm in oval-shaped nodes or 8 mm in round nodes [136, 138–140]. Lymph nodes tend to become rounded with metastatic involvement [138]. Microscopic metastatic deposits in normal-sized LNs can be missed, however, when only size criteria are used for diagnosis, thus leading to false-negative results and subsequent understaging using this threshold. For LN evaluation, the accuracy of CT ranges from 73% to 92%, with a tendency to understage nodal involvement [136]. The accuracy of MR imaging in staging LN metastases based on anatomic size criteria ranges from 73% to 90% and is comparable to that of CT [136]. Identification of metastases in LNs that are not enlarged continues to be an additional challenge for imaging. Currently, the preferred method for accurate N staging is pelvic lymphadenectomy [126]. However, recently promising results have been shown with lymphatic contrast agents for MRI [141]. After i.v. injection of highly lymphotropic superparamagnetic nanoparticles, the agents gain access to LNs by means of interstitial-lymphatic fluid transport. The nanoparticles are taken up by macrophages in healthy LNs, and therefore a lack of contrast uptake suggests the replacement of such normal macrophages by metastasis. In general, this requires two MRI examinations at two different time points: a baseline study and a second imaging after 24–36 h after administration of the iron oxide contrast medium. MR imaging with lymphatic contrast agents may improve nodal staging in patients with BC by depicting metastases even in normal-sized LNs [141].

M staging. Bladder cancer may also spread hematogenously. The incidence of distant metastases increases with increasing T and N stages [142]. Distant metastasis tends to occur late in the clinical course of BC and especially at the time of recurrence, with bones, lungs, brain, and liver being the most common sites. Both conventional abdominal/pelvic CT and CT urography (CTU), which may be combined with chest CT if needed, can be performed to detect distant metastases [125]. CT also may suggest adjacent visceral invasion, although MRI is superior because of better soft tissue contrast. A ^{99m}Tc-MDP bone scan may be used to assess the entire skeleton in the presence of metastases. The overall reported accuracy of CT in detecting and staging of BC varies from 64% to 97%, whereas that for perivesical invasion and for LN metastases range from 83% to 93% and 73–92%, respectively [138, 143]. The reported accuracy of MRI in overall staging of BC varies from 60% to 85%, depending on the sequence protocol and grouping of stages, whereas that of local staging varies from 73% to 96% [125, 138, 144]. The overall staging accuracy of gadolinium-enhanced MRI for staging extravesical extension in BC is 73–100%.

[^{18}F]FDG PET/CT for Staging and Prognosis

The treatment strategy of muscle-invasive BC is determined by tumor stage and grade. In clinical

practice CT and MRI are often the imaging modalities used. The aim of staging with imaging is to determine prognosis and provide information to guide treatment strategy. For staging of muscle-invasive BC, information on the extent of local tumor invasion, metastatic involvement of LNs, and spread of tumor to upper urinary tract or other distant organs (liver, lungs, bones, peritoneum, pleura, and adrenal glands) is required. The value of [^{18}F]FDG PET/CT in detecting localized tumor in the bladder is limited due to urinary excretion of radiotracer, which may mask tumor activity in the bladder wall. Several efforts have been made to overcome radioactivity interference in the urine, such as [^{18}F]FDG washout, early images, late images after voiding, dual-phase imaging, catheterization, bladder irrigation, and forced diuresis [36, 145–152]. Recently, a meta-analysis evaluated the diagnostic accuracy of [^{18}F]FDG PET/CT for detecting bladder cancer lesions [153]. Six studies met the inclusion criteria. The pooled sensitivity and specificity of PET or PET/CT for the detection of bladder cancer were 80.0% (95% CI, 71.0–87.0%) and 84.0% (95% CI, 69.0–93.0%), respectively. When compared with results of MRI and CT published by other studies, [^{18}F]FDG PET or PET/CT demonstrated no superiority in detecting local bladder lesions [153]. As a whole-body imaging, it was suggested that PET is more appropriate for the detection of metastasis.

NM staging. The sensitivity of CT and MRI for detection of LN metastases is low, since LN metastases rely on size criteria [145]. The specificity is also low since enlarged LN may be due to benign disease. Since [^{18}F]FDG PET may detect metabolic activity in normal size LNs, [^{18}F]FDG PET/CT has been used in clinical studies for primary NM staging [154–162]. [^{18}F]FDG PET/CT detects more malignant disease than conventional CT/MRI in 20–40% of patients [158, 159], and [^{18}F]FDG PET/CT may change the clinical management in up to 68% of the patients (Fig. 15) [159]. Upstaging is more frequent than downstaging [158]. Recently, a meta-analysis was performed to evaluate the diagnostic accuracy of [^{18}F]FDG PET/CT in detecting LN metastases [163]. Eight studies were included in the analysis [154, 160, 163–168]. The pooled sensitivity of [^{18}F]FDG PET/CT for detecting LN metastases was 56.5% (95% CI, 47.3–65.3%), specificity 95.4%

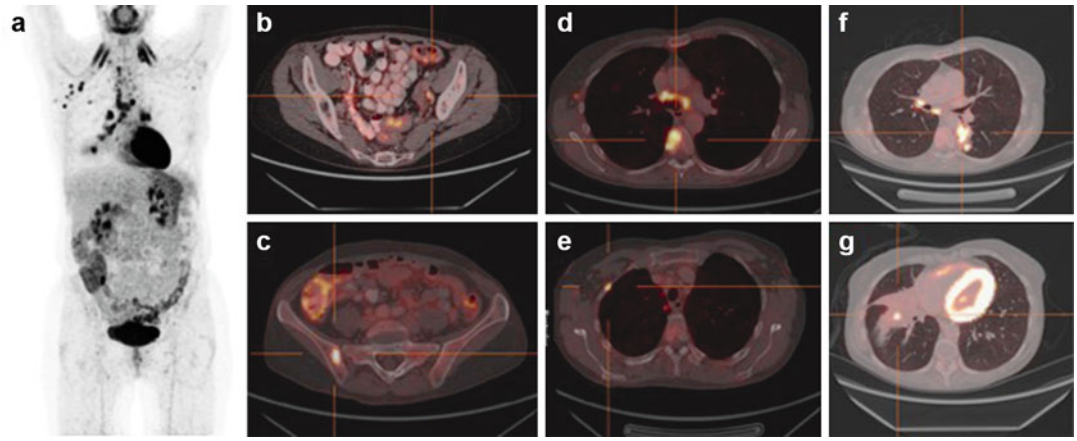

Fig. 15 Fifty-one-year-old woman with newly diagnosed muscle-invasive bladder cancer referred for staging with [^{18}F]FDG PET/CT. The tumor in the bladder is not visible on PET due to urinary excretion of [^{18}F]FDG (**a**). A metastasis in a not enlarged lymph node in left fossa obturatoria is seen on the axial fused PET/CT image (**b**). Several bone metastases are seen on the MIP (**a**) and on the axial fused PET/CT images in the right os ilium (**c**), in the spine (**d**), and in costae (**e**). Furthermore, PET/CT showed disseminated lung cancer in both the right and left lungs with metastases to the mediastinal lymph nodes (**f**, **g**). Histology showed non-small cell lung cancer, and the patient was treated with chemotherapy

(95% CI, 92.2–97.6%), positive LR 9.02 (95% CI, 4.48–18.16), and negative LR 0.50 (95% CI, 0.39–0.64). The pooled measures for CT alone in five of those studies were sensitivity 35%, specificity 95%, positive LR 4.91, and negative LR 0.7. The study concluded that [^{18}F]FDG PET/CT is better to detect LN metastases as compared to CT alone. With a pooled sensitivity of 35%, CT alone correctly identified 22% fewer patients with LN metastasis, as compared to [^{18}F]FDG PET/CT. Thus, [^{18}F]FDG PET/CT offered additional metabolic information, as compared to CT alone, and therefore is more accurate for staging BC. Another meta-analysis of [^{18}F]FDG PET/CT for the staging and restaging of BC found that the pooled sensitivity was 82%, the pooled specificity was 89%, and the global accuracy was 92% [169]. Six studies met the inclusion criteria [149, 151, 155, 159, 160, 170]. The pooled sensitivity and specificity of PET/CT for primary lesion detection of BC were 90% (95% CI, 70–99%) and 100% (95% CI, 74–100%), respectively. The pooled sensitivity and specificity of [^{18}F]FDG PET or PET/CT for staging or restaging (metastatic lesions) of BC were 82% (95% CI, 72–89%) and 89% (95% CI 81–95%), respectively. The study showed that the diagnostic accuracy of [^{18}F]FDG PET/CT is good in metastatic lesions of BC.

Recurrence. It is well known that muscle-invasive BC is a disease with a pattern of predominantly distant and early recurrences. Half of the patients with muscle-invasive BC relapse after radical cystectomy, and local occurrence accounts for 30% of relapses, whereas distant metastases are more common. The overall prognosis for recurrent and metastatic BC is poor. However, additional salvage and/or palliative therapies are prompted when recurrent disease is discovered. Accurate restaging is therefore important before additional costly and toxic therapies are considered [36]. There are few data available on the utility of [^{18}F]FDG PET or [^{18}F]FDG PET/CT in assessing for recurrence and metastatic disease in patients who have previously undergone treatment for their primary bladder tumor [149, 151, 170]. A study retrospectively assessed the diagnostic performance of [^{18}F]FDG PET/CT in the imaging evaluation of recurrent and metastatic BC [170]. In the study, 35 patients were previously treated for the primary disease. The metastatic sites detected in the study included the mediastinum, lung, and bone, and overall hybrid PET/CT diagnostic information was valuable in detecting, localizing, and characterizing the extent of metastatic disease. The complementary information provided by the combined PET/CT scanner affected the clinical management in 17% of patients, by prompting either additional therapy or a wait-and-watch strategy.

Response to therapy. Patients with BC and regional LN metastases could be targeted for neoadjuvant chemotherapy, and patients with distant metastases could be spared the unnecessary morbidity of radical cystectomy. Neoadjuvant cisplatin-based combination chemotherapy has demonstrated improved outcomes for muscle-invasive BC [171]. Since nonresponse rate to neoadjuvant chemotherapy is relatively high, monitoring the LN response to neoadjuvant chemotherapy may guide the selection of patients for further surgery. Conventional imaging modalities like CT and MRI are often ineffective in detection of therapy response in metastases because of difficulty in indentifying viable tumor in residual necrotic masses and small tumors in LNs of normal size. [^{18}F]FDG PET/CT has been used in the study for measuring therapy response to neoadjuvant chemotherapy in 19 patients with muscle-invasive BC [172]. Metabolic response was assessed according to European Organisation for Research and Treatment of Cancer (EORTC) recommendations based on the change in [^{18}F]FDG uptake on PET/CT. Radiological response was assessed on contrast-enhanced CT according to Response Evaluation Criteria in Solid Tumors (RECIST). All patients underwent pelvic lymph node dissection (PLND), and histopathological examination was the gold standard. Before neoadjuvant chemotherapy, increased [^{18}F]FDG uptake was seen in all 19 patients, which correlated the LN metastasis. Evaluating the LN response with PET/CT was feasible in all patients. PET/CT correctly distinguished responders from nonresponders (18 of 19 patients or 94.7% and 15 of 19 or 78.9%) and complete responders from patients with residual disease (13 of 19 or 68.4% and 12 of 19 or 63.2%, respectively). Although no definitive

conclusions can be drawn from these preliminary data, PET/CT may be feasible for evaluating the LN response to neoadjuvant chemotherapy and distinguishing responders from nonresponders [172]. However, this has to be investigated further in large prospective clinical trials.

Prognostic value. Few studies have investigated the prognostic value of [^{18}F]FDG PET/CT in BC. In a study, 43 chemotherapy-naïve patients underwent [^{18}F]FDG PET/CT before cystectomy [160]. Median follow-up was 14.9 months (range, 0.4–46.1 months). [^{18}F]FDG PET/CT demonstrated a positive predictive value (PPV) of 78% (7/9), a negative predictive value (NPV) of 91% (30/33), sensitivity of 70% (7/10), and specificity of 94% (30/32). Recurrence-free survival (RFS), disease-specific survival (DSS), and overall survival (OS) were all significantly poorer in the patients with positive [^{18}F]FDG PET/CT than in those with negative [^{18}F]FDG PET/CT. [^{18}F]FDG PET/CT detected occult metastatic disease in 7 of 42 patients with negative conventional preoperative evaluations (CT, ^{99m}Tc-MDP bone scan). PET findings were strongly correlated with survival in the study, and it was concluded that [^{18}F]FDG PET/CT may guide treatment strategy before radical cystectomy [160]. Recently, in a large bi-institutional study ($n = 211$), patients with muscle-invasive BC underwent [^{18}F]FDG PET/CT and CT for staging [173]. The patients were divided into two groups, a PET/CT-positive and a PET/CT-negative group. Data on staging and mortality were retrospectively analyzed from prospective databases. Median follow-up was 18 months. Patients with a positive PET/CT had a significantly shorter OS and DSS (median OS, 14 vs 50 months, $P = 0.001$; DSS, 16 vs 50 months, $P < 0.001$). In multivariate analysis, the presence of extravesical lesions on PET/CT was an independent prognostic indicator of mortality (OS, hazard ratio = 3.0, confidence interval 95% 1.7–5.1). This association was not statistically significant for conventional CT (hazard ratio = 1.6, 95% confidence interval 0.9–2.7). The study showed that the presence of extravesical metastatic disease on PET/CT might be considered an independent indicator of mortality [173].

PET Radiopharmaceuticals Other Than [^{18}F]FDG

Investigators have attempted to improve the sensitivity of PET by using tracers that are not excreted in urine. [^{11}C]choline, [^{11}C]acetate, and [^{11}C]methionine have been proposed for this purpose. Furthermore, Na^{18}F has been used for detection of bone metastases in muscle-invasive BC.

[^{11}C]Choline is an agent that is incorporated into tumor cells by conversion into [^{11}C]phosphorylcholine, which is trapped inside the cell [174]. This is followed by synthesis of phosphatidylcholine, a main component of cell membranes. The uptake of choline in tumors represents the rate of tumor cell proliferation. Minimal or no urinary excretion is seen with [^{11}C]choline. In the normal bladder wall, the uptake of choline is low, and [^{11}C]choline may visualize tumor in the bladder [175–177]. [^{11}C]choline PET/CT has also been used for primary NM staging of muscle-invasive BC [176, 178, 179]. In a recent study ($n = 59$), [^{11}C]choline PET/CT was used for detection of LN metastasis and compared the results with histological analysis [178]. [^{11}C]choline PET/CT overall detection rate was 62.7% (37/59 patients). On a regional-based analysis, [^{11}C]choline PET/CT was considered positive for primary cancer and/or local relapse in bladder bed in 54.2% of the patients (32/59). Considering LN metastasis detection, compared with histological analysis, [^{11}C]choline PET/CT showed in the whole population a sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of 59%, 90%, 71%, 84%, and 81%, respectively. The authors concluded that PET/CT with [^{11}C]choline may provide additional diagnostic information in preoperative LN staging of patients with BC [178]. [^{11}C]choline may also be used for restaging of BC [178, 180]. A study ($n = 25$) reported that [^{11}C]choline PET/CT was sensitive, specific, and accurate, with good PPV and NPV for local relapse of 66.7%, 84.6%, 76%, 80%, and 73.3%, and 90%, 93.3%, 92%, 90%, and 93.3% for LNs and distant relapse, respectively [180]. In a relative small prospective study ($n = 44$), neither CT

nor [^{11}C]choline PET/CT could predict OS or CSD in BC patients treated with radical cystectomy [181]. However, larger cohorts are needed to clarify the prognostic value of [^{11}C]choline PET/CT in BC.

[^{11}C]Methionine uptake is proportional to the amino acid transport and to some extent protein synthesis [174]. In cancer, [^{11}C]methionine has been correlated with the amount of viable tumor tissue [182]. Tumor uptake of [^{11}C]methionine occurs rapidly (a peak at around 10 min followed by a plateau) [174]. [^{11}C]methionine undergoes rapid clearance from the blood pool and is primarily metabolized in the liver and pancreas with no significant renal excretion [174]. In a small study ($n = 22$), [^{11}C]methionine PET/CT was reported superior to [^{18}F]FDG for detection of tumor in the bladder; however, the sensitivity was only 78% (18/23) . In the study tracer uptake was proportional to tumor stage. In another study methionine PET was used for the evaluation of therapy response in 44 patients with varying stages of BC treated with chemotherapy [183]. In the study, the diagnostic accuracy of PET was poor, and the technique could not monitor the therapeutic effect of neoadjuvant chemotherapy, producing results that correlated with therapy outcome.

[^{11}C]Acetate has little or no urinary excretion. Three small studies have used acetate PET in BC patients. In one pilot study, [^{11}C]acetate PET/CT was used for primary staging of muscle-invasive BC patients before cystectomy with PLND and for response assessment after neoadjuvant chemotherapy in some of the patients [184]. The results indicate that acetate PET/CT may have good sensitivity for BC and LN metastases. However, false-positive uptake due to inflammation or granulomatous infection can occur, limiting the staging utility of [^{11}C]acetate PET/CT after prior intravesical BCG therapy [184]. A small study prospectively evaluated MRI, [^{11}C]acetate PET/CT, and CT for staging of BC [185]. MRI, [^{11}C]acetate PET/CT, and CT demonstrated similar levels of accuracy. For all modalities, a history of intravesical and/or systemic chemotherapy affected staging accuracy. [^{11}C]acetate PET/CT has been compared to [^{11}C]choline PET/CT in BC [186]. [^{11}C]acetate and [^{11}C]choline scans were performed within 1 week. The two tracers demonstrated equivalent results in the preoperative evaluation.

^{18}F-Fluoride. Lytic bone metastases of BC may be better detected using Na^{18}F PET scans compared with conventional ^{99m}Tc-MDP bone scan. In a prospective study, Na^{18}F PET/CT and ^{99m}Tc-MDP bone scan were compared in the detection of skeletal metastases in 48 patients with BC [187]. Both imaging modalities were performed within 48 h. Na^{18}F PET/CT identified bony metastases and changed the management in 17 of 48 patients (35%). The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of ^{99m}Tc-MDP planar bone scintigraphy were 82.35%, 64.51%, 56%, 86.95%, and 70.83%; of ^{99m}Tc-MDP SPECT/CT were 88.23%, 74.19%, 65.21%, 92%, and 79.16%; and of Na^{18}F PET/CT were 100%, 87.09%, 80.95%, 100%, and 91.66%, respectively. The study demonstrated that Na^{18}F PET/CT is superior to both ^{99m}Tc-MDP planar scintigraphy and ^{99m}Tc-MDP SPECT/CT for detection of bone metastases in BC.

Common Therapies

Treatment of Superficial Bladder Cancer

Most BCs are "non-muscle invasive" at the time of initial diagnosis. Roughly 70% of newly diagnosed BC is superficial disease [101]. They are either confined to the mucosa (stage Ta, CIS) or invade the lamina propria but not the muscularis propria (stage T1). Among the superficial cancer groups, approximately 70% present as Ta lesions, 20% as T1, and 10% as CIS [101]. Stage Ta tumors, especially those which are low grade, have a low risk of progression over time, and there is a trend toward more conservative management of these tumors. Therefore, in the majority of these patients, management can be limited to resection and subsequent observation [188]. Stage T1 tumors represent greater challenge to the urologist. Although these tumors are grouped into the category of "superficial," their risk of progression is much higher over time. The heterogeneity of T1 disease complicates its treatment. It remains a

challenge to determine which patient is at high risk of progression versus the patients who will do well with adjuvant intravesical therapy. The European Association of Urology (EAU) and American Urological Association (AUA) have similar recommendations for induction and maintenance treatment in patients based on clinical and pathologic risk factors [99, 189]. Low-risk patients (low-grade Ta) can be monitored on surveillance protocols. Conversely, those patients with high-risk superficial disease (CIS, T1, high-grade Ta, multiple tumors, and >3-cm tumors) should strongly be considered for adjuvant intravesical therapy.

Intravesical chemotherapy. Although TURB can remove a Ta and T1 tumor completely, recurrence of the disease is often seen and can progress to muscle-invasive BC. It is therefore important to consider adjuvant therapy in the patients. A single intravesical instillation of chemotherapy may be effective against circulating tumor cells resulting from TURB, on residual tumor cells at the resection site, and on overlooked tumors in the bladder [190–193]. Mitomycin, epirubicin, and doxorubicin have shown to be effective for that purpose [191–193]. The single intravesical chemotherapy instillation should be performed as soon as possible (within the first hours) after TURB. Chemotherapy in combination with hyperthermia seems to be a new promising treatment [194]. The need for further adjuvant chemotherapy depends on prognosis. In low-risk patients, the single intravesical instillation may be sufficient and is considered to be the standard therapy. In high-risk patients with a high likelihood of recurrence and/or progression, the single instillation is insufficient, and further instillations are recommended [195]. Intravesical bacillus Calmette-Guérin (BCG) immunotherapy maintenance therapy can also be used [196, 197], but more side effects are seen with BCG as compared to chemotherapy [198]. The length and frequency of chemotherapy instillations are still a topic of debate because of conflicting results [199]. Normally the chemotherapy lasts no longer than a year. A single postoperative instillation with chemotherapy is only indicated in low-risk disease. BCG is the treatment of choice for high-grade disease [194] and should be given as maintenance [194].

Intravesical BCG immunotherapy. Several meta-analyses have demonstrated that intravesical BCG immunotherapy is superior to TURB alone or TURB + chemotherapy for preventing recurrence of non-muscle-invasive BC [200–204]. The effect of BCG treatment is long lasting [205, 206]. Two meta-analyses have shown that BCG therapy prevents or delays the risk of progression of the bladder tumor [196, 206]. BCG represents the only agent known to reduce progression into muscle-invasive BC [189]. The addition of chemotherapy to maintenance BCG does not improve the efficacy [207]. Regarding BCG toxicity, BCG is clearly associated with more side effects as compared to intravesical chemotherapy [197]. Serious side effects are seen in less than 5% of the patients and can be treated effectively in nearly all cases [208]. Because major complications can be seen after systemic absorption of BCG, contraindications of BCG instillations should be followed. Absolute contraindications are during the first 2 weeks after TURB, in patients with visible hematuria, after traumatic catheterization, and in patients with symptomatic urinary tract infection [189]. Induction BCG therapy is given as 6-weekly schedule, and for optimal therapy, BCG must be given in a maintenance schedule. However, several different maintenance schedules are used. The optimal number of BCG induction instillations and duration of maintenance therapy is still unknown [209]. In BCG failures, cystectomy is recommended [194].

Treatment failure of non-muscle-invasive bladder cancer. According to EAU guidelines, it is reasonable to consider immediate radical cystectomy in patients with non-muscle-invasive BC tumors who have a high risk of progression: (1) T1 tumor, (2) G3 (high-grade) tumor, (3) CIS, and (4) multiple and recurrent and large (>3 cm) TaG1G2 tumors [210, 211]. Furthermore, cystectomy is strongly recommended in patients with BCG refractory tumors: (1) whenever muscle-invasive tumor is detected in follow-up; (2) if high-grade, non-muscle-invasive papillary tumor is present at 3 months; (3) if CIS (without concomitant papillary tumor) is present at both 3 and 6 months; (4) if high-grade tumor appears during BCG therapy; and (5) if there is high-grade recurrence after BCG [210].

Treatment of Muscle-Invasive Bladder Cancer

Surgery. The primary modality for treatment of clinically localized muscle-invasive BC is surgery, and developments in this field focus on minimizing the morbidity of surgery. Radical cystoprostatectomy with bilateral PLND remains the gold standard for management of muscle-invasive BC [114, 115, 210]. However, the precise limits of the LN dissection are debated [114]. Data from a large group of patients support the aggressive surgical management of invasive BC [212]. Recently, interest in the patient's quality of life has resulted in a trend toward bladder-preserving treatment modalities such as radio- and/or chemotherapy. The patients' performance status and age influence the choice of primary therapy, as well as the type of urinary diversion, with cystectomy being preferred in younger patients with good performance status and without concomitant disease [210, 213]. Long-term disease-free survival of up to 70% can be achieved in most patients with organ-confined disease [114, 212]. When there are metastatic involvements of LNs, orthotopic neobladder can still be considered in the case of N1 involvement (metastases in a single LN), but this is not the case of N2 or N3 tumors [214]. In men the standard radical cystectomy includes the removal of the bladder, prostate, seminal vesicles, distal ureters, and regional LNs. In women, standard radical cystectomy includes the removal of the bladder, entire urethra, adjacent vagina, uterus, distal ureters, and regional LNs [210]. Regional LNs consist of nodes below the bifurcation of the aorta [164, 210, 215–217]. The extent of LN dissection is not established yet. The standard lymphadenectomy includes the removal of LN up to the common iliac bifurcation, extended lymphadenectomy includes LNs in the region of the aortic bifurcation and presacral and common iliac vessel, and super-extended lymphadenectomy extends cranially to the level of the inferior mesenteric artery [210]. Cystectomy may be performed as open operation, laparoscopic cystectomy, or robotic-assisted laparoscopic cystectomy. Laparoscopic operation is a technically challenging procedure that requires high level of expertise in the institution [218–220]. Urinary diversion after radical cystectomy may be performed as (a) abdominal diversion, such as ureterocutaneostomy, ileal or colonic conduit, and various forms of continent pouch; (b) urethral diversion, which includes various forms of gastrointestinal pouches attached to the urethra as a continent; (c) orthotopic urinary diversion (neobladder, orthotopic bladder substitution); or (d) rectosigmoid diversions, such as uretero(ileo) rectostomy [210]. Currently, there is no particular type of urinary diversion that is generally recommended, but most institutions prefer ileal orthotopic neobladders and ileal conducts [210].

Neoadjuvant chemotherapy. The 5-year survival after standard radical cystectomy is only about 50% [210]. Neoadjuvant and adjuvant chemotherapy have been utilized in an attempt to improve outcomes for patients with high-risk muscle-invasive BC. Systematic chemotherapy using multidrug regimens is the standard therapy for metastatic disease, and the classic combination is the four-drug regimen MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin) [115, 221, 222]. Neoadjuvant chemotherapy with cisplatin is recommended for T2-T4a, cN0 M0 bladder cancer, but is not recommended in patients who are ineligible for cisplatin-based combination chemotherapy [210]. Chemotherapy is delivered as early as possible, when the burden of micrometastatic disease is lowest as possible. The presence of micrometastases may be lower in small tumors compared to more extensive tumors. Neoadjuvant chemotherapy does not affect the outcome of surgical morbidity [223]. Currently, there is no available tool to select the patients who will benefit from neoadjuvant chemotherapy. Adjuvant chemotherapy after radical cystectomy is under debate in patients with pT3/T4 and/or LN-positive disease without detectable metastases (M0). According to EAU guidelines, adjuvant cisplatin combination chemotherapy can be offered to patients with pT3/T4 and/or pN+ disease if no neoadjuvant chemotherapy has been given [210].

Preoperative radiotherapy. Preoperative radiotherapy followed by cystectomy after 6 weeks has been investigated, but conflicting results exist. A meta-analysis of five randomized trials showed an odds ratio for the difference in 5-year survival

of 71% in favor of the preoperative radiotherapy, but when the largest study was excluded (because the patients did not receive the planned treatment), no significant difference was found, and it was concluded that the available clinical trial data do not support a role for routine use of preoperative radiation therapy in the treatment of muscle-invasive BC [224]. In the EAU guidelines, preoperative radiotherapy is not recommended to improve survival [210]. However, preoperative radiotherapy may result in downstaging after 4–6 weeks [210, 225, 226].

Unresectable tumors. Patients with locally advanced disease (T4b, invasion of pelvic or abdominal wall) are candidates for palliative radiotherapy. In patients with symptoms, palliative cystectomy may be an option. In muscle-invasive BC patients not suitable for radical cystectomy, transurethral resection of bladder tumor (TURB) may be performed, but TURB alone is not a curative treatment. External beam radiotherapy (EBRT) alone or chemotherapy alone is not recommended as a primary therapy for localized BC [210]. Multimodality bladder-preserving treatment combines TURB, radiation, and chemotherapy, and the aim is to obtain local tumor control. Multimodality treatment can be offered in selected and compliant patients, especially in patients where cystectomy is not an option [210].

Metastatic disease/recurrence. At the time of diagnosis of muscle-invasive BC, 10–15% of the patients have metastatic disease [227]. In patients treated with radical cystectomy, about 50% of the patients will get relapse, depending on the pathological stage of the primary tumor and LN metastases. About 30% are local relapse, and distant metastases are the most common site of recurrence. Distant metastases are most commonly seen in the LNs, lungs, liver, and bones. Patients with metastatic disease are treated with chemotherapy.

Surveillance. One of the distinguishing features of UC is that it has the highest recurrence rate for any cancer, thereby making rigorous post-treatment surveillance, often referred to as "urothelial surveillance," necessary in all patients. These tumors are also commonly multifocal. They involve any part of the urothelium in a seemingly random manner. An appropriate schedule for BC monitoring should be based on the natural timing of recurrence, probability and site of recurrence, functional monitoring after urinary diversion, and possible treatment of recurrence [210]. The follow-up of Ta, T1 tumors, and CIS is based on regular cystoscopy, and the time schedule of monitoring depends on tumor grade (CIS, Ta, T1) [189]. After TURB, patients should have cystoscopy and voided urine cytology every 3 months for 2 years, then six monthly for 2 years, and then once yearly indefinitely [95]. Upper tract imaging should be done every 12–24 months to establish whether a UC is present in the renal collecting system or ureters, because lifetime risk for the development of an upper tract tumor after a diagnosis of BC is about 5% [95].

Abstract

Prostate cancer (PCa) is one of the most common cancers in the male population. Its incidence, mortality, and prevalence are different across different geographical areas, depending on the different approaches adopted for screening, early diagnosis, and availability of treatments. Digital rectal exploration (DRE) and the prostate-specific antigen (PSA) test are the most common clinical practice used for PCa screening.

The choice of treatment should be patient specific and risk adjusted. The therapeutic approaches for patients with PCa include different options: watchful waiting, radical prostatectomy, radiotherapy, hormone therapy, chemotherapy, immunotherapy, and treatment of bone metastases.

Keywords

Prostate cancer • Diagnostic imaging • Bone scan • SPECT/CT • PET/CT • Biomarkers for prostate cancer

Glossary

[^{11}C]CHO	[^{11}C]choline
[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
[^{18}F]FDHT	16β-[^{18}F]fluoro-5-dihydrotestosterone

^{99m}Tc-MDP	^{99m}Tc-methylene diphosphonate
ACP	American College of Physicians
ACS	American Cancer Society
ADT	Androgen deprivation therapy
AJCC	American Joint Committee on Cancer
ALP	Alkaline phosphatase
AS	Active surveillance
ASCO	American Society of Clinical Oncology
AUA	American Urological Association
BS	Bone scintigraphy
BSI	Bone scan index
CRPC	Castrate-resistant prostate cancer
CT	X-ray computed tomography
CTX	C-terminal telopeptide of type I collagen
CYP17	17-Alpha-monooxygenase, a crucial enzyme for the synthesis of testosterone from non-gonadal sources
DCE MRI	Dynamic contrast-enhanced magnetic resonance imaging
DRE	Digital rectal exploration
DWI	Diffusion-weighted imaging, an MR imaging technique
EBRT	External beam radiation therapy
ED	Effective dose
EMA	European Medicines Agency
ERG	ETS-related gene
ETS	E26 transformation-specific family
FDA	United States Food and Drug Administration
GLUT	Glucose transporter family
GS	Gleason score
HDR	High-dose rate radiotherapy
HIFU	High-intensity focused ultrasound
ICTP	Cross-linked carboxyterminal telopeptide of type I collagen
IGRT	Image-guided radiotherapy
IMRT	Intensity-modulated radiotherapy
LDR	Low-dose rate radiotherapy
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
M	Metastasis status according to the AJCC/UICC TNM staging system
MR	Magnetic resonance
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
NCCN	National Comprehensive Cancer Network
NCCN	National Comprehensive Cancer Network
NOPR	United States National Oncologic PET Registry
NPV	Negative predictive value
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PCa	Prostate cancer
PERCIST	Positron emission tomography response criteria in solid tumors
PET	Positron emission tomography
PET/CT	Positron emission tomography/computed tomography

PET/MR	Positron emission tomography/magnetic resonance
PET/MRI	Positron emission tomography/magnetic resonance imaging
PINP	Amino-terminal procollagen propeptide type I
PPV	Positive predictive value
PSA	Prostate-specific antigen
PSA	Prostate-specific antigen
PSMA	Prostate-specific membrane antigen
RANK	Receptor activator of nuclear factor kappa-B
RANKL	Receptor activator of nuclear factor kappa-B ligand, also known as tumor necrosis factor ligand superfamily member 11 (TNFSF11), TNF-related activation-induced cytokine (TRANCE), osteoprotegerin ligand (OPGL), and osteoclast differentiation factor (ODF)
RARP	Robot-assisted radical prostatectomy
RECIST	Response evaluation criteria in solid tumors
ROC	Receiver operating characteristic, a statistical analysis to assess the performance of a binary classifier
RT	Radiotherapy
SNMMI	Society of Nuclear Medicine and Molecular Imaging
SPECT	Single photon emission computed tomography
SPECT/CT	Single photon emission computed tomography/computed tomography
SRE	Skeletal related event
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
T	Tumor status according to the AJCC/UICC TNM staging system
TMPRSS2	Transmembrane protease, serine 2
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status) and "M" (distant metastasis status)
TRUS	Transrectal ultrasound
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
US	Ultrasonography
USPSTF	United States Preventive Services Task Force
WB	Whole body
WBS	Whole-body scan

Epidemiology

Prostate cancer (PCa) is one of the most common cancers in the male population. Its incidence, mortality, and prevalence are different across the geographical areas, depending on the different approaches adopted for screening, early diagnosis, and availability of treatments. Nearly 900,000 new PCa diagnoses are recorded per year on a global scale or 28.0 per 100,000 persons-year. According to national cancer registers, Australia and New Zealand reported the highest incidence rate, with 104.2 cases per 100,000 persons-year. A high incidence rate is observed also in Northern and West Europe, 73.1 and 93.1 per 100,000 persons-year, respectively. In Northern America, the incidence is similar, with 85.6 cases per persons-year. The lowest incidence rates are observed in Asia, with 7.2 per 100,000 persons-year (particularly in India and in China). The age-adjusted PCa mortality in Europe accounts for 12.00 per 100,000 persons-year, very similar to 9.9 per 100,000 persons-year in Northern America [1, 2].

Incidence and death rates have declined in the last 20 years, most likely as a consequence of decreased application of programs for widespread and "unselected" prostate-specific antigen (PSA) tests which have led to the overdiagnosis of small and localized tumors with a limited likelihood to spread locally or at distance. On the other hand, the increased public awareness for early detection and treatment together with better use of screening programs (i.e., in high-risk patients) has improved PCa mortality [3].

Little is known about the etiology of PCa, although some risk factors can play a role; age, family history, and genetics are the most important of such risk factors [4]. Recent studies demonstrated that also ethnicity, androgen status, diet, and lifestyle are relevant. More than two-thirds of all PCa cases occur in men older than 65 years. In first-degree relatives of affected men, the risk to develop PCa increases to threefold, and PCa tends to develop before the age of 55 [5–7].

Prostate Cancer Screening

Digital rectal exploration (DRE) and the prostate-specific antigen (PSA) test are the most common clinical practice biomarkers used for PCa screening. PSA is not specific for PCa, as it is elevated in benign prostatic hyperplasia, prostatitis, trauma, and urinary retention. Screening for PCa is a controversial issue. Screening offers the opportunity to find cancers at a more curable stage. On the other hand, the variability of the natural history of PCa should be considered, since some cases show an aggressive progression but many others are indolent and carry little threat about morbidity or mortality. Moreover, transrectal ultrasound (TRUS) has been associated with a high false-positive rate, making it unsuitable as a screening tool, although it has an established role in directing prostatic biopsies.

In the absence of a method to identify patients in whom the disease will have a rapid progression if left without therapy, any screening procedures result in some degree of overtreatment. Guidelines on PCa management have been issued by different scientific organizations: American Cancer Society (ACS), National Comprehensive Cancer Network (NCCN), US Preventive Services Task Force (USPSTF), American Urological Association (AUA), and American College of Physicians (ACP). The NCCN guidelines (revised in 2016) recommend considering the patient's history (including family history, medications, and any event of prostate disease) and emphasize the importance of physical examination. The clinician should then discuss the risks and benefits to obtain a baseline PSA and consider a baseline DRE to identify high-risk cancers associated with changes in PSA [8]. In asymptomatic patients, the guidelines recommend testing every 2–4 years for men aged 45–75 years with serum PSA values below 1 ng/mL. For men with PSA ranging between 1 and 3 ng/mL, PSA tests should occur at 1- to 2-year intervals. Biopsy should be considered in those men aged 45–75 years with serum PSA >3.0 ng/mL. However, the decision to perform a biopsy should not be based on the PSA cutoff threshold alone, but should be evaluated considering all clinical variables and the patient's preference.

First Diagnosis

Patients with abnormal DRE or elevated PSA levels should be further evaluated with prostate biopsy. The risk of being diagnosed with PCa increases with increasing PSA values, amounting to 34% for men with PSA values between 3 and 6 ng/mL and from 50% to 70% for those with PSA values >10 ng/mL. In younger subjects (<65 years), the cumulative risk is consistently lower than in older subjects. Patients with a free-to-total PSA ratio of <20% and PSA velocity >0.75 ng/mL/year have a higher risk of PCa and should also undergo prostate biopsy [9, 10].

Transrectal ultrasound (TRUS) imaging is the only imaging procedure to employ in this phase. TRUS-guided core biopsy has become the standard procedure to obtain tissue for histopathological examination. The fact that PCa is often multifocal and heterogeneous makes diagnosis based on a single biopsy difficult, as only a small amount of tissue is obtained with needle biopsy; thus, sampling errors are common. Initial biopsy guided by TRUS detected PCa in only 22–34% of the cases, and repeated biopsy is required in many patients. The likelihood of PCa diagnosis increases with the number of biopsy specimens; currently, at least ten biopsy cores are recommended, and 12–16 are obtained at some centers [11, 12].

Magnetic resonance imaging (MRI) is also important to diagnose PCa and to define its size and location. Cancers in patients with increased PSA and negative transrectal prostate biopsies can be diagnosed on MRI. MRI can specifically detect the anterior and apical tumors, which are usually missed on a TRUS-guided biopsy [13].

Pathology

Histopathological Type and Cancer Growth

Acinar adenocarcinoma is the most common type of PCa, representing over 95% of these cancers. Other rare tumors are basal cell, squamous cell, adeno-squamous carcinoma, and neuroendocrine carcinoma. Adenocarcinoma commonly originates from the peripheral zone of the gland (85%), less frequently from the transitional zone (10–15%), while only 5–10% of cases arise in the central zone [14, 15]. Most cancers are multifocal, with synchronous involvement of multiple zones of the prostate, which may be due to clonal and non-clonal tumors.

The clinical outcome of PCa is highly variable, since in some patients the tumor grows slowly, while in other patients, it can exhibit a very aggressive behavior with early metastasis and death. This is summarized by the "risk of progression" concept defined by the classes of risk, which can be obtained taking into account the extension (stage TNM), the Gleason score (GS), and PSA levels [16, 17]. PCa follows a multistep course of growth. The first step is known as "carcinoma in situ" when neoplastic cells are confined into a normal gland. Following the initial event, further mutations, including p53, can lead to progression and metastasis. Prostate cells are sensitive to activation of androgen receptors on their surface. Androgens bind to the receptor, an androgen-activated transcription factor that belongs to the steroid nuclear receptor family. The receptor translocates into the nucleus, where it binds to androgen response elements and modulates transcription and cell growth [18]. As the disease progresses from hormone dependent to castration resistance status, this system is altered. Two key changes include upregulation of the androgen receptor, which confers sensitivity to small amounts of androgen, and mutation of the receptor, which results in loss of specificity for androgens [19].

According to their original location in the prostate, locally advanced PCa in the transitional-zone tumors spread to the bladder neck, while the peripheral-zone tumors extend into the ejaculatory ducts and seminal vesicles. Penetration through the prostatic capsule and along the perineural or vascular spaces is a late event. PCa spreads to bone early, often without significant lymphadenopathy. At present, two predominant theories have been proposed: (1) the mechanic theory and (2) the seed-and-soil theory. Therefore, metastases can be caused by direct spread through the lymphatics and venous

spaces into the lower lumbar spine or/and are caused by the presence of tissue factors that allow preferential growth in certain tissues. Lung, liver, and adrenal metastases have also been documented.

TNM Classification

The standard staging system for newly diagnosed PCa is that of the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC). This system incorporates the anatomic extent of disease, including the primary tumor (T), regional lymph nodes (N), and distant metastases (M). The TNM staging system is widely used to stage PCa (Tables 1 and 2) [20]. Although imaging techniques are only occasionally useful for detecting/diagnosing PCa, they are mostly used for staging once a histological diagnosis is obtained. Usually a combination of the currently available imaging modalities is necessary for defining the most appropriate treatment strategies.

The 2010 update of this system incorporated the pretreatment serum PSA level and Gleason score/grade to subdivide patients into prognostic categories. This information about prognostic categories is also combined with patient's age; life expectancy; overall medical condition, including performance status and comorbidities; the presence or absence of symptoms; and patient preferences to make decisions for the optimal treatment for an individual patient.

Histopathological Grade

Gleason score (GS) is recommended as the grading system of choice, because it takes into account the inherent morphologic heterogeneity of PCa, and several studies have clearly established its prognostic value. A primary and a secondary pattern (the range of each is 1–5) are assigned and then summed-up to yield a total score. Scores of 2–10 are possible. It has been reported that high GS is associated with poor prognosis, although the behavior of cancer can be different in accordance with other histopathological variables (i.e., lymphovascular and neurovascular invasions, infiltrated margins, positive lymph nodes).

The majority of newly biopsy-diagnosed PCas are graded GS 6 or above. In a radical prostatectomy, if a tertiary pattern is present, it is commented upon but not reflected in the GS [9]:

- Gleason X: GS cannot be processed
- Gleason $\leq$6: well differentiated (slight anaplasia)
- Gleason 7: moderately differentiated (moderate anaplasia)
- Gleason 8–10: poorly differentiated/undifferentiated (marked anaplasia).

Risk Stratification

The initial management of patients with newly diagnosed PCa relies on multidisciplinary evaluation of the patient's conditions (age, life expectancy, performance status, comorbidities, presence or absence of symptoms, and consensus) and on a pretreatment assessment of the risk of locoregional recurrence or disseminated disease. Important factors in this assessment include clinical staging of the extent of disease (Tables 1 and 2), the pretreatment serum PSA, and GS in the pretreatment biopsy [19–21].

The categories of risk derived from the abovementioned information are summarized in Table 3. D'Amico's classification is the most commonly used, validated, and cited risk stratification for PCa.

Management Strategies for Prostate Cancer

The choice of treatment should be patient specific and risk adjusted and aims at improving cancer control while reducing the risks of treatment-related complications [8]. The therapeutic approaches for patients with PCa include (1) watchful waiting, (2) radical prostatectomy

Table 1 AJCC/UICC TNM classification of prostate cancer

Primary tumor (T)	
Clinical	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Clinically inapparent tumor neither palpable nor visible by imaging
T1a	Tumor incidental histologic finding in 5% or less of tissue resected
T1b	Tumor incidental histologic finding in more than 5% of tissue resected
T1c	Tumor identified by needle biopsy (e.g., because of elevated PSA)
T2	Tumor confined within prostate[a]
T2a	Tumor involves one-half of one lobe or less
T2b	Tumor involves more than one-half of one lobe, but not both lobes
T2c	Tumor involves both lobes
T3	Tumor extends through the prostate capsule[b]
T3a	Extracapsular extension (unilateral or bilateral) including microscopic bladder neck involvement
T3b	Tumor invades seminal vesicle(s)
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles such as external sphincter, rectum, bladder, elevator muscles, and/or pelvic wall
Pathologic (pT)[c]	
pT2	Organ confined
pT2a	Unilateral, one-half of one side or less
pT2b	Unilateral, involving more than one-half of side, but not both sides
pT2c	Bilateral disease
pT3	Extraprostatic extension
pT3a	Extraprostatic extension or microscopic invasion of bladder neck[d]
pT3b	Seminal vesicle invasion
pT4	Invasion of rectum, elevator muscles, and/or pelvic wall
Regional lymph nodes (N)	
Clinical	
NX	Regional lymph nodes were not assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node
Pathologic	
pNX	Regional nodes not sampled
pN0	No positive regional nodes
pN1	Metastasis in regional node(s)
Distant metastasis (M)[e]	
M0	No distant metastasis
M1	Distant metastasis
M1a	Non-regional lymph node(s)
M1b	Bone(s)
M1c	Other site(s) with or without bone disease

[a]Tumor found in one or both lobes by needle biopsy, but not palpable or reliably visible by imaging, is classified as T1c
[b]Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified not as T3 but as T2
[c]There is no pathologic T1 classification
[d]Positive surgical margin should be indicated by an R1 descriptor (residual microscopic disease)
[e]When more than one site of metastasis is present, the most advanced category is used. pM1c is most advanced

(with or without lymphadenectomy), (3) radiotherapy, (4) hormonal therapy, (5) chemotherapy, (6) immunotherapy, and (7) treatment of bone metastases. The selection of a treatment should be taken on the basis of a multidisciplinary approach involving all specialists dealing with this pathology (Fig. 1).

Active Surveillance and Watchful Waiting

Active surveillance (AS) for patients with PCa consists in postponing the immediate therapy with a definitive treatment that should be started in case of the evidence of a consistent risk of disease progression. AS is an option for the initial management of selected men with localized, well-differentiated PCa thought to be at low risk for progression [22, 23]. This approach is based on the long natural history of PCa, and it is an attempt to balance the risks with the side effects of over-treatment against the possibility of disease progression and a lost opportunity for cure. In 2015, the Cancer Care Ontario organization (CCO) published a Clinical Practice Guideline on Active Surveillance for the Management of Localized Prostate Cancer. The ASCO Endorsement Panel reinforces these recommendations, also adding qualifying statements [24].

Table 2 AJCC anatomic stage and prognostic groups for prostate cancer. (Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, IL. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC)

Group	T category	N category	M category	PSA[a]	Gleason score[a]
I	T1a–c	N0	M0	<10	≤6
	T2a	N0	M0	<10	≤6
	T1–2°	N0	M0	X	X
IIA	T1a–c	N0	M0	<20	7
	T1a–c	N0	M0	≥10 <20	≤6
	T2a	N0	M0	<20	≤7
	T2b	N0	M0	<20	≤7
	T2b	N0	M0	X	X
IIB	T2c	N0	M0	Any	Any
	T1–2	N0	M0	≥ 20	Any
	T1–2	N0	M0	Any	≥ 8
III	T3a–b	N0	M0	Any	Any
IV	T4	N0	M0	Any	Any
	Any T	N1	M0	Any	Any
	Any T	Any N	M1	Any	Any

[a]When either PSA or Gleason is not available, grouping should be determined by T stage and/or whichever of the either PSA or Gleason is available

Table 3 Categories of risk in prostate cancer patients

Very low risk: **clinically localized PCa**	Disease detected by prostate biopsy based upon serum PSA only, without detectable abnormality on digital rectal examination or imaging
	Grade group 1 (Gleason score ≤6), <3 positive cores, no core ≥50% involved
	Serum PSA <10 ng/mL
Low risk: **clinically localized PCa**	No apparent tumor in the prostate (i.e., diagnosis based upon a biopsy only, with no abnormal findings on imaging or palpation) or limited disease in one lobe of the prostate gland
	Serum PSA <10 ng/mL and grade group 1 (Gleason score ≤6)
Intermediate risk: **clinically localized PCa**	Tumor in the prostate involves more than one-half of one lobe of the prostate (T2b), or with bilateral disease (T2c), but without detectable extracapsular extension or seminal vesicle involvement
	Patients with T1 or T2a disease are classified as having intermediate-risk disease based upon a serum PSA between 10 and 20 ng/mL or a biopsy grade group 2 or 3 (Gleason score 7)
High risk: **clinically localized PCa**	Tumor with extracapsular extension (T3a)
	Serum PSA >20 ng/mL or a biopsy grade group 4 or 5 (Gleason score of 8–10)
Very high-risk PCa	Tumors with seminal vesicle involvement (T3b), tumor fixation (T4), or invasion of adjacent organs (T4)
	Primary Gleason pattern 5 or four or more cores with Gleason score 8–10 (grade groups 4 and 5) are classified as very high risk
Lymph node involvement	Patients with lymph node involvement are classified as having stage IV (metastatic) disease
Disseminated disease	Patients with disseminated metastases (M1) are classified as having stage IV (metastatic disease)

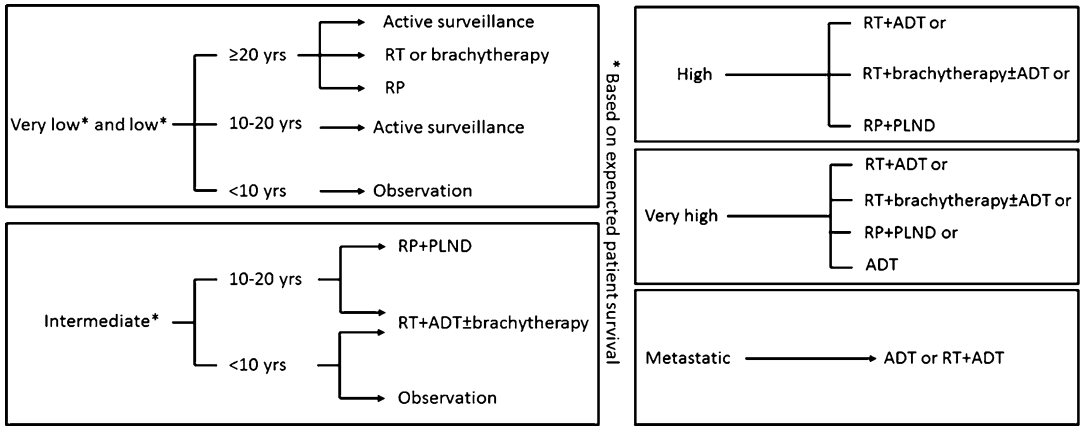

Fig. 1 A schematic illustration of treatment management in patients with PCa at different risk categories based on the anticipated years of survival (from NCCN guidelines, version 1.2016)

The distinction between AS and watchful waiting is important for clinical decision-making. AS, which carries a curative intent and involves regular monitoring with PSA, DRE, and biopsy, is appropriate for patients who have sufficient life expectancy and time to benefit from active treatment when disease progression is detected. For patients with a life expectancy of less than 5 years, watchful waiting (cessation of routine monitoring, with treatment initiated only if symptoms develop) is appropriate and further reduces the issue of overtreatment, including biopsies which carry a small but nonzero risk of infection and hospitalization. For most patients with low-risk (GS$\leq$6) localized PCa, AS is the recommended management strategy. However, since the ASCO Endorsement Panel recognizes that there is non-negligible disease heterogeneity, in selected patients with low-risk PCa, an immediate treatment instead of AS should be chosen, especially in young patients, with high-volume tumor, high GS, and African-American ethnicity, because these patients have a higher likelihood for disease progression during their lifetime.

The NCCN recommendation for follow-up schedule during AS includes PSA no more often than every 6 months unless clinically indicated, DRE no more often than every 12 months unless clinically indicated, and repeated prostate biopsy considered annually to assess for disease progression (biopsy should be repeated within 6 months of diagnosis if initial biopsy was <10 cores or assessment discordant, e.g., palpable tumor contralateral to the side of positive biopsy). A repetition of prostate biopsy is indicated when DRE changes or PSA increases, although neither parameter is very reliable for detecting PCa progression.

Radical Prostatectomy (With or Without Lymphadenectomy)

Radical prostatectomy is usually reserved to patients who are in good health and have tumor confined to the prostate gland (stage I and stage II) [25, 26]. There are two types of radical prostatectomy: retropubic and perineal prostatectomy. The perineal approach requires a separate incision for lymph node dissection. Laparoscopic lymphadenectomy is technically possible and accomplished with reduced morbidity [27]. For small, well-differentiated nodules, the incidence of positive pelvic lymph nodes is less than 20%, and pelvic node dissection may be omitted. With larger, less-differentiated tumors, pelvic lymph node dissection is more important. The value of pelvic lymph node dissection (i.e., open surgical or laparoscopic) in these cases is not therapeutic but spares patients

with positive nodes the morbidity of prostatectomy. In some cases, nerve-sparing surgery can be done. However, men with large tumors or tumors that are very close to the nerves may not be eligible for this surgery. This type of surgery may save the nerves that control erection. The advent of robotic prostate surgery offers several advantages over the traditional methods, yielding clinically superior results and reduced risk of complications and allowing a quicker recovery [28, 29]. The use of robot-assisted radical prostatectomy (RARP) for the management of localized PCa has increased dramatically in recent years. RARP is associated with improved perioperative outcomes, such as reduced blood loss and fewer transfusions. However, cancer control after RARP versus retropubic radical prostatectomy is equivalent, with similar incidences of positive surgical margins and comparable early oncological outcomes. RARP appears to provide advantages in recovery of continence, potency, and quality of life compared with retropubic radical prostatectomy [30].

External Beam Radiation Therapy

External beam radiation therapy (EBRT) is a good option as definitive treatment for patients with tumor at early or locally advanced stages and localized within the prostate. The evolution of radiotherapy techniques through three-dimensional conformal radiotherapy (3D CRT), intensity-modulated radiotherapy (IMRT), and image-guided radiotherapy (IGRT) has allowed more accurate and precise treatments and obtained significant improvements in the therapeutic ratio [31, 32]. These modalities make it possible to treat PCa with radical intent and can be an alternative to radical surgery. A critical issue in EBRT of PCa is that the therapeutic effective dose is limited by the dose delivered, since it has been shown that the biochemical disease-free survival increases with increasing radiation dose [33]. Some randomized trials have shown better results with higher doses (>70 Gy). EBRT can be combined also with hormone therapy, in a short or long course, depending on clinical stage [34]. An alternative to EBRT utilizes protons as the radiation source. The advantage of proton therapy is the reduced radiation exposure to normal tissues adjacent to the tumor, while maintaining a therapeutic dose to the lesion.

Suitable candidates for adjuvant radiation therapy are patients with multifocal disease, positive surgical margins, periprostatic tissue invasion (T3-T4), GS>7, or PSA >0.2 ng/mL after radical prostatectomy [35]. Immediate postoperative radiotherapy improves significantly the biochemical recurrence-free survival and local control, but not overall survival. EBRT is also indicated after surgery when increasing PSA levels or diagnostic imaging detects local or distant tumor localization (soft tissues and bone). In the scenario of radiation therapy, intense clinical investigations are ongoing to further optimize treatment of PCa, including dose escalation, moderate and extreme hypofractionation, optimal combination between radiotherapy and androgen deprivation therapy, and timing of postoperative RT [36].

Brachytherapy

Brachytherapy (also called seed implantation or interstitial radiation therapy) treats PCa with radiation from inside the prostate gland. There are two types of brachytherapy: (1) low-dose rate therapy (LDR) and (2) high-dose rate therapy (HDR) [37, 38]. Brachytherapy with LDR uses permanent implants of iodine-125 seeds, while HDR uses iridium-192 sources or cesium-137 sources that are removed after irradiation. LDR brachytherapy is safe and efficient and constitutes an alternative to surgery and EBRT, particularly in those patients with a prostate gland of small volume, clinical low risk, GS < 7, and a PSA <10 ng/mL. Recurrence-free survival at 5 years has been reported to range from 71% to 93% with a median follow-up between 36 and 120 months [39]. Differently from LDR, HDR brachytherapy should be performed in the presence of locally advanced PCa, often delivered as a boost in combination with EBRT.

High-Intensity Focused Ultrasound Therapy and Cryotherapy

High-intensity focused ultrasound (HIFU) therapy and cryotherapy, two sophisticated options for local treatment of PCa, can be performed both as primary treatment and as salvage treatment, after unsuccessful surgery or radiotherapy [40, 41]. At present, the diffusion of these techniques is limited. Therefore, despite some encouraging results, the overall clinical experience is limited to a few centers and data should be confirmed on larger series of patients. However, the clinical value of these techniques has a definite role, since both HIFU and cryotherapy can achieve precise ablation of small lesions (focal therapy) by treating a partial volume of the prostate gland.

Hormone Therapy

The growth of PCa cells is sustained by testosterone [42]. This is the reason why the treatment of PCa is based on suppression of this hormone [43]. This effect can be obtained by orchiectomy or by administering luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin, and buserelin) or LHRH antagonists (degarelix) that block LH production in the pituitary gland, thus inhibiting the synthesis of testosterone [44–46]. This strategy is called androgen deprivation therapy (ADT). LHRH agonists are indicated in the different phases of the disease and can be used alone or in combination with other drugs, in association with radiotherapy or after surgery. ADT has clinical and prognostic importance as adjuvant treatment after radical prostatectomy, if lymph nodes are positive for metastasis. For the treatment of extraprostatic cancer, ADT can be combined with EBRT, since clinical evidences demonstrated superiority of the combined treatment versus the single treatment. ADT should be considered as the first-choice therapy in patients with metastatic disease, with involvement of distant organs other than prostate gland and locoregional lymph node (e.g., bone, lung, or distant lymph nodes).

Another important type of hormone therapy is based on the use of antiandrogens (bicalutamide, flutamide, and cyproterone acetate), compounds that compete directly with circulating androgens for binding sites on their receptors within the prostate cells, thus promoting apoptosis and inhibiting PCa growth [47, 48]. Cyproterone acetate additionally blocks gonadotropin release by the pituitary, thus contributing to reduce the testosterone plasma levels. These drugs are administered as monotherapy or in combination with LHRH agonists.

Two new drugs have recently been made available in the armamentarium for hormone therapy: abiraterone acetate and enzalutamide, with different mechanisms of action. Abiraterone acetate is a potent inhibitor of the enzyme 17-alpha-monooxygenase (CYP17), which is essential for the synthesis of testosterone from nongonadal sources [49]. The inhibition of CYP17 (normally expressed in testicular, adrenal, and prostate tumor tissues) translates into reduced testosterone synthesis from cholesterol. Enzalutamide is a new generation antiandrogen with a higher affinity for the ligand binding the androgen receptor than the first-generation agents, such as bicalutamide [50]. This agent acts at three different steps: (1) it inhibits androgen binding to androgen receptors, (2) it inhibits androgen receptors from entering into the nucleus, and (3) it inhibits androgen receptors from binding to DNA.

Chemotherapy

Docetaxel belongs to the taxane family (antimitochondrial agents) and its use is mainly indicated in patients with metastatic PCa resistant to ADT. Docetaxel plus prednisone showed to be significantly superior to mitoxantrone in patients defined as castrate-resistant prostate cancer (CRPC) for all endpoints of efficacy, including overall survival [51, 52]. CRPC patients develop progression of disease (e.g., biochemical relapse or progression of metastases) in spite of low levels of circulating testosterone (<50 ng/dL). Another agent named

cabazitaxel, a new semisynthetic analogue of docetaxel, has been shown to be effective in metastatic CRPC patients, with significant survival benefit versus mitoxantrone [53].

Immunotherapy

Recently, some interesting results have been obtained with vaccines, such as GVAX, PROSTVAC-VF, and sipuleucel-T [54–56], and with novel anti-immune checkpoint inhibitors like ipilimumab [57–59]. Sipuleucel-T, approved by the FDA and EMA, is a dendritic vaccine obtained by isolating dendritic cells from patients, priming cells in vitro with prostate-specific acid phosphatase through a fusion protein and reinfusion of the activated cells in the patient. Ipilimumab is a fully human antibody that binds to the inhibitory cytotoxic T lymphocyte antigen 4 (CTLA-4), thereby enhancing antitumor immunity. The results achieved in PCa are so far of a very preliminary nature.

Treatment of Skeletal Metastases

Bone-modifying agents can modulate the activity of osteoclasts, osteoblasts, and osteocytes. Several bisphosphonates (e.g., zoledronic acid) and an inhibitor of the RANK/RANKL pathway (denosumab) have been approved for the treatment of bone metastases in solid tumors with the goal to reduce skeletal-related events [60]. Denosumab has been shown to have superior activity over zoledronic acid in delaying and preventing skeletal-related events in patients with skeletal metastases from metastatic CRPC. Overall, some clinical evidence supports the introduction of zoledronic acid in the treatment of hormone-sensitive metastatic PCa [61]. None of these agents, however, has induced an improvement in overall survival.

As a calcium analogue, the alpha emitter radium-223 ion (administered in the form of a chloride salt) is selectively taken up in osteoblastic areas, where it conveys high radiation energy within a short penetration range, thus resulting in irreparable DNA damage. Results of the ALSYMPCA trial indicate that, when used for the treatment of bone metastases, this radiopharmaceutical leads to an advantage in survival for metastatic CRPC patients who presented with symptoms [62, 63]. In addition to significant reduction in bone pain and better quality of life versus placebo, treatment with ^{223}Ra-dichloride caused a 30% reduction in the risk of death versus placebo and reduction of new skeletal related events (SRE) both in post-docetaxel and in chemo-naïve patients [64].

In the new therapeutic scenario for metastatic CRPC, the appropriate algorithm for use of the available drugs is still an area of open discussion. Abiraterone acetate and enzalutamide demonstrated significantly increased overall survival and progression-free survival in the post- and pre-docetaxel setting in patients with bone metastases, respectively. Moreover, a significant impact on the incidence and severity on bone-related adverse events was observed in patients receiving enzalutamide [50]. Also EBRT represents an effective palliative treatment for control of pain in patients with localized skeletal metastases. EBRT achieves significant clinical results in 60–80% of patients, with more than 50% of patients obtaining complete pain relief at the treated site [65–67].

For initial treatment of CRPC patients with skeletal metastases, NCCN Clinical Practice Guidelines recommend abiraterone, enzalutamide, and docetaxel (for rapidly progressing patients), radium-223 (for patients with bone metastases and no visceral metastases), or participation in clinical trials. Nevertheless, no consensus exists on the sequence of therapies to be employed alone or in combination after failure of initial therapy or first-line docetaxel. All agents plus cabazitaxel and salvage chemotherapy are options for second-line therapy. Figure 2 shows some examples of treatment strategies in PCa.

Biochemical and Diagnostic Modalities

Laboratory Tests

PSA is recognized as the first-choice tumor marker for PCa, since it has an absolute prostate specificity and is expressed by the majority of prostate cancers [50]. However, several nonneoplastic conditions

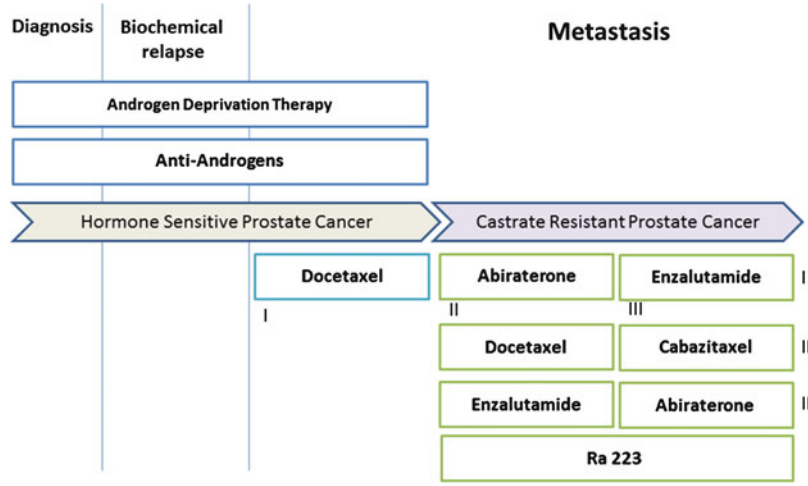

Fig. 2 Possible treatment strategies in different phases of PCa

of the prostate gland are associated with increased PSA levels; therefore, it has a lack of tumor specificity [68], which is the major drawback of PSA as a circulating marker for PCa. A number of patients with PCa have serum PSA levels below the cutoff of 4 ng/mL, even if about 15% of men with PSA below this threshold will have a biopsy-proven PCa. The probability of having a PCa rises as the PSA levels rise; the highest values correspond to the highest probability to have a PCa. Subjects with PSA levels ranging from 4 to 10 ng/mL have a 25% chance of having PCa (one out of four patients); when PSA concentrations are >10 ng/mL, the chance of having PCa is over 50–60%. Patients with a free-to-total PSA ratio <20% and PSA velocity >0.75 ng/mL per year have a higher risk of PCa. Different approaches were adopted in the past to optimize the sensitivity of the PSA test, for instance, by changing the cutoff threshold, variously elaborating on the PSA test (PSA density, PSA velocity), and investigating PSA isoforms (i.e., free PSA, conjugated PSA, pro-PSA). Novel biomarkers have also been explored, belonging to various molecular families (i.e., PCA-3, TMPRSS2-ERG gene fusions) [69, 70].

At variance with the use of PSA for the initial diagnosis, PSA is to be considered a strictly cancer-specific marker in patients in whom PCa has already been diagnosed and/or after primary treatments. In patients radically treated with curative intent, prostate tissue would not be represented anymore in the body, since it was fully removed by surgery or destroyed by radiotherapy. Then PSA should become undetectable in the serum after radical prostatectomy or should keep very low levels after radiotherapy. In these conditions, any significant and/or progressive increase of PSA values has to be considered cancer specific, particularly when the increase is constant over time. All patients with residual or relapsing PCa exhibit PSA changes, which therefore represent a clear biochemical sign of cancer presence [70–72]. There are two main characteristics of PSA as tumor marker: (a) a high proportion of prostate cancers produce PSA; (b) PSA is exclusively synthesized by prostatic tissue and this avoids any other analytical confounding noise that might mask PSA. Therefore, PSA is useful for monitoring patients radically treated, because the false-positive results are extremely rare in these conditions and any small increase of PSA may be considered to indicate cancer relapse.

Bony metastases are very frequents in PCa patients and are associated by high focal bone turnover with increased activity of osteolysis and/or osteogenesis. Markers of bone turnover might therefore be ideal to monitor progression of osteolytic or osteoblastic metastasis and/or to evaluate response to treatment. At present, bone alkaline phosphatase (bALP), total alkaline phosphatase (tALP), and amino-terminal procollagen propeptide type I (PINP) are considered as standard markers of bone formation, while cross-linked

C-terminal telopeptide of type I collagen (CTX) and cross-linked C-terminal telopeptide of type I collagen (ICTP) are utilized as markers of bone resorption [73–75]. The results from several studies conclude that in cancer patients with skeletal metastases, serum or urinary levels of bone turnover markers may be increased for various concomitant causes, in addition to skeletal metastases (e.g., age, vitamin D deficiency, and adjuvant hormone therapy). This makes it impossible to distinguish the contribution of the different components that determine high levels of bone markers; therefore, markers of bone turnover should not be considered as diagnostic tools for skeletal metastasis. Instead, markers of bone turnover can be considered as indicators of prognosis and parameters of progression. Some clinical investigations demonstrated a positive association between high levels of these markers and presence or progression of skeletal metastases from PCa [76, 77]. The highest diagnostic accuracy was described for b-ALP (72% sensitivity, 88% specificity), and the greatest diagnostic specificity was reported for PINP (92%). According to other reports, both baseline and on-study elevations in bone marker levels were associated with increased risks of SRE, disease progression and death [78–80]. In conclusion, clinical evidences confirm that all markers of bone turnover at present can be considered as parameters of prognosis or of response to therapy, but they have a very poor diagnostic value.

Radiological Imaging

Transrectal ultrasonography is used to look at the prostate when a patient has PSA abnormalities (e.g., high/increased levels, or altered free-to-total ratio, and/or high PSA velocity) or has abnormal DRE findings. TRUS has become the standard procedure to obtain material for histopathological examination [81]. Since early studies indicated that TRUS-guided single-spot biopsies detected PCa only in 22–34% of the cases, the current procedure is based on multiple sampling [14, 15]. The likelihood of PCa diagnosis increases with the number of biopsy specimens, and at least ten biopsy cores are recommended; 12–16 samples are obtained in some centers [17, 18]. Besides this recommendation, some US abnormalities do not correspond to a cancer lesion; therefore, the procedure can be affected by both false-negative and false-positive results. Attempts to improve its accuracy are based on the use of color Doppler, power US, and 3-D US. Moreover, TRUS can be used also to measure the size of the prostate gland, which can help in determining the PSA density, or can represent also a guide during some forms of treatment such as brachytherapy [82, 83].

CT scan has no value when the cancer is likely to be confined to the gland. Therefore, CT cannot be used for studying the prostate gland itself. However, CT can be helpful when spread to lymph nodes and adjacent structures is suspected (see Fig. 3), and for restaging patients. The role of CT scan in the current clinical routine consists in studying bone and soft tissues of the entire body, since it is the most available and reliable radiological whole-body method to detect and monitor lymph node, visceral, and skeletal metastases [84].

Magnetic resonance imaging (MRI) has recently emerged as the modality of choice for the detection of PCa after an inconclusive biopsy, for local staging, and for seminal vesicle evaluation. T2-weigted MRI sequences allow a precise definition of the local anatomy (see Fig. 4). The use of functional MRI sequences (namely, dynamic contrast-enhanced (DCE), diffusion-weighted imaging (DWI), and MRI spectroscopy) enables more accurate examinations [85, 86]. MRI associated with a systematic biopsy determines a better cancer detection also in patients with previous standard US-guided negative biopsies and elevated serum PSA [87, 88]. Although the bone itself does not have an MR signal, skeletal metastases are visualized by MRI through the detection of early changes in bone marrow that precede bone reaction to tumor invasion. MRI could represent an imaging technique of choice for detection and follow-up of bone metastases [89, 91]. New whole-body (WB) protocols have been adopted, and ad hoc WB-DWI sequences were developed to explore with multiparametric projections (MPR) areas that are difficult to analyze on standard anatomical imaging. In very few

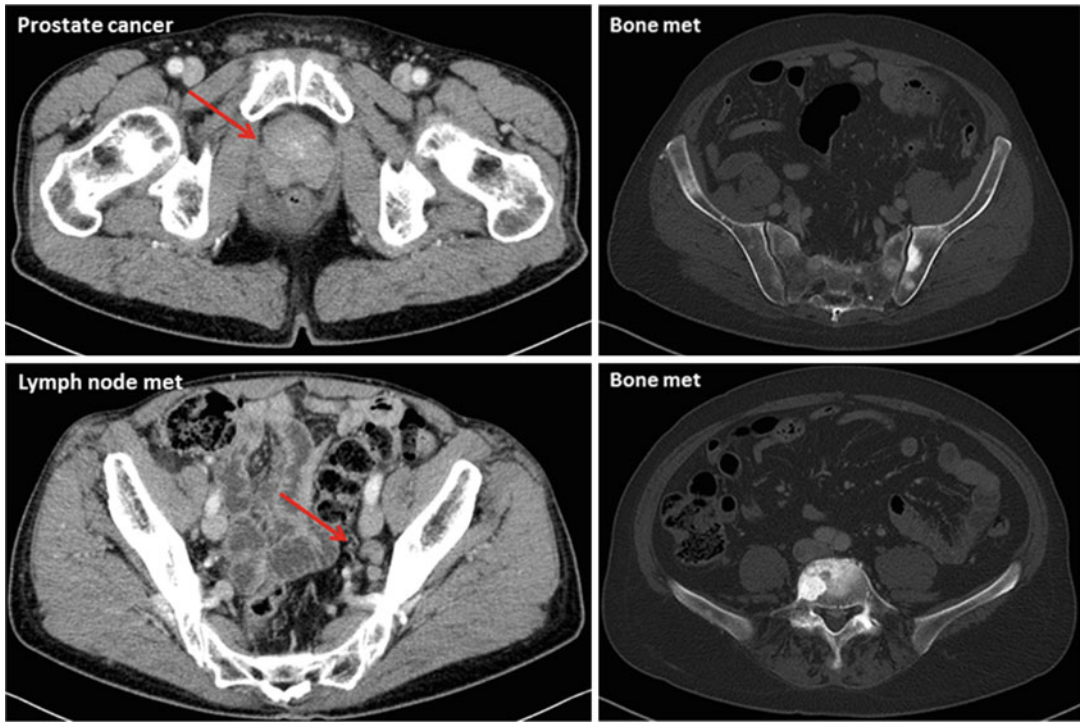

Fig. 3 CT images suggesting primary prostate cancer (*upper left panel*), pelvic lymph node involvement (*lower left panel*) in a 78-year-old patient with newly diagnosed PCa, before any treatment. Bone window CT images show bone metastases in the pelvis (*upper* and *lower right panels*)

centers, WB hybrid PET/MRI scanners have been introduced, for simultaneous acquisition and exact anatomical coregistration of PET and MRI. A limitation of this modality is that such sophisticated approaches are available in a limited number of specialized centers and these examinations are time-consuming, require specific expertise, and have an intrinsic high cost.

Nuclear Medicine Modalities

Nuclear medicine modalities can be classified according to the physical characteristics of the tracers (based on γ-emitting or β^+-emitting radionuclides), the type of detection (planar scintigraphy, SPECT, SPECT/CT, PET/CT,), the mechanism of accumulation of the agents (targeting bone or targeting cancer cells), and their availability in the clinical practice (already approved or experimental).

The choice of the best imaging strategy depends on several factors, such as availability and costs. Planar imaging and SPECT with bone targeting agents are the most commonly employed techniques, both for their availability and for economic reasons. PET/CT represents the more sophisticated technique that can be used with different radiotracers, both for bone and for cancer imaging.

Radiopharmaceuticals for PCa can be divided into two main groups: (1) targeting bone (^{99m}Tc-labeled diphosphonates and ^{18}F-fluoride) and (2) targeting cancer cells ([^{11}C]choline, ^{18}F-choline, [^{18}F]FDG, ^{68}Ga-PMSA-ligand, ^{18}F-FACBC, etc.).

^{99m}Tc-Biphosphonates Bone Scan, SPECT, and SPECT/CT

The commonest radiopharmaceuticals used to visualize bone metastases belong to the bisphosphonates family labeled with ^{99m}Tc, such as ^{99m}Tc-hydroxymetilendiphosphonic acid

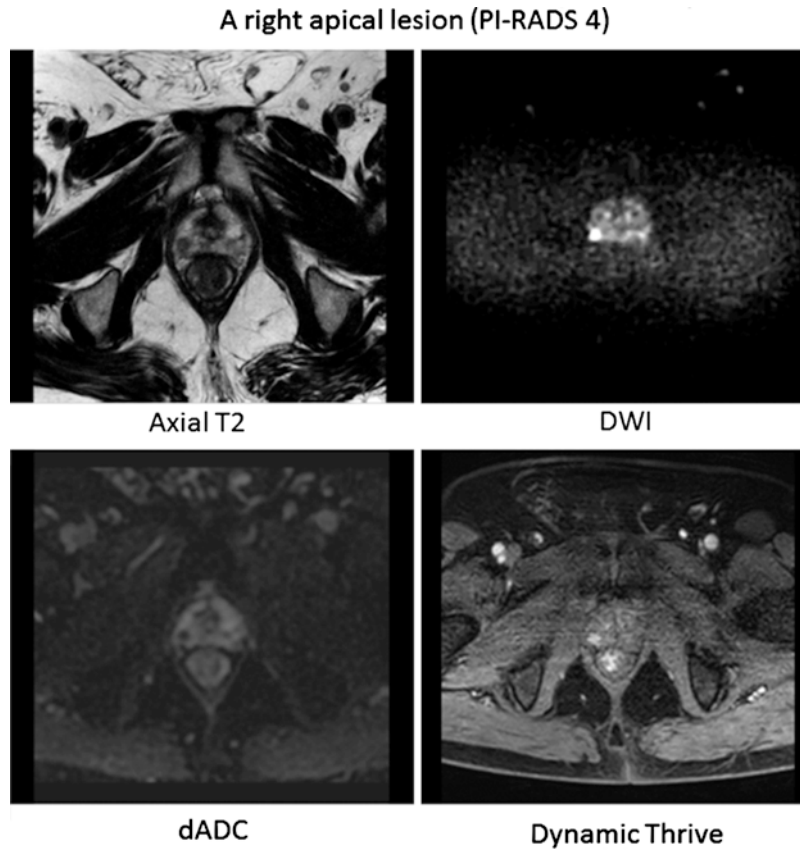

Fig. 4 MRI images obtained in a patient with PCa. A focal hypointense tumor focus in the right apical region of the prostate gland is shown in different sequences

(^{99m}Tc-HMDP), ^{99m}Tc-methylene diphosphonate (^{99m}Tc-MDP), and ^{99m}Tc-3,3-diphosphono-1,2-propanedicarboxylic acid (^{99m}Tc-MDP) [90–92]. ^{99m}Tc-MDP accumulates in the mineral component of bone: nearly two-thirds in the hydroxyapatite crystals and one-third in calcium phosphate. Its uptake is related to the osteoblastic activity, blood flow, and extraction efficiency. The vast majority of skeletal metastases from PCa are osteoblastic, lesions that can easily be depicted on a whole-body scan. Bone scintigraphy (BS) is the cornerstone of nuclear medicine for the assessment of the skeleton, particularly in oncology. The conventional whole-body scan (WBS) is recommended in the most important guidelines for PCa, because it is widely available, has low costs and high sensitivity, and is able to detect bone metastases several months before they are revealed by planar x-ray. In fact, more than 40% of trabecular bone has to be destroyed before the lesion becomes detectable by conventional x-ray [92, 93]. It is well known that the highest sensitivity of BS for PCa metastases is achieved in presence of osteoblastic lesions. BS can efficiently image both the osteoblastic and the mixed lesions, while the detection of osteolytic lesions is less efficient due to reduced calcium deposit and consequent poor uptake of the radiolabeled phosphonates. Another important notion to keep in mind is that BS cannot detect cancer invasion in the bone marrow per se, unless an osteoblastic reaction is activated.

The diagnostic sensitivity of BS in PCa patients varies from 75% to 95%; its specificity is relatively lower (from 60% to 75%), because metabolic bone reactions can also occur in benign conditions such as arthrosis, inflammation, and trauma [93–95]. The high variability reported across the clinical studies depends on differences between patient populations and pretest probability of bone metastases.

When is BS indicated in PCa patients? In asymptomatic newly diagnosed patients, we

have to consider the class of risk described above, in order to keep to a minimum the use of diagnostic investigations, especially in patients with a very low probability of having bone metastases. PSA levels represent the most common parameter to evaluate the probability of having bone metastases. Several retrospective studies indicate that PSA levels <20 ng/mL can exclude with a high probability the presence of bone metastases at BS, with a negative predictive value closed to 99% [96]. Conversely, WBS should be performed in PCa patients at high risk or very high risk (PSA >20 ng/mL or GS>8) (NCCN recommendations). In patients with intermediate risk, BS should be considered only in presence of clinical conditions suspected for bone metastases. In these patients, calculation of the pretest probability would be useful; several statistical approaches that produce complex nomograms are now available [97–101].

In patients with PCa after primary treatment (surgery or radiotherapy), the indications for bone imaging occur in two different situations: (a) symptomatic patients or biochemical recurrence (increase in PSA levels) and (b) patients under treatment, for monitoring response to therapy. In the first case, the physician faces the clinical problem to detect a possible cancer relapse with or without bone involvement, often driven by the appearance of clinical and/or biochemical symptoms based on the trend of rising PSA [102–107] (see Fig. 5). There are established cutoff values for PSA doubling time and PSA velocity (doubling time less than 2–3 months and velocity >5 ng/mL per year) suggesting the presence of bone metastases. Moreover, BS is often indicated to solve equivocal/non-diagnostic findings at radiological imaging.

In the second case, the goal is to describe changes in radiopharmaceutical uptake (i.e., intensity, size, or number) as an index to assess response to therapy. The use of BS to evaluate the response of bone metastases to therapy has recently been extensively discussed by Evangelista et al. reporting various important critical issues, such as timing of the scan, the possibility of false-positive results due to the flare phenomenon (a marked increase in multifocal skeletal tracer uptake as a result of a change in therapy within 2-3 months of the bone scan) the criteria of interpretation at different times during and after therapy, and other factors [108]. Of course, the flare phenomenon is the most important factor to consider; in spite of some existing standard criteria to carry out a correct interpretation of bone uptake, at present it still constitutes a limitation that affects the value of BS in assessing the response to therapy [46, 109–111]. It can be concluded that, in patients with bone metastases, WBS is more reliable for defining tumor progression than for measuring the changes of response to therapy.

A bone scan index (BSI) has been developed to quantitate the load of bone metastases from PCa. This index is calculated by considering the average weight of bones derived from a reference man and the fractional contribution of each bone expressed as a percentage of the entire skeleton [112]. Therefore, BSI represents the percentage of the skeletal mass occupied by metastases, and this value indicates the extent of bone involvement. BSI was demonstrated to represent a reproducible prognostic tool and can be used both for stratifying patients in treatment protocols and for assessing treatment response [113, 114]. Since calculation of the BSI is a very laborious and time-consuming procedure, various automated computer-assisted methods were developed, resulting in a clear improvement of accuracy and feasibility [115]. Significant correlation has been described between BSI and overall survival. However, BSI has not entered in the diagnostic routine and the general opinion is that BSI would be mainly adopted for clinical trials [116, 117].

SPECT can improve on the limited specificity of planar BS, as it enables better definition of particular skeletal areas, such as the spine, pelvis, hip, and knee. SPECT was shown to improve the sensitivity, specificity, negative predictive value (NPV), positive predictive value (PPV), and accuracy of conventional BS up to 92%, 91%, 94%, 82%, and 90%, respectively, over planar imaging [118–120]. In particular, hybrid SPECT/CT, by integrating the anatomical information from CT with the metabolic-functional information from SPECT, results in better interpretation of bone areas with increased tracer uptake, thus making it easier to distinguish benign from malignant lesions [121]. Several clinical studies on

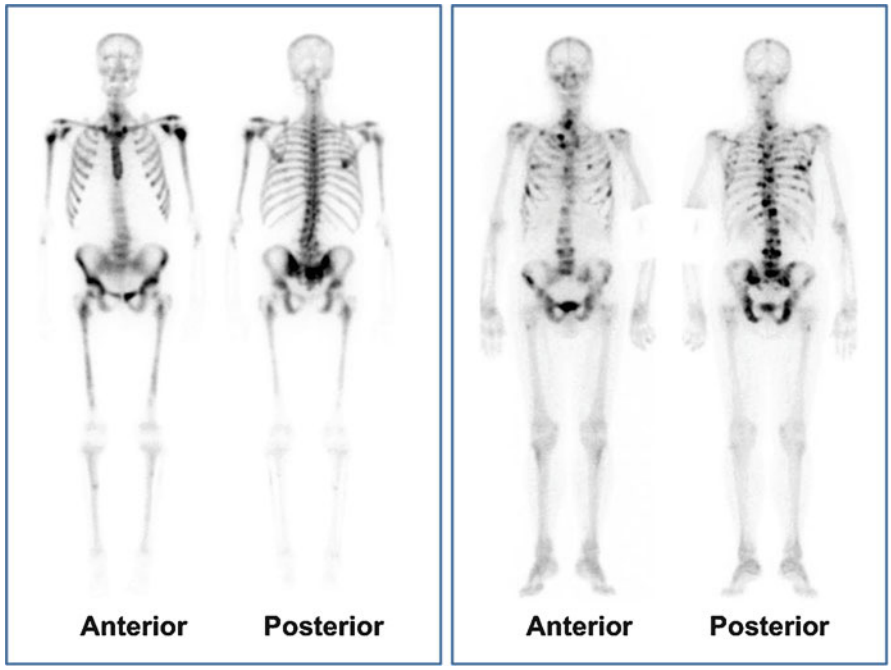

Fig. 5 Restaging BS in patients with biochemical PCA recurrence. (*Left*) A 65-year-old patient with a nonsurgical treated PCa with PSA 1,015 ng/mL, showing intensely increased tracer uptake in virtually all the skeletal segment ("super scan"). (*Right*) A 68-year-old patient with recurrent PCa, in whom the BS shows many areas of focally increased tracer uptake throughout several skeletal segments

scintigraphically equivocal lesions, the majority localized in the spine, demonstrated that SPECT/CT significantly improves the assessment of skeletal metastases from PCa [122–124]. Sharma et al. [125] showed that among 49 indeterminate lesions on planar BS, 96% were correctly classified with SPECT/CT and the patient management was changed in 61% [127]. Palmedo et al. compared SPECT/CT to ^{99m}Tc-HMDP BS and ^{99m}Tc-HMDP stand-alone SPECT in a series on PCa patients and found that SPECT/CT significantly improved specificity (94% versus 78%) and PPV (88% versus 59%) [126]. Although SPECT/CT has the advantage, over conventional BS, to allow a more detailed study of a limited region of the skeleton, its use in treatment monitoring is hampered by the hardware which prevents the WB acquisition in a reasonable time frame. In this regard, attempts have been undertaken to develop particular WB SPECT protocols enabling to image the entire body [127]. However, in spite of some particular multi-FOV methods reliable for the analysis of the WB scan, these modalities are not currently adopted in the clinical routine, due to their long acquisition time, limited compliance. Moreover, they do not solve the main drawback of conventional BS, which maintains a low diagnostic specificity and the inability to visualize the osteolytic lesions.

^{18}F- Fluoride PET/CT

^{18}F-Sodium fluoride (^{18}F-NaF) PET/CT detects skeletal metastatic disease by a mechanism of similar to that of ^{99m}Tc-HMDP. Clinical indications are the same as for ^{99m}Tc-HMDP WBS, including the detection of primary and secondary bone tumors, the evaluation of equivocal findings at radiological imaging, and the assessment of response to therapy [127, 128]. The clinical imaging protocol has been described by Segall et al. in the procedure guidelines published by the Society of Nuclear Medicine and Molecular Imaging (SNMMI) [129]. The recommended activity of ^{18}F-NaF is 1.5–3.7 MBq/kg (40–100 μCi/kg) up

Fig. 6 Mismatch between ^{18}F-fluoride PET/CT and BS in a 76-year-old patient with a significant increase in PSA (from 2 to 38 ng/mL) after radiotherapy. ^{18}F-fluoride PET/CT shows multiple sites of uptake in the skeleton, while the bone scan is negative

to a maximum of 370 MBq for oncologic imaging. Due to the lower injected activity and the physical decay characteristics, the total absorbed dose for ^{18}F-NaF PET is similar to that of the ^{99m}Tc-MDP BS [130, 131]. The kinetics of ^{18}F-NaF is characterized by a rapid plasma clearance and a high uptake in skeletal metastases with an especially favorable target-to-background ratio. Imaging quality of ^{18}F-NaF PET/CT is better than with ^{99m}Tc-MDP, with superior spatial resolution (4–5 mm versus 10–15 mm); imaging with ^{18}F-NaF is acquired earlier than with ^{99m}Tc-MDP (0.5–1 h versus approx. 3 h).

The overall diagnostic sensitivity of ^{18}F-NaF PET/CT is higher than that of conventional BS (Fig. 6). In a study by Even-Sapir et al. on 23 patients, patient-based sensitivity was 100% for ^{18}F-NaF PET/CT and 70% for BS, with 100% and 57% specificity, respectively. This advantage was reported also on a lesion-based analysis. Furthermore, the authors observed that PET/CT has significantly better sensitivity and specificity than SPECT/CT imaging [128]. A review article by Langsteger et al. on 22 patients with PCa found sensitivity, specificity, and accuracy values of 91%, 83%, and 88%, respectively, for skeletal metastases [132]. This superior sensitivity was reported also in other studies with ^{18}F-NaF PET/CT [133–136]. For example, Poulsen et al. described the superiority of ^{18}F-NaF PET/CT over conventional BS by studying 50 patients bearing 526 metastatic bone lesions from PCa; ^{18}F-NaF PET/CT had sensitivity, specificity, accuracy, and positive and negative predictive values of 93% versus 51%, 54% versus 82%, 81% versus 61%, 82% versus 86%, and 78% versus 43%, respectively [138].

Evangelista et al. confirmed that ^{18}F-NaF PET/CT has the highest weighted sensitivity (range of 81–100%) among the nuclear medicine modalities for the evaluation of bone metastases from PCa [108]. An important advantage of ^{18}F-NaF PET/CT is the ability to image both blastic and lytic skeletal metastatic lesions [137]. Despite the good performance of ^{18}F-NaF PET in detecting bone metastases (mainly in sensitivity), the interpretation of focal uptakes should be careful because of the increased number of false-positive results (which lowers specificity). A more accurate interpretation of the focal skeletal uptake can be achieved by semiquantitative

evaluation of uptake with the standardized uptake value (SUV) [143]. This approach has been employed by different authors, in particular for lesions located in the spine, demonstrating that SUV evaluation can play a role in better discriminating metastases from degenerative lesions [130, 138, 144, 145]. A large-cohort study based on data from the American National Oncologic PET Registry (NOPR) was carried out with the aim to elucidate the clinical impact of ^{18}F-NaF PET/CT on the management of patients. Results from 2,839 PET/CT scans performed in patients with different neoplastic diseases (68% prostate, 17% breast, 6% lung, 8% others) were evaluated. It was found that ^{18}F-NaF PET/CT induced changes of strategy in 40% of the cases [140]. Early diagnosis of cancer progression and early detection of metastatic lesions can lead to different successful treatments capable of altering prognosis. The prognostic impact of ^{18}F-NaF PET/CT was recently assessed by Apolo et al. in patients with bone metastases from PCa. A significant correlation was found between overall survival and modifications of SUV (besides the number of sites of skeletal uptake in the baseline PET scan) [137]. ^{18}F-NaF PET/CT was used in patients with bone metastases from PCa for evaluating the response to therapy and resulted in better performance than BS [139]. However, similar to conventional WBS, also the ^{18}F-NaF PET/CT findings can be affected by a "flare phenomenon" [141, 142].

There are sufficient data to demonstrate that PET/CT offers several advantages over conventional BS. However, PET/CT scanners are still less available than gamma cameras and the test is more expensive. ^{99m}Tc- MDP is easily and widely available, while the production of ^{18}F requires a cyclotron. Again, a conclusive and complete cost-effectiveness study on the clinical use ^{18}F-NaF PET/CT supported by a statistically significant number of tests is not available; for all these reasons, this modality is not still established worldwide in the current clinical practice.

[^{11}C]Choline and ^{18}F-Choline PET/CT

PET/CT with either [^{11}C]choline or ^{18}F-choline visualizes PCa using a metabolic tracer involved in phospholipid and in membrane metabolism, with the rationale that PCa is characterized by an upregulated choline transport, phosphorylation, and membrane metabolism. Choline (CHO) is phosphorylated to phosphoryl choline by the enzyme choline kinase; in this chemical form, it is trapped within the cancer cell [146, 147]. The radioisotopes used for labeling CHO are ^{11}C (half-life 20.4 min) or ^{18}F (half-life 109.7 min), to produce the imaging agents [^{11}C]CHO and ^{18}F-CHO, respectively.

Unfortunately, ^{18}F-CHO has a high urinary excretion, which may interfere with evaluation of tracer uptake in the prostate. On the other hand, [^{11}C]CHO has the disadvantage of a short physical half-life, thus making the [^{11}C]CHO PET scan feasible only in centers with an on-site cyclotron. An analog of [^{11}C]choline labeled with ^{18}F, ^{18}F-CHO can be distributed and utilized in centers without cyclotron facilities. Moreover, the emission energy of ^{18}F allows better detection with PET than ^{11}C [148, 149]. Nevertheless, [^{11}C]CHO and ^{18}F-CHO exhibit many similar characteristics, and for this reason, they are currently an established imaging modality to evaluate patients with PCa. [^{11}C]CHO is available in the USA with FDA approval (September 2012), while ^{18}F-CHO is available for routine clinical use in Europe. [^{11}C]CHO PET/CT imaging protocols are based on the i.v. bolus injection of 370–740 MBq. The effective dose (ED) is estimated to be approx. 0.3 Sv and the dose critical organ is the liver. The PET/CT scan starts 3–5 min after tracer injection and images are acquired for a total of 10–20 min with 2–5 min per bed position, depending on the PET camera. Similarly to ^{18}F-CHO, fasting is not strictly necessary, although many studies suggest to fast at least 4–6 h before PET scanning. For ^{18}F-CHO PET/CT imaging, patients receive an i.v bolus injection of 4.07 MBq/kg, whole-body imaging starting 60–90 min after tracer administration (see Fig. 7). Occasionally, for prostate bed evaluation, early static or dynamic pelvic images may be obtained 2 min after tracer administration [150–152].

Evangelista et al. analyzed the diagnostic effectiveness of radiolabeled choline PET/CT in different phases of patient management: in primary cancer localization, preoperative staging, and restaging and for the evaluation of therapy response [153]. The data suggest that the use of choline PET

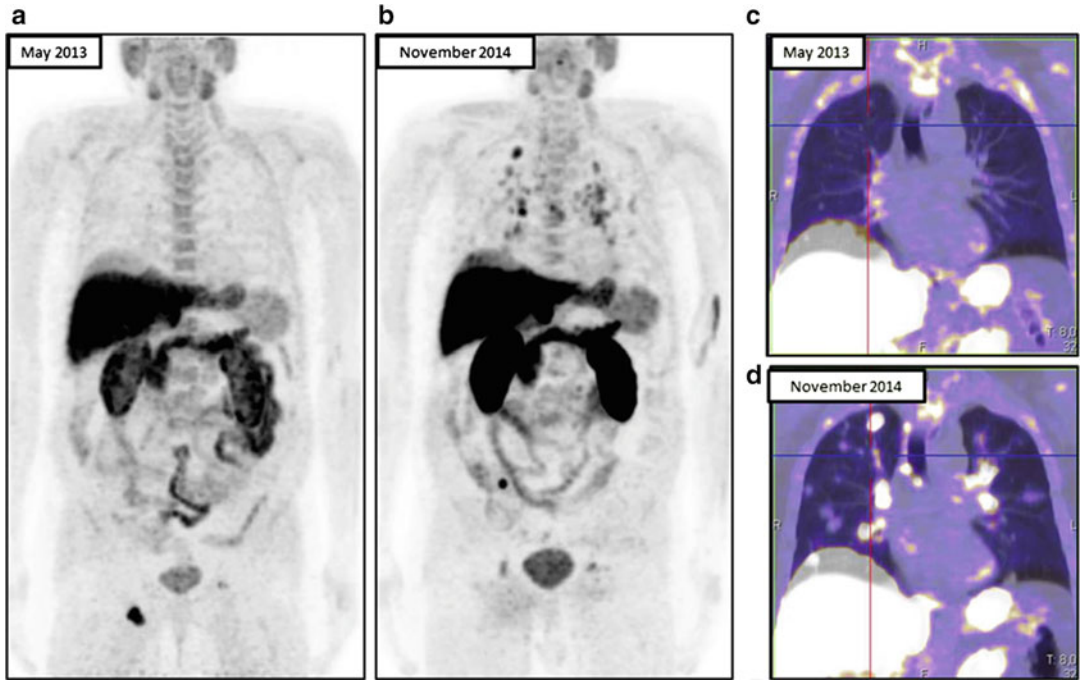

Fig. 7 ^{18}F-choline PET/CT for the detection of lymph node metastases in a 65-year-old patient with high-risk PCa. Radical prostatectomy was performed in 2011 (pT3bN1; GS = 9). The patient started Enantone in 2013 for disease progression in bone (**a**, **c**). Because of further increase in PSA level (36 ng/mL), the patient underwent PET/CT with ^{18}F-choline (**b**, **d**) that showed disease progression in the bone and lung

imaging for primary cancer detection in the preoperative phase is not supported by sufficiently convincing elements nor by a consistent number of observations. The region of the prostate gland can be successfully imaged by alternative radiological imaging modalities (US, MRI, CT), while preoperative evaluation of lymph node involvement with [^{11}C]CHO and ^{18}F-CHO PET/CT gave controversial results [154]. In a previous meta-analysis, Evangelista et al. had reported 49.2% pooled sensitivity with 95% pooled specificity for radiolabeled choline PET/CT in the detection of metastatic lymph node disease before a curative treatment. However, wide heterogeneity (between 22.7% and 78.4%) was reported across the studies [155]. Data from other studies showed sensitivity ranging from 33% to 45%, but confirmed high specificities when including larger patients' cohorts [156, 157]. The variability in the detection rate of lymph node metastasis was related to different biases, such as nonhomogeneity of GS, stage of disease, and other clinical factors. Therefore, despite good specificity, the current guidelines do not recommend choline PET imaging for lymph node staging of patients with primary PCa.

On the basis of clinical experience, the use of radiolabeled choline PET/CT in newly diagnosed patients should be limited to the detection of early osseous metastatic disease in high-risk patients [158]. When evaluating the value of ^{18}F-CHO PET/CT in the initial staging of 210 patients, Poulsen et al. found that a high focal bone uptake, consistent with bone metastasis, was seen in 18 patients. On the other hand, ^{18}F-CHO PET/CT has demonstrated some limitations in detecting densely sclerotic malignant lesions [159], since they are generally characterized by low metabolic activity.

At present, the best indication for [^{11}C]CHO or ^{18}F-CHO PET/CT consists in detecting PCa recurrence in patients already treated, but with biochemical recurrence (Fig. 8).

Krause et al. demonstrated a linear correlation between PSA values and the detection rates of

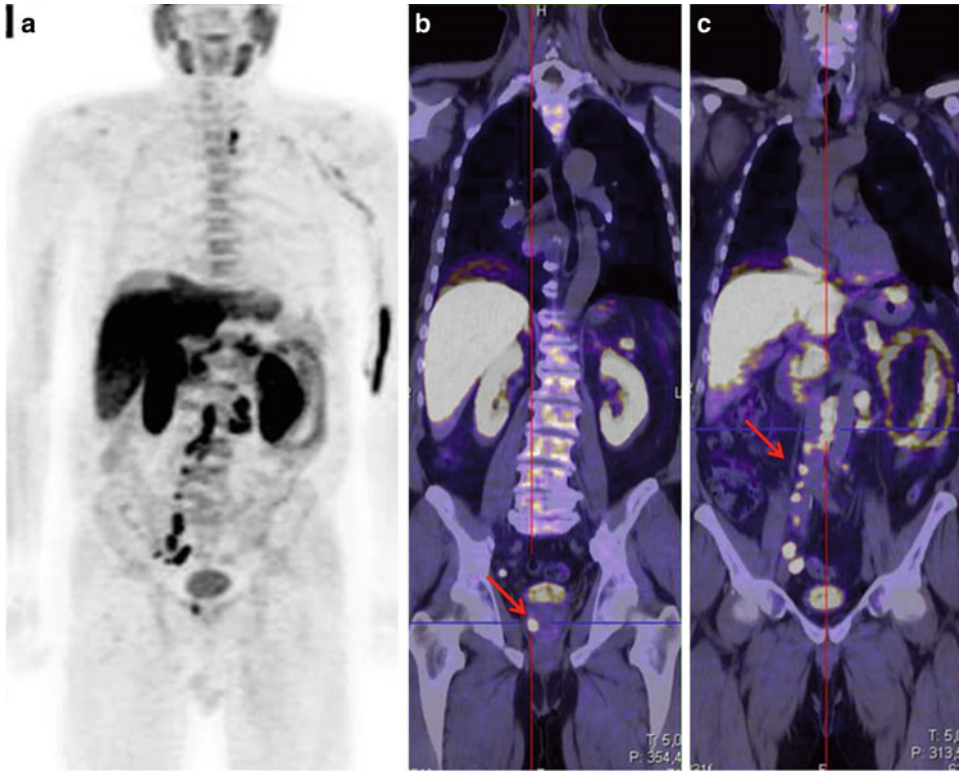

Fig. 8 Patient with increasing PSA after radical prostatectomy. This 72-year-old man had a high PSA level (36 ng/mL) at the time of initial diagnosis and underwent ^{18}F-choline PET/CT for staging. The MIP image (**a**) and coronal PET/CT images at two different depths demonstrate diffusion of the disease in the prostate (**b**) and in lymph nodes (**c**)

recurrences at radiolabeled choline PET/CT; this rate reached 75% in patients with PSA >3 ng/mL [160]. In patients with PSA values <1 ng/mL, recurrences were detected in approximately one out of three patients. The precise localization of the site of recurrence (local recurrence, recurrence as lymph node metastases, or systemic recurrence) is crucial for the choice of the subsequent treatment, as it directly influences personalized therapy. Graziani et al. published a retrospective analysis of 9,632 choline PET/CT scans performed for restaging in an academic center between 2007 and 2015. The inclusion criteria were radical prostatectomy, available levels of PSA, and proven biochemical relapse (PSA >0.2 ng/mL after radical prostatectomy or PSA >2 ng/mL above the nadir after primary EBRT with rising PSA levels); 3,203 patients matched the inclusion criteria and 4,426 scans were considered [161]. Overall, 52.8% of the [^{11}C]CHO PET/CT scans were positive. In patients with PSA levels between 1 and 2 ng/mL, 995 scans were performed and the positive rate was 44.7% with an incidence of distant findings of 19.2% and an incidence of oligometastatic disease of 37.7% These findings confirm the feasibility of [^{11}C]CHO PET/CT for detecting the site of metastatic disease in patients with confirmed biochemical recurrence.

Beheshti et al. investigated the ^{18}F-CHO PET/CT value for detecting bone metastases in patients with biochemical recurrence of disease and found that ^{18}F-CHO PET/CT had 79% sensitivity, 97% specificity, and 84% accuracy. The use of ^{18}F-CHO PET/CT for discovering skeletal metastases in general yields a detection rate

lower than conventional BS, but with greater specificity. The interpretation of focal uptakes with ^{18}F-CHO PET/CT leads to fewer false-positive and indeterminate findings and reduces the number of indeterminate lesions [162–166]. Beheshti et al. compared the diagnostic performance of ^{18}F-CHO and ^{18}F-fluoride PET/CT in 38 patients with biopsy-proven PCa for the detection of bone metastases. The authors found 81% sensitivity, 93% specificity, and 86% accuracy ^{18}F-fluoride, while the corresponding values were 74%, 99%, and 85%, respectively, for ^{18}F-CHO. In addition ^{18}F-CHO induced a change in the management in 2 out of 38 patients, due to the early detection of bone marrow metastases (bone invasion by cancer, before involvement of cortical bone) [134]. In a similar series of patients, Picchio et al. observed that [^{11}C]CHO PET/CT had lower sensitivity but higher specificity than BS in the detection of bone metastases in PCa patients with biochemical progression. The ranges of sensitivity, specificity, PPV, NPV, and accuracy for [^{11}C]CHO PET/CT were 89–89%, 98–100%, 96–100%, 94–96%, and 95–96%, respectively. For conventional bone scintigraphy, the corresponding values were 70–100%, 75–100%, 68–100%, 86–100%, and 83–90%. [^{11}C]CHO PET/CT and bone scan achieved a diagnostic concordance in 55 of 78 (71%) cases. This means that, in some selected cases, the combination of [^{11}C]CHO PET/CT with bone scan can provide additional useful information [164] (Fig. 9).

Sometimes patients with a single bone metastasis visualized by BS undergo [^{11}C]CHO PET/CT in order to obtain additional information about the extent of disease, both in bone and in other organs. In fact, some authors reported that PET/CT is able to depict multiple bone metastases and may provide images of bone lesions in up to 15% of patients with biochemical relapse after radical prostatectomy [167]. A recent article by Ceci et al. including 304 bone lesions from PCa found some differences in terms of SUV and PSA kinetics at [^{11}C]CHO PET/CT among osteoblastic lesions, osteolytic lesions, and bone marrow involvement. Osteoblastic lesions showed lower values of SUV_{max}, while osteolytic lesions had higher values. This interesting approach can represent an important proposal for classifying skeletal involvement [168] and may be of interest in terms of treatment choice and patient management.

Evaluation of response to treatment is a very critical issue, since in the clinical practice, this evaluation has a strategic role. The use of morphological and functional imaging criteria (e.g., with CT, PET, MRI) for assessing response to therapy is already well established, but its application and interpretation are, at present, still a matter of discussion (Fig. 10).

Radiolabeled CHO PET/CT has been proposed as biomarker for response evaluation in PCa patients, and the PERCIST criteria (PET response criteria in solid tumors) might be applied to this purpose. Furthermore, quantitative parameters such as the metabolically active tumor volume and SUV derivatives are under study, and some preliminary confirmations were obtained as prognostic parameters (related to overall survival) or as tool for assessing the efficacy of treatments [169–171].

^{68}Ga-PSMA-Ligand PET/CT and PSMA Derivates

The prostate-specific membrane antigen (PSMA) is a cell surface membrane-bound enzyme highly expressed in prostate carcinoma cells versus benign prostatic tissue. The localization of the catalytic site of PSMA in the extracellular domain allowed for the development of small specific inhibitors that are internalized after ligand binding [172, 173].

PSMA ligands have been labeled with different radionuclides enabling the use for PET imaging (^{89}Zr, ^{68}Ga, and ^{18}F), for single-photon scintigraphy (^{111}In, ^{99m}Tc), or for therapy (^{177}Lu, ^{90}Y) [174]. ^{111}In-capromab pendetide (a monoclonal agent against the intracellular epitope of PSMA) has been approved for clinical use to visualize PSMA expression by the FDA in 1996, with the trade name of ^{111}In-ProstaScint [175]. The use of this radiopharmaceutical has then been progressively abandoned in clinical practice, since the antibody cannot bind the intracellular domain of PSMA of intact cells, but only

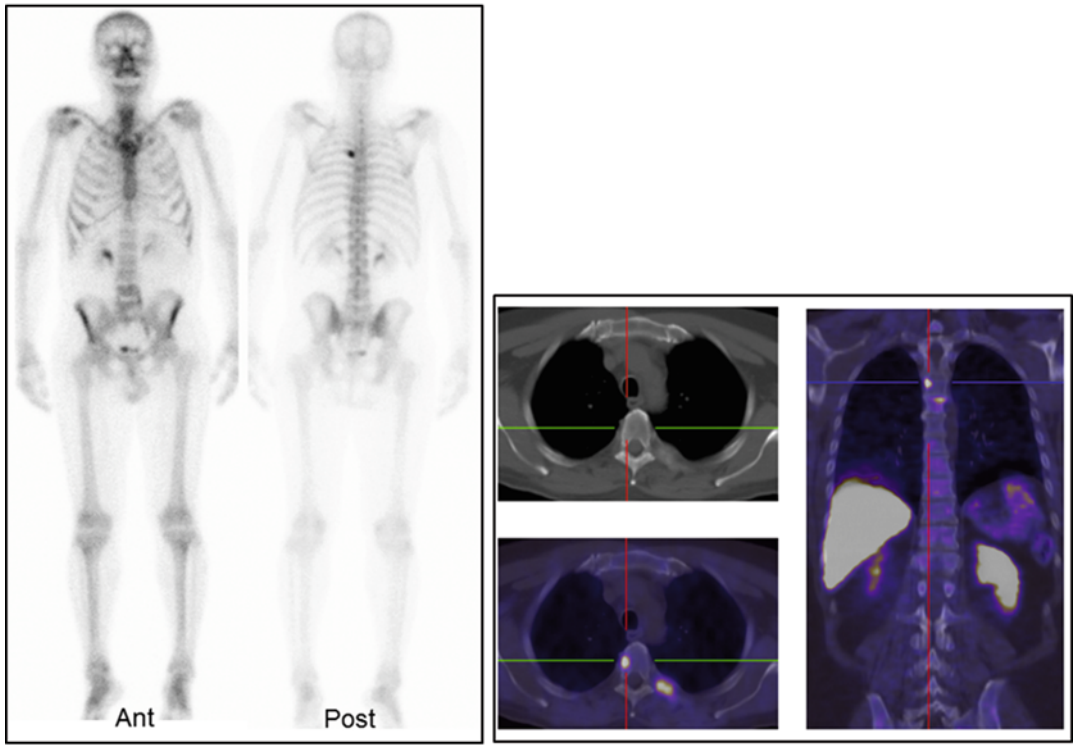

Fig. 9 Mismatch between BS and ^{18}F-choline PET/CT findings. (*Left*) The bone scan shows a single focus of uptake in the fourth left rib. (*Right*) ^{18}F-choline PET/CT confirms focal uptake in the fourth left rib but also in the right hemibody of T4

PSMA exposed in either apoptotic or dead cells. Therefore, the diagnostic performances of this immunoscintigraphic modality, in spite of some acceptable results, are not comparable with those that can be obtained with the most recent radiopharmaceuticals and novel PET/CT modalities for PCa assessment. Alternative monoclonal preparation probes targeting the extracellular domain of PSMA are under study, and a new ^{99m}Tc-labeled radiopharmaceuticals are being developed [176]. The ^{68}Ga-PSMA-ligand represents the most promising agent for the evaluation of patients with early biochemical recurrence of disease. Many studies have been published comparing the diagnostic performances of radiolabeled choline PET/CT with those of ^{68}Ga-PSMA-ligand PET/CT.

Preliminary studies demonstrated that PET/CT with the ^{68}Ga-PSMA-ligand (Glu-NH-CO-NH-Lys-(Ahx)-^{68}Ga(HBED-CC)), an inhibitor of the extracellular portion of PSMA molecule, resulted in significantly higher accuracy for the detection of early recurrence compared to ^{18}F-choline PET/CT [177]. These investigations also reported a higher tumor-to-background ratio for ^{68}Ga-PSMA-ligand PET/CT for the detection of suspected PCa metastases versus ^{18}F-choline PET/CT; moreover, highly promising performances were reported also at very low PSA levels.

Conversely, few data are available about the use of ^{68}Ga-PSMA-ligand PET/CT for the primary diagnosis of PCa. Fendler at al. recently evaluated the accuracy of this modality to localize cancer in the prostate and surrounding tissue at initial diagnosis. ^{68}Ga-PSMA-ligand PET/CT was able to detect invasion of the seminal vesicles and the extracapsular tumor spread [178].

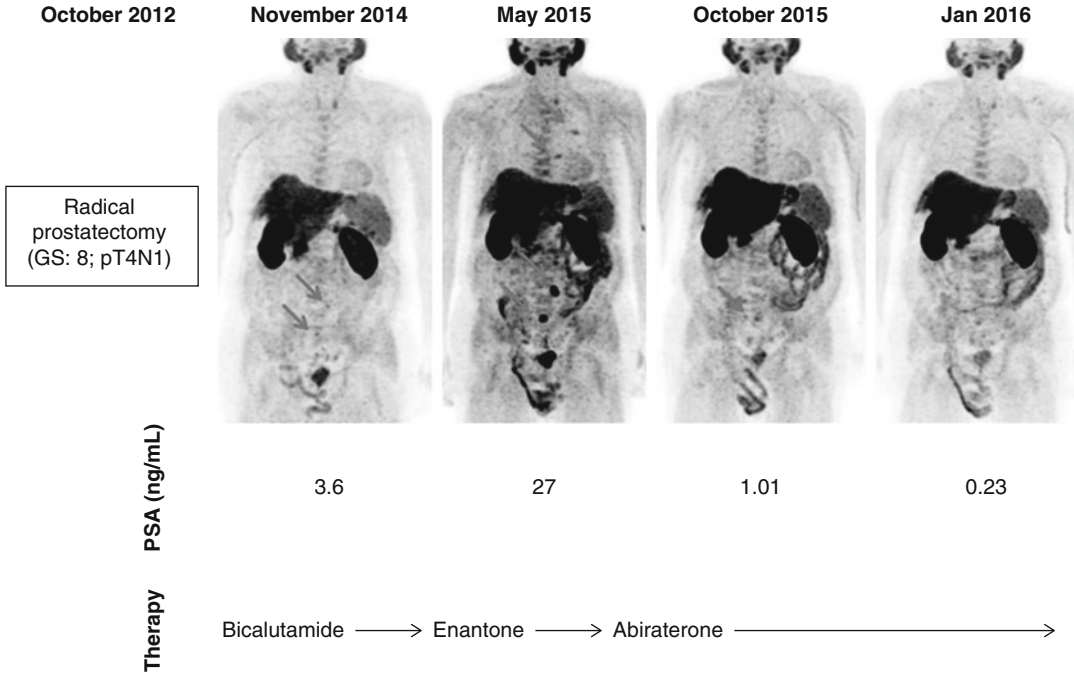

Fig. 10 Evaluation of response to therapy with ^{18}F-choline PET/CT. A 73-year-old with PCa shows progressively increasing PSA level during androgen deprivation therapy (bicalutamide). For this reason, therapy was switched to Enantone, then again to abiraterone acetate for further increasing serum PSA. The serial ^{18}F-choline PET/CT scans show a significant reduction in ^{18}F-choline uptake in the lymph nodes, after the start of treatments, particularly with abiraterone acetate

The combined use of ^{68}Ga-PSMA-ligand PET with multiparametric MRI can enable targeted fusion biopsies, especially in patients with a negative biopsy. At present, these preliminary experiences are too limited [179].

Interesting results were reported by Maurer et al. regarding primary staging of PCa patients. In a retrospective analysis on 130 consecutive patients with intermediate- and high-risk PCa who had radical prostatectomy with lymph node dissection, ^{68}Ga-PSMA-ligand PET/CT showed a 65.9% sensitivity and 98.9% specificity [180]. Conversely, Budaus et al. evaluated 30 PCa patients who underwent radical prostatectomy and lymph node dissection, using a preoperative ^{68}Ga-PSMA-ligand PET/CT for the identification of lymph node involvement, reporting overall sensitivity, specificity, PPV, and NPV of ^{68}Ga-PSMA-ligand PET/CT for the detection of lymph node metastasis of 33.3%, 100%, 100%, and 62.9%, respectively. Moreover, per site analysis revealed values of 27.3%, 100%, 100%, and 52.9% [181]. ^{68}Ga-PSMA-ligand PET/CT is able to detect visceral and skeletal lesions not visible by other modalities [182]. In recurrent disease, Afshar-Oromieh et al. studied 319 patients with PCa [177]. In this series, despite the non-homogeneous features of the patients' population (mean PSA 161 ng/mL, median PSA 4.59 ng/mL, 28 patients not treated with radical therapies), ^{68}Ga-PSMA-ligand PET/CT showed an overall detection rate of 82.8%. A detection rate of 50% was observed for serum PSA values <0.5 ng/mL and of 58% for PSA values ranging from 0.5 to 1 ng/mL. Interestingly, the detection rate was not influenced by the Gleason score or by ADT (Fig. 11).

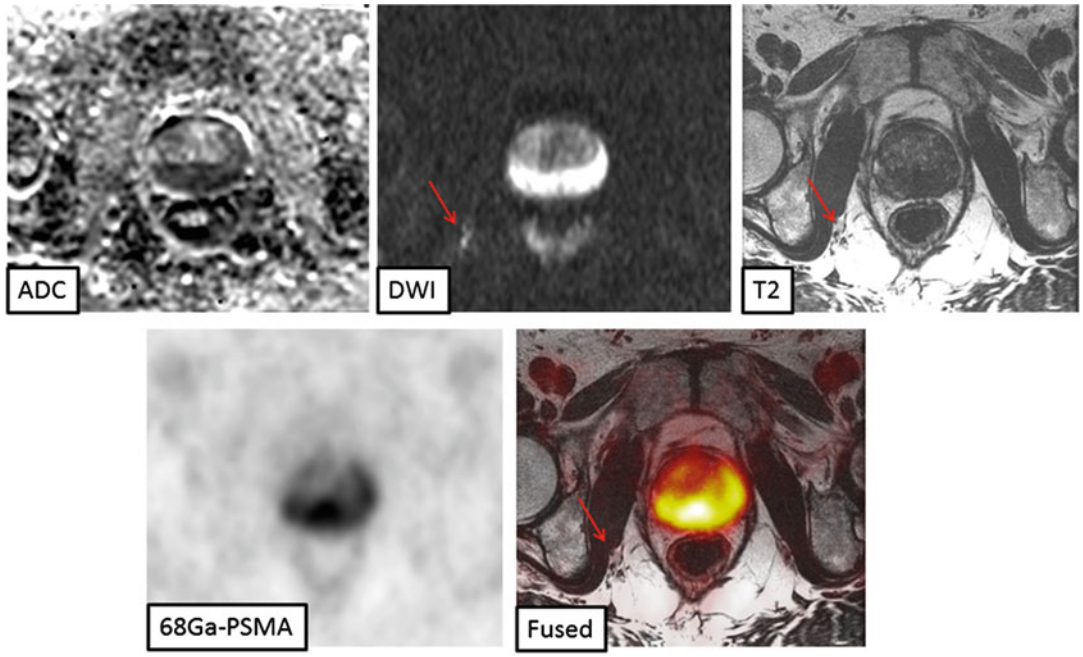

Fig. 11 A 59-year-old patient with PCa showing a slight increase in serum PSA level (0.6 ng/mL) after radical prostatectomy. The ^{68}Ga-PSMA-ligand PET/MRI shows significant tracer uptake in a right internal iliac lymph node (Images supplied by courtesy of Thomas A. Hope, Department of Radiology and Biomedical Imaging, University of California, San Francisco, California, USA)

In a cohort of 248 recurrent patients with median PSA of 1.99 ng/mL, Eiber et al. reported an overall positivity of 89.5% for ^{68}Ga-PSMA-ligand PET/CT [183]. Verburg et al. evaluated with ^{68}Ga-PSMA-ligand PET/CT the extent of disease in 151 patients with recurrent PCa. The imaging results were correlated to PSA levels, PSA doubling time, and GS [184]. In this study, the presence of recurrent lesions was correlated with absolute PSA levels and PSA kinetic. The detection rate resulted in 30% of GS values of less than 8 and 32% for values between 8 and 10. This finding confirms other data suggesting that PSMA overexpression is not directly related to GS and that fast PSA kinetics are more likely to be associated with a positive PSMA-ligand scan.

A critical review was recently published by Perera et al. [185]. Sixteen articles involving 1,308 patients were analyzed. ^{68}Ga-PSMA-ligand PET was positive in 40% of patients for primary staging and in 76% for biochemical recurrences. Positive ^{68}Ga-PSMA PET scans for biochemical recurrences increased with the pre-PET PSA value. For the PSA categories 0–0.2, 0.2–1, 1–2, and >2 ng/mL, the rates of positive scans were 42%, 58%, 76%, and 95%, respectively. A shorter PSA doubling time increased the PET/CT positivity. The conclusions indicate a favorable sensitivity and specificity profile, compared to choline-based imaging techniques, particularly in case of low PSA levels. New emerging indications for ^{68}Ga-PSMA-ligand PET/CT are in the management of radiotherapy [186].

At present, the most widely applied indication for ^{68}Ga-PSMA PET/CT is the detection of recurrent disease and restaging of treated patients. This modality seems to increase the rate of detection, even with serum PSA values <0.5 ng/mL [187]. Despite these promising findings, the results obtained up to now with ^{68}Ga-PSMA-ligand PET/CT have not been extensively validated

with either histology (biopsy of the areas of uptakes) or with lesion-directed imaging techniques characterized by high specificity. Furthermore, the overall clinical experience is still limited and derived from retrospective series and mostly from German institutions. For these reasons, further prospective studies and larger series of patients should be investigated in order to confirm the promising results.

A number of alternative radiopharmaceuticals to ^{68}Ga-PSMA-ligand are being explored, and the most interesting radiopharmaceuticals under development today are PSMA-ligand-based fluorinated compounds. The advantages of ^{18}F over ^{68}Ga are mainly based on the wider availability of the tracer without problems in production and distribution and better quality of imaging because of the favorable emission energy of ^{18}F for PET imaging. Two radiopharmaceuticals at present raise the interest of the nuclear medicine community: ^{18}F-DCFBC (N-[N-{(S)-1,3-dicarboxypropyl] carbamoyl} 4-^{18}F-fluorobenzyl-L-cysteine]) and ^{18}F-DCFPyLis (2-[3-{1-carboxy-5-[(6-[^{18}F]fluoro-pyridine-3-carbonyl)-amino]-pentil}-ureido]-pentanedioic acid). Both ^{18}F-DCFBC and ^{18}F-DCFPyLis exhibit favorable parameters in terms of radiation dosimetry, and biodistribution [188, 189]. Preliminary data in a limited series of patients suggest advantages of both tracers versus the current imaging modalities; however, these data require further confirmation in large-scale clinical trials [190, 191].

^{18}F-FACBC PET/CT

The anti 1-amino-3-^{18}F-fluorocyclobutane-1-carboxylic acid (^{18}F-FACBC or ^{18}F-fluciclovine) is a synthetic L-leucine analogue characterized by an excellent uptake in PCa cell lines [192]. The uptake is mediated through three L large-neutral amino acid sodium-independent systems, involving transporters related to proliferation and angiogenesis [193, 194]. ^{18}F-FACBC was initially evaluated in PCa patients with recurrence after radical treatment. This radiopharmaceutical has recently obtained FDA approval (May 2016).

Biodistribution and radiation dosimetry studies of ^{18}F-FACBC in healthy volunteers demonstrated that the organs with the highest initial uptake are the liver, red bone marrow, lung, and pancreas. Bone marrow demonstrates moderate and heterogeneous uptake, similarly as skeletal muscles [195–197]. A retrospective analysis by Kairemo et al. evaluated the role of ^{18}F-FACBC PET/CT in 26 patients with treated PCa related to PSA concentrations, PSA doubling time, and correlative images [198]. ^{18}F-FACBC PET/CT scans found 58 lesions: 12 (20.7%) were due to local relapse in the prostate bed and seminal vesicles, 9 (15.5%) were located in regional lymph nodes, 10 (17.2%) in distant lymph nodes, and 26 (44.8%) in the skeleton. The mean serum PSA level in ^{18}F-FACBC-positive patients was higher than in the negative patients (9.5 versus 1.9 ng/mL), and PSA doubling time was shorter in patients with metabolically active uptake.

Turkbey et al. carried out a study in 21 patients with localized PCa, benign prostate hyperplasia, and normal prostate, who underwent dynamic and static abdominopelvic ^{18}F-FACBC PET/CT and multiparametric MRI before robotic-assisted prostatectomy [198]. SUVs of ^{18}F-FACBC PET/CT were compared with the MR findings and histopathologic analysis was carried out. Sector-based comparison with histopathologic analysis revealed 67% sensitivity and 66% specificity for ^{18}F-FACBC PET/CT versus 73% and 79% for T2-weighted MRI. The sensitivity of combined PET and multiparametric MRI to localize tumors was 90%. The uptake of ^{18}F-FACBC was higher in intraprostatic tumor foci than in normal tissue; however, ^{18}F-FACBC uptake is similar in cancer as in benign prostate hyperplasia. Therefore, even though ^{18}F-FACBC turned out not to be specific for PCa, the combined use of PET/CT and MRI can enable a more accurate localization of cancer [199].

A retrospective analysis was performed in 53 patients with suspected recurrent prostate carcinoma and negative BS who underwent ^{18}F-FACBC PET/CT and diagnostic CT within 90 days. ^{18}F-FACBC PET/CT and CT were

positive in 41 (77.4%) and 10 (18.9%) patients, respectively. Positive rates were higher for ^{18}F-FACBC PET/CT than for CT, at all ranges of PSA concentration, PSA doubling time, and GS. ^{18}F-fluciclovine PET/CT had diagnostic performance superior to those of CT, both for detecting lesions in the prostate bed and for imaging metastases in extraprostatic regions. For 51 patients with a follow-up adequate enough to correctly evaluate the diagnostic performances in the prostate bed, the sensitivity, specificity, accuracy, PPV, and NPV were 88.6%, 56.3%, 78.4%, 81.6%, and 69.2% for ^{18}F-FACBC PET/CT and 11.4%, 87.5%, 35.3%, 66.7%, and 31.1% for CT, respectively. In 41 patients evaluated for lesions in extraprostatic regions, the corresponding values for ^{18}F-FACBC PET/CT were 46.2%, 100%, 65.9%, 100%, and 51.7%, respectively, versus 11.5%, 100%, 43.9%, 100%, and 39% for CT, respectively [200].

A prospective clinical trial was published by Shuster et al. who compared ^{18}F-FACBC PET/CT with ^{111}In-ProstaScint in 93 PCa patients with recurrent PCa [201]. ^{18}F-FACBC PET/CT was positive in 77 (82.8%) patients, including 49 (63.6%) in the prostate/bed only, 24 (31.2%) in the prostate/bed and in extraprostatic regions, and 4 (5.2%) only in extraprostatic regions. In 70 of 93 patients with a definitive consensus on extraprostatic disease, ^{18}F-FACBC demonstrated 55% sensitivity, 96.7% specificity, 72.9% accuracy, 95.7% PPV, and 61.7% NPV, figures significantly higher than with ^{111}In-ProstaScint scintigraphy.

In spite of very limited data published in the literature ^{18}F-FACBC has shown some favorable characteristics in comparison with CHO-PET/CT in terms of acquisition protocol, biodistribution, and image quality [199]. The very low excretion of this radiopharmaceutical in the urinary tract improves the detection of small lesions in the pelvis and namely in the prostatic region. The very rapid uptake in prostate cells and its very fast blood clearance allows the acquisition of images 4–5 min after the injection. The first study comparing ^{18}F-FACBC with [^{11}C]CHO PET/CT has been published by Nanni et al. who conclude that the detection rate with ^{18}F-FACBC PET/CT is better than with [^{11}C]CHO PET/CT, regardless of the PSA levels [202]. Therefore, this radiopharmaceutical may be useful for the primary diagnosis, staging and for restaging patients after treatment. Further studies are needed to confirm these preliminary results.

[^{18}F]FDG PET/CT

[^{18}F]FDG is a biomarker of the expression of glucose transporters (mainly GLUT-1) and hexokinase enzymatic activity in tissues [203]. GLUT-1 is overexpressed in poorly differentiated PCa cell lines [204]. The expression of GLUT-1 is modulated by androgens [205]; however, such enhanced expression occurs not only in PCa but also in benign prostatic hyperplasia. Furthermore, a strong correlation exists between GLUT-1 expression and GS [206–208].

Nevertheless, [^{18}F]FDG PET is not recommended for the diagnosis and staging of organ-confined PCa, nor for the detection of locally recurrent disease, because of the overlap of the intense activity accumulated in the urinary bladder on tumor uptake. Furthermore, [^{18}F]FDG is not a cancer-specific molecular probe and the tracer localizes in areas of wound healing, and inflammatory conditions [207–209]. However, [^{18}F]FDG uptake in PCa increases in advanced clinical disease high PSA levels, and elevated GS [210].

There is limited experience on the detection of lymph node metastases by [^{18}F]FDG PET/CT in patients with biochemical recurrence after potentially curative therapy [211, 212]. Chang et al. evaluated the performance of [^{18}F]FDG PET in 24 patients with rising serum PSA levels after treatment for PCa and who had negative findings on bone scan and equivocal CT results [213]. For the detection of metastatic pelvic lymph nodes, [^{18}F]FDG PET/CT showed 75% sensitivity, 100% specificity, 83.3% accuracy, 100% PPV, and 67.7% NPV. Schoder et al. reported that [^{18}F]FDG uptake was higher in patients with treatment failure and was associated with higher PSA levels [214]. Moreover, using ROC analysis, the authors found that the best compromise between the optimal

sensitivity and specificity would be reached for a PSA concentration of 2.4 ng/mL (80% and 70% respectively) and a PSA velocity of 1.3 ng/mL per year (71% and 77%, respectively). Since [^{18}F]FDG uptake is associated with metabolic activity, [^{18}F]FDG PET/CT can be useful for to assess tumor response to treatment. In a preclinical study, Zhang et al. evaluated immunodeficient mice harboring prostate tumor cell line CWR22 xenografts, by performing [^{18}F]FDG microPET to assess [^{18}F]FDG uptake before, during, and after treatment with a proteasome inhibitor (bortezomib). The reduction observed in [^{18}F]FDG uptake was more reliable than the reduction in tumor volume as a parameter of response to therapy [215].

Zukotynski et al. performed [^{18}F]FDG PET/CT, ^{18}F-NaF PET/CT, and standard ^{99m}Tc-MDP bone scintigraphy in nine patients with CRPC before and after 8 weeks of therapy with abiraterone and cabozantinib [216]. They found that the intensity of uptake of ^{18}F-NaF PET/CT in bone lesions did not predict response to treatment, while [^{18}F]FDG PET/CT enabled to stratify patients into three groups (widespread cancer [^{18}F]FDG-avid versus oligometastatic [^{18}F]FDG-avid versus non-[^{18}F]FDG-avid metastases). This approach could drive the choice of a tailored appropriate treatment. Another recent investigation showed that [^{18}F]FDG PET could be useful for assessing response to treatment with a mTOR inhibitor, everolimus, in combination with docetaxel [217]. Yu et al. compared [^{11}C]acetate and [^{18}F]FDG PET/CT for assessing treatment response to androgen deprivation therapy in eight patients with >3 PCa metastases on bone scintigraphy [218]. A lesion-by-lesion analysis of [^{18}F]FDG PET was performed by Morris et al. in 17 patients with progressive metastatic PCa with 134 skeletal lesions [219]. Ninety-five lesions (71%) were detected on both the [^{18}F]FDG PET and the bone scans, 31 lesions (23%) were only seen on the bone scan, and 8 lesions (6%) were seen only on [^{18}F]FDG PET scan. All metabolically active lesions on the [^{18}F]FDG PET were noted to be active on the follow-up bone scans (thus suggesting true-positive findings on PET). The authors concluded that the added value of [^{18}F]FDG is to identify metabolically active lesions from those scintigraphically quiescent. The extent and the intensity of [^{18}F]FDG uptake in metastatic lesions may also provide prognostic information. In fact, a >33% increase in the average SUV_{max} of metastatic lesions or the appearance of new lesions assigned patients to different groups: patients in progression versus patients with stable disease.

The prognostic value of bone scan and [^{18}F]FDG PET/CT was evaluated also by Meirelles et al. in a prospective trial in 43 men with metastatic CRPC [220]. This study demonstrated that the overall survival was inversely correlated with SUV_{max} obtained from the skeletal uptake. In patients with a median survival of 14.4 months SUV_{max} was >6.10, while it was ≤6.10 in patients with a median survival of 32.8 months. Although the BSI was also prognostic, in the multivariate analysis only SUV_{max} of [^{18}F]FDG uptake resulted an independent factor as a predictor of survival.

Vargas et al. evaluated 38 patients with metastatic CRPC who underwent CT, [^{18}F]FDG PET and ^{18}F-16β-fluoro-5-dihydrotestosterone (^{18}F-FDHT) PET/CT [221]. The number of lesions seen on CT, [^{18}F]FDG, and ^{18}F-FDHT PET was significantly associated with overall survival. However, in this trial, the association between tracer uptake and survival was demonstrated only with ^{18}F-FDHT, while it was not seen with the intensity of [^{18}F]FDG uptake.

On the contrary, a positive relationship was found by Jadvar et al. who showed in a multivariate analysis, after considering several confounding factors (such as age, PSA and serum AP levels, use of pain medication, prior chemotherapy, and GS at diagnosis) that the sum of SUV_{max} of up to 25 metabolically active lesions (lymph nodes, bone, and soft tissue metastases) was statistically significant as a predictor of overall survival [222].

The current clinical experience with [^{18}F]FDG PET/CT suggests this radiopharmaceutical has less to offer for clinical management compared

Table 4 Pros and cons of diagnostic imaging modalities and their current applications for PCa in clinical practice

	Pros	Cons	Current clinical indications
TRUS	1. Wide availability	1. Sensitivity is limited by the high number of isoechoic tumors originating in the peripheral zone	1. To guide prostate biopsies
	2. Possibility to perform biopsy	2. Reduced sensitivity in detecting transition zone tumors	2. To deliver local treatments such as brachytherapy
	3. No radiations	3. Inability to detect the anterior portion of the gland	3. To monitor cryotherapy treatment
CT	1. Wide availability	1. High radiation dose	1. Initial staging (for lymph node disease)
	2. Allows assessment of fine bone details and characterization of smaller lesions	2. Not used for systematic bone screening	2. Recurrence of disease
	3. Allows detection of lymph node and visceral metastases	3. Not useful for assessing response to therapy	3. Evaluation of response to therapy (RECIST criteria v. 1.1)
MRI	1. Good availability	1. Bone metastases outside vertebral spine or pelvic bones are not detected (in case of spinal MRI)	1. Active surveillance
	2. Earlier detection of tumor foci	2. Advanced diagnostic techniques only available in diagnostic imaging centers of excellence	2. Initial staging (for primary tumor and locoregional lymph node involvement)
	3. Better diagnostic performance in detection and characterization of bone lesions	3. Longer duration of examination, higher costs	3. Recurrence of disease (particularly in prostatic fossa)
	4. Highest diagnostic performance in detection and characterization of bone lesions		
	5. Allows detection of lymph node and visceral metastases		
	6. Possible role of DWI in assessment of response to therapy		
BS	1. Low cost	1. Low sensitivity for osteolytic lesions	1. Initial staging of disease (bone involvement)
	2. Wide availability	2. Does not detect bone marrow disease	2. Recurrence of disease (high PSA levels)
	3. Detection of bone metastases several months before they are revealed by planar x-ray	3. Poor sensitivity for osteolytic lesions without bone remodeling	3. Assessment of response to therapy
		4. Low specificity (false-positive findings in case of degenerative changes, inflammatory processes, trauma, mechanical stress, and Paget's disease)	
		5. Necessity of bone reactive changes to achieve the optimal sensitivity	
		6. Flare phenomenon due to some systemic treatments (also ^{223}Ra)	

(*continued*)

Table 4 (continued)

	Pros	Cons	Current clinical indications
SPECT	1. Improves the sensitivity of planar images	1. Limited field of view	1. See BS
		2. No improvement in terms of specificity over planar images	2. Not standardized
		3. As bone scan (*see above*)	
SPECT/CT	1. Improved sensitivity over planar images	1. Whole-body imaging with this modality is not currently standard practice	1. See BS
	2. Improved specificity over planar images	2. Resource implications of increased cost, specialist equipment, and specialist manpower hours	2. Not standardized
		3. Increased radiation dose than BS (from 3 to 5 mSv)	
		4. As bone scan (*see above*)	
^{18}F-fluoride PET/CT	1. The extraction of fluoride from the blood is rapid. The first-pass extraction is 100% vs. 64% for diphosphonates	1. Very sensitive to minimal degenerative changes	1. Restaging of disease (as an alternative to BS)
	2. Superior image quality and therefore high diagnostic accuracy	2. High costs	2. Assessment of response to therapy (in some clinical trials and as an alternative to BS)
	3. Rapid acquisition protocol (after 15 or 60 min from the injection)	3. Clinical impact when used to monitor treatment response is uncertain	
	4. As for ^{99m}Tc-diphosphonate is able to identify high bone turnover and remodeling	4. Flare phenomenon due to some systemic treatments (also ^{223}Ra)	
	5. Quantitative and automatic semiquantitative analyses of uptake in the lesions		
[^{18}F]FDG PET/CT	1. Can detect bone metastases at early stage of disease (bone marrow involvement)	1. Sclerotic metastases can be missed due to the relatively small amount of viable tumor tissue	1. Restaging of disease in patients with undifferentiated tumors (GS>8)
	2. In case of osteolytic lesion and in presence of aggressive prostatic cancer, tracer accumulation is higher for an increase in the glycolytic rate	2. [^{18}F]FDG uptake is limited in moderately or well-differentiated prostate cancer	
	3. Lack of FDG uptake in the osteoblastic lesion can be associated with the present of quiescent cells	3. Higher costs and increased radiation dose versus BS (from 3 to 5–7 mSv)	
	4. Superior image quality and therefore high diagnostic accuracy		
	5. Prognostic information		
	6. Quantitative and automatic semiquantitative analyses of uptake in the lesions		
[^{11}C]/^{18}F-CHO PET/CT	1. More specific for prostate cancer	1. Flare phenomena reported during the administration of abiraterone acetate and GCSF	1. Restaging of disease (based on PSA levels and PSA kinetic)
	2. Able to identify three patterns of bone disease (bone marrow	2. [^{11}C]CHO is not available in centers without an on-site cyclotron	2. Assessment of f response to therapy

(*continued*)

Table 4 (continued)

	Pros	Cons	Current clinical indications
	involvement, osteoblastic lesions, no active tumor)		
	3. No uptake in chronic degenerative bone disease	3. High costs and increased radiation dose versus BS (from 3 to 5–7 mSv)	
	4. Quantitative and automatic semiquantitative analysis of uptake in the lesions		
^{68}Ga-PSMA-ligand PET/CT	1. More specific for prostate cancer	1. PSMA expression is apparently differentially regulated by androgens	1. Restaging of disease (based on PSA levels and PSA kinetic)
	2. High detection rate, in the recurrence setting, for low PSA level	2. It is still considered an experimental imaging agent	
	3. Able to detect all sites of prostate cancer recurrences (lymph nodes, bone, visceral sites)	3. High costs and increased radiation dose versus BS (from 3 to 5–7 mSv)	
	4. No uptake in chronic degenerative bone disease	4. High costs for the production of the radiotracer	
	5. Quantitative and automatic semiquantitative analyses of uptake in the lesions		
^{18}F-FACBC PET/CT	1. More specific for prostate cancer	1. High uptake in the muscles	1. Restaging of disease (based on PSA levels and PSA kinetic)
	2. Higher detection rate, in the recurrence setting, than [^{11}C]CHO	2. It is still considered an experimental imaging agent	
	3. It is able to detect all sites of prostate cancer recurrences (lymph nodes, bone, and visceral sites)	3. High costs and increased radiation dose versus BS (from 3 to 5–7 mSv)	
	4. No uptake in chronic degenerative bone disease		
	5. Quantitative and automatic semiquantitative analysis of uptake in the lesions		

to more specific radiopharmaceuticals targeting PCa, although the intensity of [^{18}F]FDG uptake in lesions might be an independent predictor of overall survival [223].

Clinical Considerations

PCa is evolving both in terms of development of new therapeutic options and in terms of better definition of strategies for cancer cure and/or management. For this reason, a general overview of the available modalities of imaging in the different steps of PCa can be useful, as summarized in Table 4.

Based on the overall considerations reported in this chapter and on the current strategy of treatment for PCa patients, in closing this chapter, the author proposes a flow chart including a reasonable approach for the management of PCa patients, according to the state of the art of general knowledge on the diagnostic and therapeutic armamentarium currently available. (Fig. 12).

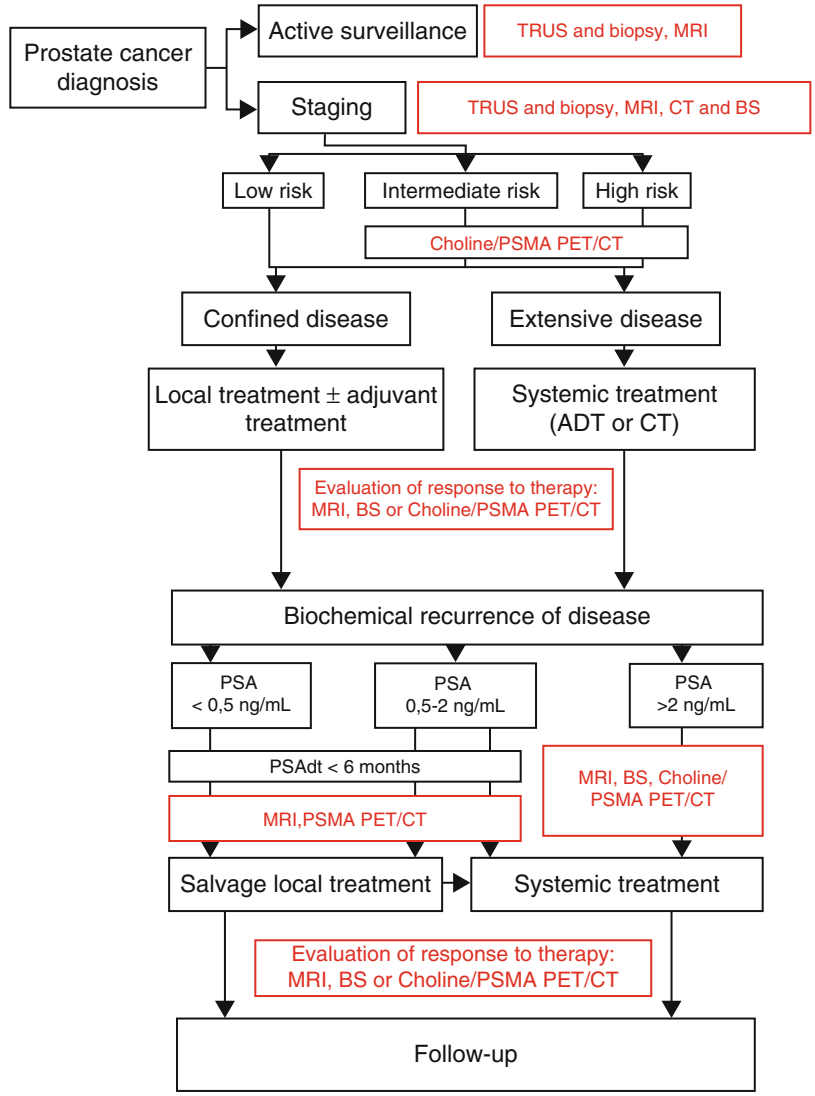

Fig. 12 A suggested diagnostic flow chart for patients with PCa. *TRUS* transrectal ultrasonography, *MRI* magnetic resonance imaging, *CT* computed tomography, *BS* bone scintigraphy, *PSMA* ^{68}Ga-PSMA-ligand PET/CT

Aknowledgments The authors are grateful to Dr. Thomas A. Hope, Department of Radiology and Biomedical Imaging, University of California (USA), for his scientific contribution and to Ms. Annaluisa De Simone Sorrentin for her kind editorial assistance.

Diagnostic Applications of Nuclear Medicine: Testicular Cancer

32

Abedallatif AlSharif, Serena Chiacchio, and Giampiero Giovacchini

Abstract

Testicular cancer is the most common solid-non hematological cancer diagnosed in young adult men. Personal history of testicular cancer is a major risk factor for developing testicular cancer. Testicular germ cell tumors are the most common tumors, these are further divided into seminomas and non seminomatous germ cell tumors. Tumors generally present as painless testicular mass, the first investigation is testicular ultrasound followed by serum biomarkers. MRI can be used as a problem solver only in equivocal cases. Radical orchiectomy provides therapy as well as pathological T staging. CT scan is the primary investigation for assessing lymph node status and for evaluation of distant metastasis. [^{18}F]FDG PET/CT is not recommended for diagnosis of primary testicular cancer with reported unsatisfactory negative predictive value. Nevertheless PET/CT offers several advantages over CT particularly for patients with equivocal CT findings and in patients who exhibit elevated tumor markers and negative CT scan. In addition, [^{18}F]FDG PET/CT is especially useful for evaluation of post chemotherapy residual masses in metastatic seminoma. [^{18}F]FDG PET/CT is, however, not routinely indicated for post chemotherapy evaluation of non seminomatous germ cell tumors because of high false negative rate in teratomas.

Keywords

PET/CT • Testicular cancer • Seminoma • Germ cell tumor • Non germ cell tumor • Teratoma

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
AFP	α-Fetoprotein
AJCC	American Joint Committee on Cancer
Beta-hCG	Beta-human chorionic gonadotropin
BRAF	Gene encoding for the B-Raf protein, a serine/threonine-protein kinase (also known as the proto-oncogene B-Raf and v-Raf murine sarcoma viral oncogene homolog B)

C-KIT	Proto-oncogene encoding for tyrosine-protein kinase Kit (or CD117), also known as mast/stem cell growth factor receptor (SCFR)
CT	X-ray computed tomography
CXCR4	Gene encoding for C-X-C chemokine receptor type 4 (CXCR-4), also known as fusin or CD184 (cluster of differentiation 184)
EGFR	Epidermal growth factor receptor; the mutated form EGFRvIII plays a prominent role in tumorigenesis and proangiogenic signaling
GCT	Germ cell tumor
IGD	In greatest dimension
IGF	Insulin-like factor
LDH	Lactate dehydrogenase
M	Metastasis status according to the AJCC/UICC TNM staging system
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
NCCN	National Comprehensive Cancer Network
NSGCT	Nonseminomatous germ cell tumor
p53	Tumor protein p53, also known as cellular tumor antigen p53, phosphoprotein p53, tumor suppressor p53, antigen NY-CO-13, or transformation-related protein 53 (TRP53)
PET	Positron emission tomography
PET/CT	Positron emission tomography/Computed tomography
RAS	Oncogene regulating signaling cascades
SDF-1	Gene encoding for the stromal cell-derived factor 1, also known as C-X-C motif chemokine 12 (CXCL12)
SNP	Single nucleotide polymorphism
SPECT	Single-photon emission tomography
SPECT/CT	Single-photon emission tomography/Computed tomography
T	Tumor status according to the AJCC/UICC TNM staging system
TGCT	Testicular germ cell tumor
TNM	AJCC/UICC staging system based on parameters "T" (tumor status), "N" (lymph node status), and "M" (distant metastasis status)
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
ULN	Upper limit of normal range

Epidemiology of Testicular Cancer

The incidence of testicular cancer was estimated at 5.6 cases per 100,000 men in the United States in 2011, with a rising trend over the past decades in the United States and in the Western world in general [1]. Testicular cancer can affect men at all ages; its incidence peaks at ages between 25 and 29 years, with 14.3 cases diagnosed per 100,000 men per year in this age group. With this incidence, testicular cancer is the most common solid non-hematological cancer diagnosed in young adult men. There is a wide variability of incidence of testicular cancer among different races, the highest rates being reported among Caucasians and the lowest rates among Blacks and Asians. In the United States, the incidence of testicular cancer in White Americans is fivefold more common than in Black Americans and fourfold more common than in Asians [1].

Risk Factors

Personal history of prior testicular cancer is a major risk factor for developing testicular cancer, as there is actually a 12-fold increase in the risk of developing another testicular cancer in patients with prior cancer in the contralateral testicle [2]. In addition, 2% of germ cell testicular cancers is bilateral at presentation. History of surgically uncorrected undescended testicle increases the risk for developing testicular cancer by up to eightfold; this risk remains high in cases where surgical correction was performed after puberty [2]. There is a growing body of evidence suggesting that exposure to toxic substances increases the risk of testicular cancer. The main substances with a potential association with testicular cancer include organic chlorides, polychlorinated biphenyls, polyvinyl chlorides, phthalates, marijuana, and tobacco [1]. Prenatal exposure to estrogens has been suggested as a risk factor as well, although this notion remains controversial [1]. Male infertility increases the risk of developing testicular cancer by nearly threefold, an observation that suggests a common etiology between testicular cancer and the testicular dysgenesis syndrome, Hiwi protein and chromosome 12 aneuploidy, DNA mismatch repair, and Y chromosome instability [1]. Microcalcifications are often seen on testicular ultrasonography; although this finding is not known to be a risk factor per se, testicular tumors are more likely to be found in young men with microcalcifications than in those without [1, 3].

Histologically, the presence of intratubular germ cell tumor (carcinoma in situ) is considered to be a well-established risk factor for testicular cancer. Intratubular germ cell tumors are frequently seen in surgical specimens of orchiectomy and in the contralateral testis of patients with history of testicular cancer [1].

Genetic Predisposition

There is evidence that family history of testicular cancer is a significant risk factor for developing the disease, and it has been estimated that sons or brothers of patients with testicular cancer are at a six- to tenfold higher risk of developing the cancer themselves. It is not clear, however, whether this familial risk factor is genetic or environmental. Furthermore, linkage analysis studies have failed to identify any significant genetic linkage in these cases of familial testicular germ cell tumors (TGCTs) [1, 4].

In sporadic cases, the most common genetic alteration in patients with infertility is a deletion of 1.6 Mb (deletion gr/gr) in the AZF region of the Y chromosome, which doubles the risk for developing TGCTs [5]. In addition, at least 25 single nucleotide polymorphism (SNPs) associated with genetic predisposition in several chromosomal regions have been identified in patients with TGCTs; these SNPs most likely increase genetic susceptibility to develop TGCT [5]. Although these SNPs may be biologically

significant, they account for less than 20% of the familial risk of TGCTs [5].

Underlying Molecular Biology Changes

A number of molecular alterations have been described in testicular germ cell tumors. C-KIT mutations are the most common single-nucleotide variations, with 10% of all TGCTs and 20% of seminomas harboring a C-KIT mutation microsatellite instability (MSI); BRAF mutations are associated with chemo-refractory TGCT. One study has shown evidence for epidermal growth factor receptor (EGFR) amplification as a possible genetic aberration associated with chemoresistance [6]. A small subset of TGCTs (predominantly seminomas) have mutations in this RAS oncogene family, but these mutations are of unclear clinical and pathobiologic significance. TP53 mutations are not common in TGCTs; however, overexpression of wild-type p53 may be seen at immunohistochemistry [5, 7].

Genomic DNA methylation studies have shown a contrast in methylation patterns between TGCT tissue and normal tissue, as well as between seminoma and normal tissue (generally decreased/hypomethylated) versus nonseminomatous TGCT (generally methylated) [5, 7].

Skakkebæk proposed a model that suggests that fetal gonocytes beyond normal development in spermatogonia could present abnormal cell division mediated by a receptor/SCF kit, a paracrine circuit leading to uncontrolled proliferation of gonocytes. The subsequent invasive growth is mediated by stimulation of postnatal and pubertal gonadotropins [5, 8]. A second model proposed by Chaganti and Houldsworth suggests that aberrant chromatid exchange during meiotic division could lead to block p53-dependent apoptotic response and to cell cycle reset, therefore to genomic instability [5, 9].

Several molecular mediators in the testicular microenvironment have recently been associated with the transition from germ cell tumor in situ to an aggressive phenotype of TGCT cells. Several data indicate that the IGF-1/IGF1R and SDF-1/CXCR4 signaling pathways are important mediators in the pathogenesis of TGCTs and also in the acquisition of phenotypic features associated with metastatic ability, such as proliferation, differentiation, migration, cellular survival, and angiogenesis [5].

Histopathology of Testicular Cancer

Testicular germ cell tumors (TGCTs) are the most common testicular cancers, as this group constitutes approximately 95% of all testicular cancers. TGCTs arise from the germinal epithelium in seminiferous tubules. Other rare sites of GCTs are the pineal gland, neurohypophysis, mediastinum, and retroperitoneum [1, 7, 10].

TGCTs are currently subdivided according to the 2004 World Health Organization (WHO) classification into seminomas and nonseminomatous germ cell tumors (NSGCTs). Pure seminomas are the most common TGCTs, accounting for approximately 50% of all TGCTs. Typically, seminomas occur in older men when compared with NSGCT; the mean age of patients at presentation is 40 years, and more than 80% occur after the age of 30. The clinical and pathological diagnosis of a seminoma is restricted to pure seminoma histology and a normal serum concentration of α-fetoprotein (AFP). Seminomas are chemo- and radiosensitive, and these tumors are characterized by a high 5-year survival – reaching approximately 95% [1, 7].

NSGCTs are clinically more aggressive than pure seminomas and often include multiple cell types including embryonal cell carcinomas, choriocarcinomas, yolk sac tumors, and teratomas. Approximately one-third of TGCTs contain mixed features of seminomas and NGCTs; when both features of seminomas and NSGCT are present, clinical management is adopted according to guidelines for nonseminoma tumors. These mixed neoplasms are actually the second most common testicular cancer after seminomas [1, 7, 10].

Pure embryonal carcinomas are only occasionally encountered, whereas choriocarcinomas and yolk sac tumors are rarely seen after puberty. Yolk sac tumor is the most common testicular cancer in boys younger than 2 years. Pure choriocarcinomas

are exceedingly rare; in contrast to other TGCTs, choriocarcinomas usually present with symptoms of metastasis rather than as a testicular mass. Teratomas are further classified into mature or immature type, depending on cell differentiation. Rarely, a teratoma histologically resembles a somatic cancer, such as sarcoma or adenocarcinoma, and is then referred to as a teratoma with malignant transformation. Pure teratoma is uncommon in the postpubertal setting, accounting for fewer than 5% of all TGCTs. In children, prepubertal pure teratoma comprises nearly one-third of the testicular tumors; mature prepubertal teratomas are benign and do not metastasize. Postpubertal teratomas may be associated with metastasis in approximately one-third of the cases and typically contain other TGCT components [1, 7, 10].

Non-germ cell tumors are rare and comprise approximately 5% of testicular cancers; they include Leydig cell, Sertoli cell, and granulosa cell tumors. In men older than 60 years, lymphoma is the most common testicular malignancy. Other rare testicular tumors include leukemia, sarcoma, leiomyoma, vascular tumors, fibromas, and neurofibromas [7, 10, 11].

Serum Biomarkers

The serum tumor markers α-fetoprotein (AFP), lactate dehydrogenase (LDH), and beta-human chorionic gonadotropin (beta-hCG) are critical in the diagnosis and management of TGCTs. These serum tumor-associated markers should be evaluated before and after treatment, as well as throughout follow-up. Serum tumor markers are very useful for monitoring all stages of nonseminomas and in monitoring metastatic seminomas. AFP is a serum tumor marker produced by nonseminomatous cells (i.e., embryonal carcinoma, yolk sac tumor) and may be seen at any stage. The half-life of AFP (a glycoprotein that can be considered as the fetal precursor of serum albumin) in serum is 5–7 days. In the absence of testicular malignancy, AFP elevation can occur in infants under 1-year-old, during liver dysfunction (hepatitis, cirrhosis, hepatocellular carcinoma), and in other non-testicular malignancies (liver, pancreatic, gastric, lung). In testicular cancer, AFP is never associated with pure seminoma [12–14].

In patients with choriocarcinomas, beta-hCG is always elevated; it is also elevated in up to 10% of patients with pure seminomas and in some patients with seminomatous or other nonseminomatous tumors. Elevations of beta-hCG must be interpreted with caution, as its serum levels can be abnormally increased in patients with hypogonadism or in marijuana users; its half-life in serum is 1–3 days. LDH (an enzyme with a half-life in serum of 5–7 days) is a less specific marker than either AFP or beta-hCG; it can be elevated in both seminomas and NSGCTs, and high serum levels typically indicate bulky or extensive disease [13, 14].

Clinical Presentation, Staging, and Prognostic Stratification

A testicular tumor typically presents as a painless testicular mass. After history taking and physical examination, the first-line diagnostic test is testicular ultrasound (US), which remains the cornerstone of primary imaging in patients with testicular cancer and should be performed on both testicles. Once a suspected tumor is confirmed, the measurement of serum tumor markers including AFP, beta-hCG, and LDH is the next step for diagnosis and staging. Patients with confirmed testicular tumor must undergo computed tomography (CT) examination of the chest, abdomen, and pelvis as an integral part of the staging evaluation. Bone scan or spine MRI is indicated only in patients with bone pain. Brain MRI is indicated in patients with symptoms, in patients with lung metastasis, and in patients with high beta-hCG levels [14, 15].

Radical inguinal orchiectomy provides therapy-oriented as well as diagnostic and staging information. In particular, orchiectomy provides definitive histopathology information regarding tumor subtype and is considered curative for nearly 80% of low-stage seminomas and for approximately 60–70% of low-stage NSGCTs [14, 15].

The correct interpretation of serum biomarkers, in conjunction with correct histopathology reading and interpretation of CT images, is the mainstays of

Table 1 TNM classification of testicular cancer

pT: primary tumor[a]	
pTX	Primary tumor cannot be assessed
pT0	No evidence of primary tumor (e.g., histologic scar in the testis)
pTis	Intratubular germ cell neoplasia (testicular intraepithelial neoplasia)
pT1	Tumor limited to the testis and epididymis without vascular/lymphatic invasion; tumor may invade tunica albuginea, but not tunica vaginalis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion or tumor extending through into the tunica albuginea with involvement of tunica vaginalis
pT3	Tumor invades the spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades the scrotum with or without vascular/lymphatic invasion
N: regional lymph nodes (clinical)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass ≤2 cm IGD or multiple lymph nodes, none >2 cm IGD
N2	Metastasis with a lymph node mass >2 cm but not >5 cm IGD or multiple lymph nodes with any one mass >2 cm but not >5 cm IGD
N3	Metastasis with a lymph node mass >5 cm IGD
pN: pathologic lymph nodes	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass ≤2 cm IGD and ≤5 positive nodes, none >2 cm IGD
pN2	Metastasis with a lymph node mass >2 cm but not >5 cm IGD; or >5 nodes positive, none >5 cm IGD; or evidence of extranodal tumor extension
pN3	Metastasis with a lymph node mass >5 cm IGD
M: distant metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional lymph node(s) or lung
M1b	Other sites
S: serum tumor markers	
SX	Serum marker studies not available or not performed
S0	Serum marker levels within normal limits
S1	LDH <1.5 × ULN and hCG <5,000 mIU/mL and AFP <1,000 ng/mL
S2	LDH 1.5–10 × ULN or hCG 5,000–50,000 mIU/mL or AFP 1,000–10,000 ng/mL
S3	LDH >10 × ULN or hCG >50,000 mIU/mL or AFP >10,000 ng/mL

IGD in greatest dimension, *LDH* lactate dehydrogenase, *hCG* human chorionic gonadotropin, *AFP* α-fetoprotein, *ULN* upper limit of normal range

[a]Except for pTis and pT4, for which radical orchiectomy is not always necessary for classification purposes, the extent of the primary tumor is classified after radical orchiectomy. In other circumstances, TX is used if no radical orchiectomy has been performed

patient staging and prognostic stratification. Tables 1 and 2 summarize TNM staging of testicular cancer [14–16]. The pathologic T stage of the tumor is assigned according to the presence or absence of lymphovascular invasion and depth of invasion (tunica vaginalis, spermatic cord, scrotal involvement). During human development, the gonads are formed in the abdomen at the lumbar level, approximately at 21 weeks after conception; the testicles begin migration to the inguinal canal and then descend into the scrotum by 30 weeks after conception. As a result, blood supply and lymphatic channels drain to the abdominal retroperitoneal nodes, and typically not to the pelvis, unless scrotal violation has occurred. Metastasis from testicular cancer occurs via predictable lymphatic channels to retroperitoneal lymph nodes for right- or left-sided primary tumors (pT) [17–19]. Right-sided tumors typically spread to the aortocaval lymph nodes inferior to the renal hilar vessels, while left-sided tumors commonly spread to the left para-aortic lymph nodes. Para-aortic and aortocaval lymph nodes at the level of the kidneys are usually the first lymph node stations affected by metastasis from testicular cancer. While the spread from the right to the left retroperitoneal lymph nodes is seen frequently, the spread from left to right has never been reported [17–19].

Similarly as in other solid cancers, sentinel lymph node biopsy has been suggested as an approach to reduce the morbidity associated with de novo lymph node dissection, which currently

Table 2 Stage grouping for testicular cancer

Stage	T	N	M	Serum tumor marker
Stage 0	pTis	N0	M0	S0, SX
Stage I	pT1–T4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2–T4	N0	M0	S0
Stage IS	Any patient/TX	N0	M0	S1–3
Stage II	Any patient/TX	N1–N3	M0	SX
Stage IIA	Any patient/TX	N1	M0	S0, S1
Stage IIB	Any patient/TX	N2	M0	S0, S1
Stage IIC	Any patient/TX	N3	M0	S0, S1
Stage III	Any patient/TX	Any N	M1a	SX
Stage IIIA	Any patient/TX	Any N	M1a	S0, S1
Stage IIIB	Any patient/TX	N1–N3	M0	S2
	Any patient/TX	Any N	M1a	S2
Stage IIIC	Any patient/TX	N1–N3	M0	S3
	Any patient/TX	Any N	M1a	S3
	Any patient/TX	Any N	M1b	Any S

constitutes the recognized standard of care for proper N staging of patients with stage I testicular cancer. Funicular block using 2% lidocaine is followed by intratesticular injection of 60–100 MBq ^{99m}Tc-nanocolloidal albumin in 0.2 mL. Early dynamic anterior and lateral images for 10 min are then acquired; subsequently, delayed images at 2 h, preferably with SPECT/CT technique, are obtained (see Fig. 1). Intraoperatively, sentinel lymph nodes are localized and resected under the guidance of a handheld gamma probe; the additional use of a dedicated portable gamma camera can also be useful. As in other types of solid cancers, the identification of early metastasis in sentinel lymph nodes offers proper early treatment (elective lymph node dissection of the affected lymphatic basin) while avoiding overtreatment in patients without metastatic disease. Using this technique, no recurrences developed after a median follow-up of 21 months in patients with stage I testicular cancer and negative sentinel lymph nodes [20].

Distant hematogenous metastasis is rare in testicular cancer, ranging from an uncommon event seen in patients with choriocarcinomas to even less frequent occurrence in yolk sac tumors. Distant hematogenous spread may be seen in the lung, liver, brain, bones, kidney, adrenal gland, gastrointestinal tract, or spleen [1, 14, 15].

A prognostic staging system is used to assist treatment recommendations for patients with metastatic testicular cancer. This system was developed by the International Germ Cancer Collaborative Group in 1997 and classifies patients into either good, intermediate, or poor prognostic groups on the basis of histology, site of primary tumor, metastatic disease, and serum tumor markers (see Tables 2 and 3) [14–16, 21].

Overall Performance of Diagnostic Imaging Other than Nuclear Medicine

Scrotal ultrasound (US) examination is the initial primary imaging procedure for any patient with suspected testicular tumor. US can distinguish between intratesticular lesions (which are commonly malignant) and extra-testicular lesions (which are usually benign). Tumors typically present as a hypoechoic lesion, which can be heterogeneous with calcific or cystic changes particularly in NSGCT; in addition, blood flow is increased within the tumor or at its fibrous septa on Doppler

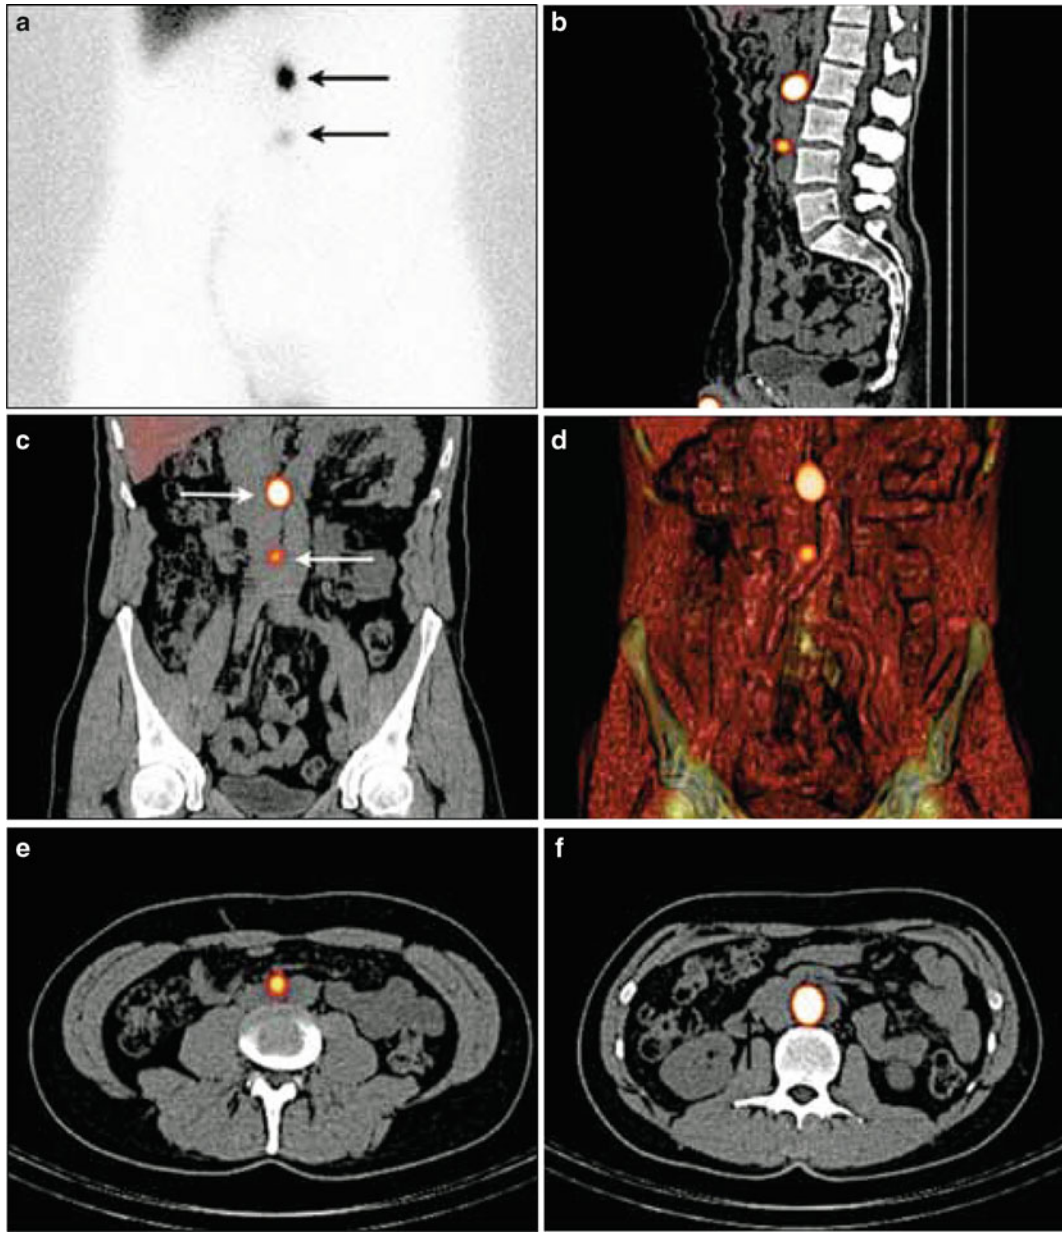

Fig. 1 Preoperative lymphoscintigraphy in a 42-year-old patient with cancer in the right testicle; abdominal CT showed no enlarged lymph nodes. ^{99m}Tc-nanocolloidal albumin (87 MBq) was injected intratumorally under ultrasound guidance. Static planar imaging was acquired about 30 min postinjection, a ^{57}Co flood source being placed beneath the patient's body in order to delineate the body outline; SPECT/CT was acquired about 2 h postinjection. (**a**) Early planar anterior image showing lymphatic drainage to two abdominal sentinel lymph nodes (*arrows*). (**b**) Sagittal SPECT/CT image fusion showing the injection site (at the very *bottom* of the image) and both sentinel nodes along the great abdominal vessels. (**c**, **d**) The coronal SPECT/CT image fusion and 3D volume-rendered image reveal that both sentinel lymph nodes are located interaortocavally (*arrows*). (**e**, **f**) Axial SPECT/CT fused images provide additional information about anatomic location of the two sentinel lymph nodes. Both nodes were harvested laparoscopically and were tumor-free at histopathology (Reproduced with permission from Brouwer et al. [53])

imaging. Overall, US has a high reported sensitivity (92–98%) in detecting testicular cancer, with a specificity of 95–99.8%. False-positive US findings have been reported in patients with testicular infarction, hematoma, or infection as these conditions may also present as mass-like structures with variable blood flow on Doppler images [22–25].

Testicular microlithiasis is a common finding on US examination, with an incidence of 5% in young healthy adults; this is 1,000 times greater than the incidence of testicular malignancy. Testicular microlithiasis in an otherwise normal testicular US scan does not predispose to testicular malignancy. However, clustering of more than ten microlithiasis lesions in certain areas of the testis is associated with an increased risk of developing testicular cancer, and these areas may contain foci of carcinoma in situ [24–28].

Sonoelastography is a new US technique that quantifies the stiffness of tissues; real-time sonoelastography has high sensitivity and specificity for discriminating malignant from benign lesions of the testis, as most malignant testicular lesions demonstrate heterogeneous color pattern with increased stiffness values [28–30].

MRI is usually the second imaging modality of choice for testicular lesions, as it can be considered as a problem-solver procedure when the primary diagnosis is still equivocal after US examination. Low T2 signal intensity with intra-tumoral septal enhancement after contrast administration is more compatible with seminomas, whereas heterogeneous signal intensity on both T1- and T2-weighted images with cystic and necrotic components and a heterogeneous enhancement pattern indicates NSGCT [31]. The sensitivity and specificity of MRI in differentiating benign from malignant intratesticular lesions were reported at 100% and 87.5%, respectively [24, 25, 28]. This diagnostic performance can be further improved by the addition of diffusion-weighted images to routine MRI examinations, with reported sensitivity of 93.3%, specificity of 90%, positive predictive value of 87.5%, and negative predictive value of 94.7% in the characterization of intratesticular masses [32]. Furthermore, MRI can provide useful preoperative information regarding T staging, with reported accuracy of 92.8% [29, 31].

Whereas surgical pathology determines the T stage of the tumor, imaging provides both N and M components of the staging system. CT is the primary imaging technique used in staging testicular cancer, as the scan can efficiently detect lymph node metastasis in addition to distant metastasis involving the liver and lungs. Metastatic lymph nodes are identified based on size criteria, with malignant nodes usually considered to be 8–10 mm or greater in diameter. Using size criteria, abdominopelvic CT offers sensitivity of approximately 70–80%; this criterion is, however, suboptimal because testicular cancer has a high propensity for nodal micrometastases [30]. In 1997, Hilton et al. assessed preoperative CT images in 70 patients who underwent retroperitoneal lymphadenectomy and found that using 10 mm or larger as a cutoff for positive lymph nodes, the sensitivity was only 37% (with 100% specificity); of course, sensitivity improves using 4 mm as cutoff (reaching approximately 93%), associated however with reduced specificity (57%) [33]. In another study, Hudolin et al. adopted a cutoff criterion of 7–8 mm and reported 70% sensitivity and 80% specificity in patients with testicular cancer who underwent retroperitoneal lymphadenectomy [34].

It is currently recommended that lymph nodes 8 mm or larger should be considered suspicious, especially in higher-risk patients who have lymphovascular invasion, which constitute a high proportion of embryonal subtype or T category $\geq$ II [25]. In addition to size criteria, lymph nodes from NSGCT may appear heterogeneous with cystic changes [28]. Because of the growing concern regarding the frequent use of CT in young male patients, more recently MRI has been shown to be equivalent to CT scan in detecting metastatic retroperitoneal lymph nodes, when assessed by experienced specialists [35].

Nuclear Imaging for Diagnosis and Staging

There is at present no sufficient evidence justifying a recommendation to use [^{18}F]FDG PET/CT for diagnosis or staging of testicular cancer. A meta-analysis on the accuracy of the diagnostic

Table 3 Prognostic-based staging system for metastatic germ cell cancer (International Germ Cell Cancer Collaborative Group)

Group	Type	Criteria
Good prognosis	Nonseminoma (56% of cases)	All of the following criteria:
	5-year PFS 89%	Testis/retroperitoneal primary
	5-year survival 92%	No nonpulmonary visceral metastases
		AFP <1,000 ng/mL
		hCG <5,000 mIU/mL (1,000 ng/mL)
		LDH <1.5 × ULN
	Seminoma (90% of cases)	All of the following criteria:
	5-year PFS 82%	Any primary site
	5-year survival 86%	No nonpulmonary visceral metastases
		Normal AFP
		Any hCG
		Any LDH
Intermediate prognosis	Nonseminoma (28% of cases)	All of the following criteria:
	5-year PFS 75%	Testis/retroperitoneal primary
	5-year survival 80%	No nonpulmonary visceral metastases
		AFP 1,000–10,000 ng/mL or
		hCG 5,000–50,000 mIU/mL or
		LDH 1.5–10 × ULN
	Seminoma (10% of cases)	All of the following criteria:
	5-year PFS 67%	Any primary site
	5-year survival 72%	Nonpulmonary visceral metastases
		Normal AFP
		Any hCG
		Any LDH
Poor prognosis	Nonseminoma (16% of cases)	Any of the following criteria:
	5-year PFS 41%	Mediastinal primary
	5-year survival 48%	Nonpulmonary visceral metastases
		AFP >10,000 ng/mL or
		hCG >50,000 mIU/mL (10,000 ng/mL) or
		LDH >10 × ULN
	Seminoma	No patients classified as poor prognosis

Prechemotherapy serum tumor markers should be assessed immediately before administration of chemotherapy (same day)

PFS progression-free survival, *AFP* α-fetoprotein, *hCG* human chorionic gonadotropin, *LDH* lactate dehydrogenase, *ULN* upper limit of normal range

[^{18}F]FDG PET in testicular cancer has recently been published; the analysis included a total of 16 published studies, with an overall 957 [^{18}F]FDG PET scans in 807 patients. Pooled sensitivity and specificity were 75% and 87%, respectively [36]. This reported sensitivity, with a negative likelihood ratio of 0.31, is unsatisfactory to confidently exclude testicular malignancy. False-negative studies are mostly explained by small tumor volume and micrometastases; in addition, teratomas do not demonstrate significant metabolic activity on [^{18}F]FDG PET [36]. Furthermore positive findings have occasionally been reported, due to infective/inflammatory processes [36, 37].

Nevertheless, as a functional/metabolic imaging procedure (see Fig. 2), [^{18}F]FDG PET offers in principle several advantages over CT, which uses mere size criteria to define metastatic lymph node

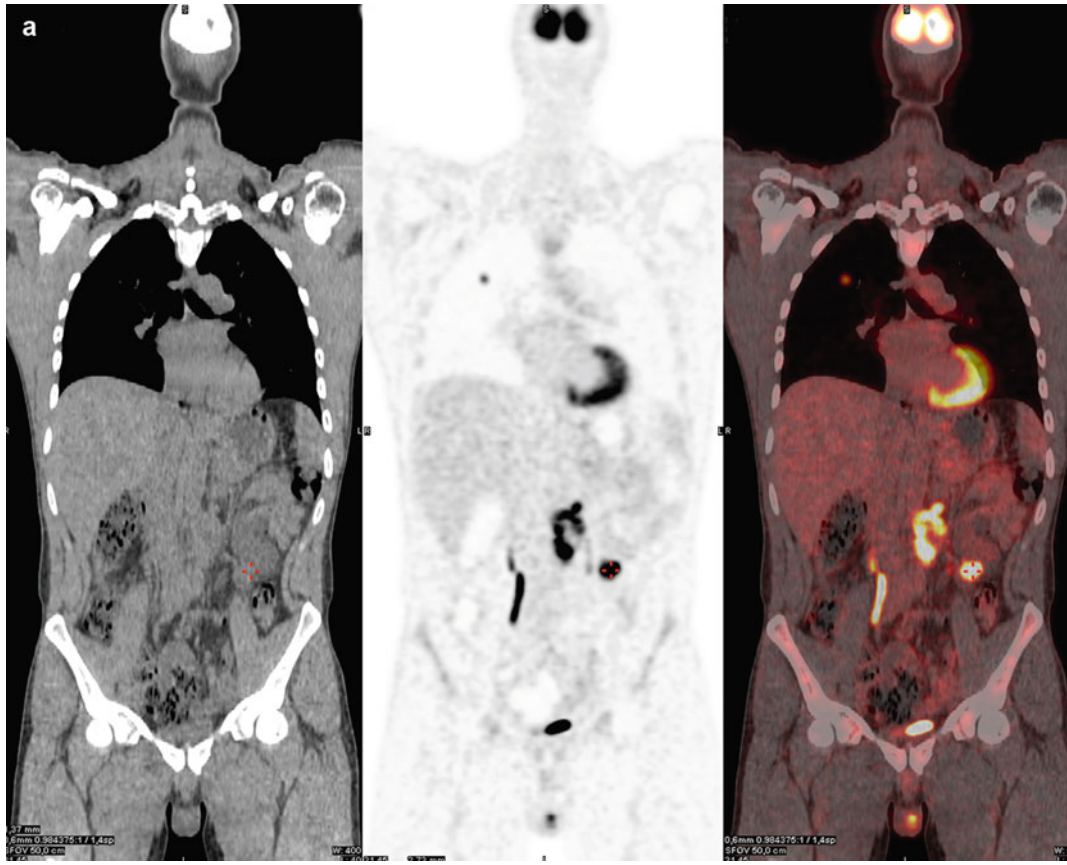

Fig. 2 (continued)

involvement. [^{18}F]FDG PET/CT can be especially useful in patients with a negative CT scan who exhibit elevated tumor markers or in patients with equivocal findings on the CT scan [38–40].

In a recent study by Gary Cook, [^{18}F]FDG PET was used at initial staging of 16 patients (ten with seminoma, five with NSGCTs, and one with mixed GCT). In 11 patients, the PET/CT scans were performed to clarify equivocal staging diagnostic CT results, usually with para-aortic lymph nodes that were in the expected drainage of the primary tumor but were less than the 1 cm cutoff size value required to be classified as positive on CT. In addition, five patients with normal primary staging CT scans but high-risk disease underwent [^{18}F]FDG PET/CT scans to aid decisions for surveillance versus adjuvant chemotherapy [41]. Eight of the 11 patients with equivocal CT scans had true-negative [^{18}F]FDG PET/CT scans, while three patients had a true-positive [^{18}F]FDG PET scan. These findings are in line with previous reports that have concluded that [^{18}F]FDG PET is most useful in patients with equivocal CT scans [38–40]. The five high-risk patients with normal staging CT scans had negative [^{18}F]FDG PET/CT scans, but two subsequently relapsed. This finding is also in line with a previous report that prospectively investigated whether [^{18}F]FDG PET could correctly detect high-risk patients without occult metastatic disease [42]. It is concluded that [^{18}F]FDG PET/CT is helpful when primary staging CT scans are equivocal, but it is insufficiently sensitive to predict relapse in high-risk patients with normal CT scans [41, 42].

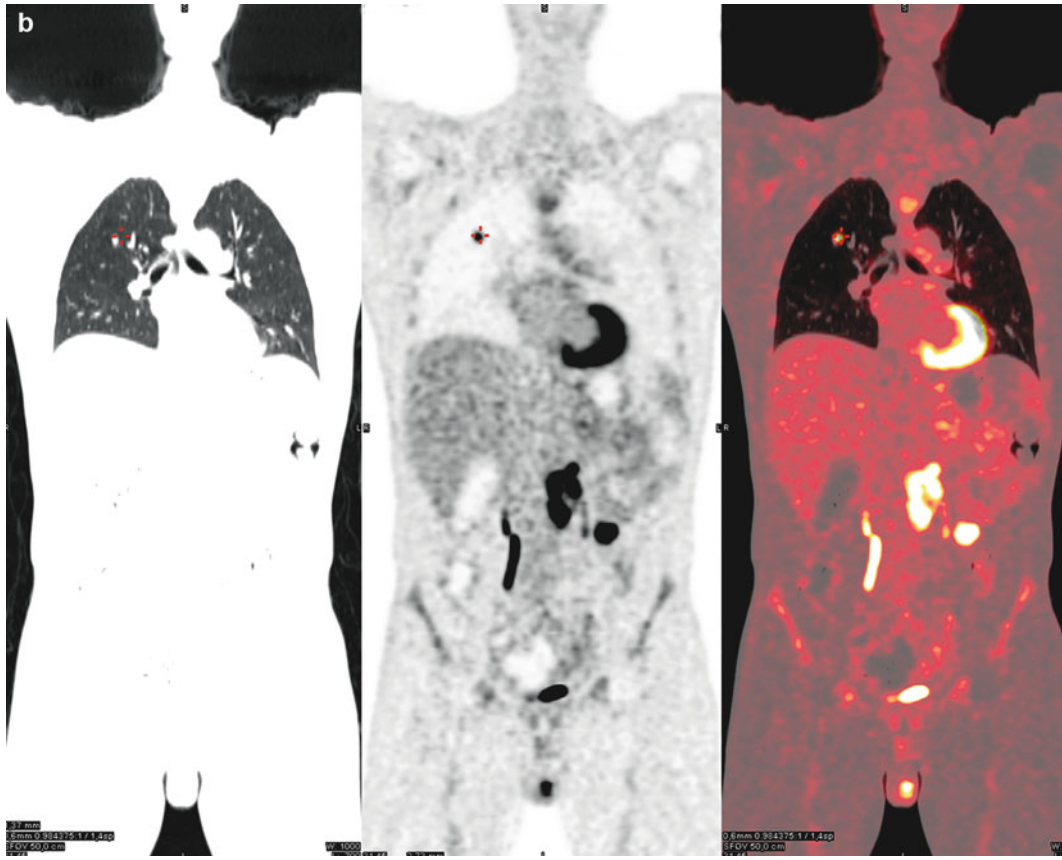

Fig. 2 (continued)

Common Therapies

Management of testicular cancer involves a multidisciplinary team including urologists, medical oncologists, radiation oncologists, and pathologists. As mentioned previously, the survival rate of testicular cancer approaches 97%; however, this high cure rate is achievable in excellent clinical settings, where diagnosis, treatment facilities, and specialized experience are available [14, 15].

One of the important points to emphasize when counseling patients with a new diagnosis of testicular cancer is that it is generally a treatable and highly curable disease. Sperm banking should be offered to the patients prior to commencement of therapy. Over 80% of men with stage I seminoma are cured by radical orchiectomy. Staging procedures reveal that 15–20% of stage I seminomas have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchiectomy alone. The decision regarding adjuvant therapy (one cycle of adjuvant carboplatin or adjuvant radiotherapy course) should be based on discussion with the patient, after explaining advantages and disadvantages based on the individual patient's situation. Most clinicians set reduced treatment long-term toxicity as a management goal in patients with stage I seminoma. The overall cancer-specific survival rate under surveillance performed by experienced centers is 97–100% for stage I seminoma [14, 15, 43].

Patients with stage I NSGCT have subclinical metastases in 30% of the cases; they will usually

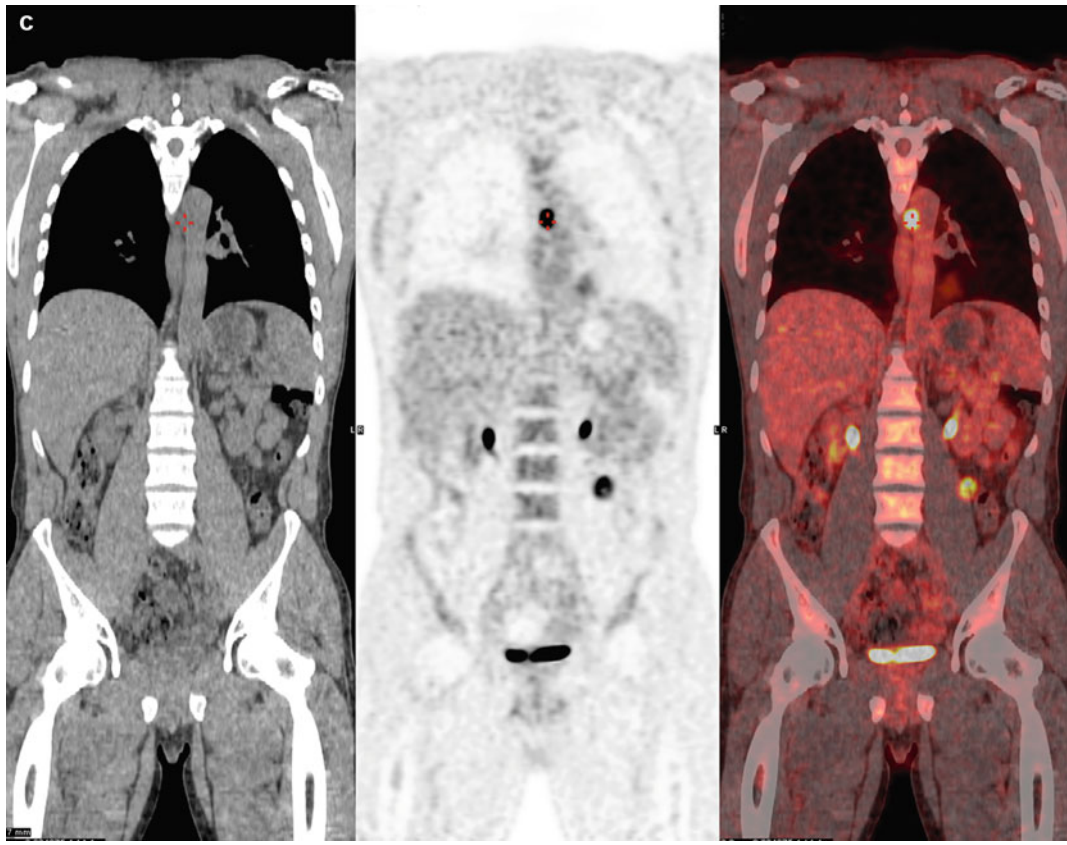

Fig. 2 [^{18}F]FDG PET/CT performed for staging in a 35-year-old male patient after incidental discovery of a mass in the right lung with associated enlarged mediastinal lymph nodes; this had originally been interpreted on CT as possible primary lung cancer with metastatic spread to mediastinal lymph nodes, although with a somewhat atypical pattern. In addition to the expected foci of increased [^{18}F]FDG uptake in the chest lesions, the PET/CT scan detected a distinct focus of increased tracer uptake in the left testicle, subsequently confirmed to be a primary seminomatous testicular cancer. (**a**) Coronal sections of the CT component (*left*), the PET component (*center*), and corresponding fused hybrid PET/CT image (*right*), showing increased [^{18}F]FDG uptake in the left testicle, in left common iliac lymph nodes, and in the mass of the right lung. (**b**) Same sections as in (**a**), but with the CT component being displayed with the imaging window for the lung. (**c**) Coronal sections of the CT component (*left*), the PET component (*center*), and corresponding fused hybrid PET/CT image (*right*) in a more posterior plane than in (**a**) and (**b**); in addition to the still visible increased [^{18}F]FDG uptake in the left common iliac lymph nodes, there is distinct tracer uptake in the aortopulmonary space

relapse if surveillance alone is undertaken after orchiectomy, mostly within the first year. The treating clinician should discuss with the patients the advantages and disadvantages of each treatment option; surveillance is usually offered to non-risk compliant patients [14, 15].

First-line treatment of stage II or stage III TGCT depends on histology of the primary tumor and on prognostic groups (see Table 3). To date, the standard treatment of stage IIA/B seminoma has been radiotherapy, with reported recurrence rates of 9–24% [14, 15]. Alternatively, these patients may undergo three courses of chemotherapy with bleomycin, etoposide, and cisplatin (BEP) or four courses with etoposide with cisplatin. Stage IIA/B NSGCT with elevated tumor markers should receive chemotherapy followed by residual tumor resection if indicated. Stage IIA/B NSGCT patients without elevated tumor markers can be managed by primary retroperitoneal lymphadenectomy or surveillance. Chemotherapy is the standard treatment of

metastatic TGCTs with varying chemotherapy protocols according to histology and prognostic stratification [14, 15].

Assessing the Efficacy of Treatment(s)

[^{18}F]FDG PET/CT is especially useful for evaluation of post-chemotherapy residual masses and metastatic seminoma, an occurrence observed in an average 25% of cases [24, 25, 28]. Several studies have reported that [^{18}F]FDG PET is superior to CT in predicting viable tumor in seminoma residuals after chemotherapy, with accuracy greater than 90% [24, 25, 28, 44, 45].

When the residual lymph node mass is larger than 3 cm in its long axis, particularly in cases with pure seminomas, surgical treatment is usually recommended [46]. However, the prospective SEMPET study has suggested that [^{18}F]FDG PET/CT can confidently differentiate residual disease from fibrosis [44]. When [^{18}F]FDG PET is negative, then there is no need to perform surgery, and the patient is put under surveillance. False-positive [^{18}F]FDG PET scans are infrequent if scans are scheduled more than 2 months after chemotherapy [15]. A retrospective validation of the SEMPET trial including 127 patients yielded sensitivity, specificity, negative predictive value, and positive predictive values of [^{18}F]FDG PET at 50%, 77%, 91%, and 25%, respectively [47]. To reduce the post-chemotherapy false-positive cases, it is currently recommended to repeat the [^{18}F]FDG PET scan at least after six additional weeks. Repeating [^{18}F]FDG PET is a helpful strategy particularly if residual disease is considered unlikely from the clinical point of view; it is also helpful to guide biopsy in those patients who otherwise can also be falsely classified as negative. If the repeat scan is not performed, the residual mass must then be biopsied [15, 39, 41, 47, 48].

[^{18}F]FDG PET is not routinely indicated for post-chemotherapy staging in NSGCT [15]. Residual masses after completion of first-line chemotherapy are found in approximately 40% of patients, even after normalization of serum tumor markers [49]. Histology of the resected lesions reveals necrosis in 40%, vital carcinoma in 20%, and mature teratoma in 40% of cases [50]. Mature teratomas are completely chemoresistant; in addition, they carry the risk of subsequent malignant transformation, and as mentioned previously, they are usually not [^{18}F]FDG avid. Therefore, tumor resection is mandatory for all patients with residual masses >1.0 cm along the short axis on CT images [15]. In a prospective trial of 121 stage IIC or III NSGCT patients, [^{18}F]FDG PET was performed after completion of chemotherapy, and the results were correlated with histopathology, CT scan, and serum tumor markers [51]. Prediction of tumor viability with [^{18}F]FDG was correct in 56% of the cases, therefore, with an accuracy that was not better than CT (55%) or tumor markers (56%). Sensitivity and specificity of [^{18}F]FDG PET were 70% and 48%, respectively. The positive predictive values were not significantly different (55%, 61%, and 59% for CT, serum tumor markers, and PET, respectively). Judging only vital carcinoma as a true malignant finding, the negative predictive value increased to 83% for [^{18}F]FDG PET. As mentioned previously, the presence of vital carcinoma and mature teratoma is common in residual masses in patients with NSGCT; this prospective, histology controlled study demonstrated that [^{18}F]FDG PET does not yield a clear additional clinical benefit with respect to the standard diagnostic procedures (CT and serum tumor markers) for predicting tumor viability in residual masses [51]. [^{18}F]FDG PET, on the other hand, can be used to localize post-chemotherapy hypermetabolic tissue and therefore serve as a guide for biopsy or surgical intervention.

Surveillance in Seminomas

The National Comprehensive Cancer Network (NCCN) has recently published clinical practice guidelines in testicular cancer, describing in details surveillance of testicular cancer according to stage of disease, histopathological findings, and treatment plan. Since a detailed discussion of the

proposed surveillance plan is beyond the scope of this chapter, we summarize here the relevant recommendation particularly regarding seminomas, where [^{18}F]FDG PET plays a major role for clinical decision-making [14].

Pure Seminoma Stage IA and IB

The relapse rate seen in these patients is 15–20% at 5 years; the risk of relapse is highest in the first 2 years, and most of the relapses are first detected in infradiaphragmatic lymph nodes. Surveillance is considered as the preferred option for patients with pT1–pT3; if surveillance is not possible, adjuvant chemotherapy or radiotherapy should be considered.

Follow-Up During Active Surveillance

It includes a medical history and physical examination, with measurement of post-orchiectomy serum tumor markers every 3–6 months for the first year, every 6–12 months for years 2–3, and annually thereafter. There is controversy regarding how many imaging studies should be performed in patients during active surveillance. The NCCN Panel recommends abdominal/pelvic CT every 3, 6, and 12 months for the first year; every 6–12 months for years 2 and 3; and then every 12–24 months for years 4 and 5. No initial relapses in the lung have been reported for patients with stage I seminoma managed by active surveillance; therefore, according to the NCCN Panel, routine chest imaging during surveillance is only indicated for patients with thoracic symptoms.

Follow-Up After Adjuvant Treatment

The risk of recurrence 5 years after adjuvant treatment is $<0.3\%$ annually. Follow-up of patients treated with adjuvant therapy includes a history and physical examination, with measurement of post-orchiectomy serum tumor markers performed every 6–12 months for the first 2 years and annually thereafter. The NCCN Panel recommends performing abdominal and pelvic CT scans annually for 3 years in patients treated with radiotherapy or carboplatin. Chest x-rays should be obtained only when clinically indicated.

Pure Seminomas Stages IIA and IIB

Follow-Up for Stages IIA and Non-bulky IIB Pure Seminoma After Radiotherapy Treatment

The recommended follow-up after radiation therapy for patients with stage IIA and non-bulky IIB tumors includes a history and physical examination, with measurement of post-orchiectomy serum tumor markers performed every 3 months for year 1 and then every 6 months for years 2 through 5. Chest x-ray is recommended every 6 months for the first 2 years. An abdominal CT scan is recommended at 3 months, then at 6 and 12 months in year 1, and then annually for years 2 and 3 after radiotherapy and as clinically indicated thereafter.

Follow-Up of Bulky Stages II A, IIB, IIC, and III Treated with Chemotherapy

After chemotherapy these patients are evaluated with serum tumor markers and a CT scan of the chest, abdomen, and pelvis. Patients are then classified according to the presence or absence of a residual mass and the status of serum tumor markers. Patients with normal markers and either no residual mass or residual mass of 3 cm or less need no further treatment. They should undergo surveillance as pure seminoma bulky stage II and stage III after chemotherapy. In cases of residual tumor >3 cm and normal marker levels, the NCCN Panel recommends an [^{18}F]FDG PET scan in these patients approximately 6 weeks after chemotherapy in order to decide whether to continue with surveillance or resume treatment. If the PET scan is negative, no further treatment is needed; however, the patient should undergo follow-up as discussed in pure seminoma bulky stage II and stage III after chemotherapy. In cases with a positive [^{18}F]FDG PET scan, retroperitoneal lymph node dissection

(RPLND) may be considered if technically feasible; alternatively, second-line chemotherapy is indicated.

Follow-Up of Pure Seminoma Bulky Stage II and Stage III After Chemotherapy

The NCCN Panel recommends follow-up schedules for patients with bulky stage II or stage III disease *after* treatment with chemotherapy *and* either no or $\leq$3 cm residual mass and normal tumor markers, including history and physical examination plus measurement of post-orchiectomy serum tumor markers every 2 months for the first year, every 3 months for the second year, every 6 months for the third and fourth years, and annually for year 5. An abdominal/pelvic CT scan is recommended at 3 and 6 months and then as clinically indicated. The [^{18}F]FDG PET scan may be performed if clinically indicated. Chest x-ray is recommended every 2 months during the first year, every 3 months during the second year, and annually during years 3 through 5. Chest CT is preferred over chest x-ray in patients with thoracic symptoms.

The NCCN Panel notes that patients with PET-negative result and tumor residual mass measuring >3 cm after chemotherapy should undergo an abdominopelvic CT scan every 6 months for the first year and then annually for 5 years.

Surveillance in NSGCT

Follow-Up for Nonseminoma Stage IA

In the updated NCCN Guidelines, the long-term follow-up tests for stage IA patients electing primary surveillance, post-RPLND, or post-chemotherapy include serum marker assessment, chest x-ray, and an abdominal CT scan.

Follow-Up for Nonseminoma Stage IB

In the updated NCCN Guidelines, the long-term routine follow-up tests for the selected patients with T2 disease undergoing surveillance and for those who underwent chemotherapy include serum marker assessment, chest x-ray, and an abdominal/pelvic CT scan. The frequency of these tests varies depending on the adjuvant management strategy.

Follow-Up for Nonseminoma Stages IIA and IIB and Metastatic Nonseminoma

After primary treatment, the subsequent management depends on tumor marker levels and the residual masses detected on CT scan; lesions less than 1.0 cm may still harbor residual disease and therefore must be interpreted with caution. [^{18}F]FDG PET scans have limited negative predictive value in patients with residual masses, but still might be useful in guiding multimodality treatment [52].

Diagnostic Applications of Nuclear Medicine: Penile Cancer

33

Serena Chiacchio, Abedallatif AlSharif, Zia Saad, Giampiero Giovacchini, and Jamshed Bomanji

Abstract

Penile carcinomas are rare in most developed countries; in contrast, this cancer is not infrequent in the tropical and subtropical regions of Latin America, Asia, and Africa. In addition, penile cancer is common in regions with high prevalence of human papilloma virus infection. More than 95% of penile carcinomas are of the squamous cell type; other histologic types include basal cell carcinoma, melanoma, and sarcoma. Penile carcinoma usually spreads through lymphatic channels to the superficial and deep inguinal lymph nodes; subsequently iliac lymph nodes are involved. The presence and extent of metastatic disease in inguinal nodes is the single most important prognostic factor in patients with penile cancer. Primary evaluation of penile cancer is based on physical examination including inguinal lymph node palpation. Ultrasound and MRI can provide information on tumor invasion of the corpora cavernosa if organ preservation is planned. Ultrasound can be used to evaluate nonpalpable inguinal lymph nodes, whereas pelvic CT scan can be used to assess pelvic lymph nodes. Lymphoscintigraphy, preferably with SPECT/CT imaging, and subsequently sentinel lymph node biopsy is gaining popularity in clinical practice, especially in patients with nonpalpable lymph nodes; sensitivity reported for this local staging approach ranges from 70% to 86%. Assessment of distant metastases should be performed in patients with positive inguinal nodes; this includes abdomen and pelvis CT, chest X-ray, or thoracic CT. [^{18}F]FDG PET/CT can be used for initial staging of penile cancer with pooled sensitivity and specificity of 80.9% and 92.4% respectively; this staging technique is particularly advocated for patients with positive lymph nodes. [^{18}F]FDG PET/CT can also be employed to monitor the efficacy of induction chemotherapy. Follow-up of penile cancer is based mainly on clinical evaluation, while radionuclide imaging techniques have rarely been used for restaging purposes during regular follow-up.

Epidemiology and Environmental Factors

Penile carcinomas are rare in most developed nations including in Europe and the USA where the rate is less than 1 per 100,000 men per year. Incidence is also affected by race and ethnicity in North America [1, 2], with the highest incidence of penile cancer found in white Hispanics (1.01 per 100,000), followed by a lower incidence in

Alaskan, Native American Indians (0.77 per 100,000), blacks (0.62 per 100,000), and white non-Hispanics (0.51 per 100,000), respectively.

In contrast, penile cancer is not infrequent in the tropical or subtropical regions of Latin America, Asia, and Africa. In South America, Southeast Asia, and parts of Africa, the incidence of penile cancer is much higher and can represent 1–2% [2, 3] of all malignant diseases in men. The annual age-adjusted incidence is 0.7–3.0 per 100,000 men in India, 8.3 per 100,000 men in Brazil, and even higher in Uganda, where it is the most commonly diagnosed cancer in men [3, 4].

Penile cancer is common in regions with a high prevalence of human papilloma virus (HPV) infection, and therefore much knowledge about penile cancer comes from research in countries with a high incidence of the disease. HPV infection in the population may account for the wide variability in incidence observed across countries, as the HPV infection prevalence varies considerably worldwide. Whereas at least one third of cases can be attributed to HPV-related carcinogenesis, there are no clear data linking penile cancer to HIV infection or AIDS.

In the USA, the overall age-adjusted incidence rate decreased between 1973 and 2002 from 0.84 per 100,000 in 1973–1982 to 0.69 per 100,000 in 1983–1992 and further declined to 0.58 per 100,000 in 1993–2002 [1, 2]. In European countries, the overall incidence has remained stable from the 1980s until today [5]. Recently, an increased incidence has been reported from Denmark [6] and the UK, where a longitudinal study has confirmed a 21% increase in incidence over the period 1979–2009 [7].

Risk Factors and Association with Other Conditions

The incidence of penile cancer increases with age [3] and have a peak during the sixth decade of life, although this disease can indeed occur in younger men [8].

Infection by the human papilloma virus is an important risk factor in the development of penile cancer. DNA of HPV has been identified in 70–100% of intraepithelial neoplasias and in 40–50% of invasive penile cancer tissue samples. The HPV virus plays an important role in oncogenesis through the interaction with oncogenes and tumor suppressor genes (p53, Rb genes) [9, 10]. The rate of HPV positive differs between different histological subtypes of penile cancer. This suggests that HPV is a cofactor in the carcinogenesis of some variants of penile SCC, while other variants of penile cancer are not related to HPV [2]. HPV subtypes most commonly found associated with penile cancer are types 16 and 18 [11]. The risk of penile cancer is also increased in patients with *condyloma acuminata* [12]. It is not clear whether HPV-associated penile cancer differs in prognosis from non-HPV-associated penile cancer. A significantly better 5-year disease-specific survival has been reported for HPV-positive versus HPV-negative cases (93% vs. 78%) in one study [13], while no difference in lymph node metastases and 10-year survival rate was reported in another study [14].

No direct association between the incidence of penile cancer and that of cervical cancer has been established yet, except the coexistent link with the prevalence of HPV infections [2, 15, 16]. In particular, female sexual partners of patients with penile cancer do not have an increased incidence of cervical cancer.

Other known risk factors for penile carcinoma include conditions such as phimosis, chronic inflammations leading to balanoposthitis and *lichen sclerosus et atrophicus*, sexual history (multiple partners, early age at first intercourse), history of condylomata, and smoking [9–17].

Around 25–60% of phimosis patients develop penile cancer at some stage of their lives [18]. The phimosis causes retention of desquamated epidermal cells and urinary products, collectively called "smegma," which leads to chronic inflammation of prepuce and glans penis causing balanitis. Sexual promiscuity which plays a major role in sexually transmitted diseases also poses increased risk of developing penile cancers.

Some, but not all, observational studies also suggest that male newborn circumcision is associated with a decreased risk of penile cancer [19, 20]. According to one study, the risk among

uncircumcised men was found to be 3.2 times higher [21], while according to another published data, if the relationship is causal, the number needed to treat is about 909 circumcisions to prevent a single case of invasive penile cancer [22]. In addition, the treatment of psoriasis by ultraviolet light in the region was also found to increase significantly the risk of cancer development [23].

Prevention

Circumcision is a precautionary measure taken by a few healthy adult subpopulations, although no published literature has shown clear advantage in adult circumcision. Similarly, smegma is blamed to be a strong risk factor, but again without any definite correlation having been published so far. Practicing better hygiene, however, has shown to decrease the risk of chronic recurrent inflammation, which is in some situations a precursor of squamous cell carcinoma (SCC).

Raising the awareness regarding sexual health and protective sex can also be considered an effective preventive measure to both privileged and poor socioeconomic countries.

There is at present no recommendation for the use of HPV vaccination in boys due to a different HPV-associated risk pattern in penile and anal cancer; furthermore, the epidemiological effects of HPV vaccination and its acceptance in girls will have to be assessed before any further recommendations can be made [24, 25]. The newer available vaccines against HPV 16 and 18 have shown to be effective with protection for around 5 years; however, their true efficacy in the long term has not yet been established [26].

Due to high rates of developing SCC of the genitalia after psoralen plus ultraviolet light A (PUVA) therapy, genitalia shielding and serial checkups should be in place [27].

Genetic Predisposition

To date no genetic predisposition to penile cancers has been identified.

Underlying Molecular Biological Changes

So far only few datasets are available linking chromosomal abnormalities in penile SCC (the predominant histological type of penile cancer) to biological pattern and patient outcomes [2, 10]. The alterations in DNA copy number found in penile carcinoma are comparable to those found in SCC of other origins. Lower copy numbers and alteration numbers in penile SCC have been linked to poorer survival. Alterations in the locus 8q24 seem to play a major role and have also been assumed to be involved in the carcinogenesis of other neoplasms such as prostate cancer [28, 29]. Telomerase activity has been demonstrated in invasive penile carcinoma [30]. It has also been reported that aneuploidy changes according to tumor grade [31].

Epigenetic alterations evaluating the methylation pattern of CpG islands in *CDKN2A* have been described as well [32]. *CDKN2A* encodes for two tumor suppressor proteins (p16INK4A and p14ARF) that control cell growth through the Rb and p53 pathways. Poetsch at al. showed that 62% of invasive SCCs of the penis displayed allelic loss of p16 and 42% promoter hypermethylation. Tumors immunohistochemically negative for p16 showed hypermethylation of and/or copy number neutral loss of heterozygosity (LOH) near the p16INK4A locus; furthermore, p16 negativity was linked to greater probability of lymph node metastasis and to poor prognosis [33]. Allelic loss of the p53 gene is a frequent event in penile SCC (42%) and has been linked to poor prognosis [34]. Another factor influencing lymph node metastasis is the metastasis-suppressor protein KAI1/CD82; in particular, decreased expression of this protein favors lymph node metastasis [35].

Staging and Prognostic Stratification

The TNM classification of penile cancer is shown in Tables 1 and 2. Ultrasound (US) is useful in evaluating suspected penile masses and has been advised for primary penile cancer deemed to invade the corpora cavernosa [36]; SCC usually

Table 1 AJCC TNM classification of penile cancer

Definitions of TNM	
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Ta	Noninvasive verrucous carcinoma[a]
T1a	Tumor invades subepithelial connective tissue without lymph-vascular invasion and is not poorly differentiated (i.e., grades 3–4)
T1b	Tumor invades subepithelial connective tissue with lymph-vascular invasion or is poorly differentiated
T2	Tumor invades corpus spongiosum or cavernosum
T3	Tumor invades urethra
T4	Tumor invades other adjacent structures
Regional lymph nodes (N)	
Clinical stage definition[b]	
cNX	Regional lymph nodes cannot be assessed
cN0	No palpable or visibly enlarged inguinal lymph nodes
cN1	Palpable mobile unilateral inguinal lymph node
cN2	Palpable mobile multiple or bilateral inguinal lymph nodes
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral
Pathologic stage definition[c]	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in a single inguinal lymph node
pN2	Metastasis in multiple or bilateral inguinal lymph nodes
pN3	Extranodal extension of lymph node metastasis or pelvic lymph node(s) unilateral or bilateral
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis[d]
Histopathological grading	
GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3-4	Poorly differentiated/undifferentiated

presents as a hypoechoic lesion with heterogeneous appearance. However, US evaluation is unreliable in the presence of microscopic invasion. On MR imaging, penile carcinoma is often a solitary, ill-defined mass infiltrating the adjacent corpora, hypo-intense on both T1- and T2-weighted images [37]. The local extent, the depth of tumor invasion, and the extension to adjacent structures can be accurately depicted using MRI, and this information is valuable for surgical planning [38].

Both clinical examination and conventional imaging techniques, including US, CT, and MRI, are unreliable in accurately detecting lymph node metastases [36]. Hence, prophylactic inguinal lymphadenectomy is often recommended, particularly in high-risk patients, with the expectation to improve survival. However, the morbidity of groin dissection is high, with complication rates between 30% and 50%, thus stimulating interest in the search for other techniques able to noninvasively assess the lymph node status and possibly reduce the need for groin dissection [39].

Grading

Tumor grade has been included into the penile cancer TNM classification because of its prognostic relevance. However, tumor grading of penile cancer according to Broder's classification has been shown to be highly observer dependent and is therefore no longer used, similarly as has occurred for the WHO grading system [40]. The currently recommended grading according to the pTNM system is reported in Table 1.

Pathologic Prognostic Factors

More than 95% of penile malignancies are of the SCC type (see Fig. 1). SCC displays multiple subtypes with different prognostic features. Other

Table 2 AJCC anatomic stages and prognostic groups for penile cancer

Group	T category	N category	M category
Stage 0	Tis	N0	M0
	Ta	N0	M0
Stage I	T1a	N0	M0
Stage II	T1b	N0	M0
	T2	N0	M0
	T3	N0	M0
Stage IIIa	T1–3	N1	M0
Stage IIIb	T1–3	N2	M0
Stage IV	T4	Any N	M0
	Any T	N3	M0
	Any T	Any N	M1

histologic types include basal cell carcinoma, melanoma, and sarcoma. The glans penis is the most common site of SCC (48%) [41].

Lymphatic Involvement

Penile carcinoma usually spreads through penile lymphatic channels to regional lymph nodes, especially the superficial and deep inguinal nodes, and subsequently to the iliac nodes. Presence and degree of lymph node involvement is the most important prognostic factor for penile carcinoma. The prevalence of nodal disease is related to the stage of the primary lesion and occurs in 20% of T1 penile cancers and in 47–66% of T2–T4 tumors [42, 43]. Between 30% and 60% of patients with penile carcinoma have palpable inguinal nodes, but nearly half of these are linked to inflammatory reaction [44]. Some tumors metastasize directly to deep inguinal nodes.

Basaloid tumors are poorly differentiated subtypes of SCC, are infiltrative, and frequently metastasize to inguinal lymph nodes. The prognosis for survival in patients with lymph node metastases is closely correlated with the number and location of involved lymph nodes and with the presence of extranodal extension [9, 45]. Involvement of deep

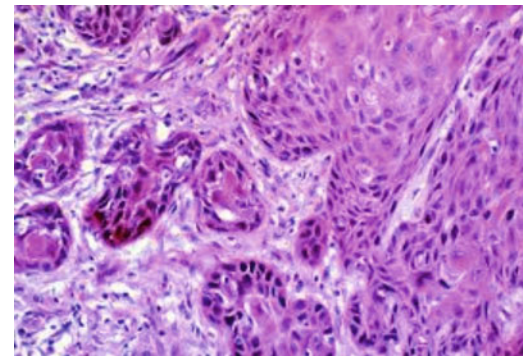

Fig. 1 Penile cancer: typical histopathologic pattern of a squamous cell cancer (also called "spinocellular" cancer) of the penis. Hematoxylin and eosin staining; original magnification approximately 250×

inguinal nodes is more ominous than involvement of superficial inguinal nodes. The 5-year overall and disease-free survival rates are as high as 80% for unilateral, superficial inguinal lymph node involvement with no more than one node (N1), only 10–20% for bilateral or pelvic lymph nodes involved (N2/N3), and less than 10% in the presence of extranodal extension [9, 41].

Hungerhuber et al. recommend prophylactic lymphadenectomy for high-risk patients [46]. Chaux et al. proposed a "prognostic index" based on findings in 193 patients; this index incorporates several pathological parameters (such as grade, deepest anatomical level, perineural invasion) and permits scoring in a ranking system that can be used to predict the likelihood of inguinal lymph node metastases and the likelihood of 5-year survival [47]. Low scores confer a 95% chance of 5-year survival, intermediate scores a 65%, and high scores a 45% likelihood of 5-year survival.

Widespread dissemination occurs in 20–40% of the patients; distant metastases occur most frequently in the lung, liver, and skeleton. Histopathologic features affecting patients' outcome are multiple. Poorer prognosis is related to histological grade, patterns of growth, perineural and vascular invasion, corpus cavernosum invasion, and histological subtype of SCC [41]. For example, verrucous carcinomas are well differentiated, have an expansile border, and are essentially nonmetastatic.

Performance of Diagnostic Imaging Other Than Nuclear Medicine

While penile cancer can be cured in over 80% of all cases, it is a life-threatening disease with poor prognosis once metastatic spread has occurred. Furthermore, local treatment, although potentially lifesaving, can be mutilating and devastating for the psychological well-being of the patient. Therefore, the treatment of patients with penile cancer requires a careful diagnosis and adequate staging before treatment decisions can be made [2].

Primary Lesion

Penile carcinoma is often a clinically obvious lesion, but can be hidden under a phimosis. Physical examination of a patient with penile cancer should include palpation of the penis with a view to examining the extent of local invasion.

Ultrasound can give information about infiltration of the corpora [48, 49]. Magnetic resonance imaging (MRI) in combination with an artificial erection induced by prostaglandin E1 can also be used for excluding tumor invasion of the corpora cavernosa if organ preservation is planned and preoperative decisions are needed [37, 50].

Regional Lymph Nodes

Careful palpation of both groins for the detection of enlarged inguinal lymph nodes must be part of the initial physical examination of patients with penile cancer.

- *Palpable inguinal nodes*

  Palpable lymph nodes are highly suspicious for the presence of lymph node metastases. Physical examination should note the number of palpable nodes on each side and whether these are fixed or mobile. Additional inguinal imaging does not alter management and is usually not required. A pelvic CT scan can be performed in order to assess the pelvic lymph nodes.

- *Non-palpable inguinal nodes*

  The management of clinically node-positive groin in penile cancer is clear-cut with radical inguinal lymph node dissection being the surgical option. It is known that lymph node metastases have an inverse prognostic outcome for these patients. In clinically node-negative groin with occult metastases, the dilemma remains whether to perform lymphadenectomy (with the associated risk of high morbidity) or to continue close observations. In the absence of palpable abnormalities, the likelihood of the presence of micrometastatic disease is about 25%. However, current imaging techniques are not reliable in detecting micrometastases. Inguinal ultrasound (7.5 MHz) can reveal abnormal lymph nodes with some enlargement. The longitudinal/transverse diameter ratio and the absence of the lymph node hilum have been reported to be relatively specific for lymph node metastasis [51]. Conventional CT or MRI scans similarly cannot detect micrometastases reliably [38]. Imaging studies are therefore not helpful in staging clinically normal inguinal regions. An exception can be represented by obese patients, in whom palpation is unreliable or not possible. The further diagnostic management of patients with normal inguinal nodes should be guided by pathological risk factors. Several series have identified lymph-vascular invasion, local stage, and grade as risk factors predicting the likelihood of lymphatic metastasis [52, 53]. Nomograms are unreliable as they cannot achieve an over 80% accuracy. Invasive lymph node staging is required in patients at intermediate or high risk of lymphatic spread.

Distant Metastases

An assessment of distant metastases should be performed in patients with positive inguinal nodes [44, 54, 55]. Computed tomography of the abdomen and pelvis and a chest X-ray are recommended, although thoracic CT will be more sensitive than a plain chest X-ray, and in symptomatic M1 patients a bone scan is also advisable,

as per guidelines of the European Association of Urology (EAU) [2, 56].

There is no established tumor marker for penile cancer. The squamous cell carcinoma antigen (SCC Ag) is increased in less than 25% of penile cancer patients. In one study, SCC Ag was not a predictor for occult metastatic disease, but it was a prognostic indicator of disease-free survival in lymph node-positive patients [57].

Performance of Nuclear Imaging for Staging and Prognosis

Due to its low incidence, penile cancer is best managed at specialized centers. Imaging with CT or MRI can neither accurately detect occult metastases nor predict on tumor characteristics reliably. Lymphoscintigraphy to visualize lymphatic drainage, especially its early dynamic sequence to look for sentinel lymph node(s) (the first node in a given lymphatic pathway from the primary tumor), has been a standard technique for over a decade [58, 59]. This imaging procedure (the preliminary phase of sentinel lymph node biopsy) is recommended for patients without palpable inguinal lymph nodes by the latest guidelines both of the EAU [2] and of the National Cancer Comprehensive Network (Version 1.2014, at www.nccn/guideline/urological/english/penile.pdf, last accessed March 5, 2016). However, it has not yet been sufficiently utilized in Europe or the USA in patients with penile cancers to identify non-palpable metastasis, despite the well-known notion that only 20–25% of clinically negative inguinal nodes harbor metastatic disease [60]. Nevertheless, sentinel lymph node biopsy (SLNB) as a diagnostic procedure in patients with malignancies, especially SCC, has proven to be of tremendous advantage for the detection of subclinical lymph node metastases [61, 62]. The technique of SLNB with the primary penile tumor has become standardized for the identification of a patient population with subclinical or clinically negative groin (see Fig. 2); when metastasis is found in sentinel

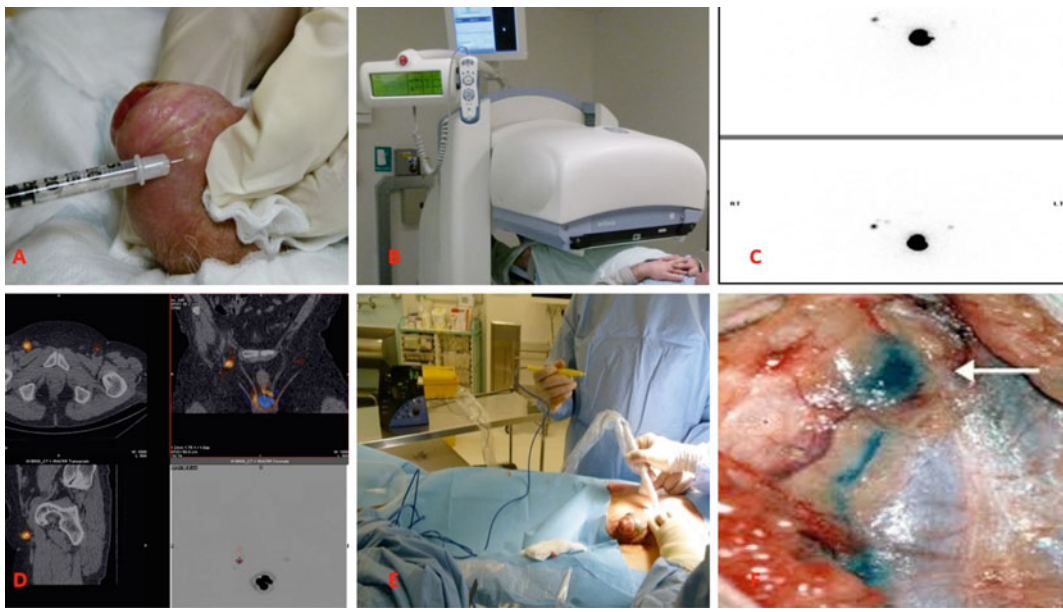

Fig. 2 Pictorial sequence of sentinel lymph node biopsy in penile cancer. (**a**) Interstitial injection of the radiocolloid (^{99m}Tc-nanocolloidal albumin) proximally to the primary tumor. (**b**) Imaging with dual-head gamma camera imaging. (**c**) Planar imaging: early (*top*) and delayed (*bottom*), showing lymphatic drainage to both right and left inguinal lymph nodes. (**d**) Fused SPECT/CT images in the three axial planes (maximum intensity projection image in the *bottom right panel*). (**e**) Intraoperative localization of sentinel lymph node(s) with the gamma probe (after *blue dye* injection). (**f**) Probe-positive sentinel node localized (*white arrow*) demonstrating in-transit *blue dye*

lymph node(s), then elective lymph node dissection is currently recommended [63, 64]. Recent data indicate that correct application of this treatment algorithm can confer an effective survival benefit to patients with penile SCC [65].

Staging

Early detection plays a vital role in disease control, and appropriate diagnostic modalities must be used in order to accurately identify the cancer and its progression. The use of imaging in combination with biopsy is an effective mean in determining disease stage and grade [26]. One of the most important factors that affect the outlook for people with penile cancer is whether nearby lymph nodes contain cancer cells or not.

The management of the regional lymph nodes is of critical importance to both quantity and quality of life for these patients. Importance of inguinal and pelvic nodes cannot be overlooked in this uncommon malignancy, and the final management of penile cancer relies on the timely and appropriate management of the inguinal and pelvic lymph nodes. In fact, the presence and extent of metastatic disease in the inguinal lymph nodes is the single most important prognostic indicator in patients with penile cancer. In particular, the 5-year survival rate is approximately 95% when no metastasis is present in inguinal lymph nodes, while it is 80% when metastatic disease is limited to a single inguinal lymph node, and it drops to 40% if there are two or more metastatic inguinal lymph nodes; in addition, the 5-year survival rate is virtually 0% when metastatic disease at diagnosis involves pelvic lymph nodes [66].

Penile lymphatic drainage follows a well-validated pattern, draining to superficial inguinal nodes (above the fascia lata) and to deep inguinal nodes surrounding the saphenofemoral junction. After these two basins/regions, it flows to pelvic nodes following the ipsilateral iliac and obturator vessels. The pattern of lymphatic drainage can be accurately depicted by lymphoscintigraphy following interstitial injection of a suitable radiopharmaceutical (typically a ^{99m}Tc-labeled colloid) around the tumor. This imaging procedure constitutes an essential component of radioguided biopsy of the sentinel lymph node (SLN). Seminal work with SLN biopsy was originally described by Cabañas in the late 1970s [67]; nevertheless, his pioneering intuition of the clinical relevance of the SLN tumor status was based on the incorrect assumption of a fixed anatomic location of the SLN, a concept that was later corrected after lymphoscintigraphic demonstration of a certain degree of variability in lymphatic drainage patterns from the penis and following the currently accepted definition of the SLN as the first lymph node encountered on a direct drainage pathway from the primary tumor [68, 69]. In this regard, there can be more than one single pathway of direct lymphatic drainage from the penis. In fact, both *unilateral* (Fig. 3) and *bilateral* drainage patterns are recognized and could be either a physiological variant, secondary to previous inguinal surgeries, or could be due to extensive metastatic infiltration (a recent concept) [70]. The advanced hybrid SPECT/CT systems are at present gaining popularity in clinical practice. The value of lymphoscintigraphy can be greatly enhanced by performing a tomographic acquisition 2 h post-injection and by correlating scintigraphic findings to regional morphology assessed with CT; with this combined approach, the sensitivity of SPECT may be as high as 95% [38, 70].

The eventual survival criteria in patients presenting with penile cancer rests with the detection and complete resection of nodal metastases. This resection can be curative even in advanced disease, but carries with it a significant burden of morbidity that has led the thrust to develop protocols and techniques to maximize detection and minimize morbidity and unnecessary surgery.

The sensitivity of sentinel lymph node (SLN) biopsy in patients with penile cancer with non-palpable lymph nodes ranges between 70% and 86% [71, 72]. In patients with clinically palpable nodes, SLN biopsy is less useful due to the possibility of false-negative results as a result of massive invasion of lymphatic pathways by cancer cells.

PET/CT with [^{18}F]FDG has also been used for initial staging of penile cancer [73–75]. In a systematic review and meta-analysis of the literature,

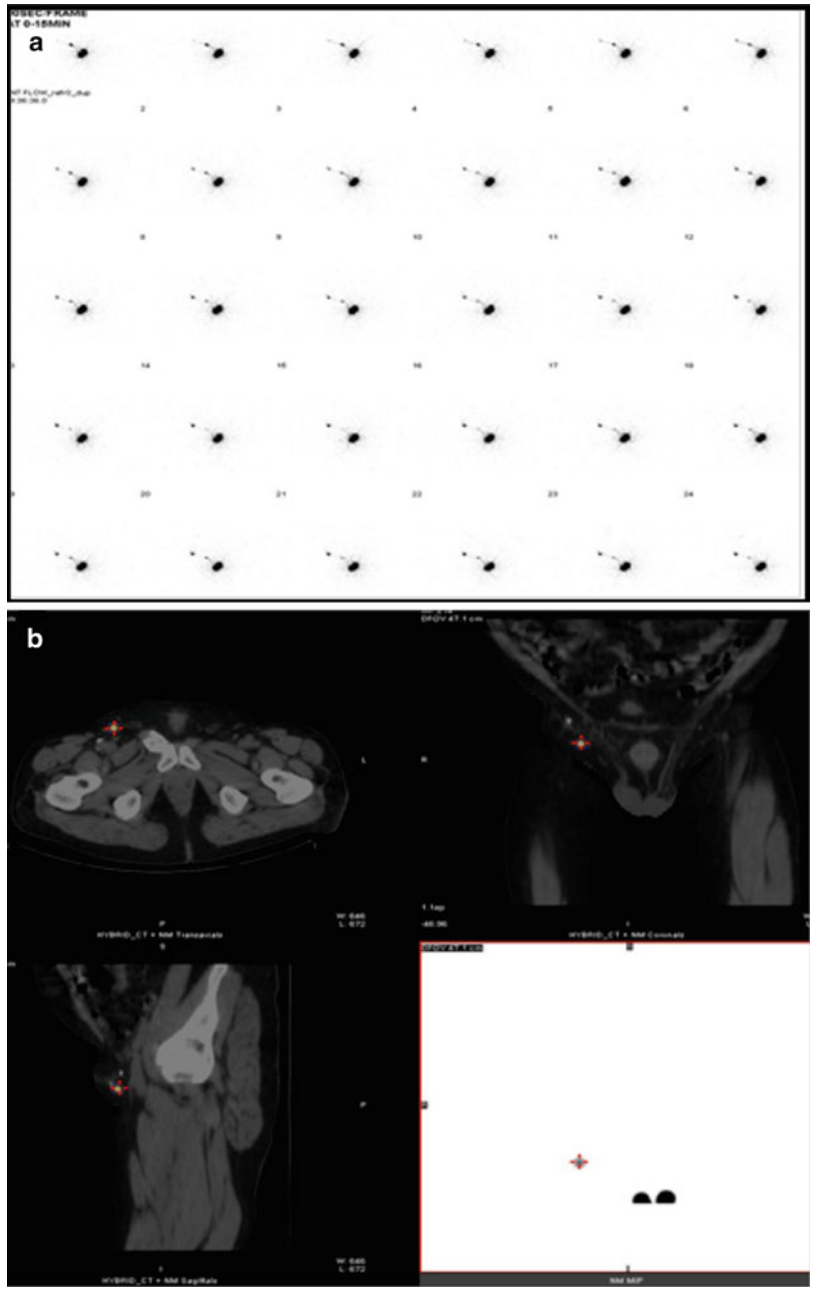

Fig. 3 Dynamic sentinel lymph node biopsy following intradermal peritumoral injection of ^{99m}Tc-nanocolloidal albumin in a patient with penile cancer. (**a**) Dynamic acquisition for approximately 15 min, showing unilateral lymphatic drainage to the right groin. (**b**) Fused SPECT/CT images in the axial, coronal, and sagittal planes (*upper left*, *upper right*, and *lower left* images, respectively), confirming visualization of a single lymph node in the right groin

overall pooled sensitivity and specificity of [^{18}F]FDG PET/CT were 80.9% (95% CI: 69.589.4%) and 92.4% (95% CI: 86.8–96.2%), respectively. However, sensitivity for clinically negative patients was only 56.5% (95% CI: 34.5–76.8%), considerably lower than in patients with palpable inguinal lymph nodes (96.4%, with 95% CI 81.7–99.9%) [76]. The authors concluded therefore that the routine use of [^{18}F]FDG PET/CT is not justified in patients without palpable inguinal lymph nodes, while patients with palpable lymph nodes may benefit from this imaging procedure. Nevertheless, [^{18}F]FDG PET/CT can occasionally be useful to evaluate also sub-centimeter lymph

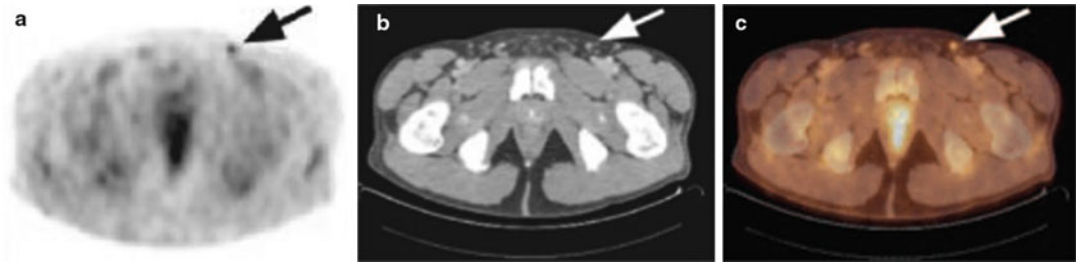

Fig. 4 [^{18}F]FDG PET/CT in a 61-year-old patient with newly diagnosed penile SCC (T2; G3) with clinically negative inguinal lymph nodes. Axial sections at the level of the groin: (**a**) PET component; (**b**) CT component; (**c**) fused PET/CT image. Despite the small size (maximum diameter was 8 mm by CT estimate), metastasis in a left inguinal lymph node showed distinct focal [^{18}F]FDG uptake (*arrows*) (Reprinted with permission of the Society of Nuclear Medicine)

nodes that would be deemed as negative both clinically and on morphological imaging alone (Fig. 4). A more recent study has explored the diagnostic performance of combined [^{18}F]FDG PET/CT and sentinel lymph node biopsy in a group of 129 patients, showing a combined sensitivity of 94.4% (95% CI: 81–99%) and a false-negative rate as low as 5.6% (95% CI: 1–11.9%) [77].

Since distant metastasis is detected in 20% of the patients with cytological positive inguinal disease, routine use of [^{18}F]FDG PET/CT at initial staging has been advocated for patients with positive lymph nodes (see Fig. 5), as integration of PET/CT scanning into preoperative staging algorithms may avoid surgical staging in selected patients [74, 76]. Since bone metastases are rare, bone scintigraphy is not yet commonly used in newly diagnosed penile SCC.

Follow-Up and Restaging

Most relapses are seen during the first 2 years after primary treatment, while late recurrences are uncommon [41]. Conservative treatment and surveillance are recommended for pN0 disease, at 2–4 month intervals in the first 2 years, 3–6 months in the third year, and 6–12 months thereafter. Follow-up is based mainly on clinical evaluation, while radionuclide imaging techniques have rarely been used for restaging purposes during regular follow-up. Whereas it has been shown that [^{18}F]FDG PET may be used for assessing the metabolic response to induction chemotherapy in patients with positive inguinal lymph nodes, in fact, changes in glucose metabolism preceded morphological changes, thus indicating that functional assessment is more sensitive than morphological assessment. However, the implications of such findings on long-term survival are still unknown [52].

Treatment Options for Penile Cancer

The primary tumor and regional lymph nodes are usually treated separately [78]. The front-line treatment for managing the primary lesion remains surgical; however, the options are corresponding to the stage and grade of the disease. The gold standard remains partial or total penectomy with local control rates of above 90%, but carries very high psychosexual morbidity [79]. In the light of the new EAU guidelines, margins of up to 1–2 cm are enough to provide the same control rates [2].

- *Treatment option for carcinoma in situ*
  It ranges from topical use of 5% 5-fluorouracil cream for 6 weeks, laser, circumcision, resurfacing glans penis to total glansectomy in case of urethral involvement [79].
- *Treatment options for T1*
  This group requires careful selection of patients and close surveillance as it involves wide local excision with primary closure or split skin graft (depending on the size of lesion) in case where there is no urethral involvement and complete amputation for recurrences [80].

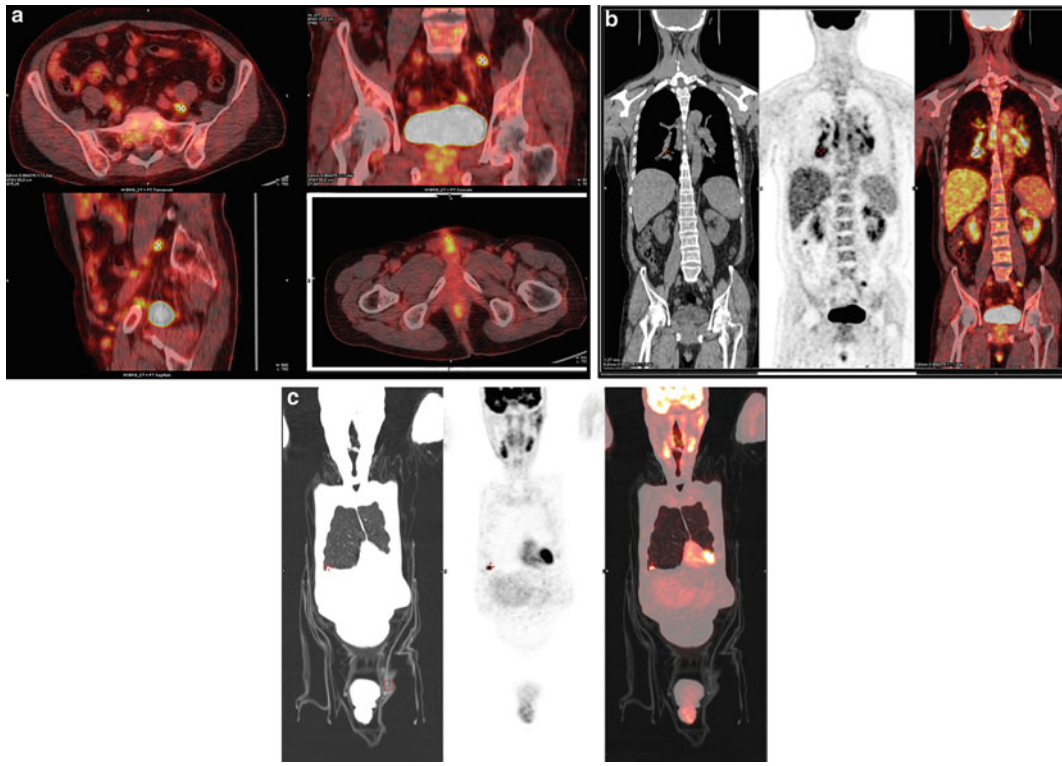

Fig. 5 Fused images obtained at various plane levels after i.v. injection of [^{18}F]FDG and PET/CT performed for staging purposes in a 48-year-old patient with newly diagnosed penile carcinoma. (**a**) Besides increased metabolic activity at the primary tumor site (axial section shown in *lower right panel*), this patient had clinically silent metastatic disease in left common iliac lymph nodes (axial section shown in *upper left panel*, coronal section in *upper right panel*, and sagittal section in *lower left panel*). (**b**) Coronal sections of the CT component (*left panel*), of the PET component (*center panel*), and corresponding fused PET/CT image (*right panel*) demonstrating metastatic disease in mediastinal and para-hilar lymph nodes (bilaterally). (**c**) Coronal sections of the CT component (*left panel*), of the PET component (*center panel*), and corresponding fused PET/CT image (*right panel*) demonstrating a pulmonary metastasis in the right anterior costophrenic space

- *Treatment options for T2*

  According to the new TNM stage classification, the previous two T2 stages (T2a, involvement of corpus spongiosum, and T2b, involvement of corpus cavernosa) have been amalgamated into one stage, which is T2. T2 has higher lymph node metastases, and if corpus cavernosa is involved, then conservative surgery is not an option. Therefore, in most cases partial penectomy is carried out unless the tumor has proximal extension warranting total penectomy with phalloplasty.
- *Radiotherapy*

  Radiotherapy either by conventional external beam therapy or brachytherapy is commonly indicated for patients with tumors of less than 4 cm in size. Due to their high rate of complications and morbidity secondary to urethral stenosis, fibrosis, or even penile necrosis leading to amputation, the EAU guidelines restricted its use for T1–T2 tumors of glans penis or penile sulcus and for palliative use in advanced metastatic disease [56, 80].
- *Chemotherapy*

  Chemotherapeutic regimens such as combination of bleomycin, methotrexate, and cisplatin have played positive role when used as neoadjuvant therapy. A new agent, cetuximab, has shown its promise in head and neck SCC, and due to close cross resemblance of SCC

prevalent in penis, anal canal, and vulva, the efficacy of this agent is presumed to be high [81].

Since tumors are often localized in the penis at the time of diagnosis, they can be treated either by local excision or circumcision, laser ablation, brachytherapy, external radiation, or partial penectomy. Preservation of the penis is a concern for most patients, but more proximal or advanced lesions require total penectomy. With adequate treatment of the primary tumor, however, the rate of local recurrence is very low [82].

The management of inguinal metastasis is crucial, as distant metastases are rare in the absence of inguinal metastases. The standard recommendation for patients with palpable lymph nodes is bilateral inguinal lymphadenectomy. Inguinal lymphadenectomy, however, is associated with high morbidity, including severe lymphedema, wound infection, etc. The decision to opt either for imaging coupled with minimally invasive sentinel lymph node sampling or to predict nodal disease on the basis of primary tumor characteristics and pathology imposes significant challenge.

In patients with non-palpable lymph nodes, decision-making is based on risk stratification and recommendations that vary between surveillance, SLN biopsy, and radical inguinal lymph node dissection. Patients with high risk of distant disease are treated using a multimodality approach. Possible strategies in this setting include neoadjuvant chemotherapy followed by surgery (penectomy and bilateral groin dissection), or chemoradiotherapy, either cytoreductive or adjuvant.

In case of inoperable advanced penile cancer with distant metastasis, [^{18}F]FDG PET/CT has been employed to monitor the efficacy of induction chemotherapy, by performing the scan at baseline, then after two cycles of therapy [83]; although a relatively small group of patients was studied, the [^{18}F]FDG PET/CT findings were compared with CT data and with histopathological analysis. The preliminary results so obtained suggest that the metabolic tumor response is more reliable than morphologic imaging with CT to monitor the efficacy of induction chemotherapy in patients with penile cancer.

Diagnostic Applications of Nuclear Medicine: Vulvar Cancer

34

Sonia Mahajan, Weining Ma, and Neeta Pandit-Taskar

Abstract

Vulvar cancer is an uncommon malignancy in females and is less frequently seen as compared to cervical or endometrial cancer. Human papillomavirus (HPV) infection, chronic lichen simplex infection, and genital warts are considered some of the predisposing factors. While metastases occur in late-stage disease (usually via lymphatic spread), many lesions are seen in the early stages. Anatomic imaging is the mainstay of evaluation for local extent. [^{18}F]FDG PET imaging has incremental value for evaluation of equivocal lesions, assessing nodal status and detecting distant metastasis. Lymphoscintigraphy for sentinel node mapping is useful for surgical planning and limiting postoperative morbidity from extensive nodal dissection. This review summarizes the current status and emerging trends in imaging vulvar cancer using radiopharmaceuticals.

Introduction

Introduction and Epidemiology

Vulvar carcinoma comprises of about 0.4% of all new cancer cases and approximately 5.4% of all gynecologic cancers with 5,950 estimated new cases in the USA in 2016 [1]. It accounts for approximately 0.2% of all cancer-related deaths. Based on 2009–2013 statistics, the number of new cases of vulvar cancer was 2.4 per 100,000 women per year, and the number of age-adjusted deaths was 0.5 per 100,000 women per year [1]; a steady increase in vulvar cancer incidence has been noted over the past 40 years [2].

The median age for vulvar cancer at diagnosis is 65–70 years and that for vulvar intraepithelial neoplasia (VIN) is 45–50 years. It has slightly higher preponderance in whites and Native Americans compared to Asians and blacks. The higher incidence of VIN in women younger than 55 years is probably related to human papillomavirus HPV16 infection. An increasing incidence of vulvar cancers involving clitoral and periurethral region [2] has been noted that is generally associated with worse prognosis as compared to those not involving these regions [3]. A majority of vulvar cancers are usually detected in early clinical stages (59.2%) that are associated with a high 5-year survival rate of about 85.8% as against 55.4% for those with regional metastasis and 15.5% for those with distant metastatic disease. The age of the patient and characteristics of the tumor including size of the lesion, depth of invasion, cellular differentiation and grade, nodal status, and extranodal extension are independent prognostic variables associated with vulvar cancer with lymph nodal status the most important factor [4, 5].

Environmental factors and genetic predisposition: Cigarette smoking is considered a cofactor of HPV in the development of vulvar squamous cell carcinoma [6]. Certain studies have linked smoking to immunosuppression, and although the exact mechanism underlying the association is unknown, it is also postulated that the presence of nicotine, cotinine, and other

constituents may be seen in cervical mucus which affect the presence of cervical Langerhans cells and T lymphocytes [6]. Active smokers have about greater than threefold increased risk of developing vulvar SCC compared to nonsmokers, while former smokers may have little or no increased risk [7].

Persistent infection with HPV, an encapsulated DNA virus, is a known risk factor for hyperplasias associated with low-risk HPV types as well as for premalignant lesions caused by high-risk HPV types such as 16, 18, 31, 33, and 45 [8]. While the mechanism of such association is not fully known, it appears to be related to disruption of cellular gene functions caused by insertion of HPV genomes into host genomes [9]. It has been noted that following infection there is replication of viral DNA in basal cells with stable retention of multiple copies in preneoplastic lesions (episomal state). The viral DNA then integrates with the genome of the cell, and transcription of specific viral gene products occurs in invasive state [9, 10], some of which directly interfere with function of p53 and pRB.

The p16 and p53 expression has also been associated with variable presentation and prognosis [11, 12]. Diffuse p16 expression has been associated with younger age at presentation and basaloid and warty subtypes, while p53 immunopositivity is negatively associated with VIN [11]. Nonneoplastic epithelial cell disorders of vulva such as lichen sclerosis, squamous hyperplasia, and other dermatoses may develop cellular atypia or VIN in about 10% cases. Higher p53 mutations are more likely associated with HPV-negative tumors and point mutations more likely in metastatic lesions, suggesting a role in disease progression [12].

Prevention of HPV infections by vaccines can help decrease the incidence of vulvar intraepithelial neoplasias, genital warts, and cervical cytological abnormalities [13–15]. General recommendation is to offer vaccination to adolescents/young adults in three-dose series at 0, 2, and 6 months interval [16–18].

Histopathologic categories of vulvar cancer (Table 1): The most common histology of vulvar cancer is squamous cell carcinoma that forms more than 90% of the total, followed by vulvar melanoma that accounts for 2–4% of primary vulvar malignancies [19, 20]. The squamous cell carcinomas are further divided as keratinizing, warty, or basaloid. Keratinizing subtype is more commonly (60–80%) seen in postmenopausal women, is generally well to moderately differentiated, and is not associated with VIN or HPV, while warty or basaloid subtypes occur more commonly in pre- or perimenopausal women and are associated with VIN [21]. Verrucous carcinoma is a variant of SCC that is slow growing and less aggressive and rarely metastasizes though can be locally invasive. Basal cell carcinomas present in about 2% of patients who generally have other lesions in the body. The lesion may appear as discoloration or plaque and may be indolent. Sarcomatous lesions are less frequent and occur in less than 2% of patients. These are associated with poor prognosis and higher recurrence is seen in those with high-grade histology and large tumor size (>5 cm). Paget's disease of the vulva is rare

Table 1 Histological variants of vulvar carcinoma [21–23]

1. Squamous cell carcinoma
(a) Invasive
(b) Squamous variant of Bartholin gland carcinoma
2. Malignant melanoma
3. Anaplastic carcinoma
4. Vulvar intraepithelial neoplasia – high grades II and III (4% develop invasive cancer)
5. Paget's disease (5–10% are associated with underlying adenocarcinoma)
6. Adenocarcinoma
(a) Invasive
(b) Adenocarcinoma variant of Bartholin gland carcinoma
7. Other tumors
(a) Transitional cell variant of Bartholin gland carcinoma
(b) Adenoid cystic carcinoma – variant of Bartholin gland carcinoma
(c) Primary mammary adenocarcinoma
(d) Verrucous carcinoma
(e) Basal cell carcinoma
(f) Histiocytosis X
(g) Sebaceous carcinoma
(h) Sarcomas

(<1%) and presents as an eczematoid well-demarcated lesion. It can be multifocal and may be associated with invasive adenocarcinoma in deeper tissues.

Staging and Prognosis

The clinical staging of vulvar cancer is generally performed based on the International Federation of Gynecology and Obstetrics (FIGO) classification [24, 25] (Table 2). The classification is based on lesion size, tumor grade, and depth of invasion [24]. Vulvar melanomas are staged similar to cutaneous melanomas (Table 3). Staging of vulvar melanomas is based on Breslow's and modified Clark's classification [27].

Early-stage disease (stage I) has a very good overall 5-year survival (84.0%) as against FIGO stage II, III, and IV patients with overall survival (OS) of approximately 74.6%, 47.8%, and 9.4%, respectively. Nodal metastasis is correlated with worse prognosis; pooled data showed a 5-year OS of 84.5% for patients without LN metastasis and 30.1% for patients with three or more LN metastasis [28]. Inguinal and/or femoral node involvement is the most significant prognostic factor for survival in patients with vulvar cancer [29]. Other factors like tumor size and thickness, depth of invasion, and lympho-vascular space invasion also adversely affect prognosis. The presence of high mitotic rate, aneuploidy, infiltrative growth pattern, and basaloid histologic pattern is correlated with poor prognosis [30, 31]. Extranodal extension, defined as the extension of tumor from the node to adjacent soft tissue, is also associated with adverse outcomes. In a meta-analysis, Luchini et al. showed significant increase in all-cause mortality, cancer-specific mortality, and recurrence in patients with extranodal extension of tumor as compared to those without [32].

Clinical presentation and management: Vulvar cancer can present in various forms either as subtle nonspecific presenting symptoms or as a frank ulcerating lesions or mass. Patients most commonly present with chronic itching or pain in introitus. The lesion may appear like lichen sclerosis, contact dermatitis, or warts and can be overlooked as inflammatory or benign condition. Patients may have skin changes including discoloration or thickening. Lesions may appear like plaques or exophytic or fungating growths. A chronic condition of the vulva that recurs or does not respond to treatment should be therefore further investigated and preferably biopsied [33]. Diagnosis is usually made with wedge biopsy; however, excision biopsy is preferred for lesions that are <1 cm. Clinical examination helps to rule out multifocal or multicentric involvement, while colposcopic examination is required to know the extent [34].

Surgical excision is the mainstay of management of vulvar cancer. Radical vulvectomy with wide excision of the vulva up to the deep fascia of the thigh and urogenital diaphragm is performed in order to achieve a tumor-free margin ≥1 cm to minimize local recurrence. Unilateral or bilateral inguinal nodes may be sampled and dissected based on extent of the primary lesion. Lesions in the midline or crossing the midline may spread to bilateral inguinal nodes seen in up to 3–5% of cases; however, the rates vary with inclusion of other factors such as tumor size and depth of invasion [30, 35]. Pelvic node involvement is not common and occurs in about 5% of patients [36]. T1 lesions without extension to adjacent perineal structures (i.e., urethra, vagina, and/or anus) may be effectively treated by wide local excision [37]. NCCN guidelines for SCC of vulva [38] recommend wide local resection followed by observation for early-stage T1 and smaller T2 lesions less than or equal to 4 cm that have ≤1 mm invasion. For lesions greater than 1 mm invasion, radical local resection or modified radical vulvectomy is recommended. For midline lesions, bilateral inguinofemoral groin lymph node dissection should be considered with or without sentinel lymph node detection. For a lesion that is lateral (≥2 cm from midline), ipsilateral lymph node dissection with or without sentinel lymph node detection is performed. T2 lesions with extension to adjacent perineal structures are best treated with radical vulvectomy or hemivulvectomy. In locally advanced disease, neoadjuvant radiation and chemotherapy is administered; residual tumor, if present, is surgically excised [38, 39].

Table 2 FIGO (2009) and AJCC classification [26]

FIGO stage	Description
I	Tumor confined to the vulva
Ia	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm, no nodal metastases
Ib	Lesions >2 cm in size or with stromal invasion >1 mm, confined to the vulva or perineum, with negative nodes
II	Tumor of any size with extension to adjacent perineal structures (lower third of the urethra, lower third of the vagina, anus) with negative nodes
III	Tumor of any size with or without extension to adjacent perineal structures (lower third of the urethra, lower third of the vagina, anus) with positive inguinofemoral nodes
IIIa	With 1 lymph node metastasis (≥5 mm) or with 1–2 lymph node metastases (<5 mm)
IIIb	With 2 or more lymph node metastasis (≥5 mm) or with 3 or more lymph node metastases (<5 mm)
IIIc	Positive lymph nodes with extracapsular spread
IV	Tumor invades other regional (upper two thirds of the urethra, upper two thirds of the vagina) or distant structures
IVa	Tumor invades either upper urethral/vaginal mucosa, bladder mucosa, rectal mucosa, fixed to pelvic bone, or fixed/ulcerated inguinofemoral lymph nodes
IVb	Any distant metastases including pelvic lymph nodes
TNM staging	
Primary tumor (T)	
Tx – Primary tumor cannot be assessed	
T0 – No evidence of primary tumor	
Tis – Carcinoma in situ (preinvasive)	
T1a – Lesions ≤2 cm, confined to the vulva or perineum and with stromal invasion ≤1 mm (FIGO IA)	
T1b – Lesions >2 cm or any size with stromal invasion >1 mm, confined to the vulva or perineum (FIGO IB)	
T2 – Tumor of any size with extension to adjacent perineal structures (distal third of the urethra, distal third of the vagina, anal involvement) (FIGO II)	
T3 – Tumor of any size with extension to any of the following proximal two thirds of the urethra, proximal two thirds of the vagina, bladder mucosa, or rectal mucosa or fixed to pelvic bone (FIGO IVA)	
Regional lymph nodes (N)	
Nx – Regional lymph nodes cannot be assessed	
N0 – No regional lymph node metastasis	
N1a – 1 or 2 lymph node metastases, each <5 mm (FIGO IIIA)	
N1b – 1 regional lymph node metastasis ≥5 mm (FIGO IIIA)	
N2a – 3 or more lymph node metastases, each <5 mm (FIGO IIIB)	
N2b – 2 or more regional lymph node metastases ≥5 mm (FIGO IIIB)	
N2c – Regional lymph node metastasis with extracapsular spread (FIGO IIIC)	
N3 – Fixed or ulcerated regional lymph node metastasis (FIGO IVA)	
Distant metastasis (M)	
M0 – No distant metastases	
M1 – Distant metastases (including to pelvic lymph nodes) (FIGO IVB)	

Role of Imaging

Diagnosis of vulvar cancer initiated based on clinical history and examination; a suspicious lesion is biopsied. Imaging plays a limited role in the evaluation of primary disease. For evaluation of disease extent and treatment planning, contrast-enhanced CT or MRI or PET with 2-deoxy-2-[^{18}F] fluoro-D-glucose be used based on clinical need and suspicion. In patients with locally advanced disease, chest radiograph, CT, and/or MRI is recommended to establish staging (Fig. 1). Assessment of inguinofemoral region is critical

Table 3 Breslow's classification and Clark's classification

Stage	Depth
Breslow's classification	
Stage I	Less than or equal to 0.75 mm
Stage II	0.76–1.50 mm
Stage III	1.51–2.25 mm
Stage IV	2.26–3.0 mm
Stage V	Greater than 3.0 mm
Clark's classification	
Level 1	Melanoma confined to the epidermis (melanoma in situ)
Level 2	Invasion into the papillary dermis
Level 3	Invasion to the junction of the papillary and reticular dermis
Level 4	Invasion into the reticular dermis
Level 5	Invasion into the subcutaneous fat

for management and to segregate patients for nodal sampling and surgical dissection prior to treatment with chemotherapy and/or radiation.

MRI is useful in evaluating the local extent of disease in patients with advanced tumor, especially for assessment of extent in the perineum and extension to the vagina or anus, and therefore useful for surgical planning. The tumor is best visualized in T2-weighted sequences and may be seen as a mass or skin thickening with intermediate to high signal intensity. The extent of the lesion is better visualized on contrast-enhanced fat-suppressed T1-weighted images. MRI may also be useful to assess the depth of tumor invasion and local extent, especially involvement of the clitoris or urethral meatus [40]. MRI provides accurate assessment of lymph node metastasis [41, 42] and is highly specific in identifying abnormal lymph nodes by using size criteria and morphology. However, the sensitivity is low ranging between 40% and 50% [37]. Using short/long axis (S/L) ratio as a quantitative marker for diagnosing lymph node metastasis, a higher sensitivity of 87% and specificity of 81% have been reported [37].

Ultrasound (US) is used mainly to detect abnormal inguinal lymph nodes or for ultrasound-guided biopsy of suspicious lymph nodes. Focused ultrasound imaging is performed using a high-frequency transducer (linear 8–18 MHz). Abdominopelvic CT scans may be useful in detecting local and distant lymph nodes or other distant metastases and are generally used in conjunction with US and MRI for staging or restaging based on patient's clinical presentation and suspicion.

Radiopharmaceutical imaging: Of the various techniques and tracers available, [^{18}F]FDG-PET/CT imaging and lymphoscintigraphy are primarily used for imaging and evaluation of patients with vulvar cancer. Currently, the role of [^{18}F]FDG PET/CT has not been fully established though early data suggests a complimentary role and advantages in assessing distant disease [43, 44].

[^{18}F]FDG PET Imaging

Generally vulvar cancer shows avid uptake of [^{18}F]FDG (Figs. 2 and 3). For initial staging, FDG PET is more often used to detect distant metastatic disease while assessment of nodal disease is less critical. Anatomic imaging provides superior details in determining local extent, and [^{18}F]FDG PET may play a complimentary role in evaluating equivocal findings on conventional imaging, especially in assessing nodal disease in non-enlarged or borderline-sized nodes (Fig. 4). In a small prospective study in vulvar SCC ($n = 15$, stages IB–IV), [^{18}F]FDG PET was performed prior to surgery and compared with results of groin dissection (Table 4). All patients showed avid uptake in primary tumors [45]. [^{18}F]FDG PET showed suspicious nodes in six out of nine groins (in four out of five patients) that were pathologically positive. In a single patient, [^{18}F]FDG PET was also positive for pelvic nodes that were further treated with radiation. Other distant sites that showed uptake included adrenal gland adenoma and physiologic prominent uptake in the cecum.

In a prospective study that analyzed CT, MRI, and [^{18}F]FDG PET imaging in 23 patients, [^{18}F]FDG PET showed high uptake in the primary tumor with an average SUV of 11; however, the values ranged between 2.4 and 28.5. In 2/17 patients, [^{18}F]FDG had a positive impact on management by either detecting a distant metastasis or excluding pelvic metastasis [46]. For those evaluated for recurrence, 2/14 had unknown metastatic sites detected on [^{18}F]FDG PET as compared to

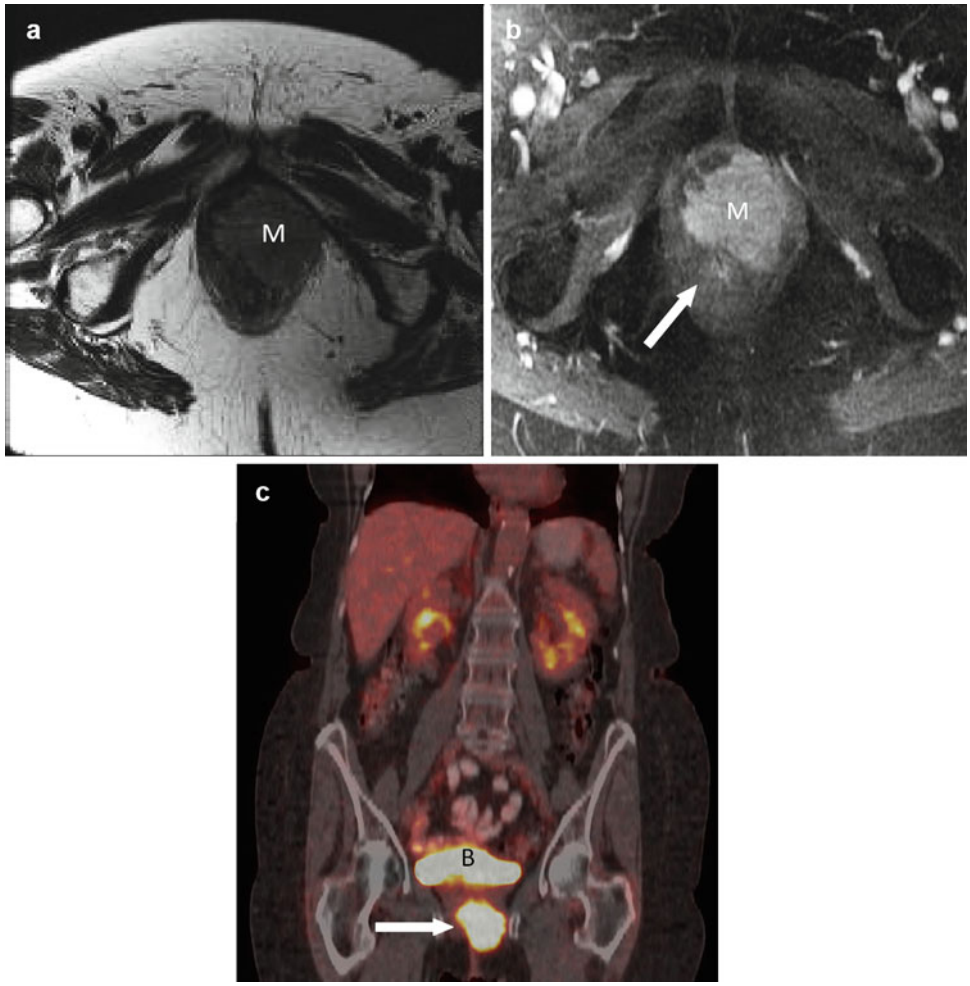

Fig. 1 MR pelvis (**a**) axial T2-weighted (**b**) gadolinium-enhanced T1 image shows a left vulvar soft tissue mass (*M*); T2 mildly hyperintense with homogenous enhancement invading through the pelvic floor with involvement of posterolateral urethral, lower vaginal, and anal walls (*white arrow*). (**c**) Coronal fused PET/CT image showed [^{18}F]FDG avid (SUV_{max} 10.8) left vulvar mass (*white arrow*), *B*: urinary bladder. HPE revealed moderately differentiated invasive SCC

other conventional imaging. However in this study, the overall accuracy and specificity of [^{18}F]FDG PET imaging were lower as compared to CT and/or MRI [46]. In evaluating the role of [^{18}F]FDG PET in staging prior to planned radical vulvectomy and inguinofemoral lymphadenectomy, imaging analysis in 20 patients showed high uptake in vulvar lesions ranging from 2.5 to 14.7 and uptake of 2.4–3.0 in groin nodes [47]. In a very small study ($n = 8$), [^{18}F]FDG localized to all primary well-differentiated SCC of the vulva; the nodal uptake was higher (SUV range of 3.5–15) in metastatic nodes versus reactive nodes (SUV range of 1.7–3.1) [48].

[^{18}F]FDG PET has been evaluated for assessing nodal status especially the involvement of inguinofemoral lymph nodes and as a noninvasive tool for preoperative assessment [45–48] (Figs. 5 and 6). Kamran and colleagues evaluated the usefulness of [^{18}F]FDG PET in categorizing

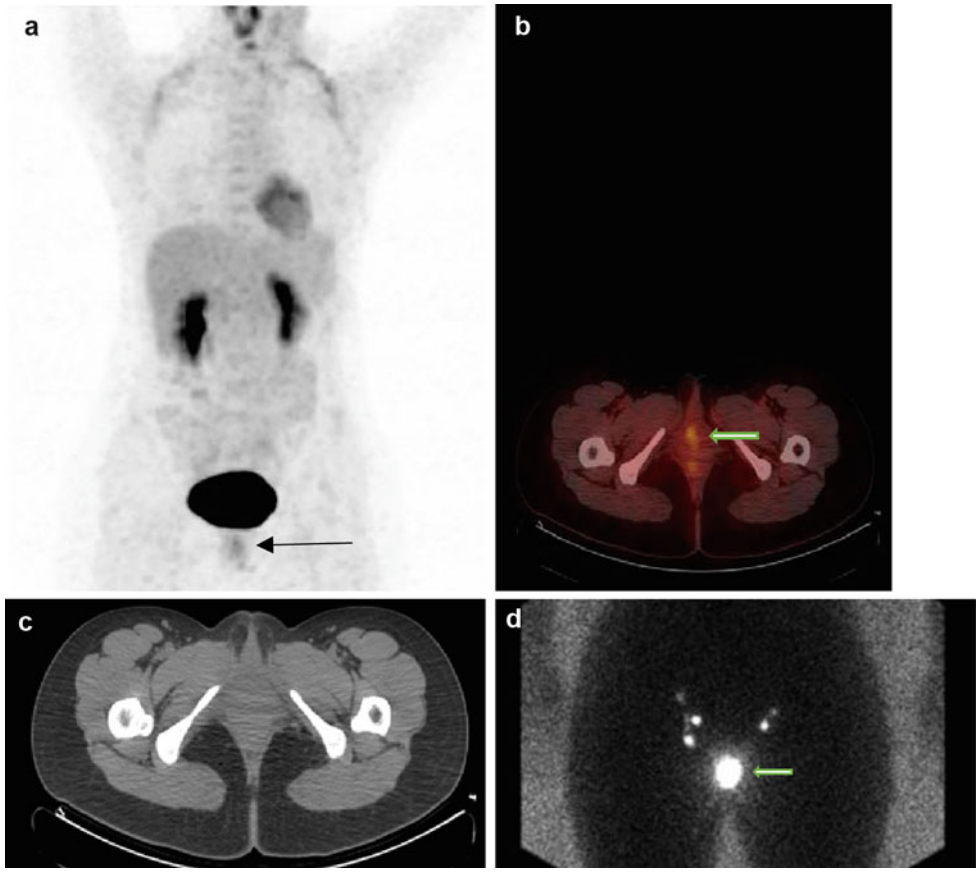

Fig. 2 Primary vulvar carcinoma (VIN III). A 28-year-old with biopsy-proven high-grade squamous intraepithelial lesion (**a)** MIP (*black arrow*) and **(b)** axial fused PET/CT image of pelvis show minimal asymmetric [^{18}F]FDG uptake in the perineum (SUV_{max} 1.9) (*white arrow*); no gross disease is seen on the noncontrast CT (**c**). No other metastatic lesion was seen in the rest of the body. **(e)** Patient underwent presurgical lymphoscintigraphy. LSG planar and SPECT images, following ^{99m}Tc-sulfur colloid injection intradermally, show lymph nodes in bilateral groin region and pelvis (*arrow*, injection site)

stage III disease accurately and in comparison to histopathology; while the specificity was high (100%), the sensitivity and overall accuracy were low for nodal assessment. In this small study, it was noted that there were larger, multiple, and bilateral nodal metastases in those with a more avid primary tumor versus those with a less avid primary tumor. Due to low negative predictive value (NPV) of [^{18}F]FDG the low-risk patients could not be reliably identified; however, the high PPV suggested that it could be a useful guide in proceeding with a full lymphadenectomy [47]. This however needs to be evaluated in a more systematic and larger group.

Cohn and colleagues evaluated [^{18}F]FDG PET for detecting groin nodal metastasis in correlation with pathologic finding and detected higher sensitivity for nodal detection on a per patient basis as against nodal basin-based analysis (80% vs 67%); however, the specificity was higher in site-specific analysis (95% vs 90%). The positive and negative predictive values for nodal detection were about 80–90%. The overall sensitivity was however less optimal to preclude surgical lymphadenectomy using [^{18}F]FDG data only [45]. Similar result, though with lower sensitivity, was noted by Kamran et al.; [^{18}F]FDG PET had sensitivity of 50% only, though high

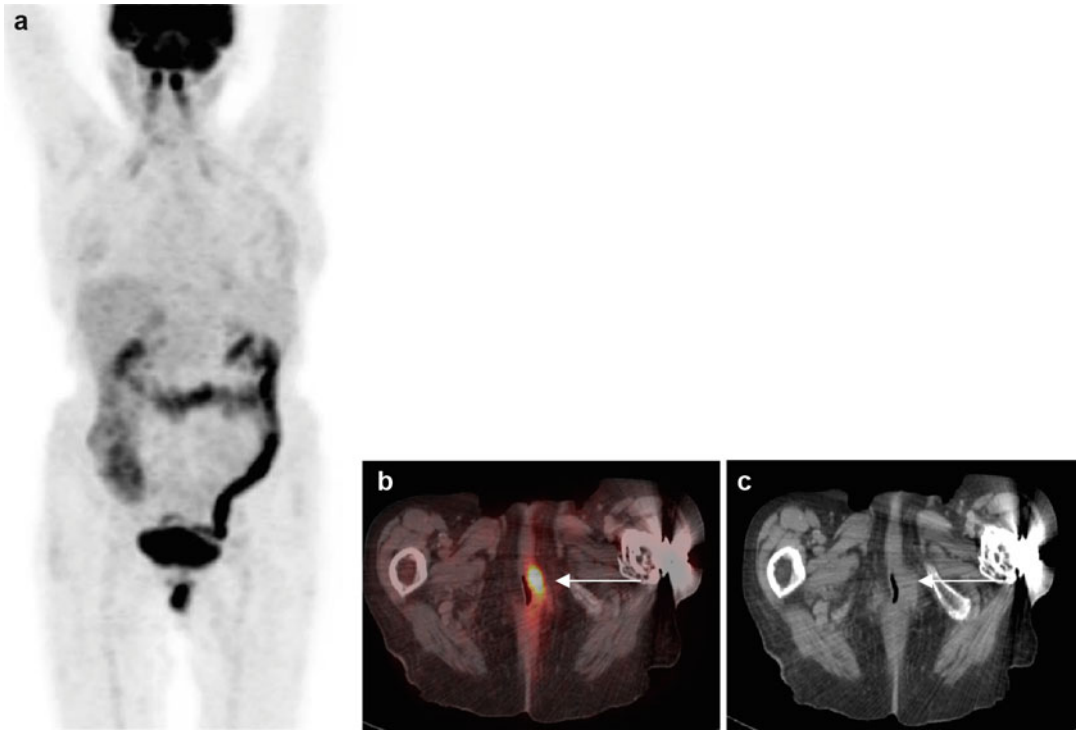

Fig. 3 Primary vulvar carcinoma. A 76-year-old with left vulvar lesion that shows intense [^{18}F]FDG uptake on MIP (**a**) and fused PET/CT images (**b**, SUV_{max} 10.7). The lesion measured 2.8 × 1.6 cm as seen on axial CT (**c**). No other metastatic lesion was seen in the rest of the body (**a**)

specificity of 100% was seen with a positive predictive value of 100 [47].

In those with high-risk disease, [^{18}F]FDG PET can help detect metastatic disease especially to the distant sites (Fig. 6) and affect management change. A recent study that analyzed the impact of [^{18}F]FDG PET/CT in the management of 54 patients with vulvar cancer showed a change in prognosis in 54% of which 33% (18/54) had improved prognosis and 20% (11/54) had worse prognosis [49]. Though the data is combined with vaginal cancer patients, it appears that additional disease sites were detected by [^{18}F]FDG PET in lungs and adrenals that contributed to worsening of prognostic outlook with an overall change in management in 36% of the combined population.

Recurrences are common in vulvar cancer patients. In a study of 502 patients, reported rates were 22% for stage I, 35.8% for stage II, and about 44–45% for stage III and IV disease with higher recurrences seen in the inguinal region as against pelvic regions [29]. [^{18}F]FDG PET/CT may play a role in restaging and planning treatment in recurrent disease (Fig. 7). Extent of local, groin, and other sites of disease helps guide salvage or palliative therapy in individual cases. The data is limited for systematic evaluation of the use of [^{18}F]FDG PET in restaging as well as for the assessment of treatment response (Figs. 7 and 8) and would need well-designed studies.

Lymphoscintigraphy

The concept of sentinel lymph node (SLN) mapping was initially developed by Cabanas in 1977 for penile cancers [50] which was extended to map nodes in melanoma using isosulfan blue dye intraoperatively [51]. Later, radionuclide scintigraphy was used in conjunction with blue dye that yielded superior results in nodal

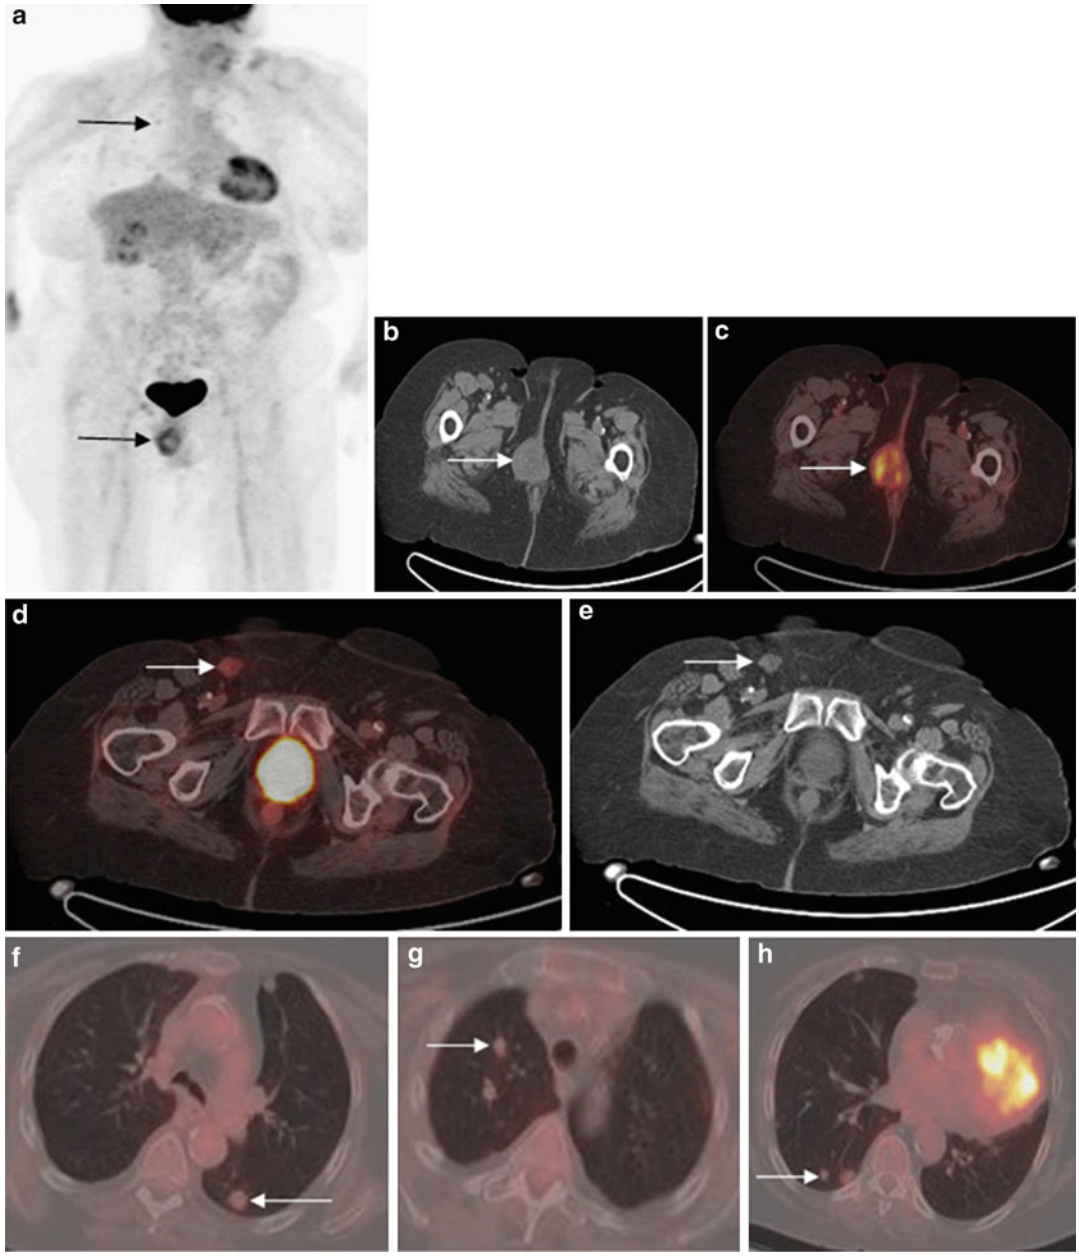

Fig. 4 Patient with vulvar carcinoma referred for staging of the disease. Whole-body MIP (**a**, *black arrow*) image shows increased [^{18}F]FDG uptake in the primary lesion seen on CT (**b**, *white arrow*) and fused PET/CT image (**c**, SUV_{max} 4.7). Additional uptake is seen in inguinal lymph nodes (**d**, **e**, *white arrow*) (SUV_{max} 1.1). On whole-body PET/CT, multiple suspicious lesions showing mildly increased [^{18}F]FDG uptake were noted in both lungs (**f**, **g**, **h,** *white arrows*)

localization in breast cancer and melanoma [52, 53]. Extensive nodal dissection can lead to significant morbidity which can be considerably alleviated by sentinel node technique.

SLN with filtered ^{99m}Tc sulfur colloid is performed as a single-day procedure either on the day of surgery or a day prior to surgery. Intradermal, subcutaneous, or intratumoral injections may

Table 4 [^{18}F]FDG PET in vulvar cancer – literature

Author, year	Type	Indication	Number of patients/stage	Comparative imaging (CT or MRI)	Histopathology confirmation (yes/no)	Sensitivity/ specificity/ accuracy
Lin et al., 2015	Prospective	Primary staging ($n = 17$), response assessment ($n = 7$), restaging ($n = 14$) (38 PET studies)	23: SCC ($n = 15$) stages I–IV, adenocarcinoma ($n = 2$), melanoma ($n = l$), Paget's disease ($n = 4$), small cell ca ($n = l$)	CT/MRI	Yes	ILN: [^{18}F] FDG– 92%/91%/ 91%; CT/MRI – 92%/ 100%/97%
Kamran et al., 2014	Retrospective	Staging: detection of inguinal and femoral LN	20 SCC stage I/II ($n = 8$), III ($n = 12$)	No	Yes	50%/ 100%/70%
Cohn et al., 2002	Prospective	Staging: detection of groin lymph node metastases	15 SCC stage IB ($n = 3$), M ($n = 7$), Nl ($n = l$), IVA ($n = 4$)	No	Yes	Per patient basis – 80%/90%/ NA. Per groin basis – 67%/ 95%/NA
Dolanbay et al., 2015	Prospective	Staging: assessment of inguinofemoral lymph nodes	8 SCC stage IB ($n = 4$), IIIB ($n = 4$)	No	Yes	100%/ 100%/NA

SCC squamous cell carcinoma, *ILN* inguinal lymph nodes

be performed. The intradermal injection is administered at the periphery of the lesion, approximately at the four corners of the lesion or post biopsy scar site. Dynamic images are obtained soon after the injection in the anterior projection. This is followed by static images in anterior, posterior, and lateral projections. A SPECT/CT may be performed, and is increasingly used, to localize the nodal site especially if there is a suspicion of localization of a deeper node. Blue dye (isosulfan blue) is injected intraoperatively as the transit is fast; many times the initial nodes may not be visualized. Handheld gamma probes have been used for detecting "hot nodes" for removal during surgery. In vivo and ex vivo counts are done over the node. Generally, nodes with counts more than ten times the background levels are considered sentinel.

SLN mapping is increasingly being used in gynecological cancers including vulvar cancer (Table 5) to prevent morbidity from en bloc inguinofemoral dissection. Standard treatment of vulvar SCC in those with T1–2, N0–1, and M0 tumor includes surgical excision of the tumor with unilateral or bilateral nodal dissection of the inguinofemoral nodal basins. The recurrence rate in the groin in those with pathologic negative nodes is less than 2%, and even in those with positive nodes on pathology, recurrence rates range between 5% and 10% [54, 55]. Total lymphadenectomy is associated with postoperative sequelae including cellulitis and lymphedema that results in increased morbidity and lower quality of life. SLN mapping is useful in allowing sampling of nodes and planning lymphadenectomies.

In an observational multicenter study (GROningen INternational Study on Sentinel lymph nodes in Vulvar cancer – GROINSS V), 276/403 patients with early-stage disease (T1/T2, primary lesion <4 cm, and clinically non-suspicious inguinofemoral LN) had negative SLN and did

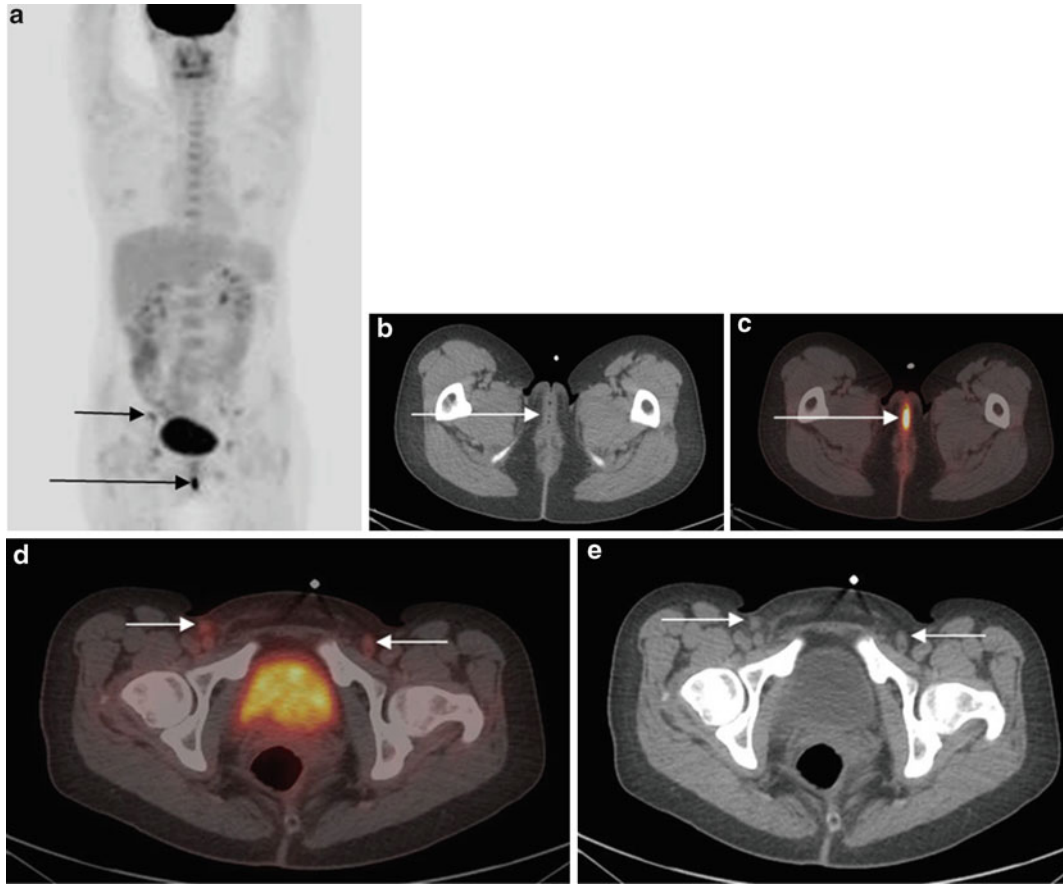

Fig. 5 A 36-year-old woman with history of recurrent vulvar carcinoma referred for restaging. (**a)** Whole-body MIP image shows [^{18}F]FDG uptake in the perineum (SUV_{max} 8.8) (*long arrow*) localizing to thickening in vulvar region noted on CT (**b**, *white arrow*) and fused PET/CT image (**c**, *white arrow*). Additional foci of uptake are seen in bilateral inguinal regions (MIP image a, *short arrow*) (**d**, **e**, SUV_{max} 2.5 on the left side) which were considered equivocal. The patient underwent radical vulvectomy with bilateral inguinal lymph node dissection; histopathology showed invasive squamous cell carcinoma vulva and negative nodes. (Teaching point: faint uptake in nodes is nonspecific and may be related to reactive uptake; however, assessment is best correlated with clinical suspicion)

not undergo lymphadenectomy. Groin recurrence rate was 3% at 2 years. Low incidence rates of short- and long-term morbidity were reported in patients who had negative SLN versus patients who underwent lymphadenectomy following positive SLN procedure, such as wound breakdown (11.7% vs 34%) and cellulitis (4.5% vs 21.3%). Incidence rates of long-term morbidities such as lymphedema and recurrent erysipelas were also more common in patients who underwent SLN with lymphadenectomy as compared to the group with only SLN (25.2% and 16.2% vs 1.9% and 0.4%, respectively) [56].

Histopathological sampling guided by SLN mapping using blue dye and ^{99m}Tc-sulfur colloid has been reported to be an effective method to detect inguinofemoral LN involvement in patients with early-stage disease with primary lesions less

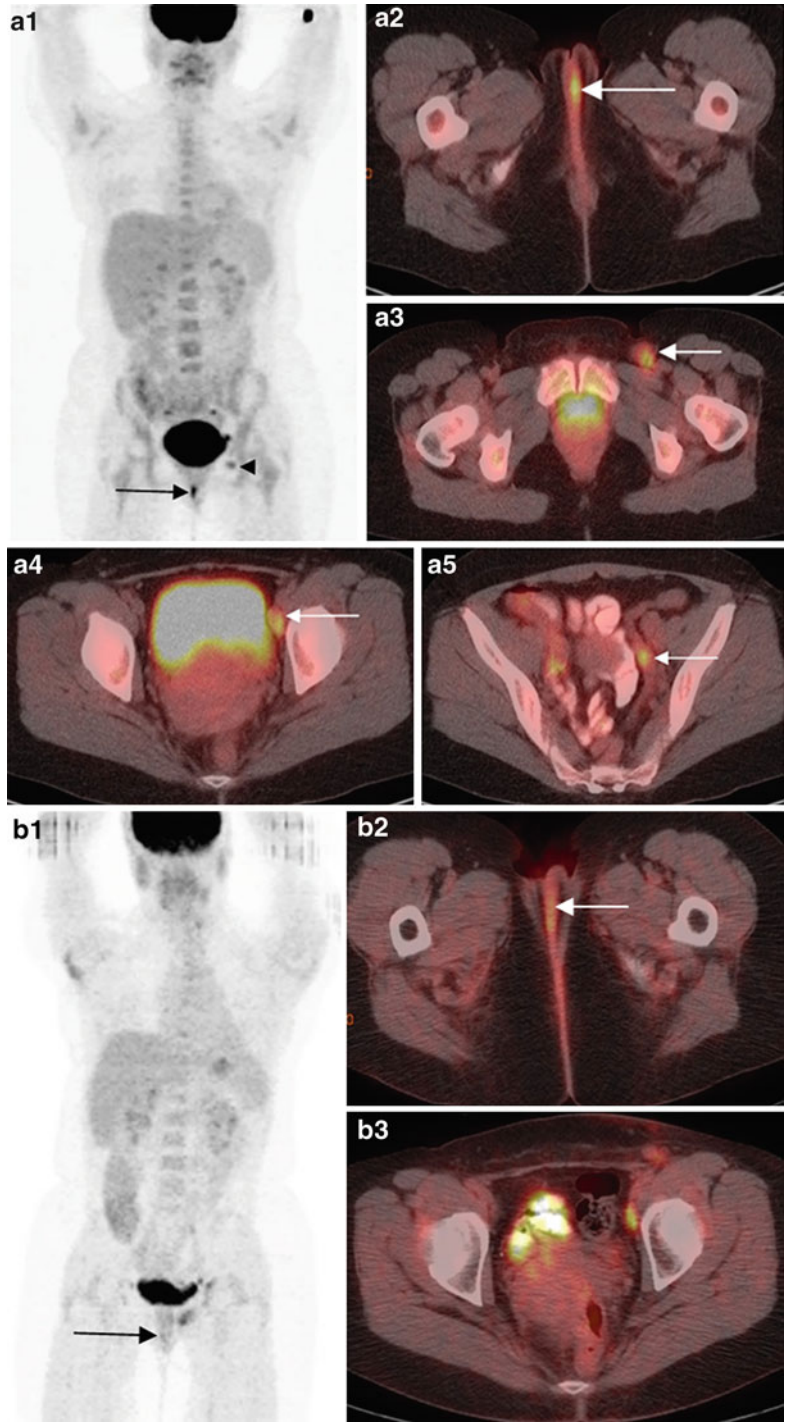

Fig. 6 (continued)

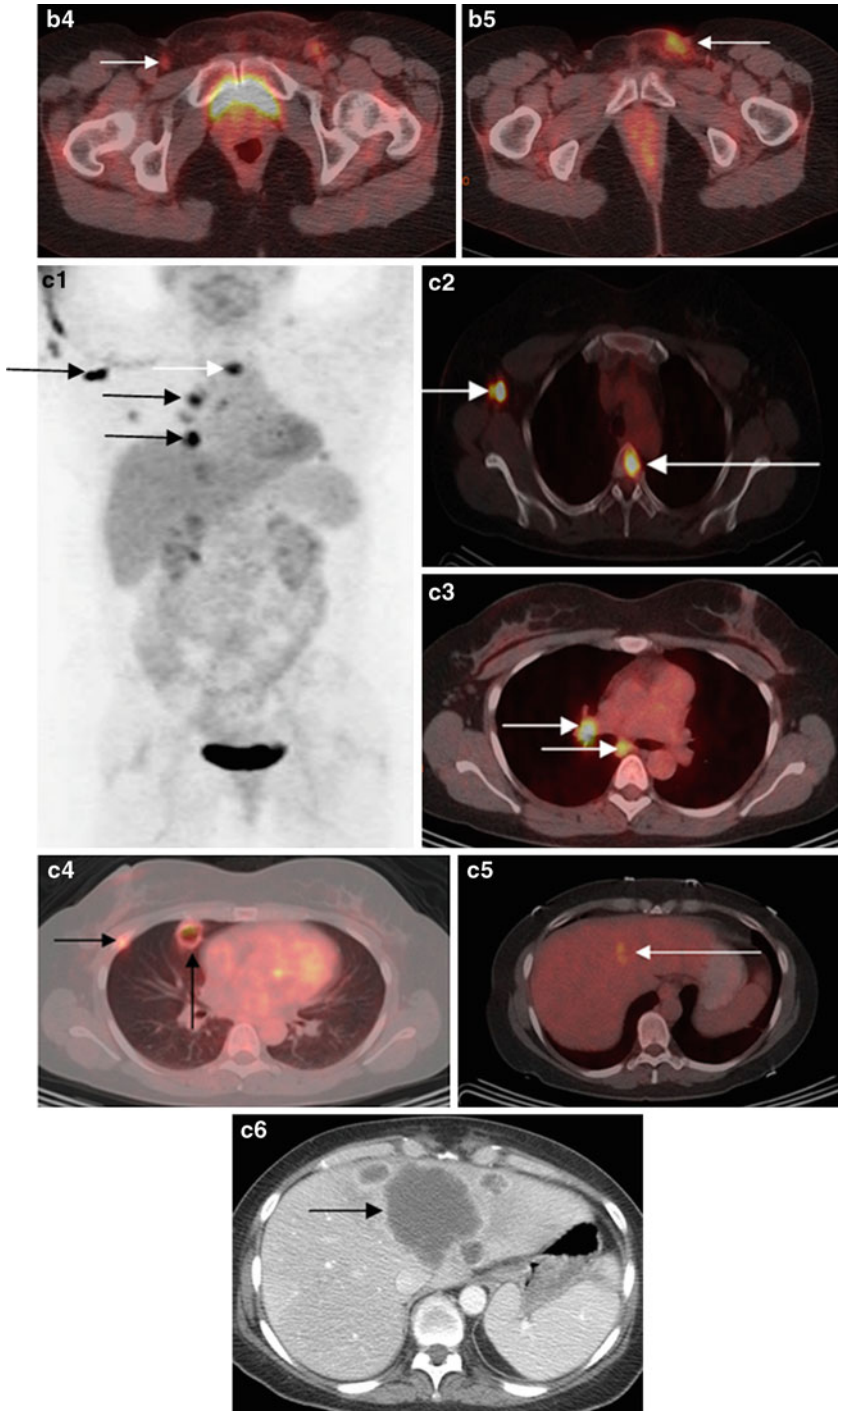

Fig. 6 (continued)

than 4 cm in size [57]. In a GOG 173 study, false-negative predictive value of SLN in those with primary lesion measuring less than 4 cm was only 2% but was higher at 7.4% for lesions measuring 4–6 cm. On a patient-based analysis, SN of the SLN procedure was 91.7% and false NPV was 3.7% [56, 57].

Using lymphoscintigraphy and intraoperative gamma probe, Decesare and colleagues reported sensitivity and NPV of 100% in a small number of patients [58]. In a slightly larger study, using the same technique, SN of SLN detection was 90% [59]. Using a combination of ^{99m}Tc-nanocolloid and blue patent dye to identify the sentinel node [60], de Hullu et al. noted superior (100%) localization of sentinel nodes by ^{99m}Tc-nanocolloid as against 56% with blue dye. A number of studies subsequently [61–63] have reported high detection rates using both blue dye and radiocolloid scintigraphy with sensitivity ranging between 90% and 100%. ^{99m}Tc-phytate also has been used for mapping with comparable results [64]. With midline vulvar cancer, the drainage is often to bilateral nodes that may miss detection [65] and bilateral lymphadenectomy is recommended. In a GOG 173 study, Coleman and colleagues studied the significance of SLN in those with larger tumors measuring 2–6 cm, lateral, midline, or lateral ambiguous tumors; many of these may have bilateral lymphatic drainage necessitating bilateral inguinal nodal dissection. In 234 patients with early-stage disease, lymphoscintigraphy however detected only unilateral drainage in 32 of 105 patients with midline tumor, which prevented nodal dissection on the contralateral side. Also larger tumors showed more ambiguous drainage suggesting value of SLN mapping in this subgroup of patients [66].

SPECT/CT imaging is more sensitive and combines the tracer localization with anatomic details providing a superior three-dimensional localization, thereby facilitating surgical excision (Fig. 9). It is reported to identify sentinel nodes in higher number of patients [67]. In a prospective study of 40 patients with direct comparison of planar vs SPECT/CT imaging, a higher number of nodes were detected with SPECT/CT; mean nodes/patient for SPECT were 8.7 vs 5.9 for planar imaging. In 17.5%, aberrant lymph drainage was noted with localization to gluteal, paravaginal, vesical, paravesical, and retrovesical regions [67]. Overall sensitivity and NPV was 100% for inguinofemoral nodal SLN detection in correlation with histopathology. About 71% (5/7) of patients with aberrant nodal drainage had midline tumors, highlighting the importance of SLN mapping in midline tumors. Similar experience in small number of patients was reported by another group [68]. Overall, the existing data documents feasibility and usefulness of LSG in vulvar cancer.

There has also been increasing interest in the use of fluorescent dyes like indocyanine green (ICG) [69] for evaluation of nodes based on

Fig. 6 A 41-year-old with vulvar SCC was initially referred for pretreatment evaluation of the primary disease and extent Panel **a**: Whole-body MIP image **a1** (*arrow*) shows abnormal uptake in vulvar region also noted on fused images **a2** (SUV_{max} 7.8). Increased uptake was also seen in left inguinal node (**a3**, SUV_{max} 4.3) as well as in left obturator node (**a4**, SUV 8.0). Foci of increased uptake superiorly in bilateral pelvis corresponded to physiologic uptake in bilateral adnexa (**a5**). Panel **b**: The patient was treated with chemoradiation and a follow-up [^{18}F]FDG scan showed resolution of focal uptake in the vulva (**b1**, **b2** *arrows*) as well as decreased uptake in the inguinal and obturator nodes (**b3**). Heterogeneous uptake in the mons pubis corresponding to ill-defined infiltrative changes and mildly avid right inguinal node (**b4**, **b5**) was likely post-radiation changes. Patient underwent partial vulvectomy and left inguinal node dissection. Panel **c**: Patient returned for routine follow-up imaging after 6 months. The scan showed several new lesions suspicious for metastatic disease including T3 vertebra (SUV_{max} 8) (**c2** *long arrow*), right axillary (**c2** *short arrow*), subcarinal and hilar lymph nodes (**c3**, *arrows*), and right lung lower lobe (**c4**, SUV_{max} 10.4). Mild focal uptake was also noted in the liver (**c5**, SUV_{max} 4.4), suspicious for metastatic lesion. Lung lesion was positive for malignant disease, and while the liver lesion was negative on biopsy, a follow-up CT revealed a large lesion in the same region and additional lesions in the liver, positive for metastatic disease (**c6**, *arrows*). Teaching point: [^{18}F]FDG PET can help detect unknown distant metastatic sites and early lesions

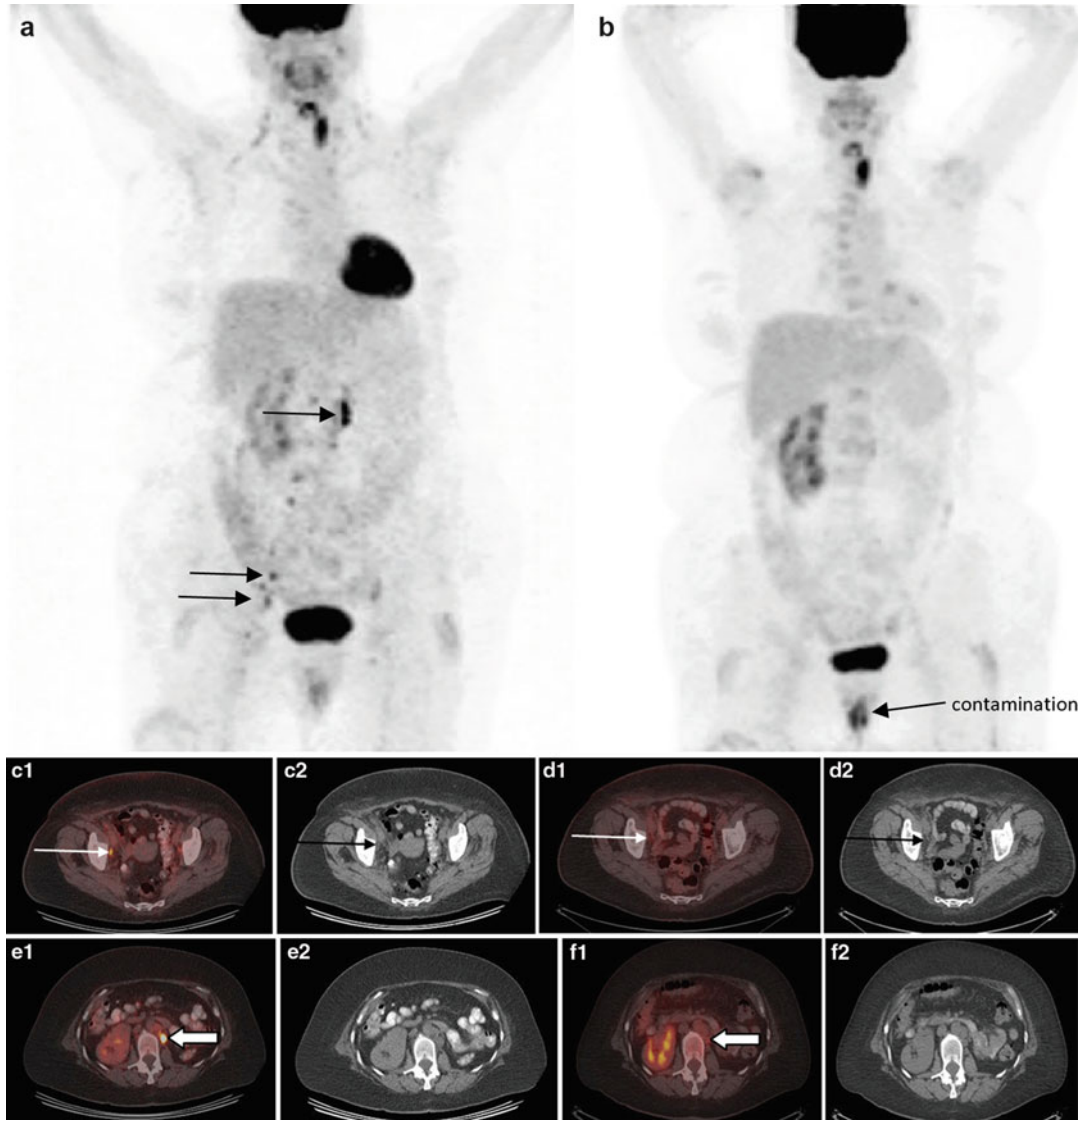

Fig. 7 Patient with poorly differentiated adenosquamous vulvar carcinoma referred for follow-up evaluation of extent of disease. Patient was prior treated with radical vulvectomy and nodal dissection. Whole-body MIP showed foci of increased [^{18}F]FDG uptake in the pelvis and abdomen (**a**, *arrows*) localizing to right obturator lymph node (**c1**, **c2** SUV_{max} 4.5) and left para-aortic lymph node (**e1**, **e2** SUV_{max} 11.6 *thick arrow*). Patient was treated with chemoradiation; a follow-up PET/CT to assess response showed complete resolution of disease and pelvic lymph nodes (**d1**, **d2** *arrows*) with partial response in para-aortic lymph node (**f1**, **f2** SUV_{max} 3.3, *thick arrow*)

near-infrared fluorescent imaging (NIRF). The faster transit and change in color that can be easily detected by the surgeon using infrared light are significant advantages of the use of fluorescent dyes. In a pilot study of ten patients with early-stage SCC of vulva, SLN were mapped using ^{99m}Tc-nanocolloid blue dye, and ICG to evaluate the feasibility of ICG SLN mapping. While largest numbers of nodes were mapped using nano-colloid, ICG mapped most of the SLN with added advantage of transcutaneous localization, especially in leaner patients [70].

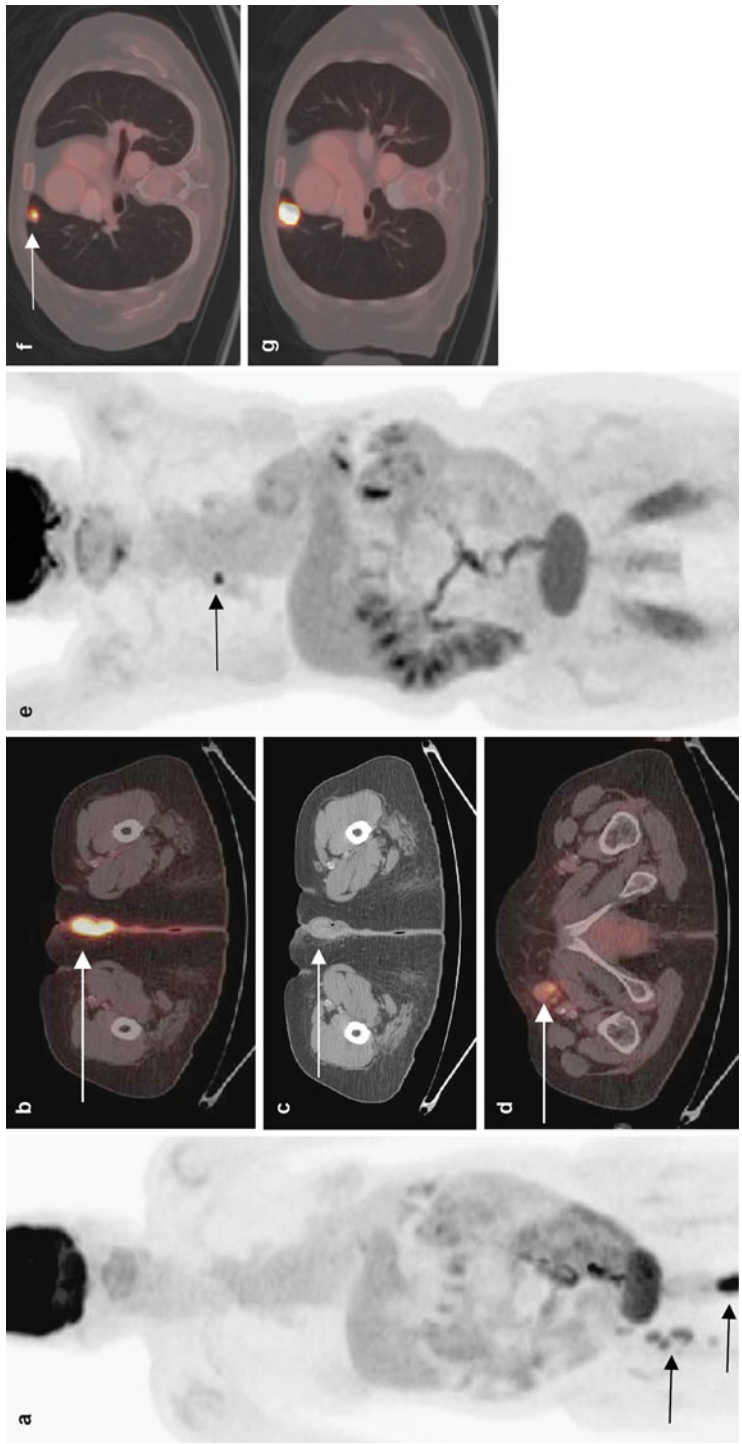

Fig. 8 A 72-year-old female with vulvar adenocarcinoma was referred for pretreatment evaluation of disease. Whole-body MIP image (**a**) showed abnormal uptake in the vulvar region (*arrows* **a**, **b**, **c**, SUV_{max} 9.0) and inguinal lymph nodes (**d**, SUV_{max} 4.9). A 6-month follow-up scan post chemoradiotherapy showed resolution of all the disease sites seen previously in the vulvar region and inguinofemoral nodes. However, a new focal uptake was noted in the right chest (**e**, *black arrow*) localizing to a nodule in the right lung upper lobe (**f**, SUV_{max} 5.9), which showed progression (**g**, SUV_{max} 12.6) on further follow-up imaging obtained after 3 months and was positive on pathology for metastatic disease

Table 5 Lymphoscintigraphy in vulvar cancer

Author and year	Type	Number of patients: FIGO staging	Histopathology confirmation (yes/no)	Comparison with blue dye (detection rate)	Sensitivity of LSG
de Hullu et al., 2000	Prospective	59: SCC stage I ($n = 25$), II ($n = 34$)	Yes	Yes (60%)	100%
Van der Zee et al., 2008	Prospective	403: SCC stage I	Yes	Yes	94.10%
Lindell et al., 2010	Retrospective	77: SCC stage I/II ($n = 76$), IVA ($n = 1$)	Yes	Yes (94% blue dye alone $n = 17$) (98% LSG and blue dye $n = 60$)	NA
Levenback et al., 2012	Prospective	452: SCC stage I	Yes	Yes (92.4%)	By patient basis 91.7%, by groin basis 92.1%
Klapdor et al., 2015	Prospective	40: SCC stage IA ($n = 5$), IB ($n = 26$), II ($n = 8$), III ($n = 1$)	Yes	Yes	100%
Collarino et al., 2015	Prospective	83: SCC stage IB ($n = 51$), II ($n = 9$), III ($n = 18$), IVA ($n = 2$), melanoma ($n = 2$), adenocarcinoma (n=l)	Yes	Yes	96.30%
Bogliolo et al., 2015	Retrospective	45: SCC stage I ($n = 14$), II ($n = 31$)	Yes	No	90%

Diagnostic Applications of Nuclear Medicine: Uterine Cancers

35

Neeta Pandit-Taskar, Sonia Mahajan, and Weining Ma

Abstract

Cervical and uterine malignancies are a significant health issue for women worldwide. Uterine cancers are the most common gynecological cancers, although ovarian cancers have the highest mortality. The primary modalities for anatomic imaging are ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI). These imaging tools are used for the diagnosis, staging, and posttherapy follow-up for detection of recurrent disease; however, they lack biologic information. Positron emission tomography (PET) with [^{18}F] fluoro-2-deoxy-D-glucose ([^{18}F]FDG) imaging plays a critical role in the evaluation of cervical and uterine malignancies. A number of studies have established the role of [^{18}F]FDG PET in the staging and prognosis of advanced cervical cancer. PET/MRI scanners with newer technology are available and in future may be the mainstay in assessment of gynecologic malignancies.

Radionuclide lymphoscintigraphy is an established technique for sentinel lymph node (SNL) mapping in vulvar cancer. For cervical and endometrial cancer, it can help prevent morbidities that follow lymphadenectomies and there is convincing evidence that SLN mapping can be useful in early-stage disease.

In this chapter, we discuss the role of nuclear imaging, especially [^{18}F]FDG PET scanning, and summarize the initial experiences with PET/MRI in cervical and uterine cancers; we also discuss the use of lymphoscintigraphy in gynecological cancers.

Cervical Cancer

Epidemiology and Prevalence

Cervical cancer is the second most common cancer in women worldwide and the third most common gynecologic cancer in the United States with 12,990 new cases and 4,120 deaths predicted in 2016 [1]. Cervical cancer was once a leading cause of cancer death for women in the United States; however, the prevalence and mortality have decreased significantly in the past few decades largely as a result of effective screening with the Papanicolaou (Pap) smear test. A continuous decline in the death rate has been observed, at a rate of nearly 0.8% each year. Cervical cancer is uncommon in women younger than 20 years, and most often occurs in women younger than 50 years although about 15–20% cases may occur in women over 65 years. It is more common in Black and Hispanic women compared

with non-Hispanic White women. The 5-year relative survival rate for early-stage invasive cervical cancer is 91.3%, while the overall 5-year survival rate for all stages is about 67.5% [1] (Fig. 1).

Cervical cancer is associated with several risk factors such as human papilloma virus (HPV), cigarette smoking, chlamydia, and human immunodeficiency virus (HIV) infection, long-term use of oral contraceptives or exposure to diethylstilbestrol (DES), diet low in fruits and vegetables, low socioeconomic status, multiple pregnancies, and younger age at first pregnancy. The most important risk factor for cervical cancer is HPV infection. The high-risk viral types are HPV 16, HPV 18, HPV 31, HPV 33, and HPV 45, with about two thirds of all cervical cancers being associated with HPV 16 and 18 [2]. Vaccines have been developed to help prevent infection with some types of HPV; currently three HPV vaccines have been approved for use in the United States by the Food and Drug Administration (FDA) [2].

Pathophysiology and Clinical Presentation

There are generally no symptoms in women with precancerous lesions and early cervical lesions.

The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC. http://www.springer.com)

Abnormal postmenopausal vaginal bleeding, including postcoital bleeding, intermenstrual bleeding, menorrhagia and spotting between periods, abnormal discharge, painful coitus, and bleeding after vaginal examination are some of the symptoms that are associated with advanced stages and invasive cancers. In some advanced-stage cases, symptoms of bowel obstruction or urinary tract obstruction may be found at presentation [3].

Cervical intraepithelial neoplasia (CIN) is a precursor lesion of cervical cancer and is graded into three groups based on cellular dysplasia: CIN 1 with minor dysplasia; CIN 2 with moderate dysplasia; and CIN 3 or carcinoma in-situ with severe dysplasia. Up to 40% of CIN 3 lesions could develop into invasive cervical cancer if left untreated.

Histologically, 80–90% of all cervical malignancies are squamous cell carcinoma (SCC) (Table 1), with 25% well-differentiated, keratinizing, large-cell SCC histology while 70% are moderately differentiated, non keratinizing, large-cell SCC. Small-cell undifferentiated carcinomas account for only about 5% of cases, but are associated with a poor prognosis. Adenocarcinomas arise from endocervical-type cells and constitute 5–20% of all cervical malignancies. The histologic patterns of adenocarcinoma include well-differentiated mucinous adenocarcinoma, papillary adenocarcinoma, and clear-cell types. Poorly differentiated and aggressive histologic subtypes of cervical adenocarcinoma are associated with a poorer prognosis compared with SCC. Miscellaneous, uncommon, or rare cancers of the cervix include variants of SCC and adenocarcinomas, mixed carcinomas, small-cell carcinoma, sarcoma, lymphoma, melanoma, and metastatic tumors. The most common metastases arise from endometrial primary tumors while others include the ovary, colon, and breast primaries [3–4].

Preinvasive lesions can be treated with electrocoagulation, conization, cryotherapy, laser ablation, or local surgery, while invasive cancers require surgery (total hysterectomy, modified radical hysterectomy, or radical trachelectomy), radiation or chemotherapy, or combination therapy. The survival rate for women with localized cancer is about 91% at 5 years. However, it is lower for women with advanced disease with relative 1-year and 5-year survival rates of 88% and 73%, respectively. The 5-year survival rate is 57% when tumor has spread to surrounding tissues or organs and/or the regional lymph nodes and is only 16.8% in the presence of distant metastatic disease [1].

Diagnosis of Cervical Cancer

The Pap test is a very effective screening test that has led to the detection of a large number of cervical cancers at early stages. The American Cancer

b. Secondary tumors

Society recommends screening for cervical cancer to start approximately 3 years after a woman begins to have vaginal intercourse, but no later than 21 years of age [2]. For women between 21 and 29 years of age, the Pap test is recommended every 3 years. At 30 or more years of age, both a Pap test and an HPV test should be performed every 5 years, or a Pap test only every 3 years. In women who have three normal test results in a row, screening may be performed every 2–3 years. Women with a higher risk such as those with HIV infection or a weak immune system may need to get screened more frequently. Women aged 65 years and older, who have had three or more consecutive normal Pap tests in the past 10 years and have not had any precancerous histology (CIN 2 or 3) detected in the previous 20 years, may choose to stop cervical cancer screening. Screening after total hysterectomy is not necessary, unless surgery was done for cervical cancer [2].

Patients with suspicious findings on Pap smear or patients with high-risk HPV strains could be further evaluated with colposcopy or colposcopy-directed biopsies of the suspicious areas and if necessary with conization to establish the diagnosis [2–5]. Those diagnosed with cervical cancer should undergo clinical staging with imaging and detailed pathology followed by surgical staging.

Role of Conventional Imaging

Patients are staged clinically according to the International Federation of Gynecologic and Obstetrics (FIGO) staging system (Table 2). Conventional imaging studies recommended for clinical staging include chest x-ray, barium enema, and intravenous urogram. However, ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) are increasingly being used. Intravenous pyelography (IVP) and barium enema are usually restricted for selective patients.

Surgical staging is generally done to assess pelvic and para-aortic lymph node (PALN) involvement, critical for further treatment and follow-up. Establishing the local extent of the primary tumor is very important and, while involvement of pelvic or para-aortic lymph nodes may not affect the FIGO staging, it identifies patients with a worse prognosis [6–9]. Spread of cervical cancer occurs initially by direct extension to local structures and regional lymphatics, later disseminating hematogenously to distant organs, such as the lung, bone, liver, and brain. Nodal metastasis sequentially involves first the pelvic lymph nodes followed by para-aortic and supraclavicular lymph nodes. Scalene nodes can also be involved in up to 17% of the cases, seen more commonly in patients who have para-aortic nodal disease [6, 10–11]. Bone metastasis occurs infrequently and therefore bone scans are not routinely indicated. Bone scans are indicated in patients with bone pain. For initial staging, imaging is critical to define the local extent of cervical cancer and detect local *and* distant nodal metastatic disease. Abdominal and pelvic CT provides high-resolution anatomic detail and is an integral part of routine staging. Disease in the cervix, uterus, parametrium and adnexa, as well as pelvic and abdominal nodes and extrapelvic disease sites, can be assessed with high sensitivity [12]. Evaluation of microscopic disease, however, is limited since the anatomic changes are subtle, thereby reducing the sensitivity of CT. In high-risk cases, CT of the chest is performed to detect lung and mediastinal disease.

MRI has superior soft tissue characterization and is preferred for assessment of the local extent of tumors (Figs. 2, 3, and 4). MRI can help predict endometrial involvement in about 84–96% of the cases compared with 55–80% for CT and has a high negative predictive value (NPV) [12–14]. Para-aortic nodal metastasis can be detected with high specificity; however, the sensitivity is only 50% [14]. Staging using physical examination, colposcopy, lesion biopsy, and cystoscopy or sigmoidoscopy may understage up to 30% of stage I and II cases and up to 40% of stage III cases. Conversely, it may overstage approximately 64% of patients with stage IIIB disease [8–9, 15–17]. Accurate assessment of tumor size, especially in endocervical location, parametrial and pelvic sidewall invasion, lymph node and distant metastases is extremely important for prognosis. Although CT is an integral part of the clinical staging, useful to evaluate both local extent and metastatic disease [18], CT is limited, especially in early stage [9] disease. Additional

Table 2 TNM and FIGO classification of carcinoma of the cervix

TNM categories (FIGO stage)	Description
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis[a]	Carcinoma in situ (preinvasive carcinoma)
T1 I	Cervical carcinoma confined to uterus (extension to corpus should be disregarded)
T1a[b] **(IA)**	Invasive carcinoma diagnosed only by microscopy. Stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium and a horizontal spread of 7.0 mm or less. Vascular space involvement, venous or lymphatic, does not affect classification
T1a1 (IA1)	Measured stromal invasion 3.0 mm or less in depth and 7.0 mm or less in horizontal spread
T1a2 (IA2)	Measured stromal invasion more than 3.0 mm and not more than 5.0 mm with a horizontal spread 7.0 mm or less
T1b (IB)	Clinically visible lesion confined to the cervix or microscopic lesion greater than T1a/IA2
T1b1 (IB1)	Clinically visible lesion 4.0 cm or less in greatest dimension
T1b2 (IB2)	Clinically visible lesion more than 4.0 cm in greatest dimension
T2 (II)	Cervical carcinoma invades beyond uterus but not to pelvic wall or to lower third of vagina
T2a (IIA)	Tumor without parametrial invasion
T2a1 (IIA1)	Clinically visible lesion 4.0 cm or less in greatest dimension
T2a2 (IIA2)	Clinically visible lesion more than 4.0 cm in greatest dimension
T2b (IIB)	Tumor with parametrial invasion
T3 (III)	Tumor extends to pelvic wall and/or involves lower third of vagina, and/or causes hydronephrosis or nonfunctioning kidney
T3a (IIIA)	Tumor involves lower third of vagina, no extension to pelvic wall
T3b (IIIB)	Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
T4 (IVA)	Tumor invades mucosa of bladder or rectum, and/or extends beyond true pelvis (bullous edema is not sufficient to classify a tumor as T4)
Nodal stage	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1 (IIIB)	Regional lymph node metastasis
Metastasis	
M0	No distant metastasis
M1 (IVB)	Distant metastasis (including peritoneal spread, involvement of supraclavicular, mediastinal, or para-aortic lymph nodes, lung, liver, or bone)

[a]Note: FIGO no longer includes stage 0 (Tis)
[b]All microscopically visible lesions, even with superficial invasion are T1b/IB

imaging with MRI and [^{18}F]FDG PET/CT can provide critical information for management of disease.

[^{18}F]FDG PET Imaging

PET/CT is useful in the staging of cervical cancer patients to assess local extent, pelvic nodal involvement, and detect distant metastases. This information is useful for planning surgery and/or for radiation therapy planning. It is useful in assessing response to neoadjuvant therapy and for identification of persistent/recurrent disease after treatment.

Primary Cervical Cancer

[^{18}F]FDG avidly localizes in cervical cancer. The uptake of [^{18}F]FDG in cervical cancer appears to be related to high GLUT-1 expression in tumor cells; however, there is no established correlation of PET/CT-based standardized uptake value (SUV) or GLUT-1 expression with the initial

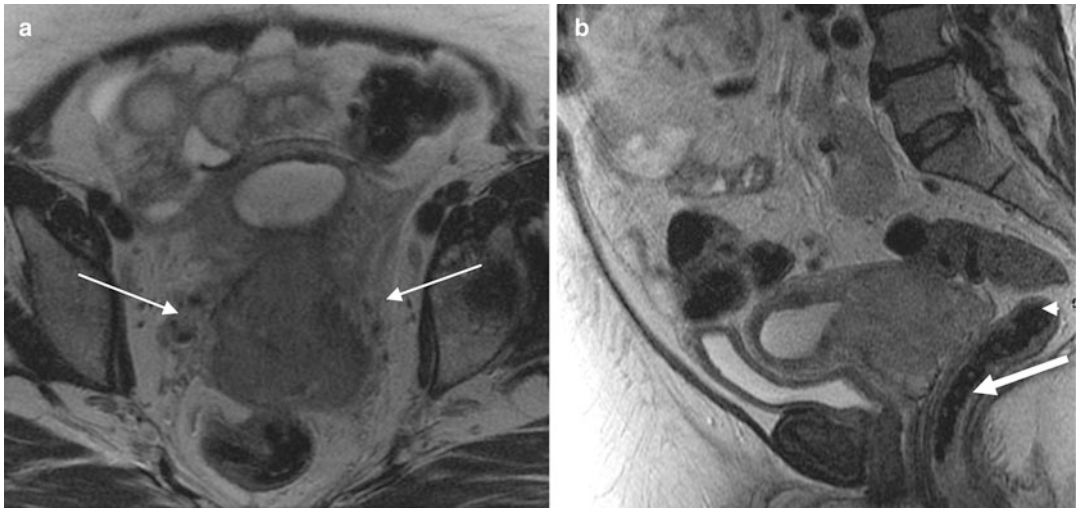

Fig. 2 Magnetic resonance imaging of the pelvis: axial T2-weighted (**a**) and sagittal T2-weighted images (**b**) show a large soft tissue mass in the cervix invading the parametrium bilaterally (*white arrows*), involving the upper third of the vagina (*thick arrow*), and abutting the anterior wall of the rectosigmoid colon (*arrow head*). No bladder or lower vaginal invasion is noted. Biopsy revealed well- to moderately differentiated squamous cell carcinoma

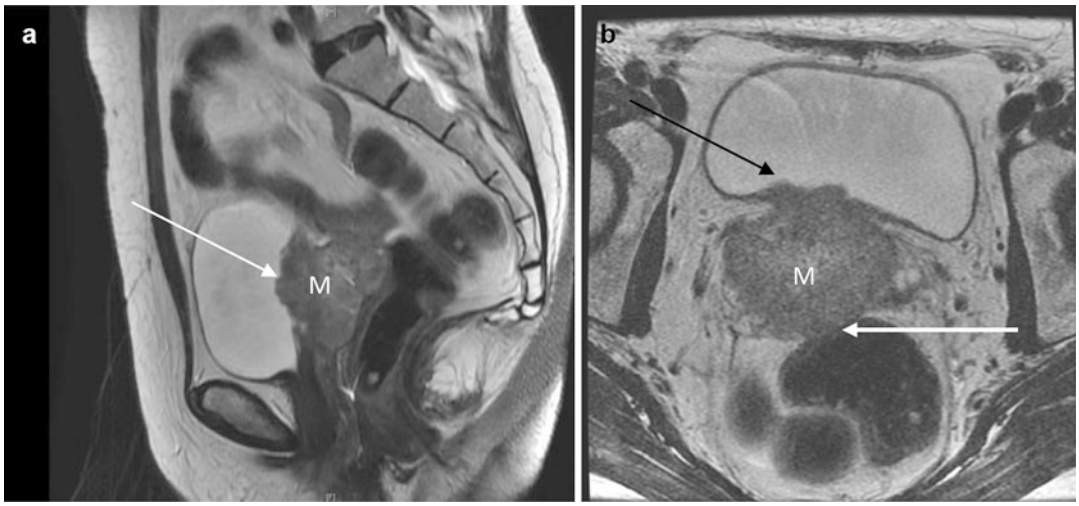

Fig. 3 Magnetic resonance imaging of the pelvis: (**a**) sagittal T2-weighted image shows a soft tissue mass (*M*) arising from cervical stump, status after prior supracervical hysterectomy for cervical cancer, invading posterior bladder wall (*black arrows*); (**b**) axial T2-weighted image shows cervical stump of recurrent mass again invading the posterior bladder wall (*black arrow*) and possibly invading anterior rectal wall, with obliteration of fat planes (*white arrow*). Surgical pathology showed squamous cell carcinoma, moderately or poorly differentiated

grade of histologic differentiation and FIGO staging. Higher GLUT-1 expression is seen in recurrent or persistent disease than in metastatic lymph nodes [19]. Similarly, a higher PET positivity has been noted in pathologically positive nodes with higher expression of GLUT-1 and HK-II [20].

Although most primary cervical cancers accumulate [^{18}F]FDG (Fig. 5), poorly differentiated and squamous cell histology tumors are more [^{18}F]FDG avid. In 240 patients with stage I–IV disease, a significant difference in uptake was seen in well vs. poorly differentiated lesions with a mean

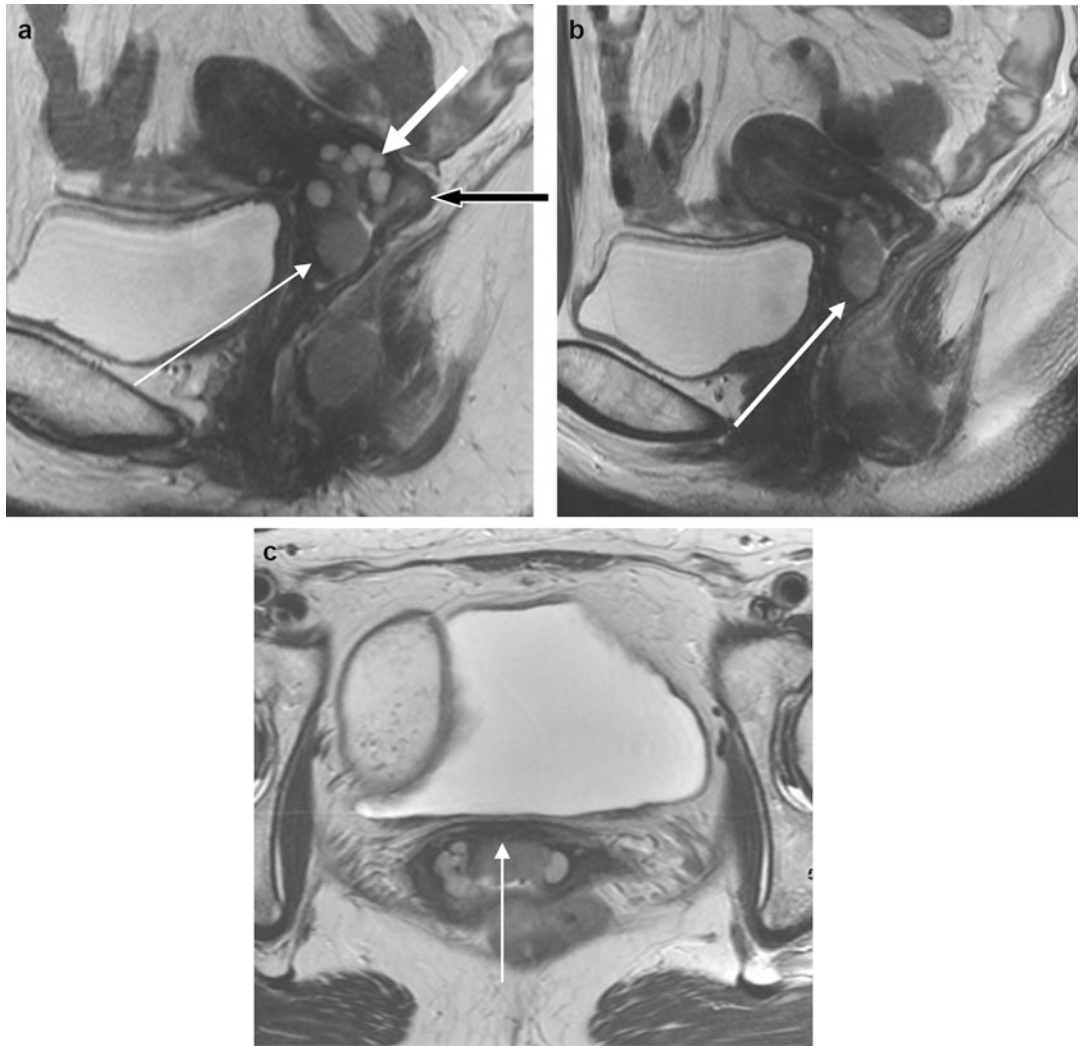

Fig. 4 Magnetic resonance imaging of the pelvis: (**a**, **b**) sagittal T2-weighted and axial T2-weighted images (**c**) show intermediate T2 signal intensity of cervical lesion consistent with cervical cancer (*white thin arrows*). The bulk of the lesion within the ventral aspect of the cervical canal demonstrates deep stromal invasion, without extension involving the parametrium. Then tumor extends into the posterior aspect of the cervix into the posterior fornix of the vagina (**a**, *black arrow*). Multiple nabothian cysts are seen in the cervical canal (**a**, *white thick arrow*). The tumor abuts the internal cervical os and no extension into the lower uterine segment is seen

SUV_{max} of 8.58 for well-differentiated, 11.56 for moderately differentiated, and 12.23 for poorly differentiated tumors [19]. Higher uptakes were seen in squamous cell histology (average SUV_{max} of 11.91, range 2.50–50.39) than in non-squamous histology (average SUV_{max} of 8.05, range 2.83–13.92). A higher SUV_{max} is associated with an increased risk of nodal involvement: Patients with $SUV_{max} < 5$ had 24% nodal involvement compared with 59% for patients with SUV_{max} 5–14, and 72% for those with $SUV_{max} > 14$ [19]. Similar findings were noted for 43 patients with cervical cancer (stage IB–IVB) where, using a cut-off SUV_{max} value of 13.5 for defining high- vs. low-uptake groups, it was noted that lymph node metastasis, predominantly pelvic, was more commonly seen in the high SUV_{max} group (73%, 16/22) than in the low SUV_{max} group (38%, 8/21) [21].

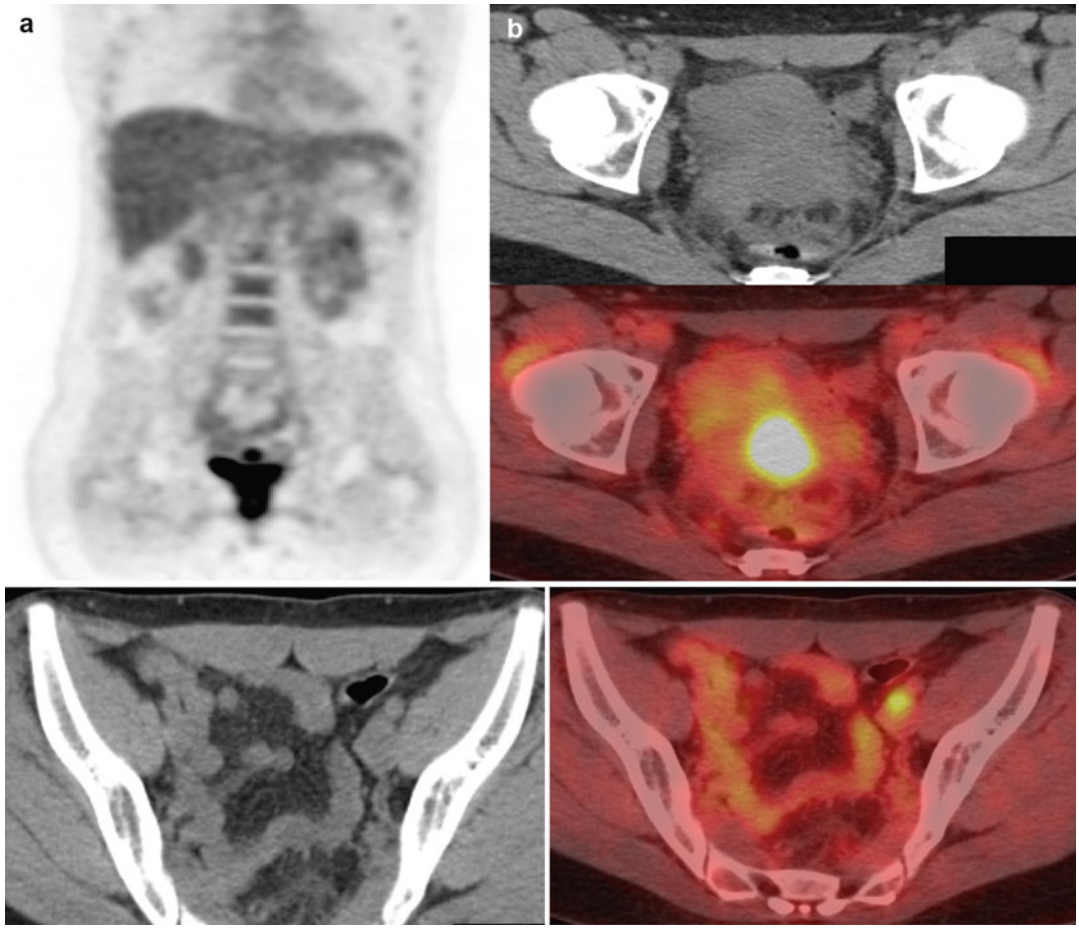

Fig. 5 (**a**, **b**) Primary carcinoma of the cervix: extent of disease at diagnosis. A 50-year-old woman with cervical cancer. [^{18}F]FDG PET/CT showed abnormal uptake (SUV_{max} 13.6) in the cervix and uptake in left external iliac node

Early studies used dedicated PET scanners without CT capability [22]. Fusion imaging with PET/CT scanners improves localization and hence diagnosis thereby leading to a decrease in equivocal results. This is especially relevant for gynecologic malignancies where peritoneal and serosal bowel implants may be obscured by physiological [^{18}F]FDG activity. Early studies showed the increased accuracy of hybrid PET and CT imaging compared with side-by-side reading of CT and PET. These studies demonstrated improved accuracy in detecting nodal involvement and lesions adjacent to the chest or abdominal wall or bowel [23]. The hybrid method also improved characterization of physiological and inflammatory uptake [24].

In 13 primary and metastatic uterine cervical cancer patients, PET/CT provided more definite lesion localization in 30% and additional definite lesion characterization in 20% of patients compared with PET alone. There was higher diagnostic accuracy with PET/CT than with PET alone on a lesion-based analysis (92% vs. 78%), although no difference was noted for evaluation of metastatic disease [25].

[^{18}F]FDG PET in Staging of Cervical Cancer

Clinical studies have shown the usefulness of PET/CT in staging cervical cancer (Table 3). While

NA not available, *SCC* squamous cell carcinoma

the reported sensitivity is variable ranging from 38% to 86%, a definite advantage of [^{18}F]FDG PET is the ability to detect (a) involvement of lymph nodes that are benign using size criteria and (b) distant metastases that were not detected by other imaging modalities [26], especially defining pelvic and distant nodal status [27–29]. In a retrospective analysis ($n = 41$) [^{18}F]FDG PET showed 100% accuracy in detecting disease for initial staging, while for restaging, sensitivity and specificity were 82% and 97%, respectively [22]. MRI facilitates an excellent evaluation of local tumor and parametrial involvement, while PET is more useful for the evaluation of pelvic lymph nodes; however, microscopic disease is missed by both modalities [30]. An additional advantage of PET/CT over MRI includes the ability to image larger scanning areas allowing for an estimation of thoracic or suprathoracic disease in a single study. Tran and colleagues detected supraclavicular nodal involvement in about 8% of patients with a 100% positive predictive value (PPV) [11].

The sensitivity and accuracy of [^{18}F]FDG for detection of lesions are higher for advanced disease but lower in early-stage disease including stage IA2–IIA, although abnormal lymph nodes may be detected better with [^{18}F]FDG PET than with CT [31–34].

[^{18}F]FDG PET is more sensitive than CT or MRI for detecting lymph node metastases [27–28, 32, 34–37]. Using a cut-off SUV_{max} value of 2.5 on PET/CT and 1 cm or greater lesion size on MRI, higher sensitivity and accuracy for detecting lymph node metastases were noted with [^{18}F]FDG PET compared with MRI (91% and 98%, respectively, vs. 37.3% and 95%, respectively). MRI yielded negative findings for 63% of positive lymph nodes diagnosed, and 56% (19/34) of patients were inappropriately classified. MRI also gave false-positive results in 16 lymph nodes [37]. However, the sensitivity for micrometastasis in early cervical cancer is low for both; in 120 patients who had a normal MRI for pelvic nodes, PET had low sensitivity for detection of micrometastasis;, all PET-undetected nodes had micrometastasis with a mean tumor focus of 4.0 × 3.0 mm (range 0.5 × 0.5 to 7 × 6 mm) [32]. Other groups have reported a false-negative lymph node detection rate for [^{18}F]FDG PET between 13% and 32% cases, although detection was overall better compared with CT [33, 38–39]. Higher sensitivity with MRI (93%) has been reported using iron oxide nanoparticles for contrast-enhanced imaging for nodal detection than when using the conventional size criteria (29%) [40].

In a study of 22 patients with stage IB–IVA cervical cancer, Choi et al. found that PET/CT had a higher sensitivity (57%) than MRI (33%) for lymph node detection, and that nodal size was critical for detection. In their study, the short-axis dimension of metastatic lymph nodes was 11.8 ± 3.5 mm while that of nonmetastatic nodes was (6.5 ± 4.6 mm); understandably, the detection of lymph node metastases was higher for areas of larger involvement. Regionwise, the overall sensitivity of MRI for detecting lymph node metastases (32.0%) appears to be lower than PET, with a detection rate of 42.9% and 54.5% for tumor diameters of 5–10 mm and >10 mm, respectively [41]. Some studies report a high number of false negatives (8/10 or 80%) in lesions smaller than 10 mm in diameter, noted on thin-slice examination of the pathological specimen [32]. Overall reported sensitivities for disease detection in cervical cancer are widely variable, possibly due to differences in the completeness of surgical staging and the number of lymph nodes removed.

The value of PET/CT in early-stage cervical cancer is limited and while not recommended as a routine evaluation for staging [32–33, 42–43], it has a high specificity especially for detecting nodal disease, although small-volume disease may be missed. In a study by Sironi et al., 47 patients with stage IA and IB disease were evaluated preoperatively. The overall patient-based sensitivity and specificity of PET/CT was 73% and 97%, respectively. The overall node-based specificity was 99.7% and while the overall sensitivity was lower (72%), a 100% sensitivity was seen for lymph nodes larger than 0.5 cm in diameter [44].

In a recent retrospective analysis of 113 patients, [^{18}F]FDG PET/CT showed high accuracy in preoperative staging (94.7%) and was superior to clinical staging. Six patients were upstaged based on [^{18}F]FDG findings. Nodal staging had lower sensitivity (53.8%) but was more specific (95%)

[45]. The study evaluated use of metabolic tumor volume (MTV) for predicting stromal invasion and showed that an MTV cut-off of 8.76 had a sensitivity of 75.0% and specificity of 76.2% for predicting stromal invasion and may be a useful parameter. This, however, needs to be established in a larger study.

In a prospective study of 120 patients with newly diagnosed cervical cancer with FIGO stage ≥IB, [^{18}F]FDG PET/CT had 75% sensitivity and 96% specificity for nodal status in those who underwent surgery [46]. For para-aortic nodal disease, the PPV was 94%, NPV 100%, sensitivity 100% and specificity 99%, while for distant metastasis PPV was 63%, NPV 100%, sensitivity 100%, and specificity 94%. This highlights the ability to decide on the management of patients: Those with PET-positive nodes can be offered radio/chemotherapy instead of surgery, and patients with para-aortic nodal involvement may be treated with extended-field radiotherapy [46]. In comparison with MRI, [^{18}F]FDG PET shows higher sensitivity for the detection of para-aortic nodes and may be useful in guiding PALN dissection [47].

False-positive findings on [^{18}F]FDG PET may be seen for lymph nodes with granulomatous involvement or in reactive nodes especially in sites such as the axilla and groin, which may raise concern for metastatic disease and lead to further evaluation. The limitations of [^{18}F]FDG PET also include false-negative results related to low spatial resolution and micrometastasis, and false-positive results related to bowel uptake and urinary artifacts. Distant metastases are uncommon in sites like the neck or mediastinum, while metastases in the liver, lung, omentum, or bones are seen in more aggressive and higher-stage disease [46].

Pelvic and Para-Aortic Lymph Node Assessment at Initial Staging, in Locally Advanced and Advanced Cervical Cancer

The rate of PALN involvement in locally advanced cervical cancer (LACC) is 15–20%, and it carries a poor prognosis with an overall survival (OS) rate of only 17% [48–49]. Early studies using [^{18}F]FDG PET with 12 or more subjects and with a clinical follow-up of 6 months or longer, or histopathology as the reference standards, showed a pooled sensitivity of 79% (95% CI, 65–90%) and a pooled specificity of 99% (96–99%) for detection of pelvic or para-aortic lymph node metastasis in patients with newly diagnosed cervical cancer [27–29, 44, 50]. In comparisons of PET with MRI with CT, PET was superior to both [31, 33, 50]. CT had a pooled sensitivity of 47% (95% CI, 21–73%) and MRI had a pooled sensitivity of 72% (95% CI, 53–87%) and a pooled specificity of 96% (95% CI, 92–98%).

Sugawara et al. in a study of 21 patients with cervical cancer of stages IB to IVA, reported a sensitivity of 86% for [^{18}F]FDG PET in pelvic lymph node and PALN metastasis detection, which was higher than CT (57% sensitivity) [51]. Rose et al. studied presurgical patients with stages IIB–IVA and reported a sensitivity of 75% and specificity of 92% for [^{18}F]FDG PET in depicting PALN metastasis. In these studies there was overall higher sensitivity (100%) for PLN detection than for PALN metastases [27].

In prospective studies comparing [^{18}F]FDG PET imaging for PALN metastasis with histopathology after para-aortic lymphadenectomy, the pooled sensitivity of PET for the detection of PALN metastasis was 84% (95% CI, 68–94%) and the pooled specificity was 95% (89–98%) [33, 52–54]. Pooled data from 15 studies on [^{18}F]FDG PET in cervical cancer showed 84% sensitivity (range 68–98%) and 95% specificity (range 89–98%) for PALN metastasis, with a 79% sensitivity (range 65–90%) and 99% specificity (range 96–99%) for PLN metastasis [55].

In a meta-analysis of PALN detection, data from ten studies involving 385 patients showed the overall specificity of [^{18}F]FDG PET to be as high as 97% (95% CI, 93–99%), but with a low overall sensitivity that was highly variable among the studies (average 34%; 95% CI, 10–72%). In the five studies with a prevalence of PALN metastasis greater than 15%, the estimated sensitivity and specificity were 73% (95% CI, 53–87%) and 93% (95% CI, 86–97%), respectively. With this diagnostic performance and assuming a 15%

prevalence, the calculated false-positive and false-negative rates were 35% and 5%, respectively. This suggests a greater value of PET in those with high clinical probability of PALN metastasis than when used for patients with a low risk of PALN involvement [35]. [^{18}F]FDG PET may be of value in patients with normal CT or MRI of the abdomen [52–53, 56]. In a small-sized study of patients with locally advanced (FIGO stage IIB-IVA) cervical squamous cancer with normal, conventional CT findings, PET/CT scans were done prospectively, followed by surgery. Based on histopathological confirmation, the accuracy, sensitivity, specificity, PPV, and NPV of PET/CT for PALN metastasis were 75%, 50%, 83.3%, 50%, and 83.3%, respectively. Change of management based on PET/CT findings occurred for four of 16 (25%) patients [56]. Compared with the histopathological analysis of pelvic and para-aortic nodes from 22 patients, two of the four para-aortic metastatic nodes were missed on preoperative PET/CT imaging [31]. The false-negative rate for detection of PALN involvement by PET can vary between 4% and 17%, most likely related to small lesions and micrometastasis, which should be considered before planning radiation treatment. In 98 patients with LACC (stage IB2–IVA), 8.4% of patients with negative PET/CT findings had metastatic disease within PALN; all of the patients also had no evidence of extrapelvic disease detected on preoperative CT or MRI. Nodal metastases of 5 mm or smaller were found in four patients and larger than 1 cm in the other four patients [57]. Similar results were noted from other studies, which found a low sensitivity (33–36%) for the detection of microscopic involvement and disease in small nodes [58–59]. Of the 27 patients with positive pelvic nodes but negative PALN on PET/CT, six patients (22%) had histopathologically positive PALN. PALN dissection should be part of pretherapeutic staging for every LACC patient before undergoing definitive concurrent chemoradiotherapy [57–60].

For pelvic nodal assessment, the use of [^{18}F]FDG PET imaging for routine staging prior to radical hysterectomy and PLN dissection is still controversial, although the high specificity and NPV of [^{18}F]FDG PET may be helpful in planning the appropriate surgical procedure [61]. In a retrospective review, PET/CT was found to have limited sensitivity (36.4%) but high specificity for predicting PLN metastasis. With a median number of harvested lymph nodes of 29 (range 13–57), 17 (50.0%) had PLN metastases. The overall region-specific sensitivity and specificity of PET/CT was 36.4% and 98.8%, respectively [61].

Overall, PET is of value in nodal assessment and can also guide management. While microscopic disease and small nodes may be missed, the clinical significance and impact of such findings in conjunction with normal conventional imaging remains to be determined in view of systemic therapy that may be instituted.

Prognostic Value of PET/CT

High uptake of [^{18}F]FDG in the primary disease may influence the outcome and is linked to survival and recurrence. In 44 patients with FIGO clinical stage IB–IIA, SUV_{max} was significantly higher in patients with deep stromal invasion, lymph-vascular space invasion, and a tumor size of more than 4 cm. An SUV_{max} greater than or equal to 13.4 correlated with a reduced disease-free survival rate and was a significant independent predictor of recurrence. If validated in larger studies, the uptake and cut-off may be used in planning a more aggressive multimodal treatment [62].

Recent studies have evaluated and shown prognostic value of volume-based quantification of tumor [^{18}F]FDG uptake in patients with cervical cancer. In a comparison between MRI and PET findings, quantitative MRI parameters such as mean apparent diffusion coefficient (ADC) on pretreatment diffusion-weighted MRI, MTV (with threshold 42%), and total lesion glycolysis (TLG) from PET/CT showed a significant correlation with adverse prognostic factors such as advanced FIGO stage and lymph node metastases, disease-free survival, and OS, while no correlation was found for the SUV_{max} value of the lesions [63]. Chung et al. demonstrated that preoperative MTV more than or equal to 23.4 ml was a better predictor of disease-free survival and recurrence in patients with early-stage disease [64]. In 73 patients (stage IB1–IVA), a primary tumor TLG cut-off value of 7,600 was

better than SUV_{max} for identifying patients with higher risk of recurrence [65]. Overall, there is variation in the TLG and MTV cut-off values correlated with prognostic factors. Several studies have shown TLG cut-off values of 215 or 562 to be an independent predictor of recurrence-free survival [66–67]. In a more recent study, lower values of MTV larger than 5.6 ml and TLG greater than 21.6 ml were significantly associated with OS and progression-free survival (PFS) [68].

Nodal uptake and extent detected by [^{18}F]FDG PET in cervical cancer also stratifies patients for recurrence and survival outcomes. Assessment of PALN metastasis is prognostically important and is related to PFS in advanced cervical cancer. The presence of nodal disease on the [^{18}F]FDG PET scan can help predict cause-specific survival, prognosis, and OS. In a study of 47 patients with FIGO stage IIIB cervical cancer who were evaluated before therapy, the 3-year cause-specific survival was highest for patients without nodal metastasis at 73%, lower for those with only PLN metastasis at 58%, 29% for patients with pelvic and PALN disease, and the lowest (0%) for those with pelvic, para-aortic, and supraclavicular lymph node metastasis [69]. Similar findings were noted in a larger prospective study of patients with newly diagnosed cervical cancer patients ($n = 560$, stage IA2–IVA) that showed decreased survival with nodal involvement for all stages and an increased risk of recurrence with the number and site of distant nodal metastasis being the highest for supraclavicular nodal involvement and lowest for pelvic nodal disease only [70]. Distant nodal uptake is linked to an adverse prognosis. Involvement of the supraclavicular node or scalene nodes can be seen in about 0–17% of patients, more commonly in those who have para-aortic node disease [71–72] with a PPV as high as 100% [72]. Therefore, PET findings might help in selecting suitable patients for curative primary and/or salvage treatment. In a follow-up study by the same group, recurrence-free survival, disease-specific survival, and OS were correlated with PET-based cervical tumor volume, SUV_{max}, and lymph node status. Lymph node status had the highest influence on patient outcome, followed by cervical tumor volume [73].

A number of studies have shown an adverse effect on outcomes and higher recurrence rates in patients with PALN disease. In a retrospective study of 336 patients, OS at 2 years was significantly lower for patients who were surgically or imaging positive for PALN on PET or CT compared with those who were negative for PALN disease by surgery or imaging [10]. [^{18}F]FDG uptake in nodes on PET studies has also been correlated with outcomes. SUV_{max} in PALN is also a significant prognostic factor; in 70 patients with FIGO stage I–IV, SUV_{max} greater than or equal to 3.3 for PALN was a significant adverse factor [74]. SUV_{max} values of PLN have been correlated with PALN recurrence and survival after chemoradiotherapy; an SUV_{max} cut-off value of 3.85 or more was found to be an independent risk factor and those with SUV_{max} greater than 3.85 had significantly worse PFS than those with lower SUV_{max} [75]. The definitive SUV_{max} cut-off that can be universally applied clinically is not yet definite, as others have noted higher SUV_{max} cut-off values of up to 7.5 correlating with recurrences [76].

In multivariate analysis, the detection of nodes by imaging was independently associated with a poorer prognosis compared with those detected at surgery only [77]. A recent meta-analysis including 14 studies ($n = 1{,}150$) summarized the findings on prognostic indicators in imaging. While there is variation in the methodology and descriptions of SUV_{max} cut-off and some studies have found no significant correlation [78–80], the majority of data support the association of a higher risk of recurrence and poor outcomes with a higher SUV_{max} of the primary or nodal lesions [81]. Only limited studies have shown the value of SUV_{max} in PLN and PALN as a single independent predictor of outcomes [82–84]. Outcomes following chemoradiation therapy were found to be best for patients without PALN by surgical and radiographic imaging. In multivariate analysis, detection of metastatic lymph nodes by imaging was independently associated with a poorer prognosis for disease progression compared with nodal positivity at surgery only [77].

In patients with LACC, PET and MRI were compared with FIGO staging for impact on outcomes measured by OS, relapse-free survival,

time to failure, local failure, nodal failure, and distant failure. In 206 patients the OS rate was 59% at 5 years. Local failure was mostly associated with adenocarcinoma, and involvement of the corpus on MRI was significantly associated with nodal involvement. Nodal status on PET was a major predictor of outcome in LACC undergoing chemoradiation and was superior to FIGO staging, while MRI tumor volume was a predictor of locoregional relapse [85].

[^{18}F]FDG PET in Cervical Cancer: Impact on Management and Treatment Planning

[^{18}F]FDG PET/CT can alter management by detecting nodal disease or unknown metastatic sites (Figs. 6 and 7) [71, 86–87]. Patients with cervical cancer whose CT and MRI studies showed metastases limited to para-aortic, inguinal, and/or supraclavicular lymph nodes were prospectively evaluated for the impact of the addition of PET or PET/CT on management. PET had a positive clinical impact in 21 (44.7%) of the 47 patients, including detection of additional curable sites ($n = 8$), down-staging ($n = 6$), offering metabolic biopsy ($n = 4$), or change of treatment to palliation ($n = 3$) [71]. In a more recent study, [^{18}F]FDG PET led to a major change in management in 32% patients owing to the detection of more extensive local nodal involvement, occult metastatic disease, synchronous tumors, or exclusion of otherwise equivocal lymph nodes on MRI [87].

An accurate status of nodal involvement is critical for treatment planning. For those patients with PET-negative lymph nodes, there is no benefit of combined treatment with radiation therapy and chemotherapy vs. radiation therapy alone [88]. PET/CT maximizes patient triage to correct therapy in pretreatment of early-stage disease; combined MRI and PET/CT spares patients unnecessary trimodality therapy [89].

[^{18}F]FDG PET has been useful for management and therapy planning in about 14–35% of cases [90–91]. Pretherapeutic assessment with [^{18}F]FDG PET is useful in guiding therapy [50, 87]. PET/CT led to modifications of the radiotherapy dose or field in 32–34% and to major alterations in treatment plans in 23% of patients with widespread disease, with a reported minor impact in 8% of patients [50, 87].

Pretreatment [^{18}F]FDG PET improves the detection of extrapelvic metastasis, mainly PALN, and helps select patients for extended-field radiotherapy [92]. [^{18}F]FDG PET has been increasingly used for radiation treatment planning with intensity-modulated radiation therapy (IMRT) and brachytherapy enabling the use of higher radiation doses while sparing adjacent normal organs and tissues [93–94]. The concept of prophylactic extended radiotherapy based on PET guidance has been examined; the rate of para-aortic failure in patients with only pelvic node involvement was 2.5%. The study shows that routine application of extended-field IMRT with concurrent chemotherapy can lower the rates of PALN relapse [95].

Persistent uptake of [^{18}F]FDG after therapy is linked to poor outcome and the need for more aggressive treatment and follow-up [96]. The ratio of posttreatment vs. pretreatment SUV_{max} is, as expected, lower for those who achieve complete response and have better outcomes; a cut-off SUV_{max} of 4.0 yielded a sensitivity and specificity of 92% and 94%, respectively [96].

[^{18}F]FDG PET in Recurrent Cervical Cancer

[^{18}F]FDG PET has a high sensitivity in the detection of recurrent disease (Figs. 8 and 9; Table 4). The overall sensitivity and specificity for detection of recurrence are reported to be 86% and 94%, respectively [97–102]. While detection of small-volume disease is limited, owing to the lack of resolution, peritoneal disease can be detected when metabolically active [103]. [^{18}F]FDG PET increases physician confidence and decision-making in cases with equivocal findings on conventional imaging [104]. However, some have questioned the cost-effectiveness of [^{18}F]FDG PET in this clinical scenario and further data are needed [105].

Combining PET with contrast-enhanced CT (ceCT) may improve detection, although the

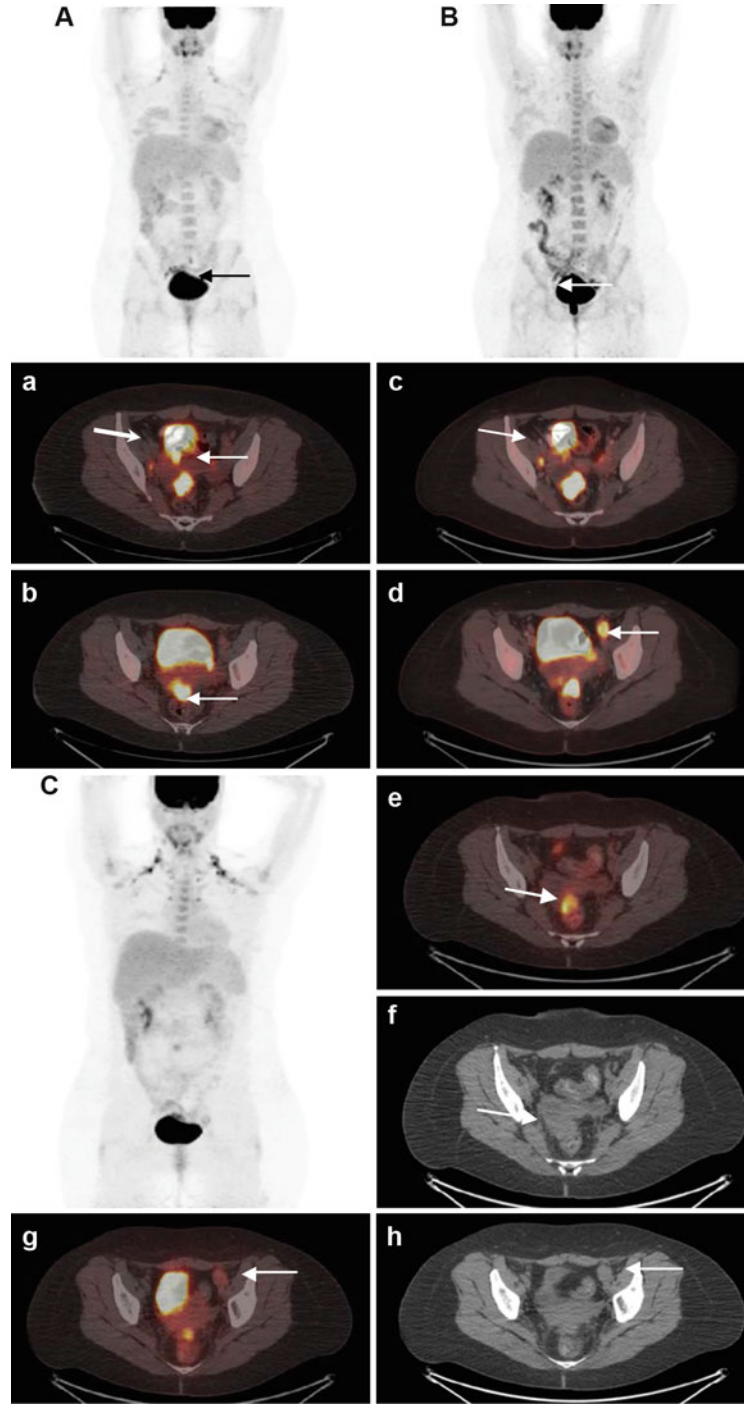

Fig. 6 A 22-year-old female patient diagnosed with invasive squamous cell carcinoma of the cervix was evaluated for recurrence. [^{18}F]FDG PET/CT scan (**A**, *black arrow*) shows uptake in the cervix consistent with a recurrence. Additional uptake was noted in the right external iliac node (SUV_{max} 5.1) (**a**, **b** *white arrow*, SUV 13.3) that was confirmed on pathology. She was treated with chemotherapy. A follow-up scan at the end of treatment showed an increase in size of an external iliac node (MIP – **B**, *black arrows* and **c**, *white arrows*, SUV 8.5) and depicted a new left abdominal anterior peritoneal nodule (**d**, *arrow*, SUV 7.8). The patient was treated with pelvic and para-aortic radiotherapy and chemotherapy. Follow-up PET/CT scan (**C**) showed metabolic resolution of right external iliac node, partial metabolic response in pelvic sidewall metastases (**e**, **f** *arrows* SUV_{max} 7.4), and peritoneal nodules (**g**, **h** *arrows* SUV_{max} 2.93)

increment in value may not be significant depending on the distribution of the disease. In 100 women with either uterine cervical ($n = 55$) or endometrial cancer ($n = 45$), while there was no significant difference in sensitivity or specificity between contrast-enhanced and low-dose CT [99], PET/ceCT led to better delineation of equivocal lesions; four equivocal regions by PET/low-dose

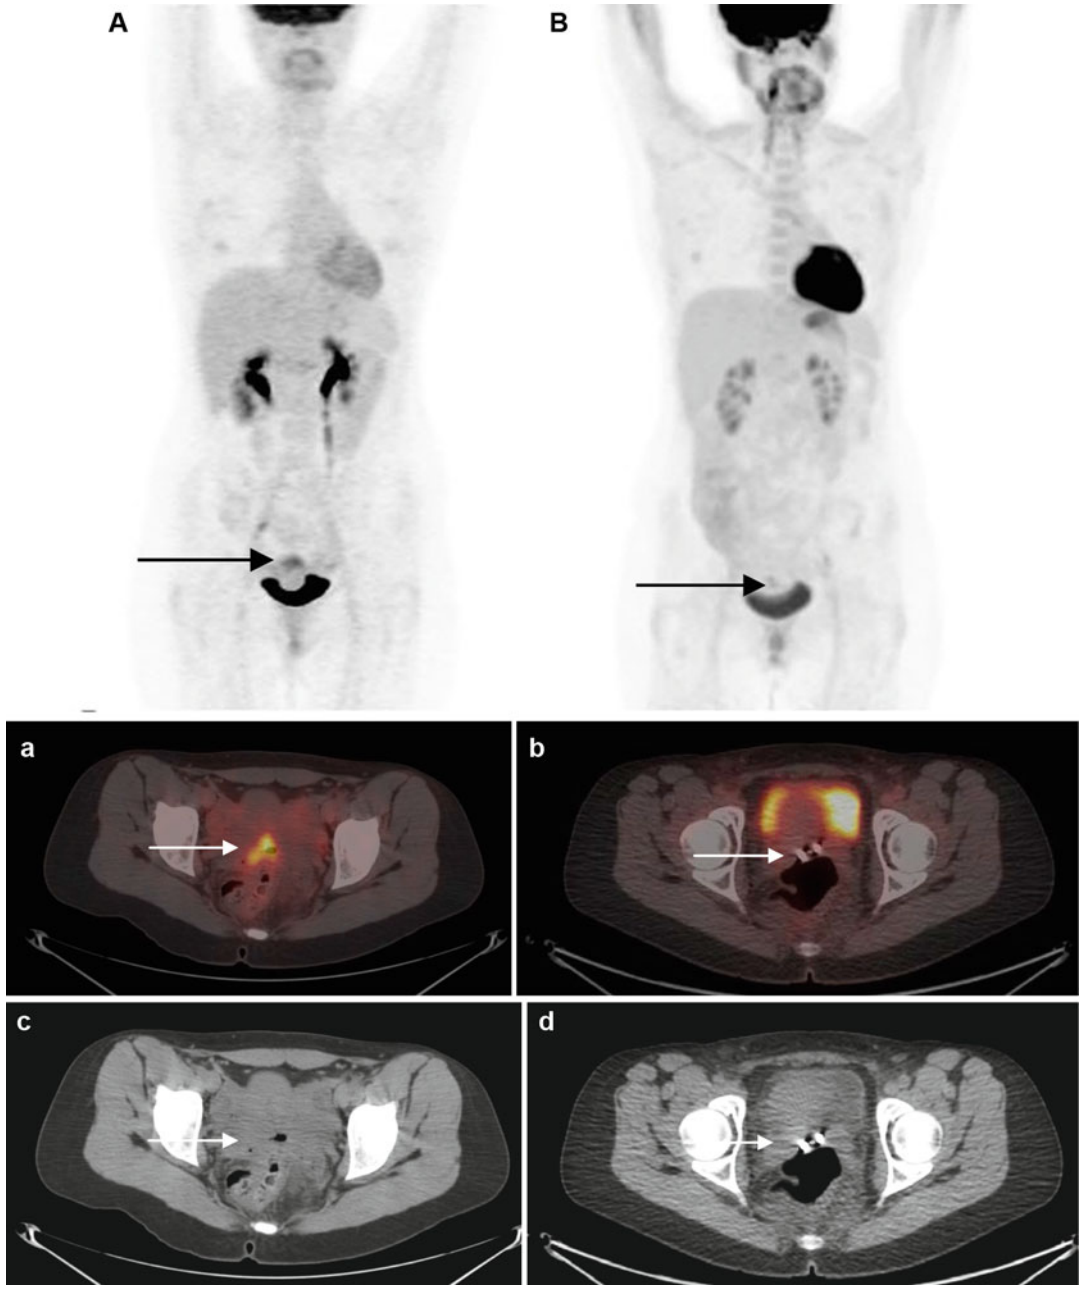

Fig. 7 A 33-year-old female patient with poorly differentiated invasive squamous cell carcinoma of the cervix. [^{18}F]FDG PET/CT maximum intensity projection (MIP; **A**) shows abnormal uptake in the pelvis (*black arrow*) corresponding to primary lesion in the cervix (**a**, **b** *white arrows*, SUV_{max} 6.2). The patient was treated with chemoradiotherapy. On follow-up PET/CT scan, whole-body MIP (**B**) shows resolution of the primary lesion in the cervix (**c**, **d** *white arrows*) suggestive of complete metabolic response to therapy

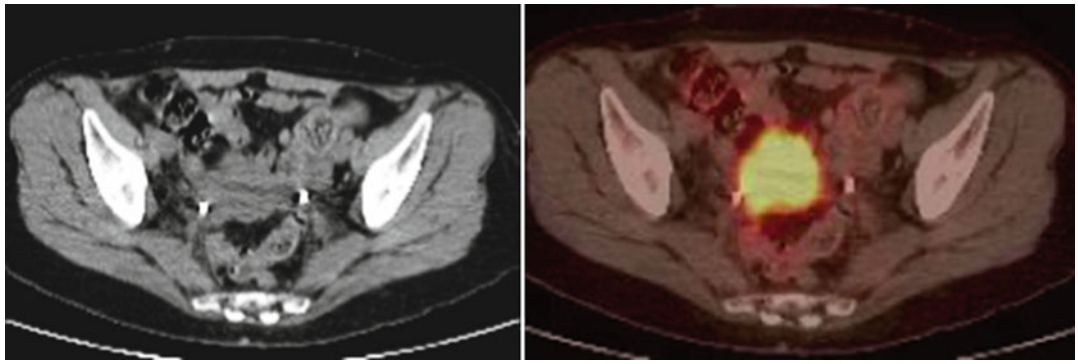

Fig. 8 A 32-year-old woman with carcinoma of the cervix, stage IIa, treated with chemoradiation therapy, was referred for PET/CT evaluation of residual disease and restaging. Focal ^{18}[F]FDG PET uptake is seen in the cervix consistent with residual/recurrent disease

CT (local recurrence, PLN metastasis, liver metastasis and muscle metastasis) were correctly interpreted as positive by PET/ceCT [99]

[^{18}F]FDG PET has a high sensitivity for detecting recurrence; the sensitivity in asymptomatic women is lower than that for symptomatic women (80% vs. 100%) [101, 106] and in those with rising markers with normal conventional imaging enabling institution of early therapy or management [107]. [^{18}F]FDG PET is not routinely performed or recommended for surveillance. In asymptomatic patients treated with radiation, [^{18}F]FDG PET can help in early detection of recurrent disease, or help confirm disease in those with abnormal serum tumor marker values. In such patients, the sensitivity for the detection of extrapelvic lymph node metastases was extremely high (100%); by contrast, the sensitivity and specificity for lung and bone lesions were 75.0% (12/16) and 33.3% (1/3), respectively [108]. Chang et al. [109] reported the detection of disease in 94% of patients with normal conventional imaging, leading to institution of earlier therapy.

[^{18}F]FDG PET has the advantage of facilitating the identification of extrapelvic metastases with high sensitivity and specificity [110] and plays a complimentary role to conventional imaging. In 150 patients who had findings suggestive of recurrence on CT or MRI, or elevated serum squamous cell carcinoma antigen SCC-Ag levels, an additional benefit from [^{18}F]FDG PET over CT–MRI was seen in 73.8% of patients; in particular, [^{18}F]FDG PET CT led to the correction of false-negative findings on CT-MRI in 74.2% and of false-positive findings on CT-MRI in 25.8% of cases. About 75.4% of these lesions were extrapelvic. In 26.2% patients, CT-MRI findings were discrepant from [^{18}F]FDG PET, which was able to confirm false-negative lesions in nine patients and exclude disease in 19; most of these lesions were extrapelvic.

[^{18}F]FDG PET provides useful prognostic information in patients with recurrent disease [104, 111]. The most significant prognostic factor was the presence of more than three [^{18}F]FDG-positive lesions. The median survival for those with more than three PET-positive lesions was shorter than for those with a normal scan or fewer lesions on PET [111]. Similarly, posttreatment [^{18}F]FDG PET/CT is also useful for prognosis and planning management. In a retrospective study involving 276 patients, the 5-year PFS and OS in patients with negative scan findings for recurrence were significantly better than those with positive scan findings (98.6% vs. 17.8%, $p < 0.0001$ for PFS, 99.3% vs. 85.3%, $p = 0.0015$ for OS) [112].

Increasingly, [^{18}F]FDG PET is being used for radiation treatment planning in recurrent cervical cancers. Using PET/CT, radiation dose to various organs like the stomach, liver, and colon could be significantly reduced, while radiation to other structures such as the spinal cord, kidneys, and small intestine was possible but depended on the beam sparing [113]. PET/CT-guided treatment planning for IMRT and brachytherapy allows for dose escalation without harming the surrounding

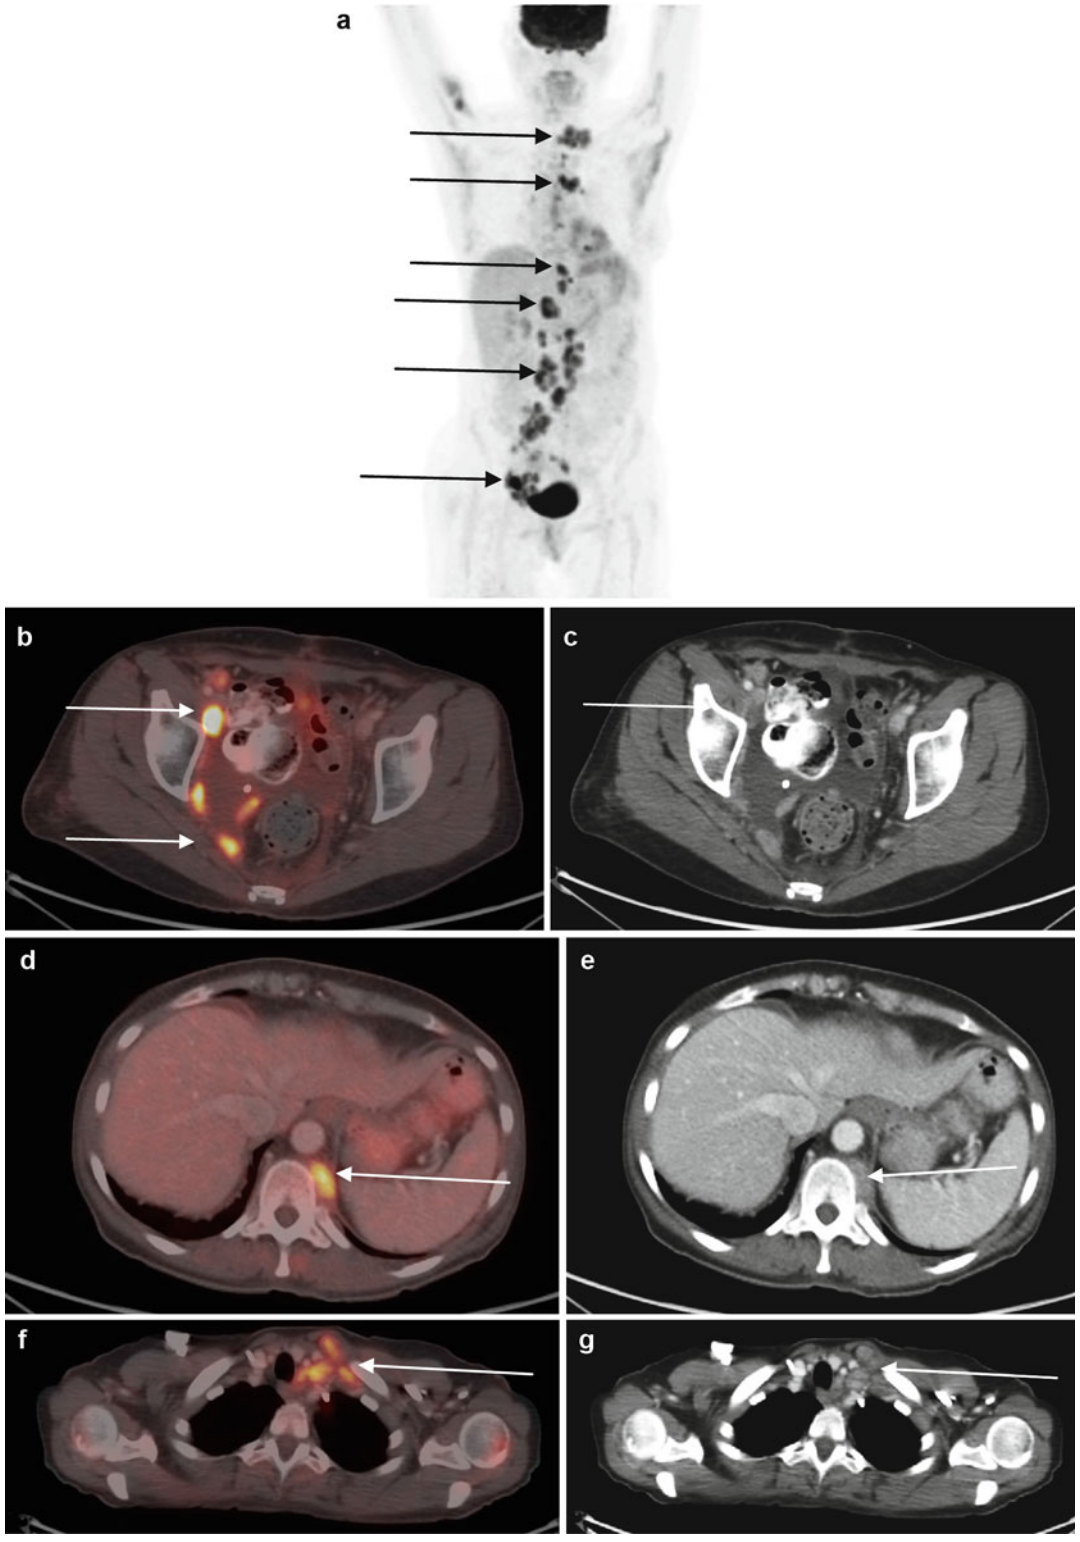

Fig. 9 (continued)

tissues [93–94]. Such escalated treatments may have better outcomes [114, 115], and a similar approach has been effectively used by others [95, 116].

Hypoxia is known to be a limiting factor in response to therapy (especially radiation therapy), and is increasingly recognized as an important aspect of treatment planning. It is associated with an increased likelihood of local recurrence and distant metastasis and heralds poor response to therapy [117–118]. The phenomenon has also been recognized in cervical and uterine cancers and is associated with a more aggressive tumor phenotype [111]. Tumor hypoxia can be measured through the tumor PO_2 levels using oxygen probes; however, this technique is invasive and needs special instruments and technical expertise.

A number of PET tracers are under investigation for noninvasive assessment of tumor hypoxia. Radiocopper-labeled diacetyl-bis(*N*(4)-methylthiosemicarbazone) [^{64}Cu-ATSM] has been described as a potential tracer for imaging hypoxia [119–120]. In cervical cancer, an inverse correlation between outcome and uptake of ^{64}Cu-ATSM has been shown [121]. Hypoxic tumors have a significantly increased risk of nodal or distant metastases, and noninvasive methods of metabolic imaging would be critical in providing guidance for management. Another tracer for hypoxia evaluation is [^{18}F-] fluoromisonidazole (^{18}F-MISO), which has been extensively evaluated in cervical cancer. The feasibility of combined [^{18}F]FDG and ^{18}F-MISO PET/MRI was recently evaluated in LACC. Combined metabolic [^{18}F]FDG and hypoxia PET imaging with ^{18}F-MISO in conjunction with MRI can help identify discordant areas and tumor heterogeneity and also help direct radiation dose escalation to the hypoxic regions [122].

There is an emerging role of PET/MRI in gynecologic tumors. In cervical cancer, it can improve the detection of nodal involvement compared with PET/CT [123–124] and helps in better assessment of local disease extent for staging [125]. MRI has superior soft tissue contrast resulting in better characterization of lesions with PET/MRI [126]. An additional advantage includes the reduction in radiation dosage. While the sensitivity is high, PET/MRI is likely to show more false-positive lesions. In a total of 79 patients where 553 nodal groups were assessed, PET/MRI detected an additional six positive nodal groups compared with PET/CT; however, it gave false-positive results in eight nodal groups [124]. In comparison with MRI alone, PET/MRI can help identify more disease (92% vs. 100%, respectively) and shows better characterization of lesions (88.8% vs. 98.9%, respectively) [127]. Specifically, PET/MRI is superior in the characterization and detection of lesions in the liver, peritoneum, and lymph nodes; however, it is limited in the assessment of lung lesions compared with PET/CT [128, 129].

Endometrial Cancers

Epidemiology and Prevalence

Endometrial cancer is the most common female pelvic malignancy, and the fourth most common cancer in women after breast, gastrointestinal, and lung cancer. It is more common in postmenopausal women, in Western countries, and is linked to exposure to unopposed estrogen. In 2016, 60,050 new cases and 10,470 deaths were predicted. The overall 5-year survival rate is estimated to be 81.7% – 95.4% for patients with localized disease, 68.7% for those with regional spread, and 16.8% for distant metastatic disease

Fig. 9 A 60-year-old female patient with invasive squamous cell carcinoma of the cervix, after total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH/BSO) and chemoradiotherapy, referred for evaluation of recurrent disease. Whole-body MIP (**a**, *black arrows*) shows multiple foci of increased [^{18}F]FDG uptake in the neck, chest, abdomen, and pelvis localizing to disease in the surgical bed (**b**), consistent with recurrence. [^{18}F]FDG-avid lesions are also noted in the peritoneum (**b**, **c** *white arrows*, SUV_{max} 11.3) and retrocrural lymph node (**d**, **e** *white arrows*, SUV_{max} 7.05); additional lesions are noted in retroperitoneal nodes, mediastinal nodes, including prominent uptake in left upper paratracheal node. Additional distant nodes are also noted in the left axillary and left supraclavicular regions (**f**, **g** *white arrows*, SUV_{max} 5.6)

[1]. There is a slight increase in death rates annually, at a rate of 1.2% per year.

Pathophysiology and Clinical Presentation

Endometrial cancer results in abnormal bleeding in about 80% of patients. About 15% of postmenopausal women presenting with abnormal bleeding have endometrial carcinoma [3–4]. Uterine cancer most commonly presents as polypoid fungating masses in the endometrial cavity causing asymmetric enlargement of the uterus. Invasion occurs directly into the myometrium, while distant spread of the tumor occurs through blood vessels or lymphatics. Prognostic factors include histology, tumor grade, depth of endometrial invasion, extension into the cervix or vascular space or adnexa, and pelvic or aortic node involvement. Surgical staging is definitive and nodal sampling is routinely performed. Clinical staging is commonly based on the FIGO classification (Table 5).

The most common histological type is adenocarcinoma (Table 6), which is seen as areas of irregular glands lined by malignant columnar epithelial cells. Although most adenocarcinomas are well-differentiated, areas of squamous differentiation can occur and are prominent in adenoacanthomas. Squamous areas that are poorly differentiated and show cytologic features of malignancy are seen in adenosquamous carcinoma. Endometrial carcinomas are graded according to their degree of histologic differentiation. Well-differentiated carcinomas are grade 1. The presence of large solid areas qualifies the tumors as grade 2, and poor differentiation is grade 3; both grades 2 and 3 carry a worse prognosis. Papillary serous adenocarcinoma is a variant that resembles ovarian serous carcinoma and has a worse prognosis than adenocarcinoma.

Leiomyosarcoma is a rare uterine neoplasm, accounting for 3% of all uterine malignancies and the most common uterine sarcoma arising from smooth muscle of the myometrium. These are generally bulky, fleshy masses that commonly occur in older women and have a high incidence of local recurrence and hematogenous metastases. Hemorrhage and necrosis are seen, with marked

Table 5 AJCC and FIGO staging for endometrial cancer

Stage I: cancer confined to the corpus uteri
IA: invasion to less than 50% of the myometrium
IB: invasion to greater than 50% of the myometrium
Stage II: cancer involves stromal connective tissue of the cervix but has not extended outside the uterus[a]
Stage III: extension beyond the uterus but not beyond the true pelvis
IIIA: tumor invades serosa and/or adnexa and/or positive peritoneal cytology
IIIB: vaginal involvement (direct extension or metastasis) or parametrial involvement
IIIC: metastases to pelvic and/or para-aortic lymph nodes
IIIC1: pelvic lymph node involvement
IIIC2: para-aortic lymph node involvement (with or without pelvic nodes)
Stage IV: involves the bladder or bowel mucosa or has metastasized to distant sites
IVA: tumor invasion of bladder and/or bowel mucosa
IVB: distant metastases, including intra-abdominal and/or inguinal lymph nodes
Grading:
G1: no more than 5% of a nonsquamous or nonmorular solid growth pattern
G2: 6–50% of a nonsquamous or nonmorular solid growth pattern
G3: >50% of a nonsquamous or nonmorular solid growth pattern
FIGO staging
Tumor limited to corpus
Stage IA; G123: tumor limited to endometrium
Stage IB; G123: invasion to less than 50% of the myometrium
Stage IC; G123: invasion to greater than 50% of the myometrium
Tumor extends beyond the uterus, within the pelvis
Stage II; G123: cervical stromal invasion
Extension beyond the uterus but not beyond the true pelvis
Stage IIIA; G123: tumor invades serosa and/or adnexa and/or positive peritoneal cytology
Stage IIIB; G123: vaginal metastases
Stage IIIC; G123: metastases of pelvic and/or para-aortic lymph nodes
Extension to bladder, intestinal mucosa or distant metastasis
Stage IVA; G123: tumor invasion of bladder and/or bowel mucosa
Stage IVB; distant metastases including intra-abdominal and/or inguinal lymph nodes

[a]Endocervical glandular involvement should only be considered as stage I and no longer as stage II

Table 6 Endometrial carcinoma: histopathologic types

1. Endometrioid adenocarcinoma
a. Papillary villoglandular

4. Clear cell carcinoma
5. Squamous carcinoma
6. Undifferentiated carcinoma
7. Mixed cell type
8. Secondary tumors

cytologic pleomorphism and atypia with a high rate of mitotic cells, which is diagnostic.

Role of Conventional Imaging

The diagnosis is generally made by obtaining an endometrial biopsy specimen [130]. Transvaginal ultrasonography may be used initially to evaluate those who cannot undergo biopsy. Ultrasound allows for a quick early preliminary examination that may be performed on patients with abnormal bleeding. A thickened and heterogeneous endometrium suggesting the presence of hyperplasia, polyps, or suspicious lesions may be noted that can be further evaluated by biopsy. In premenopausal women, the thickness of the endometrium varies with menstrual phase; however, a thickness of more than or equal to 5 mm in postmenopausal patients with bleeding should be considered abnormal and investigated further [131]. Recent studies, however, advocate the use of a 3–4-mm cut-off [132–134].

Chest imaging/CT of the chest may be performed for initial assessment to exclude disease. MRI is helpful in evaluating the disease extent to the cervix. MRI and CT of the abdomen and pelvis are performed before surgery to assess the presence of extrauterine disease [135]. MRI is sensitive in detecting myometrial invasion and involvement of the lower uterine segments, and it should be considered for the presurgical evaluation of patients who are suspected to have gross cervical involvement, thus affecting further management. CT and/or MRI of the abdomen and pelvis is specifically helpful in evaluating endometrial stromal tumors to assess the extent of the primary tumor and the presence of extrauterine disease including pelvic and para-aortic nodal involvement [135].

Role of [^{18}F]FDG PET in Endometrial Carcinoma

Increased uterine [^{18}F]FDG uptake is commonly seen in young premenopausal patients related to cyclical changes in the endometrium. Intense uptake is frequently detected during active menstruation, while focal endometrial uptake is common in the late follicular and early luteal phases (Fig. 10) [136]. Careful interpretation is needed especially when focal uterine uptake is noted in close proximity to a known cervical tumor so as to differentiate physiological activity from uterine invasion. Variable [^{18}F]FDG uptake has also been demonstrated in different benign pathologies of the uterus such as fibroids and polyps (Fig. 11) [137].

[^{18}F]FDG accumulates in uterine tumors [138–139] (Table 7). Presurgical assessment with [^{18}F]FDG PET for staging in high-grade endometrial cancer allows for the detection of extrapelvic sites of disease and distant metastasis (Fig. 12). Preoperative [^{18}F]FDG PET/CT detects primary lesions with a high sensitivity. In high-risk malignancy, while there is lower sensitivity for detection of nodal disease (57.1%), the detection of distant disease is high (sensitivity 100%). The specificity, however, is high for both nodal disease (100%) and distant disease (96%) [140].

[^{18}F]FDG PET/CT is more useful than MRI for assessing lymph node metastasis [141]. In a prospective multicenter study, the diagnostic performance of PET/CT, MRI, and transvaginal ultrasound was assessed preoperatively in 318 women with endometrial cancer. For lymph node metastases, the sensitivity and specificity were 74% and 93%, respectively, for PET/CT while for MRI it was 59% and 93%, respectively [141].

The SUV_{max} of [^{18}F]FDG PET correlates with histological grade, tumor size, and glucose transporter GLUT-1 expression. In 44 patients, the mean SUV_{max} of the primary endometrial cancer tumors was 17.6 (range, 3.04–34.74) [142]. In

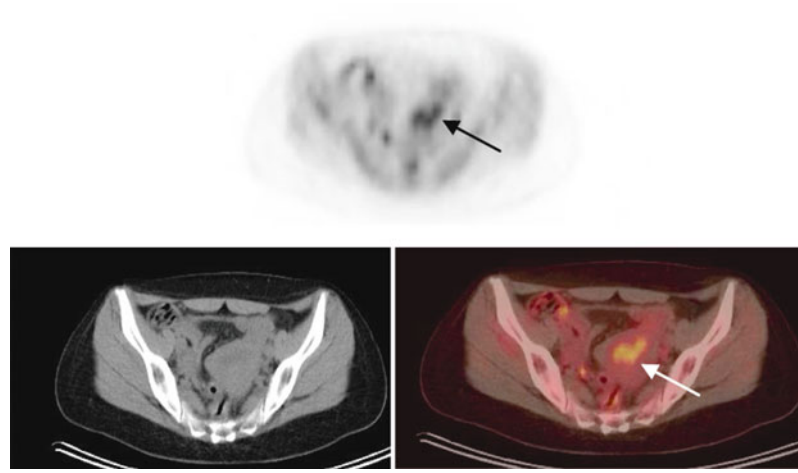

Fig. 10 Physiologic uptake in the uterus. Woman with lung malignancy imaged with [^{18}F]FDG PET for restaging. Uptake is seen in the uterine cavity (*arrows*). Patient was menstruating at the time of the scan, consistent with physiologic uptake

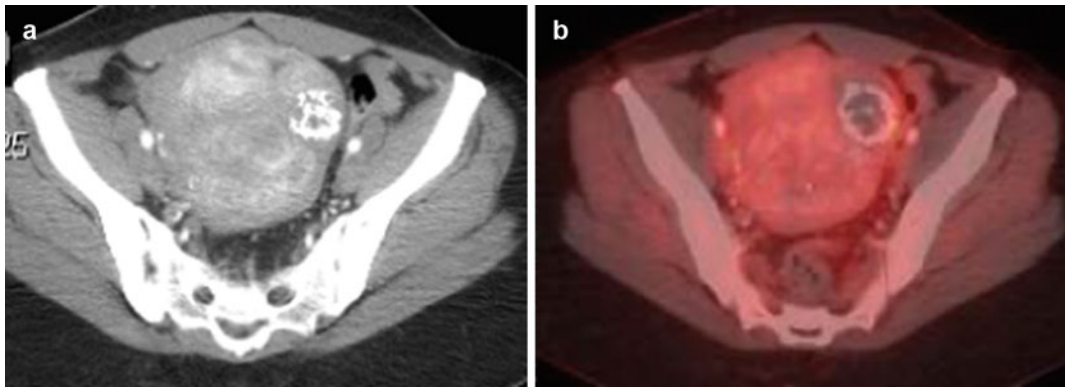

Fig. 11 Variable uptake in uterine fibroids. CT images (**a**) show heterogeneously enlarged uterus with lesions that have calcification consistent with fibroids. [^{18}F]FDG PET/CT (**b**) shows no uptake in the region of calcified fibroid and mild heterogeneous activity associated with remainder of the enlarged uterus

106 patients, the SUV_{max} of the primary tumor was inversely correlated with disease-free survival and OS rates. A mean SUV_{max} cut-off of 16.4 of the primary tumor was found to delineate prognostic groups [143].

In patients with high clinical risk and early-stage endometrial cancer, [^{18}F]FDG PET has a high NPV that can serve as a guide in selecting patients for lymphadenectomy and thus minimize operative and surgical complications in others. PLN metastases were found at histopathological analysis in nine of 37 patients (24.3%). Patient-based sensitivity and specificity of [^{18}F]FDG PET for detection of nodal disease were 77.8% and 100.0%, respectively, while nodal lesion site-based sensitivity and specificity were 66.7% and 99.4%, respectively [144]. In more recent and larger studies, high PPV and NPV for pelvic lymph node metastases have been reported, up to 93% and 94%, respectively [145]. The specificity for nodal detection was also high ranging between 91% and 99% [146–147].

Preoperative [^{18}F]FDG PET with ceCT is superior to conventional imaging in detecting metastatic disease, but it is limited in the assessment of small lymph nodes. In 45 patients with endometrial carcinoma, the overall node-based sensitivity and specificity were 51.1% and 99.8%, respectively. For smaller lymph nodes, the sensitivity was only 12.5% for nodes below 4 mm, 66.7% (16/24) for nodes 5–9 mm in size, and 100.0% for nodes 10 mm or larger(5/5) [148].

Table 7 Role of [^{18}F]FDG PET CT in endometrial cancer

Author and year	Type	Disease stage evaluated	Indication	Number of cases	Comparative imaging (CT or MRI)	Histopathology confirmation (yes/no)	Sensitivity/specificity/accuracy

TV 2DUS transvaginal 2D ultrasonography, *NA* not available

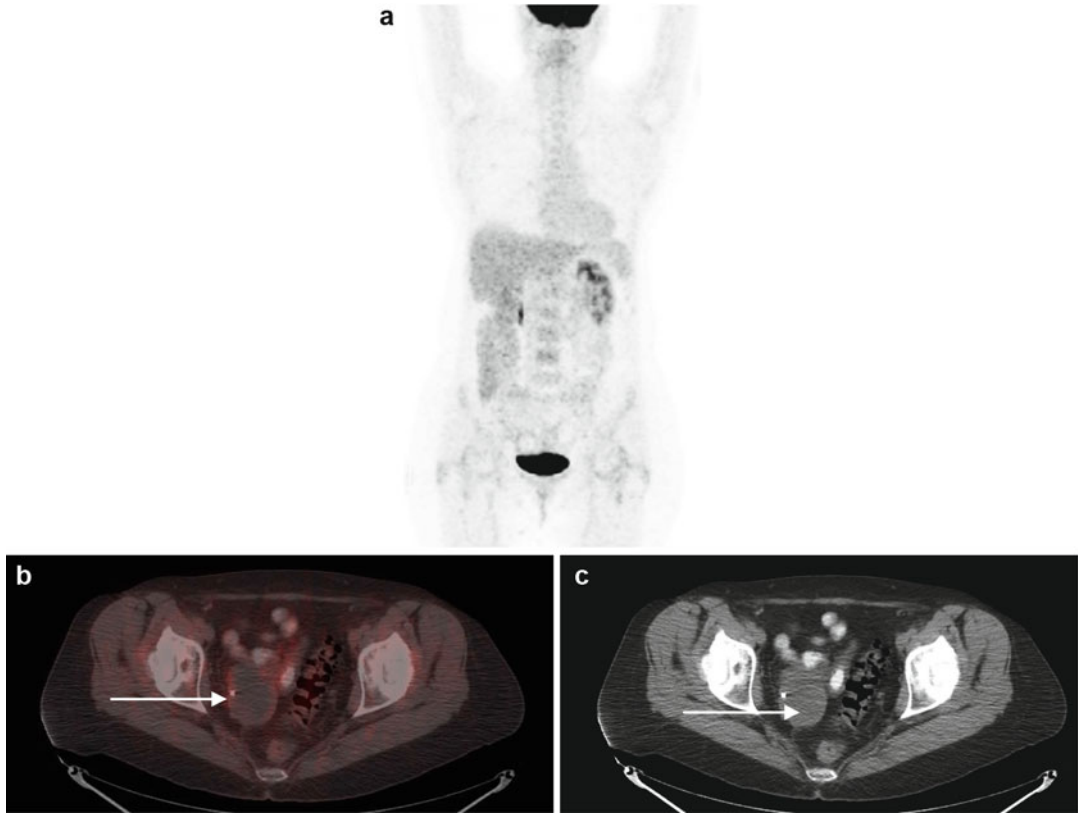

Fig. 12 A 50-year-old female patient with a history of recurrent endometrial adenocarcinoma was noted to have a pelvic lesion on CT. The patient was treated with chemoradiation, but the lesion persisted, although there was a decrease in size. The patient was referred for PET/CT imaging for response evaluation and to rule out extrapelvic disease. The scan revealed a mildly [^{18}F]FDG-avid (**b**, **c**, *white arrow*, SUV_{max} 2.8) pelvic mass adjacent to the urinary bladder with central necrosis. No other [^{18}F]FDG-avid lesions were noted elsewhere (MIP, **a**). Patient underwent surgery; pathology confirmed necrotic tumor. Teaching point: [^{18}F]FDG PET has lower uptake and sensitivity for necrotic or cystic lesions and will be generally photopenic. [^{18}F]FDG PET helped rule out other disease sites

In uterine cancers [^{18}F]FDG PET is useful for postsurgical monitoring and surveillance for recurrent disease (Figs. 13, 14, and 15). Belhocine and colleagues retrospectively analyzed findings from 34 women (41 scans) with suspected recurrence based upon tumor markers or findings of other radiographic imaging. PET confirmed recurrence in 88% of the cases; it also helped localize the site of disease and detected asymptomatic recurrences in 12% of patients. Moreover, in nine of 26 patients (35%) additional metastatic sites were detected with PET, a finding which significantly altered the treatment choice [149]. Similar results were noted in a larger study involving 101 posttherapy patients; the reported sensitivity and specificity were 89% and 94%, respectively [150].

Earlier studies in a small number of patients showed superior results with [^{18}F]FDG PET compared with conventional imaging or tumor markers for recurrent disease. In 21 patients with 30 studies, PET showed 100% sensitivity and 88% specificity, compared with 85% sensitivity and 86% specificity for conventional imaging, or 100% sensitivity and 70.6% specificity with tumor markers. [^{18}F]FDG-PET affected the patient management in one third of the cases, and patients with negative PET results had a trend to show longer disease-free courses [151]. The combination of [^{18}F]FDG PET with

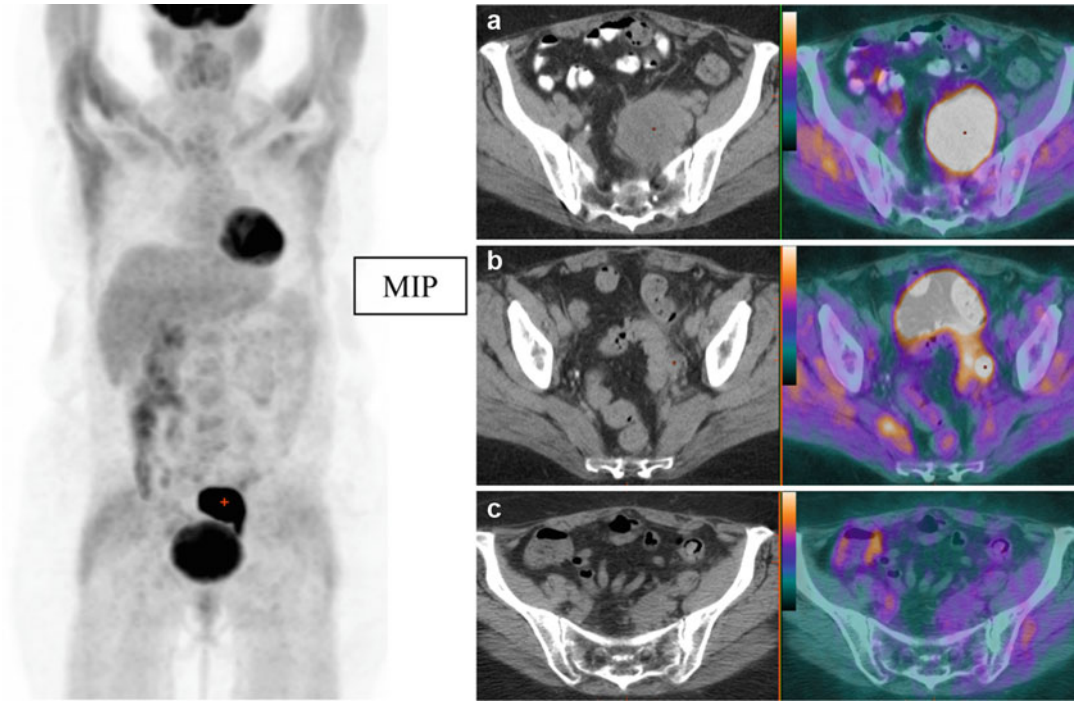

Fig. 13 A 57-year-old female patient with endometrial carcinoma was referred for evaluation of recurrent disease. MIP images show large area of abnormal activity superior to the bladder. Axial CT and fused [^{18}F]FDG PET/CT images show large left pelvic mass consistent with recurrent disease (**a**) and a node (**b**). Follow-up study shows resolution of [^{18}F]FDG avidity and a decreased size of the pelvic mass (**c**) after chemoradiation

ceCT is superior in categorizing the lesions as malignant vs. benign in comparison with low-dose CT owing to decreasing equivocal results, although no significant difference was noted in overall accuracy [99]. In a more recent follow-up study of 35 patients, PET/CT was compared with manually fused PET/MRI; while no significant difference was noted in diagnosing primary tumors, PET/MRI detected the extent of disease better than PET/CT (83% vs. 53.3%, respectively) [152].

Metabolic parameters derived from preoperative [^{18}F]FDG PET/CT can help in the characterization of endometrial carcinomas. In 129 patients, preoperative [^{18}F]FDG PET-derived MTV, using an absolute SUV_{max} threshold of 2.5, and TLG significantly correlated with deep myometrial invasion, lymph node metastases, and high histological grade. The potential cut-off value of MTV for predicting deep myometrial invasion and lymph node metastases was 30 ml (85% sensitivity, 76% specificity) [146]. A similar evaluation in patients with recurrent disease ($n = 84$) calculated an MTV cut-off of 17.5 ml (75% sensitivity, 58% specificity) and a TLG of 56.43 g (75% sensitivity, 53% specificity) as useful parameters [153].

Uterine sarcomas constitute less than 5% of the uterine corpus malignancies, and, based on the type of cell they developed from, belong to three groups: endometrial stromal sarcomas, uterine leiomyosarcomas, and uterine carcinosarcomas. These tumors are very aggressive and have high mortality. MRI is presently the most accurate imaging modality for these lesions. Leiomyosarcomas are [^{18}F]FDG avid [154]. When compared with MRI in five patients, PET was positive in all five patients vs. four for MRI. The uptake in most cases was high, with a mean SUV of 4.5. In 53 patients with either uterine sarcomas, endometrial carcinomas, or leiomyomas, [^{18}F]FDG uptake (SUV_{max}) was higher in uterine sarcomas and endometrial carcinomas than for leiomyomas; however, there

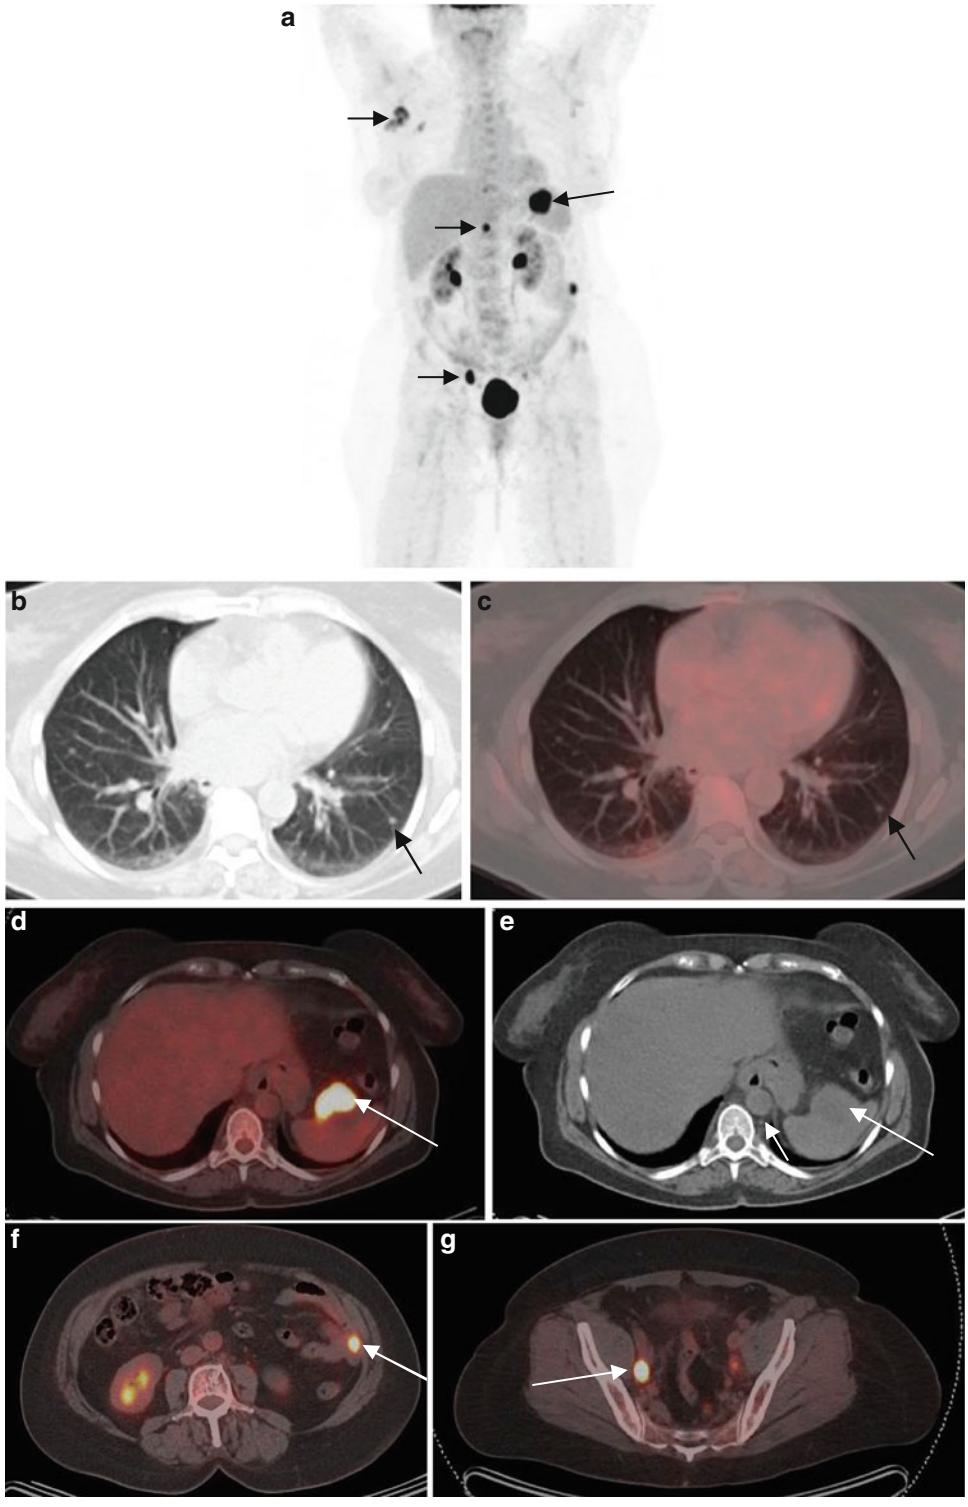

Fig. 14 (continued)

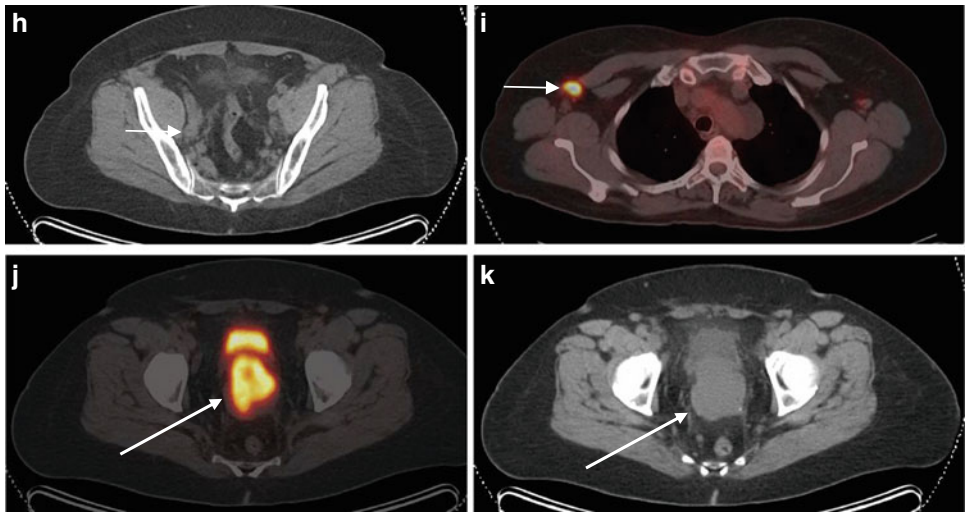

Fig. 14 A 61-year-old female patient with endometrioid adenocarcinoma referred for [^{18}F]FDG PET/CT for restaging. The patient had presented with vaginal spotting and slightly elevated CA-125 markers (~43 ng/mL); CT imaging showed new subcentimeter pulmonary nodules, limited in the PET assessment, negative for uptake in the lungs (**b**, **c**; *arrows*). PET/CT MIP (**a**, *black arrows*) demonstrated splenic hilar implant (**d**, **e,** *arrows*, SUV_{max} 20.1), peritoneal nodules (**f**, *arrow*; SUV_{max} 10.1), and pelvic nodes (**g**, **h**, *arrows*, SUV_{max} 16.9). Additionally PET/CT showed suspicious lesions in bilateral axillary nodes (**i**, *arrow*, SUV_{max} 7.4 on the right) and a bilobed mass in the vaginal cuff (**j**, **k** *arrow*; SUV_{max} 31.3), which was later confirmed to be recurrent disease on histopathology. Teaching point: [^{18}F]FDG PET/CT helps identify distant sites of disease involvement. Small lesions including subcentimeter lesions may be limited in assessment due to size

was no significant difference in SUVs among endometrial carcinomas, carcinosarcomas, and leiomyosarcomas [155]. The diagnostic accuracy for leiomyosarcomas was only 73%. Sarcomas had higher GLUT-1 expression than endometrial carcinomas (EC). However, frequently, the uptake in leiomyomas can be very high, too, making it difficult to distinguish malignant from benign lesions based on uptake alone (Fig. 16).

In summary, the role of [^{18}F]FDG PET is primarily in the evaluation of nodes or lesions in cases of equivocal conventional imaging and for detection of pelvic and distant disease in high-grade disease and high-risk patients.

Lymphoscintigraphy

Sentinel node mapping for cervical and uterine malignancies has been evaluated over the past decade for its feasibility and accuracy in early cervical and uterine cancers, and more clinical data are emerging of its use to prevent morbidity associated with nodal dissections [156–167]. Vascular and neural injuries with pain and paresthesia, formation of lymphoceles and seromas, and late and chronic sequelae of lymphedema associated with lymphadenectomies cause significant morbidity.

Lymph node status in cervical and endometrial cancer remains the most important prognostic factor for recurrence and survival and a major decision criterion for adjuvant therapy [168–169]. In cervical cancer of stage IA1, the rate of lymphatic/vascular invasion is less than 1% [170]. Pelvic node metastases are detected in 0–4.8% of patients with stage IA disease, in 0–17% of those with stage IB disease, and in approximately 20–40% of stage II cervical cancers [49, 171]. In stage I and occult stage II endometrial cancers, the incidence of lymph node metastases is approximately 10% [172]. Accurate assessment of the disease status of pelvic and paraaortic lymph nodes preoperatively is suboptimal and requires surgical staging [31]. Routinely performed extensive nodal dissection in patients who otherwise have a low likelihood of nodal metastasis suggests

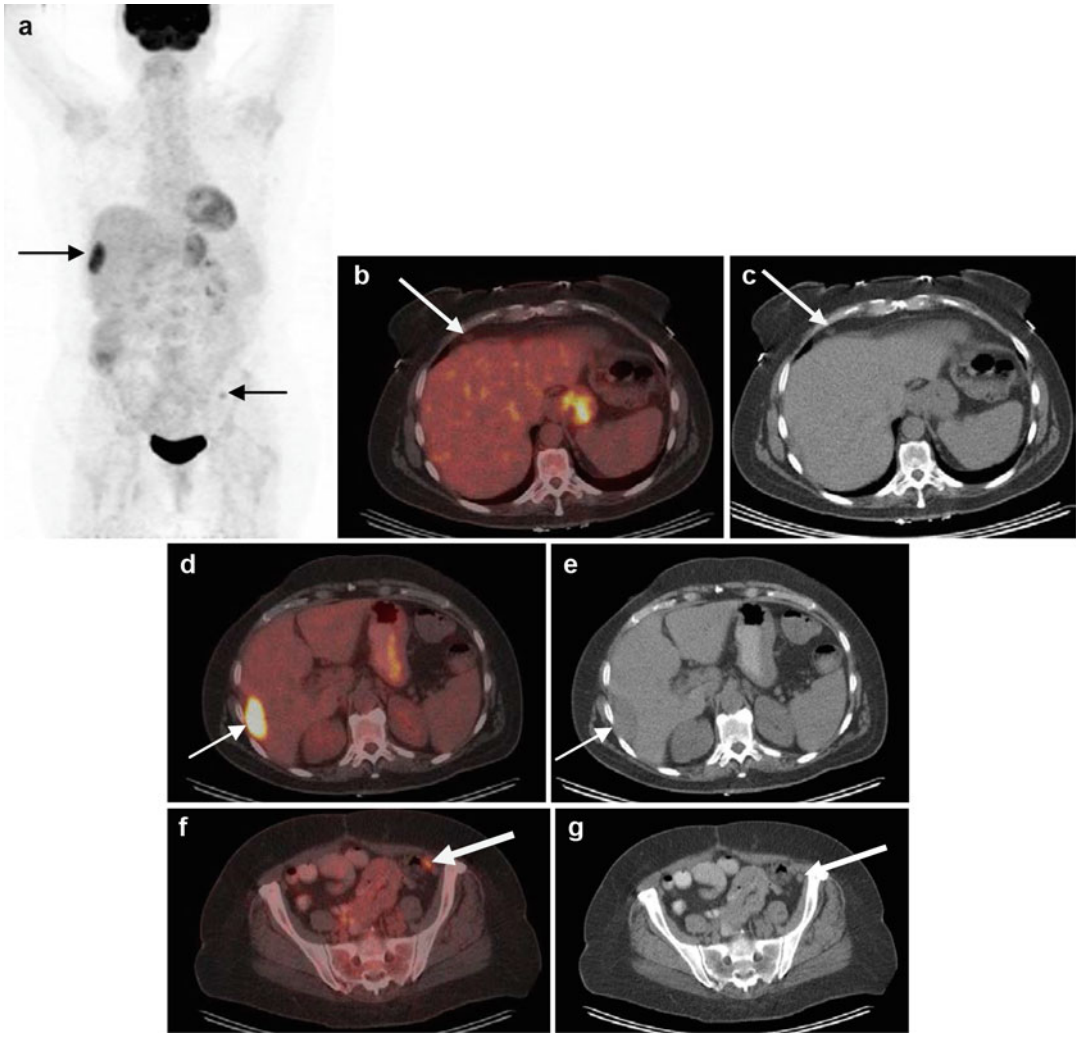

Fig. 15 A 59-year-old patient with stage I endometrioid adenocarcinoma, previously submitted to TAH/BSO, with suspected recurrence underwent [^{18}F]FDG PET/CT for restaging. MIP images (**a**, *black arrows*) revealed hypermetabolic implants in the parahepatic region (**d**, **e,** *arrows* SUV_{max} 9.5) and left paracolic gutter (**f**, **g,** *arrows* SUV_{max} 3.3). A small supradiaphragmatic lymph node was also noted (*white arrow* **b**, **c**). No other lesions were noted elsewhere. The patient underwent surgery and all the [^{18}F]FDG-positive lesions were confirmed metastasis. Teaching point: [^{18}F]FDG PET excluded extensive disease and distant organ metastasis that would have otherwise required systemic therapy

that a number of patients undergo dissection without clinical benefit and with a potential for increased complications and morbidity [173–174]. The incidence of nodal metastasis is low in patients presenting with a low-grade endometrioid adenocarcinoma [175] and the overall prognosis is excellent [176]. The use of lymphatic mapping and SLN identification in these patients may help reduce the morbidity of surgery without compromising the identification of patients who require adjuvant treatment [157, 177–179, 180–181].

Lymphoscintigraphy (LSG) is a noninvasive and convenient technique that can be performed either on the day of surgery or 1 day before surgery to map the nodal drainage. Various injection techniques of radiolabeled colloids have been applied for nodal mapping in cervical and endometrial cancers. Generally, they involve injecting

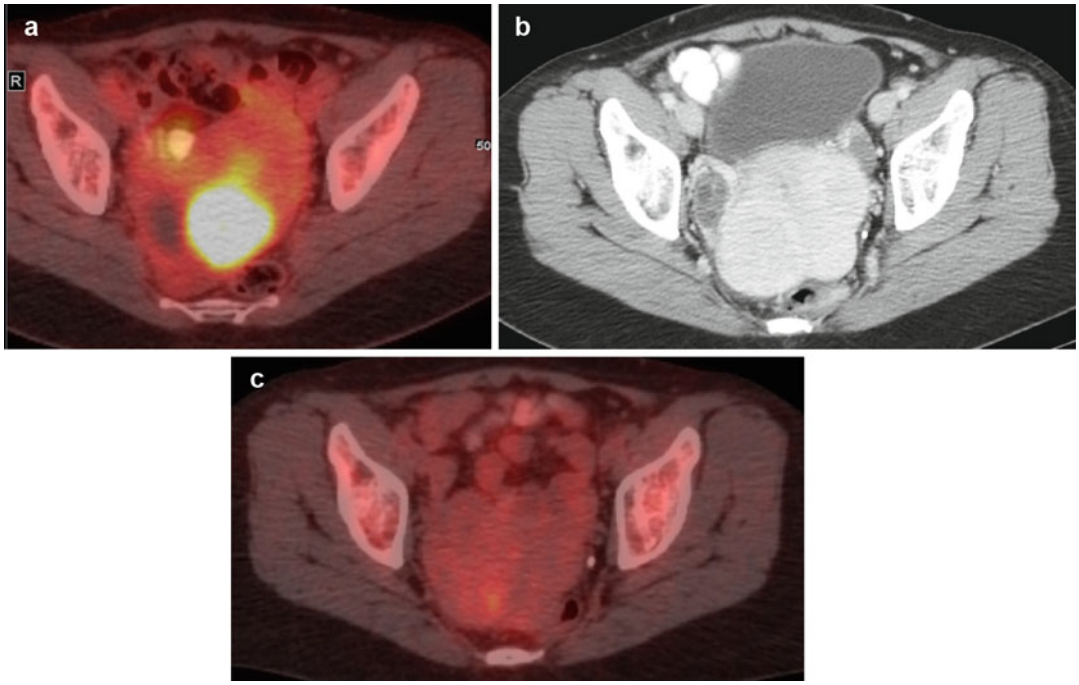

Fig. 16 PET/CT fused image in a patient with non-gynecologic malignancy. Intense [^{18}F]FDG uptake (**a**, SUV_{max} 8.5) seen in the uterus localizing to posteriorly lying fibroid on CT image (**b**), which increased in comparison with prior study 1 year earlier (**c**). MRI and further evaluation confirmed intense uptake within the dominant intramural posterior leiomyomata. Teaching point: Fibroids may show variable uptake and intensity may vary with time. It is difficult to distinguish between benign and malignant lesions based on [^{18}F]FDG uptake alone

1–2 mCi of radiocolloid in 1–1.5 mL volume at the site of the lesion; filtered ^{99m}Tc-sulfur colloid is generally used in the United States, while ^{99m}Tc-albumin nanocolloid is has been more commonly applied in Europe and elsewhere. More recently, ^{99m}Tc-tilmanocept, a node-seeking tracer that targets the mannose receptor CD206 has been approved for use in a variety of tumors [182–183]. More recently, fluorescent dyes such as indocyanine green have been explored in both cervical and endometrial cancer, providing an advantage of better intraoperative visualization of SLN with infrared light [184–185].

For cervical cancer, submucosal injection of tracer is carried out around the lesion or in four quadrants of the cervix using a 3.5-inch-long spinal needle. Imaging is acquired immediately after injection, and dynamic flow and static imaging in anterior, posterior, and lateral images are obtained. Handheld gamma probes have been used to detect "hot nodes" for removal during surgery. In vivo and ex vivo counts are recorded over the node. Generally, those with counts more than ten times the background levels are considered sentinel. The optimal site to inject radiotracer during LSG in patients with endometrial cancers is not well established and various techniques have been used including cervical, fundal, or hysteroscopic injections for SLN mapping [157, 178, 186–187]. Cervical injection for SLN mapping has several advantages over the other methods such as being easily accessible, less invasive, and having fewer chances of being influenced by anatomic variation in the uterus that may affect fundal injection and tumor infiltration [188].

External iliac and obturator nodes are more frequently seen on LSG, and bilateral nodal drainage is common. Using LSG alone, the detection rate is between 80% and 93% while combined blue dye and colloid scintigraphy increases the

detection rate with a reported range of 78–100% [157, 179, 178]. False-negative rates are very low, with an overall rate of less than 1% and a high NPV reported up to 100% [177].

Single photon emission computed tomography (SPECT) provides three-dimensional imaging information that, when combined with CT imaging (fusion imaging), can help to improve localization of SLNs (Fig. 17). This is more helpful in endometrial and cervical cancers, owing to the complex pelvic anatomy. Detection of SLNs with the hand-held probe requires experience. If the site of cervical injection is close to the sites of SLN basins in the pelvis, detecting the SLN uptake can be difficult because of scatter from the site of injection in the cervix. The closer the injected radiolabeled colloid is to the nodal sites, the more likely the interference with the hand-held

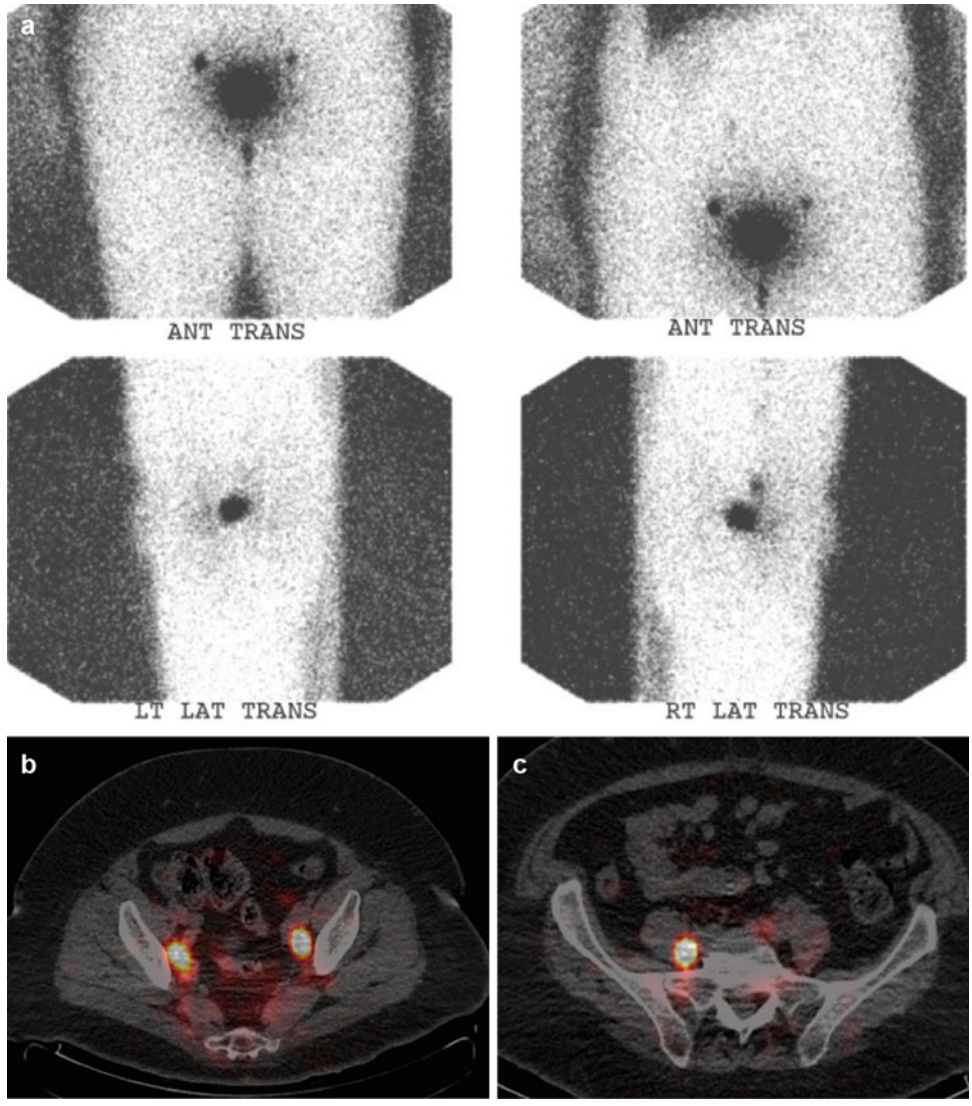

Fig. 17 Cervical carcinoma patient referred for lymphoscintigraphy. Planar images (**a**) show intense tracer activity in the injection site in the cervix. Two foci are seen superolaterally to the injection site localizing to the external iliac nodal region on SPECT/CT images (**b**). Additional focus seen faintly in the right side on planar images that localizes to the right common iliac nodal region on SPECT/CT (**c**)

probe. For similar reasons, a nodal basin like the parametrium (that is closer to the injection site) would be difficult to assess both by planar imaging and by probe counting. This is also true for blue dye, since the blue dye diffuses easily into the parametrium and can make it difficult to identify parametrial SLNs.

Several studies have shown that SPECT imaging for SLN detection in endometrial and cervical cancer is superior to planar imaging and improves the sensitivity of detection and localization of SLN [188]. Using SPECT imaging, there was increased sensitivity of SLN detection, with a 100% detection rate using SPECT/CT compared with either planar LSG, hand-held probe, or blue dye alone (75%, 92.5%, and 82.5%, respectively, for endometrial cancer and 70%, 90%, and 90%, respectively, for cervical cancer), as well as compared with combined imaging plus probe and blue dye injection (94.2%). A recent meta-analysis of data from eight studies ($n = 208$) for SLN in early-stage cervical cancer showed an overall SLN detection rate of 98.6% for SPECT/CT vs. 85.3% for planar LSG, although bilateral nodal site localization was similar (69% vs. 67%) [189]. Accurate anatomic localization of SLNs preoperatively can also aid in probe-directed surgery and in reducing operator-dependent variation and time involved in surgery. SPECT/CT helps achieve faster intraoperative localization and SLN removal; an average time advantage of 25 min in lymph node retrieval was noted with the use of SPECT/CT [190]. Similarly, in a group of 59 patients with early-stage cervical cancer, Klapdor et al. demonstrated a detection rate of 84.3% for planar imaging and 92.2% for SPECT/CT [191–192].

A similar advantage of SPECT/CT was shown in SLN mapping in early-stage endometrial cancer: The detection rate for planar imaging ranges between 50% and 67% while with SPECT/CT the range is 84–91% [193] [186]. With SPECT/CT, fewer false-positive findings are seen and localization of para-aortic and pelvic nodes is superior to planar imaging [188, 194], leading to a change in location in 37% of patients and in 22% of nodal sites compared with planar imaging. A recent study of 136 women with low-to-intermediate-risk endometrial carcinoma detected SLN with micrometastasis that resulted in upstaging of 22 patients and a higher risk group identified in ten cases, influencing management [195].

Certain limitations and potential issues with SPECT must be understood; for example, detection of multiple nodes can occur depending on the time of imaging, injection volume, and rate. Therefore, all these parameters should be standardized. Nodal localization may be seen on both sides of the pelvis, the first most intense node on each side may be regarded as the SLN; however, more data are needed to establish this clearly. With the current data, there is incremental value in using SPECT/CT and it should be employed in conjunction with planar imaging whenever possible and especially in patients with negative findings on planar imaging, to enhance SLN detection and localization.

LSG can identify patients with an atypical drainage pattern and identify unusual sites of SLN. In a prospective SENTICOL study comprising 139 patients with early-stage cervical disease, about 57% patients were noted to have atypical sites of SLN localization using LSG compared with 38% by intraoperative mapping. About 49% of patients with atypical SLN sites on LSG also had atypical sites detected by intraoperative mapping. In 13 patients, a parametrial SLN was seen with LSG only; 3% of patients also showed common iliac and para-aortic SLNs with LSG only [196].

In the SENTI-ENDO study, SLN mapping was performed on 118 of 133 patients with early endometrial cancers, for whom delayed imaging was performed at 120 min after injection (long protocol) vs. 90 min after injection (short protocol).The overall detection rate of LSG was 74.6% (88/118) with no significant difference in overall detection rate; however, a higher detection of para-aortic SLN was seen in patients imaged with the long protocol [197].

In summary, the feasibility of LSG in cervical and endometrial cancers has been documented. The overall detection rates with LSG are high and superior when used in conjunction with blue dye. Recent developments and the increasing use of fluorescent dyes may influence the future applications and use of LSG.

Diagnostic Applications of Nuclear Medicine: Ovarian Cancer

36

Neeta Pandit-Taskar, Sonia Mahajan, and Weining Ma

Abstract

Ovarian malignancies are a leading cause of death in women in the United States and a significant health issue for women worldwide. Anatomic imaging with ultrasound, computed tomography, and magnetic resonance is a main tool for the diagnosis, staging, and follow-up of recurrent disease; however, it lacks biologic information. Nuclear imaging, primarily positron emission tomography (PET) with 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG), has been increasingly used for the detection of cancer. Encouraging data have emerged in recent years that support the use of [^{18}F]FDG PET in a variety of clinical settings in ovarian cancer management.

Keywords

Ovarian cancer • Imaging • Staging • Prognosis • Response to therapy

Glossary

[^{18}F]FDG	2-[^{18}F]fluoro-2-deoxy-D-glucose
AJCC	American Joint Committee on Cancer
BRCA1	Breast cancer type 1 susceptibility protein
BRCA2	Breast cancer type 2 susceptibility protein
CA-125 U/mL	A tumor-associated marker for ovarian cancer (also known as carbohydrate antigen 125 or mucin 16)
CT	X-ray computed tomography
CTce	Contrast-enhanced computed tomography
FIGO	International Federation of Obstetrics and Gynecology
GLUT	Glucose transporter family
LBMI	Large bowel mesentery implants
LI	Labeling index
M	Metastasis status according to the AJCC/UICC TNM staging system
MIB-1	Marker of cell proliferation based on an antibody against an epitope of the nuclear protein different from that recognized by the Ki-67 antibody
MRI	Magnetic resonance imaging
MTV	Metabolic tumor volume
N	Lymph node status according to the AJCC/UICC TNM staging system

NPV	Negative predictive value
PET	Positron emission tomography
PET/CT	Positron emission tomography/computed tomography
PFS	Progression-free survival
PPV	Positive predictive value
RO	Right ovary
SLL	Second look laparotomy
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
T	Tumor status according to the AJCC/UICC TNM staging system
TAHBSO	Total abdominal hysterectomy with bilateral salpingo oophorectomy
TLG	Total lesion glycolysis
TNM	AJCC staging system based on parameters "T" (tumor status), "N" (lymph node status), and "M" (distant metastasis status)
TVUS	Transvaginal ultrasound
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
US	Ultrasonography

Ovarian Cancer

The American Cancer Society estimated 22,280 new cases of ovarian cancer and 14,240 deaths related to ovarian cancer in 2016 in the United States [1]. Ovarian cancer is the ninth most common non-skin-related cancer in women and the fifth most common cause of cancer deaths in women. Ovarian cancer is an insidious disease, and patients often present with an advanced stage of disease. Despite clinical advances and improved surgical techniques, it remains a form of gynecologic malignancy with the highest mortality (Fig. 1). Ovarian cancer represents the second most common gynecologic malignancy and leads to more than half of all deaths related to gynecologic cancer. There is no fully reliable screening tumor marker, but CA-125 U/mL has proven useful. Treatment with surgical debulking is critical. Surgery is usually followed by chemotherapy. However, there is high recurrence rate, and the overall 5-year survival rate for advanced disease is only 17% [2].

Pathogenesis

The pathogenesis of ovarian cancer is multifactorial [1–3]. About 5–10% of ovarian cancers are familial and include three distinct hereditary patterns: breast–ovarian cancers (genetically linked to mutations in the *BRCA1* and *BRCA2* tumor suppressor genes), site-specific ovarian cancer, and ovarian and nonpolyposis colon cancers or Lynch syndrome II. The remaining 90% of ovarian cancers are sporadic.

Pathology

Ovarian neoplasms are classified according to their histogenesis (Table 1). Tumor derived from surface epithelium is most common with almost 90% of ovarian cancers originating from germinal epithelium. Other tumors include germ cell neoplasms, stromal neoplasms, and metastases, which comprise the remaining 10%. Epithelial ovarian cancer subtypes include serous, endometrioid, mucinous, clear

Fig. 1 Observed survival rates for 11,738 cases of primary ovarian epithelial cancer. Data from the National Cancer Database (Commission on Cancer of the American College of Surgeons and the American Cancer Society), diagnosed in the period 1998–2002. Stage 0 includes 60 patients; stage IA, 1, 415; stage IB, 160; stage IC, 878; stage IIA, 211; stage IIB, 304; stage IIC, 473; stage IIIA, 284; stage IIIB, 425; stage IIIC, 3,815; and stage IV, 3,773 (Used with the permission of the American Joint Committee on Cancer [AJCC], Chicago, IL. The original source for this material is the *AJCC Cancer Staging Manual*, Seventh Edition (2010) published by Springer Science and Business Media LLC. http://www.springer.com)

cell, undifferentiated, and Brenner types. Serous tumors are the most common, accounting for approximately 40% of primary ovarian neoplasms and 40% of primary cancers. They occur in the age group of 15–50 years. Benign neoplasms tend to occur in younger women than malignant neoplasms. Serous tumors are frequently bilateral; 25% of benign, 30% of low malignant potential (borderline), and 70% of malignant serous tumors are bilateral. Mucinous tumors account for 20% of ovarian neoplasms and occur commonly in the age group of 15–50 years. These are mostly benign and more commonly unilateral. Mucinous cystadenocarcinoma accounts for 10% of ovarian cancers [2, 3].

Endometrioid carcinoma accounts for 20% of malignant ovarian neoplasms and is frequently bilateral. It is defined by its microscopic resemblance to endometrial carcinoma. Associated endometriosis is found in about 25% of cases. In some cases, concurrent endometrial carcinoma is present, raising the question of whether the ovarian neoplasm is metastatic or a second independent primary. An origin from endometriosis has been demonstrated for some endometrioid carcinomas; however, the frequency with which this

Metastatic neoplasms	**Common**

occurs is probably low, and in most cases the tumor is believed to represent endometrioid differentiation of a neoplasm derived from the celomic epithelium. Endometrioid carcinomas grossly appear as solid and cystic masses that frequently show areas of hemorrhage and necrosis. Microscopically, the cells resemble endometrial carcinoma. Squamous metaplasia is seen in 50% of cases [2, 3].

Staging

Staging is surgically based. Both the International Federation of Obstetrics and Gynecology (FIGO) and the TNM classification of ovarian cancer are based on the intraoperative findings [4–6] (Table 2). Early-stage ovarian cancer is treated with comprehensive staging laparotomy, whereas advanced but operable disease is treated with primary cytoreductive surgery (debulking) followed by adjuvant therapy. Patients with unresectable disease may benefit from neoadjuvant (preoperative) chemotherapy before debulking. Factors that generally indicate inoperable disease include: invasion of the pelvic sidewall, rectum, sigmoid colon, or bladder; tumor deposits greater than 1–2 cm in the porta hepatis; intersegmental fissure of the liver, lesser sac, gastrosplenic ligament, gastrohepatic ligament, subphrenic space, mesenteric root, and presacral space; suprarenal adenopathy; and hepatic parenchymal, pleural, or pulmonary metastases.

Diagnosis of Ovarian Cancer

Pelvic or transvaginal ultrasonography and CA-125 U/mL tumor marker levels are used in combination for identification of ovarian carcinoma in early stages. There is some evidence that supports the use of these screening tools in high-risk populations, i.e., women with genetic predisposition or positive family history [6, 7]. The impact of such routine screening on reducing the mortality of patients with ovarian carcinoma is not yet clearly established.

In women presenting with a suspected ovarian mass, confirmation should be obtained pathologically by either biopsy or laparoscopic removal [6].

Role of Conventional Imaging in Primary Ovarian Cancer

Ovarian cancer usually presents as: unilateral or bilateral adnexal complex cystic masses with a thick, irregular wall; thick septations greater than 3 mm in thickness; and mural nodularity, papillary projections, or a solid component with variable degree of necrosis. Advanced stages of ovarian cancers are often associated with pelvic organ invasion, ascites, and peritoneal carcinomatosis.

Ultrasound (US) is usually an initial imaging modality for detection and characterization of

Table 2 International Federation of Obstetrics Gynecology (FIGO) and TNM staging for ovarian cancer

Primary tumor (T)			
TNM	FIGO		
Tx			Primary tumor cannot be assessed
T0			No evidence of primary tumor
T1	I		Tumor limited to the ovaries (one or both)
T1a	IA		Tumor limited to one ovary; capsule intact, no tumor on surface; negative washings
T1b	IB		Tumor limited to both ovaries; rest same as IA
T1c	IC		Tumor limited to one or both ovaries with any of the following: surgical spill; capsule rupture; tumor on ovarian surface; malignant cells in ascites or peritoneal washings
		IC1	Tumor limited to one or both ovaries with surgical spill
		IC2	Tumor limited to one or both ovaries with ruptured capsule or tumor on ovarian surface
		IC3	Tumor limited to one or both ovaries with malignant cells in ascites or peritoneal washings
T2	II		Tumor involving one or both ovaries with pelvic extension
T2a	IIA		Extension and/or implants on uterus and/or fallopian tube
T2b	IIB		Extension and/or implants on other pelvic tissues
T2c[a]	IIC		[a]
T3	III		Tumor involving one or both ovaries with histologically or cytologically confirmed peritoneal spread outside pelvis and/or metastasis to retroperitoneal lymph nodes
T3a[a]	IIIA		Positive retroperitoneal lymph nodes and/or microscopic metastases outside pelvis
		IIIA1	Positive retroperitoneal lymph nodes
		IIIA1(i)	Size $\leq$10 mm
		IIIA1(ii)	Size >10 mm
	IIIA2		Microscopic peritoneal spread outside pelvis and/or retroperitoneal lymph nodes
T3b	IIIB		Macroscopic peritoneal spread (metastases $\leq$2 cm) and/or positive retroperitoneal lymph nodes. Including extension to liver/splenic capsule
T3c	IIIC		Macroscopic peritoneal spread (metastases >2 cm) and/or positive retroperitoneal lymph nodes. Including extension to liver/splenic capsule
Regional lymph nodes (N)			
TNM	FIGO		
Nx			Regional lymph nodes cannot be assessed
N0			No regional lymph node metastasis
N1	IIIC		Regional lymph node metastasis
Distant metastasis (M)			
TNM	FIGO		
M0			No distant metastasis
M1[a]	IV		Distant metastasis (excluding peritoneal metastasis)
	IVA		Pleural effusion with positive cytology
	IVB		Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)

[a]Changes made to FIGO staging criteria have not yet been resolved by TNM system. FIGO stage IIC has been eliminated

adnexal masses and pelvic ascites (Figs. 2 and 3). Computed tomography (CT) is the imaging modality of choice for preoperative staging. Magnetic resonance imaging (MRI) better characterizes adnexal lesions (Fig. 4) and is especially helpful in cases with inconclusive US findings and those with complex changes or involvement of nodes and adjacent organs (Fig. 5); it is also the modality of choice for evaluation of pelvic side wall invasion (Fig. 6). MRI increases the specificity of detection for indeterminate lesions on US and decreases the incidence of resections for

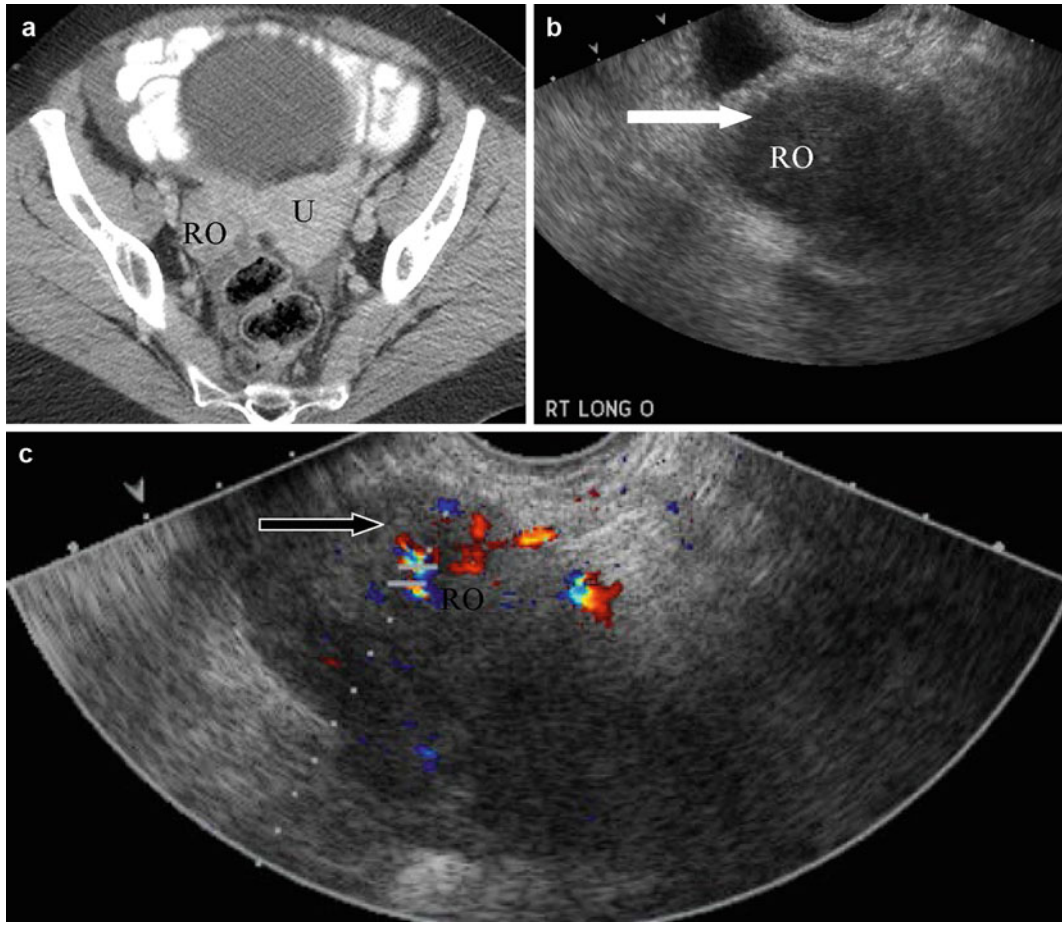

Fig. 2 (**a**) Contrast-enhanced axial computed tomography of the pelvis shows prominent right ovary (*RO*) and adjacent uterus (*U*). (**b**, **c**) Transvaginal pelvic ultrasound shows right ovarian hypoechoic solid mass (*white arrow*) with internal vascularity (*black arrow*) on color Doppler image (**c**). Surgical pathology analysis of the right ovary proved to be metastatic signet ring cell adenocarcinoma of the stomach

benign lesions (Fig. 7). CT is more useful in staging and treatment planning once malignancy is proven (Fig. 8).

[^{18}F]FDG PET Imaging

Normal Variants and Limitations

Increased uptake of 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) can be seen in some benign lesions and physiological conditions. Functional uptake in ovaries related to cyclical changes and maturing or growing follicles is frequently seen [8] (Fig. 9). This is commonly noted in younger females of reproductive age. Physiologic ovarian uptake may also be seen during cyclical variation in premenopausal females. Increased ovarian uptake may be seen in nonmalignant lesions such as serous and mucinous cyst adenoma, dermoid cyst, endometriosis, inflammation, teratoma, and schwannoma [9, 10]. An absolute standardized uptake value (SUV) to distinguish benign from malignant lesions is not known, but in general malignant lesions show higher uptake although a significant overlap is seen. Cutoff SUV_{max} values ranging between 2.75 and 3 have been suggested to distinguish benign from malignant lesions. In an

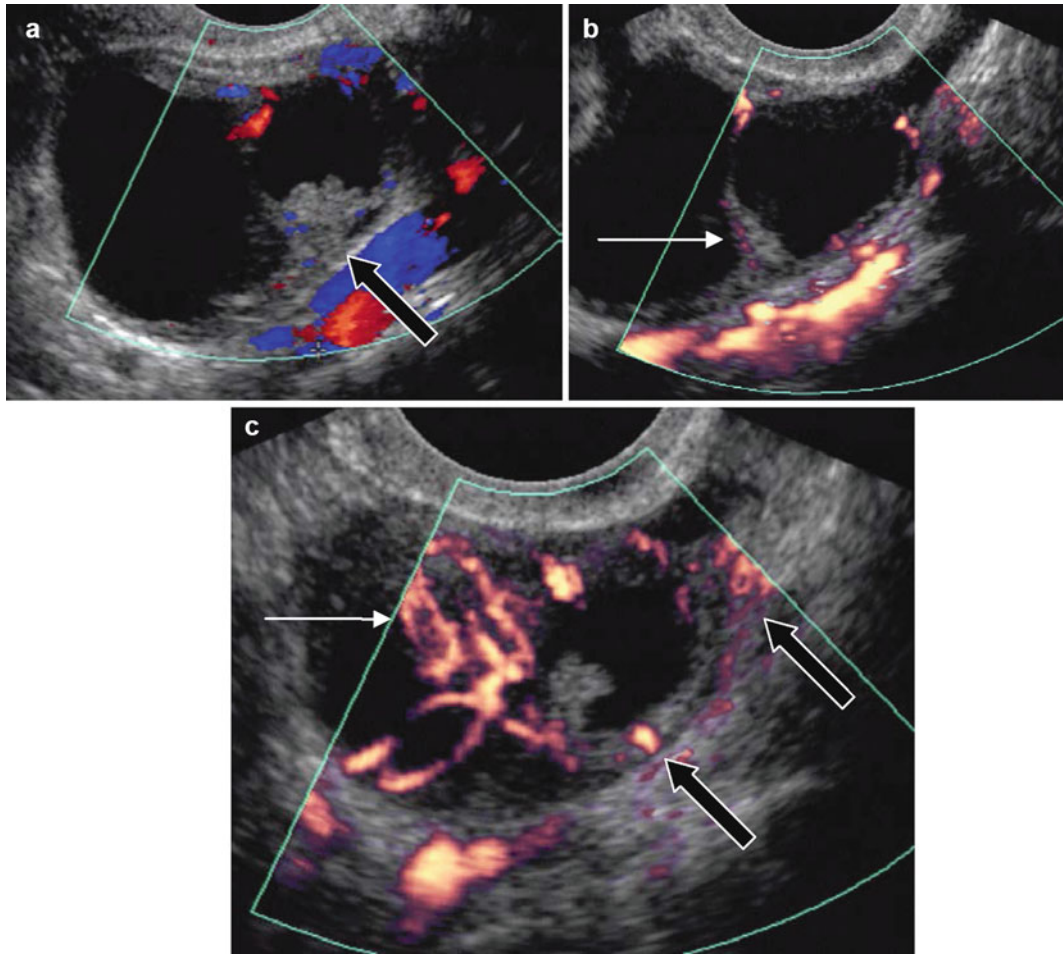

Fig. 3 (**a**) Transvaginal pelvic ultrasound color Doppler images show a left ovarian complex cystic mass containing vascular thick septations (*white arrows*) and vascular solid components (*black arrows*); (**b**, **c**). Surgical pathology analysis from the left ovarian cystectomy showed papillary serous tumor, a borderline tumor

analysis of 160 patients, Tanizaki et al. demonstrated that a cutoff SUV_{max} of 2.9 had a sensitivity and specificity of 80.6% and 94.6%, respectively, for differentiating between benign and malignant ovarian tumors [11]. Only three of 79 cases (3.8%) with benign tumors were PET positive (SUV_{max} >2.9). Castellucci et al. suggested a cutoff SUV_{max} of 3 (sensitivity and specificity of 87% and 100%, respectively) [12], and Kitajima et al. found that a cutoff SUV_{max} of 2.75 (sensitivity and specificity of 86.3% and 73.7%, respectively) [13] could help distinguish benign/borderline from malignant ovarian masses. Contrary to these findings, Lerman and colleagues determined an SUV of 7.9 for determining benign versus malignant uptake, with a sensitivity of 57% and a specificity of 95% [14]. The SUV for those with ovarian cancer was on average 9.1 ± 4 and in premenopausal females without known ovarian malignancy it was 5.7 ± 1.5. This variation may likely be due to differences in the sample size of patients that were evaluated. Increased ovarian uptake in postmenopausal patients is associated with malignancy and should be further evaluated when visualized. It is therefore important that any uptake in the ovaries be correlated with clinical history and corresponding CT findings.

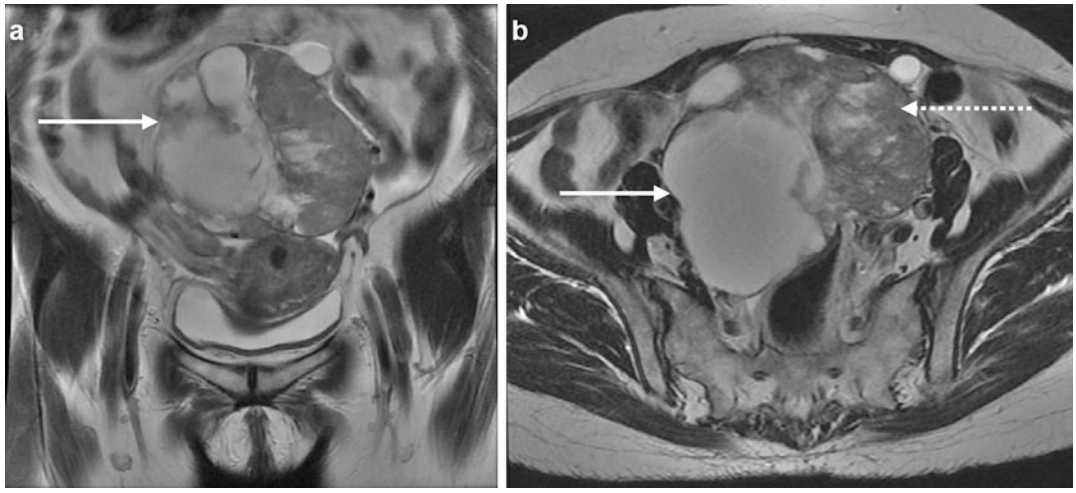

Fig. 4 Magnetic resonance imaging of the pelvis. (**a**) Coronal T2-weighted and (**b**) axial T2-weighted images show a large pelvic multiloculated/septated complex cystic mass (*white arrow*) containing a large soft tissue component (*dashed white arrow*), probably arising from the left adnexa. Histopathology revealed bilateral ovarian high-grade serous carcinoma

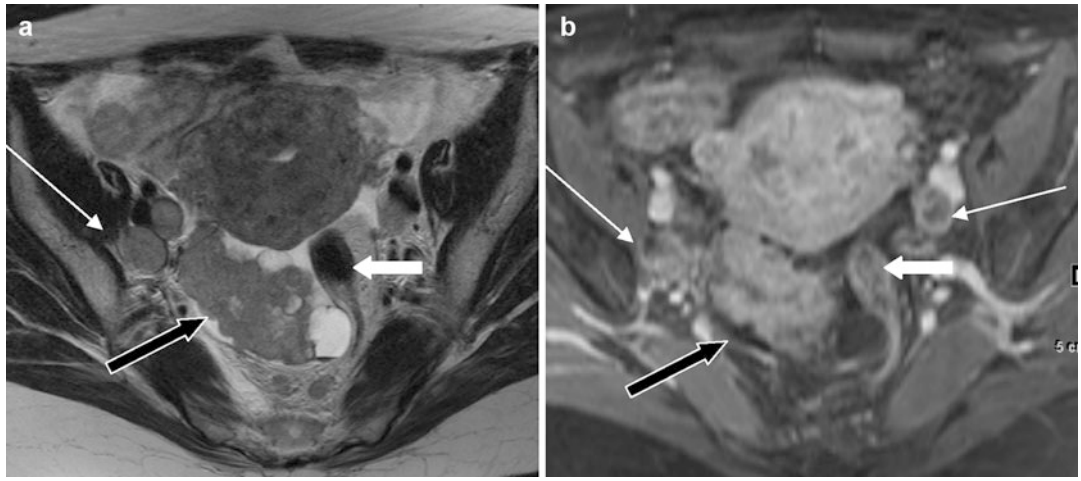

Fig. 5 Magnetic resonance imaging of the pelvis. (**a**) Axial T2-weighted and (**b**) gadolinium-enhanced axial T1-weighted images show a large right adnexal mass containing an enhancing component (*black arrows*) that is inseparable from the rectum (*small white arrow*), bilateral external iliac enlarged lymph nodes (*large white arrows*), and pelvic ascites. Pathology confirmed high-grade serous carcinoma

Demonstration of a functional ovarian cyst on CT and correlation with menstrual history can help in identifying functional cysts. Focal uptake in the pelvis can also be seen related to fallopian tubes predominantly in premenopausal women at mid-menstrual cycle, owing to the influence of estrogen on the fallopian tubes [15] (Fig. 10).

In the primary diagnosis and staging of ovarian cancer, the role of [^{18}F]FDG PET is limited by size resolution. Although [^{18}F]FDG-avid ovarian uptake in postmenopausal women is considered suggestive of malignancy, PET/CT is not recommended for primary cancer detection because of the high false–positive rates

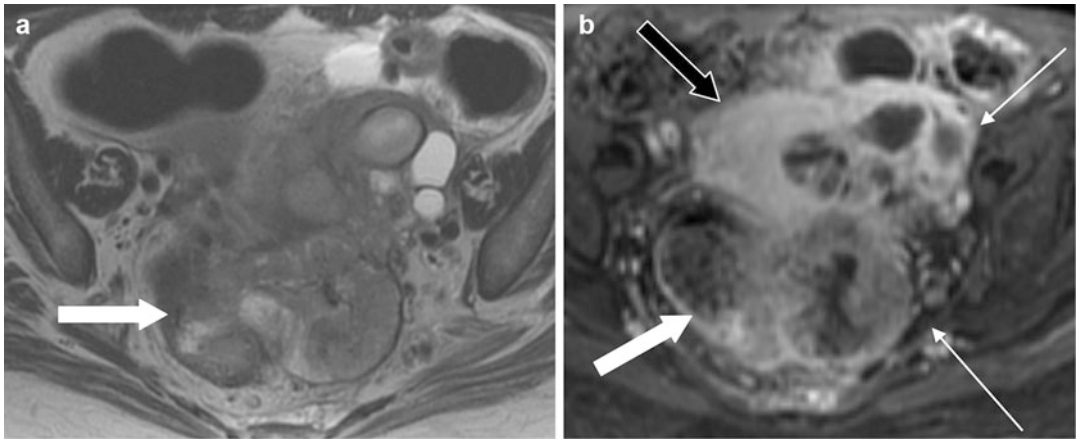

Fig. 6 Patient with high grade papillary serous carcinoma. MRI Pelvis (**a**) axial T2-weighted and (**b**) Gadolinium-enhanced axial T1 weighted images showed a left adnexal complex mixed cystic and solid mass invading adjacent rectum (small white arrows), uterus (black arrow) and left pelvic side wall (large white arrows).

[16]. Most primary lesions show high [^{18}F]FDG activity (Fig. 11) although detection of small lesions and peritoneal deposits is still limited. Earlier studies using only PET reported a positive predictive value (PPV) of 86–96% and a negative predictive value (NPV) of 76% with an overall accuracy of about 90% [17, 18]. PET does seem to add incremental value to conventional imaging in staging ovarian cancer either through confirmation of disease or exclusion of distant disease [19] (Fig. 12).

Most epithelial tumors show intense accumulation of [^{18}F]FDG. There was no positive correlation of SUV with clinical stage, tumor grade, cell proliferation, and glucose metabolism in 17 patients suspected of having ovarian epithelial cancer . Intensity of GLUT-1 expression, MIB-1 LI, and histologic grading score showed statistically significant positive correlations with [^{18}F]FDG uptake. GLUT-1 transporter expression was the strongest parameter to predict positive [^{18}F]FDG uptake [20]. For distinguishing malignant from benign pelvic lesions, [^{18}F]FDG PET/CT is similar to transvaginal ultrasound (TVUS) in sensitivity; however, it is more specific (100% vs. 61%). In staging ovarian cancer, PET/CT appears to be superior to CT alone. When correlated with final pathological staging, PET was concordant in 22 of 32 (69%) patients as compared with CT, which was concordant in 17 of 32 (53%) patients. Staging was modified correctly suing PET, leading to upstaging four out of six patients by detecting distant metastasis in the liver, pleura, mediastinum, and left supraclavicular lymph nodes [12].

A prospective study by Hynninen et al. found that PET/CT provided incremental information to CT in the detection of intra-abdominal disease, particularly mesenteric and subdiaphragmatic peritoneal disease, and was more effective for detection of extra-abdominal disease. In 35 patients with ovarian cancer, the overall site-based sensitivity, specificity, and accuracy for [^{18}F]FDG PET/CT were 51%, 89%, and 64% and for CT 41%, 92%, 57% [21]. Dauwen et al. assessed the value of [^{18}F]FDG PET/CT in evaluating suspicious ovarian masses. In comparison with CT, [^{18}F]FDG PET had higher specificity (77% vs. 38% for CT) for detecting malignant tumors and extra-abdominal metastases [22].

[^{18}F]FDG PET/CT has a low diagnostic value in differentiating between borderline malignant or benign tumors and other malignant ovarian tumors. The reported sensitivity and specificity of [^{18}F]FDG PET/CT in detecting malignant lesions are as high as 100% and 85.0%, respectively, while the rates for borderline tumors are only 71.4% and 81.3%, respectively. The SUV_{max} of borderline tumors is generally lower than that of malignant tumors and is very similar to benign

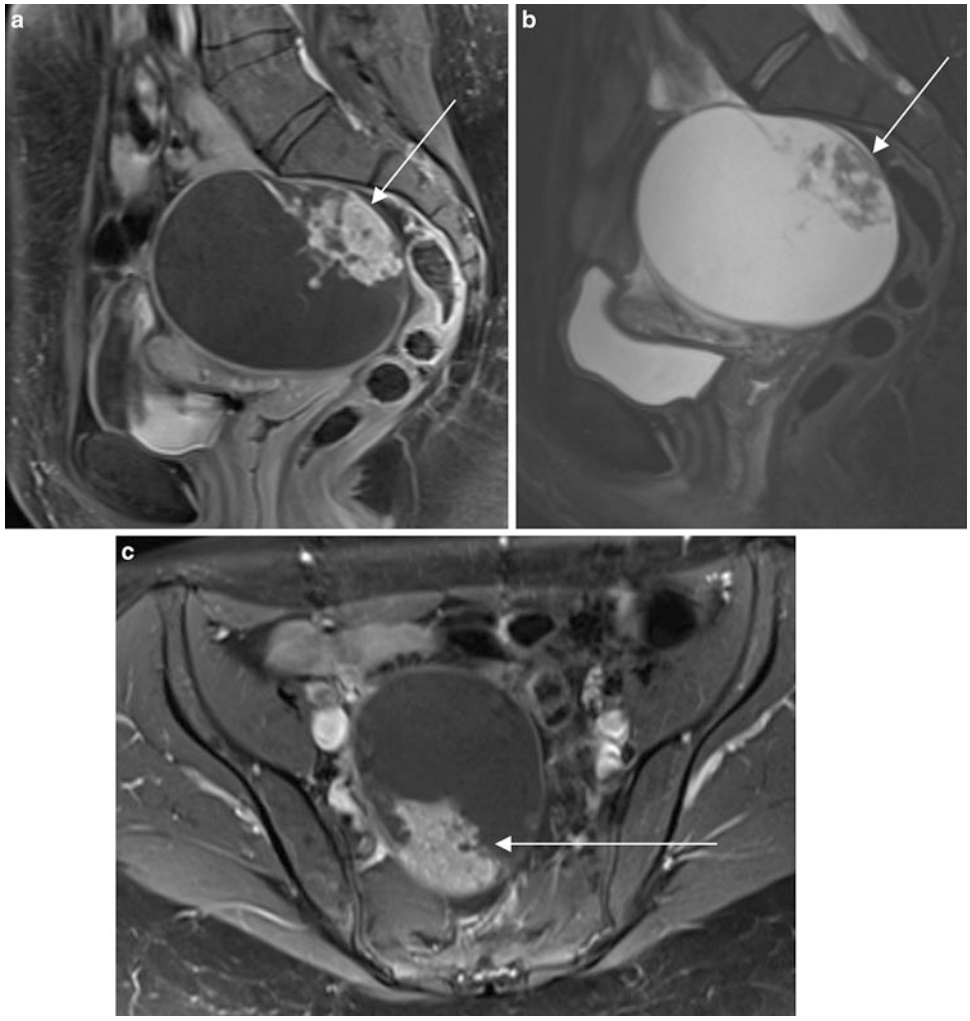

Fig. 7 MRI pelvis (**a**) Gadolinium-enhanced sagittal T1 weighted (**b**) sagittal T2 weighted and (**c**) Gadolinium-enhanced axial T1 weighted images showed a right adnexal large complex cystic mass containing an enhancing solid component (large white arrows). Surgical pathology revealed right ovarian Sertoli Leydig cell tumor (right ovarian sex cord stromal tumor).

tumors, making it difficult to conclusively reach the diagnosis [23]. Mucinous tumors and germ cell tumors are also generally less avid. It is important to be aware of this variation so that false negatives can be recognized. In a retrospective study of 98 patients, PET/CT had high sensitivity and specificity in detecting primary tumors. PET/CT yielded true-positive findings in 87 of 94 patients and true-negative findings in four of four patients with benign lesions [24]. PET/CT can be a useful adjunct to conventional imaging, especially in equivocal cases. It has incremental value in staging through detection of disease in normal-sized or small nodes and metastatic disease especially at distant sites. In comparison with Doppler US, CT, or MRI, PET/CT was concordant with surgical staging in 78% of patients and revealed 15 (15.8%) cases of unpredicted extra-abdominal lymph node metastasis in 95 patients with ovarian cancer. Furthermore, PET/CT was more specific in distinguishing malignant from benign lesion, although overall sensitivity did not

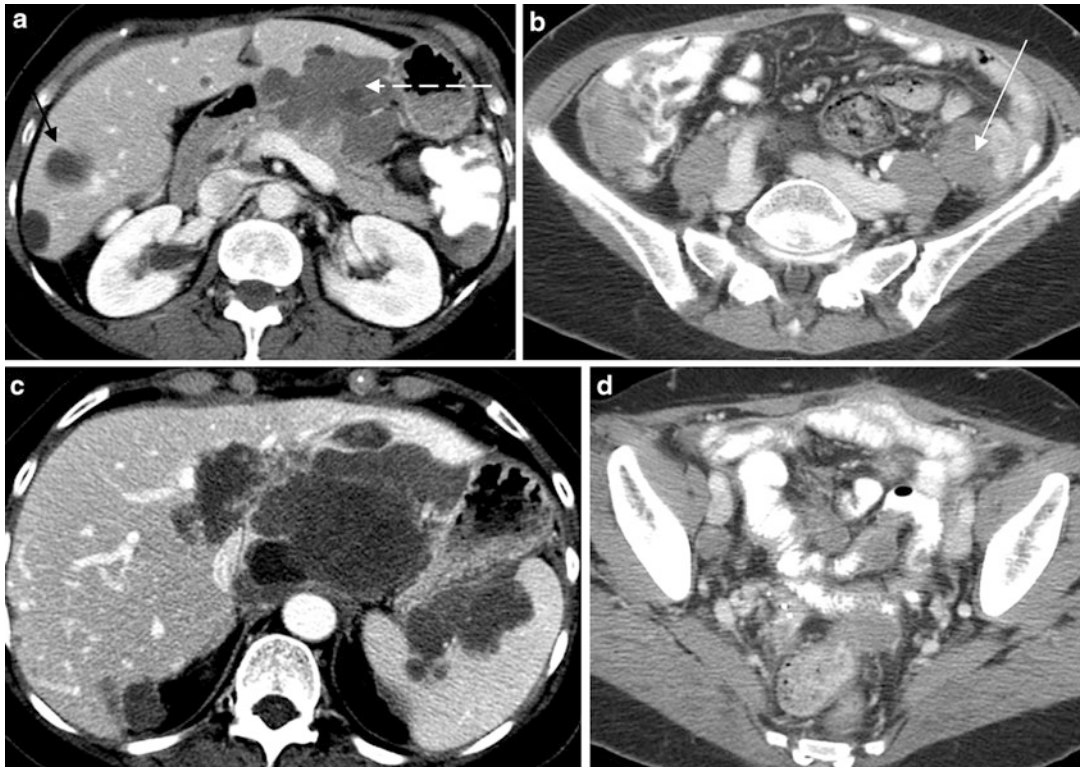

Fig. 8 Contrast enhanced axial CT abdomen and pelvis of 58 yo woman who presented with intermittent abdominal pain and increased CA-125 U/mL (~169.9) showed (**a**) hepatic metastases [black arrow], perihepatic implant (dashed white arrow), (**b**) serosal implant in the left paracolic gutter (white arrow) (**c**) perisplenic implant (white arrow), (**d**) right external iliac lymph node (white arrow) and minimal pelvic ascites (black arrow). Histopathology was positive for high grade ovarian adenocarcinoma.

vary significantly between the three modalities. In detecting malignant lesions in the extra-ovarian pelvis and the abdomen, the sensitivity was similar (94.6% vs. 94.1%), but specificity was significantly higher for PET/CT at 82.8% than for CT at 71.4% [25]. In detecting malignant nodes, including the bilateral pelvic and the para-aortic lymph nodes, both the sensitivity and specificity of PET/CT were higher (83.8%, 92.6%, respectively) than for CT and/or MRI combined (62.5%, 83.6%, respectively). PET/CT was shown to have higher accuracy than pelvic US, CT, or MRI (0.749; $p = 0.013$). False-negative findings on PET/CT included bowel mucosal invasion, small peritoneal seeding, and adjacent adnexal invasion [25]. Physiologic activity in the bowel and low resolution are known to lead to false negatives. Unknown supradiaphragmatic metastases were found in 15 cases of which ten (66.6%) were supraclavicular lymph node metastasis [25]. Michielsen et al. evaluated the role of whole-body diffusion-weighted MRI in staging and compared it with CT and [^{18}F]FDG PET/CT in 32 patients with suspected ovarian cancer. Comparable accuracy was similar for all modalities; however, the specificity for characterizing primary lesions was the highest with MRI [26]. PET/CT is valuable in staging as it can detect unexpected sites and can lead to stage migration [27]. In a large prospective study of 101 patients with primary ovarian cancer, Risum and colleagues reported a high sensitivity of PET/CT in detecting malignant pelvic tumor of ~100% (57/57) with a specificity of 92.5% (37/40) and an incremental value in staging. In three of five patients (60%) with stage IV disease, metastases were found only on PET/CT, located in an inguinal

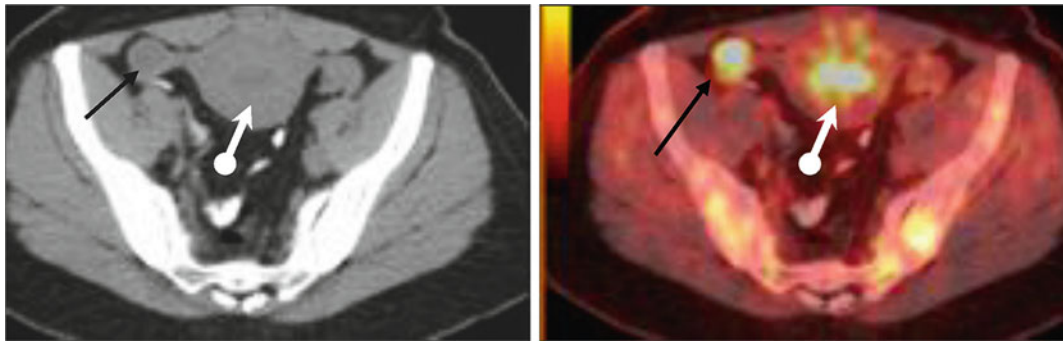

Fig. 9 Physiologic [^{18}F]FDG uptake in the right ovary and uterine cavity (*arrows*). No abnormality was detected on follow-up. Findings consistent with uptake related to cyclical changes in the uterus and corpus luteal cyst in the right ovary

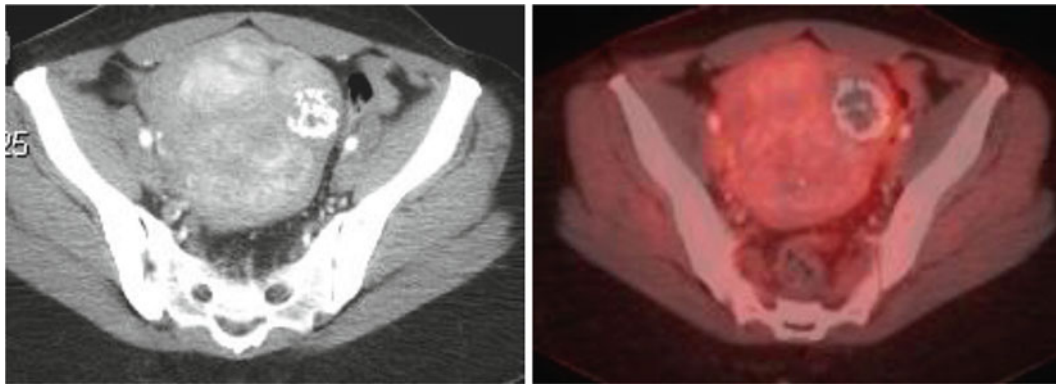

Fig. 10 Variable uptake in uterine fibroids. CT images (*left*) show heterogeneously enlarged uterus with lesions that have calcificationconsistent with fibroids. [^{18}F]FDG PET/CT (*right*) shows no uptake in the region of calcified fibroid and mild heterogeneous activity associated with the remainder of the enlarged uterus

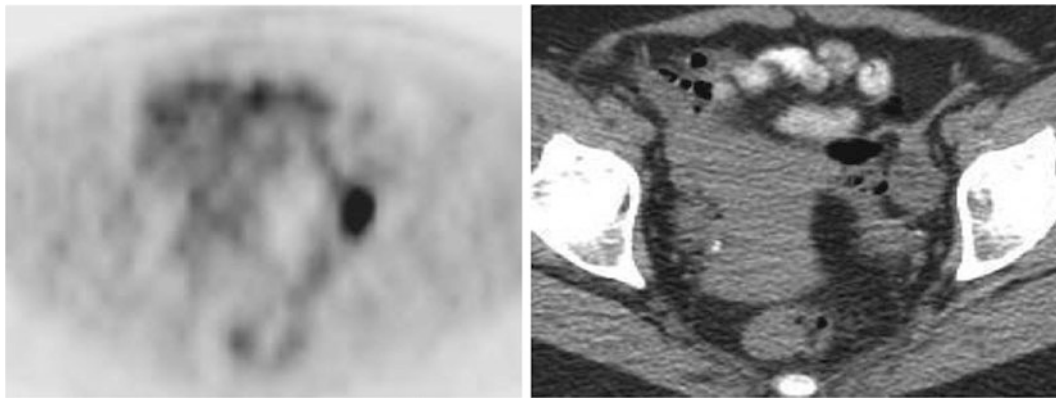

Fig. 11 A 60-year-old woman with breast cancer and elevated CA-125 U/mL level referred for evaluation of a left ovarian cyst. PET/CT shows intense [^{18}F]FDG uptake in the mildly enlarged left ovary. Pathology showed poorly differentiated serous adenocarcinoma of the left ovary

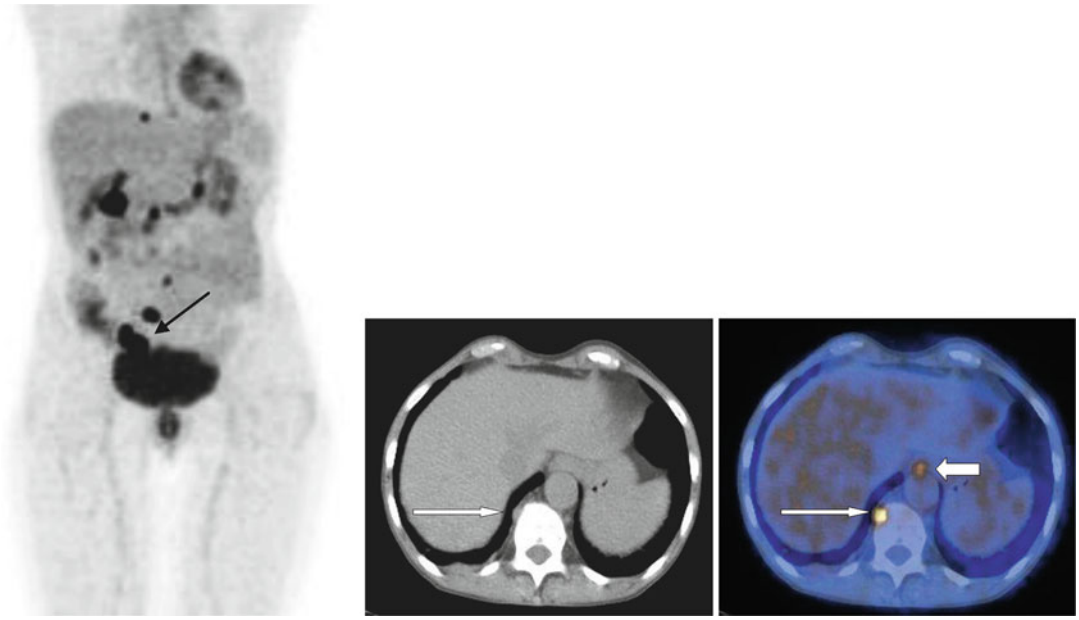

Fig. 12 A 56-year-old woman with ovarian cancer referred for staging. Uptake is seen in the primary tumor in the pelvis and pelvic adenopathy (*black arrow*). [^{18}F]FDG PET images show uptake in the right retrocrural (*white long arrow*) and preaortic (*white short arrow*) node that were not suspicious based on size criteria

lymph node and in a supraclavicular lymph node [28]. In limited studies, a combination of PET with contrast-enhanced CT (CTce) was shown to improve detection. A comparison of modalities (CTce vs. PET/CTce) in 40 patients showed improvement in overall lesion-based sensitivity from 37.6% (32/85) to 69.4% (59/85), while the specificity between CTce and PET/CTce was comparable (97.1% and 97.5%, respectively) [29].

[^{18}F]FDG PET/CT is useful in detecting lymph node involvement in patients with ovarian cancer. In a meta-analysis of 18 studies analyzing 882 patients, the diagnostic performance of CT, MRI, and PET was compared. [^{18}F]FDG PET or [^{18}F]FDG PET/CT was more accurate than CT and MRI in the detection of lymph node metastasis in patients with ovarian cancer (sensitivity and specificity were 73.2% and 96.7% for [^{18}F]FDG, 42.6% and 95% for CT, and 54.7% and 88.3% for MRI, respectively) [30]. Nodal staging in 68 patients (stage IA–IIIC) revealed a sensitivity of 83.3%, a specificity of 98.2%, and an NPV of 96.5% for [^{18}F]FDG PET/CT; however, the sample size was small with nodal disease found in only 12 patients. All false–negative results were seen in patients with a nodal size less than 5 mm. Sensitivity in detecting pelvic nodes (63.6%) was lower compared with that for para-aortic nodes (82.3%), which is likely attributable to the difficulty in assessing the pelvic region because of anatomic location close to the ovarian primary tumor [31].

[^{18}F]FDG PET/CT may be limited in detecting small lesions and peritoneal disease. De Iaco et al. compared the sensitivity of [^{18}F]FDG PET with histopathology for detecting peritoneal disease in 40 patients with ovarian cancer. PET/CT yielded positive results in 268 of 360 quadrants, with a sensitivity and specificity of 78% and 68%, respectively, and a PPV of 95%. False–negative results were seen in those with adhesions and in lesions smaller than 5 mm such as in carcinomatosis [32]. Some have found PET/CT comparable to MR and multidetector CT in assessing peritoneal carcinomatosis and have reported an added value of PET in detecting small peritoneal implants in patients with ascites due to a better separation of bowel loops, allowing for easier

distinction between physiological intestinal activity and pathological uptake [33].

Impact on Management at Staging

Primary treatment for ovarian cancer is primary cytoreduction, which when performed optimally has prognostic value. Presence of disease outside the abdomen can have significant implications in further management of ovarian cancer. Detecting distant metastases is therefore critical. The current FIGO staging system allows for the use of any imaging modality to evaluate metastatic disease. A number of studies have shown the value of PET and PET/CT in detecting previously unrecognized distant metastases [28, 29, 34, 35].

[^{18}F]FDG PET/CT can help identify disease in sites that may prevent primary cytoreductive surgery; in six of 21 cases, [^{18}F]FDG PET detected previously unknown hepatic hilar infiltration (4/6) and disease in the mesenteric root (2/6) that was confirmed at surgical exploration [36].

PET/CT, through more accurate staging, provides prognostic information. Of 201 patients with primary ovarian cancer, the overall survival and prognostic variables were analyzed in 66 patients ($n = 64$, stage III; $n = 2$, stage IV). Using PET/CT, 51% (39/66) of the patients were diagnosed as having stage III and 41% (27/66) as having stage IV disease. With a median follow-up of 30.2 months and using univariate analysis, a lower stage on PET/CT was a significant prognostic variable besides optimal debulking and performance status; however, it was not an independent prognostic factor. The study was somewhat limited owing to the lack of histological correlation for distant metastatic sites detected on PET [27].

Preoperative PET/CT may help predict surgical outcomes. In a prospective study of 179 patients, the predictive value of ten parameters of preoperative PET/CT findings were evaluated for optimal versus suboptimal cytoreduction [37]. In 77% of women undergoing incomplete cytoreduction, PET/CT showed large bowel mesentery implants or ascites. In 31% of women undergoing incomplete cytoreduction, PET/CT showed pleural effusion, and in 89%, PET/CT showed peritoneal carcinomatosis that were predictors of incomplete cytoreduction. Using multivariate analysis, large bowel mesentery implants was the only independent predictor of incomplete cytoreduction, and no predictor of suboptimal cytoreduction was found. PET/CT can be a useful supplementary imaging modality before surgery in primary ovarian cancer and may also have a role in the appropriate selection of patients for neoadjuvant chemotherapy [38].

Imaging in Recurrent Ovarian Cancer

Approximately 50% of patients with ovarian cancer will present with recurrence after cytoreductive surgery and first-line chemotherapy. The presentation is pelvic masses, recurrence at the vaginal cuff or pelvic side wall, peritoneal tumor implants, malignant ascites, lymphadenopathy, or distant metastases including of the lung, pleura, liver, or bone (Figs. 13 and 14). CT is the most commonly used modality for detection of recurrent tumor (Fig. 15), while MRI provides superior information on the local extent of disease including evaluation of the involvement of other organs, the pelvic side wall, and vascular invasion.

In general clinical practice, [^{18}F]FDG PET has been a secondary imaging modality after CT and MRI, with [^{18}F]FDG PET indicated only in cases with equivocal findings by other imaging modalities or cases with negative findings on other imaging in the presence of rising tumor markers.

There are significant data published on the utility of [^{18}F]FDG PET in recurrent ovarian cancer including in the surveillance and assessment of patients with rising tumor markers as well as in management decisions (Table 3). [^{18}F]FDG PET has been shown to be superior to CT or MRI in the detection of recurrent disease, with reported sensitivity and specificity of 83–91% and 66–93% for [^{18}F]FDG PET, respectively, versus 45–91% and 46–84% for CT or MRI [39, 40]. [^{18}F]FDG PET helps identify disease in those with rising CA-125 U/mL levels. In a retrospective study by Dragosavac et al., PET/CT detected disease in 42 of 45 patients and unsuspected lesions in 20 of 45 patients; 11 of these patients had normal conventional imaging. [^{18}F]FDG PET/CT was

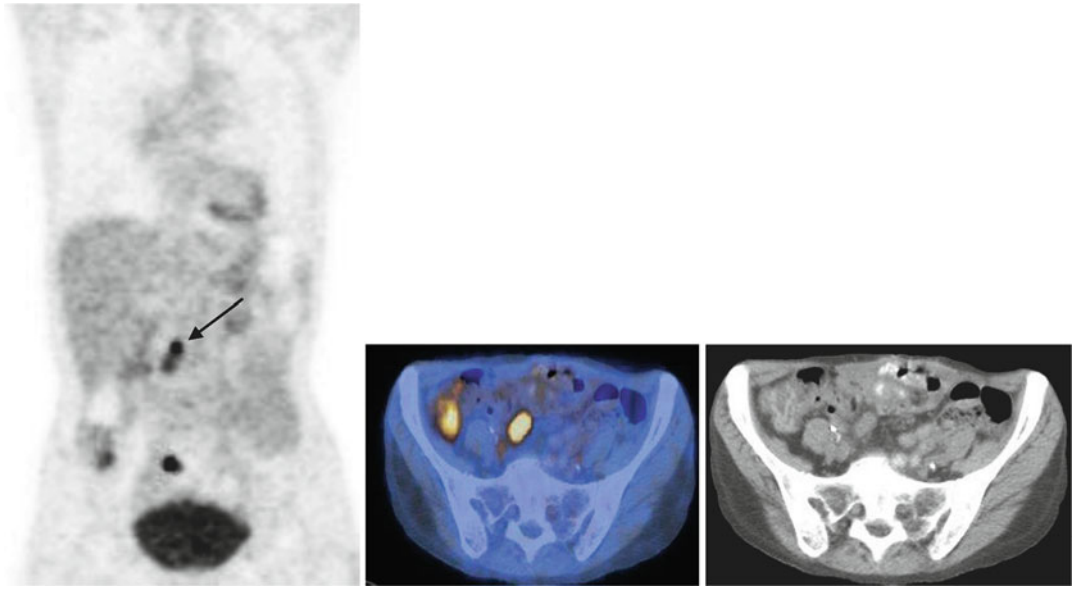

Fig. 13 Recurrence of ovarian carcinoma. A 62-year-old woman with ovarian cancer, submitted to total abdominal hysterectomy with bilateral salpingo-oophorectomy, referred for evaluation of metastatic disease. Whole-body images show focal [^{18}F]FDG uptake in the pelvis and mid-abdomen localizing to the nodes in common iliac region and para-aortic region (*arrow*)

true negative in the remaining three patients. A limitation of this study was the lack of histopathological confirmation of the lesions, although the conclusion was supported by concurrent clinical data and follow-up [41].

The role of [^{18}F]FDG PET has, however, been uncertain owing to variable results. Its role is limited in the detection of microscopic and small-volume disease where earlier studies reported low sensitivity in detecting disease. A study by Rose et al. of 17 ovarian cancer patients reported poor results for [^{18}F]FDG PET [42]. The study was done with patients who had optimal primary cytoreduction, using PET only, and most of the lesions not detected were smaller than 6 mm. In 36 patients, Kim et al. observed an overall significant difference in lesion-based sensitivity for PET/CT (66%) and MRI (86%). MRI was, however, more accurate than PET in detecting peritoneal lesions, with the overall lesion-based sensitivity and accuracy of PET/CT being 43% and 86% and that for MRI being 75% and 94%, respectively [43]. For peritoneal implants that are slightly larger, the results have been variable, although some authors have reported equivalent or higher sensitivity for [^{18}F]FDG PET. In a recent study, the sensitivity of PET/CT was better than MRI in detecting small to medium-sized peritoneal implants (<2 cm); the reported sensitivity was 95.4% for [^{18}F]FDG versus 50% for MRI (for sizes of 0.5–1 cm) [44]. In a meta-analysis of 29 studies involving 1,651 patients, the pooled sensitivity and specificity of [^{18}F]FDG were 88.6% and 90.3%, respectively, for detection of recurrence in ovarian carcinoma [45].

Detection is improved with combined PET/CT than with PET alone (Figs. 16 and 17). Reported sensitivities for the detection of peritoneal disease range between 57% and 88%, although with higher specificity for PET than for CT (94% vs. 77%, respectively). In these studies, the combined sensitivity ranged from 88% to 100% and the specificity from 79% to 93% [46–50].

[^{18}F]FDG PET can help in the early detection of disease in patients who are asymptomatic with normal CA-125 U/mL levels as well as in those with rising CA-125 U/mL levels and normal conventional imaging including CT scan or MRI [50–52].

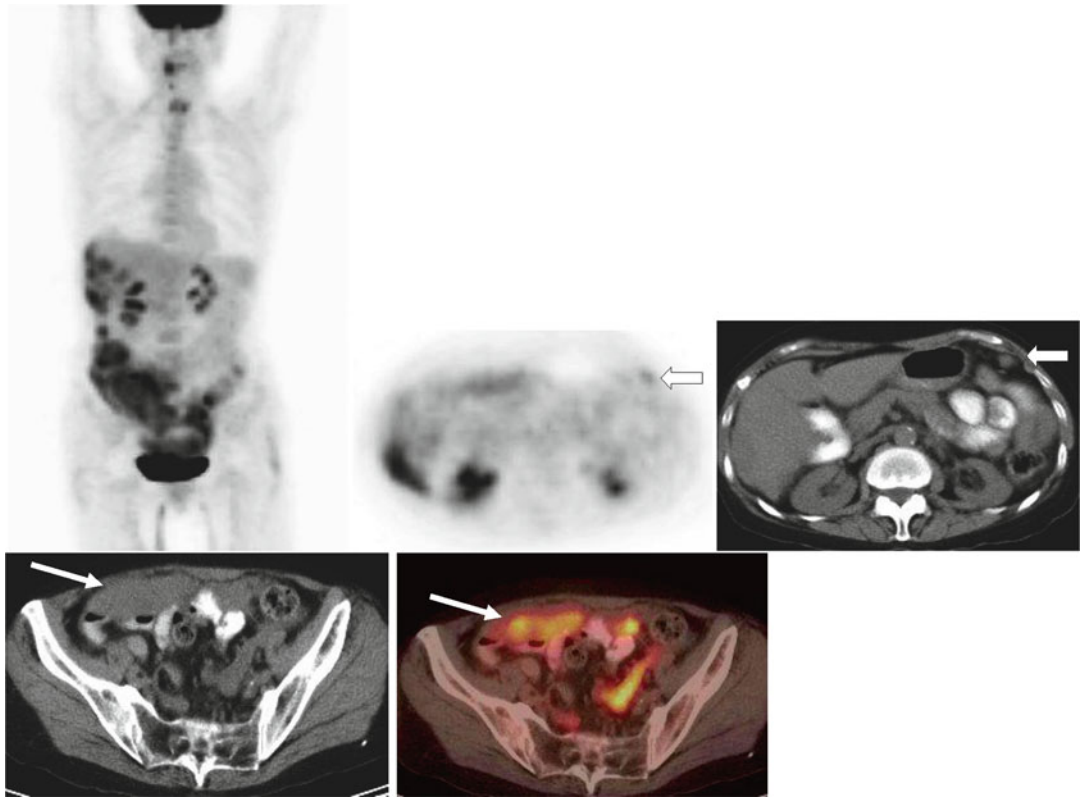

Fig. 14 A 64-year-old woman with ovarian carcinoma and rising CA-125 U/mL level referred for assessment of disease extent. [^{18}F]FDG uptake is seen in the lower anterior pelvic peritoneal lesion, small peritoneal implant in the left abdomen (*white short arrow*), and right perihepatic implants

Fig. 15 Contrast-enhanced axial computed tomography of the abdomen in a 68-year-old woman with recurrent ovarian carcinoma shows omental disease (caking; *white arrow*) and small loculated ascites (*black arrow*) in the left hemiabdomen. Pathology showed high-grade serous ovarian carcinoma

A single study reported a sensitivity of 100% with a specificity of 85% for this modality; however, this was a study with a very small number of patients who underwent exploratory laparotomy ($n = 22$) or diagnostic laparoscopy ($n = 15$) [50]. In a meta-analysis, Gu et al. compared data from 34 studies to evaluate the accuracy of CA-125 U/mL, PET alone, PET/CT, CT, and MRI in diagnosing recurrent

Table 3 Performance of [^{18}F]FDG PET in the assessment of recurrent ovarian carcinoma

Author and year	Type	FIGO stage	Total number of patients studied	Comparative imaging (CT or MRI)	Number of cases with negative/equivocal CT and MRI findings	Histopathology confirmation (yes/no)	Sensitivity/specificity/accuracy
Rusu et al. (2015)	Retrospective	II ($n = 1$), III ($n = 41$)	42	CT	23	Yes	[^{18}F]FDG: 92.2%/100%/92.5%; CT: 60.8%/NA/52.8%
Dragosavac et al. (2013)	Retrospective	I ($n = 2$), II ($n = 3$), III ($n = 34$), IV ($n = 6$)	45	US/CT/MRI	23	Yes	[^{18}F]FDG: 100%/100%/NA
Antunovic et al. (2012)	Retrospective	NA	121	US/CT/MRI	41	Yes	[^{18}F]FDG: 82%/87%/83%; CA-125 U/mL: 59%/80%/63%; conventional imaging: 69%/47%/66%
Sanli et al. (2012)	Retrospective; Assessed detection of peritoneal implants by [^{18}F]FDG PET	NA	47	MRI	NA	Yes	**Overall**:
							[^{18}F]FDG: 97.5%/100%/97.8%; MRI; 95%/85.7%/93.6%
							For implants 0.5-1 cm: [^{18}F]FDG: 95.4%/100%/97.8%; MRI: 50%/100%/78.7%
							For implants >3 cm: [^{18}F]FDG: 100%/100%/100%; MRI: 87.5%/100%/97.8%
Pan et al. (2011)	Prospective	I ($n = 7$), III ($n = 23$), IV ($n = 7$)	37	None	NA	Yes	[^{18}F]FDG: 100%/84%/94%; CA-125 U/mL: 58%/100%/72%; CA15-3: 29%/100%/54%
Bilici et al. (2010)	Retrospective	I ($n = 8$), II ($n = 6$), III ($n = 43$), IV ($n = 3$)	60	CT	20	Yes	[^{18}F]FDG – 95.5%/93.3%/95%. CT – 55.5%/66.6%/58.3%

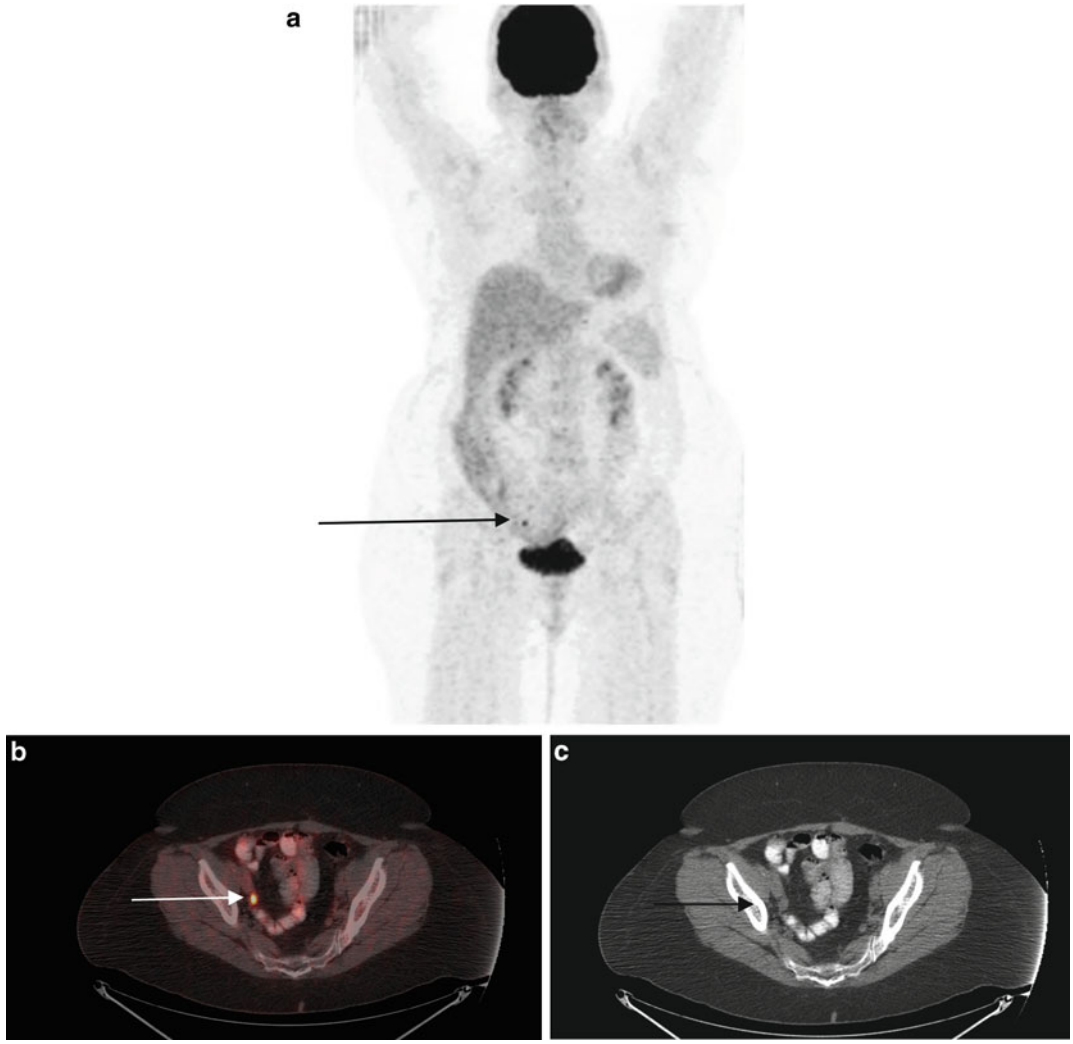

Fig. 16 A 67-year-old patient with papillary serous adenocarcinoma of the left ovary, who underwent status post total abdominal hysterectomy/bilateral salpingo-oophorectomy, was referred for PET/CT for restaging in view of rising CA-125 U/mL levels (34 U/ml). The patient was clinically asymptomatic and had normal findings on conventional imaging. Maximum intensity projection image (**a**, *arrow*) shows focal abnormal [^{18}F]FDG uptake in the right side of the pelvis localizing to a right para-iliac soft tissue nodule measuring 1.5 × 1.1 cm (**b**, **c** *arrows*; SUV_{max}, 7.3), likely a lymph node. No other metabolically active lesion was noted elsewhere. Pathology findings were positive for metastatic carcinoma

ovarian carcinoma. Pooled data showed the highest specificity for CA-125 U/mL at 0.93 (95% CI: 0.89–0.95), while PET/CT had the highest pooled sensitivity at 0.91 (95% CI: 0.88–0.94). There was significant heterogeneity among studies and evidence of publication bias. The pooled sensitivity of PET alone was 0.88 (95% CI, 0.84–0.92), not statistically significant from PET/CT [47]. The combined pooled data supported the use of PET/CT as a supplement to current surveillance techniques, particularly for those patients with an increasing CA-125 U/mL level and normal CT or MRI findings.

Similar results were seen for PET in more recent studies of patients who were clinically disease-free [46, 49]. PET compared with

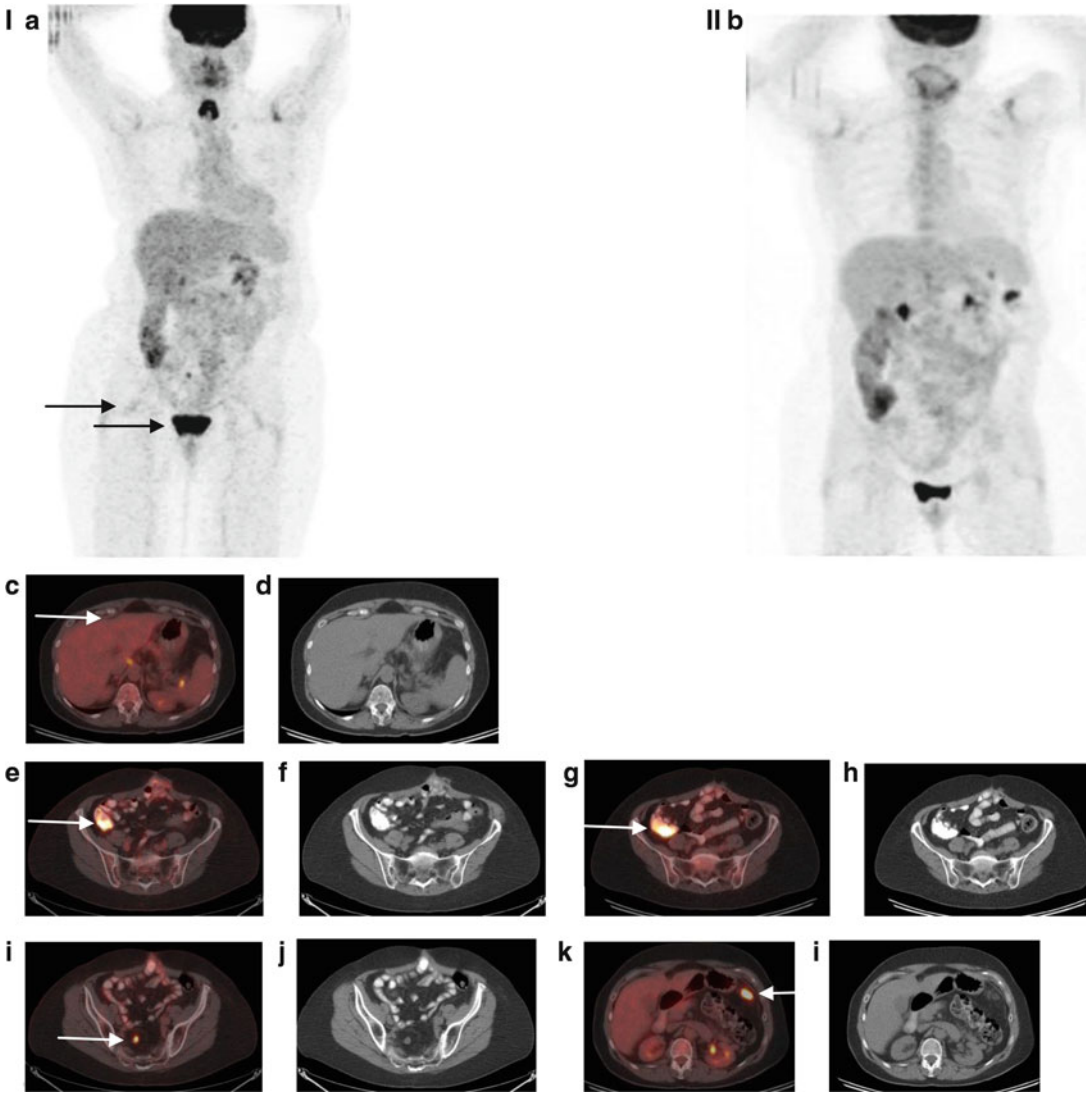

Fig. 17 A 66-year-old patient with ovarian carcinoma, who underwent and status post primary (total abdominal hysterectomy/bilateral salpingo-oopherectomy) and secondary (partial resection of transverse colon/omentectomy) cytoreduction was referred for restaging in view of rising CA-125 U/mL levels (from 11 U/mL to17 U/mL in 3 months). PET/CT (*panel I*) shows a peritoneal nodule in the pelvis (**a**, **b** *arrow*; SUV_{max}: 6.2) suggestive of recurrence. The patient was treated with chemotherapy. A follow-up PET/CT (panel II), however, shows progression (**g**, **h** *arrow*) with appearance of new peritoneal nodules in the perihepatic portacaval region (**c**, **d** *arrow*; SUV_{max}: 4.2) and in the left upper abdominal peritoneum (**e**, **f** *arrows*; SUV_{max}: 8.2)

conventional imaging and serum CA-125 U/mL levels showed superior results than conventional imaging, with a sensitivity of 86.9% and a specificity of 78.8% versus 53.3% and 81.8%, respectively. [^{18}F]FDG PET detected disease in 23 patients with positive serum CA-125 U/mL levels but who had normal findings on other imaging modalities and in 11 patients with negative serum CA-125 U/mL levels and normal findings with other imaging modalities [46]. Murakami and colleagues reported the detection of disease using PET in 46 patients (51%); in eight of 41 patients (19.5%) with normal CA-125 U/mL levels, disease was seen with PET only. The

sensitivity of the combination of PET and CA-125 U/mL was highest at 97.8%. PET detected intraperitoneal and retroperitoneal metastases and normal-sized nodal metastases and was able to detect recurrence at relatively low titers of CA-125 U/mL [49]. In a more recent study, Antunovic et al. evaluated 121 patients for recurrence using [^{18}F]FDG PET/CT and conventional imaging with a sensitivity of 82% and 70%, respectively. Of these patients, only 55 had serum CA-125 U/mL levels greater than 35 U/mL, whereas 52 patients presented with CA-125 U/mL levels in the normal reference range [51]. The detection rates with [^{18}F]FDG PET are generally higher with a greater increase in the CA-125 U/mL level; the reported detection rates were around 53% for CA-125 U/mL levels less than 30 U/mL compared with 89% for CA-125 U/mL levels greater than 286 U/mL [52].

PET/CT may be considered for the evaluation of patients suspected of having recurrent disease [6].

Impact on Management of Recurrent Disease

The use of PET/CT in conjunction with conventional imaging has potential impact on management [53]. It has also been suggested that the combination of PET/CT and staging laparoscopy has a significant effect on the multimodal approach through its complementary role in the assessment of disease (Fig. 18).

Fagotti and colleagues evaluated [^{18}F]FDG PET and staging laparoscopy in identifying surgically treatable or untreatable patients in 70 recurrent ovarian cancer cases [54]. The sensitivity and specificity of PET were 93.0% and 55.6%, respectively, versus 95.0% and 64.0% for staging laparoscopy. Combined radiological and laparoscopic evaluation improved all parameters, with an NPV of 88.9% and a sensitivity of 95.3%.

[^{18}F]FDG PET/CT may be helpful in optimizing the selection of patients for site-specific treatment, including radiation treatment planning and selection of optimal surgical candidates. In a retrospective review of 39 ovarian cancer patients, [^{18}F]FDG PET/CT detected disease in three patients with clinical symptoms of recurrence but normal CA-125 U/mL levels, while in four patients with no clinical evidence of recurrent disease, PET was true negative in all cases [55]. PET/CT facilitated the accurate localization of disease, guided treatment, and helped avoid surgery in four patients in whom additional disease was detected in unresectable anatomic areas. In five of eight patients, PET confirmed the presence of disease following treatment [55]. In another study, PET/CT led to a change in the clinical management in 44% of cases when PET/CT information was added to conventional follow-up findings [56]. For 32 patients, both CTce and PET/CT were performed: PET/CT yielded positive findings in 91% of cases compared with 63% for CT. Intermodality changes in management were indicated for 14 of 32 (44%) patients undergoing PET, with the decision changed from observation in five, further examinations in three, and chemotherapy in six additional patients [56].

In a larger study of 132 women, the combination of CTce with PET improved the diagnosis, resulting in a change of management for 51 of the 132 patients (39%). In comparison, CTce alone changed management in 12% while PET/CT (non-contrast) affected management in only 2% of cases [57]. For patient-based analysis, the sensitivity, specificity, and accuracy of PET/ceCT was the highest and significantly different at 78.8%, 90.9%, and 84.8%, respectively, whereas those of PET/non-contrast-enhanced CT were 74.2%, 90.9%, and 82.6%, respectively, and those of CTce were 60.6%, 84.8%, and 72.7%, respectively [57].

Similar results were reported by Chung and colleagues in their study where PET/CT modified the diagnostic or treatment plan for 19 patients (24.7%), by leading to the use of previously unplanned therapeutic procedures in 11 (57.9%) and the avoidance of previously planned diagnostic procedures in eight (42.1%) patients [58].

In 56 women with elevated CA-125 U/mL levels of more than 35 IU/mL, all but one had a positive finding on PET/CT. PET/CT altered the known disease distribution in 40 scans (64%). Overall, PET/CT showed less disease in six scans (9%) and more disease in 34 scans (52%). Regardless of the value of CA-125 U/mL, PET/CT identified a subgroup of women with

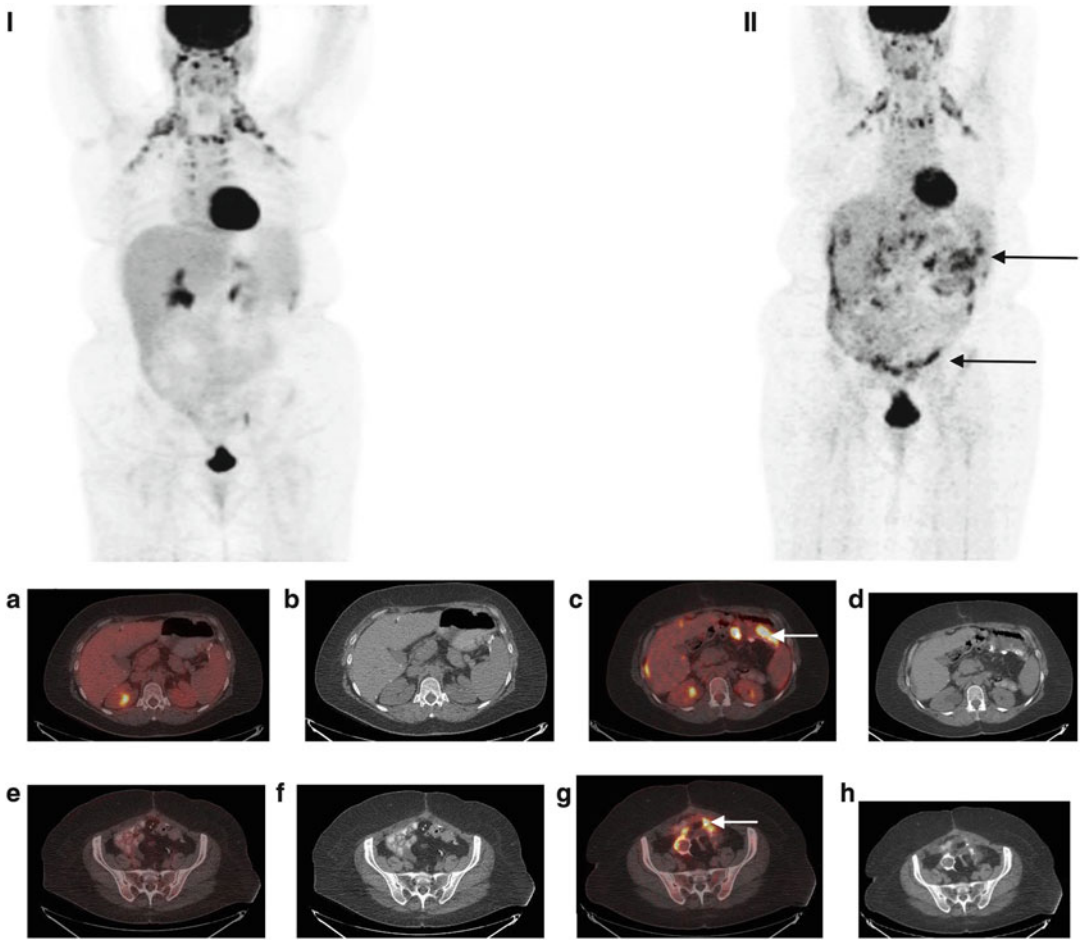

Fig. 18 A 58-year-old patient with stage-III high-grade papillary serous carcinoma who underwent status post partial primary cytoreduction and chemotherapy. PET/CT performed after completion of therapy (*panel I*) does not show evidence of any [^{18}F]FDG-avid disease (**a**–**d**). In view of rising CA-125 U/mL levels 4 months later, the patient was referred for PET/CT scan (*panel II, arrows*) revealing hypermetabolic disease in the peritoneum (**e**–**h** *arrows*) and retroperitoneal lymph nodes. No other distant metastases were seen in the whole-body scan. She was started on chemotherapy and underwent a second debulking procedure

apparently localized disease or no definite evidence of disease. This group had improved survival compared with women shown to have systemic disease. PET/CT resulted in a major change of management plan in 34 patients (58%) [59]. In a recent study, [^{18}F]FDG PET/CT changed the management of 31 patients (51.6%), leading to the use of previously unplanned treatment procedures in 19 patients (61.2%) and the avoidance of previously planned therapeutic procedures in 12 patients (38.8%) [60].

When pre- and post-PET/CT questionnaires completed by the oncologists were examined for the impact of PET/CT results on decision-making, there was a statistically significant change in the decision-making for ten patients (34%, $p < 0.0001$). PET had positive findings in 93% of patients compared with the CT scan (76%) and it modified the disease distribution for 16 patients (55%; $p < 0.001$) compared with CT [61].

In a recent prospective, multicenter, cohort study where referring doctors were asked to specify a management plan pre- and post-PET imaging, PET/CT affected management in 60% of cases (49% high, 11% medium impact) and identified 168 more lesions than conventional imaging

that were mostly nodal or peritoneal sites of disease. Patients in whom more disease was detected with PET/CT were more likely to experience disease progression in the following 12 months [62].

Role in Assessment Before Second-Look Laparotomy or Secondary Debulking

At second-look laparotomy (SSL), about 36–73% of patients are found to have persistent ovarian cancer [42]. Even patients with negative results from second-look procedures have a relapse rate of 30–50% with a mean interval of 24 months. About 60% of recurrence is in the peritoneal cavity [63]. Careful monitoring of the patients is therefore mandatory. SLL is performed on patients without clinical evidence of disease in order to assess tumor response. If SLL cannot confirm presence of disease, then adjunctive therapy is discontinued while reductive surgery is performed on those with residual disease before further chemotherapy [64, 65]. Some feel that the clinical impact of the diagnostic SLL is limited because even when there is no disease (negative SLL), 40–60% of patients relapse within 5 years [66, 67]. Additional drawbacks include invasive surgical procedure, associated complications and morbidity, risk of anesthesia, and all the associated expenses leading to an overall more costly management [67].

Prior to cytoreductive surgery, [^{18}F]FDG PET/CT may be helpful in confirming discrete macroscopic disease in those cases where conventional imaging is unable to detect disease or has equivocal results. It can also help localize the sites of disease so that surgery or biopsy can be directed better. This is useful in cases where detection by conventional imaging fails because of postsurgical changes. Use of a PET probe in the operating room can aid identification and localization of disease sites for resection and help establish the completeness of surgical resection. In a feasibility study, intraoperative gamma probe detection, specimen PET/CT, and postoperative PET/CT verified complete resection of the clinical and hypermetabolic lesions and helped identify disease sites when the extent of disease was not fully apparent intraoperatively by gross palpation or inspection. The intraoperative gamma probe also helped characterize extensive, unresectable disease in the porta hepatis and celiac axis of a patient, much of which was not recognized with the initial intraoperative survey [68]. This, however, needs to be validated in larger studies.

[^{18}F]FDG PET is cost-effective for the evaluation of recurrent disease and helps guide surgical management; reported change may be affected in about 50–60% patients [40, 69]. In their study of 42 patients, Rusu et al. noted a change in therapeutic procedures in 30 out of 53 (56.6%) cases, leading to a change from surgical intervention to conservative treatment in 11, while three patients were eligible for surgery contrary to the prior plan of either systemic treatment or observation [40].

The high NPV of PET scanning may be useful for avoiding second-look surgery, and by better selection of patients for secondary cytoreductive surgery [^{18}F]FDG PET may be a substitute for second-look surgery [70–72]. In a prospective evaluation of 60 patients, Risum and colleagues compared [^{18}F]FDG PET/CT with abdominal/TVUS and CT performed before secondary cytoreductive surgery. All patients had a CA-125 U/mL level greater than 50 U/mL or more than 15% over the baseline level. The sensitivities of US, CT, and PET/CT for diagnosing recurrence were 66%, 81%, and 97%, respectively. The specificity of US, CT, and PET/CT for diagnosing recurrence was 90% for all three modalities. PET/CT detected recurrence in ten (50%) of 20 patients without evidence of recurrence on CT. Multiple versus solitary tumors were found using PET/CT on 27 of 39 (69%) patients compared with 19 of 39 (48%) by CT [72].

Smith et al. demonstrated a reduction in unnecessary invasive staging procedures and healthcare costs following the introduction of [^{18}F]FDG PET. PET led to a decrease in unnecessary laparotomies from 70% to 5%; 35% of patients underwent the less-invasive laparoscopy instead of laparotomy [71]. Mansueto and colleagues also reported on the cost-effectiveness of using PET/CT in recurrent disease through accurate detection of disease sites and its ability to direct the clinical

management [70]. The study compared treatment strategies based on CT only, PET/CT for those with normal CT scans, and PET/CT for all cases. The expected costs, avoided surgery, and incremental cost-effectiveness ratio were calculated to identify the most cost-effective strategy. PET/CT reoriented physician choice in 31% of patients submitted to PET/CT after a negative CT scan, and in 62% of patients who always underwent PET/CT –irrespective of the CT findings. While applying PET/CT in all cases adds to the cost, it is offset by cases where surgery is avoided. In this study, surgery was avoided in three cases [70].

PET/CT offers a noninvasive method for assessing and predicting full resectability of recurrent disease when planning cytoreductive surgery and hyperthermic intraperitoneal chemotherapy [73]. In 206 patients with recurrent ovarian cancer who were evaluated with either [^{18}F]FDG PET or conventional imaging ($n = 103$ each), those who had secondary cytoreductive surgery guided by PET/CT had fewer residual lesions and showed prolonged overall survival (43 months vs. 22 months) and progression-free survival (median 20 months vs. 9 months, respectively) compared with those who underwent conventional imaging [74]. When compared with a scoring system based on clinical parameters of resectability, PET/CT showed a higher sensitivity of 100% and an NPV of 100%, although overall specificity at 60% was low. A very good prediction of full resectability was shown for patients undergoing concordant PET/CT and clinical scoring, with a sensitivity of 100% (63–100), specificity of 75% (20–96%), PPV of 89%, and NPV of 100%. PET/CT can provide complimentary information to clinical parameters or score and may be a noninvasive tool for the assessment of resectability [75].

Response Assessment and Prognostication

Limited data exist on the role of monitoring treatment response. In a small study of ovarian cancer patients receiving neoadjuvant therapy, response using [^{18}F]FDG PET was retrospectively analyzed in eight patients and compared with histopathological parameters to identify responders or nonresponders. Posttherapy SUV in responders was significantly lower than that in nonresponders, and an SUV cutoff of 3.8 on posttherapy scans differentiated responders and nonresponders, with a sensitivity of 90%, a specificity of 63.6%, and an accuracy of 76.2%; a percent change in SUV of 65 as the cutoff showed a sensitivity of 90%, a specificity of 81.8%, and an accuracy of 85.7% for differentiating responders from nonresponders [76]. More data and studies are needed to consolidate and define the role of [^{18}F]FDG PET in assessing treatment response.

Quantitative PET parameters may be useful for prognostication and assessing treatment outcomes although their role is yet to be fully understood and defined in routine practice. Metabolic tumor volume (MTV) and total lesion glycolysis (TLG) are some parameters associated with outcomes of surgery and prognosis. In 175 patients with primary disease, TLG was an independent prognostic factor for progression-free interval [77]. For presurgical staging, MTV and TLG values were inversely associated with clinical outcome. Patients with values higher than the cutoff value of 70 for MTV and 563 for TLG were associated with worse outcome and shorter progression-free interval compared with those with lower values [78]. Similar results were also shown in patients with recurrent disease [79, 80]. While there are data available on this topic, many of the studies are limited owing to their retrospective design and small cohort of patients. The use of such parameters and relevance in routine practice remains to be established.

Diagnostic Applications of Nuclear Medicine: Sarcomas

37

Janet F. Eary

Abstract

Sarcomas most commonly occur in the muscles, bones, fat, and connective tissues. These tumors constitute approximately 1% of cancers in adults and about 20% of pediatric cancer. The American Joint Committee on Cancer (AJCC) criteria are often used clinically for staging soft tissue sarcoma patients. Bone tumor staging follows the schemes utilized for other tumors. Adverse prognostic factors include deep tumor location, largest dimension >5 cm, locally recurrent disease, proximal lower extremity site, and presence of metastasis.

Imaging studies, including plain films, chest X-ray, CT with and without contrast, MRI, and [^{18}F]FDG PET, are used in combination to stage and restage sarcoma patients. Serial imaging studies, especially [^{18}F]FDG PET scans, can identify treatment response to neoadjuvant chemo- and radiation therapy. The bone scan with ^{99m}Tc-MDP is still routinely used because of its sensitivity in detection of bone metastases and to occasionally identify metastatic lesions in soft tissues. ^{18}F-Fluoride is increasingly being used as a sensitive bone scanning agent for metastatic surveys.

[^{18}F]FDG PET/CT can reliably distinguish low-grade from high-grade soft tissue sarcoma based on the SUV. Special features and [^{18}F]FDG uptake are related to specific histologic types. Moreover, by identifying areas of increased uptake within a lesion, [^{18}F]FDG PET can be helpful to localize a site for diagnostic biopsy. [^{18}F]FDG PET has been used for tumor staging identifying bone and soft tissue metastases and nodal metastases. A high-resolution contrast chest CT is preferred to visualize small lung metastases.

Disease Overview

Sarcoma is a cancer that originates from the mesenchymal body tissues [1]. These comprise the connective, muscle, fat, bone, cartilage, peripheral nerve, and blood vessel tissues. Sarcomas most commonly occur in the muscles, bone, fat, and connective tissue. While the bone marrow is also derived from mesenchymal tissues, in clinical practice the hematologic malignancies are considered separately from the solid tumors, or sarcomas. Sarcomas are a complex group of tumors that have many different clinical manifestations, but they most often present as a mass.

Sarcomas occur in children and adults. Although the overall cancer incidence is much lower for children, sarcomas account for about one fifth of pediatric cancers. In adults, on the other hand, sarcomas constitute about 1% of cancers [2]. In the USA approximately 10,000 people are diagnosed with sarcomas each year and approximately 3,700 people per year succumb to their disease [2]. The median age of adult sarcoma patients is 59–60 years. There are approximately 30 common sarcoma subtypes that occur in both adults and younger age groups [3]. Most adult sarcomas are the soft tissue types, while bone tumors and cartilage tumors occur less frequently. Women comprise approximately 60% of sarcoma patients [3]. The majority of childhood sarcomas are bone sarcomas which have different clinical presentations, age preponderance, and outcomes compared to childhood soft tissue sarcomas.

The complexity of clinical presentations and diagnoses for sarcomas are based on their pathological characteristics. As these tumors are derived from mesenchymal elements, the tumors at presentation may have histologic and tissue marker characteristics that identify their tissue of origin. They can arise in any mesenchymal tissues. Some sarcomas appear to have no cell of origin identified in normal tissues, supporting the theory that sarcomas form and may differentiate according to surrounding tissue signals or other environmental and genetic factors. There are more than 50 histologic subtypes of sarcoma [4]. They most commonly occur in the extremities and trunk regions. Table 1 lists the mesenchymal tissues, while Table 2 lists the most common soft tissue sarcoma subtypes in adults. Table 3 lists the most common pediatric sarcomas. Bone tumors predominate in the pediatric population.

Adults with sarcomas have approximately a 50% 5-year overall survival rate [1]. Patients with poor outcomes succumb to metastatic disease, local recurrence, or both. Local recurrence after resection occurs in 25% of patients with soft tissue sarcomas,

an event that portends eventual metastatic spread [1]. Typically, pulmonary metastases are the leading site, followed by bone and other soft tissue locations. Disease prognostic factors include patient age, tumor grade (a risk assessment based on histopathological characteristics), tumor depth (superficial or deep), size, histologic subtype, surgical margin status at resection, and disease status (primary or recurrent disease) [1].

Adverse prognostic factors affecting patient survival with soft tissue sarcomas are deep tumor location, a tumor greatest dimension of 5 cm or larger, locally recurrent disease, proximal lower extremity site, and microscopic or grossly involved tumor margins at surgical resection [1]. Sixty percent of adult soft tissue sarcomas occur in the extremities. The proximal lower extremity is a common location for soft tissue sarcomas in adults, which increases risk for poor outcome because of its association with other poor risk factors. Poor risk factors include depth beneath the fascial plane and large tumor growth before diagnosis. In most patients, once metastases occur, survival time diminishes rapidly, despite salvage combination therapy regimens [4]. There are a number of treatment protocols for adults with sarcomas. Patients with low-grade, small sarcomas are likely to proceed to tumor resection with the possibility of adjuvant radiation. Those with high-grade large tumors are often treated with doxorubicin-based neoadjuvant chemotherapy with or without radiation followed by resection and adjuvant therapy. Surgical resection ranges from simple excision with wide margins to complex limb salvage procedures.

Experimental therapy clinical trials for sarcoma are now incorporating targeted therapy agents,

which may influence imaging considerations in the future for clinical care. Adult bone tumors are most often cartilaginous histologic types. Usually, only high-grade tumors are metastatic. The intermediate-grade and low-grade cartilage tumors have high morbidity rates due to repeated local recurrence and poor responses to neoadjuvant chemotherapy. The bone tumors are less frequent in older adults, and osteosarcomas and Ewing's sarcomas are typically seen in younger adults. They are rarely observed in adults over age 50. Bone sarcomas are metaphyseal tumors that primarily spread to the lungs. Risk factors for osteosarcoma include prior radiation therapy and germ line mutations [5]. There are a few soft tissue sarcoma histologic types that can also occur in the bone. Synovial sarcoma is a common example of a cancer that is more biologically consistent with its soft tissue tumor counterparts. As in the soft tissue sarcomas, prognostic factors include the presence of metastases at presentation and chemotherapy resistance. Treatment for the bone sarcomas in adults is similar to the soft tissue sarcomas. Neoadjuvant doxorubicin-based chemotherapy is given and is followed by surgical resection and additional chemotherapy. Five-year survival depends largely on the level of chemotherapy resistance, which is approximately 60%. The lower-grade osteosarcomas are treated with wide local excision and limb salvage procedures. They typically recur in about 5% of cases; however, these recurrences decrease 5-year survival significantly if the tissue recurrence degenerates into a higher-grade or undifferentiated tumor type.

Pediatric sarcomas are dominated by the osteosarcomas and Ewing's sarcomas. The osteosarcomas have a peak incidence in patients in their second decade of life, and the age range begins at approximately 10 years. They predominately present in the extremities, and 15–20% of patients have pulmonary metastases at the time of diagnosis. In addition to prior radiation, the list of possible predisposing factors includes germ line p53 mutations, growth abnormalities, trauma, fetal and parental X-ray exposure. Metastases present at the time of diagnosis are prognostic of poor outcome. Treatment with intensive neoadjuvant chemotherapy results in 60–80% 5-year survival [5]. The treatment response rate and overall survival rate for pediatric sarcomas are significantly higher than that for adults with osteosarcomas.

Ewing's sarcomas are also a bone tumor of adolescence with a peak incidence around the age of 15 years [5]. They most commonly present as a painful mass in the extremities and are often metastatic at presentation. Bone metastases (15–30% of patients), lung metastases, and soft tissue involvement adjacent to the primary tumor mass are common. Presumably, these tumors arise from postsynaptic neural crest precursors and are synonymous with the peripheral neuroectodermal tumors (PNETs), which occur more predominantly in soft tissues [5]. The presence of the EWS-FL1 fusion protein in the tumor confers poor prognosis. There are no known risk factors for causing these tumors, and they are rarely associated with other syndromes.

Patients with sarcoma have highly variable characteristics and clinical outcomes. Sarcomas are often multidrug resistant [6, 7]. The multidrug resistance systems are tissue transporters that remove toxins from tissues. Normally occurring in tissue epithelial linings in the intestines, kidneys, and blood-brain and placental barriers, their activity is unregulated in sarcomas [8–10]. This is a major cause of increased treatment failure and disease progression. The pathobiological basis of multidrug resistance activity and other sarcoma characteristics are complexities that are likely a result of a substantial variety of genetic abnormalities. These consist of broad categories of tumor-specific translocations that contribute to tumor diagnostic criteria and to sarcoma subtypes that have genetic and chromosomal instability [11]. Sarcomas in all body locations present unique challenges for diagnosis and management. These challenges have presented opportunities for evaluation and validation of new imaging techniques.

Approaches to Staging

Because sarcomas are difficult to risk stratify for outcome, staging systems have been devised to improve patient treatment and outcome. The American Joint Committee on Cancer (AJCC) criteria are often used clinically for staging soft tissue sarcoma patients (Tables 4 and 5). This system undergoes periodic analyses and revisions. The current AJCC

Table 4 AJCC definition of TNM and stage grouping for soft tissue sarcoma

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 5 cm or less in greatest dimension[a]
T1a	Superficial tumor
T1b	Deep tumor
T2	Tumor more than 5 cm in greatest dimension[a]
T2a	Superficial tumor
T2b	Deep tumor
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1[b]	Regional lymph node metastasis
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

[a]Superficial tumor is located exclusively above the superficial fascia without invasion of the fascia; deep tumor is located either exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia

[b]Presence of positive nodes (N1) in M0 tumors is considered Stage III

Table 5 AJCC anatomic stage and prognostic groups for soft tissue sarcoma

	Any T	Nl	M0	AnyG
Stage IV	Any T	Any N	Ml	AnyG

soft tissue sarcoma system stratifies patient tumor by size (T1≤5 cm, T2≥5 cm). Additionally, the tumor is characterized by histologic grade (I–III), the presence or absence of nodal and distant metastasis, and special location descriptions. Revisions that have been suggested include categories for very large tumors (T3≥15 cm), specific primary tumor sites, tumor margin status, histologic subtypes, the presence or absence of tumor local recurrence, and specific markers for biologic aggressiveness.

Sarcoma groups are incorporating these parameters in clinical practice more routinely each year. The pathologic tumor grade is an important component of any tumor staging system; however, there are pitfalls that exist in its application to individual patient tumors. The most widely used sarcoma grading system is the FNCLCC designed by the French Fédération Nationale des Centres de Lutte Contre le Cancer [12]. Even with well-defined grading systems, there are several challenges with grading soft tissue sarcomas. Tumors for which it is difficult to assign histologic grade because of their rare characteristics include tumors where the grade applied does not provide additional prognostic information beyond what is conferred from accurately determining the tumor histologic subtype. These include differentiated liposarcomas, the tumors that are considered "ungradable"; the epithelioid, clear cell, and angiosarcomas; and those where the histologic grade does not predict outcome well, such as the malignant peripheral nerve sheath tumors [13]. These findings reflect the heterogeneity of biological behavior in the sarcomas, and they provide the stimulus for incorporation of newer systems that integrate tumor characteristics from a number of different sources that identify patient risk for malignant behavior more accurately.

A comparative analysis of the AJCC, the Memorial Sloan Kettering Cancer Center system, and the Surgical Staging System of the Musculoskeletal Tumor Society soft tissue sarcoma staging systems found that schemes that include tumor depth, grade, and size are most predictive of tumor relapse in patients with extremity tumors. Wunder et al. suggest that these systems can be used to identify patients that are most likely to benefit from participation in adjuvant therapy trials [14].

Bone tumor staging follows the schemes utilized for other tumors, with a few notable exceptions. The primary tumor is assessed by whether it is confined to cortex (T1) or if it extends beyond this bone structure (T2) [15]. The tumor histologic type and grade predominate the staging criteria for prognosis. The presence or absence of distant metastases is also significant. As with soft tissue

sarcoma staging, bone sarcoma staging includes a careful examination of the lungs to discover metastases, which are often present at the time of initial diagnosis. Inclusion of nomograms for improved prognosis has also been developed, and their use may help to improve selection of multimodality treatment for bone sarcoma patients [16].

Imaging plays an increasingly important role in sarcoma staging. All types of examinations – including plain films, chest X-ray, CT with and without contrast, MRI, and [^{18}F]FDG PET – are now used routinely in combination to stage sarcoma patients and to restage patients when treatment decisions are contemplated. The bone scan is still used routinely because of its sensitivity in detection of bone metastases, although most sarcomas predominantly metastasize to the lungs. If necrosis or ossification is present in the lung metastasis, the lesion may appear as a focal region of low-level uptake in the pulmonary parenchyma. It is rare, however, to detect lung metastasis on a bone scan that is not visible on CT. Several types commonly have associated bone metastases, such as the osteosarcomas, Ewing's sarcomas, and highly undifferentiated tumors. Imaging methods and their uses in sarcoma management are discussed more thoroughly in the following sections.

Radiopharmaceuticals

Disease staging in sarcoma involves all aspects of imaging the body with radiopharmaceuticals. Since these tumors vary considerably in their presentation, local recurrence rates, and patterns of metastatic spread, different imaging studies that provide complementary information for disease staging are used in clinical practice. These are for characterizing the extent of tumor; presence of bony, lymph node; and soft tissue metastases. Some tumor types involve multifocal primary disease presentation, synchronous tumors, and skip metastases. In most sarcoma clinics, a combination of nonspecific, highly sensitive, and tissue-specific imaging agents is used in diagnosis, staging, response, and restaging aspects of patient management.

^{99m}Tc-MDP

The bone scan is widely used in oncology for staging the skeleton for the presence of bony metastases. Sarcoma metastases generally show osteoblastic behavior and are less likely to show lytic metastases. For soft tissue masses, the bone scan is also a standard part of disease staging. Patients with bony metastases show increased uptake in typical metastatic disease patterns in the axial skeleton and extremities. The presence or absence of uptake is often diagnostic in separating benign or locally aggressive tumors from malignant types. Bone scans also have special utility in primary bone tumors. These tumors form malignant osteoid matrices that are undergoing disordered calcification; therefore, they are ^{99m}Tc-MDP avid (Fig. 1). Both the osteosarcomas and some chondrosarcomas with osteoblastic differentiation contain malignant osteoid. Ewing's sarcomas cause bone destruction and reaction that result in bone scan positivity. Primary bone tumors have frequent bone metastases and can present with skip lesions in the affected bone. The osteosarcomas also frequently have bone metastases, but bone scan positive appearance in multiple sites is also common in Ewing's sarcoma. In this latter group of tumors, metastases are often present at the time of diagnosis.

The bone scan is a sensitive method for identifying osteosarcoma pulmonary metastases (Fig. 2). These are often highly ^{99m}Tc-MDP avid. Some clinicians use the relative decrease in ^{99m}Tc-MDP uptake in pulmonary metastases as an indicator of treatment response and suitability for wedge resection metastasectomy. In osteosarcoma patients with limited pulmonary metastasis, this procedure has been shown to increase disease-free survival [17]. The ^{99m}Tc-MDP scan has been reported to contribute to the diagnosis of bone-forming malignant tumors by revealing unusual sites and presentations. The ^{99m}Tc-MDP bone scan is also a means of monitoring treatment response. A decrease in malignant osteoid matrix calcification indicates a response to treatment in this cellular portion of the tumor. The bone scan appearance in metastatic

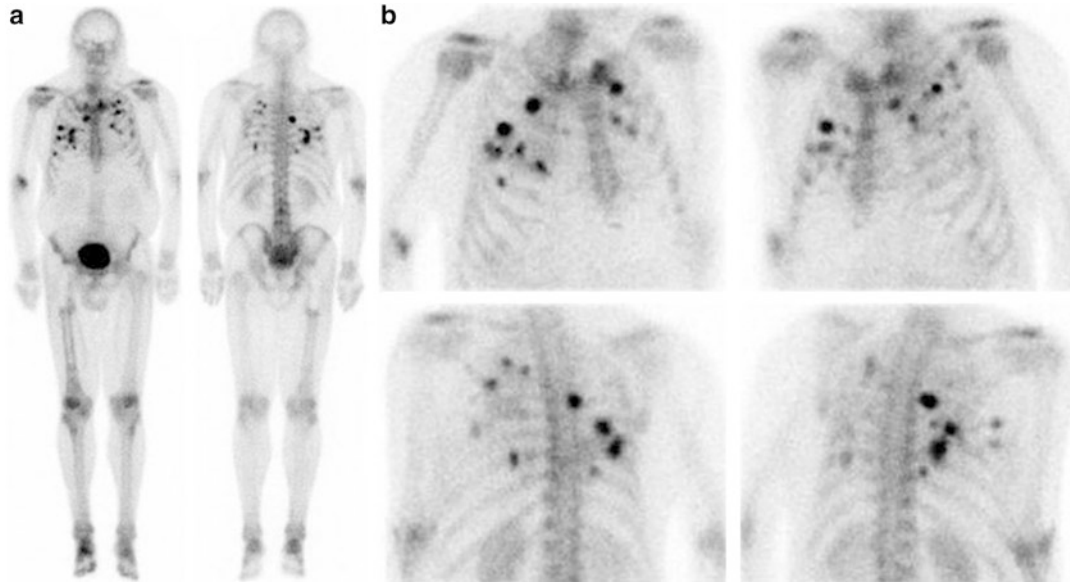

Fig. 2 Bone scan in a patient with active osteosarcoma pulmonary metastases

disease, as with other tumors, can also underestimate the extent and severity of skeletal metastases. In these cases, the metastases involving the bone may only be apparent when a cortical reaction occurs. Subsequent other whole-body surveys such as CT or [^{18}F]FDG PET may provide a complimentary picture of the extent of diseased skeleton [18].

^{201}TI-Chloride

^{201}TI-Chloride as a nonspecific tumor imaging agent has been described for use in many tumors, including sarcoma. Most often, higher uptake is noted in malignant tumors, while lower uptake more frequently signifies benign neoplasms. Soft tissue, bone, and cartilaginous tumors have all shown positivity [19]. Typical high-grade tumor features, such as central necrosis, can also be noted in ^{201}Tl-chloride imaging; this finding is predictive of decreased survival [20].

^{18}F-Fluoride

^{18}F-Fluoride is increasingly being used as a sensitive bone scanning agent for metastatic surveys for many cancers. Recent imaging study results indicate that a combination of [^{18}F]FDG and ^{18}F-fluoride may provide a more complete visualization of bone metastases than either agent alone. This is also the case for sarcomas; however, the use of ^{18}F-fluoride may extend beyond the detection of metastases in bone sarcomas. Since the hallmark of these tumors is new bone formation, uptake of ^{18}F-fluoride will likely change in response to therapy. A particular use may be in evaluating activity in lung metastases since it is common practice to resect lung metastases when they are quiescent after successful chemotherapy. Figure 3 shows a whole-body ^{18}F-fluoride bone scan.

[^{18}F]FDG and Sarcoma Diagnosis

Positron emission tomography (PET) with 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG) has been evaluated for use in sarcoma imaging. Imaging in primary cancers has several critical aspects for patient treatment planning. It is used to determine the biological behavior of the tumor, often determining if the tumor is benign or malignant; however, sarcomas include numerous tumors that do not fit well with either category because they can be locally aggressive, yet rarely metastatic. Using a combination of tumor histopathology from biopsy and imaging data is helpful in determining the tumor grade, which is the propensity of the tumor to behave aggressively.

Fig. 3 Whole Body [F^{18}]Fluoride PET bone scan

Several retrospective studies and meta-analyses describe the utility of [^{18}F]FDG PET in sarcoma clinical practice. It is recommended as a part of the clinical work-up for a patient undergoing diagnosis, disease staging, and treatment planning [21–32]. Numerous studies describe [^{18}F]FDG PET utility in both soft tissue and bone tumors as well as rhabdomyosarcomas and Ewing's tumors in the pediatric population [33–37].

Tumor grade describes the probability of a tumor to exhibit malignant biological behavior. This implies patient outcome and survival. Following early studies in mixed sarcoma populations, additional studies have correlated patient prognosis with [^{18}F]FDG PET tumor uptake measures prior to therapy. These have established [^{18}F]FDG PET imaging in sarcomas as an independent biomarker for tumor risk stratification [30, 38–44]. Additional refinements in imaging techniques such as tumor uptake measures by dual-time point imaging, reporting tumor SUV_{max} versus total lesion glycolysis, necrosis volume, and combination with MR

imaging characteristics may provide improvements in prognostic capabilities [45–51].

Several prospective and retrospective studies have described histologic type determined from the utility of [^{18}F]FDG PET in sarcoma diagnosis. In soft tissue sarcoma, this imaging can reliably distinguish low-grade from high-grade tumors [52–54]. There is less ability to discriminate benign from low-grade tumors or intermediate-grade types from either high-grade or low-grade processes. Low-grade tumors are often difficult to distinguish through histologic criteria as well. Combinale et al. found that [^{18}F]FDG PET could be used to identify malignant transformation in patients with neurofibromatosis type 1 (NF1) [55]. This finding implies that [^{18}F]FDG PET could be used for other benign mesenchymal tumor conditions such as enchondromatoses and Paget's disease where malignant transformation is a potential occurrence in existing masses. [^{18}F]FDG PET has been used for effective tumor staging. It can be used to identify bone and soft tissue metastases and nodal metastases in those types where they occur (epithelioid and synovial sarcomas). While lung metastases are the most common site of metastases in patients with high-grade tumors, these are often small and are not visualized on [^{18}F]FDG PET. For this reason, a complete staging examination for both soft tissue and bony sarcomas also consists of a high-resolution contrast chest CT scan.

Additionally, special features and [^{18}F]FDG uptake are related to specific histologic types. For example, the atypical lipomas and the low-grade liposarcomas may have very similar tissue features and biological behavior. They often result in repeated local recurrence; nevertheless, in a large mass, the [^{18}F]FDG appearance can be significant for identifying small areas of high-grade de-differentiation, which can lead to a much worse outcome than the low-grade majority of the tumor mass composition. Figure 4 shows several [^{18}F]FDG PET examples of primary sarcoma tumors.

The [^{18}F]FDG image can also be helpful in identifying areas for diagnostic biopsy. Soft tissue sarcomas can be highly heterogeneous in their histologic characteristics, a feature which often confers heterogeneity in [^{18}F]FDG spatial uptake distribution. These unique tumor features may account for high levels of treatment resistance and variable responses to multimodality therapy. Spatial heterogeneity in sarcoma uptake has been shown to be independently predictive of patient outcome. This finding reported by Eary et al. found that baseline [^{18}F]FDG in diagnostic scans and tumor grade were somewhat weaker in outcome prediction, suggesting that new methods for incorporating [^{18}F]FDG tumor uptake distribution and for incorporating SUV into diagnostic methods for sarcomas can provide significant tumor prognostic information [56]. Additional image analyses such as texture feature extraction may also provide important diagnostic and prognostic information [57]. Figure 5 shows several tumors with high levels of [^{18}F]FDG uptake heterogeneity.

Sarcoma Treatment

Soft tissue sarcoma treatment plans are determined primarily by tumor grade. Large intermediate-grade and high-grade soft tissue sarcomas often receive neoadjuvant doxorubicin-based chemotherapy with or without preoperative radiation. After resection, if a response was obtained based on percent tumor necrosis in the resected tumor, adjuvant therapy is started. If an adequate response was not obtained, an alternative regimen usually replaces the ineffective treatment. Bone tumors are also treated through clinical protocols that have varying durations for neoadjuvant treatment, depending on patient age. Pediatric patients receive the most intense therapy, which yields good long-term outcome rates. Ewing's sarcoma patients also participate in protocol studies, and therapy with bone marrow transplant is considered in some advanced cases.

[^{18}F]FDG in Sarcoma Restaging and Treatment Response

A review of cancer treatment response for sarcoma as with other cancers begins with consideration of the pathological basis of the tumor process. Sarcomas are complex pathobiologic processes that may exhibit a wide range of blood flow, cell proliferation rate, cell viability, inflammation, pH, oxygenation, and numerous other processes. Because of these

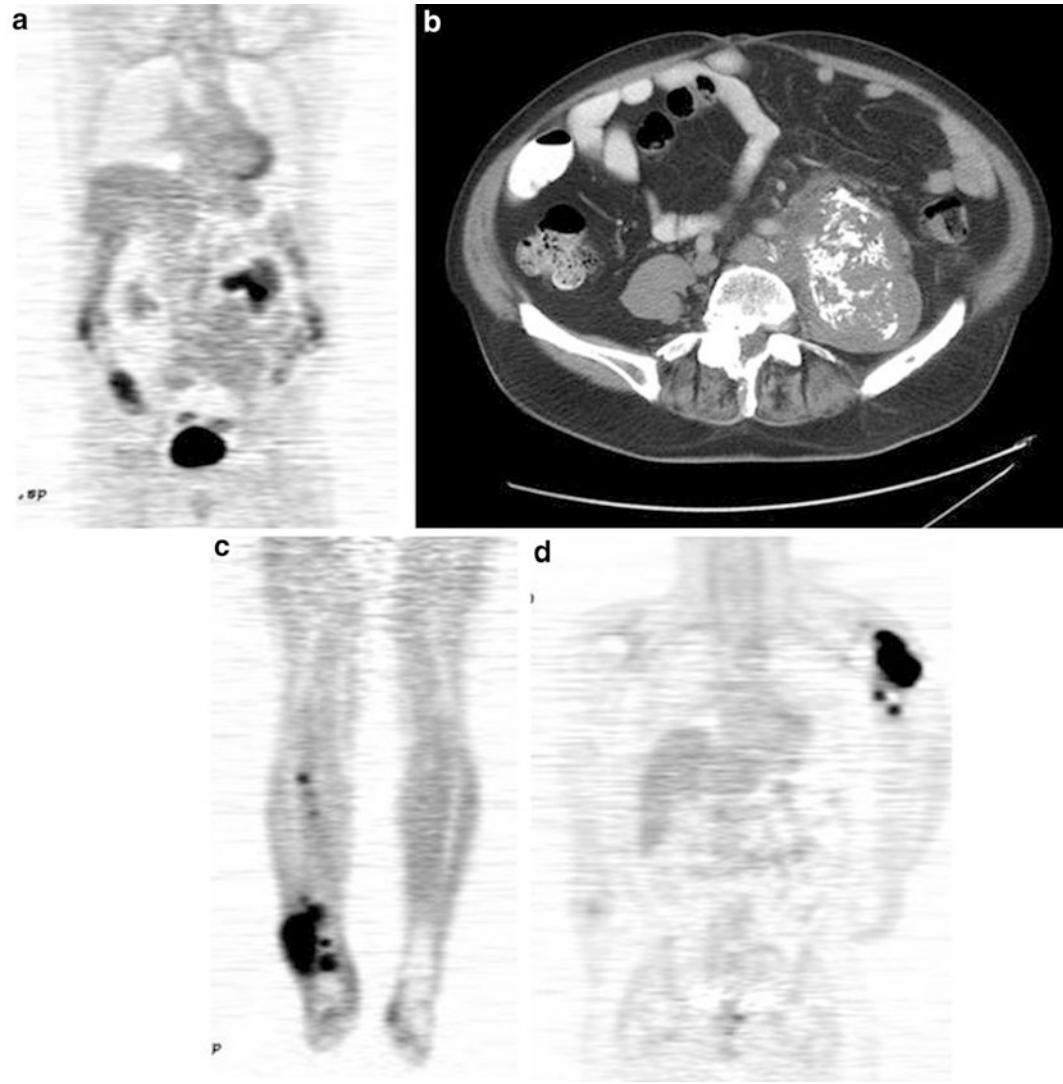

Fig. 4 Primary sarcoma presentations. (**a** and **b**) [^{18}F]FDG PET and contrast CT of a patient with an unusual calcifying abdominal liposarcoma. (**c**) [^{18}F]FDG PET right ankle Ewing's sarcoma, [**d**] [^{18}F]FDG PET left proximal humerus high grade undifferentiated soft tissue sarcoma with nodular extensions

processes, treatment response can differ significantly from a standard treatment combination or from treatments with different mechanisms of action. The ability of [^{18}F]FDG PET to identify treatment response is an important goal for the sarcoma patient population.

These tumors often do not change size in response to neoadjuvant chemotherapy because they can be composed of tissue elements that do not change in tumor response or undergo very slow changes in size reduction, such as in bone, cartilage, scar, and myxoid areas. Consequently, the RECIST criteria for treatment response do not apply well to this group, and [^{18}F]FDG has an advantage, as described by Evelevitch [58]. In this work, a 60% decrease in tumor [^{18}F]FDG uptake compared to baseline had a sensitivity of 100% and a specificity of 71% for histologic response, whereas RECIST criteria for response applied to the same group showed a sensitivity of 25% and a specificity of 100% [59, 60]. In sarcoma clinical practice, tumor treatment response assessments must provide information on the nature and timing of response.

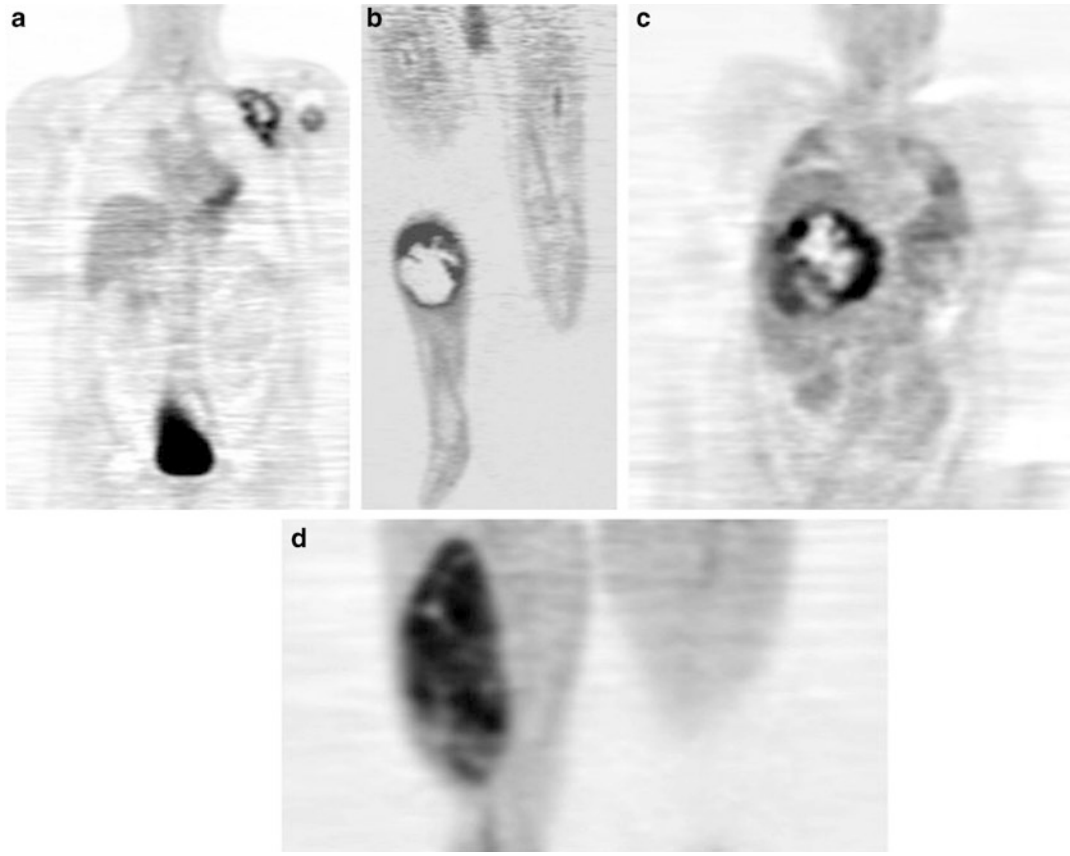

Fig. 5 (**a-d**) Primary sarcomas with high levels of spatial heterogeneity in [^{18}F]FDG uptake

Since clinical and histopathological response evaluations can be subjective, imaging tumor response quantitatively can provide clinically relevant objective information for treatment planning. For sarcoma patients where treatment choices are limited and often highly toxic, newer therapies that are directed at specific molecular targets may be cytostatic and result in tumor growth arrest, which can be observed effectively with [^{18}F]FDG PET. These changes may indicate effective therapy for a patient, as opposed to direct cell killing mechanisms and tumor shrinkage, and they may indicate improved patient outcome [61].

Tumor cellular necrosis fraction is considered the hallmark of treatment response to chemotherapy in sarcomas; however, overinterpretation of tumor cellular necrosis in a tumor specimen may result in cases where necrosis was present as a distinguishing feature of the primary tumor. Figure 6 shows an example of a primary sarcoma where significant necrosis is present prior to therapy. Scarring is a common treatment response and is also common in radiation treatment. Compared to necrosis, scarring as a treatment response is metabolically active and can cause significant [^{18}F]FDG uptake. In cases where granulation tissue formation precedes scarring, the inflammatory cells present may also elevate the apparent tumor bed tissue metabolism. Activated white cells can show as much as a tenfold difference in [^{18}F]FDG uptake, complicating image interpretation. An important part of treatment response interpretation in sarcoma is identifying the treatment agent mechanism, tumor subtype, and timing of the scan observation in relation to the course and type of treatment. Early after therapy, observations may reveal very different findings from those obtained after the biological mechanisms involved in

Fig. 6 Primary pelvic sarcoma with a large central area of tumor necrosis at presentation

treatment response have reached a more static state. Radiation responses to tumor and surrounding tissues may have very different timescales in relation to the end of the final therapy response. Early detection of treatment response that indicates improved patient outcome with newer therapies is an area of active research.

Many groups advocate the use of the [^{18}F]FDG PET tumor SUV to measure sarcoma uptake and to monitor treatment response [58, 61]. If the [^{18}F]FDG PET study is performed in a standard and consistent manner, the SUV is a robust value for comparison of one imaging study to another in the same patient at a later time and between patients in different groups. The optimum parameters for [^{18}F]FDG imaging in cancer were described in a report of a National Cancer Institute consensus committee where standard techniques for the use of [^{18}F]FDG as a biomarker for cancer treatment are presented [62]. The use of [^{18}F]FDG PET as a biomarker or surrogate endpoint for patient outcome is the basis for clinical research studies that determine the sensitivity and specificity of the method for following response to treatment and for assessing normal tissue damage as a result of treatment. Few effective treatment strategies exist for sarcoma, yet there is a great potential for new therapy strategies. [^{18}F]FDG PET can be a powerful tool for noninvasive treatment effectiveness evaluation [63–66].

The most dramatic example of [^{18}F]FDG PET as a biomarker for treatment response assessment is in gastrointestinal stromal tumors (GISTs) treated with Gleevec. GISTs are [^{18}F]FDG avid and can yield impressive PET images. Goerres et al. found that median survival of patients who demonstrated an [^{18}F]FDG PET response was 100% at 2 years compared to a group with residual tumor uptake after treatment. The study also demonstrated ability to separate patients by time to tumor progression based on [^{18}F]FDG tumor uptake levels [67].

Early response to Gleevec in the GIST population detected by [^{18}F]FDG PET has also been shown. As much as a 65% decrease in tumor [^{18}F]FDG uptake was demonstrated at the end of 1 week of effective therapy, and as high as a 95% response detected by 1 month after treatment initiation has been found by other groups. Response detection using CT criteria was less accurate, including no significant CT responses noted in [^{18}F]FDG-responsive patients [68–73]. [^{18}F]FDG PET imaging for GIST patients at baseline to observe for maximum tumor activity levels and for accurate staging is recommended. Repeat imaging is suggested in the first month after therapy initiation to observe response and to predict treatment effect. Another image may be helpful if treatment resistance is suspected and if a new baseline tumor uptake and location for treatment observation need to be established. [^{18}F]FDG imaging for GIST treatment response evaluation has been incorporated into the guidelines for GIST management determined by an international consensus conference [74].

Treatment response in other sarcomas using [^{18}F]FDG PET has been demonstrated in a number of studies. Soft tissue sarcomas represent the majority of sarcomas that occur in adults. Treatment response imaging for this group of patients is emerging [75–79]. In an extremity soft tissue sarcoma group treated with adriamycin-based neoadjuvant chemotherapy, Scheutze et al. showed that

separating patients by their [^{18}F]FDG response (>40%) showed a significant difference in survival for each of the groups [80]. Patients in the [^{18}F]FDG PET nonresponse group had a 90% risk of disease recurrence at 4 years compared to [^{18}F]FDG responders. These data, and that of others, may indicate the effectiveness and survival increase in soft tissue sarcoma patients treated with neoadjuvant chemotherapy prior to tumor resection. Figure 7 shows an example of a patient who had a treatment response documented by [^{18}F]FDG PET for neurofibrosarcoma in the base of the neck. This imaging technique may be useful for patients who have tumor resistance during the course of therapy and, therefore, might benefit from treatment intensification or early resection.

A similar finding was shown in Ewing's sarcoma population reported by Hawkins et al. [81]. Patients whose tumors increased SUV ratios between the baseline and pre-resection (after neoadjuvant chemotherapy) scans had significantly improved survival. In the future, good responders may be identified for less toxic treatment protocols. Studies in imaging osteosarcoma for treatment response have also been conducted. Early studies by Schulte et al. showed that changes in tumor [^{18}F]FDG uptake correlated with tumor necrosis levels in patients treated with neoadjuvant chemotherapy. Implications for limb salvage surgery were described because such complex tumor resection procedures might not be considered in nonresponders [82]. Others have recently shown similar results for [^{18}F]FDG imaging in osteosarcoma [83, 84].

Pediatric sarcomas are usually bony tumors, but they have been separated in studies because the treatment for pediatric patients differs compared to protocols for adults. Similar to their findings in Ewing's sarcomas in this mixed group of osteosarcoma and Ewing's sarcoma patients, Hawkins et al. found that the ratios in [^{18}F]FDG uptakes correlated with histologic response [85]. Noting a need for prospective imaging studies to be conducted in the pediatric sarcoma populations, both Franzius et al. and McCarville et al. published data on small pediatric sarcoma subgroups to demonstrate the clinical utility of [^{18}F]FDG imaging [86, 87]. The latter group included a rhabdomyosarcoma subgroup, a tumor subtype where most patients are treated under cooperative group therapy protocols. Correlation of longer survival with [^{18}F]FDG changes in response to therapy in a large pooled patient group retrospective study in patients with rhabdomyosarcomas has been published showing similar results.

[^{18}F]FDG imaging in treatment response can make a significant contribution to sarcoma patient care in identifying clinically relevant responses, or a lack thereof, and in providing predictive information for patient outcome. Although sarcomas are a less

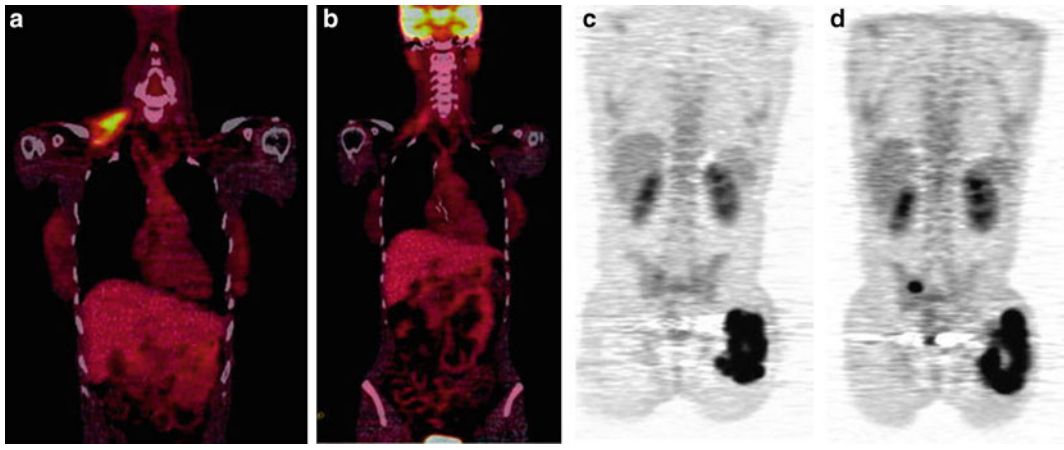

Fig. 7 Two examples of sarcoma tumor treatment [^{18}F]FDG PET responses. Shown in (**a**) is a patient with a right neck base malignant nerve sheath prior to neoadjuvant chemotherapy. (**b**) Response in base of neck tumor. (**c**) [^{18}F]FDG PET image of a patient with a large high grade proximal thigh tumor. (**d**) Lack of response, with sacral metastasis development

frequent form of malignancy in the population, they affect the entire human age span, and they constitute a large number of affected individuals in aggregate. Currently, treatment for the more aggressive high-grade tumors and for locally recurrent low-grade tumors often results in less than optimum treatment outcomes. Future clinical trials for newer treatment combinations for sarcoma patients will benefit from the incorporation of [^{18}F]FDG PET imaging treatment response information as a part of their treatment strategies, as they have for patients with other cancer types. For the individual patient, [^{18}F]FDG PET can provide critical information about treatment response and indicate further treatment planning. Increasingly for patients with standard therapy refractory disease, [^{18}F]FDG PET has been effective in identifying response to newer combination treatments and experimental therapy clinical trials. Recent experience described by Andreou et al. demonstrated that [^{18}F]FDG PET SUV_{max} in soft tissue sarcoma response to combination neoadjuvant isolated limb perfusion and TNF was correlated with response [88]. Similar imaging results have been reported in trials with sunitinib in extraskeletal myxoid chondrosarcoma [89], desmoid tumors with imatinib [90], insulin-like growth factor 1 in Ewing's sarcoma [91], and regional hyperthermia for soft tissue sarcomas [92]. Often these imaging observed responses predicted overall survival [93, 94].

Although currently there are no specific recommendations for [^{18}F]FDG PET in sarcoma patient care, the findings from the previously summarized reports indicate that baseline [^{18}F]FDG PET is important for contributing information for disease grade and staging that complements other imaging and histologic diagnostic information. This information aids in treatment planning and sets the baseline quantitation for tumor metabolic activity for treatment response assessment. Treatment response assessment with [^{18}F]FDG PET recommendations would be similar to those in other solid tumors. Approximately every 3 months on treatment, or when a change in treatment is envisioned, [^{18}F]FDG PET imaging results can be especially helpful when complete response or treatment nonresponse is suspected, as it provides objective information on tumor viability. Table 6 describes suggestions for sarcoma evaluation and treatment response imaging.

Table 6 Suggested lines of imaging procedures for sarcomas in patient care

Staging	***Soft tissue sarcomas***	***Bone sarcomas***
	MR of tumor region	MR and plain x-ray of tumor area
	[^{18}F]FDG PET	[^{18}F]FDG PET and ^{18}F-fluoride PET
	Whole body	Whole body
	^{99m}Tc-MDP bone scan	^{99m}Tc-MDP bone scan
	Whole body	Whole body
	Lung CT with contrast	Lung CT with contrast
Treatment response		
	MR of tumor region	MR of tumor region
	[^{18}F]FDG PET	[^{18}F]FDG PET and ^{18}F-fluoride PET
	Whole body	Whole body
	^{99m}Tc-MDP bone scan	^{99m}Tc-MDP bone scan
	Whole body if positive at baseline	If lungs positive at baseline
	Lung CT with contrast	Lung CT with contrast

PET/MR imaging experience in sarcomas is emerging. Current reports indicate that potential utility in sarcoma surgical resection planning may be improved with the better tumor edge detection provided by this imaging combination [95].

Other PET radiopharmaceuticals that are more specific than [^{18}F]FDG for biologically relevant aspects of sarcomas are under investigation in the sarcoma population. Determination of levels of tumor hypoxia is a measurement with clinical significance for many tumors, including sarcoma [96, 97]. Hypoxia is known to confer resistance to both radiotherapy and chemotherapy in sarcomas. Most sarcomas have some level of hypoxia present that confers treatment resistance. Newer therapies that target hypoxic tumor tissues after identification of these regions may improve patient outcome. PET radiopharmaceuticals designed to quantify tumor proliferation will also play an important role in sarcoma patient diagnosis and treatment assessment [98, 99]. Since sarcomas are a highly variable group of tumors, with similarly variable clinical outcomes, their cellular proliferation levels likely indicate increased risk of metastasis and poor clinical

outcome. Sarcoma patients are likely to benefit from these more biologically specific imaging techniques that may provide insight regarding treatment effectiveness. Molecular imaging research efforts in PET are directed toward identifying tumor characteristics that can be used to define patient risk for aggressive disease behavior and for noninvasive treatment monitoring.

Diagnostic Applications of Nuclear Medicine: Malignant Melanoma

38

Andrew M. Scott, Marika Ciprotti, and Sze-Ting Lee

Abstract

Malignant melanoma was diagnosed in approximately 74,000 patients in 2015 in the USA. Melanoma accounts for about 3% of all skin cancers. Major parameters that impact prognosis include Breslow thickness, ulceration, tumor location, growth pattern, histological subtype, patient's age, gender, and tumor status of regional lymph nodes. Melanomas are staged using the American Joint Committee on Cancer (AJCC) TNM system, which has incorporated the histological status of SLN into its latest staging system version of cutaneous malignant melanoma.

In early stage melanoma (AJCC I–II), sentinel lymph node biopsy (SLNB) is the standard of care for nodal staging. Lymphoscintigraphy with SPECT/CT improves the detection of SLN. In AJCC stage I–II melanoma, [^{18}F]FDG PET/CT has poor sensitivity for the detection of nodal metastases but it is sensitive for the detection of distant metastases. In patients with AJCC stage III (regional nodal involvement) or stage IV disease (systemic metastases), [^{18}F]FDG PET/CT is useful to identify metastatic disease. PET imaging in melanoma patients should include the arms and legs, especially in patients whose primary lesions arise on extremities. False-negative results can occur with small skin and brain metastases, and lesions adjacent to the heart, kidneys, or urinary bladder.

Although [^{18}F]FDG PET/CT is more specific in the diagnosis of melanoma pulmonary metastases, chest CT is more sensitive. Most PET false negatives in recurrent disease are typically less than 1 cm in diameter and are mainly pulmonary and hepatic in location, or in the brain. [^{18}F]FDG PET/CT is useful in treatment monitoring of metastatic melanoma and in posttherapy surveillance.

bFGF	Basic fibroblast growth factor
BRAF	RAF serine-/threonine-specific protein kinase
Breslow thickness	A prognostic factor in cutaneous melanoma, based on description of how deeply tumor cells have invaded the skin (also called "Breslow depth")
c-KIT	A proto-oncogene encoding for tyrosine-protein kinase Kit (or CD117), also known as mast/stem cell growth factor receptor (SCFR)
CDK4	Cyclin-dependent kinase 4
CDKN2A	Cyclin-dependent kinase inhibitor 2A
ceCT	Contrast-enhanced computed tomography
CI	Confidence interval
Clark level	A staging system for cutaneous melanoma based on description of the level of anatomic invasion of the melanoma in the skin (generally used in conjunction with Breslow's depth)
COT	A mitogen-activated protein serine/threonine kinase involved in T-cell activation
CR	Complete response
CT	X-ray computed tomography
ERK	Extracellular signal-regulated kinase
FDA	United States Food and Drug Administration
GLUT	Glucose transporter family
HR	Hazard ratio, a statistical parameter used in survival analysis
IDO	Indoleamine 2,3-dioxygenase
IFN	Interferon
IGFR1	Insulin-like growth factor 1
LAG-3	Lymphocyte-activation gene 3
LDH	Lactate dehydrogenase
LS	Lymphoscintigraphy
M	Metastasis status according to the AJCC/UICC TNM staging system
MAGE	Melanoma-associated antigen gene
MAPK	Mitogen-activated protein kinase
MHC	Major histocompatibility complex
MRI	Magnetic resonance imaging
N	Lymph node status according to the AJCC/UICC TNM staging system
NCCN	National Comprehensive Cancer Network
NRAS	Oncogene encoding for a membrane protein that shuttles between the Golgi apparatus and the plasma membrane
ORR	Overall response rate
OS	Overall survival
PD-L1	Programmed death ligand
PDGF	Platelet-derived growth factor
PET	Positron emission tomography
PET/CT	Positron emission tomography/computed tomography
PFS	Progression-free survival
PFS	Progression-free survival
PI3K	Phosphatidylinositol 3-kinase
PlGF	Placental growth factor
PTEN	Gene encoding for the phosphatase and tensin homolog protein, a tumor suppressor (PTEN deletions indicate a poor prognosis)
RAF	Rapidly accelerated fibrosarcoma, related to retroviral oncogenes
RECIST	Response evaluation criteria in solid tumors
S-100	A low-molecular-weight calcium-binding protein expressed in melanomas, but also in other benign and malignant conditions
SLN	Sentinel lymph node
SLNB	Sentinel lymph node biopsy
SLNE	Sentinel lymph node excision
SPECT	Single photon emission computed tomography

SPECT/CT	Single photon emission computed tomography/computed tomography
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
T	Tumor status according to the AJCC/UICC TNM staging system
TGF	Transforming growth factor
TIM-3	T-cell immunoglobulin and mucin-domain containing-3
UICC	Union Internationale Contre le Cancer (International Union Against Cancer)
UV	Ultraviolet
VEGF	Vascular endothelial growth factor
WHO	World Health Organization

Epidemiology

Malignant melanoma is an increasingly common public health problem in many countries. It most often arises from the melanocytes found in the basal layer of the skin, although it can also derive from noncutaneous melanocytes such as those lining the choroidal layer of the eye, gastrointestinal and genitourinary mucosal surfaces, or the meninges. It accounts for about 3% of all skin cancers, with an annual increase in the order of 3–7% per year for fair-skinned Caucasian populations [1].

According to the World Health Organization (WHO), the number of melanoma cases worldwide is increasing faster than that of any other type of cancer. The highest incidence of melanoma occurs in Australia and New Zealand where the annual incidence rates are more than two to three times higher than those found in Canada, the USA, and the UK [2]. In Australia, it is the fourth most common cancer. Recently reported statistical data suggest that the risk of an individual being diagnosed with melanoma skin cancer by their 85th birthday is 1 in 18 (1 in 14 males and 1 in 23 females) [3]. In Europe, approximately 100,300 people were estimated to be diagnosed with melanoma in 2012. In the same year, 22,200 Europeans were estimated to have died from the disease [4]. In 2015, an estimated 73,870 patients were diagnosed with melanoma in the USA, and approximately 9,940 of them died of the disease [5]. Data from the USA and Europe show that the lifetime risk of developing malignant melanoma has increased from 1 in 800 individuals in 1960 to 1 in 74 individuals in 2000.

Risk Factors

The factors associated with an increased risk of developing melanoma remain incompletely understood, but people with a family history of melanoma, multiple benign or atypical nevi, and a previous melanoma are at the greatest risk for cutaneous melanoma. Inherited mutations in the cyclin-dependent kinase inhibitor 2A (CDKN2A) and cyclin-dependent kinase 4 (CDK4) genes,

which have been documented in some families with hereditary melanoma, confer a 60–90% lifetime risk of melanoma. Overall, CDKN2A mutations have been observed in approximately 25–40% of the members of melanoma-prone families. In addition, around one-half of families with three or more cases of melanoma show evidence of linkage to the 9p21 region [6]. According to the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute (SEER), the rate of subsequent cutaneous melanomas among persons with a history of melanoma was more than ten times the rate of a first cutaneous melanoma among the general population [7].

Immunosuppression, sun sensitivity, and exposure to ultraviolet radiation are also associated with an increased risk of cutaneous melanoma. Sensitivity to ultraviolet light is associated with variations in particular genes (polymorphisms) that affect both the defensive response of the skin to ultraviolet light and the risk of melanoma. A defensive measure to ultraviolet lights includes the tanning response, and variations in pigmentation and tanning response are associated with variations in susceptibility to melanoma [8]. Unlike the more common skin cancers, which are associated with total cumulative exposure to ultraviolet radiation, melanomas are associated with intense intermittent exposure, specifically with exposures that induce sunburn during adolescence [9]. Differences in the amount of exposure to ultraviolet (UV) radiation by geographic latitude may also contribute to the wide geographic variation in melanoma incidence rates. Educational efforts to promote recognition of early lesions (including ABCD criteria for asymmetry, border irregularity, unevenness of distribution of color, and a diameter that is greater than 6 mm or increasing in size) and avoidance of sun exposure have not prevented these increases in incidence and mortality.

Pathogenesis

Understanding of the pathogenesis of melanoma is crucial to develop new markers for diagnosis and prognosis and identify new targets for rational therapy.

Ras/Raf/MEK/Erk Pathway

One of the most studied molecular pathways in melanoma is the intracellular Ras-regulated Raf/MEK/ERK and MAPK signal cascade. Melanocytes require this cascade to maintain a balance between proliferation and differentiation. There is a strong link between dysregulation of this pathway and uncontrolled cell proliferation and survival. Dysregulation of the MAPK signaling pathway through constitutive activation is a frequent event in multiple human cancers [10]. Mutations of the PTEN tumor suppressor have also been reported in up to 25% of melanomas, and alterations of the PI3K pathway, in conjunction with dysregulation of the MAPK pathway, play an essential role in melanoma development and progression.

BRAF is a RAF serine-/threonine-specific protein kinase and has been identified as a common oncogene in many cancers, particularly melanoma where it regulates many cellular responses, such as proliferation, survival, and invasion/metastasis. BRAF mutations occur in about 60% of melanomas occurring on skin without signs of chronic sun-induced damage, but infrequent in melanomas that occur on skin showing evidence of chronic sun-induced damage as well as on sun-protected skin such as the palms, soles, or subungual sites, and on mucosal membranes. Recent studies have shown that over 90% of BRAF mutations occur in codon 600, usually resulting in a valine to glutamate substitution (designated V600E) [11].

Immune Regulation

The immune system plays a vital role in regulating the growth of tumors and immune-regulation of T-cells is an essential link in understanding the pathophysiology of melanoma. When naïve T cells are presented tumor antigens complexed with MHC molecules by antigen-presenting cells (APCs), they mature into effector cells. However, a second costimulatory signal is required to induce activation. This signal is provided by the interaction of B7 molecule on the surface of APCs with the T-cell CD28 receptor. However the immune-checkpoint protein cytotoxic T lymphocyte antigen 4 (CTLA-

4), which is upregulated on CD-8$^+$ T cells after activation, can bind to B7 molecule and replace the activation signal with an inhibitory signal.

Once activated (priming phase), the CD-8$^+$ T cell matures and travels from peripheral lymphoid organs to peripheral tissues to carry out its cytotoxic effector function against tumor cells (effector phase). During this phase, binding the MHC-antigen complex is sufficient to induce effector functions, without the need of a costimulatory signal. An inhibitory pathway consisting of the expression of the programmed death 1 (PD-1) receptor on the T-cell surface may lead to the inactivation of the T-cell after binding to the programmed death ligand 1 (PD-L1) on tumor tissue. Tumor cells can upregulate PD-L1 on their surface to evade immune-mediated destruction [12]. The traditional approach to immunotherapy has focused on increasing the frequency of tumor-specific T cells (i.e., vaccines, interleukin-2), improving the presentation of tumor antigens to the immune system, or trigger innate immune activation and inflammation in the tumor microenvironment (i.e., interferons) [12]. More recently, a better understanding of immune regulatory mechanisms has led to the development of agents that can modulate immune checkpoints (i.e., CTLA-4, PD-1, PD-L1) and effectively overcome tumor-induced immunesuppressive mechanisms.

Angiogenesis

Angiogenesis is a fundamental physiological process by which new vascular networks are formed from pre-existing capillaries. Many tumors overexpress multiple angiogenic factors such as vascular endothelial growth factor (VEGF), which is strongly associated with new vasculature formation in melanoma, and its overexpression is correlated with a poor prognosis [13, 14]. Although VEGF is only expressed in 32% of primary melanomas, its expression level in metastases [15, 16] is increased. Several other angiogenic factors have been implicated in the pathology of human melanomas, such as IL-8, placental growth factor (PlGF), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF)-AA, and PDGF-BB [17, 18]. Innovative antiangiogenic strategies in oncology drug development are currently being explored with monoclonal antibodies and small-molecule kinase inhibitors.

Tumor Histology

Melanoma often arises from precursor pigmented lesions, which demonstrate changes in shape, color, and irregular borders, or develop ulceration. The most common form is superficial spreading melanoma (up to 70% of cases), where lesions may be flat or elevated, demonstrate change in color or border, and is most commonly seen in the legs and trunk. Nodular melanoma (10–20% of cases) typically grows rapidly, is elevated, and also occurs mainly on the legs and trunk. Lentigo maligna melanoma usually occurs on sun-exposed areas such as the face, more typically seen in darker-skinned patients, and is seen in 5–15% of cases. Acral melanoma most commonly occurs on the sole of the feet, or palm and nail beds, and is seen in 2–8% of patients. Superficial spreading melanoma, lentigo maligna melanoma, and acral melanoma are also characterized by an early in situ phase of radial growth, prior to deeper extension, which is associated with a worse prognosis. Microscopic examination of melanomas demonstrates sheets of malignant cells which may be associated with pigment cells and various infiltrative cells including lymphocytes. The extent and depth of malignant cell infiltration, ulceration, mitotic rate, and morphologic appearance all influence diagnosis, treatment, and prognosis; hence, full excision and careful pathologic examination are critical in the initial diagnosis and management of melanoma patients.

Staging Systems for Melanoma

Breslow Staging, AJCC Classification

The histologic pattern and depth of infiltration of the primary melanoma, together with the site and extent of metastatic disease, have a significant impact on treatment selection and prognosis [19,

20]. Clinical and histologic variables that have been shown to impact on prognosis include Breslow thickness (the total vertical height of the lesion: <1 mm, 5-year survival >95%; 1–2 mm, 5-year survival 80–95%; 2.1–4 mm, 5-year survival 60–75%; >4 mm, 5-year survival 37–50%), Clark Level (depth of penetration: Level I, confined to the epidermis; Level II, invasion of the upper dermis; Level III, invasion of the papillary dermis but to the junction of the reticular dermis; Level IV, invasion of the reticular dermis; Level V, invasion of deep subcutaneous tissue), ulceration, tumor location, growth pattern, histological subtype, patient age, gender, and tumor status of regional lymph nodes [21]. Clinical studies exploring risk factors and their impact on prognosis have clearly shown that the metastatic involvement of lymph node(s) draining the primary tumor, also called sentinel lymph node(s) (SLN), is the most powerful prognostic factor in early stage melanoma patients [22, 23]. The American Joint Committee on Cancer (AJCC) has recently incorporated the histological status of SLN into its latest staging system version of cutaneous malignant melanoma (Tables 1 and 2).

Melanoma may metastasize through local extension, via lymphatics prior to first draining lymph node (in-transit metastases) to regional lymph nodes, or systemic metastases to distant sites. AJCC stage I–II melanomas usually develop regional nodal metastases as the initial first site of metastatic disease; of those patients who develop nodal metastases, the majority will also present with satellite/in-transit disease or distant metastases [24]. Apart from lymph nodes, the most common sites for metastatic disease are skin, lung, liver, and brain, although almost any site in the body may be affected [24–26]. The patterns of spread of disease are dependent on tumor site and thickness, with approximately one-third of melanomas from the lower extremities metastasize locally to satellite/in-transit metastases, whereas nearly one-third of melanomas from the trunk and upper extremities disseminated directly to distant sites [24]. In contrast, head and neck primary melanomas develop local, regional, and distant metastases in nearly the same proportions (about one-third). Distant metastases were most often observed in men (mainly trunk melanomas), while locoregional metastases were rather detected in women, who have an increased incidence of lower limb melanomas.

Treatment for Localized Melanoma

Surgical excision is the primary treatment for melanoma. Several randomized, controlled trials have determined appropriate resection margins according to the thickness of the primary melanoma. For melanoma in situ, margins of 0.5–1 cm around the visible lesion or biopsy scar are recommended. Resection margins of 1–2 cm are recommended for 1–4 mm thickness primary lesions, and 2–3-cm margins if the primary lesion is >4.0 mm thick.

Regional lymph node spread of melanoma, or intransit disease, may occur at the time of initial presentation, or usually within 3 years of initial diagnosis. Lymph node resection is usually performed for regional nodal disease. Local radiation treatment may also be performed for regional lymph node metastases, depending on the extent of disease and success of initial surgery, and is also commonly used for in-transit disease.

Prognostic Factors

Patients with melanoma can be stratified into various risk groups: those with stage IA disease who carry a very low risk of recurrence and a 5-year survival of approximately 95%; those with stage IB and IIA disease, who have an intermediate risk and a 5-year survival from 65% to 90%; those with IIB, IIC, and IIIA disease who have a higher risk; and those with stage IIIB and IIIC disease who carry a very high risk of recurrence and a 5-year survival from 45% to 70%.

Over the past 10 years, there has been a debate focused on the optimal diagnostic, prognostic, and therapeutic strategies for cutaneous melanoma. It is important to identify and evaluate prognostic factors that can accurately categorize patients into different risk groups for distant metastatic disease. Currently, the most useful prognostic factors in clinical practice

Table 1 AJCC definitions of TNM for malignant melanoma

Primary tumor (T)	
TX	Primary tumor cannot be assessed (e.g., curettaged or severely regressed melanoma)
T0	No evidence of primary tumor
Tis	Melanoma in situ
Tl	Melanomas 1.0 mm or less in thickness
T2	Melanomas 1.01–2.0 mm
T3	Melanomas 2.01–4.0 mm
T4	Melanomas more than 4.0 mm

Note: a and b subcategories of T are assigned based on ulceration and number of mitoses per mm^2 as shown below

T classification	Thickness (mm)	Ulceration status/mitoses
Tl	<1.0	(a) w/o ulceration and mitosis <l/mm^2
		(b) with ulceration or mitoses >l/mm^2
T2	1.01–2.0	(a) w/o ulceration
		(b) with ulceration
T3	2.01–4.0	(a) w/o ulceration
		(b) with ulceration
T4	>4.0	(a) w/o ulceration
		(b) with ulceration

Regional lymph nodes (N)	
NX	Patients in whom the regional nodes cannot be assessed (e.g., previously removed for another reason)
NO	No regional metastases detected
Nl-3	Regional metastases based upon the number of metastatic nodes and presence or absence of intralymphatic metastases (intransit or satellite metastases)

Note: N1–3 and a–c subcategories assigned as shown below

N classification	No. of metastatic nodes	Nodal metastatic mass
Nl	1 node	(a) Micrometastasis[a]
		(b) Macrometastasis[b]
N2	2–3 nodes	(a) Micrometastasis[a]
		(b) Macrometastasis[b]
		(c) Intransit met(s)
		Satellite(s) without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or intransit met(s)/satellite(s) *with* metastatic node(s)	

[a]Micrometastases are diagnosed after sentinel lymph node biopsy and completion lymphadenectomy (if performed)

[b]Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension

Distant metastasis (M)	
M0	No detectable evidence of distant metastases
M1a	Metastases to skin, subcutaneous or distant lymph nodes
Mlb	Metastases to lung
Mlc	Metastases to all other visceral sites or distant metastases to any site combined with an elevated serum LDH

Note: Serum LDH is incorporated into the M category as shown below

[a]Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases

[b]Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes

for localized melanoma are Breslow thickness, presence of lymph node involvement, and ulceration.

Sentinel lymph node biopsy (SLNB) is important for planning therapy, although it has failed to show any benefit in overall survival (OS). There has been no consensus on which patient categories benefit from SLNB. The National Comprehensive Cancer Network recommends that SLNB should be considered for patients with high-risk stage IA melanoma and discussed and offered to patients with stage IB–IIC melanomas [27]. SLNB can identify patients who may benefit from more extensive staging investigations and, based on pathology results, may be suitable for adjuvant therapy [28].

Thickness and ulceration of melanoma are highly correlated with each other, and studies have shown that the incidence of melanoma ulceration rises with increasing tumor thickness, ranging from 6–12.5% for thin melanomas to 63–72.5% for thick (>4.0 mm) lesions. The presence of ulceration is associated with decreased survival in all tumor thickness categories. Thin (<1.0 mm) ulcerated tumors have approximately a 4% decreased 5-year survival rate compared to nonulcerated tumors. This survival decrement is as high as 22% in thick (>4.0 mm) tumors [21]. Furthermore, the tumor mitotic rate is an additional independent prognostic factor that has emerged as more powerful than ulceration in several studies [29–31]. A better understanding of prognostic factors together with accurate staging in cutaneous melanoma allows the identification

of patients whose risk of recurrence is sufficiently high to justify adjuvant systemic treatment.

Adjuvant Therapy

Attempts to reduce the incidence of recurrent melanomas with adjuvant therapy have been studied in more than 100 randomized controlled trials [32, 33]. However, adjuvant treatment has historically been challenging, with fewer options available. The role of chemotherapy remains unclear with no tangible benefit in terms of prolonged OS.

Until recently, interferon was the only FDA approved adjuvant option in over 20 years. High-dose interferon (IFN) was evaluated in three large United States cooperative group trials. The data from ECOG 1684, which led to FDA approval of IFN for the treatment of patients with resected stage IIB and stage III melanoma, showed a 5-year relapse-free survival improvement and suggested a statistically significant benefit in overall survival at a median follow-up of 6.9 years [34]. However, at 12.6 years of follow-up, the OS was not significantly different between the two groups, even though the relapse-free survival benefit was confirmed. A pooled analysis of three large randomized trials of high-dose IFN confirmed a consistent and significant effect on recurrence-free survival in patients with high-risk resected melanoma, but did not find a statistically significant improvement in OS [35]. High-dose IFN is approved in the USA and Canada, but it is not currently accepted worldwide due to its considerable toxic effects and to the fact that the benefit occurs in only a minority of the patients at risk. A large phase-III trial (EORTC18991) compared the treatment with pegylated interferon-a2b for up to 5 years with observation in Stage III patients. The results indicated a significant impact on relapse free survival without a significant improvement of distant metastasis-free survival or OS [36]. Based on this data, pegylated interferon alfa received approval by the FDA in March 2011 for the adjuvant treatment of stage III disease. Efforts to improve the efficacy and toxicity profiles of interferon have also included the use of lower-dose regimens, and combination with various drugs and vaccines [37–39].

Due to the only marginally effective adjuvant therapies with interferons and the recent successes of novel immunotherapeutic agents in metastatic melanoma, several clinical trials using these agents were initiated. In October 2015, Ipilimumab was approved by FDA for use in the adjuvant setting for patients with stage III melanoma. The approval was based on the results from the EORTC 18071 study, which randomly assigned 951 patients to ipilimumab or placebo [40]. Adjuvant ipilimumab significantly improved recurrence-free survival for patients with completely resected high-risk stage III melanoma.

Various phase III studies are currently testing the potential role of other immunotherapies (anti-PD1 antibodies MAGE 3 vaccine), as well as BRAF and MEK inhibitors (vemurafenib, dabrafenib, trametinib) in the adjuvant setting. Decisions regarding adjuvant therapy for neoplastic diseases represent a balancing of risk of disease recurrence against the relative value of the agent used in terms of its activity, toxicity, and cost.

Treatment of Metastatic Malignant Melanoma

Approximately 2–5% of new patients with melanoma present with metastatic disease, and 30% of patients initially diagnosed as localized or regional disease develop distant metastasis [41]. The prognosis for patients with advanced visceral metastatic melanoma in the pretargeted and pre-immunotherapy era was particularly poor with 3-year survival rate of only 6–12% [42]. At that time, the only standard first line treatment was dacarbazine despite its limited clinical benefit. The response rate observed with single-agent dacarbazine chemotherapy did not exceed 12% [43] and no other chemotherapeutic agents either alone or in combination have proved superior to single-agent dacarbazine chemotherapy [43]. With the recent development of targeted therapies and immunotherapies which have demonstrated better efficacy than conventional chemotherapy,

the therapeutic landscape for metastatic melanoma is rapidly changing.

Targeted Therapies Against BRAF Mutations

About half of patients with metastatic melanoma harbor an activating mutation in BRAF, the most common being BRAF V600E [44].

Vemurafenib is a selective BRAF inhibitor that targets the V600 mutant forms of the BRAF and was the first BRAF inhibitor to gain FDA approval in August 2011. A phase 2 trial (BRIM2) involving patients with previously treated BRAF V600E mutant stage IV melanoma showed a response rate of 53%, with a median duration of response of 6.7 months [44]. A subsequent phase 3 randomized trial (BRIM3) of previously untreated patients compared vemurafenib with dacarbazine. This study demonstrated an improvement in progression free survival (PFS) (6.9 months vs. 1.6 months), OS (13.6 months vs. 9.7 months), and overall response rate (57% vs. 8.6%) [45].

Following vemurafenib, two additional agents targeting BRAF-mutated disease have been approved by the FDA.

Dabrafenib has shown similar results to those with vemurafenib in phase I/II studies [46, 47]. A Phase III randomized trial compared dabrafenib with dacarbazine in previously untreated patients with BRAFV600E-mutated metastatic melanoma. Dabrafenib significantly improved PFS (5.1 months vs. 2.7 months, HR = 0.30, $P < 0.001$) and response rates (53% vs. 19%) compared with dacarbazine [48]. These results have led to FDA approval in May 2013.

Trametinib is an oral small-molecule inhibitor of MEK 1 and MEK 2, which are downstream of BRAF in the MAP kinase signal transduction pathway. In the open-label phase III trial (METRIC) that led to FDA approval in May 2013, 322 patients with BRAF V600E/K-mutant metastatic melanoma were randomized to receive either trametinib or chemotherapy with either dacarbazine or paclitaxel [49]. The median PFS was improved to 4.8 months in the trametinib group, as compared to 1.4 months in the chemotherapy group (HR = 0.45, 95% CI: 0.33–0.63; $P < 0.001$). The OS rate at 6 months was 81% in the trametinib group and 67% in the chemotherapy group (HR = 0.54, 95% CI: 0.32–0.92; $P = 0.01$), despite 65% of patients in the chemotherapy arm crossing over to the trametinib arm.

Numerous studies are being conducted so as to find methods of overcoming or delaying the resistance. In January 2014, FDA approved the first combination of a BRAF inhibitor dabrafenib and a MEK inhibitor trametinib to treat patients with unresectable or metastatic melanoma with BRAF V600E or V600K mutation. A phase 3 study tested the combination of dabrafenib with trametinib versus dabrafenib and placebo [50]. The median PFS was longer in the combination therapy group compared to the dabrafenib only group (9.3 vs. 8.8 months with HR of 0.75, $P = 0.03$). In the patient population with elevated LDH levels, the median PFS was longer in the combination therapy group compared to monotherapy (7.1 vs. 3.8 months). Interestingly, the BRAF and MEK inhibitor combination demonstrated not only a potential reduction in drug resistance but also a lower incidence of skin toxicity and secondary cancers.

Another combination of Cobimetinib and vemurafenib was associated with a significant improvement in PFS among patients with BRAF V600 mutated metastatic melanoma and was approved by the FDA in November 2015 [51].

Immunotherapy

Although melanoma has historically been considered as one of the most immunogenic types of cancer, clinically translated immunotherapies including treatment with interleukin-2, interferon alpha therapy, vaccination with peptide-pulsed dendritic cells, or adoptive T-cell therapies had not led to a statistically significant improvement in OS until recent years. Three immune-therapeutic agents (ipilimumab, pembrolizumab, and nivolumab) have been approved since 2011 and they have each produced survival advantage in patients with metastatic melanoma.

Ipilimumab, a monoclonal antibody binding to the CTLA-4 receptor expressed in activated T cells,

was the first agent to demonstrate an OS benefit in the treatment of advanced melanoma. It received FDA approval in March 2011. Approval was based on a phase III study of 676 previously treated metastatic melanoma patients [52] who were randomized to receive ipilimumab plus a gp100 vaccine versus ipilimumab alone versus the vaccine alone in a 3:1:1 ratio. OS was significantly longer for patients treated with the combination (10 months; HR = 0.68; $P < 0.001$) or ipilimumab alone (10.1 months; HR = 0.66; $P < 0.003$) versus gp100 alone (6.4 months). A second phase III study compared dacarbazine with or without ipilimumab in previously untreated melanoma patients [53]. The addition of ipilimumab to dacarbazine significantly improved the OS compared with dacarbazine alone (11.2 vs. 9.1 months; $P < 0.05$). However, the trial employed a dose of Ipilimumab more than three times higher than currently licensed.

Pembrolizumab, an anti-PD-1 monoloclonal antibody, was approved by FDA in September 2014 for the treatment of patients with unresectable or metastatic melanoma with disease progression after treatment with ipilimumab or BRAF-inhibitor in case of BRAF-positive disease. KEYNOTE-001 was an open label phase Ib study randomizing 655 patients (342 ipilimumab treated (IPI-T) and 313 ipilimumab naive (IPI-N)) with unresectable or metastatic melanoma to receive pembrolizumab 2 mg/kg or 10 mg/kg IV once every 3 weeks or 10 mg/kg every 2 weeks [54]. At the time of analysis, ORR was 34% (29% IPI-T, 38% IPI-N), with a 6% complete remission (CR) rate; median PFS was 5.2 months (IPI-T, 4.9 months (3.0–5.5); IPI-N, 5.4 months (3.1–6.9)) and the 1-year OS rate was 67%. KEYNOTE-002 was a phase 2 randomized study which demonstrated an improvement in PFS in the pembrolizumab 2 mg/kg arm (HR of 0.57 [95% CI: 0.45, 0.73]; $P < 0.001$) and in the pembrolizumab 10 mg/kg arm (HR of 0.50 [95% CI: 0.39, 0.64]; $P < 0.001$) when compared to investigator-choice chemotherapy in 540 patients with advanced melanoma who were previously treated with ipilimumab and, if BRAF V600 mutation positive, a BRAF or MEK inhibitor [55]. The phase 3 KEYNOTE-006 study randomized 834 patients with advanced melanoma to receive pembrolizumab (10 mg/kg every 2 or 3 weeks) or ipilimumab [56]. In the planned interim analysis of the coprimary endpoints, pembrolizumab demonstrated superior PFS and OS compared to ipilimumab. Following the results from this study, FDA approved (December 2015) an expanded indication for pembrolizumab to include the first-line treatment of patients with unresectable or metastatic melanoma regardless of BRAF status.

Nivolumab is a monoclonal antibody that targets the PD-1 protein and was initially approved by FDA in December 2014 for patients who progressed after treatment with ipilimumab and in patients whose tumors express BRAF V600 mutation. The indication for nivolumab was then expanded to include the first-line treatment of unresectable or metastatic melanoma. The approvals were based on the results from two phase 3 trials: Checkpoint 037 and Checkmate 066. Checkpoint 037 enrolled 272 patients with metastatic melanoma who had received prior anti-CTLA-4 therapy and a BRAF inhibitor if a V600 mutation was present [57]. Patients were randomly assigned to nivolumab or chemotherapy (either dacarbazine or carboplatin plus paclitaxel). Nivolumab led to a greater proportion of patients achieving an objective response (31.7% vs. 10.6%) and fewer toxic effects than with alternative available chemotherapy regimens. In the previously untreated setting, 418 patients without BRAF mutation were randomly assigned to nivolumab or dacarbazine [58]. OS was significantly increased in those treated with nivolumab (1-year survival rate 73% vs. 42%). PFS was also increased with nivolumab (median 5.1 vs. 2.2 months), as was the ORR (40% vs. 14%).

Finally, the combination of nivolumab and ipilimumab has been recently (September 2015) approved in the USA for the treatment of patients with BRAF V600 wild-type and BRAF V600 mutation-positive unresectable or metastatic melanoma based on findings from the phase 2 CheckMate-069 study and from the phase 3 CheckMate-067 trial. This marks the first approval for an immunotherapy combination for patients with cancer. The phase 3 CheckMate-067 study, where 945 previously untreated patients with advanced melanoma were assigned to nivolumab alone, nivolumab plus ipilimumab, or ipilimumab alone, showed a median PFS of 11.5 months for the nivolumab plus ipilimumab regimen and 6.9 months for nivolumab

monotherapy, versus 2.9 months for ipilimumab monotherapy [59]. The combined regimen demonstrated a 58% reduction in the risk of disease progression vs. ipilimumab (HR: 0.42; $P < 0.0001$), while nivolumab monotherapy demonstrated a 43% risk reduction versus ipilimumab monotherapy (HR: 0.57; $p < 0.0001$).

Novel Targets and Combination Therapies

The advent of new treatment options has resulted in various novel combination approaches involving targeted therapies, immunotherapies, as well as other treatment modalities (i.e., chemotherapy, radiotherapy). Resistance to BRAF inhibitors develops in the majority of patients within 6–8 months and can be mediated by a number of different mechanisms occurring along the MAPK pathway (e.g., mutations in MEK, NRAS, overexpression of COT) or via bypass signalling pathways (e.g., activation of PI3K/AKT signalling, loss of PTEN, RTK overexpression, IGFR1). In addition to the combinations that have already been approved, other targeted combinations to overcome resistance are currently being evaluated.

Another possible way of overcoming the resistance to BRAF inhibitors is the combination of immunotherapeutic agents and BRAF inhibitors. A phase I/II trial combining vemurafenib and ipilimumab was conducted by Ribas et al. [60]. While the combination was shown not to be feasible due to hepatotoxicity leading to discontinuation of the study, sequential administration was shown to be safe, with some potential for efficacy. Clinical trials evaluating combinations of PD1 pathway inhibitors with BRAF inhibitors such as vemurafenib (NCT01656642), or dabrafenib and with MEK inhibitor trametinib (NCT02224781) are underway. Furthermore, preliminary safety data from the combination trial of MEDI4736 (a PDL1-specific mAb), dabrafenib and trametinib appear promising [61].

Combining immunological agents may also improve response rates and the duration of response by stimulating an antitumor immunological memory regardless of BRAF-mutational status. Dual blockade of PD-1 and CTLA-4 with nivolumab and ipilimumab has proven benefit in advanced melanoma, although it is associated with higher toxicity than either monotherapy. The combination of ipilimumab with the oncolytic virus, T-VEC, another immunotherapy, also obtained a very promising ORR of 55%, with a good safety profile. Novel immunomodulatory candidates for rational combination with immune checkpoint inhibitors are at various stages of clinical development. Early phase studies involve the combination of nivolumab with other immunomodulating antibodies targeting inhibiting receptors, such as LAG-3 or TIM-3, and with antibodies targeting activating receptors, such as CD 137 or OX-40. Other strategies are also being explored, such as agents that may block the inhibition of natural killer cell activity (i.e., KIRs, C-type lectins, CD244 and CD48, ILT family) or target the tumor microenvironment (i.e., IDO, TGFβ).

c-KIT Inhibitors

Mutations in c-KIT are seen in up to 6% of cutaneous melanomas, although the frequency may be higher in mucosal and acral lesions. In an open-label, single-arm, phase II clinical trial 51 patients with mutations were identified out of the 295 screened and 28 patients were treated with imatinib [62]. The authors did find an association between clinical response and mutation pattern. Further clinical studies using other CKIT inhibitors such as dasatinib and nilotinib are in progress and results are pending.

Antiangiogenic Therapy

Blockade of the VEGF pathway has been achieved by many different approaches, including blocking antibodies targeted against VEGF or its receptors, soluble decoy receptors that prevent VEGF from binding to its normal receptors (VEGF trap), as well as small-molecule inhibitors of the tyrosine kinase activity of the VEGFRs. Bevacizumab is a potent antibody against the VEGF and has been shown to be effective for the treatment of various

advanced cancers. Bevacizumab has also been studied in phase II trials in metastatic melanoma [63, 64]. Prolonged disease stabilization and response rates have been demonstrated in one-quarter of metastatic melanoma patients after the addition of bevacizumab to low-dose IFN, and dacarbazine [65]. In addition, the combination of temsirolimus and bevacizumab demonstrated an objective clinical response in patients with BRAF/RAS–wild-type melanomas suggesting that the combination of an angiogenesis inhibitor with an mTOR inhibitor may be promising in a subset of melanoma patients who lack activating mutations in both BRAF and RAS and for whom no targeted therapies are currently available [66]. Further trials of bevacizumab combined with chemotherapy, immunotherapy, and other targeted therapies are ongoing in melanoma patients, and numerous other antiangiogenic agents are currently in clinical trials or in development.

Apoptotic Therapy

The Bcl-2 protein is one of the most important inhibitors of apoptosis, and it is overexpressed in approximately 90% of melanomas. Drug resistance in melanoma has been partially attributed to overexpression of Bcl-2. Oblimersen sodium is a Bcl-2 antisense oligonucleotide that selectively targets Bcl-2 RNA for degradation. Although promising results were seen in an initial phase III trial which demonstrated significant increases in PFS and response rate when oblimersen was combined with dacarbazine [67], these findings were not confirmed in a second trial.

Role of Nuclear Medicine in Melanoma Patients

Initial Staging of Primary Melanoma

Staging Nodal Metastases

Lymphoscintigraphy. In early stage melanoma (AJCC I–II), SLNB has become the standard of care for staging the regional draining lymph nodes, which are typically the first site of possible metastatic spread of disease [28, 68]. Compelling evidence from the literature indicates that SNLB is the procedure of choice for detection of occult regional lymph node metastases, particularly in patients presenting with an intermediate Breslow thickness lesion (1–4 mm) [22, 23] (see also ▶ Chap. 48, "Radioguided Surgery for Malignant Melanoma" of this book). Preoperative lymphoscintigraphy is normally performed, followed by intraoperative detection with blue dye and/or a gamma probe [69]. Precise identification of sentinel lymph node (SLN) site(s) is essential, as there may be true nodal sites, intransit nodes, and alternate drainage basins in some situations (Fig. 1). Lymphoscintigraphy has been shown to be highly sensitive and specific (>90%) for the detection of SLN, thus assisting surgical biopsy and decisions regarding subsequent therapeutic options.

Lymphoscintigraphy for SLN detection must be performed with transmission scans, and/or with hybrid SPECT/CT systems, to precisely define the location of sentinel nodes and eliminate false-positive results. All nodes demonstrating uptake must be evaluated by detailed histology, as a SLN may not be the lymph node which demonstrates the highest tracer uptake, and different drainage basins may occur from a single primary melanoma site (Fig. 2). Intransit and aberrant metastatic lymph nodes occur in 14–22% of cases [69]. Status of the sentinel lymph node is an important prognostic factor for disease-free and overall survival. In the Multicenter Selective Lymphadenectomy Trial (MSLT-1), patients who had immediate lymph node dissection following positive SLNB had a higher survival rate than those who underwent delayed lymphadenectomy [28].

Anatomic correlation of the lymphoscintigram with SPECT/CT improves the accuracy of lymphoscintigraphy by defining anatomical site and excluding false-positive results, compared to planar gamma camera imaging. In one study of patients with primary melanoma located in the head and neck or trunk region, SPECT/CT identified "hot" nodes missed on planar images including nodes invaded by metastases in 43% of cases [69]. These SLNs identified by SPECT/CT were nodes hidden by the injection-site-scattered radiation, deeply located or intransit nodes. Multiple draining basins were clearly identified in 50%

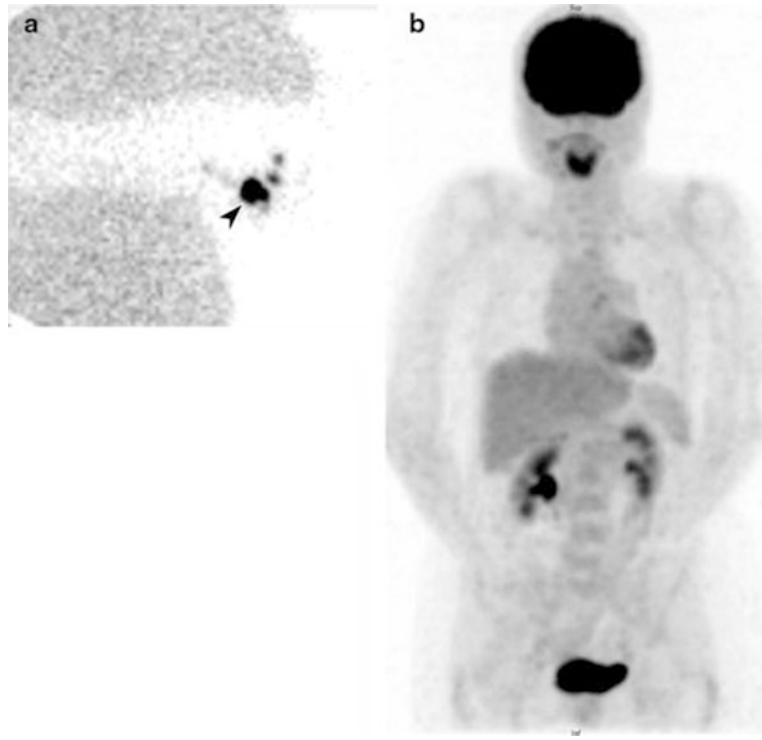

Fig. 1 Lymphoscintigraphy of primary melanoma of the right thumb. Right axillary lymph node (*arrow*) identified on sentinel lymph node scintigraphy with transmission scan (**a**) and negative whole-body staging [^{18}F]FDG PET scan (**b**)

patients with trunk melanoma and in 33% patients with head and neck malignancy. Further validation of lymphoscintigraphy with SPECT/CT in clinical studies is ongoing and may help to provide additional information on improvement in outcomes of patients evaluated preoperatively with this investigation.

[^{18}F]FDG PET. In patients with AJCC stage I–II melanoma, multiple studies with [^{18}F]FDG PET alone, and PET/CT, have shown a poor sensitivity for the detection of metastatic disease in draining lymph nodes. Cumulative data from over 800 patients with early stage melanoma show that PET has a low sensitivity for detecting SLN metastases (Table 3) [68, 70–87]. The small size of involved lymph nodes, which are often <5 mm in size, is a major factor in detection of disease, as most metastatic melanoma sites are [^{18}F]FDG-avid. In an early study by Crippa et al., the sensitivity of PET significantly varied with the size of lymph node metastases [88]. The sensitivity of PET was only 23% for lymph nodes <5 mm and increased to 83% and 100% for lymph nodes with a size of 6–10 and >10 mm, respectively. In another study exploring the impact of spatial resolution of PET scanners with typical size of metastatic lymph nodes, a spatial resolution of 4–6 mm resulted in less than 50% of lymph nodes being potentially detectable [89]. Other studies have confirmed the small size of metastatic disease in SLN and corresponding low sensitivity for PET and PET/CT for AJCC stage I–II disease [68, 70–87] (Table 3).

There is a potential role for [^{18}F]FDG PET in patients with apparent AJCC stage I–II disease but higher risk of metastatic disease, including those with intermediate/high-risk lesions (Breslow ≥ 1 mm, regression, ulceration) or high-risk lesions (Breslow >4 mm). These patients have a prevalence of regional lymph node or distant metastases at the time of initial presentation of $>10\%$. For example, in one study of 43 patients with intermediate/high-risk melanomas, extensive staging identified disease resulting in early treatment in 12 patients (28%) [81]. The analysis of melanomas for gene signatures that are associated with a worse prognosis is the subject of ongoing research, and this may also in the future identify

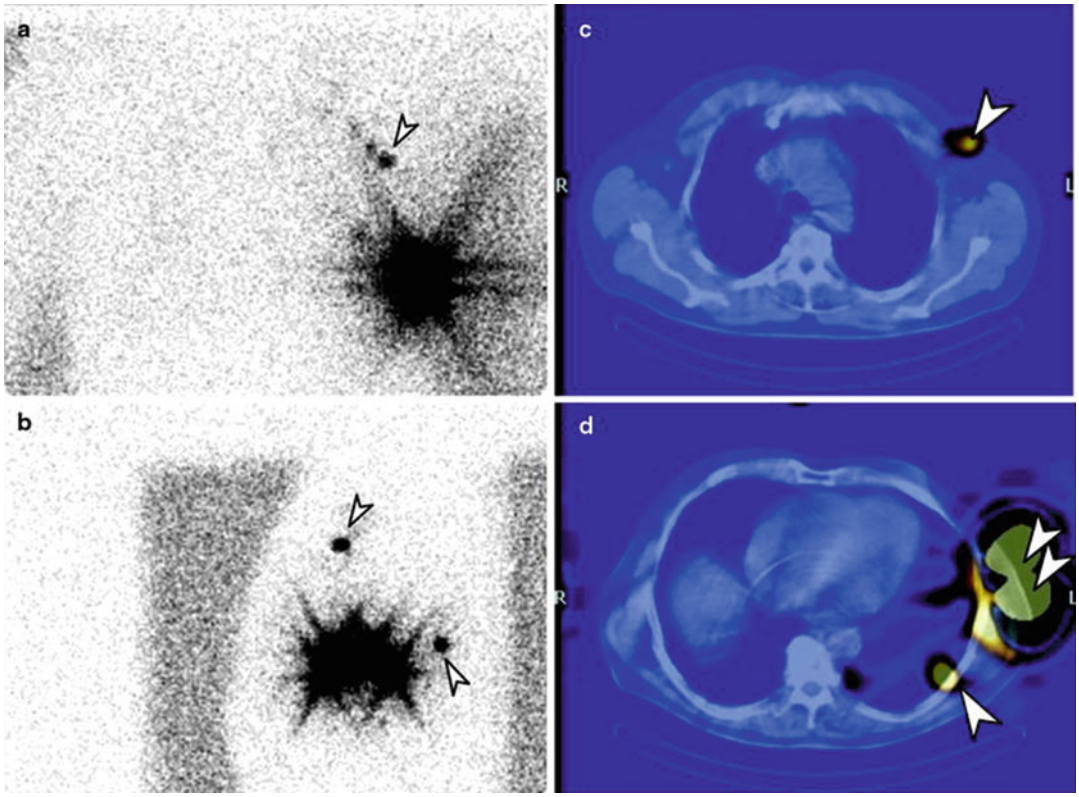

Fig. 2 Lymphoscintigraphy of primary melanoma of the left chest. Planar transmission scan images in the anterior (**a**) and lateral (**b**) projections. SPECT/CT confirms two separate SLN, one lateral to left pectoral muscle (**c**) and one in left midthoracic intercostal space (**d**) (Courtesy of Dr Martin Cherk, Alfred Hospital, Melbourne, Australia)

patients who would benefit from more extensive staging procedures such as PET [69].

These results have led to [^{18}F]FDG PET not being recommended for the routine detection of regional nodal involvement in AJCC I–II melanoma patients. However, PET in initial staging may have a role in situations where AJCC stage I–II patients are considered at higher risk of distant metastatic disease, such as in intermediate-high-risk or high-risk primary lesions, multiple melanomas, or unusual gene signatures in melanoma lesions [90].

Staging of Metastatic Disease

Initial Staging

Melanoma patients presenting with AJCC stage III disease (regional nodal involvement) are at higher risk of presenting with systemic metastases, and as this can impact on therapy, accurate staging is essential (Fig. 3). [^{18}F]FDG PET has been shown to be more accurate than conventional imaging techniques in identifying metastatic disease in stage III patients in a number of reported studies [91–97] (Figs. 4, 5, and 6). In a recent large prospective study evaluating 251 patients with PET/CT prior to surgery for known metastatic melanoma and nodal involvement, lymph node metastases were visualized in 91% of patients by PET, and 92% by CT, although in this series most lymph nodes were large [97]. Systemic metastases were suspected in 32% of patients by PET and in 24% by CT. Upstaging by PET was correct in 27% and in 24% by CT, and more bone and soft tissue sites were detected by PET compared to CT. [^{18}F]FDG PET and CT performed at initial diagnosis for patients with confirmed stage III melanoma conferred survival benefits for both the patients

Table 3 Studies using [^{18}F]FDG PET in regional lymph node staging in early-stage cutaneous melanoma

Study	Study type	Patients	AJCC stage	Clinical use of PET	Reference test	Sensitivity
Wagner et al. [68]	Prospective	70	I–III	Detection of sentinel node metastases	SLNB	PET: Sensitivity 7.7% (stage I–II), 40% (stage III)
Klein et al. [70]	Prospective	17	I–II	Detection of sentinel node metastases	LS/SLNB or clinical follow-up (20 months)	PET: Sensitivity 67%
Acland et al. [71]	Prospective	50	T2–T4 or lymphatic invasion	Detection of regional lymph node metastases	LS/SLNB and clinical follow	PET: Sensitivity 0% SLNB: Sensitivity 100%
Kokoska et al. [72]	Prospective	18	T1–T4 N0 M0	Detection of sentinel node metastases	LS/SLNE	PET: Sensitivity 40%
Belhocine et al. [73]	Prospective	21	T2–T4 N0 M0	Detection of sentinel node metastases	LS/SLNE	PET: Sensitivity 14% SLNB: Sensitivity 86%
Havenga et al. [74]	Prospective	53	T2–T4 N0	Prediction of sentinel node metastases	LS/SLNB	PET: Sensitivity 15% SLNB: Sensitivity 100%

who were negative for disseminated disease and those whose disease was upstaged because of distant metastases, which they attributed to the early detection of occult subclinical metastases and subsequent modifications in treatment decisions [98]. The use of PET in assessing systemic metastatic disease in this patient group is also included in established clinical guidelines [90].

In patients with known or suspected AJCC stage IV disease (systemic metastases), [^{18}F]FDG PET also has an important role in identifying metastatic disease sites and extent (Tables 4 and 5), which can impact on initial treatment, including surgical options and decisions regarding chemotherapy/biologic therapy [69, 90] (Fig. 7). The majority of melanoma metastases are [^{18}F]FDG-avid, provided lesions are >5–6 mm in size. The exceptions are brain metastases, which may be difficult to identify due to gray matter [^{18}F]FDG uptake, and hepatic metastases of uveal melanoma, which have been shown to be negative on [^{18}F]FDG PET in up to 59% of cases and which do not appear to be related to GLUT-1 expression [111].

Melanoma patients should have whole-body PET imaging, including arms/legs in patients whose primary lesions arise on extremities

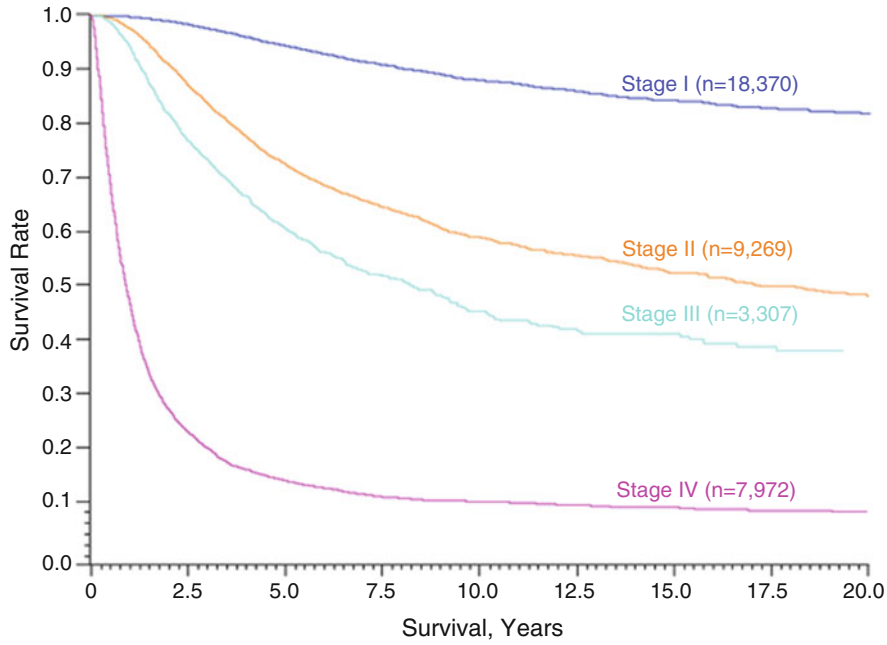

Fig. 3 Fifteen-year survival curves for patients with localized melanoma (stages I and II), regional metastases (stage III), and distant metastases (stage IV). The numbers in parentheses are the numbers of patients from the AJCC Melanoma Staging Database used to calculate the survival rates. The differences between the curves are highly significant ($p < 0.0001$). (Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, IL. The original source for this material is the *AJCC Cancer Staging Manual* Seventh Edition (2010) published by Springer Science and Business Media LLC www.springer.com)

(Figs. 5 and 6). Reported studies have shown the value of whole-body imaging in melanoma patients, where primary lesions were in the limbs. In one retrospective study of 153 patients, abnormal PET findings in the legs were observed in 53 (35%) of patients; in these 53 patients, 72% also had distant metastases detected. Only patients with primary melanoma of the legs had PET findings justifying inclusion of the legs in the whole-body PET scan [112]. Published guidelines support the use of whole-body PET with extremities in patients with primary melanoma of the arms or legs and full images of the head in patients with primary scalp melanoma [113]. False-negative results can occur with small skin and brain metastases, and lesions adjacent to the heart, kidneys, or urinary bladder. Furthermore, while PET is more specific in the diagnosis of melanoma pulmonary metastases, chest CT is more sensitive. [^{18}F]FDG PET/CT provides an improved technique for assessing pulmonary disease (see later section), although it should be performed in conjunction with brain MR imaging to optimally identify brain metastases.

Recurrent Metastatic Disease

Identifying metastatic disease is critically important in melanoma patients, as the median survival after the appearance of distant metastases is approximately 6 months. An additional consideration is that treatment decisions are based on site and extent of disease [21]. While a comprehensive clinical history and physical examination may assist in identifying possible recurrent disease, particularly in stage III and IV patients, accurate staging is vitally important to guide decisions regarding surgery (which may extend survival) or radiotherapy in patients with recurrent disease [114, 115]. It has been shown that conventional staging investigations (CT chest, abdomen, brain MRI with or without bone scan) have limited sensitivity and specificity for the detection of

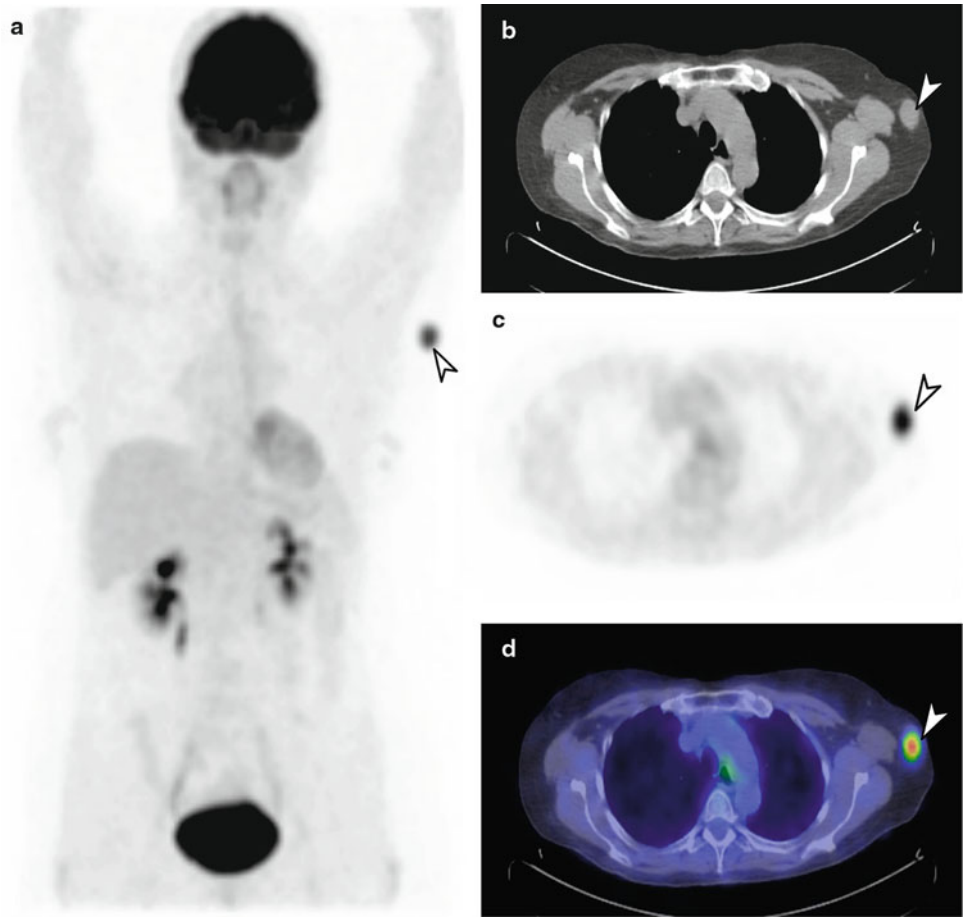

Fig. 4 [^{18}F]FDG PET/CT staging of biopsy-proven left axillary melanoma metastasis. Whole-body PET image (**a**) shows a solitary metastatic lymph node in the left axilla (*arrow*), with no distant metastatic disease. Also seen on axial CT (**b**), PET (**c**), and fused PET/CT (**d**) images

melanoma metastases and have been estimated in patients with stage II–IV melanoma to have a sensitivity of 57–81% and a specificity of 45–87%, respectively, on the basis of single melanoma lesions [92, 93, 95]. In a further study of 347 patients with clinical stage III melanoma, CT scans identified twice as many false positives as true-positive melanoma lesions [116].

In published studies (Table 4) and meta-analyses of the literature, the reported sensitivity, specificity, and accuracy of [^{18}F]FDG PET in detecting recurrent melanoma ranges from 70% to 100% [94, 96, 117]. PET is particularly sensitive and specific for detecting soft tissue and lymph node metastases that are not assessable by clinical examination and have not been demonstrated by CT [92, 93, 96, 99] (Fig. 8). [^{18}F]FDG PET has also been shown to detect disease up to 6 months earlier than conventional techniques. In studies directly comparing PET to conventional imaging in patients with recurrent melanoma, PET has had superior accuracy for the detection of both locoregional and distant metastases [96, 100] (Figs. 9, 10, 11, and 12). In patients with pulmonary metastases, PET-staged patients have also been shown to have improved survival compared to patients staged with conventional imaging techniques [118]. In a prospective, multicenter study of [^{18}F]FDG PET in 134 patients with known or suspected recurrent metastatic melanoma, PET identified an additional 189 lesions in 55.2% of patients, principally in soft tissue, bone, and nodal

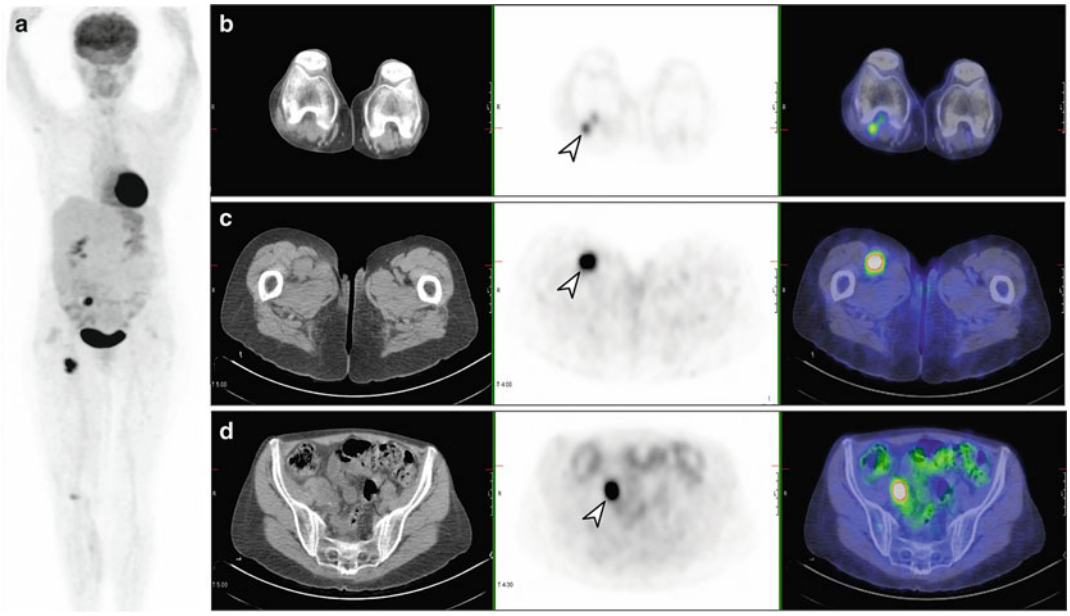

Fig. 5 [^{18}F]FDG PET/CT staging postresection of primary melanoma from right calf. Whole-body PET image (**a**) shows local and distant lymph node involvement in right popliteal (**b**), femoral (**c**), and iliac (**d**) lymph nodes

sites [110]. Most PET false negatives in recurrent disease are typically less than 1 cm in diameter and are mainly pulmonary and hepatic in location, or in the brain (Fig. 13). The majority of these false negatives can be detected by CT scanning or MRI for brain metastases. Therefore, PET should complement rather than replace CT/MRI scanning in patients with suspected recurrent disease. Most CT false negatives are located in the abdomen, suggesting that PET can especially assist in the staging of this region.

Unsuspected additional primary tumors may be detected with [^{18}F]FDG PET. In one series of 92 patients with stage IV melanoma staged with [^{18}F]FDG PET, seven new primary tumors were detected, emphasizing the importance of considering differential diagnoses and obtaining a tissue diagnosis particularly at the time of the first relapse [96].

[^{18}F]FDG PET

[^{18}F]FDG PET/CT is superior to PET alone in the assessment of metastatic melanoma, with improved detection of nodal spread and distant metastases, although some false positives are seen [101, 107–109, 119–121] (Fig. 14). PET/CT has a significant impact on the interpretation of suspicious metastatic lesions, and the false-negative and false-positive rates of standalone PET can be reduced through the use of PET/CT, particularly by providing clarity for normal [^{18}F]FDG uptake variants. Precise anatomic localization of sites of [^{18}F]FDG uptake can define a patient's suitability for surgery as well as pinpoint metastases. [^{18}F]FDG PET/CT is also helpful for the staging of unusual sites of primary melanoma such as ocular melanoma and vaginal melanoma (Fig. 15). In addition, [^{18}F]FDG PET/CT can assist in identifying incidental metastatic melanoma in patients with other malignancies, although this is an unusual finding.

The use of contrast-enhanced CT as part of the [^{18}F]FDG PET/CT study has also been evaluated in melanoma patients. In a study of 56 patients evaluated with contrast-enhanced [^{18}F]FDG PET/CT, lymph node detection was poor (38% vs. 23% for CT), and the detection of systemic metastases was slightly improved, although no statistically significant difference was seen [101]. The precise role of contrast-

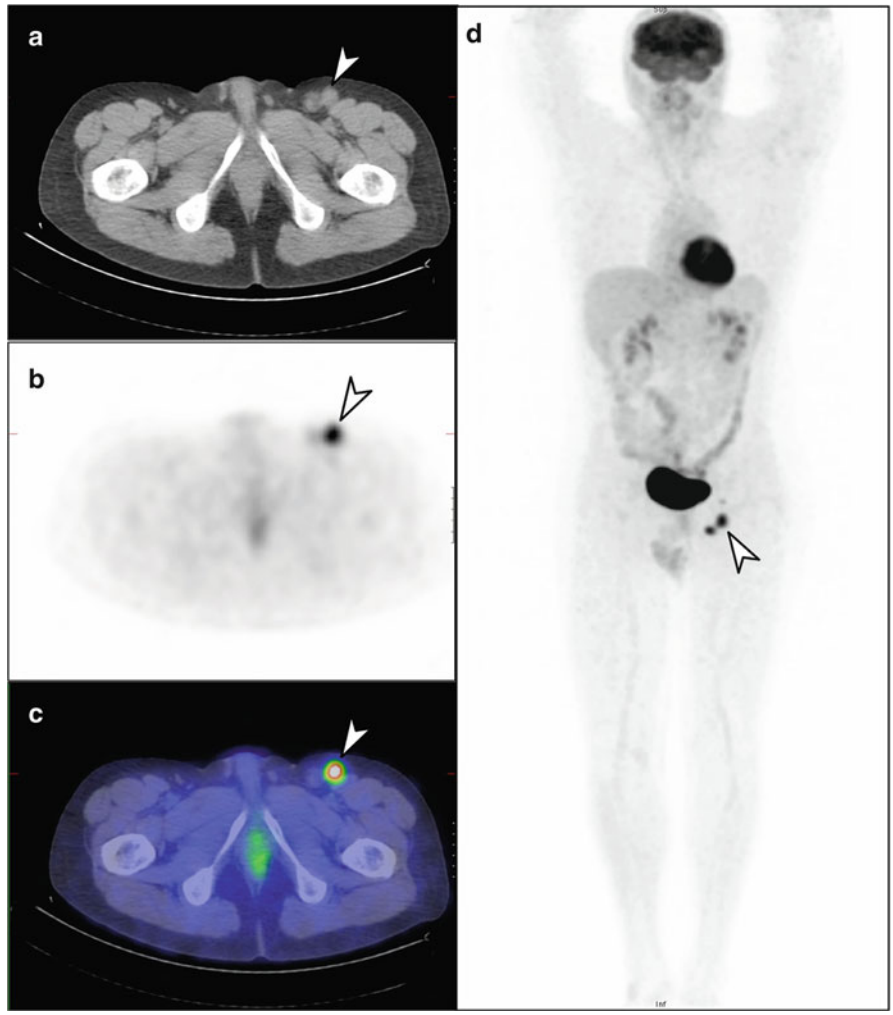

Fig. 6 Staging [^{18}F]FDG PET/CT scan of left heel primary melanoma. (**a**) Transaxial PET, (**b**) CT, and (**c**) PET/CT images show metastatic lymph nodes in the left inguinofemoral region (*arrow*), also seen on (**d**) whole-body PET image, without other metastatic disease identified

enhanced CT with [^{18}F]FDG PET/CT in melanoma is still to be determined. In a study comparing [^{18}F]FDG PET/CT with whole-body MRI in stage III/IV patients, PET/CT was found to be more accurate (86.7% compared to 78.8%), particularly for nodal and skin/subcutaneous metastases, whereas MRI was more accurate for liver, bone, and brain metastases. Changes in treatment were implemented in 64% of patients due to imaging findings, indicating the potential clinical value of combined [^{18}F]FDG PET/CT and organ-specific MRI in melanoma patients [122].

Monitoring Treatment Response

Whole-body [^{18}F]FDG PET can also play a useful role in the treatment monitoring of metastatic melanoma. This is particularly relevant in patients with unresectable regional or distant metastatic disease who are enrolled in immunotherapy, chemotherapy, or biologic therapy protocols. PET has been shown to accurately detect early metabolic response to conventional and experimental therapies in patients with metastatic melanoma (Fig. 16). Therefore, the timely incorporation of whole-body PET into clinical trial protocols may help improve the efficacy of

Table 4 Selected studies of [^{18}F]FDG PET in staging distant metastatic melanoma

Study	Patients	Study type	Clinical use of [^{18}F]FDG PET	Results
Crippa et al. [88]	38	Prospective	Detection of lymph node metastases	Sensitivity 100% of metastases ≥10 mm, 83% of metastases 6–10 mm, and 23% of metastases ≤5 mm

treatment regimens including dosage and scheduling optimization.

In a study of 25 patients with stage IV melanoma, [^{18}F]FDG PET/CT and S-100B (tumor marker) was evaluated after 2–3 cycles of chemotherapy. [^{18}F]FDG PET/CT and CT showed a good correlation with overall response, with a trend for OS to be better in PET initial responders versus nonresponders, and PFS was significantly longer in PET responders versus nonresponders [123]. Brain metastases were better detected with MRI/CT and were often the sites of subsequent relapse. Other studies have also confirmed the utility of [^{18}F]FDG PET in assessing treatment response to chemotherapy and biologic agents [121, 124, 125] (Fig. 17).

Early data suggest that [^{18}F]FDG PET may be suitable for monitoring treatment response to mutation-driven therapies such as vemurafenib and dabrafenib. Mutated BRAF kinase has been shown to activate signaling pathways that up-regulate glucose metabolism, facilitating tumor growth [126]. The inhibition of this pathway by BRAF inhibitors could theoretically be visualized

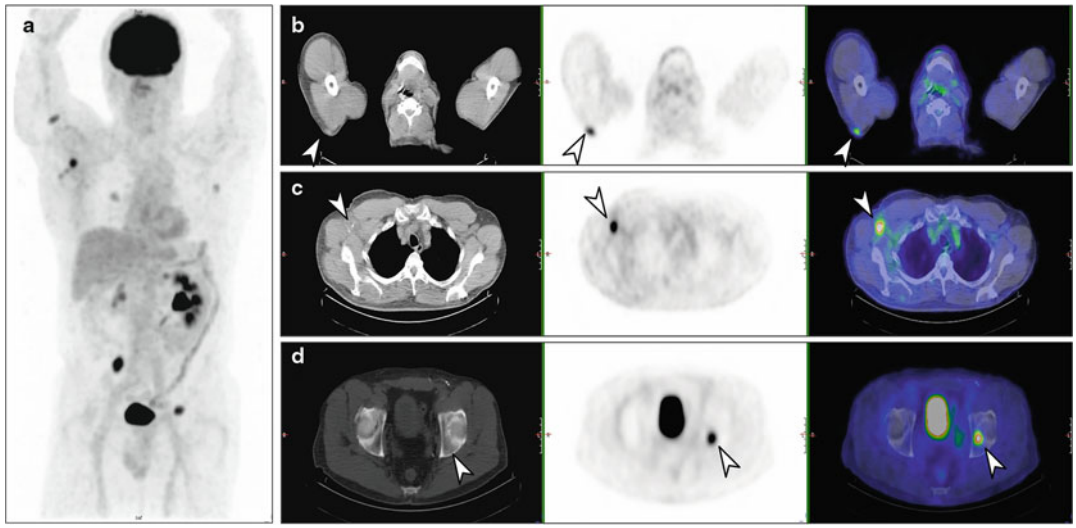

Fig. 8 [^{18}F]FDG PET/CT for postoperative restaging in a patient presenting with a seroma postresection of metastatic melanoma in the right axilla. (**a**) Whole-body PET shows a lesion in the right abdomen, localized to the right kidney (*arrow*) on axial PET/CT (**c**). The left frontal lobe metastasis seen on MRI was not [^{18}F]FDG avid (**b**)

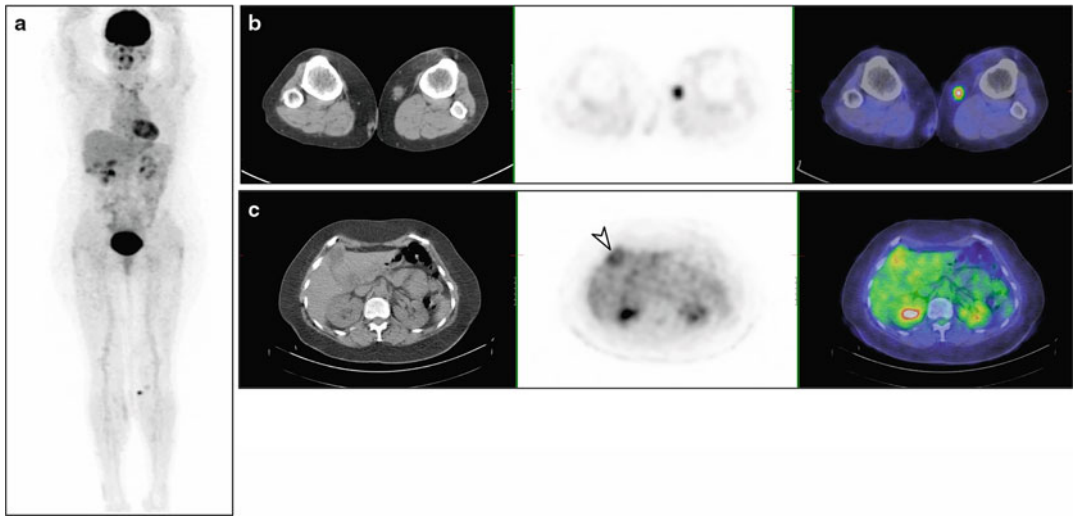

Fig. 14 False-positive [^{18}F]FDG PET/CT scan for liver metastasis. Fifty-year-old lady with melanoma in the left ankle resected 15 years ago presents with intransit recurrence in the left knee for restaging. Whole-body PET (**a**) and PET/CT show increased [^{18}F]FDG uptake in left medial knee intransit metastasis (**b**) and increased [^{18}F]FDG uptake in a 4-cm liver lesion (**c** *arrow*). The liver lesion was biopsied and diagnosed as a hepatic adenoma, with no features of melanoma on immunohistotyping

using [^{18}F]FDG PET (Figs. 18, 19, and 20). In one study the intrapatient heterogeneity of response in metastatic melanoma treated with dabrafenib was evaluated with [^{18}F]FDG PET, and compared with clinical outcomes. They reported that [^{18}F]FDG PET/CT showed responses in all patients, with 26% showing a homogeneous PET response and 74% exhibiting a heterogeneous PET response. Heterogeneity was associated with a shorter time to progression (3.0 months vs. 7.4 months for PET homogeneous responders) [127]. In a phase I study, [^{18}F]FDG PET/CT was found to be a useful marker of an early biologic response to vemurafenib [128]. There was a trend for patients with greater reductions in uptake of [^{18}F]FDG to have longer PFS and the study showed a positive correlation between percentage of injected dose in all identified disease and target-lesion SUV_{max}, although no relationship was found between the reduction in target lesion SUV_{max} and best response according to RECIST.

[^{18}F]FDG PET/CT is commonly used in evaluating melanoma treatment response to immunotherapy, although there are no published studies that have rigorously assessed its role. Several case reports have described the radiologic features of the immune-related adverse reactions and highlighted the challenges of monitoring immunotherapy response, such as the presence of inflammatory cells which are known to be [^{18}F]FDG-avid and can mimic tumor FDG uptake in lymph nodes. [^{18}F]FDG PET/CT may have a role to in the early detection of immune-related adverse events and in directing earlier treatment [129, 130].

Management Impact of [^{18}F]FDG PET/CT

Information on the direct impact of [^{18}F]FDG PET on the clinical management of patients with melanoma strongly supports its role in the surveillance of patients for recurrent disease. In the majority of cases, this involves alteration of decision-making regarding the surgical treatment of recurrent disease (Table 5). Surgery can be curative for stage III disease and is the only therapy that influences survival in patients with stage IV disease [131] (see Figs. 4 and 5). Up to one-quarter of patients with metastatic disease are candidates for potentially curative surgical resection, and 20% of patients who achieve a curative resection become long-term survivors [132].

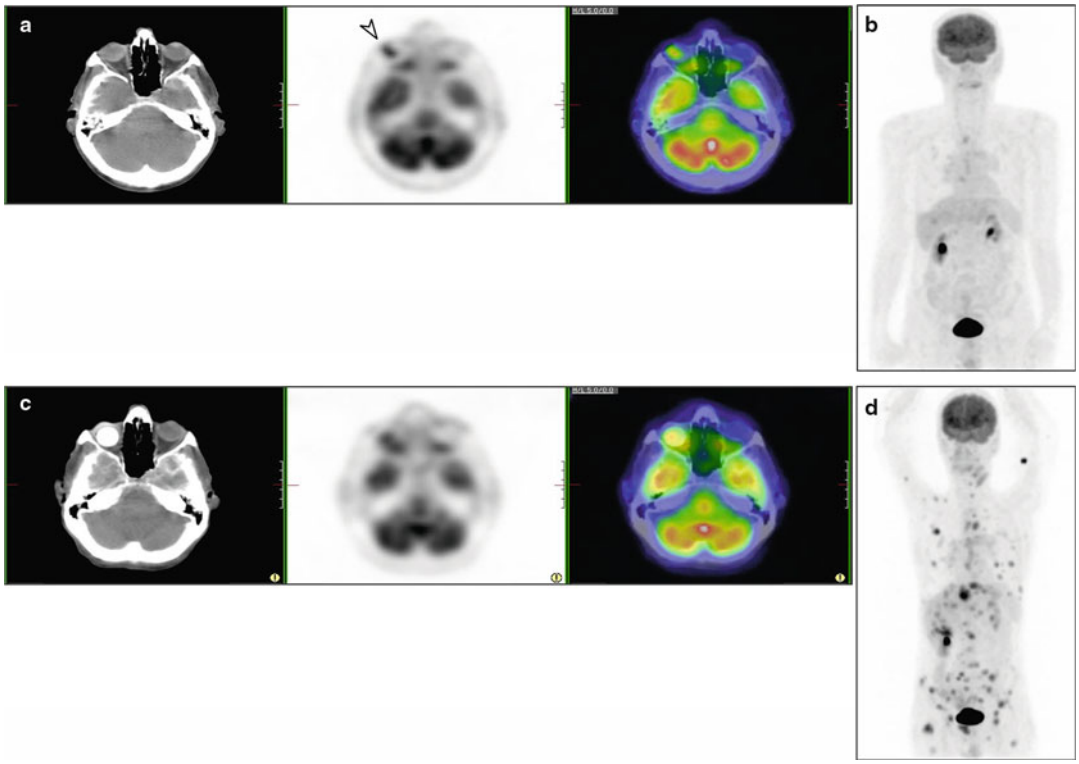

Fig. 15 Ocular melanoma staged with [^{18}F]FDG PET/CT. Primary melanoma of the right eye (*arrow*) seen on axial PET/CT images (**a**) with an involved solitary subcarinal lymph node seen on whole-body PET images (**b**). The patient represented 9 months later with biopsy-proven cervical nodal metastasis for restaging. Recurrent disease is evident on PET/CT around the right eye prosthesis (**c**), and widespread distant metastatic disease is seen in pulmonary, liver, mediastinal, skeletal, and subcutaneous sites (**d**)

Retrospective studies of patients with predominantly stage III and IV disease have suggested that the PET result influences the management of 13–49% of patients [92, 95, 96, 104, 107, 109, 121]. In two prospective studies, the PET result changed patient management 16% of the time in one series of 95 patients with stage III disease and contributed to a change in therapy in 40% of a second series of 58 patients with suspected recurrent melanoma [94, 103]. In a study of 92 patients with primarily stage IV disease, management impact was seen following [^{18}F]FDG PET scans in 40 patient studies (32%), particularly assisting in the selection of patients for surgery [96]. In a recent prospective multicenter study of 134 patients with known or suspected metastatic melanoma evaluated with PET prior to surgery, clinical management was changed in 62% of patients, and the pre-PET surgical plan was reduced by 33%. In addition, patients with additional [^{18}F]FDG-avid lesions were more likely to have progressive disease within 12 months of the initial PET scan [110]. It should be noted that PET can miss small-volume disease and/or micrometastatic disease, as evidenced by some false-negative PET studies and by the number of patients who relapse soon after surgery. It is clear that [^{18}F]FDG PET can assist in appropriate selection of patients for surgery, which in turn can lead to improved progression-free survival, although further studies are required to establish if this may also lead to improved overall survival.

Surveillance

Surveillance follow-up of patients with melanoma is guided by risk factors, patient history, and institutional guidelines. The natural history of melanoma and the likelihood of recurrent disease provide guidance about the frequency and

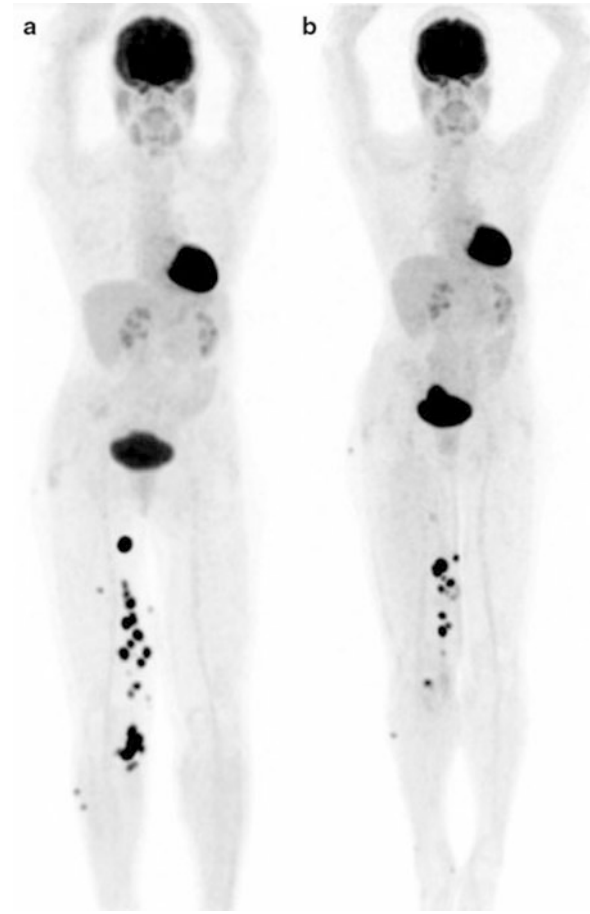

Fig. 16 [^{18}F]FDG PET/CT assessment of treatment response. Initial staging whole-body PET scan (**a**) shows intransit disease in the right leg (**a**). Posttreatment whole-body PET scan performed after resection of the primary lesion and radiotherapy (**b**) shows a partial metabolic response, with persistent intransit disease

duration of follow-up required. In patients with stage I–II melanoma, most recurrences occur within 2 years after initial diagnosis. In a study of 340 patients with stage III melanoma, the sites of relapse were principally systemic in IIIB and IIIC patients, and most relapses occurred within 2–3 years [133]. In stage IV patients, metastatic recurrence usually occurs within 2 years. Melanoma patients with asymptomatic and locoregional recurrences that are subsequently treated have been shown to have improved survival compared to those with symptomatic and distant recurrences [134]. In addition, the type of metastases (i.e., visceral vs. nonvisceral), the number of metastatic sites, and the evolution of metastatic burden over time are significant prognostic factors in treated melanoma patients [135]. Thus, regular follow-up is required for at least 2 years for most melanoma patients, extending to 5 years or more for long-term survivors.

The selection of follow-up investigations in melanoma patients includes blood tests, CT and MRI, and [^{18}F]FDG PET. Blood tests including serum lactate dehydrogenase (LDH) and S-100B have been explored as markers of possible recurrence, but as yet have not achieved routine use. In asymptomatic melanoma patients CT and MRI are of limited value for detecting nodal and visceral metastases [114]. The role of [^{18}F]FDG PET in routine surveillance is also unclear. In one study of 38 patients (AJCC II–III), the ability of PET to uncover silent metastases from melanoma was estimated at 34%, thereby avoiding futile and cost-prohibitive interventions [136]. In a cost-effectiveness study exploring the use of [^{18}F]FDG PET/CT versus whole-body CT for

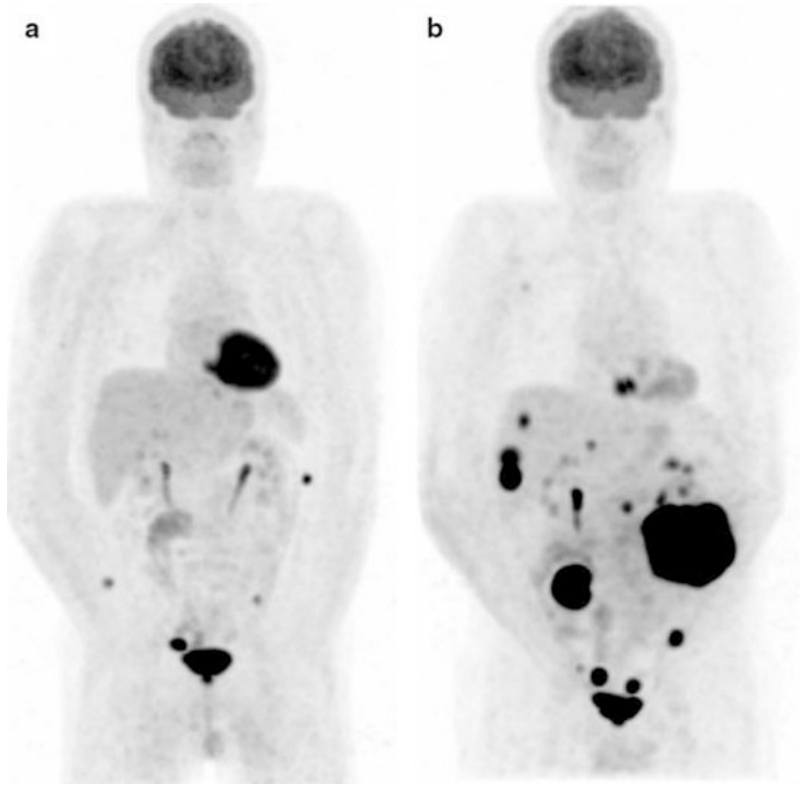

Fig. 17 [^{18}F]FDG PET/CT assessment of treatment response to chemotherapy. The patient had a history of metastatic melanoma and right axillary dissection and underwent chemotherapy for systemic disease. Whole-body PET image before treatment (**a**), and 6 months later (**b**) shows progressive metastatic disease despite treatment

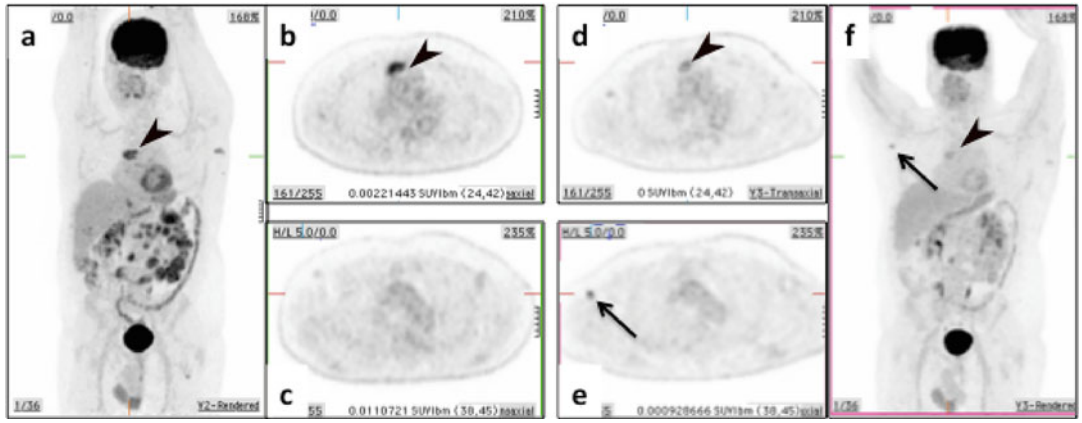

Fig. 18 [^{18}F]FDG PET/CT assessment of treatment response to combination BRAF/MEK1 inhibitor treatment (dabrafenib/trametinib). The patient had [^{18}F]FDG-avid disease in the abdomen and mediastinum seen on baseline (**a**, **b**); with posttreatment scans showing a partial metabolic response to treatment (**d**, **f**) and the appearance of a [^{18}F]FDG-avid node in the right axilla (**c**, **e**) due to reactive node rather than progressive disease

surveillance of melanoma patients with suspected pulmonary metastases, [^{18}F]FDG PET/CT was found to be less costly and resulted in 20% less futile surgeries and a potential survival benefit at 10 years [137]. The likelihood of PET detecting recurrent disease is higher in patients with symptoms and recent treatment of metastatic disease, and in these clinical scenarios, PET is more likely

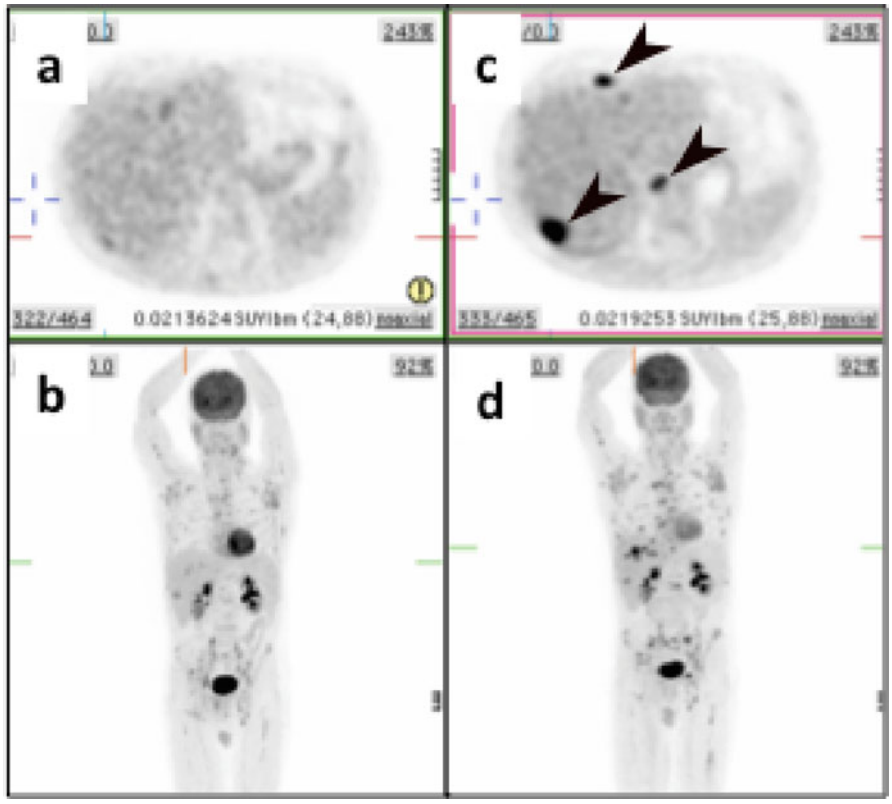

Fig. 19 [^{18}F]FDG PET/CT assessment of treatment response to combination BRAF/MEK1 inhibitor treatment (dabrafenib/trametinib). Baseline study (**a**, **b**), with progressive metabolic disease noted in the liver on follow-up study (**c**, **d**)

to detect sites of recurrence compared to other investigations. The use of [^{18}F]FDG PET for surveillance is yet to be formally established in practice guidelines, and its use should be guided by individual patient history and clinical suspicion of recurrence.

Non-[^{18}F]FDG PET Tracers in Melanoma

[^{18}F]FDG PET has gained wide acceptance in patients with malignant melanoma, in particular, for staging, restaging, and therapy monitoring. However, the detection of metastatic lesions in the brain may be difficult due to the high background; elsewhere in the body there may be false-positive sites due to nonmalignant lesions such as inflammation or infection. In view of this, a number of other PET tracers have been evaluated in melanoma patients.

In a study of ^{18}F-fluorothymidine (^{18}F-FLT) PET in 10 patients with clinical stage III melanoma, ^{18}F-FLT PET had a sensitivity of 88% and a specificity of 60% for metastatic disease when compared with histopathological evaluation. The detection limit for lymph node metastases was approximately 6 mm, which is similar to the [^{18}F]FDG and a consequence of the spatial resolution of the PET camera. It is still unlikely that ^{18}F-FLT PET could be a suitable alternative to [^{18}F]FDG PET in melanoma patients with stage III disease [138].

Another PET compound receiving particular interest in melanoma is [^{18}F]fluoro-L-dopa (^{18}F-DOPA). Experimental studies have shown that ^{18}F-DOPA is incorporated into melanin and therefore represents an indicator of melanogenesis [139]. In a study of 11 pretreated patients with metastatic melanoma studied with ^{18}F-DOPA [^{15}O]water and [^{18}F]FDG PET, ^{18}F-DOPA PET was found to provide different information from [^{18}F]FDG PET because its uptake was not perfusion dependent, and the detectability of metastases was enhanced when both tracers were used (combined sensitivity of 95%). ^{18}F-DOPA PET could therefore be helpful to increase the accuracy of PET for therapy management in those patients with treated metastases and negative [^{18}F]FDG findings [140].

^{18}F-Galacto RGD (specific for a beta-integrin found in tumor vasculature and on melanoma cells) is another PET tracer that has been investigated in a clinical setting. In a study of 19 patients, 7 of whom had malignant melanoma, most known lesions were identified; however, intensity of uptake varied, most likely related to differing levels of a b-integrin found in tumors [141]. Additional PET tracers including ^{18}F-*N*-(2-(diethylamino)ethyl)-6-fluoronicotinamide have been shown to have promise in preclinical studies [142]. Further studies are required to define the utility of non-[^{18}F]FDG PET tracers in melanoma.

Conclusions

Nuclear medicine has a pivotal role to play in the management of patients with melanoma, including initial staging, restaging, assisting in therapy selection, treatment response assessment, and surveillance. Lymphoscintigraphy has a major role in sentinel node identification, and SPECT/CT provides improved lesion detection and anatomical localization in this clinical setting. In initial staging, [^{18}F]FDG PET has an important role in detecting extent of metastatic spread beyond microscopic locoregional nodal involvement and has a potential role in evaluating AJCC stage II patients with thick primary tumors or high risk factors and in patients with stage III disease. Published guidelines clearly indicate the importance of PET in staging patients with stage IV disease and assisting in treatment decisions. Studies comparing PET with [^{18}F]FDG PET/CT have convincingly shown the improved accuracy of [^{18}F]FDG PET/CT over PET alone. In restaging, PET may be indicated where there are suspicious clinical symptoms, intransit disease or palpable lymphadenopathy, or other suggestions of possible locoregional or metastatic disease. PET clearly impacts on patient management and can guide treatment decisions. Although there is controversy over the role of PET in surveillance, the sensitivity of [^{18}F]FDG PET/CT makes it valuable in patients with high-risk disease. The use of new PET tracers may assist in more accurate staging of disease in the future and assist in developing biologic therapies targeted to specific oncogenic pathways in melanomas.

Abstract

Pediatric cancers are defined as cancers occurring before the age of 15 years and account for only 2% of all cancers. Intracranial tumors are the most common solid neoplasms in children. Although [^{18}F]FDG uptake is associated with more malignant and aggressive tumor types, [^{18}F]FDG-PET is not routinely used for the clinical management of pediatric brain tumors. PET/MRI coregistration/image fusion improves localization of the lesion. [^{18}F]FDG-PET is also helpful to differentiate indolent and active components of the lesion and to improve the diagnostic yield of stereotactic biopsies and the accuracy of the radiosurgical dosimetry planning.

Lymphomas account for 10–15% of all childhood malignancies and are the third most common cause of cancer. Non-Hodgkin's lymphoma is more frequent. Staging of Hodgkin's lymphoma (HL) is performed according to the Cotswold revision of the Ann Arbor classification. Non-Hodgkin's lymphoma in childhood is significantly different from adults. The predominant subtypes are Burkitt's lymphoma, large B-cell lymphoma, and primary mediastinal B-cell lymphomas, followed by lymphoblastic lymphoma and anaplastic large-cell lymphoma. Most cases are extensive at diagnosis, corresponding to stages 3 and 4 of the St. Jude Children's Research Hospital

classification (Murphy staging). Contrast-enhanced diagnostic CT (ce-CT) or MRI together with thoracic CT remains mandatory at least at diagnosis (performed either simultaneously with [^{18}F]FDG-PET by using hybrid PET/CT or PET/MRI scanners or separately). Diagnostic CT reliably detects enlarged lymph nodes, and contrast media are required to accurately distinguish lymphadenopathy. Diagnostic CT also allows detailed evaluation of the pulmonary parenchyma, pleura, and pericardium. Ultrasonography has a definite role in both initial evaluation and follow-up of superficial lymph nodes and is an effective method to detect testicular infiltration and to explore liver and spleen. Chest radiography remains useful in HL to classify disease as "bulky" or "nonbulky." MRI is superior to ce-CT for evaluation of the bone marrow, liver, soft tissue, and central nervous system.

^{67}Ga-citrate scintigraphy and bone scintigraphy have been replaced by [^{18}F]FDG-PET/CT or PET/MRI, which depicts nodal and extranodal disease as well as focal bone marrow disease. The role of [^{18}F]FDG-PET is well established to stage HL before treatment. Early response assessment can be evaluated by interim PET in HL. When interim PET is negative, no other examination needs to be performed at the end of therapy in the absence of clinical signs. Systematic [^{18}F]FDG-PET is not indicated during follow-up.

In non-Hodgkin's lymphoma, [^{18}F]FDG avidity is high for Burkitt's lymphoma, large B-cell lymphoma, lymphoblastic lymphoma, and anaplastic large-cell lymphoma. The main indications for [^{18}F]FDG-PET in children with non-Hodgkin's lymphoma are inconclusive. However, [^{18}F]FDG-PET appears to be a useful tool for characterization of residual masses, as no reliable CT or MRI criteria are available for distinguishing residual disease from fibrosis or necrosis.

Wilms' tumor is the most common renal malignancy in childhood. The diagnostic workup includes a CT or MRI scan of the abdomen and pelvis, lymph nodes, and intra-abdominal or pelvic tumor deposits. A Doppler ultrasound is recommended to evaluate if there is a tumoral thrombus in the renal vein and inferior vena cava. For the detection of bilateral disease and the assessment of nephroblastomatosis representing premalignant lesions, MRI is the imaging modality of choice. ^{123}I-MIBG scintigraphy can be very helpful for the differentiation of neuroblastoma from Wilms' tumor. There is no major role for [^{18}F]FDG-PET in these patients.

Neuroblastoma accounts for about 8% of pediatric malignancies and is responsible for 15% of cancer deaths in children. It arises from the neural crest cells, and the tumor is usually situated in the adrenal gland or anywhere else along the sympathetic nervous system chain. Staging is crucial in order to choose the appropriate treatment. Imaging of neuroblastoma consists of ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and ^{123}I-MIBG scintigraphy. ^{123}I-MIBG is sensitive and specific for the detection of neuroblastoma involvement. [^{18}F]FDG-PET is less sensitive than ^{123}I-MIBG scintigraphy in neuroblastoma patients. However, in any case of a discrepancy between ^{123}I-MIBG scintigraphy and morphological imaging (CT and/or MRI), [^{18}F]FDG-PET should be considered for further tumor evaluation.

Sarcomas are a heterogeneous group of neoplasms with different tumor biology, malignancy, and therapeutic options. The two major groups of primary bone tumors in children and adolescents are osteosarcomas and the Ewing family of tumors. As regards soft-tissue sarcomas, the most common histologic entities in children and adolescents are rhabdomyosarcoma, extraosseous Ewing sarcoma and peripheral neuroectodermal tumor, synovial sarcoma, neurofibrosarcoma, fibrosarcoma, and leiomyosarcoma. Langerhans cell histiocytosis (LCH) is a proliferation of Langerhans-type histiocytes. Despite its clonal origin, there is no definitive proof of malignancy. Primary bone tumors are best classified using a conventional planar x-ray. Local CT and MRI supply further information on tumor

localization and extension. Bone scintigraphy is very sensitive in the detection of osseous metastases of osteosarcoma, and even soft-tissue metastases are often visible on the bone scan.[^{18}F]FDG-PET has a high accuracy in detecting primary sarcomas and its metastases, with the exception of pulmonary metastases. Therefore, a thoracic CT is additionally necessary for staging sarcomas.

Cancer in children is much less common than in adults. Pediatric cancers, defined as cancers occurring before the age of 15 years, account for only 2% of all cancers [1]. Nevertheless, cancer is the second most common cause of death in children in developed countries. However, improvement of treatment strategies has increased the probability of survival. For example, EUROCARE data showed an 8% reduction in the relative risk of death when comparing the 2000–2002 time span to the 1995–1999 period. Also in the interval from 1995 to 2002, pediatric cancer patients had an overall 5-year survival of 81% in Europe and the USA (Table 1) [2].

The most common tumors among the under 15-year-olds are leukemias, at 34%, brain tumors, at 23%, and lymphomas, at 12%, according to the International Classification of Childhood Cancer [2]. The most frequent single diagnoses are acute lymphoblastic leukemia, astrocytoma, neuroblastoma, non-Hodgkin's lymphoma, and nephroblastoma. There is considerable variation between countries. Incidence rates range from 130 (British Isles) to 160 cases (Scandinavian countries) per million children. Incidence rates have shown an increase over time since the middle of the last century. In Europe, the yearly increase averages 1.1% for the 1978–1997 period and ranges from 0.6% for the leukemias to 1.8% for soft-tissue sarcomas [2].

Nuclear medicine is important in the diagnosis, staging, and long-term surveillance of a number of pediatric cancers. Skeletal scintigraphy is used to evaluate primary skeletal cancers, such as osteosarcoma and Ewing sarcoma, and nonskeletal

Table 1 Five-year survival rates for childhood cancer (0–14 years) according to ACCIS (European Automated Childhood Cancer Information System 1988–1997) and SEER (US-Surveillance, Epidemiology and End Results 1985–1999)

cancers, such as neuroblastoma, medulloblastoma, rhabdomyosarcoma, and retinoblastoma. Meta-iodobenzylguanidine scintigraphy is valuable in examinations of children with neuroblastoma, and [^{18}F]FDG-PET/CT is useful in lymphoma, thymoma, and embryonal cell tumors. Recent years have witnessed a growing role of [^{18}F]FDG-PET/CT in the management of children with cancer. The conventional staging evaluation of these children includes magnetic resonance imaging (MRI) or CT for detection of the primary tumor and regional nodal beds, chest CT for detection of pulmonary metastases, and technetium-99m methyldiphosphonate (^{99m}Tc-MDP) bone scan for detection of bone metastases. The Response Evaluation Criteria in Solid Tumors (RECIST), introduced in 2000 as an alternative to the World Health Organization (WHO) criteria, provides a standard, reproducible, and objective method of assessing the efficacy of solid tumor therapies [3]. Unfortunately, they rely on changes in unidimensional tumor measurements to define tumor response or progression. In this regard, it must be emphasized that solid malignancies, such as bone sarcomas and cystic soft-tissue sarcomas, may respond well to chemotherapy without substantially changing in size. Furthermore, sarcomas do not shrink or grow in a uniform manner; therefore, unidimensional measurements may not accurately reflect response or progression of the tumor. Tumors that respond poorly to therapy may be followed for months before a unidimensional measurement increases significantly. Meanwhile, patients are exposed to toxic but ineffective chemotherapy and are likely to have a diminished probability of survival. [^{18}F]FDG-PET, on the other hand, provides a three-dimensional assessment of viable tumor tissue based on metabolic activity. A decrease in tumor glucose uptake after treatment suggests a reduction in the number of viable tumor cells or a decrease in metabolism of the tumor tissue. Therefore, [^{18}F]FDG-PET may offer a more sensitive evaluation of the response or progression of some pediatric solid malignancies than anatomic imaging modalities [4]. It should be noted that virtually all stand-alone PET scanners have recently been replaced with integrated hybrid PET/CT scanners that intrinsically allow the combination of the functional PET data with the morphological data of CT. Hybrid PET/CT imaging has shown clear advantages over PET imaging alone, by improving correction for tissue attenuation as well as by providing better anatomical resolution and correlation, thus resulting in better characterization and localization of the lesion and in reduction of the doubtful results [5, 6].

Interest is growing also in the use of hybrid PET/MRI scanners, although the diffusion of this technology is currently still limited by high cost and complexity of operation. Nevertheless, this novel imaging modality is emerging as an especially attractive technique for application in pediatric patients, because it does not involve the radiation burden pertaining to the CT component of the PET/CT scanners. This feature is particularly relevant in children with cancer, who frequently need to perform periodic diagnostic tests [7, 8]. Although several studies have shown the feasibility of PET/MRI in pediatric oncology, clear diagnostic advantages over PET/CT have not been established, also because of the paucity of studies comparing head-to-head in the same patients (especially in the pediatric age group) the diagnostic performances of PET/MRI with those of PET/CT [9–13]. Further validation studies are therefore needed [14, 15].

Pediatric Brain Tumors

Epidemiology

Intracranial tumors are the most common solid neoplasms in children and the second most common malignancy of childhood after leukemia. Among children younger than 19 years, the prevalence rate for all pediatric brain tumors was 9.5 per 10,000, while the incidence rate was 29.1 cases per 1,000,000 [16].

Pediatric brain tumors differ from adult tumors on various grounds. About 60–70% of all pediatric brain tumors, including astrocytomas, medulloblastomas, and ependymomas, develop in the infratentorial compartment. The remaining 30–40% of tumors are supratentorial and consist of gliomas, optic pathway tumors, hypothalamic tumors, and

craniopharyngiomas. The reason why pediatric brain tumors have a propensity to occur in the posterior fossa has not yet been elucidated.

In contrast to those that occur in adults, most gliomas that occur in children are low-grade gliomas. Moreover, in the pediatric age mixed (glioneuronal) and atypical (xanthoastrocytoma) tumors are frequent as also frequent are lesions with very low or questionable evolving potential (hamartoma). Young age is a favorable prognostic factor for malignant gliomas. In adults, the majority of high-grade gliomas are primary and show amplification of the epidermal growth factor receptor (EGFR) gene, which encodes a tyrosine kinase involved in cell replication. In contrast, in pediatric patients high-grade gliomas more commonly derive from low-grade gliomas and often have mutations in TP53 (a gene encoding for p53 protein) but seldom display amplification of EGFR [17, 18].

Many types of supratentorial pediatric brain tumors are well delineated; they have a moderate tendency to infiltrate neighboring tissue and are usually amenable to total resection. However, some pediatric brain tumors may not be accessible surgically because they are close to vital brain structures. This typically occurs for medulloblastoma, a primitive neuroectodermal tumor that originates from the cerebellum, close to the brainstem and to the fourth ventricle.

Finally, 5–10% of brain tumors in childhood are thought to be linked to a genetic predisposition, while such proportion is much lower in adults. Hereditary brain tumors occur in some familial cancer syndromes, such as the Li-Fraumeni syndrome. At variance, hereditary brain tumors in adult subjects are associated with rare hereditary syndromes, such as tuberous sclerosis, neurofibromatosis types 1 and 2, and familial adenomatous polyposis.

Symptoms

The diagnosis of brain tumor may be challenging in children because tumor signs and symptoms may resemble those of more common inflammatory or infectious diseases. Recurrent bouts of headache, nausea, or vomiting without focal deficits are frequently observed in children. For medulloblastoma early symptoms are secondary to increased intracranial pressure due to blockage of the fourth ventricle. The child typically becomes lethargic, with repeated episodes of vomiting and morning headache. In more advanced stages, the child develops stumbling gait, frequent falls, diplopia, papilledema, and sixth cranial nerve palsy.

[^{18}F]FDG PET Scan

The preparation and acquisition procedures are very similar to those adopted for adult studies. Systemic sedation with benzodiazepines may be necessary for very young children, to ensure compliance during the scan. Dynamic scans are rarely performed.

The most important issue in pediatric PET scanning is to limit the radiation burden. The procedure guidelines of the Society of Nuclear Medicine and Molecular Imaging recommend an administered activity of [^{18}F]FDG ranging from 5 to 10 MBq per kg of body weight, from a minimum activity of 37 MBq to a maximum of 750 MBq [19]; nevertheless, with the high sensitivity of modern PET/CT scanners, lower activities can be administered without reducing diagnostic quality of the PET scans. Good hydration and early urine voiding are recommended to reduce bladder toxicity. The absorbed dose to the brain in infants is about 0.24 $\pm$ 0.05 mGy/MBq, a higher value than in adult subjects, because of the higher glucose consumption in the infant brain than in the adult brain [20].

Experience with [^{18}F]FDG-PET

The very first study in a relatively large population of pediatric patients with brain tumor was reported by Hoffman et al. in 1992 [21]. They studied 17 pediatric patients with posterior fossa brain tumors with [^{18}F]FDG-PET. [^{18}F]FDG uptake was visually ranked by two observers, and the results were correlated to tumor histology. Increased [^{18}F]FDG uptake was associated with more malignant and

aggressive tumor types. Heterogeneity of [^{18}F]FDG uptake was associated with previous therapy, including radiation therapy and chemotherapy. The authors concluded that [^{18}F]FDG-PET would likely be an important adjunct in the management of pediatric posterior fossa tumors and predicted a rapid dissemination of PET technology for pediatric applications [21].

Nevertheless, PET has not become routinely used for the clinical management of pediatric brain tumors. Literature remains relatively scarce on this matter, and the difference between adult and pediatric studies cannot be merely attributed to differences in prevalence of the disease [21].

Borgwardt et al. studied 38 untreated pediatric patients with primary CNS tumors using PET with [^{18}F]FDG and, when possible, (n = 16), with ^{15}O-water at rest. Image processing included coregistration to MRI in all patients. The [^{18}F]FDG uptake in tumors was semiquantitatively estimated with a region-of-interest approach. They found a positive correlation between [^{18}F]FDG uptake and malignancy grading. On the other hand, there was no correlation between blood flow as measured with ^{15}O-water and histological grade, a finding that was attributed to some uncoupling between glucose metabolism and blood flow. Image fusions based on digital PET/MRI coregistration improved the information on the tumor location in 90% of cases. The results of the PET scan altered management in 77% of the patients [12].

Pirotte et al. reported their experience at the Erasme Hospital Pediatric Center, where between 1995 and 2005 they examined with [^{18}F]FDG-PET about 400 pediatric patients with brain tumor. In their retrospective analysis, they included 126 patients in whom pre- and postoperative MR imaging showed limitations for assessing the evolving nature of an incidental lesion, selecting targets for biopsy, and delineating tumor tissue for surgical resection. In this group of patients (about one-third of the whole case series), PET was expected to be most useful. They found that PET was helpful on several grounds, i.e., to (1) take a more appropriate decision in incidental lesions by detecting tumor/evolving tissue, (2) better differentiate indolent and active components of the lesion, (3) improve target selection and diagnostic yield of stereotactic biopsies, especially when performed in eloquent areas such as the brainstem or the pineal region, (4) provide prognostic information, (5) better delineate ill-defined tumor borders, (6) increase the number of tumor resections and the amount of tumor tissue surgically removed, (7) improve detection of tumor residues in the operative cavity at the early postoperative stage, (8) facilitate the decision of early second-look surgery for optimizing the radical resection, and (9) improve the accuracy of the radiosurgical dosimetry planning [22].

Utriainen et al. used PET [^{18}F]FDG and [^{11}C]MET to ascertain whether metabolic characteristics could be used as an index of clinical aggressiveness. SUV (standardized uptake values) for both tracers were compared with histopathology and selected histochemical features. The accumulation of both [^{18}F]FDG and [^{11}C]MET was significantly higher in high-grade than in low-grade tumors, but a considerable overlap was found. High-grade tumors showed higher proliferative activity and vascularity than the low-grade tumors. In univariate analysis, [^{18}F]FDG SUV, [^{11}C]MET SUV, and apoptotic index were independent predictors of event-free survival [22].

Kruer et al. [23] examined with [^{18}F]FDG-PET a cohort of 46 children/adolescents with low-grade astrocytomas (LGAs, WHO grade 1 or 2) in order to identify LGAs at risk for progressive disease (PD); they found that tumors with [^{18}F]FDG hypermetabolism were significantly more likely to demonstrate aggressive behavior and PD.

Galldiks et al. [24] investigated the diagnostic accuracy of [^{11}C]MET-PET to distinguish between tumorous and nontumorous lesions in 39 children and adolescents. [^{11}C]MET-PET was able to distinguish brain tumors and nontumorous brain lesions with a high sensitivity (83%) and specificity (92%). The authors suggested that [^{11}C]MET-PET may be helpful when results of routine anatomic diagnostic imaging are not sufficient enough to obtain a treatment decision and planning.

In pediatric patients with central nervous system (CNS) germinomas, the diagnostic utility of [^{11}C]MET was also recently demonstrated by Okochi et al. [25].

Despite these promising results, both [^{18}F]FDG and [^{11}C]MET PET are still not routinely used for clinical evaluation of pediatric brain tumors. The physiologic high [^{18}F]FDG uptake of the normal brain cortex limits tumor detection, especially in low-grade gliomas [26], whereas the short half-life (20 min) of [^{11}C]MET limits its application to centers with an on-site cyclotron.

In the last few years, new fluorinated tracers have emerged as alternative radiolabeled compounds for characterizing pediatric brain tumors. Among them, ^{18}F-DOPA was found to be a multitargeted molecule in children, since it can be used for primary/recurrent brain tumors [27, 28], for neuroblastoma diagnosis, prognosis, and surveillance [29], including detection of CNS metastasis [30], and in nontumoral conditions such as congenital hyperinsulinism [31], with a potential impact on healthcare cost optimization.

Recent findings suggest that also ^{18}F-FET imaging is able to detect metabolic active tumor tissue within diffuse tumors or pretreated lesions [32] and can be used for target selection and to guide surgical treatment in pediatric brain tumors [33].

Childhood Lymphoma

Lymphoma accounts for 10–15% of all childhood malignancies and is the third most common cause of cancer, after leukemia and brain tumors. Non-Hodgkin's lymphoma (NHL) is more frequent than Hodgkin's lymphoma (HL) (about 60% and 40%, respectively) [34].

Hodgkin's Lymphoma

HL, exceptional before the age of 5 years (median age: 14 years), usually presents with asymptomatic enlarged lymph node(s). The malignant cell in HL is the Reed-Sternberg cell, located in the tumor masses within a background of inflammatory cells and fibrosis. Four histologic subtypes of HL are described: lymphocytic predominance, mixed cellularity, lymphocytic depletion, and nodular sclerosis. Nodular sclerosis is the most common subtype, affecting 60% of children, whereas the lymphocytic depletion subtype is very rare. During therapy, residual masses are frequent and usually correspond to fibrosis and/or necrosis [35], especially in the nodular sclerosis subtype of HL because of its abundant fibrotic component [36]. Extent of disease at staging must be evaluated as accurately as possible because treatment is related not only to stage but also to each site of disease in order to plan conformal radiotherapy when it is indicated.

According to the Cotswold revision of the Ann Arbor classification, stage I is defined as involvement of a single lymph node region. Stage II has involvement of two or more lymph node regions on the same side of the diaphragm. Stage III has involvement of lymph node regions on both sides of the diaphragm. Stage IV has extranodal involvement, such as bone, liver, or lung disease. Involvement of the spleen is considered to be lymph node involvement. Each stage is also classified by the presence or absence of symptoms. "A" indicates that the patient is asymptomatic; "B" indicates that the patient has at least one of the following systemic symptoms: inexplicable weight loss of more than 10% within the last 6 months, unexplained persisting or recurrent temperature above 38 °C, and/or drenching night sweats. "E" stage is defined as involvement of a single extranodal site contiguous or proximal to known nodal sites. Clinical and imaging evaluation must be performed at the end of therapy to confirm that therapy has been fully effective and has achieved complete response.

Major therapeutic progress has been made in HL, with current cure rates ranging from 90% to 95% for all stages [37, 38]. Most treatment regimens for childhood HL consist of chemotherapy with or without radiotherapy, with current efforts to reduce the use of radiotherapy and late effects related to cumulative doses of cytotoxic agents [39].

Treatments for pediatric HL can induce important long-term side effects on both quality of life and on life expectancy per se; for these reasons, many studies aim at defining protocols capable of minimizing treatment-related toxicity without compromising the cure rate [40, 41].

Non-Hodgkin's Lymphoma

NHL in childhood is significantly different from NHL in adults, as, in almost every case, it corresponds to high-grade malignancies with frequent invasion of the bone marrow and central nervous system [42]. In children, the predominant subtypes are Burkitt's lymphoma, large B-cell lymphoma, and primary mediastinal B-cell lymphomas, followed by lymphoblastic lymphoma and anaplastic large-cell lymphoma [43]. NHL is very rare before the age of 2 years and has a peak incidence at the age of 7 years. NHL requires urgent treatment, consisting of combination chemotherapy (without radiotherapy) and neuromeningeal prophylaxis of recurrences by intrathecal chemotherapy. Most cases are extensive at diagnosis, corresponding to stages 3 and 4 of the St. Jude Children's Research Hospital classification (Murphy staging) [44].

Stage I disease is defined as a single tumor or nodal area outside of the abdomen and mediastinum. Stage II is a single tumor with regional lymph node involvement, two or more tumors or nodal areas on one side of the diaphragm, or a primary gastrointestinal tract tumor (completely resected) with or without regional node involvement. Stage III consists of tumors or lymph node areas on both sides of the diaphragm, or any primary intrathoracic (mediastinal, pleural, or thymic disease) or extensive intra-abdominal disease, or any paraspinal or epidural disease. Stage IV includes central nervous system and/or bone marrow involvement, regardless of other sites of involvement. Residual masses after treatment are less frequent in NHL than in HL but more frequently correspond to a persistent active disease [45].

The prognosis of childhood NHL has improved over the past 20 years with a 2-year event-free survival of 95% for B-cell lymphoma (Burkitt's lymphoma and large-cell lymphoma) [46, 47], 75% for lymphoblastic lymphoma [48], and 70% for anaplastic large-cell lymphoma [49].

Role of Nuclear Medicine Techniques

^{67}Ga-citrate scintigraphy and bone scintigraphy have largely been replaced by [^{18}F]FDG-PET/CT or – recently – PET/MRI. Compared to ^{67}Ga-citrate scintigraphy, [^{18}F]FDG-PET detects more disease sites [50, 51], especially in the abdomen, where the diagnostic performance of gallium scintigraphy is limited by physiologic bowel uptake. The other advantage of [^{18}F]FDG-PET over ^{67}Ga-citrate scintigraphy is same-day imaging with PET (in contrast with imaging over 2 or 3 days for gallium) and a more favorable dosimetry [51]. Bone scintigraphy is also less sensitive than [^{18}F]FDG-PET to detect bone and bone marrow involvement [52].

[^{18}F]FDG-PET/CT and PET/MRI

The majority of PET systems now consist of hybrid PET/CT scanners which use the CT portion of the examination for attenuation correction and anatomic localization of lesions identified on PET. Low-dose CT (typically 5 mA at 80 kVp for attenuation correction/anatomic correlation, which may be increased to several hundred mA for thin slice diagnostic quality contrast-enhanced CT) that is usually performed with PET has been shown to be more accurate in adults with lymphoma than PET alone [53]. However, contrast-enhanced diagnostic CT (ce-CT) or MRI with thoracic CT remains mandatory at least at diagnosis (performed either simultaneously with PET or separately).

Diagnostic CT and MRI reliably detect enlarged lymph nodes, and contrast media are required to accurately distinguish lymphadenopathy from other structures, especially in the abdomen and pelvis due to the lack of retroperitoneal fat in children [54]. Diagnostic CT also allows detailed evaluation of the pulmonary parenchyma, pleura, and pericardium.

[^{18}F]FDG-PET/CT must also be considered in relation to:

- Ultrasonography, which has a definite role in both initial evaluation and follow-up of superficial lymph nodes. It is also the best method to detect testicular infiltration [54] and an effective imaging method to explore liver and spleen [54].
- Chest radiography, which remains useful in HL to classify disease as "bulky" or "nonbulky," which constitutes an important prognostic factor. Disease is classified as "bulky" when the ratio of the largest tumor diameter to chest diameter is greater than one-third.
- MRI is superior to ce-CT for evaluation of the bone marrow [55], liver, soft tissue, and central nervous system [56]. MRI is currently performed as a complement to other imaging modalities, but its role as a whole-body imaging technique is under evaluation for pediatric and adolescent lymphoma staging [57]. However, whole-body MRI is increasingly performed by using hybrid PET/MRI scanners instead of PET/CT scanners in children [11].

[^{18}F]FDG-PET frequently detects nodal and extranodal disease sites that are missed by conventional staging methods and improves the characterization of lesions that are equivocal on other types of imaging. [^{18}F]FDG-PET is especially accurate to detect bone marrow disease, even in the case of negative iliac crest bone marrow biopsy.

Various studies in adults indicate that [^{18}F]FDG-PET for the detection of bone marrow involvement is superior not only to conventional imaging modalities but also to bone marrow trephine biopsy [51, 58, 59]. This appears to be true also in children [51, 60–64], bone marrow biopsy being now not yet indicated in HL and replaced by [^{18}F]FDG-PET [65]. When bone marrow involvement is detected by PET, it is often not detected by diagnostic CT and must be confirmed by another modality, preferably MRI or bone scan when MRI is not available. In contrast, [^{18}F]FDG-PET/CT can understage disease, especially in the case of lung sites (more reliably detected by diagnostic CT than by PET) [64] and because some lesions, even large lesions, may not be [^{18}F]FDG avid, while other lesions take up [^{18}F]FDG. Careful comparison of functional and morphologic imaging therefore remains essential.

Indications for [^{18}F]FDG-PET/CT

The role of [^{18}F]FDG-PET in childhood lymphoma has been specifically assessed in short series [6, 50, 52, 61, 64–76] and review articles [51, 77–80]. The objectives of [^{18}F]FDG-PET are different in HL and NHL and will be discussed separately.

Hodgkin's Lymphoma

HL has a reported [^{18}F]FDG avidity of 97–100% (defined as at least one [^{18}F]FDG-avid HL site detected, on a per-patient basis), according to four studies, comprising a total of 489 patients (adults and children), with an unspecified proportion of children [81–84]. No difference in intensity of [^{18}F]FDG uptake is observed according to HL subtypes [85], and the intensity of uptake at diagnosis does not appear to have any prognostic value.

[^{18}F]FDG-PET at staging must be performed before starting chemotherapy, as [^{18}F]FDG uptake very rapidly reflects the metabolic response to chemotherapy. In children with aggressive disease, [^{18}F]FDG-PET must also be performed before corticosteroid therapy, as HL is a malignancy comprising a large background of inflammatory cells [86, 87].

Initial Staging

In adults, [^{18}F]FDG-PET/CT and -PET/MRI is useful for pretreatment staging. PET/CT cannot replace diagnostic ce-CT, but it can provide complementary information, potentially resulting in a modification of disease stage (usually upstaging) in about 15–20% of adult patients, with an impact on management in about 5–15% [88]. In children, [^{18}F]FDG-PET modified the stage in 10–23% of patients [51] (Fig. 1). Apart from its role in staging and radiation therapy planning pretreatment, [^{18}F]FDG-PET/CT or PET/MRI is also essential because it provides a

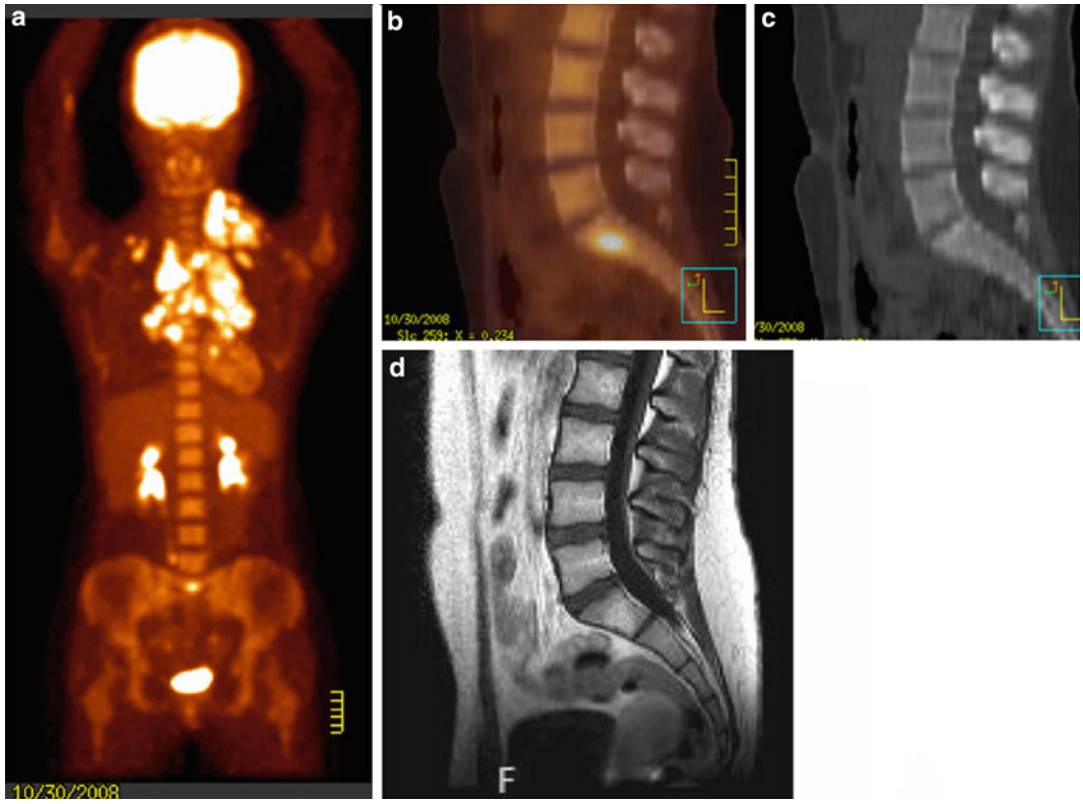

Fig. 1 Hodgkin's lymphoma in a 14-year-old girl, classified stage II before [^{18}F]FDG-PET/CT with extensive supradiaphragmatic lymph node involvement. [^{18}F]FDG-PET/CT showed an unexpected focus in the sacral bone marrow (**a**, **b**), with no abnormality on CT (**c**). Bone marrow involvement was confirmed by MRI (**d**), leading to upstaging of the disease from stage II to stage IV

reference, facilitating interpretation of subsequent treatment evaluation with PET, as recurrences usually occur in previously involved lesions, and de novo sites of uptake observed during follow-up must be primarily suspected to be false-positive [89].

Monitoring of Response to Therapy

As HL is a curable disease, it is essential to ensure that therapy has been fully effective at the end of treatment. [^{18}F]FDG-PET/CT or PET/MRI is routinely performed for this purpose, usually after completion of chemotherapy and before radiotherapy, as a negative [^{18}F]FDG-PET is a reliable indicator of complete remission [88] (Fig. 2). The metabolic information provided by [^{18}F]FDG-PET at the end of therapy is very important, as assessment of response by morphologic imaging modalities is particularly difficult, due to the generally slow and protracted regression of the size of enlarged lymph nodes [51]. Moreover, in HL, malignant cells comprise only a small fraction of the tumor volume, which is mostly composed of reactive infiltrating cells not directly affected by antineoplastic therapy [90].

Early response assessment can also be evaluated by [^{18}F]FDG, as PET has been shown to be an effective prognostic tool in adults with HL [90]. In pediatric HL interim [^{18}F]FDG-PET/CT, after two to three cycles of standard chemotherapy, has shown high negative predictive value, and therefore an early negative scan is a reliable indicator for therapy response [67, 76]. Interim PET must not modify the scheduled therapy except in the context of a controlled clinical trial [91]. When interim PET is negative, no other PET needs to be performed at the end of therapy in the absence of clinical signs [92].

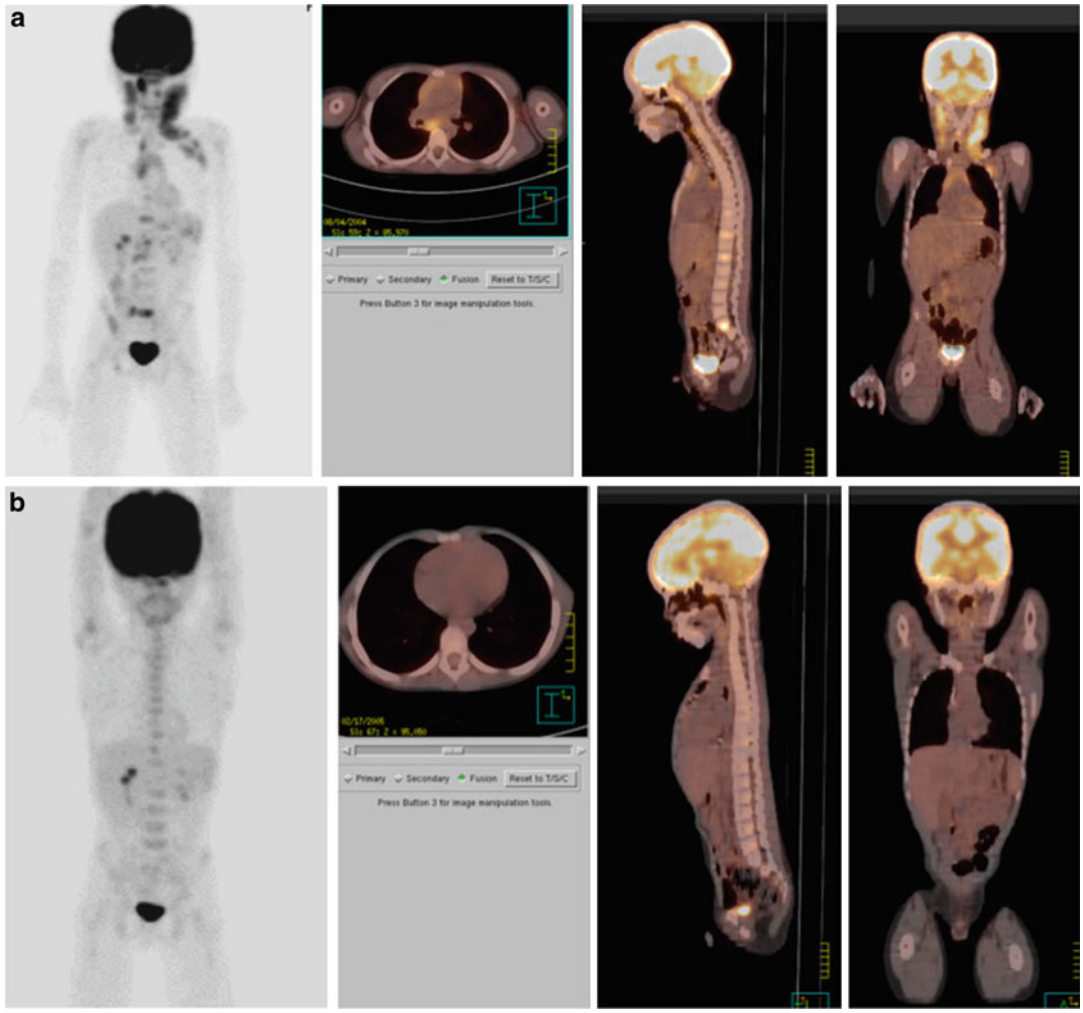

Fig. 2 Hodgkin's lymphoma stage IV (lymph node and bone marrow involvement) in an 8-year-old boy. [^{18}F]FDG-PET/CT at staging (**a**) and after completion of chemotherapy and before radiotherapy (**b**), with metabolic complete response. Persistent clinical remission 4 years after the end of therapy

Systematic [^{18}F]FDG-PET/CT is not indicated during follow-up because it can result in false positives [93], thus contributing to an increase in costs and radiation exposure in the absence of evident benefits [94–96]; therefore, [^{18}F]FDG-PET/CT must only be performed in the case of suspected recurrence.

Non-Hodgkin's Lymphoma

In contrast with HL, [^{18}F]FDG uptake cannot be considered to be constant in NHL. In adult NHL, [^{18}F]FDG uptake tends to be more intense in higher-grade lymphomas than in lower-grade lymphomas [97], and some low-grade NHL, especially T-cell lymphoma, present inconstant [^{18}F]FDG uptake [81]. As most NHLs in children are high-grade and aggressive tumors, it can be assumed that false-negative PET at staging would probably be very rare. However, no study has specifically assessed [^{18}F]FDG uptake according to the various subtypes of NHL in children. According to three studies [82, 83], based on a mixed population of adults and children, [^{18}F]FDG avidity (defined as

at least one [^{18}F]FDG-avid lymphoma site detected on a per-patient basis) was 100% for Burkitt's lymphoma (24/24), 97% for large B-cell lymphoma (294/303), 100% for lymphoblastic lymphoma (6/6), and 100% for anaplastic large-cell lymphoma (24/24), corresponding to the most frequent subtypes of NHL encountered in children. However, in a limited experience of [^{18}F]FDG-PET performed for NHL in 18 children, two false-negative [^{18}F]FDG-PET scans were reported in patients with anaplastic T-small-cell lymphoma, an uncommon subtype of anaplastic T-cell lymphoma [98].

[^{18}F]FDG-PET staging is frequently difficult to organize in a timely fashion and rarely performed due to the urgency of therapy for NHL in children. Moreover, and in contrast with HL, in which all disease sites must be precisely detected in order to plan therapy, the detection of all involved sites is less important in NHL, as treatment consists of high-dose intensive chemotherapy without radiotherapy. Nevertheless, an exception can be staging of Burkitt's lymphoma; in fact, since this subtype frequently occurs as a single site of disease, [^{18}F]FDG-PET can confirm the absence of other site of disease and thus be of help in choosing the initial therapy.

[^{18}F]FDG-PET is therefore rarely performed at staging in NHL and is not performed routinely during follow-up.

The main indications for [^{18}F]FDG-PET in children with NHL are inconclusive results of conventional imaging modalities, that is, suspicion of recurrence (Fig. 3) or characterization of residual masses after treatment [99]. [^{18}F]FDG-PET performed for these purposes can be difficult to interpret firstly because a reference [^{18}F]FDG-PET is usually not available for comparison (and there is no absolute certainty that the NHL subtype is able to take up [^{18}F]FDG). [^{18}F]FDG-PET can also be falsely positive in the presence of inflammation and/or necrosis, very frequent after surgery and chemotherapy for gut involvement in Burkitt's lymphoma [100].

However, [^{18}F]FDG-PET appears to be a useful tool for characterization of residual masses, as no reliable CT or MRI criteria are available for

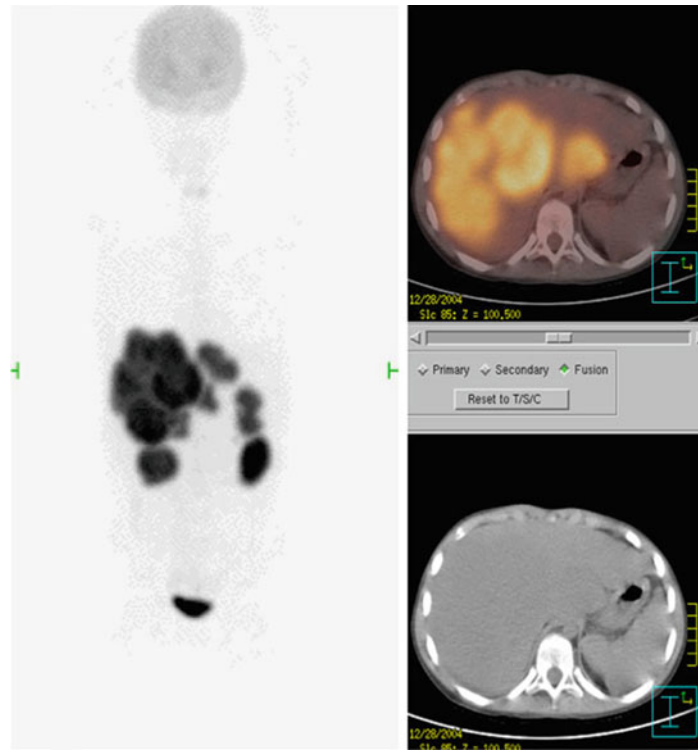

Fig. 3 Liver recurrence of Burkitt's NHL. Note the very high intensity of [^{18}F]FDG uptake by liver lesions, higher than physiologic brain uptake

distinguishing residual disease from fibrosis or necrosis [101]. In the presence of a posttreatment residual mass, negative [^{18}F]FDG-PET has been shown to be a reliable indicator of complete clinical remission [51, 79].

Limitations of [^{18}F]FDG-PET

False-Negative Results

It must be remembered that, even with the most recent PET scanners, [^{18}F]FDG-PET is unable to detect low-grade metabolic lesions measuring less than about 5 mm. Very small lung nodules, with minimal increased metabolic rates, are therefore more reliably detected by diagnostic CT than by PET [64]. During follow-up, persistence of microscopic active disease within residual masses also cannot be detected by PET. Hyperglycemia may also induce false-negative results by reducing [^{18}F]FDG uptake in the tumor [51].

Physiologic Uptake, Pitfalls, and False-Positive Results

Certain physiologic sites of [^{18}F]FDG uptake in children must be recognized. For example, physiologic [^{18}F]FDG uptake may be observed in the endometrium (during menstruations) and in the ovaries (usually at mid-cycle) in adolescent girls and should not be confused with residual or recurrent tumor in pelvic lymph nodes [102, 103]. Due to the increasing resolution of PET systems, some normal structures can now appear to be slightly active on PET, for example, spinal cord, especially in the two sites of physiologic anatomic enlargement, that is, cervical and lumbar regions [104].

In children thymus uptake of [^{18}F]FDG is frequent, physiologic, and enhanced by treatment. The physiologic appearance of thymus uptake is usually easily recognized because it is diffuse and moderately active and frequently has an inverted "V" shape. Sometimes, especially in the presence of an accessory gland, differentiation of normal thymic activity from tumor or inflammation may be difficult or impossible, and PET must then be compared with MRI, which is able to differentiate thymic tissue from recurrent lymphoma [51]. Characterization of the mass can be particularly difficult when ectopic thymic tissue is located in the neck [105].

Brown fat activation is also frequently seen in children. Brown fat is normally distributed in the neck, around the diaphragm, in the perinephric space, and in para-aortic and intercostal regions [102]. Brown fat activation is more easily recognized with hybrid PET/CT scanners (Fig. 4), as [^{18}F]FDG uptake corresponds to low density structures on CT. Nevertheless, even after comparison with CT images, interpretation remains difficult when brown fat activation occurs in previously involved sites. Brown fat activation can be prevented by keeping children warm prior to [^{18}F]FDG administration and during uptake, but these measures may not be sufficient. Benzodiazepine pretreatment may also reduce this activation [101]. More recently, beta-blockers have been shown to be particularly effective and can be used with the agreement of pediatric oncologists [106].

False-positive results are relatively frequent because [^{18}F]FDG is not specific for malignancy and increased uptake can occur in benign conditions associated with increased glycolysis, such as infection, inflammation, granulomatous disease, and more rarely benign tumors (e.g., Fig. 5).

In children and adolescents, false-positive results can be related to infectious mononucleosis [107] or vaccination. [^{18}F]FDG-PET was positive in draining axillary nodes close to the vaccination site in all ten patients recently vaccinated against the pandemic H1N1 virus [108].

False-Positive Results Can Also Be Treatment Induced

In patients treated with low-dose-involved field radiation, [^{18}F]FDG uptake can be slightly increased even months after therapy [102], but the uptake observed in a context of acute radiation pneumonitis can be intense [102].

Granulocyte colony-stimulating factor (GCSF) is a useful adjunct in patients receiving

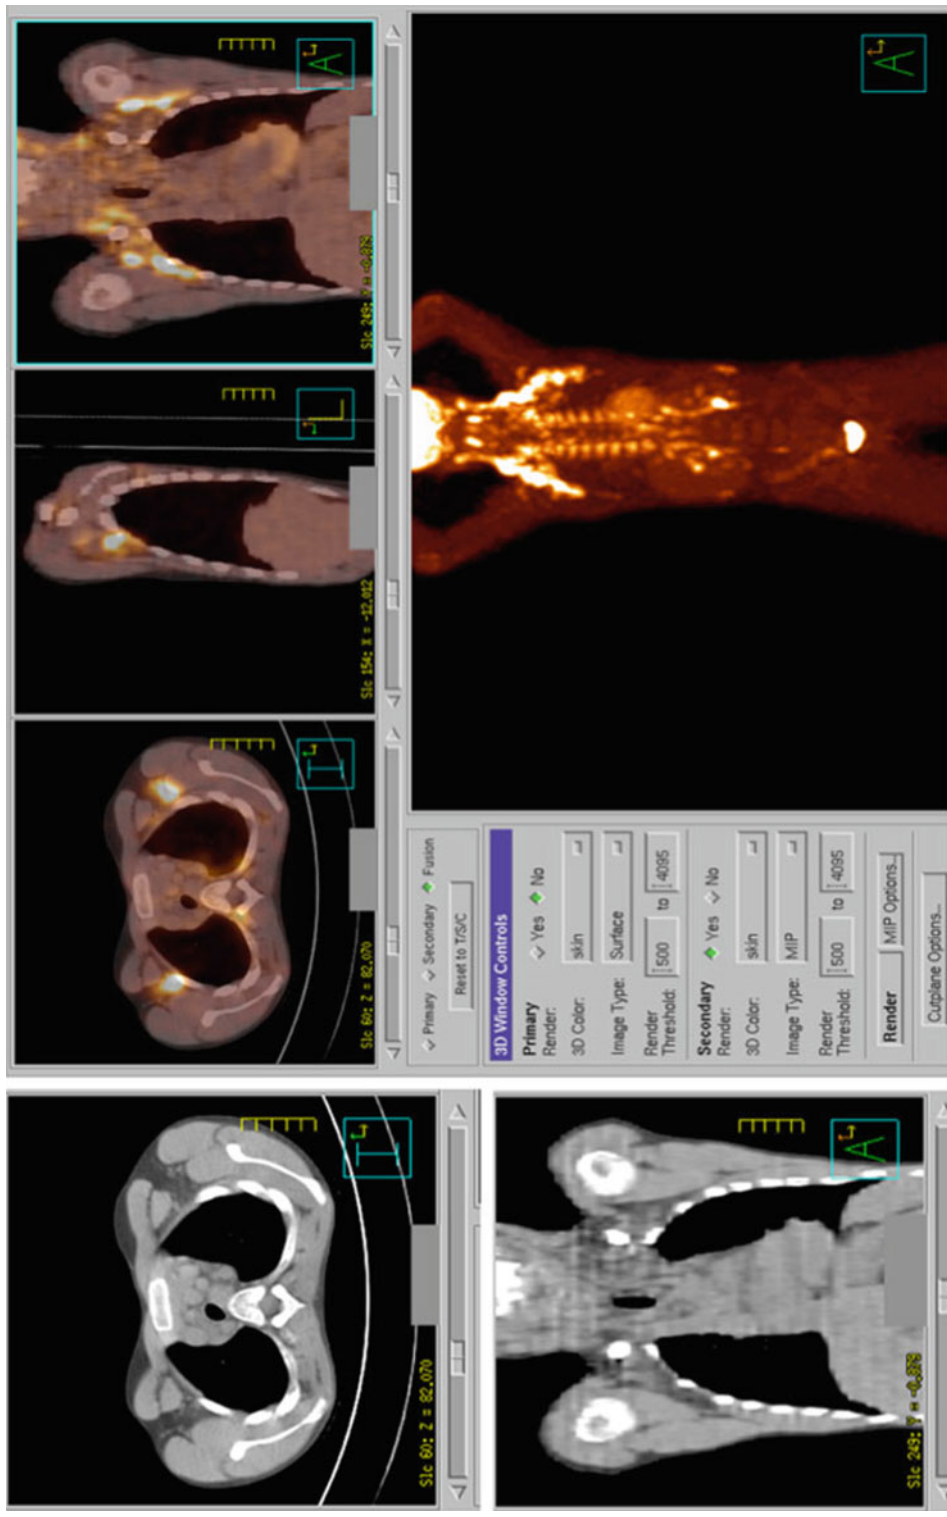

Fig. 4 Extensive brown fat activation. Correlative [^{18}F]FDG PET and CT imaging easily identifies the low density of fat on CT images

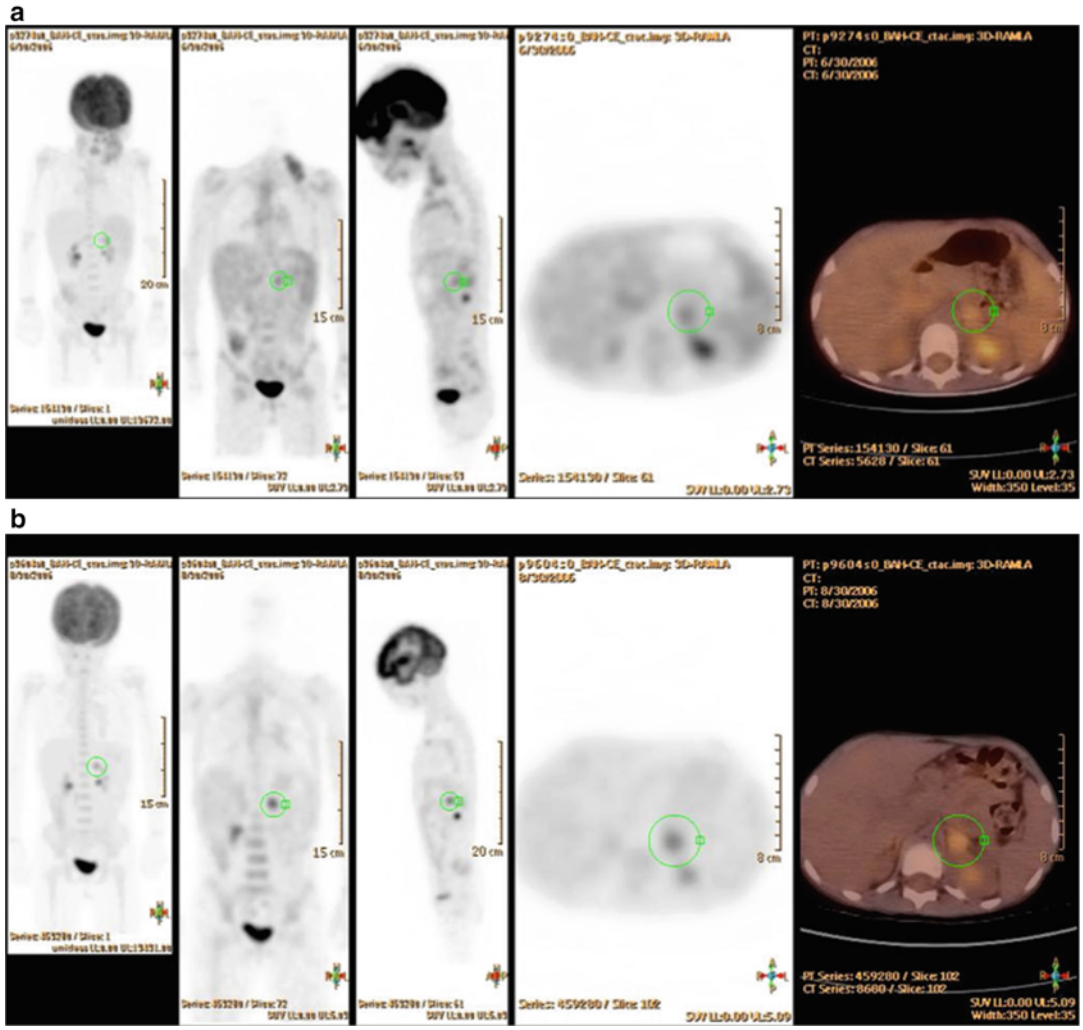

Fig. 5 Unexpected [^{18}F]FDG uptake in the left adrenal gland in a 5-year-old girl with stage II HL (supradiaphragmatic lymph node involvement), at staging (**a**) and persistent after chemotherapy (**b**) although all supradiaphragmatic sites became [^{18}F]FDG negative. This adrenal uptake was suspected to be a false-positive finding, which was confirmed at surgery. The adrenal lesion was benign, corresponding to a leiomyoma

myelosuppressive chemotherapy. Administration of hematopoietic growth factors can induce reconversion from fatty marrow to red marrow, resulting in increased [^{18}F]FDG uptake in the spine, pelvis, and long bones and in the spleen [102]. Increased activity in the spleen has also been observed both during and after GCSF treatment [102]. However, this very diffuse and homogeneous uptake is usually easy to recognize and typically declines after discontinuation of treatment but can remain increased for up to 4 weeks post-therapy [102].

Prospects

[^{18}F]FDG-PET/CT or PET/MRI is already an integral part of the management of childhood HL for staging, adaptation of conformal radiotherapy, and assessment of therapy and suspected

recurrence. [^{18}F]FDG-PET/CT is the subject of a major ongoing European study (Euronet) designed to minimize late toxicity of therapy without compromising the cure rate. Patients who obtain a good early response to two cycles of chemotherapy (complete remission or partial remission and negative [^{18}F]FDG-PET) do not receive radiotherapy [51].

Nevertheless, the actual role of [^{8}F]FDG-PET in the management of childhood NHL has not yet been defined. Although various studies have addressed this issue, the data are still scarce; furthermore, most of the studies are retrospective, and most of them include also patients with LH, therefore resulting in some heterogeneity in the data [109].

The role of [^{18}F]FDG-PET in childhood NHL is currently under evaluation in a trial in France, designed to address several major issues: Does NHL histology affect PET staging and PET response? What is the optimal timing of interim PET during NHL treatment? Should children with poor early PET be considered for treatment intensification?

Wilms' Tumor

Wilms' tumor is the most common renal malignancy in childhood [110]. The 5-year survival rate currently is about 91.9% [111]. Therapy follows multimodality approaches, including surgery/nephrectomy, chemotherapy, and radiation treatment. In general, recurrent disease manifests as local relapse in the lungs, regional lymph nodes, distal urinary tract, and liver but may also occur elsewhere [110]. Two histopathologic findings are described: the favorable and the anaplastic.

Imaging studies are mainly used to define the origin and anatomic extent of the tumor, determine the status of metastatic disease, survey therapy, and detect relapse. So far, the diagnostic workup of newly diagnosed Wilms' tumor includes a CT or MRI scan of the abdomen and pelvis, lymph nodes, and intra-abdominal or pelvic tumor deposits. A Doppler ultrasound is recommended to evaluate if there is a tumor thrombus in the renal vein and inferior vena cava [110]. For the detection of bilateral disease and the assessment of nephroblastomatosis representing premalignant lesions, MRI is the imaging modality of choice (Fig. 6) [112]. In cases with unclear definition of the organ of origin (the kidney, adrenal gland, sympathetic trunk), ^{123}I-MIBG scintigraphy can be very helpful for the differentiation of neuroblastoma versus Wilms' tumor (Fig. 7).

Fig. 6 Four-year-old boy with bilateral Wilms' tumor and nephroblastomatosis. Transversal fat-suppressed T1-weighted image after contrast enhancement reveals bilateral nephroblastoma (*arrows*) and a right-sided nephroblastomatosis lesion (*arrowheads*)

Chemotherapy is usually used prior to surgery. Therefore, a reliable response assessment using noninvasive imaging even prior to definite surgery is needed to modify therapy and to gain prognostic information [113].

Although [^{18}F]FDG-PET was successfully used to image Wilms' tumor for the first time [113] in the 1990s and [^{18}F]FDG uptake is usually consistent with a metabolically active tumor, no difference in uptake can distinguish between favorable and unfavorable histological findings [110]. Only a few years later, it became known that [^{18}F]FDG-PET did not provide additional information during the first diagnostic workup but appeared helpful in the follow-up [113].

PET/CT scans of patients with extensive disease were studied in a follow-up setting. [^{18}F]FDG-PET was reported to detect metastatic

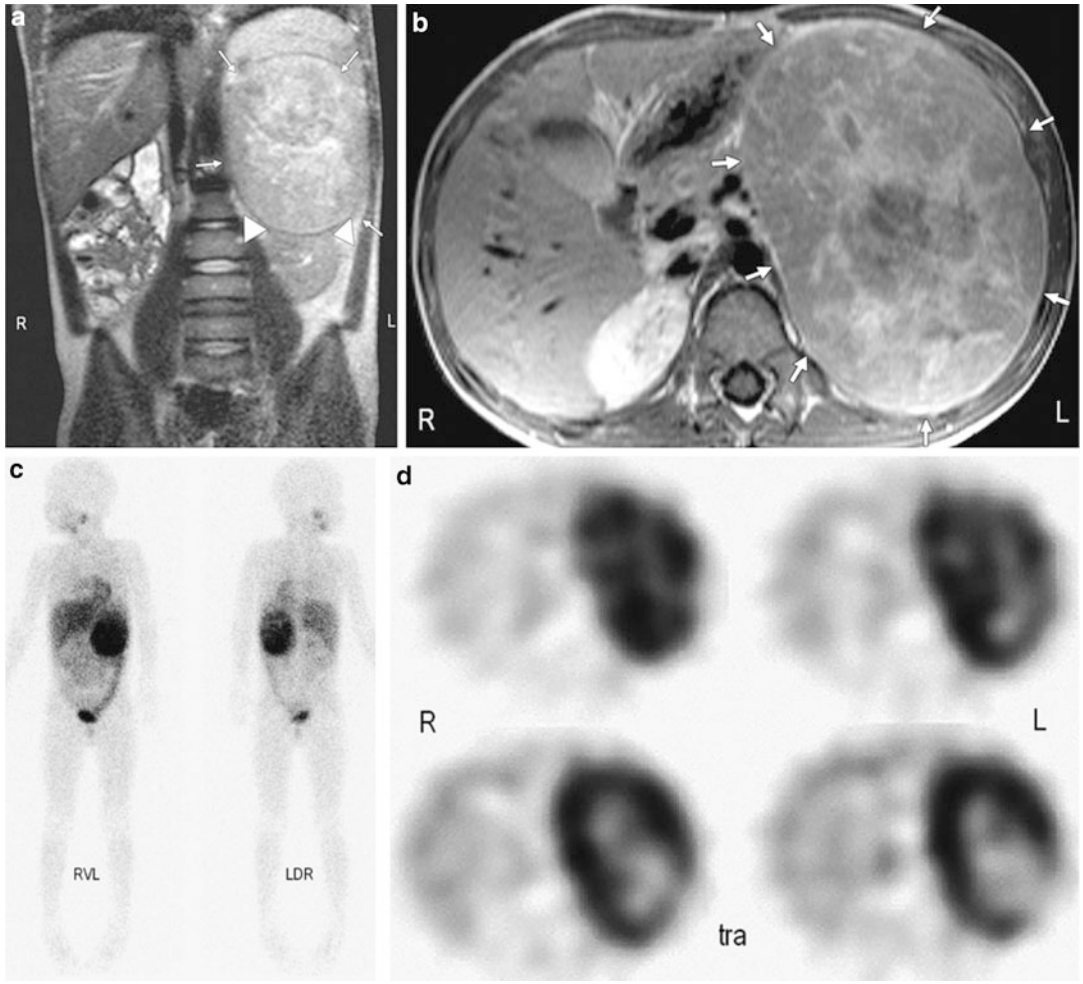

Fig. 7 Six-year-old boy with large neuroblastoma originating from left adrenal gland. **(a)** Coronal T2-weighted image reveals large mass in left abdomen (*arrows*) with appearance typical of Wilms' tumor with pseudocapsule and apparent origin from kidney (*arrowheads*). **(b)** Corresponding transverse T1-weighted image depicts large mass (*arrows*). **(c)** Strong focal uptake by mass visible on ^{123}I-MIBG scintigrams led to correct differential diagnosis of neuroblastoma. *RVL* right side, ventral view, left side, *LDR* left side, dorsal view, right side. **(d)** Transverse (*tra*) SPECT reconstructions that correlate to MRIs show tumor extent and central tumor necrosis

lesions that would have been missed by the conventional imaging [110–114]. Nevertheless, [^{18}F]FDG-PET failed to visualize small pulmonary metastases [102]. Consequently, PET/CT with the increased spatial resolution of the CT component seems to be the modality of choice in defining tumor involvement and evaluating therapy in patients with extended disease, in particular for tumors that are not amenable to surgical resection [110]. Whether PET/CT is useful for primary diagnosis of Wilms' tumors is yet to be determined. Therefore, [^{18}F]FDG-PET/CT does not seem to be of great importance for staging patients with Wilms' tumor with limited disease [113].

Neuroblastoma

Neuroblastoma, an embryonic tumor, is the most frequent extracranial solid malignancy in pediatric patients (about 8% of pediatric malignancies) and remains, despite treatment intensification,

responsible for approximately 15% of cancer deaths in children [115–118]. It arises from the neural crest cells, which form the adrenal medulla and the sympathetic nervous system [119]. The tumor is usually situated in the adrenal gland or anywhere else along the sympathetic nervous system chain [115]. At diagnosis, roughly 50% of patients have distant hematogenous metastases [120]. Neuroblastoma presents a wide spectrum clinical behavior and survival rates; therefore, staging is crucial in order to choose the appropriate treatment [121].

The therapeutic spectrum depends upon clinical stage and consists of supportive care with no treatment (stage IVS), definitive excision if possible, or chemotherapy before and after surgery. The treatment approaches are partially combined with total-body irradiation and ^{131}I-MIBG therapy, followed by autologous bone marrow transplantation [118, 120, 122, 123].

Imaging of neuroblastoma consists of sonography, computed tomography (CT), MRI, and radionuclide examinations such as bone scintigraphy, ^{123}I-MIBG scintigraphy, positron-emission tomography (PET) with different tracers (primarily [^{18}F] FDG), and recently hybrid imaging (PET/CT and SPECT/CT) [124, 125, 200–206].

MIBG Scintigraphy

Radiolabeled MIBG was originally developed in the late 1970s as a norepinephrine (NE) analog for imaging of the adrenal medulla [126, 127]. With the amount of radioiodinated MIBG administered for diagnostic imaging, uptake is mediated primarily by the NE transporter located on the surface of sympathetic neurons [128, 129]. Based on this mechanism, both ^{123}I-MIBG and ^{131}I-MIBG have been proven effective agents for scintigraphic imaging of tumors arising from the embryonologic precursors of the sympathetic nervous system, particularly the neural crest tumors neuroblastoma and pheochromocytoma [130, 131].

Scintigraphy with ^{123}I- or ^{131}I-labeled MIBG has become a well-established method in the diagnosis and staging of neuroblastoma [132–134] because of its high specificity, which is reported in the literature to be between 90% and 100% [122, 135, 136].

Moreover MIBG scintigraphy is used to determine eligibility for ^{131}I-MIBG therapy, as the presence of MIBG-avid disease must be ascertained prior to treatment.

For diagnosis, ^{123}I-labeled MIBG is superior to ^{131}I-MIBG [137]. Due to more favorable dosimetric properties, a higher activity of ^{123}I-MIBG can be administered enabling to obtain SPECT acquisitions that may increase sensitivity and provide more precise anatomical localization of the disease especially after coregistration with radiological modalities such as CT scan or MRI [138].

Reasons for false-negative studies are not entirely clear: it may be related to modifications of the active uptake mechanism due to differentiation of tumor cells or to pharmacologic interference [139–141]. Pharmacological interference: ((1) tricyclic antidepressants and related drugs – should be avoided for 6 weeks prior to the study: (a) amitriptyline and derivatives (Elavil, Endep, Etrafon, Triavil, Amitril, Emitrip, Enovil), (b) amoxapine (Asendin), (c) loxapine, (d) doxepin (Adapin, Sinequan), (e) imipramine and derivatives (Tofranil, Imavate, Janimine, Presamine, SK-Pramine, Tipramine). (2) Antihypertensives – should be avoided for 2 weeks prior to the study: (a) labetalol (Normodyne, Trandate), (b) calcium channel blockers, (c) reserpine (Serpasil, Sandril). (3) Sympathetic amines – should be avoided for 2 weeks prior to the study: (a) pseudoephedrine (Halofed, Sudafed, Sudrin, others), (b) phenylpropanolamine HCL (Propagest, Sucrets Cold Decongestant, Entex, others), (c) phenylephrine HCL (Neo-Synephrine, Alconefrin, Rhinail, others), (d) ephedrine, (4) cocaine – should be avoided at all times and for 2 weeks prior to the study) is probably the most frequent cause of a false-negative study. False-negative MIBG findings have been described in children with ganglioneuroblastoma, where the ganglioneuroma elements were predominant, suggesting that uptake is influenced by histology and the degree of tumor cell maturation, whereas no relationship with the secretion of catecholamines could be assessed [139]. However, other studies in

children with completely negative MIBG scans at diagnosis did not find any correlation with histopathology, biological factors, or stage of disease [132]. On the other hand, in recent studies it could be shown that there is a correlation between a high MIBG uptake and an unfavorable histopathology [142]. Furthermore, combined MIBG scintigraphy and tumor marker analysis can predict unfavorable histopathology of neuroblastic tumors with high accuracy [143].

When looking at lesion-based evaluations, bone and bone marrow lesions are identified more consistently than soft-tissue lesions. Overall sensitivities range between 60% and 70% [133, 144, 145].

Physiological distribution of MIBG is present in the heart and salivary glands because of their sympathetic innervation, while other systems (urinary tract, gastrointestinal system) represent excretion routes of the tracer [146]. Most of false-positive MIBG findings are due to a nonspecific radioactivity accumulation in the urinary tract, and/or gastrointestinal structures, and not to specific MIBG uptake by nonneuroblastic cells [145, 147–154]. Using SPECT/CT to acquire MIBG images reduces the likelihood of false-positive scans.

Bone Scintigraphy

In the literature, usefulness of bone scintigraphy for the staging of neuroblastoma is under discussion. When comparing MIBG and bone scintigraphy in patients with confirmed neuroblastoma, it was found that ^{99m}Tc-MDP and MIBG scans were concordant for the presence or absence of skeletal disease. However, nearly twofold greater number of skeletal lesions was evident on MIBG scanning. In patients with histological evidence of bone marrow involvement, each study suggested skeletal lesions in approximately 70%. In addition, no patients with normal bone scans had MIBG scans indicating bone involvement. In conclusion, both MIBG and ^{99m}Tc-MDP are useful for the detection of skeletal neuroblastoma. ^{123}I-MIBG is the better agent for characterizing the extent of disease, and ^{99m}Tc-MDP is a valuable adjunctive agent that provides skeletal landmarks for comparison [155].

Therefore, bone scintigraphy with ^{99m}Tc-diphosphonates could be important to check for bone metastases when neuroblastoma does not concentrate radioiodinated MIBG. However, in primary staging in particular, whole-body MRI will replace bone scintigraphy as has been shown by several studies demonstrating that whole-body MRI has a higher sensitivity than skeletal scintigraphy in children for the detection of bone marrow metastases [156] and shows a higher number of bone lesions than standard skeletal scintigraphy in children and young adults with malignancies [157].

However, MRI has poor specificity for metastatic osteomedullary infiltration which is most important for follow-up evaluation. False-positive results of MRI for bone marrow infiltration persisted even months after successful treatment completion in children with stage 4 neuroblastoma who had normal ^{123}I-MIBG scans and bone marrow biopsy at the end of treatment [158].

Positron-Emission Tomography

Despite the high diagnostic accuracy of ^{123}I-MIBG imaging, there are several disadvantages of this modality such as limited spatial resolution, limited sensitivity in small lesions, need for two or – in the case of SPECT – even more acquisition sessions, and a delay between the start of the examination and result. Furthermore, MIBG imaging is not sufficient for operative or biopsy planning in most of the cases. The majority of these disadvantages can potentially be overcome with PET [159] due to its higher spatial resolution and the possibility of a whole-body tomography versus SPECT (that has a more limited field of view). PET or PET/CT is completed in one examination within 30–60 min after injection versus ^{123}I-MIBG scintigraphy and SPECT or SPECT/CT that require at least 18–24 h to achieve tumor-to-background ratios adequate for imaging. The resulting shorter scanning time of PET has the potential for reducing the number of sedations in small children.

The use of [^{18}F]FDG-PET in the evaluation of pediatric neuroblastoma is increasing, although its role remains less clear. Questions remain regarding when and in which patients [^{18}F]FDG-PET is most useful. Three studies have compared MIBG scintigraphy and [^{18}F]FDG-PET in neuroblastoma [160–162]. In these studies, MIBG was labeled with either ^{131}I or ^{123}I. These authors demonstrated that most neuroblastomas concentrate [^{18}F]FDG. However, they found that [^{18}F]FDG is inferior to MIBG in the evaluation of neuroblastoma because of its lower tumor-to-nontumor uptake ratio (especially after therapy) and because of [^{18}F]FDG uptake in nontumor sites (such as bone marrow, thymus, and bowel), causing potential false-positive or false-negative results. They concluded that [^{18}F]FDG was most beneficial in tumors that failed to accumulate or weakly accumulated MIBG [162]. In another study, 92 [^{18}F]FDG-PET scans were performed in conjunction with staging evaluations including ^{123}I-MIBG scans, bone scans, CT (or MRI) scans, urine catecholamine, and bone marrow examinations. In this study, PET was equal or superior to MIBG scans for identifying neuroblastoma in soft-tissue and extracranial skeletal structures, for revealing small lesions, and for delineating the extent and localizing sites of disease [161]. Their results showed that [^{18}F]FDG-PET and bone marrow sampling are sufficient to monitor for progressive disease in patients whose primary tumor has been resected and in whom cranial vault lesions are absent or resolved [161].

The third study found stage-dependent results for both modalities [160]. [^{18}F]FDG was superior in depicting stage 1 and 2 neuroblastoma. [^{18}F]FDG also better depicted disease in stages 3 and 4 when tumors did not accumulate ^{123}I-MIBG or did so only weakly. Furthermore, [^{18}F]FDG can better delineate disease extent in the chest, abdomen, and pelvis and should always be considered when ^{123}I-MIBG reveals less disease than suggested by clinical symptoms or conventional imaging modalities (Fig. 8) [119].^{123}I-MIBG was superior in stage 4 neuroblastoma, primarily because of the better detection of bone or marrow metastases. This was especially true during initial chemotherapy or under treatment with granulocyte colony-stimulating factor, conditions associated with marked increase in bone marrow uptake, which can either mask or mimic metastatic disease [160].

However, in all these comparative studies, there is a consensus that [^{18}F]FDG-PET should be considered if there is a discrepancy between morphological imaging and ^{123}I-MIBG scintigraphy [163].

As [^{18}F]FDG is a marker for the viability of malignancies in general, more specific PET tracers have been developed for imaging the sympathetic nervous system like hydroxyephedrine labeled with carbon-11 ([^{11}C]HED) [164, 165]. The aromatic portion of HED is less lipophilic than that of MIBG, and while HED bears closer structural similarity to norepinephrine, it is not metabolized as is norepinephrine. Biodistribution studies in experimental animals and humans have shown selective uptake in organs with rich sympathetic innervation, including the heart and adrenal medulla. When HED is labeled with ^{11}C, its distribution can be portrayed in vivo using PET. In a study, neuroblastomas were located by PET scanning with [^{11}C]HED in all seven participants [165]. The uptake of [^{11}C]HED into neuroblastomas was rapid; tumors were evident on images within 5 min post-intravenous injection. Those lesions in the field of view of the PET camera were also identified on ^{123}I-MIBG scintigraphic images. In two patients, however, tumor deposits in the abdomen were better visualized with ^{123}I-MIBG scintigraphy due to relatively less hepatic accumulation of ^{123}I-MIBG than [^{11}C]HED. The authors concluded that PET scanning with [^{11}C]HED for neuroblastoma results in high-quality functional images of the tumors that can be obtained within minutes following injection [165].

Furthermore, [^{11}C]HED PET/CT was shown to be feasible in tumors of the sympathetic nervous system [166]. In this study, [^{11}C]HED PET/CT detected more tumor lesions than ^{123}I-MIBG SPECT/CT, but not in neuroblastoma, where one large local relapse was missed with [^{11}C]HED in contrast to ^{123}I-MIBG. Moreover, tumor-to-background contrast of [^{11}C]HED in

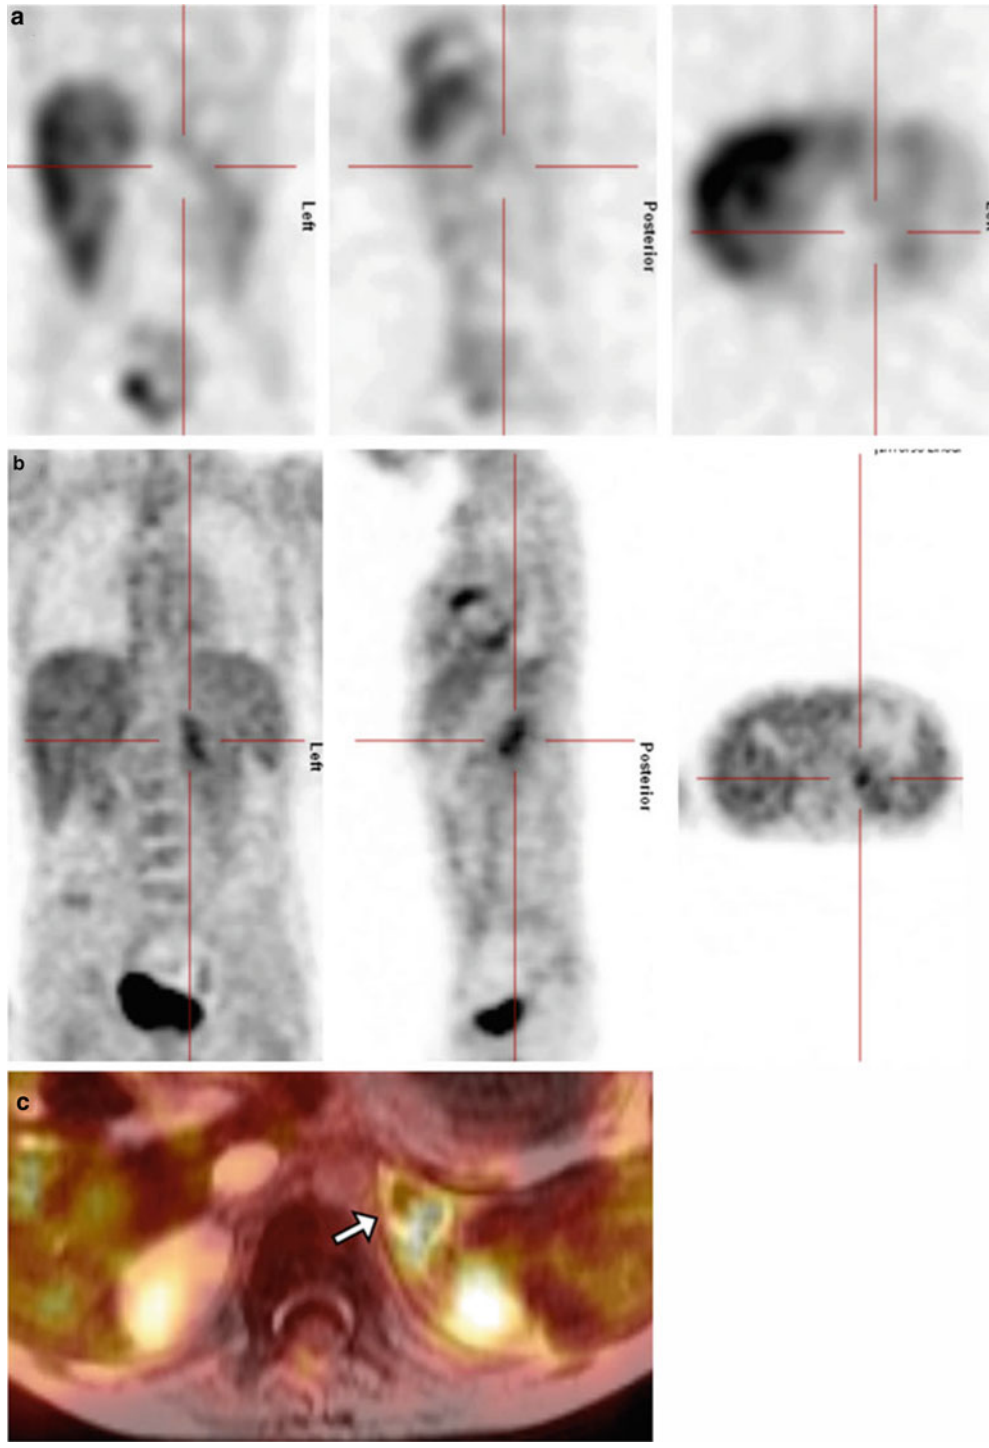

Fig. 8 A 7-year-old boy with a histologically proven recurrent neuroblastoma in the region of the left adrenal gland. **(a)** ^{123}I-MIBG SPECT does not show any pathological uptake in the left adrenal region (*crosshair*) leading to a false-negative result. **(b)** [^{18}F]FDG-PET clearly demonstrates an increased glucose metabolism in the respective region (*crosshair*) suspect for recurrent disease. **(c)** Image fusion between [^{18}F]FDG-PET and MRI shows increased [^{18}F]FDG uptake within a contrast-enhancing soft-tissue mass (*arrow*)

lesions can be higher, equal, or lower compared with ^{123}I-MIBG [166]. The relatively high physiologic liver uptake of [^{11}C]HED may impede the detection of small liver metastases. Some of these shortcomings may be avoided by using PET/CT with ^{18}F-labeled tracers (half-life: 110 min), such as ^{18}F-DOPA which has been used for imaging of a variety of neuroendocrine tumors [167–169]. However, there are a few studies reporting the results of ^{18}F-DOPA PET in pediatric neuroblastoma [29, 170–172], and there are no comparative studies between [^{11}C]HED PET and ^{18}F-DOPA PET [166]. Attention is currently being paid to the role of ^{18}F-DOPA-PET in pediatric neuroblastoma, as well as that of PET with ^{124}I-MIBG, ^{68}Ga-DOTA-TOC (or other radiolabeled somatostatin analogs), because new, highly sensitive and specific PET tracers would be of great clinical interest for imaging during initial staging and for assessing response to therapy, in the perspective of individualizing therapeutic strategies.

Morphological and Multimodality Imaging

The major limitation of morphological imaging (CT and/or MRI) is in the assessment of the viability of morphologically detectable lesions. On the other hand, functional imaging (MIBG or PET) often lacks in distinguishing physiological changes versus tumor lesions. Ideally, multimodality imaging helps to increase diagnostic safety for defining the adequate therapeutic consequence [173].

In contrast to CT, MRI has several advantages in the diagnosis of neuroblastoma: high sensitivity in detecting bone marrow abnormalities [158], lack of ionizing radiation, high intrinsic soft-tissue contrast resolution [125], depiction of internal structure [174], and exact definition of intraspinal tumor extension (Fig. 9) or diaphragmatic involvement of thoracic tumors [124, 175]. All these factors are decisive, especially in primary diagnosis and for operative or biopsy planning [176]. In a comparative study, the benefit of a combined analysis with MRI and ^{123}I-MIBG scintigraphy in pediatric neuroblastoma lesions was assessed. In this study, ^{123}I-MIBG scintigraphy, MRI, and combined analysis showed a sensitivity of 69%, 86%, and 99% and a specificity of 85%, 77%, and 95%, respectively. On MRI, 15 false-positive findings were recorded: post-therapeutic reactive changes ($n = 10$) (Fig. 10), benign adrenal tumors ($n = 3$), and enlarged lymph nodes ($n = 2$). On ^{123}I-MIBG scintigraphy, ten false-positive findings occurred: ganglioneuromas ($n = 2$), benign liver tumors ($n = 2$), and physiologic uptake ($n = 6$). Thirteen neuroblastoma metastases and two residual masses under treatment with chemotherapy were judged to be false-negative findings on MRI. Two primary or residual neuroblastomas and one orbital metastasis were misinterpreted as Wilms' tumor, reactive changes after surgery, and rhabdomyosarcoma on MRI. Thirty-two bone and bone marrow metastases (Fig. 11), six other neuroblastoma metastases, and one adrenal neuroblastoma showed no ^{123}I-MIBG uptake. On combined imaging, one false-negative (bone metastasis) and three false-positive (two ganglioneuromas and one pheochromocytoma) findings remained. In conclusion, MRI showed a higher sensitivity and ^{123}I-MIBG scintigraphy a higher specificity. However, integrated imaging showed an increase in both sensitivity and specificity [145].

With regard to a combined PET/CT or PET/MRI approach, hybrid imaging significantly improved the characterization of abnormal [^{18}F]FDG foci in children with cancer, mainly by excluding the presence of active malignancy in sites of increased tracer activity [9, 10, 177].

The CT component of the PET/CT acquisition is not very sensitive for the detection of malignant marrow infiltrations, which can be diffuse rather than focal or multifocal, in particular, in patients with neuroblastoma, rhabdomyosarcoma, and Ewing sarcoma [178, 179]. Thus, in patients with a high suspicion for bone and bone marrow metastases, additional imaging modalities such as MRI may be needed (Fig. 11) [180, 181], or acquisition using a PET/MRI hybrid scanner.

PET/CT also has been shown to be superior to PET alone by allowing precise CT localization of metabolic abnormalities shown on PET and superior to CT alone by allowing metabolic

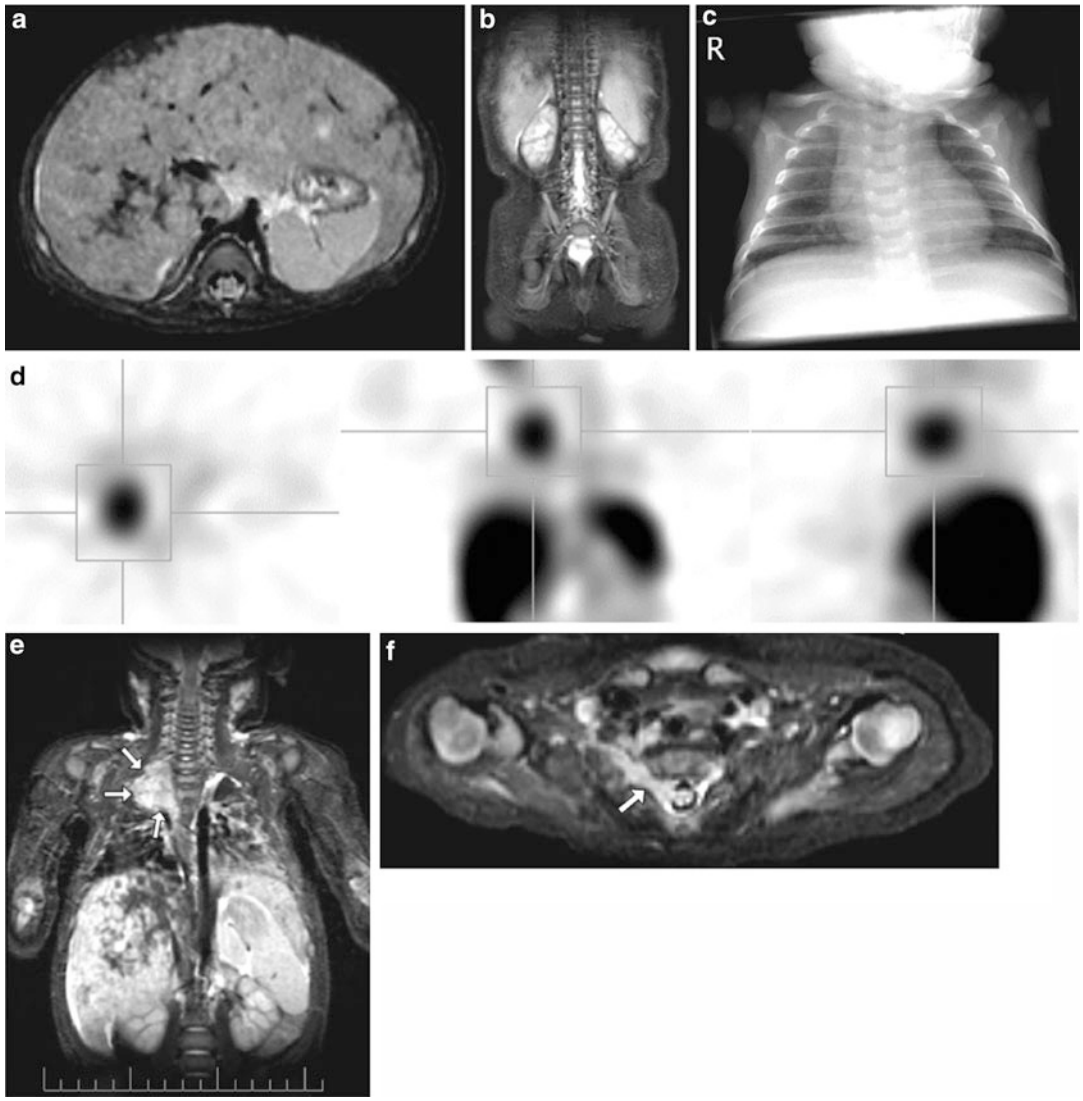

Fig. 9 A 2-month-old suckling with a stage IV neuroblastoma. Clinical and ultrasound findings did not demonstrate a primary tumor. (**a)** Transversal T2-weighted MRI of the abdomen demonstrated diffuse liver metastases. (**b)** Coronal T1-weighted MRI did not show a primary in the adrenal glands or the sympathetic trunk of the abdomen. (**c)** Chest x-ray could not detect a neuroblastoma in the thorax. (**d)** SPECT reconstructions of ^{123}I-MIBG scintigraphy clearly depict the right paravertebral primary as well as diffuse liver metastases. However, exact extent of the tumor and intraspinal involvement cannot be assessed. (**e**, **f)** Coronal and transversal T1-weighted MRI demonstrate the exact extent of the primary and tumor growth through intervertebral foramina (*arrows*) which is decisive for further therapy planning

characterization of abnormal and normal findings shown on CT, thereby increasing diagnostic confidence and reducing equivocal image interpretations [177, 182–185].

Concerning the added value of ^{123}I-MIBG SPECT/CT compared to contrast-enhanced CT, it was observed that all equivocal cases on CT were solved by SPECT/CT, related to the high specificity of ^{123}I-MIBG for tumoral tissue, and concluded that during follow-up of children with MIBG-positive neuroblastoma at diagnosis, SPECT/CT should be performed first and, if

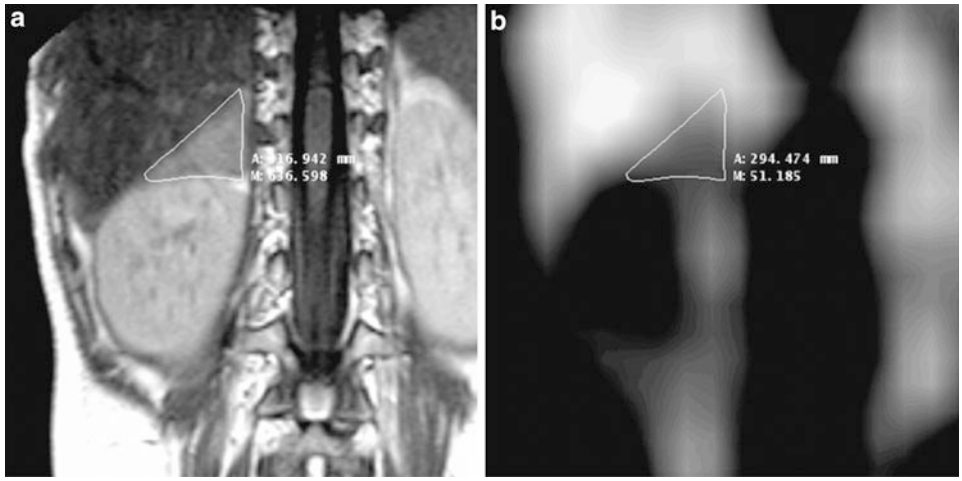

Fig. 10 A 4-year-old boy with reactive changes 6 months after resection of stage II neuroblastoma of the right adrenal gland. (**a)** Coronal T1-weighted MRI demonstrated a contrast-enhancing tumor (region of interest) suspect of residual or recurrent viable tumor tissue. Differentiation between residual tumor and reactive changes is not possible with MRI (false-positive finding). (**b)** Coronal SPECT reconstructions of ^{123}I-MIBG scintigraphy reveal a negative finding. True-negative diagnosis was confirmed by follow-up control examinations over 2 years

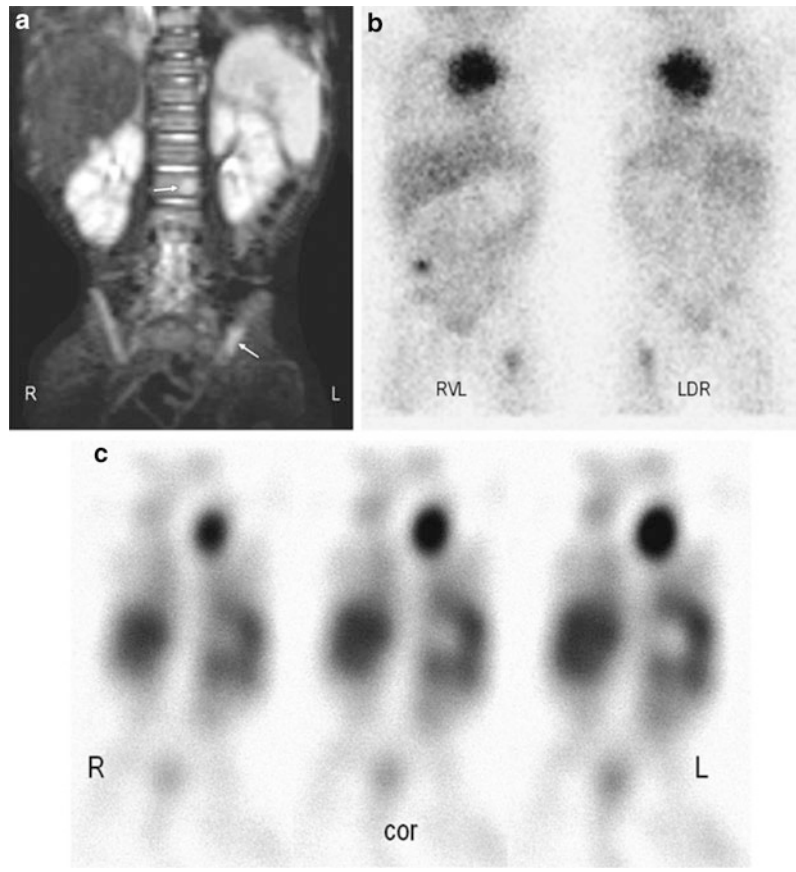

Fig. 11 An 8-month-old girl with stage IV neuroblastoma who presented with multiple bony metastases. (**a)** MRI from STIR sequence shows high signal in two bone marrow metastases in left iliac bone and second lumbar vertebra (*arrows*) (true-positive findings). (**b)** In corresponding regions, planar ^{123}I-MIBG scintigrams show no uptake (false-negative findings). Strong uptake can be seen in mediastinal primary tumor as well as in a left-sided femoral bone metastasis. *RVL* right side, ventral view, left side, *LDR* left side, dorsal view, right side. (**c)** Corresponding coronal (*cor*) SPECT reconstructions of ^{123}I-MIBG scintigraphy support findings of planar images

negative, contrast-enhanced CT could be discarded. Inversely, single positive/equivocal ^{123}I-MIBG foci without concordant morphological changes may need histological confirmation [186].

Conclusion

There is strong evidence that ^{123}I-MIBG scintigraphy (planar images and SPECT) remains the method of choice for the noninvasive staging of children with neuroblastoma. PET imaging using [^{18}F]FDG or the more specific tracer [^{11}C]HED has not definitely proven to be superior to ^{123}I-MIBG.

With regard to multimodality imaging, it has been shown that a combined approach with ^{123}I-MIBG/MRI, ^{123}I-MIBG/CT, and PET/CT has the potential to increase diagnostic sensitivity and specificity as compared to single modalities. Unfortunately, PET/CT represents no one-stop shop for the evaluation of pediatric neuroblastoma as PET cannot surpass ^{123}I-MIBG scintigraphy, and CT cannot replace MRI especially in primary diagnosis (delineation of the infiltration of the spinal canal and detection of bone marrow edema).

Concerning the state-of-the-art diagnostic strategy in neuroblastoma imaging, it is important to differentiate between primary diagnosis and follow-up controls.

In primary diagnosis, ^{123}I-MIBG scintigraphy (i.e., whole-body staging, differential diagnosis) and MRI (i.e., operability, bone marrow metastases) are indispensable. In case of any discrepancy between these two modalities, further staging should be performed with [^{18}F]FDG-PET/CT or -PET/MRI.

In follow-up examinations, ^{123}I-MIBG scintigraphy is most important in MIBG-positive neuroblastoma as specificity of morphological imaging is very low here. In ^{123}I-MIBG-negative neuroblastoma or equivocal MIBG findings, [^{18}F]FDG-PET/CT or -PET/MRI represents the imaging modalities of choice.

Pediatric Osseous and Soft-Tissue Sarcomas

Sarcomas are a heterogeneous group, combining various tumor entities with different tumor biology, malignancy, and therapeutic options. There are different age patterns in different tumor entities. Some entities such as embryonal rhabdomyosarcomas, osteosarcomas, or Ewing tumors are mainly or exclusively found in childhood and adolescence. The metastatic spread of sarcomas is mainly hematogenous to the lungs and the bones. However, in soft-tissue sarcomas, also lymphatic spread occurs. The presence or absence of metastases and the tumor histology and grade mainly influence the treatment.

Bone Sarcomas

The two major groups of primary bone tumors in children and adolescents are osteosarcomas and the Ewing family of tumors.

Soft-Tissue Sarcomas

Soft-tissue sarcomas in children are a heterogeneous group of malignant tumors that originate in the soft tissues and have a predominantly mesenchymal origin. The most common histologic entities in children and adolescents are rhabdomyosarcoma (embryonal and alveolar, 61%), extraosseous Ewing sarcoma and peripheral neuroectodermal tumor (PNET, 8%), synovial sarcoma, neurofibrosarcoma, fibrosarcoma, and leiomyosarcoma.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a proliferation of Langerhans-type histiocytes. Despite its clonal origin, there is no definitive proof of malignancy. The term “LCH” replaces a number of synonyms that have been used in the past to describe various conditions: histiocytosis X, Abt-Letterer-

Siwe syndrome, Hand-Schüller-Christian disease, and eosinophilic granuloma.

Role of Imaging

Three-Phase Bone Scintigraphy

Primary Bone Tumors and Tumor-Like Lesions

Even in the age of cross-sectional imaging, primary bone tumors are best classified using a conventional planar x-ray. CT and MRI supply further information on tumor localization and extension. A three-phase bone scan with increased tracer uptake in all three phases supports a presumptive diagnosis of a primary malignant bone tumor. However, the pattern is not specific since acute inflammation shows the same tracer pattern. Additionally, some benign lesions demonstrate a clearly increased tracer uptake in all three phases, for example, osteoid osteoma. A normal or only marginally increased blood pool phase and a moderately increased bone phase suggest a benign lesion.

After chemotherapy of primary bone tumors, bone scintigraphy can be used for therapy control. A decrease in tracer uptake in the blood pool phase and in the bone phase of more than 30% indicates a good response [187, 188]. However, even in good responders there might be an increased tracer uptake during chemotherapy due to the flare phenomenon. Therefore, therapy response should be assessed by bone scintigraphy more than 6 weeks after the end of chemotherapy.

Osseous Metastases

Although bone metastases are usually visualized by ^{99m}Tc-diphosphonate bone scan 3–6 months earlier than by plain x-ray films [189], the specificity of skeletal scintigraphy is only 60–70%. Therefore, verification of abnormal findings is often necessary. Many studies have demonstrated the superiority of MRI in comparison to bone scintigraphy in the detection of osseous metastases, especially in the vertebral column [190].

A distinctive feature of osteosarcoma and its metastases is the capability to produce premature osseous matrix, the point of chemoadsorption of the radiolabeled phosphonates. Therefore, skeletal scintigraphy is very sensitive in the detection of osseous metastases of osteosarcoma, and even soft-tissue metastases are often visible on the bone scan [191–193]. Because of this characteristic feature, therapy with bone-seeking radiopharmaceuticals can be applied in patients with osteosarcoma. Despite highly efficacious chemotherapy, patients with osteosarcomas still have a poor prognosis if adequate surgical control cannot be obtained. These patients may benefit from therapy with radiolabeled phosphonates, such as samarium-153 ethylenediaminetetramethylene phosphonic acid (^{153}Sm-EDTMP) [194].

For a more extensive discussion of osseous and soft-tissue sarcomas, see chapter ▶ Chap. 37, "Diagnostic Applications of Nuclear Medicine: Sarcomas".

Langerhans Cell Histiocytosis

No large-scale studies have yet been done on the use of [^{18}F]FDG-PET, [^{18}F]FDG-PET/CT, or PET/MRI of LCH. One multicase report with three patients found that coincidence [^{18}F]FDG-PET was better able to distinguish between active and healed bony LCH lesions than plain x-ray or bone scans [195]. This observation is supported by a study on various pediatric tumor entities including LCH [196]. Another small study in three patients with cerebral LCH involvement demonstrated that [^{18}F]FDG-PET could detect intracerebral foci of increased or decreased glucose metabolism [197]. Like the authors of a single case-report [198], Calming et al. conclude that [^{18}F]FDG-PET is useful for the evaluation of disease activity during follow-up.

In a comparative study, Mueller et al. evaluated 53 LCH lesions in 21 combined MRI and [^{18}F]FDG-PET studies (15 patients). They concluded that the retrospective analysis suggests a pivotal role of [^{18}F]FDG-PET in lesion follow-up due to a lower number of false-positive findings

after chemotherapy. MRI showed a higher sensitivity and is indispensable for primary staging, evaluation of brain involvement, and biopsy planning. Combined MRI/PET analysis improved sensitivity by decreasing the false-negative rate during primary staging indicating a future role of simultaneous whole-body PET/MRI for primary investigation of pediatric histiocytosis [199].

Part III

Radionuclide Therapy

Radionuclide Therapy of Lymphomas 40

Heather A. Jacene, Sree Harsha Tirumani, and Richard L. Wahl

Abstract

Radioimmunotherapy is an effective therapy for NHL in a variety of settings and is well tolerated. Current studies continue to investigate the role of NHL at various time points in the management of patients with NHL. The limited clinical use of RIT seems to have been driven by economics rather than by a lack of clinical effectiveness. As new radiolabeled agents and indications and nonradioactive agents are being investigated, probably in parallel with nonradioactive agents, close collaborations between medical oncologists and nuclear medicine physicians/radiologists are paramount for optimal integration of these agents into the overall treatment schema for patients with lymphoma.

Radioimmunotherapy (RIT) for treatment of non-Hodgkin lymphoma (NHL) has been undergoing investigations since the early 1990s and became available for clinical use to treat relapsed/refractory NHL in the early 2000s. Since then, the indications for the use of RIT in NHL have been expanded. RIT for NHL is an effective therapy; however, the use in clinical practice has been limited as there are multiple other competing nonradioactive therapies for NHL, several developed in the past few years.

This chapter will provide a review of the current and possible future roles of RIT in patients with lymphoma.

Rationale and Mechanism of Action

The rationale for the use of radioimmunotherapy (RIT) in cancer is that radiolabeled monoclonal antibodies will specifically target and irradiate tumor cells while sparing normal tissues. The specific tumor targeting of RIT theoretically allows higher doses of radiation to be delivered to tumor compared to external beam radiation because there are less effects of the radiation on normal tissues with RIT. Two radiolabeled anti-CD20 monoclonal antibodies, yttrium-90 (^{90}Y)-ibritumomab tiuxetan and iodine-131 (^{131}I)-tositumomab, are approved by the United States Food and Drug Administration (FDA) for the treatment of NHL as part of the Zevalin® (Spectrum Pharmaceuticals, Irvine, CA [1]) and Bexxar® (GlaxoSmithKline [2]) therapeutic regimens, respectively.

^{90}Y-ibritumomab tiuxetan is composed of the radioisotope ^{90}Y and the murine monoclonal antibody ibritumomab. ^{131}I-tositumomab is composed of the ^{131}I radioisotope and the murine monoclonal antibody tositumomab. Both components contribute to the drugs' mechanism of action. The antibodies recognize slightly different epitopes of the extracellular domain of the CD20 antigen, which is found on the surface of pre-B lymphocytes, mature B-lymphocytes, and >90% of B-cell NHLs [3, 4]. Formation of the antibody-antigen complex results in induction of apoptosis, complement-dependent cytotoxicity, and antibody-dependent cytotoxicity [5, 6]. The radioisotopes emit β^- radiations, which deposit enough energy in the tumor to result in cell death. Because the distribution of the radiolabeled antibody within a tumor can be heterogeneous [7], an additional advantage of RIT is that the β^- emissions of the radiolabel can also target the surrounding malignant cells via the cross-fire effect and thus result in killing of residual microscopic disease in cells that the unlabeled antibody did not reach.

Efficacy and Safety of RIT in Recurrent NHL

In clinical trials investigating ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab in patients with recurrent NHL, overall response rates ranged from 60% to 83%, with complete response (CR) rates of 15–52% [8–15]. The median duration of response with RIT ranges from 6 to 16 months for all responders, but seems to be associated with the quality of the initial response. At the time of publication of several studies, the median duration of response for patients who achieved a CR was much longer than for those achieving a less robust response, and had not yet been reached. Higher response rates were reported for RIT compared to the unlabeled anti CD-20 antibody. In a cross-over study of ^{131}I-tositumomab, 42% of patients non-responsive to unlabeled tositumomab achieved a CR after receiving a therapeutic dose of ^{131}I-tositumomab [16]. Again, a partial explanation for the improved overall response rates with the

radioactive monoclonal antibodies is that the addition of the radioactivity probably allows more cells to be targeted and killed due to the cross-fire effect.

Although the initial results of the studies investigating RIT in recurrent NHL (mostly follicular) were excellent, the initial studies preceded the widespread use of the anti CD-20 mouse-human chimeric antibody, rituximab. These trials included mostly patients who were rituximab-naïve and studies were needed to show efficacy of RIT in the group of patients previously treated with unlabeled rituximab. Rituximab is now a routine component of B-cell lymphoma regimens. Two important studies showed excellent efficacy (overall response rates, 65–74%; complete response rates, 15–42%), durations of response, and progression-free survival (6.8–12.4 months) of RIT in patients with a prior history of rituximab therapy compared to the prior studies of rituximab-naïve patients [8, 13]. In addition, responses to radioimmunotherapy were seen in patients who appeared to be refractory to rituximab therapy.

Numerous prognostic factors have been evaluated in an attempt to identify which patients are most likely to respond to RIT. In individual studies, factors reported to be associated with response are low-grade follicular histology, non-bulky disease, no bone marrow involvement, fewer prior regimens, normal serum lactate dehydrogenase levels, lower IPI, higher total body radiation dose, and no prior history of transplant [8–15]. Of all of these, low-grade follicular histology and non-bulky disease at the time of treatment are the most reliable predictors, especially in patients who had received no or minimal prior therapy for lymphoma.

In patients with NHL, RIT is generally well tolerated. The most common adverse events are serious cytopenias, notably declines in platelets and white blood cells, which are experienced by a majority of patients. Sixty to 70% of patients enrolled in clinical trials developed grade III/IV thrombocytopenia and/or neutropenia. Count nadirs typically occurred between 4 and 7 weeks post-RIT, and cytopenias may last for approximately 30 days. Consequently, monitoring of complete blood counts is required for at least 10–12 weeks post-therapy. Hematologic support is required for ~15–32% of patients after RIT [1, 2]. Notably, count nadirs occur later than typically seen with cytotoxic chemotherapies.

Additional non-hematologic short-term side effects are usually mild and may include fatigue, asthenia, nausea, and fever. There are several long-term side effects of which prescribing nuclear medicine physicians/radiologists, oncologists and patients must also be aware of [1, 2, 17, 18]. In patients with recurrent NHL treated with RIT, human anti-mouse or chimeric antibodies are found in 4–11%. Acute side effects due to HAMA/HACA (such as serum sickness-like illness) are not typically seen in this population due to a history of prior therapies and relative immune compromise, but could affect future treatment decisions (treatment with additional monoclonal antibody, eligibility for clinical trials) or interfere with certain laboratory evaluations. In studies in which ^{131}I-tositumomab RIT has been used as the initial therapy of lymphoma, HAMA rates have been even higher. Hypothyroidism has been reported to occur in ~18% of patients who receive ^{131}I-tositumomab, despite attempted thyroid blockade prior to therapy with cold iodine; this occurrence is probably less frequent with careful attention to thyroid blockade.

Secondary myelodysplastic syndrome/acute myelogenous leukemia (MDS/AML) has been reported in 2–4% of patients with recurrent NHL who received RIT [1, 2, 17, 18]. Nevertheless, the patients in these studies were heavily pretreated; thus, the role of RIT versus exposure to prior cytotoxic agents and a history of NHL in the development of MDS/AML remains unresolved. Czuczman et al. [17] retrospectively reviewed the data from 746 patients previously treated with ^{90}Y-ibritumomab tiuxetan from 1996 to 2002 who were participating in clinical trials and compassionate use trials. Nineteen patients (2.5%) developed MDS/AML at a median of 5.6 years (1.4–13.9 years) after RIT. The annualized incidences of MDS/AML after NHL diagnosis (0.3% per year) and after treatment (0.7% per year) were not more than expected in heavily pretreated patients with NHL. At a median follow-up of 5.1 years, no cases of MDS/AML were reported in 76 patients with untreated follicular NHL treated with ^{131}I-tositumomab as front-line therapy [19]. This patient population

is generally at higher risk for the development of MDS/AML and should be monitored carefully.

Front-Line and Consolidation Therapy with RIT

RIT has also been investigated in front-line and consolidation settings. In both instances, single doses of RIT are effective and can produce long-term remissions. In 76 untreated patients with follicular NHL, Kaminski et al. reported a 95% overall response rate and 75% complete response rate to a single dose of ^{131}I-tositumomab [19]. The estimated median progression-free survival rate at 5 years was 59% and progression-free survival was 6.1 years, with 5 years of follow-up. The relapse rate decreased progressively with time from the first RIT, and the long-term observations suggest that the quality of initial response may be important for subsequent relapse. HAMA was seen with greater frequency in this patient population.

A pivotal, multicenter phase III trial of ^{90}Y-ibritumomab tiuxetan by Morschhauser et al. (FIT trial) led to the approval of ^{90}Y-ibritumomab tiuxetan in the United States in the consolidation setting in 2009 [20] and long-term follow-up results have since been published [21]. Patients with untreated advanced follicular NHL received first-line chemotherapy, and if a response (complete, complete unconfirmed, or partial) was attained, patients were randomized to no treatment or ^{90}Y-ibritumomab tiuxetan consolidation. In the updated results of the FIT trial and similar to the initial publication, median progression-free survival (PFS) was significantly longer for patients in the ^{90}Y-ibritumomab tiuxetan consolidation arm ($n = 207$) versus the no treatment arm ($n = 202$) (4.1 years versus 1.1 years, $p < 0.001$) [21]. More patients in the ^{90}Y-ibritumomab tiuxetan arm who achieved a PR to first-line chemotherapy converted to CR/CRu than in the no treatment arm (77.2% versus 17.5%, $p < 0.001$) [20] and in long-term follow-up the benefit of ^{90}Y-ibritumomab tiuxetan was better in this group than in those who achieved a CR. Time to next treatment was 8.1 years in the ^{90}Y-ibritumomab tiuxetan arm versus 3 years in the control arm ($p < 0.001$) [21]. Response rates to second-line therapy and 8-year overall survival rates were the same in both arms, which the authors attributed to salvage therapy [21]. The major criticism of this study is the lack of a comparison arm with maintenance rituxumab, which has also been shown to improve PFS, and the lack of rituximab in the chemotherapy alone arms in this trial [22, 23]. Press et al. with the Southwest Oncology Group (SWOG) reported similar encouraging results in a phase II study using ^{131}I-tositumomab in the consolidation setting after six cycles of CHOP. In 90 patients, the overall and complete response rates were 91% and 69%, respectively, and 5-year progression-free survival was 67%. These outcomes were higher versus historical studies with CHOP alone [24]. Based on these results, a phase III study of CHOP/rituximab versus CHOP/^{131}I-tositumomab was conducted in patients with previously untreated follicular lymphoma (SWOG S0016). Patients were randomly assigned to six cycles of CHOP with rituximab ($n = 267$) or six cycles of CHOP and a single dose of therapeutic ^{131}I-tositumomab ($n = 265$). After a median of 4.9 years of follow-up, no difference in PFS or OS survival was seen between the CHOP-R and CHOP-RIT groups [25]. The Spanish intergroup PETHEMA/GELTAMO/GELCAB conducted a randomized phase II trial comparing consolidation with ^{90}Y-ibritumomab tiuxetan ($n = 63$) and maintenance rituximab ($n = 61$) after a response to R-CHOP in patients with grades 1-3a follicular lymphoma. Thirty-six month PFS survival was higher in the maintenance rituximab group than the RIT group (86% versus 64%, $p = 0.01$) [26]. Overall survival was similar between the two arms at the time of follow-up in that study. Overall, it seems that consolidation or maintenance anti-CD20 therapy is helpful in terms of PFS and the optimal regimen remains to be determined. Press et al. also raised additional questions about maintenance rituximab versus RIT and a combination of these to further optimize PFS [25].

As in the recurrent setting, RIT is also very well tolerated in the front-line and consolidation settings. Hematologic side effects were again the most common, but more modest compared to the recurrent setting [19–21]. One difference is the

occurrence of HAMA (~50% in Kaminski's initial treatment with RIT study [19]) and the observation of associated clinical symptoms. A flu-like illness (fever, chills, myalgias, arthalgias) developed in 26% of patients with HAMA [19]. Symptoms were moderate and resolved without sequelae in 3–4 days. An association with shorter progression-free survival was suggested in post-hoc analysis for patients who developed very high HAMA levels (>5 times the lowest level found in the first 7 weeks). No cases of MDS/AML were reported by Kaminski et al. using ^{131}I-tositumomab [19]; however, in the long-term follow-up of the FIT trial, the annualized incidence of rate of MDS/AML was higher in the ^{90}Y-ibritumomab tiuxetan consolidation arm than controls (0.50% versus 0.07%, $p = 0.42$) [21]. The eight patients who developed MDS/AML received various subsequent treatments, and a common cytogenetic abnormality (−7 and/or 5q deletion) was found in six. The rate of MDS/AML was similar to those reported in other studies investigating RIT and non-RIT treatment [17, 25], but certainly raises a concern given that all eight patients with MDS/AML were in the RIT arm.

Logistics of RIT Regimens and Practical Considerations

The logistics of administering RIT, including determining which patients are eligible for treatment, are described and reviewed in the agents package inserts as well as by Wahl, Wagner et al. and by Goldsmith [1, 2, 27–29].

First, patient eligibility for RIT must be determined. This is largely determined by indication and the ability to safely administer the agents. Patients must have CD20$^+$ lymphoma and the currently approved indications are listed in Table 1. The use of RIT has been evaluated for other indications (i.e., diffuse large B-cell lymphoma, less common indolent lymphomas, mantle cell lymphoma). In these cases, RIT is best administered in the clinical trial setting and on an individual basis in close consultation with the referring oncologist, and with full informed consent of the patient who is made aware of the potential risks and benefits.

The minimum laboratory requirements for treatment are shown in Table 2. The minimum recommended platelet requirement is 100,000/mm^3 and absolute neutrophil requirement is 1,500/mm^3. The prescribed therapeutic activities for both ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab are based on platelet count (Table 2). Patients with a prior history of transplant can be treated safely, although reduced doses of RIT may be considered [10, 30, 31]. In order to avoid extensive and prolonged toxicity to the bone marrow, patients should have <25% of the marrow involved with lymphoma at the time of RIT. Traditionally, this is ascertained by marrow biopsy within 6–8 weeks before RIT, but [^{18}F]FDG PET may provide complementary information as well. Pertinent medical history also includes, but is not limited to, allergies to medications, reactions to prior administrations of monoclonal antibody therapy, and concurrent medications (e.g., anti-platelet and anti-clotting agents).

There are additional considerations for ^{131}I-tositumomab. Creatinine levels should be assessed because free radioiodine is renally excreted and there is potential for a high radiation dose to the uro-epithelium in a patient with renal obstruction. Radiation safety issues, including home environment, must also be assessed and this may play a role in deciding which agent to use for RIT (discussed below). Radiation safety precautions to be followed are reproduced in the review article by Goldsmith [27].

Table 1 Clinical indications for radioimmunotherapy of lymphomas

^{131}I-tositumomab	^{90}Y-ibritumomab tiuxetan
CD20$^+$ relapsed or refractory low-grade, follicular, or transformed NHL, including patients with rituximab-refractory NHL	Relapsed or refractory low-grade or follicular B-cell NHL
	Previously untreated follicular NHL who achieve partial or complete response to first-line chemotherapy

Table 2 General eligibility and dosing for radioimmunotherapy of lymphomas

General eligibility criteria	For both agents:
	Tumor-expressing CD20
	Platelet count $\geq$100,000/mm^3
	Absolute neutrophil count $\geq$1,500/mm^3
	<25% lymphomatous marrow involvement
	Other pertinent medical history:
	Medications
	Allergies
	Absence of infusion reactions to prior antibody therapy
	For ^{131}I-tositumomab:
	Baseline creatinine level
	Ability to follow radiation safety precautions
Therapeutic dosing of RIT	
Platelet count $\geq$150,000/mm^3	
^{90}Y-ibritumomab tiuxetan	0.4 mCi/kg
^{131}I-tositumomab	75 cGy total body radiation dose
Platelet count =100,000–150,000/mm^3	
^{90}Y-ibritumomab tiuxetan	0.3 mCi/kg
^{131}I-tositumomab	65 cGy total body radiation dose

Until very recently, the regimens for both ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab consisted of two steps in the United States. For both regimens, the first step consisted of imaging studies and the second step consisted of the administration of the therapeutic radiolabeled antibody. The schemas for each are shown in Fig. 1, and although similar, the major difference is the method for determining the amount of radioactivity to administer for the therapeutic dosage.

Because ^{90}Y is a pure β^- emitter, imaging studies are performed with ^{111}In-ibritumomab tiuxetan (185 MBq, or 5 mCi). The purpose is to assure normal biodistribution of the tracer and avoid inadvertently delivering high radiation doses to normal organs. The incidence of abnormal biodistribution studies with ^{111}In-ibritumomab tiuxetan is low [30]. In the United States, the requirement for ^{111}In-ibritumomab tiuxetan imaging prior to therapeutic ^{90}Y-ibritumomab was removed by the Food and Drug Administration in late 2011. Kylstra et al. presented a meta-analysis of five clinical trials and 9 years of post-approval safety data [32]. There was no difference in incidence of serious adverse events or bone marrow failure in countries performing imaging (United States/Japan) and not performing imaging (rest of world) [32]. The amount of ^{90}Y radioactivity to administer for the therapeutic dosage is calculated based on platelet count and patient weight because, despite some patient-to-patient variability, only modest correlations between pharmacokinetic/dosimetric parameters using ^{111}In-ibritumomab tiuxetan and hematologic toxicity have been demonstrated [31, 33].

Although biodistribution is also assessed, imaging before therapeutic ^{131}I-tositumomab is performed (with 185 MBq ^{131}I-tositumomab) mainly to determine patient-specific kinetics. The amount of radioactivity (in mCi) to achieve a desired total body radiation dose is then calculated based on this patient-specific kinetics, and a single therapeutic amount of ^{131}I-tositumomab is administered [34–36].

Prior to administration of both the tracer and therapeutic doses of ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab, unlabeled anti-CD20 antibody (rituximab and tositumomab, respectively) is given to increase the tumor radiation dose relative to normal tissue radiation dose, as well as to increase the serum half-life of the radiolabeled antibody [37]. There has been some suggestion

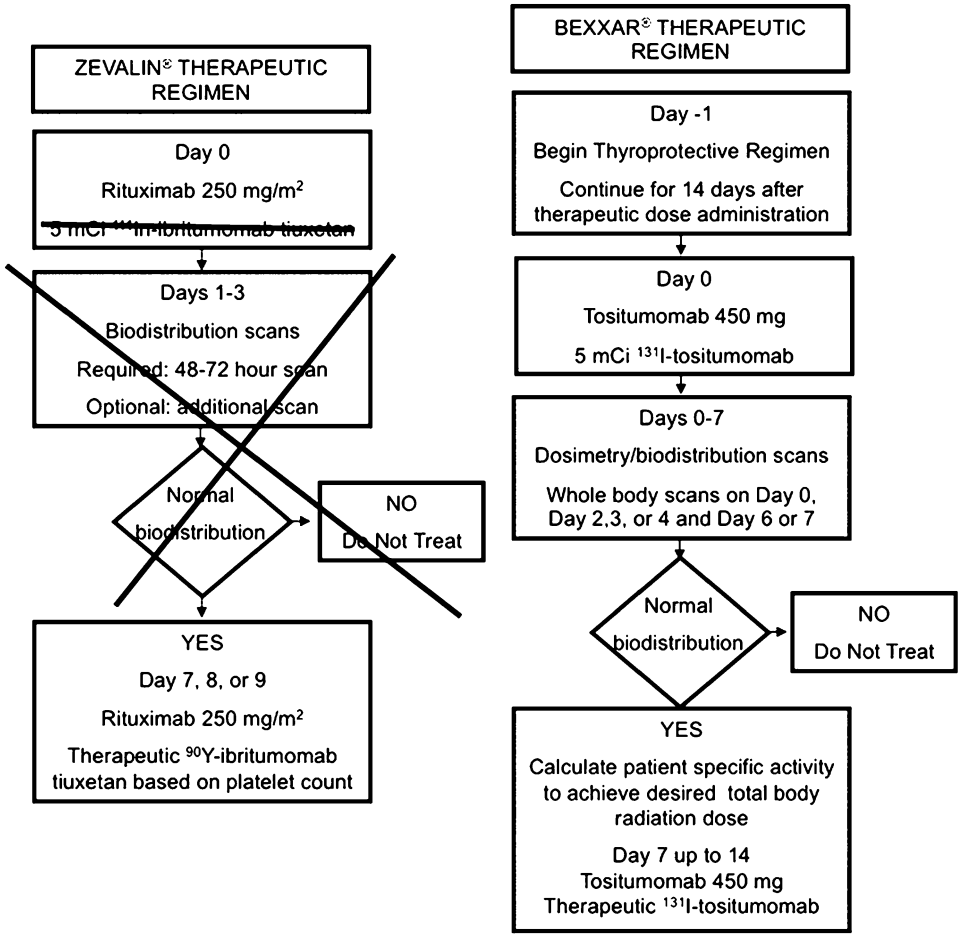

Fig. 1 Schemes for Zevalin® and Bexxar® therapeutic regimens adapted from prescribing information. The infusions of unlabeled and labeled antibody are administered intravenously and preceded by pre-medications to decrease infusion reactions and side effects. Biodistribution with ^{111}In-ibritumomab tiuxetan is no longer required in the United States prior to therapy with ^{90}Y-ibritumomab tiuxetan (Zevalin®)

that administration of unlabeled antibody may, in some settings, block available tumor CD-20 positive sites and prevent the radiolabeled antibody from binding to tumor [38]. There is some logic to this, and it is noted that in the initial studies showing improved tumor dosimetry with pre-dosing, clinical efficacy of RIT in the recurrent and consolidation settings were performed mostly in rituximab-naïve patients. Regardless, no clinical data yet supports that prior rituximab, or unlabeled tositumomab pre-dosing, decreases the clinical efficacy of RIT [39], and further work on this issue is needed.

There are currently no randomized controlled trials comparing ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab. The clinical efficacy and safety profiles of the single agents, ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab, are similar in the clinical trials reported so far. From a practical standpoint, once a patient is determined to be a candidate for RIT, either agent may be used. However, as of February 2014, commercial production of ^{131}I-tositumomab was discontinued, thus limiting the clinical choice.

Prior to 2014, we used both ^{131}I-tositumomab and ^{90}Y-ibritumomab tiuxetan routinely. When a

patient was felt to be a candidate for RIT, one of the agents was chosen based on patient and disease characteristics as well as referring physician preference and familiarity. Differences in the physical properties of the agents and resultant studies, although very limited, helped to guide our decision process [40, 41].

Song et al. [41] performed a Monte-Carlo based dosimetric analysis and found that when compared to ^{90}Y, ^{131}I has a narrower distribution of tumor absorbed doses of radiation and is predicted to be more efficacious in the treatment of lung nodules, particularly those with radii less than 2 cm, presumably because of the shorter path length of ^{131}I (0.8 mm) compared to ^{90}Y (5.3 mm) [27]. This may be of particular relevance in small tumor foci near normal structures, if these findings can be extrapolated beyond the lungs [41].

We also retrospectively evaluated our clinical experience with ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab from 2002 to 2006 and found less severe declines in platelet count with ^{131}I-tositumomab (which is based on patient-specific dosimetry) than with ^{90}Y-ibritumomab tiuxetan (for which dosimetry measures are not performed) [40]. We suggested that ^{131}I-tositumomab may be a more appropriate choice for patients with limited bone marrow reserve or lung metastases, or conditions which might alter the biological clearance rate of the radioantibodies; however, large, randomized, prospective trials would be needed for further evaluation.

The entire patient and clinical situation must be considered when assessing appropriateness for RIT, including radiation safety regulations at the institution and the ability of the patient to follow radiation safety precautions. The choice of RIT agents is currently limited to ^{90}Y-ibritumomab tiuxetan due to commercial availability in the United States. In Australia, ^{131}I-rituximab is available for treatment in select patients.

Subsequent therapies have been well tolerated after RIT. Multiple cycles (up to seven) of chemotherapy and radiation therapy have been given post-RIT [42, 43]. Autologous and allogeneic transplants have been performed after RIT, with adequate stem cell collection occurring after RIT. The toxicity of various subsequent therapies has not been shown to be different after RIT.

Repeat Therapies

Neither ^{90}Y-ibritumomab tiuxetan nor ^{131}I-tositumomab are approved by the FDA for repeat dosing, but repeat dosing for both agents has been studied to a limited extent. A consideration for repeat dosing is the induction of a host immunologic response, because both ^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab are mouse antibodies. The chance of developing human anti-mouse antibodies (HAMA) is higher with tositumomab/^{131}I-tositumomab because the pre-dose (and larger protein load) of antibody is also mouse antibody, whereas the pre-dose for ^{90}Y-ibritumomab tiuxetan is the human/mouse chimeric antibody rituximab. Most patients with follicular NHL who receive RIT have also received prior therapies and are somewhat immunocompromised, thus probably decreasing the chance of developing HAMA.

Kaminski et al. reported on 28 of 32 patients with relapsed follicular NHL who received a second dose of ^{131}I-tositumomab after previously responding to ^{131}I-tositumomab for at least 3 months [44]. The median duration of response in this population was similar for the first and second doses of ^{131}I-tositumomab and 10 of the 18 re-responders had a longer duration of response with the repeat dose, 5 of which lasted longer than 1.5 years. Hematologic toxicity was similar after the first and second doses of ^{131}I-tositumomab. Ten percent of patients developed HAMA and 12% had an elevated thyroid-stimulating hormone [44].

A retrospective study was done describing experience with ^{90}Y-ibritumomab tiuxetan re-treatment. Eighteen patients were identified from the Biogen-IDEC database. Similar to ^{131}I-tositumomab, the safety and efficacy profiles after the second course of ^{90}Y-ibritumomab tiuxetan were overall similar to the first. There are also several case reports of individuals tolerating and benefiting from repeat doses of RIT [45–47]. These data suggest that, in selected patients, repeat treatment with RIT may be beneficial.

Others have evaluated administering ^{90}Y-ibritumomab tiuxetan with fractionated or sequential schedules. A phase II study evaluated fractionated ^{90}Y-ibritumomab tiuxetan for initial therapy of follicular lymphoma [48]. Seventy-four patients were enrolled: 55 received both doses of ^{90}Y-ibritumomab tiuxetan 8–12 weeks apart and 17 received only a single dose of ^{90}Y-ibritumomab tiuxetan due to hematologic toxicity, treating physician preference, HAMA, or premorbid condition. Overall response rate was 94.4% with CR/CRu rate of 58.3% after the initial dose, and nine patients improved their response after the second dose. Estimated 3-year overall survival was 95%, and median PFS was 3.35 years. Toxicity was primarily hematologic, as expected, with slightly higher percentage of grade 3–4 toxicity and duration of toxicity with the second dose [48].

Witzig et al. performed a phase I study to determine the maximally tolerated dose (MTD) of two rapidly sequenced doses of ^{90}Y-ibritumomab tiuxetan given 12–24 weeks apart [49]. Eighteen patients were enrolled and dose-limiting hematologic toxicity was seen in the cohort receiving 0.3 mCi/kg for the second dose of ^{90}Y-ibritumomab tiuxetan. The authors concluded that the MTD for the second dose of ^{90}Y-ibritumomab tiuxetan was 0.2 mCi/kg [49]. Consideration of the time from last treatment, response to last treatment, baseline and previous hematologic toxicity and time to recovery, and bone marrow tumor burden are all important considerations in the repeat setting, which again is not an FDA indication.

Barriers to the Use of RIT

Radiolabeled anti-CD20 antibody therapy for low-grade follicular lymphoma is effective and it has a predictable and very tolerable safety profile. Nevertheless, despite improvement in response rates compared to unlabeled rituximab and anti-lymphoma activity in patients with rituximab-refractory disease, these agents are not widely applied in the clinical setting. Limited drug sales led to the discontinuation of production of the ^{131}I-tositumomab agent in 2014. Schaefer et al. conducted two surveys in the United States to identify barriers to use of RIT [50, 51]. The first was an eight-question survey sent to medical oncologists, and 5% (216 of 4,239) responded [51]. The three top concerns were bone marrow damage and limiting future therapies, late side effects and too many effective nonradioactive alternatives. Contrary, the literature supports that subsequent therapies are well tolerated after RIT. There were some differences in concerns amongst oncologists practicing in academic versus nonacademic settings. Nonacademic oncologists had significantly greater concerns regarding adverse economic effects on their own practice, lack of referral centers, complicated referral process and lack of interest by Nuclear Medicine specialists. Despite these concerns, 37% thought that RIT would grow in use in the United States [51].

The second survey was sent to nuclear medicine physicians and radiation oncologists; 4.6% (613 of 13,221) responded [50]. About 40% did not treat NHL with RIT. The biggest concerns among this group was that referring providers wanted to treat patients themselves with nonradioactive drugs, and the cost of RIT. Those who thought RIT had a negative future believed that the procedure was time consuming, had concerns about the dosimetry procedure and radiation safety, and the high-cost. Those from academic centers had less concerns about these issues than those in nonacademic settings [50].

Other Settings for RIT

In addition to non-follicular NHL subtypes, the use of RIT is under investigation in several additional clinical situations. In the transplant setting, standard and high dose (myeloablative) RIT has been included in conditioning regimens. The approaches have varied from institution to institution, but results from multiple phase II trials have shown that the addition of RIT is tolerable without increasing toxicity, and the efficacy results have shown promise. They are reviewed

by Gisselbrecht et al. [52]. A phase III intergroup study comparing Rituxan/BEAM ($n = 113$) versus BEXXAR/BEAM ($n = 111$) conditioning prior to autologous stem cell transplant for persistent or relapsed chemosensitive DLBCL showed similar 2-year PFS and OS between the groups [53].

[^{18}F]FDG-PET for Evaluation of Response to RIT

[^{18}F]FDG uptake in tumors typically drops significantly following RIT [54–60] (Fig. 2). Large declines in [^{18}F]FDG uptake tend to be seen in patients with the longest progression-free survival [55, 56].

Semi-quantitative parameters on pre-RIT PET have been evaluated as possible predictors of response. In 1991, Okada et al. reported that patients with the worse prognoses after chemotherapy and/or radiotherapy had higher levels of [^{18}F]FDG uptake [57]. Several subsequent studies have not shown a correlation between pre-RIT SUV_{max} corrected for whole body or lean body weight of the hottest tumor and response [54, 55]; however, a trend for this was very recently reported by Cazaentre et al. [54]. In this study, Cazaentre et al. [54] also found that pre-RIT total lesion glycolysis (a measure of [^{18}F]FDG uptake and tumor volume) was higher for those who did not respond to RIT compared to those who did. Tumor volume has previously been shown to be a prognostic factor for response to RIT and may be more indicative of disease state than the metabolic activity of a single lesion. In a study of 59 patients with follicular NHL treated with ^{90}Y-ibritumomab tiuxetan, post-RIT PET response was the only independent predictive factor for progression-free survival in the multivariate analysis [56].

The optimal timing to obtain a PET scan after RIT is still being defined. We, and others, have performed PET scanning 2–3 months after RIT with several interesting observations. At this time point, it is possible to identify those with a complete response, those with progressive disease (most commonly due to new lesions) and in such instances, management decisions are clear [55, 58]. However, [^{18}F]FDG-PET cannot adequately predict the subsequent outcome of the group of patients who achieves a partial response by the revised IWG at 12 weeks. Some patients

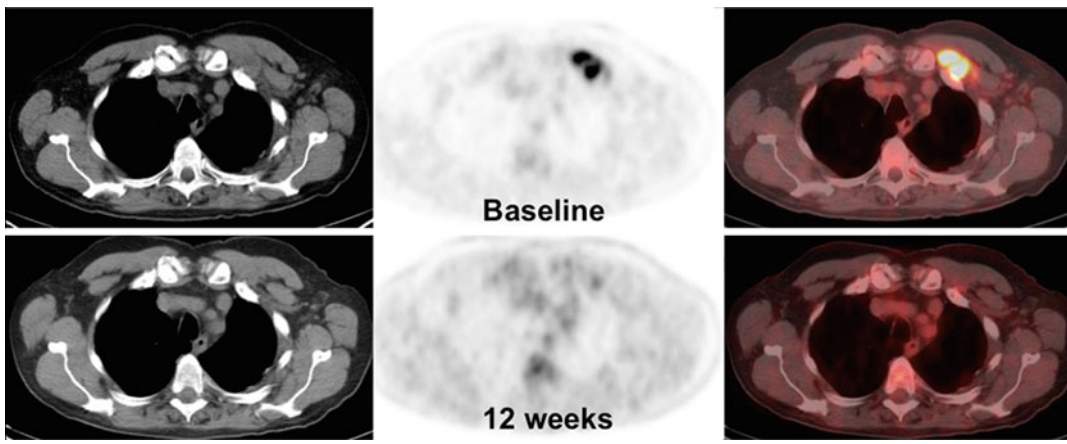

Fig. 2 A 62-year-old man with a history of transformed non-Hodgkin's lymphoma (NHL). He received five regimens for low-grade NHL and then progressed with transformation to diffuse large B-cell lymphoma after R-CHOP. He was referred for radioimmunotherapy (RIT). At the time of therapy, his platelet count was 180,000/mm^3 and the absolute neutrophil count was 3,320/mm^3. He received 0.4 mCi/kg ^{90}Y-ibritumomab tiuxetan. The baseline PET/CT scan shows intense [^{18}F]FDG uptake in left supraclavicular lymph nodes (A: *top row*). At 12 weeks after therapy, the [^{18}F]FDG uptake in lymph nodes resolved, which is consistent with complete response to RIT. The duration of response was 10 months. (*Left*: CT; *Center*: PET; *Right*: Fused PET/CT)

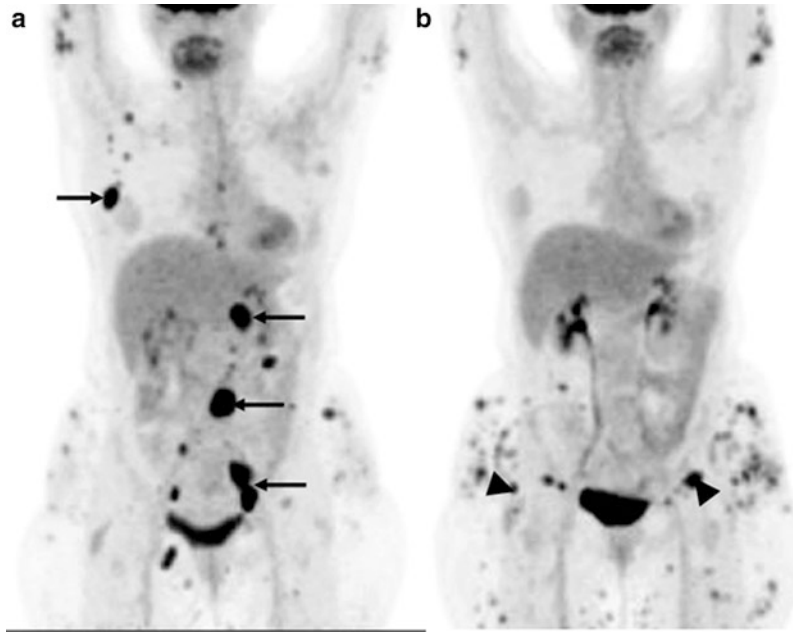

Fig. 3 A 59-year-old woman with a long history of stage 4 splenic marginal zone lymphoma status post splenectomy and multiple treatments with local external beam radiation and single-agent rituximab was referred for radioimmunotherapy and treated with a 75 cGy total body radiation dose of ^{131}I-tositumomab. The pre-RIT PET/CT scan (**a**) shows multiple foci of abnormal [^{18}F]FDG uptake in right axillary, upper abdominal, para-aortic, iliac, and inguinal lymph nodes, which is consistent with active lymphoma. There were also numerous subcutaneous nodules present indicating lymphoma. Post-RIT (**b**), many of the large lymph nodes resolved (e.g., *arrows*); however, new lymph node lesions (*arrowheads*) and subcutaneous lesions were seen, suggesting overall progressive disease. The patient refused further systemic chemotherapy but has received further external beam radiation to sites causing local symptoms

may have a continued response, warranting further observation, while others may progress necessitating treatment. Several authors have found longer response durations and time to progression with patients who have a response seen on PET scans performed even earlier, at 4–6 weeks post-RIT [59, 61]. Further prospective studies in larger numbers of patients are needed.

The use of [^{18}F]FDG-PET for evaluating response to RIT has helped to demonstrate an interesting pattern of relapse after RIT. In our own study, we found that progressive disease was only due to "new" lesions in a majority of patients (11/12) who progressed at 12 weeks (Fig. 3) [55]. Aviles et al. found that bulky disease was a negative factor for achieving a CR to RIT, but if a CR was achieved, the site of bulky disease was not at increased risk for recurrence [62]. Lymphoma is more likely to recur outside initial radiation ports after external beam radiation therapy; whereas, recurrence is more likely at initial sites and less frequently at new sites after chemotherapy alone. These data suggest that the quality of the initial response may predict long-term outcome and that progressive disease/relapse may be more likely to occur at new sites of disease rather than at sites of previous involvement.

Other Radiolabeled Monoclonal Antibodies and Strategies

Several other radiolabeled monoclonal antibodies are currently under investigation [63, 64]. ^{90}Y-veltuzumab (Immunomedics, Inc, Morris Plains, NJ) is a humanized anti-CD20 monoclonal antibody. The potential benefit of the humanized

antibody is less HAMA formation. Initial phase I/II clinical studies have been reported with the unlabeled antibody [65] and the therapeutic activity of the radiolabeled agent in animal models of NHL is reported [64].

Epratuzumab is an anti-CD22 monoclonal antibody. CD22 is a B-cell marker found on 60–80% of B-cell malignancies. Epratuzumab has been radiolabeled with ^{131}I and ^{90}Y radioisotopes [64]. In a pilot study of 11 patients with refractory B-cell lymphomas, six patients responded to ^{131}I-epratuzumab, three with a complete response [66]. More responses were seen with follicular and transformed NHL than DLBCL, and toxicity was higher in patients with decreased marrow reserve. A potential disadvantage with ^{131}I-epratuzumab is internalization and a short intracellular half-life. Better tumor dosimetry has been reported for ^{90}Y-epratuzumab. Using a fractionated schedule of ^{90}Y-epratuzumab in 16 patients with NHL, the same group reported overall response rates of 62% and CR rates of 25% [66]. Epratuzumab has also been labeled with Rhenium-186 and administration is feasible in phase I trials [67].

The group at Fred Hutchinson Cancer Research Center in Seattle (WA, USA) has demonstrated therapeutic activity of ^{131}I-anti-CD45 antibodies in NHL B-cell and T-cell xenograft models, with minimal toxicity [68, 69].

In addition to targeting various isotopes, improving approaches and schedules for administration of RIT are areas of active investigation. These approaches were recently reviewed by Sharkey et al. [64]. In the pre-targeting approach, bispecific antibodies recognize both the tumor target and a radiolabeled hapten-peptide. The unlabeled bispecific antibody is given first and allowed to bind to the target. Several days later, the radiolabeled hapten-peptide is given which binds the bispecific antibody. Pre-targeting should help to decrease the serum half-life of the radiolabel in the blood and subsequently exposure of non-tumor hematopoietic tissue and toxicity. Combinations of antibodies targeting different surface antigens may also help to increase the amount of tumor targeting and circumvent the issue of "tumor blocking" by unlabeled antibody.

Radionuclide Therapy of Leukemias and Multiple Myeloma

41

Martina Sollini, Sara Galimberti, Roberto Boni, and Paola Anna Erba

Abstract

Monoclonal antibodies (MAbs) raised against cancer antigens may mediate antibody-dependent cell-mediated cytotoxicity. This form of cancer control arises from cytolysis of a target cell by effector lymphocytes, such as cytotoxic T lymphocytes or natural killer cells. However, most of these antibodies have low/moderate efficacy for tumor control. Antibodies targeting hormone receptors expressed by cancer have shown greater tumor control compared with other cell membrane targets. Moreover, the labeling of these antibodies with a toxin can potentiate their efficacy for tumor control. In this way, the antibody becomes an invaluable targeting vector for delivery of the toxin to the cancer cells. The toxin/antibody complex is called an immunoconjugate. Different molecules, chemicals, or radioisotopes can serve as toxins; toxins may have long half-lives in the body (e.g., ricin), thus increasing the toxicity to both the cancer cells and normal tissues.

Beta emitting radioisotopes, predominantly iodine-131, have had only modest success in radioimmunotherapy. More recently, high-linear-energy transfer (LET) radiation in the form of alpha particles has been studied: alpha radiation is ideal for killing isolated cancer cells in transit in the vascular and lymphatic systems and regressing tumors by disruption of tumor capillary networks by targeting and killing tumor capillary endothelial cells.

Over the past 20 years, the development of alpha-immunoconjugates has enabled targeted alpha therapy (TAT) to progress from in vitro studies, through in vivo experiments, to clinical trials. The dose to normal tissues limits the injected dose and that received by the tumor. However, TAT can achieve cancer regression within the maximum tolerance dose for normal tissue. TAT was originally thought to be an ideal therapy for "liquid" cancers, e.g., leukemia and micrometastases, as the short half-lives of the radioisotopes were sufficient to target these cancer cells and the short range ensured that the targeted cancer cells received the highest radiation dose. Different antibodies have been developed and tested in clinical trials as conditioning treatment, but none of them have yet been approved for RIT in MM. Additionally, bone-seeking radiopharmaceuticals are being evaluated in MM patients in the transplant setting.

Radioimmunotherapy of Leukemia

Radiolabeled antibodies with affinity for hematopoietic cells may be used for myeloablative radioimmunotherapy (RIT) to increase the radiation dose to the bone marrow spearing normal cells prior to autologous stem cell transplantation (ASCT) in patients with leukemia.

This strategy relies on a well-known side effect of treatments with radiolabeled antibodies: accumulation in the bone marrow which is evident even in the presence of low burden bone marrow disease or when the targeted antigen is co-expressed on healthy hematopoietic cells. In these cases, ASCT may be required to limit severe therapy-induced cytopenia and to prevent complications such as severe infections or bleeding [1–3].

Treatment of Acute Lymphocytic Leukemia (ALL) in Adults

When the diagnosis is established, treatment should start immediately. The outcome of ALL is strictly related to the age of patient, with probability of success from 80% to 90% in childhood ALL, decreasing to <10% in elderly/frail ALL patients [4].

Currently, the use of monoclonal antibodies is a promising approach in the treatment of ALL. There are four types of monoclonal antibodies developed for ALL: (1) those destroying neoplastic cells by the antibody-dependent cell-mediated cytotoxicity (ADCC), such as rituximab, ofatumumab (anti-CD20), alemtuzumab (anti-CD52), and epratuzumab (anti-CD22); (2) antibodies conjugated with a drug, such as inotuzumab ozogamicin (anti-CD22 plus calicheamicin); (3) antibodies conjugated with a toxin, such as combotox (anti-CD22 combined with ricin A); and (4) bispecific antibodies T-cell engaging, such as blinatumomab (anti-CD19/CD3).

Epratuzumab added to conventional therapy (clofarabine and cytarabine) increased CR to 52% of patients versus 17% of the control arm [5].

Inotuzumab ozogamicin improved overall response rate (81% vs. 33%), with an evident advantage by achieving eradication of minimal residual disease (MRD) [6].

In a recent phase-3 trial, adults with relapsed or refractory ALL were randomized to receive either inotuzumab ozogamicin or standard intensive chemotherapy: the rate of CR was significantly higher in the inotuzumab ozogamicin group (81% vs. 29%), with an advantage also in terms of PFS (median, 5 vs. 2 months), but comparable OS [7].

In a series of relapsed ALL patients, blinatumomab induced 33% of CR and 82% of MRD negativity, but up to 70% of cases presented fever, hypotension, cerebellar symptoms, or encephalopathy [8].

Despite the existence of studies and meta-analyses comparing chemotherapy and allogeneic transplantation (alloSCT) [9], the indications for alloSCT in adult ALL patients in first CR is not defined and requires update. This is due to the improving results with conventional and targeted chemotherapy regimens on one hand and to the decreasing mortality and broader availability of alloSCT on the other. Several attempts have been made to provide evidence-based guidelines for indication of alloSCT [10–13]: some studies reported that alloSCT when performed in first remission was superior to the conventional chemotherapy, but other authors suggest it is useful only in a second remission. A pre-phase treatment with corticosteroids (usually prednisone or dexamethasone) alone, or in combination with another drug (e.g., vincristine, cyclophosphamide), is often given together with allopurinol (sometimes rasburicase to prevent the tumor lysis syndrome) and hydration for ~5–7 days as well as intrathecal prophylaxis. Interestingly, the response to this pre-phase therapy defines the chemosensitivity of the disease, with good responders to prednisone having a better outcome [14].

Supportive therapy should be initiated whenever necessary in particular to treat infections or to maintain circulating levels of platelets/erythrocytes. Severe neutropenia (<500/μL) is often seen at diagnosis and is most frequent (>80%) during induction therapy, causing infections and infection-related death [4]. The goal of induction therapy is the achievement of a complete response (CR) or, even better, a molecular CR or a good molecular response, usually obtained within 6–16 weeks from start of chemotherapy.

Most regimens are centered on vincristine, corticosteroids, and anthracyclines (daunorubicin, doxorubicin, idarubicin), sometimes with cyclophosphamide or cytarabine.

There are no randomized trials comparing different induction regimens; however, in 6617 patients from 14 studies, the weighted mean for

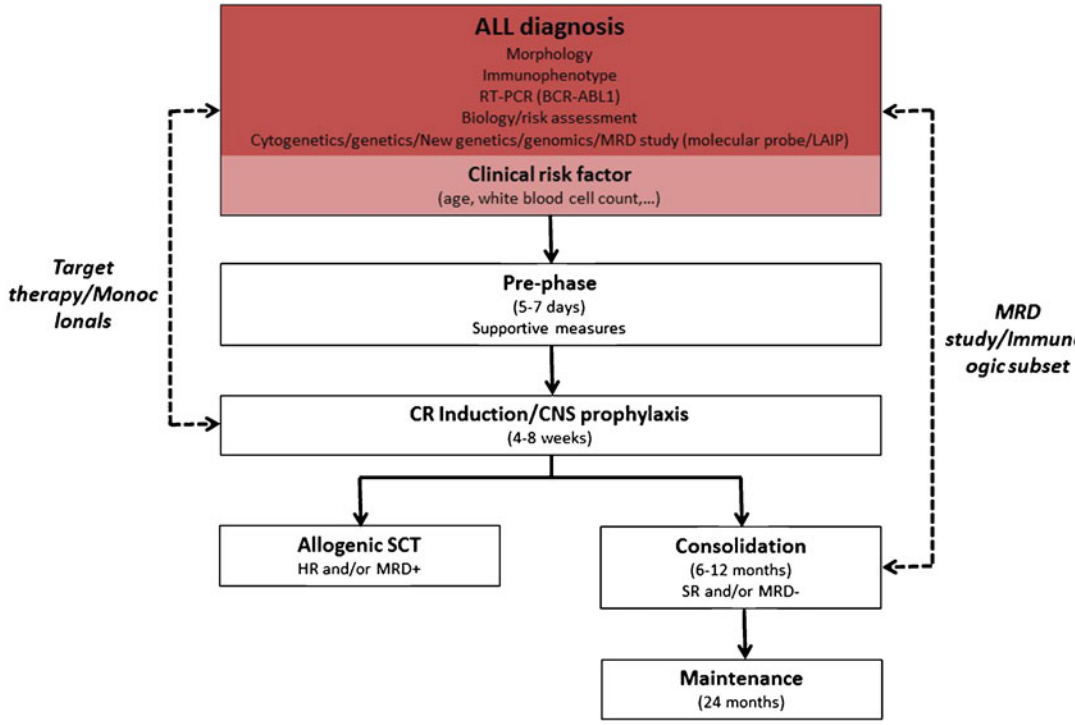

Fig. 1 Diagnosis and risk assessment in adult ALL for achievement of CR and risk-oriented post-remission therapy. Major diagnostic subsets are identified within 1–2 days to allow start of pre-phase therapy, identify cases eligible to targeted therapy (TKI in Ph+ ALL), and set up the MRD study. Pre-phase therapy allows for management/prevention of metabolic/infectious/hemorrhagic complications before the start of induction therapy and checks HLA identity between patient and siblings. Induction/early consolidation therapy (incorporating CNS prophylaxis) aims to induce CR with a deep MRD response, to support subsequent risk- and MRD-oriented therapy with/without allogeneic SCT. *ALL* acute lymphoblastic leukemia, *RT-PCR* reverse transcriptase polymerase chain reaction, *MRD* minimal residual disease, *LAIP* leukemia-associated immunophenotype, *WBC* white blood cells, *CR* complete remission, *CNS* central nervous system, *SR* standard risk, *HR* high risk, *SCT* stem cell transplantation, *TKI* tyrosine kinase inhibitor, *Ph+* Philadelphia positive, *HLA* human leucocyte antigen (Modified from Holzer et al. [4])

the CR rate was 83% (62–92%) [15]. Using current approaches, the CR rate had increased to 80–90% [4], according to the risk score. There are two prevalent approaches: one includes 2 cycles of induction followed by the consolidation [4] and represents the most frequently adopted in Europe. A schematic treatment algorithm in adult ALL according to ESMO Clinical Practice Guidelines [4] is reported in Fig. 1.

The second approach uses two different alternating intensive chemotherapy cycles, identical for induction and consolidation, accounting for a total of eight cycles, such as the hyper-CVAD (cyclophosphamide, vincristine, doxorubicin, dexamethasone) protocol, preferentially used in the United States [4].

Effective prophylaxis to prevent CNS relapse is an essential part of ALL therapy: treatment modalities include CNS irradiation and intrathecal methotrexate, eventually combined with steroids or cytarabine and systemic HD therapy with either methotrexate and/or cytarabine. The combination of these measures reduces CNS relapses from 10% to <5%. Patients with CNS involvement (mostly of the leptomeninges) at diagnosis are treated with the standard chemotherapy regimen and additional intrathecal applications until there is complete blast clearance in the spinal fluid [4].

The rationale to use systemic high-dose (HD) therapy in the post-remission consolidation is to reach sufficient drug levels in sanctuary sites (e.g., CNS). Most protocols employ 6–8 cycles containing either HD methotrexate or HD cytarabine ± L-asparaginase [4].

Maintenance therapy usually consists of daily 6-mercaptopurine and weekly methotrexate; in some treatment regimens, repeated cycles of vincristine, dexamethasone, or other drugs in monthly or longer intervals are given. Treatment duration of 2.5–3 years is optimal and is usually recommended [4]. Omission of maintenance worsens outcome significantly in BCP-ALL, less in T-ALL [16], and probably not in B-ALL [17].

Nevertheless, relapses are still a major clinical challenge, especially in adults: indeed, there is no universally accepted treatment, and evidence based on randomized, controlled trials is still lacking [4]. The most commonly used regimens in Europe are fludarabine- and anthracycline-containing regimens, such as FLAG-Ida (fludarabine, high-dose ara-C, granulocyte colony-stimulating factor, and idarubicin). Despite its common use and inclusion as "standard of care" arm in several trials for relapsed ALL, there is remarkably a small number of publications in relapsed ALL [18]. Clofarabine-based regimens including cytarabine, cyclophosphamide, or etoposide are also commonly used based mostly on data in childhood ALL [19]. Liposomal vincristine [20] is licensed for the treatment of relapsed ALL. These standard chemotherapy approaches are applicable in BCP-ALL as well as in T-ALL.

Additionally, nelarabine has been licensed for this indication: it offered 31% CRs, with median DFS and OS of 20 weeks, thus demonstrating that nelarabine is well tolerated and has significant antitumor activity in relapsed or refractory T-ALL [21].

Advances have also been made in the setting of Ph'+ ALL, because of the use of tyrosine kinase inhibitors, such as imatinib, dasatinib, and ponatinib [4].

The Italian group GIMEMA treated frontline elderly ALL patients with imatinib 800 mg daily, associated to steroids without further chemotherapy: 100% obtained CR, with a median BCR-ABL1 reduction of 2 logs. No major toxicities occurred and the median survival from diagnosis was 20 months [22].

In another GIMEMA protocol, patients with Ph'+ ALL received dasatinib induction therapy for 84 days combined with steroids for the first 32 days and intrathecal chemotherapy: also in this case, all patients achieved CR by the first month, with 20-month OS of 69% and DFS of 51%. The reduction of BCR-ABL1 levels to <10–3 did significantly an impact on DFS [23].

Dasatinib was used in combination with low-intensity chemotherapy (vincristine and dexamethasone, followed by consolidation with dasatinib, reduced doses of sequential cytarabine and methotrexate for 6 months) in patients older than 55 years. CR rate was 96%, and 65% of patients achieved a 3-log reduction in BCR-ABL1 transcript levels during consolidation, with 5-year OS of 36% [24].

The MDACC recently published about the combination of the HyperCVAD regimen and ponatinib: 2-year event-free survival was 81%, with an 8% incidence of cardiovascular/thrombotic events [25].

Although targeted therapies are used increasingly in hematologic malignancies, RIT is not extensively used in ALL, even though this radiosensitive tumor expresses CD22, potentially a good target for this approach. Positive results have been published using ^{90}Y-epratuzumab tetraxetan [26].

Chevallier et al. [27] published results of a standard 3 + 3 phase I study which evaluated ^{90}Y-DOTA-epratuzumab RIT in refractory or relapsed CD22-positive B-cell acute lymphoblastic leukemia (with CD22 expression on at least 70% of blast cells). Treatment protocol included one cycle of ^{90}Y-DOTA-epratuzumab on days 1 and 8 at one of four dose levels: 92.5 MBq/m^2 (level 1), 185 MBq/m^2 (level 2), 277.5 MBq/m^2 (level 3), and 370 MBq/m^2 (level 4). Seventeen patients were treated (5 at level 1, 3 at level 2, 3 at level 3, and 6 at level 4): one dose-limiting toxic effect (aplasia lasting 8 weeks) occurred at level 4, but the MTD was not reached. The most common grade 3–4 adverse events were pancytopenia and infections. Authors concluded recommending the dose of 370 MBq/m^2 for two doses 1 week apart per cycle.

RIT using murine ^{131}I-anti-CD52 mAb has been used in the conditioning regimen for allogeneic hematopoietic stem cell transplantation in recurrent refractory CD52-positive ALL preceded by ^{124}I-labeled anti-CD52-mAb PET to evaluate dosimetry [28].

A patient with Ph'+ B-ALL in third relapse received RIT with ^{90}Y-labeled anti-CD22 epratuzumab tetraxetan; 7 weeks after initiating therapy, the patient became BCR-ABL1 negative by quantitative PCR lasting at 6 months before alloSCT. Although with limited clinical data, ^{90}Y-epratuzumab tetraxetan may be a promising therapeutic option for CD22+ B-ALL [26].

Treatment of Chronic Lymphocytic Leukemia

The first decision to be made in CLL is whether the patient requires therapy. A schematic treatment algorithm in adult CLL according to ESMO Clinical Practice Guidelines [29] is shown in Fig. 2.

Previous studies have shown that early treatment with chemotherapeutic agents does not translate into a survival advantage in patients with early-stage CLL. The standard treatment of patients with early disease is a watch-and-wait strategy. Blood cell counts and clinical examinations should be carried out every 3–6 months [29]. In Binet stage A and B with active disease or Binet stage C, Rai 0–II with active disease or Rai III–IV, treatment should be initiated in patients with symptomatic, active disease. Active disease is defined as significant B symptoms (weight loss, sweating, itching); cytopenias not caused by autoimmune phenomena and symptoms or complications from lymphadenopathy, splenomegaly, or hepatomegaly; lymphocyte doubling time of $<$6 months (only in patients with more than 30×10^9/L lymphocytes), as well as autoimmune anemia and/or thrombocytopenia poorly responsive to conventional (steroid) therapy. The presence of del(17p) or TP53 mutation without the abovementioned conditions is not an indication for treatment by itself [29].

In physically fit patients (physically active, with no major health problems, normal renal

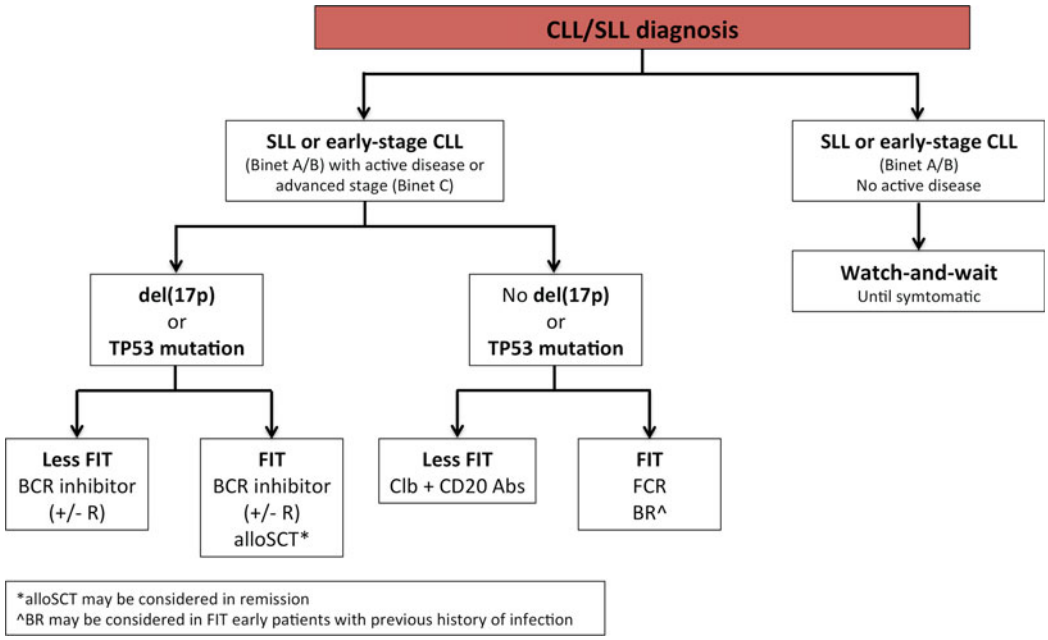

Fig. 2 Algorithm for frontline treatment in CLL. *CLL* chronic lymphocytic leukemia; *SLL* small lymphocytic leukemia; *BCR* B-cell receptor; *R* rituximab; *alloHSCT* allogeneic hematopoietic stem cell transplantation; *FCR* fludarabine, cyclophosphamide, and rituximab; *BR* bendamustine plus rituximab; *Clb* chlorambucil (Modified from Eichhorst et al. [29])
