function) without TP53 deletion/mutation, fludarabine, cyclophosphamide, and rituximab (FCR) therapy is the standard first-line therapy with significantly improved OS [29, 30]. Combinations based on other purine analogues, such as cladribine [31] or pentostatin [32], have shown similar activity, but it is uncertain whether they can replace fludarabine in the FCR regimen. In fit but elderly patients, FCR was shown to be associated with a higher rate of severe infections when compared with bendamustine plus rituximab (BR) [29]. Therefore, in this group of patients, therapy with BR may be considered, although it produces fewer complete remissions than FCR [29]. In patients with relevant comorbidity, who are usually older, but without TP53 deletion/mutation, the combination of chlorambucil plus an anti-CD20 antibody (rituximab, ofatumumab, or obinutuzumab) prolongs progression-free survival when compared with monotherapy and is therefore the standard approach [33]. In a head-to-head comparison of chlorambucil-based combinations, the type II antibody obinutuzumab (GA-101) was superior to the type I antibody rituximab with regard to PFS, complete remission, and minimal residual disease remissions [29].

Nevertheless, patients with TP53 deletion/mutation have a poor prognosis even after FCR therapy [30]: therefore, it is recommended to treat them with novel inhibitors (ibrutinib, idelalisib plus rituximab) in frontline and at relapse.

Ibrutinib, an inhibitor of Bruton's kinase, in 17p CLL patients induced objective responses in more than 80% of cases, with 2-year PFS of 60%, comparing favorably with historical treatments that offered a median PFS of 1 year [34].

Idelalisib, a BCL2 inhibitor, in combination with rituximab was able to offer 82% of overall responses and median PFS of 17 months [35].

For fit patients responding to inhibitor treatment, the option of alloSCT can be discussed, using individual and transplant-related risk factors [36].

Maintenance therapy in CLL patients with higher risk of relapse may have some benefit, but are not generally recommended [29].

At relapse, the same regimen used as first-line may be repeated if the relapse occurs at least 24 months after chemoimmunotherapy and if TP53 deletion/mutation was excluded [29]. If relapse occurs before or in case of refractory disease, the therapeutic regimen should be changed with ibrutinib or rituximab combined with idelalisib [29, 37, 38]. A schematic treatment algorithm in adult CLL according to ESMO Clinical Practice Guidelines [29] is reported in Fig. 3.

Fit patients achieving the second remission should proceed to alloSCT [36]. On the contrary, autologous stem cell transplantation is not advantageous in CLL, but could be offered to patients achieving a good response after new drugs [29, 39].

Radiation therapy in CLL is indicated in case of large, bulky lymphoid masses causing compression symptomatology, especially if patients are unresponsive to chemotherapy. Splenic irradiation has been performed in patients with painful splenic enlargement or cytopenias related to hypersplenism, but splenectomy remains preferable. Following splenectomy, major improvements in blood counts can be achieved in 50–90% of patients [40]. Total body irradiation was used in the 1970s (response rates of 80–90%) [41] but no longer recommended since comparative studies of TBI with chemotherapy demonstrated a higher response rate with chemotherapy.

Radioimmunotherapy for the treatment of CLL has been limited by frequent extensive bone marrow involvement. Lym-1 is a radioimmunoconjugate consisting of a ^{131}I-labeled mouse IgG_k. The antibody recognizes a 31–35 kDa antigen presumed to be a polymorphic variant of the HLA-DR antigen and thought to be specific for B cells [42–46]. In a phase Ia trial including 10 patients, the antibody was well tolerated, but not active enough [47]. Repeated administration of ^{131}I-Lym-1 showed a dose-limiting thrombocytopenia in up to 28% of patients, but tumor regression was documented in some cases.

^{90}Y-ibritumomab tiuxetan and ^{131}I-tositumomab have also been used in patients with CLL excluding patients with bone marrow involvement >25% because of safety concerns. Nevertheless, Kaminski et al. [48] reported their experience in 14 patients with SLL and a median of four prior chemotherapeutic regimens, with responses occurring in

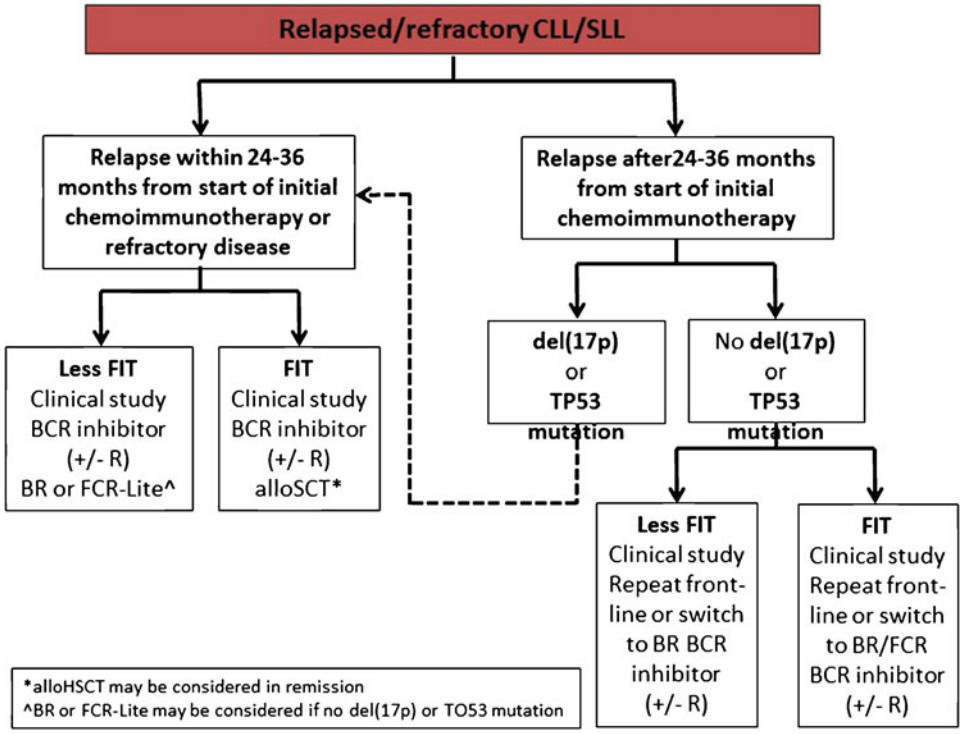

Fig. 3 Algorithm for relapse treatment in CLL. *CLL* chronic lymphocytic leukemia; *SLL* small lymphocytic leukemia; *BCR* B-cell receptor; *R* rituximab; *BR* bendamustine plus rituximab; *FCR* fludarabine, cyclophosphamide, and rituximab; *alloSCT* allogeneic hematopoietic stem cell transplantation (Modified from Eichhorst et al. [29])

64% of patients (including 21% complete remissions). The median duration of response was 24.7 months.

An interesting strategy under development is the reduction of bone marrow involvement prior to RIT therapy since the use of RIT in CLL is limited by the extent of bone marrow involvement. Thus, reducing the number of CLL cells in the bone marrow prior to RIT by the administration of an agent that is effective in clearing the bone marrow, such as anti-CD52 antibody (alemtuzumab), is a potentially interesting strategy.

Furthermore, ^{188}Re-alemtuzumab has been proposed by De Decker et al. [49] in an in vitro (HuT-78 cell line) and murine study (female NMRI mice) showing excellent receptor binding as well as a fast clearance from blood ($t_{1/2\alpha}$=4.79 h) and slower clearance from the body ($t_{1/2\beta}$=55.45 h). Mean radiation dose estimates, calculated for the human adults using the residence times derived from mice biodistribution data, identified the kidney (0.159–3.26 mGy/MBq), heart (0.0705–0.132 mGy/MBq), and liver (0.0602–0.220 mGy/MBq) as critical organs. The effective dose for the human reference adult was estimated to be approximately 0.0486–0.195 mSv/MBq [49, 50].

The ^{177}Lu-DOTA-HH1 (anti-CD37 monoclonal antibody) has been tested in nude mice to evaluate the toxicity profile; results demonstrated that ^{177}Lu-DOTA-HH1 was well tolerated at dosages about ten times above those considered relevant for RIT in patients with CLL and other non-Hodgkin lymphomas (NHL) [51].

^{131}I-tositumomab has been used in patients in complete/partial response after induction chemotherapy; 3 months after RIT, complete response was achieved (50%) or sustained (25%), and one third of patients cleared the minimal residual disease. Hematologic toxicities were anemia (6%), neutropenia (81%), and thrombocytopenia (50%);

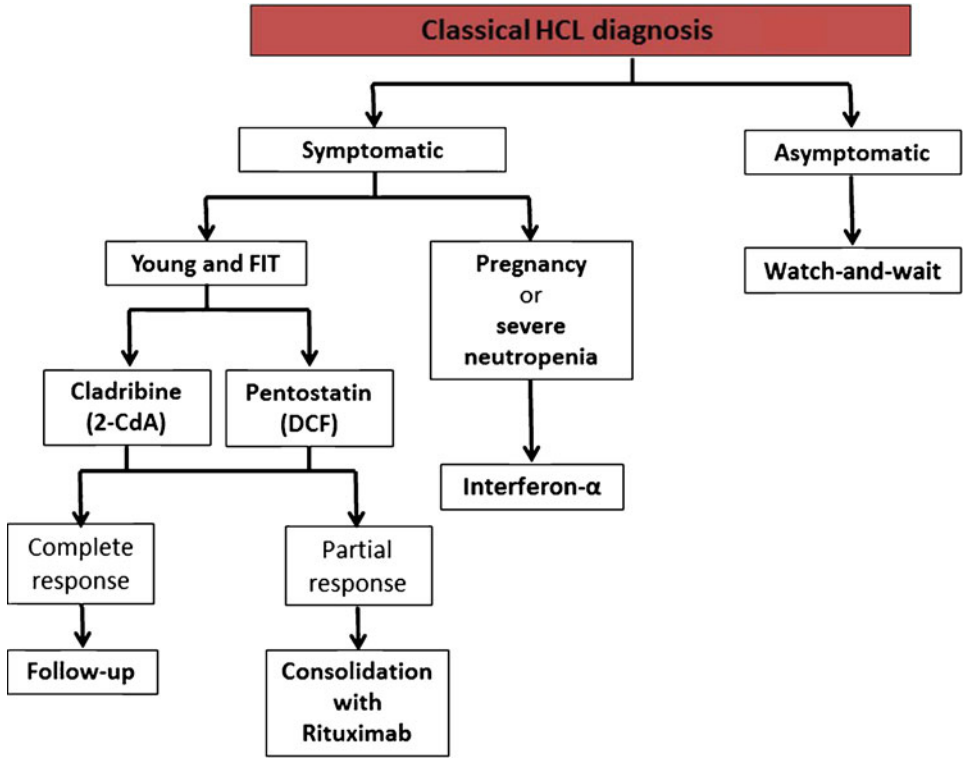

Fig. 4 Therapeutic algorithm for newly diagnosed classical hairy cell leukemia (Modified from Robak et al. [56])

12% of patients developed myelodysplastic syndromes 17 and 20 months after consolidation [52].

Fourteen patients with relapsed CLL either in partial remission or in complete remission but with disease documented by flow cytometry were treated with ^{90}Y ibritumomab tiuxetan. Grade 3 or 4 hematologic toxicity was seen in 92% of evaluable patients. In addition, myelosuppression was prolonged, with a median duration of grade 3–4 thrombocytopenia of 37 days. Five patients had persistent thrombocytopenia 3 months post-therapy. Even in patients with CLL and limited marrow involvement, the use of RIT results in unacceptable hematologic toxicity [53].

Treatment of Hairy Cell Leukemia

As with CLL, treatment for HCL is not indicated in asymptomatic patients; patients should be closely monitored with a complete history, physical examination, and complete blood cell count every 3–6 months. In contrast to CLL, asymptomatic patients, who may be diagnosed by chance, are rare, and in practice most patients need treatment shortly after diagnosis, either because of symptoms or to correct cytopenias. Treatment should be initiated in patients with symptomatic disease manifested by bulky or progressive, symptomatic splenomegaly or cytopenias (hemoglobin <10 g/dl and/or platelets $<100 \times 10^9$/L and/or neutrophils $<1 \times 10^9$/L), recurrent or severe infections, and/or systemic symptoms [54–56]. A schematic treatment algorithm in classical HCL (diagnosis and relapsed) and HCL variant according to ESMO Clinical Practice Guidelines [56] is reported in Figs. 4, 5, and 6, respectively.

Purine analogues, cladribine (2-CdA) or pentostatin (DCF), are recommended as initial treatment of symptomatic HCL patients who are young and fit. 2-CdA, subcutaneous or intravenous, induces durable and unmaintained response in 87–100% patients, including CR in 85–91%, after a single course of therapy [56]. Grade 3–4

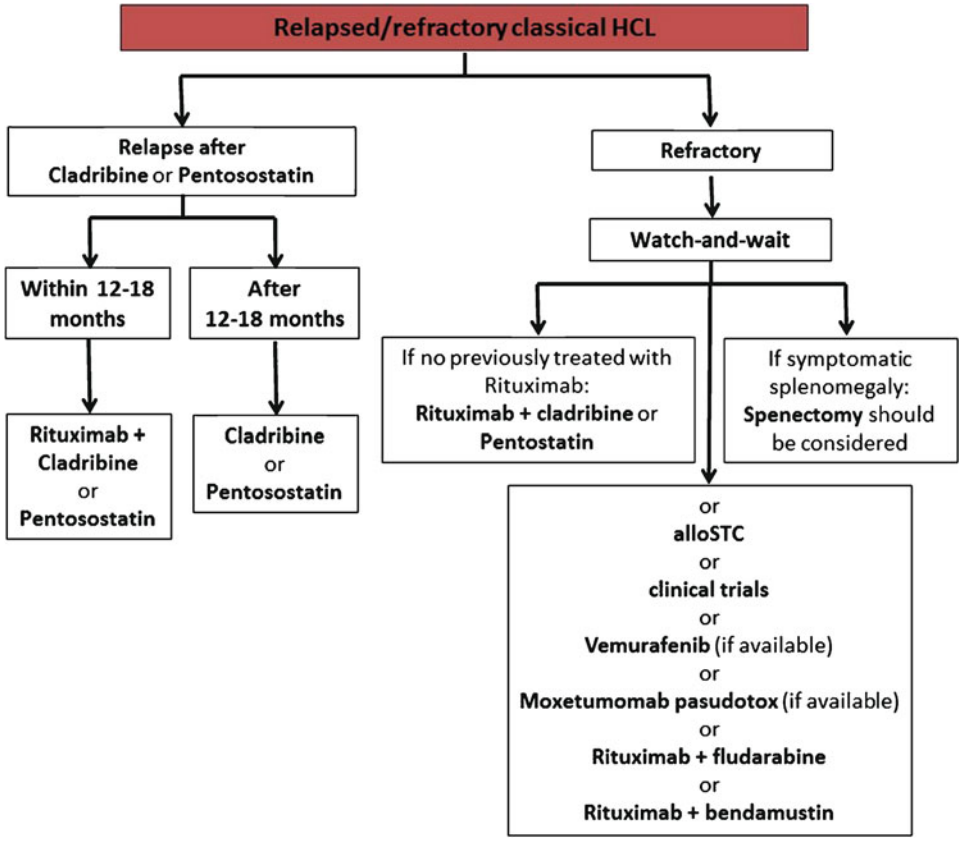

Fig. 5 Therapeutic algorithm for refractory/relapsed classical hairy cell leukemia (Modified from Robak et al. [56])

toxicities, largely represented by neutropenia and infections, were less frequent when low doses were used (0.5 mg/kg vs. 0.7 mg/kg), with similar OR [57]. A CR following 2-CldA administration is durable even without maintenance therapy [58]. In patients demonstrating a partial remission after the first course of 2-CldA, a second course should be repeated to achieve CR at least 6 months after the end of the first course, with or without rituximab [59]. Similarly to 2-CdA, DCF induces a high rate of long-lasting CR. In patients with a normal creatinine clearance, DCF is usually given at a dose of 4 mg/m^2 i.v. every second week until CR, plus one or two consolidating injections [60]. After 8–9 courses, the full blood count usually normalizes, and the bone marrow biopsy should be performed to confirm a CR. If a CR is documented, one or two further cycles are indicated [58]. DCF and 2-CdA appear to induce similar high response rates, duration of response, recurrence rates, and adverse events [58]. However, no randomized, direct comparison between the two drugs has been performed [56]. The advantage of DCF over interferon-α (IFN-α) in HCL patients has been confirmed in a multicenter, randomized trial [61]. The use of IFN-α in the treatment of HCL is limited since purine analogues produce higher and more durable remissions and are more convenient to patients [56]. However, IFN-α may still have a place in the treatment of HCL in pregnancy. It can also be used in patients presenting with very severe neutropenia [56, 62]. Relapsed patients can be successfully retreated with 2-CdA or DCF if relapse occurs after 12–18 months [63]. The alternative nucleoside analogue can be used in early relapse within 2 years after the first-line treatment [64]. The ability to attain CR decreases with each

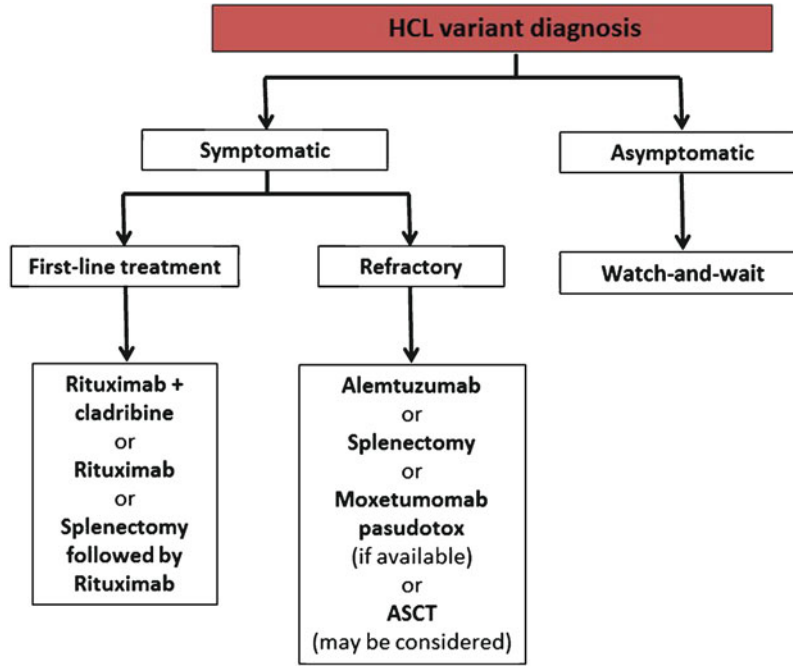

Fig. 6 Therapeutic algorithm for newly diagnosed variant hairy cell leukemia (Modified from Robak et al. [56])

course of therapy, but CR duration appears to be similar after first-, second-, or third-line therapy [58, 65]. Rituximab given weekly (dose of 375 mg/m^2 for 4–8 doses) can be used in early relapsed patients [66–68]; however, rituximab alone is inferior to purine analogues and is not the treatment of choice. Outcomes for patients with recurrent HCL appear to be better when a combination of rituximab and 2-CdA or DCF is used rather than the purine analogue alone [69, 70]. Concurrent therapy of rituximab and purine analogues induces higher response rates, and higher rates of toxic events than in the sequential administration [71]. IFN-α is also a possible option for selected patients relapsing after purine analogue therapy [72, 73]. Patients refractory to purine analogue therapy should be enrolled whenever possible on clinical trials that use new agents.

Oral fludarabine (dose of 40 mg/m^2) for five consecutive days in combination with rituximab for four cycles can be a therapeutic option in relapsed or refractory patients previously treated with 2-CdA [56].

Bendamustine (70–90 mg/m^2) combined with rituximab is another therapeutic option in multiple relapsed/refractory HCL and could be considered in HCL patients after the failure of standard therapies [74].

Other promising drugs active in purine analogue refractory HCL patients include moxetumomab pasudotox, an anti-CD22 recombinant immunotoxin, and vemurafenib, a BRAF V600E inhibitor [56, 75, 76]. A phase I trial of moxetumomab pasudotox in relapsed/refractory HCL induced an 86% OR rate and a 46% CR [58, 59].

Recently, the efficacy of vemurafenib was assessed in a cohort of 21 HCL patients treated outside of clinical trials: vemurafenib improved blood counts in all patients by 1.5–2 months, with a CR rate of 40% and a median EFS of 17 months [77].

The therapeutic potential of the Bruton's tyrosine kinase (BTK) inhibitor ibrutinib also needs to be taken into consideration in a relapse setting, given the proven in vitro activity of this drug in hairy cells [78].

Splenectomy may be indicated in patients with resistant massive symptomatic splenomegaly (>10 cm below the costal margin) with accompanied low-level bone marrow infiltration (OR rates of 60–100%) [62, 79]. Splenectomized patients respond better and faster to the subsequent

chemotherapy. Splenectomy can also be considered when progressive HCL develops during pregnancy and in patients refractory to nucleoside analogues and IFN-α [62]. Systemic therapy should not be performed earlier than 6 months after splenectomy to reach full benefits of this treatment [64]. Allogeneic stem cell transplantation has a potential role in younger, heavily pretreated HCL patients who have had multiple relapses and are refractory to purine analogues and rituximab [80, 81]. In pregnant woman, treatment is indicated only when truly warranted, and the appropriate therapy depends on the stage of pregnancy, the rate of disease progression, and the response to previous therapies. IFN-α shows good tolerance, uncomplicated pregnancy, and normal child development [82].

Splenectomy is another option to consider, should INF-α fail, especially in early gestation when the risks are lower [83, 84]. Administration of 2-CdA and rituximab is not indicated in pregnancy because of the risk of teratogenic effects, although successful pregnancy has also been reported [56, 85].

The results of the treatment of hairy cell leukemia variant (HCL-V) with purine analogues are poor [56, 86]. In addition, the majority of HCL-V patients required more than 1 cycle to maintain a response. Using DCF, PR was observed in 8/15 (54%) patients, and no CR was achieved; rituximab alone, or splenectomy followed by rituximab, can also induce CR in HCL-V [87–89]. However, administration of 2-CdA immediately followed by rituximab appears to be more effective than 2-CdA alone or rituximab alone and should be considered as the initial treatment of HCL-V patients [56, 69, 90].

Alternatively, case reports suggest that alemtuzumab is an active agent in treating HCL-V, even in patients who have relapsed after rituximab [91]. Splenectomy induces clinical responses in some patients with HCL-V and is recommended because it corrects cytopenias, removes the bulk of the tumor, and may improve response to purine nucleoside analogues [56, 92]. Splenic irradiation could be performed in elderly patients with a high surgical risk of splenectomy [56]. Although limited data, clinical case reports support the use of moxetumomab pasudotox in patients with HCL-V and the use of autologous or allogeneic hematopoietic cell transplantation in refractory patients [56, 75, 93].

Treatment of Acute Myeloid Leukemia (AML)

Whenever possible, AML treatment should be offered in clinical trials and given only in experienced centers offering an adequate multidisciplinary infrastructure as well as a suitably high case load. Treatment should be planned with curative intent whenever possible. Intensive chemotherapy of AML is divided into an induction phase, consolidation, and (rarely) maintenance. Potential candidates for alloSCT (scheduled for the consolidation phase) must be identified early at diagnosis or during induction chemotherapy. Treatment of acute promyelocytic leukemia (APL) differs in several important aspects from therapy of all other AML types [94].

Patients with excessive leukocytosis at presentation and with clinical signs of leukostasis may require emergency leukapheresis coordinated with the start of chemotherapy. These patients are at particular risk of a tumor lysis syndrome under induction chemotherapy and need appropriate monitoring. In these cases, a single injection of rasburicase may be considered to prevent hyperuricemia and hence renal failure, but data are insufficient to support a firm recommendation in this respect.

In respect of a common induction regimen, the strategy of consolidation eventually followed by autologous or allogeneic transplantation depends on the cytogenetic/molecular features of disease. Induction chemotherapy usually includes an anthracycline and cytarabine in the well-known “3+7” regimen. Data on dose escalation of daunorubicin to improve AML outcome look promising, but longer follow-up is required to support a firm recommendation [95–101]. Consolidation therapy in AML is warranted once patients have reached clinical and hematological remission. There is no consensus on a

single "best" post-remission treatment schedule. In good-risk AML patients in first remission, who have a relapse risk of 35% or less, alloSCT is not justified because its toxic effect and/or the risk of mortality exceed the benefit. Also, these patients may receive salvage therapy including alloSCT in second remission. Good-risk AML patients (including NPM-mutated AML with absence of internal tandem duplications of FLT3 (FLT3-ITD), core binding factor (CBF) AML, and bi-allelic mutant CEBPα AML), as well as patients who are unsuitable for alloSCT for other reasons, should receive at least one cycle of intensive consolidation chemotherapy preferably incorporating intermediate or high-dose cytarabine [94].

Patients in intermediate- and poor-risk groups with an HLA-identical sibling may be candidates for alloSCT, provided their age and performance status allow for such treatment [102–112]. Newer data suggest that alloSCT may no longer be mandatory in intermediate-risk patients, but these data need to be confirmed [96]. Patients in these risk groups without a family donor may qualify for alloSCT with an HLA-matched unrelated donor identified through an international donor registry. In fact, peripheral stem cells harvested from unrelated HLA-matched donors have become the most frequently used source of stem cells. If a killer immunoglobulin-like receptor (KIR) mismatch is present, haploidentical transplant may be considered. Conditioning regimens for alloSCT with dose-reduced chemotherapy intensity (RIC) may be used for patients in the upper age range (particularly those >50 years of age), but there is some evidence that RIC may also be used in adults at a younger age.

The role of high-dose chemotherapy with autologous stem transplantation in AML is still controversial. Recent data suggest that it may be a good option (and thus an alternative to alloSCT) in patients in the intermediate-risk group [100]. While it may prolong time to relapse or remission duration, its potential to prolong overall survival is uncertain [104, 106, 107].

Patients with significant comorbidity and elderly are often not eligible for intensive treatment; they should receive best supportive care or palliative systemic treatment. Nevertheless, recently demethylating agents have been approved for patients with 20–30% of blasts (5-azacytidine) or aged more than 65 years (decitabine) [94].

A recent retrospective study evaluated the efficacy of 5-azacitidine in a cohort of 130 elderly patients ineligible for intensive chemotherapy: patients received 5-azacitidine for a median of four cycles, with overall response rate of 36% and 37% of hematologic improvement. Median OS was 18 months for responders and 12 months for nonresponders [113].

Decitabine has been reported to offer 18%–24% of CRs, but no overall survival benefit [114].

Excessive leukocytosis due to spilling of malignant blasts into the periphery may be reduced with cytoreductive agents such as hydroxyurea or low-dose cytarabine, which, however, also can reduce also normal blood cell counts and red cells, neutrophils, or platelets. Treatment of infections due to neutropenia and transfusions to improve anemia or thrombocytopenia are important additional measures. Erythropoietin is of questionable value in patients with anemia due to extensive infiltration of the marrow with leukemia. In severely neutropenic patients, hematopoietic growth factors may be tried when neutropenic fever or infections are a problem; however, there is no evidence to support their continuous use [94, 95, 98, 104, 112].

Resistance to therapy (refractory or relapsed AML) is the major cause of treatment failure, rather than mortality due to infections and other treatment-related complications. Patients failing to respond to one or two cycles of induction are considered refractory and can be candidates for alloSCT, albeit with limited chances of success and at the cost of considerable morbidity from this procedure. For patients unsuited to this approach, best supportive care or palliative systemic treatment is often a reasonable option with, at least, limited toxic effect. The prognosis of such patients is often dismal regardless of treatment attempts. Patients presenting with relapse after a first remission may be offered intensive re-induction, with better chances of success in patients with a longer interval from first remission. Patients in second or subsequent remission

may still qualify for alloSCT with a family or unrelated HLA-matched donor or with cord blood-derived stem cells [94].

Suspicion of or established diagnosis of acute promyelocytic leukemia (APL) must trigger a distinctive therapy program [115–118]: oral all-trans retinoic acid (ATRA) should immediately be started, because of the high risk of bleeding caused by the disseminated intravasal coagulation (DIC) [94]. Risk assessment of APL is based on white blood cell count at presentation, where patients with a WBC count $>10 \times 10^9$/L fare worse. APL induction chemotherapy consists of ATRA as a differentiating agent and idarubicin. The use of arsenic trioxide (ATO) in first-line APL therapy is promising, but long-term results are not yet available.

However, the results of ATRA-ATO combination without chemotherapy look promising, particularly in good-risk APL: in the GIMEMA APL0406 study, adults between 18 and 71 years with low- or intermediate-risk APL were randomly assigned to receive ATRA-ATO or ATRA-chemotherapy. All patients achieved CR in the ATO arm versus 97% in the chemotherapy group, with a significant advantage in terms of 4-years EFS (97% vs. 80%) and OS (99% vs. 92%) [119].

The need for daily i.v. application of ATO over a prolonged period of time, electrolyte as well as cardiac problems (including potentially fatal torsade-de-pointe ventricular arrhythmias), and case reports on secondary cancers after ATO must all be considered [120].

RIT could potentially circumvent multidrug resistance and yield remissions in drug-resistant AML. The choice of the most suitable radionuclide to label specific antibodies is based on purely clinical considerations such as the type of disease, the degree of leukemic bone marrow infiltration, and the presence of extramedullary burden. Furthermore, the decision to combine different radioimmunoconjugates may also be applied to improve the therapeutic efficacy if compared to monotherapies [121].

Radiolabeled antibodies with specificity for the antigens CD33, CD45, and CD66 have been developed and studied for myeloablative radioimmunotherapy in patients with AML or MDS. CD33 is an antigen expressed from the promyelocyte stage to the stage of mature myeloid cell and in most AML blasts. The CD45 antigen is expressed on almost all leucocytes (except plasma cells) and on 80–95% of leukemic blasts of the myeloid and lymphoid line. The CD66 antigen belongs to the group of nonspecific cross-reacting antigens and is present from the promyelocyte stage to the mature granulocyte stage, rarely on myeloid leukemic blasts. Nevertheless, none of the antibodies currently tested in clinical trials for myeloablative RIT (Table 1) are approved for this purpose. The only commercially available antibody is ^{99m}Tc-BW250/183 (IgG1; NCA 95, scintimun, besilesomab; CIS Bio International, Schering, Switzerland), but it is registered for the scintigraphic diagnosis of infections only. Preliminary results suggest that myeloablative RIT may

Table 1 examples of antibodies developed and tested in clinical trials for leukemia and multiple myeloma

Type of antibodies	Antigen specificity	Clinical indications	Radiolabeling
M195 (IgG_{2a}, murine)	CD33	AML	^{131}I
HuM195 (IgG_{2a}, humanized)	CD33	AML	^{90}Y, ^{213}Bi, ^{131}I
Lintuzumab (whole antibody, humanized)	CD33	AML	^{225}Ac
p67 (IgG, murine)	CD33	AML	^{131}I
BC8 (IgG_1, murine)	CD45	AML, MM	^{131}I
YTH24.5 (IgG_{2b}, rat)	CD45	AML, CML, ALL	^{99m}Tc (dosimetry)
YAML568 (IgG_{2a}, rat)	CD45	AML, MM	^{90}Y
BW250/183 (IgG_1; murine)	CD66b	AML, MM	^{90}Y, ^{188}Re
Lym-1 (IgG_K, murine)	HLA-DR	CCL	^{131}I
Ibritumomab tiuxetan (IgG_1, murine)	CD20	CLL	^{90}Y
Tositumomab (IgG_{2a}, murine)	CD20	CLL	^{131}I

close the gap between benefit and toxicity of conditioning therapies. When myeloablative RIT is used to condition patients scheduled for transplantation, it provides high-energy doses into the bone marrow thus inducing hypoplasia/aplasia, the rate of relapse is decreased, and normal organs that do not express the target antigen are spared from toxicity. Additionally, myeloablative RIT does not significantly increase the rate of therapy-related mortality. Generally, RIT is employed in younger patients in good general condition in addition to dose-escalated conditioning, while in patients >55 years and/or with comorbidities, it should be added to reduce the intensity of "standard" conditioning therapies [121]. ^{188}Re-alemtuzumab RIT followed by fludarabine (150 mg/m^2), busulfan (8 mg/kg), and alemtuzumab (75 mg) has been evaluated before alloSCT in a phase II trial enrolling 22 patients with advanced myeloid malignancies. The extramedullary toxicity in the first 100 days posttransplantation was limited, and all patients engrafted with complete donor chimerism. The probability of OS at 2 years was 40%. A comparison with a younger historical cohort having received the same dose of fludarabine and busulfan but neither radioimmunotherapy nor alemtuzumab showed no difference in outcome. Although the use of alemtuzumab reduced the incidence of acute graft-versus-host disease, it was associated with a relapse incidence of 40% despite the incorporation of RIT. These data confirmed the feasibility of combined RIT and reduced-intensity conditioning in elderly patients [50]. Current clinical trials for myeloablative RIT are designed to obtain an individual dosimetric study either to calculate the therapy doses or, in dose-escalating protocols, to ensure not to exceed the dose-limiting organ doses. For monotherapy in patients with AML or MDS and a low tumor load, the radiolabeled anti-CD66 mAb is considered the optimal choice, and the use of DTPA-derived chelators is suggested to improve the biodistribution profile (increased bone marrow/liver doses ratio). In patients with extensive bone marrow infiltration with blast cells or significant extramedullary disease, anti-CD33 and anti-CD45 radioimmunoconjugates are preferred [121].

Low linear energy transfer (LET)-ionizing radiation is an important form of therapy for acute leukemias. Ionizing radiation is also a potential source of DNA damage. High LET-ionizing radiation produces structurally different forms of DNA damage and has emerged as potential treatment of metastatic and hematopoietic malignancies. Haro et al. [122] created a stable myeloid leukemia HL60 cell line radioresistant to both γ-rays or α-particles to understand possible mechanisms in radioresistance. Cross-resistance to each type of ionizing radiation was observed, but resistance to clustered, complex α-particle damage was substantially lower than that to equivalent doses of γ-rays. The resistant phenotype was driven by changes in apoptosis, late G2/M checkpoint accumulation that was indicative of increased genomic instability, stronger dependence on homology-directed repair, and more robust repair of DNA double-strand breaks and sublethal-type damage induced by γ-rays, but not by α-particles. The more potent cytotoxicity of α-particles warrants their continued investigation as therapies for leukemia and other cancers [122].

The key properties of the alpha particles generated by ^{225}Ac are the following: (i) limited range in tissue of a few cell diameters, (ii) high linear energy transfer leading to dense radiation damage along each alpha track, (iii) a 10-day half-life, and (iv) four net alpha particles emitted per decay [123].

Treatment of Chronic Myeloid Leukemia (CML)

The introduction of tyrosine kinase inhibitors at the beginning of 2000s revolutionized the outcome of patients affected by CML, improving survival from the 40% to 90%, with a good quality of life [124]. TKIs interfere with the ATP-binding site in the BCR-ABL1 pocket blocking its uncontrolled tyrosine kinase activity. Imatinib was the first TKI to be introduced in the clinical practice on the basis of a randomized trial versus IFN-α and low-dose arabinosylcytosine (IRIS study); thus, IFN and hydroxyurea are not still recommended in treatment of CML patients.

Now, second-generation TKIs offering faster and more complete responses are available. After onset of mutations of the ABL1 that often abrogated the efficacy of the TKI, other third-generation TKIs have been designed; thus, today five different compounds are available. Each of them has a specific toxicity profile, with increased cardiovascular events for nilotinib and ponatinib, increased pleural effusion for dasatinib, diarrhea for bosutinib, and fluid retention for imatinib [125]. Consequently, European and American guidelines suggest if and when TKIs have to be changed, but not which one has to be used in the first line [126].

Moreover, no substantial progress has been made in the treatment of blast-phase disease; allogeneic transplantation is now reserved to patients failing at least 2 TKIs.

Projected annual 3–5-year survival rates range from 38% to 80%, with the higher values reported from more experienced centers. BMT in accelerated and/or blast-phase disease is relatively unsatisfactory; nonetheless, 15% to 20% of patients may become long-term survivors.

A recent multi-institutional randomized trial compared the use of bone marrow with peripheral blood stem cells from HLA-identical siblings for relatively favorable patients with a variety of hematologic neoplasms, including CML, undergoing transplantation. Hematologic recovery was more rapid and the 2-year OS significantly increased (70% vs. 45% of BMT). Drug treatment is superior to allogeneic stem cell transplantation in first-line therapy of CML, because of transplant-related mortality. Thus, initial allogeneic SCT cannot be recommended anymore [127].

Therapies with Radiolabeled Antibodies

Therapies with Radiolabeled Anti-CD33 mAb

Schwartz et al. [128] conducted a dose-escalation study with fractionated doses of ^{131}I-M195 (185–7.77 MBq/m^2) in 24 patients with relapsed/refractory myeloid leukemia. Post therapy whole-body scintigraphy demonstrated marked uptake of the antibody into all involved areas in every patient. A significant decrease of bone marrow blasts was observed in 83% of cases, with sufficient bone marrow cytoreduction allowing subsequent ASCT in 33% of the patients. These data suggest that a safe leukemic cytoreduction may be achieved with ^{131}I-M195, and it may be useful as part of a myeloablative conditioning regimen. Nevertheless, in 37% of patients, human anti-mouse antibody (HAMA) was produced, preventing effective retreatment with the same murine M195 MaAb. To avoid immunogenicity leading to HAMA development [128], humanized MoAbs for the treatment of leukemia have been developed (Hu-M195). Caron et al. [129] evaluated the biodistribution profile and leukemia cell targeting, as well as safety concerning especially immunogenicity, in 13 patients with AML and CML treated with increased doses of ^{131}I-Hu-M195. The pharmacokinetics of Hu-M195 were very similar to M195 with serum $t_{½-a}$ more rapid than that of the murine M195, probably because of the rapid targeting of Hu-M195 to leukemia cells (Hu-M195 affinity is 8 times higher compared to the murine form). Additionally, the amount of antibody binding to splenic targets during the "first pass" may contribute to the shorter serum $t_{½-a}$. Whole-body scintigraphy also confirmed the rapid and specific binding of radiolabeled Hu-M195 to the target areas. A similar trial was reported by Appelbaum et al. [130] in patients with advanced AML using ^{131}I-labeled p67, a murine IgG targeting CD33. However, their results were not satisfactory since the administration of a single dose of ^{131}I-p67 due to its short marrow residence times; this was presumably due to the modulation of the antigen-antibody complex with subsequent rapid release of ^{131}I from the marrow space [130, 131]. In fact, to be effective for myeloablation, antibodies should be retained longer in the bone marrow, as in the case of ^{131}I-M195 and ^{131}I-HuM195 that presented a bone marrow retention of at least 3 days [132].

Sgouros et al. [133] analyzed imaging data obtained from the phase I trial of ^{131}I-HuMl95: response to RIT was influenced by tumor burden, antibody clearance kinetics, and the antibody-antigen interaction. Compartmental modeling

analysis provided biodistribution data for absorbed dose calculations to tissues not directly sampled, to determine the optimum therapeutic dose of radiolabeled antibody for a given patient [134]. The results demonstrated a large inter- and intrapatient variability, such differences suggesting that dosimetry based upon the activity concentration at a single site may not adequately assess the potential for marrow toxicity in any patient. Red marrow dosimetry is important only if it provides a better index of potential marrow toxicity than other more easily determined parameters, such as whole-body absorbed dose or administered activity. Marrow dose estimation is critical since the biological clearance rate, fractional uptake in marrow, radionuclide half-life, and emission characteristics are accounted for in assessing absorbed dose. Both the variability in regional bone marrow radiosensitivity and the effect of treatment before absorbed dose estimates, are directly related to complication treatment-induced.

To determine the possible use of RIT in the conditioning phase, Jurcic et al. [135] associated the myeloablative action of ^{131}I-M195 or ^{131}I-HuM195 (4.4–14 GBq) to cyclophosphamide and busulfan in 30 patients with refractory/relapsed AML de novo or secondary to CML: no significant toxicities were reported and complete remissions were observed in 93% of patients; 19% of patients were alive and disease-free after 4.5–8 years.

A median survival of 4.9 months was also reported by Burke et al. [132] with the same treatment schedule and dose of ^{131}I-M195 or ^{131}I-HuM195 (4.5–16.17 MBq) combined with busulfan and cyclophosphamide; moreover, imaging confirmed good targeting of the radioimmunoconjugate to all areas of leukemic involvement, including vertebrae, pelvis and long bones, liver, and spleen. The bone marrow-absorbed radiation dose was calculated to range between 0.27 and 1.47 Gy. When comparing the performance of ^{131}I-M195 with that of ^{131}I-HuM195, this latest offers some advantages, including the ability to mediate antibody-dependent cellular cytotoxicity and complement-mediated cytotoxicity, the lack of immunogenicity, and the modest intrinsic antileukemic activity.

Nevertheless, ^{131}I-labeled anti-CD33 in the setting of myeloablative RIT does not represent the optimal compound: in fact, radioiodination of antibodies decreases their ability to bind to the antigen (about 1/3 of the tyrosine residues binding ^{131}I are located in the hypervariable regions) and thus prevents the delivery of high radiation doses to the bone marrow. Furthermore, the relatively long half-life of ^{131}I delays transplantation, since the radionuclide retained within the bone marrow must decay totally in order to prevent injury to the grafted hematopoietic stem cells; finally, ^{131}I requires hospitalization in a radioprotected ward. Radiometals such as ^{90}Y and ^{188}Re have been evaluated as alternatives to ^{131}I: such radioisotopes offer better retention by target cells after internalization of antigen-antibody complexes, while the higher energy of their β emissions permits a lower effective dose, and the absence of γ emission reduces radioprotection restrictions [132].

Jurcic et al. [136] conducted a phase I trial to determine the safety and biological activity of ^{90}Y-HuM195 (185–1036 MBq, as a single administration). Biodistribution and dosimetry studies were also performed after the administration of ^{111}In-HuM195 (370 MBq). Dose-limiting toxicity (leucopenia G4) was seen at 11 MBq/kg. Scintigraphy showed uptake of ^{111}In-HuM195 in the bone marrow, liver, and spleen within 1 hour of administration and for at least 3 days. Radiation doses to the bone marrow and liver were 0.29–0.70 Gy and 0.12–0.30 Gy, respectively. ^{90}Y-HuM195 may overcome the limitations of ^{131}I-anti-CD33 conjugates, being safer but still retaining a significant antileukemic activity.

The first clinical trial with ^{213}Bi was conducted at Memorial Sloan Kettering Cancer Center in New York in collaboration with the National Institutes of Health and the Institute for Transuranium Elements in Karlsruhe [137].In this study, 18 patients with relapsed and refractory acute myelogenous leukemia or chronic myelomonocytic leukemia were treated with 10.4 to 37.0 MBq/kg of ^{213}Bi-HuM195. Fourteen of fifteen evaluable patients (93%) had reductions in circulating blasts, and 14 of 18 patients (78%) had reductions in the percentage of bone marrow blasts. No significant extramedullary toxicity was seen. Jurcic et al.

demonstrating the safety, feasibility, and antileukemic effects of ^{213}Bi-HuM195 provided the first proof-of-concept for systemic radiometal-based RIT in patients with relapsed/refractory AML or CML [137]. Based on the encouraging results of this pioneering study, another phase I/II study was conducted to determine the maximum tolerated dose and efficacy of ^{213}Bi-HuM195 after partially cytoreductive chemotherapy with cytarabine. Thirty-one patients with newly diagnosed (n = 13) or relapsed/refractory (n = 18) AML were treated: significant reduction in marrow blasts was seen at all dose levels and complete remissions, and partial responses were seen in 6/25 patients (24%) who received doses of ≥37 MBq/kg. Myelosuppression was tolerable, and no significant extramedullary toxicity was observed [138].

Sgouros et al. [139] analyzed the results of a phase I trial, demonstrating that ^{213}Bi-HuM195 rapidly localized to areas of leukemic involvement and all patients developed myelosuppression with absorbed dose ratios 1000 times greater than with β-emitting radioimmunoconjugates. Moreover, 93% of evaluable patients had a reduction in circulating blasts, while 78% of patients had reductions in the percentage of bone marrow blasts [137]. Kolbert et al. [140] developed a method to provide a "whole-body" assessment of the pharmacokinetics of ^{213}Bi-HuM195 in the patients enrolled in this phase I trial: images were acquired after multiple injections of ^{213}Bi-HuM195 with progressively increasing antibody concentration, over 2–4 days. A linear expression to the counts in each pixel was applied to obtain parametric rate images defining clearance and uptake rates in each organ. Planar images of antibody distribution showed significant uptake in the liver, spleen, and bone marrow. The generated rate images displayed different patterns (i.e., with negative values in the liver and spleen and positive values in bone marrow), reflecting clearance and uptake rates rather than total accumulation. The inter-patient comparison developed with this method showed that rate image patterns varied based on patient-specific conditions, such as the amount of disease and previous therapies. Maximum-tolerated dose has been established for ^{213}Bi-immunoconjugates in AML at about 37 MBq/kg [137].

Miederer et al. [141] analyzed the pharmacokinetics profile, dosimetry, and toxicity of the targetable atomic generator ^{225}Ac-HuM195 in nonhuman primates and found severe renal toxicity and anemia at a cumulative activity of 377 kBq/kg. The longer blood $t_{1/2}$ and the lack of target cell antigens in cynomolgus monkeys may increase toxicity compared with the human setting, where an activity level of 28 kBq/kg may be a safe starting dose (no toxicity at 6 months).

More recently, Maguire et al. [142] described three strategies to stably chelate ^{225}Ac and evaluated ^{225}Ac-HuM195 in a mouse model of leukemia (NSG) which demonstrated a lower dose-limiting toxicity (2.22 kBq) than other mouse models. Despite this aspect possibly related to the immunocompromised state of NSG mouse or to the lack of circulating antibody, reductions in tumor growth rate and a significant difference between specific and control antibodies was observed. These observations supported the hypothesis that in immunocompetent hosts, higher or repeated doses may be used, and consequently a greater absolute therapeutic effect can be achieved.

Kersemans et al. [143] recently demonstrated that ^{111}In-HuM195 and ^{111}In-M195 modified with peptides harboring nuclear-localizing sequences may decrease cell growth and clonogenic survival for both drug-resistant AML cell lines and primary AML patient specimens expressing MDR transporters, through the emission of Auger electrons, after CD33-mediated internalization. More than 99% of the Auger electrons emitted by ^{111}In have a range of less than 1 μm, which obviates the cross-fire effect and yields high-linear-energy transfer comparable to that of highly cytotoxic a-emitters (i.e., 50–100 keV/mm). Targeted Auger electron RIT using ^{111}In-NLSHuM195 and ^{111}In-NLS-M195 may be able to overcome resistance [143, 144].

^{211}At has been shown to be a promising, highly cytotoxic RIT in CD33-positive AML and kills tumor cells more efficiently than calicheamicin-conjugated antibody. Labeling techniques leading to higher chemical yield and specific activities have been evaluated to increase ^{211}At-anti-CD33 therapeutic effects [145].

Clinical experience with ^{225}Ac therapy is currently still limited. The ongoing phase I clinical trial was initiated at Memorial Sloan Kettering Cancer Center with a primary goal to define both safety and the MDT of ^{225}Ac RIT in advanced AML patients through a dose-escalation series. The trial has been successful in demonstrating that ^{225}Ac RIT targeted by lintuzumab had anti-leukemic activity across all dose levels and it is now being investigated in a multicenter USA phase I/II trial in combination with low-dose cytarabine for elderly AML patients [146].

A study of combined modalities for treating AML has been recently completed at the Memorial Sloan Kettering Cancer Center using chemotherapy to reduce the cancer load followed by RIT (^{213}Bi- or ^{225}Ac-immunoconjugates) [147].

^{213}Bi-anti-CD33 exhibits its cytotoxic effects specifically in CD33-expressing AML cells via induction of the intrinsic, mitochondrial pathway of apoptosis. The abrogation of chemo- and radioresistances and the reactivation of apoptotic pathways seem to be promising for the treatment of patients with so far untreatable resistant AML and underline the importance of this emerging therapeutic approach of targeted alpha-therapies [148].

Therapies with Radiolabeled Anti-CD45 mAb

^{131}I-BC8 (2.8–22.6 GBq) prior to transplantation in combination with cyclophosphamide and fractionated total body EBRT (12 Gy) has been used by Matthews et al. [149] in patients with advanced acute leukemia or MDS after first complete remission. Bone marrow doses obtained with this compound were up to 30 Gy, with maximum liver doses of 7 Gy [149].

A comparative study of the biodistribution and biokinetics of two other immunoconjugates, ^{99m}Tc-BW250/183 and ^{99m}Tc-YTH24.5, in patients with AML, CML, and ALL was performed by Buchmann et al. [150], who concluded that YTH24.5 is not appropriate for myeloablation because of its unfavorable biodistribution profile. Thus, YTH24.5 has been modified from IgG_{2b} to IgG_{2a}; this compound, named anti-CD45 MoAb YAML568, demonstrated a significant improvement of the bone marrow/liver dose ratio. Although the biodistribution and dosimetry of YAML568 are less favorable than those of BW250/183, the former represents an alternative option for leukemia patients with a high medullary tumor load or with extramedullary disease.

To improve the efficacy of RIT, Kletting et al. [151] developed a physiologically based pharmacokinetic model to describe the biodistribution of ^{90}Y-labeled anti-CD45 antibody YAML568. Dosimetric estimates in patients receiving unlabeled antibody before the injection of ^{111}In-labeled anti-CD45 MoAb (121±21 MBq), demonstrated that the preload with cold antibody increased selective delivery of radioactivity to the target organ as well as reducing toxicity to normal tissue [151, 152]. The method is in principle applicable also to RIT with other antibodies to decrease nonspecific binding of the labeled antibody to the liver or spleen. Validation of this model is still under evaluation.

Additionally, the conjugation with (Ab)-streptavidin and DOTA-biotin labeled with β-emitting radionuclides has been explored in AML as a strategy to decrease relapse and RIT toxicity, suggesting that anti-CD45 RIT may be highly effective and minimally toxic for treatment of AML [153].

In theory total body irradiation may be replaced by RIT in hematopoietic cell transplantation conditioning regimens, leading to positive outcomes on transplant overall survival. Anti-CD45 RIT can increase the dose of cytotoxic radiation targeted to malignant cells, while sparing normal organs. Opportunities for further optimization of CD45-targeted RIT exist, including alternate radioisotopes with different physical properties and energy characteristics. The continued combinations of innovative preclinical studies and supportive clinical trials suggest that CD45-targeted RIT will continue to develop as a critical option for improving hematopoietic cell transplantation outcomes for hematological malignancies [154].

Mawad et al. [155] used RIT with ^{131}I-anti-CD45 antibody (332–1561 mCi) combined with fludarabine and total body irradiation (2 Gy) to

improve hematopoietic cell transplantation success in advanced AML or high-risk MDS patients. Marrow doses were arbitrarily capped at 43 Gy to avoid radiation-induced stromal damage; no graft failure or evidence of stromal damage was observed. Graft-versus-host disease was observed in the majority of patients treated. Six patients (40%) were still alive after a median of 5 years (range 4.2–8.3 years), with 1-year OS of 73%. Moreover, the arbitrary limit of 43 Gy to the marrow may be unnecessarily conservative, and continued escalation of targeted radioimmunotherapy doses may be feasible to further reduce relapse [155]. The relative therapeutic efficacy and toxicity of the anti-CD45 RIT employing ^{90}Y and ^{177}Lu in a syngeneic, disseminated murine myeloid leukemia (B6SJLF1/J) model has been compared. ^{90}Y-DOTA-30F11 RIT demonstrated a dose-dependent survival benefit and was associated with transient, mild myelotoxicity without hepatic or renal toxicity. Conversely, ^{177}Lu- anti-CD45 RIT yielded no long-term survivors. Thus, in this murine leukemia model, ^{90}Y was more effective than ^{177}Lu for anti-CD45 RIT of AML [156]. Efficacy and toxicity of anti-CD45 RIT using ^{211}At were positively evaluated in a disseminated murine AML model suggesting that ^{211}At-anti-CD45 RIT in conjunction with hematopoietic stem cell transplantation may be a promising therapeutic option for AML [157].

Very recently, Orozco et al. [158] evaluated a conditioning regimen employing ^{90}Y-anti-CD45 RIT replacing total body irradiation (TBI) before haploidentical alloSCT in a murine model, suggesting the possible introduction of RIT in clinical practice.

A phase II trial evaluated ^{131}I-BC8, fludarabine, TBI, and donor stem cell transplant followed by cyclosporine and mycophenolate mofetil in patients with advanced AML or myelodysplastic syndrome is currently ongoing [147].

Therapies with Radiolabeled Anti-CD66 mAb

The anti-CD66 MoAb ^{188}Re-BW250/183 (8.2±4.1 GBq) was employed in very poor prognosis childhood leukemia: the protocol consisted in a conditioning regimen including RIT, high-dose chemotherapy, and, optionally, total body EBRT before allogeneic transplantation. In this setting, the kidney was the dose-limiting organ (doses higher than the liver), and doses to the bone marrow were in the 5.5–30 Gy range. The results of this study were disappointing, since after a follow-up of 5–8 months, 6/7 patients died [159]. Subsequently, the same antibody and schedule were applied to adult AML or MDS presenting bone marrow infiltration <25% and high risk of relapse: RIT was administered at a mean activity of 11.1 GBq, associated with conventional conditioning therapy with cyclophosphamide combined with either total body EBRT (12 Gy) or busulfan. The majority of patients received T-cell depleted graft, while others had autologous transplantation. Mean bone marrow dose was 14.9 Gy, with moderate acute toxicity; the kidney was the dose-limiting organ; 18-month DFS was 45% [160, 161]. Patients with >50–60% bone marrow infiltration were excluded from treatment with ^{188}Re-BW250/183 because specific marrow doses were lower than the non-specific doses to the liver (Buchmann, unpublished data), probably due to low number of binding sites on the normal hematopoietic cells. Associating ^{188}Re-BW250/183 to conditioning regimens in patients receiving BMT did not significantly increase the incidence of acute graft-versus-host disease compared to the conventional conditioning therapies [162].

A phase I/II study with the anti-CD66 MoAb BW250/183, labeled with either ^{188}Re or ^{90}Y in adult patients with AML and MDS, demonstrated the feasibility and safety of RIT also in reduced dose-intensity conditioning regimens prior to allo-SCT. Bone marrow doses were 21.9±8.4 Gy, with a significantly higher dose for ^{90}Y- versus ^{188}Re-labeling. Comparison of biodistribution profile of ^{188}Re- and ^{90}Y-BW250/183 suggested a more favorable profile of the ^{90}Y-labeled MoAb, especially concerning the kidney doses. Kidney toxicity was observed in 6.4% of patients after intensified conditioning with ^{188}Re-BW250/183, but none in patients treated with ^{90}Y-BW250/18. Following these results, ^{90}Y was coupled to the

antibody via the chelator MX-DTPA, and further improvements had also recently been reported by Orchard et al. [163], with the use of different DTPA derivatives, such as the chelator 2B3M-DTPA [164]. Intraindividual dosimetric evaluation between PET and conventional scintigraphy, using ^{18}F- and ^{99m}Tc-labeled anti-CD66, respectively, in a patient with high-risk leukemia, displayed a similar distribution pattern, with high preferential uptake in bone marrow. Nevertheless, urinary excretion of radioactivity after administration of ^{18}F-anti-CD66 was faster, and bone marrow uptake was lower than after administration of ^{99m}Tc-anti-CD66 [165].

The combination of reduced-intensity conditioning, ^{188}Re-anti-CD66 RIT, and in vivo T-cell depletion was successfully applied in elderly patients with AML or MDS; a prospective phase II protocol evaluated if a dose reduction of alemtuzumab (from 75 mg to 50 mg) would improve leukemia-free survival by reducing the incidence of relapse. Fifty-eight patients received RIT followed by fludarabine (150 mg/m^2) and busulfan (8 mg/kg) combined with standard (75 mg; n = 26) or low (50 mg; n = 32) dose of alemtuzumab. The overall incidence of engraftment and the disease-free and overall survival did not differ, and the dose reduction had no positive impact on overall outcome [166].

In vitro studies showed that the human polynucleotide kinase/phosphatase inhibitor A12B4C3 radiosensitized AML cells to the DNA-damaging effects of ^{111}In-NLS-7G3 (which recognizes the CD123$^+$/CD131$^-$ phenotype displayed by leukemia stem cells), suggesting that the combination treatment may improve the effectiveness of Auger electron RIT of AML targeting the leukemia stem cells subpopulation [167].

The CSL360 is a chimeric IgG_1 monoclonal antibody that recognizes CD123 (IL-3 receptor α-subchain) expressed in the absence of CD131 (β-subchain), an epitope that is displayed by leukemia stem cells (LSCs) and has been evaluated for RIT of AML in a model mouse (NOD/SCID mice). Additionally, microSPECT/CT has been used to assess engraftment of primary human AML specimens into NOD/SCID mice. The targeting of ^{111}In-DTPA-NLS-CSL360 to sites of AML engraftment in the NOD/SCID mouse model is encouraging for future RIT studies [168, 169].

Treatment of Multiple Myeloma

Targeted therapies employing anti-CD45, anti-CD66, and anti-CD138 antibodies against hematopoietic or bone marrow stromal cells radiolabeled with beta-emitting radiopharmaceuticals have been developed for myeloablative RIT in MM. The CD45 antigen is overexpressed in clonogenic myeloma stem cells, and the CD66 antigen is expressed in all the intermediate stages from promyelocyte to the mature granulocyte, while anti-CD138 (syndecan-1), a heparan sulfate proteoglycan, is constantly expressed on tumor cells in MM. Different antibodies have been developed and tested in clinical trials as conditioning treatment, but none of them have yet been approved for RIT in MM (Table 1) [121]. Typically, bone marrow toxicity represents the major and dose-limiting side effect of all RIT regimens proposed so far. In fact, the radiolabeled antibodies can accumulate in the bone marrow irrespective of the severity of bone marrow infiltration or when an antibody cross-reacting with healthy hematopoietic cells is employed. Bone marrow doses of 2–8 Gy induce moderate myelosuppression, while doses >8–10 Gy induce relevant hypoplasia or aplasia. Thus, ASCT or supportive care is often required to prevent life-threatening complications. When RIT is used in the setting of conditioning regimens prior to stem cell transplantation, myelotoxicity takes on a "positive" role since it contributes to the destruction of plasma cells infiltrating the bone marrow. This option has been proposed to overcome the relative toxicity of intensified chemo- and EBRT, given the selective mechanism of action of radiolabeled antibodies. The maximum bone marrow dose applied in this clinical setting is generally limited to 35–40 Gy to avoid stromal cell damage that may affect engraftment of the transplanted stem cells. The anti-CD45 monoclonal antibody YAML568 is an option for patients with MM. Orchard et al. [163] published promising

data obtained in patients with MM treated in a dose-escalated phase I trial with ^{90}Y-labeled 2B3M-DTPA anti-CD66 BW250/183 followed by ASCT, thus prompting an ongoing phase II trial. Myeloablative RIT as conditioning treatment in patients with MM still remains difficult. It is assumed that there is a progenitor myeloma stem cell that is CD45 positive and circulates as an isolated single cell in peripheral blood. Taking these considerations into account, patients with MM should be treated beneficially with an anti-CD45 monoclonal antibody labeled with a combination of alpha-emitters (to damage the single progenitor cells circulating in the blood, the myeloma cells, and myeloma progenitor cells in the margin of the marrow) and beta-emitters (to enhance the effect in the bone marrow). Furthermore, malignant plasma cells may build clusters in the bone marrow, thus making tumor targeting more difficult. Therefore, RIT protocols should include only patients with a diffuse pattern of bone marrow infiltration and clusters <1 mL [121]. Before going into the details of the main application of RIT in MM, we will provide a brief overview on the current treatment options in MM.

When only one osteolytic bone lesion is seen in the presence of 10% or more clonal plasma cells, no clear indication is present for systemic therapy if no other criteria are met for active myeloma. This circumstance is rare, and we recommend that patients could be given radiation therapy and observed. Clinical trials to determine the value of adjuvant systemic therapy for these patients are being planned [170]. Treatment should be initiated in all patients with active myeloma fulfilling the CRAB criteria and in those symptomatic due to the underlying disease [171]. A major discriminant among the different treatment options for high-risk patients is the possibility to perform high-dose chemotherapy regimens plus either autologous stem cell transplantation (ASCT) or allogeneic bone marrow transplantation (Fig. 7). Initial treatment for newly diagnosed MM (induction therapy) was historically performed with high-dose melphalan. Given the possibility of such initial therapy to adversely affect the ability to collect stem cells and considering the recent introduction of new class of drugs in transplant eligible patients, thalidomide/lenalidomide and bortezomib-based regimens are currently preferred to single agent dexamethasone and VAD (vincristine, adriamycin, doxorubicin), with strong recommendation for the use of bortezomib-containing regimens in high-risk patients. Oral combinations of melphalan and prednisone (MP) plus novel agents or lenalidomide and steroid are considered as standards of care for elderly patients (non-transplant setting) [171] (Fig. 8). The two following options are recommended (level IA): melphalan/prednisone/thalidomide (MPT) [173] and bortezomib/melphalan/prednisone (VMP) [174]; both are approved in this setting by the European Medicines Agency

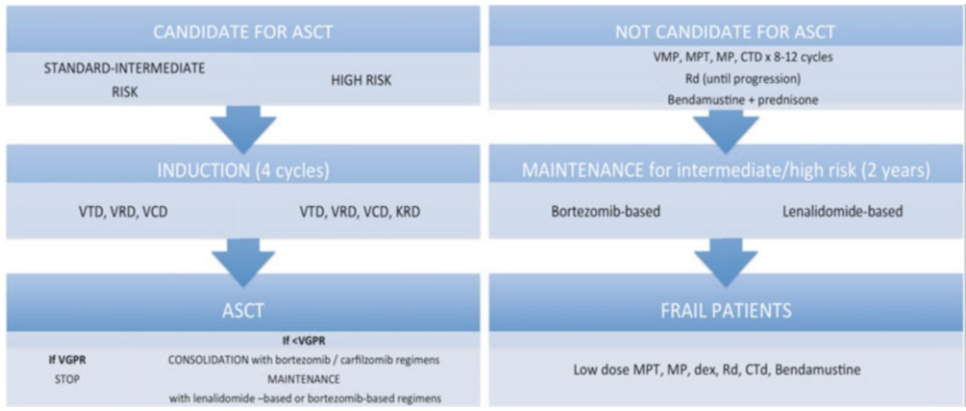

Fig. 7 Treatment options for multiple myeloma (Adapted from Rajkumar et al. [170] and Moreau et al. [171])

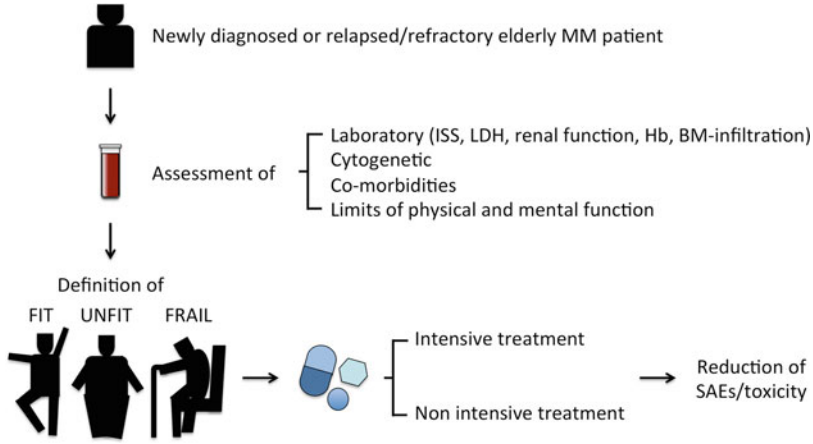

Fig. 8 Special considerations prior to therapy in elderly or frail patients. In multiple myeloma patients with newly diagnosed or refractory disease, a detailed geriatric and functional assessment helps to define more precisely "fit" *versus* "frail" patients and to evaluate patients' risk for treatment toxicity and treatment discontinuation. These definitions of fit, unfit, and frail patients are anticipated to influence selection of therapeutics, as well as the correct allocation to intensive or nonintensive treatment should reduce side effects/SAEs and treatment toxicity (Modified from Terpos et al. [172])

(EMA). Bendamustine plus prednisone is another regimen that is also approved by the EMA in patients who have clinical neuropathy at time of diagnosis precluding the use of thalidomide (MPT regimen) or bortezomib (VMP regimen) [175]. Melphalan/prednisone/lenalidomide (MPR) allowed 81% of patients to achieve at least a partial response, and to about half of them to achieve a very good partial response, to 24% to reach a CR, with 12-month EFS of 92% and OS of 100% [176]. Moreover, in a randomized trial comparing MPR followed by lenalidomide as maintenance versus MPR without maintenance versus MP, MPR-R significantly prolonged progression-free survival (median, 31 months) as compared with MPR (median, 14 months) and MP (median, 13 months), but without any significant impact on OS. At least a very good partial response was reported in 33% in the MPR-R and MPR groups versus 12% in the MP group. Even in this trial, OS was not different among the 3 arms [177]. Cyclophosphamide/thalidomide/dexamethasone (CTD) combination has also been compared with MP and is superior in terms of response rates, but does not induce a clear survival advantage over MP [178]. In patients in good clinical condition (e.g., fit patients), induction followed by high-dose therapy with autologous stem cell transplantation (ASCT) is the standard treatment (level IIb) [171]. ASCT improves complete response and prolongs median overall survival by approximately 24 months, though with an intrinsic mortality rate ranging from 1% to 2%. Response rates to induction therapy have been significantly increased by the use of novel agent-based combinations. Bortezomib-dexamethasone, which is superior to the classical VAD regimen (vincristine, adriamycin, and high-dose dexamethasone) [179], has become the backbone of induction therapy before ASCT (level IIb) [171]. The addition of a third agent to bortezomib-dexamethasone, e.g., thalidomide (VTD), doxorubicin (DVD or PAD), lenalidomide (RVD), or cyclophosphamide (VCD), has shown to offer higher response rates in phase II trials [180]. Three prospective studies have already shown that VTD is superior to TD or bortezomib-dexamethasone [181–183]. Based on response rates, depth of response, and PFS as surrogate markers for outcome, three-drug combinations including at least bortezomib and dexamethasone are currently the standard of care before ASCT. Three to four courses are recommended before proceeding to stem cell collection [171]. Melphalan (200 mg/m^2 i.v.) is the standard preparative regimen before ASCT [184]

(level IIb) [171]. Peripheral blood progenitor cells are the preferred source of stem cells, rather than BM [171]. Tandem ASCT has been evaluated before the era of novel agents. The benefit of tandem ASCT was observed in patients that were not reaching very good partial response after the first ASCT [185]. In a recent study phase III (Hovon 65-GMMG HD4 trial) in the context of bortezomib induction and maintenance treatment, OS was better in the GMMG group, which carried out tandem ASCT in contrast to HOVON (single ASCT) [186]. Nevertheless, the trial was not powered to compare single versus double high-dose melphalan. Ongoing trials running both in Europe and the USA comparing prospectively single versus tandem ASCT in the era of novel agents will solve this important issue. Allogeneic stem cell transplantation should only be carried out in the context of a clinical trial and only in patients with good response before transplant [171]. Myeloablation as part of radioimmunotherapy (RIT, see above) can be used 10–14 days before transplantation to reduce the dose of the conditioning treatment. Ongoing studies aim at assessing whether the conditioning regimen can be improved by the addition of bone-seeking radiopharmaceuticals such as ^{166}Ho-DOTMP or ^{153}Sm-EDTMP. A second sequential ASCT has been investigated as additional consolidation therapy to further reduce disease burden. Such tandem ASCT seems to be beneficial for patients who have failed to achieve good partial response after the first ASCT. Allogeneic stem cell transplantation is not recommended as part of initial therapy, but can be considered in young patients at high risk achieving a good response after the first ASCT. Indeed, notwithstanding the new conditioning strategies and the possibility of employing sibling or unrelated donors, the treatment-related mortality (TRM) rate is still about 10–20%, in addition to the high probability of graft versus host disease (GVHD) [187]. Thus far, in the era of novel agent-based induction therapy, there is still not enough evidence that consolidation therapy should be systematically applied [171]; even some studies suggest that consolidation after ASCT could be advantageous in terms of OS and PFS [188]. In elderly patients following induction, three randomized trials have explored the benefit of maintenance therapy in terms of OS using either immunomodulatory drugs (IMiDs) or bortezomib: MP versus MPR versus MPR-R [177], bortezomib-melphalan-prednisone-thalidomide/bortezomib-thalidomide versus VMP [189], VMP versus VTP followed by either bortezomib-prednisone (VP) or VP maintenance [190]. Due to the trial design, the benefit in OS is not well established. Therefore, systematic maintenance therapy is not recommended in elderly patients [171]. In young patients following ASCT, phase III randomized trials have demonstrated that maintenance therapy with IMiDs, either thalidomide or lenalidomide, prolongs PFS [191, 192], but the OS benefit is still unclear. Bortezomib maintenance is also under evaluation [186]. These three agents are not approved in this setting; therefore, systematic maintenance therapy is not recommended [171]. The choice of therapy in the relapse setting depends on several parameters, such as age; performance status; comorbidities; the type, efficacy, and tolerance of the previous treatment; the number of prior treatment lines; the available remaining treatment options; and the interval since the last therapy [171]. The EMA has approved lenalidomide in combination with dexamethasone [193, 194] and bortezomib either alone as single agent [195] or in combination with pegylated doxorubicin [196]. Thalidomide and bendamustine are effective drugs, often used, but not approved [197]. Triplet combinations have proved effective in phase II trials, but only one single randomized trial has shown the superiority of VTD over TD for PFS in patients relapsing following ASCT [198]. In young patients, a second ASCT may be considered, provided the patient responded well to the previous ASCT and had a PFS of more than 24 months [199]. In the relapse setting, allogeneic SCT should only be carried out in the context of a clinical trial. When possible, patients should be offered participation in clinical trials. Pomalidomide, the third-in-class IMiD, and carfilzomib [197] are now available in Europe also. Moreover, monoclonal antibodies, such as daratumumab and elotuzumab, are very promising options: daratumumab as single agent offered overall response to one third of patients refractory either to IMIDs or to bortezomib, with median duration of response of 7.4 months and 12 months OS of 65% and good tolerability [200].

Intravenous elotuzumab, in combination with lenalidomide and dexamethasone, offered to more than 90% of resistant patients a response and to more than 40% a very good partial response [201]. In a recently published phase 3 trial, refractory or relapsed MM patients were randomized to receive ixazomib (oral proteasome inhibitor) plus lenalidomide and dexamethasone or placebo plus lenalidomide and dexamethasone. PFS was 21 months in the ixazomib group versus 15 months in the control group, with similar percentage of serious adverse events [202]. Finally, histone-deacetylase inhibitors, such as panobinostat, have been licensed in association with bortezomib for relapsed patients: in the PANORAMA 2 trial, panobinostat was administered to relapsed MM patients in combination with bortezomib and dexamethasone (overall response rate of 34%, with PFS of 6 months for responsive cases) [203]. Supportive care with bisphosphonates can decrease bone pain as wells as reduce the progression of osteolytic lesions and prevent pathologic fractures. The exact time of start and optimal duration of treatment are still under investigation. However, according to ASCO recommendations, such therapy should be started in the presence of significant bone loss or of pathological spine fractures (lower bone density leads to weaker bones) and should continue for no longer than 2 years [204, 205]. A fully humanized mAb to RANKL (denosumab, which binds and inhibits the RANK ligand thus reducing bone resorption markers) is still under clinical investigation. Erythropoietin or darbepoetin is useful in patients with persistent symptomatic anemia. Indication for prophylactic antibiotic therapy in patients undergoing chemotherapy is still debated, while it should be considered in all patients receiving high-dose steroid therapy [205]. Intravenous immunoglobulin administration is indicated if patients have recurrent severe infections associated with severe hypogammaglobulinemia. Plasmapheresis is useful in patients with the hyperviscosity syndrome. Vertebroplasty and kyphoplasty generally result in rapid and long-lasting reduction of bone pain and improvement in functional activity in patients with vertebral compression fractures. The standard treatments for cord or cauda equina compression are steroids and radiation therapy, whereas surgical decompression is rarely necessary. Radiotherapy is generally used for the treatment of painful bone lesions or to prevent complications and is performed at least once in about 70% of patients with MM. Typically, doses <30 Gy are preferred, to avoid permanent side effects which could jeopardize subsequent chemotherapy or ASCT [205, 206]. Among the radionuclide therapies for MM, CXCR4-targeted radiotherapy with pentixather appears to be a promising novel treatment option in combination with cytotoxic chemotherapy and autologous stem cell transplantation, especially for patients with advanced MM as recently reported in a first in human experience [207].

Radioimmunotherapy in Multiple Myeloma

In 1999 Couturier O. et al. [208] evaluated RIT in MM targeting a specific monoclonal antibody (B-B4) coupled to ^{213}Bi by a chelating agent (pentaacetic triamine diethylene *p*-aminobenzyl acid). The efficacy of alpha-RIT was assessed in vitro by analysis of thymidine incorporation, cell mortality, apoptosis of myeloma cells, and the study of nonspecific irradiation of hematopoietic cell lines not recognized by B-B4-pentaacetic triamine diethylene *p*-aminobenzyl acid immunoconjugate. B-B4 has been shown to induce apoptotic death of more than 40% of myeloma cells at a dose of 7.4 kBq/10^5 cells. Similarly, Burtun et al. [209] explored the biochemical nature and potential of MUC1 as antigenic target in MM. MA5 mAb was strongly reactive with 6/8 human MM cell lines as shown by flow cytometry. In 7/8 MM patient samples (bone marrow and/or peripheral blood), reactivity was found in 10–90% of the cells, whereas normal control (n = 5) and leukemia and lymphoma (n = 5) cells showed only 0–6% reactivity. ^{125}I-labeled MA5 whole-cell binding studies showed quantitatively similar amounts of binding between strongly positive MM lines and high-MUC1-expressing breast carcinoma lines. MM cell lines were positive for mRNA expression (Northern blotting and reverse transcription-PCR), with strong similarity in the sizes of the mRNAs and cDNAs.

Finally, biodistribution experiments were carried out with ^{131}I-labeled MA5 versus a nonbinding control ^{125}I-labeled mAb in a MM xenograft model. Selective MM tumor uptake of the MA5 mAb was demonstrated, with a potential for delivering a tumor radiation absorbed dose of 8540 cGy/mCi of injected dose compared with 3099 cGy/mCi of tumor-absorbed dose delivered by nonspecific antibody. Results of a direct comparison between B-B4 and MA5 labeled with iodine-131 and bismuth-213 in vitro have been demonstrated that B-B4 RIT might be more effective than MA5 and suggested that alpha-RIT might be more suitable than beta-RIT for treating single-cell tumor models [210]. Different mechanisms (cell cycle synchronization, DNA damage, and apoptosis) that might underlie potential synergy between chemotherapy (paclitaxel or doxorubicin) and RIT with alpha radionuclides have been analyzed in three different MM cell lines (LP1, RMI 8226, and U266). Cells were treated with ^{213}Bi-B-B4 24 hours after paclitaxel (1 nmol/L) or doxorubicin (10 nmol/L) treatment; radiation enhancement ratio showed that paclitaxel and doxorubicin were synergistic with alpha RIT. After a 24-h incubation, paclitaxel and doxorubicin arrested all cell lines in the G2-M phase of the cell cycle. Doxorubicin combined with alpha RIT increased tail DNA in the RPMI 8226 cell line but not the LP1 or U266 cell lines compared with doxorubicin alone or alpha RIT alone. Neither doxorubicin nor paclitaxel combined with alpha RIT increased the level of apoptosis induced by either drug alone or alpha RIT alone. Both cell cycle arrest in the G2-M phase and an increase in DNA double-strand breaks could lead to radiosensitization of cells by doxorubicin or paclitaxel, but apoptosis would not be involved in radiosensitization mechanisms [211].

In myeloma xenografts models, treatment with ^{213}Bi-anti-CD38-MAb suppressed tumor growth via induction of apoptosis in tumor tissue and significantly prolonged survival compared to controls [212, 213].

In order to define where alpha-RIT stands in MM treatment, melphalan was compared with alpha-RIT using a ^{213}Bi-anti-CD38-MAb in a syngeneic MM mouse model. Fifty percent of untreated mice died by day 63 after MM engraftment. In mice treated with melphalan alone, 200 μg improved median survival. No animal was cured after melphalan treatment, whereas 60% of the mice survived with RIT alone at day 22 after tumor engraftment, with only slight and reversible hematological radiotoxicity. No therapeutic effect was observed with alpha-RIT 25 days after engraftment. Melphalan and alpha-RIT combination does not improve overall survival compared to RIT alone, resulting in increased leukocyte and red blood cell toxicity. Based on these data, alpha-RIT seems to be a good alternative to melphalan, while their association provides no benefit [214].

To promote an efficient and long-lasting antitumor response, combining α-RIT (^{213}Bi-radiolabeled anti-CD138 antibody) and adoptive T-cell transfer (ovalbumin-specific CD8+ T cells) have been evaluated in an animal model. Animals treated with the combination had significant tumor growth control and an improved survival compared to control mice or the ones that received RIT alone or adoptive T-cell transfer alone [215].

Pretargeting with biotin may improve RIT efficacy. A comparison between conventional RIT using anti-CD38-MAb and streptavidin-biotin pretargeted RIT (PRIT) demonstrated more favorable results for PRIT. Particularly, PRIT demonstrated better biodistribution with a very high tumor-to-blood ratio (638:1 24 h after PRIT; ratios never exceeded 1:1 with conventional RIT). Objective remissions were observed within 7 days in 100% of the mice treated with PRIT (800–1200 μCi of anti-CD38 pretargeted ^{90}Y-DOTA-biotin), including 100% of complete remissions by day 23. Furthermore, 100% of animals bearing NCI-H929 multiple myeloma tumor treated with 800 μCi of anti-CD38 pretargeted ^{90}Y-DOTA-biotin achieved long-term myeloma-free survival (>70 days) compared with none of the control animals [216].

More recently, preliminary biodistribution and dosimetry results were obtained in refractory MM patients in a phase I/II RIT study using ^{131}I-B-B4. Four patients at the fourth relapse received 370 MBq (20 mg/m^2) of ^{131}I-B-B4: each patient underwent three-point images (day 0, day 1, and day 3–4) to assess doses absorbed by organs and

the bone marrow. Images obtained 1 h after ^{131}I-B-B4 injection showed high bone marrow and liver uptake without kidney uptake. The bone marrow uptake confirmed the bone marrow involvement as detected by [^{18}F]FDG-PET/CT. Absorbed doses were calculated at 2.03 ± 0.3 mGy/MBq for the liver, 1.10 ± 0.9 mGy/MBq for the kidney, and 0.52 ± 0.20 mGy/MBq for the bone marrow. Grade III thrombocytopenia was documented in two cases (highest bone marrow-absorbed doses), and no grade IV hematological toxicity was observed. One patient experienced partial response, with 60% reduction of M-spike on serum electrophoresis, and total relief of pain, lasting for 1 year. This proof-of-concept study based on dosimetry demonstrated the feasibility of the anti-CD138 antibody RIT [217]. Animal model studies confirmed the efficacy of ^{213}Bi-labeled anti-mCD138 for the treatment of residual disease in the case of MM, with only moderate and transient toxicity [213].

Promising results have been reported also by using ^{131}I-Radretumab. Radretumab is a fully human antibody binding the extradomain-B splice variant of fibronectin. Strong extradomain-B expression in almost all lymphoma subtypes and in the bone marrow from MM patients has also been reported [218].

Based on these preclinical data, a phase I/II study was performed in patients with solid tumors and hematological malignancies. Two MM patients were treated with 3.7 GBq and 1.85 GBq of ^{131}I-Radretumab, respectively, achieving disease stabilization lasting few months [219].

The newly synthetized te2a-Ph-NCS has been conjugated to a new anti-CD138 mAb (9E7.4) to evaluate its in vivo behavior and potentiality as bifunctional chelating agents and to explore a first attempt of PET-phenotypic imaging in MM (^{64}Cu-9E7.4-CSN-Ph-te2a). Animal experiments were carried out on 5 T33-Luc(+) tumor bearing mice: a millimetric bone uptake was localized in the sacroiliac myeloma. Nonspecific uptakes were observed at 2 h postinjection, but, unlike for the tumor, a significant decrease was observed at 20 h postinjection [220].

Very recently, the therapeutic efficacy of RIT in the 5 T33 murine MM model using 9E7.4 labeled either with ^{213}Bi for α-RIT or ^{177}Lu for β-RIT has been evaluated. α-RIT performed with 3.7 MBq of ^{213}Bi-9E7.4 increased median survival to 80 days compared to untreated control (37 days) and effected cure in 45% of animals. β-RIT performed with 18.5 MBq of ^{177}Lu-9E7.4 mAb was well tolerated and significantly increased mouse survival (54 vs. 37 days in the control group); however, no mice were cured with this treatment [221].

Radiotherapy with Bone-Seeking Radionuclides

Bone-seeking radiopharmaceuticals, although used more widely in the palliation of bone pain for patients with metastases from prostate or breast cancer, are also being evaluated in MM patients in the transplant setting.

In vitro studies showed that myeloma cell lines treated with ^{153}Sm-EDTMP showed a 50% decrease in clonogenic activity and mice who received treatment improved median survival from 18 to 25 days ($p<0.001$) [222].

A phase II trial using high-dose ^{153}Sm-EDTMP conducted at the Mayo Clinic included 46 patients treated with melphalan 200 mg/m^2 and 40 Gy of ^{153}Sm-EDTMP: engraftment was comparable to that seen after conventional ASCT. No dose-related toxicity or cases of thrombotic thrombocytopenic purpura, radiation nephritis, or bladder toxicity were observed with a median follow-up of 14.2 months [223].

In another study, the clinical impact and quality of life after treatment with ^{153}Sm-EDTMP (2 GBq every 12 weeks) and zoledronic acid (4 mg every 28 days) for symptomatic refractory MM were evaluated in elderly patients. A single course of ^{153}Sm-EDTMP plus zoledronic acid prolonged duration of the clinical response (reduction of MM-related symptoms). No significant hematological or non-hematological side effects were observed [224]. This combination is therefore safe and may be useful in the setting of refractory bone pain for MM patients with bone disease. It is currently ongoing a phase I/II trial which evaluates the efficacy and side effects of ^{153}Sm-

lexidronam pentasodium when given together with zoledronic acid or pamidronate [147]. More recent studies also showed that many of the newer agents (including bortezomib, thalidomide, and arsenic trioxide) have a radiosensitizing effect, possibly through inhibitory effects on the NF-κB pathway that usually upregulates the anti-apoptotic signaling following exposure to ionizing radiation [222, 225, 226].

Very interesting results were obtained by a phase I dose-escalation study assessing the safety, tolerability, and efficacy of ^{153}Sm-lexidronam combined with bortezomib (as radiosensitizing agent) for patients with relapsed/refractory MM: the maximum tolerated was not reached and no dose-limiting toxicities were observed. Responses occurred in five (21%) patients, including three (12.5%) complete and two (8.3%) minimal responses. These results suggested that bortezomib combined with ^{153}Sm-lexidronam is a well-tolerated regimen and it might be effective in patients with relapsed or refractory MM [227].

Results of a phase I/II trial evaluating the side effects and best activity of samarium ^{153}Sm-lexidronam when given together with high-dose melphalan in patients with MM undergoing stem cell transplant are not available [147]. However, therapy with ^{186}Re-HEDP used as part of an intensified conditioning regimen before allogeneic stem cell transplantation has been reported in two patients with advanced ALL during the second partial or third complete remission [228]. After a pre-therapeutic dynamic scintigraphy with ^{99m}Tc-Mag3 showing normal renal function, a dynamic bone scintigraphy with ^{99m}Tc-MDP was used to calculate the expected bone marrow and kidney doses, with effective doses equal to 2.1 Gy and 1.6 Gy, respectively. No unexpected complications occurred after completing conditioning and allogeneic stem cell transplantation, and no deterioration of renal function was noticed. The authors therefore concluded that ^{186}Re-HEDP is expected to increase the total additional bone marrow dose without inducing clinically significant nephrotoxicity; in these conditions, doses near 10 Gy to the bone marrow can be achieved.

Radionuclide Therapy of Thyroid Tumors

42

Rossella Elisei, Laura Agate, Sara Mazzarri, Valeria Bottici, Federica Guidoccio, Eleonora Molinaro, Giuseppe Boni, Marco Ferdeghini, and Giuliano Mariani

Abstract

When indicated, ablation of postsurgical thyroid remnants with ^{131}I-iodide constitutes a unicum with surgery as the primary form of treatment for differentiated thyroid cancer (DTC) derived from the follicular epithelium. According to the most recent guidelines, thyroid remnant ablation is indicated in DTC patients with a moderate to high risk of recurrence. Patients are prepared with low-iodine diet and with either withdrawal of replacement therapy with L-thyroxine (l-T4) for a period sufficient to achieve serum TSH levels >30 μIU/mL (usually within 4–6 weeks) or administration of exogenous human recombinant (rhTSH). Administered activities of ^{131}I-iodide vary considerably between 1.11 and 3.7 GBq (30–100 mCi), according to the estimated risk of recurrence. A whole-body scan (^{131}I-WBS, preferably completed with SPECT/CT acquisitions at selected sites) is performed 4–7 days after ^{131}I-iodide administration, as it can detect lymph node involvement or unexpected metastases. Therapy with ^{131}I-iodide causes in some instances side effects that are usually mild, transient, and well manageable. More important side effects (e.g., a radiation-induced second malignancy) can be expected only after repeated administrations of radioiodide for therapy of recurrent metastatic disease and for very high cumulative doses.

The major diagnostic modalities employed to follow patients with DTC treated with remnant ablation are measurement of serum Tg, ^{131}I-WBS, and neck US. Additional diagnostic imaging (e.g., CT, MRI) is applicable in selected circumstances; in fact, although CT and MRI can in principle localize very small lesions in the neck, chest, and bones, the features of such lesions are rarely specific for recurrent/metastatic DTC.

If lymph node metastasis is suspected on the basis of imaging findings, a FNAC should be performed, also assaying Tg in the needle washing. Serum Tg levels that become detectable or show an increasing trend during follow-up indicate the need for further evaluation, possibly with additional ^{131}I-iodide therapy in case of small metastatic lesions (<1 cm in size) with a relatively high radioiodine uptake. In case of bigger lymph node metastasis, surgery is preferable – possibly followed by adjuvant radioiodine therapy. External beam radiation therapy (EBRT) has little role in treatment of recurrent/metastatic DTC, except in case of tumors

exhibiting a trend to dedifferentiation. Patients with recurrent DTC may develop poorly differentiated lesions that cannot concentrate radioiodide. In these patients [^{18}F]FDG PET/CT has an important prognostic role and is useful to determine the sites and extent of these metastases. When DTC becomes refractory to ^{131}I-iodide therapy, metastatic and progressive lesions can be treated with tyrosine kinase inhibitors (TKI) such as sorafenib and lenvatinib.

Radionuclide therapy has no role in the treatment of anaplastic or poorly differentiated thyroid cancers, because these tumors cannot concentrate radioiodide; in these patients therapy is based on surgery (whenever possible – also with simple debulking/palliative purposes), chemotherapy, and EBRT. Prognosis of these patients is very poor.

Surgery is the first-choice option for the treatment of patients with medullary thyroid cancer (MTC). Follow-up is based on monitoring of biochemical tumor recurrence (rising serum calcitonin and/or CEA levels) and on diagnostic imaging with radiopharmaceuticals that are commonly used for the whole spectrum of neuroendocrine tumors: ^{123}I-MIBG, radiolabeled somatostatin analogs (^{111}In-DTPA-pentetreotide, ^{68}Ga-DOTA-NOC/TATE) in addition to the overall tumor-imaging agent [^{18}F]FDG. Radionuclide therapy of recurrent/metastatic DTC can include ^{131}I-MIBG and ^{90}Y- or ^{177}Lu-DOTA-TOC/NOC/TATE. As in the case of radioiodide-refractory DTC, treatment of advanced recurrent/metastatic MTC can include novel targeted therapies such as TKIs.

Treatment of thyroid cancers derived from the follicular epithelium that are either poorly differentiated or plain anaplastic relies on the main pillars of the vast majority of biologically aggressive tumors, i.e., surgery (whenever possible with curative intent – but frequently only for palliative purposes), chemotherapy, and new targeted therapies. In this scenario, there is very little or no role for therapy with radiopharmaceuticals. Whereas, radiopharmaceuticals have multiple important roles for treatment and follow-up of more differentiated forms of thyroid cancer derived from either the follicular epithelium (papillary and follicular thyroid cancer) or from the parafollicular C cells (medullary thyroid cancer). The focus of this chapter is on treatment and follow-up of differentiated thyroid cancers.

Primary Treatment of Differentiated Thyroid Cancer

Surgery

Unlike follicular thyroid cancer (FTC, which usually presents as a solitary nodule), papillary thyroid cancer (PTC) frequently exhibits multifocal growth. Until recently, total thyroidectomy was always indicated as initial treatment when the diagnosis of PTC was known before surgery, e.g., when the ultrasound (US) findings had been typical for cancer, or fine needle aspiration cytology (FNAC) had shown a Thy 4 or Thy 5 pattern. In fact, given the high rate of multifocality and bilaterality of PTC, total thyroidectomy results in lower recurrence rates than lobectomy or subtotal thyroidectomy [1]. However, with the wide diffusion of neck ultrasound and the possibility to detect early possible recurrence in the residual lobe, simple lobectomy is nowadays indicated when the PTC is in a single nodule and of small size [2]. The main reason for this choice is the lower prevalence of complications after lobectomy than after total thyroidectomy, either vocal cord palsy and/or hypoparathyroidism.

When locoregional disease is not detected preoperatively (as assessed by, e.g., US examination of the neck [3] or by preoperative FNAC), the prevailing consensus is that there is no need to routinely perform lateral lymph node dissection in patients with DTC. Conversely, some authors suggest central lymph node dissection for primary surgery in lymph node-positive PTC, in order to abrogate the serum levels of thyroglobulin (Tg) – which would then become a tumor-associated marker [4]. However, since total thyroidectomy and systematic lymph node dissection in the central, and especially in the lateral neck, have been linked to higher surgical morbidity, there is no universal consensus on the necessity to perform central neck dissection by principle. In this regard, recently published studies demonstrate that the outcome of patients treated with prophylactic central neck dissection is characterized by a higher proportion of postsurgical hypoparathyroidism – but with the same long-term clinical outcome of those treated only with total thyroidectomy [5, 6]. Nevertheless, if neck lymph node metastases, either in the central or lateral compartment, are diagnosed by US examination before thyroidectomy, surgery must include lateral neck dissection [7]. Selective excision of confirmed lymph node metastases (the so-called "cherry picking" or "node plucking" technique) is justified only in those patients with thyroid cancer who have already had systematic dissections of the respective neck area(s) during prior operations [8].

Adjuvant Ablation of Postsurgical Remnants with ^{131}I-Iodide

The rationale of performing radioiodide therapy of DTC after surgery in order to ablate postsurgical thyroid remnants is based on the selective ability of thyroid cells to concentrate iodine, which is then utilized to synthesize Tg and thyroid hormones. This capacity (which is maintained by DTC tumor cells to a much lesser extent than in normal thyroid cells) is significantly enhanced by TSH stimulation, a condition that can be achieved either by discontinuing replacement/suppressive hormonal therapy with L-thyroxine or by administering exogenous rhTSH (see further below); full benefits of the diagnostic and therapeutic uses of ^{131}I-iodide can be achieved on the basis of this property.

Ablation of postsurgical thyroid remnants with ^{131}I-iodide is indicated in DTC to eliminate any residual, macroscopically normal thyroid tissue left after total or near-total thyroidectomy [9–11]. This therapeutic strategy ensues four major benefits:

1. Since 50% of PTCs are multifocal, ^{131}I-iodide ablation may decrease the recurrence and mortality rates, by destroying postoperative microscopic residual tumor foci.
2. ^{131}I-iodide ablation of normal appearing residual thyroid tissue facilitates the early detection of recurrences based on sequential measurements of serum Tg. In this regard, it should be noted that thyroid remnants synthesize and secrete Tg that is indistinguishable from Tg possibly produced by residual thyroid cancer cells.
3. ^{131}I-iodide ablation makes it possible to perform a highly sensitive diagnostic whole-body scan (^{131}I-WBS) 4–7 days after administration of the ablative ^{131}I activity, which may reveal previously undetected metastatic tumor lesions, as identified by foci of uptake outside the thyroid bed (see example in Fig. 1).
4. By reducing/ablating the mass of normal thyroid tissue, any subsequent therapeutic use of ^{131}I-iodide in case of recurrent/metastatic DTC will be more effective.

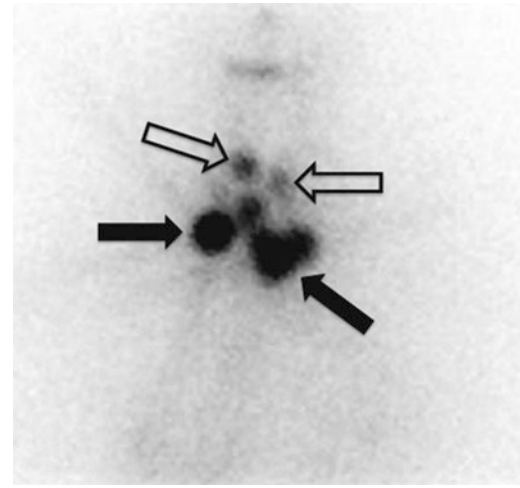

Fig. 1 Spot planar imaging of the upper chest and neck region (anterior view) obtained 7 days after administration of 3.7 GBq (100 mCi) ^{131}I-iodide for thyroid remnant ablation in a patient treated for PTC. In addition to at least two obvious thyroid tissue remnants with intense radioiodide uptake (*solid black arrows*), there are at least two areas with lower intensity uptake (indicated by *open arrows*), corresponding to lymph node metastases that were previously unknown; subsequent characterization by FNAC with assay of Tg in the needle washing confirmed the presence of metastasis (From Volterrani et al. [301], with permission of Springer Science+Business Media)

However, since the indication for ablation with ^{131}I-iodide is based on prognostic factors and no benefits from radioiodine ablation for patients with intrathyroidal tumors <1.5 cm has been demonstrated [10, 12–14], the prevailing consensus is that these "low-risk" thyroid cancer patients should not undergo postsurgical radioiodine ablation. In this regard, the most recent US guidelines for the treatment of thyroid cancer do not recommend as mandatory the use of ^{131}I-iodide thyroid remnant ablation in patients with lymph node-negative, unifocal intrathyroidal microcarcinomas (T1aN0M0) [2]. Also in patients with larger tumors (>1.5 cm), with multifocal tumors, or with extension beyond the thyroid capsule or with lymph node metastasis, the so-called "intermediate-risk" cases, the benefits of ablation with ^{131}I-iodide continue to be debated [10, 13–16]. Therefore, in these patients the use of radioiodine

for the purpose of ablating normal remnant tissue should be "selective" and debated case by case, although the prevailing consensus is that these conditions should indeed be treated [17]. In patients with high-risk DTC, there is instead a clear need for ^{131}I-iodide treatment to prolong disease-free and overall survival (Table 1).

Even if a real clinical benefit of ^{131}I-iodide remnant ablation is not fully recognized for lower-risk tumors, its role in making easier the follow-up of DTC patients in any risk category has been proposed for many years as one of the rationales to perform it. In fact, since either normal and/or neoplastic thyroid tissue may be responsible for Tg production in patients with thyroid remnants, serum Tg measurement will be more useful for detecting persistent/recurrent disease after all sources of Tg secretion alternative to tumor tissue (i.e., normal thyroid remnants) have been eliminated. Any detectable serum Tg level after total thyroidectomy and successful remnant ablation should therefore indicate the presence of residual tumor. Nevertheless, over the years it has been recognized that the trend of increase of serum Tg is more important than the absolute value to follow up these patients [18], especially when combined with a neck US scan performed by expert endocrinologists or radiologists [19].

On the other hand, also the diagnostic ^{131}I-WBS is more sensitive and specific after radioiodine ablation of normal thyroid remnants; furthermore, imaging with radioiodide WBS and US evaluation of the neck are the only reliable diagnostic modalities in patients in whom the assay of serum Tg is unreliable because of the presence of circulating anti-Tg antibodies.

Although ^{131}I-iodide can be very successful in achieving all of the above objectives, many factors may affect the degree of success of ^{131}I-iodide thyroid remnant ablation. These include, but are not limited to, the extent of surgery, percent radioiodide uptake in normal residual thyroid tissue, volume of normal residual thyroid tissue, prescribed activity of ^{131}I-iodide, geometrical shape of normal residual thyroid tissue, effective half-life of ^{131}I in the normal residual thyroid tissue, patient's compliance with low-iodine diet, serum level of TSH, prior use of diagnostic ^{131}I-iodide with possible stunning, and definition of successful radioiodine ablation.

The kinetics of radioiodine accumulation in DTC cells differs from that in normal thyroid tissue. In the latter, uptake of radioiodide is approximately 1% of the administered activity per gram of tissue, with a biological half-life of about 8 days; whereas, in the tumor tissue uptake of ^{131}I-iodide varies from 0.5% to 0.001% of administered activity per gram, with half-lives ranging from a few days to a few hours [20]. This difference explains why, following administration of any given activity of ^{131}I-iodide, the amount of radiation delivered to the tumor is small compared to that delivered to normal thyroid tissue. A quantitative dosimetric approach determines the therapeutic activity required to deliver a sufficient dose of radiation to treat and can also predict the outcome of ^{131}I-iodide therapy. The recommended radiation dose for ablation of thyroid remnants is 300 Gy [9].

It should also be considered that the dosimetric burden must not exceed the maximum permissible irradiation to the whole body and particularly to the bone marrow (2 Gy); to this purpose, an empiric estimate has been suggested, i.e., to administer ^{131}I-iodide activities such that whole-body retention at 48 h post-administration should not exceed 4.44 GBq (or 120 mCi). Furthermore, particular attention should be paid to dosimetric estimates in patients with diffuse lung metastases, in whom radioiodine might cause pulmonary fibrosis over certain values of accumulation/retention; in these patients the estimated whole-body

Table 1 Indications for radioiodide treatment in DTC patients

Risk category	TNM (6th ed.)	Benefits	Indication to ^{131}I-iodide
Low	T1aN0M0	None	No
Intermediate	T1b-T2N0M0 T1-2N1M0	Could reduce relapses	Yes/no[a]
High	T1-2N0-1MI, T3-4 N0-1, and/or M0-1	Reduces relapse and death	Yes

European Consensus: Pacini et al. [303]
[a]"Yes": European Consensus; "no": ATA guidelines

retention of ^{131}I at 48 h should not exceed 2.96 GBq (80 mCi) [21, 22]. Nevertheless, at the same time, therapeutic activity to be administered should be calculated so as to ensure the delivery of an effective dose to the tumor lesions; if this condition cannot be achieved because of low radioiodine uptake, then it would be appropriate to consider therapies alternative to radioiodine therapy, such as surgery (whenever possible), EBRT, and/or chemotherapy [9, 22].

Administration of ^{131}I-iodide in activities prefixed according to certain thresholds irrespective of pretreatment dosimetric estimates is still the most widely employed approach. Its main advantage is simplicity, although probably not being the optimal solution for all cases; in fact, any prefixed activity may be excessive in some cases and insufficient in others. For ablation purposes, a single administration of either 1.11 or 3.7 GBq (30 or 100 mCi) of ^{131}I-iodide ensues complete destruction of the remnants in 90% of the cases when uptake of a tracer amount of radioiodide in the residue is <2% (which translates into a residual thyroid tissue mass <2 g), while ablation is successful in only two-thirds of the cases when uptake is >2% (i.e., a residual thyroid mass >2 g) [9].

Accurate individual patient-tailored dosimetric estimates require a set of information on the target tissue. Considering that the radiation dose is basically delivered energy per mass, such information includes the volume (or mass) of the target tissue and the retention kinetics of ^{131}I-iodide in that target. While imaging techniques can provide volumetric estimates of the target tissue, the kinetics of uptake and retention of radioiodide can be derived from serial measurements following administration of a tracer activity of ^{131}I-iodide (such as, e.g., 3.7 MBq); since such measurements are usually limited to only 24 h (or 48 h at the latest) post-administration, certain assumptions derived from standard pharmacokinetic models are adopted for describing the kinetics of radioiodide retention from the last time point onward. Although preferable in principle to more simplistic empiric approaches, from a practical standpoint, the approach of administering ^{131}I-iodide activities based on pretreatment dosimetric estimates has four major drawbacks, which apply not only to the remnant ablation case but also to the case of radioiodide therapy of recurrent/metastatic lesions from DTC:

1. The estimated volume in which radioiodide is concentrated is in general only an approximation derived from, e.g., US evaluation; moreover, this volume cannot be measured in patients with metastases that are too small for viewing by imaging techniques, as is the case for diffuse lung metastases that are not discernible as separate lesions by chest x-ray or CT.
2. The biological half-life of ^{131}I-iodide in the target tissues differs from one patient to another, and even between different metastatic lesions in any given patient, or in different periods; thus, dosimetric estimates based on standard models may have a wide range of approximation.
3. The intestinal absorption of ^{131}I-iodide can vary even over short intervals of time, such as those occurring between administration of the tracer activity for the dosimetric study and administration of the actual therapeutic activity.
4. Dose distribution in a certain tumor target tissue can be heterogeneous, as shown by the typical patchy distribution of radioiodide visualized on tissue autoradiographs. In this case, voxel dosimetry could be useful for predicting the possibility of either whole or partial ablation of tumor tissue. In this regard, 3D dosimetry makes it possible to obtain the so-called dose-volume histogram, a map of the different absorbed dose values in different portions of the target tissue [23].

Thyroid remnant ablation with ^{131}I-iodide must be performed under adequate TSH stimulation, which is necessary in order to increase the uptake of radioiodine by follicular thyroid cells. After the effectiveness and safety of the use of rhTSH have been recognized [24], ablation of thyroid remnants can be performed by administering ^{131}I-iodide after two i.m. injections of

0.9 mg of rhTSH performed 24 and 48 h before the treatment [25]. If rhTSH administration is unfortunately not available, a period of L-thyroxine (l-T4) withdrawal of at least 4 weeks is required; in this case, serum TSH should be >30 μIU/mL before radioiodide is given; otherwise, the withdrawal period is prolonged for another 1–2 weeks. The main drawback of this traditional modality of patient's preparation for radioiodide therapy is the development of hypothyroidism symptoms after about 2–3 weeks from hormone withdrawal and continuing for other 2–3 weeks after the reintroduction of the l-T4 therapy. Replacing l-T4 with T3 for 2 weeks before complete hormonal withdrawal and taking T3 with l-T4 during the 2–3 weeks after the radioiodine treatment can be useful to limit the hypothyroidism symptoms, because of the much faster metabolic clearance of T3 versus that of T4 (biologic half-life about 10 h versus 7 days, respectively). However, T3 requires a three times per day administration, and many patients experience tachycardia soon after its consumption.

The use of rhTSH (Thyrogen®) is approved in the USA and Europe for pre-therapeutic stimulation before administering radioiodide for ablation of thyroid tissue remnants after near-total or total thyroidectomy for DTC, in patients without evidence of distant metastases. Very recently two independent multi-center randomized studies, one performed in France [26] and one in the UK [27], have clearly demonstrated that low-risk and intermediate-risk DTC patients can successfully be ablated when treated either with 1.11. or 3.7 GBq ^{131}I-iodide (30 or 100 mCi) and regardless of the type of TSH stimulation (i.e., obtained after withdrawal of LT4 therapy or after rhTSH administration). After these studies, the use of rhTSH for remnant ablation has been approved in combination with activities ranging from 30 to 100 mCi of ^{131}I-iodide.

Irrespective of the modality of TSH stimulation (i.e., through increased endogenous secretion following l-T4 withdrawal or through administration of exogenous rhTSH), an important component of patient's preparation for radioiodide therapy is to ensure that the pool of native iodide in the body fluids is reduced as much as possible. In fact, reducing competition from unlabeled iodide for uptake of radioiodide in the thyroid cells increases the chances for the radioactive iodide atoms to be accumulated in the thyroid cells or in the DTC cells. Depletion of the iodide pool in the body is achieved by following a low-iodine diet (Table 2A) for at least 2 weeks before radioiodide administration. This is of particular relevance in countries with normal-high levels of iodine in the population while it is not mandatory in countries with median-low levels of iodine. Patients should also avoid excessive iodine intake through other sources, such as drugs, iodinated contrast agents, etc. (Table 2B) for list of products/drugs with high-iodine content) [28, 29].

Very recently, the question of whether the iodine content expressed as urinary iodine content can represent a limitation to the success of radioiodine therapy has been questioned. However, the absence of iodine contamination should always be verified by measuring urinary iodine content, preferably normalized as iodine/creatinine ratio (i.e., as microgram of iodine per gram of creatinine, μg/g); in case this value is greater than 250 μg/g [29], ^{131}I-iodide therapy should be delayed until the body stores of iodine have decreased [30]. Assessing urinary iodine might be relevant especially in those patients who have a negative post-ablation/therapy scan despite evidence of residual/recurrent disease as assessed by serum Tg. In women of childbearing age, pregnancy must be excluded before administering radioiodine for therapy.

Although the issue of thyroid stunning (characterized by a reduction of therapeutic radioiodide uptake consequent to prior administration of a diagnostic activity of ^{131}I-iodide) was recognized more than 50 years ago [31, 32], it still is a matter of debate, and its clinical significance and even its existence have been questioned [33]. The frequency of thyroid stunning, a condition that potentially compromises the therapeutic efficacy and outcome of radioiodide treatment, appears to increase with increasing activities of radioiodide administered in the diagnostic phase [34, 35]. Indeed, the exposure of follicular thyroid cells

Table 2 High-iodine content foods/products, to be limited/avoided before scintigraphy or therapy with radioiodide in patients with DTC

A) Food Products	Amount of time it should be avoided before therapy
Iodized salt, sea salt	2 weeks
Milk or other dairy products, including ice cream, cheese, yogurt, etc.	2 weeks
Eggs	2 weeks
Seafood, including fish, shellfish, kelp, or seaweed	2 weeks
Foods that contain the additives carrageenan, agar-agar, and algin alginates	2 weeks
Cured and corned foods (ham, lox, corned beef, sauerkraut)	2 weeks
Breads made with iodinated dough conditioners	2 weeks
Foods and medications containing red food dyes	2 weeks
Chocolate	2 weeks
Molasses	2 weeks
Soy products (soy sauce, soy milk)	2 weeks
B) Drugs with high content of iodine possibly interfering with 131-I uptake	
Lugol's solution	3 weeks
Potassium iodide solution	3 weeks
Topical iodine (e.g., surgical skin preparation)	3 weeks
Iodinated radiographic contrast agents:	
Intravenous (water soluble)	4 weeks (with normal renal function)
Lipophilic (rarely used)	>4 weeks
Amiodarone	>3 months
In addition, restaurant food should be avoided, because there is no way to know whether they use iodized salt	3 weeks

(or of follicular-derived tumor cells) to sublethal doses of radiation from ^{131}I-iodide (as it might be caused by radioiodide administered for a diagnostic ^{131}I-WBS, usually in the order of 185 MBq) may decrease the efficiency of subsequent treatment with ^{131}I-iodide [36, 37]. This effect is associated with nonablative radiation doses (up to 10 Gy) that reduce by as much as 50% the ability of the tissue to concentrate and store radioiodide [32]. Although reduced radioiodide uptake in thyroid tissue on the post-ablation ^{131}I-WBS evaluated by visual analysis has been reported [36], quantitative studies have failed to definitely confirm the occurrence of stunning [38, 39]. Furthermore, there is no conclusive evidence that stunning does indeed lead to a higher rate of unsuccessful ablations.

As to the possible mechanisms that have been proposed to explain thyroid stunning, reduced expression of the sodium/iodide symporter (NIS) [40] seems to be the main determinant of this event, as it is involved in the response to irradiation-induced DNA damage [41, 42]. Because of the fear of this effect, a diagnostic ^{131}I-WBS is usually not recommended before thyroid remnant ablation with ^{131}I-iodide. If a diagnostic ^{131}I-iodide scan prior to ablation therapy is deemed useful (e.g., in patients with suspected metastases or to evaluate the size of the remnants), then it is recommended to administer no more than 74 MBq of ^{131} I-iodide and to perform ablation within 48–72 h. Alternatively, ^{123}I-iodide can be used for scintigraphic pre-ablation assessments [43], as the low-energy Auger electrons emitted by this radionuclide are devoid of any stunning effect on thyroid follicular cells. For radiodosimetric purposes using simplified models, uptake of radioiodide in the thyroid remnant can be measured (and scintigraphy of the neck can be performed) by administering a very low activity of ^{131}I-iodide, such as 1.85 or 3.7 MBq (50 or 100 μCi).

A ^{131}I-WBS performed 4–7 days after treatment with ^{131}I-iodide for thyroid remnant ablation is extremely useful to evaluate the distribution and the sites of radioiodide uptake. Scintigraphic detection of focal areas of radioiodide uptake outside the thyroid bed demonstrates the presence of metastatic disease, so that additional treatments must be considered, either further radiometabolic therapy (at an adequate interval, e.g., at least 6 months after ablation) or surgery. Similarly as with the post-ablation scan, the presence of additional metastatic foci has been reported in 10–26% of patients in the post-therapy scan compared to those detected in the diagnostic scan, leading to change the management strategy in 9–15% of the patients [44, 45]. Post-ablation SPECT/CT fusion imaging provides

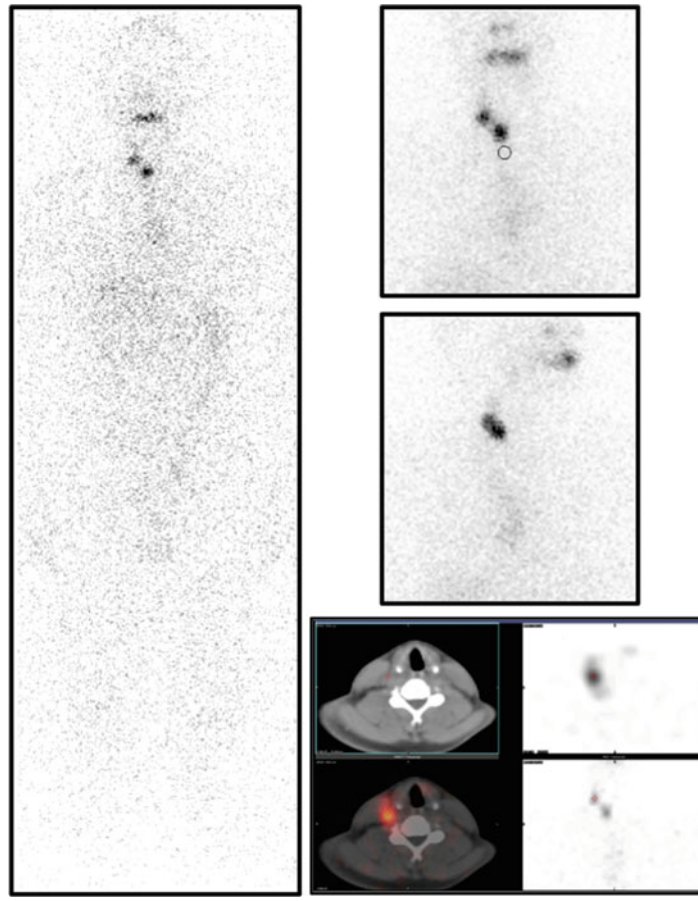

Fig. 2 ^{131}I-WBS and SPECT/CT acquisitions of the cervical region obtained 8 days after administration of 3.7 GBq (100 mCi) ^{131}I-iodide for thyroid remnant ablation in a 21-year-old man who had been submitted 2 months earlier to thyroidectomy because of a PTC occupying virtually the entire right thyroid lobe (4.5 cm in maximum diameter, pT3). The planar whole-body scan (*left panel*) reveals two foci of uptake in the right paramedian aspect of the neck; spot acquisitions in the anterior view (*upper right panel*) and right oblique view (*middle right panel*) confirm the presence of the two foci of uptake, one more intense, almost central just above the sternal notch (indicated by the *open circle*), and one less intense, more laterally and superiorly; the inferior focus of intense uptake was interpreted as representing postsurgical thyroid remnant, while the focus of uptake located more laterally and superiorly was interpreted as possibly representing lymph node metastasis. *Right lower panel*: CT component (*upper left*), SPECT component (*upper right*), and fused SPECT/CT image (*lower left*) of axial section centered on the focus of less intense uptake (MIP image, *lower right*). Although performed with a low-definition system, the CT component suggests that the focus of less intense uptake corresponds to an enlarged lymph node. Subsequent characterization by FNAC with assay of Tg in the needle washing confirmed the presence of metastasis

superior diagnostic information, concerning especially lymph node involvement, than planar ^{131}I-WBS or even stand-alone SPECT (see examples in Figs. 2 and 3) [46–58]. SPECT/CT plays therefore an important role in the evaluation of disease after ablation therapy, as it may alter management of these patients, either by upstaging or by downstaging the disease in about 25% of the cases [49].

Side Effects of Radioiodide Therapy

Short-term side effects of therapy with ^{131}I-iodide for thyroid remnant ablation are usually minimal and transient [59, 60]. Nausea and gastric pain occur frequently after ^{131}I-iodide treatment and last a few days; these symptoms can be prevented/treated by administering proton-pump

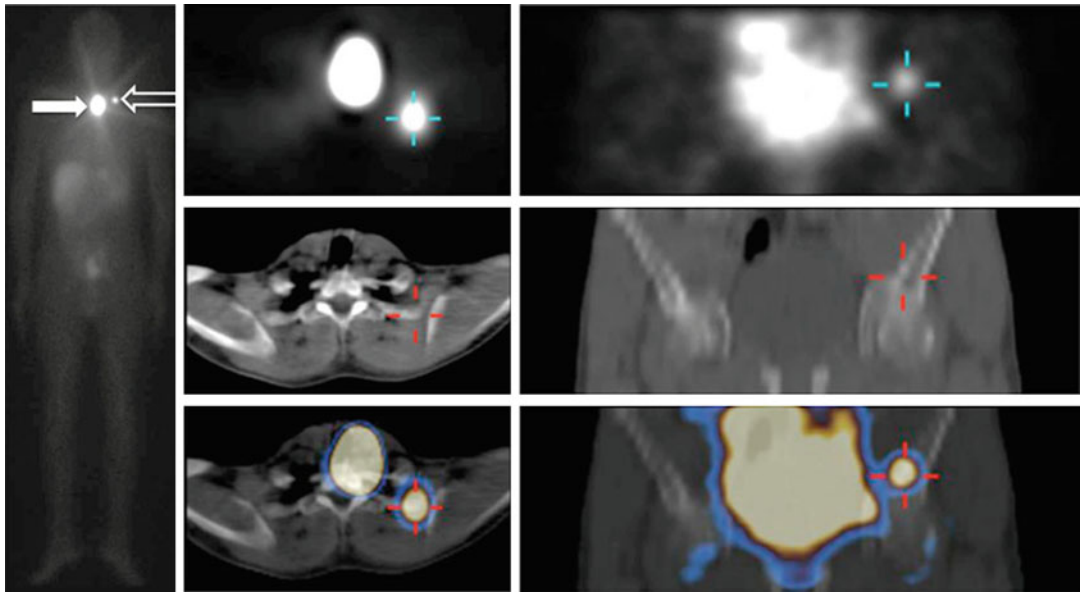

Fig. 3 *Left panel*: Post-ablation ^{131}I-WBS in a 33-year-old man previously submitted to thyroidectomy and left cervical lymphadenectomy because of PTC of the left lobe (follicular variant) with presurgical diagnosis of lymph node metastasis; serum Tg under rhTSH stimulation was 94 ng/mL at the time of administering ^{131}I-iodide. Besides intense uptake in the thyroid remnant, there was an area of focal uptake in the left cervical region (interpreted as a lymph node metastasis in the ^{131}I-WBS), while important bladder activity hampered correct interpretation of the pelvic region. *Center panel*: Representative transverse SPECT/CT section of the cervical region (SPECT component at the *top*, CT component in the *middle*, and SPECT/CT fusion at the *bottom*): the focal area of uptake was actually bone metastasis located in the posterior arc of a left rib. *Right panel*: Representative coronal SPECT/CT section of the pelvic region (SPECT component at the *top*, CT component in the *middle*, and SPECT/CT fusion at the *bottom*): the distinct focal area of uptake lateral to radioactivity accumulation in the bladder represented metastasis in the left iliac bone (From Mariani et al. [302], with permission)

inhibitors or similar drugs. Sialoadenitis is also frequent, with pain and enlargement of the salivary glands but rarely leading to permanent xerostomia; for prophylaxis, patients are advised to drink large quantities of fluids and to stimulate salivary secretion with lemon juice. Loss or change of taste is reported by the majority of patients receiving therapy with ^{131}I-iodide, but usually lasts only a few days. When large thyroid remnants are present and completion thyroidectomy is not feasible, steroids should be given to prevent swelling in the neck due to radiation-induced inflammation.

As to the long-term side effects, the overall relative risk of a second primary tumor is increased only in patients treated with high cumulative activities of ^{131}I-iodide, an occurrence that is encountered in patients with recurrent/metastatic DTC. In particular, a significantly greater risk of leukemia or other second primary tumor has been reported for patients treated with cumulative activities exceeding 22 GBq (or 600 mCi) of ^{131}I-iodide, especially if radioiodide therapy has been associated with external radiotherapy [61]. On the other hand, controversial reports continue to fuel the ongoing debate on the possibility that treatment of DTC with radioiodide per se at any administered activity increases the risk of second primary malignancies [62, 63]. In particular, Bhattacharyya and Chien analyzed the incidence of second primary malignancies in a total of 29,231 DTC patients, 18,882 of whom had been treated and 10,349 had not been treated with radioiodide (with mean follow-up of 55.5 and 61.8 months, respectively). According to univariate analysis, patients treated with ^{131}I-iodide actually had significantly fewer second primary malignancies than the untreated patients (4.8% versus 6.1%, $P < 0.001$), while

radioiodide therapy did not exhibit a statistically significant hazard ratio on multivariate analysis [64]. On the other hand, in a more recent meta-analysis, Sawka et al. confirmed an increased relative risk for leukemia in DTC patients treated with radioiodide versus those nontreated with radioiodide (relative risk of 2.5, with $P = 0.024$); the overall relative risk for all second primary malignancies pooled together in DTC survivors treated with radioiodide was 1.19 ($P = 0.010$), without however a significantly increased risk for any specific type of tumor [65]. It is also noteworthy to emphasize that some reports support the notion that, although the incidence of second primary malignancies is indeed increased in patients with DTC, this increase is not linked to long-term effects of radioiodide therapy but rather to some not yet identified genetic factors [66, 67].

Considering that many patients with DTC are women in their reproductive age, one of the concerns for radioiodide therapy is the possibility of long-term adverse effects on fertility and on the outcomes of pregnancies posttreatment. In this regard, a recent study based on 2,673 pregnancies in DTC patients who had been treated with radioiodide concluded that there is no evidence that exposure to radioiodine affects the outcome of subsequent pregnancies and offspring [68].

Radioiodine treatment may result in transient impairment of male gonadal function, consisting in a reduction of motility and reduced sperm count in a variable number of patients [69]. Changes in the germinal epithelium and Leydig cell function (with consequent increase in serum FSH levels) are usually transient and may have some clinical significance in subjects with a preexisting impairment of fertility [70]. Permanent damage to the germinal epithelium with the consequent increased risk of infertility is related to cumulative dose, and it may become permanent following delivery of high-radiation doses [70, 71]. The use of sperm banks should be considered in young men who will be treated with high activities (14 GBq or more) or with pelvic metastases [72, 73].

Radiation fibrosis may develop in patients with diffuse lung metastases who have received repeated excessive activities (over 5.55 MBq or 150 mCi) of radioiodide at short intervals, especially if less than 6 months [74, 75].

Evaluation of Success of Thyroid Remnant Ablation

The success of thyroid remnant ablation is usually evaluated 6–12 months after radioiodine therapy based on the following criteria [25, 76]:

1. Negative radioiodine uptake in the thyroid bed ("no visible uptake in the thyroid bed" or, if visible, uptake <0.1%, an arbitrarily set threshold) on diagnostic ^{131}I-WBS.
2. RhTSH-stimulated serum Tg levels <1 ng/mL in the absence of detectable anti-Tg antibodies (although a 2 ng/mL threshold is frequently adopted in the clinical routine, and the FDA recommends the 2.5 ng/mL threshold).
3. Absence of suspicious findings on neck US.

Levothyroxine Therapy

Endocrine function of the excised thyroid gland can only be replaced by administration of thyroid hormones; l-T4 is the medication of choice for such long-term replacement. The thyroid gland produces both tetraiodothyronine (or thyroxine, T4), which contains four atoms of iodide, and triiodothyronine (T3), which contains three atoms of iodide and is the true biologically active hormone; T4 (which has a biological half-life of 7 days) constitutes about 75–80% of thyroidal hormone production, while T3 (which has a biological half-life of 20–30 h) constitutes the remainder 20–25% [77–79]. These hormones have two isomers, which can be levo- (l) or dextro-rotatory (d): the levo-rotatory isoform (i.e., l-T4 in the case of T4) is the active variant. Since l-T4 is physiologically converted to the active hormone, T3, in the peripheral tissues, in a steady state, the oral administration of l-T4 mimics physiological conditions and stabilizes serum T3 levels [80].

There are two main goals for l-T4 treatment in PTC and FTC patients after thyroidectomy:

1. To correct postoperative hypothyroidism
2. To suppress the endogenous secretion of TSH (which is a potent growth factor for follicular thyroid cells as well as for follicular-derived tumor cells), at least until the evidence that the patient has been cured is achieved

In contrast, both ATC and MTC, which are constituted by TSH-independent cells, do not benefit from TSH suppression and only require l-T4 replacement therapy to correct postoperative hypothyroidism. The optimal daily l-T4 dose for suppressing TSH secretion ranges between 1.6 and 2.8 μg/kg body weight. However, it is recognized that this dose must be tailored on an individual basis, since it is only roughly correlated with body weight and age. Younger patients, especially children, and patients with a high lean body mass usually require higher doses per kg of body weight [81]. By contrast, older patients require lower l-T4 daily doses, and further reductions are needed for subjects with concurrent heart disease [82]. Since l-T4 has a blood half-life of about 7 days, a single daily dose is usually sufficient. After oral administration, up to 80% of l -T4 is absorbed in the gut, subject however to some interindividual variability [83]. Food intake can reduce l-T4 absorption; therefore, patients are usually advised to take their l-T4 dose on an empty stomach, preferably early in the morning 20–30 min before breakfast. However, recently new l-T4 formulations have been produced whose absorption does not require fasting [84, 85]. Nevertheless, several substances are known to interfere with l-T4 absorption in the gut, including commonly used components such as dietary fiber and coffee. Furthermore, several commonly used drugs, such as bile acid sequestrants, ferrous sulfate, sucralfate, calcium carbonate, aluminum-containing antacids, phosphate binders, raloxifene, and proton-pump inhibitors, have been shown to interfere with the absorption of l-T4 [83, 86, 87]. In addition, several chronic diseases, such as regional enteritis, pancreatic disease, and cirrhosis, may be associated with decreased l-T4 absorption [88, 89]. Patients should be also aware that, since bioavailability of the drug may vary in different preparations, it is preferable that they do not change not only their usual l-T4 daily dosage but also the commercial brands too frequently, since this may change the hormone levels in their blood. If this happens, a reassessment of the daily dosage should be performed 45–50 days after the changing of the therapy.

The effectiveness of l-T4 therapy in DTC patients must be monitored by measuring serum TSH with an ultrasensitive assay [75]. In addition to monitoring serum TSH (which should be suppressed, i.e., less than 0.1 μIU/mL), the serum levels of free T3 (FT3) and free T4 (FT4) must also be measured; even when the TSH suppression is required, both FT3 and FT4 levels should be in the normal range in order to avoid possible iatrogenic thyrotoxicosis [80, 90]. A major concern for patients and physicians is the possibility that (despite the normal FT3 levels) normal to high levels of l-T4 may have negative effects on some target organs during long-term suppressive therapy [91–95]. In this regard, the bone and heart are considered organs at major risk. However, when patients are monitored as described above, l-T4 suppressive therapy is safe and devoid of any long-term adverse effects. It is also important to emphasize that l-T4 suppressive therapy in children has no adverse effect on bone maturation, final height, and pubertal development. Since a 25% increase in the FT4 level is usually observed when blood is drawn 3–4 h after ingestion of l-T4, patients should be instructed not to take their medication the morning before blood testing.

An important issue for DTC patients is for how long l-T4 therapy must be continued on a TSH-suppressive dose. There is no doubt that patients with evidence of persistent or recurrent disease or at a high risk of recurrence should be kept on suppressive therapy in order to decrease the risk of recurrence [96]. However, in patients with favorable prognostic factors and evidence of complete cure (i.e., a negative ^{131}I-WBS and undetectable TSH-stimulated serum Tg in the absence of anti-Tg autoantibodies), the dose of l-T4 may be decreased with the aim of maintaining serum TSH levels between 0.1 and 0.5 μU/ml. Currently, low-risk patients who are cured with initial treatment constitute more than

80% of the cases. Long-term suppressive therapy is thus maintained only in patients with persistent disease or, less commonly, in those at high risk of recurrence [88]. The age and the general health conditions must be also considered in the decision to continue a TSH-suppressive l-T4 therapy or to reduce it for a better balance between a real efficacy in reducing the risk of recurrence and the risk of developing severe side effects such as atrial fibrillation [93, 97].

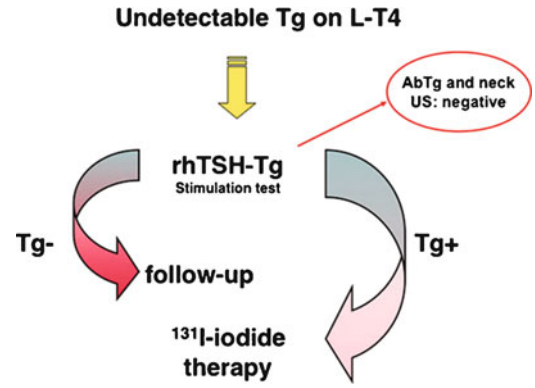

Fig. 4 Suggested algorithm of follow-up in patients with DTC previously treated with total thyroidectomy and post-surgical remnant ablation with ^{131} I-iodide. When serum Tg on l-T4 suppressive therapy is undetectable, an rhTSH stimulation test for Tg should be performed to confirm the absence of recurrent/metastatic disease. A negative rhTSH stimulation test (*left arm* of the diagram) does not require further therapy, and the patient is included in a regular follow-up program. A positive rhTSH stimulation test (*right arm* of the diagram) indicates instead the presence of recurrent/metastatic disease and should be treated with further therapy with ^{131}I-iodide; localization of the sites of recurrence and/or metastasis is usually possible in the post-therapy WBS (preferably integrated with SPECT/CT) acquired between 5 and 10 days after administration of radioiodide therapy

Follow-Up

The aims of follow-up for patients treated with surgery and with radioiodide remnant ablation for DTC are twofold:

1. To maintain adequate l-T4 therapy
2. To discover the persistence or recurrence of thyroid cancer early on (see Fig. 4)

Follow-up is virtually lifelong because, especially in DTC patients, recurrences can occur even 10–20 years after apparently successful initial treatment [13, 14, 98]. The major diagnostic modalities employed for the follow-up of DTC patients are measurement of serum Tg, ^{131}I-WBS, and neck US examination. Evaluation of these parameters at 6–12 month intervals enables the clinicians to assess the clinical status of the patients and to identify early those patients who need additional treatment(s) [99, 100].

Measurement of Serum Tg

Since Tg is produced exclusively by normal or neoplastic thyroid follicular cells, it constitutes an excellent tumor marker after removal of the thyroid gland. In fact, serum Tg should be undetectable after total thyroidectomy and successful thyroid remnant ablation. Whereas, when the serum Tg levels of these patients remain detectable or rise, they indicate the presence of persistent or recurrent disease [101]. Tg is produced by virtually all papillary and follicular cancer tissues, as demonstrated by immunohistochemistry using anti-Tg antibodies [102] or, more recently, by molecular biology techniques such as RT-PCR [103]. There are two major limitations with regard to the measurement of serum Tg as a tumor marker for DTC:

1. The presence of circulating anti-Tg autoantibodies (TgAb) may interfere with the measurement of serum Tg. According to the method used for assaying serum Tg, TgAb may cause false-positive results (i.e., when employing a radioimmunoassay method) or false-negative results (i.e., when employing an immunoradiometric assay method) [14]. It should also be noted that even noncompetitive immunometric assays based on detection techniques other than radioactivity counting can be affected by circulating heterophilic autoantibodies [104]. In patients with circulating TgAb, who account for about 20–25% of all patients with DTC [105], serum

Tg measurement alone cannot be relied upon if not correlated to the assay of serum TgAb.

2. Since TSH is a growth factor for both normal follicular cells and follicular-derived cancer cells, the production of Tg (therefore its level in circulating blood) is kept to a minimum under l-T4 suppressive therapy. Therefore, undetectable serum Tg levels under l-T4 suppressive therapy (which would indicate cure of the disease) must be confirmed by a TSH stimulation test. Nowadays, Tg stimulation is performed by administering exogenous rhTSH rather than by discontinuing administration of suppressive l-T4 so as to induce hypothyroidism; in fact, the latter is an uncomfortable condition that, though only temporary, may profoundly impact the quality of life of many patients [106]. The protocol for performing rhTSH administration to stimulate serum Tg (i.e., the rhTSH stimulation Tg test) is illustrated in Fig. 5.

An rhTSH-stimulated serum Tg measurement is usually obtained 6–12 months after total or near-total thyroidectomy and ^{131}I-iodide ablation in DTC patients with undetectable serum Tg (<0.1 ng/mL when using the newer-generation, ultrasensitive assays) on l-T4 suppression therapy. The resulting change in serum Tg levels at the peak of rhTSH stimulation (48–72 h after the last of two 0.9-mg doses in the euthyroid state) versus baseline is recorded. According to the cutoff of serum Tg chosen (which may vary in different institutions, but is usually set at 2 ng/mL although the FDA recommends 2.5 ng/mL), the following situations may be encountered [107]:

1. Serum Tg remains undetectable (<0.1 ng/mL); up to 65% of the low-risk patients have no rise in serum Tg concentrations after rhTSH.
2. Serum Tg rises between 1 and 2 ng/mL; this occurs in about 20% of low-risk patients and necessitates further periodic rhTSH stimulation tests, perhaps as often as once yearly. Neck US plays an important diagnostic role in this group. In some patients, the high TSH-stimulated serum Tg level will spontaneously decline over one or more years [108], while in others it will steadily rise, and metastases will become apparent [109].
3. Serum Tg rises above 2 ng/mL; this occurs in about 20% of low-risk patients and usually indicates a substantial thyroid remnant or residual cancer. Patients with this pattern usually require further imaging evaluation to localize the source of the Tg.

With the introduction and wide clinical acceptance of the ultrasensitive Tg assays [110], the rhTSH stimulation test can be avoided when the basal serum Tg is <0.1 ng/mL and reserved to those cases with a serum Tg level on the gray zone (i.e., from 0.1 to 1 ng/mL). In fact, in this latter group, the stimulation test can clearly distinguish the true "positive" cases (about 25%) that require further investigation from negative

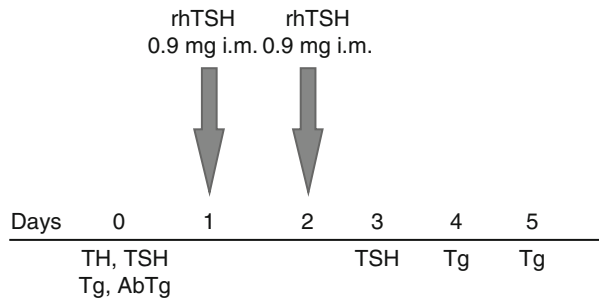

Fig. 5 Outline of rhTSH administration for the Tg stimulation test: before the administration of rhTSH (day 1), blood is taken for assaying thyroid hormones (TH), TSH, Tg, and Tg-antibodies (TgAb). Two i.m. injections of rhTSH are given at day 1 and 2: at day 3 serum TSH must be assayed again to verify the correct stimulus, while serum Tg levels must be measured at days 4 and 5

cases for which the clinical remission of the disease can be defined [111].

Whole-Body Scintigraphy with ^{131}I-Iodide

A ^{131}I-WBS performed 6–12 months after thyroid remnant ablation is useful in the follow-up of patients with high- or intermediate-risk for persistent disease, although its diagnostic sensitivity is lower than that of the serum Tg stimulation test [112]. Similarly as for the Tg stimulation test, radioiodide scintigraphy is performed under TSH stimulation (following either l-T4 withdrawal or administration of rhTSH); images are usually acquired 72 h after administration of 185 MBq (5 mCi) of ^{131}I-iodide if patients have been prepared with l-T4 withdrawal or 48 h in case of preparation with rhTSH. When there is high risk of persistent/recurring disease (such as detectable serum Tg levels with suppressed TSH levels), ^{123}I-iodide can be used instead of ^{131}I-iodide in order not to jeopardize with a possible stunning effect the efficacy of subsequent radioiodide therapy. In this instance, images are usually acquired 48 or 24 h after administering i.v. 185 MBq of ^{123}I-iodide depending on preparation of the patient, i.e., with l-T4 withdrawal or with rhTSH stimulation, respectively [113, 114].

Diagnostic radioiodide WBS is not necessary in low-risk patients who are clinically free of disease, with undetectable (<0.1 ng/mL) serum Tg, while on l-T4 suppressive therapy and whose neck US examination is negative [112], provided they have not circulating TgAb possibly interfering with the serum Tg assay (see above).

Serum Tg levels that become detectable upon TSH stimulation indicate the need for further treatment therapy with ^{131}I-iodide [115, 116]. In the last years, a cut off of 10 ng/ml of rhTSH stimulated serum Tg has been identified as convenient to decide to treta again with 131–I. Clearly, a positive serum Tg stimulation test does not provide per se any information on topographic location of persistent/recurring disease nor on the ability of tumor lesions to concentrate radioiodide (therefore on their susceptibility to be treated with further ^{131}I-iodide therapy). Such information would instead be provided by a positive radioiodide WBS. On the other hand, some patients with DTC may have persistent/recurring disease (as demonstrated by their abnormal serum Tg levels), yet their tumor lesions may have lost the ability to concentrate and retain radioiodide, either as a biologic feature of some DTC histologic types [117, 118] or at some point in the evolution of the disease after having been treated with ^{131}I-iodide therapy [119].

Whereas, if stimulated serum Tg remains undetectable (in the absence of serum TgAb), the patient can be considered as cured [120]. The diagnostic ^{131}I-WBS plays an important role when it is not possible to rely neither on baseline nor on stimulated serum Tg because of a positive serum TgAb titer [99]. In this regard, some role as a surrogate tumor marker can be played also by the TgAb titer itself, which should decline and disappear when the disease is cured (as a consequence of reduced/absent antigenic stimulation on TgAb production), while it usually persists elevated or increases even further in case of persistent or recurring disease [105, 121].

Neck Ultrasound

Neck US examination is nowadays a fundamental component of follow-up evaluation in all DTC patients, especially those at high risk for recurrent disease and those with suspicious clinical findings. Metastatic lymph nodes can be detected with neck US in the lateral and, even though to a lesser degree, in the central neck compartments. The US features of metastatic lymph nodes differ in a number of respects from those of possibly enlarged but benign lymph nodes. In particular, benign lymph nodes are usually smaller, thin, or oval in shape and have a conspicuous hilus, while lymph nodes with metastasis are roundish in shape, may display microcalcification, are hypoechoic, and do

not have a visible hilus [3]. However, if a lymph node metastasis is suspected, an FNA should be performed and the aspirate sent both for cytology and for Tg measurement [122].

Other Diagnostic Procedures

Other imaging modalities can be used in patients with evidence of elevated serum Tg but negative post-therapeutic ^{131}I-WBS and neck US. These include CT or MRI of the chest and neck; bone scintigraphy; scintigraphy with single-photon-emitting, nonspecific tumor-seeking agents (such as ^{201}Tl-chloride, ^{99m}Tc-Sestamibi, or ^{99m}Tc-tetrofosmin) [123]; and positron emission tomography (PET). Although CT and MRI can in principle localize very small lesions (2–5 mm) in the neck, chest, and bones, the morphologic features of such lesions are rarely specific for recurrent/metastatic DTC [124, 125].

PET with the glucose analog [^{18}F]fluoro-2-deoxyglucose ([^{18}F]FDG) is emerging as a powerful diagnostic and prognostic imaging technique in DTC patients with non-iodine-avid recurrences and/or metastases [126, 127]. Enhanced glucose metabolism is a nonspecific feature of many tumor cells that is directly correlated with their proliferative activity, therefore with the degree of biological aggressiveness of the tumor. Considering that DTCs are in general characterized by low biological aggressiveness, PET with [^{18}F]FDG does not play a relevant diagnostic role in DTC patients whose tumor lesions concentrate radioiodide as a thyroid-specific differentiation feature. Nevertheless, the incidental detection of well-DTCs during [^{18}F]FDG PET performed in patients with other malignancies has been the object of several reports (see ▶ Chap. 19, "Diagnostic Applications of Nuclear Medicine: Thyroid Tumors" of this book) [128–136].

Radioiodide remains therefore the radiopharmaceutical of choice for diagnostic and/or localizing purposes in most patients with DTC as well as for therapy when using ^{131}I as the radionuclide. However, some DTCs do exhibit a clinical pattern characterized by higher biological aggressiveness, either at some late time after primary treatment or even earlier in the course of the disease; these biological features are usually associated with poor differentiation that can be identified also on histopathologic analysis. The biologic pattern thereby DTC recurrences/metastases that lose the thyroid-specific iodide-trapping properties and exhibit enhanced aggressiveness become more [^{18}F]FDG avid (see clinical example in Fig. 6) has been termed "flip- flop" mechanism (Fig. 7) [126, 137]. [^{18}F]FDG PET-positive thyroid cancers have a worse prognosis than PET-negative tumors [138, 139]; this information may be useful to adapt management of patients to their individual clinical condition. Nevertheless, the flip-flop paradigm should not be considered as a rigid concept implying evolution of DTC toward less differentiated, aggressive forms; in fact, even well-differentiated classical variants of PTC can occasionally show avid uptake of [^{18}F]FDG, yet maintaining a nonaggressive pattern of tumor growth (see ▶ Chap. 19, "Diagnostic Applications of Nuclear Medicine: Thyroid Tumors" of this book).

Although [^{18}F]FDG PET can be performed while the patient is on thyroxine treatment, TSH stimulates the expression of GLUT on cell membranes; thus [^{18}F]FDG uptake by DTC cells is higher under TSH stimulation [140–142]. The clinical counterpart of these biological events translates into greater sensitivity of the [^{18}F]FDG PET scan in the TSH-stimulated than in the TSH-suppressive state [143–149]. Metastatic lymph nodes even smaller than 1 cm can be detected by [^{18}F]FDG PET, although small lung metastases identified by CT can occasionally be missed on the PET scan. Although highly useful in certain clinical settings, [^{18}F]FDG PET cannot systematically replace WBS with radioiodide in all DTC patients and should be performed preferentially in patients with a negative high-dose ^{131}I-WBS and a high likelihood of persistent or recurrent disease.

Although the use of ^{124}I-iodide in patients with DTC was described over 50 years ago [150], it is only recently that sufficient evidence has

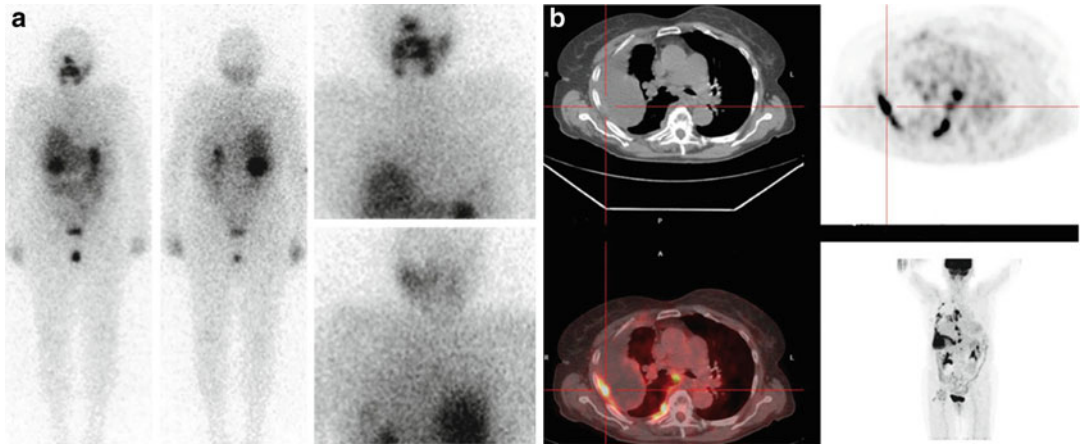

Fig. 6 (**a**) Anterior and posterior whole-body and spot images obtained 8 days after administration of 7.4 GBq (200 mCi) ^{131} I-iodide in a patient who had been submitted 17 years previously to thyroidectomy because of metastasis from DTC in a cervical lymph node. Histology had revealed two papillary cancers (columnar cell variant) measuring only 1 mm each. The patient was subsequently treated with several cycles of ^{131} I-iodide therapy totalling 35.5 GBq (960 mCi), with progressive loss of the iodine-trapping capability in metastatic lesions gradually spreading from cervical lymph nodes to the lung and pleura. Despite high levels of serum Tg and x-ray evidence of metastasis in the chest, the post-therapy scan does not reveal any focal area of abnormal ^{131} I-iodide uptake; nevertheless, scintigraphic visualization of the liver indicates some degree of radioiodide uptake in metastatic lesions, with subsequent release of radioiodinated hormones that are then metabolization in the liver. (**b**) Whereas PET/CT reveals high uptake of [^{18}F]FDG in pleuropulmonary lesions that are obvious also in the CT images (From Volterrani et al. [301], with permission of Springer Science+Business Media)

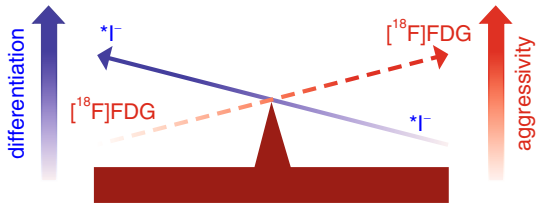

Fig. 7 Diagrammatic representation of the so-called "flip-flop" phenomenon that can be observed in patients with DTC, e.g., a somewhat inverse correlation between radioiodide uptake by tumor lesions (an index of cell differentiation generally associated with relatively low biologic aggressivity) and uptake of [^{18}F]FDG (an index of cell dedifferentiation almost invariably associated with high biologic aggressivity) (From Volterrani et al. [301], with permission of Springer Science+Business Media)

accumulated to propose clinical application of ^{124}I-iodide PET/CT to improve lesion detection in recurrent and/or metastatic DTC disease [151]. In fact, ^{124}I-iodide PET/CT provides images of higher spatial and contrast resolution (translating into higher target-to-background ratios) compared to planar or SPECT imaging with either ^{131}I- or ^{123}I-iodide [152] (see example in Fig. 8), thus resulting in superior accuracy combined with lower radiation exposure [153–155].

^{124}I-iodide PET/CT shows a 97% overall lesion detectability compared to 83% with the ^{131}I-WBS scan [156]. In particular, local lymph node and distant metastases that were undetected on the ^{131}I-iodide WBS are detected by ^{124}I-iodide PET/CT in 12% and 4% of the cases, respectively [157]. The superiority of ^{124}I-iodide PET/CT over ^{131}I-WBS has recently been confirmed also by Van Nostrand et al. who reported that, in 32% of patients with DTC, PET with ^{124}I-iodide identified 50% more foci of radioiodide uptake than planar scintigraphy with ^{131}I-iodide [158].

When restaging patients with recurrent DTC as shown by rising serum Tg levels, yet with a negative US of the neck, the combination of ^{124}I-iodide PET/CT with [^{18}F]FDG PET results in improved sensitivity (91%) compared with

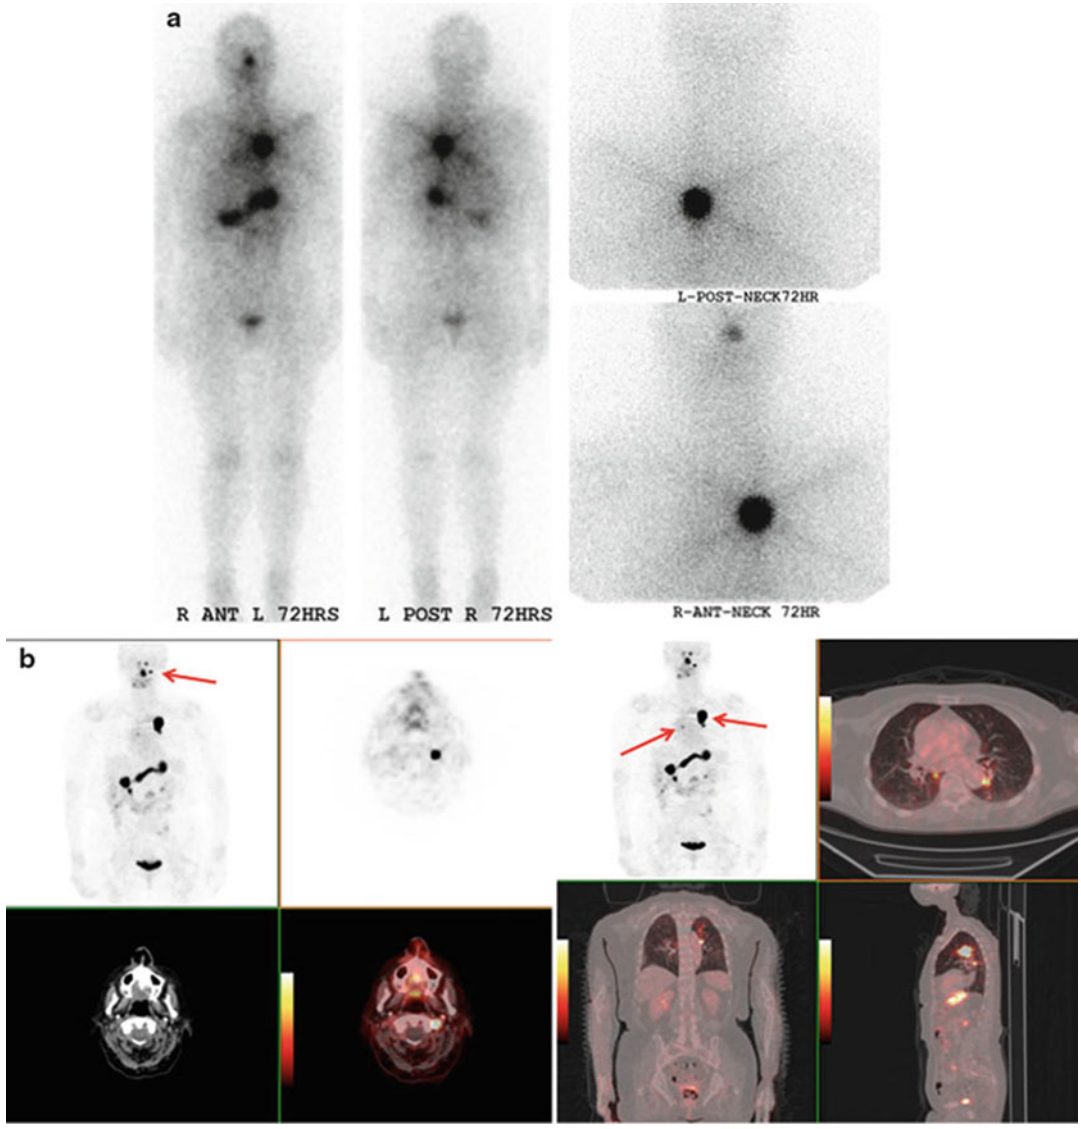

Fig. 8 Seventy-six-year-old woman with DTC (classified histologically as well differentiated). After total thyroidectomy she was treated with 7.4 GBq (200 mCi) ^{131}I-iodide, with evidence on post-therapeutic ^{131}I-WBS of pulmonary radioiodine-avid disease (**a**). Serum Tg progressively increased over time, with no evidence of disease progression on the CT scan and a negative [^{18}F]FDG PET/CT. PET/CT with ^{124} I-iodide showed high uptake in a voluminous mediastinal adenopathy, in two lung lesions and in a cervical left node (**b**). She was then retreated with 5.55 GBq ^{131} I-iodide (150 mCi), and the post-therapeutic ^{131}I-WBS showed high uptake only in the mediastinal adenopathy, but no uptake in the lung lesions or in the cervical region (Courtesy of Dr. Ravinder Grewal, Division of Nuclear Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY, USA)

each PET imaging technique alone (80% and 70%, respectively) [159]. Nevertheless, although highly promising in principle, in patients with suspicion of diffuse lung metastases, quantitative analysis based on the lung/background ratio does not invariably allow to define an unequivocal diagnosis [160]. Furthermore, "shine-through" activity near the trachea, which is present in 17% of patients, can induce incorrect interpretation of imaging in this location [161].

Management of Locoregional Recurrences

Although recurrences are usually identified during the first year postprimary treatment, they may develop later on in the course of follow-up [13, 14]. In case of local recurrence, mortality at 30 years is 12%. Detection of a local or regional recurrence dictates complete workup to evaluate its extent and to search for distant metastases. Early detection of local relapse increases the survival rates of patients, especially if the recurring lesions are operable and/or radioiodine avid [10, 21].

In patients with local or locoregional recurrence, treatment with ^{131}I-iodide is often effective, as shown by a 50% reduction in the rate of further subsequent recurrences and in mortality at 30 years [11]. Therapy with radioiodide ensues complete response in 75–80% of the patients with regional lymph node metastasis, provided the radiation dose absorbed by the tumor tissue is at least 80–100 Gy, a target that is, however, difficult to achieve when the tumor lesion is large (i.e., greater than 1 cm in maximum diameter). Therefore, in case of bulkier recurrences, but still limited to lymph nodes (as shown by morphologic imaging, such as US, CT, and/or MRI), the first therapeutic option should be surgery, whenever possible [162]. In fact, surgical removal of metastatic lymph node(s) can successfully prevent further recurrence in 62% of the patients [163]. In this clinical setting, ^{131}I-iodide can play a role as adjuvant therapy.

Whereas, in case of small lymph node metastasis with high radioiodide uptake, the initial therapeutic approach can be based on administration of radioiodide [162]. The ^{131}I activity to be administered can be based on dosimetric estimates aiming at releasing the maximal safe dose to the patient, yet with a radiation dose >85 Gy to the lymph node(s), as well as to metastatic lesions at other sites (see example in Fig. 9). Alternatively, an empiric activity based on average estimates and prior experience can be administered, usually 3.7–5.5 GBq of ^{131}I-iodide.

As mentioned above, response to ^{131}I-iodide therapy is better in tumor foci smaller than 1 cm in diameter. In young patients with metastatic DTC, response to treatment with radioiodide is generally favorable concerning both locoregional recurrences and distant metastases. Indeed, radioiodide uptake was still detectable after three ^{131}I-iodide treatments in only 24% of patients who initially had small lymph node metastases and who then underwent surgery [109]. In contrast, treatment with ^{131}I-iodide is less effective in patients with larger tumor lesions, radioiodide uptake being still detectable after repeated ^{131}I-iodide treatments in 80% of the cases [164–166].

Even when lymph node metastases from DTC lose the ability to concentrate radioiodide, they may continue to be palpable or detectable by US examination. Nevertheless, although imaging modalities, such as US, CT, and MRI, generally have high sensitivity, their interpretation may be difficult in previously dissected areas, because of anatomic distortion and scar tissue. In contrast, ^{131}I-WBS may demonstrate neoplastic foci more specifically. Furthermore, a ^{131}I-WBS performed after administration of a large (i.e., therapeutic) amount of ^{131}I-iodide may detect new previously unrecognized lesions in up to 60–80% of the cases and remains the most sensitive diagnostic/localizing imaging modality in patients with functioning metastases from DTC [165].

Small and not growing cervical lymph nodes should not necessarily be treated. A “wait-and-see” strategy is nowadays suggested in these cases since the neck US can easily allow to monitor these lesions and be ready to perform a surgical treatment or any other appropriate therapeutic strategy [167]. When a significant increase in number or size is detected.

Management of Distant Metastases

Distant metastases occur in a subgroup of patients with DTC and can be discovered from 2 to 3 up to more than 10 years after initial treatment. This observation indicates that follow-up must continue throughout the patient’s life. In general, early detection of distant metastases is based on

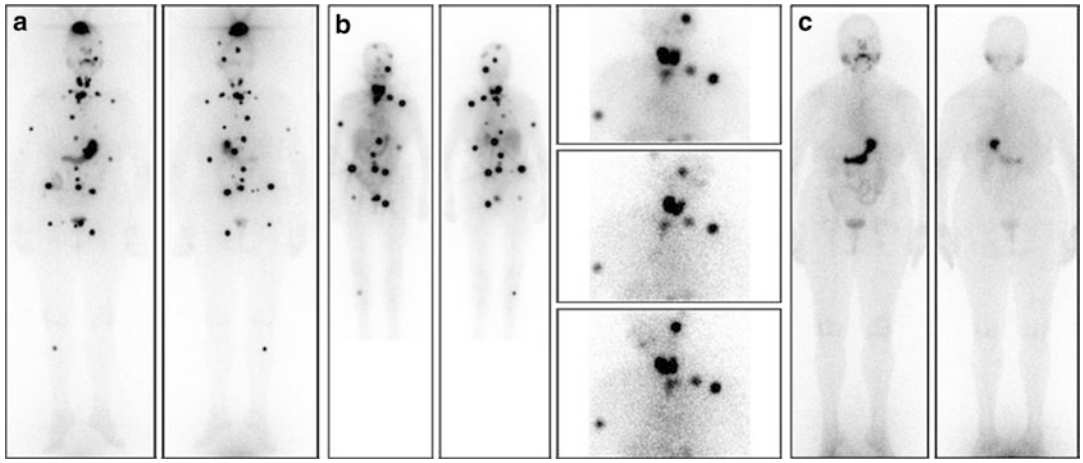

Fig. 9 Seventy-five-year-old patient referred to our center after histology of a lesion removed from the lumbar spine had revealed metastasis from DTC (well differentiated). The patient had been submitted 3 years previously to total thyroidectomy because of multinodular goiter (histology was not available). A dosimetric study was performed with ^{123}I-iodide (and converted into ^{131}I-equivalent data), scanning the patient until 72 h post-administration with both whole-body and spot acquisitions (including SPECT/CT at selected areas). In addition to uptake in the postsurgical remnant, diagnostic scintigraphy revealed numerous bone metastases scattered throughout virtually all the skeleton, including two bulky lesions in the skull (**a**); the peak of serum Tg at this time was 3,810 ng/mL after stimulation with rhTSH. The dosimetric study yielded very favorable estimates for the absorbed radiation dose, i.e., 63.5 mGy corresponding to an average absorbed dose of 250 Gy per lesion based on administration of 3.7 GBq ^{131}I-iodide. The two bulky lesions in the skull were removed surgically, and radioiodide was administered for therapy. The post-therapeutic ^{131}I-WBS scan acquired 10 days later confirmed high uptake in the metastatic bone lesions, with only some residual uptake in the skull (**b**). At the 1-year follow-up, serum Tg was undetectable with suppressed TSH, peaking at 0.6 ng/mL following rhTSH stimulation; the WBS performed with ^{131}I-iodide was completely negative (**c**). Six years later, follow-up continues to be negative (From Volterrani et al. [301], with permission of Springer Science+Business Media)

the combined use of serum Tg measurement and ^{131}I-WBS.

Most distant metastases from DTC are located in the lung (50–60%) or bones (20–30%). Liver, brain, and skin metastases, which are much more rare, are found in about 3% of patients at the time of the identification of a diffuse metastatic disease. They may also occur late after initial discovery of lung metastasis during the course of distant dissemination. In this latter instance, they yield a prognostic indication of rapid evolution of the disease (concerning especially skin metastases, a rather poor prognostic factor for survival). Metastases at multiple sites are present in about 10% of the patients with metastatic disease [165, 168]. The site of metastatic disease depends on a number of factors. Metastases in the lungs are more frequently observed in patients with PTC and in younger patients; indeed, they are virtually the only sites of distant metastases in children [169, 170]. In contrast, bone metastases are more frequently observed in patients with FTC and in older patients [165].

DTC patients with metastatic disease should undergo complete diagnostic workup. An ^{131}I-WBS performed after the administration of a therapeutic activity of ^{131}I-iodide (3.7 GBq, or 100 mCi) may clarify the extent and location of metastatic disease. In particular, a ^{131}I-WBS so performed often reveals lung metastases not visible on plain chest x-rays nor on CT. In this regard, only about half the patients with normal chest x-rays, who have diffuse uptake of ^{131}I-iodide in the lungs, have peripheral micronodular lung metastases detectable in the CT scan [171, 172]. X-rays are required also for patients with bone metastases that are painful and accumulate radioiodide, although it is either CT or MRI that helps

to delineate more precisely the extent of these metastatic lesions. MRI is particularly useful in the workup of metastases of the spine and base of the skull. Since most bone metastases from DTC are hypervascularized, arterial embolization may help to facilitate subsequent surgical removal [173–177].

Conventional therapeutic strategies such as surgery, radioiodide, external beam radiation therapy (EBRT), and systemic therapy with the new "targeted" therapies can all be used to treat metastatic DTC. The therapeutic strategy must be tailored to the individual patient by considering the number, size, location, and iodine avidity of the metastatic sites. Surgery should be considered with curative intent in patients with a single or few brain metastases. Lung metastases are often multiple, and surgical excision or pulmonary resection is rarely curative; in these conditions, surgery can prevent or delay the onset of clinical symptoms. Palliative surgery is required for bone metastases, ideally before orthopedic or neurological complications arise, especially when the risk of complications, such as vertebral collapse, is high [178]. Although no controlled studies have been performed on patients with metastatic thyroid cancer, diffuse metastatic bone disease may benefit from systemic therapy with zoledronate, similarly as it happens in patients with bone metastasis deriving from other solid tumors [179].

In approximately two-thirds of the patients, distant metastases from DTC concentrate radioiodide, a factor that facilitates their detection and treatment. Since accumulation of radioiodide may be higher in small lesions with a relatively low uptake than in bulky metastases with higher uptake, therapy with ^{131}I-iodide can ablate small foci of neoplastic tissue, whereas it can seldom ablate large tumor deposits [165]. A radiation dose higher than 80 Gy should be delivered to achieve cure; instead, the chances of success are remote in case of radiation doses lower than 35 Gy [9]. Although based on empiric estimates that do not take into account uptake measurements for each lesion in each individual patient, recommended therapeutic activities that should satisfy such desired radiation dose threshold are generally in the range of 3.7–5.5 GBq (100–150 mCi) of ^{131}I-iodide in adults and approximately 37 MBq/kg body weight (or 1 mCi/kg) in young children [180–183]. Higher activities, i.e., 7.4 GBq (200 mCi), or more have instead been recommended in patients with bone metastases [183]. In patients with diffuse, small lung metastases that are not visible on x-rays, a dosimetric approach is not feasible, as the mass of neoplastic tissue cannot be estimated. In these cases, some centers adopt the so-called Benua–Leeper approach, which is based on the maximum tolerable absorbed dose to the organ at risk [184]. For therapy with ^{131}I-iodide, the organ at risk is the red bone marrow; 2 Gy is the maximum limit that the red marrow can absorb. The maximum tolerable administered activity (i.e., the activity that would imply a 2 Gy dose to the red marrow) can be calculated using simple parameters, such as the blood kinetics following administration of a tracer activity of ^{131}I-iodide [185].

The outcome of ^{131}I-iodide therapy in patients with pulmonary metastases from DTC is variable from patient to patient (see examples in Figs. 10 and 11) and not obviously related to the initial total uptake of radioiodide in the lungs. Neoplastic masses are probably smaller in patients with lower uptake. Subsequent treatments with ^{131}I-iodide are given 6 months later for 1–2 years and then annually until there is no more evidence of residual radioiodide uptake on post-therapeutic ^{131}I-WBS. Of course, between two treatment courses, l-T4 TSH-suppressive therapy is continued with the aim of reducing serum TSH to levels not stimulating tumor growth.

Although there is virtually no limit to the cumulative ^{131}I-iodide activity that can be given to patients with distant metastases, the risk of second primary malignancies (especially leukemia) rises slightly for cumulative administered activities higher than 22.2 GBq (600 mCi) [61, 62]. Furthermore, it should be considered that higher cumulative activities are presumably of little benefit because of the progressive loss of iodine-trapping property of metastatic lesions [186].

As mentioned in ► Chap. 19, "Diagnostic Applications of Nuclear Medicine: Thyroid Tumors" with reference to postsurgical ablation of thyroid remnants, radioiodide therapy of

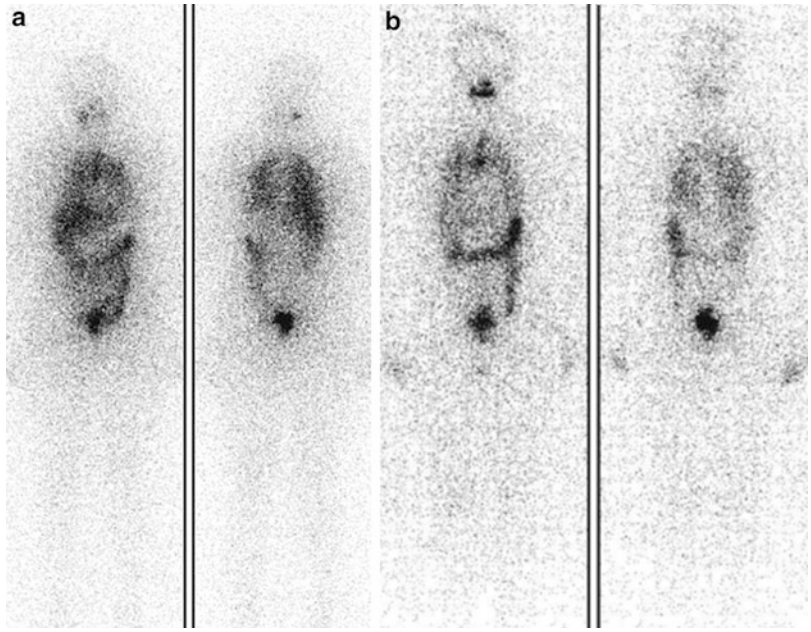

Fig. 10 ^{131}I-WBS images obtained in two separate occasions 7–10 days after administration of ^{131}I-iodide for therapy of pulmonary metastases in a patient already treated for DTC with total thyroidectomy and radioiodide remnant ablation. (**a**) October 2005 (at the age of 25 years): diffuse uptake in the pulmonary parenchyma, indicating miliary-type metastatic involvement (serum Tg 21 ng/mL under endogenous TSH stimulation achieved with l -T4 withdrawal). (**b**) June 2009: progressive improvement of the pulmonary metastatic involvement following repeated therapies totalling 28.5 GBq (770 mCi) of ^{131} I-iodide (serum Tg 8 ng/mL under endogenous TSH stimulation achieved with l-T4 withdrawal); thymic uptake of radioiodide (frequently seen in younger patients) is now more evident in the post-therapy scan (From Volterrani et al. [301], with permission of Springer Science + Business Media)

recurrent/metastatic lesions from DTC must be performed under TSH stimulation, with a minimum threshold conventionally set at a serum TSH level of 30 μIU/mL. These high TSH levels can be obtained through withdrawal of l-T4 therapy, with resulting transient hypothyroidism; unfortunately, the use of recombinant human TSH has not been approved yet for the preparation of patients with metastatic DTC before therapy with ^{131}I-iodide (except in case of failure of the pituitary to produce TSH), although there is evidence that it can produce the same result as the withdrawal of the l-T4 [187–189]. However, when a severe consequence of the hypothyroidism can be envisaged, the rhTSH may be employed inside the "compassionate" program or, in some countries, as "off label." It should be also considered that the use of rhTSH greatly reduces the exposure of the body (i.e., bone marrow) to the possible damage from radioiodine exposure [190, 191].

Pre-therapy evaluation with a diagnostic ^{131}I-WBS (performed by administering 185 MBq ^{131}I-iodide) is useless in patients with known metastases, since the results of this evaluation will not alter the therapeutic strategy and, because of the possible "stunning" effect, may actually interfere with the uptake of the subsequent therapeutic activity of ^{131}I-iodide. Instead, a ^{131}I-WBS performed 4–7 days after administration of a therapeutic activity of ^{131}I-iodide may clarify both the distribution and metabolic activity of metastases, including those that had gone undetected prior to ^{131}I-iodide therapy (see Fig. 12). Alternatively, the use of ^{123}I-iodide can be envisaged in the pre-therapy phase (either for diagnostic/localization purposes and/or for dosimetric estimates), since this radionuclide does not induce a stunning effect.

Furthermore, one of the main advantages perceived with the use of ^{124}I-iodide PET/CT in patients with DTC candidate to therapy with

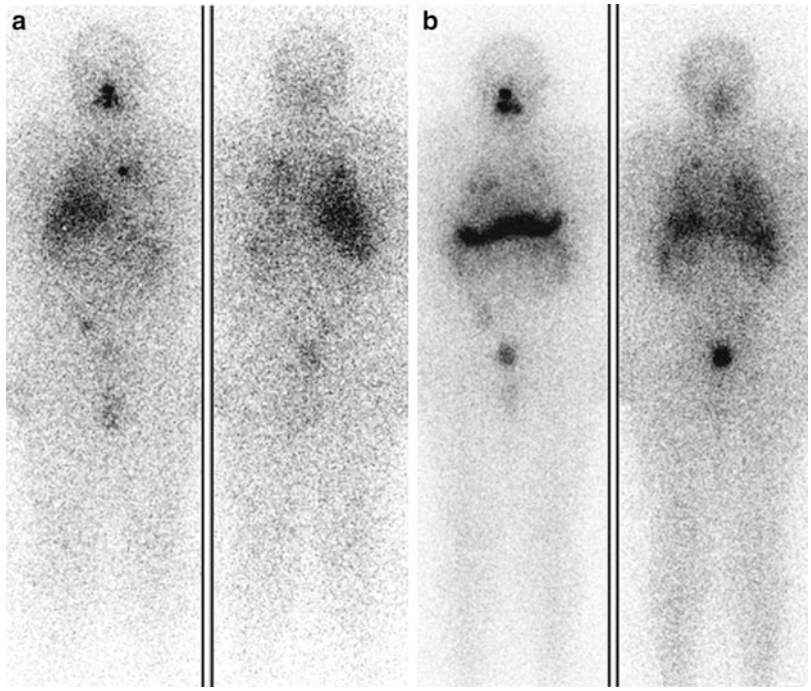

Fig. 11 ^{131}I-WBS images obtained in two separate, sequential occasions 7–10 days after administration of ^{131}I-iodide for therapy of pulmonary metastases (with predominantly macronodular pattern) in a patient already treated for DTC with total thyroidectomy and radioiodide remnant ablation. (**a**) September 2006: besides a pattern of diffuse metastatic involvement, radioiodide uptake can clearly be seen also with a macronodular pattern, more obvious in the left para-hilar region (serum Tg 251 ng/mL under stimulation with rhTSH). (**b**) July 2007: partial regression of the left para-hilar lesion, but development of macronodular lesions in the right lung (serum Tg 1,918 ng/mL under stimulation with rhTSH) (From Volterrani et al. [301], with permission of Springer Science+Business Media)

^{131}I-iodide – whenever this procedure is available – is the possibility of accurate quantification of radioiodide uptake as a basis for more accurate dosimetric estimates than with the single-photon-emitting radionuclides [192, 193]. In fact, lesion dosimetry based on planar gamma camera or SPECT images may result in inaccurate estimates of the absorbed dose due to the difficulty of measuring the target lesion volumes (especially for small lesions) and of reliably measuring radioiodine uptake using ^{131}I-iodide as the tracer (due to low spatial resolution and imaging sensitivity). The feasibility of calculating the mean absorbed dose in patients using ^{124}I-iodide PET images was described in 1999 [194], after reports on preliminary quantitative phantom studies [152].

Accurate lesion quantification for dosimetry estimates is possible using the approach of recovery coefficients (RCs), a method that allows to correct the activity concentration in the lesions imaged for partial-volume effect and for the prompt gamma coincidence effect due to the complex decay scheme of ^{124}I-iodide [195]. Several protocols for dosimetry estimates have used serial PET measurements from three to five time points, combining imaging scans at 4, 24, 48, 72, and 96 h post-administration (more rarely until 144 h) [192, 193]. The five-point protocol is certainly the most accurate approach, although even a simplified two-point protocol (i.e., 24 and 96 h) can be employed for determining the lesion absorbed dose per administered ^{131}I-iodide activity (LDpA) within a 20% uncertainty compared to the more complex protocol [196].

As a quantitative tomographic imaging modality, PET/CT with ^{124}I-iodide is especially useful to

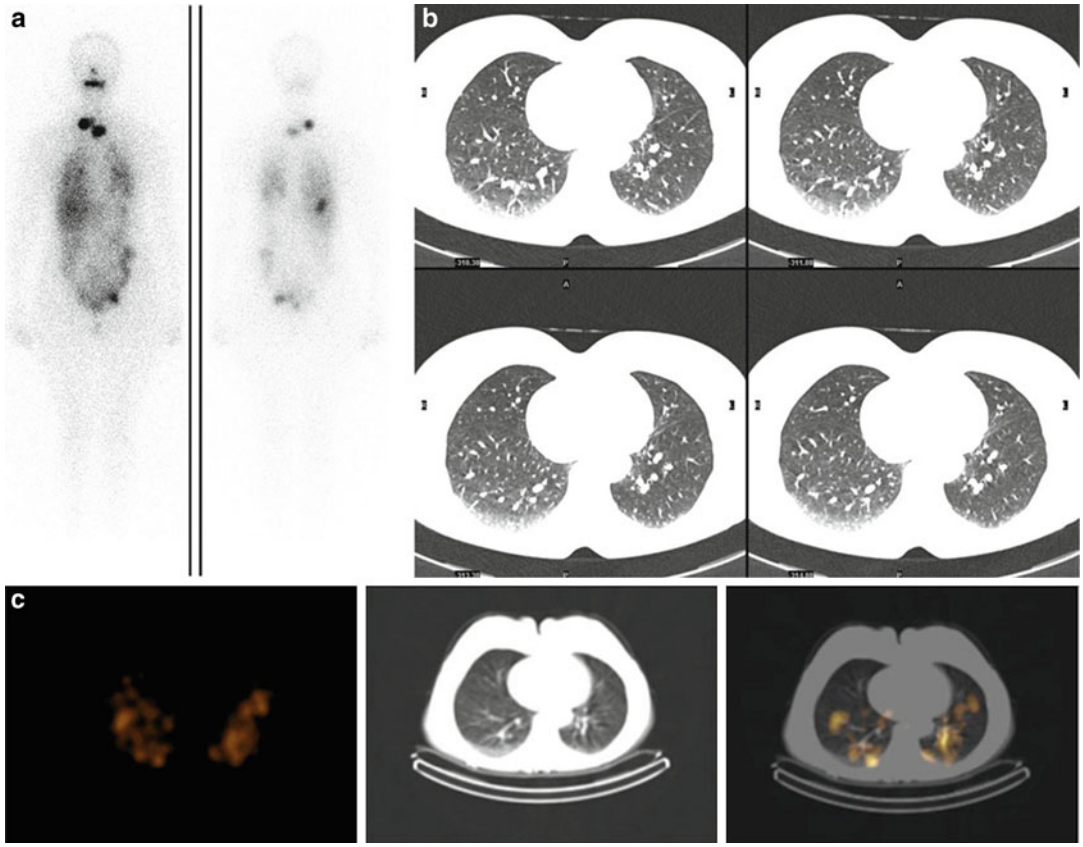

Fig. 12 Fifty-three-year-old patient with follicular variant of PTC infiltrating the thyroid capsule. US examination prior to remnant ablation with ^{131}I-iodide revealed metastasis in cervical lymph nodes; 4.8 GBq (130 mCi) of radioiodide was administered upon stimulation with rhTSH (with ensuing 219 ng/mL peak Tg level). Post-therapy WBS (**a**) showed radioiodide uptake in the metastatic cervical lymph nodes, as well as a pattern of diffuse uptake in the lungs indicating presence of metastasis that was unrecognized before therapy and was undetectable on diagnostic CT (**b**, with transaxial sections at different levels). SPECT/CT (**c**) better characterized the pulmonary areas that, despite not being associated with abnormalities on the CT component, were the site of lung metastasis from DTC

calculate the mean dose for normal organs using a three-dimensional internal dosimetry software, and the results of which are comparable with those obtained with OLINDA dosimetry [197]. Widely variable values have been reported for the mean absorbed dose estimated with ^{124}I-iodide PET, ranging 0.4–49 Gy/Bq (absorbed dose distribution from 0.3 to a maximum of 4,000 Gy). This is probably the result of the wide range in the ^{124}I effective half-life values observed in recurrent/metastatic lesions from DTC, that is, between 22 and 65 h in one report [194], between 14 and 43 h in another study [188], and between 6 and 80 h in a more recent report [196]. As per today's knowledge, ^{124}I-iodide PET dosimetry certainly constitutes an important tool in pre-therapy evaluation of patients with DTC [198], to be possibly used in the clinical routine whenever available [199]. However, evidence-based long-term data on the clinical impact of such accurate dosimetric calculations have not yet been published.

When radioiodide uptake is no longer demonstrable on post-therapeutic WBS, treatment with ^{131}I-iodide should be discontinued. EBRT and local treatments (thermoablation, laser-therapy, etc.) may be considered as first approach when radioiodide is no more effective and surgical

removal of metastases is not feasible. However, since the growth rate of DTC metastases is usually slow, a "wait-and-see" approach with six monthly controls seems warranted in this setting [18, 162]. Instead, if the lesions are rapidly growing and fulfilling the Response Evaluation Criteria in Solid Tumors (RECIST) criteria, a targeted therapy can be initiated [200].

Advanced DTC Refractory to Radioiodide Treatment

About 15% of DTCs become radioiodide refractory after several courses of ^{131}I-iodide treatments because of tumor dedifferentiation. In these patients, other therapeutic strategies must be defined. Among these, the approaches most commonly adopted in the past attempted at inducing "redifferentiation" of the "dedifferentiated" TC cells.

Reinduction of the Ability to Take Up Iodine

The possibility to restore the ability to take up iodine in radioiodine-refractory DTC has been recently explored. Treatment with all-trans-retinoic acid has proven effective in re-differentiating neoplastic cell clones in patients with acute promyelocytic leukemia, thus making them susceptible to chemotherapy [201]. This favorable experience has prompted similar attempts with retinoic acid in patients with non-iodine-avid metastatic DTC, aimed primarily at restoring the ability to trap iodine by acting on the NIS system [202, 203]. Several studies have been performed which demonstrated the ability of retinoic acid to reinduce iodine uptake [203–209]. Despite all these efforts, the final result is that retinoic acid can work, but only on a relatively low percentage of dedifferentiated DTCs, determining just a small control of tumor growth.

Recently, selumetinib, a new drug able to block the activity of MEK, has been demonstrated to be able to both reinduce the ability concentrate iodine in dedifferentiated DTC and determine an objective tumor size reduction as documented by CT scan [210]. Clinical trials on the effect of selumetinib on metastatic radioiodine-refractory DTC are ongoing in different academic centers throughout the USA.

Conventional Chemotherapy

When DTCs are metastatic, non-iodide-avid and rapidly growing, conventional therapies such as EBRT and chemotherapy are only minimally effective. The only chemotherapy agent that appeared to be effective in patients with metastatic DTC is doxorubicin [211]. Although a 33% response rate has been reported with doxorubicin as a single agent (60 mg/m^2 every 3–4 weeks), this observation has not been confirmed by subsequent studies, in which response rates ranged from 0% to 22% (all responses being partial and lasting only few months, without any survival benefit) [212, 213]. In two studies where doxorubicin was combined with cisplatin, the response rates were similar as those observed with doxorubicin alone, but at the expense of major toxicity [214, 215]. Although an increased response rate has been observed in patients treated with cisplatin plus epirubicin after TSH stimulation relative to non-stimulated patients treated with the same drugs [216], these promising results should be confirmed in larger series. With the introduction of new targeted therapies based on tyrosine kinase inhibitors (TKIs), the use of conventional chemotherapeutic agents is strictly limited to those few cases that cannot be treated with TKIs [2].

New Targeted Therapies

Following the discovery of oncogenic mutations involved in the pathogenesis of PTC and MTC, several novel targeted drugs have been developed in the last decade for treating these patients. These biological agents inhibit tumor growth by blocking physiological processes such as angiogenesis (i.e., they act as antivascular agents) and/or intracellular signaling. Most of them are

tyrosine kinase inhibitors (TKIs) and are able to partially inhibit multiple kinases and signaling pathways alike. Since the RET oncogene plays an important pathogenic role in both PTC and MTC, its inhibition may be relevant for controlling tumor growth. Motesanib (AMG706), vandetanib (Caprelsa®), imatinib (Gleevec®), sorafenib (Nexavar®), lenvatinib (Lenvima®), and cabozantinib (Cometriq®) are all RET inhibitors that effectively block tumor growth in vitro [217]. It is worth noting that all these TKIs have multiple targets, and they act also against VEGFR1-3, PDGFRβ, and others. In many cases the anti-VEGFR action is the most significant, and the antiangiogenic effect highly contributes to shrinkage of the tumoral mass. Sorafenib is the only known TKI agent able to block the serine kinase BRAF that is mutated in about 40% of PTCs. Motesanib has been the first TKI tested in a phase II/III trial, in which it was shown to induce partial responses in patients with progressive advanced metastatic DTC [218] and MTC [219]. Unfortunately, motesanib was not submitted to the authorities for the approval in the treatment of advanced DTC. Recently, the results of the phase III study (ZETA trial), which explored the activity of vandetanib in the treatment of advanced MTC, have been published showing a significant prolongation of progression-free survival (PFS) in patients with progressing MTC [220].

Cabozantinib has been also tested for the treatment of advanced MTC showing progressing disease, according to RECIST criteria, in the prior 14 months (EXAM study). The study, a multicenter, randomized, and international phase III study, clearly demonstrated that patients treated with this drug had a longer PFS time and a greater objective response rate (ORR) [221]. Based on these results, cabozantinib has been approved by both FDA and EMA for the treatment of advanced and progressive MTC. Interestingly, cabozantinib showed good results also in patients who had previously been treated with vandetanib and entered into progression after initial response; this observation implies the possibility of efficaciously using cabozantinib as a second-line treatment in progressive MTC [222].

Sorafenib, which is being used for the treatment of advanced hepatocellular and renal cell cancer since several years, has been recently approved by both FDA and EMA for the treatment of advanced and progressive DTC. Approval was promoted by the excellent results obtained in a phase III trial (DECISION study) in which patients treated with sorafenib showed a significantly longer PFS with respect to those treated with placebo [223]. As for the majority of TKIs, the efficacy of sorafenib in controlling tumor growth has a limited time span (mean 10.8 months); for this reason, other TKIs have been explored for the treatment of advanced DTC. The very promising results of a phase II study regarding the use of vandetanib in advanced DTC [224] are now being better explored in a phase III study (VERIFY trial) that is still ongoing. Recently, another TKI, Lenvima, has been approved both in the USA and in Europe, for the treatment of advanced, metastatic, and progressive DTC and PDTC. The phase III study (SELECT study) [225] showed promising results regarding both PFS and ORR in patients treated with the drug with respect to those treated with placebo. Most interestingly, both the FTC subgroup and the group of older patients (>65 years) showed also a significant prolongation of the overall survival. Moreover, lenvatinib showed excellent results also in patients who had previously been treated with other TKIs and entered into progression.

All TKIs have very important side effects that must be taken into consideration before starting the treatment. Fortunately, most of these side effects can be controlled with other drugs, as in the case of hypertension or diarrhea or allergies, while others require a dose reduction. In many cases the dose reduction is a reasonable compromise between the drug efficacy and the drug toxicity [226].

Despite the approval of two TKIs for MTC and two for DTC/PDTC, it is still necessary to identify other drugs with different actions, for example, nivolumab, a humanized IgG_4 anti-programmed death-ligand 1 (anti-PD-1) monoclonal antibody, or other biologically logical combinations of therapeutic targets in order to maximize synergistic effectiveness. In this regard, the American

Thyroid Association guidelines for the treatment of either DTC or MTC clearly indicate that patients with advanced disease should be offered to participate in clinical trial with TKIs or to be treated with TKIs already approved – rather than with conventional chemotherapy [162, 227].

External Beam Radiation Therapy

The role of EBRT for the treatment of recurrent DTC confined to the neck remains controversial [228]. There are no prospective randomized controlled trials to confirm a therapeutic value, which is so far suggested by retrospective analyses only. Although some authors have reported that EBRT was rather ineffective [211, 229], other data support the view that this modality of treatment may actually improve local control in selected patients. In particular, EBRT may be warranted in patients older than 40 years with PTC and extrathyroidal invasion without significant ^{131}I-iodide uptake in the neck. In these patients, EBRT may destroy neoplastic cells unresponsive to radioiodine therapy. Indeed, the analysis of patients with recurrent PTC showed that locally invasive carcinoma, in contrast to lymph node recurrence, often did not concentrate iodine [211]. Patients with inoperable gross residual disease after surgery also appear to benefit from EBRT, which can be combined with ^{131}I-iodide therapy to treat a poorly differentiated tumor component. In these patients, a combination of EBRT with low-dose doxorubicin (10 mg/m^2 per week) may improve tumor response [230]. The most common acute complications of EBRT are transient esophagitis and tracheitis. Long-term complications are neck fibrosis, decreased salivary flow, and consequent parodontitis. Arterial thrombosis, brachial plexus neuropathy, laryngeal necrosis, or radiation-induced tumors (soft tissue sarcomas) have been observed in about 5% of the patients [231]. These severe complications clearly demonstrate that EBRT should be offered only to those patients with non-iodine-avid tumors who are technically inoperable or too ill to tolerate major resections. EBRT can be used as palliative therapy for some bone metastases (especially if they cannot be treated with surgery), to control local pain. Similarly, EBRT could be indicated for diffused brain metastases.

Treatment of Anaplastic Thyroid Cancer

Multimodality treatment of ATC includes surgery, EBRT, and combination chemotherapy; nevertheless, despite all therapeutic attempts, median survival does not exceed 1 year. The possibility to perform radical surgery should always be considered in patients with newly diagnosed ATC, since this option somewhat improves survival of these patients [232, 233]. If total thyroidectomy is not possible, at least debulking of the tumoral mass to improve the local symptoms should be performed, whenever possible [234]. Tracheostomy is performed for impending airway obstruction, but not as a prophylactic approach. Radiometabolic therapy with ^{131}I-iodide does not apply to ATC, because the original follicular cells have lost all features of differentiation, among which the ability to concentrate and retain iodine. In some instances, neoadjuvant hyperfractionated EBRT and chemotherapy with doxorubicin followed by surgery can achieve local control of the disease prior to surgery [235, 236].

Several chemotherapy regimens either with single agents or with various combinations (such as doxorubicin, etoposide, cisplatin, bleomycin, and vincristine) have been attempted [237–239], but none of these approaches has shown adequate control of the disease. ATC cells are particularly chemoresistant, possibly through a mechanism of multidrug resistance mediated by overexpression of the P-glycoprotein [236, 239].

Novel therapeutic strategies based on molecular approaches are under investigation, such as RET proto-oncogene or BRAF-targeting drugs [240, 241]. Inhibition of the EGFR and VEGFR signaling pathways have also been shown to inhibit tumor growth and angiogenesis in experimental ATC models, thus opening a new avenue to the treatment options available for ATC [242, 243]. Recently, new drugs have been explored for the treatment of ATC such as combretastatin, a "vascular disrupting agent" that inhibits the

polymerization of tubulin of cytoskeleton with a selective action on newly formed tumoral endothelial cells. Combretastatin has been shown to have direct antitumor effects in vivo and in vitro, by destabilizing spindles and inducing apoptosis; the end result is the disruption of neovascular endothelial cells with interruption of blood flow to the tumor. A phase II/III study showed a clinical advantage of the use of combretastatin associated with chemotherapy (carboplatinum and placlitaxel [CP]) with respect to chemotherapy alone. In fact, the 1-year survival for CP/combretastatin versus CP alone was 26% versus 9%, respectively [244].

New therapeutic approaches are being explored with lenvatinib in vitro (using ATC cell lines) and in animal models (xenografted mice) [245], and a phase II/III international multicenter study is planned to start soon.

Initial Treatment of Medullary Thyroid Cancer

Wide consensus has been reached on the concept that total thyroidectomy and lymph node dissection of the central neck compartment is the treatment of choice for MTC; therefore, a definite presurgical diagnosis of MTC is crucial for planning this surgical approach, and any effort to achieve such diagnosis should be undertaken [246]. In this regard, measuring calcitonin (Ct) concentration in the washout of the needle used for FNAC of a suspected thyroid nodule may be useful for diagnosing MTC [247]. This approach is of particularly useful also to ascertain the nature of enlarged neck lymph nodes, especially before thyroidectomy, in order to better plan the surgical approach or the most appropriate therapeutic strategies [247]. The possibility of avoiding central node neck dissection in RET gene carriers who undergo prophylactic thyroidectomy and who do not yet have evidence of clinical and/or biochemical disease has been well defined in the more recent MTC guidelines [248].

Cure and survival rates in patients with MTC strongly correlate with age and with the stage at diagnosis. Elevated serum CEA levels (above 5–10 ng/mL) preoperatively are correlated with a bigger tumor size and greater number of lymph node metastases, thus reflecting the burden of disease. Postoperative hypercalcitoninemia indicates persistent MTC, which occurs in 30–55% of the patients after primary surgical treatment, particularly when the tumor is not more confined to the thyroid [249]. Instead, rising serum Ct levels after the initial decline to biochemically free disease following surgery indicate recurrent disease, an occurrence observed in 5–12% of patients after total thyroidectomy [250].

Follow-Up of Medullary Thyroid Cancer

MTC patients are followed by monitoring the serum Ct and CEA levels and by neck US examination. Evaluating these biochemical and clinical parameters every 6–12 months allows the clinicians to assess the clinical status of the patients and to discover early those who need medical treatment. Overall survival is closely related to postsurgical recurrences and/or to the appearance of distant metastases, events that reduce the 10-year survival rate to 40%.

Serum Ct is the most specific and sensitive marker for MTC, both before and after thyroidectomy. It is a small polypeptide hormone (32 amino acids) normally produced almost exclusively by the parafollicular C cells. Ten years after the recognition of MTC as a distinct histologic type of thyroid cancer, high levels of Ct have been demonstrated to be present both in the tumoral tissue and in the serum of patients with MTC [251, 252]. Elevated baseline serum levels of Ct are diagnostic for MTC [252]. Routine measurement of serum Ct in patients with nodular thyroid disease allows the preoperative diagnosis of unsuspected sporadic MTC [246]. In this regard, assaying serum Ct facilitates the early diagnosis of MTC, usually when the tumor is still at stage I, thus favoring successful surgical treatment [253]. Ct doubling time in serum is the most sensitive biomarker for MTC progression. On the other hand, normal postoperative CEA levels are sometimes observed in patients with metastatic disease. Nevertheless,

serum CEA may be used as a surrogate tumor-associated marker in those MTCs that do not secrete Ct [254]. There are some recent evidences that elevated levels of serum Ca 19.9 in patients with advanced MTC represent a prognostic factor for poor survival [255, 256].

Accurate identification of the sites of recurrences is essential for patient management. Diagnostic imaging workup for the evaluation of local relapse or of regional recurrence includes US of the cervical region, CT scan, and MRI.

Radionuclide Imaging in Recurrent MTC

The role of nuclear medicine in patients with MTC is important mostly in the postoperative workup, to detect residual or recurrent tumor. Nevertheless, radiopharmaceuticals can also be employed for therapy of recurrent/metastatic MTC (see below). Diagnostic agents for MTC include both single-photon-emitting and positron-emitting radiopharmaceuticals. Of particular interest among the former group is pentavalent ^{99m}Tc-labeled dimercaptosuccinic acid (^{99m}Tc(V)-DMSA), a nonspecific tumor-seeking agent that has been used to evaluate many types of cancers including breast tumors, head and neck cancers, osteosarcomas, and hepatocellular carcinoma. Although the exact mechanism of ^{99m}Tc(V)-DMSA uptake in tumor cells is still poorly understood, it seems to be mediated by the sodium phosphate cotransporter type III [257]. Concerning MTC, this radiopharmaceutical has been used to localize the site of disease in patients whose serum Ct levels increase, yet who are clinically free of disease. Scintigraphy with ^{99m}Tc(V)-DMSA has sensitivity up to 70%, associated however with low specificity because of its accumulation also at inflammatory sites [258, 259]. It should also be noted that this radiopharmaceutical is not currently commercially available in most countries, although it can be prepared according to relatively easy to perform in-house formulations.

Scintigraphy with the nonspecific tumor-seeking agent ^{99m}Tc-Sestamibi has overall 56% sensitivity for detecting recurrent MTC in patients with serum Ct levels in excess of 6 ng/mL; this imaging procedure is especially useful for postoperative evaluation of cervical and mediastinal regions, where a high target-to-background ratio can be observed [260] (Fig. 13). ^{99m}Tc-Sestamibi scintigraphy has improved sensitivity when combined with CT scan and/or other imaging procedures.

Scintigraphy with the somatostatin analog ^{111}In-pentetreotide (OctreoScan®) is not extensively employed for the evaluation of MTC patients, because the distribution of somatostatin receptors is not homogeneous among different tumor lesions and generally lower than in other neuroendocrine tumors [261]; these features explain the wide range in sensitivities reported for OctreoScan® scintigraphy, from 35% to 75% [262, 263]. The highest sensitivity is reported in patients with neck and mediastinal lymph node involvement, while it is lowest for distant metastases [264]. An important indication for somatostatin-receptor scintigraphy with OctreoScan® is for pretreatment evaluation in patients candidate to therapy with radiolabeled somatostatin analogs.

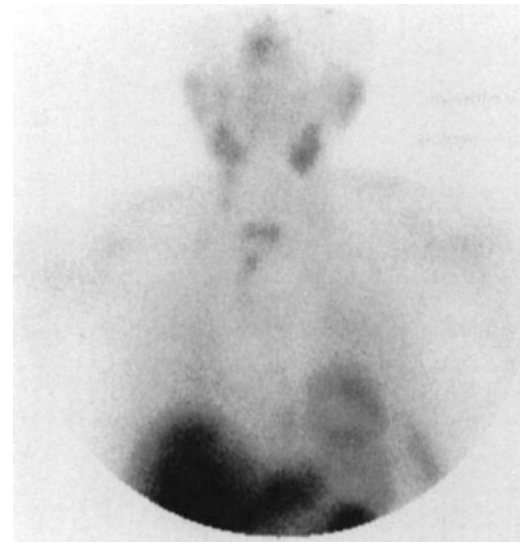

Fig. 13 Planar scan with ^{99m}Tc-Sestamibi of the neck and chest in a patient who had undergone total thyroidectomy because of medullary thyroid cancer 2 years earlier. During follow-up serum calcitonin reached 6.24 ng/mL. This spot view demonstrates the presence of three mediastinal lesions and two cervical lesions (*right side*) (From Learoyd et al. [260], with permission)

^{123}I-metaiodobenzylguanidine (^{123}I-MIBG, structurally similar to norepinephrine) accumulates in tumors arising from the neural crest. Scintigraphy with ^{123}I-MIBG has very high sensitivity (about 95%) in patients with MTC [265], with an especially high accuracy for staging patients with MEN II and familial MTC. Instead, the sensitivity of ^{123}I-MIBG scintigraphy in patients with increased serum Ct but who are clinically free of disease is only 38% [266] (Fig. 14).

Ligands for the gastrin/cholecystokinin B receptor (CCK-BR) constitute a new class of peptides that can be radiolabeled and utilized for diagnosis or for therapy of CCK-BR-expressing tumors; among these, MTCs express the CCK-BR in almost 90% of the cases [267]. ^{111}In-labeled derivatives of gastrin (^{111}In-DTPA-D-Glu^{1}-minigastrin) showed excellent targeting of CCK-BR-expressing tumors, with 94% sensitivity [268, 269]. Minigastrin may also be labeled with ^{90}Y or with ^{177}Lu for therapeutic purposes [270, 271].

Immunoscintigraphy with radiolabeled monoclonal anti-CEA antibody provides high sensitivity (75–100%) to detect recurrent MTC in patients with aggressively growing forms of this tumor [272]. However, this radiopharmaceutical is not commercially available.

The diagnostic performance of single-photon-emitting radiopharmaceuticals is in general unsatisfactory in MTC patients, due to variable tracer uptake and to relatively low spatial resolution. Instead, PET imaging agents can be successfully employed in MTC (see example in Fig. 15).

[^{18}F]FDG PET suffers from several limitations in the case of MTC, because these tumors are generally characterized by a metabolic activity that is only slightly increased with respect to normal cells, while their degree of differentiation and secretory profile are quite variable. Indeed, [^{18}F]FDG PET sensitivity in patients with MTC is associated with Ct serum levels higher than 500 pg/mL, Ki-67 scores higher than 2.0%, and short Ct doubling time in serum [273]. In particular, sensitivity of [^{18}F]FDG PET in patients with Ct levels below 500 pg/mL is only 20%, while it is 78% in patients with more elevated serum Ct levels (1,000 pg/mL) [274]. On the other hand, the diagnostic performance of [^{18}F]FDG PET in detecting lymph node involvement in the cervical and mediastinal regions is higher than that of

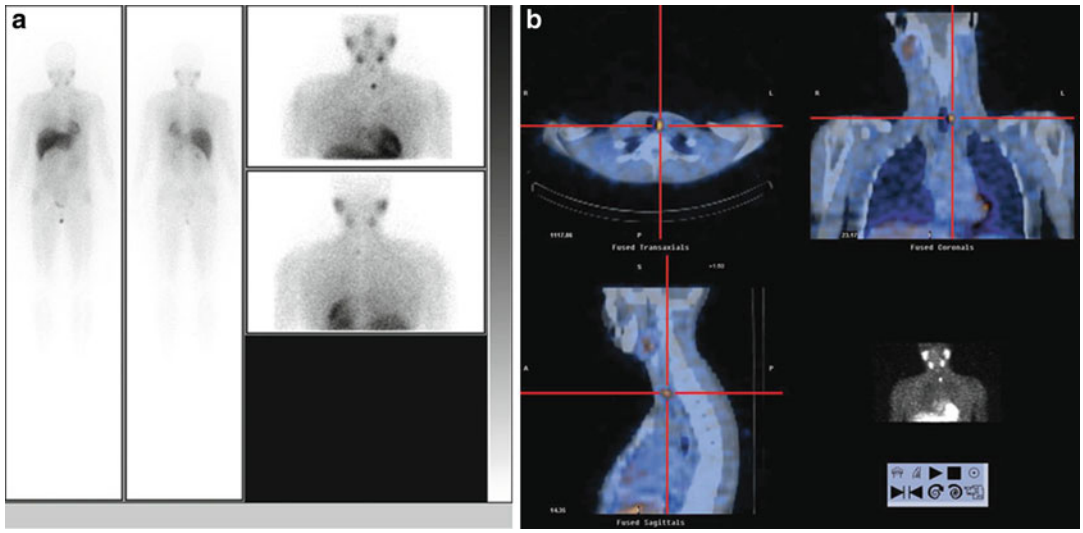

Fig. 14 Scintigraphy with ^{123}I-MIBG in a patient already submitted to thyroidectomy because of medullary thyroid carcinoma; investigation performed because of progressively rising serum Ct levels. (**a**) Planar whole-body images and spot acquisition on the chest and neck (both acquisitions in the anterior and the posterior views), showing local recurrence in the neck. (**b**) SPECT/CT of the 3neck (fused SPECT/CT images in the three planes), showing exact topographic localization (left thyroidal postsurgical bed) of the lesion detected in the planar images

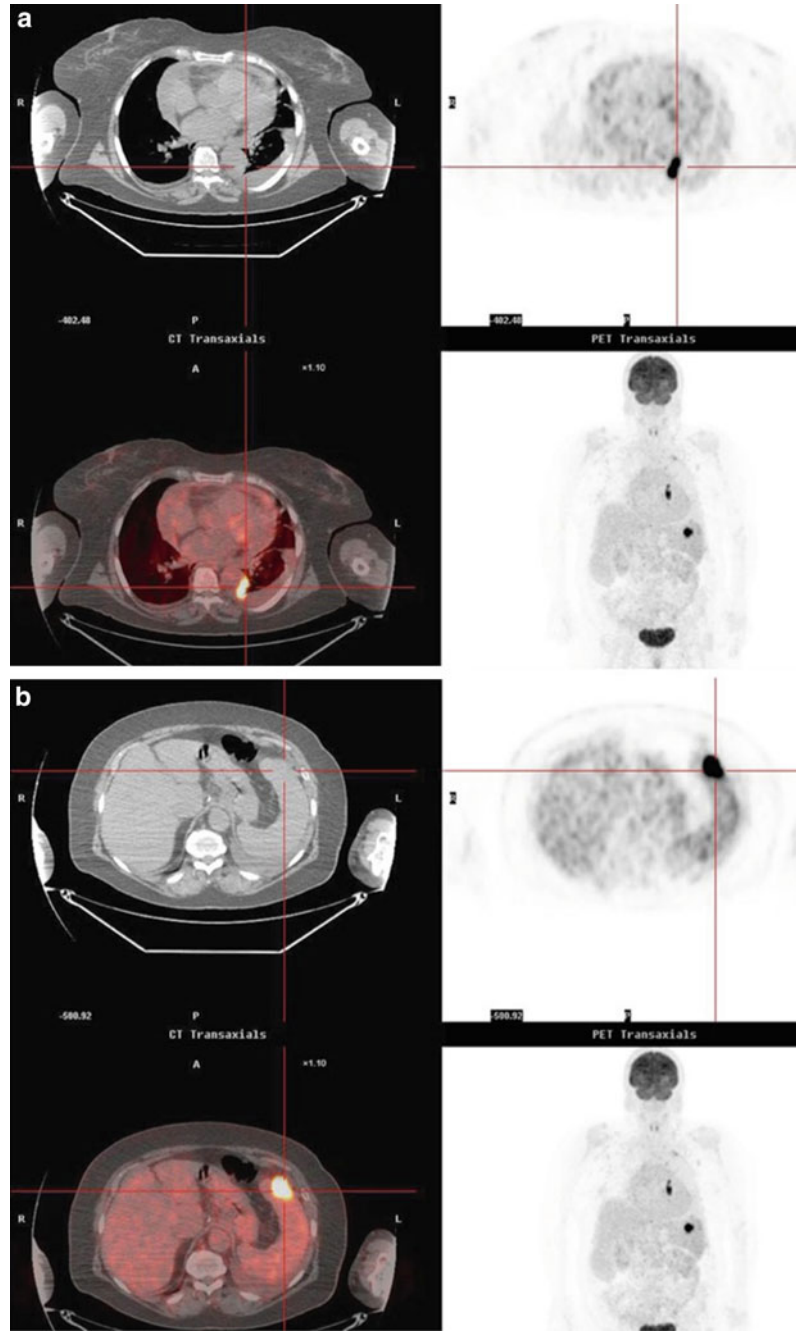

Fig. 15 [^{18}F]FDG PET/CT in a patient developing distant metastases from MTC, about 18 months after surgery of the primary tumor. (**a**) Left pleural metastasis of disease. **b** Splenic metastasis

other imaging methods (CT, MRI, and ^{131}I-MIBG scintigraphy) with sensitivity ranging from 76% to 96% [275]; nevertheless, sensitivity of PET with [^{18}F]FDG is low for small pulmonary metastases and for detecting bone involvement [276].

PET with ^{18}F-DOPA or with ^{68}Ga-labeled somatostatin analogs has recently been proposed for patients with MTC. Concerning in particular the former PET agent, it should be considered that the C cells are neuroendocrine cells belonging to the APUD system, i.e., they have the property to

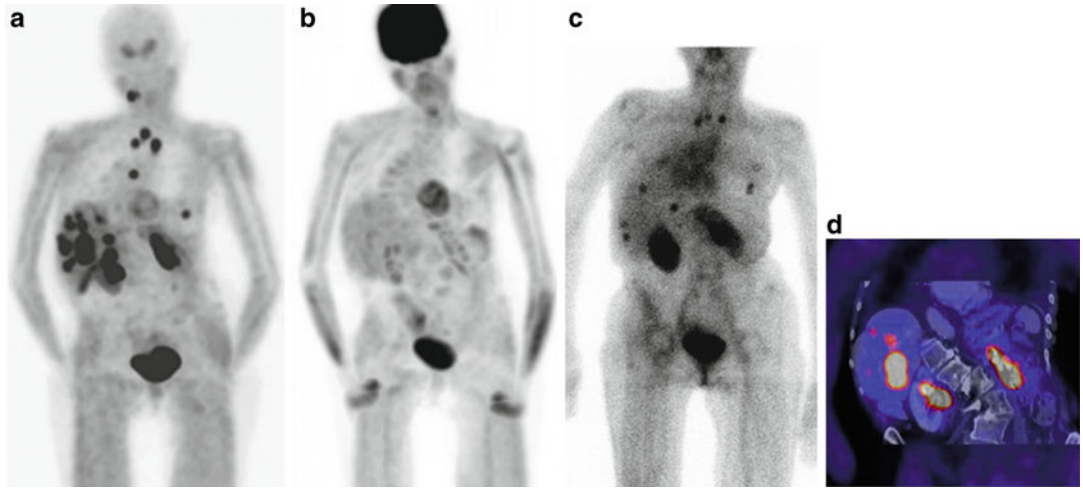

Fig. 16 Comparative imaging of a 68-year-old woman with metastatic medullary thyroid cancer related to a MEN 2A syndrome. Her Ct doubling time was 91 months (Ct, 27,190 ng/L), and her CEA doubling time was 151 months (CEA, 1,460 mg/L). (**a**) ^{18}F-DOPA PET shows the largest number of lesions, located in the neck, upper mediastinum, left thorax, liver, and skeleton. (**b**) [^{18}F]FDG PET shows only physiologic uptake but no tumor lesions. (**c**) ^{99m}Tc(V)-DMSA shows lesions in the upper mediastinum, left thorax, liver, and skeleton, although with much smaller number of lesions. (**d**) ^{18}F-DOPA PET/CT fusion slice shows liver lesions (From Koopmans et al. [278], with permission)

uptake and decarboxylate monoamine precursors. Therefore, 6-L-^{18}F-fluorodihydroxyphenylalanine (^{18}F-DOPA), an intermediate in the catecholamine synthesis pathway, can successfully be employed for PET imaging. Indeed, PET with ^{18}F-DOPA is more accurate than other imaging modalities in patients with MTC, in particular for detecting recurrent disease and lymph node involvement (with up to 81% sensitivity), even in patients with long serum Ct doubling times [277–279] (Fig. 16). In general, PET with [^{18}F] FDG offers important clinical information in patients with predominantly aggressive tumors such as the sporadic form of MTC.

Other promising PET agents to image neuroendocrine tumors include somatostatin analogs labeled with ^{68}Ga through the DOTA chelator (such as ^{68}Ga-DOTA-TOC, ^{68}Ga-DOTA-TATE, ^{68}Ga-DOTA-NOC) [280] (Fig. 17). However, the diagnostic role of ^{68}Ga-DOTA-peptides is still under extensive investigation and validation, because of controversial reports probably linked to the fact that even well-differentiated MTCs show a variable and often low somatostatin-receptor subtype expression [281].

Treatment for Recurrent or Persistent MTC

Local or regional recurrence of MTC in the neck and mediastinum can be effectively treated with surgical removal, possibly followed by EBRT when neck involvement is extensive [282]. Nevertheless, biochemical cure (i.e., normalization of serum Ct and/or CEA levels) is observed in only 5–35% of the cases; these patients are at high risk of developing distant metastases [250]. The main cause of MTC-related death is distant metastasis, which affects more frequently the lungs, bones, and liver, more rarely the brain and skin [283]. The 5-year survival rate of patients with distant metastases is 25% [284], with low response rates elicited by any of the therapeutic options available. Combination chemotherapy induces a response in only 20% of the cases [285–287], while Interferon-α and somatostatin analogs only induce transient improvement of the symptoms [288]. Bone metastases can be treated with surgery, EBRT, and/or bisphosphonates. In patients with predominant metastasis in the liver,

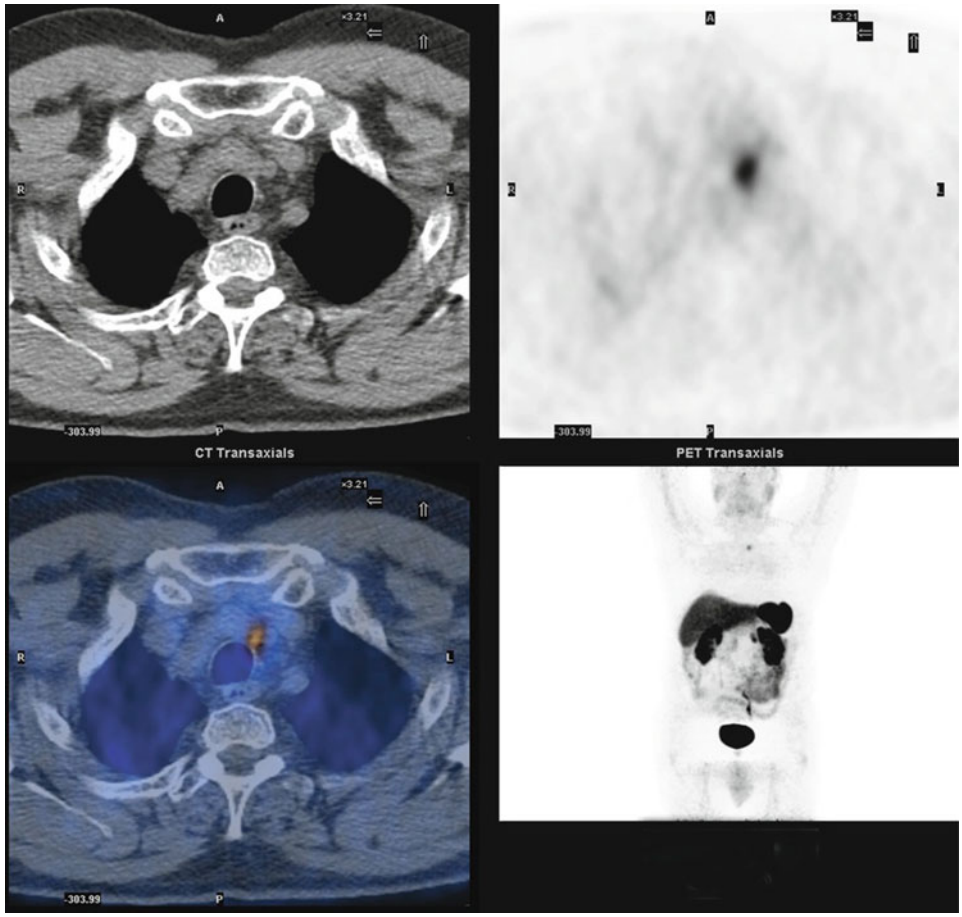

Fig. 17 PET/CT with ^{68}Ga-DOTA-TOC in a patient previously submitted to thyroidectomy because of MTC but with rising serum Ct levels. The images demonstrate uptake of the radiolabeled somatostatin analog in a metastatic lesion located in the upper mediastinum, in the left pretracheal region. The MIP image in the *right lower* panel demonstrates physiologic distribution of the ^{68}Ga-labeled peptide in the remainder of the body (Courtesy of Prof. Stefano Fanti, Nuclear Medicine Division, "S. Orsola – Malpighi" University Hospital, Bologna, Italy)

chemoembolization has proven effective in reducing the tumor mass [289].

Radiolabeled anti-CEA antibodies have been used for radioimmunotherapy in addition to surgical treatment and have been shown to induce long-term disease stabilization and significantly prolonged survival in high-risk MTC patients [290, 291].

More recently, radionuclide therapy with the radiolabeled somatostatin analog ^{90}Y-DOTA-Tyr^3-octreotide (^{90}Y-DOTA-TOC) has been tested in metastatic MTC. This therapy has resulted in favorable biochemical response in about one-third of the patients (irrespective of the result of the pre-therapeutic scintigraphy), associated with a long-term survival benefit [292]. Further studies are in progress to investigate the effect of other radiolabeled somatostatin analogs, including ^{177}Lu-DOTA-TATE and other radiopeptides, among which gastrin-like ligands, on the survival of patients with advanced metastatic MTC [267, 293–295]. Mostly due to the limited number of patients enrolled in each study, at present there is no clear evidence for a definite clinical benefit from such therapies for patients with advanced metastatic MTC.

Molecular targets represent the new frontier for treating patients with metastatic MTC [296]. In

particular, the RET gene is a promising target for therapy in patients with familial MTC as well as for some patients with sporadic MTC. Several inhibitors of the RET kinase activity (i.e., sorafenib, motesanib, sunitinib), which are active also against the VEGF receptor (thus causing cytostatic rather than cytotoxic effects), have been evaluated in the last decade [296–298]. In particular, results of the ZETA® phase III study showed a promising therapeutic potential of a new molecule named vandetanib, so that in April 2011 and in February 2012, the FDA and EMA, respectively, approved the use of vandetanib (Caprelsa®, AstraZeneca, USA) in patients with unresectable locally advanced or metastatic MTC [298]. Vandenatib seems to exert its antiangiogenic activity through three combined mechanisms, i.e., inhibition of VEGF, EGF, and RET. More recently, another multitarget TKI, cabozantinib (Cometriq®, Exelixis, USA), has been approved by both the FDA and EMA for the treatment of advanced and progressive metastatic MTC. Cabozantinib is also an antiangiogenic drug active against RET, MET (hepatocyte growth factor receptor), and VEGFR2 and less effective against VEGFR1, VEGFR3, KIT, and other tyrosine kinase receptors [299]. Its ability to block cell growth has been explored in a phase III study (EXAM study) [300] that demonstrated a significant prolongation of progression-free survival in the group of MTC patients treated with cabozantinib with respect to those treated with placebo. At present, vandetanib and cabozantinib represent the two options for the treatment of advanced and progressive MTC.

Neuroendocrine Tumors: Therapy with Radiolabeled Peptides

43

Lisa Bodei, Laura Gilardi, Duccio Volterrani, Giovanni Paganelli, Chiara M. Grana, Mark Kidd, and Irvin M. Modlin

Abstract

Treatment of neuroendocrine tumors (NETs) is typically multidisciplinary and should be individualized according to the tumor histology, lesion extent, patient performance status, and symptoms. Surgery is the only potentially curative option. NET liver metastases are typically hypervascular, and chemoembolization or bland embolization of the hepatic artery, performed mechanically by microspheres or chemically with cytotoxic agents, can lead to significant necrosis. Medical therapy is directed at the control of symptoms and/or reducing tumor growth. Strategies range from the use of bioactive agents (somatostatin analogues or interferon) to conventional chemotherapy. PRRT uses radiolabeled somatostatin analogue peptides to treat unresectable or metastasized NETs. The therapeutic strategy of PRRT has been utilized for more than two decades and is accepted as an effective therapeutic modality in the treatment of inoperable or metastatic GEP, bronchopulmonary, and other NETs. PRRT with either ^{90}Y-DOTATOC or ^{177}Lu-DOTATATE is generally extremely well tolerated, with modest toxicity to the target organs, such as the kidneys and bone marrow. The chapter illustrates the efficacy and safety features of these compounds.

Therapy with Radiolabeled Peptides

Overall Therapeutic Strategy

Treatment of neuroendocrine tumors (NETs) is typically multidisciplinary and should be individualized according to the tumor histology, lesion extent, patient performance status, and symptoms. An optimal management strategy includes a clinical assessment of the patient followed by characterization of the primary tumor and thereafter delineation of the grade and stage of the lesion [1]. Whenever possible and clinically/technically feasible, removal of the primary tumor should be undertaken to prevent the consequences of local events (bleeding, obstruction, perforation) and locoregional invasion and reduce the likelihood of metastatic spread. Surgery is the only potentially curative option; however, effective en bloc resections can only be obtained in 20% of cases due to the frequent presence of metastatic disease [2]. The surgical options include en bloc removal of the primary tumor, resection of hepatic metastases, radiofrequency ablation, and, in selected cases, hepatic or even enteric transplantation [3]. Tumors located in the head of the pancreas or in the duodenum are resected using the Kausch–Whipple pancreaticoduodenectomy procedure, while neuroendocrine tumors (carcinoids) of the distal ileum are managed by ileal resection and/or right hemicolectomy [4]. For bronchial carcinoids, lung resection surgery, including lymphadenectomy, is the option of choice. In the situation of more aggressive categories of thoracic NETs (large cell and small cell neuroendocrine carcinomas, LCNEC and SCLC, respectively), surgery is seldom feasible, and the outcomes are quite poor [5]. Liver transplantation for GEP-NETs remains controversial and can be proposed in selected situations (Milan criteria) when the liver is the sole site of disease, usually in a setting of stable metastases from intestinal NETs and low Ki67 index [6]. The definitive treatment for pheochromocytoma/paraganglioma is surgical. Laparoscopic removal of intra-adrenal and extra-adrenal pheochromocytomas is regarded as the surgical technique of choice [7]. Operative mortality is less than 1%, if adequate preparation with alpha and beta blockade is undertaken in the event of catecholamine-secreting tumors [8, 9]. Cortex-sparing adrenalectomy can be performed in hereditary, frequently bilateral, tumors, while malignant and diffusely spread tumors are approached utilizing conventional transabdominal resection. Interventional radiology techniques are helpful to treat multiple or dominant metastatic hepatic lesions not amenable to surgical resection. NET liver metastases are typically hypervascular, and chemoembolization or bland embolization of the hepatic artery, performed mechanically by microspheres or chemically with cytotoxic agents, can lead to significant necrosis. More recently radioembolization with ^{90}Y-labeled microspheres have been reported to have excellent results [10–12]. Other ablative techniques employed in routine approach to liver metastases include "umbrella" radiofrequency ablation, cryoablation, and high-intensity focused ultrasound (HIFU) ablation [13, 14]. Medical therapy is directed at the control of symptoms and/or reducing tumor growth. Strategies range from the use of bioactive agents (somatostatin analogues (SSAs) or interferon) to conventional chemotherapy. In functional tumors such as gastrinomas or insulinomas, symptomatic treatment with proton pump inhibitors or anti-hypoglycemic agents, respectively, is effective. More recently, a variety of novel agents (everolimus, sunitinib, and bevacizumab) with putative molecular targets (e.g., mTOR, VEGF) have been introduced with varying degrees of efficacy [15]. Everolimus and sunitinib have been approved by FDA for the treatment of pancreatic NETs. Early reports of efficacy have been tempered by concerns regarding adverse advents [16]. Traditional chemotherapy has little place in well-differentiated NETs, since most of them are indolent. Nevertheless, several studies have reported efficacy of the combination capecitabine + temozolomide in pancreatic NETs [17, 18].

Somatostatin analogue biotherapy is regarded as a basic therapeutic agent for the management of NETs. The over expression of somatostatin receptors (SSTR) on NETs allows effective

targeting and hence effective treatment of symptoms due to hyper or paroxysmal secretion of bioactive peptides and amines. There is some inhibitory effect growth of primary and metastatic lesions, but it is limited and difficult to predict or define given limitations in imaging sensitivity and suboptimal biomarker availability [19]. All SSTR subtypes bind somatostatin (both 14- and 28-amino-acid isoforms) and its analogues with varying degrees of efficacy. Somatostatin has an extremely short plasma half-life (about 2 min) and cannot be used for clinical purposes. Octreotide and lanreotide are two somatostatin analogues with high affinity for sst 2 receptor, moderately high affinity for sst 5, and intermediate affinity for sst 3 [20]. Somatostatin analogues are generally well tolerated, and long-acting formulations effectively control symptoms in up to 70% of patients, although tachyphylaxis frequently occurs [21]. Objective partial responses are identifiable in less than 10% [22]. Individuals with a clinical syndrome (flushing and diarrhea) have a reduced survival (5-year survival of 21%, 38 months median survival from the first facial flushing, 23 months from the biological diagnosis). Thus, SSA therapy, which reduces symptomatology and its sequelae, improves quality of life and decreases tumor growth, has merit, and is widely used as an initial therapeutic strategy [23]. An Italian multicenter trial [24] in NETs of various origins (using octreotide 0.5–1 mg t.i.d.) demonstrated symptomatic and biochemical responses in 73% and 77% of patients, respectively, with only 3% objective (partial) responses in carcinoids. The use of high-dose lanreotide (up to 12 mg/day) gave similar biochemical and symptomatic responses, as well as similar tumor responses (partial responses in 5% of patients) [25]. In the medical treatment of advanced SCLC, both octreotide and lanreotide were able to reduce growth factors, such as IGF-1, but did not show any antitumor efficacy [26–29]. Recently, an agonist with broader SSR affinity (pasireotide) has been introduced in the clinical practice to overcome resistance to octreotide or lanreotide. Current efficacy data appear limited and substantial adverse events have limited its utility [30].

Peptide Receptor Radionuclide Therapy (PRRT)

Neuroendocrine cells are typically regulated by numerous hormones, acting via specific receptors on the membrane surface. These receptors are usually 7-transmembrane domain G-protein-coupled receptors. The presence of a suitable density of internalizing somatostatin receptors (SSTR) on the cell surface of NETs is the basis for a somatostatin receptor-targeted therapy. Agonists binding to somatostatin receptors are internalized into endosomes and activate post-receptor mechanisms, such as adenyl cyclase, phospholipase, and ion channels, that are responsible for activation of the biological/pharmacological events within the cell. The receptor is either recycled on the membrane surface or entrapped into lysosomes for degradation. This retention into the lysosomes enables a radionuclide-based peptide diagnosis and/or therapy, depending on the radionuclide utilized (Figs. 1, 2, and 3 [31]).

Peptide receptor radionuclide therapy (PRRT) uses radiolabeled peptides to treat unresectable or metastasized NETs. The radiopharmaceutical is concentrated in the tumor cell, where the sensitive targets, such as DNA, can be attained. To estimate the radioactivity concentration in tumors, all PRRT protocols include a baseline assessment of the SSTR density, obtained in vivo with the conventional ^{111}In-pentetreotide scintigraphy or ^{68}Ga-SSA-PET/CT. The information obtained with these exams is used to determine the probability of clinical efficacy. It has been established that an uptake greater than that of kidneys and/or spleen (on planar scintigraphic images) is correlated with an objective response in ~60% of individuals [32]. The quantification of this uptake utilizing ^{68}Ga-DOTATOC PET/CT has indicated that a SUV_{max} threshold of >16 has sensitivity and specificity of 95% and 60%, respectively, in the prediction of tumor response [33].

PRRT consists in the systemic administration of a radiolabeled somatostatin analogue, in sequential cycles up to a cumulative activity that is calculated on renal irradiation. Cycles are usually administered

6–12 weeks apart in order to ameliorate any potential hematological toxicity. To mitigate any renal risk, PRRT is usually accompanied by the coadministration of nephroprotective amino acids, such as lysine and arginine that diminish the renal absorbed dose by 50–60% [34].

Given the high first-pass extraction of the radiopeptides, the technique of intrahepatic arterial administration has been investigated with some success in clinical trials, although further information is needed to rigorously define its efficacy and safety [35].

The therapeutic strategy of PRRT has been utilized for more than two decades and is accepted as an effective therapeutic modality in the treatment of inoperable or metastatic GEP, bronchopulmonary, and other NETs [36]. It was initially utilized in 1992 at Erasmus University, Rotterdam, as a logical step following the introduction by this group of somatostatin receptor scintigraphy with [^{111}In-DTPA^{0}-D-Phe^{1}]-octreotide or ^{111}In-pentetreotide [37]. The two most commonly used radiopeptides for PRRT, ^{90}Y-octreotide and ^{177}Lu-octreotate, produce disease-control rates of 68–94% (SWOG or RECIST based) (Table 1) [34, 41, 42, 44, 50, 51]. In addition to tumor volume reduction, biochemical and symptomatic responses are commonly (up to 70%) observed [52]. The resulting progression-free survival (PFS) and overall survival (OS) rates compare favorably with SSAs, chemotherapy, and more recent usage of "targeted" therapies such as everolimus and sunitinib [32, 43]. The preliminary results of the current phase III randomized trial (NETTER-1) unequivocally indicated the clear advantage of ^{177}Lu-octreotate over high-dose SSAs in midgut NETs, in terms of PFS, OS, and objective response [53].

PRRT with ^{111}In-octreotide was initiated in the 1990s by Eric Krenning and coworkers at

Table 1 Review of the efficacy of PRRT with ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE

Erasmus University, in Rotterdam. A subsequent multicenter trial demonstrated some clinical benefit due to the Auger and conversion electrons emitted by indium-111 in close proximity to the cell nucleus. Despite these premises, partial remissions were unusual [54]. Higher-energy and longer-range emitters, such as pure β-emitter Yttrium-90 (E_{max} 2.27 MeV, R_{max} 11 mm, $T_{1/2}$ 64 h), were considered more suitable for therapeutic purposes. Therefore, a new analogue, Tyr^3-octreotide, with a similar pattern of affinity for somatostatin receptors, was developed. This analogue exhibited high hydrophilicity, simple labeling with ^{111}In and ^{90}Y, and tight binding to the macrocyclic chelator DOTA (1,4,7,10-tetraazacyclododecane- N,N′,N″,N‴-tetraacetic acid), to form ^{90}Y-[DOTA]^0-Tyr^3-octreotide or ^{90}Y-DOTATOC [55]. As a consequence of this optimization in 2000, the newer analogue {octreotate (Tyr^3,Thr^8-octreotide)}, with six to ninefold higher affinity for SSTR2, was introduced into clinical practice. The chelated analogue [DOTA]^0-Tyr^3-octreotate or DOTATATE can be labeled with the β–γ-emitter lutetium-177 ($E_{\beta max}$ 0.49 MeV, $R_{\beta max}$ 2 mm, $T_{1/2}$ 6.7 days) (Fig. 4).

In principle, Auger electron emitters represent an attractive alternative to β-particle emitters for cancer therapy if they can be placed

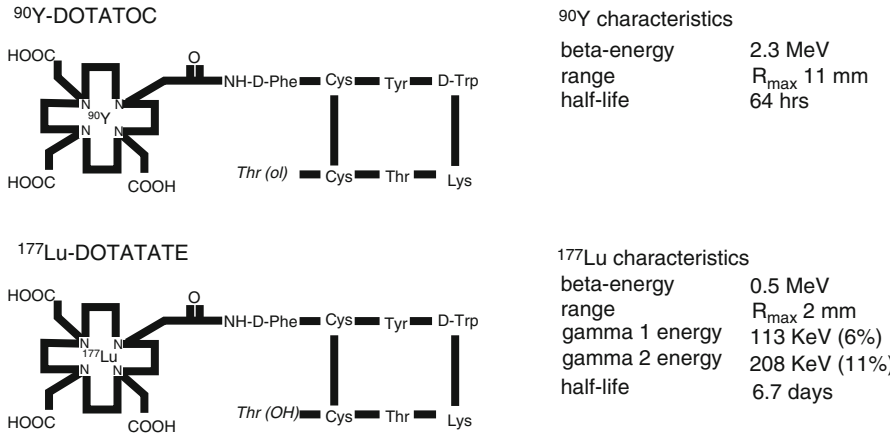

Fig. 4 Chemical structures of ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE, the most used radiopeptides for PRRT. Note the substitution of a natural Thr in the eight octreotide amino acid in ^{177}Lu-DOTATATE. This modification increases the affinity for the SSTR2 receptor by six to nine fold

intracellularly, especially in close proximity to (or within) the nuclear DNA. Incorporation of Auger electron emitters into the DNA is a particularly efficient source of irradiation, capable of inducing cell death with virtually no damage to the surrounding cells. However, nuclear translocation of radiolabelled somatostatin analogues has never been clearly demonstrated so far, and PRRT is currently performed primarily with β-emitters to maximize ionization in the region of the nucleus [56, 57].

The most widely used radiopeptides are ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE based upon their optimal pharmacokinetic considerations. Yttrium-90 has a higher β-particle emission compared to lutetium-177. The analysis of the residence times for DOTATATE and DOTATOC, calculated by means of the ^{177}Lu-labeled peptides, indicated that residence times for DOTATATE are significantly longer in kidney and tumor (ratios DOTATATE:DOTATOC = 1.4 and 2.1, respectively). This property enables the delivery of higher tumor doses although a similar increase in renal exposure occurs [58]. Based upon this consideration (higher tumor dose), ^{177}Lu appears of more benefit for labeling DOTATATE; while given the higher renal dose burden, ^{90}Y appears more useful in labeling DOTATOC.

A high expression of somatostatin receptors is a critical variable for determining the inclusion criteria of an individual for effective PRRT. As opposed to other treatments, the unique opportunity to identify and quantify the target (SSTR) prior to initiation of therapy informs the likelihood of success with PRRT [59]. Assessment of SSTR expression enables the possibility of quantification of the absorbed dose [32]. These values as well as the evaluation functioning somatostatin receptor overexpression can be accurately determined by somatostatin receptor imaging with either ^{111}In-pentetreotide or ^{68}Ga-SSA-PET/CT (Fig. 5). While immunohistochemistry for sst 2 can provide information on receptor status, it should be regarded as representing a "photographic image" taken at the moment of bioptic sampling and provides no information in respect of the actual internalizing capacity and the possible evolution with time of receptor density.

The development of molecular tools, such as transcript analysis of specific circulating NET mRNA signature, has demonstrated exciting possibilities in facilitating prediction of outcome (efficacy, tolerability). Such information is of considerable clinical utility in determining the most effective multidisciplinary sequencing of extensive and expensive therapies, particularly since conventional (morphologic/functional) imaging and biomarkers have been demonstrated to have substantial limitations in predicting effective therapy or defining progression and outcome. The

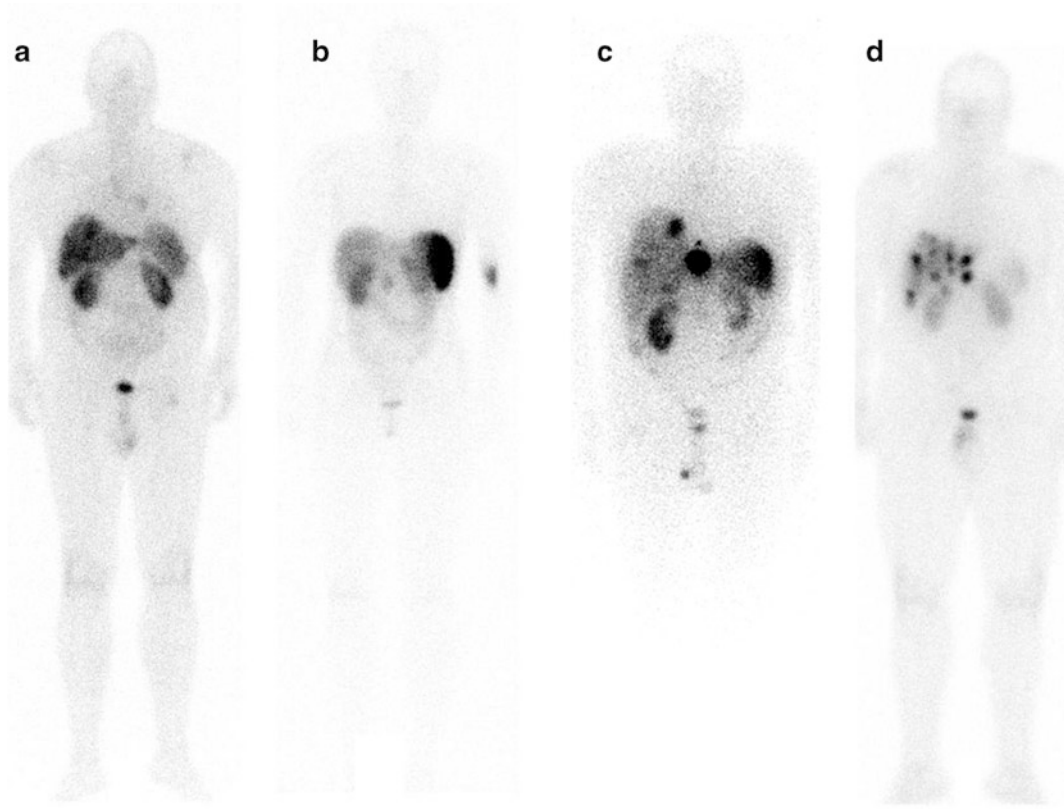

Fig. 5 Tumors candidates to PRRT are those with an uptake on planar images at least equal to the one of the normal liver (grade 1, image **b**), higher than that (grade 2, image **c**) or higher than the one of kidneys and spleen, the "hottest" organs at ^{111}In-pentetreotide scintigraphy (grade 3, image **d**)

introduction into clinical practice of measurement of circulating multianalyte 51-gene NET molecular signature has demonstrated significant advantage in early detection of residual disease of surgery-treated patient or in the assessment of somatostatin analogue response [60, 61]. Preliminary results indicate highly effective prediction of response to PRRT and accurate monitoring of therapeutic efficacy [62].

PRRT Safety

PRRT with either ^{90}Y-DOTATOC or ^{177}Lu-DOTATATE is generally extremely well tolerated, with modest toxicity to the target organs, such as the kidneys and bone marrow. Toxicity may be divided into acute, subacute, and long term. Acute side effects include mild nausea (25%), more rarely vomiting, related to the coadministration of renal protective amino-acid solutions, which is easily controlled or prevented by proper antinausea preparations, and abdominal pain (10%) [63]. Subacute effects comprise mild to moderate fatigue, depending also on the extent of disease, which is common in the 7–10 days following the therapy and mild (grade 1) alopecia, which is frequently reported after ^{177}Lu-DOTATATE [64]. The most common subacute side effect is hematologic toxicity, which is mild (WHO grades 1 or 2) and transient in 85–90% of patients [36]. Severe (grades 3 and 4) toxicity occurs in 10–15% of patients irrespective of the radiopeptide; however, this is usually reversible and rarely requires transfusion or granulocyte support [63, 65]. Chronic and permanent effects in the

kidneys and the bone marrow, such as renal function loss and reduction of bone marrow reserve, are rare and generally mild. The likelihood of such adverse events is significantly ameliorated if the necessary precautions, such as renal protection with amino acids and dosage adaptation to the clinical scenario, are undertaken. Secondary myeloproliferative diseases (myelodysplastic syndrome and leukemia) are extremely rare but have been noted [34, 38, 42, 64, 66, 67] (Table 2). Whether they represent a specific toxicity or susceptibility to an as yet unidentified genomic predisposition remains to be determined.

Renal Toxicity

The kidneys are considered the critical "at risk" organs in PRRT, particularly after ^{90}Y-DOTATOC administration. Proximal tubular reabsorption of the radiopeptide and the subsequent retention in the interstitium result in renal irradiation. Nephrotoxicity is increased in patients with preexisting long-standing and poorly controlled hypertension or diabetes. Given the high kidney retention of radiopeptides, positively charged molecules, such as L-lysine and/or L-arginine, are used to competitively inhibit the proximal tubular reabsorption of the radiopeptide. This leads to a reduction in the renal dose by 9–53% [70, 71] and can be further reduced by ~40% by prolonging infusion over 10 h and up to 65% by prolonging it over 2 days after radiopeptide administration. This time frame covers almost the entire renal elimination phase of the isotope [72, 73]. Kidney radiation toxicity is typically evident several months after irradiation due to the slow repair characteristics of renal cells (Fig. 6). The accepted renal tolerated dose is 23–25 Gy, as proposed by the National Council on Radiation Protection and Measurements (NCRPM). It has however more been determined that 23 Gy to the kidneys causes detrimental deterministic effects in 5% of patients within 5 years [75, 76].

Long-term evaluation of renal toxicity in a cohort ($n = 28$) undergoing PRRT with ^{90}Y-DOTATOC and dosimetric analysis showed that, of the 23 treated with ^{90}Y-octreotide, a low (28 Gy BED) threshold was observed with risk factors (mainly long-standing hypertension and/or poorly controlled diabetes), in comparison to 40 Gy in the absence of such risk factors [74]. These observations are consistent with the evidence that a higher and more persistent decline in creatinine clearance and the consequent development of renal toxicity are more likely to occur in the presence of preexisting risk factors [76]. The reason for the more frequent association of ^{90}Y-PRRT with renal function reduction is intrinsic to the specific physical characteristics of the ^{90}Y radionuclide, namely, the much more extensive intrarenal particle penetration.

In a retrospective series ($n = 1{,}109$) treated with ^{90}Y-octreotide, 103 subjects (9.2%) experienced grade 4–5 permanent renal toxicity [42]. Multivariate regression analysis indicated that the initial kidney uptake was predictive of severe renal toxicity. However, this relatively high

Table 2 Summary of long-term tolerability of PRRT with ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE

	Patients	Follow-up (months)	Renal toxicity	MDS	Acute leukemia	Reference
^{90}Y-octreotide	40	19	10% grade 1	0	0	[39]
	39	6	3% grade 2	0	0	[38]
	58	18	3% grade 4	1	0	[40]

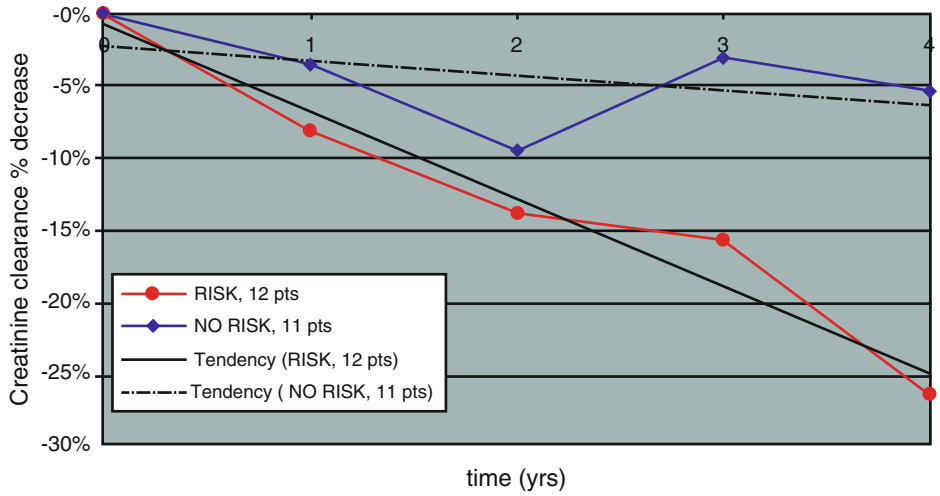

Fig. 6 The influence of risk factor on the course of renal parameters. Patients with risk factors for delayed renal toxicity (mainly longstanding and poorly controlled hypertension and diabetes) had more marked and persistent reduction in creatinine clearance and a lower bioeffective dose (BED) threshold for renal toxicity than did patients without risk factors (Adapted from Bodei et al. [74])

incidence was possibly related to the high administered activities per cycle (3.7 GBq/m^2 body surface, namely, activities of about 6.4 GBq per cycle in a standard male). In addition, subjects with preexisting impairment of renal function were not excluded from PRRT, and infusion of protective amino acids was not a routine procedure in the initial phases of the study [77].

Recently, the results of an analysis of long-term tolerability of PRRT ($n = 807$) treated with ^{90}Y-octreotide, ^{177}Lu-octreotate, or the combination (^{177}Lu, 34.4%; ^{90}Y, 44.4%; ^{177}Lu + ^{90}Y, 19.5%) have provided additional information on the issue of PRRT tolerability. The large numbers included in this analysis allowed clarification of the exact role for preexistent clinical parameters (such as diabetes, hypertension, and chemotherapy) in the determination of toxicity. Nephrotoxicity (transient and persistent) was detectable in 279 (34.6%) and was severe in 1.5%. ^{90}Y-peptides or the combination of ^{90}Y/^{177}Lu-peptides showed greater nephrotoxicity than ^{177}Lu-peptides alone. However, <30% of toxicities could be modeled by clinical parameters of which hypertension and anemia were identifiable as the most relevant risk factors. These results suggest that an individual susceptibility to radiation-associated disease, possibly of genetic origin, might play a determinant role [68].

An accurate assessment of glomerular filtration rate (GFR), as a measure of renal function (scintigraphic Gates' method), was carried out after PRRT ($n = 74$) with a median of 21 months (range 12–50) follow-up. The evaluation included potential risk factors, such as diabetes mellitus, hypertension, and chemotherapy. Results confirmed an alteration in GFR, with a relative yearly reduction of 1.8 ± 19%. Sixteen patients experienced a more pronounced reduction (>10 ml/min/year). However, toxicity was only evident in one. None of the described clinical factors, including the cumulative administered activity, contributed significantly to the decline of renal function [69].

Hematological Toxicity

PRRT is generally well tolerated. Hematologic toxicity is typically mild (WHO grades 1–2) and transient within few weeks from treatment completion. Severe, grade 3 or 4, toxicity may occur in <15% patients, with either ^{90}Y-DOTATOC or ^{177}Lu-DOTATATE, and are also generally

reversible within 2–3 months. In ~50% recovery may be longer (mean 12 months in a series of 203 ^{177}Lu-octreotate-treated patients) [63, 67]. Tumor diffusion in the bone marrow is a common feature in these cases [78]. PRRT is well tolerated, and severe, grade 3 or 4, hematological toxicity only occurred in <13% of patients treated with ^{90}Y-DOTATOC and ~10% of those treated with ^{177}Lu-DOTATATE (Table 2) [38–40, 43].

Sporadic cases of myelodysplastic syndrome (MDS) or even overt acute leukemia have been reported in ~2% [63]. Although predicted absorbed doses are lower than the conventional threshold for toxicity, both acute and permanent bone marrow damage remain a cause for concern, particularly when repeated radionuclide administrations are planned or the patients undergo several potentially myelotoxic treatments [36]. Dose-finding phase I studies indicate that the maximum cumulative administrable activity per cycle of ^{90}Y-octreotide, with renal protection, is 5.18 GBq, as determined by dose-limiting hematological toxicity [39]. Investigations employing the dose-limiting toxicity method were abandoned, since published data identified that 7.4 GBq could be safely used as a maximum activity per cycle [79]. This dosage was based on the experience of thyroid cancer therapy with ^{131}I, a radionuclide with physical characteristics similar to ^{177}Lu [65].

In data from a cohort with GEP-NENs ($n = 33$) treated in a salvage study, toxicity results were encouraging. Thus, re-treatment with median 18 GBq of ^{177}Lu-octreotate (two to four cycles, up to a median cumulative activity of 44.3 GBq: range 30–84) resulted in neither severe nephrotoxicity nor MDS during the follow-up (37 ± 16 months from initial PRRT and 23 ± 7 months from the start of salvage PRRT) [80].

An analysis of 203 patients treated with four intended cycles of 8 GBq each at 3-month intervals included the assessment of risk factors, including bone metastases, chemotherapy, or cumulative administered activity. The incidence of MDS was 1.4%. Myelosuppression was almost invariably reversible, and the cumulative administered activity and initial cytopenia were identified as the most important risk factors for myelotoxicity [67].

An analysis of a large group of 807 subjects treated with ^{90}Y-octreotide, ^{177}Lu-octreotate, or the combination showed that MDS occurred in 2.35%. This study also noted that commonly considered risk factors, such as prior chemotherapy, were associated with toxicity in up to 30%. Associated clinical features, such as platelet toxicity grade and the increasing duration of PRRT, were relevant. This led to speculation that unidentified individual susceptibilities, presumably of a genetic basis, could better explain the radiation-associated disease at the low marrow doses commonly obtained with PRRT [68].

Recent studies demonstrated that ^{177}Lu-octreotate can be safely utilized even in the presence of diffuse bone metastases, with severe bone replacement and potential elevated exposure of bone marrow. Significant G3/G4 reversible hematological toxicity occurred in 35% ($n = 4$) of 11 patients. Toxicity either resolved spontaneously ($n = 1$) or was controlled by support therapy ($n = 3$). A return to baseline values was obtained in 23 months after completion of PRRT [81].

Dosimetry in PRRT

Measuring the radiation burden to normal organs and malignant lesions is necessary to select the appropriate dose for therapy. The potential risk of kidney and red marrow toxicity limits the amount of radioactivity that may be administered. Indeed, when tumor masses are irradiated with suitable doses, volume reduction may be observed [82].

Techniques for radio-dosimetric estimates are illustrated in detail in ▶ Chap. 13, "Radiobiology and Radiation Dosimetry in Nuclear Medicine" of this book. Briefly, they include the generation of time–activity curves in normal organs and tumor lesions, based on data obtained from serial images recorded using a diagnostic activity of ^{111}In-pentetreotide or ^{86}Y-DOTATOC PET for ^{90}Y-DOTATOC PRRT or with ^{177}Lu-DOTATATE directly [83, 84] (Table 3).

Radiation dosimetry of normal organs and malignant lesions provides an insight for optimizing the delivery of radiation, allowing

Table 3 Absorbed radiation dose estimates following PRRT with ^{90}Y-DOTATOC and ^{177}Lu-DOTATATE. Values are organ absorbed doses per unit activity (Gy/GBq); mean ± SD or median (range)

maximization of the absorbed dose to the tumor while minimizing the dose delivered to normal organs. Absorbed doses are largely dependent on the administered activity, radionuclide used, and individual organ mass. Absorbed or biological effective doses in organs are calculated from the spatial activity distribution of the radionuclide as a function of time. This distribution is obtained from planar scintigraphy, SPECT/CT, or PET/CT images. The computer codes used to derive the dose vary from a simple and reproducible method based on standard phantoms, such as MIRD, OLINDA, which may not necessarily represent the organ anatomy of a single individual, to accurate but complicated and time-consuming codes utilizing personalized Monte Carlo simulations [91, 92].

Dosimetry is an obligatory procedure in planning external radiotherapy, yet the prediction of the dose–response relationship in nuclear medicine therapy remains inaccurate. This is due to the large variability in the individual organ volume, diversity of biodistribution and tumor uptake among individuals, the lack of uniform tissue distribution of the radioactivity, the inaccuracy of the absorbed dose to the kidneys in predicting renal toxicity, and, finally, the difficulty in modeling organs such as the bone marrow. These variables when summated render the accurate prediction of toxicity difficult [83, 93]. As a consequence, dosimetry is not widely performed, and skepticism among clinicians is pervasive. However, dosimetry is the only form of personalization that takes into account the actual radiation dose – namely, the effector of the desired effect – delivered to the target tissue and therefore represents a worthwhile area for development and its refinement.

The initial clinical studies that assessed the individual tolerance to radiopeptides identified clinical factors that could modify the renal dose threshold for radiopeptides, suggesting a consequent modification of the PRRT schedule [74]. Subsequently, based on the conventional dose thresholds of tolerance of the bone marrow and kidneys, Sandström et al. demonstrated that the same scheme of PRRT (four cycles of 200 mCi each of ^{177}Lu-octreotate) could result in different absorbed doses at the targets. Thus conversely, a substantial number of patients could tolerate higher cumulative activities or number of cycles – hence higher tumor doses and, potentially, efficacy. On the contrary a not irrelevant number of patients could tolerate lower cumulative activities

or number of cycles – possibly inefficient to control the tumor [94]. This represents a major step toward a dosimetry-based personalized treatment.

PRRT Efficacy

Experience with ^{111}In-Octreotide

Objective responses were rare due to the short range of the emission (0.0025 μm) of the particles. Among 40 patients treated with cumulative doses of 20–160 GBq, 1 partial remission, 6 minor remissions, and 14 stabilization of disease were reported. Mild hematological toxicity was observed, but three cases of myelodysplastic syndrome (MDS) or leukemia occurred in those treated with high activities (>100 GBq) and high estimated bone marrow doses (about 3 Gy). In a separate GEP-NETs study ($n = 27$), partial responses occurred in 2 of 26 patients with measurable disease. Renal insufficiency was reported in one patient, although possibly not treatment-related [54, 95].

Experience with ^{90}Y-DOTATOC

GEP-NET Tumors

All the published results derive from phase I to II trials and reflect heterogenous patient selection, inclusion criteria, treatment schemes, and dosages (cumulative activities ranged from 2 to 32 GBq). This has diminished the ability to derive rigorous conclusions. Complete and partial remissions were registered in 10–30% of patients, a higher rate than that obtained with ^{111}In-pentetreotide (~5%). In the initial report, 29 persons were treated with a dose-escalation scheme consisting of four or more cycles of ^{90}Y-DOTATOC with cumulative activities of 6.12 ± 1.35 GBq/m^2. Twenty showed disease stabilization, two had partial remission, four had minor remission, and three progressed [96]. In a subsequent study ($n = 39$) four equal intravenous injections were administered with a total of 7.4 GBq/m^2 of ^{90}Y-DOTATOC. The objective response rate was 23%, with complete remission in 2, partial remission in 7, and stabilization in 27. Pancreatic NETs ($n = 13$) exhibited a higher objective response rate (38%). A significant reduction of clinical symptoms was recorded in 83% of patients with diarrhea, in 46% of patients with flushing, in 63% of patients with wheezing, and in 75% of patients with pellagra [38]. Toxicity was generally mild and involved the kidney and the bone marrow. However, renal insufficiency was reported in five individuals who did not receive renal protection during the therapy. Severe hematological toxicity occurred in individuals receiving high cumulative activities [72].

In cohorts receiving up to an administered activity of 5.55 GBq per cycle, reversible grade 3 hematological toxicity was noted in 43% of patients injected with 5.18 GBq, which was defined as the maximum tolerated dose per cycle. None developed acute or delayed kidney toxicity, although follow-up was short. Partial and complete responses were reported in 28% of 87 patients with NETs [39].

In the multicenter phase 1 study, 60 patients received escalating activities of up to 14.8 GBq/m2 in four cycles or up to 9.3 GBq/m^2 in a single dose, without reaching the maximum tolerated single administration. All patients received renal protection. Three patients suffered dose-limiting toxicity: one with hepatic toxicity, one grade 4 thrombocytopenia, and one MDS. Four of 54 patients (8%) treated with the maximum allowed dose underwent a partial response, and 7 patients (13%) had minor responses. The median time to progression in the 44 patients showing stable disease, minor or partial response, was 30 months [97].

A multicenter study evaluated the role of ^{90}Y-octreotide in 90 patients with symptomatic, metastatic "carcinoids" (small bowel NENs). The data identified stabilization of tumor response (SWOG criteria) in 74% as well as a durable amelioration of symptoms related to the tumor mass and the hypersecretion of bioactive amines [41]. This trial reported a PFS of 16 months and an overall survival of 27 months.

Figure 7 illustrates an example of objective response to ^{90}Y-DOTATOC in a patient affected by gross liver metastases from a resected pancreatic insulinoma treated with 23 GBq in seven cycles.

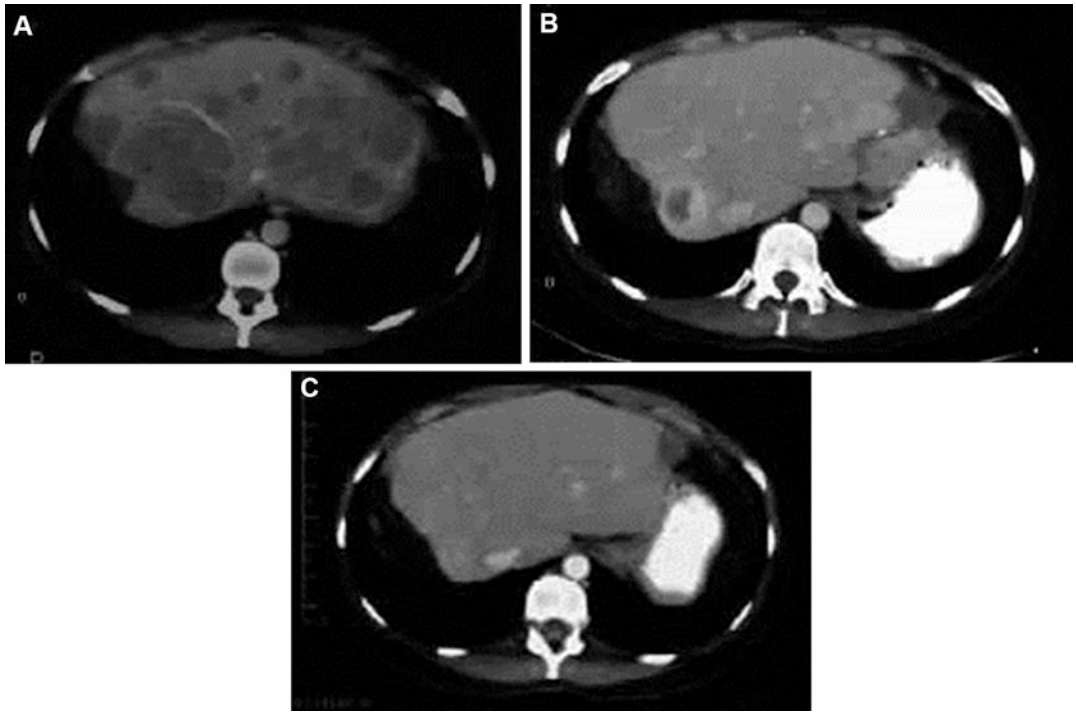

Fig. 7 Illustrates an example of objective response to ^{90}Y-DOTATOC in a patient affected by massive liver metastases from a resected insulinsecreting pancreatic neuroendocrine tumor after treatment, treated with ^{90}Y-DOTATOC (23 GBq in seven cycles) (**a**–**c** CT scans)

In respect of survival after ^{90}Y-DOTATOC, a phase I–II study of GEP-NETs ($n = 58$) treated with 1.7–32.8 GBq reported a clinical benefit (including stabilization and minor response) in 57% (with true objective response in 20%), a median overall survival of 36.7 months (vs. 12 months in the historic group treated with ^{111}In-pentetreotide), and a median progression-free survival of 29.3 months. Characteristically, patients stable at baseline had a better overall survival than those progressive at baseline, while the extent of disease at baseline was an additional predictive factor for survival [40].

A favorable clinical response after ^{90}Y-DOTATOC, as determined by a scoring system that included weight, patient-assessed health score, Karnofsky score, and tumor-related symptoms, was reported in 14/21 patients who were treated with 13.3 GBq in three cycles [98].

More recently, the Basel group published the results of an open-label phase II trial in 1,109 patients with different NET lesions (GEP, BP, and other endocrine tumors, such as medullary thyroid cancer, paraganglioma, and neuroblastoma) treated with ^{90}Y-octreotide, divided into multiple cycles of 3.7 GBq/m^2 each. Objective morphologic responses (RECIST criteria) were observed in 378 (34.1%), biochemical responses in 172 (15.5%), and symptomatic responses in 329 (29.7%). In this series, the NEN groups were 265 small bowel and 342 pancreatic tumors. The rates of objective response were 26.8% and 47%, respectively. A longer survival was correlated with tumor and symptomatic response. The best predictor of survival was tumor uptake at baseline determined by OctreoScan® [42].

Other Endocrine and EndocrineRegulated Tumors

Limited experiences in the treatment of medullary and follicular thyroid carcinomas, lymphoproliferative disorders, pheochromocytomas, and paragangliomas have been reported. ^{90}Y-DOTATOC (7.5–19.2 GBq in two to eight

cycles) was administered to 21 patients with metastatic medullary thyroid carcinoma with positive OctreoScan®, progressive after conventional treatments. Two patients (10%) obtained a complete response (CR), as evaluated by CT, MRI, and/or ultrasound, while a stabilization of disease (SD) was observed in 12 (57%); 7 (33%) failed to respond to therapy. The duration of the response ranged from 3 to 40 months. Using biochemical parameters (calcitonin and CEA), a complete response was observed in one patient (5%), while partial response occurred in five (24%) and stabilization in three (14%). Twelve had progression (57%). Complete responses were observed in those with lower tumor burden and calcitonin values at the time of the enrolment. Medullary thyroid cancers showed a lower response rate compared to classic GEP-NETs; nevertheless, patients with smaller tumors and higher uptake of the radiopeptide tended to respond better [99].

In a phase I study involving 17 children and young adults (2–24-year-old) affected by SSTR-positive tumors (including neuroblastomas, MEN2B, and gliomas), patients were treated with ^{90}Y-DOTATOC (1.1–1.85 GBq/m^2 per cycle for a total of three cycles, administered 6 weeks apart). Partial response according to the Pediatric Oncology Group criteria was observed in 12%, while 29% exhibited minor responses; the most obvious clinical benefit was overall improved quality of life. Thus, PRRT with ^{90}Y-DOTATOC is effective and well tolerated also in young patients [100].

Experience with ^{177}Lu-DOTATATE in GEP-NETs

The somatostatin analogue [DOTA^0, Tyr^3, Thr^8]-octreotide or DOTATATE has a ninefold higher affinity for the SSTR2 compared with [DOTA^0, Tyr^3]octreotide in vitro. Radiolabeling with the β/γ-emitter lutetium-177 yielded tumor regressions and prolonged animal survival in a rat model [55]. The compound ^{177}Lu-octreotate was thereafter investigated in several clinical phase I and II studies [43, 44, 101, 102] and shown to have enhanced efficacy and greater manageability, due to a lower dosimetric burden to the kidney. An additional advantage is provided by the possibility of obtaining both scintigraphic images and dosimetric studies simultaneously since ^{177}Lu exhibits gamma photon co-emission. Currently this compound represents the most frequently used radiopeptide for PRRT.

In a preliminary report by the Rotterdam group, GEP-NETs ($n = 35$) were treated with 3.7, 5.6, or 7.4 GBq of ^{177}Lu-DOTATATE per cycle, up to a final cumulative activity of 22.2–29.6 GBq. Complete and partial responses were noted in 38% with no serious adverse events observed [79].

In a larger study ($n = 131$) of somatostatin, receptor-positive tumors were treated up to a cumulative activity of 22.2–29.6 GBq of ^{177}Lu-DOTATATE. One developed renal insufficiency, and another hepatorenal syndrome. Severe hematological toxicity occurred in <2% of the administrations. In the 125 evaluated patients, complete remission was observed in 3 (2%), partial remission in 32 (26%), minor response in 24 (19%), and stable disease in 44 (35%), while 22 (18%) progressed. Better responses were more frequent in the case of a high uptake on baseline OctreoScan® scintigraphy and when a limited number of liver metastases were present, while progression was significantly more frequent in those with a low performance score and extensive disease at enrollment. Median time to progression was more than 36 months, comparing favorably to chemotherapy. A categorization of objective response showed again that pancreatic tumors tended to respond better than other GEP tumors, although pancreatic gastrinomas tended to relapse in a shorter interval (median TTP 20 months vs. >36 in the rest of GEP tumors). In addition, ^{177}Lu-DOTATATE significantly improved the global health/QoL and various function and symptom scales in individuals with metastatic disease. The effect was more frequent in patients obtaining tumor regression but, surprisingly, was observed also in progressing patients [51, 103]. Of note was the fact that there was no significant decrease in QoL in individuals asymptomatic prior to therapy [52].

An enlargement of the previous series to 504 subjects treated with ^{177}Lu-DOTATATE was undertaken. Efficacy was evaluated in 310, along

with the confirmation of the occurrence of complete and partial remissions in 2 and 28% of cases, demonstrated a survival benefit of 40–72 months, compared to historical controls treated with chemotherapy. Reported prognostic factors for predicting tumor remission (CR, PR, or MR) as treatment outcome were uptake on the OctreoScan® ($P < 0.01$) and Karnofsky performance status (KPS) > 70 ($P < 0.05$). The degree of uptake at OctreoScan® is crucial and can be regarded roughly as a surrogate of the future absorbed dose provided by the therapy. Response benefit was more frequent in individuals with limited liver involvement and a high uptake on baseline ^{111}In-pentetreotide scintigraphy. Conversely, progression was significantly more frequent in those with a low performance score and extensive disease at enrolment. Categorization of objective responses identified that pancreatic NENs tended to respond better than other GEP-NENs and that functioning tumors, e.g., pancreatic gastrinomas, tended to relapse after a shorter interval (median time to progression 20 months vs. >36 in the remaining GEP-NENs) [43].

Figure 8 illustrates an example of objective response in a patient with liver and bone metastases from ileal neuroendocrine carcinoma treated with ^{177}Lu-DOTATATE (24 GBq in five cycles).

It is interesting to note that a small proportion of patients, responding to PRRT with either SD or mixed response at the first evaluation 3 months after therapy completion, showed a further objective response at 6 and 12 months of follow-up [43]. These observations allow speculation on the possible radiobiological implications, such as a "bystander effect," triggered by the low dose rate, protracted irradiation of lutetium-177.

The results of a phase I–II escalation dose study aimed at defining toxicity and efficacy of ^{177}Lu-octreotate were published in 2011 [44]. A cohort ($n = 51$) with unresectable/metastatic NENs, mainly of GEP origin, were divided into two dosage groups. One group received escalating activities, from 3.7 to 5.18 GBq and the second from 5.18 to 7.4 GBq, with dosimetry-based cumulative activities up to 29 GBq. Partial and complete responses were observed in 15 (32.6%). The median time to progression was 36 months, with an overall survival of 68% at 36 months. Nonresponders and patients with extensive tumor involvement were noted to have a lower survival [44].

Efficacy in Skeletal Involvement

It was generally considered, at the beginning of the PRRT experience, that bone metastases were less responsive to PRRT and that therefore these patients should receive additional therapies to treat skeletal locations. Despite the fact that neither SWOG nor RECIST criteria however include the evaluation of bone metastases, more recent studies indicate that PRRT is efficient in bone metastases. In a retrospective series ($n = 68$) treated with ^{177}Lu-octreotate (four intended cycles, 8.1 GBq each, at 3-month intervals; followed up for a median of 48 months). The observed objective response rate was comparable to other studies of PRRT in GEP-NENs, with 2.9% and 33.8% complete and partial responses, respectively. The median PFS was 35 months. Individuals with PRRT-responsive bone metastases exhibited longer overall survivals (median 56 vs. 39 months). In this group, high neuron-specific enolase (NSE) values and Ki67 > 10% were associated with a shorter overall survival. Of note was the observation that Karnofsky performance status and multifocal bone metastatic disease did not limit the efficacy of PRRT [104].

Efficacy in Different Types of NETs

Pancreatic NETs

Recent advances on pathobiological and molecular genomics have indicated that pancreatic and small intestine NETs are two separate entities. Therefore, current studies have tended to address the role of PRRT in single-system pathologies.

A prospective phase II study used ^{177}Lu-octreotate in a cohort ($n = 52$) with advanced well-/moderately differentiated pancreatic NETs. Based on the reported existence of putative risk factors for renal toxicity (hypertension and diabetes), patients were divided into two groups treated with different levels of activity. Thus, a full dose (21–28 GBq) was compared to a reduced dose

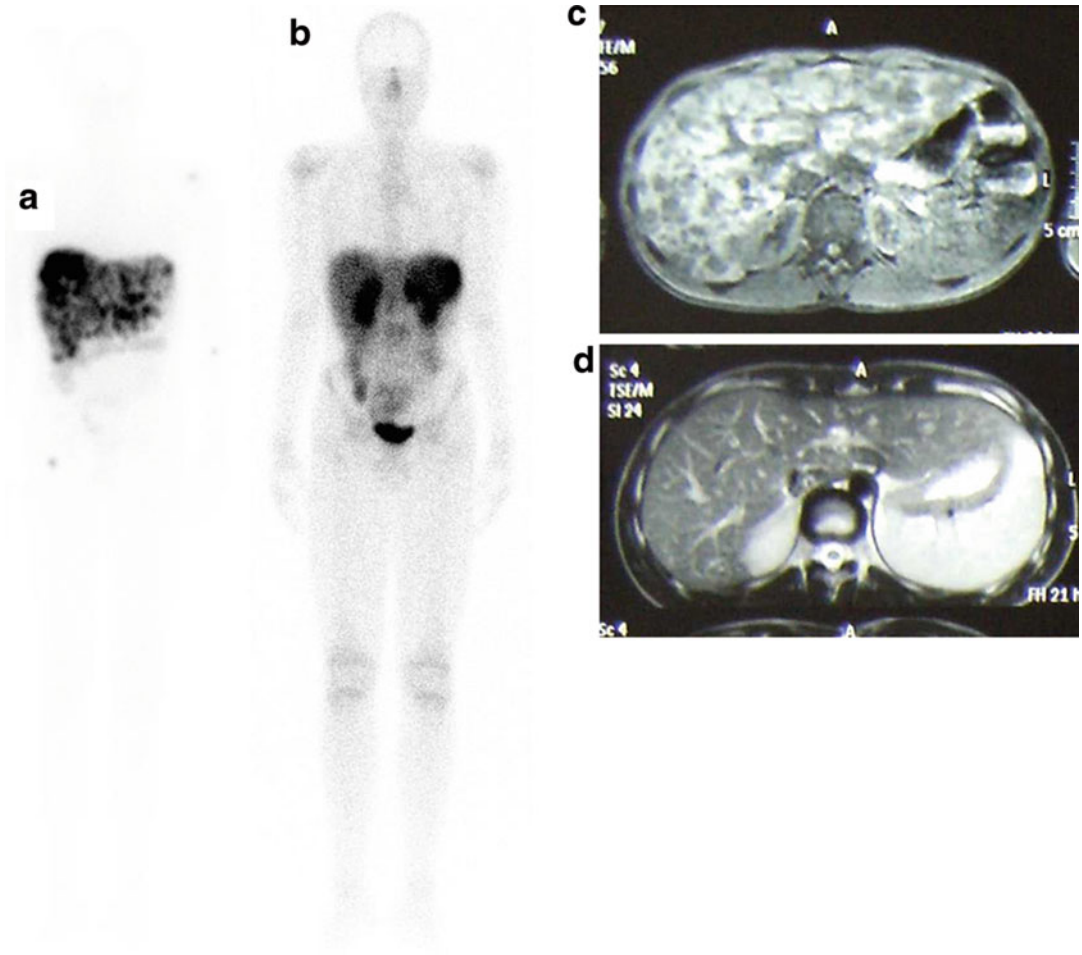

Fig. 8 Serial functional and morphologic imaging in a young male patient affected by liver and bone metastases from ileal neuroendocrine carcinoma treated with ^{177}Lu-DOTATATE (24 GBq in five cycles). Basal evaluation (**a** ^{177}Lu-DOTATATE scintigraphy; **c** MRI) showed extensive liver involvement. Final evaluation (**b** ^{177}Lu DOTATATE scintigraphy; **d** MRI) showed an almost complete response

(11–20 GBq) for a normal and risk subset of subjects, respectively. Both regimens resulted in antitumor efficacy. PFS was not reached at the time of the analysis in the cohort treated with the full-dose regimen, while it was 20 months in individuals treated with a reduced dose. This suggests the full-dose scheme should be recommended, when possible [45].

A recent retrospective study evaluated a cohort with metastatic pancreatic NENs ($n = 68$, 52% at their first systemic treatment) treated with ^{177}Lu-octreotate (four intended cycles, 8 GBq each, at 3-month intervals). In this group 68% were in progression at enrolment. Partial responses were noted in 60%, with a median PFS of 34 months. Multivariate analysis indicated that G1 tumors had a longer PFS. Reduced performance status (KPS $\leq$ 70), a high liver burden ($\geq$25% of volume), and increased NSE (>15 ng/ml) were associated with a poorer prognosis [56]. To better define the predictors of long-term outcome, the same group undertook a multivariate analysis in a cohort of metastatic GEP-NENs ($n = 74$) who had previously undergone PRRT with

^{177}Lu-octreotate (four cycles, 7.9 GBq each, at 3-month intervals). A Ki67 index >10%, a Karnofsky performance status ≤70, a tumor burden in the liver ≥25%, and a baseline NSE >15 ng/ml were independent predictors of shorter survival. However, even individuals with Ki67 > 10% benefited from PRRT, with a median PFS of 19 months as opposed to 26 months for the entire cohort [102].

A separate study by van Vliet E et al. considered non-resectable or borderline resectable or oligometastatic (≤3 liver metastases) non-functioning pancreatic NETs ($n = 29$). This group was treated with ^{177}Lu-octreotate with neo-adjuvant intent. After PRRT, successful surgery could be undertaken in nine individuals (31%) [Whipple procedure ($n = 6$), pylorus-preserving pancreaticoduodenectomy ($n = 1$), and splenopancreatectomy ($n = 1$)]. PFS was significantly longer in those in whom surgery could be undertaken (69 vs. 49 months). A further comparison with 90 plurimetastatic subjects treated in the same fashion provided a PFS of 25 months [105]. This study supports the proposal of early treatment and the possibility of downstaging tumors with PRRT.

Small Intestinal NETs

A phase II study of PRRT in progressive G1-G2 tumors ($n = 43$) from the Meldola group applied the same principle of reducing cumulative activities (median 25.7 vs. 18.4 GBq) in patients at risk for delayed renal or hematological toxicity. Both activities proved to be safe and effective (84% disease-control rate (SWOG criteria) and PFS of 36 months) in all. Of note is the observation that [^{18}F]FDG-PET-negative patients exhibited a significantly longer PFS than those with an [^{18}F]FDG-positive scan [47].

A more recent study by the Bonn group utilized the standard approach and described the benefit of ^{177}Lu-octreotate in a uniformly treated group (four cycles of 7.9 GBq each). The cohort ($n = 61$) included unresectable small intestine tumors, in progression or with uncontrolled symptoms, which were treated and followed for 62 months. Disease control rate was 91.8% (SWOG criteria). Median PFS was 33 months, OS was 61. Objective response was significantly associated with longer survival. Independent predictors of shorter PFS were functionality and high plasma CgA levels >600 ng/mL at baseline [48].

The recent phase III study of small intestine NETs using ^{177}Lu-DOTATATE named NETTER-1 was undertaken by a bicontinental multicentric group sponsored by Advanced Accelerator Applications (AAA). This randomized trial compared ^{177}Lu-DOTATATE vs. high-dose octreotide in patients with inoperable, progressive, midgut carcinoid tumors. Preliminary results indicate that ^{177}Lu-octreotate significantly improves PFS (PFS not reached vs. 8.4 months; hazard ratio 0.21) [49].

Efficacy of Repeated Treatments: Salvage Therapy

The Rotterdam group published the results of salvage therapy with ^{177}Lu-DOTATATE in NET patients with progressive disease after initial response to PRRT with the same agent administered with cumulative activities of 22.2–29.6 GBq. A total of 32 patients received two additional cycles of ^{177}Lu-DOTATATE totaling 15 GBq, with ensuing new objective response in 8 (two partial and six minor responses) and stabilization of disease in 8; median time to progression in those responding was 17 months. Although the rate of response was lower than that observed after primary treatment and tumor response lasted for shorter periods, salvage therapy represents a valuable option in individuals with advanced disease, who have relapsed after responding to a first course of PRRT [106].

A more recent analysis by the Meldola group included 26 subjects in progression after an initial treatment with ^{90}Y-octreotide. All patients had preserved kidney and hematological parameters and received an intended cumulative activity of 14.8–18.5 GBq of ^{177}Lu-octreotide in four or five cycles. Disease control rate was 84.6%, the median PFS 22 months (95% CI 16 months – not reached) and was comparable to that obtained after ^{90}Y-octreotide (28 months; 95% CI 20–36 months). Tumor burden and number of liver metastases were significant negative prognostic factors [107].

Efficacy of PRRT in Combination with Chemotherapy or Biomolecular Agents

This concept is consistent with recent combinatorial therapeutic trends in oncology. A variety of different studies have demonstrated feasibility and efficacy. However, adequately powered, optimally randomized, and rigorously analyzed studies are required to define the exact benefit of this approach.

A phase II study of NET patients with progressive disease ($n = 33$) used a regimen including four cycles of ^{177}Lu-DOTATATE (7.8 GBq) plus the radiosensitizer chemotherapy agent capecitabine (1,650 mg/m^2), for the following 2 weeks. No additional toxicity was observed, while objective response (according to RECIST criteria) was achieved in 24%, stable disease in 70%, and disease progression in 6% [108].

A more recent adaptation of the chemo-radiotherapy protocol utilized 5-fluorouracil (5-FU) as opposed to its oral prodrug capecitabine. A retrospective analysis of patients with progressive disease ($n = 68$) or uncontrollable symptoms from NETs reported that the combination strategy (median cumulative activity of ^{177}Lu-octreotate 31 GBq and 200 mg/m2/24 h 5-FU, from 4 days before to 3 weeks after PRRT cycle 2–4) resulted in 70% benefit for at least 6 months for symptomatic patients and 68% disease-control rate in progressive disease. Non-pancreatic primary site, dominant liver metastases lesions <5 cm, and the use of 5-FU were associated with objective response [109].

A combination of ^{177}Lu-octreotate with capecitabine and temozolomide was studied in a phase I–II trial of advanced low-grade NETs ($n = 35$), with the aim of evaluating safety and efficacy. Standard dosages (7.8 GBq) of ^{177}Lu-octreotate every 8 weeks were combined with 14 days of capecitabine 1,500 mg/m2 and, in successive cohorts, to escalating doses of temozolomide (100, 150, and 200 mg/m^2 in the last 5 days of each capecitabine cycle). Treatment was well tolerated without dose-limiting toxicities. Complete responses were observed in 15%, partial response in 38%, and stable disease in 38%. Responses tended to be higher in gastropancreatic than in small intestine primaries. Median PFS was 31 months [110].

An alternative combination phase I study evaluated the combination of everolimus with ^{177}Lu-octreotate in subjects with advanced GEP-NETs ($n = 16$). Standard PRRT (four cycles of 7.8 GBq each) was administered in cohorts of patients receiving escalating doses of everolimus (from 5 to 10 mg daily for 24 weeks). The maximum tolerated dose of everolimus was 7.5 mg (hematological and renal toxicity). The overall response rate was 44%, with no progression over the period of treatment. The optimal response occurred in pancreatic NENs, where four of five patients achieved 80% reduction of disease [111].

Efficacy of Combinations of ^{90}Y- and ^{177}Lu-Peptides

Protocols combining both ^{177}Lu- and ^{90}Y-peptides have been assessed with the purpose of exploiting the different physical properties of each radionuclide. Theoretically, this approach should result in a synergistic effect and allow simultaneous treatment of both large lesions (exploiting the higher energy and penetration range of the particles emitted by ^{90}Y) and small lesions (exploiting the lower energy and penetration range of ^{177}Lu). Combined ^{90}Y- and ^{177}Lu-PRRT was undertaken in a Danish cohort of 69 subjects treated in Basel. Complete responses were noted in 5 (7.4%), partial remissions in 11 (16.2%), and stabilization in 42 (61.8%). The median PFS was 29 months. Pancreatic NENs responded better than small bowel tumors [66]. However, to ascertain if this strategy is advantageous in terms of response and tolerability over more conventional PRRT protocols, validation is required in adequately powered and randomized trials with long-term follow-up, rather than empirically designed single-armed ^{177}Lu and ^{90}Y protocols [112, 113].

Conclusions

PRRT has become a well-established effective therapeutic modality for inoperable or metastatic GEP, bronchopulmonary, and other NETs over the last two decades. Experience with ^{90}Y-octreotide and ^{177}Lu-octreotate from phase I to II studies and

the preliminary results of the phase III studies in intestinal NETs suggest antitumor activity and a consistent survival benefit. PRRT is overall well tolerated by the majority with only moderate toxicity if the necessary precautions are undertaken. The two most commonly used radiopeptides, ^{90}Y-octreotide and ^{177}Lu-octreotate, produce significant objective response rates, with positive impact on PFS and OS. In addition, both biochemical and symptomatic responses are commonly observed. Molecular analysis of nephro- and hematotoxicity genes in cohorts of treated patients is likely to further improve the prediction of toxicity [36].

Neuroendocrine Tumors: Therapy with ^{131}I-MIBG

44

Jorge A. Carrasquillo and Clara C. Chen

Abstract

Metaiodobenzylguanidine (MIBG) is an analog of guanethidine which has been used for imaging a variety of neuroendocrine tumors (NETs). While ^{131}I-MIBG is approved by the FDA for imaging, it is not yet approved for therapy, whereas it is approved for therapy by the EMA. Thus, in the United States ^{131}I-MIBG used for therapy trials is either made in accordance with USP regulations or used under an investigational new drug application (IND).

Procedure guidelines for the use of ^{131}I-MIBG in therapy have been published. ^{131}I-MIBG is used mostly to treat pheochromocytoma/paraganglioma (PHEO/PARA), carcinoid tumors, and neuroblastoma. Preparation of patients prior to treatment with ^{131}I-MIBG includes discontinuing therapy with drugs known to interfere with uptake of MIBG by tumor cells and blocking thyroid uptake of radioiodine. Because patients may have nausea and vomiting after administration of MIBG, antiemetics are often administered prior to therapy and in the first 3 days post-administration. To minimize the bladder dose, hydration is encouraged. Candidates for ^{131}I-MIBG therapy should have a reasonable performance status and a life expectancy of at least 3 months. Acceptable hematopoietic parameters are required prior to MIBG therapy. There are no uniform guidelines for selecting or excluding patients from consideration for ^{131}I-MIBG therapy. Most investigators require tumor localization on a diagnostic MIBG scan. Other selection criteria often include evidence of disease progression or symptoms.

^{131}I-MIBG is administered i.v. by pump through a plastic indwelling catheter or central line. Slow administration is a precaution to minimize pharmacologic effects from the unlabeled MIBG. There is no standard activity for therapy. Most studies use fixed activities based on empirical evidence of limited toxicity. Others have used fixed activities adjusted to body weight based on dose escalation studies. Some studies use estimates of dose to radiosensitive organs to define a safe upper limit.

Response assessment may be performed as early as 2 months, but more frequently at 3–6-month intervals unless the patient is known to have fast-growing disease. Follow-up typically involves anatomic and functional imaging with ^{123}I-MIBG or [^{18}F]FDG. The frequency of retreatment is variable, ranging from every 4 weeks to every 6 months.

PHEO/PARA are tumors that originate in the chromaffin tissue of the adrenal medulla and sympathetic nervous system and often secrete catecholamines. Some PHEO/PARA are related to genetic defects and are associated with an increased incidence of malignant and/or extra-adrenal disease. The lymph nodes, bone, liver, and lung are the most common sites of metastases.

The optimal therapy for PHEO/PARA consists of surgical resection when feasible. In patients in whom a surgical cure is not possible, chemotherapy regimens have been developed. However, given the often suboptimal response to chemotherapy, other therapeutic modalities such as ^{131}I-MIBG are now being applied. Although many patients benefit from ^{131}I-MIBG treatment, complete response rates are low. It appears that the response of soft tissue disease to MIBG therapy is superior to that of bone and that patients with smaller volume disease are more likely to respond than those with high-volume disease. Biochemical catecholamine response has often been reported after treatment. Responses vary in duration, with reported 5-year survivals between 45% and 85%. Low-, medium-, or high-dose activities of ^{131}I-MIBG have been used in PHEO/PARA, but there have been no systematic comparisons between these groups. However, there is some evidence that higher activities $>$500 mCi or myeloablative regimens are associated with higher response rates. The use of high specific activity ^{131}I-MIBG for therapy seems to reduce acute side effects. Few data have been published regarding combined chemotherapy with ^{131}I-MIBG therapy in this patient group.

Carcinoids are slow-growing NETs that often secrete substances leading to hormonal syndromes. The most frequent sites for carcinoids are the gastrointestinal tract (73.7%) and the bronchopulmonary system (25.1%).

Initial staging and follow-up relies on CT and MRI to evaluate for nodal and metastatic liver disease. Imaging with ^{111}In-pentetreotide or, more recently, with ^{68}Ga-somatostatin analogs is performed. Scintigraphy with ^{123}I-/^{131}I-MIBG is also often performed and a published review reported a sensitivity of 70%. At presentation, the best management is surgical resection, or in cases with metastatic disease, debulking for palliation. Unfortunately, metastatic disease at presentation is frequent, and no consistently effective therapeutic strategies are available. Symptomatic tumor response is often seen following therapy with cold octreotide analogs, whereas objective tumor regression is rare. Interferon may also result in symptomatic improvement. Multiple chemotherapy regimens have been utilized with none showing objective tumor responses greater than 15%. The uptake of ^{131}I-MIBG in carcinoid led to the use of this radiopharmaceutical therapeutically. Recently, radiolabeled octreotide analogs have recently been utilized and shown a higher overall accumulation in carcinoids than MIBG.

Although carcinoid patients rarely have a complete response to ^{131}I-MIBG therapy, objective response rates of 11–27.5% and symptomatic response rates ranging from 38% to 92% have been reported. Biochemical responses are less common. Median 5-year survivals of 42–78% have been reported after ^{131}I-MIBG therapy in carcinoid. Initial single activities of $>$14.8 GBq (400 mCi) have been recommended to improve survival and symptomatic improvement. Studies combining ^{131}I-MIBG with chemotherapy or biologic therapy are rare.

Neuroblastoma is a tumor that arises from primordial neural crest cells and is almost exclusively found in infants and young children. It is the most common tumor of childhood. Therapy relies on induction chemotherapy, surgery, and radiotherapy (given that this is a radiosensitive tumor), followed by consolidation of remission with autologous stem cell transplant (ASCT) or *cis*-retinoic acid with or without antibody immunotherapy. High-risk patients often relapse and are resistant to conventional therapy. ^{131}I-MIBG therapy has been utilized as first-line therapy, combined with chemotherapy or biologic therapy for consolidation, and as palliative therapy for patients with multiple relapses. Several ^{131}I-MIBG dosing strategies have been pursued. Most ^{131}I-MIBG trials have selected patients

with advanced disease that have failed first-line therapy, while others have incorporated ^{131}I-MIBG into multiprong treatment strategies. Several trials demonstrated that repeated doses of ^{131}I-MIBG could be administered safely. Partial objective responses have been reported in up to 40% of patients, but complete response rates are usually much lower (seldom over 10%). Because many trials were not prospective, reporting criteria in terms of outcome were variable, and the parameters measured in terms of duration of response have been inconsistent and include survival, overall response, and event-free survival (EFS).

The most significant toxicity associated with ^{131}I-MIBG therapy in both children and adults is hematologic. Nadirs in children have been reported to occur approximately 28 days after a single ^{131}I-MIBG administration (range 9–42). When chemotherapy is combined with ^{131}I-MIBG therapy, this nadir may occur earlier and is felt to be predominantly driven by the chemotherapy. Patients treated with high activities of ^{131}I-MIBG ($\geq$444–666 MBq/kg (12–18 mCi/kg)) may require bone marrow transplant because of significant and prolonged marrow toxicity, particularly in heavily pretreated subjects. Because higher doses induce considerable neutropenia, significant infections are occasionally encountered.

Myelodysplasia (MDS)/acute myelocytic leukemia have been reported in patients who have received both chemotherapy and large amounts of ^{131}I-MIBG. Secondary malignancies have been also reported. The occurrence of secondary malignancies and bone marrow disorders indicates that these patients require close follow-up, especially those with prolonged survival. Hypothyroidism can also occur. Common systemic/constitutional toxicity associated with large doses of ^{131}I-MIBG includes asthenia, nausea, and vomiting. Although ^{131}I-MIBG localizes in normal organs such as the heart, lung, kidney, liver, and adrenals, complications related to cardiac, renal, liver, or adrenal insufficiency have been very limited. Pulmonary complications are most frequently related to infectious disorders.

Summary 1299

References 1299

Metaiodobenzylguanidine (MIBG), also known as iobenguane, was developed at the University of Michigan by Wieland et al. [202]. As an analog of guanethidine, MIBG shares structural features with norepinephrine, binds to the norepinephrine transporter, and is internalized. Having entered the cell, MIBG is transported to secretory granules via vesicular monoamine transporters [101] or, in some cells without many granules, localizes in the cytoplasm [106, 171, 177]. For imaging purposes, MIBG is labeled with ^{131}I or ^{123}I. For diagnostic imaging, ^{123}I is superior to ^{131}I [57], and imaging methods are described in imaging guidelines [15].

Radiolabeled MIBG has been used for imaging a variety of neuroendocrine tumors (NETs) and other disorders [26, 156]. The sensitivity for tumor detection of pheochromocytoma/paraganglioma (PHEO/PARA) and neuroblastoma (NB) tends to be higher than for other NETs. Given the excellent localization often seen with radioiodinated MIBG (Fig. 1a), therapy with ^{131}I-MIBG has been evaluated. In this chapter, we focus on the therapeutic use of MIBG in the three most frequently treated tumors: PHEO/PARA, carcinoid, and neuroblastoma.

^{131}I-MIBG Preparation

Procedure guidelines for the use of ^{131}I-MIBG in therapy have been published [65]. The specific activity of the ^{131}I-MIBG used for imaging typically is low (123 MBq/mg, or 3.33 mCi/mg), while the specific activity of the ^{131}I-MIBG used for therapy is higher, ranging from 1.11 to 1.85 GBq/mg (30–50 mCi/mg) [41, 51, 70, 85, 118, 170]. At these specific activities, approximately 1 in every 2,000 molecules of MIBG will be labeled with ^{131}I. Therefore, for an activity of 18.5 GBq (500 mCi), a total of 10–17 mg of MIBG is administered. Even higher specific activity ^{131}I-MIBG has been developed, in the range of 92.5 GBq/mg (2,500 mCi/mg) [80, 112, 113]. Theoretical and preclinical studies in small animals have shown that higher specific activity results in greater tumor uptake and higher tumor to normal tissue ratios than lower specific activity reagents [112, 114]. However, a study with high specific activity MIBG resulted in higher activity in heart but not in tumor xenografts [189]. Limited studies in humans using high specific activity ^{131}I-MIBG have also failed to show higher tumor targeting [145], including phase I clinical trials with high specific activity ^{131}I-MIBG, and have not clearly confirmed an advantage in terms of tumor targeting, although its safety has been documented [36]. Even if high specific activity ^{131}I-MIBG does not have a clear advantage over low specific activity material in terms of tumor targeting, administration of lower mass amounts of MIBG over a shorter period of time with a lower incidence of nausea, vomiting, and hypertension may be possible [6]. It should be noted that while ^{131}I-MIBG was approved by the FDA for imaging, it has yet to be approved for therapy in the USA. Thus, for therapy trials in the United States, ^{131}I-MIBG is either made in accordance with USP regulations or used under an investigational new drug application (IND). Whereas, the use of ^{131}I-MIBG for therapy has been approved by the EMA as well as by regulatory authorities in other countries.

Logistical Issues

At present, there are few centers performing ^{131}I-MIBG therapy. One major impediment is that the radiopharmaceutical is not yet FDA approved for therapeutic use, as previously described above. Other impediments relate to the safe handling of large amounts of therapeutic materials. In establishing an ^{131}I-MIBG therapy program, there needs to be adequately trained staff to carry out the treatment safely and within regulatory compliance with NRC mandates, and a significant institutional commitment is necessary [167]. In addition to radiation safety-related issues, a dedicated multimodality group of physicians that deal with the relevant diseases are necessary to provide optimal patient care. High-activity administration in the range of 18 mCi/kg, as is often used in patients with neuroblastoma, has its own safety challenges that must be appropriately addressed, especially when dealing with small children [32].

Patient Preparation

Proper preparation of patients is required prior to treatment with ^{131}I-MIBG. A variety of drugs are known to interfere with uptake of MIBG by tumor cells and should be discontinued prior to therapy, including labetalol, tricyclic antidepressants, reserpine, and some sympathomimetics (Table 1) [5, 76, 97, 133, 172]. A detailed list of drugs that may interfere has been compiled [172] and recommendations of which to avoid have been proposed [87]. When possible, these drugs are eliminated or substituted prior to therapy with ^{131}I-MIBG. The amount of time necessary for

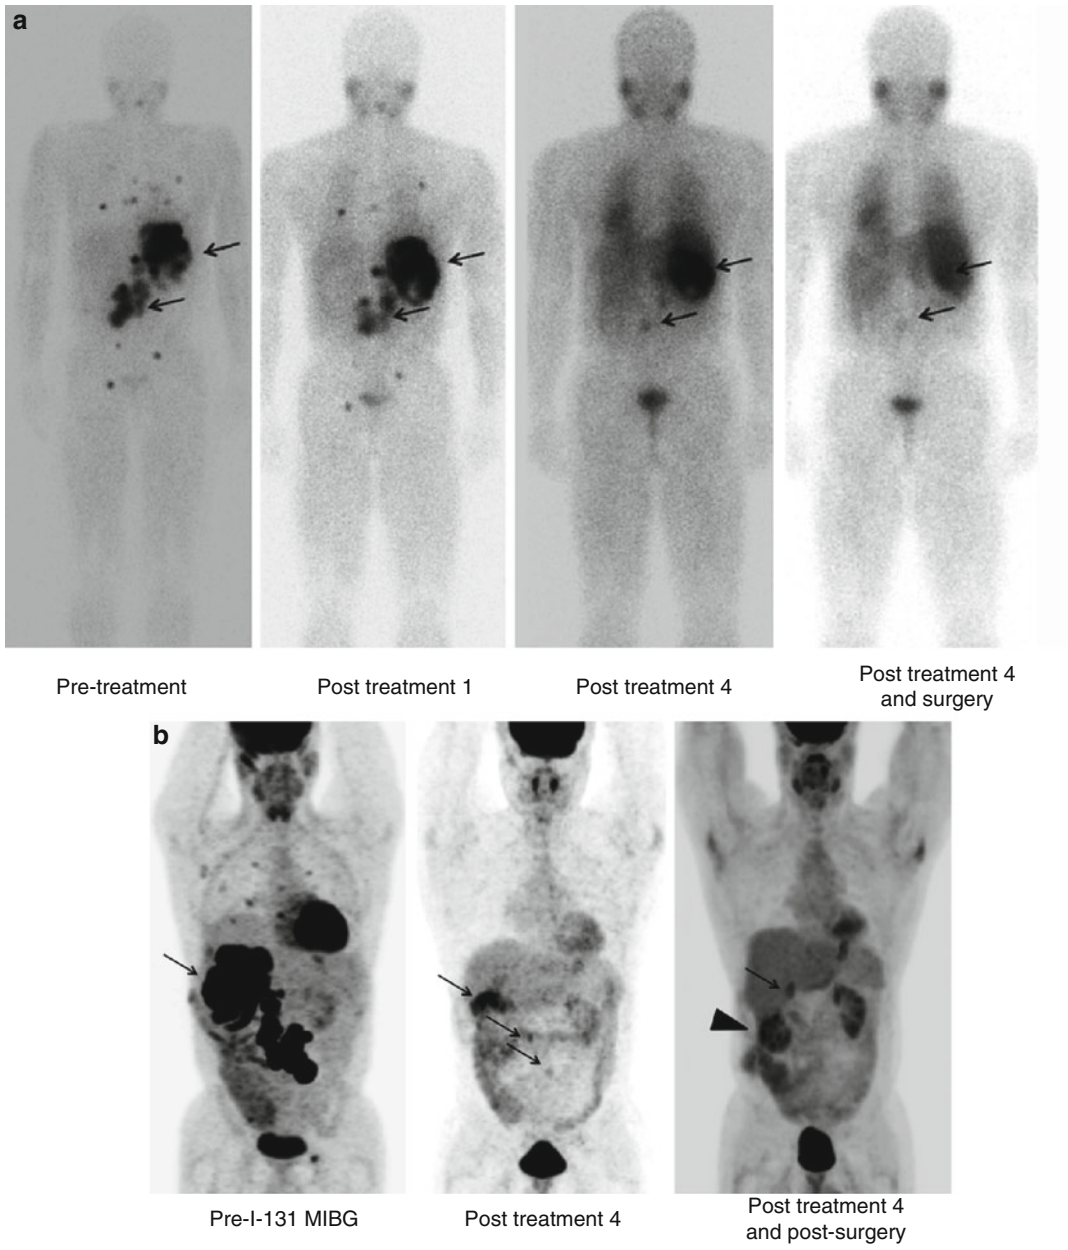

Fig. 1 (continued)

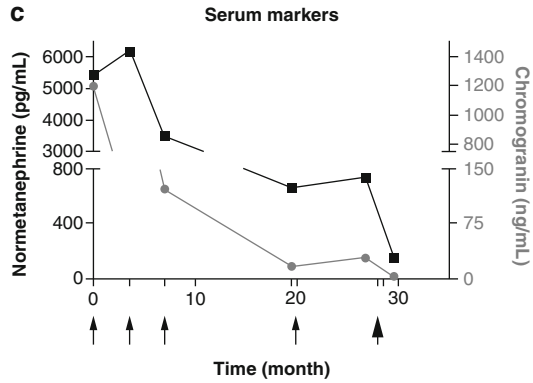

Fig. 1 (**a**) Serial ^{123}I-MIBG posterior whole-body images from a patient with unresectable primary PHEO of the right adrenal (*upper arrows*) and metastatic disease to retroperitoneal nodes (*lower arrows*), spine, pelvis, ribs, and bilateral lung metastases are also present. He received four treatments consisting of 204, 211, 215, and 243 mCi of ^{131}I-MIBG over a 14-month period. The initial posttreatment scan 1 showed some decrease in retroperitoneal nodes and disappearance of some lung and bone lesions. Posttreatment 4, all lung and bone lesions had disappeared, and retroperitoneal nodes had resolved or improved markedly. The adrenal mass had decreased in size and intensity and was resected for palliative reasons. (**b**) Anterior [^{18}F]FDG PET/CT MIP images of the same patient as in Fig. 1a, showing extensive [^{18}F]FDG avid PHEO uptake in the primary adrenal tumor (*arrow*) and retroperitoneal, bone, and lung metastases. After four treatments (cumulative activity of 873 mCi ^{131}I-MIBG) (*middle panel*), residual [^{18}F]FDG activity was only seen in the right adrenal bed and retroperitoneal nodes (*two lower arrows*). The adrenal mass had shrunk considerably and become largely necrotic. Because persistent mild elevation of normetanephrines was observed and this was the site of largest disease, this residual adrenal mass was resected. [^{18}F]FDG PET 6 months postsurgery (*right panel*) showed small residual uptake in the surgical bed and two small hypermetabolic nodes in the abdomen (not clearly seen in this MIP image). Note that the activity in the right upper quadrant (*arrowhead*) represents kidney, not tumor. (**c**) Biochemical parameters may be used to track response in PHEO. This is the same patient shown in Fig. 1a and b who had elevated chromogranin and normetanephrine levels pretreatment. The *arrows* represent the four ^{131}I-MIBG treatments, totaling 873 mCi. Although chromogranins started to improve after the first treatment, it was not until after the second treatment that metanephrines started to improve. Chromogranin levels were in the normal range at the time of the fourth treatment, but normetanephrine levels did not normalize until after surgery (*arrowhead*)

withdrawal is related to their half-life [172]. In PHEO/PARA patients, hypertension can usually be controlled with oral phenoxybenzamine and atenolol as they do not block ^{131}I-MIBG uptake in vivo. In addition, nifedipine can be added to antihypertensive regimens since interference has not been observed [11]. As a practical matter, patients generally undergo a diagnostic ^{123}I-MIBG study on their current drug regimen to assess targeting of MIBG prior to considering therapy [209].

Thyroid Blockade

Although USP release criteria require >95% ^{131}I bound to MIBG, ^{131}I-MIBG preparations all contain a small amount of free radioiodine. In the interval between manufacture and dose administration, there is a time-dependent breakdown, with the release of free iodine [197] into solution. In addition, a small amount of free iodide may be generated in vivo from metabolism [115]. Therefore, blocking the thyroid is necessary to prevent thyroid damage from radioiodine. A variety of regimens using potassium iodide (KI), saturated solution of potassium iodide (SSKI), or Lugol's solution have been used for this purpose. Several studies have shown the efficacy and timing of cold iodine administration to block thyroid uptake of radiolabeled iodine [176, 208]. The dose of KI recommended by the FDA for use during radiation emergencies is 130 mg of KI (100 mg iodine) per day for adults and is scaled down for children (http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm080542.pdf).

Table 1 Drugs that interfere with MIBG uptake[a]

	Documented in patients	Documented in vitro
Antihypertensives	Labetalol [97, 133], phenoxybenzamine [172][b]	Propranolol but not other beta-blocker [5], guanethidine, reserpine, nifedipine, verapamil
Opioids	Cocaine [209]	
Tricyclic antidepressants	Imipramine [139]	Amitriptyline derivatives
Sympathomimetics		Phenylpropanolamine, amphetamines, pseudoephedrine, phenylephrine
Antipsychotic		Phenothiazines, haloperidol

[a]For detailed list of drugs that have the potential to interfere, see Solanski et al. [172] and Giammarile et al. [65]
[b]Phenoxybenzamine at low doses does not interfere; i.v. administration at high doses is reported to interfere

This regimen is in line with what others have suggested for blockade prior to diagnostic MIBG scanning [173]. Typically, the dose of KI prior to ^{131}I-MIBG therapy is higher than 130 mg. Thyroid blockade usually starts 1 day prior to administration of the ^{131}I-MIBG [150, 183, 205], although some protocols start up to 5–7 days prior [59, 61]. However, this appears to be unnecessary [176, 208]. The amount of KI has ranged from 120 to 200 mg/day with smaller amounts for children [13, 64, 65, 104, 148, 166]. The length of blockade has ranged from 7 to 45 days [17, 41, 59, 61, 64, 153, 183, 206]. Some have used more intensive regimens including thyroid suppression with thyroid hormone, in order to decrease TSH [37, 52, 61]. In pediatric populations, some regimens add potassium perchlorate and T3 to lower the TSH [81]. A report analyzing various phase I and II studies in children utilized an oral loading dose of 6 mg/kg of KI solution 8–12 h prior to ^{131}I-MIBG infusion, then 1 mg/kg every 4 h on days 0–6, and 1 mg/kg/day through day 45 post-infusion. Potassium perchlorate was also given as an additional oral blocking agent for 5 days post-infusion with a loading dose of 8 mg/kg and then 2 mg/kg every 6 h on days 0–4, beginning 4 h after the start of ^{131}I-MIBG infusion.

The EANM guidelines suggest starting iodide blockade 24–48 h prior to treatment and continuing for 10–15 days and do not recommend thyroxine administration [65]. Pharmacokinetic studies of radioiodinated ^{131}I-MIBG have shown that there is less than 10% in blood at 1 h post-administration [122] and that >80% of radiolabeled MIBG is released from the body over 4–5 days [36, 198, 199]. MIBG clears from the body with a terminal effective half-life of 37 h [45]. Therefore, it is reasonable to stop administering iodide for thyroid blockade 14 days after treatment. In spite of these blocking measures, it is not unusual to see some uptake of ^{131}I in the normal thyroid with some series showing that only 52% of subjects had no visualization of the thyroid posttreatment [17, 153].

SSKI and Lugol's are well tolerated. Infrequent side effects include sialadenitis, gastrointestinal disturbances, allergic-like reactions, and minor rashes. Thyroidal side effects include iodine-induced thyrotoxicosis, which is more common in older people and in iodine-deficient areas, and hypothyroidism, particularly in iodine-sufficient areas.

Additional Precautions

Because patients may have nausea and vomiting after administration of ^{131}I-MIBG, antiemetics such as ondansetron are often administered prior to therapy and in the first 3 days post-administration. Since the major route of ^{131}I-MIBG excretion is renal, the bladder is exposed to high concentrations of radioactivity. To minimize the radiation dose to the bladder, hydration is encouraged. Some investigators administer 3 L/m^2 or 150 mL/h for several days [68, 107]. In small children, urinary catheterization is often performed to decrease both the radiation dose and the potential for contamination [82, 107, 205].

Patient Eligibility

Candidates for ^{131}I-MIBG therapy should have a reasonable performance status (Karnofsky >60)

and a life expectancy of at least 3 months, unless they have intractable bone pain. Reasonable hematopoietic parameters (WBC >3,000/μL, platelets >100 K/μL) are required prior to ^{131}I-MIBG therapy, especially when stem cells are not available [65]. The degree of acceptable liver function required has not been well established, although some have used bilirubin ≤2.5 and liver enzymes ≤2.5 times the upper limit of normal as criteria [70]. Kidney glomerular filtration rate >30 mL/min or serum creatinine ≤2.5 the upper limit of normal are also desirable [65, 70]. Recently, it has been found that patients with nephrotic syndrome receiving large activities of ^{131}I-MIBG may be prone to bronchiolitis obliterans organizing pneumonia (BOOP) or acute distress respiratory distress syndrome (ARDS), and a recommendation has been made to limit the cumulative activity in these patients to less than 800 mCi of ^{131}I-MIBG [70].

^{131}I-MIBG is administered by pump i.v. through an indwelling catheter or central line. A variety of infusion times have been used, ranging from 1 to 2 h [164, 161, 150, 148, 23]. Six and even 24 h infusions have also been evaluated [81, 99, 181]. Slow administration is a precaution to minimize pharmacologic effects from the unlabeled MIBG, although some have administered the therapy over 30–60 min without sequela [14, 148, 23]. Our practice at MSKCC is to administer the drug over ~45 min. When high specific activity material is given, the infusion rate has been shortened to 15–30 min, since the total mass of MIBG is reduced [89, 36]. Monitoring of vital signs during the administration is recommended since patients may develop a hypertensive response. This can be particularly significant in PHEO/PARA patients and requires slowing of the infusion or pharmacologic intervention.

Administering therapy on an inpatient versus outpatient basis depends on multiple considerations. In many countries, there are policies or regulations that define the limits of administered activity for outpatient treatment. In the USA, patients must be given oral and written instructions to ensure that there is less than 500 mrem exposure to caregivers or other household members when they return home. Several groups have confirmed that this exposure rate to caregivers can be achieved. Caregiver exposures of 30–125 mrem with activities up to 5.55 GBq (150 mCi) were observed by Hoefnagel et al., and a median exposure of 60 mrem/3.7 GBq (60 mrem/100 mCi) was reported [61, 77]. With a higher median activity of 16.2 GBq (437.8 mCi), radiation exposure to caregivers was within regulatory range with median dose to them of 302 mrem [58]. At MSKCC, we perform most adult MIBG therapy as outpatients, although internal policies require that patients receiving >9.25 GBq (>250 mCi) ^{131}I-MIBG be inpatients. In children, most groups are more conservative and will hospitalize for ease of treatment, monitoring, and radiation safety considerations. Furthermore, in order to reduce bladder radiation, a Foley catheter is often placed for 3 days to minimize bladder dose and avoid contamination.

Patient Selection Criteria

There are no uniform guidelines for selecting or excluding patients from consideration for ^{131}I-MIBG therapy. Most investigators require demonstration of tumor localization on a diagnostic MIBG scan, although it is not always stated whether all known lesions were MIBG avid [70, 141, 148, 150, 165, 180]. Criteria for deciding how much tumor localization is required range from >20 cGy/37 MBq (>20 cGy/mCi) [165], 5 Gy/3.7 GBq (5 Gy/100 mCi) [104], visual localization above background, higher than two times background [70], and >1% of ID in tumor [13, 137]. Requiring a positive diagnostic MIBG scan is required since not all tumors take up MIBG. Furthermore, this also helps to avoid the presence of interfering medication.

Other selection criteria often include evidence of disease progression or symptoms [141, 148]. Patients need to follow radiation safety precautions; thus, a Karnofsky performance status of greater than 60% is advisable. Patients must not be pregnant or breast-feeding and must agree to birth control, although it is not known for exactly how long. Sperm banking or ovum harvest may be considered in younger patients.

Activity/Dose Selection

Various approaches have been utilized to select the dose for ^{131}I-MIBG therapy. Most studies have used fixed activities based on empirical evidence of limited toxicity [28, 37, 40, 61, 64, 72, 77, 81, 85, 110, 117, 120, 161, 164, 186]. Others have used fixed activities adjusted to body weight based on dose escalation studies [63, 70, 82, 94, 99, 121, 124, 126, 155]. Yet others have performed dosimetry analysis using a diagnostic scan and have calculated activities to deliver less than 2–4 Gy to blood or whole body [50, 62, 107].

There is also no standardized practice in terms of frequency of ^{131}I-MIBG therapy administration. If the patient responds to treatment or is stable and has no dose-limiting toxicity, the therapy is usually repeated. The frequency of retreatment is variable, ranging from a minimum of every 4 weeks to 6 months and requiring adequate recovery from toxicity [13, 40, 64, 72, 77, 92, 110]. Some investigators tailor the frequency based on tumor growth rate, with fast-growing tumors treated every 2.5–3 months and slower-growing tumors every 6 months [23]. Others perform three treatments and then reassess whether to proceed [23, 148]. High-activity therapy often requires longer intervals between treatments to allow marrow recovery; lower activities are much better tolerated. High-activity regimens delivering 18 mCi/kg on two occasions have shown the feasibility of stem cell rescue with 50–71% of patients achieving platelet transfusion independence [82, 91].

Thus, there are no predefined limits in terms of repeated treatments. In patients with PHEO/PARA (Table 2), patients have received 1–11 treatments with ^{131}I-MIBG [14, 64, 104]. Krempf et al. observed that 1–8 treatments were needed before a response was observed and no patient had a complete biochemical response until at least three treatments were given [104]. Similarly, Sisson et al. reported variable responses in patients ($n = 5$) receiving 2–4 treatments and suggested a minimum tumor dose of 150 Gy (15,000 rad) [168]. Those utilizing very large doses have found that continued response may be seen many months after treatment and sometimes wait a year before considering retreatment [68].

The cumulative activity administered has ranged up to 118.1 GBq (3,191 mCi) in PHEO/PARA (Table 2), 78.1 GBq (2,112 mCi) in carcinoids (Table 4), and 89.3 GBq (2,414 mCi) or 31.325 GBq/kg (35.8 mCi/kg) in neuroblastoma (Tables 6 and 7).

Dosimetry

Several studies have reviewed the pharmacokinetics of ^{131}I-MIBG. The pharmacokinetics of carrier-free ^{131}I-MIBG in adults has been reported [36] – with alpha $T_{1/2}$ of 3 h and beta $T_{1/2}$ of 38.3 h. In adults, the mean urinary excretion was 27.4% in the first 6 h, 49.8% in 24 h, and 80.3% in 120 h. Detailed pharmacokinetics in children with neuroblastoma has been published [100, 198, 199]. A terminal biologic $T_{1/2}$ in serum of 45.8 h is reported. In addition, at 24 h there was a cumulative urinary excretion of 32%, 71% at 48 h, and 65% at 6 days. MIRD dosimetry of ^{131}I-MIBG [88, 185] identifies the main target organs as the liver, myocardium, and gonads. Dosimetry of no-carrier added ^{131}I-MIBG is somewhat different, with higher radiation dose per mCi to most normal organs than those described in the package insert for low specific activity ^{131}I-MIBG [36]. While some of these dosimetry differences can be related to the specific activity, differences in methodology where self-irradiation is not considered likely plays a large role; dosimetry estimates performed from diagnostic scans in NB patients are often significantly different from those estimated from the therapy dose. Fielding et al. found that estimates from the diagnostic scan would have resulted in under dosing 65% of the patients. Nonetheless, this was more reproducible than weight-based dosing [21, 50]. Using dosimetry from diagnostic scans, Lashford et al. predicted therapy doses to within −20–30% of that seen with the therapeutic dose [107]. It is not known what the required doses are to obtain biochemical or tumor responses. Estimates of radiation-absorbed dose to tumor vary considerably between patients and diseases. For

Table 2 PHEO/PARA: treatment schema (administered activities are listed here in mCi; multiply by 37 for conversion to MBq)

Author	# patients	Single administration (mCi)	Cumulative (mCi)	# Doses

instance, tumor dose estimates of 10–40 cGy/37 MBq (10–40 cGy/mCi) have been reported [36, 164], with cumulative doses ranging from 10 to 198 Gy [77, 104, 109, 168] in patients with PHEO/PARA. The impression has been that cumulative doses 60–100 Gy are beneficial [104, 168]. Other studies suggested that doses of 150 Gy were necessary to obtain tumor response [168]. Because there is large variability in determining tumor dose due to inherent problems in quantification of single-photon emitters, many studies use estimates of dose to whole body as a

safe upper limit [50, 164]. Whole-body doses ranged from 50 to 231 cGy [85, 164]. New methods to evaluate the biodistribution and residence time of ^{131}I-MIBG are now feasible using the surrogate positron emitting reagent ^{124}I-MIBG [73, 84, 144].

Evaluation of Response

Response assessment may be performed as early as 2 months [14] but more frequently at 3–6-month intervals unless the patient is known to have fast-growing disease [64, 70, 166, 205]. Follow-up typically involves anatomic imaging such as CT or MRI to evaluate changes in lesion size. Functional imaging is performed using ^{123}I-MIBG [43] and, in known [^{18}F]FDG avid lesions (Fig. 1b), changes in SUV may be an indication of response, although limited studies have been reported [149]. In hormone-secreting tumors, biochemical parameters can be used to assess response (Fig. 1c).

Following therapy, response is usually evaluated at 8–24 weeks. As in many cancers, response is determined using size measurement criteria, most often using WHO criteria [27, 141, 148, 181]. WHO criteria for complete response include the disappearance of all lesions and negative ^{123}I-MIBG scans; partial response is a 50% or greater reduction of all measurable disease; and progression is the appearance of new lesions or an increase of 25% or more in tumor size. In PHEO/PARA, because most patients have elevated catecholamines, levels of these and their metabolites are also used to gauge response. Biochemical CR is defined as complete normalization of biochemical markers, partial response typically by $\geq$50% drop but not normalization, and progression by $\geq$20% increase in these levels (Fig. 1c).

In neuroblastoma, posttreatment diagnostic ^{123}I-MIBG scintigraphy is routinely used to assess response (Fig. 2) [43, 91]. Interestingly, Johnson et al. noted that in four patients with CR based on negative ^{123}I-MIBG imaging following their initial treatment, a post-therapy ^{131}I-MIBG scan performed after a second treatment showed residual disease [91]; this is probably related to the higher sensitivity of tumor detection on post-therapy scans that have shown to be more sensitive for tumor detection [204]. These authors suggest that ^{131}I-MIBG therapy could be used to consolidate first remission in patients with newly diagnosed high-risk neuroblastoma. Patients

undergoing high-dose therapy invariably have significant hematologic toxicity, and stem cell harvesting is routinely performed in these patients [91]. The parameter that determines if the patient needs stem cell transplant is the duration and resistance of the hematologic toxicity to respond to supportive treatment. When transplantation is required, it is usually not performed for at least 3 weeks post- ^{131}I-MIBG treatment [82, 124, 205].

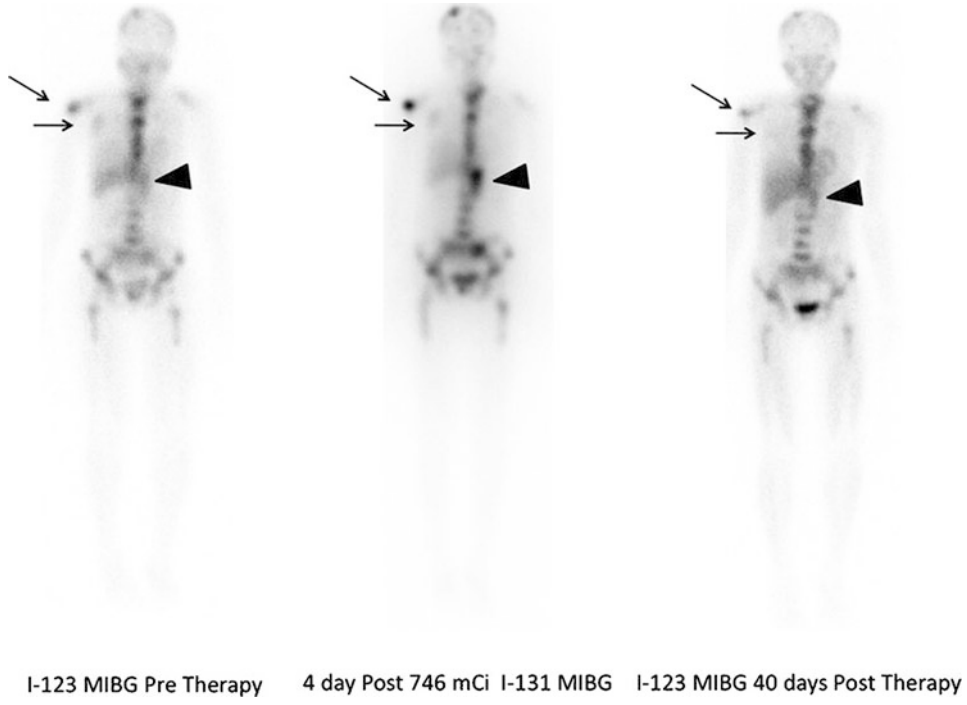

Fig. 2 A 26-year-old woman with neuroblastoma. ^{123}I-MIBG diagnostic scan (*left panel*) pre-therapy shows extensive bone disease (*arrows*) and left adrenal mass (*arrowhead*). After receiving 27.6 GBq (746 mCi) ^{131}I-MIBG, she was imaged at 4 days (*middle panel*). This showed excellent targeting of sites of disease. A follow-up ^{123}I-MIBG scan (*right panel*) showed that in spite of excellent tumor targeting, there was little response with only minor decreases in uptake in the left scapula and humerus compared to baseline

Pheochromocytoma/Paraganglioma

PHEO/PARA are tumors that originate in chromaffin tissue of the adrenal medulla or sympathetic nervous system. The incidence of PHEO/PARA is estimated to be ~1–2 per million [9, 49], although in autopsy series an incidence of 1 in 2,031 cases has been reported [125]. These tumors are most often found in the adrenal and in this location are referred to as PHEO. If they occur outside of the adrenal they are referred to as PARA. Three percent of adrenal "incidentalomas" are PHEO [95]. These tumors often secrete catecholamines, and consequently, patients present with hypertension and other symptoms of adrenergic excess. In some instances, however, these tumors are nonfunctional and presentation is related to mass effect or incidental discovery.

Traditionally, PHEO/PARA were known as the "10% tumor" due to the thought that they were 10% bilateral, 10% metastatic, 10% extra-adrenal, 10% non-hypertensive, and 10% inherited. However, in the last decade, it has become increasingly clear that this rule no longer holds, as was explicitly pointed out by Elder et al. in 2005 [46]. While the majority of PHEO/PARA are still thought to be sporadic, up to 35–40% of PHEO/PARA are now estimated to be related to genetic defects, and 15% or more with somatic mutations [39, 116, 147]. With ever expanding genetic testing, mutations are now frequently found in patients with apparently sporadic disease, no family history, and a non-syndromic presentation [1, 140]. Since 2002, when SDHx mutations were first associated with PHEO/PARA [3, 8], at least 17 genetic mutations have been identified to date, as well as somatic mutations occurring in the same susceptibility genes as the genetic ones [22, 147]. Depending on the mutation, two major pathways have been recognized: a pseudo hypoxic pathway referred to as Cluster 1 (including

SDHx, SDHAF2 VHL, HIF2A, and *FH*) and a tyrosine kinase signaling pathway (including *MEN*, *RET*, *NF1*, *MAX*, and *TMEM127*) referred to as Cluster 2 [39].

While most PHEO/PARA are benign, up to 26% or more are malignant [152, 210], with higher rates in certain inherited forms of disease [39, 116, 147]. In addition, extra-adrenal tumors which are also more prevalent in certain inherited PHEO/PARA are often malignant [1, 7, 140, 210]. In particular, SDHB related PHEO/PARA are known to have a high risk for metastases [66]. Pathologically it is difficult to differentiate benign from malignant tumors because of lack of robust morphological and histological criteria [182]. Therefore, in order to classify PHEO/PARA as malignant, one must find disease in sites where this tissue is not normally present [33]. The most common sites of metastatic disease include lymph nodes, bone, liver, and lung [18].

The most sensitive tests to confirm the diagnosis of PHEO/PARA are plasma-free metanephrines or urinary fractionated metanephrines, with sensitivities of 97% and 99%, respectively [30, 108]. The diagnostic imaging modalities most often used for staging are CT and MRI; functional imaging modalities are also useful, including radiolabeled MIBG (Fig. 1a), ^{18}F-fluorodopamine PET, ^{18}F-DOPA PET, [^{18}F]FDG PET (Fig. 1b), ^{111}In-pentetreotide scintigraphy [26, 146, 213], and ^{68}Ga-DOTA-somatostatin analog-scans (REF below). ^{68}Ga-DOTATATE has recently been approved by the FDA.

The optimal therapy for PHEO/PARA consists of surgical resection when feasible. Even in patients with metastatic disease, surgical debulking is often used with palliative intent, although no controlled studies have been performed to show an effect on survival. Patients with benign disease have normal overall survival after complete surgical resection, whereas patients with malignant disease typically have an overall 5-year survival of less than 50% [31, 90, 160]. Nonetheless, it is recognized that there is a subset of patients with malignant disease who have a more indolent course and may live >20 years with limited therapy [135]. Patients that are asymptomatic and have slow growth rates may opt for observation until symptoms require therapy.

Averbuch et al. evaluated the use of cyclophosphamide, vincristine, and dacarbazine (CVD) for metastatic disease [4]. In 14 patients with malignant PARA, they observed a complete or partial response in 57%, with median duration of 21 months. A second analysis of this data expanded to 18 patients was performed with long-term follow-up of 22 years [83]. A CR was present in 11% of the patients, 44% had a partial response, and 72% had a biochemical response with a median duration of 20 months. Nonetheless, 16 of the 18 patients died of their disease and one was lost to follow-up. Patients that responded had a median survival of 3.8 years compared to 1.8 years for nonresponders. The common toxicities were myelosuppression, peripheral neuropathy, and gastrointestinal toxicity. Overall, the treatment was well tolerated as evidenced by the ability to administer a median of 23 cycles. These authors conclude that the treatment is not for all patients with metastatic disease but can be considered when patients are symptomatic or tumor shrinkage is desirable. Results in other small series or case reports have shown similar findings, with remissions typically lasting less than 2 years [162]. CVD have become the most often used first-line chemotherapy regimen for metastatic disease, although other regimens have also been utilized [60, 175]. Given the suboptimal response to chemotherapy, newer therapeutic modalities such as ^{131}I-MIBG therapy are being applied in patients with PHEO/PARA, and guidelines have been published [65], but others believe 60–100 Gy is adequate [104, 186]. Patients with disease limited to the liver have also been treated successfully with RFA ablation [192]. In patients with rapidly progressive disease, chemotherapy with the CVD regimen is often used first.

There has not been a systematic evaluation comparing regimens using low, mid, or high doses of ^{131}I-MIBG in PHEO/PARA. Initial reports, first by Vetter et al. [193] and followed shortly by a report of treatment of five patients at the University of Michigan [168] appeared in the early 1980s. In the latter report, five patients were treated with total activities ranging from

9.99 to 17.91 GBq (270–484 mCi), resulting in 35–180 Gy to tumor [168]. A significant reduction in tumor size was observed in a few patients. Since then, a variety of dose ranges have been used. Individual doses ranging from low activity (2.96–7.4 GBq or 80–200 mCi), intermediate (up to 18.5 GBq, or 500 mCi), to high activities that are often weight based (444–666 GBq/kg, or 12–18 mCi/kg) have been used (Table 2). Strategies using low-intermediate activity rely on repeat treatment, with which cumulative doses as high as 85.1 GBq (2.3 Ci) have been achieved, although median cumulative activities are generally in the 18.5–37 GBq (500–1,000 mCi) range (Table 2). Even higher total doses have been achieved using high activities doses The UCSF group has been a proponent of high doses with stem cell support, based on a phase I dose escalation trial [54, 70, 155]. Activities >12 mCi/kg usually require having stem cells available for transplantation.

A meta-analysis of publications from 1983 to 1997 on 116 patients treated with ^{131}I-MIBG has been reported [109]. These studies used a mean single activity of 5.85 GBq (range 3.55–11.1 GBq) or mean 158 mCi (range 96–300 mCi) with a mean of 3.3 (1–11) repeated treatments, resulting in cumulative activities of 3.55–85.9 GBq (mean of 18.1 GBq) and 96–2,322 mCi (mean of 490 mCi). Although these retrospective studies had different methodologies, clear therapeutic results were observed using what are now regarded as relatively low activities. Of the 116 patients, 4% had an objective CR and 26% had partial response (PR). Biochemical catecholamine response demonstrated complete normalization in 13% of 96 patients, 32% had >50% improvement, and 76% of 99 patients had improvement in symptoms.

Other reports describe results with low (median below 7.4 GBq or 200 mCi) [28, 64, 166], intermediate (median above ≥7.4 GBq or above 200 mCi) [14, 28, 72, 158], and high activities (>44.4 MBq/kg or >12 mCi/kg) (Table 3) [70, 155]. A retrospective review of the Duke experience in 33 patients treated with ^{131}I-MIBG with cumulative activities ranging from 2.59 to 45.3 GBq or 70–1,223 mCi (mean individual activity 14.47 GBq or 391 mCi) demonstrated an objective response rate of 38%, a symptomatic response rate of 86%, and a biochemical response rate of 60%. Responders had a median survival of 4.7 years compared to 1.7 years for nonresponders. Patients receiving high-activity therapy (>18.5 GBq or 500 mCi) had a survival advantage with median survival of 3.8 years versus 2.6 years for the low-activity group [158].

A prospective study using high-dose therapy, median individual activity of 30.27 GBq (818 mCi), showed a CR of 8% and objective response in 36%. In this group, the majority of the patients only received a single administration, with a small proportion receiving two or three treatments. Because of the expected myelotoxicity, peripheral stem cells were harvested, although some patients recovered adequate marrow function and did not require stem cell infusion [70].

The use of high specific activity ^{131}I-MIBG for therapy was recently evaluated in a phase I clinical trial [36]. In a group of 11 patients receiving no-carrier added ^{131}I-MIBG, no side effects were observed related to the injection. Estimated tumor doses ranged from 11 to 40 rad/37 MBq (11–40 rad/mCi). In this phase I study, activities ranged from 222 to 333 MBq/kg (6–9 mCi/kg) with a maximum activity of 24.98 GBq (675 mCi).

When comparing objective responses in different studies where patients received median activity of approximately 7.4, 14.47, or 30.27 GBq (200, 391, or 818 mCi), the observed response rates overlap, in the range of 20–40% (Table 3) [64, 70, 158]. Within a single institution, Castellani et al. reviewed patients treated with a median activity of 5.51 GBq (149 mCi) versus 9.92 GBq (268 mCi). Their conclusion was that in these ranges, higher activities could deliver the desired dose faster, with a modest increase in toxicity and similar overall response rates [28].

Several protocols have combined chemotherapy with ^{131}I-MIBG therapy in neuroblastoma, but there has been only one such prospective report in patients with PHEO [170]. In this small series, six patients underwent dosimetry and were scheduled to receive three ^{131}I-MIBG treatments at 3-month intervals with activities estimated to deliver 85–90 cGy to the whole body per single

administration. The patients would then start the CVD chemotherapy regimen [4]. Three of the six patients had improvement in tumor following ^{131}I-MIBG therapy. Two patients completed 9 months of sequential chemotherapy with further improvement and were considered to have partial response. Toxicity from ^{131}I-MIBG was minimal but forced reduction of chemotherapy doses in some patients.

The most frequent sites of metastatic disease include the lymph nodes, bone, lung, and liver [18]. There is suggestion that soft tissue disease response to ^{131}I-MIBG therapy is superior to that of the bone [69, 104, 168]. It also appears that patients with smaller volume disease following surgical resection are more likely to respond.

In summary, high-quality data on the use of ^{131}I-MIBG therapy in PHEO/PARA is limited, with few prospective trials, and there is currently no consensus on an optimal dosing strategy. Differences in patient selection and follow-up may account for differences in response rates and survival. It is clear that many patients will benefit from treatment, and objective responses are often observed, but complete response rates are low, ranging from 0% to 18%. The duration of responses is also variable, with 5-year survivals between 45% and 85% [137, 158]. There is some suggestion that higher activities >18.5 GBq (500 mCi) or myeloablative regimens may be associated with higher response rates. However, there are no direct comparisons to determine if fractionated smaller activities, that are associated with lesser toxicity, result in different overall survival. Nonetheless, the ease of performing this therapy, the evidence of objective responses, symptomatic improvement, biochemical improvement, and the limited toxicity and few late effects compared to other chemotherapy and external beam regimens make this an acceptable strategy in patients with metastatic PHEO/PARA.

Carcinoid

^{131}I-MIBG is used most frequently to treat neuroblastoma and PHEO/PARA. The third largest experience is with carcinoid tumors (Tables 4 and 5) [148, 23]. Carcinoids are slow-growing NETs that often secrete substances leading to hormonal syndromes. These tumors are rare, with incidence in the range of two cases per 100,000 [67, 132]. The most frequent sites for carcinoids are the gastrointestinal (GI) tract (73.7%) and the bronchopulmonary system (25.1%). Within the GI tract, most occur in the small bowel (28.7%), appendix (18.9%), rectum (12.6%), and stomach (6%). Although 45% exhibit metastases at the time of diagnosis, the overall 5-year survival is 50–67% [131, 132]. Higher incidences of carcinoids are found in patients with MEN1, VHL, and neurofibromatosis. In 2000, recognizing the heterogeneity of presentation, prognosis, and outcome, the WHO developed a classification system for NET reflecting a better understanding of cell biology, therapeutic implications, and pathology [174]. Three types of NET were defined: (1) well-differentiated NET (benign behavior, low grade), (2) well-differentiated neuroendocrine carcinoma (low-grade malignant), and (3) poorly differentiated neuroendocrine carcinoma (high-grade malignant). However, this classification is relatively new, and most reports of ^{131}I-MIBG therapy in carcinoid have not incorporated this classification.

Initial staging and follow-up relies on conventional imaging, such as CT and MRI, to evaluate for nodal or metastatic liver disease. Because these tumors often express somatostatin receptors, functional imaging with ^{111}In-pentetreotide or, more recently, with ^{68}Ga-somatostatin analogs is performed [26]. Before ^{111}In-pentetreotide was available, ^{131}I/^{123}I-MIBG scintigraphy was often performed following an initial report by Fischer et al. [53]. These tumors also express norepinephrine transporters, as do PHEO/PARA. Reports have shown that ^{131}I-MIBG has a lower sensitivity for the detection of carcinoid than for pheochromocytoma [26]. A review of 275 carcinoid patients demonstrated a sensitivity of 70% for tumor detection with ^{131}I-MIBG [74].

At presentation, the best management is surgical removal for curative intent, or in cases with metastatic disease, debulking for palliation. Unfortunately, metastatic disease at presentation

is frequent, and no consistently effective therapeutic strategies are available. Symptomatic tumor response is often seen following therapy with octreotide analogs [2], whereas objective tumor regression is rare [130]. Interferon may also result in symptomatic improvement in 58–65% of patients [130]. Multiple single and multi-agent chemotherapy regimens have been utilized, with none showing objective tumor response greater than 15%, and newer molecularly targeted reagents are now being evaluated [130]. Because liver metastases are commonly present, interventional radiology techniques including embolization and ablation with radiofrequency or cryoablation are often utilized [105, 130].

The uptake and accumulation of ^{131}I-MIBG in carcinoid raised the possibility of using the radiopharmaceutical for treating these tumors [78]. More recently, ^{111}In-, ^{90}Y-, and ^{177}Lu-octreotide or other somatostatin analogs have been utilized since somatostatin reagents have higher overall accumulation in carcinoid and gastroenteropancreatic tumors [93]. In this chapter, we focus on the use of ^{131}I-MIBG therapy of carcinoid, since radiolabeled somatostatin analog therapy is discussed in the chapter "▶ Neuroendocrine Tumors" by Dr. Bodei of this book.

Hoefnagel et al. treated five patients with ^{131}I-MIBG which produced some symptomatic responses [78]. Numerous additional reports have since followed (Table 4). Activities have ranged from ~2 to 20.5 GBq (54–554 mCi), with most series having median single activity <7.4 GBq (<200 mCi). As in PHEO/PARA, patients are often treated repetitively (1–11 treatments, median 1.2–3 treatments) until toxicity or lack of response is seen. Cumulative activities have ranged from 2 to 78.14 GBq (54–2,112 mCi), with median activities between 6.73 and 21.98 GBq (182–594 mCi). In contrast to neuroblastoma and PHEO/PARA, no series have included marrow ablative doses and stem cell transplant in carcinoid patients.

Although carcinoid patients rarely have a complete response to ^{131}I-MIBG therapy, measurable objective response rates of 11–27.5% have been reported (Table 5). The cumulative experience in 52 patients treated up to 1994 reported a 15% objective response rate and 65% symptomatic response. Multiple publications suggest that symptomatic response rates range from 38% to 92%, with partial symptomatic improvement more common than complete relief [137, 150, 159]. Patients whose symptomatic disease is resistant to octreotide or chemotherapy may benefit from ^{131}I-MIBG [159]. Biochemical responses are seen less commonly than symptomatic responses and range from 13% to 73% (Table 5), with complete biochemical normalization being infrequent [137, 148, 159]. For instance, Taal et al. observed that 60% of patients had symptomatic improvement, whereas only 13% had decreases in biochemical markers [180]. It is not well understood why only some patients with symptomatic response also show biochemical response [148, 180]. Symptomatic responses last a median of 8–17 months [148, 150, 180].

Because evaluation and outcome reporting is not standardized, the exact advantage in terms of survival is difficult to gauge from the literature. Median 5-year survivals of 42–78% have been reported [137, 159]. This is in the same overall survival range for carcinoid patients undergoing other, non-^{131}I-MIBG treatments [131, 132]. The largest series of 98 patients was reported by Duke University [159]. Their median initial activity was 11.32 GBq (306 mCi), although over time, this increased, and they now recommend initial single activities of >14.8 GBq (>400 mCi). Patients receiving >14.8 GBq (>400 mCi) survived an average of 4.69 years compared to 1.86 years for those receiving <14.8 GBq (<400 mCi). Most of these patients received only a single treatment. The authors also noted that patients that had symptomatic improvement had a 5.76-year survival compared to 2.09 years for those that did not. Interestingly, in those with biochemical improvement, survival was not significantly different from those without biochemical response (4.11 years versus 3.42 years). In this study, 49% of progressive metastatic carcinoid patients had improvement in symptoms. Similarly, others have also reported high rates ranging from 56% to 92% (Table 5). Nwosu et al. also found that patients with symptomatic improvement had a longer

survival of 59 months compared to 22 months in those without improvement [143].

Few studies have directly compared ^{131}I-MIBG treatment to untreated controls or patients undergoing other therapies. Sywak et al. reported a 5-year survival of 63% in patients treated with ^{131}I-MIBG compared to 47% for those not receiving it [178]. In these patients, further deaths occurred over time, with a 10-year survival of 38% in the ^{131}I-MIBG treatment group versus 33% in the no treatment control. In a separate report, Taal et al. compared ^{131}I-MIBG therapy to nonradioactive MIBG therapy and the median survival times were similar, approximately 28 months from start of treatment. Interestingly, they found a symptomatic response rate in both groups of 60%, although responses lasted longer with ^{131}I-MIBG than with nonradioactive MIBG (8 months versus 4–5 months) [180].

Studies combining ^{131}I-MIBG with chemotherapy or biologic therapy are rare. Zuetenhorst et al. evaluated whether interferon or cold MIBG increased the uptake of ^{131}I-MIBG in carcinoid tumors [212]. They found a 10% increase in ^{131}I-MIBG uptake in 19% of the patients receiving interferon and a 10% increase in 83% receiving cold MIBG. Unfortunately, no objective responses or synergistic effect from combined treatments with ^{131}I-MIBG were observed.

Another approach that may result in improved response is direct intra-arterial injection of the radiopharmaceutical. This approach delivered a 69% higher dose of ^{131}I-MIBG to the targeted tumor [20], but the therapeutic consequences of this approach are still to be determined.

With the advent of improved somatostatin analogs that exhibit better targeting of carcinoids than MIBG, the role of ^{131}I-MIBG therapy in this disease has diminished. ^{90}Y- and ^{177}Lu-labeled DOTATOC and DOTATATE have already demonstrated promising results [24, 190]. Nonetheless, in octreotide negative patients or those with borderline renal function, ^{131}I-MIBG remains a useful palliative option.

Case reports and smaller series have been reported on therapy of other NETs (non-PHEO/PARA carcinoid and neuroblastoma). For example, in a review article, the experience in 52 patients with medullary thyroid carcinoma was presented. There was a 38% objective response rated and palliation in 22% of the patients [74]. Treatment of 38 patients with gastroenteropancreatic tumors with a median of 6.8 GBq (range 1.6–10.57 GBq) of ^{131}I-MIBG has been reported. At 3–6 month following single treatment, 75%, 67%, and 63% of patients showed either a partial response (PR) or stable disease (SD) on radiological, biochemical, and symptomatic criteria, respectively. Overall survival from the date of the first therapy was 4 years $\pm$ 0.69 years, with 29% of patients alive at 10 years [138].

In summary, this modality is safe in patients with carcinoid, and there is evidence of objective, symptomatic, and biochemical benefit, although rarely complete responses are reported. There is a lack of prospective well-designed trials to compare with other modalities. Many carcinoid patients failing surgical resection or local ablation procedures are treated with radiolabeled somatostatin rather than ^{131}I-MIBG because of better targeting with somatostatin analogs. Nonetheless, in patients in whom radiolabeled somatostatin may be contraindicated (e.g., poor renal function) or not available, ^{131}I-MIBG is a reasonable strategy for symptomatic palliation.

Neuroblastoma

Neuroblastoma is a tumor that arises from primordial neural crest cells and is almost exclusively found in infants and young children. It is the most common tumor of childhood with an incidence rate of 9.5 per million [71]. Prognostic markers include age, stage at presentation, and MYCN amplification status [127]. The 5-year survival is 83% for infants, 55% for children 1–4 years, and 40% for older children [71]. Children less than 1 year may present with a self-limited disease with spontaneous remission (stage 4S). These children have an excellent long-term prognosis with 70–97% survival [142]. Stage 4 disease consists of dissemination to the distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs. In patients younger than 18 months and without

MYCN amplification, these tumors have more favorable prognosis and are usually treated with intermediate dose chemotherapy without autologous stem cell transplant (ASCT). Patients at high risk are those >18 months old with stage 4 disease and those with MYCN amplification. Therapy for these patients usually relies on induction chemotherapy, surgery, and radiotherapy (given that this is a radiosensitive tumor) followed by consolidation of remission with ASCT or *cis*-retinoic acid with or without antibody immunotherapy [127]. High-risk patients often relapse and are resistant to conventional therapy. Newer strategies include immunotherapy such as anti-GD2 antibodies [127]. ^{131}I-MIBG therapy has also been utilized, and several retrospective studies and a few phase I and II studies have been reported. ^{131}I-MIBG applications have included palliative therapy for patients with multiple relapses, first-line therapy, localized symptomatic inoperable disease, and combined therapy with chemotherapy or biologic therapy for consolidation.

Patient preparation for ^{131}I-MIBG therapy is simple and similar to that described above, where patients are taken off drugs that may interfere with uptake or release of MIBG [172]. The patient's thyroid is blocked with an age-appropriate dose of KI. A diagnostic ^{123}I-MIBG scan is obtained to document MIBG uptake, which is typically seen in 93–97% of neuroblastoma patients [86, 194].

Several ^{131}I-MIBG dosing strategies have been pursued in patients with neuroblastoma (Tables 6 and 7). Fixed activities are most commonly used, usually consisting of single 3.7–7.4 GBq (100–200 mCi) administrations that are repeated at a similar activity. Treatment regimens such as this that are not weight based have been repeated up to seven times with cumulative activities of up to 1.1 Ci. Another strategy is based on activity per body weight where phase I dose escalation trials have been performed using single activities of 96–666 MBq/kg (2.6–18 mCi/kg), number of doses ranging from 1 to 7 [61, 77, 94, 99, 121]. Typically, activities above 444 MBq/kg (12 mCi/kg) require preharvesting of stem cells because of marked hematologic toxicity. Other groups have based dosing on a delivered whole-body radiation dose, where the goal is to deliver 1–4 Gy to the whole body based on a dosimetric study or on an initial ^{131}I-MIBG therapy study [62, 81, 107]. Using these strategies, whole-body doses of 2 Gy can be administered without bone marrow support. Typically, the large myeloablative strategies utilize high doses, delivering 666 MBq/kg (∼18 mCi/kg) [124] or large whole-body radiation doses, >4 Gy [21, 62]. A high-dose study that allowed up to 8 Gy fractionated marrow dose recommended a maximum cumulative activity of 1.33 GBq/kg (36 mCi/kg) [123]. In addition, some have utilized a combination of strategies coupled to the concomitant administration of chemotherapy (Table 7).

Response criteria have been developed for the objective assessment in patients with neuroblastoma [19]. Most ^{131}I-MIBG trials have selected patients with advanced disease that have failed first-line therapy, while others have incorporated ^{131}I-MIBG into a multiprong dosing strategy (Tables 6 and 7). Initial trials were focused on feasibility and toxicity and represented single center, poorly controlled trials [61, 81, 184, 186]. Nonetheless, these trials demonstrated that repeated administrations of ^{131}I-MIBG could be given safely in patients with advanced disease who had failed conventional therapy. Overall, evidence of objective response was often observed (Table 6) with several trials reporting partial responses of up to ∼40% in patients who had failed other treatments. The incidence of objective complete response was usually much lower and seldom over 10%. In Tables 6 and 7, objective response rates are utilized although it is recognized that symptomatic or biochemical improvements are also important outcome measures [61, 94, 110, 184, 187]. Because many of these trials were not prospective, reporting criteria in terms of outcome were variable, and the parameters measured in terms of duration of response are inconsistent and include survival, overall response, and event-free survival (EFS).

Early studies such as those of Garaventa et al. reported their experience in patients with stage 3 or 4 neuroblastoma who had not achieved a complete response following conventional therapy. These patients received 1–5 treatments of 2.52–5.51 GBq (68–149 mCi) ^{131}I-MIBG and

had a 30% objective response rate with 2% achieving a CR. The 5-year EFS was 40% for stage 4 and 92% for stage 3 [61]. In a retrospective review, Kang et al. treated 20 patients, the majority of whom had residual or recurrent disease, with submyeloablative doses (median single activity of ^{131}I-MIBG 351 MBq/kg (9.5 mCi/kg) and cumulative activities of 1.02–1.13 GBq/kg, or 27.6–30.5 mCi/kg) [94]. These patients experienced a 31% objective partial response rate and effective symptomatic relief.

A formal phase I study was reported by Matthay et al. in patients with stage 3–4 relapsed neuroblastoma receiving escalating activities of 111–666 MBq/kg (3–18 mCi/kg) [121]. In patients receiving >444 MBq/kg (>12 mCi/kg), stem cells were harvested because of the significant bone marrow toxicity that was expected. Dose-limiting toxicity requiring stem cell transplant was observed in patients receiving 555 and 666 MBq/kg (15–18 mCi/kg). After transplant, a significant proportion of the patients did not achieve platelet independence before death (49–150 days posttransplant), although neutrophils recovered. Thirty-seven percent of patients had objective responses, 3% achieved CR, and median survival for all patients was 6 months.

In a phase I trial, Lashford et al. treated patients with advanced chemoresistant neuroblastoma using escalating whole-body doses of 1, 2, or 2.5 Gy based on a diagnostic scan [107]. Overall, the activity ranged from 2.37 to 12.1 GBq (64–327 mCi) with activities >5.29–9.18 GBq (143–248 mCi) required to deliver 2.5 Gy to the whole body. In this study, 56% of the measured post-therapy whole-body doses were a median of 10% lower than the prescribed dose. Whole-body doses of 1 Gy were well tolerated. However, 31% of patients receiving 2 Gy developed grade 3 or 4 thrombocytopenia, and at 2.5 Gy, 80% developed grade 3 or 4 thrombocytopenia and 40% developed grade 3 or 4 neutropenia. A 33% objective response was seen, similar to the range of results seen by Matthay et al. [124].

While most studies have administered more than one therapeutic dose of ^{131}I-MIBG (Table 6), there have been several studies using a single administration [79, 107, 121, 124]. The response rates reported in these trials are in the range of 25–46% (Table 6). Although single large amounts of ^{131}I-MIBG may target sites of disease well, this does not guarantee response to treatment (Fig. 2). Several studies have also repeated large doses of ^{131}I-MIBG. Howard et al. delivered high-cumulative doses of ^{131}I-MIBG by administering a median of 1.325 GBq/kg (35.8 mCi/kg). This was delivered in a median of two sessions (range 1–4) [82]. These treatments resulted in a response rate of ~40% with median overall survival of 12 months. Matthay et al. used two sequential administrations of ^{131}I-MIBG totaling 0.81–1.89 GBq/kg (22–51 mCi/kg) delivered over 14 days, with a response rate of 10% and overall survival of 48% at 18 months [123]. A compassionate use report in 53 subjects with relapsed neuroblastoma administered tandem doses of 18 mCi/kg to 41 patients with the second dose administered at 6 weeks (within 100 days). In these patients, stem cell support was available. Response rates are shown in Table 6 [91]. In these patients, 30% response rate was seen to initial treatment with a further 29% response on repeat treatment. While one report suggests that the greatest benefit occurs after the first of multiple treatments [82], this has not been adequately studied. A report using ^{131}I-MIBG in conjunction with chemotherapy concluded that two administrations were optimal, whereas reports in patients with pheochromocytoma have indicated that it may take more than one treatment before objective responses are noted.

Most studies have used ^{131}I-MIBG therapy in the setting of resistant or recurrent disease at the time of relapse or in conjunction with chemotherapy regimens. One group used it as first-line therapy with intent to obtain better results at time of tumor surgery with less toxicity than that of conventional approaches. Hoefnagel et al. treated 31 patients with stages 3 and 4 disease with an initial activity of 7.4 GBq (200 mCi) followed by 2–6 treatments with 3.7 GBq (100 mCi) treatments [75]. This regimen was well tolerated and resulted in an overall 71% response rate in primary tumors and 81% in metastatic lesions. Initial ^{131}I-MIBG resulted in successful surgical resection of >95% of tumor in 70% of the patients. Furthermore, they observed a greater than 50% drop in

catecholamines in 70% of patients. The same group reported on their expanded experience in 41 patients treated with frontline ^{131}I-MIBG using the same regimen of 7.4 GBq (200 mCi) followed by 3.7 GBq (100 mCi) every 4 weeks, with cumulative total doses of 12.95–35.15 GBq (350–950 mCi). In this study, an objective partial response rate of 63% was observed along with a 2% complete response rate [41]. Their conclusion was that the optimal response appeared to occur after two treatments. This was part of a planned therapy regimen that was to be followed by surgery and chemotherapy, and the overall response rate after surgery was 73%.

A retrospective study focused on patients with stage 1–3 with localized inoperable disease causing compromised organ dysfunction or respiratory effects [163]. These patients received a regimen previously described by the group consisting of a fixed dose of 5.5–7.4 GBq (200 or 150 mCi) followed by a second dose of 3.7–5.5 GBq (150 or 100 mCi), with adjustments based on weight. That study concluded that ^{131}I-MIBG therapy is an effective treatment modality for unresectable localized neuroblastoma causing or in danger of causing organ or respiratory dysfunction and offers a good alternative to chemotherapy if urgent treatment is needed. Toxicity was mainly hematologic and mostly well tolerated.

There is some data to suggest that older patients with NB have improved response rates compared to younger patients [55, 96]. Neuroblastoma is predominantly seen in young children. In a retrospective study a total of 39 patients were treated with median large cumulative doses of 720 mCi (17.8 mCi/kg) ^{131}I-MIBG for those 10–17 years old and 857 mCi (16.9 mCi/kg) for those $\geq$18 years old. The overall response rate was 39% for those 10–17 years old and 56% for those $\geq$18 years old. Overall survival rates at 3 years were 32.8% and 43.2%, respectively.

In a retrospective analysis of 218 patients, 72 had refractory disease and 146 patients had relapsed disease. These patients were then treated with 6.3–20.9 mCi/kg ^{131}I-MIBG. Less favorable outcomes were seen in patients with relapsed disease, with 24% of relapsed patients having progressive disease compared to only 9% of refractory patients, and 39% of relapsed patients had stable disease compared to 59% of refractory patients. Among all patients, the 24-month OS was 47.0%. The 24-month OS for refractory patients was significantly higher at 65.3%, compared to 38.7% for relapsed patients ($p < 0.001$) [211].

Sixteen patients with high-risk neuroblastoma were treated with two upfront courses of ^{131}I-MIBG combined with topotecan. An overall response rate of 57% was noted with a response in 94% of primary tumors but only 34% of bone marrow disease. Further treatment with induction chemotherapy, surgery, or ASCT resulted in additional responses [103].

Because of the response rate to ^{131}I-MIBG as a single agent in relapsed or refractory neuroblastoma, several investigators have used ^{131}I-MIBG prior to chemotherapy, attempting to improve the remission status prior to myeloablative chemotherapy and ASCT. In one such study, eight refractory NB patients were administered ^{131}I-MIBG treatment at doses of 16–19 mCi/kg i.v. followed by autologous stem cell transplant approximately 2 weeks later. Some patients received local radiation to primary tumors and/or residual sites of disease. After 6–8 weeks, the patients received myeloablative treatment with busulfan and mephalan followed by ASCT [56]. Seven of the eight patients were alive 10 months after ASCT, demonstrating that combined therapy was possible and engraftment was achieved. One patient died of sinusoidal obstructive syndrome at day 50. Two patients had PR and three had CR. Other investigators have aimed to combine ^{131}I-MIBG with arsenic, based on preclinical studies that have shown a radiosensitizing effect. A group of 19 recurrent or refractory NB patients were treated with ^{131}I-MIBG and arsenic. By international research criteria, 12 patients had no response while 7 had progressive disease (PD), including six out of eight who entered the study with PD. Objective improvements in semiquantitative MIBG scores were observed in six patients. Five-year overall survival for NB was 37 $\pm$ 11%. The adverse drug-related side effects were similar to those for ^{131}I-MIBG alone [129]. Overall, the addition of arsenic had no additional effect on toxicity.

Full courses of irinotecan and vincristine have been administered with high-dose ^{131}I-MIBG with stem cell transplant in the setting of a dose escalation phase I [42]. Significant responses were observed in 26% when a combination of MIBG, CT, and bone marrow was used for assessment. Furthermore, responses were seen in 43% of seven patients receiving more than one therapy cycle.

Other pharmaceuticals that may enhance the therapeutic effect of ^{131}I-MIBG have been combined, taking advantage of potentially synergistic mechanisms and pathways. Vorinostat, a histone deacetylase inhibitor and radiosensitizer [136], also increases density of norepinephrine receptors [134]. Based on these preclinical studies, ^{131}I-MIBG has been combined with vorinostat in a dose escalation trial. This combination resulted in an overall 12% response rate and 17% response rate at the highest dose level [43].

There is no consensus on how to best incorporate ^{131}I-MIBG in the treatment of high-risk patients. It is clear that ^{131}I-MIBG has efficacy in advanced neuroblastoma, but research continues as to how best to incorporate its use as part of a multimodal approach to therapy, taking advantage of synergies of mechanism of actions and to some extent non-overlapping toxicities. There is also ongoing work using improved reagents with ^{131}I-MIBG at high specific activity [36] and work using ^{211}At-MIBG [188]. Furthermore, future imaging may be used to select candidates that may benefit from the combination of ^{131}I-MIBG and peptide receptor radionuclide therapy such as ^{177}Lu-/^{90}Y-labeled somatostatin analogs [25].

Toxicity

The most significant toxicity associated with ^{131}I-MIBG therapy in both children and adults is hematologic. There is a larger drop in platelets than white blood cells, likely related to binding of MIBG to platelets [48]. These drops in counts are dependent on the administered activity and are minor when activities in the range of 7.4 GBq (200 mCi) are used [47], whereas doses >444 MBq/kg (12 mCi/kg) cause hematologic toxicity. Grade 3 or 4 thrombocytopenia is observed in 80–87% of patients, requiring platelet transfusion and/or growth factors [70, 91, 124]. After whole-body doses up to 2.5 Gy in children with neuroblastoma, grade 3 or 4 thrombocytopenia was seen in 80% [107]. The nadir in children has been reported to occur at approximately 28 days after a single administration (range 9–42) [107]. When chemotherapy is combined with ^{131}I-MIBG therapy, nadirs may occur earlier and are felt to be predominantly driven by the chemotherapy [120].

In patients with upfront ^{131}I-MIBG treatment receiving median activities of 441 MBq/kg as a first dose and a repeated median dose of 328 MBq/kg, the main toxicity was also hematologic with grade 4 thrombocytopenia in 1% of patients after first treatment and 3% after the second [12]. This is lower than that seen in patients with multiple prior treatments. Other predictors of increased marrow toxicity include whole-body or marrow absorbed dose, extensive marrow/bone involvement, and prior stem cell transplantation [12, 44, 59, 169].

Children and adults treated with activity ≥444–666 MBq/kg (12–18 mCi/kg) may require bone marrow transplant because of significant and prolonged marrow toxicity [44, 91]. Howard et al. reported thrombocytopenia requiring platelet transfusion in 78% and 82% of patients after the first and second infusion, respectively, while only 50% had grade 4 neutropenia that was usually transient. Ten patients required stem cell transplant. Nonetheless, in this and other trials, there are patients who fail to engraft adequately at these high levels of activity [44, 82]. In this and other trials, stem cells are transplanted when severe neutropenia is present, requiring growth factors, or when the patient requires platelet transfusion more than 2 times a week [82, 124]. In other cases, stem cells are routinely transplanted at 21 days post high-dose ^{131}I-MIBG [206]. With tandem therapy of 18 mCi/kg, 85% of patients receiving two treatments required stem cell support, which typically was administered a median of 15 days after the second therapy dose [91]. Gaze et al. used dosimetry to deliver 4 Gy to the whole body

[62]. These doses often required transplant that was performed 14 days post last ^{131}I-MIBG treatment and when the estimated whole-body retention of ^{131}I was less than 0.8 mCi. In patients receiving ^{131}I-MIBG and myeloablative chemotherapy, the stem cells were infused 21 days after MIBG and 7 days after the chemotherapy [205]. At a mean activity of 381 mCi, Safford et al. reported that 12% of patients had enough hematopoietic depression to required hospitalization [158]. Because neutropenia is infrequent with low activity, the incidence of infections is low. As expected with higher activity that induces considerable neutropenia, significant infections are occasionally encountered [107, 124, 205]. In addition, when high-dose ^{131}I-MIBG is given with myeloablative chemotherapy, a high incidence of febrile neutropenia was observed in 70% of treated patients [206]. With tandem high-dose treatment, 29% of patients remained thrombocytopenic and transfusion dependent in spite of stem cell transplant. Toxicity was similar for adult patients, young adolescent receiving high-dose therapy compared to younger patients [151]. Combined chemotherapy and high-dose ^{131}I-MIBG results in hematotoxicity similar to when ^{131}I-MIBG is given alone, but other toxicities are new/more prominent when combined with chemotherapy; for example, when irinotecan, vincristine, and MIBG therapy were combined, diarrhea was frequently seen [42].

Myelodysplasia (MDS)/acute myelocytic leukemia have been reported in patients who have received both chemotherapy and large amounts of ^{131}I-MIBG. In adult PHEO patients, a ~4% incidence was reported with high-dose therapy [42, 70]. MDS has also been reported after therapy in patients with medullary thyroid carcinoma and carcinoid tumors [29]. MDS in children receiving ^{131}I-MIBG is also reported [59, 79]. The timeline for MDS after ^{131}I-MIBG is typically >2 years [28, 70]. The UCSF group reviewed their experience in 95 patients with neuroblastoma as well as a review of the literature. In their patients, the cumulative incidence of MDS was 3.9% at 60-month post-therapy [201]. A further review of the literature only yielded three additional patients out of 500 treated with ^{131}I-MIBG. The authors felt that alkylating chemotherapy agents played a significant role. Garaventa et al. reviewed 119 patients treated with a mean of two therapy regimens using activity estimated at ~240 MBq/kg (6.5 mCi/kg) where whole-body doses were usually less than 200 cGy. At follow-up, 78 patients had died and five secondary malignancies were reported at a median of 3 years (1–15 years) including acute monolymphoblastic leukemia, chronic myelomonocytic leukemia, angiomatoid malignant fibrous histiocytoma, malignant schwannoma, and rhabdomyosarcoma [60]. This occurrence of secondary malignancy and bone marrow disorders indicates that these patients require close follow-up, especially in patients with prolonged survival.

The thyroid is routinely protected with iodine-containing solutions (see above). Nonetheless, hypothyroidism has been reported. The incidence of hypothyroidism has ranged from 11% to 32% [41, 61, 164, 166, 205]. One investigator reported that 48% of treated patients developed hypothyroidism [59]. In children receiving high-dose ^{131}I-MIBG (~18 mCi/kg), there was a high baseline incidence of elevated TSH in 24% of patients [153]. In the latter report, the 2-year cumulative incidence rates of hypothyroidism was 35 ± 14% in those with baseline thyroid dysfunction and 10 +/± 5% in those without baseline abnormal thyroid function, possibly attributed to the KI and potassium perchlorate regimen. In patients with neuroblastoma, the incidence of non-visualization of the thyroid in post-therapy images ranges from 52% to 59% [35, 153]. In adults, the incidence of hypothyroidism is lower [150, 190]. There have also been reports of thyroid cancer attributed to ^{131}I-MIBG [191].

Common systemic/constitutional toxicity associated with large doses of radiation from ^{131}I-MIBG is often observed (6–67% of patients) including asthenia, nausea, and vomiting. Nausea and/or vomiting may start as early as 8–12 h and last a week; this appears to be more frequent in patients with larger liver metastatic burdens [64, 104, 109, 158, 164]. While some have reported a low incidence [47, 61, 109, 158], other have encountered it more frequently, sometimes in >40% of the patients [12, 164]. In our institution, ondansetron

is administered prophylactically starting immediately before treatment and continued for several days. This regimen minimizes the incidence of nausea and vomiting due to therapy. Salivary gland tenderness and short-term dysfunction have been reported [128].

Although ^{131}I-MIBG localizes in normal organs such as the heart, lung, liver, and adrenal, there have been very limited complications related to cardiac, renal, liver, or adrenal insufficiency. Pulmonary toxicity is most frequently related to infectious disorders. Nonetheless, infrequent reports of ARDS, bronchiolitis obliterans, and other serious pulmonary disorders have been described [12, 70, 82, 126]. Mild changes in liver function have been encountered [41, 137, 150], but severe hepatic dysfunction is rare [13, 16, 107]. Sinusoidal obstructive syndrome has been reported when ^{131}I-MIBG is combined with chemotherapy, that was though to be mainly related to the chemotherapy component [206]. In children receiving a median dose of 18.2 mCi/kg ^{131}I-MIBG, there were 20 patients who developed grade 3 or 4 liver toxicity, although there suggestion of causality with ^{131}I MIBG in only eight cases [153]. Changes in glomerular filtration rate have been documented, but the induction of renal failure is unlikely [41]. Drops in hormone levels such as corticosteroids and testosterone have been reported, as well as primary ovarian failure [34, 195].

Hypertension can occur and cases of hypertensive crises have been reported in PHEO patients [72, 154]. Hypertension can also occur following administration of ^{131}I-MIBG therapy in patients with neuroblastoma [102, 111]. Hypertension was reported in 5% of 50 patients receiving 110 infusions of ^{131}I-MIBG, more commonly in those with pre-existing hypertension, including hypertensive crises with seizure [102]. In this report, a $>$15 mm Hg rise was seen in 12% of the patients. Most adverse hypertensive events occur between 20 and 25 h post-administration [12, 102, 203]. Risk factors for a hypertensive response not only include pre-existing hypertension but also younger age and eGFR prior to treatment [203]. When therapy is administered, antihypertensive medication should be available, particularly in patients with PHEO [54], and observation over 48 h has been suggested. In 218 administrations of ^{131}I-MIBG, the administration of antihypertensive medication (nifedipine) was only required in 2.8% of patients [203].

Summary

Therapeutic ^{131}I-MIBG is safe and well tolerated in both children and adults with few side effects, when used in low-to-moderate doses in patients with PHEO/PARA, carcinoid, and neuroblastoma. Myeloablative doses are associated with more toxicity but are still relatively well tolerated. The role of ^{131}I-MIBG has been best characterized in patients with PHEO/PARA where symptomatic and biochemical improvements are frequently observed. In patients with carcinoid, studies have also shown that, in selected patients, good palliative results can be obtained. In both carcinoid and PHEO/PARA, objective partial responses are often seen and can be long lasting. In neuroblastoma, good responses, albeit often temporary, have also been obtained with ^{131}I-MIBG. In neuroblastoma, most studies have been used with therapeutic rather than palliative intent. It is clear that new, combined approaches must be developed if ^{131}I-MIBG is to find more general use and to have greater impact on quality of life or survival in neuroblastoma, PHEO/PARA, and carcinoid.

Targeted Radionuclide Therapy for Bone Metastasis

45

Neeta Pandit-Taskar and Chaitanya R. Divgi

Abstract

Bone metastases markedly reduce the quality of life due to bone pain, pathologic fractures, loss of mobility, and hypercalcemia. A graded three-step approach, as recommended by the World Health Organization (WHO), is used to treat pain according to its severity. Nonsteroidal anti-inflammatory drugs are used in patients with mild to moderate pain. When pain persists or increases, a weak opioid such as codeine or hydrocodone is added. Higher doses or more potent opioids are used if the pain persists or becomes more severe. Bisphosphonates (BPs) are useful in the treatment of osteoporosis and metastatic disease by decreasing the resorption of the bone. BPs bind to bone mineral and directly interfere with the activation of osteoclasts. They are internalized by osteoclasts and inhibit specific biochemical and metabolic pathways in these cells; they also reduce skeletal complications and reduce the rate of development of new lesions and delay progression in bone metastases. External beam radiation therapy given as a single or multifractionated dose is an effective treatment and provides early relief, especially for localized bone pain due to bone metastasis. Therapy with bone-seeking radiopharmaceuticals is effective for reducing pain in patients with widespread, painful bone metastases from various malignancies particularly prostate cancer. A variety of radiopharmaceuticals have been used and tested, including many beta-emitting nuclides and alpha emitting radium-223 (^{223}Ra) dichloride. Each of these agents target the bone by chemical bonding or adsorbing to the trabecular surface of the bone, the metal-chelated radiotracer to the trabecular surface, while ^{32}P-sodium orthophosphate and ^{89}Sr-chloride distribute more widely throughout the bone. ^{89}Sr-chloride and ^{153}Sm-EDTMP are two FDA-approved beta-emitting radiopharmaceuticals that have largely replaced ^{32}P-sodium orthophosphate in the treatment of metastatic bone pain in the United States. More recently, alpha-emitting ^{223}Ra-dichloride has been used in symptomatic castration-resistant prostate cancer (CRPC). The onset of pain relief commonly occurs within 7–21 days. Re-treatment is possible after allowing for marrow recovery; however, multiple therapies require consideration of cumulative marrow toxicity.

^{89}Sr-chloride and ^{153}Sm-EDTMP have been used extensively, primarily for the treatment of bone pain from breast and prostate cancer due to the presence of osteoblastic

disease that enables high uptake of the agents. Radionuclide therapy may be used alone or in combination with chemotherapy or radiation therapy to enhance pain relief and delay onset of new pain; consideration needs to be directed to overlapping or cumulative toxicities especially in the marrow that may require supportive treatment. Patients most suitable for bone pain therapy are those with multiple sites of bone metastases confirmed by a bone scan showing focal sites of increased radiopharmaceutical uptake and those who have symptoms related to osseous disease that requires increased doses of pain medication or is refractory to pain medication. ^{223}Ra is an alpha-emitting radionuclide that accumulates in the bone as it is analogous to calcium. The high linear energy transfer of alpha radiation leads to double-strand DNA breaks within the cells. While effective for pain palliation, it has also shown survival benefit in those with metastatic osseous disease from prostate cancer. However, it is currently approved for use only in symptomatic CRPC patients who have no other visceral diseases.

Introduction

Bone metastases are commonly seen in the advanced stages of a number of malignancies, including cancers of the prostate, breast, lung, thyroid, bladder, melanoma, kidney, and myeloma [1, 2]. Overall, the skeleton is the third most common site of metastasis, and it is estimated that one of every five patients with metastatic disease will have symptomatic osseous involvement [3]. Skeletal metastases markedly reduce the quality of life due to bone pain and pathologic fractures and loss of mobility. Analgesic medications are used in a graded three-step approach (recommended by WHO) to treat metastatic osseous pain according to severity [4]. Usually, nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin, ibuprofen, and naproxen are used in patients with mild to moderate pain. When pain persists or increases while on

NSAIDS, a weak opioid such as codeine or hydrocodone is added. Higher doses or more potent opioids such as morphine, hydromorphone, or fentanyl are used if the pain persists or becomes more severe. The National Comprehensive Cancer Network (NCCN) guidelines recommend treatment based on an initial comprehensive assessment of severity of pain, pathophysiology of causes, cancer pain syndromes, and skeletal-related events. General management includes initiation of analgesic NSAIDS, and corticosteroids are added if associated inflammation is a factor. Localized radiotherapy or systemic radionuclide treatment may be added as needed for local or diffuse disease pain, respectively. Continuous pain is treated with regular doses of pain medication with small doses of opioids given additionally for breakthrough pain. Opioid dosage and type may be changed when pain persists or increases [5]. Bisphosphonates and RANKL-inhibiting monoclonal antibody, denosumab, are approved medications useful to prevent bone resorption and skeletal-related events.

Narcotics may reduce the pain, but can cause significant side effects including constipation and/or drowsiness, as well as physical and psychological dependence (addiction). When a patient has pain from a localized bone metastasis, external beam radiation therapy is often used. In patients with symptomatic widespread skeletal metastases, therapy with bisphosphonates and bone-seeking radiopharmaceuticals helps reduce pain.

Pathophysiology of Metastasis

Metastasis occurs when tumor cells detach from the tumor mass and migrate to a new location where the tumor cells adhere to endothelial cells, with subsequent invasion and colonization of the metastatic site [6, 7]. Chemical mediators, such as cadherins, integrins, immunoglobulins, E- and P-selectins, and CD 44, are involved in this complex process. Tumor cell adherence to the extracellular matrix (ECM) is mediated by integrins, while cell-cell adhesions are mediated by cadherins [8].The activation of integrins is accompanied by the activation of proteases that together help to degrade the ECM, forming a pathway for invasion. Matrix metalloproteinases, plasmin, urokinase, cathepsins, and heparinases promote tumor invasion [6]. An embolus of tumor cells bound to coagulation factors like fibrinogen, fibrin, thrombin and tissue factor gets trapped in capillary beds. The endothelial cell E- and P-selectins contribute to tumor cell arrest and initiate adhesion to the endothelium. E-selectin, produced de novo by activated endothelium, also facilitates the process. In vitro, E-selectin mediates binding of colon carcinoma cell line to endothelial cells. It has also been associated with breast cancer metastasis. P-selectin is likely involved in binding of cells in a range of tumors, including those of the lung, melanoma, and colon [9–14]. Greater endothelial tumor cell adhesion involves cadherins or immunoglobulin-like cell adhesion molecules [15].

Invasiveness is mediated by a number of enzyme systems including serine proteases like matrix metalloproteinase and urokinase plasminogen activation systems. Tumor cell motility, critical for the development of distant metastases, appears to be mediated by a number of factors, including growth factors, hyaluronans, components of matrix, and other host- or tumor-secreted factors (e.g., cytokinins such as autotoxin and hepatocyte growth) [16–18].

Metastatic involvement of the bone meets the "seed and soil theory of metastasis" hypothesis proposed by Paget, which holds that interactions between tumor cells and their environment influence why certain tumors metastasize to the bone. The dissemination pattern can sometimes be explained by anatomic predisposition. For example, prostate cancer has propensity to spread to the pelvis and vertebrae because of the venous plexus of Batson.

Osteoblastic metastases occur due to mediators that stimulate osteoblast proliferation or differentiated osteoblast function. Prostate cancer cells express transforming growth factor-beta (TGF-β), which has a bone stimulatory effect; fibroblast growth factors can stimulate osteoblast proliferation and increased bone formation, as well as other proteins that are growth factors

belonging to the TGF-β family, the most potent stimulants of in vivo bone formation [19–21]. The loss of bone mineral in osteolytic lesions is mediated predominantly by increased osteoclast activity. Numerous factors produced either by tumor cells, e.g., parathyroid hormone-related protein (PTHrP), or the bone matrix stimulate this resorptive action of osteoclasts, leading to increased destruction of the bone. Higher PTHrP in primary breast tumors predicts the subsequent development of bone metastasis [22].

Metastatic osseous disease often leads to debilitating pain. Anatomic factors and chemical mediators contribute to this pain; tumor in the bone may cause expansion, periosteal stress, or nerve compression. Bone cancer pain may also occur due to interaction with and sensitization of the nervous system [23]. Peripheral sensitization results in increased release of substance P from nociceptors even with minor stimulation, leading to allodynia and hyperalgesia. Central sensitization of dorsal horn of the spinal cord also leads to increased sensitivity to pain. Increased astrocytosis, enhanced expression of c-Fos (a marker of neuronal activity), and the presence of the prohyperalgesic peptide dynorphin have been seen in the spinal cord. Prostaglandins are associated with inflammation and cancer pain [24]. Upregulation of glial fibrillary acidic protein (GFAP) occurs, and isoenzyme cyclooxygenase-2 (Cox-2) has also been found in tumor cells [25].

Low intra- and extracellular pH in tumors can also contribute to pain [23]. Neuropathic pain may occur due to entrapment or injury to nerves by tumor growth.

Prevention of Bone Resorption

Bone metastasis is linked to bone destruction caused by osteoclastic activity that can be prevented by the use of bisphosphonates [26, 27]. Proliferation, survival, and activity of osteoclasts are regulated by osteoprotegerin ligand (OPGL), which belongs to the TNF family of molecules. Osteoblasts and activated T cells are key sources of OPGL that act via binding to RANK receptors expressed on osteoclast precursors and mature osteoclasts [28]. RANK-ligand inhibition has been shown to be effective and is approved as a therapy to reduce osteoclastic activity in skeletal metastases.

Bisphosphonates are a class of agents in which two phosphonate groups are linked via phosphoether bonds to a carbon core. BPs bind with high affinity to calcium in the bone mineral matrix, hence the avidity for bones, and are thought to act primarily by inhibiting osteoclast-mediated bone resorption. BPs bind to bone mineral and directly interfere with the activation of osteoclasts; they get internalized in the osteoclasts and inhibit their action by interfering with specific biochemical and metabolic pathways. BPs inhibit ATP-dependent intracellular enzymes or enzymes of the mevalonate pathway, preventing formation of proteins required for modification of GTP-binding proteins. The key target is farnesyl pyrophosphate synthase (FPPS) [29]. Another mechanism may be stimulating osteoblasts to produce osteoclast inhibitory factors [30].

BPs act by decreasing the resorption of the bone [31] and have become an important part of management of osseous metastases [32], especially those with significant osteolytic component such as breast cancer and multiple myeloma [33, 34] by significantly reducing skeletal complications, lowering the rate of development of new lesions, and delaying progression in bone metastases [34]. Increasing evidence is emerging regarding their potential to prevent disease recurrence and metastases [35] and possible effect on survival [36]. Zoledronic acid (ZA) has been shown to be effective for the treatment of bone metastases in patients with metastatic prostate, lung, renal cell, and other carcinomas [37, 38].

In prostate cancer, the use of ZA has been shown to reduce pain and the number and rate of skeletal-related morbidities [39]. The use of BPs in conjunction with other agents in prostate cancer may improve efficacy [40]. Osteoclast inhibition via a human monoclonal antibody denosumab that targets RANKL is useful in preventing bone resorption and increases bone mineral density. In

patients with nonmetastatic prostate cancer, it showed a lower incidence of vertebral fractures in comparison to placebo [41, 42]. Also in comparison to ZA, it showed an increased time to skeletal related events [43]. As with BP, osteonecrosis of the jaw is a common side effect as well as increased hypocalcemia that needs active calcium supplementation [44]. Recent guidelines suggest denosumab as a first-line treatment for prevention of skeletal-related events in metastatic prostate cancer [45].

Radiation Therapy

External beam radiation therapy (EBRT) is the treatment of choice for localized bone pain due to bone metastasis and is very effective in providing early and rapid pain relief that may be seen as early as 48 h after the commencement of therapy. Radiation destroys viable tumor cells, resulting in shrinkage of tumor, and enables osteoblastic repair of damaged bone.

Local radiotherapy to a small area may be given as a single or multifractionated dose. The choice of one over the other is still controversial, however. While single-fraction dose is convenient and less expensive for patients, there is concern that the equivalent biologic dose may be smaller compared to multifractionated method, leading to an inferior response in pain palliation [46]. Re-treatments may be required more with single-fraction therapy than with multifractionated therapy [47]. Single-fraction treatment doses vary, though a minimum of 8 Gy is preferred, and higher pain responses are seen with this dose as compared to lower doses [48]. Varied fractionation schemes including a single 8 Gy and 20 Gy in five fractions, 24 Gy in six fractions, and 30Gy in ten fractions can result in similar results for pain relief [49]. For repeat treatments of spinal metastasis, SBRT, IMRT, and proton beam therapy are more suitable, although re-treatment carries a higher risk of radiation myelitis. For those with severe pain or spinal compression in sites previously irradiated, surgical intervention should be considered for palliative purposes. Survival benefit from aggressive local therapy of oligometastasis is not yet proven.

Radiopharmaceutical Therapy

Advanced cancers, especially prostate and breast cancer, often cause skeletal metastases that may cause significant pain at multiple sites. Systemic antitumor therapy like chemotherapy and hormone therapy is used to treat and prevent the spread of metastatic disease; however, the benefit in advanced disease may be limited, and symptomatic pain relief usually requires pain-relieving medication. In patients with painful osseous metastatic disease, refractory to conventional analgesia, radiopharmaceutical therapy has played a key role in pain palliation.

The radioisotope's half-life should be long enough to enable cytocidal doses of radiation to be delivered. Radiopharmaceuticals that have been used to target bone metastasis include the beta-emitting nuclide phosphorus-32 (^{32}P) sodium phosphate or orthophosphate, strontium-89 (^{89}Sr) chloride, samarium-153 ethylenediamine tetramethylene phosphoric acid (^{153}Sm-EDTMP), rhenium-186 and rhenium-188 hydroxyethylidene diphosphonate (^{186}Re-HEDP and ^{188}Re-HEDP), lutetium-177 ethylenediamine tetramethylene phosphonic acid (^{177}Lu-EDTMP), and ^{117m}Sn diethylenetriaminepentaacetic acid (^{117m}Sn-DTPA), as well as radium-223 dichloride, an alpha-emitting radiopharmaceutical (Table 1). Bone pain palliation therapy with radiopharmaceuticals is a cost-effective systemic therapy to relieve pain from skeletal metastases with a consequent decrease in morbidity and an improvement in quality of life [50–52].

Mechanism of Action

^{32}P orthophosphate, ^{89}Sr-chloride, and ^{223}Ra dichloride have direct affinity for the bone. On the other hand, ^{153}Sm, ^{186}Re, ^{188}Re, and ^{177}Lu are

Table 1 Radiolabeled agents for targeting bone metastasis

Isotope	Compound	Half-life (days)	Emission	Maximum energy MeV	γ-energy MeV (%)	Soft tissue range mm (maximum)
^{177}Lu	^{177}Lu-EDTMP	6.7	β^-	0.497	0.208 (11)	–
^{32}P	^{32}P-phosphate	14.3	β^-	1.71	–	**8**
^{89}Sr	^{89}Sr-chloride	50.5	β^-	1.46	0.91 (0.01)	**2.4**
^{223}Ra	^{223}Ra-dichloride	11.4	α	5.78	0.269 (13.6%) 0.324 (3.9%); 0.154 (6.04%)	**0.1 mm**
^{186}Re	^{186}Re-HEDP	3.7	β^-	1.07	0.137 (9)	**2.4**
^{188}Re	^{188}Re-HEDP	0.7	β^-	2.12	–	**3**
^{153}Sm	^{153}Sm-EDTMP	1.9	β^-	0.81	0.103 (28)	**0.6**
^{117m}Sn	^{117m}Sn-DTPA	13.6	Conversion electron	–	–	**0.3**

targeted to the bone by complexing the radionuclide to phosphonate complexes like EDTMP (lexidronam) or HEDP (etidronate). The sources of radiation within the bone differ depending on the radiopharmaceutical. The metallic-chelated radiotracers tend to chemically absorb to the trabecular surface, whereas ^{32}P-sodium orthophosphate, ^{89}Sr-chloride, and ^{223}Ra dichloride distribute more widely throughout the bone because of the natural distribution of phosphate and the fact that strontium behaves very much like calcium in the body, as both are members of Periodic Table Family II. Due to the heterogeneity of radiopharmaceutical uptake, spicule thickening, and tumor and marrow distribution, there is variation in dosimetry between the various agents [53].

^{32}P

^{32}P was the radionuclide initially used in the treatment of bone pain, and it remained the most widely used agent until the 1980s [54]. It is a reactor-produced, pure beta-emitting radionuclide with a physical half-life of 14.3 days and emission of an energetic beta particle of 1.71 MeV. Its high energy allows a maximum tissue range of 8 mm and an average range of 3 mm and is available in both oral and injectable forms. The mechanism of action appears to be DNA damage from decay to ^{32}S with subsequent tumor cell death.

Its uptake in malignant tissue was demonstrated by Lawrence and colleagues who used it to treat leukemia [55, 56]. The pain response rates for ^{32}P therapy are reported between 59 and 93% for prostate cancer and 52–94% for breast cancer with overall response rates of 77% and 84%, respectively [57, 58]. No dose-response relationship was seen. Pain palliation is usually observed within 14 days with a range of 2 days–4 weeks. The long beta particle range results in significant radiation to the bone marrow, with frequent hematopoietic side effects [59]. Dose-dependent pancytopenia occurs at around 4–5 weeks, with recovery by 6–7 weeks.

^{89}Sr-Chloride

^{89}Sr-chloride is an FDA-approved radiopharmaceutical that has been extensively used in the treatment of metastatic bone pain and largely replaced ^{32}P in the United States. It belongs to the II-A family of the Periodic Table of Elements, the same family as calcium. ^{89}Sr has a physical

half-life of 50.5 days and emits a beta particle with a maximum energy of 1.46 MeV, with a maximum beta particle range of 7.2 mm and an average soft tissue range of 2.4 mm. It has very low gamma emissions (0.01% abundant gamma emission with a 0.91 MeV photopeak) precluding external imaging. Following an intravenous administration, it is rapidly concentrated in the bones, primarily in osteoblastic areas. About 80% of free ^{89}Sr is excreted through the kidneys and 20% through the gastrointestinal system. Its biological half-life is 4–5 days with biexponential clearance, such that 20% remains in the body, mostly in the bone, at 90 days [60].

The administered activity is generally 40–60 μCi/kg or 4 mCi. The onset of pain relief commonly occurs within 7–21 days, and the mean duration of relief is about 2–6 months. Transient increased bone pain (flare) may occur in about 10–15% of patients and is usually seen within 24–120 h posttreatment. This is usually mild, self-limited, and controlled with analgesics. A flare also usually heralds a good treatment response [61]. Hematologic toxicity is usually mild and reversible, and there is a minimal decrease in red cell counts. In various studies, platelet and white cell counts may drop by an average of 30–40% from the pretreatment level, though nadirs as low as 25–30% of pretreatment values have been seen [62–64].

^{89}Sr has been extensively used, mainly in the treatment of bone pain from breast and prostate cancer, with 60–80% of patients respectively obtaining some relief of bone pain [65–68]. An early phase I/II studies treated 38 patients (45 treatments) with 1–4.5 mCi or 16–70 μCi/kg of ^{89}Sr. All patients had an increasing need for pain medication and highly variable performance status at baseline. One patient had complete pain relief, and 18 patients had an overall 25% reduction in narcotic use lasting at least 1 month, and/or a 20% improvement in Karnofsky scale rating was seen after 48% of treatments [62]. A multicenter study in 83 prostatic carcinoma patients showed an effectiveness of ^{89}Srin relieving bone pain even in those who had failed to respond to conventional therapies. About 75% experienced pain relief and 22% became pain-free at treatment dose of 1.5 MBq/kg or more. Symptomatic improvement was seen as early as 6 weeks and the mean duration of effect was 6 months [61]. A clear benefit over placebo was seen in a prospective randomized double-blind controlled study [68]. A dose-response relationship may exist between the dose of ^{89}Sr administered and complete relief of pain due to skeletal metastases [65]. Early studies on combination treatment with chemotherapy suggested that a low dose of carboplatin may have an enhanced effect on pain relief [69]. Multiple doses combined with low-dose docetaxel are also feasible and may have antitumor activity [70]. Pain relief and performance improvement was achieved in 76% and 40% of patients, respectively, and a prostate-specific antigen (PSA) decrease of 75% or more from baseline was seen in 32% of evaluable patients [70].

Repeated therapy with ^{89}Sr is effective in relieving pain, though the response rate and duration of response may be lower than after first treatment. Re-treatment is permitted after 90 days; however, detailed reassessment and close follow-up is recommended because multiple therapies may lead to cumulative marrow toxicity [71–77]. Quilty et al. compared ^{89}Sr-chloride with radiation therapy in patients with prostate cancer. Individuals treated with ^{89}Sr experienced a longer time to onset of new painful sites than those who received radiation therapy alone, and fewer patients reported new pain sites after strontium therapy than after local or hemibody radiotherapy. However, there was no survival benefit [78]. When given as an adjuvant to external beam radiation, ^{89}Sr-chloride improved pain relief and delayed bone disease progression in hormone-resistant prostate cancer [79]. In a randomized phase III study, 126 hormone-refractory prostate cancer patients were treated with a higher dose (400 MBq) of ^{89}Sr-chloride as adjunct to radiation therapy while a comparable number received placebo. Patients who received ^{89}Sr-chloride had better response to pain control with reduced need for analgesia. Delayed progression of disease was noted as evidenced by lower requirement for subsequent radiotherapy; some showed lower tumor marker levels. Patients receiving strontium-89

also showed enhanced quality of life by some measures. Even with higher dose (10.8 mCi), the hematologic toxicity was reversible; however, no effect was noted on survival improvement [79] (Table 2).

^{89}Sr-chloride therapy given concurrently with chemotherapy may enhance pain relief and delay the onset of new painful metastases [80]. The role of ^{89}Sr in combination with a variety of chemotherapeutic agents has shown response rates (complete plus partial response) of between 55 and 80%. In a randomized trial in patients with hormone-refractory prostate cancer, cisplatin administered with ^{89}Sr-chloride showed better overall pain relief (91% vs. 63%), longer median duration of pain relief (120 days vs. 60 days), lower incidence of new sites of pain (14% vs. 30%), and lower progression of bone metastasis (27% vs. 64%) as compared to those with ^{89}Sr and placebo, respectively. Importantly, there were no significant differences in toxicities between the groups. There was no therapeutic effect noted as measured by PSA change and survival [81].

In patients with progressive bone metastases, hormonal therapy or chemotherapy alone is unable to provide durable control in pain

Table 2 ^{89}Sr-chloride clinical studies

Author, date	Disease	# of patients	Activity/dose	Major endpoints	Results
Ma et al. (2008)	Prostate cancer	116	40–60 μCi/kg	Toxicity, pain relief, PSA, ALP, LDH	84% with pain reduction. Decrease in bone markers
Tu et al. (2005)	Androgen-independent prostate cancer	34	55 μCi/kg and docetaxel +Sr or docetaxel alone	Long-term survival from prior study (Tu et al. 2001)	No bone marrow failure at 6 months; follow-up other treatments
Nilsson et al. (2005)	Androgen-independent prostate cancer	35	55 μCi/kg 5-FU, epirubicin, and mitomycin C	Double-blind randomization; toxicity, PSA, ALP	Higher toxicity in chemotherapy group while mild toxicity in ^{89}Sr group. Significant reduction in intensity and frequency of pain after 3 weeks in both groups
Baczyk et al. (2003)	Prostate cancer	70	4 mCi	Toxicity, pain relief, PSA, ALP, LDH	88% with pain reduction
Tu et al. (2001)	Androgen-independent prostate cancer	34/103	55 μCi/kg and docetaxel or docetaxel alone	Toxicity, PSA, ALP, survival	Overall 60% with >50% PSA decrease; 52% with complete pain reduction
Dafermou et al. (2001)	Prostate cancer	527	4 mCi	Toxicity, pain relief, PSA, ALP, LDH	60% with pain reduction
Turner et al. (2011)	Prostate cancer	93	4 mCi	elief, PSA, ALP, LDH	63% with pain reduction
Kraeber-Bodeara et al. (2000)	Prostate cancer	94	4 mCi	Toxicity, pain relief, PSA, ALP, LDH	78% with pain reduction
Porter et al. (1993)	Endocrine-resistant prostate cancer	126	10.8 mCi adjuvant therapy with ^{89}Sr vs. placebo	Pain relief, markers, QOL, cost	Significant improvement in pain and bone markers for those treated with ^{89}Sr vs. placebo
Quilty et al. (1994)	Prostate cancer	294	5.35 mCi	Local or hemibody radiation vs. ^{89}Sr	Pain relief up to 3 months: 63.6% after hemibody RT, 66.1% after ^{89}Sr. Fewer new pain sites after ^{89}Sr than RT. Average 30–40% decrease in platelet and WBC after ^{89}Sr

symptoms. It is likely that tumor cells that metastasize to the bone are intrinsically resistant or can withstand such treatments as a result of either continued exposure to factors in the bone microenvironment or secretion of factors that enhance the cell. For metastatic prostate cancer, initial therapy for metastatic disease involves androgen withdrawal, to which most patients respond. Relapse is usually seen accompanied by a change in phenotype that renders the tumor cells "castration resistant" and disease continues to progress despite conventional antiandrogen therapy.

Systemic therapy for castration-resistant prostate cancer (CRPC) has evolved considerably in the past decade, with the initial taxane-based therapy approved for metastatic CRPC followed by recent approval of nonsteroidal antiandrogens (enzalutamide) and androgen synthesis inhibitors (abiraterone) showing survival benefit. Multimodality therapy is therefore of interest, and more studies have emerged that evaluate various regimens.

Combined ^{89}Sr-chloride and chemotherapy may result in survival benefit in androgen-independent prostate cancer. A significant increase in both disease-free and median overall survival was seen in those who received ^{89}Sr and doxorubicin (27.7 months) compared to those who received doxorubicin alone (16.8 months) [82, 83]. In a randomized phase II trial, 103 patients received induction chemotherapy using ketoconazole and doxorubicin alternating with estramustine and vinblastine. Patients who did not progress following induction were randomized either to ^{89}Sr with doxorubicin or to doxorubicin only. Patients who received the bone-targeted therapy had a 14-month progression-free survival as opposed to a 7-month progression-free survival achieved by the patients who received chemotherapy alone. More importantly, patients treated with the strontium achieved an overall survival of 27.7 months as opposed to 16.8 months for those who received chemotherapy alone [83]. Although the trial was not powered to make direct comparisons of the two arms, the data do suggest that combinations of chemotherapy and treatments directed at bone metastases should be pursued. In a subgroup analysis of randomized phase II trial in which patients were administered either doxorubicin alone or doxorubicin with ^{89}Sr, patients who received the combination appeared to have an improvement in both disease-free and overall survival [82]. There is no conclusive data on survival benefit with ^{89}Sr monotherapy in metastatic bone disease though a significant decrease in PSA or pain may be accompanied by a longer survival [84, 85].

Small studies using docetaxel and ketoconazole with other chemotherapy agents like estramustine, paclitaxel, and vinblastine in prostate cancer have shown feasibility [81, 86]. A small randomized phase III trial (35 patients per arm) was conducted in which patients were randomized to either ^{89}Sr and cisplatin or ^{89}Sr alone. Chemotherapy enhanced the palliative effects of strontium (91% vs. 63%, $p < 0.01$) and increased the duration (134 days vs. 68 days, $p = 0.002$) of these effects. In addition, a lower proportion of patients who received both therapies progressed in the bone than in those who received strontium only (27% vs. 64%, $p = 0.01$). However, there was no significant therapeutic effect seen (PSA or survival), which is not surprising given that cisplatin as a single agent is not active in prostate cancer and given the small size of the study.

A more recent TRAPEZE trial performed in the UK compared the outcomes from administration of docetaxel alone vs. docetaxel plus ^{89}Sr or ZA, or both, and had a minimum follow-up of 12 months. Primary outcome measures such as clinical progression-free survival (CPFS) were collected, including progression of pain, skeletal-related events, or death. About 349/757 patients (46%) completed docetaxel treatment. A benefit of ^{89}Sr on CPFS was noted. While ZA had no significant effect on CPFS, it did have a significant effect on SRE-free intervals and fewer skeletal-related events in about a third of patients ($P = 0.01$). Neither ZA nor ^{89}Sr had a significant effect on OS [87].

The treatment can also be safely administered with conventional radiation therapy, ideally given just prior to or on the day of RT [88]. Concurrent administration may be more effective in preventing skeletal-related events. In a randomized

study comparing ^{89}Sr vs. placebo in patients with advanced castrate-sensitive prostate cancer, all had a follow-up treatment with androgen deprivation therapy and ZA and docetaxel. The treatment was found to be safe and feasible, though survival benefit could not be clearly defined in this small study [89].

While RP therapy is most effective in prostate cancer, it is also effective in breast cancer patients with bone metastases. Sciuto et al. observed pain relief in 84% of patients, with duration of pain relief ranging from 2 to 14 months [90]. Other studies in breast cancer have also reported pain relief in about 60–80% of patients, with duration of response between 3 and 12 months. Good relief (in 83% of patients) was also seen in patients re-treated with ^{89}Sr [72, 91]. Responses are better in patients with osteoblastic lesions and in those with limited involvement and higher performance status [92]. Clinical cases showing a decrease in the disease burden have been reported [93].

^{89}Sr has also been used successfully in other cancers, though large studies evaluating the effectiveness for pain control and survival are lacking [94, 95].

^{89}Sr-chloride is cost-effective, as the need for radiotherapy narcotic analgesic use and hospitalization is reduced [96]. A quality of life (QOL) and cost per additional quality-adjusted life-year (QALY) analysis were more favorable for ^{89}Sr than non-generic ZA; however, the use of generic ZA was most cost-effective [97]. Addition of both ZA and ^{89}Sr to standard chemotherapy was cost-effective and led to a small improvement in QALY with a modest increase in cost. The incremental cost-effectiveness ratios (ICER) were lower than the threshold for conventional willingness-to-pay per QALY thresholds for both ZA and ^{89}Sr [98].

^{153}Sm-EDTMP (Lexidronam)

^{153}Sm is a fission product with a half-life of 46.3 h. The radionuclide emits a beta particle with a maximum energy of 0.81 MeV, a mean energy of 0.23 MeV, an average soft tissue range of 0.6 mm, and a 28% abundant gamma emission with a photopeak of 0.103 MeV. Gamma emissions of ^{153}Sm allow gamma camera imaging to confirm the targeting of lesions [99, 100] as demonstrated on bone scans.^{153}Sm-EDTMP is usually administered at a dose of 1 mCi/kg.

^{153}Sm-EDTMPis made by complexing ^{153}SmCl acid with the calcium salt of EDTMP. It is a stable complex that selectively accumulates in skeletal tissue in association with hydroxyapatite. It accumulates in high concentration in areas of high bone turnover such as such as bone metastases [99, 100] (Fig. 1). Bone metastasis may contain 3–5 times more ^{153}Sm-EDTMP than healthy bone tissue; hence, the amount of drug retained in the body is related to the extent of metastases rather than the administered activity. About 50–60% of the administered dose localizes to bone in 2–3 h, with 30–50% excretion in urine and with larger relative amounts of activity deposited in bone in subjects with impaired renal function [100] or with widespread metastases.

^{153}Sm-EDTMP is cleared rapidly from the blood; 4–34% of the dose remains in the serum 1 h after administration [101]. An initial rapid phase is followed by a slower second phase with T1/2b that may range from 8.1 to 17.1 h. Urinary excretion is the main route of elimination, with the majority cleared at 6–8 h [101]. The low energy of the beta particle reduces the radiation burden to the bone marrow compared to ^{89}Sr. Hematological side effects are generally reversible and mild.

In an early study of dose escalation, Farhangi and colleagues studied 22 patients, giving escalating doses of ^{153}Sm-EDTMP from 0.1 to 1.0 mCi/kg (3.7–37 MBq/kg) [101]. The therapy was well tolerated with transient grade 1 myelotoxicity observed in 34.5% of cases; those with extensive metastases were more likely to have myelotoxicity. A later study in 52 prostate cancer patients used escalated doses from 0.5 to 3.0 mCi/kg (18.5–111 MBq/kg) [102]. Treatment at higher doses was also well tolerated, and maximum tolerated dose (MTD) was determined to be 2.5 mCi/kg (92.5 MBq/kg). Bone marrow suppression is generally mild (grade 1, 2) and reversible. Platelets and leukocytes may decrease about 10–40% from the pretreatment values, generally reaching nadir at 3–4 weeks. The recovery of both is

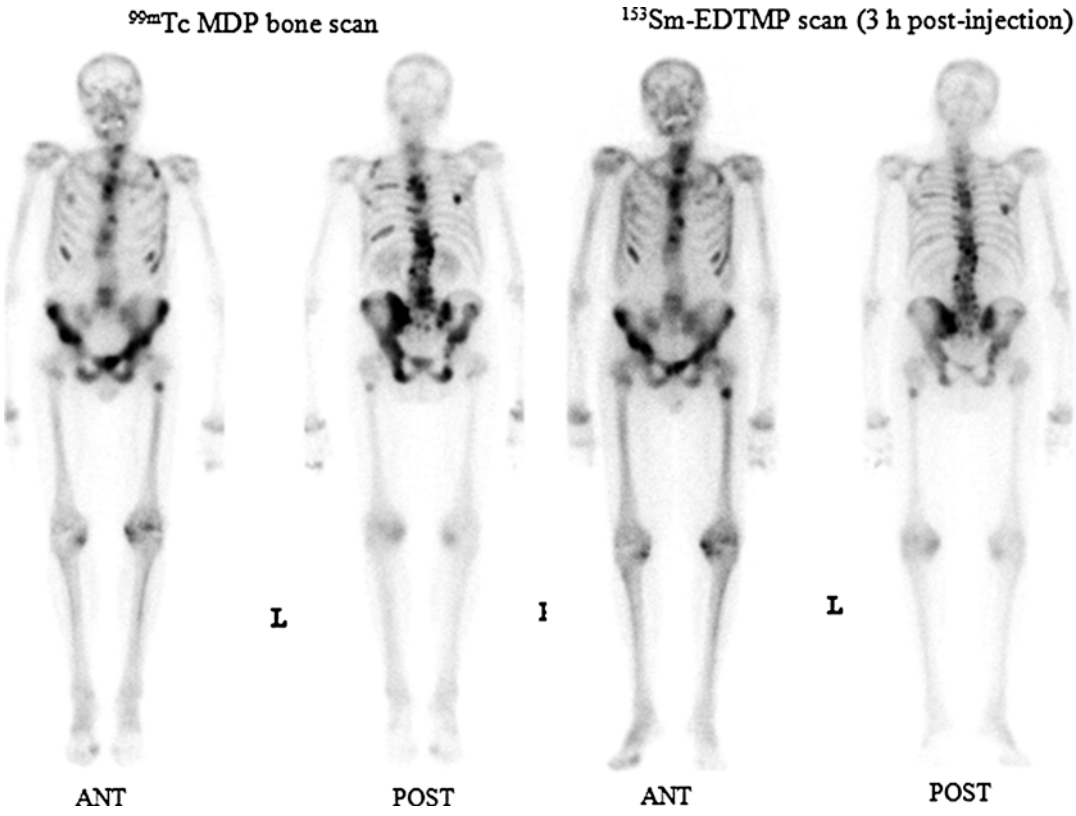

Fig. 1 Whole-body imaging: ^{99m}Tc-MDP bone scan and ^{153}Sm-EDTMP scan. Bone scan (*left*) shows multiple areas of abnormal uptake in the bones consistent with metastatic disease; targeting of all sites by ^{153}Sm-EDTMP is seen on whole-body scans (*right*)

generally complete, reaching the pretreatment values by 6–8 weeks [67, 103].

Multiple studies have shown the efficacy of ^{153}Sm-EDTMP therapy in pain palliation with the average response in variable malignancies between 62 and 74% [104, 105] (Table 3). A statistically insignificant trend toward improved survival was seen in those treated with higher doses than those treated with lower doses. Placebo-controlled studies have shown significant pain reduction with ^{153}Sm-EDTMP in a variety of cancers including CRPC [106]. ^{153}Sm-EDTMP showed an improved overall efficacy in pain relief of 77.8% compared to 44.4% with pamidronate alone, though transient myelotoxicity was also higher [107]. It has been suggested that prior treatment with pamidronate does not affect ^{153}Sm-EDTMP skeletal uptake [108].

Pain relief is generally noted within 5–10 days and can last up to 4 months. Repeated dosing of ^{153}Sm-EDTMP is feasible if pain returns or increases [109]. As with ^{89}Sr-chloride, transient exacerbation of the preexisting pain (flare) after ^{153}Sm-EDTMP has been seen in 12–20% of patients [110]. A change in whole-body uptake values for ^{99m}Tc-MDP on follow-up scanning after samarium therapy may be seen [100], though some studies suggest no change in bone scan appearance [101].

In a randomized dose-controlled study, 114 patients received either 18.5 MBq/kg or 37 MBq/kg of the ^{153}Sm-EDTMP. At 4 weeks, pain relief was better with the higher dose (55% vs. 70%). In patient-rated efficacy assessments including degree of pain, level of daytime discomfort, quality of sleep, and pain relief, improvement

Table 3 ^{153}Sm-EDTMP clinical studies

Author, date	Disease	# of patients	Activity	# ^{153}Sm injections	Chemotherapy	Major endpoints	Results
Resche et al. (1997)	Phase III dose-controlled study – CRPC and breast ($n = 36$)	114	18.5 MBq/kg vs. 37 MBq/kg	1	NA	Efficacy, toxicity, optimal dose	VAS-AUPC, PGA scores better for 37 mB/kg dose at 4 weeks, with responses seen up to 16 weeks. Response in up to 80%
Alberts et al. (1997)	Phase I/II, dose escalation	82	27.75–55.55–111 MBq/kg	1 or more	NA	Efficacy, toxicity	Pain control at all doses in 78–95% patients; duration of pain control 40–56 days, greater at higher doses. No dose-response relationship seen. Multiple doses are feasible but cause higher toxicity limiting treatment to only 38%
Serafini et al. (1998)	Double-blind placebo-controlled study; prostate cancer	118	18.5 MBq/kg vs. 37 MBq/kg	1	NA	VAS-AUPC, efficacy, toxicity, optimal dose	Pain response: Gr.1 in 20–40%; Gr.2 in 55–60%; Gr.3 in 62–72%; better responses at higher dose; no grade 4 toxicity
Tian et al. (1999)	Various malignancies (lung, breast, esophagus, prostate, GI, renal, others). Phase III, randomized study	105	18.5 MBq/kg vs. 37 MBq/kg	1	NA	Pain score, SEP, PGA, efficacy, toxicity	Effective pain response and palliation in 84%; temporary myelosuppression was the main SE; side effects were not dose-related
Sartor et al. (2004)	CRPC, phase III randomized trial – ^{153}Sm vs. nonradioactive Sm	152	37 MBq/kg	1	NA	Safety, efficacy	Pain relief noted within 1–2 weeks; reductions in opioid use noted at 3–4 weeks. Hematologic toxicity was mild; nadir WBC and platelet count seen at 3–4 weeks, recover at 8 weeks. No grade 4 hematologic toxicity
Suttmann et al. (2008)	Hormone-resistant prostate cancer	12	37MBq/kg	1	Docetaxel 35 mg/m^2	Toxicity, pain relief, PSA, ALP	50% with at least 50% PSA drop; pain reduction in 58%; decrease in bone markers

(*continued*)

Table 3 (continued)

Author, date	Disease	# of patients	Activity	# ^{153}Sm injections	Chemotherapy	Major endpoints	Results
Morris et al. (2009)	CRCP	28	18.5 MBq/kg; 27.75 MBq/kg; 37 MBq/kg	1–6; Average 2.9	Docetaxel (65, 70, 75, 75, 75 mg/m^2) +^{153}Sm; both multiple doses; average docetaxel dose #: 5.6 (range 1–13 doses)	Toxicity, PSA, ALP	Overall 54% with >50% PSA decrease; significant decrease in bone markers
Fizazi et al. (2009)	CRCP	43	37 MBq/kg	1	Consolidation docetaxel 20 mg/m^2 ×6	Toxicity, PSA-PFS survival; pain relief	5% grade 2 thrombocytopenia; median PSA-PFS was 6.4 months
Tu et al. (2009)	CRCP	18	37 MBq/kg	2	Docetaxel 25, 30, 35 mg/m^2 ×2	Toxicity	Mild toxicity with transient myelosuppression. Five patients (28%) with Gr.3 and no Gr. ≥ 4 hematologic toxicities
Lin et al. (2011)	CRCP	13	37 MBq/kg	2	Docetaxel 50, 75 mg/m^2 ×4	Toxicity	Transient myelosuppression, 35 episodes Gr. 3/4 neutropenia. One DLT Gr. 3 thrombocytopenia in cohorts 3 and 4. 8/13 (62%) with PSA drop >50%
Valicenti et al. (2011)	High-risk M0 prostate cancer; phase I		Dose escalation; phase I 9.25–74 MBq/kg	28	Postoperative hormone and radiation therapy (46.8 Gy pelvic region; 23.4 Gy prostate)	Toxicity	At 23 months median follow-up, 7% experienced Gr.3 hematologic toxicity. No increased toxicity seen at 74 MBq/kg dose vs. lower doses
Barai et al. (2015)	CRPC	44	37 MBq/kg	1	Plus capecitabine (1650 mg/m^2) orally for 8 days or placebo	Safety, pain/ analgesia	Improved pain control in study arm with capecitabine vs. placebo; low side effects

Abbreviations: *PGA* physician's global assessment, *VAS-AUPC* visual analog scale-area under the pain curve, *CRPC* castration-resistant prostate cancer, *SEP* sum of effect product, *PSA* prostate-specific antigen, *ALP* alkaline phosphatase, *PFS* progression-free survival, *DLT* dose-limiting toxicity

was seen in all patients. Among the subsets of patients examined, female patients with breast cancer receiving 1.0 mCi/kg had the most noticeable improvement. A predictable level of dose-related marrow suppression was seen with platelet and WBC nadirs at 3 or 4 weeks that recovered by 8 weeks [105].

Repeat therapy is feasible and safe and produces pain relief of similar magnitude as the first treatment. Hematologic toxicity may be cumulative, and larger decreases in blood counts may be noted with multiple dosing. No increase in frequency or severity of adverse events has been reported with repeated dosing. The treatment option should be considered in those whom bone pain recurs after an initial dose if baseline hematologic criteria are adequate [111].

In an early phase II study, re-treatment with ^{153}Sm-EDTMP was studied in 15 patients with treatment dose based on prospective evaluation of marrow dose limited to 2 Gy [109]. The re-treatment median radiation-absorbed dose to red marrow was 1.9 Gy at a median of 9 weeks (range 6–38) given after initial treatment. Pain control was seen in 13 patients (87%). A higher median duration of pain control (24 weeks) and survival (9 months) was seen in the re-treated group as against 8 weeks and 4 months, respectively, in those treated with a single dose [109]. Additional toxicity seen in the re-treated patients was confined to anemia, requiring blood transfusion in 9 of the 15 patients (60%).

In a prospective study with 202 patients treated with 37 MBq/kg of ^{153}Sm, 55 received $\geq$2 doses of ^{153}Sm-EDTMP. Pain scores, adverse events, and hematologic parameters were assessed after each dose. Common side effects included mild, transient suppression of platelets and white blood cell counts with nadir levels at 4 weeks post-treatment approximately half that at baseline. Recovery was generally seen by week 8 in 90% of patients. Temporary grade 3 thrombocytopenia occurred in 11, 12, and 17% of patients after the first, second, and third dose administration, respectively. Grade 3 leukopenia occurred in less than 7% of patients independent of the number of administrations. Significant decreases in pain scores ($P < 0.001$) were observed at week 4 after each of the first three doses and maintained at week 8 after the first two doses ($P < 0.003$), but not the third. Decreases in pain scores were observed in 70, 63, and 80% of patients, respectively, at week 4 after the first three administrations [111].

No significant data exists on the survival benefit of using ^{153}Sm alone. While studies showed a trend toward survival benefit, this was generally seen with higher doses or multiple dosing. In a randomized dose-controlled study, survival benefit was noted in breast cancer patients at larger dose of only 37 MBq/kg of ^{153}Sm-EDTMP; however, no confirmatory controlled trial has been conducted [105].

There is an increasing effort to utilize RP to improve patient outcomes. A particular focus has been in CRPC. In a small study, a single dose of samarium at the 37 MBq/kg (1 mCi/kg) dose level combined with six weekly infusions of 35 mg/m^2 docetaxel was given in 12 patients. With a mean follow-up of 11.4 (range, 1.1–25.8) months, overall 1-year survival was 48.6%, and median survival was 11.5 months. A PSA response of >50% was seen in 50% of patients and pain relief was seen in 58.3% of patients [112].

In a phase I study, patients were treated with a combination of escalating doses of ^{153}Sm-EDTMP and docetaxel; this combination was found to be safely administered at full doses over repeated cycles. Patients were assigned to six different cohorts based on increasing doses first of docetaxel and then of ^{153}Sm-EDTMP. Cycle 1 toxicity was used to define dose-limiting toxicity (DLT). The key aspect of this study was a starting dose of docetaxel at 65 mg/m^2, well within therapeutic range [113] escalated to 75 mg/m^2 in subsequent cohorts. Similarly, the starting dose of the ^{153}Sm-EDTMP was 0.5 mCi/kg in the combination, which escalated to the full FDA-approved dose of 1.0 mCi/kg. Dose reductions were imposed for both drugs in the event of hematologic or serious nonhematologic toxicities. Patients were removed from the study if they required more than two dose reductions. Twenty-eight men were treated in six cohorts. MTD was not reached because full doses of both agents were well tolerated, even when using an every-6-weeks

dosing schedule of ^{153}Sm-EDTMP. Patients received an average of 5.6 docetaxel doses (range, 1–13 doses) and 2.9 ^{153}Sm-EDTMP doses (range, 1–6 doses). Fifteen patients demonstrated a more than 50% decline in PSA, and some responses were also seen in the small group of patients with taxane-resistant disease [113]. Longer follow-up of these patients showed a median biochemical or radiographic progression-free survival of 7.0 months and an overall survival of 14.3 months. Nine patients (30%) did not recover platelet counts to >100 K/mm^3 after a median of three cycles to allow for additional treatment, with four patients experiencing prolonged thrombocytopenia. The most common reasons for trial discontinuation were progressive disease and hematologic toxicity [114].

Tu and colleagues also used a concurrent combination of weekly docetaxel with repeated ^{153}Sm-lexidronam in patients with CRPC. Eighteen patients were treated in three cohorts comprising two cycles of weekly docetaxel at 25, 30, and 35 mg/m^2, respectively, on days 1, 8, and 15 of a 28-day cycle in combination with ^{153}Sm-EDTMP (1 mCi/kg) on day 1 [115]. Failure to recover by day 56 of either combination cycle was considered unacceptable toxicity. Most toxicity was mild, with transient grade 3 myelosuppression in five patients (28%) and no grade 3 or more nonhematologic toxicities.

In a phase II study, Fizazi and colleagues treated 43 patients with docetaxel and ^{153}Sm-EDTMP as a consolidation therapy docetaxel 20 mg/m^2/week for 6 weeks with ^{153}Sm-EDTMP (37 MBq/kg) given in week 1 [116]. The PSA response was the primary endpoint, and pain response was assessed secondarily using a visual analog scale. A PSA response was obtained in 77% of patients and the pain response rate was 69%. The median PSA-PFS was 6.4 months. Median survival was 29 months, 1-year survival rate was 77%, while the 2-year survival rate was 56%.

Concurrent 6-month administration of four doses of docetaxel at doses of 75 mg/m^2 in a standard 3-week schedule with two doses of 37 MBq/kg ^{153}Sm-EDTMP given at 3-month intervals has also been shown to be feasible [117] as well as the combination with radiosensitizer capecitabine. A randomized prospective study with 44 patients with bone metastasis from various primary malignancies was carried out. The test group received a single dose of 1 mCi/kg ^{153}Sm-EDTMP plus capecitabine (1650 mg/m^2) orally for 8 days, while the control group received 1 mCi/kg ^{153}Sm-EDTMP dose plus placebo for the 8 days. A follow-up of 12 weeks showed significant improvement in degree of pain relief experienced by patients treated with concurrent capecitabine than those who did not receive capecitabine (pain score of 1.29 ± 1.05 and 3.59 ± 2.77, respectively). No significant differences in toxicity were seen between the two groups [118].

Samarium-153 EDTMP may be useful in patients with osteosarcoma. Early evaluation in a mouse model showed localization and significant effect on tumor [119]. In unresectable osteosarcoma cases, high-dose therapy with about 150 MBq/kg dose of Sm was found to be feasible and potentially useful [120–122]. Initial small experience of combined treatment with gemcitabine showed feasibility; however, pain response was not significant, so larger data sets and studies may be needed to establish this [123].

Therapy with Alpha Emitter Radium-223 Dichloride ($^{223}RaCl_2$)

Radium-223 (^{223}Ra) is an alpha particle-emitting radionuclide that has been approved by the US FDA for treatment of symptomatic bone metastatic disease from CRPC, with no visceral metastasis. ^{223}Ra decays ($t_{1/2}$ = 11.4 days) to stable lead, producing four α-particles and a chain of short-lived daughter radionuclides. In the decay of ^{223}Ra, 94% of the total decay energy is released as α-particles (Fig. 2). The noble gas first daughter ^{219}Rn has a $t_{1/2}$ of ~4 s, in contrast to the long-lived radon daughters from the other naturally occurring radium isotopes. ^{223}Ra can be produced efficiently in large amounts. The precursor ^{227}Ac ($t_{1/2}$ = 21.7 years) can be used as a long-term operating generator for ^{223}Ra [124, 125]. Actinium-227 is produced by neutron irradiation of

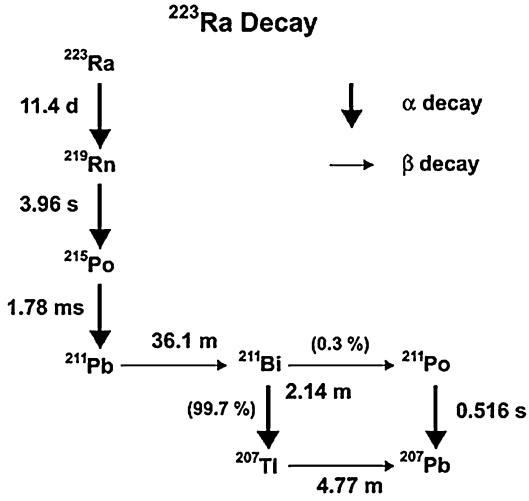

Fig. 2 ^{223}Radium decay

natural ^{226}Ra and decays via thorium-227 (half-life 18.7 days) to ^{223}Ra. The long $t_{1/2}$ of ^{223}Ra provides sufficient time for its preparation, distribution (including long-distance shipment), and administration to patients. Its low γ-irradiation is favorable from the point of view of handling, radiation protection, and treatment on an outpatient basis in the United States.

Alpha particles from the first three nuclides in the decay chain are emitted almost instantaneously. They are therefore likely to contribute to the radiation dose in the vicinity of the site of ^{223}Ra decay. Hence, ^{223}Ra has the potential to deliver a therapeutically relevant tumor dose from a relatively small amount of administered activity without causing unacceptable doses to nontargeted tissue.

The intrinsic bone-targeting properties of ^{223}Ra are similar to that of other alkaline earth elements, like calcium.^{223}Ra emits α-particles with high linear energy transfer (LET) alpha radiation and a limited range of less than 100 μm. These radiation characteristics generate highly localized and effective radiation zones with a high probability of inducing DNA double-strand breaks in cells. An α-emitter localized in or near bone metastases will deliver most radiation at the site of the lesion, thereby reducing exposure of surrounding normal tissues, especially marrow leading to less myelotoxicity. Initial assessment in animal models shows a significant ^{223}Ra antitumor effect in nude rats. All tumor-bearing control animals showed signs of induced paralysis 20–30 days after tumor cell injection, whereas rats treated with 110 kBq/kg showed a significantly increased symptom-free survival ($p < 0.05$). Approximately 40% of the treated rats were alive beyond the 67-day follow-up period compared to none in the control group [126].

Following an intravenous injection, ^{223}Ra clears rapidly from the blood and concentrates in increasing amounts in the bones. The major route of elimination is through the gut via the small intestine; only 1–5% radioactivity is seen in the urine in 48 h. The kidney and bladder exposure is low [127] (Table 4). On imaging, early radioactivity in the gut decreases and is thought to be within the gut contents, as it is seen to move with time on delayed imaging. There is no specific retention seen in other normal organs such as the heart, liver, gallbladder, stomach, or spleen. The highest radiation-absorbed doses are in the GI tract, bone, and red marrow [127, 128]. Imaging of lesions is possible (Fig. 3); however it is limited by low gamma counts and is not routinely recommended. Dosimetric estimations have been attempted but are not predictive of response due to high variations [129].

Initial studies showed promising results in patients with CRPC and potential application to other cancers such as breast, lung, and kidney cancer. In a dose escalation study, 31 patients with bone metastases from breast and prostate cancer received single and multiple doses of $^{223}RaCl_2$. The single-dose escalation ranged from 46 to 250 kBq/kg b.w., and multiple doses escalated from 50 kBq/kg to 125 kBq/kg including five or two doses at 3 or 6 weeks, respectively. Pain relief was observed in more than 50% of patients [127]. When the pain score data was pooled from all dose groups, a statistically significant decrease in pain score after treatment ($p < 0.05$) occurred during the 8-week observation period. Decreases in mean total alkaline phosphatase (ALP) values after injections of ^{223}Ra were observed in all dose groups.

Table 4 ^{223}Radium-dichloride clinical studies

Author, date	Disease	# of patients	Activity (kBq/kg); dose	Major endpoints	Results
Nilsson et al. (2005)	Breast, prostate. Phase I	25 (10 breast/ 15 prostate)	46, 93, 163, 213, or 250 ×1	Toxicity, ALP	Mild myelosuppression with nadirs at 2–4 weeks; few Gr. 3/4 SE; diarrhea, nausea, and vomiting were common SE, seen more at higher doses. Greater decrease in ALP in prostate vs. breast patients; about 52% reported pain relief by 7 days
Nilsson et al. (2007)	Prostate cancer; randomized phase II double-blind	64	50 vs. placebo q 4 weeks ×4	ALP, SRE, PSA progression, OS	Greater decrease in bone ALP post-^{223}Ra (median 65.6% vs. 9.3% in placebo arm); longer time to first SRE, time to PSA progression, median OS and OS with ^{223}Ra vs. placebo
Nilsson et al. (2012)	Prostate cancer; randomized phase II double-blind	100	5, 25, 50, or 100 x 1	Pain	Significant dose-response for pain seen as early as 2 weeks; higher pain response at largest dose (40% at 5 kBq/g vs. 56% at 50kbq/kg vs. 71% at 100 kBq/kg). Significant improvement in brief pain inventory functional index in all dose groups
Nilsson et al. (2013)	Prostate cancer; randomized phase II double-blind	64	50 q 4 weeks ×4 vs. placebo after XRT	Long-term safety, treatment-related AEs; 2-year survival	30% treated with ^{223}Ra were alive after 2 yrs. vs. 13% in placebo group; longer median OS (65 vs. 46 weeks) for ^{223}Ra and placebo group, respectively
Parker et al. (2013)	Prostate cancer; randomized phase III double-blind ALSYMPCA	921	50 vs. placebo q 4 weeks ×6	OS, SRE, PSA response, ALP, toxicity, QOL	^{223}Ra arm showed survival benefit as against placebo (median, 14.9 mos vs. 11.3 mos); low myelosuppression and adverse events rates
Sartor et al. (2014)	Prostate cancer; results from phase III, double-blind, randomized ALSYMPCA	921	50 vs. placebo q 4 weeks ×6	OS, SRE, QOL analysis	Symptomatic SRE in ^{223}Ra arm 33% vs. 38% in placebo; longer time to first symptomatic SRE with ^{223}Ra vs. placebo (median 15.6 vs. 9.8 months); reduced risk for EBRT and cord compression with ^{223}Ra; no significant reduced risk for pathologic bone fracture or tumor-related surgical intervention
Vogelzang et al. (2016)	Post-ad hoc analysis of hematologic toxicity from ALSYMPCA	901	50 q 4 weeks ×6	Hematologic toxicity	Gr.3/4 thrombocytopenia more common in ^{223}Ra vs. placebo patients (6% vs. 2%). Predictors of Gr.2 or more toxicity: disease extent,

(*continued*)

Table 4 (continued)

Author, date	Disease	# of patients	Activity (kBq/kg); dose	Major endpoints	Results
					PSA, hemoglobin, and decreased platelets
Saad et al. (2016)	CRPC, single-arm phase IIIb	696	50/55 q 4 weeks ×6 and concomitant medications	Safety, efficacy, OS	All grade SAE in 35%; Gr.3/4 SE included anemia (5%); thrombocytopenia (2%); neutropenia (1%); longer OS in those with baseline higher than ULN of ALP and Hb >10

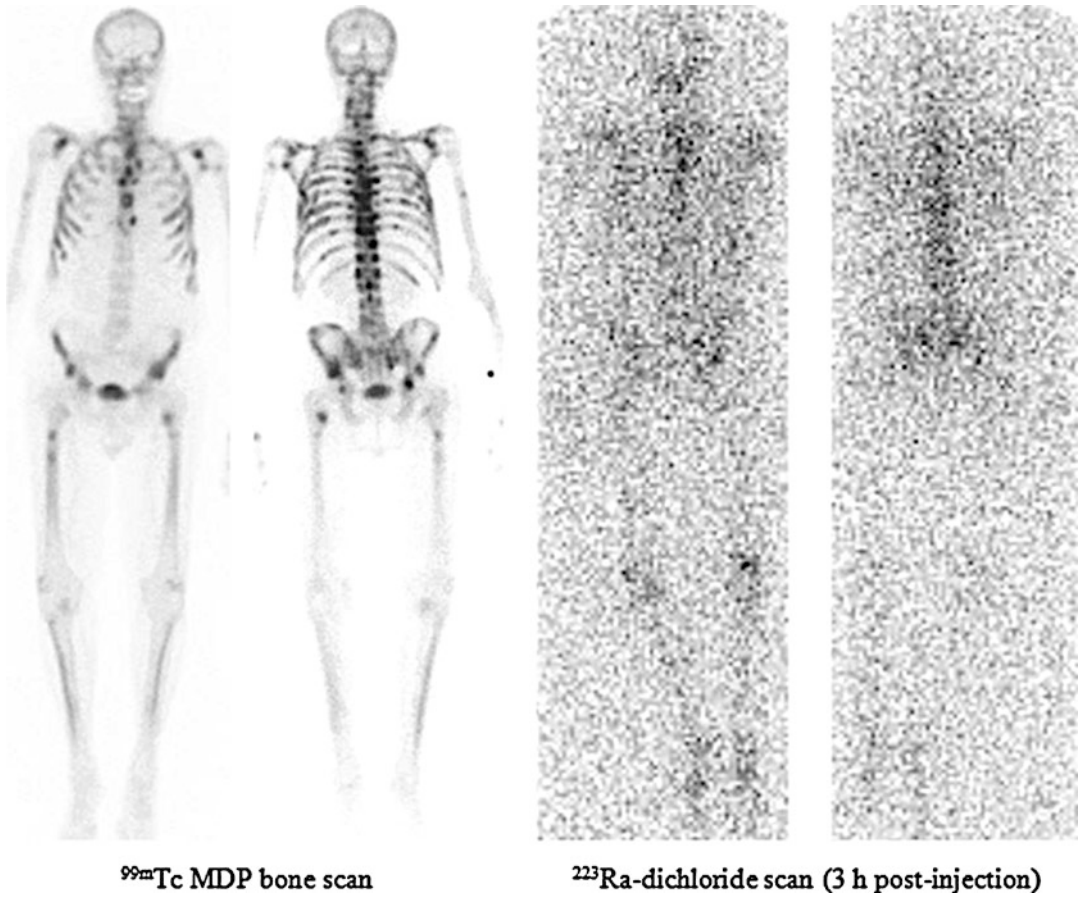

Fig. 3 Whole-body imaging: ^{99m}Tc-MDP bone scan and ^{223}Ra-dichloride scan. Bone scan (*left*) shows multiple areas of abnormal uptake in the bones consistent with metastatic disease; targeting of all sites by ^{223}Ra-dichloride is seen on whole-body scans (*right*)

In a follow-up randomized, multicenter phase II study, 33 patients received four doses of 50 kBq/kg (0.0014 mCi/kg) at 4-week intervals while 31 patients received placebo. Primary efficacy endpoint was decrease in serum bone markers; PSA response and time to PSA

progression were also monitored. Interim analysis showed a statistically significant decrease in bone alkaline phosphatase (~66%) from baseline compared with placebo (9.3%) [130]. Follow-up data for overall survival from the phase II study showed an increase in median survival time from 46 to 65 weeks for the $^{223}RaCl_2$ group vs. the placebo. At 2 years, 10 of 33 of patients (30%) treated with $^{223}RaCl_2$ were alive compared to 4 of 31 of placebo patients (13%), showing a trend for survival benefit with $^{223}RaCl_2$ [131].

A pivotal multicenter randomized, double-blind, placebo-controlled phase III study (ALSYMPCA) showed survival benefit from the use of radium dichloride in patients with CRPC. The efficacy and safety of ^{223}Ra-dichloride was compared with placebo in 921 patients receiving best standard-of-care treatment including local radiotherapy, corticosteroids, antiandrogens, estrogens, estramustine, or ketoconazole. All patients were allowed to continue androgen deprivation therapy. Patients received either ^{223}Ra at a dose of 50 kBq/kg or placebo every 4 weeks for up to six doses. Interim analysis in 809 patients showed improved survival with ^{223}Ra as compared to placebo (median time of 14.0 months vs. 11.2 months); this was confirmed in the final analysis of all 921 patients (median survival 14.9 months vs. 11.3 months). The myelosuppression rates and adverse events were low [132]. $^{223}RaCl_2$ treatment was also found to be helpful in patients who had not received prior docetaxel with the median overall survival of 16.1 months in this subgroup compared to placebo, with a median OS of 11.5 months. $^{223}RaCl_2$ was approved by the FDA in May 2013 and is currently marketed as Xofigo.

Single and multiple injections of $^{223}RaCl_2$ have been found to be safe and well tolerated, with manageable myelotoxicity and no indication of long-term toxicity. In general, most AEs seen are mild to moderate in severity and included nausea, bone pain, diarrhea, and fatigue. The most commonly reported serious adverse event (SAE) was bone pain, which was considered related to disease itself and not directly a result of the treatment. No dose-limiting hematotoxicity or increased risk of neutropenia was observed upon multiple administrations of $^{223}RaCl_2$ [127].

Multivariate analyses to assess baseline risk factors for hematologic toxicities in 901 patients treated in the phase III study with either $^{223}RaCl_2$($n = 600$) or placebo ($n = 301$) showed slightly higher incidence of grade 3/4 thrombocytopenia (6%) with $^{223}RaCl_2$ vs. 2% in placebo-treated patients. However, a greater number of patients completed all six cycles of treatment in the $^{223}RaCl_2$ arm (65%) compared to 48% in the control arm. The extent of disease with involvement of six or more sites and elevated PSA at baseline were predictors for grade 2–4 anemia; baseline hemoglobin and platelet levels and prior treatment with docetaxel were predictors for thrombocytopenia. The number of injections of $^{223}RaCl_2$ was not found to be significantly associated with cumulative hematologic toxicity [133].

A phase IIIb study performed following the ALSYMPCA trial as part of the early access program prior to regulatory approval of $^{223}RaCl_2$, evaluated safety and survival. Asymptomatic CRPC patients were also included; patients with two or more skeletal metastases by imaging were eligible. An additional criterion for inclusion was the absence of visceral disease (lymph node metastases <3 cm were allowed). Dosing was similar to the ALSYMPCA trial, though based on recalibration; some received a 55 kBq/kg dose. Other concomitant anticancer therapies were allowed. A total of 696 patients were treated; 403 (58%) received all six doses. About 523/696 (75%) patients had adverse events; 281 (40%) were treatment-related. Grade 3 or greater hematologic toxicity was seen in 1–5%. The median overall survival was 16 months. Median overall survival was longer in patients with nonelevated baseline alkaline phosphatase concentration, hemoglobin levels of 10 g/dL or greater, good performance status, and no pain at baseline. The study also showed safety of combined $RaCl_2$ and antiandrogen therapy and noted a higher median overall survival in patients who received concomitant denosumab, abiraterone, and/or enzalutamide [134]. A detailed analysis of quality of life (QOL) data from the ALSYMPCA trial showed that improved

survival was associated with a higher percentage of patients with meaningful improvement in QOL and a slower decline in QOL over time.

A follow-up evaluation of ALSYMPCA patients who had follow-up chemotherapy showed that generally the interval to start chemotherapy was later for those who were treated with ^{223}Ra than for placebo patients, though the duration of chemotherapy received was similar. There was low incidence of grade 3–4 hematologic toxicity in both groups; however, a greater decrease in platelet count from the baseline prior to chemotherapy was noted in ^{223}Ra vs. placebo patients. No significant difference was noted in median OS between those who had prior ^{223}Ra vs. placebo dose (16.0 and 15.8 months, respectively). The data suggests that subsequent treatment with chemotherapeutic agents is effective and safe in those treated with ^{223}Ra, as well as those who were not chemotherapy naïve prior to ^{223}Ra [135].

Other trials in prostate cancer are under way to assess feasibility and efficacy in different clinical states of prostate cancer and in combination with chemotherapy and antiandrogen therapy. Interim results of the "ERADICATE" trial assessing the efficacy of ^{223}Ra-dichloride with concurrent abiraterone acetate and prednisone in 36 symptomatic CRPC patients showed improvement of symptoms with decreased pain, significant improvement in QOL, and enhanced quality of sleep [136].

Data on ^{223}Ra in other malignancies such as breast cancer is emerging. Early studies in mouse models have shown decreased osteolysis and tumor growth leading to improvement in survival [137]. Safety and short-term efficacy of ^{223}Ra in breast cancer have been reported in a small study with 23 patients. This was an open-label, phase IIa nonrandomized study in breast cancer patients with progressive bone metastasis who were not candidates for endocrine therapy; patients were treated with 50 kBq/kg IV of ^{223}Ra every 4 weeks for four cycles. ^{223}Ra significantly reduced urinary N-telopeptide of type 1 (uNTX-1) and serum bone alkaline phosphatase. Metabolic response with decrease in [^{18}F]FDG avidity was seen in 50/155 lesions following two treatments. The overall metabolic response rate at the end of four cycles of treatment or week 17 was 41.5% [138].

Randomized studies evaluating the role of ^{223}Ra in estrogen receptor (ER)-positive breast cancer patients with and without combination therapies such as exemestane or everolimus have been initiated (NCT02258464, NCT02258451); exploratory studies in other malignancies such as lung cancer and myeloma are under way. It should be noted that the "bone tropism" of prostate cancer metastases may make it preferentially suitable for such therapy.

Other Agents

With the availability of alpha therapy with ^{223}Ra, the development of other bone-seeking agents has declined in recent years. These agents remain investigative and the subject of research interest. Specific advantages and clinical applications are yet to be established with these agents.

Rhenium-Labeled Radiopharmaceuticals: ^{186}Re-HEDP and ^{188}Re-HEDP (Etidronate)

Two rhenium isotopes (^{186}Re and ^{188}Re) (Table 1) linked to bisphosphonates have been tested in patients, but have not gained regulatory approval for clinical use in the US or European Union [84]. ^{186}Re has a physical half-life of 3.7 days, emits a beta particle with a maximum energy of 1.07 MeV and a mean energy of 0.349 MeV, and has an average range of 0.5 mm in dense bone and 1.1 mm in soft tissue. It has low abundance (9%) of 137 keV gamma emissions. ^{186}Re is conjugated to 1-hydroxyethylidene-1,1-diphosphonate (^{186}Re-HEDP/^{186}Re(Sn)HEDP or etidronate) complex, which attaches to hydroxyapatite crystals by forming hydroxide bridges.

^{186}Re-HEDP has a plasma half-life of 41.0 ± 6.0 h [84] with about 70% of the activity excreted in the urine in 24 h in subjects with no evidence of bone metastases. The maximum tolerated activity is 2960 MBq in patients with metastatic prostate cancer. The bone marrow-absorbed dose is about

1.04 mGy/MBq [85]. A number of initial studies reported safety and efficacy for the use of ^{186}Re-HEDP in bone pain palliation. A study by Sciuto et al. with ^{186}Re-HEDP showed an overall pain palliation rate of 92% in breast cancer patients [69]. Pain relief was established early, and tumor-/bone marrow-absorbed dose ratio was 14:1, suggesting clinical relevance in patients with more compromised bone marrow reserve. Typical marrow recovery times ranged from 4 to 6 weeks. A small study in breast cancer patients ($n = 12$) showed an MTD of 2405 MBq (65 mCi), limited primarily by thrombocytopenia [139].

An evaluation of pain response and hematologic toxicity in prostate and breast cancer patients receiving single or multiple therapies with ^{186}Re-HEDP while on ZA treatments showed a slightly greater decrease in WBC, hemoglobin, and platelet levels. However, only platelets showed a significant decrease compared to baseline levels after repeat therapies. Pain responses were seen in all patients, and improvements were seen after therapies even with multiple doses [140]. A single study has shown a baseline hemoglobin level to be predictive of pain response [141]. High-dose therapy has been tested in a preliminary phase I study in 25 patients with progressive hormone-refractory prostate cancer with bone metastasis. Doses ranging between 2500 and 5000 MBq (67.6–135 mCi) of ^{186}Re-hydroxyethylidene diphosphonate were administered, followed by reinfusion of peripheral blood stem cells 14 days later. Five of 25 patients (20%) showed a PSA drop at 4 weeks [142]. The concept, however, has not been evaluated in larger studies, and other forms of treatment are now available that are less intensive.

^{188}Re is a generator-produced isotope that may be "milked" on demand from a ^{188}W/^{188}Re generator. A kit is available for conjugating it to HEDP. Methods have been developed to obtain a high yield of GMP-radiolabeled agent [143, 144].^{188}Re has a beta energy of 2.1 MeV with a gamma emission of 155 keV (15% abundance) that allows for imaging. The high beta energy has the potential to kill tumor cells. The physical half-life is 16.8 h. The biodistribution of ^{188}Re (Sn)HEDP is identical to ^{186}Re(Sn)HEDP with rapid urinary excretion; 60 ± 12% of administered activity is in the urine by 48 h, which varies with renal function and extent of osteoblastic metastases [145].

Limited data exists on the use of this agent in the treatment of bone pain. An initial study demonstrated pain palliation in 60–75% of prostate cancer patients receiving a dose of 2.6 GBq or higher [146]. Pain responses in breast and prostate cancer patients are noted and similar to other agents [147]. The possibility of repeated therapy at low cost has led to the agent being investigated for use in developing countries. The effectiveness of repeated therapy using ^{188}Re-HEDP has been demonstrated in 64 patients with progressive, hormone-resistant prostate cancer [148]. A QOL assessment following treatment in prostate ($n = 45$) and breast cancer ($n = 47$) patients showed a significant decrease in pain visual analog scale and overall pain response of 69%and an overall QOL response rate of 68% after a single injection of ^{188}Re-HEDP. The responses were similar even after repeated therapies [149].

^{117m}Sn-Pentetate and ^{177}Lu-EDTMP

^{117m}Sn-pentetate emits conversion electrons with therapeutic potential; their high LET and very short range in soft tissue (0.2–0.3 mm) may explain lower myelosuppression with ^{117m}Sn-pentetate as compared to other agents.

^{117m}Sn is injected as the pentetate (DTPA) chelate and has no affinity for hydroxyapatite. The mechanism of localization is unclear and is postulated to occur via precipitation of stannous oxide on bone surfaces and possibly involving hydrolysis reaction with hydroxyapatite. The uptake pattern is similar to 99mTc-MDP. There is biexponential clearance related to a soft tissue component (22%) with clearance average half-life of 1.45 d and the second bone phase (77.6%) that showed no biologic clearance. Urinary clearance was not very high, with 11.4% excreted in urine within 24 h and 22.4% in 14 days [150]. Studies have estimated that the pain palliation rate is approximately 75%. No apparent dose-response relationship is evident; at doses more than 12 mCi

Table 5 Common indications and contraindications for radiopharmaceutical therapy of bone metastasis

Indications	Contraindications
Multiple painful osseous metastases for bone pain palliation agents	Pregnancy; breastfeeding
Symptomatic castration-resistant metastatic prostate cancer without visceral metastasis	Acute/chronic renal failure
	Acute spinal cord suppression – needs external radiation therapy
	Hb <10.0 g/L
	Total white cell count $<3.0 \times 10^9$/L
	Granulocytes <2000/mL; platelets $<60 \times 10^9$/L
	GFR <30 mL/min

(per 70 kg body weight), pain palliation has been noted as early as <1 week after treatment [151]. ^{117m}Sn-DTPA is not currently approved for clinical use.

^{177}Lu has been explored as a potential radionuclide for bone pain palliation chelated to EDTMP [152], DTPMP, or TTHMP with stability for up to 14 days [153] and also with DOTMP, which shows the longest stability up to 40d [154]. ^{177}Lu has a half-life of 6.71 days and is both a beta and gamma emitter [155]. Preliminary studies have shown dose-related pain responses at low (1295 MBq/35 mCi; 55% pain response) as well as high dose (2590 MBq/75 mCi; 80% pain response). Pain response was seen prominently by 2 weeks, and toxicities at both levels were low. The low dose was found sufficient for adequate treatment of bone pain in breast cancer and hormone-refractory prostate cancer [156]. A prospective comparison of ^{177}Lu-EDTMP with ^{153}Sm-EDTMP carried out in 32 patients with bone pain showed comparable pain responses, improvement of symptoms, and QOL between the two [157].

These studies are preliminary and encouraging; however, more studies in focused clinical states are needed to establish its role and to define its specific clinical application, especially with an increasing array of currently available approved agents.

Patient Identification and Referral

Patients are generally referred for radiopharmaceutical bone pain palliation by medical or radiation oncologists or pain medicine physicians.

Table 6 Checklist prior to administration of radiopharmaceutical

Positive bone scan (within 6–12 weeks)
Symptoms: worsening bone pain despite pain medication or other related to metastatic disease
Exclude cord compression
H/o chemotherapy, external beam radiation within 6 weeks before therapy with bone-targeting radiopharmaceutical: assessment and planning
Evaluate for extent of disease: for $^{223}RaCl_2$, exclude visceral metastasis
Get informed consent
Labs:
Obtain blood counts as close as possible to treatment – preferably within 2 weeks prior
Ensure adequate blood cell count levels

A detailed history should be taken to evaluate patient eligibility based on performance status, presence of other systemic illness like renal failure, and any symptoms that may suggest vertebral fracture or acute cord compression. Cord compression is an emergency that warrants immediate radiation therapy and/or sometimes surgery. RPs have no place in the management of spinal cord compression or pathological fracture (Tables 5 and 6).

Administration of Radiopharmaceutical Agent

Once eligibility is established, the patient is usually treated in an outpatient setting. Patient identifiers are checked, and informed consent is obtained for administration of systemic radiopharmaceutical therapy after discussing the possibility

of transiently increased pain due to flare response. An intravenous line is inserted and checked for good blood return and free flow of the saline flush. Care must be taken to prevent extravasation of tracer, which may cause tissue necrosis. Patient weight is checked and used to calculate the treatment dose for ^{153}Sm-EDTMP and ^{223}Ra. The radiopharmaceutical is injected as a slow intravenous injection over a period of 1–2 min and flushed with 10–20 ml of saline. In the United States, the use and administration of these RPs fall under the guidelines of the Nuclear Regulatory Commission (NRC).

Radiation level in the patient at surface and 1 m is checked. The patient is instructed about radiation safety precautions (Table 7). For those administering the dose, contamination control involves employing universal body fluid precautions when working with the patient. Federal guidelines [158] do not require patient-specific ALARA (as low as reasonably achievable) instructions for patients receiving up to 140 mCi of ^{153}Sm-EDTMP. In addition, no limit is placed on patients receiving the pure beta emitter ^{89}Sr because of minimal exposure to members of the public. Alpha emitters generally pose no major radiation exposure concern for outpatient treatments. The nuclear medicine physician or a radiation safety officer typically discusses detailed radiation safety precautions after reviewing individual patient specifics.

Table 7 Suggested radiation safety specifications for beta-emitting therapy to treat painful bone metastases

Radiation safety specifications
1. Many of the agents are primarily removed from the body via urine or stool. Practice good hygiene when using the toilet: Sit down to urinate to reduce possibility of contamination Flush toilet twice after use Wipe any spilled urine with a tissue and flush it away Avoid soiling underclothing or areas around toilet bowls Wash hands thoroughly after using the toilet
2. Wash clothes and bed linens if they become soiled. Wash them separately from other clothes
3. If cut, wash away blood. Wipe spilled blood with tissue and flush it away
4. There is generally no medically significant exposure to other people; no requirement for isolation or limiting interaction with others
5. Eat a normal diet

The patient usually follows up with the referring physician, who evaluates the patient's clinical response and obtains blood counts at recommended intervals (usually weekly for the first 6–10 weeks and more frequently if there is evidence of toxicity, although a drop in counts is uncommon before 7–14 days after treatment). Blood counts, notably platelet and white blood cell counts, should be obtained until all counts are normal; return to pretreatment baseline may not always occur.

Summary

Bone pain palliation therapy with radiopharmaceuticals is a cost-effective systemic therapy to relieve pain from skeletal metastases with a consequent decrease in morbidity and an improvement in quality of life. Both beta- and alpha-emitting agents are effective in improving symptoms and quality of life. ^{223}Ra has been approved by the FDA for specific use in symptomatic CRPC with no visceral metastasis, and studies are under way to evaluate its role in other clinical states and in combination with other therapies. Beta emitters have been available for many years for bone pain palliation in metastatic disease. RPs should be considered in patients with widespread osteoblastic metastases causing multiple painful skeletal sites. Bone-seeking radiopharmaceuticals as part of a multimodality regimen may also slow disease progression. Repeat therapies should be carefully administered when blood counts have returned to safe levels. Combination therapy with other agents is possible with careful planning and follow-up for additional toxicities.

Radionuclide Therapy of Tumors of the Liver and Biliary Tract

46

Giuseppe Boni, Federica Guidoccio, Duccio Volterrani, and Giuliano Mariani

Abstract

The liver represents a frequent site for both primary cancer and metastatic disease, In these circumstances, liver-directed therapies as cytoreduction via surgery or in situ ablative techniques may influence the natural history of the disease progression and improve clinical outcomes.

Radioembolization (RE) is a selective internal radiotherapy technique in which ^{131}I-lipiodol or 90Y microspheres are infused through the hepatic arteries. It is based on the fact that primary and secondary hepatic tumors are vascularized mostly by arterial blood flow whereas the normal liver perfusion is mostly from the portal network. This enables high radiation doses to be delivered, sparing the surrounding non-malignant liver parenchyma.

Although there are some clinical evidences that RE may play an important role in the management of hepatocellular carcinoma of intermediate or advanced stage and in liver-dominant metastatic colorectal cancer and metastatic neuroendocrine tumors, further randomised clinical trials are mandatory to better assess the potential beneficial and harmful outcomes of trans-arterial radioembolisation either as a monotherapy or in combination with other systemic or locoregional therapies.

In this chapter we discuss some technical aspects, patient selection, current clinical evidence, and future directions of radioembolisation for primary and secondary liver cancer.

Introduction

Both primary tumors and metastatic malignancies can arise in the liver. Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide, and its incidence is rising [1]. In addition, the liver is one of the most common sites for hematogenous metastases from different solid tumors primarily arising in other tissues/organs, most importantly colorectal cancer (CRC). About 15–25% of all CRCs may present synchronous hepatic metastases or develop metachronous metastatic involvement of the liver disease during the course of the disease [2].

Although significant survival benefit can be achieved with curative resection or liver transplantation in selected cases [3], less than 15% of the patients with newly diagnosed HCC are candidates for surgical procedures with curative intents. Although various treatments have been proposed for the remaining patients, definite agreement has not been reached on which option offers the greatest survival benefit associated with the least toxicity.

External beam radiation therapy has a limited role in the treatment of HCC due to the relatively high radiosensitivity of normal hepatic tissue [4]. In fact, exposure of the liver to radiation doses greater than 40 Gy may result in a clinical syndrome called "radiation-induced liver disease" (RILD) or radiation hepatitis. This syndrome, which occurs weeks to months following therapy, includes elevated liver enzymes, anicteric hepatomegaly, and ascites [4, 5].

Minimally invasive, percutaneous ablative treatments include radiofrequency ablation (RFA), microwave ablation, cryoablation, and irreversible electroporation (IRE) that have become widely accepted as potentially curative therapies for either HCC or metastatic liver disease [6]. In particular, these ablative techniques are useful for treating patients who do not meet the criteria for surgery but in whom curative treatment is desired.

Transcatheter arterial chemoembolization (TACE) is the mainstay of catheter-based locoregional therapies for unresectable primary liver cancer; its use is expanding and includes liver metastatic disease from other malignancies [7]. Conventional TACE typically involves the injection of chemotherapeutic agents mixed with lipiodol and embolic particles into the branch of the hepatic artery that feeds the tumor [8]. TACE with drug-eluting beads (DEB) involves the injection of DEBs into the tumor-feeding artery, offering simultaneous delivery of chemotherapy and embolization with sustained and controlled drug release over time [9]. Both TACE and DEB-TACE are effective as palliative treatments for primary and metastatic liver cancers [10, 11].

There are substantial differences in the treatment strategies for primary or metastatic malignancies of the liver. While locoregional treatments are a mainstay in primary liver cancers [12], transcatheter techniques such TACE or DEB-TACE are not commonly used for patients with metastatic liver disease.

The recent successful development of transarterial radioembolization (TARE) with ^{90}Y-labeled particles has revived interest in an approach to locoregional treatment of liver tumors with radionuclides that had been introduced earlier with the use of lipiodol containing ^{131}I but had shown little benefit for long-term survival (see further below). This technique is also defined as "selective internal

radiation therapy" (SIRT); therefore, the acronyms TARE and SIRT can be employed in an interchangeable manner.

Rationale of Radioembolization Therapy for Liver Tumors

In order to deliver the highest possible therapeutic doses to the tumor while sparing normal liver parenchyma, techniques based on minimally invasive intra-arterial administration of therapeutic radionuclides have been developed, an approach that takes advantage of the dual blood supply to the liver. Normal hepatic tissue derives greater than 70% of its blood supply from the portal system, whereas blood to malignant tissue is preferentially supplied by the arterial system. High tumoricidal doses can thus be selectively delivered to the tumor lesions (more than 70 Gy, usually 200–300 Gy) through locoregional administration of agents emitting β^- particles (labeled with either ^{131}I, ^{90}Y, ^{188}Re, or ^{166}Ho), with low levels of associated damage for the non-affected liver and therefore a minimal risk of inducing RILD [13–17].

Radioactive Lipiodol

Upon injection into the hepatic artery of patients with HCC, the iodinated oil ^{131}I-lipiodol (a suspension of lipidic particles) follows the preferential blood flow toward the tumor; the radiolabeled micellae are then retained by pinocytosis both in the tumor cells and in the endothelial cells of the arteries feeding the tumor [18]. Following this route of administration (which is performed under angiographic monitoring), more than 75% of the injected ^{131}I-lipiodol remains in the liver, while the remainder distributes mainly to the lungs. Release of free radioiodine results in some accumulation of radioactivity in the thyroid gland. Dose to the thyroid gland can be minimized by pretreatment with sodium iodide. Tumor/non-tumor uptake ratios in the liver are generally higher than 5, and more than 10% of the injected radioactivity remains within the tumor with an effective half-life greater than 6 days, longer than in the normal liver tissue [14, 15, 19]. Administered activity can be either a fixed amount of 2.4 GBq (65 mCi) or defined on the basis of patient-specific dosimetric estimates. Due to the long half-life of ^{131}I-lipiodol in the tumor, current legislation in some countries requires hospitalization for about 1 week, for the purpose of radioprotection of the general population.

Treatment is in general well tolerated, and serious adverse effects are very rare, while generic asthenia is commonly reported; hematologic toxicity is exceptionally rare, although blood cell counts may be altered due to the cirrhosis-related hypersplenism often present in these patients. Interstitial pneumopathy due to trapping and retention of the radiolabeled particle suspension is reported as the main risk of this treatment [20].

Both retrospective studies [21–23] and prospective trials [21, 24, 25] have demonstrated the safety of ^{131}I-lipiodol therapy, while the objective response rate is reported in the 40–50% range. In particular, a randomized controlled trial comparing ^{131}I-lipiodol therapy versus best supportive care in a group of 27 HCC patients with portal thrombosis demonstrated that survival at 3 months was 71% in the treatment arm versus 10% in the best supportive care arm (with median overall survivals of 26 weeks and 10 weeks, respectively) [24].

In the adjuvant setting, the efficacy of ^{131}I-lipiodol therapy was tested in a phase II study involving 28 patients [26]. Median time to recurrence was 28 months (range 12–62 months) in the 16 patients who were apparently disease-free at follow-up; overall survival in the responding patients was 86% at 3 years and 65% at 5 years. In a recently published phase III study, 21 patients without evidence of residual disease after potentially curative resection for HCC received 1,850 MBq of ^{131}I-lipiodol intra-arterially as adjuvant therapy, while 22 patients treated with surgery alone served as the control group [27]. The recurrence rate in the patients treated with surgery alone was 63.6%, while it was 47.6% in those receiving adjuvant radioembolization. The 5-year, 7-year, and 10-year disease-free survivals were 61.9%,

52.4%, and 47.6%, respectively, in the adjuvant therapy group, significantly higher than the values in the corresponding control group (31.8% with $P = 0.0397$, 31.8% with $P = 0.0224$, and 27.3% with $P = 0.0892$, respectively). Also, overall survivals in the treated group (66.7% at both 5 and 7 years, 52.4% at 10 years) were higher than in the control group (36.4% with $P = 0.0433$ at 5 years, 31.8% with $P = 0.0243$ at 7 years, and 27.3% with $P = 0.0905$ at 10 years, respectively). When compared with chemoembolization, embolization with ^{131}I-lipiodol has yielded similar results in terms of efficacy but better tolerance [23].

More recently lipiodol labeled with ^{188}Re using 4-hexadecyl 2,2,9,9-tetramethyl-4,7-diaza-1,10-decanethiol (HDD) as the chelating agent [28] was shown to be a promising agent for radioembolization in patients with inoperable large and/or multifocal HCCs. ^{188}Re has potentially favorable physical characteristics, such as a shorter half-life than ^{131}I (16.9 h versus 8 days), a β^- emission of high energy with ensuing good tumoricidal effect ($E_{max} = 2.1$ MeV), and a 155-keV γ emission favorable for gamma-camera imaging (for the purpose of dosimetric estimates). Furthermore, the relatively short-lived ^{188}Re can be obtained through a generator system based on its parent radionuclide (^{188}W) that has a physical half-life of 69 days, suitable for distribution logistics.

Therapy of HCC with ^{188}Re-HDD-lipiodol results in higher tumor-killing efficacy than ^{131}I-lipiodol, yet combined with lower toxicity. The ^{188}Re-labeled agent represents therefore an excellent alternative to the ^{131}I-labeled agent [29].

Promising results of both safety and clinical response following therapy with ^{188}Re-HDD-lipiodol were obtained in a multicenter study performed in 93 patients with inoperable HCC [30]. Treatment was well tolerated, and an objective response (including either tumor regression of some degree or stabilization of disease that was in progression prior to therapy) was observed in 66/93 patients (71%); out of these 66 objective responses, there were 5 cases with complete ablation of the tumor mass, 17 cases of partial response, and 23 cases with stabilization of disease.

^{90}Y-Microspheres

Intra-arterial radioembolization with ^{90}Y-labeled particles was approved in 2002 for the treatment of liver tumors, both primary malignancies and metastatic lesions originated by other tumors [31]. ^{90}Y is a pure β^- emitter that decays to stable ^{90}Zr and has a physical half-life of 64.2 h. The average energy of β^- emission is 0.936 MeV, with a mean tissue penetration of 2.5 mm and a maximum tissue range of 10 mm. The physical properties of ^{90}Y allow the delivery of high-radiation doses to hepatic malignancies, when administered with this technique, while minimally affecting the non-affected surrounding liver parenchyma.

Two types of microspheres labeled with ^{90}Y are currently available, made, respectively, of glass (TheraSphere®, MDS Nordion, Ottawa, Ontario, Canada) and of resin (SIR-Spheres®, Sirtex Medical, Sydney, Australia). These two preparations differ in some important respects [32]. TheraSphere® consists of particles 20–30 μm in diameter, each one carrying 2,500 Bq of ^{90}Y (high specific activity); about 1.2 million microspheres is injected intra-arterially for a single treatment, corresponding to a total administered activity of about 3 GBq (81 mCi). SIR-Spheres® consists instead of particles 20–60 μm in diameter, each one carrying 50 Bq of ^{90}Y (low specific activity); 40–80 million microspheres are injected for a single treatment to achieve a similar total administered activity of 3 GBq [32].

Patient Selection

After the diagnosis of inoperable liver tumor has been made on the basis of proper imaging and biopsy, the pretreatment functional status of the liver is evaluated by routine blood chemistry workup. Patients with an ECOG performance status of greater than two are not considered ideal candidates for this treatment.

An inadequate liver function reserve with total bilirubin >2.0 mg/dL and serum albumin <3 g/dL is considered a contraindication to treatment with

^{90}Y-microspheres. In case of concomitant renal failure, care must be taken to avoid or minimize the use of iodinated contrast medium during angiography (see further below).

Pretreatment evaluation for TARE/SIRT with ^{90}Y-microspheres is based on cross-sectional imaging and arteriograms in the individual patient, with the fundamental prerequisite that the patient has liver-dominant unresectable disease. The workup should include CT or MR imaging of the liver for assessment of tumoral and non-tumoral volume, portal vein patency, and extent of extrahepatic disease. Distribution of the tumor disease is typically characterized as unilobar or bilobar; however, the correlation of tumor lesions with hepatic arterial supply is variable and can only be ascertained through arteriography. Ascites indicates poor hepatic reserve or peritoneal metastasis, both of which bear poor prognosis.

The final decision-making about treatment with ^{90}Y-microsphere TARE/SIRT for each individual patient should be achieved after careful consideration of all functional and anatomic parameters within a multidisciplinary team involving interventional radiologists, surgical oncologists, medical oncologists, nuclear medicine physicians, radiation oncologists, medical physicists, and radiation safety experts.

Assessment of Arterial Anatomy

Pretreatment angiography (an essential requisite for the therapeutic procedure) is performed to assess the vascular anatomy of the liver, patency of the portal vein, and presence of artero-portal shunting and/or shunting to extrahepatic territories, the most important of which is the liver-to-lung shunt (see further below). Abnormal blood flow spreading the radiolabeled microspheres outside the liver vasculature is prevented by prophylactic embolization of some vessels identified during angiography, such as the gastroduodenal artery and the right gastric artery [5]. This is a safe and effective procedure to minimize the risks of hepato-enteric flow. Mesenteric angiography is necessary to ensure that blood supply to the lesions has been adequately identified, as incomplete/inaccurate definition of the pattern of blood supply to the tumor may lead to incomplete/ineffective targeting of the tumor lesion.

Pretreatment Imaging with ^{99m}Tc-MAA

During pretreatment angiography, ^{99m}Tc-macroaggregated serum albumin ((^{99m}Tc-MAA) or alternatively ^{99m}Tc-HSA-microspheres) is injected into the hepatic artery to confirm that the radiolabeled particles home in the tumor lesion(s), as well as to assess for the presence of shunting to the splanchnic and/or pulmonary vascular bed. To this purpose, scintigraphy of the lung and upper abdomen by either planar and/or SPECT/CT imaging (i.e., the optimal imaging technique) is routinely performed (Figs. 1, 2, and 3) [33]. Images can be acquired within 4 h of the administration of ^{99m}Tc-HSA-microspheres, while the optimal time window for imaging after administration of ^{99m}Tc-MAA is within 1 h post-administration. In fact, albumin macroaggregates undergo a relatively fast intrahepatic degradation, with possible redistribution of radioactivity (constituted either by smaller fragments and/or free $^{99m}TcO_4^-$) from the capillary bed of the liver to the capillary bed of the lung. As a consequence, the liver-to-lung shunt fraction can be overestimated at later time points after administration [34], or radioactivity accumulation at other sites (e.g., free $^{99m}TcO_4^-$ accumulating in the stomach) can be misinterpreted as shunting to extrahepatic sites. In order to avoid such occurrence, sodium perchlorate is administered orally about 30 min before ^{99m}Tc-MAA injection [35].

It is crucial to correlate the ^{99m}Tc-MAA scintigraphic images to the angiography pattern, as topographic proximity of the duodenum and stomach to the liver may decrease the ability to identify extrahepatic shunting by scintigraphy alone, especially if based solely on planar imaging. Based on ROI technique, the lung shunt fraction (LSF) is calculated and employed to estimate the radiation dose delivered to the lungs for any given amount of radioactivity, so that appropriate adjustments in the administered activity can be made to minimize the risk of radiation pneumonitis (see further below).

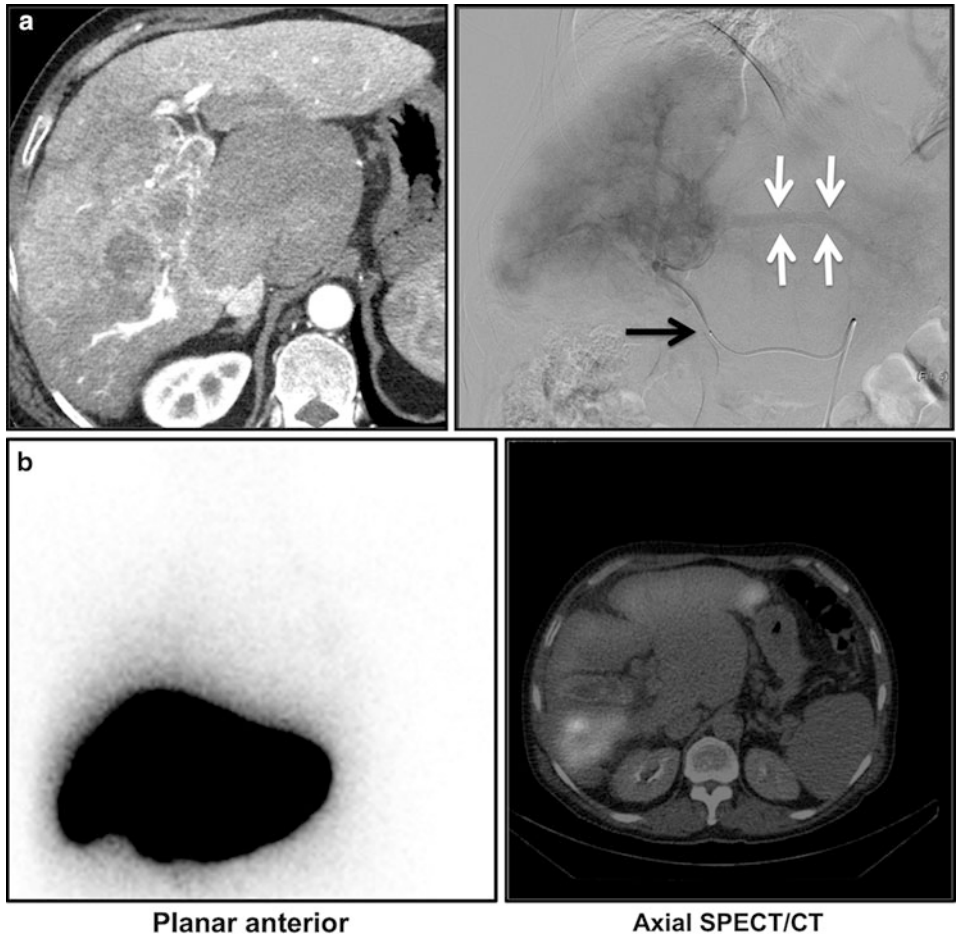

Fig. 1 Angiographic and scintigraphic pretreatment evaluation of a 67-year-old patient with a large, infiltrating hepatocellular carcinoma (HCC) candidate to radioembolization therapy with ^{90}Y-microspheres. (**a**) *Left panel* shows contrast-enhanced CT *demonstrating massive infiltration of segment 1 by a large HCC, with extension to the adjacent liver segments. Right panel* shows an early phase of digital subtraction angiography through the hepatic artery (catheter indicated by *black arrow*); there is intense diffuse enhancement of the left branches of the portal vein, with a wide-lumen artero-portal fistula (indicated by *white arrows*). (**b**) *Left panel* shows planar scintigraphy acquired after trans-arterial injection of ^{99m}Tc-MAA (anterior view) demonstrating widespread diffusion of the injected particles to virtually the entire liver. *Right panel* shows the fused axial SPECT/CT image, which better defines the intrahepatic distribution of ^{99m}Tc-MAAs, mostly to both the right and the left lobes of the liver, while there is minimal perfusion of the main site of the tumor. On the basis of the angiographic and scintigraphic characterization, this patient was excluded from trans-arterial radioembolization with ^{90}Y-microspheres, because this treatment would have exposed the non-tumor liver parenchyma to excessive, unjustified radiation doses without actually an expected benefit for what concerns tumor therapy

Radiodosimetric Aspects

The choice of the most appropriate ^{90}Y activity to be delivered into the tumor target and to the normal liver parenchyma requires adequate knowledge of many factors, mainly the liver function and reserve, that are frequently influenced by concomitant pathologies (i.e., cirrhosis) or by prior chemotherapy and/or external beam radiation therapy.

The main complications possibly linked to ^{90}Y-microsphere radioembolization are caused by excessive irradiation of nontarget tissue. In

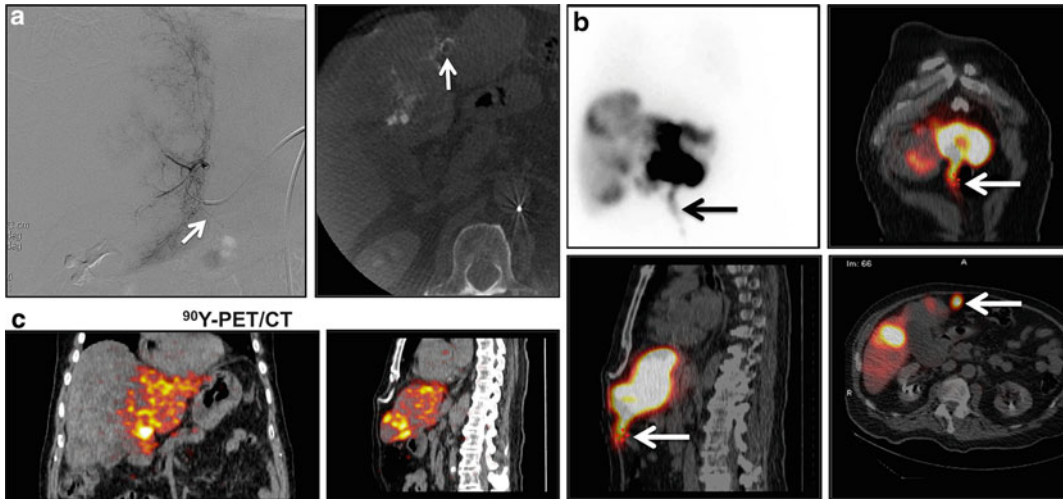

Fig. 2 Angiographic and scintigraphic pretreatment evaluation of a 75-year-old man with metastasis from an urothelial carcinoma in both lobes of the liver, with posttreatment PET/CT acquisition based on internal pair production during decay of ^{90}Y. Selective angiography was performed by injecting contrast medium separately into the right, the median, and the left branches of the hepatic artery. (**a**) *Left panel* shows digital subtraction angiography obtained upon injection into the median hepatic artery, revealing a thin branch (indicated by the *white arrow*) identified as a patent falciform artery. *Right panel* shows the corresponding contrast-enhanced CT phase (falciform artery indicated by *white arrow*). (**b**) Scintigraphy acquired after trans-arterial ^{99m}Tc-MAA injection clearly demonstrate the abnormal arterial branch (indicated by *arrows*) in the planar anterior view (*upper left panel*) as well as in the fused SPECT/CT images (coronal in *upper right*, sagittal in *lower left*, axial in *lower right panels*, respectively). During the subsequent trans-arterial treatment phase, an ice pack was positioned on the cutaneous projection of the falciform artery before injecting the ^{90}Y-microspheres, in order to induce vasoconstriction and thus reduce as much as possible inadvertent deposition of the radiolabeled particles in the periumbilical region, which would have caused delivery of a high-radiation dose to this region. The procedure was uneventful, and the post-treatment PET/CT acquisition based on internal pair production of ^{90}Y (**c**) showed excellent tumor targeting without visualization of the area fed by the patent falciform artery (fused coronal image in *left panel*, fused sagittal image in *right panel*)

this regard, the key limiting factor is the lower tolerance to radiation of normal liver parenchyma relative to the dose required to destroy the tumor target. The maximum external beam acceptable cumulative dose to the whole liver is 35 Gy (based on prior experience with external beam radiation therapy) [36], while the estimated dose to destroy a solid tumor is more than 70 Gy. Above the 35 Gy threshold radiation dose to the liver parenchyma, the risk of liver failure rises sharply.

The other absolute and relative contraindications for the procedure are related to the possible flow/reflux of part of the ^{90}Y-microspheres to arteries feeding the wall of the gastrointestinal tract and to excessive lung radiation due to a high hepato-pulmonary shunt, frequently observed in HCC as well as in metastatic disease with a large tumor burden. In this case, the administration of therapeutic amounts of ^{90}Y-microspheres increases the risk of clinically relevant radiation pneumonitis.

To warrant the safety of the procedure, it is crucial to quantify the lung shunt fraction (LSF) as detected in the pretreatment evaluation with the ^{99m}Tc-MAA scan, in order to calculate the expected radiation dose to the lungs. Previous data extrapolated from the large body of experience accumulated with external beam radiation therapy indicate that the highest tolerable dose to the lungs is 30 Gy for a single administration and less than 50 Gy as the cumulative dose for multiple treatments [36].

The LSF value is routinely calculated by ROI analysis of the planar scans acquired after ^{99m}Tc-MAA administration in the pretreatment phase, using the geometric mean of the lung and liver

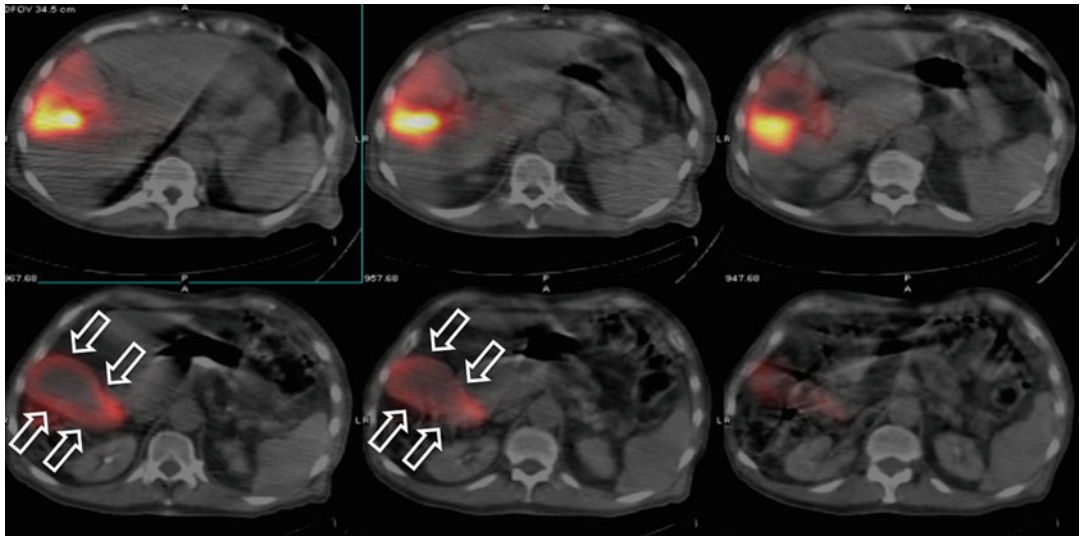

Fig. 3 Scintigraphic pretreatment evaluation (fused axial SPECT/CT images at various levels) of a 72-year-old patient with a tumor lesion between segments 5 and 6 of the liver. Trans-arterial ^{99m}Tc-MAA injection results in satisfactory distribution to the tumor lesion but also in scintigraphic visualization of the gallbladder wall, due to flow of the radiolabeled particles through the cholecystic artery. Therapy with ^{90}Y-microsperes was not performed, because of the fear of causing necrotizing radiation-induced cholecystitis. In patients with vascular patterns similar to this (as those regarding the mesenteric artery feeding the gastric wall), further attempt to ^{90}Y-microsphere radioembolization therapy must be preceded by coil embolization of the arteries feeding extrahepatic territories

counts, respectively, in the anterior and posterior views, according to the following equation:

$$LSF(\%) = \frac{\text{Lung Counts}}{\text{Lung Counts} + \text{Liver Counts}} \times 100$$

Radioembolization with ^{90}Y-microspheres has no restrictions for any LSF value <10%, whereas an LSF value >20% constitutes per se an absolute contraindication to treatment. Activity adjustments can be adopted for LSF values between 10% and 20%, that is, a 20% reduction in administered activities for LSF values included between 10% and 15% and a 40% reduction for LSF values included between 15% and 20% (see Fig. 4).

Different models have been proposed and can be employed to calculate the ^{90}Y activity to be administered that would allow delivery of the highest dose to the tumor while sparing normal liver tissue. The so-called partition model (based on the MIRD approach) takes into account three different compartments for radiation dose estimates, i.e., the liver tumor, the non-tumoral liver, and the lungs [37]. The basic assumption is that the LSF and the relative distribution of ^{99m}Tc-MAAs in the tumor and non-tumor liver compartments (expressed as T/N ratio) reliably predicts distribution of the ^{90}Y-microspheres that will be administered during another interventional radiology procedure performed a few days later by the same radiologist trying to replicate exactly the same position of the intra-arterial catheter as during ^{99m}Tc-MAA administration. The activity of ^{90}Y-microspheres to be administered can be estimated using the LSF derived from the ^{99m}Tc-MAA scintigraphic images. This approach is adopted routinely when administering the glass ^{90}Y-microspheres and has been shown to yield safe and reproducible estimates regarding expected toxicity and clinical outcomes.

When using the resin ^{90}Y-microspheres, two additional methods can be employed to estimate the activity to be administered, i.e., empiric method and the body surface area (BSA) method. The empiric method is based on the volume of the liver occupied by the tumor tissue expressed as a fraction of the overall liver volume, as estimated by

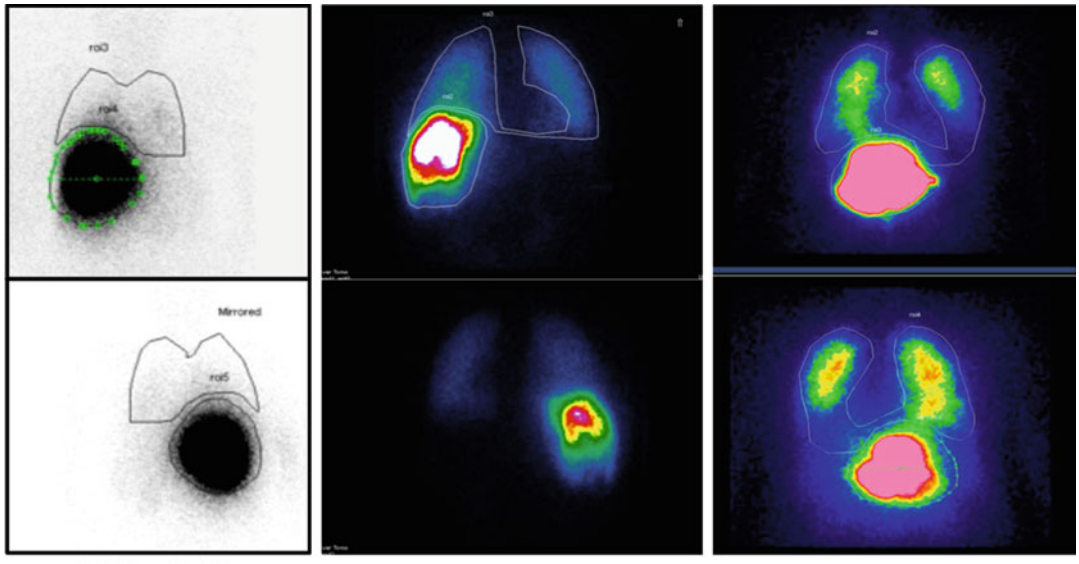

Fig. 4 Representative examples in three different patients of estimation of the lung shunt fraction (LSF) as derived from planar gamma-camera imaging after trans-arterial injection of ^{99m}Tc-MAA. For each patient, the anterior and posterior views are displayed, with delineation of regions of interest (ROI) for the liver and for the lung fields, respectively; each ROI is first manually drawn on the anterior view, and then it is flipped on the horizontal axis to match the posterior view. The geometric means of the ROI counts from the two orthogonal views are utilized to calculate the LSF value according to the equation described in the text. The LSF value calculated for the patient in *left panel* resulted to be 6.4%; the ^{90}Y-microsphere activity injected in this patient was therefore the full amount planned on the basis of the dosimetric estimate. A 20% reduction for administered ^{90}Y-microsphere activity was instead applied to the patient in the *center panel* (whose LSF was 12%), while the patient represented in *right panel* was excluded from treatment because of a LSF exceeding 20%

cross-sectional imaging (either CT or MRI). A ^{90}Y-microsphere activity of 2 GBq is recommended for a tumor/liver fraction <0.25, increasing to 2.5 GBq for tumor fractions between 0.25 and 0.5 and increasing further to 3 GBq for tumor fractions >0.5 (keeping in mind that a value above 0.7 constitutes per se an absolute contraindication to treatment).

The body surface area (*BSA*, expressed in square meters) method uses the following equation to calculate the ^{90}Y-microsphere activity (A) to be administered:

$$A(GBq) = (BSA - 0.2) + \frac{\text{tumor volume}}{\text{total liver volume}}$$

Although these two methods based on clinically derived data of intraoperative activity calculations are routinely used in some centers, they are not optimal in certain situations, in particular when the target is well identified and the total volume of the three compartments is accurately known. Moreover, it has been demonstrated that both the BSA method and the empiric method frequently overestimate the activity to be administered to the patient [38, 39]. Therefore, the use of the MIRD partition model should be recommended when administering the resin ^{90}Y-microspheres.

Patient-specific dosimetry requires accurate evaluation of the liver and tumor mass (usually derived from anatomic imaging such as CT) and of ^{99m}Tc-MAA biodistribution based on scintigraphic imaging. However, the predictive value of ^{99m}Tc-MAA scintigraphy as to the distribution of ^{90}Y-microspheres in the liver is still a matter of debate [40–42]. Parameters that may induce some

discordance between the distribution of ^{99m}Tc-MAAs and that of the ^{90}Y-microspheres include interval differences in catheter position during injection in the two separate occasions, physiologic changes in hepatic blood flow, tumor histopathology, and tumor load, size, and morphology differences between the ^{99m}Tc-MAA particles and the ^{90}Y-microspheres [42]. These factors may all limit the concordance between ^{99m}Tc-MAA distribution as assessed in the pretreatment procedure and actual distribution of the ^{90}Y-microspheres administered for therapy [41].

Although the ability of ^{99m}Tc-MAA to predict radiation dosimetry expected from ^{90}Y-microsphere administration is far from ideal, most of the retrospective studies based on ^{99m}Tc-MAA scintigraphy for these estimates have shown a definite dose-response correlation with a threshold value from 120 to 205 Gy [43, 44] and even up to 500 Gy [45]. However, no prospective studies have confirmed these observations, and no single cutoff value that ensures tumor response has been identified as yet.

The dosimetry-based methods utilized to calculate the activity to be administered during radioembolization are described in detail in ► Chap. 13, "Radiobiology and Radiation Dosimetry in Nuclear Medicine" of this book.

^{90}Y-Microsphere Administration

During the radioembolization session, the vessel perfusing the tumor is reached under fluoroscopic guidance, and the ^{90}Y-microsphere suspension is injected into the artery feeding the target lesion. A delivery system that allows the administration in a step-by-step manner is useful to avoid early full embolization of the vasculature that prevents infusion of the total estimated activity. The infusion is usually done with alternating injections of iodinated contrast medium and sterile water/glucose solution when using the resin ^{90}Y-microspheres or of saline solution during infusion of the glass ^{90}Y-microspheres. Continuous fluoroscopy monitoring ensures that no stasis occurs during infusion and also serves to confirm that the flow of microspheres is similar to that observed during the prior angiographic workup.

According to topography of the tumor, treatment can be either selective (i.e., directed to one liver lobe) or super-selective (directed to one liver segment).

Posttreatment Scan

Early posttreatment assessment of the pattern of ^{90}Y-microsphere deposition by high-quality imaging is necessary to exclude radioactivity accumulation in gastrointestinal tract and to evaluate the radiation-absorbed dose delivered to the tumor.

A post-therapy planar and SPECT/CT scan based on the bremsstrahlung emission generated by the high-energy β^- particles of ^{90}Y helps to confirm correct deposition of the radiolabeled microspheres in the tumor lesions [46]. However, the low-resolution and poor-quality imaging obtained from the bremsstrahlung emission does not allow an accurate quantification of microsphere distribution, especially when dealing with small lesions.

More recently imaging with ^{90}Y PET has been used to assess the distribution of the microspheres [47] (Fig. 5). PET imaging is made possible by the fact that, despite the commonly held notion that ^{90}Y is a pure β^- emitter, in reality, a certain fraction of ^{90}Y decays (even if extremely small, i.e., 32 per million) occur through internal pair production that generates 511 keV annihilation photons. The annihiliation radiation generated from these emissions can be imaged by PET. In the case of radioembolization of liver tumors with ^{90}Y-microspheres, the therapeutic agent remains concentrated in a relatively small volume at the administration site; therefore, even the extremely small fraction of ^{90}Y decays occurring through internal pair production are sufficient to acquire clinically useful PET images for validation and dosimetric purposes [48–51]. The better resolution images provided by PET may allow easy detection of extrahepatic distribution of ^{90}Y-microspheres and assessment of the absorbed dose delivered during the radioembolization procedure [47, 48].

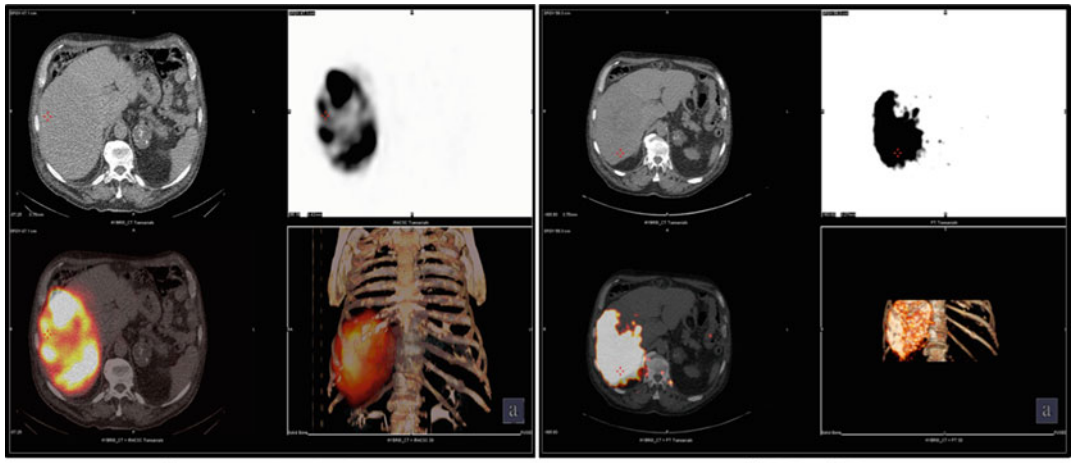

Fig. 5 Good correspondence in the patterns of intrahepatic distribution of radiolabeled particles injected into the right hepatic artery between pretreatment ^{99m}Tc-MAA SPECT/CT (*left*) and posttreatment ^{90}Y-PET/CT (*right*). For SPECT/CT, the MIP image is displayed in *upper right panel*, the axial CT image in *upper left panel*, the fused axial SPECT/CT image in *lower left panel*, and the 3D surface volumetric rendering in *lower right panel*. Similar displays for PET/CT: MIP image in *upper right panel*, axial CT image in *upper left panel*, fused PET/CT image in *lower left panel*, and 3D surface volumetric rendering in *lower right panel*

Radioembolization with ^{90}Y-microspheres can be performed as an outpatient procedure, and the patient can be discharged from the hospital on the same day of treatment or on the following day.

Patient Follow-Up and Assessment of Response to Therapy

Tumor response to radioembolization is monitored both clinically and radiologically. Routine follow-up includes blood chemistry to monitor possible toxicity due to treatment; in the case of HCC, measurement of the serum levels of the tumor-associated marker AFP serves to assess evolution of the malignant disease. Contrast CT is performed at 1 month posttreatment, while additional CT scans are performed every 3 months to assess response to treatment or progression of disease. Although tumor response to therapy can be assessed by classical RECIST criteria, specific criteria set by the World Health Organization (WHO) and by the European Association for the Study of the Liver (EASL) based on size parameters and on necrosis parameters, respectively, are employed to assess response in the target lesions [13, 52].

In metabolic assessment with [^{18}F]FDG-PET provides useful prognostic information in response of either primary or metastatic liver tumors to trans-arterial radioembolization with ^{90}Y-microspheres [40, 53–55]. The superiority of functional metabolic imaging with PET versus the conventional morphology-based criteria such as RECIST for early assessment of tumor response to radioembolization with ^{90}Y-microspheres has been demonstrated in different clinical settings such as HCC [56, 57], intrahepatic cholangiocellular carcinoma [55] (Fig. 6), metastatic CRC [58, 59] (Figs. 7 and 8), and liver metastases from breast cancer [60] and metastatic neuroendocrine malignancies (the latter using ^{68}Ga-DOTANOC as the PET tracer) [61] (Fig. 9).

^{90}Y-Microsphere Radioembolization Combined with Other Therapies

Radioembolization with ^{90}Y-microspheres is a valid therapeutic option per se, preferably in patients with early stage inoperable liver-

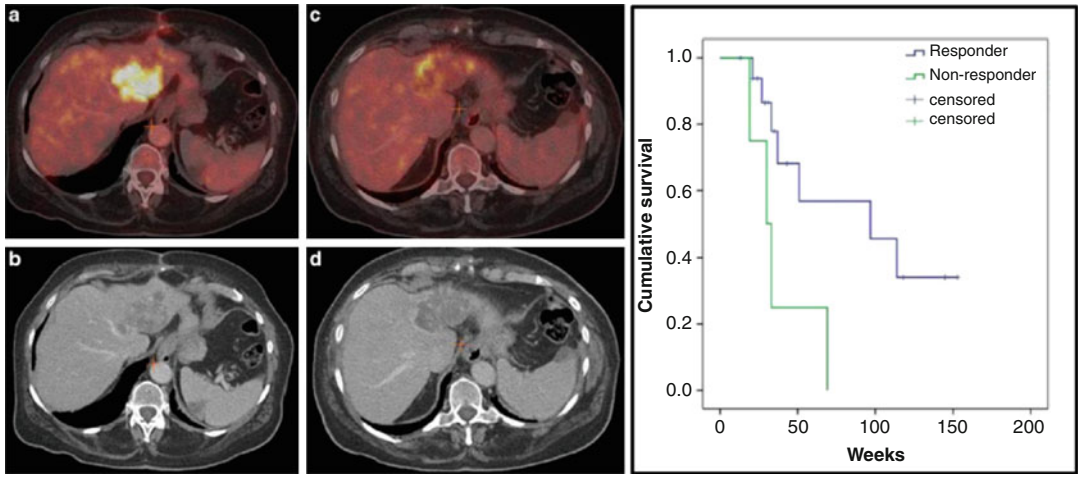

Fig. 6 *Left panel*: response to trans-arterial therapy with ^{90}Y-microspheres in a patient with intrahepatic cholangiocarcinoma. (**a**) Axial fused pre-therapeutic [^{18}F]FDG-PET/CT image; (**b**) corresponding slice of diagnostic CT; (**c**) axial fused post-therapeutic [^{18}F]FDG-PET/CT image; (**d**) corresponding slice of diagnostic CT. The SUV_{max} declined by 70% 3 months after radioembolization, and the serum levels of CA 19-9 fell from 85.2 to 49.2 U/mL; the patient was still alive 12 months after radioembolization without evidence of progression within the liver. *Right panel*: Kaplan-Meier survival curves as a function of ΔSUV_{2SD}. Responders (*blue line*) had a significantly ($P < 0.05$) longer survival than nonresponders (*green line*) (Modified and reproduced with permission from: Haug et al. [55])

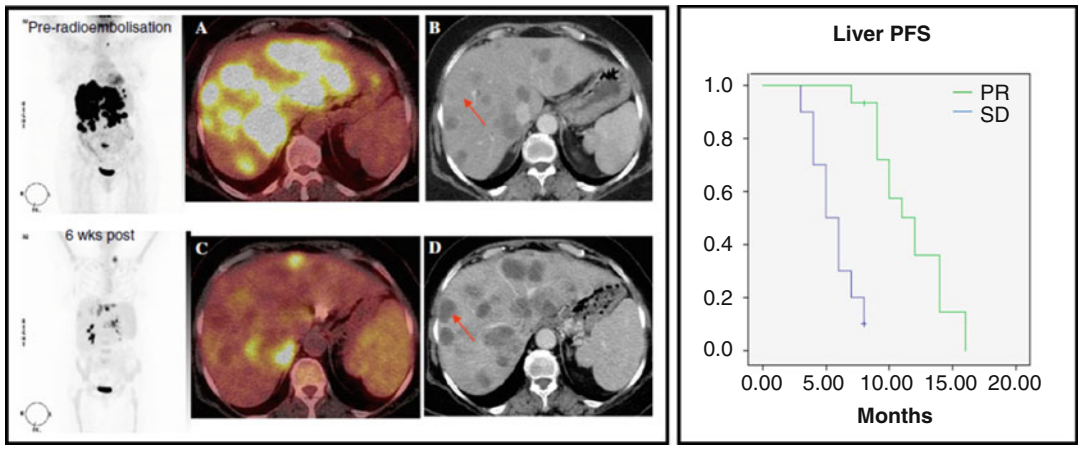

Fig. 7 *Left panel*: coronal PET (*left*), axial fused [^{18}F]FDG-PET/CT images (**a**, **c**), and axial contrast-enhanced CT (ce-CT) images (**b**, **d**) in a patient with metastatic colorectal cancer before and 6 weeks after radioembolization with ^{90}Y-microspheres. (**a**) Baseline PET/CT shows increased [^{18}F]FDG uptake in metastases in segments I, II, IVa, VII, and VIII. (**b**) The ce-CT image before radioembolization shows some of the metabolically active metastases as low-attenuation lesions, but several of them are isointense compared to the liver parenchyma and are difficult to delineate, such as the lesions in segment VIII (*arrow*). (**c**) PET/CT after radioembolization shows an excellent partial response (PR) with marked reduction in the intensity and extent of uptake in the metastatic lesions. (**d**) Post-radioembolization ce-CT shows multiple new low-attenuation lesions, which are more apparent as they have become necrotic, such as the metastasis in segment VIII (*arrow*). This ce-CT image was incorrectly reported as showing disease progression. *Right panel*: Kaplan-Meier plots of progression-free survival (PFS) in relation to responses seen on [^{18}F]FDG-PET/CT. Patients who had a PR or stable disease on [^{18}F]FDG-PET/CT had median PFS of 12 and 5 months, respectively (Modified and reproduced with permission from: Zerizer et al. [58])

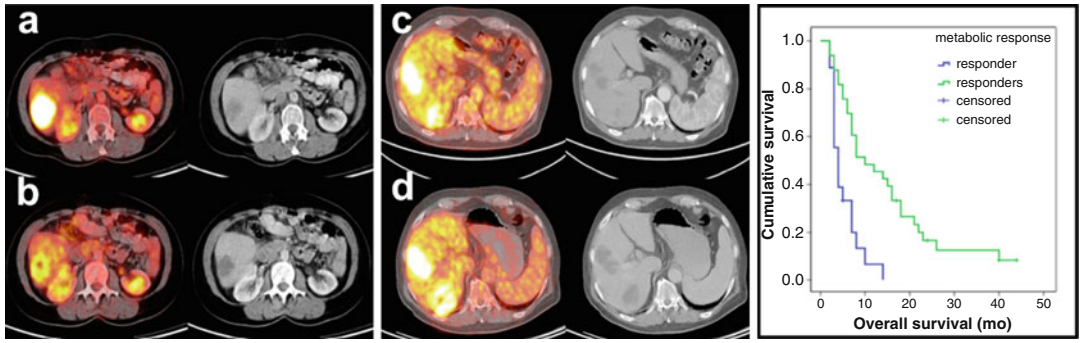

Fig. 8 *Left panel*: axial fused [^{18}F]FDG-PET/CT images before (**a**) and 4 weeks after (**b**) trans-arterial radioembolization with ^{90}Y-microspheres of a patient with metastatic colorectal cancer; the marked metabolic response was associated with a survival of 12 months after treatment. *Center panel*: Axial fused [^{18}F]FDG-PET/CT images before (**a**) and 4 weeks after (**b**) trans-arterial radioembolization with ^{90}Y-microspheres of a patient with metastatic colorectal cancer; this metabolic nonresponder survived 5 months after treatment (Modified and reproduced with permission from: Sabet et al. [59])

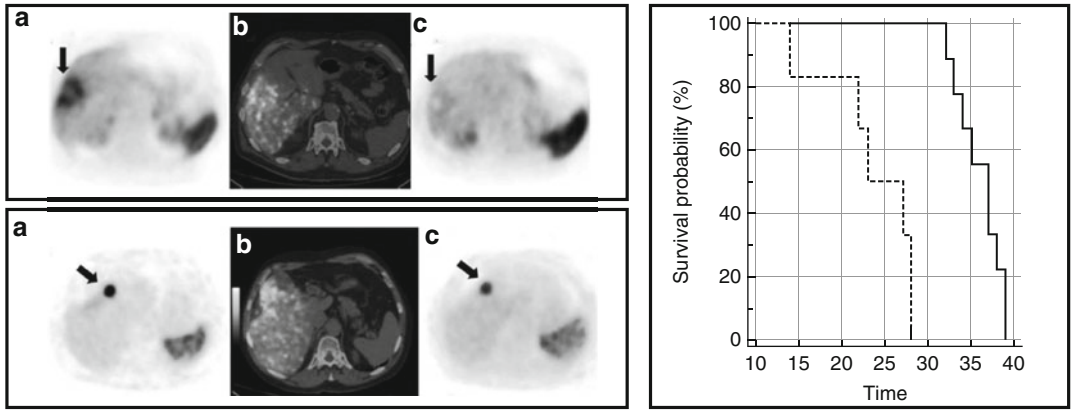

Fig. 9 *Left upper panel*: (**a**) ^{68}Ga-DOTANOC PET axial slice acquired before trans-arterial radioembolization with ^{90}Y-microspheres shows intense tracer accumulation in a patient with a large metastasis from a neuroendocrine neoplasm in the right hepatic lobe (*arrow*). (**b**) Fused unenhanced CT slice and ^{90}Y PET axial slice acquired after administration of ^{90}Y-microspheres shows radioactivity accumulation in the tumor mass with a necrotic core surrounded by a hot circular region. (**c**) ^{68}Ga-DOTANOC PET axial slice acquired 6 weeks after radioembolization shows significant reduction of tracer uptake in the tumor uptake (*arrow*), consistent with a molecular response (ΔT/S was −73.4%); overall survival was 34 months. *Left lower panel*: (**a**) ^{68}Ga-DOTANOC PET axial slice acquired before trans-arterial radioembolization with ^{90}Y-microspheres shows intense tracer accumulation in a patient with a metastasis from neuroendocrine neoplasm in hepatic segment IV (*arrow*). (**b**) Fused unenhanced CT slice and ^{90}Y-PET slice acquired after administration of ^{90}Y-microspheres shows radioactivity accumulation in the tumor mass. (**c**) ^{68}Ga-DOTANOC PET/CT axial slice acquired 6 weeks after treatment shows substantially unchanged tumor uptake (*arrow*), consistent with no response (ΔT/S was −24.6%). Overall survival was 23 months. *Right panel*: Kaplan-Meier survival analysis in relation to ΔT/S measured 6 weeks after radioembolization. Patients with ΔT/S less than −50% (*dashed line*) had significantly lower ($P < 0.001$) survival than those with ΔT/S more than −50% (*solid line*) (Modified and reproduced with permission from: Filippi et al. [61])

predominant malignancies. Nevertheless, it can be used also in combination with systemic molecular/chemotherapies in patients presenting with an intermediate or even advanced stage of HCC [62] or with unresectable liver-predominant metastases from colorectal cancer. Moreover, thanks

to its ability to downsize/downgrade the disease, SIRT/TARE may be used as neoadjuvant therapy also in patients with HCC not meeting the criteria for resection, percutaneous ablation, or transplantation.

The clinical situations in which patients with nonresectable/ablatable HCC can be used with radioembolization combined with other therapies can be summarized as follows:

- Before planned resection or transplantation [63], radioembolization may be considered as a neoadjuvant treatment to reduce the tumor burden and simplify surgery or to stop/slow down tumor progression in order to keep patients on the transplant waiting list or to improve the long-term outcome – even achieving in some cases downstaging of the disease [64]. In selected clinical situations where the non-tumoral liver is too small in terms of functional reserve (thus hindering any type of resection), lobar or segmental selective radioembolization may lead to ipsilateral lobar of segmental parenchymal hypotrophy and contralobar hypertrophy (ranging from 21% to 35%) allowing subsequent surgery [65].
- As an alternative option when other ablative treatments cannot be applied. ^{90}Y-microsphere radioembolization as well trans-arterial chemoembolization may improve the survival in patients with poor prognosis with portal vein occlusion, who are often excluded from a targeted therapy [66].
- In combination with systemic therapies. Although preliminary data suggest a synergistic beneficial effect of ^{90}Y-microsphere radioembolization when combined with sorafenib (with associated tolerable toxicity) [67–70], large-scale multicenter trials are still ongoing to confirm these data and to define the safety profile and the impact of the combination on survival of this combination regimen.
- In patients with unresectable liver-predominant metastases from colorectal cancer, preliminary results of the SIRFLOX study indicate that radioembolization combined with systemic therapy as first-line treatment can lead to downstaging of the disease in a significant proportion of cases and to improved PFS for the liver lesions (but not overall PFS, while the follow-up phase is ongoing for overall survival) [71].
- As a second-line treatment and in the salvage setting for liver-predominant metastatic colorectal cancer, there are clinical evidences that combination of radioembolization and systemic chemotherapy using radiosensitizing drugs (i.e., oxaliplatin, 5-FU, and irinotecan) is safe, with preliminary results indicating a 79% response rate [72].

Clinical Indications

Radioembolization with ^{90}Y-microspheres has shown to be an effective procedure with significant impact on survival of patients with either primary or secondary liver malignancies.

Primary Liver Tumors

Hepatocellular Carcinoma

Radioembolization as a treatment option has been extensively investigated for the most common primary liver malignancy, i.e., HCC, especially after Geschwind and coworkers published their landmark comprehensive analysis on the use of ^{90}Y-microspheres for HCC. Besides demonstrating overall clinical safety and benefit of this therapy, the study also indicated better survival as treatment was employed earlier in the course of disease, i.e., in Okuda stage I (63% for 1-year survival and 628-day median survival) rather than in Okuda stage II patients (51% for 1-year survival and 384-day median survival, with $P = 0.02$) [73].

The response rates to radioembolization with ^{90}Y-microspheres may vary widely not only because of variable tumor biology but also because of differences in evaluation times or in treatment intensity. Tumor shrinkage after therapy may take months to occur, with a median time to response of approximately 6 months according to WHO criteria [74]. Nevertheless, response in

tumor size is not an adequate parameter to define all the antitumor effects of therapy. When combining different response criteria, such as tumor size and arterial contrast enhancement with the EASL response criteria, the overall tumor response rates vary between 40% and 90%, with a disease control rate in targeted lesion of 80–100%. According to changes in vascular enhancement, time to response occurs in the treated tumor lesions earlier than response in tumor size, around 2 months after ^{90}Y-microsphere radioembolization [74].

Surgery is the optimal standard of care with curative intents for patients with HCC; however, resection is possible only for lesions limited in size and number and if the liver function is well preserved; the latter is not a frequent condition considering that most HCCs originate in patients with liver cirrhosis. On the other hand, patients with a single lesion <5 cm in diameter, or with ≤ 3 lesions, all <3 cm without extrahepatic metastases or portal vein thrombosis (PVT), are eligible for liver transplantation. Nevertheless, orthotopic liver transplantation has had a limited role in the management of patients with HCC due both to limited availability of donor organs and to dropout of patients because of tumor progression. Since radioembolization has been shown to slow the progression of HCC, this procedure may allow patients more time to wait for donor organs and thus increases their chance of undergoing liver transplant [75–77].

Patients whose disease is too advanced to meet transplant criteria, but do not have malignant PVT or metastatic HCC, are good candidates for radioembolization. In fact, radioembolization has been shown to downstage the disease so that 56% of the patients who were initially stratified as non-eligible for transplant according to Milan criteria then become eligible for transplant after therapy; 8 out of 34 downstaged patients actually underwent subsequent liver transplantation, with 84%, 54%, and 27% overall survivals, respectively, at 1, 2, and 3 years. In addition to downstaging, radioembolization also prolongs overall survival of these patients [75–77].

Survival benefit following radioembolization has been observed also in patients with malignant vascular involvement, with a 70% response rate according to EASL criteria [78]. The presence of distant metastases contraindicates treatment, as a survival benefit has not been demonstrated for this subset of patients.

Intrahepatic Cholangiocarcinoma

Resection has a modest survival benefit in patients who have resectable intrahepatic cholangiocarcinoma (ICC). Some improvement in survival has been observed after trans-arterial chemoembolization, but toxicity associated with this treatment remains high. On the other hand, while radioembolization has been shown to be an effective treatment for HCC, its role in the management of ICC patients has not been extensively investigated. Nevertheless, a pilot study in 24 patients with biopsy-proven ICC has shown favorable tumor response and favorable survival outcomes following therapy with ^{90}Y-microspheres, especially for patients with better ECOG performance status [79].

A recent systematic review on the use of TARE in the treatment of ICC identified 12 studies including a total of 73 patients. PR and SD at 3 months were reported in 28% and 54% of patients, respectively. In a pooled analysis, the overall weighed median survival was 15.5 months, and downstaging to surgery was achieved in seven patients [80]. The combination of TARE and chemotherapy as a strategy for downstaging ICC to achieve resectability has recently been proposed, with encouraging initial data [81]. However, when comparing different locoregional treatments for ICC, TARE may not be the most effective approach. In a comparative analysis, TARE performed second in terms of tumor response to intra-arterial chemotherapy but was more effective than TACE or DEB-TACE both in terms of tumor response and in terms of overall survival. In fact, overall survival was 22.8 months for intra-arterial chemotherapy, 13.9 months for

TARE, 12.4 months for TACE, and 12.3 months for DEB-TACE. Nevertheless, intra-arterial chemotherapy had the highest toxicity [82]. Despite the lack of randomized controlled trials, locoregional treatments appear to be somewhat more effective than the current standard chemotherapy regimens with oxaliplatin and gemcitabine [83]. For patients with unresectable ICC, trans-arterial radioembolization with ^{90}Y-microspheres seems to be best suited for patients who are not eligible for intra-arterial chemotherapy.

[^{18}F]FDG-PET is the best independent predictor for patient outcome after radioembolization treatment, based on reduction in the metabolically active tumor volume at 3 months after therapy [55].

Metastatic Liver Tumors

Extrahepatic metastasis and comorbidities limit the role of surgical resection in patients with secondary liver tumors [84]. The use of radioembolization in these patients has been extensively investigated, either as a single treatment or in adjunct to systemic chemotherapy.

Metastatic Colorectal Carcinoma

Liver metastases from colorectal carcinoma (CRC) are resectable in less than 10% of the patients [84]. Radioembolization has been shown to be effective in the treatment of metastatic CRC to the liver. Candidates for radioembolization are those patients who have unresectable liver metastases and are on systemic chemotherapy or have failed to respond to first- or second-line chemotherapy. In these patients, [^{18}F]FDG-PET has been shown to be more sensitive than CT for assessing tumor response to radioembolization [54, 85]. Furthermore, reduction of the hepatic metastatic load can be assessed quantitatively by [^{18}F]FDG-PET, by evaluating the percent change of total liver SUV after treatment [53, 54].

Most of the studies on ^{90}Y-microsphere TARE reported so far have been conducted in patients with chemorefractory liver-predominant metastatic CRC. A systematic review of 20 studies including a total of 979 patients treated with resin ^{90}Y-microspheres has demonstrated the overall safety and efficacy of TARE for unresectable, chemorefractory metastatic CRC, with a median time to intrahepatic progression of 9 months and overall survival of 12 months [86].

In a randomized controlled clinical trial involving 74 patients, the combination of systemic therapy with radioembolization resulted in significantly better tumor response (44% objective response versus 17.6% in the control group), longer time to progression, and longer survival than systemic chemotherapy alone [87]; furthermore, the safety profile of the combined regimen was acceptable [87], and dose escalation studies have shown improved tumor response with increasing doses [88].

Several prospective trials have investigated the efficacy of TARE in combination with systemic chemotherapy versus systemic chemotherapy alone. In an early study, TARE combined with systemic 5-fluorouracil (5-FU) induced better objective response rates than 5-FU alone: 73% versus 0%, with time to progression of 18.6 months versus 3.6 months and overall survival of 29.4 months versus 12.8 months [89]. More recent prospective studies have evaluated chemotherapy regimen more up-to-date than 5-FU. In a first-line setting, TARE combined with FOLFOX4 achieved a 90% PR rate [90], while TARE with irinotecan in a second-line setting after failure of previous chemotherapy reported an overall 87% response rate, with 48% PR and 39% SD [91]. In the SIRFLOX study, a randomized clinical trial including 530 patients, the results of mFOLFOX 6 with or without bevacizumab were compared with TARE + mFOLFOX 6 with or without bevacizumab. While there was no difference in progression-free survival, there was a significant difference in progression-free survival in the liver, favoring the combination with TARE (20.5 months) over chemotherapy alone (12.6 months, with $P = 0.002$). Objective response rates were somewhat better with the combination therapy than with chemotherapy

alone (76.4% versus 68.1%, but without reaching statistical significance, with $P = 0.113$) [92].

Also the recently published results obtained by Hong and coworkers show that radioembolization is safe and effective as a salvage therapy in the management of metastatic CRC when compared with chemoembolization [93].

A recent systematic review on TARE in unresectable, chemorefractory metastatic CRC includes 20 studies for a total of 979 patients enrolled after failure of two to five lines of chemotherapy. TARE achieved CR, PR, and SD in 0% (range 0–6%), 31% (range 0–73%), and 40.5% (range 17–76%) of patients, respectively. The median time to intrahepatic progression was 9 months (range 6–16), and median overall survival was 12 months (range 8.3–36) [94]. In a large multicenter trial, overall survival was strongly dependent on previous treatments; in particular, median survival after ^{90}Y-microsphere radioembolization was 13 months (95% CI 10.5–14.6) when TARE was performed as second-line treatment, 9 months (95% CI 7.8–11.0) for third-line treatment, and 8.1 months (95% CI 6.4–9.3) for fourth-line treatment and over, respectively, with $P < 0.001$ [95].

Metastatic Neuroendocrine Tumors

Several neuroendocrine tumors, such as carcinoids, VIPomas, gastrinomas, and somatostatinomas, metastasize to the liver. These lesions are often well arterialized and represent a target for transarterial therapies, similarly to patients with HCC. The goals of treatment in these patients are both control of symptoms and survival. Systemic chemotherapy and ablative procedures have all been shown to produce modest benefit in these patients. Patients with unresectable disease are considered candidates for radioembolization. The results obtained in a multicenter study including 148 patients have shown that radioembolization of metastatic neuroendocrine tumors to the liver is safe and effective, with very high response rates: any response in 95.1% of patients and progressive disease in only 4.9% of the patients. Response rates were even longer than 2 years, especially in non-pancreatic NETs [96, 97].

Absolute and Relative Contraindications

Two absolute contraindications exist for therapy with ^{90}Y-microspheres intra-arterially. The main contraindication is represented by a pretreatment ^{99m}Tc-MAA scan demonstrating significant hepatopulmonary shunting. This occurrence would in fact result in the delivery of a radiation dose to the lungs greater than 30 Gy with a single infusion or as much as 50 Gy for multiple infusions. The second contraindication is the inability to prevent deposition of the radiolabeled microspheres in the gastrointestinal tract. Relative contraindications include reduced pulmonary function, inadequate functional liver reserve, serum creatinine >2.0 mg/dL, and platelet count $<75 \times 10^9$/L. When such relative contraindications exist, clinical judgment should be exercised for determining whether or not a patient is appropriate to undergo the procedure, taking into consideration either ^{90}Y-microspheres or ^{131}I-lipiodol [98].

Early and Late Toxicities

The most common clinical toxicity observed with ^{90}Y-microsphere therapy is a mild post-embolic syndrome. Similarly as observed with other embolic treatments such as trans-arterial chemoembolization, this syndrome includes fatigue, vague abdominal discomfort, pain, and fever [99, 100]. Other toxicities that can occur as a result of nontarget radiation (and should therefore be avoided by adequate pre-therapy procedures and by accurate treatment planning) include the following: cholecystitis, gastric ulceration, gastroduodenitis, pancreatitis, radiation pneumonitis, and RILD [75, 78, 79, 101]. By adopting meticulous planning, careful selection of patients, and proper techniques, the majority of these toxicities can be mitigated. Finally, a common hematologic toxicity observed in the immediate post-radioembolization period is represented by lymphopenia, not an unexpected finding considering the sensitivity of lymphocytes to radiation. Despite this possible occurrence, no infectious complications have been reported [13, 33, 52–54, 99–102].

Perspectives on Radioembolization for Primary and Metastatic Liver Tumors

A growing body of evidence supports the use of TARE with ^{90}Y-microspheres as an effective monotherapy in patients with HCC. Future avenues to be explored concern the scenario of combination therapies with systemic and locoregional agents, specifically sorafenib and TARE, in the adjuvant or neoadjuvant setting. Although the mechanisms of action for the two therapeutic approaches can in principle be considered as complementary one to the other from the pathophysiologic point of view, there are currently scarce data confirming the actual clinical benefit of regimens based on this combination.

In the only prospective study so far reported for combination therapy of TARE with sorafenib, the rate of objective responses was 25%, somewhat disappointing with respect to that expected on the basis of the underlying rationale. Moreover, 39% of the patients could not complete the prescribed dose of sorafenib due to important side effects [67]. On the other hand, initial safety results in the first 40 patients enrolled in a randomized controlled clinical trial comparing TARE with resin ^{90}Y-microspheres followed by sorafenib with sorafenib only indicate a similar tolerance for the two treatment arms [69]. Long-term outcome data from ongoing randomized controlled clinical trials such as SORAMIC, SARAH, or SIRveNIB (based on the use of resin ^{90}Y-microspheres) or STOP-HCC (using glass ^{90}Y-microspheres) have not been published yet.

Regarding treatment of metastatic disease, there is the need of randomized controlled clinical trials comparing TARE with up-to-date chemotherapy regimens, since the few data so far available have been obtained in studies comparing the efficacy of therapy with resin ^{90}Y-microspheres versus chemotherapeutic regimen that are now obsolete or the studies lack survival data. An ongoing randomized controlled clinical phase III trial evaluates treatment with glass ^{90}Y-microspheres and second-line chemotherapy after failure of first-line chemotherapy in comparison to second-line chemotherapy alone for metastatic CRC; 360 patients have been enrolled in this trial, and the first results of the analysis are expected to be released soon.

The FOXFIRE global is an international phase III study assessing the value of additional resin ^{90}Y-microspheres in the setting of first-line treatment with FOLFOX6m (NCT01721954). Enrollment of 530 patients has been completed, and the preliminary results are encouraging, with significantly prolonged PFS in the liver by competing risk analysis, from a median of 12.6 months for control patients to 20.5 months ($P = 0.002$) for patients receiving resin ^{90}Y-microspheres; this translates into a 31% reduction in the risk of disease progression in the liver. Pooling the data of studies with similar designs (SIRFLOX, FOXFIRE, and FOXFIRE global) from over 1,100 patients will provide sufficient statistical power to assess the survival benefit derived from the addition of resin ^{90}Y-microspheres to current chemotherapy regimens. Survival data from the three combined studies are expected to be released in 2017.

Further ongoing studies evaluate the role of TARE in uveal melanoma with liver metastasis (SIRUM trial, NCT01473004) or the combination of TARE and pasireotide and everolimus in liver metastatic neuroendocrine tumors (NCT01469572) [103].

Abstract

Sentinel lymph node biopsy is the standard surgical procedure for staging clinically tumor-free regional nodes in patients with early-stage breast cancer. This technique has spared the additional morbidity of axillary lymph node dissection without compromising diagnostic accuracy and prognostic information. However, it is still important to discuss current techniques and some controversies. Current data indicate that the combined radiocolloid injection approach (both superficial and deep injections) results in a higher identification rate of sentinel lymph nodes. Routine preoperative scintigraphic imaging helps the intraoperative search for sentinel lymph nodes and is vital for detecting extra-axillary or aberrant nodes, as well as for patients who have had prior core breast biopsy or surgery. SPECT/CT imaging, in addition to conventional lymphoscintigraphy, leads to improved preoperative visualization and localization of sentinel lymph nodes, especially if performed for specific indications. The combined use of radioactive tracers and blue dyes is more effective in detecting sentinel lymph nodes than either modality used alone and is therefore recommended for routine use.

Intraoperative imaging with portable gamma cameras is being increasingly employed, enhancing the reliability of the gamma probe by adding clear imaging of the surgical fields, especially when the injection site is close to the lymphatic basin. Portable gamma cameras can also be useful during radioguided occult lesion localization procedures in patients with non-palpable breast lesions.

Introduction

General Background

Radioguided surgery constitutes a wide range of procedures which involve close collaboration between different specialties (nuclear medicine and surgery, often pathology) [1].

"Radioguided surgery" includes a set of pre-, intra-, and postoperative techniques and procedures that are designed to optimize oncologic surgery. All these technologies and applications can be encompassed in the recently coined concept of guided intraoperative scintigraphic tumor targeting (GOSTT) [2]. The basic feature that most obviously characterizes GOSTT is the preoperative administration of a radiopharmaceutical (either interstitially or systemically), associated with the intraoperative use of a handheld radioactivity counting probe (most often the so-called gamma probe) that facilitates the task of the

surgeon – that is, the identification and removal of the target tissue, either a lymph node or the tumor itself – by virtue of preferential radioactivity accumulation in the target tissue. Intraoperative exploration of the surgical field with the gamma probe (which has recently evolved to allow intraoperative imaging as well) is made possible by a set of preoperative techniques employed by the nuclear medicine physician to achieve accumulation of the radiopharmaceutical in the specific target lesion. In this scenario, the most recent advances are based on growing interaction among different components of the complex armamentarium now available to the imaging community (including hybrid imaging, hybrid imaging agents, and/or virtual navigation systems) and to the surgical community (including robot-assisted surgery) [2–6].

The concentration of a radiopharmaceutical in a target lesion can be achieved by three main mechanisms: (1) interstitial administration of an adequate radiopharmaceutical, typically a radiocolloid, that scintigraphically depicts the pattern of lymphatic drainage from the site of a solid epithelial tumor, i.e., performing lymphoscintigraphy to identify the sentinel lymph node (s) (SLN) of the tumor; (2) systemic administration of a radiopharmaceutical that preferentially accumulates in the target lesion, e.g., ^{99m}T-sestamibi for localization of parathyroid adenomas or [^{18}F]FDG for [^{18}F]FDG-avid tumor lesions; and (3) direct intralesional administration of a radiopharmaceutical such as ^{99m}Tc-macroaggregated human albumin (^{99m}Tc-MAA, comprised of particles that, by virtue of their relatively large size, are virtually indefinitely retained at the injection site) for the so-called radioguided occult lesion localization (ROLL) for non-palpable breast tumors.

In the last few years, GOSTT applications have rapidly expanded especially to perform sentinel lymph node biopsy (SLNB). The sentinel lymph node (SLN) procedure is a diagnostic staging procedure that is applied in a variety of tumor types. The procedure aims to determine the tumor status of the SLN(s). Although historically the term "sentinel lymph node" was used to describe a group of nodes seen in patients with penile carcinoma [7], an SLN is currently defined as the first lymph node on a direct drainage pathway from the primary tumor [8, 9]. The concept is based on the premise that lymph flow from the primary tumor travels sequentially to the SLN and then onto the other regional lymph nodes (Fig. 1). The SLN is the node most likely to harbor metastases.

The histopathologic status of this node should reflect the histopathologic status of the entire nodal basin, and additional treatment of the nodal basin (e.g., surgery) is routinely performed in case of metastatic involvement of the SLN – although the presence per se of metastatic tumor cells in the SLN is not the only factor determining lymph node dissection of the basin of interest (see further below in this chapter). A negative SLN, however, would justify a wait-and-see policy avoiding unnecessary elective lymph node dissections and the associated morbidity, hospital stay, and costs.

In addition to being continually applied in patients with breast cancer and cutaneous melanoma, radioguided SLNB is being explored in patients with a wide variety of other solid epithelial cancers. In particular, malignancies where the feasibility and/or clinical impact of radioguided SLNB is increasingly being investigated include head and neck cancers, gynecological cancers (vulvar, cervical, and endometrial), gastrointestinal cancers (esophagus, stomach, colorectal, anus), prostate cancer, non-small cell lung cancer, differentiated thyroid carcinoma, and others [10–15].

Breast Cancer

Breast cancer is the most frequent cancer diagnosed in women worldwide [16]. In patients with breast cancer, accurate lymph node (LN) staging is essential for both prognosis (of early-stage disease) and treatment both for regional control of disease and for adjuvant therapies [17].

Clinical examination (i.e., palpation) is not accurate enough for assessing the axillary status, and preoperative imaging modalities including PET/CT with [^{18}F]FDG and ultrasound have low sensitivity, especially in case of micrometastatic disease [18–24]. Thus, in breast cancer, the traditional staging approach has been axillary LN dissection (ALND). However, ALND results in a

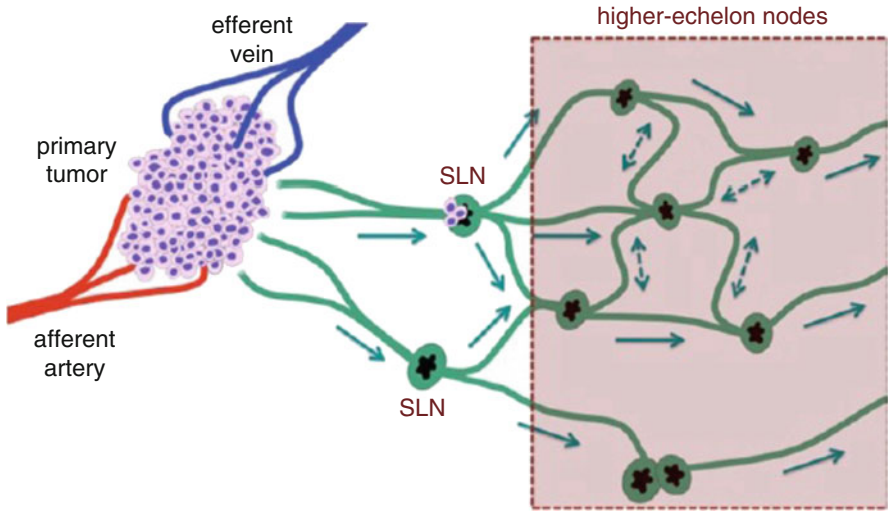

Fig. 1 Schematic representation of the sentinel lymph node concept. Assuming that lymph drainage from a solid tumor proceeds in an orderly way from lower-echelon to higher-echelon lymph nodes, the first node (s) encountered in such pathway, that is, the sentinel node (s), should be the site where tumor cells migrating through lymphatic channels are most likely to be entrapped and possibly originate metastasis before spreading to higher-echelon lymph nodes. As illustrated in the figure, even in any given lymphatic basin, there can be more than one sentinel lymph node, as lymph can drain from the site of the primary tumor via different lymphatic channels toward the same basin. The diagram also illustrates the complex interconnections that can exist at higher levels, with variable directions of lymph flow at intermediate levels within the general pattern of overall centripetal flow. The pattern of lymph flow is even more complex when considering that lymph from the tumor site can drain to more than one lymphatic basin, each one repeating the basic pattern represented here for a single basin

high incidence (about 25–30%) of postoperative complications that can reduce quality of life, such as delayed wound healing; lymphedema; peripheral nerve injury or even brachial plexus injury, with sensory/motor impairment; and pain. Furthermore, in early breast cancer, nearly 80% of axillary dissections reveal no metastasis and, therefore, could have been avoided [25].

Based on the definition of SLNs as those regional nodes that directly drain lymph from the primary tumor, SLNs are the first nodes to potentially receive the seeding of lymph-borne metastatic cells [26, 27]. After the initial description by Morton et al. of a method of SLNB in the management of melanoma patients, more than two decades ago [28, 29], SLN mapping and biopsy were applied in breast cancer [30, 31]. Since then, SLN mapping and biopsy have become routine techniques in breast cancer management, contributing to the development of less invasive surgical procedures [32–44]. Sentinel node biopsy is extremely accurate and effective. A systematic review showed an axillary 0.6% relapse rate in negative SLN patients and no benefits to completion ALND in terms of survival after negative SLNB [42, 45]. Thus, when the SLN is free of metastasis, the patient can be spared an ALND that until a few years ago was considered the standard staging procedure for breast cancer [31, 46, 47].

Despite the widespread application of SLNB for early-stage breast cancer, there is significant variation in performance characteristics reported for such procedures. Differences in institutional experience and in lymphatic mapping techniques are two of the main contributing factors to variations in the proportions of successful mappings [48–50]. The ranges of rates for false-negative findings and for SLN identifications emphasize the variability of this procedure. Learning curves for this technical procedure also vary [48]. Nevertheless, once a multidisciplinary team is experienced with the procedure, reasonable levels of accuracy are achieved, with identification rates of more than 95% reported routinely [25, 47, 51–54].

Sentinel Lymph Node in Breast Cancer

Pathophysiological Aspects

The breast embryologically originates from ectodermal tissue, as a skin appendage, and therefore shares a pattern of lymphatic drainage with the overlying skin. The mammary gland is interposed between the superficial (subdermal) and the deep (subcutaneous) lymphatic plexuses, the two systems being interconnected by a dense network of lymphatic vessels (Fig. 2a). Lymphatic vessels surrounding the mammary lobules predominantly drain to the subareolar Sappey's plexus, which is part of the superficial plexus of the skin. Most of the lymph produced in the breast is therefore drained to the subareolar region, progressing then toward the ipsilateral axillary nodes (Fig. 2b). A small fraction of the lymph produced in the breast (about 3%) is instead drained to lymph nodes of internal mammary chain, while an even smaller amount drains to other lymph nodes such as the intercostal, pectoral muscles, contralateral breast, or even abdominal nodes [55].

By following these routes of drainage, lymph and cancer cells entering the lymph space spread initially to the first node, which is the SLN. If the SLN is free of metastasis, the probability of tumor cells skipping that lymph node and metastasizing to second- or third-echelon nodes is an exceptionally rare event [39, 46, 56–64].

Indications

The main objective of SLN mapping and SLNB in breast cancer patients is axillary staging. These procedures are an appropriate alternative to routine staging axillary LN dissection for patients with early-stage biopsy-proven breast carcinoma without cytologically or histologically proven axillary lymph node metastases [65]. Appropriately identified patients with negative SLN biopsy do not need to undergo axillary LN dissection.

Currently, the SLNB procedure is recognized as the standard treatment for stage I and stage II breast cancer patients [40, 66, 67]. In these stages, the results showed that SLNB has a positive LN rate similar to that observed after ALND [40, 68, 69], yet with a significant reduction in morbidity [68] and similar gold standard (i.e., axillary LN recurrence rates at 5 years) [40]. The technique is validated if SLNs are found in more than 95% of the cases (i.e., the probability of detecting tumor cells in non-sentinel nodes is less than 5%). False-negative rates are higher in grade 3 lesions and when a single SLN is harvested, compared to cases where multiple SLNs are harvested [70].

The recognized indications for SLNB, together with recommendations as to whether an SLN procedure is the established standard of care, are listed in Table 1 [71].

Procedures

Generally, the procedure for SLN mapping and SLNB involves interstitial tracer injection, preoperative scintigraphic imaging, and intraoperative gamma probe localization for surgical removal of the detected LNs. Although there is consensus on some broad aspects of SLN protocols for breast cancer, consensus does not exist on all details. Controversies exist with regard to the particle size of the radiotracer, the optimal route for injection, timing and type of scintigraphy and intraoperative detection, and whether or not extra-axillary LNs should be considered for harvesting and analysis. The specific radiotracer and technique used are additionally guided by local availabilities, regulations, and practices [71].

Procedures in Nuclear Medicine

Three main parameters define an optimal tracer administration technique for radioguided SLNB: injection site, injected volume, and injected activity. A fourth parameter to be taken into account is the time elapsed between injection and surgery, as it specifically influences the amount of radioactivity to be injected [72, 73].

Radiopharmaceuticals

Several ^{99m}Tc-based agents have been used for radioguided SLNB for breast cancer (see Table 2) [74]. The radiopharmaceuticals most widely used

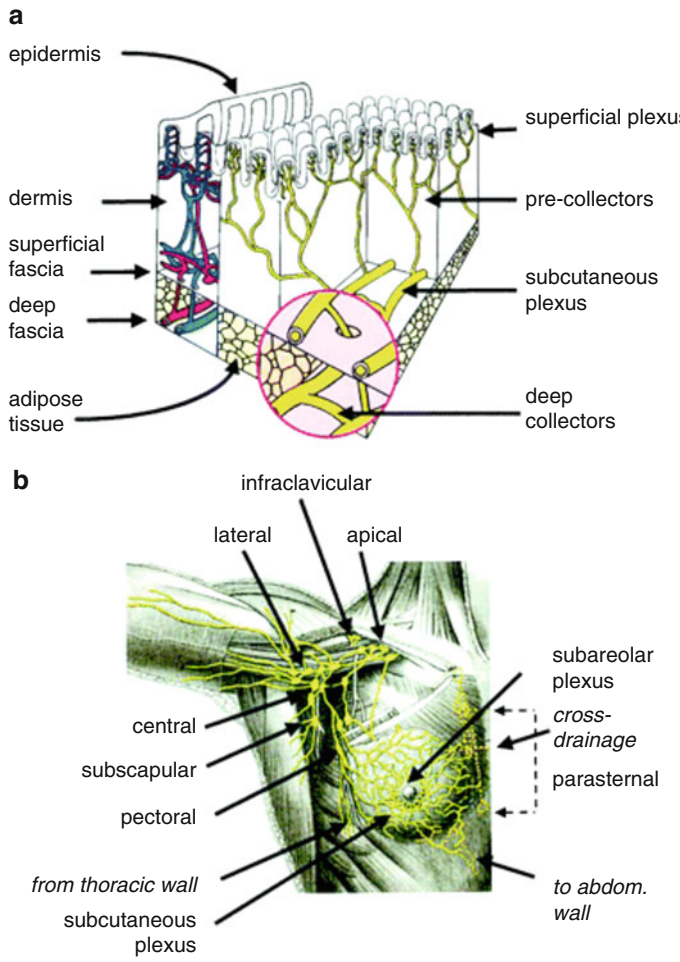

Fig. 2 (**a**) Schematic structure of cutaneous blood and lymph vessels. For easier comprehension, the lymph and blood vessel networks (which are actually embedded in each other) are represented separately, respectively, on the *right* (*yellow*) and on the *left* (*red* and *blue*). Due to its embryologic origin in the ectoderm, the mammary gland can be placed in an ideal space between the subcutaneous plexus and the deep lymphatic collectors (magnified insert in the figure). Branches of the periductal plexus drain lymph mostly toward the skin surface (via the subareolar plexus), while a minor component drains toward the deep collectors (which in turn drain toward the internal mammary chain). Radiocolloids injected intradermally over the mammary gland drain to the subcutaneous plexus that also receives most of the lymph draining from the mammary gland. (**b**) Pathways of the lymphatic vessels and lymph node stations draining the mammary gland. Most of the lymph produced in the breast drains to the subareolar plexus, then merges with the subcutaneous plexus of overlying skin, and flows mostly toward the axilla. Lymph from deeper portion of mammary gland drains either through the same pathway or through deep lymphatics that reach the parasternal, internal mammary chain (and even the contralateral side). *abdom* abdominal (From [38] with permission)

are ^{99m}Tc-sulfur colloid (particle size: 15–5,000 nm, but usually filtered to select a more restricted range of particles' size), ^{99m}Tc-nanocolloid (5–100 nm), and ^{99m}Tc-antimony trisulfide (3–30 nm).

The ideal radiotracer should show rapid transit to SLNs with prolonged retention in the nodes. In general, the drainage, distribution, and clearance of radioactive colloids by the lymphatic system may vary and are dependent on the size of the particles. Small particles are drained and cleared first; large particles are drained and cleared last and may be retained longer at the injection site.

Table 1 Recommendations on the use of SLN biopsy (Modified from [71])

Clinical circumstance	Use of SLN biopsy
T1 or T2 tumor	Established
T3 or T4 tumor	Controversial
Multicentric or multifocal tumor	Controversial
Inflammatory breast cancer	Not recommended
DCIS with mastectomy	Established
DCIS without mastectomy, but with suspected or proven microinvasion	Established
DCIS without mastectomy	Controversial
Suspicious, palpable axillary nodes	Controversial
Older age	Established
Obesity	Established
Male breast cancer	Established
Pregnancy	Controversial
Evaluation of internal mammary lymph nodes	Controversial
Prior diagnostic or excisional breast biopsy	Controversial
Prior axillary surgery	Controversial
Prior non-oncologic breast surgery	Controversial
After preoperative systemic therapy	Controversial
Before preoperative systemic therapy	Established

Controversial indications are those for which SLN biopsy is not universally accepted or for which the evidence behind the practice is limited or entirely missing. *DCIS* ductal carcinoma in situ

Table 2 Radiopharmaceutical characteristics (Modified from [74])

^{99m}Tc-based agents	Particle size max (nm)	Particle size mean (nm)
Sulfur colloid	350–5,000	100–220 (filtered)
Antimony trisulfide	80	3–30
Sulfide nanocolloid (Lymphoscint®)	80	10–50
Nanocolloidal albumin (Nanocoll®)	100	5–80
Rhenium sulfide nanocolloid (Nanocis®)	500	50–200
Tin colloid	800	30–250
Labeled dextran	800	10–400
Hydroxyethyl starch	1,000	100–1,000
Stannous phytate	1,200	200–400
Tilmanocept (Lymphoseek®)	~7 (equivalence)	~7 (equivalence)

Studies have shown that the success rate of identification of axillary SLNs is not significantly affected by the particle size of the radiotracer [38, 75–77]. Thus, the selection of radiotracer is based more on local availability than on differences in SLN detection. However, there is general agreement that a 100–200nm sized radiocolloid should be considered the best compromise between fast lymphatic drainage and optimal retention in SLNs [78].

New tracers have been developed in recent years. The tracer most recently made commercially available is Lymphoseek®, which is composed of a dextran backbone with multiple glucose and mannose residues attached to DTPA for ^{99m}Tc-labeling. The potential advantages of its small molecular size (7.1 nm) and the receptor-targeted nature of the mannose moieties in ^{99m}Tc-Tilmanocept include rapid transit from the primary site to the SLN as well as selective accumulation in that node, with limited pass-through to second-echelon nodes [79–82].

Activities and Volumes

Literature supports the use of small volumes with high specific activity to improve SLN detection. Nevertheless, consensus on the activity to be administered in an SLN procedure has not been reached. Activities as low as 3.7 MBq (0.1 mCi) [83] and as high as 370 MBq (10 mCi) [84] have been used. In current practice, a total injected activity of 5–30 MBq (depending on the elapsed time between scintigraphy and surgery) is generally considered sufficient for surgery planned for the same day. Prior day injection has been shown to be technically feasible by adequately increasing the amount of radioactivity injected (up to 150 MBq) [85].

Injection of large volumes may disrupt local lymphatics; therefore, a quantity of 0.2–0.5 mL should be injected. Moreover, the syringe should also contain a sufficient amount of air to clear any dead space within the syringe and the needle.

Injection Procedure

The injection site of the mapping agent is another controversial issue, mainly because lymphatic

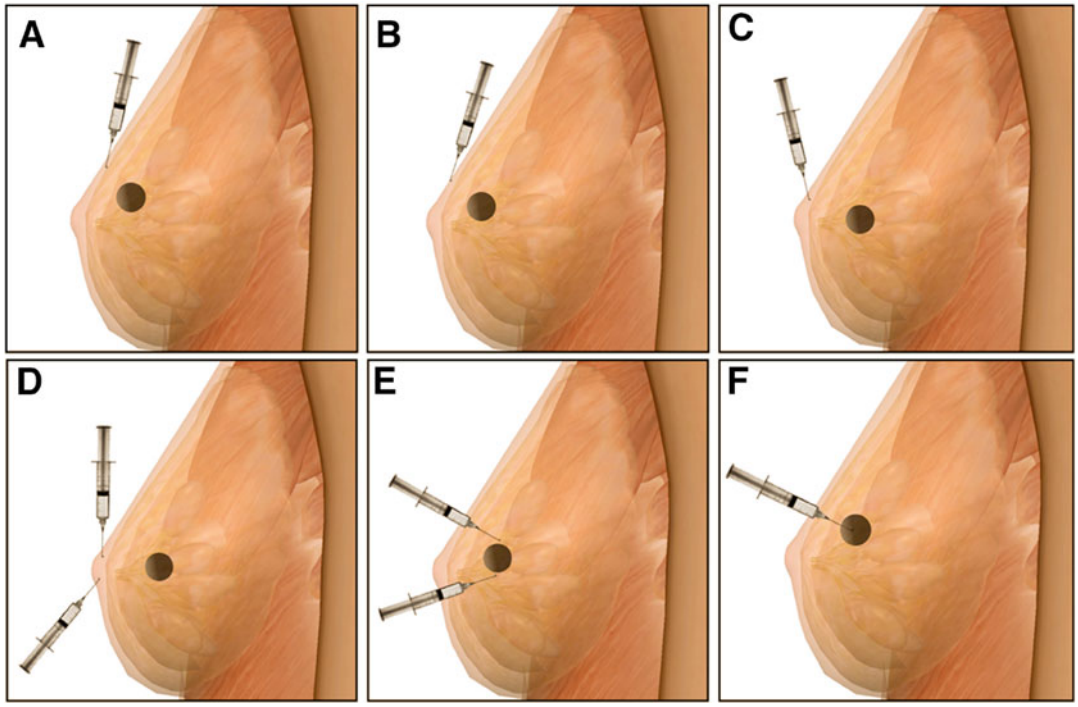

Fig. 3 Modalities of interstitial radiocolloid injection for SLNM in breast cancer. Superficial injections (**a**–**d**) and deep injections (**e**, **f**): intradermal (**a**), subcutaneous (**b**), subareolar (**c**), periareolar (**d**), peritumoral (**e**), and intratumoral (**f**)

drainage of the breast is not completely understood [86]. The most commonly used injection sites can be classified into two categories: deep (intratumoral and peritumoral) and superficial (intradermal, subdermal, subareolar, and periareolar) injection (see Fig. 3).

All injection modalities enable axillary sentinel nodes to be identified accurately, and satisfactory SLN detection rates have been reported for all injection approaches [87]. Lymphatic circulation within solid tumors (including breast cancer) is generally grossly abnormal, disrupted, and inefficient. Thus, intratumoral administration requires the injection of high activities (up to 370 MBq or 10 mCi) and large volumes (even up to over 1 mL). Injection of such large volumes can substantially increase interstitial pressure at the injection site, thus possibly altering the pattern of lymphatic drainage and forcing drainage routes different from those prevailing in baseline conditions. Furthermore, most of the injected radioactivity is retained at the injection site, often causing interference – the so-called "shine-through" effect – in scintigraphic and intraoperative sentinel lymph node detection. Finally, the slow drainage from the tumor can cause poor scintigraphic visualization of the lymphatic channels and possibly lead to failure of lymphoscintigraphic imaging and of intraoperative identification of the sentinel lymph node.

All the above considerations explain why, at present, most nuclear medicine centers prefer peritumoral or superficial injections versus the originally proposed intratumoral route of administration, although the high reproducibility of intratumoral injection has been well demonstrated [88].

Lymphatic circulation in the peritumoral area is normal and actually represents the entrance site to lymph vessels of cancer cells detached from the growing edge of the tumor, which eventually gives rise to lymph nodal metastasis. Indeed, any drainage pattern from any quadrant of the breast can occur, and most of the lymph from the breast flows toward the nodal basins with a direct course, not necessarily passing through the subareolar

plexus [87, 89]. Peritumoral injection is considered the gold standard for accurate SLN detection, because the tracer is injected near the same lymph vessels draining the tumor and is able to reveal extra-axillary drainage [90]. However, the validity of this approach has been questioned especially in non-palpable and multicentric tumors. Peritumoral administration is usually performed by depositing two aliquots on each side of the tumor, while intra-/subdermal administration is performed in or just under the skin overlying the tumor. Intradermal injection should produce a small wheal. More than one injection could be performed in adjacent sites. Periareolar administration is generally performed with two to four aliquots, each one at the edge of the areola at Sappey's plexus.

The rationale of intra-/subdermal administration stems from the fact that lymph is drained from the intra-/subdermal space to the subcutaneous plexus, which is the merging point for lymph originating from the underlying breast parenchyma (see Fig. 2a). Thus, a tracer injected intra-/subdermally displays the same pathways of lymphatic drainage as the underlying breast gland and of cancer cells entering the lymphatic space. Similar considerations apply to the periareolar route of administration: the lymph produced in the breast flows to the periareolar Sappey's plexus, before draining to axillary LNs (see Fig. 2b).

Superficial injection sites have numerous advantages, including simplicity, shorter time between injection and SLN identification, and increased radiotracer nodal uptake which may result in improved nodal identification rates. Nevertheless, superficial injection allows almost exclusive identification of axillary nodes. The use of peritumoral injections requires careful investigation of a patient's prior imaging and medical records, particularly if the tumor is non-palpable. Tumor location and injection sites may be identified by ultrasound and/or x-ray stereotactic guidance. If a tumor is in the upper outer quadrant, the relatively intense activity at the injection site may make it difficult to localize of a nearby SLN with less intense uptake [91, 92].

Regardless of the injection site, after injection, the patient is asked to gently massage the breast to facilitate lymphatic drainage of the tracer. Massage can also be employed if the passage of activity from the injection site is delayed at any time during the study [93, 94].

Results of multiple studies support the validity of both the deep and the superficial injection approaches; in particular, all injection modalities enable axillary SLN to be identified accurately, and satisfactory SLN detection rates have been reported for all injection approaches [87]. A clinical trial comparing the injection routes demonstrated, in 400 breast cancer patients, the superior intraoperative gamma probe localization of the axillary SLNs for the intradermal route (100%) compared to the subareolar route (95%) and the intraparenchymal route (90%) [95]. A preferential drainage to the same few axillary SLNs has been postulated for most of the breast tissue and its overlying skin, after merging initially to the retroareolar Sappey plexus; therefore, accurate identification of *axillary* SLNs is supposed not to be affected by the injection route [93, 94, 96, 97]. Thus, if the goal is axillary staging only, a superficial tracer injection (periareolar, subareolar, subdermal, intradermal) may be preferable to a deep injection (peritumoral, intratumoral) due to better and quicker visualization of axillary SLNs [98]. On the other hand, an important advantage of deep injection is the improved detection of extra-axillary SLNs: after peritumoral administration, lymphoscintigraphy shows drainage to the internal mammary chain in 20–30% of the cases, while this fraction is much lower (<3%) after intra-/subdermal or periareolar administration [66, 99, 100]. Thus, if one's aim is to stage extra-axillary nodal basins as well as the axilla, deep injection is recommended.

The superficial routes of administration are generally preferred in the case of superficial, easily palpable tumors and the peritumoral route for deeply seated tumors. The periareolar route can be used mainly in upper quadrant tumors to avoid possible cross talk owing to the short distance between the peritumoral depot and the axillary SLNs and is particularly recommended in cases of non-palpable or multifocal tumors [101, 102].

The combination of both injection techniques (deep and superficial) in the same patient may improve SLN detection [90].

Imaging Procedures

Lymphatic mapping allows determination of the number of LNs that are on a direct drainage pathway and to locate the SLNs [71] [103]. Preoperative imaging is strongly recommended due to variability in breast lymphatic drainage into the axilla and extra-axillary nodes [104]. Thus, preoperative lymphatic mapping has the potential to both improve accuracy (especially in extra-axillary LN) and reduce morbidity relative to the use of handheld gamma probes alone [34, 71]. Preoperative imaging also serves as quality control on the use of the appropriate tracer, failure of the injection, failure of the radiopharmaceutical, and management of the appropriate breast and axilla – injection of the proper side (L/R). Reasons not to use preoperative lymphoscintigraphy are logistical or because there is no definite evidence of a higher intraoperative success rate in the harvesting of axillary SLNs [105, 106].

Timing: In order to identify all SLNs and to avoid confusion with radiocolloid stasis in a lymphatic vessel, images are acquired with an adequate delay after injection. This delay may vary according to the radiopharmaceutical used, the injection site, and the patient's characteristics (lymphatic drainage can be slower in elderly or overweight patients). While smaller particles allow quick visualization of SLNs, larger particles have slow transit in the lymphatic system that tends to minimize visualization of non-sentinel second-tier nodes (lymph nodes downstream of SLNs) [107]. After superficial tracer administration, lymphatic drainage and subsequent lymph node visualization is usually quicker than after peritumoral injection (20–30 min compared to 2–3 h on average). After 15–18 h, during surgery, the amount of radiocolloid migrated to LNs represents about 1% of the injected activity after superficial administration, while it is about 0.1% after peritumoral administration.

SLNs are generally visualized within 1–2 h, and the patient should be in the operating theater within 2–30 h of radiocolloid injection, depending on the facility's schedule [71, 107]. In the event a surgery is scheduled for early morning, injection and imaging may be safely performed the afternoon prior to the surgery [108].

Gamma camera parameters: A single- or dual-head gamma camera system with large field-of-view (FOV) detectors is generally used to acquire planar emission and, if desired, single-photon computed tomographic (SPECT) or SPECT/computed tomographic (SPECT/CT) images. Low-energy, high-resolution, or low-energy high-resolution collimators should be used. The energy window should be 15% (±5%) centered on the 140 keV photopeak of ^{99m}Tc.

Image acquisition: Dynamic (flow) imaging is not often used in SLN procedures for breast cancer, but can provide information useful for SLN localization.

Planar (static) imaging should be performed 15–30 min, and 2–4 h post injection, and as needed thereafter up to 18–30 h. At least two, preferably all three, of the following images should be acquired: anterior, 45° anterior oblique, and lateral. Each image is typically 3–5 min in duration. For a system with large FOV detectors, the pixel size is recommended to be approximately 2 mm and the matrix size 256 × 256 with zoom 1 or, rarely, 128 × 128 with zoom 2. If 2 mm pixel size is not feasible on the system, the smallest pixel size available should be used.

Figure 4 shows different patterns of lymphatic drainage and SLN distribution as obtained by planar scintigraphic imaging in preparation for radioguided SLNB. Although conventional planar imaging certainly enables to identify the draining pattern to SLNs, it does not provide the exact anatomic location of the detected LNs, an information that is instead very useful intraoperatively [109]. By combining tomographic functional lymphoscintigrams registered with anatomic data from CT, SPECT/CT imaging provides better contrast and resolution than planar imaging and has the possibility to correct for attenuation and scatter. Fused SPECT/CT imaging considerably improves the topographic localization of the SLN within an anatomical landscape, thus providing a valuable surgical road map [110].

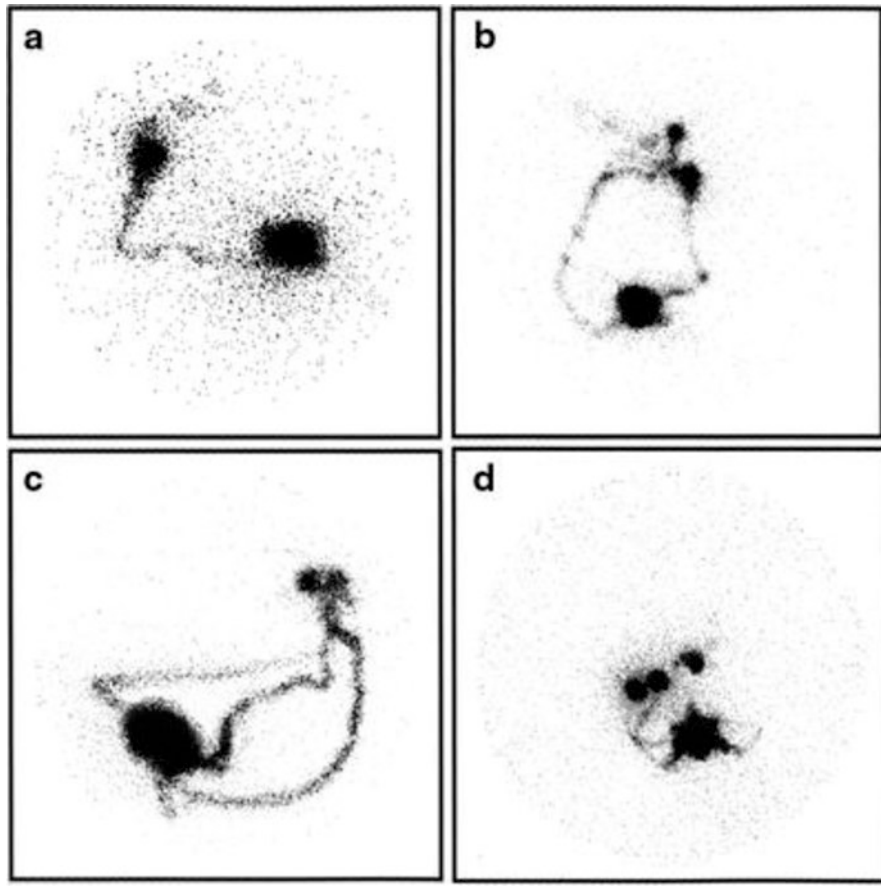

Fig. 4 Variable lymphoscintigraphic patterns visualized between 30 and 60 min after intradermal injection of ^{99m}Tc-nanocolloidal albumin in patients with breast cancer. (**a**) Single lymphatic vessel leading to a single sentinel lymph node, with faint visualization of subsequent-tier lymph nodes (right anterior oblique view). (**b**) Two separate lymphatic vessels widely diverging in their initial pathway, eventually leading to two separate but adjacent sentinel lymph nodes, with faint visualization of subsequent-tier nodes (left anterior oblique view). (**c**) Three separate lymphatic vessels widely diverging in their initial pathway, eventually leading to two separate but very close sentinel nodes (left anterior oblique view). (**d**) Multiple lymphatic vessels leading to at least three separate sentinel lymph nodes (right anterior oblique view) (From [38] with permission)

SPECT acquisition for SLN detection should be performed with a dual-detector SPECT system equipped with LEHR or LEUHR collimators. Acquisition parameters should include matrix size of 128 × 128 (4–5 mm pixels) and 120 or 128 projections over 360° with 20−25 s/projection.

Both low-dose CT (140 kVp, 2.5 mA) and conventional CT (140 kVp, 30–150 mA) can provide useful anatomical detail that can be used for anatomical localization and, if desired, attenuation correction.

Mapping of all direct tumor-draining LNs requires knowledge of the number and location of these SLNs, which will be provided by SPECT/CT in addition to planar images. SPECT/CT imaging provides significant information in the large majority of patients, with useful preoperative complimentary information to the surgeons: better location, reduced surgical time, and greater confidence of the surgeons with the technique [111].

It has been shown that SPECT/CT images can detect additional SLNs not visualized on planar images in a substantial number of patients in whom the conventional images are difficult to interpret [110–112]. In the majority of cases, the surgical team appreciates the anatomic

information provided by the fused SPECT/CT images and the surgical time is reduced [113]. However, because the current conventional approach based on combined radiocolloid and blue dye injection, preoperative planar scintigraphic imaging, and intraoperative gamma probe counting has proven very successful (with SLN detection rates over 95%), the added value of SPECT/CT imaging seems to be limited to a small fraction of breast cancer patients undergoing SLNB. Current recognized indications for SPECT/CT imaging in breast cancer patients are non-visualization of SLNs at conventional imaging, obesity, and presence of extra-axillary SLNs or otherwise unusual drainage (e.g., in cases of previous breast surgery) [71]. SPECT/CT imaging might also be performed if the conventional images are difficult to interpret (e.g., if contamination is suspected or an SLN is located near to the injection area) [112, 113].

When acquiring planar imaging, a ^{57}Co flood source can be positioned between the patient's body and the collimator in order to obtain some reference anatomic landmarks in the scintigraphic image (see Fig. 5). Alternatively, the body contour can be delineated by moving a ^{57}Co point source during scintigraphic acquisition (see Fig. 6). SPECT/CT acquisitions obviate the problem of identifying anatomic landmarks as a reference for topographic location of the SLN(s) (see Figs. 7 and 8) [109, 114–118].

Surface marks that provide a method to triangulate SLNs and to estimate their depths are desired by some surgeons. Surface locations should be marked on the skin with a small spot of indelible ink, and the depth of the node should

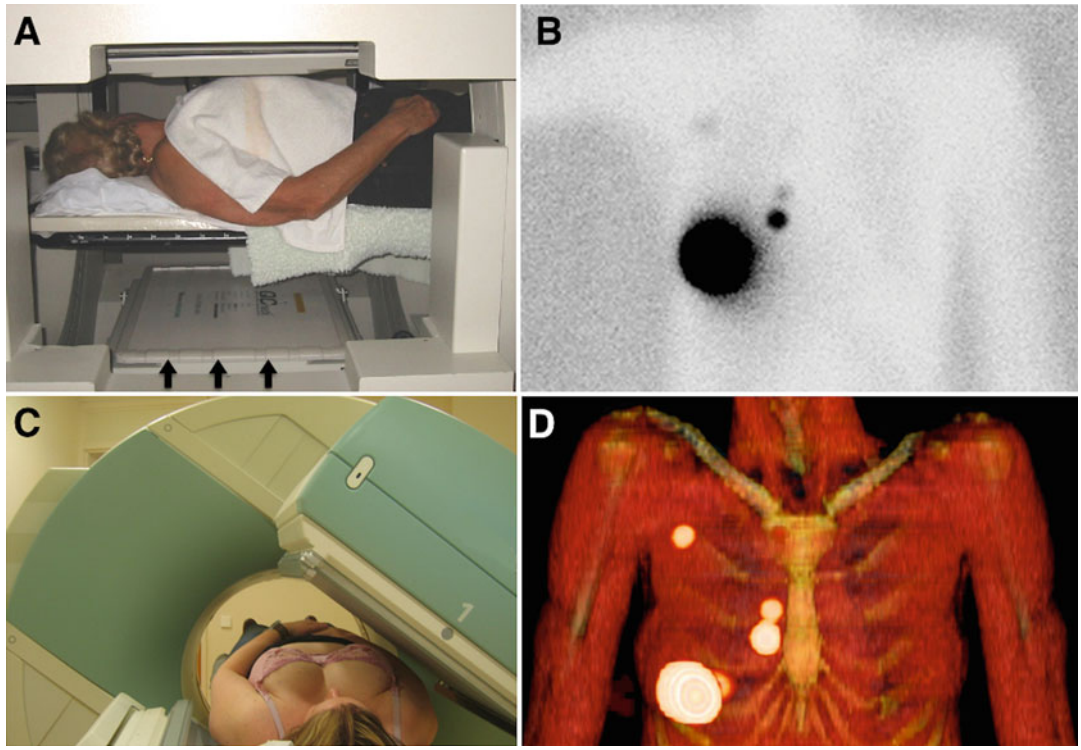

Fig. 5 Anatomical information in lymphatic mapping. (**a**) The use of a ^{57}Co flood phantom placed opposite to the gamma camera head (*black arrows*) provides body contour delineation in the anterior planar image (**b**) in a patient with cancer of the right breast and drainage to the right axilla and right internal mammary chain. In the same patient, subsequent SPECT/CT acquisition (**c**) leads to anatomically identify the axillary and parasternal sentinel lymph nodes after reconstruction of the fused SPECT/CT using volume rendering (**d**)

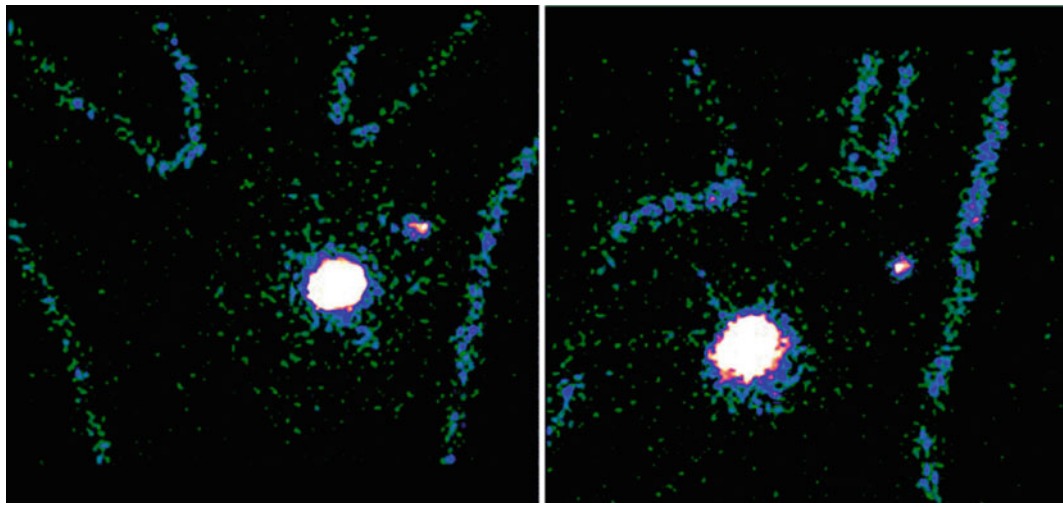

Fig. 6 Body contour delineation obtained by moving a ^{57}Co point source along the body of the patient during acquisition of the planar scintigraphic images. In this patient with cancer of the left breast, ^{99m}Tc-nanocolloidal albumin was injected at four spots periareorally. Images acquired both in the anterior projection (*left panel*) and in the left anterior oblique projection (*right panel*) visualize migration of the radiocolloid to a single sentinel lymph node in the axilla

be described. When marking the skin in the imaging process, an attempt should be made to position the patient's arm in the same position as it will be placed during surgery.

Image Interpretation

Early and delayed lymphoscintigraphic planar images identify SLNs in a majority of cases [71]. Major criteria to identify LNs as SLNs are the time of appearance and, occasionally, visualization of lymphatic channels (if dynamic imaging was performed). Usually, SLNs cannot be readily distinguished from second-tier LNs. The SLN is not necessarily the hottest node, although that is often the case. Separate lymphatic channels that drain to different LNs identify each of those as distinct SLNs, even though they may be located in the same anatomic region. When drainage to more than one anatomic region is seen, each of those regions has at least one SLN.

In current protocols SPECT/CT is performed following delayed planar images. This sequential acquisition is helpful to clarify the role of both modalities. For imaging interpretation the major criteria to identify LNs visualized on lymphoscintigraphy as SLNs are the visualization of lymphatic ducts, the time of appearance, the lymph node basin, and the intensity of lymph node uptake [105, 119]. Following these criteria visualized radioactive lymph nodes may be classified as:

(A) Definitively SLNs: this category concerns all LNs draining from the site of the primary tumor through their own lymphatic vessel or a single radioactive LN in a certain lymphatic basin.
(B) Highly probable SLNs: this category includes LNs appearing between the injection site and a first draining node or LNs with increasing uptake appearing in other lymph node stations.
(C) Less probable SLNs: all higher-echelon LNs may be included in this category.

Axillary LNs represent the main basin for breast lymphatic drainage, but different patterns can also occur in some cases. Drainage to the internal mammary basin is present in up to 35–40% of patients after intratumoral/peritumoral radiocolloid injection. Other unusually located SLNs are also observed in a non-negligible fraction of patients:

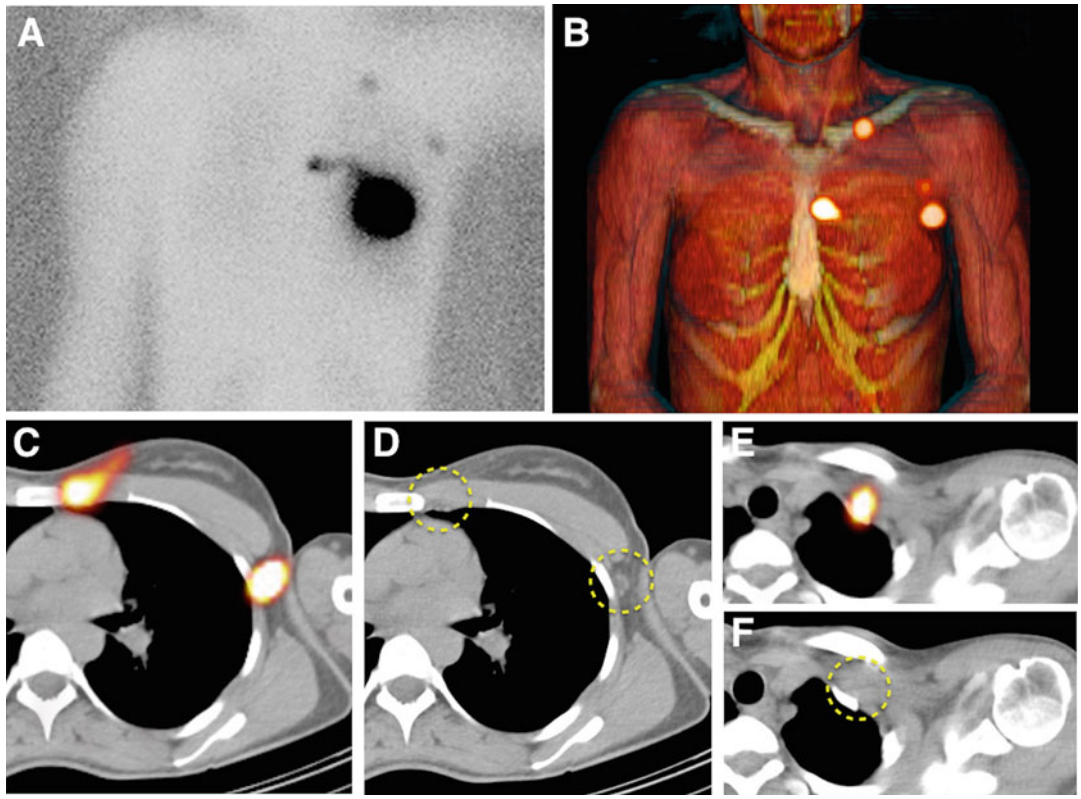

Fig. 7 Anatomical sentinel lymph node localization in breast cancer. Following deep injection of ^{99m}Tc-nanocolloidal albumin in the left breast, lymphatic drainage to the axilla, periclavicular area, and internal mammary chain is observed on anterior planar image (**a**) and on SPECT/CT fused imaging displayed with volume rendering (**b**). Lymph nodes are subsequently localized in the second intercostal space, level I of the left axilla, and behind the left clavicle (**c**–**f**)

intramammary (prepectoral) in 6%, interpectoral in 2%, and infraclavicular in 3% [120, 121].

The report to the referring physician should describe the orientations of the images acquired, the radiopharmaceutical, the method of administration, the amount and volume of activity injected, the location of the SLNs on each image, and any source of error or inaccuracy of the procedure.

The images and report should be available by the time the patient arrives in the surgical suite – in electronic form or as hard copy. If this is not possible, the critical information should be relayed directly to the surgeon. A close working relationship between the imaging department and the surgeon is critical for accurate dissemination of information regarding numbers and locations of sentinel lymph nodes.

Procedures in the Surgical Suite

Blue Dye Lymph Node Localization

Regarding the use of blue dye for optical guidance during surgery, there is general agreement that combined administration of radiocolloid and blue dye using both superficial injection and deep injection enhances SLN detection [38, 94, 97]. A possible advantage of the combined technique is where macrometastasis in the SLN may inhibit tracer accumulation [122, 123].

Blue dye can be injected around the primary tumor 10–20 min prior to surgery in a volume of 2–5 mL. The site of injection can be gently massaged after the administration or if the drainage of activity from the injection site is delayed at any time during the study [94]. Within 5–15 min, the

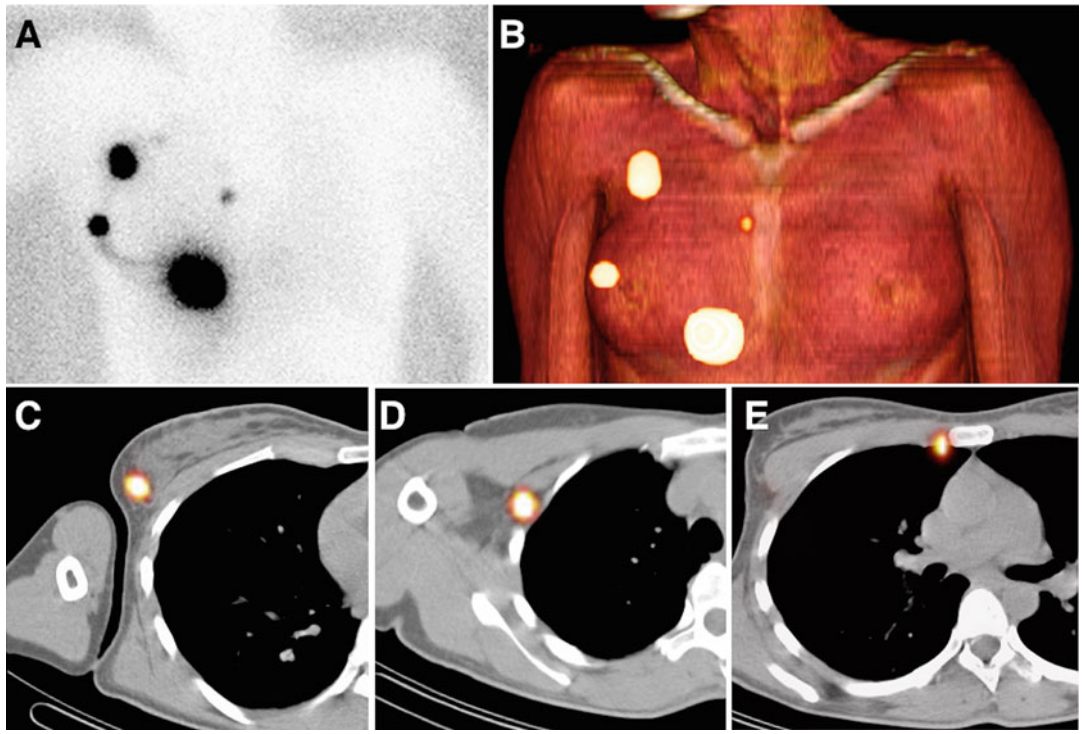

Fig. 8 Multidirectional lymphatic drainage after deep injection of ^{99m}Tc-nanocolloidal albumin on anterior planar image (**a**) in a patient with breast cancer in the medial inferior quadrant of the right breast. SPECT/CT with volume rendering (**b**) and axial fused SPECT/CT sections (**c**–**e**) depict ipsilateral sentinel lymph nodes in the breast, in the axilla, and in the internal mammary chain

SLNs are colored. Washout is evident after approximately 45 min.

Multiple studies have established the validity of blue dyes as markers for SLNs with reasonably high detection rates (ranging from 75% to 80%) [124]; nevertheless such rates are slightly lower than those achieved with radiocolloids. In most cases, the same SLNs are detected by the two methods. Disadvantages of using blue dyes are as follows: (i) impossibility to evaluate extra-axillary nodes, (ii) temporary blue tattooing of the skin or areola (for patients with breast conservation surgery), and (iii) induction of anaphylactic reactions (which require resuscitation in 0.5–1.0% of patients and that contraindicate its use in pregnant women) [124–131].

Radioguided Surgery

Intraoperative detection of SLNs is usually radioguided by a gamma-detection probe. Such probes should be designed and constructed to be suitable for intraoperative use, in order to be able to detect the SLN from the skin surface as well as within the exposed surgical cavity [26]. The probe is placed in a sterile bag to be used in the sterile surgical field. A display capable of providing clear instantaneous and cumulative counts is a major requirement. It is helpful if the instantaneous count rate is fed to an audio signal that conveys count rate information.

The count rates obtained with the gamma probe during surgery are recorded per unit time with the probe in the surgical field, over the node before excision (in vivo) and after excision (ex vivo). A background tissue count is also recorded with the probe pointing away from the injection site, nodal activity, or other physiological accumulation sites (i.e., liver) [71].

Just before starting surgery and with the patient positioned on the operating table, using the

images and skin markings as guides, the gamma probe scans the axilla or any other region where tracer accumulation has been visualized in order to confirm correct identification and localization of the SLN(s) and to select the optimum location for incision. This task requires the sensitivity of the detector to be sufficient to identify a weakly active SLN when attenuated by, typically, up to 5 cm of soft tissue. The surgeon then introduces the probe through the skin incision to guide dissection to the hot node(s). Discriminating activity counts within the SLN from those originating from nearby sites requires the probe to be well collimated with a small angle of view. The detector should offer a high level of shielding against radiation hitting the side of the probe assembly. However, when working with the probe, it is important to direct the probe away from activity at the injection sites.

When a hot SLN has been removed, the surgical bed should be checked to confirm removal of the hot node(s) and to evaluate remaining activity. Owing to the limited spatial resolution of the gamma camera, LNs closer than approximately 15–20 mm may appear on lymphoscintigraphy as one single hot spot; so, in some cases another hot node may still be present at a close location after removal of the hottest SLN. In this regard, the use of SPECT/CT imaging is very helpful because it may provide information about the actual presence of a cluster of LNs rather than a single SLN. When other sources of activity are found in the lymphatic basin, the decision of whether to remove them will depend upon the report from lymphoscintigraphy and the working definition of "nodes to remove" [132, 133]. In principle, SLNB requires the removal of all SLNs receiving direct lymphatic drainage from the site of the primary tumor. In practice, this is not always achieved. In cases with multiple radiolabeled LNs, it is often difficult to distinguish between SLNs and second-tier LNs. The issue of how many SLNs should be biopsied when multiple radioactive LNs are found is still debated. In this regard, while removing too few nodes may miss potential metastases in regional LNs, indiscriminate removal of all radioactive axillary nodes may cause morbidity similar to that experienced after conventional ALND (in addition to the unnecessarily increased burden for histopathological analysis).

Several operational definitions of the SLN have evolved over time in order to decide exactly which nodes should be removed to maximize the likelihood of locating the "true" biologic SLN and to minimize the superfluous removal of non-SLNs. Some authors base SLN identification on the absolute number of counts per second recorded for the presumed nodes, while others consider the ratio of the "in vivo" or "ex vivo" radioactive counts in the SLNs relative to background or to neighboring non-SLNs. Empiric thresholds corresponding to (i) 10% or 20% of the counting rate in the first LN removed (which is usually the most radioactive) or (ii) at least ten times the background count, taken at a location remote from the injection site, are widely reported in the literature [98, 134–137]. It is generally accepted that removing more than five LNs from the axilla does not result in marked improvement in the sensitivity of axillary SLNB [138–143]. If blue dye is used, it can be a useful adjunct for aiding SLN localization and harvesting. Blue dye generally results in a lower SLN detection rate than radiotracers, but it can be used in addition to radiocolloids. Following injection, the blue dye drains to the SLNs, staining the channels, which can be followed to the first-echelon nodes. Direct visualization and dissection of these channels facilitate SLN localization.

Deeply located SLNs are difficult to detect intraoperatively because of tissue attenuation; furthermore, the large amount of radioactivity retained at the injection site may cause nearby located SLNs to be hidden because of the shine-through effect. Patients who have undergone previous breast surgery or radiation may demonstrate nodes in locations not typically seen in patients without a history of prior surgery. The lymphatic duct to the original SLN may be obstructed by tumor growth or the original SLN may be entirely replaced by disease. Consequently, lymphatic drainage may be either diverted to a non-sentinel node or no lymph

nodes may be visualized, increasing false-negative results.

The use of SPECT/CT images can help localization of focal activity [144] as can the use of intraoperative imaging with portable gamma cameras; the latter imaging equipment is generally used simply to verify that all radioactive lymph nodes of interest are removed [4]. Finally, to minimize false-negative results, the open axilla should be palpated and suspicious lymph nodes harvested, even if these are neither hot nor blue.

SLN Non-visualization or Failed Intraoperative Detection

It is important to consider that when an SLN is not detected intraoperatively, this corresponds to a failure of the method and not to a false-negative case (better defined as when an axillary relapse is observed despite a prior negative SLNB). The majority of patients with preoperative lymphoscintigraphic SLN non-visualization will have at least one SLN detected intraoperatively, either by a gamma probe alone or by a gamma probe combined with blue dye. While logistically difficult in most centers, a second radiocolloid injection, following perhaps a different injection route, may be useful to visualize previously non-visualized SLNs.

In approximately 1–2% of the patients, SLNs will not be detected preoperatively or intraoperatively, and the status of axillary LNs cannot be determined. Old age, obesity, tumor location other than in the upper outer quadrant and non-visualization of SLNs on preoperative lymphoscintigraphy may be associated with failed SLN localization [142]. The significance of preoperative scintigraphic SLN non-visualization is not yet known. Some studies have suggested that patients with unsuccessful axillary mapping may have an increased risk of metastatic axillary involvement [145]. There is no definitive consensus on what to do if an SLN cannot be visualized. However, current standards of care recommend axillary LN dissection when intraoperative SLN identification is not achieved [146].

New approaches and strategies have been proposed in case of failure to visualize SLN(s) with conventional lymphoscintigraphy. Recently, Pouw et al. demonstrated in a large cohort of patients that SPECT/CT provided SLN visualization in 23.2% of cases with non-visualization of the SLN on planar imaging (66/284). In those patients receiving reinjection after persistent SPECT/CT non-visualization, the SLN visualization rate reached 62.1% (36/58). Thus, an adjustment of the clinical protocols (logistically not easy) may be proposed when no SLN is visualized during planar imaging [147].

Histopathology of SLNs

Detailed histopathological analysis of the SLN is the standard procedure on which to base selection of the postoperative management strategy of breast cancer patients. By focusing on only a few lymph nodes rather than on 15–20 nodes as generally harvested during an axillary dissection, the pathologist can completely dissect and examine at 50–100 μm intervals each SLN. However, protocols for SLN analysis have not yet been standardized; therefore, high variability in procedures still exists among different centers.

Immunohistochemistry (IHC) considerably improves sensitivity by identifying micrometastases and even isolated tumor cells, which are generally missed with conventional hematoxylin and eosin (H&E) staining alone [148, 149]. Methods for molecular biology analysis, such as those based on the reverse transcription polymerase chain reaction, are also being used for SLN analysis, although they are generally characterized by relatively poor reproducibility and longer time for analysis. Nevertheless, equipment for fast, even intraoperative, analysis has recently been made commercially available; a potential disadvantage of such new techniques is that the whole SLN is usually homogenized and processed for molecular analysis, without parallel conventional histopathologic analysis being conducted [150, 151].

Different procedures for intraoperative SLN analysis have been developed, including the touch imprint of one or more slices (relatively low sensitivity, but very high specificity), staining of one or several intraoperative frozen sections, and even IHC for cytokeratins as the most exhaustive method. In this case, if the SLN has

metastasis, it is possible to perform ALND immediately. On the other hand, if complete intraoperative histopathologic evaluation of the SLN is not performed, it is necessary to wait for definitive histology usually obtained within a week. If metastases are detected, ALND may be performed with a second procedure.

No significant difference exists in terms of 5-year survival rate between patients with SLN-positive and those with SLN-negative metastases by IHC. Consequently, it would seem that SLN micrometastases identified only by IHC are clinically insignificant and that IHC staining of SLNs appears to be unnecessary. IHC should be limited to particular cases, such as infiltrating lobular carcinoma, for which it is difficult to detect SLN metastases with H&E staining alone [78, 152, 153].

Qualifications and Responsibilities of Personnel

SLN studies should only be performed by surgeons and nuclear medicine specialists who have received specific training in such procedures [154].

An initial supervised learning phase is recommended to harmonize and optimize interaction between these specialists. The most important parameters to test such a multidisciplinary team are (a) percentage of SLNBs successfully identified and (b) percentage of false negatives.

It is often considered that 20–40 procedures under guidance are sufficient in order to implement radioguided SLNB into the routine clinical practice of a given hospital. These numbers, however, are highly variable, and SLNB should only be introduced to clinical practice where the team demonstrates high identification rate and accuracy [40, 71, 78, 98, 155, 156].

Clinical Controversial Aspects

T3–T4 Tumors

The evidence regarding the safety of sentinel node biopsy is mainly based on studies including T1 and small T2 tumors only [71, 78, 157–160]. However, a few reports suggest that false-negative rate and axillary recurrence reported in larger tumors are similar [63, 161].

Multiple (Multifocal/Multicentric) Tumors

Multifocal breast cancer is defined as separate foci of ductal carcinoma more than 2 cm apart within the same quadrant, while multicentric breast cancer indicates the presence of separate independent foci of carcinoma in different quadrants [101]. Until recently, SLNB was contraindicated in patients with multicentric and multifocal breast cancer because it was believed that it was difficult to localize the true SLN, and a negative SLNB would not exclude the possibility of positive LN metastasis in basins draining from other regions of the breast. However, most of the mammary gland can actually be considered as a single unit with lymph drainage to only a few designated lymph nodes in the axilla [93, 162]. In this regard, the efficacy of SLNB in patients with multifocal/multicentric cancer has been shown to be equal to that in patients with unicentric breast cancer. This means that the presence of multiple tumors should not affect lymphatic drainage and the possibility to perform SLNB with superficial injection [163, 164]. Nevertheless, it should be noted that the prevalence of axillary metastases seems higher in multifocal or multicentric tumors. Furthermore, high false-negative rates have been reported [165]. However, even if there are limited and heterogenic data on the efficacy and safety of SLNB in multiple breast cancer [102, 166], the reported axillary recurrence rates are acceptable, and the SLNb may be performed in patients with multifocal or multicentric tumors [63, 101, 163].

Ductal Carcinoma In Situ (DCIS) and Breast-Conserving Surgery

By definition, DCIS does not metastasize to regional lymph nodes. However, controversy exists over the use of SLNB in patients with preoperative diagnosis of DCIS [167]. In fact, core needle/vacuum-assisted minimally invasive biopsy may be affected by sampling error; invasive disease is found at surgery in about 15–30% of patients with DCIS [168, 169]. Because of the low prevalence of metastatic involvement and the feasibility of SLNB after breast-conserving surgery, SLNB should not be considered a standard procedure in the treatment of all patients with

DCIS, but only recommended in those patients undergoing mastectomy [170–172]. However, wide local excision before SLNB can alter lymphatic drainage, especially to the internal mammary nodes (IMNs) [173, 174]. Thus, SLNB could also be an option in women treated with breast-conserving surgery when there is a high risk of invasive cancer at final diagnosis (i.e., palpability of the lesion or presence of a mammographic mass) [175].

Suspicious Palpable Axillary Nodes

Palpable axillary LN may be tumor negative in up to 40% of the patients [176, 177]. The proportion is lower when considering suspected LN identified by noninvasive techniques during preoperative staging (US, CT, MRI, or [^{18}F]FDG-PET). In any case, axillary ultrasound with fine needle aspiration cytology or core needle biopsy from the suspicious nodes is a widely accepted policy. In that case, SLNB can be performed in patients with palpable LNs, if negative in the preoperative diagnosis. However, the suspicious, palpable LNs should be harvested for histopathological evaluation, even when neither hot nor blue.

Evaluation of Internal Mammary and Other Extra-Axillary Nodes

Although the IMNs, in the same way as the axilla, are a first-echelon nodal drainage site in breast cancer, the importance of their treatment has long been debated [71, 178]. Randomized trials have failed to demonstrate a survival benefit from surgical internal mammary chain (IMC) dissection, and several retrospective studies have shown that IMNs are rarely the first site of recurrence [179–184]. However, the recent widespread adoption of SLNB has stimulated a critical reappraisal of such early results. Furthermore, the virtually systematic application of adjuvant systemic and/or locoregional radiotherapy encourages reexamination of the significance of IMN metastases [185]. There is strong evidence that postmastectomy radiotherapy to chest wall and nodal basins (including IMC) reduces both recurrence and breast cancer mortality in axilla-positive patients, even when systemic therapy is given [186]. However, internal mammary radiation remains controversial, mainly because of the difficulties in selecting patients at risk of occult internal mammary involvement [187, 188].

It is generally recognized that mapping of IMNs requires deep injection of the lymphatic mapping agent, either peritumorally or intratumorally [99, 100, 189]. Moreover, the fused SPECT/CT images represent a further technical solution to increase the identification rate of IMNs. Nevertheless, the rates of detection and intraoperative harvesting of IMNs are much lower than those for axillary LNs. Visualization of the IMNs has been detected in approximately one third of patients with breast cancer receiving deep radiocolloid injection, of which about 63–92% could be harvested during surgery, and 11–27% of them had metastases [178, 190–192].

In conclusion, there is no doubt that IMN metastasis has prognostic significance similar to prognostic importance to axillary nodal involvement [193–195]. However, the significance of IMN biopsy is not clear. There is evidence that IMN mapping leads to upstage migration and to modifications of treatment planning with respect to radiotherapy and systemic therapy, but more evidence is necessary to support the idea that IMN mapping will improve the outcome of treatment and survival, perhaps because IMN drainage at lymphoscintigraphy is more difficult to demonstrate than axillary drainage [178, 196]. Thus, an "integrated and multidisciplinary technique" is required to evaluate IMN drainage [192, 197].

Previous Surgery

Although the lymph drainage is probably changed in patients who have undergone previous breast surgery, current data indicate that lymphatic mapping is feasible with accuracies comparable to the results obtained in the general population [198–200].

Prior excisional biopsy: The lymph drainage pattern may be altered in patients who have undergone prior procedures, as non-axillary drainage has been identified more often in reoperative SLNB than in primary SLNB. In 73% of such patients, migration to the regional nodal drainage basins has been noted in ipsilateral axillary, supraclavicular, internal mammary, interpectoral, and

contralateral axillary nodes [173, 201–203]. However, there is evidence that sentinel node biopsy performed in the area of previous breast biopsy is not affected significantly by the prior procedure as regards success of the second procedure [204, 205].

Prior other breast surgeries: SLNB can be performed in patients undergoing breast surgery due to a local recurrence after breast conservation surgery in patients with DCIS. Although plastic surgery for breast augmentation or reduction requires major tissue movements, it does not contraindicate the SLN procedure [206, 207].

Prior axillary surgery: A second SLNB can be performed in patients with a local recurrence after breast conservation surgery and negative axillary SLN biopsy, although the success rate may be lower when compared with a primary SLN biopsy. Furthermore, extra-axillary SLNs are visualized more frequently in this group of patients. Encouraging results have been reported regarding axillary recurrences but, due to the rarity of the cases, the evidence is not solid. On the other hand, there is no evidence that these patients benefit from diagnostic axillary lymph node dissection [208].

Axillary Lymph Node Dissection

Review of surveillance, epidemiology, and end-result data has shown that the use of ALND for SLN metastasis has decreased in recent years [53, 209]. Actually, the management of breast cancer continues to advance toward more minimally invasive approaches, and the role of ALND for patients whose SLNs contain metastases is likely to become less important in the future. Cancer biology is much better understood now than it was when ALND was introduced. Consequently, the decision to administer systemic therapy is influenced by a variety of patient- and tumor-related factors, with lymph node tumor status influencing [210–212], but not necessarily dictating the use of chemotherapy [213–215].

Indeed, a high rate of locoregional control is achieved with modern multimodality therapy, including axillary radiotherapy (ART), even without ALND. Likewise, no significant difference is observed in disease-free survival or in overall survival between SLN plus ALND and SLN-only groups for selected patients with early nodal metastases, suggesting that ALND might not be required for all SLN-positive breast cancer women [216–219].

Thus, the ASCO Update Committee recommended that clinicians should avoid ALND in cases of women affected by early-stage breast cancer with one or two SLN metastases, who will receive breast-conserving surgery with conventionally fractionated whole-breast radiotherapy. Instead, clinicians might offer ALND to women suffering from early-stage breast cancer with nodal metastases found on SLNB who will receive mastectomy [43, 44, 50, 220–222].

Neoadjuvant Chemotherapy

Neoadjuvant systemic chemotherapy (NACT) is established for locally advanced breast cancer and is increasingly used for early-stage disease as well [223, 224]. Debate is ongoing on whether SLNB is accurate enough after NACT or whether it should be performed before starting NACT. Performing SLNB before or after primary systemic treatment has advantages and disadvantages in both cases. Before NACT, SLNB yields a more precise axillary staging, with useful information about possible nodal spread. Nevertheless, the procedure can postpone the beginning of treatment, and two surgeries may be necessary. After NACT, SLNB may lead to an underestimation of the initial stage of the disease because the tumor regression pattern in the axilla is unknown [225–227]. On the other hand, axillary nodal status after NACT is a highly significant prognostic factor. Pathologic complete response in the axilla can be achieved in up to 40% of patients. These patients can be spared ALND and the associated morbidity. Available data show that SLNB following NACT in cN0 patients is acceptable [226, 228–238].

A second issue concerns the possibility to perform SLNB in patients with initial node-positive disease who are downstaged by NACT to cN0. At present, SLNB may not be routinely recommended after NACT in patients with prior metastatic nodes. Changes in approach and patient selection would be necessary to support

the use of SLN surgery as an alternative to ALND in this patient population [160, 239–243].

Pregnancy

Many studies have demonstrated that prenatal doses from sentinel node imaging, when properly performed, are low enough that they do not significantly increase the risk of prenatal death, malformation, or mental impairment (see further below in the "Radioprotection" section) [244–247]. Thus, pregnancy is not an absolute contraindication for SLNB, in patients with early lesions and clinically/US negative axilla, but it is recommended to reduce the time interval between lymphoscintigraphy and surgery in order to reduce the injected activity (i.e., using a single day protocol). Furthermore, since small quantities of the radioactive colloid may be excreted with breast milk, lactation should be suspended for 24 h after radiopharmaceutical administration. It is also important to consider that vital dyes may have some contraindications in pregnancy [248–250]. Pregnant women with breast cancer should be followed by a multidisciplinary team and be clearly informed about the potential risks of radioactive tracers balanced against the risk of delaying therapy or omitting nodal staging [248, 251].

Primary Localizing Techniques

ROLL

Screening programs for breast cancer have led to an increase in detection of non-palpable breast tumors. Current approaches to breast cancer surgery aim at removing the lesion with an adequate clearance margin while, at the same time, accurately assessing the risk of distant metastases. Effective localization procedures are required to ensure complete excision of small non-palpable lesions detected on either symptomatic mammography or screening mammography. Several localization techniques have been developed for this purpose.

Hook-wire localization of non-palpable lesions has been the most widely used preoperative technique for many years. Although this is a reasonably effective technique, it involves a number of disadvantages. First, the entry site of the wire is often not at the ideal location for surgical incision at the time of operation. This may lead to additional unnecessary dissection and suboptimal cosmetic results. In addition, the wire must be placed on the day of operation, necessitating the coordination of radiology and operative schedules. The most important disadvantage, however, is the inaccuracy of localizing the target lesion percutaneously and during dissection. This results in high rates of reoperation for tissue margins involved in carcinoma [252, 253].

Intraoperative US imaging without preoperative wire localization has been used to map excision of non-palpable breast lesions; however, this technique has limitations, as it is feasible only in patients whose breast lesion is visible at US imaging [254–259].

The "radioguided occult lesion localization" (ROLL) approach [260–262] has gained popularity for non-palpable tumor lesions, including breast cancer. ROLL involves injection, into the center of the lesion, of a small amount of radioactive tracer that does not migrate from the site of interstitial injection, typically ^{99m}Tc-MAA. Injection is performed on the same day or on the day before surgery, under mammographic or US guidance (activity injected ranges from 2 to 150 MBq). Surgeons identify the lesion intraoperatively as a hot spot by using a handheld gamma probe, which allows accurate lesion localization and removal with minimal excision of healthy tissue (the skin incision is made at the site with highest counts or at a site suitable for oncoplastic breast surgery). After specimen resection, residual activity in the surgical field must be checked to avoid the possibility of missing some residual involved tissue [263]. This technique enables a good cosmetic outcome.

ROLL is a well-tolerated and feasible technique for localizing early-stage breast cancer in the course of breast-conserving surgery and is a suitable replacement for wire-guided localization [264–268]. Reported advantages of the ROLL technique include (i) easy and precise intraoperative localization of the breast lesion; (ii) complete lesion resection, with free margins and reduced needs for second operations; (iii) an

Table 3 Studies comparing ROLL and hook-wire techniques [266]

Authors	*n* (ROLL–hook wire)	Detection (%)	Free margins (ROLL versus hook wire) (%)	*p*
Gallegos, 2004	132 (65–67)	100	83 versus 64	0.014
Macmillan, 2004	95 (48–47)	100	61 versus 72	NS
Nadeem, 2004	130 (65–65)	100	83 versus 57	0.001
Thind, 2005	140 (70–70)	100	84 versus 60	0.002
Zgajnar, 2004	143 (51–92)	100	70 versus 44	
Rönkä, 2005	78 (64–14)	100	89 versus 79	0.05
Fraile, 2005	233 (65–168)	100	80 versus 70	NS

increased capacity to center the lesion within the specimen; and (iv) a surgical approach (skin incision) that is independent from the intralesional radiotracer injection procedure [269–273]. Some potential pitfalls have been described; these are related to possible radiotracer spillage, contamination of the skin, or the injection path or ductal diffusion, as well as the presence of microcalcifications or DCIS [270, 271]. However, a systematic review of the ROLL technique concluded that this approach compares favorably to conventional wire localization for non-palpable breast lesions (Table 3) [267].

It is important to notice that radiation doses at the injection site and patient and staff absorbed doses are maintained well within the recommended limits established by the International Commission on Radiological Protection (ICRP) [274]. Finally, the possibility of performing ROLL after systemic intravenous administration of ^{99m}Tc-sestamibi (as a nonspecific, tumor-seeking agent) on the day of surgery has also been described [275].

SNOLL

As ROLL is an excellent technique enabling the removal of small breast cancers, the possibility to simultaneously perform SLNB without compromising oncological safety and the SLN detection rate is very important. Different techniques have been described to identify the SLNs in combination with ROLL, the so-called sentinel node occult lesion localization (SNOLL) [269, 276–284].

An intratumoral injection of ^{99m}Tc-MAA for ROLL of a tumor may be associated with a subdermal injection of ^{99m}Tc-nanocolloid for SLN mapping and SLNB. When the lesions are located near to the areola, intraoperative interference between the tracers could be avoided by elevation of the dermis and the subdermal area after skin incision [276]. Another possibility is to use a single intratumoral injection for both ROLL and SNOLL in the same session [280]. As a single procedure for localization of breast lesions and sentinel nodes, SNOLL may improve the entire surgical procedure. The majority of the studies published so far show a high percentage of successful tumor resection and intraoperative SLN localization with reduced failure [267, 269, 276, 279–284].

Radioactive Seeds

Alternatives to hook-wire localization of occult breast lesions include carbon trace as well as the use of sealed radioactive seeds. The seeds are essentially the same as the ones used in brachytherapy for cancer of the prostate, namely, a 4.5–0.8 mm titanium capsule containing a ceramic cylinder enriched with ^{125}I-iodine. Iodine-125 has a long decay time (half-life of 59.4 days) and emits low-energy photons (27 keV). The use of one or two seeds with this low photon energy has a negligible effect on the surrounding tissue. The radioactive seed is placed in the center of the breast lesion using an 18 G needle fixed in a needle holder under mammographic or ultrasonographic guidance; after successful positioning, the exact location is confirmed by mammography. During surgery, excision of the lesion is guided by using a handheld gamma probe [285].

If a SNOLL technique is scheduled, the ^{99m}Tc-colloid is subsequently injected, around the tumor or through a superficial route. Thus, the handheld gamma probe can be switched between the 27 keV energy window of the ^{125}I source and the 140 keV of ^{99m}Tc, allowing discrimination between the emissions of the two radioisotopes. Effective seed removal is verified by the absence of ^{125}I activity in the breast and its presence in the specimen. X-ray of the surgical specimen may confirm the presence of the seed and the relation of the lesion to the resection margins.

It has been shown that radioguided seed localization in non-palpable breast lesions is at least equivalent to the hook-wire technique in terms of ease of procedure, removing the target lesion, volume of breast tissue excised, obtaining negative margins, avoiding a second operative intervention, and allowing for simultaneous axillary staging [285–289].

Added Value of Intraoperative Portable Gamma Cameras

Recently, several types of portable or handheld mini gamma cameras have become available for clinical practice; while some of these portable gamma cameras are not specifically designed for radioguided surgery, other models are focused on different applications of SLNB [4, 5, 290, 291].

Appropriate use of a portable gamma camera enhances the reliability of the gamma probe by adding a clear image of the surgical field. The use of an intraoperative imaging device implies the possibility to better plan the surgical approach, to localize surgical targets in complex anatomical areas, to monitor the lymphatic basin before and after removal of the hot nodes, and, above all, to verify the correct SLN excision. Moreover, the use of point sources (e.g., ^{133}Ba or ^{125}I) facilitates SLN localization, as these sources can be depicted separately on the screen of the portable gamma camera, thus functioning as a pointer in the search for the SLNs. Nevertheless, their role in breast cancer surgery is still to be clarified. Intraoperative imaging using a portable gamma camera might be useful only when no conventional gamma camera is available for preoperative imaging, in particular in cases with extra-axillary drainage. Portable gamma cameras have also been used with promising results in other GOSTT environments regarding breast cancer, such as in ROLL or SNOLL procedures [290–296].

An interesting recent development of intraoperative imaging consists in combining conventional gamma probes with position and orientation tracking systems such as the so-called freehand SPECT, which permits a virtual reconstruction in a 3D environment (see Fig. 9) [4, 5, 293]. All these technologies will play an increasing role in the future extension of the GOSTT concept, in order to provide a better roadmap for radioguided surgery [2, 5].

Radioprotection

Nuclear medicine, surgery, and pathology professionals are involved if a radiopharmaceutical is used in a sentinel node procedure. Each involved practitioner (nuclear physician, surgeon, personnel in the surgical suite, pathologist) and the patient undergoing SLN and/or ROLL procedures are exposed to radiation. The exposures received by each, when radioactive activities standard for SLN procedures are administered, are well below recommended limits for both public and occupational exposures.

Estimates of radiation exposures for patients [244, 297–302], surgeons [299–301, 303–309], and pathologists [299–311] have been reported by several investigators. Table 4 presents a summary and interpretation of most of the available data. The estimates in the second column were extracted or derived from information in the included references. The values in the third column assume that SLN procedures were conducted on 100 patients in a year and assume that each patient was injected with an activity of 18.5 MBq. Columns four and five are International Commission on Radiological Protection (ICRP) recommended public and occupational limits [310].

Repeated measurements have clearly demonstrated that exposures to patients and personnel involved in radioguided SLN procedures (surgeon, nurse, pathologist) are minimal. Since exposures in SLN procedures of all nonnuclear medicine personnel are sufficiently low, none

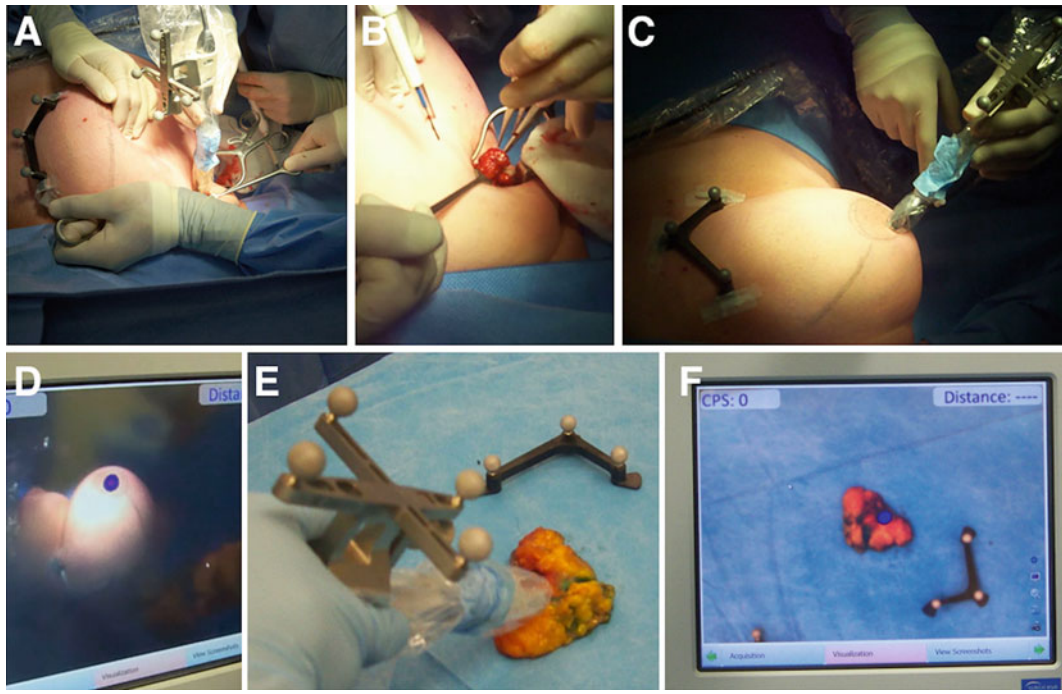

Fig. 9 Radioguided sentinel lymph node and occult lesion localization (SNOLL) in a patient with breast cancer using a single intratumoral injection of ^{99m}Tc-nanocolloidal albumin. Using a freehand SPECT probe (**a**), first the axillary sentinel lymph node is removed (**b**). Subsequently, the primary lesion is detected (**c**) following an image-guided procedure (**d**). Finally, the freehand SPECT probe (**e**) is used to visualize the primary tumor in relation to the margins of the specimen (**f**)

need be monitored routinely for occupational radiation exposure. Low patient effective doses and very low fetus/uterus equivalent doses [244, 299, 312–314] indicate that exposure to radiation is not a contraindication for an SLN procedure on any patient, including pregnant women. However, prudence dictates care should be exhibited when conducting an SLN procedure on any patient. For patients who are breastfeeding, nursing should be suspended for 24 h following radiopharmaceutical administration. Obviously, when using a ^{57}Co flood transmission source or SPECT/CT imaging, the total exposure is the emission-generated dose plus the transmission-generated dose [315].

Although the dose absorbed at the injection site can be relevant (see Table 4), there are no known negative consequences at the injection site. In fact, the site is often, though not always, excised. Furthermore, the radiation dose caused by the radionuclide-based procedure is very small relative to that received from postoperative radiation therapy.

Because exposures in SLN procedures of all nonnuclear medicine personnel are sufficiently low, none need be monitored routinely for radiation exposure. Finally, contamination with residual radioactivity of material from the operating room (surgical gauzes, liquids, and biological tissues of the patient) is minimal already at the time of surgery. Due to the fast physical decay of ^{99m}Tc, it is sufficient to wait only a few hours before disposal of operating room material to ensure an almost nonexistent radioactivity exposure to personnel [299].

Future Perspectives

The possibility of combining currently used radiotracers with other imaging agents opens new avenues for further developments. In this regard, hybrid tracers containing both a radioactive and a fluorescence label have recently been introduced (see Fig. 10), thus enabling the direct

Table 4 Ranges of estimates of radiation exposures (Modified from [71])

Radiation exposure	Range of estimates (mSv/MBq)	×18.5 MBq	×100 patients/ year (mSv/year)	Public limit (mSv/year)	Occupational limit (mSv/year)
Injection site absorbed dose	1–50	<925			
Injected breast equivalent dose	0.03–0.8	<15			
Patient effective dose	0.002–0.03	<0.56		<1	
Fetus/uterus equivalent dose	0.00003–0.0009	<0.017		<1	
Surgeon lens-of-eye equivalent dose	0.00009		<0.17	<15	<150
Surgeon hand equivalent dose	0.0004–0.01		<19	<50	<500
Surgeon effective dose	0.00004–0.0003		<0.56	<1	<20
Pathologist lens-of-eye equivalent dose	0.00001–0.00003		<0.056	<15	<150
Pathologist hand equivalent dose	0.00001–0.001		<1.9	<50	<500
Pathologist effective dose	0.000004–0.0002		<0.37	<1	<20

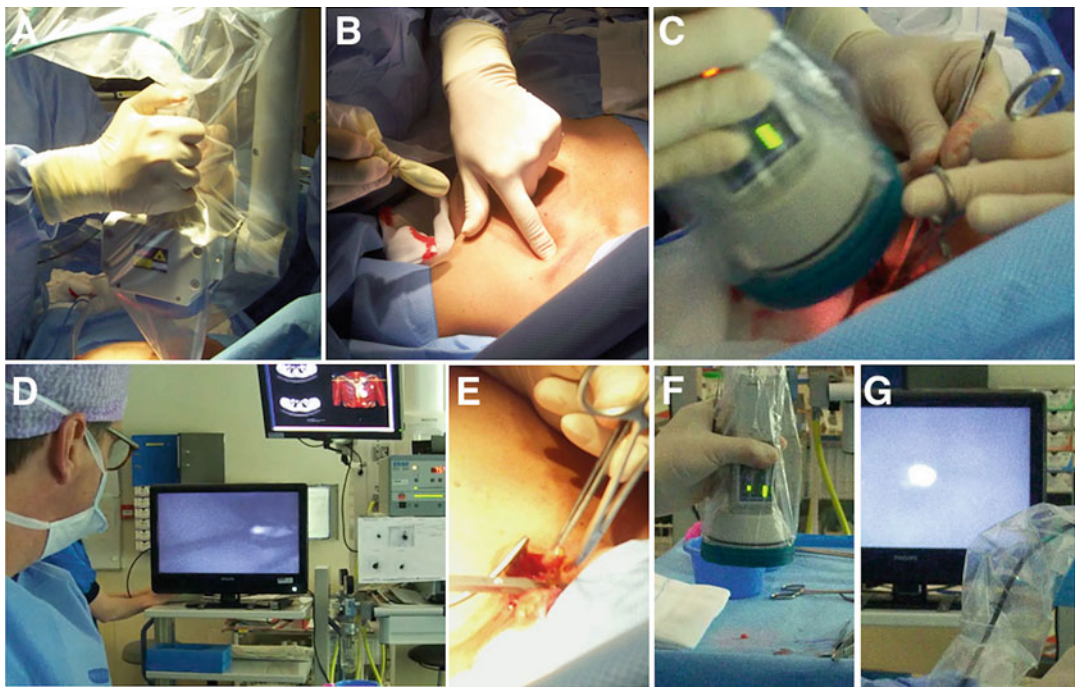

Fig. 10 Resection of an infraclavicular sentinel lymph node in a patient with high-risk breast cancer using the hybrid tracer ICG-^{99m}Tc-nanocolloid. The sentinel lymph node is first located on the skin projection using a portable gamma camera (**a**) and a handheld gamma probe (**b**). Subsequently, a portable near-infrared camera (**c**) is used to depict the fluorescence signal on the screen (**d**). This enables to remove the node (**e**) and to perform ex vivo control of the fluorescence signal (**f**, **g**)

integration of conventional preoperative imaging with intraoperative radio- and fluorescence guidance to the SLN via one single tracer injection [54].

Competitive methods are emerging: the techniques for SLNB that are not radioactivity-dependent or that refine the existing method (i.e., indocyanine green fluorescence, contrast-enhanced ultrasound using microbubbles, and superparamagnetic iron oxide nanoparticles) are particularly interesting [316–332]. In particular, the SentiMAG Multicentre Trial demonstrated that the magnetic technique with superparamagnetic iron oxide (SPIO) is feasible for SLNb, with an identification rate that is not inferior to the standard technique [333–337]. Recently, it has been shown that the SLN status can be evaluated with high accuracy preoperatively using contrast-enhanced color Doppler ultrasonography [338, 339].

However, a systematic review suggested that these new methods have clinical potential but yield high levels of false-negative results and presently cannot challenge the existing standard procedure. Further assessment of these techniques against the standard dual technique in randomized trials is thus needed [340].

Concluding Remarks

The development and wide acceptance of SLNB has deeply affected the management of breast cancer. Several technical and clinical controversies have been raised during the development of this technique. The resolution of these controversies should result in the standardization of the procedure and in the expansion of the number of patients evaluated with SLNB in the future. The modern approach in breast cancer care, which includes more detailed screening diagnostics, pathological evaluation, improved planning of surgical and radiation therapy, and more effective systemic treatment, emphasizes the need for ongoing re-evaluation of the "standard" locoregional therapy [341, 342].

Radioguided Surgery for Malignant Melanoma

48

Sergi Vidal-Sicart, Federica Orsini, Francesco Giammarile, Giuliano Mariani, and Renato A. Valdés Olmos

Abstract

Melanoma is one of the most aggressive and therapy-resistant cancers, and currently, its incidence is increasing worldwide. The metastatic involvement of lymph nodes is of utmost importance for prognosis in patients with intermediate-thickness melanoma. Other prognostic factors include tumor thickness, presence of ulceration, and mitotic rate.

Radioguided surgery has a prominent role in melanoma, because the sentinel lymph node approach is nowadays a choice procedure for regional lymphatic staging of these patients. Sentinel lymph node biopsy sensitivity is superior than that of PET/CT for the detection of lymphatic micrometastases in early stages of the disease.

The sentinel lymph node approach involves a preoperative lymphoscintigraphy and the use of a handheld gamma probe and vital dyes. Presurgical lymphoscintigraphy constitutes the "roadmap" for guiding surgeons toward draining lymph nodes potentially harboring metastasis and is extremely useful for localizing unpredictable drainage patterns that otherwise would be unnoticed. In recent years, new refinements have been added to this approach in order to improve clinical results. In particular, SPECT/CT imaging increases the sentinel lymph node identification rate and overcomes some of the limitations of planar imaging. New tracers are now available and new intraoperative devices can be added to the classical ones. In general, this radioguided approach is cost-effective, although there is a scarcity of data and the different factors involved in the whole procedure are not equally considered by different analyses that have so far been performed.

Introduction

Melanoma is one of the most aggressive and therapy-resistant cancers. Moreover, it currently is a global health problem because its incidence is increasing worldwide [1].

In recent years the melanoma incidence stands for 10–14 cases/100,000 inhabitants in Central Europe and 6–10/100,000 inhabitants in Southern Europe. In the USA the incidence has risen to 10–25/10,000 inhabitants, and Australia and New Zealand have the highest incidence with 60 cases/100,000 inhabitants [2].

According to the American Cancer Society, more than 76,000 new cases of melanoma are currently diagnosed in the USA each year, and about 9,500 people are expected to die of metastatic disease [3].

There are several risk factors related for the development of melanoma (history of sunburn, previous melanoma within the family, high UV exposure, and red or blonde hair), and the appearance of regional or distant metastases is an ominous prognostic factor for the disease [4, 5].

Thus, the prognosis for a patient depends on the stage of the disease. In the case of early melanomas (<0.76-mm Breslow thickness), surgical wide excision is sufficient and there is no need for further invasive staging. Accurate evaluation is important in cases of a more advanced primary tumor. In general, lymph node metastases often occur first, and for this reason, the regional nodal status is the most important prognostic factor and stratifies the patients for adjuvant therapy [6, 7].

The metastatic involvement of lymph nodes is of utmost importance for prognosis in patients with intermediate-thickness melanoma (AJCC stage I or II). Other prognostic factors include tumor thickness, presence of ulceration, and the recently added mitotic rate. The Clark level of invasion was omitted from the recent AJCC classification [5, 8–10].

The Clinical Problem

The clinical outcome for patients with intermediate-thickness melanoma relies on adequate surgical control of the primary melanoma site and on the accuracy of regional and systemic staging at diagnosis. It is well known that physical examination of lymph nodes is inaccurate in up to 40% of patients. Noninvasive diagnostic imaging procedures (CT, MRI, US) have been employed to rule out nodal involvement, but despite their use, their findings are not sufficiently accurate so as to avoid invasive techniques, also because small lymph node metastases cannot reliably be detected with any imaging modalities. Approximately 20% of patients with a melanoma with a Breslow thickness >1 mm may have clinically occult lymph node metastasis, therefore making histopathologic assessment of the regional lymph nodes mandatory [11].

The traditional surgical approach to cutaneous melanoma is based on elective, or prophylactic, regional lymph node dissection to reveal these occult metastases. Randomized studies, however, showed no clear survival advantages when performing regional lymphadenectomy, a surgical procedure frequently associated with morbidity, such as lymphedema, nerve injury, wound infection or dehiscence, etc. [12].

In 1992 Morton et al. reported the results of a seminal study carried out in 223 patients with melanoma to test the concept of intraoperative identification of the sentinel lymph node (SLN) using blue dye as a minimally invasive surgical alternative for nodal staging. By employing this approach to perform SLN biopsy, these authors were able to detect clinically occult nodal metastasis, thus identifying a subgroup of patients who could actually benefit from complete lymphadenectomy [13].

The procedure assumes orderly diffusion of melanoma metastasis through the lymphatic system, and the SLN is defined as the first node on a direct lymphatic drainage pathway from the primary tumor [6, 14]. According to this hypothesis, tumor involvement or lack of involvement of the SLN predicts the overall nodal status with a high accuracy [15].

Shortly thereafter, radionuclide-based techniques were introduced to perform lymphatic mapping, by injecting a suitable radiocolloid agent around the melanoma. Following such interstitial administration of the radiopharmaceutical, scintigraphy allows the identification of SLNs in the lymph node basin and this or these nodes is/are harvested during surgery with the aid of a handheld gamma probe during surgery. This approach, which constitutes the mainstay of radioguided SLN biopsy as it is currently employed, overcomes some drawbacks intrinsic in the dye approach. The feature that characterizes radioguided surgery is the use of a radiotracer to "mark" the desired tissues and the intraoperative utilization of a handheld gamma probe that facilitates the task of the surgeon, that is, identification and removal of the target tissue, either a lymph node or the tumor itself – as in other applications of radioguided surgery. Intraoperative exploration of the surgical field with the handheld probe is made possible by the preoperative techniques employed by the nuclear medicine physician to achieve accumulation of the radiopharmaceutical in the specific target lesion. This is the most common method utilized to perform a SLN biopsy, because radiocolloid alone has been shown to be very safe and to have a low false-negative rate [16, 17]. Currently, this approach is widely validated and has been adapted to additional applications for SLN biopsy in other types of cancers, such as breast, urologic, gynecologic, and head and neck cancers [18–21].

Radiotracers allow scintigraphic visualization with gamma camera of the physiology of lymphatic drainage, thereby changing the paradigm of "open and see" (blue dyes) to "see (scintigraphy) to open." In fact, preoperative lymphoscintigraphy constitutes the "roadmap" for guiding surgeons toward subsidiary lymph node sites of potential metastasis and is extremely useful for localizing unpredictable drainage patterns that otherwise would be unnoticed. The value of lymphoscintigraphy lies in different factors, as summarized in Table 1.

Table 1 Lymphoscintigraphy features for lymphatic mapping

Identification of the radioactive lymph nodes (although not all radioactive lymph nodes are SLNs nor the SLN is necessarily the most radioactive lymph node)
Identification of the lymphatic drainage basin(s) from the tumor site
Identification of the SLN and of second-tier lymph nodes
Identification of the aberrant or in-transit SLNs (lymph nodes localized outside the common drainage areas and those between the primary tumor and the region of lymph node drainage, respectively)
Confirmation of true radiotracer uptake versus false-positive uptake (originated from cutaneous folds, lymphatic dilatations, and lymphangiomas)

Nuclear medicine techniques and radioguided surgery are continuously evolving with the implementation of technological imaging advances. Even after 20 years of use, this technique of SLN biopsy may, sometimes, be challenging, especially in patients with high body mass index or in complex anatomical areas (e.g., the abdomen or head and neck). With the aim of finding more efficient methods to improve the preoperative and intraoperative images, hybrid fluorescent–radioactive tracers or more specific tracers, which enable high-quality preoperative lymphoscintigraphy and SPECT/CT imaging, have been developed. Moreover, intraoperative portable imaging technologies, such as freehand SPECT and small portable gamma cameras, have been introduced into the armamentarium available for improving intraoperative SLN identification procedure [22].

Lymphatics in Cutaneous Melanoma

The lymphatic system presents a high density of vessels in the dermis, especially in the layers between 50 and 200 μm below the epidermis. This density varies in different regions of the body, the highest vessel density being observed

in the head and neck area and the lowest in the limbs.

Moreover, the velocity of lymphatic flow is not the same in all regions of the body and varies depending on the area of the skin. Thus, the average lymph flow velocity in the head and neck region is 1.5 cm/min, it increases in the posterior trunk to 3.9 cm/min, and even higher in the forearm and hand (5.5 cm/min). The highest velocity of lymph flow is seen from the lower limb (10.2 cm/min) [23].

On the other hand, the lymphatic drainage from the primary tumor is quite predictable when this tumor is located in the extremities. So, a melanoma located in the lower limb drains usually to the ipsilateral groin, while from the upper limb, it drains to the homolateral axilla. Computer analysis from a large lymphoscintigraphic database provided new important insights into the skin lymphatic drainage. In particular, it was demonstrated that lymphatic drainage of the skin is likely to be entirely symmetric. There are well-defined areas of the skin that nearly always drain to the ipsilateral axilla, groin, cervical level II, and preauricular node fields [24].

However, the drainage patterns from lesions in the head and neck area or in the trunk are less predictable. The concepts developed by Sappey in the nineteenth century about skin lymphatic drainage went largely unaltered until the last quarter of twentieth century, when new information became available from lymphatic mapping studies using lymphoscintigraphy. In fact, the more recent lymphoscintigraphic findings have modified the concept of Sappey, that is, that lymphatic watersheds with ambiguous skin drainage are limited to a narrowband about 2.5 cm on either side of the midline of the trunk (for right–left drainage) and/or the line between the umbilicus and the level of the second lumbar vertebra on the back (for cranial or caudal drainage, respectively) [25, 26].

Instead, the width of the area of ambiguous drainage has been extended to more than 20 cm instead of the original 5 cm (Fig. 1), because lymphatic drainage is highly variable among different patients and Sappey's concepts would predict drainage to the wrong node basin in 30% of patients [27, 28].

Indications and Advantages of SLN Biopsy in Melanoma

SLN biopsy is a minimally invasive procedure, which should be indicated or considered for patients with the following characteristics:

- A risk of presenting occult metastasis >10%, which justifies the procedure.
- The tumoral status of the SLN is useful for decision-making.
- The prognostic information provided by the SLN biopsy is valuable for the patient and the physician (even for a decision to include patients in clinical trials).

The indication for SLN biopsy in melanoma should be offered and discussed to all patients with melanomas ≥1.0 mm in thickness, clinically negative regional lymph nodes on physical examination, fulfilling the abovementioned criteria and in whom the morbidity and risk are considered to be acceptable. However, SLN biopsy can also be offered to patients with melanomas ≤1.0 mm with some characteristics which increase the possibility of micrometastasis in the regional node basin (the presence of ulceration, mitotic index ≥1/mm^2, and/or Clark IV/V invasion, especially in tumors >0.75 mm in thickness) [29].

Analysis of the AJCC database demonstrated an inverse correlation between the mitotic index and survival. Then, the greater the mitotic value, the shorter the survival. In patients with melanomas from 0.5 to 1.0 mm in thickness and with <1 mitosis/mm^2, the 10-year survival was 93%. In the same group, this figure decreased to 87% when >1 mitosis/mm^2 was present [30].

On the other hand, SLN biopsy may be considered in patients with melanocytic lesions with unknown metastatic potential. The NCCN guidelines are similar in regard to melanomas with a thickness >1 mm. However, the presence of ≥1 mitosis/mm^2, which upstages IA to IB tumors, is not taken into account for indicating SLN biopsy in melanomas <1 mm in thickness. SLN biopsy is not recommended in lesions with a thickness

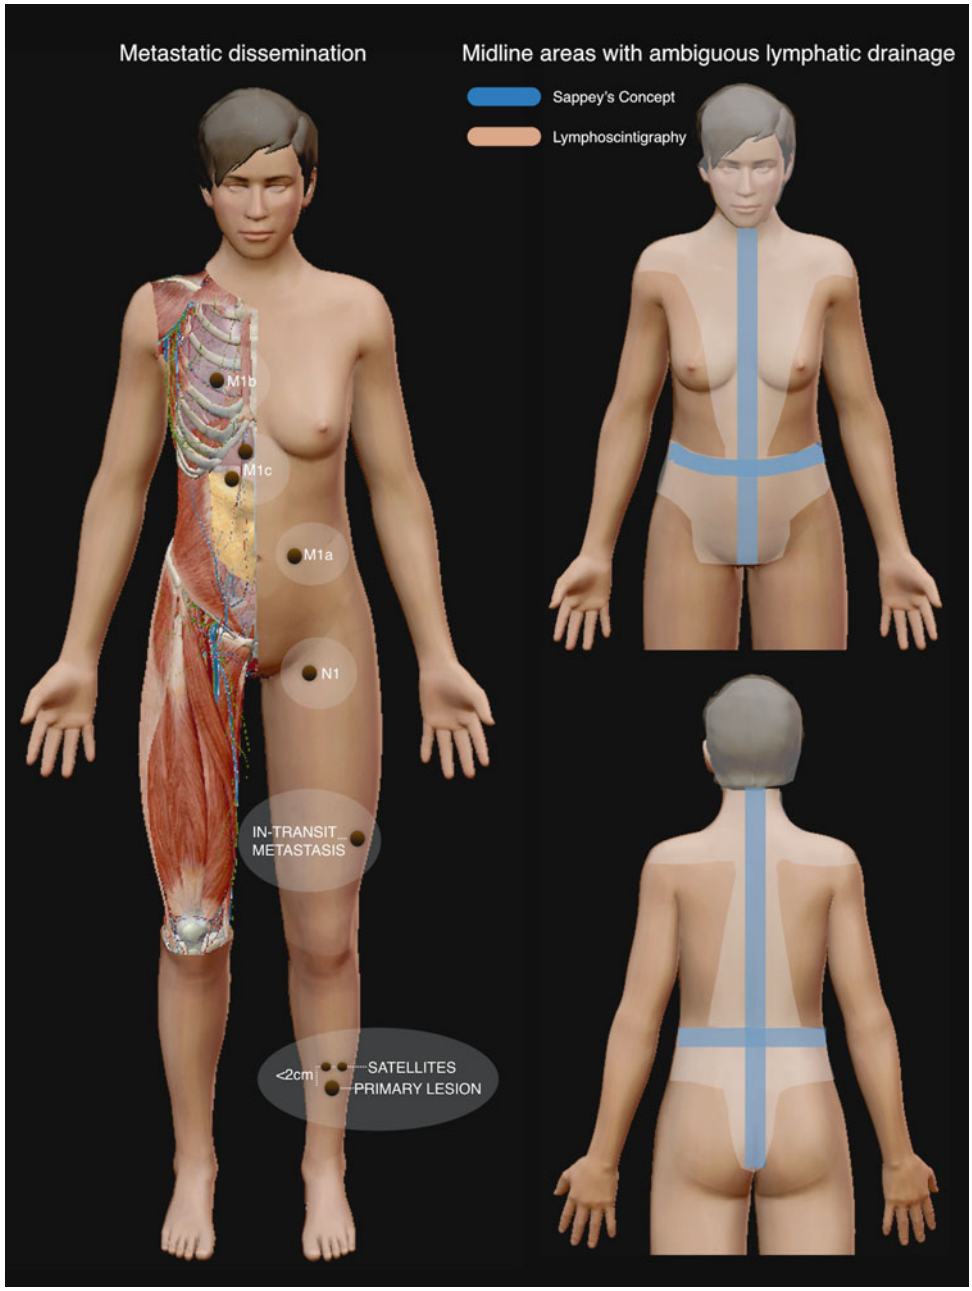

Fig. 1 On the *left*, metastatic dissemination in melanoma: *N1*, metastasis in draining lymph node basin; *M1a*, distant skin, subcutaneous, or nodal metastases; *M1b*, lung metastases; *M1c*, all other visceral metastases. On the *right*, midline areas with ambiguous lymphatic drainage according to the classical skin watershed Sappey's concept (*blue*) and its extension according to lymphoscintigraphy (slightly *brown*)

<0.75 mm, while in tumors between 0.76 and 1 mm thick, the option to perform or not SLN biopsy should be discussed with the patient, since the proportion of metastasis is low in these patients (<6%) and its clinical impact is modest [31, 32].

Although no direct therapeutic advantage has been demonstrated for the SLN approach, the final

report of the MSLT-I trial, which compared long-term outcome of SLN biopsy-positive patients with that of patients who developed regional lymphatic metastases in the observation group, showed a significant benefit in the arm of SLN biopsy with a 10-year melanoma-specific survival (MSS) advantage of 20.6%. Thus, it was concluded that SLN biopsy-based management prolongs MSS for patients with nodal metastases in the intermediate-thickness melanoma group. In addition, the information provided by the SLN may be useful for advising patients about inclusion in clinical studies.

Thus, SLN biopsy-based staging of intermediate-thickness or even thick primary melanomas provides important prognostic information and identifies patients with nodal metastases who may benefit from immediate complete lymphadenectomy [33–35].

However, some criticism has been raised about this statement. According to van Akkooi, if both groups are equally compared, the MSS difference is minimal between groups (81.4% against 78.3%, respectively). There are some reasons to be considered in the critical analysis of these data (the false-negative rate, difference in nodal positivity between groups, and tumor load of metastasis, as well as an adequate statistical analysis). Moreover, the center that treated patients should be included as a potential confounding factor, because the results may differ significantly due to the diverse experience of each multidisciplinary medical team [36].

Finally, there is a certain time delay between melanoma excision and wide local excision for adequate margins and SLN biopsy. This delay is due to several factors, including surgical scheduling, preoperative evaluation, need for further diagnostic tests, etc. The influence of this delay over the prognosis of the patient is not clear. Parrett et al. studied the time effect to perform SLN biopsy on node metastatic invasion, recurrence, and mortality. The study showed no significant differences in survival if SLN biopsy was performed within 40 days or beyond 40 days after excision of the primary tumor [37].

Tejera-Vaquerizo et al. reported surprising findings in a multicentric retrospective observational study with 1963 melanoma patients scheduled to SLN biopsy. The main outcome was disease-free survival and melanoma-specific survival. A delay of more than 40 days was associated with better 5-year disease-free survival (80.1% vs. 73.8%; $P = 0.0839$) and better 5-year melanoma-specific survival (89.5% vs. 82%; $P = 0.0002$). These results raise important issues, and the implication that early SLN biopsy reduces MMS needs to be further and prospectively explored. On the other hand, a delay in the procedure did not worsen the prognosis in any case [38].

Technical Issues

Radiotracers

The term "colloid" indicates a class of macromolecules with similar chemical and biological behaviors. These particles vary between 5 and 1,000 nm in size. Colloids circulating in the lymph or blood are removed from the circulation by macrophages, located in the bone marrow, spleen, liver, and lymph nodes.

Following their arrival to lymph nodes through the afferent lymphatic channels draining from the injection site, these particles are phagocytized by macrophages located in the node sinusoids. Therefore, retention of radiocolloids in the lymph node is a physiological process, and it does not indicate the presence or absence of metastatic involvement in the node [28].

The speed of lymphatic drainage from the injection site and the amount retained in the SLN depend on the size of the radiocolloids. Small-sized radiocolloids (less than about 100 nm) migrate quite fast from the injection site through the lymphatic system and best visualize the lymphatic vessels. Lymphoscintigraphy can be completed in a relatively short time (within 45–60 min after injection). However, more than one lymph node, often as many as three to four, can be visualized along a single lymphatic draining channel. This may result in a misleading identification of the SLN, unless there are sequential or dynamic images acquired after injection. Intermediate-sized particles (50–200 nm) migrate more slowly from the primary lesion, but exhibit a more prolonged retention in the SLN. Larger-sized

radiocolloids are retained more efficiently in the SLN, and lymphoscintigraphy usually visualizes one to two nodes only; nevertheless, migration of larger particles from the interstitial administration site is very slow, so that a longer time can be necessary to complete lymphoscintigraphy. Altogether, the choice of radiopharmaceutical varies according to geographic region and is usually guided by local legislation and the agent's commercial availability [39].

Radiotracers for SLN lymphoscintigraphy include ^{99m}Tc-antimony trisulfide (particle size 3–40 nm) with a wide application in Australia, ^{99m}Tc-sulfur colloid (100–400 nm, mostly used in North America), and ^{99m}Tc-nanocolloidal albumin (<80 nm, predominantly used in Europe). It has been suggested that the optimal particle size for SLN detection is between 100 and 200 nm. There is no specific consensus regarding the activity to inject, which should be adapted to the local logistics and to the time lapse between the injection and surgery. Activities usually range from 5 to 120 MBq, depending on the specific 1-day or 2-day protocol employed. It has been demonstrated that both procedures are equally effective for SLN detection [40, 41].

Recently, a new agent, ^{99m}Tc-tilmanocept, has been prospectively evaluated in two non-randomized phase III trials in comparison with vital blue dye. These trials showed ^{99m}Tc-tilmanocept to have a very high rate of SLN identification [42, 43]. This new radiotracer was approved by the US Food and Drug Administration (FDA) in 2013 and by the European Medicines Agency in 2014. ^{99m}Tc-tilmanocept (Lymphoseek®) is a mannosyl diethylene triamine pentaacetate (DTPA) dextran with a molecular size of 7 nm. However, its accumulation in SLNs is not dependent on particle size as with the other colloids. Tilmanocept binds to CD206 mannose receptors expressed by reticuloendothelial tissue including macrophages and dendritic cells within lymph nodes, which present it to T-cell lymphocytes. The advantages of this tracer include rapid clearance from the injection site and low migration to second-echelon nodes (see Fig. 2) [44, 45].

In the PET/CT era, there is a scarcity of PET tracers dedicated to lymphatic mapping. However, some preliminary reports have been published on the use of ^{89}Zr-nanocolloidal albumin for lymphatic mapping with PET imaging; the results reported are similar to those observed with ^{99m}Tc-nanocolloid.

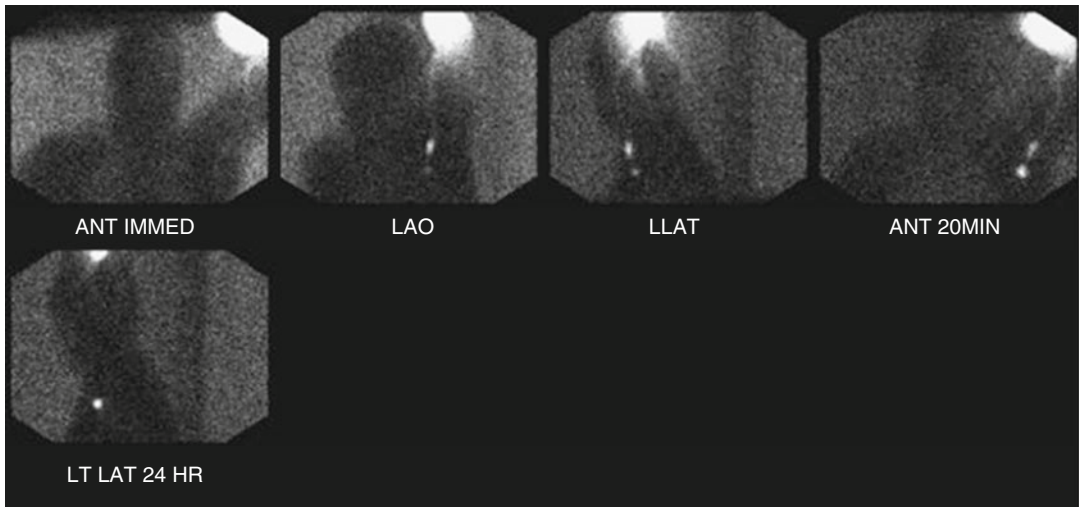

Fig. 2 Lymphoscintigraphy with ^{99m}Tc-Tilmanocept obtained in a patient scheduled for SLN biopsy for a 0.95-mm nonulcerated melanoma of the left forearm (site of injection visible in the first image, *top row*). A single axillary lymph node was visualized 20 min postinjection along with activity in lymphatic channels (variable-angle views in second through fourth image, *top row*). Radioactivity in the SLN visualized at 20 min was well retained at 24 h (image in *bottom row*). The SLN to background count ratio was >30:1 intraoperatively (Reproduced with permission from Sondak et al. [43])

Interestingly, the use of PET tracer showed an improved visualization of nodes near the primary tumor site. These preliminary results warrant further comparative studies in this field [46].

Activity and Injection

There is general consensus that the radiotracer or dye should be injected within 1 cm from the tumor margin of the biopsy scar. Injection activities range from 3.7 to 37 MBq (0.1–1 mCi) per intradermal injection, depending on the time to surgery. The recommendation is two to four intradermal injections (depending on location of the melanoma) of 0.1 mL each around the tumor site or biopsy scar (within 1 cm away from the edge of the tumor or scar). The injected volume must be small to avoid the collapse of lymphatics; furthermore, the wheal raised on the skin surface may rupture and spill over the skin. Tracer injections should be placed either in each side of the biopsy scar or tumor, although in some circumstances they may be performed in only one side. In upper extremities adequate mapping may be accomplished by injecting two injections proximal to the scar and this approach can be employed also for lesions located in the foot and leg. When lesions are located in the thigh, it is advisable to inject in both sides of the scar or tumor. In other sites (the trunk, head, and neck), it is mandatory to inject at least four aliquots around the lesion.

Topical anesthetic medications may be used to diminish the pain, especially when the primary melanoma is in a sensitive location (or when using some radiocolloid with low pH, such as ^{99m}Tc-sulfur colloid). To avoid contamination, a sheet should be placed next to the injection site, and after each injection, the skin should be covered with a swab before the needle is removed [28, 45, 47].

The tracer is injected 1 day before surgery or, alternatively, on the same day. No differences in SLN detection rate or false-negative rate have been found between these two protocols [48]. The 2-day protocol may present some advantages with flexibility in timing of lymphoscintigraphy and surgery. The 1-day protocol requires a good cooperation between the nuclear medicine staff and surgeons with respect to the estimated speed of lymphatic drainage in the affected region and the time to surgery. Intraoperative injection is not recommended because lymphatic drainage in melanoma may be aberrant or delayed to more than one nodal basin and because it is not always possible to obtain intraoperative imaging [45].

Presurgical Lymphoscintigraphy

An accurate procedure for SLN biopsy relies on preoperative lymphoscintigraphy, careful surgery guided both by vital blue dye and by a gamma probe, and finally thorough histopathologic examination.

Lymphoscintigraphy is considered to be an essential part of SLN mapping in general, and it is mandatory for melanoma. It demonstrates the flow of radioactive tracers through the lymphatic structures and visualizes any alternative routes to different regional lymphatic basins. Visualization of nodes located along the route of the lymph will be displayed, and other nodes or paths will be seen if flow has been rerouted because of, for example, block of the original lymphatic flow pattern by massive metastatic involvement of the lymph nodes or by other causes. So, lymphoscintigraphy provides a visual roadmap of nodal locations before surgery and may show the timely order in which lymphatic flow reaches those nodes, especially when a dynamic study is acquired [49–52].

All possible drainage basins must be explored during image acquisition. Therefore, a dual-head gamma camera with large field of view detectors is preferred to reduce the examination time. Nevertheless, a single-head gamma camera can equally be adequate.

Low-energy, high-resolution, or ultrahigh-resolution collimators are recommended to better distinguish individual SLNs. The energy window in gamma camera settings should be 15% or 20% centered on the 140-keV photopeak of ^{99m}Tc [53]. During image acquisition, a ^{57}Co- or ^{99m}Tc-flood source positioned on the opposite side of the camera head for transmission imaging or alternatively a radioactive pointer can be used to delineate the body contours.

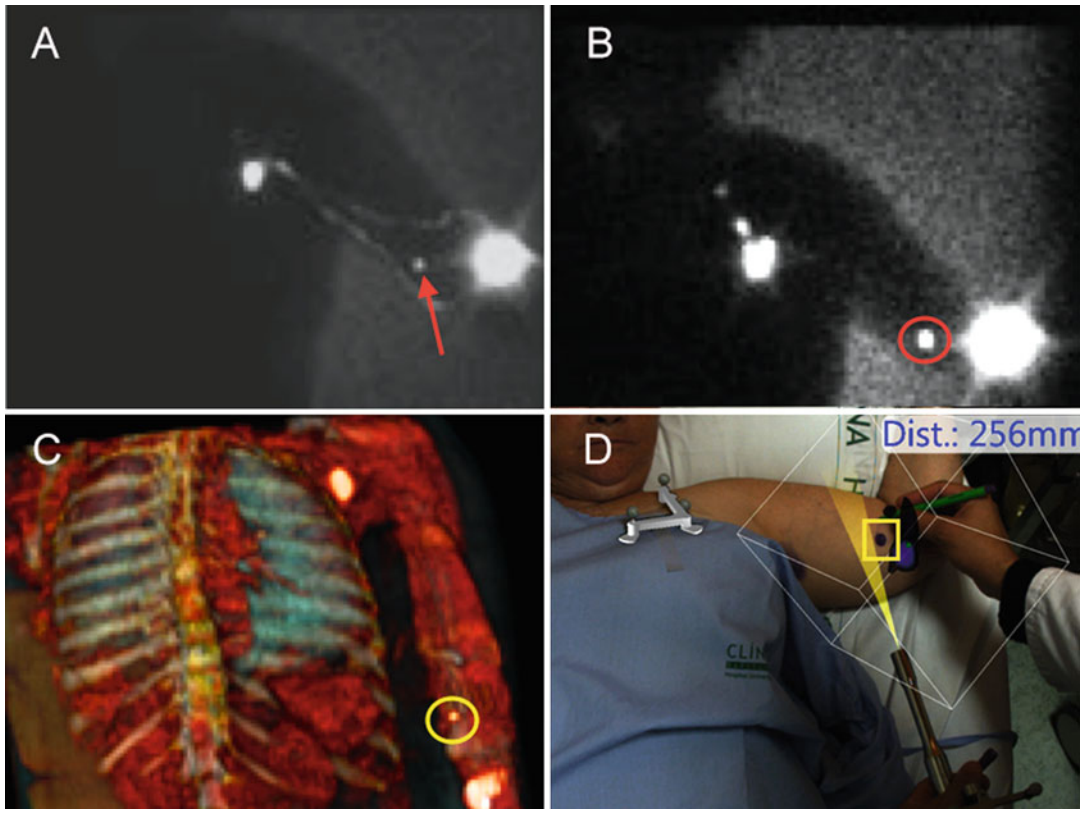

Fig. 3 Early planar image showing the radiotracer injection performed in the ventral part of the elbow, some lymphatic channels, an epitrochlear in-transit sentinel node (*red arrow*), and an axillary sentinel node (**a**). Delayed image that depicts the epitrochlear uptake (*red circle*) and the axillary sentinel node and subsequent second-tier axillary nodes (**b**). Volume rendering 3D reconstruction that depicts the sentinel nodes in the epitrochlear area (*yellow circle*) and the left axilla (**c**). Skin marking of near-epitrochlear node (*yellow square*) and confirmation using a gamma probe (**d**)

The tracer must be injected with the patient lying in the most convenient position on the bed of the gamma camera, depending on the location of the primary tumor. Starting image acquisition immediately after the injection may help to identify lymph nodes next to the injection sites and to differentiate true SLNs from second-echelon nodes. Dynamic imaging (one frame per 30 s or per 60 s in a 128 × 128 matrix) during the first 10–20 min after injection is recommended. Although acquisition of dynamic images is time consuming, it is nevertheless crucial because a lymphatic channel directly draining to a lymph node identifies this node as a true SLN.

In melanomas of the hand/forearm or foot/leg, dynamic imaging should start over the injection site and follow the lymphatic drainage to the elbow and axilla and knee/groin, respectively, to reveal ectopic basins and in-transit lymph nodes (popliteal, epitrochlear, etc.) (Fig. 3). For head and neck melanomas, immediate imaging reduces the chance of missing a SLN because of rapid drainage from intradermal injections with uptake by superimposed nodes. Imaging at a rate of 1–5 s/frame in this particular area may solve these drawbacks.

After dynamic imaging, static planar 3- to 5-min images (anterior, oblique, posterior, and lateral) should be acquired, if indicated, with a 256 × 256 matrix over the visualized lymph node basin drainage. Early images help to discriminate true SLNs from second-tier nodes. In melanomas of the trunk, usually bilateral static images of the axilla, trunk, and groin are necessary. In lower limb melanomas,

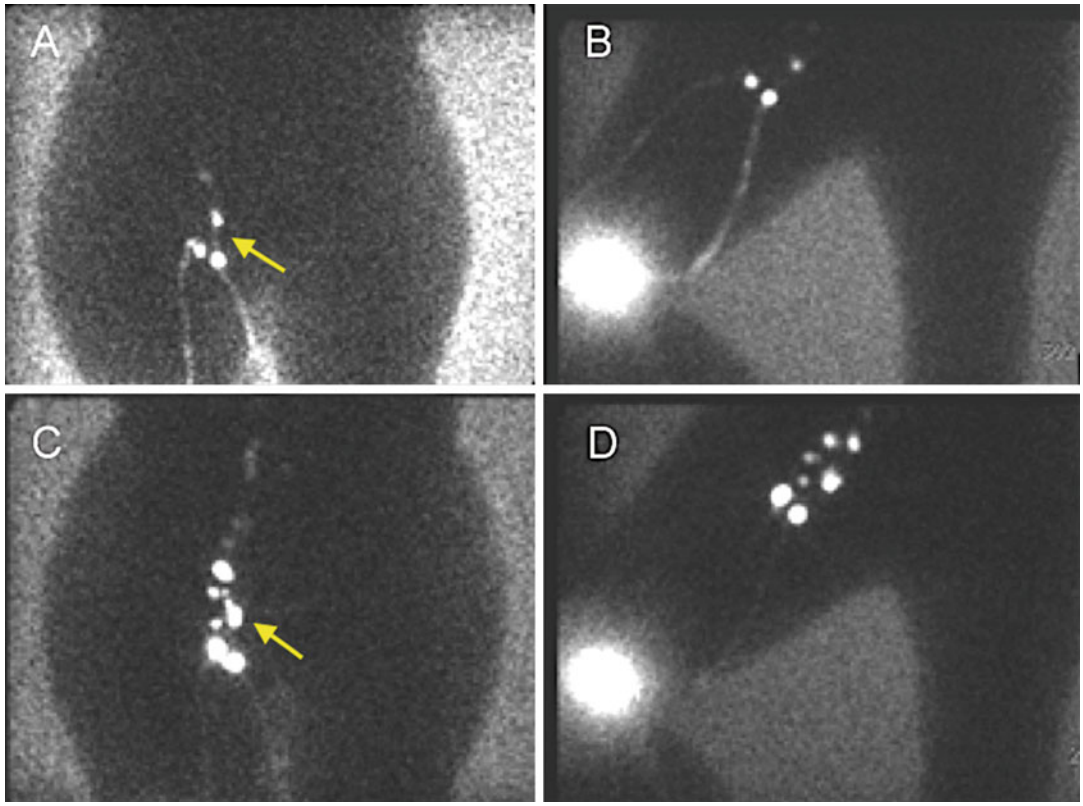

Fig. 4 Lymphoscintigraphy. Early (**a**, **b**) and delayed (**c**, **d**) planar images in anterior and oblique views. Two well-depicted lymphatic channels are visualized in (**a**) and **b** images directly connecting the injection site with right groin sentinel nodes. *Yellow arrow* in picture (**a**) shows a faint lymphatic channel cranial to one of the sentinel nodes. It could be a second-echelon node but also a real sentinel node if this channel passes below the first depicted node directly from the injection site. Oblique view can provide a more accurate assessment. *Yellow arrow* in picture (**c**) shows a high uptake in the aforementioned node, as well as in the other nodes upstream. Second-echelon nodes are more frequently observed in the groin than in other parts of the body, due to the highest velocity of lymph that is observed in the lower limb. Performing only delayed images is not accurate in those cases because it is hard to distinguish between the real sentinel nodes and the second-tier nodes

several superimposed lymphatic channels are often depicted. In this case, an oblique view helps to distinguish different channels. Second-echelon nodes are more frequently observed in the groin than in other parts of the body, due to the highest velocity of lymph occurring in the lower limb (Fig. 4) [45, 54].

To detect SLNs close to the injection site, it may be useful to mask the injection site with lead material during image acquisition. Delayed images (2–4 h or more after radiotracer injection) allow the correct SLN identification and their external marking on the skin. The SLNs are usually identified in the first 30 min after injection, although images should be obtained also at 2 h, due to possible slow lymph flow to other areas. The great variability of cutaneous drainage should be taken into account, as well as the possibility of detecting lymph nodes outside the conventional regional areas (called aberrant or in-transit nodes).

Lymphoscintigraphy for SLN mapping must be accurate and reproducible. Some studies have addressed this issue in several different malignancies. In particular, in melanoma patients a good correlation (84–96%) between two separated lymphoscintigraphic studies has been demonstrated [55–60].

Lymphoscintigraphy may, to some extent, predict the metastatic burden in lymph nodes. In this

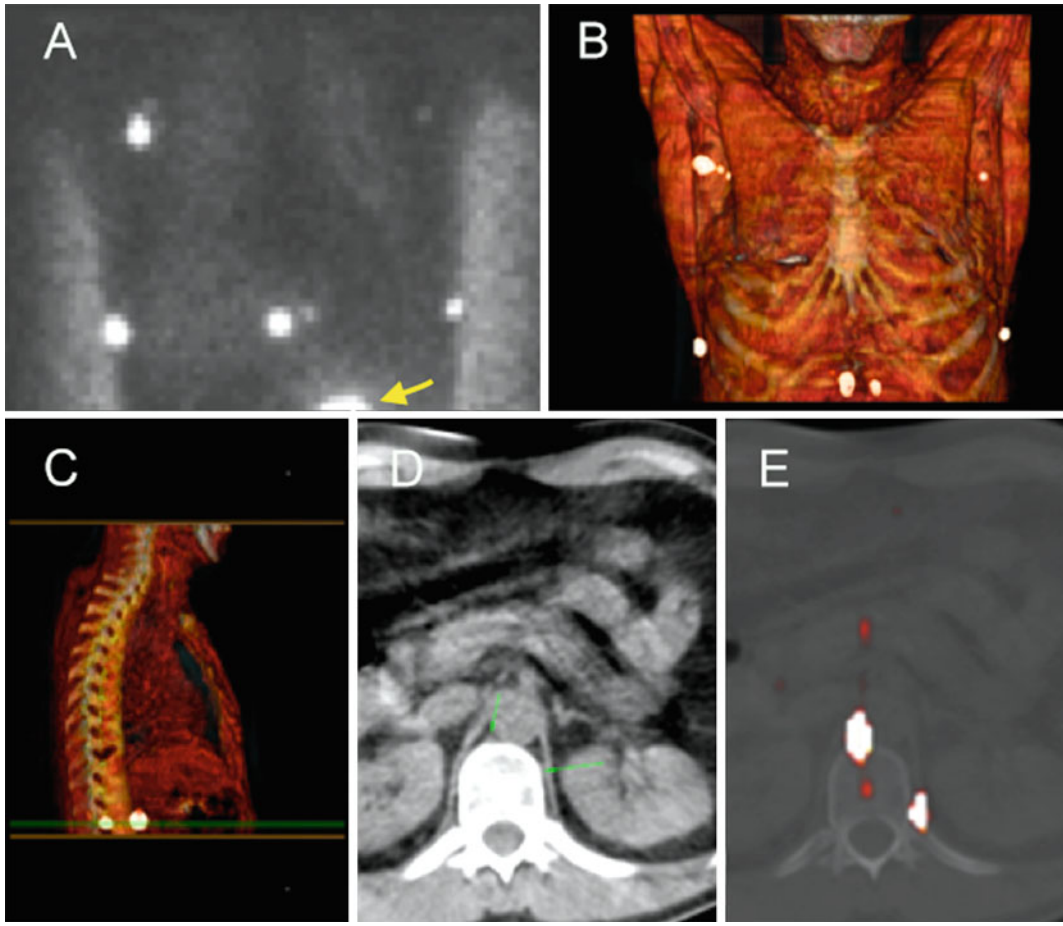

Fig. 5 Planar lymphoscintigraphic anterior view of a melanoma patient with a lesion in the left–central periumbilical area (*yellow arrow*). The image shows several hot spots in both axillae and para-costal areas and two hot spots central in the abdomen. All of them were considered as sentinel nodes (**a**). 3D reconstruction showing the anatomical location of these nodes (**b**). Sagittal view of selectively assessed "abdominal" uptake (**c**). The CT scan showed two tiny nodes in para-aortic and paravertebral areas (*green lines*) (**d**). Fused SPECT/CT images showed focal radiotracer uptake in these locations (**e**). These nodes are sentinel nodes. However, they were not resected in the surgical procedure due their deep location

regard, an interesting study in 509 melanoma patients scheduled for SLN biopsy showed that clear depiction of an afferent lymph vessel may be a sign of micrometastasis. On the other hand, the presence of macrometastasis was associated with prominent afferent vessels, delayed display of the first radioactive node, and higher number of depicted hot spots. Moreover, in patients with bidirectional or lymphatic drainage to three basins, the SLN metastatic involvement rates for the first, second, and third basin were 25%, 12%, and 0%, respectively ($P = 0.002$) [61].

Additional SPECT/CT Imaging

Planar lymphoscintigraphy provides clear visualization of the SLN, thus providing information on their number and facilitating the localization on their skin projection. However, the depth and anatomical correlates of the SLN are not easily obtained. For example, deep SLNs in the neck or in other areas (i.e., deep paravertebral, mediastinal, or para-aortic nodes) are challenging during surgery, and in certain cases, they cannot be removed (Fig. 5).

Table 2 Advantages of SPECT/CT over planar imaging

Improved anatomical SLN localization
Better sensitivity than planar images (additional lymph nodes)
Reduction of false-negative cases
Reduction of false-positive cases
Clarification of inconclusive scintigraphic patterns in planar images
Higher SLN detection rate in difficult cases (obesity, faint uptake)

The use of SPECT/CT has gained importance because this tomographic approach is more successful than planar imaging in identifying SLNs [62]. SPECT/CT is basically used for anatomical localization of SLNs and is performed in addition to lymphoscintigraphy. A requirement for accurate SLN localization is that the CT component of SPECT/CT system must be of sufficient quality to provide adequate anatomical landmarks to be recognized by surgeons. SPECT/CT may be of great utility in obese patients to demonstrate SLNs not detected on planar images, as well as to show additional SLNs in other areas. For fused SPECT/CT images, a gray scale is used to display the anatomy (CT), whereas a color scale is employed to show the SLNs in the SPECT image. Usually, a radioactive hot spot corresponds to a single lymph node on CT, but in some cases, this image correlates with a group of lymph nodes adjacent to each other (cluster) [63, 64].

Tomoscintigraphic images improve SLN identification and overcome some of the limitations of planar imaging (Table 2). Fusion with CT images shows the SLN in 2D and 3D modalities. In this way, SPECT/CT facilitates recognition of non-lymph node accumulations of the radiotracer and helps to clarify drainage in inconclusive planar images. With the use of volumetric rendering techniques with 3D viewing, images can be obtained with high anatomical detail, thus facilitating the interpretation of lymphoscintigraphy and helping to assess the images obtained with the planar study in anatomically complex areas of the body. In melanoma of the head and neck, where SLNs may be located very close to the primary site, SPECT/CT may be of outmost importance in localizing SLNs masked during planar imaging because of their proximity to injection sites (Fig. 6) [65, 66].

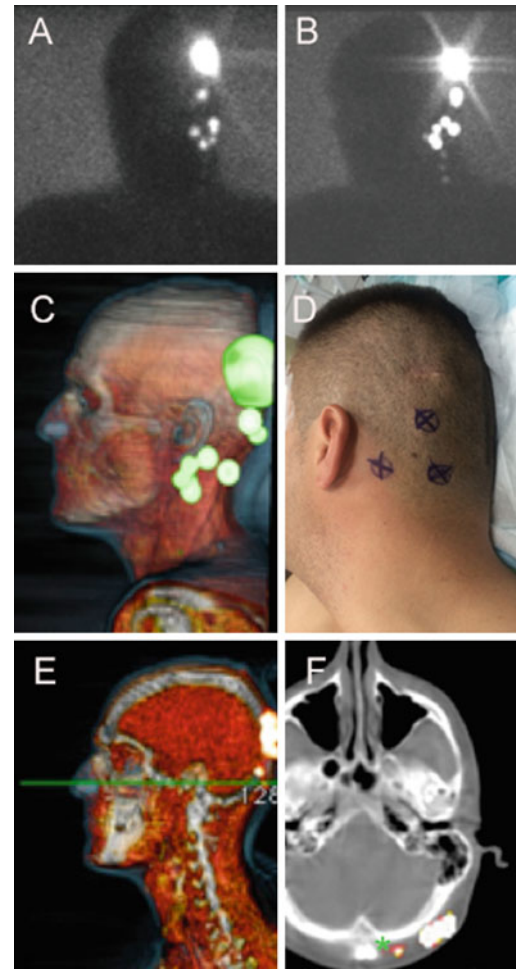

Fig. 6 Lymphoscintigraphy. Anterior (**a**) and left oblique (**b**) views showing several hot spots in the occipital and left cervical area after a radiotracer injection in left parietal scalp. 3D reconstruction after SPECT/CT acquisition (**c**). Skin marks in the areas where sentinel nodes were considered to be (**d**). Sagittal slice corresponding to the occipital uptake level (**e**). Fused SPECT/CT images showed two separate radiotracer uptakes in this area. The faint uptake (*green asterisk*) was a very tiny node (3 mm) that was positive for metastatic involvement. SPECT/CT images helped to better assess the planar images (only one hot spot depicted in that zone due to the higher activity of one of the nodes masked the tiny node)

Clinical Impact of SPECT/CT in Melanoma

SPECT/CT allows an accurate lymphatic mapping by increasing the number of SLNs resected during

surgery. Moreover, SPECT/CT may also detect more SLNs in aberrant drainage locations or when planar images show no clear radiotracer migration. SPECT/CT in melanoma has been validated for specific indications. An initial study demonstrated that SPECT/CT had a definite added value in 30 out of 85 patients (35%), by detecting extra SLNs, not visualized on planar images, by localizing SLNs in other basins, or by modifying the surgical incision planning. In seven patients, 12 additional SLNs were detected (two of them with metastatic involvement) [67].

Mucientes et al. showed, in another study with 18 patients, a visualization rate of 100% for SPECT/CT versus 89% for planar lymphoscintigraphy. Moreover, SPECT/CT provided accurate anatomical information leading to refine the surgical incision in four patients [68].

A Dutch study confirmed in a series of 35 melanoma patients that SPECT/CT detected more SLNs than planar images in 7 of them, contributing also to modify surgery in 10 patients [69].

Fairbairn et al. showed that SPECT/CT and planar lymphoscintigraphy detected SLNs in 32 patients (SLN detection rate of 97% for both techniques). The additional anatomic information provided by SPECT/CT contributed to the adjustment of surgical approach in 12 cases [70].

Kraft and Havel reported in 113 melanoma patients that SPECT/CT allowed higher SLN detection rate than planar images (95% vs. 89%, respectively). Furthermore, lymphatic drainage was visualized in eight patients without SLN visualization on planar study [71].

From the surgical point of view, the value of SPECT/CT in adjusting the operating approach is also important. Such added value was observed in 14 out of 63 (22%) melanoma cases, whereas the SLN visualization rate was similar between planar images and SPECT/CT (98% vs. 100%, respectively) [72].

SPECT/CT is able to detect also more potential metastases. A study comparing the results in 149 patients with additional SPECT/CT information with a group of 254 patients who only underwent planar imaging showed that SPECT/CT detected more SLNs than planar images (average 2.4 vs. 1.87 per patient, respectively). SPECT/CT detected more metastatic SLNs (average 0.34 vs. 0.21 per patient), and its use was associated with a significantly higher rate of disease-free interval (93.9%) in comparison with those patients without the use of SPECT/CT (79.2%) [73].

Recently, a multicenter collaborative study promoted by the International Atomic Energy Agency (IAEA), conducted in 15 centers from 10 different countries, included 262 melanoma patients. No SLN was visualized on planar images in three patients. SPECT/CT revealed an axillary SLN in a trunk melanoma patient and persistent non-visualization in two patients with head and neck melanoma. In the latter, cervical lymphadenectomy was positive for metastasis. SPECT/CT revealed 70 additional SLNs in 53 patients (25% additional nodes in head and neck melanoma: 25.5% in patients with upper limb melanoma, 20.5% in patients with trunk melanoma, and 12.9% in patients with lower extremities melanoma). The surgical approach was modified in 97 patients (37%): 41%, 39%, 33%, and 30% of head and neck, trunk, lower limb, and upper limb lesions, respectively [74].

Nevertheless, based on evidence currently available, SPECT/CT must be considered as complementary rather than alternative to planar lymphoscintigraphy. SPECT/CT is able to provide anatomical landmarks with a significant improvement of the surgical roadmap and clinical benefit for the patient as demonstrated by Stoffels et al. [73]. In a recent survey in Spain, data from 37 different nuclear medicine centers were collected. SPECT/CT studies were performed in all the melanoma patients in 24.3% of the centers (9/37), while this study was performed according to patient-based considerations in the remaining centers (28/37), the most common indication being the presence of head/neck drainage [75].

Surgery

Besides the information provided by preoperative lymphoscintigraphy, the other main cornerstone of the technique is the ability of the detector probe to guide the dissection and to identify the SLN. It is

recommended to make a preliminary search, with the patient properly positioned on the operating table, with gamma probe prior to making the incision. The scan with the gamma probe should be slow and systematic and should start between the area of the injection and the area of drainage visualized in the lymphoscintigraphy, until an increase in activity is observed. This activity should optimally be matched with the skin markings made by the nuclear medicine staff at the time of lymphoscintigraphic imaging. Precaution should be taken when the injection site overlies or is within the field of view of the detector probe, and thus, if possible, mobilization maneuvers or attempt to direct the gamma probe opposite to the injection site should be made. In vivo radioactivity (counts/sec) is measured in the surgical field opened, typically with a 2–4-cm incision over the area of highest activity determined by external counting/skin marking. SLN to background ratios are usually between 10:1 and 20:1, depending on activity injected, time to surgery, etc. After in vivo SLN identification and retrieval, the ex vivo activity of the SLN should be recorded, as should also be the remaining activity in the surgical fields to rule out the presence of other potential SLNs. Although the SLN is visualized in the lymphoscintigraphy, in practice there may be two adjacent lymph nodes seen as one in the images (especially if SPECT/CT imaging is not available); therefore, the lymphatic bed should always be reassessed. It is also advisable to palpate the lymphatic region searching for enlarged or matted lymph nodes, especially if an ultrasound study has not previously been performed [45, 76].

Vital dyes may help to visually confirm the lymphatic vessels from the primary tumor to the SLN. Combining the information provided by presurgical lymphoscintigraphy with the intraoperative use of dyes and the detector gamma probe offers the highest accuracy in SLN identification; therefore, their use in combination is recommended. The vital dye is especially important when the primary tumor is very close to the lymphatic basin, since the injected radioactivity (even after lesion removal) causes a high background count rate which does not allow the detector probe to distinguish the SLN. Isosulfan blue (Lymphazurin) and Patent Blue V are the dyes of choice for SLN mapping. Methylene blue is also used because of its lower cost, its lesser risk of anaphylaxis, and its similar ability to detect the SLN compared with the other two dyes [77].

In general, the success rate of combining presurgical lymphoscintigraphic information with intraoperative gamma probe reaches about 98% in melanoma, whereas the vital blue dye alone identifies about 80% of cases. The addition of dye improves radioguided SLN identification, to reach a 99% success rate (Fig. 7), especially when lymphatic drainage to the SLN is blocked by metastatic tumor cells and/or when the SLN capacity to retain the radiocolloid is hampered by massive replacement of the normal lymph node structure with metastatic cells.

Nonetheless, from a practical point of view, many centers around the world consider that lymph node resection should continue up to achieving lymph node activity in the surgical bed $<10\%$ of the activity of the most active SLN (10% rule), in order to reduce the potential false-negative cases [78]. However, almost all the involved lymph nodes can be identified following the concept of the SLN and using a rigorously conducted procedure [79]. In this regard, a recent revision of the 10% rule showed a 21% positive SLN rate in 665 melanoma patients. More than one SLN was removed in 105 regional basins. In 18 of these, a less radioactive node was positive for tumor when the most radioactive node was negative. Blue dye was used and stained 157 out of 175 positive SLNs (90%). In those cases, in which the involved SLN was not the hottest node, the positive node was blue in all cases. Thus, the authors concluded that, in this particular series, removing just the hottest node and all blue nodes would not have missed a positive SLN, but at the same time would have avoided to resect more nodes in comparison with the 10% rule [80].

Sentinel Lymph Node Analysis and Its Importance for Clinical Decision

Histopathologic evaluation of the SLNs is, currently, the "gold standard" in patients scheduled for SLN biopsy. The SLN status predicts

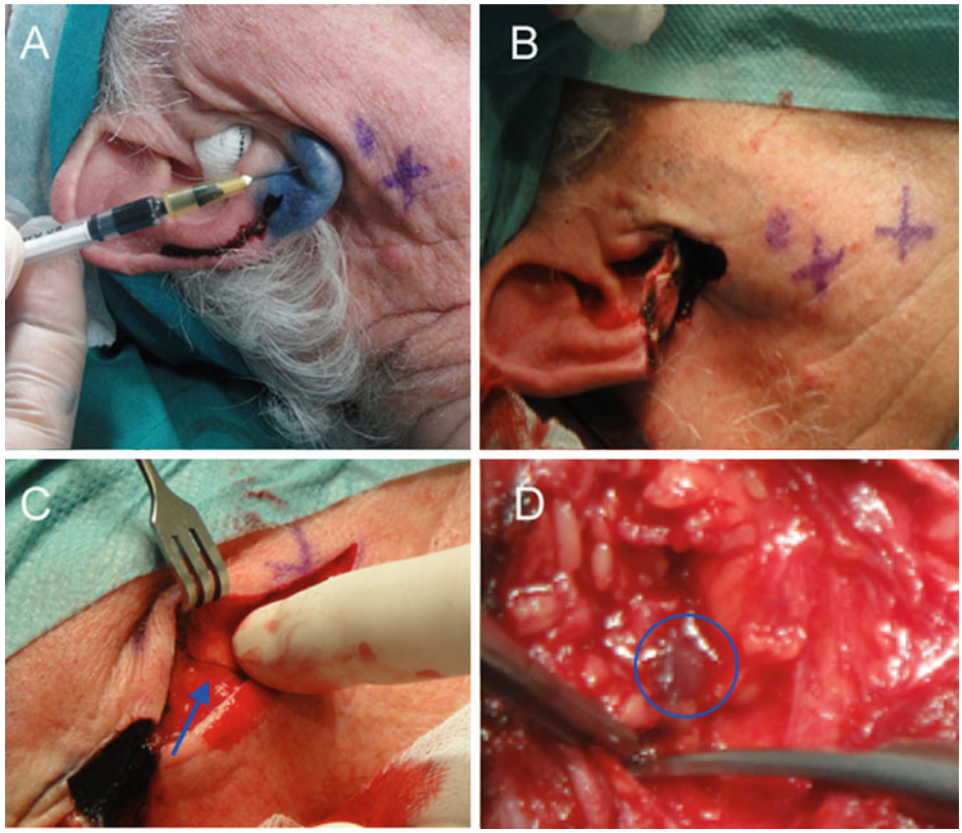

Fig. 7 Classical intraoperative approach for sentinel node biopsy. Injection of blue dye around the biopsy scar in a patient with a melanoma in the right ear (**a**). Skin marks corresponding to the depicted sentinel nodes in preoperative lymphoscintigraphy (**b**). *Blue* stained lymphatic channel (*blue arrow*) to the parotid area sentinel node (**c**). *Blue* stained node (*blue circle*) in the surgical field (**d**)

prognosis and indicates the necessity or not for further surgical treatment.

The SLN approach enables pathologists to thoroughly review this particular node or nodes using multiple sections and several staining techniques. Intraoperative frozen section histology is not reliable in the case of melanoma. The conventional approach involves, after usual sectioning and staining with hematoxylin and eosin, immunohistochemistry employing antibodies against the melanoma-associated S-100 antigen (very sensitive) and HMB-45 and MART-1/Melan A (very specific) antigens. Serial sectioning and additional immunohistochemistry may detect additional micrometastases in up to 12% of the cases [81].

Molecular analysis methods (PCR) are not part of clinical routine up to now, because they are time consuming and lack in reproducibility. However, some studies have advocated their use due to a higher sensitivity to detect metastases against conventional pathology methods and a lower rate of false-negative cases [82, 83].

It has been shown that small deposits of metastatic cells are associated with a worse prognosis in patients with negative SLN. Although isolated tumor cells (especially in the subcapsular sinuses) have been described to bear an adverse biological feature in melanoma [84–86], nevertheless the AJCC concluded that there is no definitive evidence enabling to define a minimum threshold of tumor load for defining the stage of lymph node metastasis [87].

The current practice is to wait for definitive histopathologic examination before making the choice between no further surgery (when the SLN is tumor-free) or to perform an elective regional

lymphadenectomy (when the SLN bears metastasis). Patients with positive SLN biopsy are offered complete lymph node dissection, and 12–25% of them will have additional lymph nodes involved. The final analysis of data from the MSLT-I trial has demonstrated the importance of SLN biopsy for the identification of patients with node involvement who may benefit from immediate lymphadenectomy [35].

However, recent studies indicate that lymph node dissection does not have an effect on the global survival after a positive SLN with minimal tumor load (<0.1 mm in diameter). It has therefore been suggested that lymph node dissection can safely be omitted in these patients [88, 89]. The Multicenter Selective Lymphadenectomy Trial II has been designed to assess the role of lymphadenectomy of the regional node basin in patients with positive SLN, with the intent to determine whether lymphadenectomy has any benefit in regional control or survival. The study started in 2004 and reached its scheduled accrual in 2014 [90]. Follow-up is still in progress for assessing the long-term outcomes of the trial.

Refinements for the Classical Technique

Despite the successful results in SLN localization based on lymphoscintigraphy (especially if complemented with SPECT/CT), precise localization for surgical planning may sometimes be difficult. Intraoperative use of the gamma probe provides a good overview of radioactivity distribution in the surgical field, with SLN identification rates close to 99% in patients with melanoma. Nonetheless, the technique can be further improved. The combination of vital dye and gamma probe has prevailed for many years as the standard technique. However, the dye is less effective in areas with aberrant lymphatic drainage and in deep-seated lymph nodes (i.e., head and neck region where the SLN identification rate is around 85%).

The current technological advances in portable devices and the possibility of using new signatures (i.e., fluorescence) in addition to the conventional radiotracers have led to a changing paradigm: from the "see to open" approach to the "see, open, and see again." The combination of SPECT/CT information with new portable imaging devices enhances the reliability of the gamma probe, especially in complex drainage regions and in areas where the SLN is very close to the injection site. These advances have led to the definition of the concept of "Guided intraOperative Scintigraphic Tumour Targeting" (GOSTT) to include the whole spectrum of basic and advanced nuclear medicine procedures required for providing a roadmap that would optimize surgery [91, 92].

Portable Gamma Cameras

These gamma cameras have been designed for intraoperative use, with sensitivity and resolution parameters that make them optimally suited for imaging small areas [93]. The use of these imaging devices in the surgical theater enables to precisely adapt in real time the surgical incision to the skin marks previously made in the nuclear medicine suite at the time of lymphoscintigraphy and confirms the exact SLN location, considering that position of the patients on the operating table may be different from that on the imaging table. This is especially important for melanomas located in the head and neck area, since even small changes in lateralization of the neck may imply an important change in the anatomical setting of the subjacent SLN position in relation to the cutaneous marks.

In general, when these devices are used, an overview image is recorded before the start of SLN biopsy in the operating room. To verify the completeness of SLN removal, another image must be acquired after excision. If a residual radioactive spot is visualized at the location of a previously harvested SLN, this additional node must also be resected and be assessed as a part of a cluster of nodes to be considered as additional SLNs. Furthermore, a high-resolution portable gamma camera, positioned close to the skin, is able to detect SLNs at distances as small as only 3 mm from the injection site [92]. Nevertheless, it should be emphasized that portable gamma camera designed for use during radioguided surgery procedures do not serve as an intraoperative

guidance in the same manner as conventional handheld gamma probes, since their size is not small enough for insertion in the surgical bed through the surgical incision.

The added value in the use of these devices is that they allow resection of additional SLNs, some of which result to be metastatic. Therefore, this technique may reduce the false-negative rate of SLN biopsy, while the SLN identification rate is increased and correct application of this intraoperative imaging procedure ensures that no SLNs are left in the surgical field [94, 95].

Vidal-Sicart et al. described the use of a portable gamma camera in five difficult melanoma cases. In this group, 80% of patients showed a primary lesion in the head region, and the remaining patient had a lower limb lesion. In total, 12 SLNs were detected using only the gamma probe, while two additional SLNs were found by the portable gamma camera [96].

Dengel et al. compared the performance of a portable gamma camera with preoperative conventional lymphoscintigraphy and intraoperative gamma probe findings in 20 melanoma patients. Lymphoscintigraphy depicted 29 node basins containing SLNs, while the pre-incision images with portable gamma camera detected only 27 node basins. The authors explain these somewhat disappointing results with the delay of more than 20 h between radiocolloid injection and intraoperative imaging with the portable gamma camera, an interval during which physical decay caused an important decline in radioactivity levels retained in the lymph nodes. Nevertheless, intraoperative imaging detected two additional previously undetected lymph nodes in 2/20 (10%) of the patients [97].

Stoffels et al. enrolled 60 patients (38 with melanoma, 22 with other cutaneous malignancies) for a SLN procedure using the same portable gamma camera as that used by Vidal-Sicart and colleagues. The portable gamma camera visualized all 126 SLNs identified preoperatively by SPECT/CT. More importantly, 23 additional SLNs in 15 patients (25%) were identified using the portable gamma camera device; two of these additional nodes were metastatic, thus preventing a false-negative SLN biopsy in two patients. Intraoperative imaging extended the operating time by a maximum of only 5 min [98].

Olcott et al. showed in 39 patients that intraoperative imaging using a handheld gamma camera successfully visualized 86 of the 92 SLNs detected by the gamma probe and detected 12 additional nodes that were missed by the gamma probe [99].

New perspectives in radioguided surgery may be opened by the fusion of the scintigraphic images with an optical image, thus providing a more "friendly," real-time anatomical environment during surgery [100]. New multimodality system configurations have been described that combine optical and gamma imaging. Haneishi et al. have proposed a parallel optical and gamma camera configuration resulting in a portable hybrid camera system that projects the scintigraphic image onto an optical image [101].

Hellingman et al. have recently evaluated a prototype portable hybrid camera for preoperative lymphatic mapping in SLN procedures. Fused optical and gamma imaging makes it easier to relate the position of the radioactive hot spots and the image field of view with the real-life situation (Fig. 8) [102].

Freehand SPECT

The use of a positioning system technology allows spatial localization based on two tracking devices that are attached to a conventional gamma detector probe and to the patient, respectively. The localization system consists of an optical camera and an infrared-based localization device. Virtual 3D images are generated. After scanning the area of interest with the gamma probe, images are displayed on a screen. These images may be seen in real time and provide information about the depth at which the SLN (or the tissue to be resected) is found. The procedure is called freehand SPECT and is designed for intrasurgical navigation. This method combines the acoustic signals with a 3D image to localize the SLN in the operating room [103] (Fig. 9).

Specific training in the use of the technique is required for data acquisition and for making several readings during surgery, a procedure that might

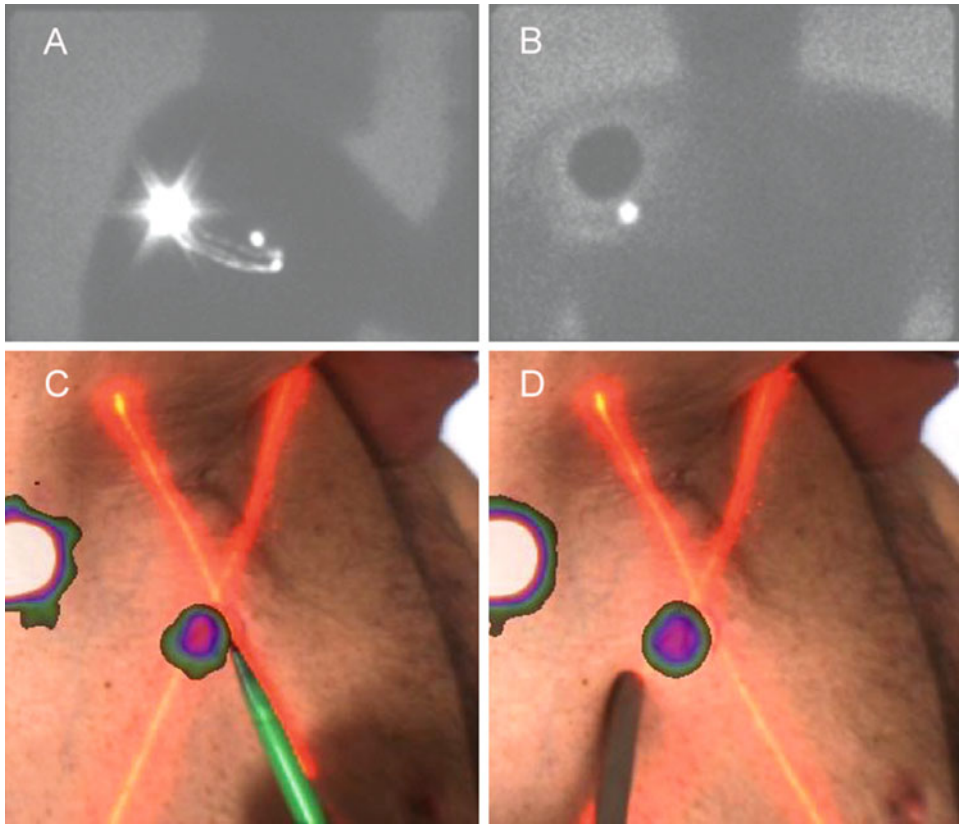

Fig. 8 Preoperative lymphoscintigraphy. Right lateral (**a**) and anterior (**b**) views from a patient with an upper right back melanoma. A clear hot spot (with several lymphatic channels to it) is visualized. Fused optical and gamma imaging is achieved in a new portable hybrid camera. The sentinel node is well depicted, and it can be precisely marked in the skin (**c**) and assessed with the handheld gamma probe (**d**) in real time

prolong the operation time. Nevertheless, in both cases the results may refine the conventional technique [104]. The use of freehand SPECT is currently yielding excellent results for SLN biopsy in melanoma and breast cancer [105].

In melanoma, Sulzbacher et al. studied 39 patients with primary lesion in different sites of the body. Surgery using radioguided freehand SPECT was performed the day after acquisition of preoperative lymphoscintigraphy (planar + SPECT/CT). Interestingly, SPECT/CT data were integrated into the 3D navigation system to enable fast and direct localization of the SLN by displaying the depth of the node from the skin surface to the gamma probe. Comparable preoperative imaging and intraoperative localization were observed in 18/39 patients. In 10 of 14 patients in whom more SLNs were resected during surgery than those visualized preoperatively, intraoperative freehand SPECT revealed additional lymph node sites. The mean surgical time using this device was 66 min (range 36–133) [106].

Fluorescent and Hybrid Tracers

The use of fluorescent agents for lymphatic mapping and SLN localization is expanding rapidly. Organic fluorescent dyes such as fluorescein or indocyanine green (ICG) have been used for human studies, as an alternative to nuclear imaging methods. Their excited light emissions are in the near-infrared (NIR) spectrum, which has several advantages over ultraviolet and mid-infrared

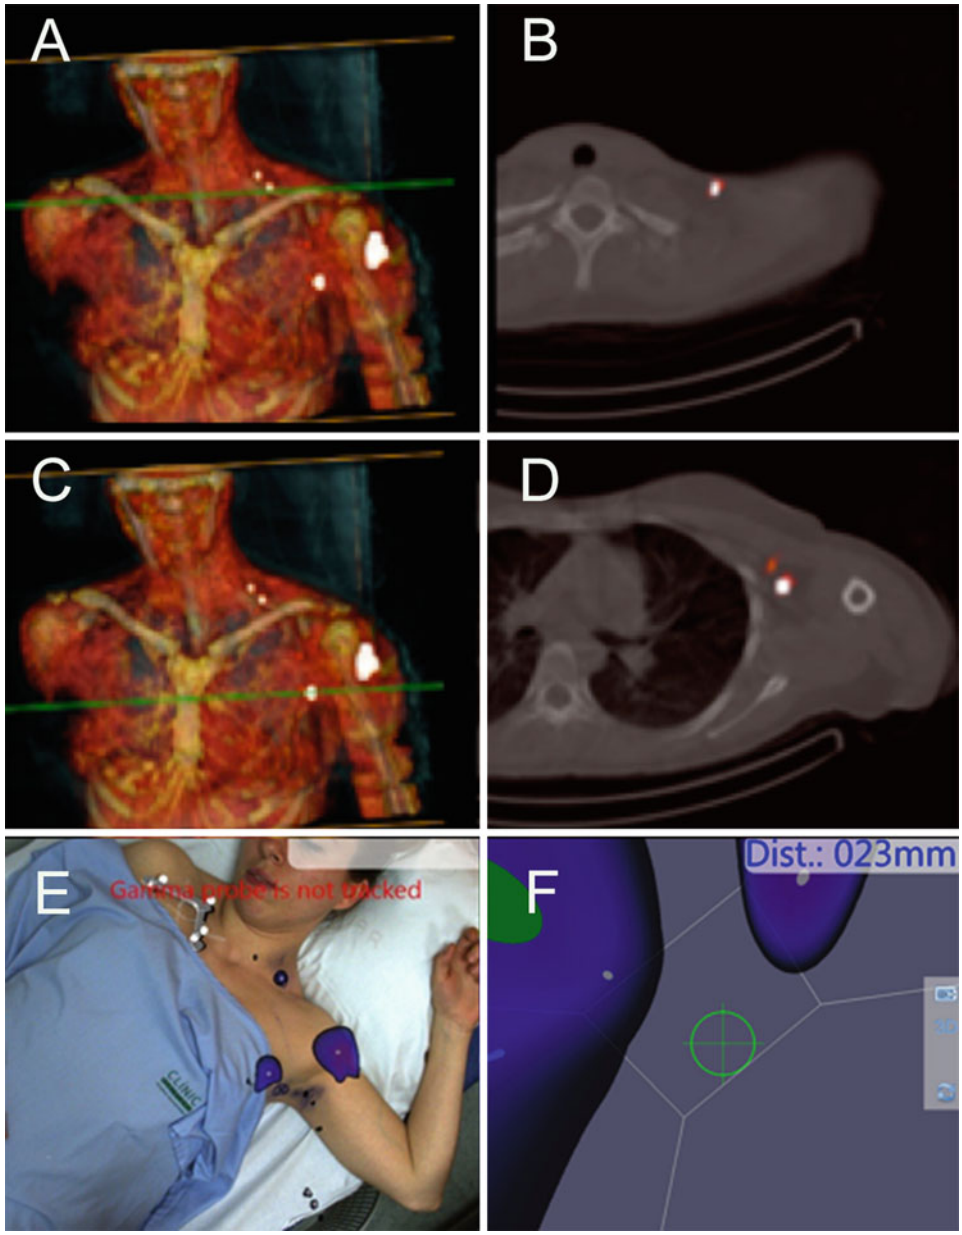

Fig. 9 3D reconstruction (**a**, **c**) and SPECT/CT fused images (**b**, **d**) of a patient with a left upper arm melanoma. These images show sentinel nodes in left axilla and left supraclavicular area. Freehand SPECT device depicted the same distribution after accurate scan (**e**). Virtual reconstruction provides real-time information about the depth at which the sentinel node is found

radiation. In particular, NIR emissions have better tissue penetration and are therefore more suitable for intraoperative guidance in a surgical field. Since the NIR window lies beyond the visible spectrum, the pathways of lymphatic drainage following interstitial injection of ICG can only be visualized by using a dedicated NIR fluorescence camera [107].

Motomura et al. first described the NIR imaging technique with ICG for SLN detection in breast cancer, reporting a 74% SLN identification rate [108]. Once injected, the fluorophore ICG binds

to serum proteins, and within several minutes, it drains through the lymphatic vessels to the SLN. Similar to blue dyes and due to its small size, ICG migrates rapidly within the lymphatic channels and is not retained in lymph nodes, thus resulting in a rather short diagnostic detection window that requires a very strict surgical protocol to reliably detect the SLN. However, sensitivity of signal detection is much better with ICG than with the blue dye, because it enables real-time percutaneous and intraoperative visualization of lymphatic channels and superficial (<1 cm in depth) SLN. Nevertheless, visualization of lymphatic drainage and SLN detection can be problematic in patients with high body mass index [109].

Van der Vorst et al. demonstrated the feasibility of NIR fluorescence for SLN mapping using an ICG:HSA conjugate and a dedicated fluorescence camera in patients with melanoma. SLN was similarly detected with fluorescence as with radiocolloids, with superior performance compared to blue dye. In particular, combining NIR fluorescence and radiotracer led to a 100% SLN detection rate, but only 73% of the SLNs were stained blue [110].

In other studies, however, the radiocolloid-based approach proved to be superior to other tracers. In a recent study with 52 melanoma patients, the SLN identification rates were 96.2% for the radiocolloid, 88.5% for ICG, and 59.6% for the blue dye [111]. In another group of patients with melanoma, Stoffels et al. observed inferior results with ICG guidance when compared to ^{99m}Tc-nanocolloid in defining lymphatic basins at risk for metastases before surgery. They detected and excised 147 SLNs in 80 patients using the radiocolloid, whereas in only 21% of the patients (17/80) was the SLN detectable by ICG before skin incision [112]. These findings are consistent with other studies showing that, although fluorescence imaging allowed intraoperative identification of the SLNs, the limited tissue penetration does not allow accurate SLN mapping prior to surgery.

Since preoperative lymphoscintigraphy is an essential component of SLN approach, novel hybrid compounds have been designed (i.e., a lymphatic mapping agent that is both radioactive and fluorescent) for combining the relative advantages of each approach. In particular, preoperative lymphoscintigraphy and SPECT/CT are possible because of the radioactive "signature" of the hybrid agent, while the fluorescent "signature" would allow recording high-resolution images in the operating room [113].

In this regard, a seminal clinical study has demonstrated the stability and reproducibility of one of these potential hybrid tracers (ICG-^{99m}Tc-nanocolloidal albumin) versus the current standard tracer in Europe, ^{99m}Tc-nanocolloidal albumin, in 25 patients with melanoma or penile cancer. Indeed, with this approach it was possible to detect fluorescent SLN up to 23 h after administration of the hybrid compound, thereby increasing the useful time window for planning surgery (Fig. 10) [114].

The combination of the properties of the two tracers (high tissue penetration of the radiotracer and high-resolution imaging of the fluorescent agent) implies greater accuracy for SLN detection, especially in areas with complex lymphatic drainage [115]. An additional hybrid approach based on ICG-^{99m}Tc-nanocolloid has recently been validated in 104 patients with melanoma. Optical SLN identification rate, made possible by the fluorescent signature of the hybrid tracer, was superior to that achieved with the blue dye, since SLNs were intraoperatively visualized in 97% of the cases with fluorescence, whereas only 62% of these nodes were stained blue. Interestingly, ex vivo examination of the excised SLNs confirmed the combined presence of a radioactive and fluorescent signature [116].

In another study, Stoffels et al. reported the results of a randomized prospective trial comprising 40 patients with different types of skin malignancies (melanoma, squamous cell, Merkel cell carcinoma) and sweat gland carcinoma in the head and neck region. Twenty patients received a derivative of the previously described ICG-^{99m}Tc-nanocolloid tracer, while the rest of the patients were given the standard ^{99m}Tc-nanocolloid. Primary study endpoints were the number of excised SLNs and duration of surgery. It was concluded that the use of the hybrid tracer for SLN biopsy is feasible in these patients and that by combining fluorescence and radioactivity in one single tracer,

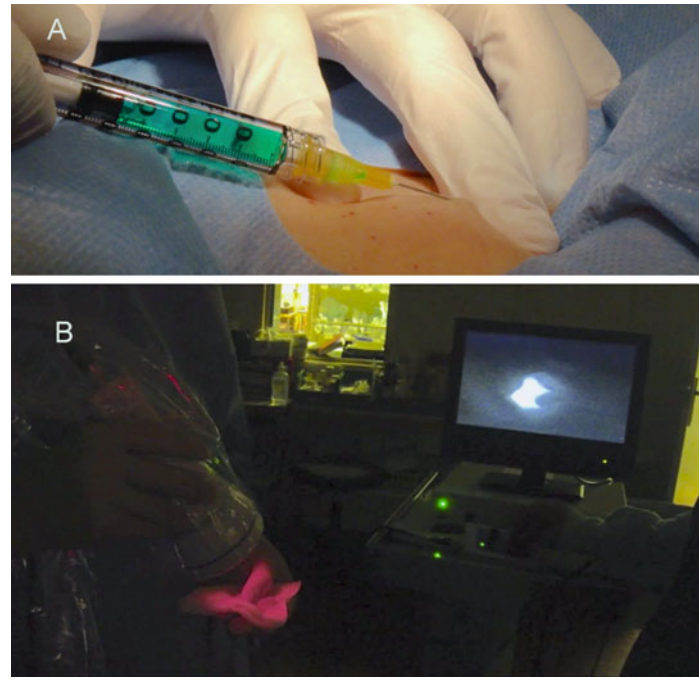

Fig. 10 Injection of hybrid tracer (ICG-^{99m}Tc-nanocolloid) in a patient with melanoma on the back (**a**). During surgery, an axillary node was retrieved (both active and fluorescent). Fluorescence is depicted on the screen when tissue is exposed to a fluorescence camera (**b**). Surgery was performed 18 h after administration of the hybrid compound

discrepancies between both signatures are less likely to occur [117].

Nevertheless, it should be emphasized that each type of signal (radioactive or optical) must be explored with dedicated, single-modality imaging/detection devices. Ongoing efforts aim at developing multimodal devices capable of providing all the potential of intraoperative imaging, thereby achieving greater reliability in the surgical procedures [100]. In this scenario, a hybrid tracer integrating radioactivity and fluorescence in one signature constitutes the basis of a novel approach to combine the best of both diagnostic worlds for the SLN procedure in melanoma as well as in other malignancies [118].

Particular Issues for SLN Mapping in Melanoma

In-Transit, Aberrant, or Ectopic Lymph Nodes

Although the majority of melanomas scheduled for SLN biopsy drain to a predictable regional lymphatic basins based on localization of the primary tumor, drainage to lymph nodes outside the expected lymphatic basins may be observed. Any lymph node visualized along the lymphatic channel between the primary localization and a regional lymphatic basin is called in-transit, interval, aberrant, or ectopic (depending on the definitions set by different investigators) lymph node and must be considered as a SLN regardless of its localization.

The presence of such nodes has been described especially in the parascapular and supraclavicular spaces (lying between muscles or, even more frequently, in the subcutaneous fat); the para-aortic, paravertebral, and retroperitoneal regions; the intercostal zones; the internal mammary lymph node chain (epitrochlear, popliteal); and even the skull. Lymph nodes have been reported in these areas between 6% and 12% of the cases, and the probability of metastatic involvement of these nodes is similar to that of the SLN in areas of classical drainage. So, melanomas in the upper extremities and the trunk are more likely to present aberrant nodes. On the other hand, tumors localized in the head and neck and the genital area show a lower rate of these nodes [51, 54, 119].

The need to identify the SLNs prior to surgery is as important as identifying and resecting them

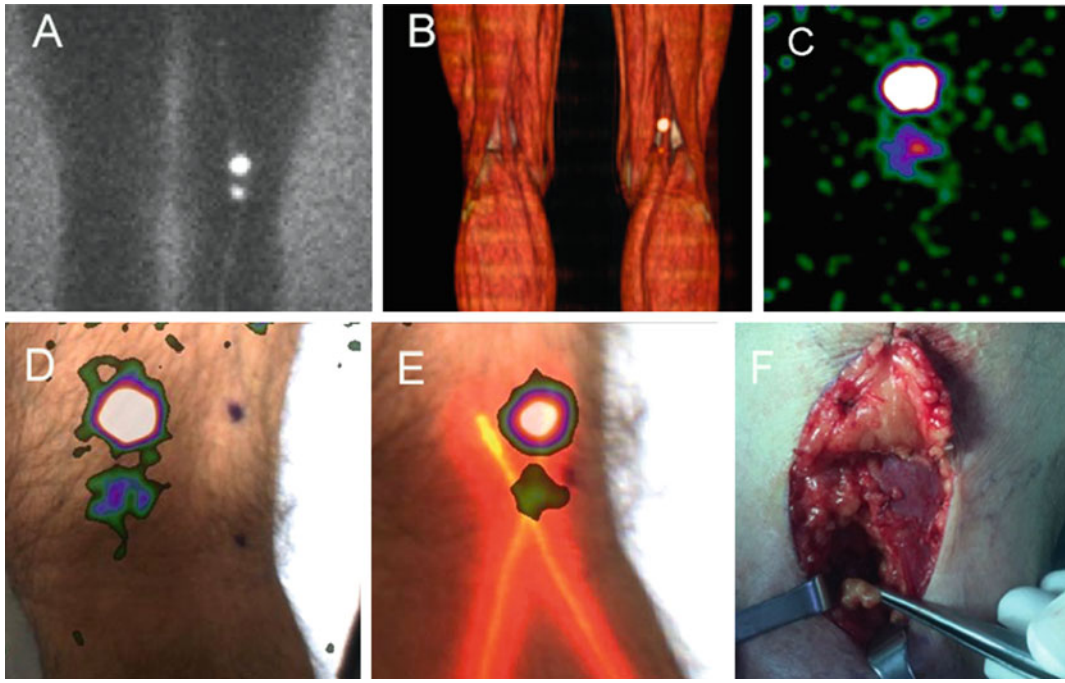

Fig. 11 Right popliteal sentinel nodes depicted on planar image (**a**), 3D reconstruction from SPECT/CT data (**b**), portable gamma camera (**c**), hybrid (gamma + optic) camera (**d**). During surgery, additional images were acquired to precisely depict the nodes' situation (**e**). Surgical removal (in the pincette) of one of these nodes (**f**)

during surgery. An in-transit SLN may indicate involvement in the lymphatic basin, but may also be the unique site with metastatic cells. Thus, in most studies the incidence of metastasis in the in-transit/aberrant SLN is quite similar, in the 14–22% range. In a review of 900 melanoma patients, Ortín-Pérez et al. reported that 19.5% of in-transit/aberrant lymph nodes bore metastasis; 11 out of 15 of these patients also presented metastatic involvement of at least one SLN in the expected lymphatic region, while the remaining 4 patients only had metastasis in the in-transit/aberrant SLN [120]. Several other studies have resulted in similar values, thus reinforcing the concept that it is necessary to identify and harvest these particular in-transit/aberrant lymph nodes since they may constitute the only focus of metastasis [121].

In this regard, the use of SPECT/CT and intraoperative imaging may refine the procedure, especially in these difficult to found lymph nodes, with the aid of precise anatomical localization (SPECT/CT) and intraoperative checking of a definite area of the body with a portable gamma camera. The use of this technology results in increased surgeon's confidence, as well as in improved preoperative planning and better staging [122–125] (Fig. 11).

Head and Neck Location

About 15–35% of primary melanomas are located in the head and neck and are associated with a worse prognosis. Several authors have demonstrated a greater rate of recurrence in this area after a negative SLN biopsy compared to other areas of the body [126]. SLN biopsy of tumors in the head and neck region is especially challenging both because of the great number of lymph nodes (>300) and because of the huge network of lymphatic vessels that contributes to the complexity of lymphatic drainage in this area, with melanomas often draining to multiple, aberrant, and bilateral lymph nodes [127].

Furthermore, during lymphoscintigraphy the radioactivity remaining at the site of injection may mask a SLN on planar imaging, and it is often hard to distinguish SLNs from second-echelon nodes. In a review of several studies comprising more than 3,400 head and neck melanomas, the sensitivity of SLN biopsy was reported to be in the range 80–100%, with a false-negative rate as high as 20% [128]. Another study with 246 patients demonstrated that melanomas located in the facial region presented a better prognosis than those in the skull, ears, or cervical region, even for thin tumors (Breslow index <1 mm). The presence of ulceration, elevated Clark level (IV/V), and young age were the strongest predictive factors to determine the presence of cervical lymph node metastasis [129].

A recent study of 152 patients with melanomas located in head or neck area compared the results of the actual presurgical lymphoscintigraphy with the expected drainage pattern derived from a predictive software based on a database of 929 patients. The concordance was complete in 80.4% of patients for all SLNs and partial in 12.2% of patients. Discrepancy was observed in 7.4% of patients. The authors concluded that lymphoscintigraphy provided an added value to personalize lymphatic mapping in each individual patient and that this imaging step is crucial to accurately detect the SLNs in head and neck melanomas, especially when faced with aberrant lymphatic drainage in unpredictable locations [130].

As mentioned above in this chapter, SPECT/CT imaging is currently considered to be mandatory for better assessing and depicting SLN located in the head and neck area. Zender et al. showed that the SPECT/CT findings led to a change in the management in 57% of patients with melanoma and suspected drainage to the parotid region. SPECT/CT precisely discriminated between parotid zone and cervical level II lymph nodes and visualized additional nodes, not visualized on planar lymphoscintigraphy, in 28% of the cases [131]. Taking into consideration that nearly 25% of cases in the head and neck area may show metastasis outside clinically predicted neck levels, it is necessary to ascertain these sites of potential involvement with the best approach, namely, to investigate the lymphatic drainage patterns using dynamic planar lymphoscintigraphy and SPECT/CT [132].

A more refined technique may include, if available, preoperative SPECT/CT, intraoperative imaging using portable devices, and hybrid tracer (multimodal approach). One study including 25 patients with head and neck malignancies demonstrated that the use of conventional lymphoscintigraphy, SPECT/CT, and the additional help of a portable gamma camera in one case were able to display 67 SLNs (55 visualized on planar images, 11 additional on SPECT/CT, and 1 additional with the portable gamma camera). Intraoperatively, 89 SLNs were resected (67 + 22 additional nodes). Twelve out of the 22 additional SLNs were located close to the injection site. The other ten additional SLNs were found by post-resection imaging with the portable gamma camera of the excision SLN site. Thus, the combined approach seems to be useful especially for tumors located approximately in the expected area of lymphatic drainage [133] (Fig. 12).

Cost-Effectiveness of SLN Biopsy in Melanoma

Currently, SLN biopsy is recommended in cases of primary melanoma without evidence of regional or distant metastasis when the risk of lymphatic node metastasis is at least 10% (AJCC stages IB and IIA, B, and C in the 7th edition). Selection criteria have not yet been standardized for cases with a Breslow thickness of less than 0.75 mm, which nevertheless account for 60–70% of melanomas diagnosed in large hospitals [134].

There is scarcity of data about the overall costs of this procedure in melanoma patients. On the other hand, the different items comprised in the whole procedure are not equally considered between different analyses. Thus, in a very complete study recently performed in 99 patients treated at a Spanish hospital, the cost of the procedure was estimated between € 9,486 and € 10,471. This analysis included an approach with radiotracer only, a major outpatient surgery operating room with only 1-day hospitalization in case of no

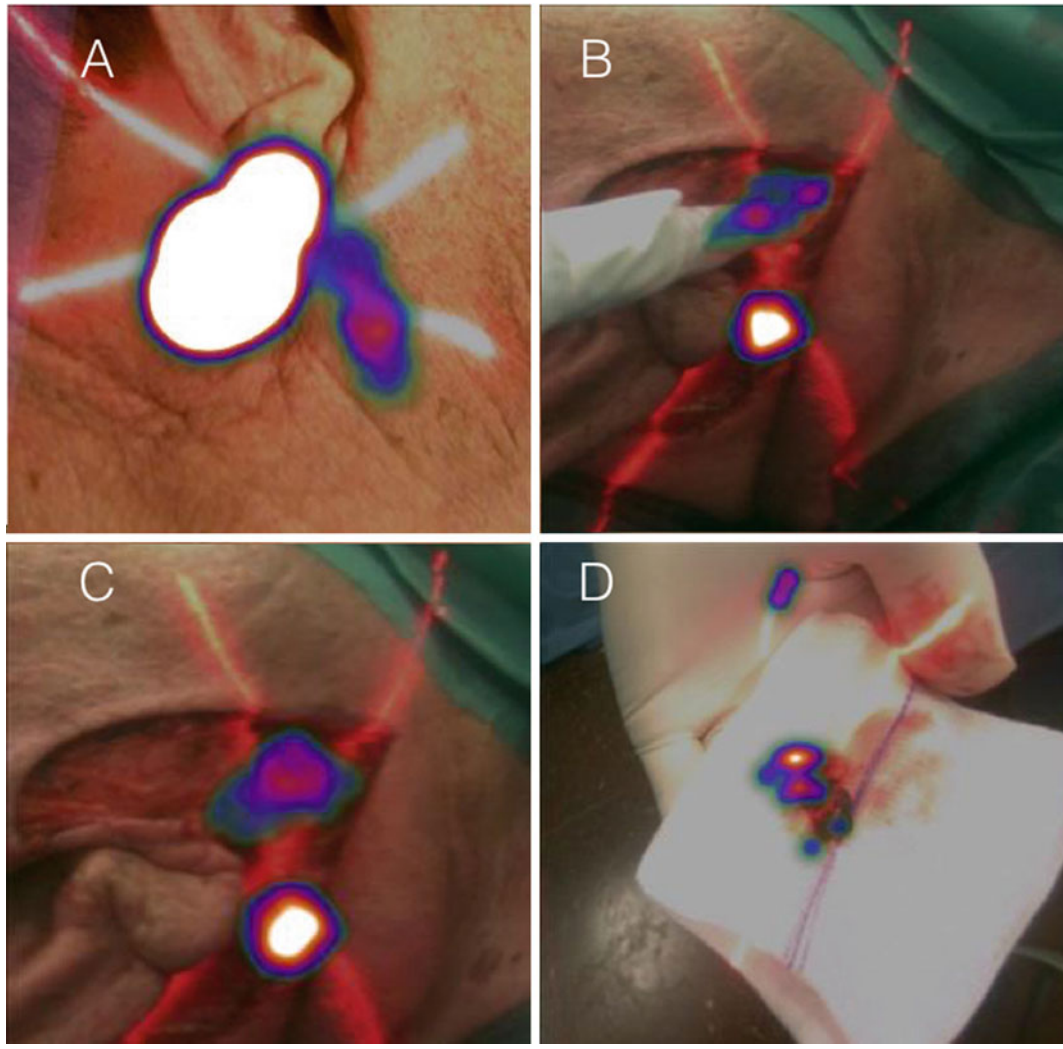

Fig. 12 Surgical approach with a portable hybrid camera. A sentinel node near the ear's injection site is depicted (**a**) and assessed with the use of gamma probe (**b**). Surgical localization and identification of the sentinel node (**c**) and "ex vivo" checking with the hybrid camera (**d**)

complications and a thorough pathological analysis. These costs are similar of those calculated in a US institution, ranging from $10,000 to $15,000 (€ 7,600–11,400) [135]. Almazán-Fernandez et al. calculated the costs of SLN biopsy in cutaneous melanoma, but they only included 1 day of hospitalization and re-excision of the melanoma scar with margins of 2 cm. The general costs reached € 682, but the authors did not take into account histopathologic analysis [136]. Similar findings were reported in an Australian study, with an estimated cost of € 1,900 [137].

Thus, it can be assumed that histologic processing increases to a great extent the overall costs of the SLN procedure; therefore, the indication criteria for SLN biopsy turn out to be crucial, especially in the patients with low risk for metastasis. On the other hand, the refinement of the procedure can save extra costs associated with extended surgery. In this regard, Stoffels et al. compared a cohort of patients in whom only planar lymphoscintigraphy was performed with a cohort of patients in whom SPECT/CT imaging was added. The fixed costs per SLN biopsy concerning infrastructure and

consumables were € 71 per procedure, while SPECT/CT imaging in that hospital represents an added cost of € 116. Obviously, the costs for SLN biopsy with either local or general anesthesia differed, with lesser costs in the group with planar imaging only (as SPECT/CT frequently visualized more deep-seated SLNs that required general anesthesia). However, a more detailed analysis demonstrated a cost saving of € 1,045 in the hospital stay expenses between patients with local or general anesthesia. Moreover, the addition of SPECT/CT imaging in the SLN biopsy group with local anesthesia saved about € 1,069 per procedure, and its use resulted in the upstaging of a proportion of patients, by detecting more metastatic SLNs. Costs for preoperative imaging increased, of course, but costs of surgery and hospital stay decreased remarkably. The economic study demonstrated that the routine use of preoperative SPECT/CT reduces the total cost of SLN biopsy per patient by € 710 [138].

In the use of hybrid tracers, the potential advantages also need to be weighed against the complexity of implementing this approach in the clinical routine and its associated costs. The cost of ICG vial is relatively cheap (about € 85 per vial). However, the highest additional costs lie in purchasing a NIR fluorescence camera system, with commercial values that range from several thousand € to hundreds of thousand €, depending on the system chosen [116].

Role of PET/CT Imaging for Radioguided Surgery

Many patients with stage I/II melanoma have no metastasis, or, if present, they are usually minimal-extent metastases. In contrast to the SLN biopsy, where diagnostic sensitivity is enhanced to the microscopic level by histologic analysis (and even to submicroscopic level by molecular analysis), the diagnostic performance of [^{18}F]FDG PET/CT in patients with micrometastasis is impaired by the relatively limited spatial resolution of imaging [139]. Indeed, the limited diagnostic value of [^{18}F]FDG PET/CT for assessing the presence of metastasis in patients with a clinically localized melanoma has been reported [140]. Some authors, however, consider that [^{18}F]FDG PET/CT can be useful in certain clinical situations where the risk of metastasis is increased (e.g., Breslow thickness >4 mm, presence of ulceration, and high mitotic index) [52].

Kell et al. assessed the preoperative value of [^{18}F]FDG PET/CT in patients with melanoma scheduled for SLN biopsy. Out of the initial 83 patients in their series, 37 were selected to undergo a preoperative [^{18}F]FDG PET/CT scan because of higher risk for metastasis. SLN biopsy demonstrated metastatic involvement in 9 of these 37 patients (24%), but only 2/9 patients had a positive [^{18}F]FDG PET/CT scan (22% positive predictive value). These results do not support the clinical validity of [^{18}F]FDG PET/CT in this population, as SLN biopsy was a more sensitive staging modality for the detection of lymph node metastasis [141]. After reviewing their findings in 30 patients with melanomas with Breslow thickness >1 mm, Constantinidou et al. observed that performing an [^{18}F]FDG PET/CT after a positive SLN biopsy did not alter the clinical management of melanoma [142]. Klode et al. reported similar findings in 61 melanoma patients and concluded that SLN biopsy is much more sensitive than [^{18}F]FDG PET/CT for the assessment of lymph node metastasis [143]. In another study, a combination of [^{18}F]FDG PET/CT and ultrasound was preoperatively employed in 20 melanoma patients scheduled for SLN biopsy, in whom 52 SLNs were eventually harvested. Ultrasound correctly identified 2 out of the 17 tumor-bearing SLNs, none of which had been identified by PET/CT [144]. In a study reported by Barsky et al. in 149 patients with at least an intermediate-thickness melanoma, [^{18}F]FDG PET/CT was positive in 41/149 cases (27.5%). Invasive procedures were subsequently performed in 18 of these 41 cases, but metastatic involvement was confirmed in only six patients; therefore, in the experience of these authors, [^{18}F]FDG PET/CT had a quite high rate of false-positive results, resulting in a low positive predictive value [145].

Although [^{18}F]FDG PET is not currently recommended as a routine investigation for staging patients with positive SLN biopsy, the technique

could be justified in patients with palpable lymph node before resection, due to its potential impact on decision-making regarding subsequent clinical management. In 70 melanoma patients with palpable lymph nodes but no clinical evidence of distant metastasis, Aukema et al. found that [^{18}F]FDG PET/CT led to change the indication for regional lymphadenectomy in 37% of the patients. The overall sensitivity of PET/CT in this subgroup of patients was 87% and specificity of 98% in the detection of additional metastases in melanoma patients with palpable lymph nodes [146].

One potential application for the intraoperative use of systemically administered [^{18}F]FDG in combination with a handheld PET detection probe has been proposed and reported in the clinical management of selected cases of metastatic melanoma [147]. Although the concept is in principle attractive, further evaluation of this approach is needed (especially regarding PET probes). A more practical approach is the intralesional administration of a radioactive or hybrid tracer in order to enable resection of isolated melanoma metastases aided by the use of a conventional handheld gamma probe (i.e., ROLL-like approach) after the PET/CT scan [148, 149].

Radioguided Surgery for Head and Neck Cancer

49

Federica Orsini, Erinda Puta, Renato A. Valdés Olmos, Sergi Vidal-Sicart, Francesco Giammarile, and Giuliano Mariani

Abstract

Tumor status of locoregional lymph nodes is an important prognostic factor in patients with squamous cells carcinomas of the head and neck (HNSCC). Sentinel lymph node biopsy (SLNB) approach meets the expectations of accurately staging the lymph node status of these patients. The procedure consists of preoperative peritumoral injection of the tracer followed by lymphoscintigraphy using planar and single photon emission tomography/computed tomography (SPECT/CT) imaging. Based on the preoperative lymphoscintigraphy findings, the position of the sentinel lymph node (SLN) is marked on the skin. Intraoperative detection of the SLN is guided by combination of a portable handheld gamma ray detection probe (radionuclide detection) and dissection/harvesting of the radioactive lymph node(s). After surgical removal, the SLN is subjected to meticulous histopathological examination.

The Clinical Problem

Tumor status of locoregional lymph nodes is an important prognostic factor in patients with squamous cells carcinomas of the head and neck (HNSCC). In these patients a locoregional metastatic sentinel lymph node is an unfavorable prognostic factor [1], and cervical node dissection has a potential curative role [2]. The management of clinically node-negative patients remains controversial, because the probability of finding an occult metastasis is approximately 20% [3]. Furthermore, there is still debate about performing prophylactic lymph neck node dissection versus a wait-and-see approach [4].

Preoperative evaluation of patients with newly diagnosed HNSCC includes physical examination, ultrasound (US) examination (possibly with US-guided fine-needle aspiration cytology [5]),

and other radiology-based imaging procedures such as CT and MRI [6]; occasionally, PET/CT with [^{18}F]FDG is also performed, depending on specific indications[7, 8]. However, all these modalities have suboptimal sensitivity for the detection of microscopic lymph node involvement; on the other hand, elective lymph node dissection is burdened with important morbidity. These considerations justify the notion that sentinel lymph node biopsy (SLNB) has the potential of enabling accurate selection of patients for elective lymph node dissection and of accurately staging the clinical and radiological N0-neck in patients with head and neck cancer.

Evaluation of the pattern of lymph drainage in the head and neck region is cumbersome due both to anatomic complexity and to unpredictable routes of lymphatic drainage. The neck contains over 300 lymph nodes and it is necessary to determine the nodes at risk of metastasis in individual patients for all head and neck cancers.

The patterns of lymph drainage from the oral cavity, oropharynx, larynx, and hypopharynx exhibit numerous intraindividual variations, even from the same primary tumor site. Unexpected aberrant lymphatic drainage can be found in 20–30% of patients with clinically negative or positive necks, a feature that has a definite impact on treatment planning on an individual patient's basis [9–12].

Lymph drainage from a primary tumor located in the midline may be directed to either side; furthermore, contralateral drainage is often seen even in well-lateralized malignancies of the tongue or floor of the mouth [13]. Although lymph drainage to submandibular nodes is expected from the anterior floor of the mouth and lingual apex, bilateral drainage to higher-level lymph nodes and to the middle jugular chains is not infrequently observed [14].

Thus, due to individual patient variability of lymphatic drainage, selective neck dissection limited to those nodal levels at highest risk has been shown to have 15–20% of "skip metastases" that have bypassed the expected first nodal basin [15]. It is conceivable that, similar to breast cancer and cutaneous melanoma), the SLNB approach can accurately stage the lymph node status of patients with head and neck cancer.

The SLNB technique has been investigated mostly for those head and neck cancers whose anatomic location allows direct and easy access to the tumor for injection of the radiocolloid (or of other lymphatic mapping agents). For this reason the procedure has already been sufficiently standardized in patients with oral squamous cell carcinoma (OSCC) [16], while it is still experimental in head and neck cancers arising at other sites.

In the last decade, the technique has undergone extensive validation against the gold-standard elective node dissection, for tumors located in the oral cavity and accessible subsites of the oropharynx. In 2013 SLNB in early oral cancer was recognized by the National Comprehensive Cancer Network (NCCN). NCCN Clinical Practice Guidelines in Oncology of Head and Neck Cancers now include the following statement: "Sentinel lymph node biopsy is an alternative to elective neck dissection for the identification of occult cervical metastasis in patients with early (T1 or T2) oral cavity carcinoma in centers where experience for this procedure is available" [8].

Current indications for SLNB include clinical T1 or T2 node-negative oral and selected oropharyngeal squamous cell carcinomas, where it may be considered a valid alternative to elective node dissection. Clinically T1 or T2 patients includes resectable tumors with size <4 cm in maximum diameter. In fact, in case of larger tumors, it is difficult to perform tracer injection all around the tumor; furthermore, large tumors tend to drain to multiple lymphatic basins and in the majority of patients require a neck dissection for access to the primary tumor or for defect reconstruction [17].

The clinically negative neck is defined by physical examination and clinical imaging by CT, contrast-enhanced MRI, US-guided fine-needle aspiration cytology, and/or [^{18}F]FDG PET/CT.

The first and most frequent target for SLNB is staging the ipsilateral clinically node-negative neck in patients with a unilateral primary tumor. A second target is the assessment of bilateral clinically node-negative necks in primary tumors close to, or

crossing, the midline. The third indication is for assessment of the contralateral clinically node-negative neck in primary tumors close to the midline with an ipsilateral clinically node-positive neck, in order to decide whether these patients need bilateral neck dissections, or an ipsilateral neck dissection and contralateral SLNB only. Patients should also be fit enough preoperatively to withstand a neck dissection.

Exclusion criteria include patients who have received prior radiation or surgical treatment to the neck. These patients are generally excluded from SLNB protocols on the assumption that the previous intervention can distort the normal lymphatic pathways and give rise to unexpected patterns of metastasis; nevertheless, these patients should be evaluated on an individual basis, taking into account the time window elapsed between such forms of treatment and the SLNB procedure. In pregnant women, the urgency and the necessity for staging the neck should be discussed. However, SLNB protocols should be modified in pregnant patients to minimize the risks of radiation exposure and blue-dye injections. SLNB can be performed in lactating women, but it is advised that breast-feeding be discontinued for 24 h following the procedure.

The routine SLNB procedure consists of preoperative peritumoral injection of the tracer (such as ^{99m}Tc-nanocolloid of albumin or similar radiopharmaceutical; see below) followed by lymphoscintigraphy using planar and single photon emission tomography/computed tomography (SPECT/CT) imaging. Based on the preoperative lymphoscintigraphy findings, the position of the SLN is marked on the skin. SLNB is performed under general anesthesia, and intraoperative detection of the SLN is guided by combination of a portable handheld gamma ray detection probe (radionuclide detection) and dissection/harvesting of the radioactive lymph node(s). Ideally, one or more radioactive ("hot") SLNs are identified and excised. After surgical removal, the SLN is subjected to meticulous histopathological examination using step serial sectioning and immunohistochemistry.

Lymphatic Drainage and Lymph Node Anatomy of the Neck

Surgical anatomy of the head and neck region is complex due to the small size of vital organs and to the close relation among different tissues. The lymph nodes in the neck are generally subdivided into specific anatomic subsites and grouped into seven levels on each side of the neck (Fig. 1), according to the so-called Robbins' Classification [18], incorporated into the AJCC-UICC TNM staging system [19].

Submental (sublevel I_A) and submandibular (sublevel I_B) lymph nodes are included in level I. Upper jugular nodes extend from the inferior border of the hyoid bone to the base of the skull and are classified as level II; in relation to the vertical plane defined by posterior surface of the submandibular gland, the lymph nodes located anteriorly constitute sublevel II_A, and the nodes located posteriorly correspond to sublevel II_B. Level III includes the middle jugular nodes (from hyoid bone up to the inferior border of the cricoid cartilage), and level IV includes lower jugular nodes (from the inferior border of the cricoid cartilage to the clavicle). The posterior border of regions II, III, and IV is the posterior border of the sternocleidomastoid muscle. Level V nodes are those located posteriorly to the posterior border of the sternocleidomastoid muscle. This latter group is further divided into sublevels V_A including the spinal accessory nodes, whereas sublevel V_B includes the nodes following the transverse cervical vessels and the supraclavicular nodes. Level VI contains the pretracheal and paratracheal nodes, the precricoid node, and the perithyroidal nodes including the lymph nodes along the recurrent laryngeal nerves. Finally, level VII includes the superior mediastinal lymph nodes.

Radiopharmaceuticals

A variety of colloidal and soluble tracers have been used for imaging the pattern of lymph flow. It is commonly held that radiocolloids are taken up by

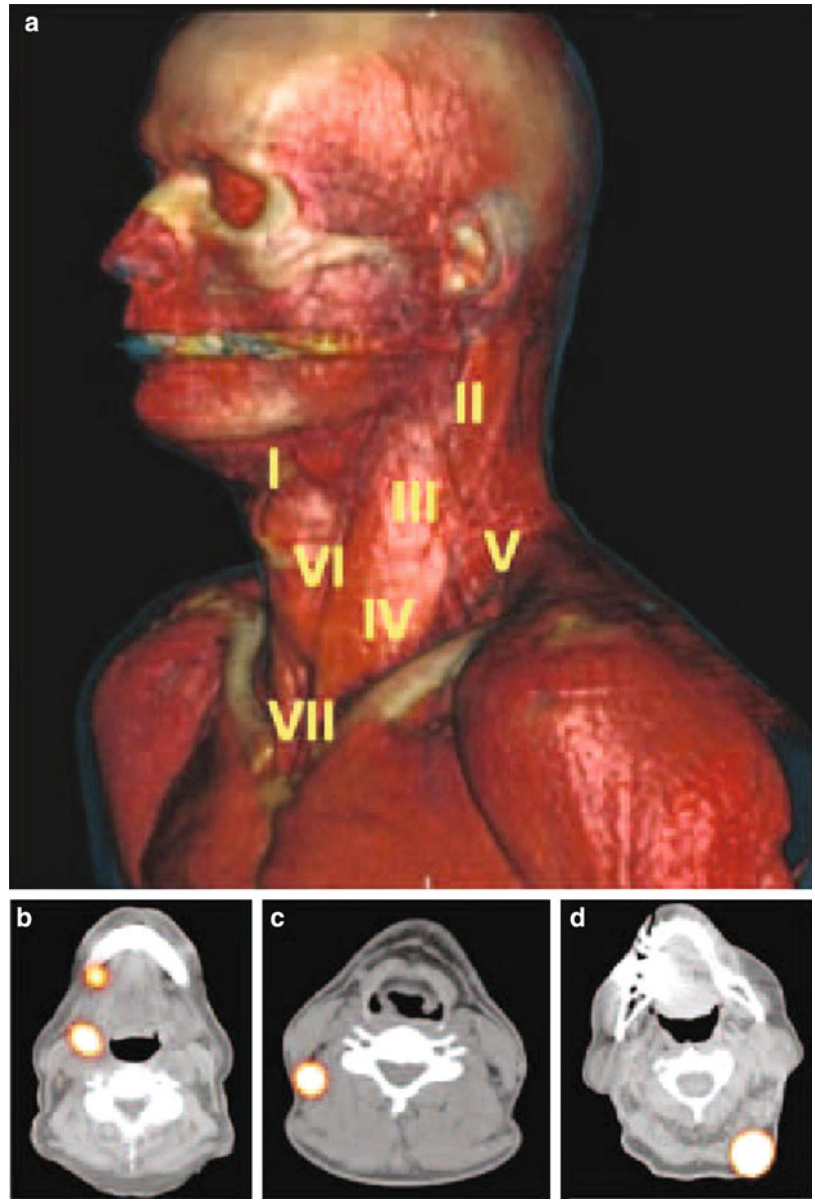

Fig. 1 Lymph node levels of the neck. (**a**) Volume rendering of the head and neck showing the anatomical levels of the neck according to Robbins. (**b**–**d**) Fused axial SPECT/CT images showing examples of SLNs located in right levels I and II (**b**), right level III (**c**), and level V of the *left side* of the neck (**d**) (Reproduced with permission from Valdés Olmos et al. [14])

macrophages in lymph nodes, whereas the transit of macromolecules through lymph nodes is delayed simply because of their large molecular size [14, 16].

The nuclear medicine physicians' experience and commercial availability of the various agents affect the choice of radiopharmaceutical. ^{99m}Tc-albumin nanocolloid (that has a quite narrow range of particle size, with over 90% of the particles being smaller than 80 nm) and ^{99m}Tc-sulfur colloid (with a wide range of particle size between about 20 and 400 nm) are commercially available and widely employed in Europe and in the USA, respectively. These tracers migrate to the SLN within minutes after interstitial injection, yet their

prolonged retention in lymph nodes allows surgery to take place even the following day [14, 16].

Recently a new tracer, ^{99m}Tc-tilmanocept, has been approved for SLNB in OSCC patients, both by the by US Food and Drug Administration (FDA) and by the European Medicines Agency (EMA). Its smaller particle size and specific targeting of mannose receptors (CD206) located on cells within lymph nodes result in rapid clearance, reduced or no drainage to second-echelon lymph nodes, and greater SLN retention, thus enabling improved SLN detection both preoperatively and intraoperatively with respect to the conventional radiocolloids. In a multicenter validation study, all SLNs could be detected and no false-negative results were reported in 20 patients with floor of mouth cancer. Nevertheless, the actual additional value of this new technique has still to be investigated in larger and comparative studies [20–22].

As an alternative to the radioactive label, near-infrared fluorescent tracers (e.g., indocyanine green – ICG) have been used that are potentially helpful for SLNB [23–25]; moreover, the combination of such fluorescent tracers with common ^{99m}Tc-labeled radiocolloids is an attractive option for improving the SLN detection rate in patients with head and neck malignancies [26–28].

Injection

Small syringes with minimal dead space are recommended; otherwise 0.1 mL of air may be drawn into the syringe behind the radiocolloid suspension to ensure complete administration. A 25- or 27-gauge needle should be used. The total activity to be injected may vary (from 15 to 120 MBq among different studies), depending on the size and location of the primary tumor. However, the total injected activity should be adjusted according to the timing of lymphoscintigraphy with respect to surgery. Greater activities are required for a 2-day protocol, in order to ensure the remaining activity exceeds 10 MBq at the time of surgery.

Small volumes of 0.1–0.2 mL per aliquot injected at a short distance from primary lesions are needed to avoid masking of SNs in the vicinity of the injection site and are recommended also to minimize contamination due to the resistance of the tongue tissue. Tracer should be injected at 0.1–0.5 cm from the tumor or scar margin. The number of aliquots to be injected varies (two to four) according to the size and location of the lesion. The tracer should be administered on each side of the tumor/scar, keeping as a reference the orientation of the surgical scar [16].

The use of a local anesthetic for topical application (10% xylocaine spray) a few minutes before radiocolloid injection is recommended for oral cavity tumors.

The most frequent pitfall is skin contamination due to spillage of the lymphatic mapping agent either during injection and/or immediately thereafter (e.g., during washing of the mouth to remove excess radioactivity possibly sipped out at the injection site). The hot spots due to contamination may be confused with sentinel lymph nodes in the vicinity of the tumor, thus leading to unnecessary intraoperative pursuit. In these cases skin decontamination is mandatory. Complementary SPECT/CT may also be helpful in detecting these artifacts, as mentioned above.

Preoperative Lymphoscintigraphy

Preoperative lymphoscintigraphy should be performed using a large-field-of-view gamma camera to assess the drainage of injected radiotracer via the lymphatic capillaries to the larger collector lymphatics until it either passes through, or is retained within, the regional lymph nodes. Accurate preoperative localization and cutaneous marking of the skin projection of SLN location correlate well with the precision of the surgical procedure.

Dynamic acquisition for 20–30 min starting immediately after radiotracer injection will show the drainage pattern and help to differentiate between SLNs (which can appear very early following injection) and second-echelon lymph nodes.

Static images in the anterior and lateral projections are acquired to localize the nodes in a pseudo-tridimensional manner. If hot nodes are not clearly depicted, static imaging can be repeated later, or even just before surgery. Alternatively, delayed images are useful to differentiate SNs from

second-echelon lymph nodes. Planar images provide a two-dimensional overview, and sentinel lymph nodes can be localized and marked on the patient's skin with the use of an external radioactive marker, such as a ^{57}Co-source pen.

SLNs are generally identified 15–60 min after radiotracer injection as one or more foci to which lymphatic drainage passes, and may be multiple, in one or several areas of the neck, ipsilateral, and/or contralateral to the primary tumor [14, 16]. Delayed planar images (2–4 h postinjection) are only considered when tumors are located in the midline (including those located in the mobile portion of the tongue or laterally in the floor of mouth), or if no SLN can clearly be identified during early imaging [29]. The SLNs so identified are marked on the skin of the neck on the basis of lateral views, in order to reproduce the patient's position during surgery.

Failure to detect SLNs may be related to an incorrect injection technique or close proximity of SLNs to the injection site (e.g., floor of mouth tumors). In addition, massive metastasis in lymph nodes may block and reroute lymphatic drainage, thus causing non-visualization of the true SLNs and possible visualization of alternative routes of lymphatic drainage. Repeat radiocolloid injection and imaging may be considered in case of totally absent visualization of lymph nodes; however, proceeding to neck dissection is preferred in these cases in order to avoid a false-negative SLNB.

Individual lymphatic mapping by lymphoscintigraphy has been reported to detect "in-transit" lymph nodes, i.e., SLNs lying between the primary tumor and the regional lymph basin [30]. These have been described in the context of malignant melanoma, but to date there have been no reports of in-transit SLNs in OSCC.

Contribution of SPECT/CT

SPECT/CT can optimize sentinel lymph node visualization and localization in the head and neck region and is therefore crucial for adequate lymphatic mapping and sentinel lymph node localization in head and neck malignancies [31] (see Fig. 2).

A number of studies have shown the added values of SPECT/CT over planar imaging; these include:

- Greater number and location of visualized hot spots and identification of SLNs missed on planar imaging. SPECT/CT has visualized one or more additional SLNs in more than half of the studies. These additional sentinel lymph nodes found on SPECT/CT imaging might be tumor positive. Especially lymph nodes adjacent to the injection site are more frequently detected by SPECT/CT, while they are frequently missed on planar imaging [32, 33]. In a recent study, SPECT/CT detected additional SLNs in 9 out of 42 patients (21.5%); in particular, a total of 16 (13.44%) additional SLNs, 1 of them in the sublingual space, were detected using SPECT/CT [34].
- Exclusion of ambiguous SLNs. Non-nodal radioactivity accumulation (radiocolloid leakage or contamination) can be more easily identified on the basis of SPECT/CT imaging [35].
- Better anatomic localization in 30–47% of patients [36], thanks to the anatomical details provided with CT in hybrid images (Fig. 3). SPECT/CT appears to be very useful for exact anatomic localization of the sentinel lymph nodes. In the head and neck area, it is very important to identify the relation of sentinel lymph nodes to several vital vascular and neural structures, to be able to safely remove these lymph nodes. SPECT/CT can localize these sentinel nodes in relation to structures such as the mandible, parotid gland, jugular vein, and sternocleidomastoid muscle. SPECT/CT also shows whether the nodes are located superficially underneath the skin or hidden below other structures. SPECT/CT thus gives anatomical reference landmarks for planning the best surgical approach. The superior information on anatomic location provided by SPECT/CT frequently leads to adapt the surgical approach, with significant shortening of operation times.

Nevertheless, it must be emphasized that SPECT/CT imaging does not replace planar

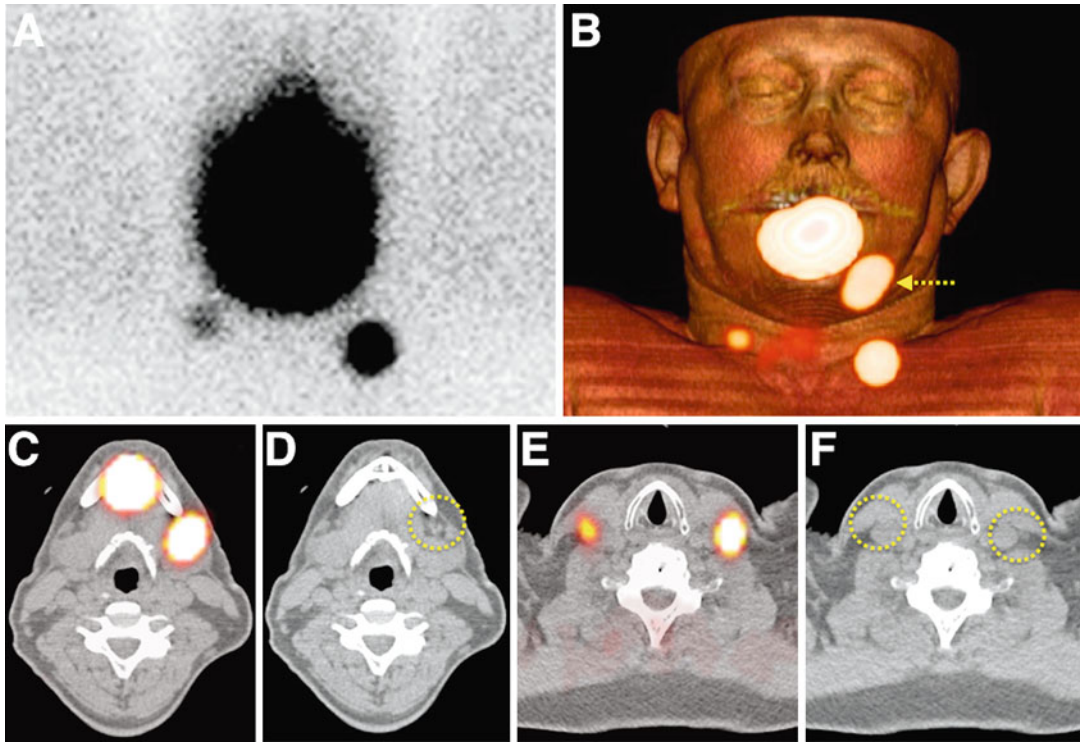

Fig. 2 In a patient with a tongue carcinoma bilateral neck drainage is observed on anterior planar scintigraphy (**a**). On SPECT/CT displayed with volume rendering (**b**), an additional sentinel node (*SN*) is also seen *left* from the injection site (*arrow*); on transversal SPECT/CT (**c**) and corresponding CT (**d**), this SN is localized in the submandibular area (*circle*). Two additional SNs are seen in the *lower part* of the neck (**e**, **f**)

lymphoscintigraphy. A thorough integration of SPECT/CT data together with planar imaging is necessary to identify radioactive lymph nodes as SLNs and to attribute to categorize the nodes as definite SLN, probable SLN, etc. for guidance during the intraoperative procedure.

Even if the benefits of SPECT/CT have not been universally accepted [37, 38], both planar and SPECT images demonstrate good or excellent inter- and intra-observer agreement for the detection/identification of SLNs [32].

A combination of the integration of modern high-end CT in hybrid scanners, the acquisition of high-resolution scans with or without contrast enhancement provides a precise anatomic reference of the SLNs displayed in 5-mm or even 2-mm slices on axial, coronal, sagittal views and maximum intensity projection, respectively. Additional volume rendering for 3-D may also be helpful. These improvements in preoperative lymphatic mapping translate into improved minimally invasive surgical approaches to SLNB that some authors have epitomized with the emblematic new paradigm of "see and open" as opposed to the former surgical attitude of "open and see" for radioguided surgery [34].

Surgical Procedure

Blue Dye

The use of blue dye in addition to radiolocalization with intraoperative gamma probe in head and neck mucosal cancer SLN surgery is optional and may be a useful adjunct to aid SLN localization and harvesting [14, 16].

The blue dye should be injected at the time of surgery, under general anesthesia. It takes

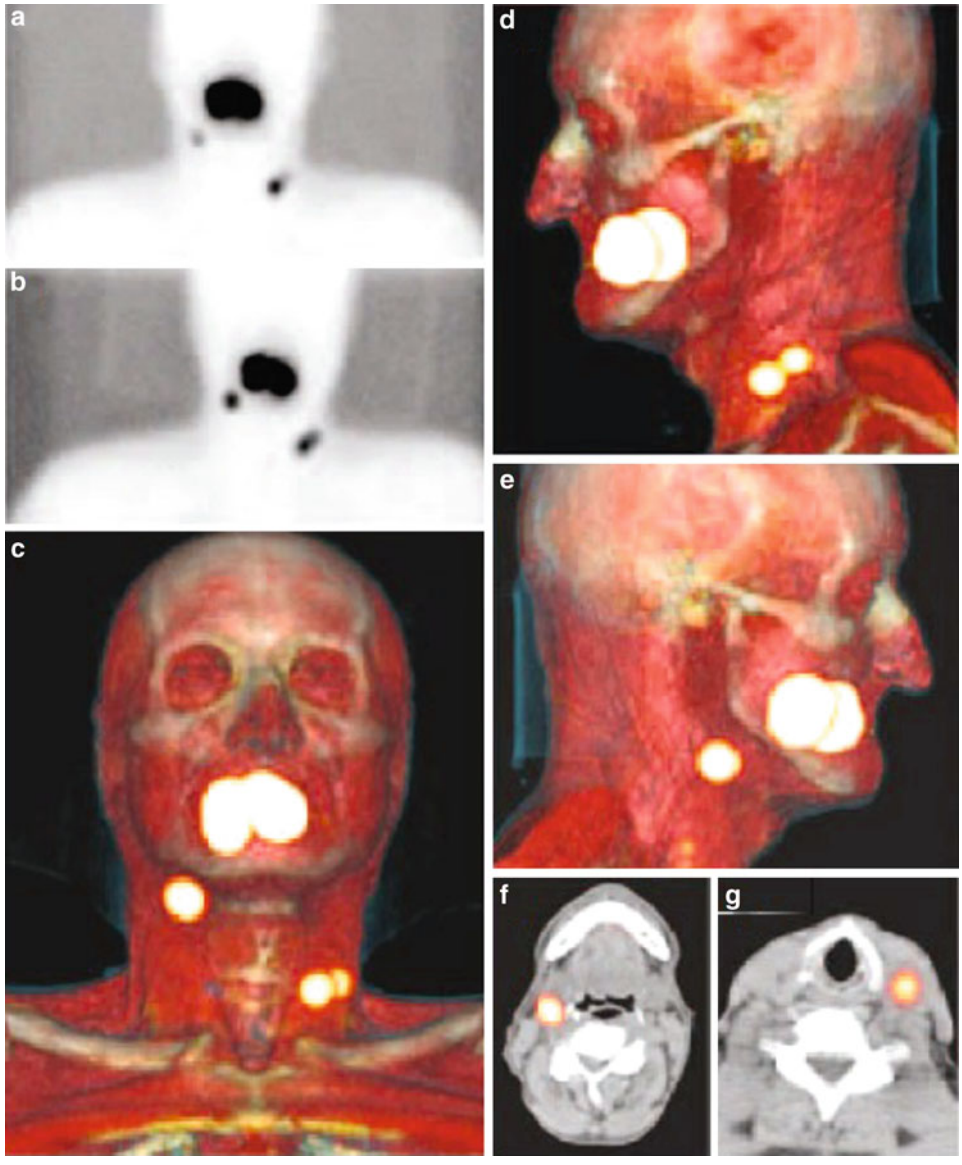

Fig. 3 An 81-year-old man with a T1 carcinoma on the *right side* of the lingual apex. After administration of 82 MBq ^{99m}Tc-nanocolloid in four injections into the mucosa around the tumor, early drainage to both sides of the neck is seen on anterior planar imaging (**a**), with subsequent increasing lymph node uptake on delayed images (**b**). Volume rendering (**c**–**e**) and axial SPECT/CT fusion images (**f**, **g**) show the SLNs in level II on the *right* and in level III on the *left*. All SLNs were tumor-free at histopathology (Reproduced with permission from Valdés et al. [14])

approximately 10–15 min for a significant amount of dye to travel from the injection site to the SLN. Following injection, blue dye drains to the SLNs via the same lymphatic pathways as radiocolloid, staining the channels, which can then be followed to the first-echelon nodes. It allows a direct visualization of SLNs.

Rarely, nonradioactive blue nodes may contain metastases in the absence of a tumor-positive radioactive node; two such SLNs were reported

in a series of 40 patients undergoing SLNB with both radiocolloid and blue-dye injections [39]. Therefore, blue dye may aid performance of SLNB, in terms of both technical success of the procedure and identification of subclinical nodal metastasis.

However, sentinel lymph nodes in the head and neck region are frequently not stained blue, due to the fast lymphatic migration of vital blue dyes. This limitation has led to the developmentof agents combining radiotracers with optical tracers.

Intraoperative Detection of Sentinel Lymph Nodes

A gamma ray detection handheld probe is routinely used for intraoperative detection of the sentinel lymph nodes in the operative filed. The handheld probe is a radiation-sensitive detector that is able to provide a count rate from gamma rays. It is connected to an analyzer unit, which receives electrical signals from the radiation detector. The analyzer provides a response related to the detected count rate, usually by audible pitch or volume variation and by a visual display as a dial or digital count rate (counts per second, cps) [14, 16]. Thus, the gamma probe provides an acoustic signal when pointing straight toward the radioactive lymph node, thereby helping the surgeon in localizing the radioactive node.

To better plan the skin incision, the surgeon or the nuclear medicine physician should usually check the skin projection of the sentinel node with the gamma probe. Sometimes the SLNs can be masked due to the close proximity of the injected radiocolloid with the first draining LN (the so-called shine-through phenomenon), which leads to reduced detection, especially in OSCC with tumors of the floor of the mouth [40]. Also after removing sentinel nodes, the activity of the injection site can complicate measurement of the residual activity in the excision fossa. For these reasons removal of the primary cancer should be performed before the SLN search. Furthermore, deep sentinel lymph nodes can be difficult to detect because of tissue attenuation; in this case accurate preoperative imaging with SPECT/CT can help surgeons for skin incision.

To sort these problems out, a number of portable and handheld mini gamma cameras have recently been developed to provide direct intraoperative visualization of radioactive foci, with the purpose of improving detection of sentinel nodes in the head and neck region. With this new tool, the entire lymph node excision procedure in the head and neck area can be monitored. Sentinel lymph nodes located close to the injection can be visualized. Most importantly, by determining residual radioactivity after excision of the sentinel lymph nodes, the gamma camera can help to assess completeness of the procedure. Imaging after excision can also lead to identifying additional sentinel lymph nodes in more than 20% of the cases [41].

Recently the use of intraoperative gamma cameras has been combined with fluorescence cameras for synchronous sentinel node signal detection using the abovementioned hybrid tracer ^{99m}Tc-nanocolloid combined with indocyanine green. Furthermore, the technology of freehand SPECT (fhSPECT) was introduced for navigational surgery, combining the acoustic information of a conventional gamma probe and intraoperative 3-D images with real-time visualization of radiotracer distribution within the surgical field. This aspect is discussed in depth in ▶ Chap. 50, "Radioguided Surgery: Novel Applications."

SLN Pathology

Histopathologic analysis of sentinel lymph nodes is extremely effective and can detect the presence of micrometastasis (<2 mm) and clusters of several cells or even isolated tumor cells. By focusing on only a few lymph nodes, the pathologist can completely dissect and examine at 50–100 mm intervals each sentinel node. Sections may be stained with hematoxylin and eosin (H&E) for conventional light microscopy, and if such examination is negative, adjacent sections may be used for immunohistochemistry.

Other methodologies such as frozen sections, imprint cytology, and molecular analysis with

reverse transcriptase polymerase chain reaction (such as cytokeratin RT-PCR) have been described. However, in OSCC the performance of SLNB has been evaluated only in the context of relatively small observational cohort studies. The clinical role of these methods in the future remains uncertain due to the fact that, at present, the significance of finding micrometastasis and isolated tumor cells is unknown in OSCC [14].

Dosimetric Considerations for Patients and Medical Staff

The currently available data on radiation dosimetry burden are derived from the SLNB literature pertinent to breast cancer, where the absorbed doses to patients are determined to be extremely low; therefore, the radiation risk associated with this procedure is very low. While no specific data exist for OSCC, the radiopharmaceuticals and administered activity are identical, leading to the assumption that SLNB is a safe procedure from the radiation protection point of view also for OSCC patients. Monitoring of operating room personnel or staff in the pathology department for occupational exposure during the procedure is therefore unnecessary, and additional shielding is not required [16].

Accuracy of Radioguided Sentinel Lymph Node Biopsy

After the SLN concept in OSCC was validated in several studies in which all patients underwent elective neck dissection following SLNB, several prospective observational studies have been reported in the last decade, with overall 1 up to almost 7 years of follow-up. In 91–99% of the cases, the SLN was successfully harvested; a sensitivity of 86–95% and a negative predictive value of 88–100% has been reported. Nine to 37% of patients were upstaged [42–48]. These data confirm that SLNB is a reliable and safe technique for staging the clinically N0 neck in patients with T1 and T2 oral cancer.

Lower sensitivity rates are reported for floor of mouth cancers as compared to other oral subsites: 80–86% versus 94–97%, respectively. In these patients, the close spatial relation between the injection site and the SLN seems to result in a lower identification rate due to the "shine-through effect." In order to improve the accuracy, especially in floor of mouth cancer, new techniques have been developed (see ▶ Chap. 50, "Radioguided Surgery: Novel Applications" of this book).

Besides these results in terms of diagnostic accuracy, patients who underwent SLNB had significantly less shoulder morbidity, as assessed by subjective and objective measurements, than patients after elective neck dissection. Patients also experienced fewer complications and less skin numbness and had shorter incisions [49, 50].

Given the current evidence and costs of the SLNB procedure followed by nodal dissection in case of metastasis versus the "wait-and-see" approach in case of a tumor-free SLN, SLNB appears to be a cost-effective strategy for diagnosing and treating OSCC patients [51, 52]. Nevertheless, this procedure should still be considered within controlled clinical trials, since no definite conclusion has been reached on some important issues, including the possibility of omitting neck dissection in patients with a negative SLNB. In this regard, a European multicenter study that included 109 OSCC patients with positive SLNB showed additional (non-SLN) metastasis in 34.4% of the neck dissection specimens. Interestingly, the risk of non-SLN metastasis far from the adjacent lymphatic areas of the positive SLN was low (7.1%), thus suggesting that the information provided by the SLNB lymphatic neck dissections can be helpful to tailor the surgical approach to the patient on an individual basis [53].

SLNB in Head and Neck Melanoma (HNM)

SLNB status is the most important prognostic factor in melanoma, including melanoma located in the head and neck region. As in HNSCC, lymphatic drainage is often aberrant and can result in identification of the sentinel node in more than one nodal basin or in an atypical, bilateral, or contralateral nodal basin. In particular, in periauricular melanomas ipsilateral drainage to both

periparotid and level II of the neck is not infrequent [54]. Also, the existence of SLN clusters is not uncommon in the head and neck [55].

For this reason, SLNB has been established as the preferred staging modality to assess nodal involvement in patients with intermediate-thickness melanomas and selected thin and thick melanomas. In the evaluation and staging of the patient with melanoma, SLNB has shown increased sensitivity to detect regional metastases, limited morbidity compared with elective nodal dissection, and capability to identify patients who may benefit from further therapies such as a neck dissection or systemic adjuvant therapy. It also has the potential of halting the regional progression of metastatic disease.

Some authors have noted a wide range of false-negative rates (3.4–10.4%) for HNM SLNB as well as a decreased HNM SLN positive rate (10–15%) compared with cutaneous melanoma elsewhere (16–23%) [56, 57]. Others have reported SLN positive rates in HNM that are not significantly different from other cutaneous melanomas, although the small patient numbers in these studies limit their interpretation. A worse survival in HNM with positive SLN compared with other anatomic locations has also been suggested (Fig. 4).

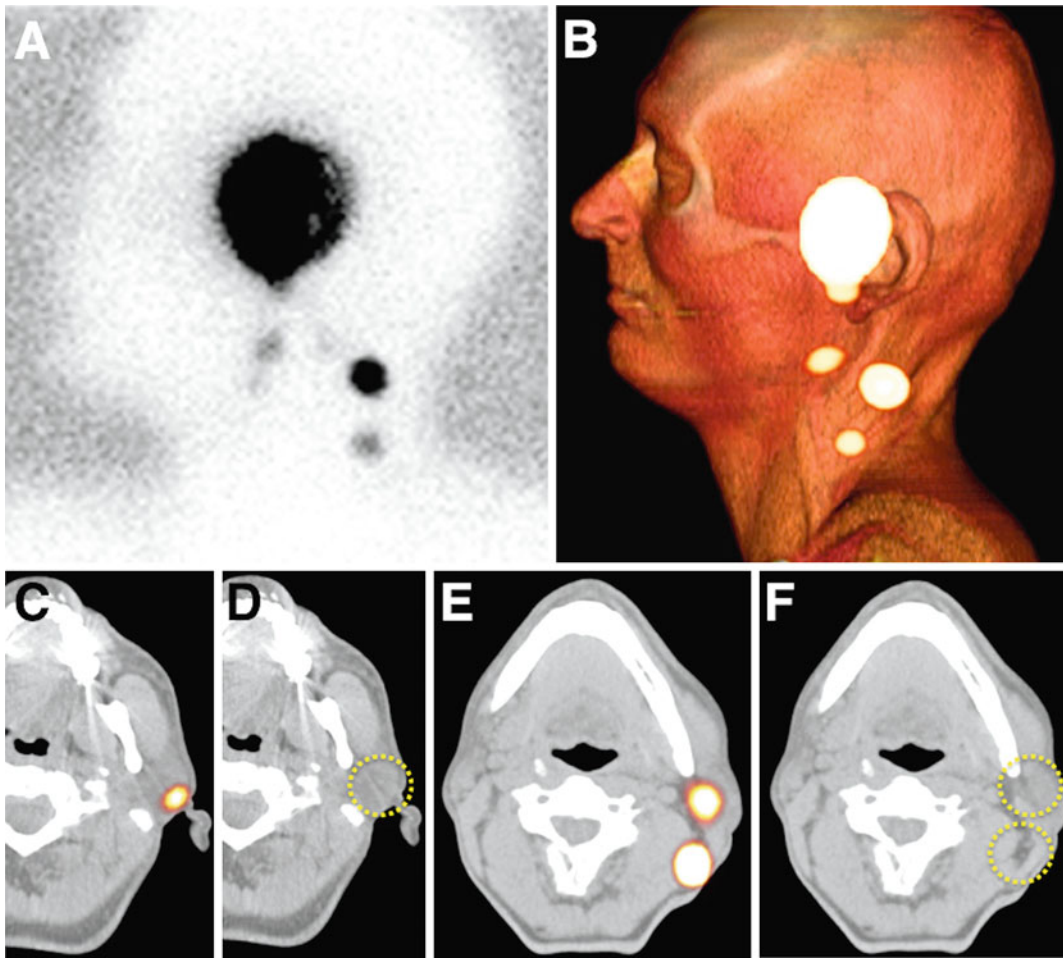

Fig. 4 In a patient with a left preauricular melanoma ipsilateral drainage to the neck is seen on lateral planar image (**a**). On SPECT/CT displayed with volume rendering (**b**), besides neck drainage, an additional sentinel node (*SN*) is also seen near the *lower part* of the injection site. On axial SPECT/CT (**c**, **d**), this SN is observed behind the *upper* pole of the parotid gland. Note that SPECT/CT (**e**, **f**) is able to localize another SN in the *lower* parotid pole and a SLN cluster in level II

Radioguided Surgery in Thyroid Cancer

SLNB in Thyroid Cancer

Differentiated thyroid cancer (DTC), which includes the papillary and follicular histologic patterns, is the most common endocrine malignancy and generally has a more favorable prognosis compared to other cancers (see ▶ Chap. 19, "Diagnostic Applications of Nuclear Medicine: Thyroid Tumors" of this book), regardless of the more or less aggressive surgical approach. For this reason, there is considerable variability when planning surgery regarding the decision to explore and remove the central and/or lateral compartment lymph nodes, considering that dissection of the central compartment can cause complications such as a damaged recurrent laryngeal nerve or permanent hypoparathyroidism.

The SLN concept in DTC has been developed as an alternative to elective lymph node dissection in patients with clinically node-negative disease, in the perspective of obtaining information about cervical lymph node involvement in patients undergoing thyroidectomy. Nevertheless, so far there is no definite evidence that SLNB is associated with long-term clinical and survival benefits.

However, several studies have shown that radioguided SLNB can easily be carried out and is feasible and safe [58], even if the actual clinical impact of this procedure is yet to be determined. The most widely used technique involves intranodular injection of 15–37 MBq ^{99m}Tc-nanocolloidal albumin in a volume of 0.1–0.5 mL, under ultrasound guidance (Fig. 5).

In principle, SLN mapping allows the identification of micrometastatic disease, thus potentially reducing patient morbidity by avoiding unnecessary de novo lymph node dissection [59]. However, the general prognostic significance of lymph node involvement in DTC is still debated.

One of the most important targets of SLNB in this scenario could be the selection of those patients with locally advanced thyroid disease at

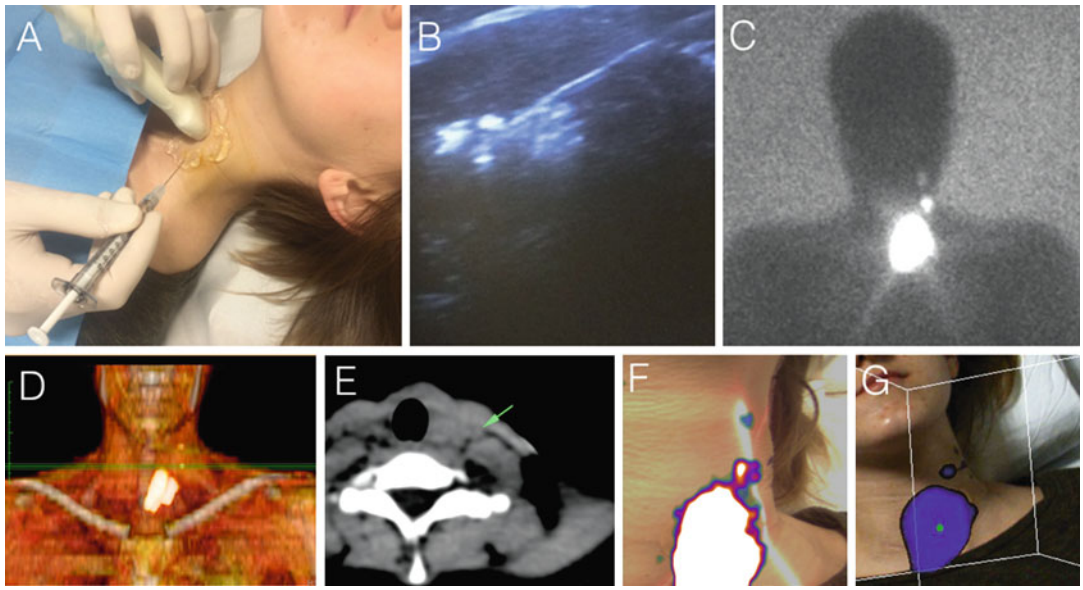

Fig. 5 SLN mapping in a 27-year-old woman with papillary thyroid carcinoma. (**a**) Ultrasound-guided intratumoral injection of ^{99m}Tc-nanocolloidal albumin. (**b**) Ultrasound monitoring of radiocolloid deposit within the thyroid nodule (**b**). (**c**) Planar scan: anterior view showing two hot spots in the left cervical area in addition to the obvious activity at the injection site. (**d**) Volume rendering SPECT/CT image showing the two hot spots in the left cervical levels III and IV, respectively. (**e**) Axial CT section showing anatomical appearance of the level IV SLN. (**f**, **g**) Preoperative assessment with a portable gamma camera and with freehand SPECT, respectively

highest risk to develop cervical lymph node metastasis, who can benefit from complete neck dissection. Lymphatic mapping and SLNB may also have a role in minimally invasive surgical technique to detect metastatic lymph node spread in thyroid cancers [60, 61].

SLNB has been also proposed for medullary thyroid carcinoma (MTC), which is generally characterized by a more aggressive behavior and early spread in lymphatic vessels than papillary/follicular carcinoma. Initial surgery for MTC with no evidence of lymph node involvement in neck compartments consists of total thyroidectomy and prophylactic central neck dissection. SLNB has been used for a more precise N staging of the lateral compartments, possibly driving the extent of prophylactic neck dissection to the involved cervical lymphatic chains [62].

Radioguided Occult Lesion Localization in Thyroid Cancer

Radioguided surgery enables the surgeon to identify lesions or tissues that have been preoperatively "marked" with radioactive substances. The radioguided occult lesion localization (ROLL) approach is being widely used to identify occult lesions in patients with breast cancer. However, few studies have reported the use of this technique in patients with recurrence of thyroid cancers in cervical lymph nodes after initial treatment (i.e., thyroidectomy and ablation of postsurgical remnants with ^{131}I-iodide.

The ROLL technique can be useful in selected cases where suspected lesions may be difficult to identify intraoperatively, due to their dimensions or location, especially in patients who have had cervical surgical procedures in whom fibrotic scar tissue or adhesions can make identification of the target lesions difficult during surgery. The procedure allows for more conservative excisions and reduces the surgery-related morbidity [63–65].

In this case, injection of ^{99m}Tc-sulfur colloid or ^{99m}Tc-macroaggregated human albumin is performed directly inside or near the suspicious lesion, generally under US guidance up to 24 h prior to the surgical procedure. Intraoperative lesion detection is carried out using a handheld gamma probe, and preoperative SPECT/CT in addition to conventional planar scintigraphy can provide an accurate three-dimensional road map for better surgical exploration of the neck [66].

Abstract

A few years ago, the concept of Guided intraOperative Scintigraphic Tumor Targeting (GOSTT) was introduced to encompass the whole spectrum of basic and advanced nuclear medicine procedures required for providing a roadmap for radioguided surgery. This concept included the use of interventional nuclear medicine imaging to depict targets to be resected by radioguided surgery. With the incorporation of SPECT/CT and PET/CT, three-dimensional roadmaps to guide surgical procedures became possible. On the other side, new intraoperative portable imaging devices (gamma cameras and other tools) were added to conventional modalities such as gamma probes and blue dye. More recently, the development of hybrid tracers integrating radioactivity and fluorescence in one single signature has enabled the additional use of near-infrared cameras. All these advances have facilitated the extension of radioguided sentinel lymph node biopsy procedures from the classical applications in cutaneous melanoma and breast cancer to other fields such as oral cavity, gastrointestinal, urological, and gynecological malignancies. At present, three GOSTT working models can be defined in relation to radiotracer administration: intralesional without tracer migration for occult lesion localization, intralesional with tracer migration for occult lesion localization and sentinel lymph node biopsy, and systemic to enable excisional biopsy of primary lesions and recurrences as well as isolated regional and distant metastases. The latter is probably the field with the largest potential due to

Introduction

Radioguided surgery is one of the applications of nuclear medicine with more relevant growth in the last quarter-century. Radioguided surgery

constitutes a wide range of combined procedures involving close collaboration with other specialties like surgery, pathology, and radiology; correct application of such multidisciplinary procedures ensues obvious immediate and long-term benefits to the patient. In general, radioguided surgical procedures are less invasive than traditional surgical approaches, while they may also result in improved local-regional control of malignant disease [1].

In 2011 the term GOSTT (Guided intraOperative Scintigraphic Tumour Targeting) was introduced in order to encompass the whole spectrum of basic and advanced nuclear medicine procedures required for providing a roadmap for radioguided surgery [2]. The GOSTT concept was recently further updated incorporating the discussion of novel modalities such as hybrid tracers for simultaneous fluorescence and radioactive signal detection, sophisticated navigation approaches based on mixed-reality protocols, and the use of Cerenkov luminescence related to PET tracers [2]. An extensive overview of the GOSTT procedures is given in a book recently edited by the International Atomic Energy Agency (IAEA) [3].

Working GOSTT Models in Interventional Imaging and Radioguided Surgery

The GOSTT concept rests on both preoperative interventional imaging and intraoperative radioguided detection. To accomplish this approach, three working models based on the concentration of an administered radiopharmaceutical in a target or index lesion can be delineated (Fig. 1): (1) local administration of a radiocolloid at the site of a solid epithelial tumor that enables the depiction of the pattern of lymphatic drainage and the identification of the sentinel lymph nodes by means of lymphoscintigraphy; (2) direct intralesional administration of a radiopharmaceutical such as ^{99m}Tc-macroaggregated human albumin (^{99m}Tc-MAA) which is comprised of particles that, by virtue of their relatively large size, are lengthily retained at the site of interstitial injection enabling excisional biopsy; and (3) systemic administration of a radiopharmaceutical that preferentially accumulates in the target lesion, e.g., ^{99m}T-sestamibi for localization of parathyroid adenomas or [^{18}F]FDG for [^{18}F]FDG-avid tumor lesions.

The basic modality to illustrate and discuss the GOSTT concept is the sentinel lymph node (SLN) procedure. Historically, the term "sentinel lymph node" was introduced to describe a group of lymph nodes retrieved in patients with penile carcinoma under the assumption that they receive direct drainage from the site of the primary lesion [5]. In the last 25 years, radioguided surgical applications have rapidly expanded especially to perform sentinel lymph node (SLN) biopsy. In addition to ongoing applications in patients with breast cancer and cutaneous melanoma, radioguided SLN biopsy has been extended to a wide variety of other solid epithelial malignancies such as head and neck cancers, gynecological cancers (vulvar, cervical, and endometrial), gastrointestinal cancers (esophagus, stomach, colorectal, anus), urological malignancies (prostate cancer, bladder cancer, penile carcinoma, and others), non-small cell lung cancer, differentiated thyroid carcinoma, and others [1, 6–15].

A second field of GOSTT applications is constituted by the excisional biopsy techniques based on direct intralesional injection of ^{99m}Tc-MAA, which are expanding from the classical application of "radioguided occult lesion localization" (ROLL) for nonpalpable breast lesions to other tumors, such as solitary pulmonary nodules as well as others [16, 17]. In more recent years, the ROLL technique has been used in breast-conserving surgery combining lumpectomy and SLN biopsy [18, 19].

The model of systemic tracer administration is illustrated by radioguided parathyroid surgery with ^{99m}Tc-sestamibi, a radiotracer with preferential uptake and/or accumulation in tumor tissues. This approach has also been described using radiolabeled monoclonal antibodies against tumor-associated antigens. These procedures also include receptor-mediated uptake of radiolabeled agents by tumors such as neuroendocrine tumors or paragangliomas, accumulation of bone-seeking agents for radioguided excision of isolated bone metastasis, and radioiodine uptake in recurrences/metastases from differentiated thyroid carcinoma. The field of applications following systemic administration

has been extended to intraoperative radioguidance using [^{18}F]FDG or other positron-emitting radiopharmaceuticals using specific probes able to detect the high-energy gamma photons originated by the annihilation reaction or directly β^+ particles [20]. More recently, an intraoperative Cerenkov luminescence device for detection of [^{18}F]FDG-avid malignant lesions has been presented [21].

This chapter will focus on radioguided surgery in the context of the GOSTT concept, emphasizing the innovative methodological aspects for both novel clinical procedures and the more recent investigational applications.

General Background of SLN Biopsy

The rationale of SLN biopsy in solid epithelial tumors relates to the general concept that initial lymphatic spread of such tumors occurs to locoregional lymph nodes in an orderly way, generally from lower- to higher-echelon levels. Of course, this orderly progress does not exclude the potential of tumors to spread hematogenously, which is associated with most distant metastases. Probably in only few circumstances do distant metastases arise from progression of an initial lymphatic metastasis.

The modern SLN concept [22, 23] concerns not only the first lymph node encountered by lymphatic vessels draining the primary tumor but also all first-echelon lymph nodes upon which a lymph vessel originating in the tumor drains directly. This definition does not always correspond to the lymph node nearest to the tumor, as the route of the lymphatic vessels may be complex and unpredictable with different lymphatic pathways leading to different sentinel lymph nodes (Fig. 1); in practice each lymph node identified as SLN should therefore be investigated for the presence of metastasis. Lymphatic mapping following interstitial radiocolloid injection is essential to precisely visualize sequential lymphatic drainage of the radiopharmaceutical and to provide surgeons an intraoperative roadmap [24, 25].

The presence or absence of SLN metastasis usually has a significant impact on therapeutic strategy. In patients with early cancer, if the SLN does not contain metastasis, the surgical approach should aim at removing the primary tumor and avoiding unnecessary regional node dissection. The likelihood that non-SLNs contain metastasis is extremely low, thus making extensive node dissection unnecessary in case the SLN is free from metastasis. Patients whose SLN contains metastasis usually require dissection of regional lymph nodes [26].

The Evolution of Intraoperative Instrumentation for SLN Biopsy and Other GOSTT Applications

Gamma probes were incorporated into the procedure of SLN biopsy in the early years of the procedure [27]. These devices were able not only to count radioactivity in the surgical field intraoperatively but also to provide numerical readouts and audible signals proportional to the counting rate. The hand-held probe is connected to a counting unit either with a cable or with a wireless system. The detector is usually limited to a long narrow cylinder with a diameter varying from about 12 mm up to 16–18 mm. It may be slightly angled in order to allow for easier access in specific applications and easier manipulation within the surgical field.

Thanks to the auditory signals and digital readouts, gamma probes enabled the surgeon to localize and remove radioactive tissue like the SLN or tumor tissue. In fact, gamma-probe counting constituted the acoustic component of the SLN identification procedure in the operating room and for surgeons was the complement of the process of visual detection as implemented by the use of blue dyes. This acoustic/visual feature was introduced in the early 1990s as a step forward in comparison with the original approach, which was exclusively based on the injection of blue dyes to visualize lymphatic ducts and SLNs as originally described by Morton et al. [22].

The combination of gamma-probe counting and blue dyes represented the second step in the evolution of the procedure. On the other hand, this possibility to combine visual and acoustic signals during the surgical SLN procedure has become the cornerstone for new portable technologies, which now enable image generation in the operating room reinforcing the visual component in the guidance of

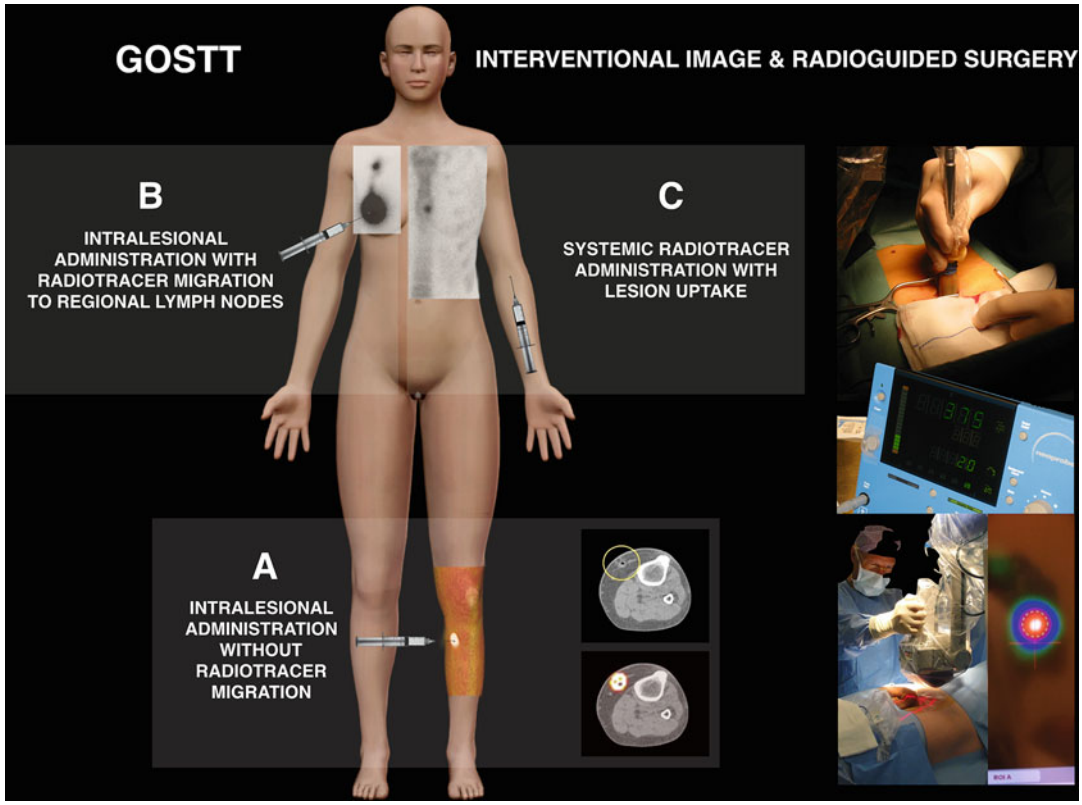

Fig. 1 Schematic working GOSTT (guided intraoperative scintigraphic tumor targeting) approaches including interventional imaging leading to radioguided surgery. (**a**) Intralesional administration of ^{99m}Tc-MAA in a melanoma metastasis of the *left* lower leg. (**b**) Intralesional administration of ^{99m}Tc-nanocolloid in a non-palpable tumor of the *right* breast with subsequent migration to axillary lymph nodes. (**c**) Systemic administration of ^{99m}Tc-diphosphonate with increased uptake in a solitary sternal metastasis

surgical excision [3]. These portable imaging technologies include devices like small gamma cameras for high-resolution planar imaging [28], gamma probe- or small camera-based devices for 3D intraoperative imaging [29], near-infrared (NIR) cameras used in combination with portable gamma devices when fluorescent detection is added to the SLN procedure [30], and cameras for Cerenkov luminescence imaging [21].

Preoperative Imaging: From Planar Images to Hybrid Computed Tomography

Lymphoscintigraphy constitutes the cornerstone of preoperative lymphatic mapping. Its incorporation to the SLN procedure helped to transform the paradigm in radioguided SLN surgery from the original "open and see" approach based on the use of vital dyes to visualize lymphatic ducts and SLNs to another "see and open" based on the gamma camera images acquired prior to the surgical procedure. This lymphatic mapping enabled not only to personalize imaging of lymphatic drainage for every individual patient but also made possible to mark with indelible ink the SLN site projection on the skin. This approach gained in popularity in Europe and was highly effective for SLN localization not only in the expected areas of drainage but also in unusual locations [24]. Lymphoscintigraphy was found to be 88–96% reproducible in melanoma [31, 32] and 100% in breast cancer as well as penile cancer [33, 34].

For SLN identification, early images, to depict first draining lymph nodes, and delayed images, to

differentiate second-echelon nodes, are required. The visualization of lymphatic ducts, the time of lymph node appearance, the lymph node basin, and the intensity of lymph node uptake are all important factors to take into account. Lymph nodes draining from the site of the primary lesion through their own lymphatic vessel, or a single radioactive lymph node in a basin, are considered as definitely SLN. Lymph nodes appearing between the injection site and a first draining node or nodes with increasing uptake appearing in other lymph node basin may be considered as SLN with a high probability. Higher-echelon lymph nodes in the trunk and extremities or lower-echelon nodes in the head and neck region may be included in the low-probability SLN category [35].

More than 10 years after planar lymphoscintigraphy, SPECT/CT imaging was introduced in the SLN procedure [36], thus enabling to incorporate an additional dimension to preoperative mapping. In fact, the functional information on draining lymph nodes provided by SPECT could be combined with the morphological information from CT by acquiring both modalities in one session. The resulting fused SPECT/CT images were able to depict SLNs in an anatomical landscape, thereby providing important reference landmarks to be recognized by surgeons in the operating theater. Lymphatic mapping complemented by SPECT/CT is currently applied both in malignancies with predominantly superficial drainage (e.g., breast cancer and melanoma) and in tumors draining to deep lymphatic basins or areas of complex anatomy such as the head and neck or the pelvis [37–46]. A specific requirement for SLN localization is that the CT component of SPECT/CT must be of sufficient high quality to provide optimal anatomical landmarks to be recognized by surgeons in the operating room. The CT component is also used to correct the SPECT signal for tissue attenuation and scattering; thanks to such corrections, SPECT/CT may be particularly useful in obese patients to detect SLNs not observed on planar images and additional SLNs in other basins. After these corrections, SPECT can be fused with CT. For fused images a gray scale is used to display the morphology in the background image (CT), whereas a color scale is used to display the SLN in the foreground image (SPECT). Most frequently, a radioactive hot spot corresponds to a single lymph node on CT, but in some cases it correlates with a cluster of lymph nodes [47].

Simultaneously with the evolution of the SLN procedure, a similar "see and open" approach is catapulting also other applications of radioguided surgery in which preoperative imaging plays an important role leading to surgical intervention. This interventional molecular imaging can be illustrated by the preoperative use of ^{99m}Tc-sestamibi scintigraphy for the localization of parathyroid adenomas, where preoperative imaging is used as a roadmap for radioguided surgery of these lesions [48]. Recently, the addition of SPECT/CT to planar imaging did significantly increase the accuracy in correctly identifying a parathyroid adenoma from 75% to 85% [49].

Radiopharmaceuticals for Interventional Molecular Imaging and Radioguided Surgery

As mentioned earlier, an important aspect in GOSTT possibilities is related to the choice of radiotracers for interventional imaging and radioguided surgery. For lymphoscintigraphy and radioguided SLN biopsy, the tracers most widely used are radiocolloids that, after their interstitial administration, migrate from the injection site allowing the visualization of the lymphatic vessels by lymphoscintigraphy and SPECT/CT [25]. These colloids are preferentially retained by the first lymph nodes encountered along the course of the draining lymphatic vessel(s), enabling their identification as SLN(s). Once within the lymph node, radiocolloids are phagocytized by macrophages lining the lymph node sinusoids. Such retention of radiocolloids in the SLN is a physiological process and does not indicate presence or absence of metastases in the lymph node. Radiocolloids can be constituted by an inorganic substance (^{198}Au-colloid, ^{99m}Tc-antimony sulfur, ^{99m}Tc-colloidal sulfur, ^{99m}Tc-stannous fluoride, ^{99m}Tc-rhenium sulfur) or can be derived from biological substances (nano- or micro-colloidal human serum albumin). Radiocolloid particle

size, varying from 5 to 1,000 nm, mainly determines the speed of lymphatic drainage from the interstitial injection site and the amount retained in the SLN. In particular, small-size radiocolloids (less than about 100 nm) migrate quite fast from the injection site through the lymphatic system. This factor underlines the need to sequentially perform dynamic images at short time intervals after interstitial injection as well as static early and delayed images in order to differentiate SLNs from secondary lymph nodes. Larger size radiocolloids are retained longer in the SLN, so that lymphoscintigraphy does not generally visualize more than one to two lymph nodes along a single lymphatic draining vessel. However, migration of larger particles from the interstitial administration site is very slow, so that a longer time, even 2 h or more, can be required to complete mapping. In Europe, ^{99m}Tc-albumin nanocolloid (which has a quite narrow range of particle size, with over 90% of the particles being smaller than 80 nm) is widely available and employed, while in the USA, ^{99m}Tc-sulfur colloid (with a wide range of particle size between about 20 and 400 nm) is the most employed; to overcome the problem of heterogeneous particle size distribution, in some nuclear medicine centers, ^{99m}Tc-sulfur colloid is filtered immediately after labeling and prior to administration, in order to remove particles with a diameter bigger than a certain size, usually 220 nm or other sizes [50, 51].

The radiopharmaceutical ^{99m}Tc-tilmanocept has recently been introduced for lymphatic mapping and SLN biopsy. This radiotracer accumulates in SLNs after binding the mannose-binding protein receptor expressed on the surface of phagocytes. ^{99m}Tc-tilmanocept contains 7 nm particles, which are rapidly cleared from the injection site through lymphatic vessels [52]. In contrast to larger particle radiocolloids, there is also significant diffusion into the blood capillaries. Although diffusion from the injection site via the blood route may limit the amount of lymphatic flow of the tracer, the reduction in signal intensity at the location of the primary lesion may facilitate identification of SLN located close to the injection site. ^{99m}Tc-tilmanocept has been used in oral cavity cancer [53], melanoma [54], and breast cancer [55].

More recently, the hybrid tracer indocyanine green-^{99m}Tc-nanocolloid (ICG-^{99m}Tc-nanocolloid) has been explored for clinical use. Concerning lymphatic drainage pattern and SLN location, this novel tracer showed a 100% reproducibility rate when compared with the parental ^{99m}Tc-nanocolloid in patients with different malignancies and lymphatic drainage basins [56]. Based on its radioactive signature, such hybrid tracer preserves the possibilities for perioperative imaging using conventional gamma cameras, SPECT/CT, and portable devices. At the same time, the added fluorescent signature leads to improved visual resolution and SLN detectability during surgery. A further validation of the clinical applicability of ICG-^{99m}Tc-nanocolloid has been reported for oral cavity cancer [57], vulvar cancer [58], penile cancer [59], prostate cancer [60], and more extensively in melanoma [61].

Intralesional tracer administration enabling excisional biopsy of primary tumors is a GOSTT application known as “radioguided occult lesion localization” (ROLL) , originally validated for breast lesions but with subsequent rapid extension to other malignancies. The first clinical validation of ROLL was based on a direct intralesional injection of ^{99m}Tc-MAA in nonpalpable breast lesions guided by ultrasonography or stereotactic mammography [16]. To accomplish concentricity in the distribution of the tracer into the tumor, the radiotracer must be injected as centrally as possible in the lesion. During excision, which can be performed on the same day or on the next day, the gamma probe is introduced through a small skin incision that can ensure an optimal cosmetic outcome without the topographic constraints required by the classical intralesional markers such as the carbon tracer of the hooked wire. Intraoperative gamma-probe counting enables the surgeon to easily localize the focal deposition of ^{99m}Tc-MAA, thereby facilitating the procedure. The surgical specimen is checked ex vivo with the gamma probe for further confirmation of radioactivity and can also be x-rayed to ensure complete removal of the area containing the lesion. The technique enabled a 99.5% lesion removal rate in the breast [62]. When used in combination with wire

localization in nonpalpable breast cancer, ROLL did significantly reduce reoperation from 21% to 2% [63]. In the last years, radioguided iodine-125 seed localization (RSL) has been introduced for excisional breast lesion [64]. Using similar gamma-probe devices, RSL appears to be comparable with ROLL concerning margin status and re-excision rates, but with significantly lower weight of the resected specimen in patients with nonpalpable ductal carcinoma in situ or invasive carcinoma [65]. In locally advanced breast cancer receiving neoadjuvant chemotherapy, RSL is also comparable with ROLL but with more practical advantages, due to the long halftime of iodine-125 which enables seed implantation before chemotherapy without additional tracer injection for excision of residual tumor [66]. The ROLL principle has been applied in other tumors such as papillary thyroid cancer [67], solitary pulmonary nodules [17], and lymph node metastases [68]. On the other hand, RSL has been helpful to localize axillary metastatic lymph nodes after neoadjuvant chemotherapy in breast cancer patients reaching a 97% identification rate [69].

More recently the ROLL technique has been used in breast-conserving surgery combining lumpectomy and SLN biopsy by means of a single intralesional tracer injection [18, 19]. This approach is known as SNOLL and is based on the use of a radiocolloid with the ability to migrate to the regional lymph nodes. Basic work based on ex vivo lymph node measurements effectuated in the 1990s when validating the SLN procedure demonstrated that when ^{99m}Tc-nanocolloid is administered into a breast tumor, only 2–3% migrate to the axillary SLNs, while the remaining predominant fraction remains at the injection site and can thus guide a ROLL procedure simultaneously with the SLN biopsy procedure [70].

Radioguided surgery related to the systemic administration of a tracer is probably the GOSTT working model with the greatest potential for the future. This potential is based on the detection by either SPECT/CT or PET/CT (depending on the radiopharmaceutical used) of target lesions with subsequent indication for resection for diagnostic or therapeutic purposes. The indication may be closely related to suspected cancer recurrence with elevation of tumor markers during follow-up. For example, PET/CT with [^{18}F]FDG in combination with a hand-held PET probe, suitable to detect 511 KeV gamma emissions, resulted in appropriate tissue sampling by excisional biopsy approach in patients with suspected lymphoma [71]. Also in patients with breast cancer, melanoma, and other malignancies, PET/CT led to the resection of [^{18}F]FDG-avid metastases using a high-energy gamma probe [72]. More recently, an intraoperative device for detection of [^{18}F]FDG-avid malignant lesions based on the detection of the Cerenkov luminescence, which is emitted by emitters of β-particles (both negatrons and positrons), has been used for optical lesion visualization [21].

Regarding radiopharmaceuticals for SPECT, besides the aforementioned ^{99m}Tc-sestamibi [48, 49], another example can be found in radioguided surgery of neuroendocrine tumors (NETs) using ^{111}In-DTPA-pentetreotide; this approach was found to be useful to guide cytoreduction in 29 out of 30 patients with abdominal NETs [73]. Also radiolabeled metaiodobenzylguanidine (MIBG) has been advocated to improve quality of resection in selected NET cases [74]. On the other hand, SPECT/CT led to improve lesion definition and localization with reduction of false-positive results in NET patients [75]. More recently, ^{68}Ga-labeled somatostatin analogues have been incorporated to radioguided surgery of NETs in a "see and open" approach on the basis of preoperative PET/CT and intraoperative gamma-probe guidance [76].

Interventional SPECT/CT and PET/CT for GOSTT

Both SPECT/CT and PET/CT may be considered as basic modalities for interventional hybrid imaging in GOSTT (Fig. 2). SPECT/CT has been incorporated in procedures for SLN localization with locally administered radiocolloids as well as for detection of metastasis with systemically administered tumor-seeking tracers. On the other hand, PET/CT using tracers as [^{18}F]FDG or ^{18}F-fluorocholine has been used to lead radioguided interventions in cases with isolated metastasis. In the SLN procedure, SPECT is primarily oriented to

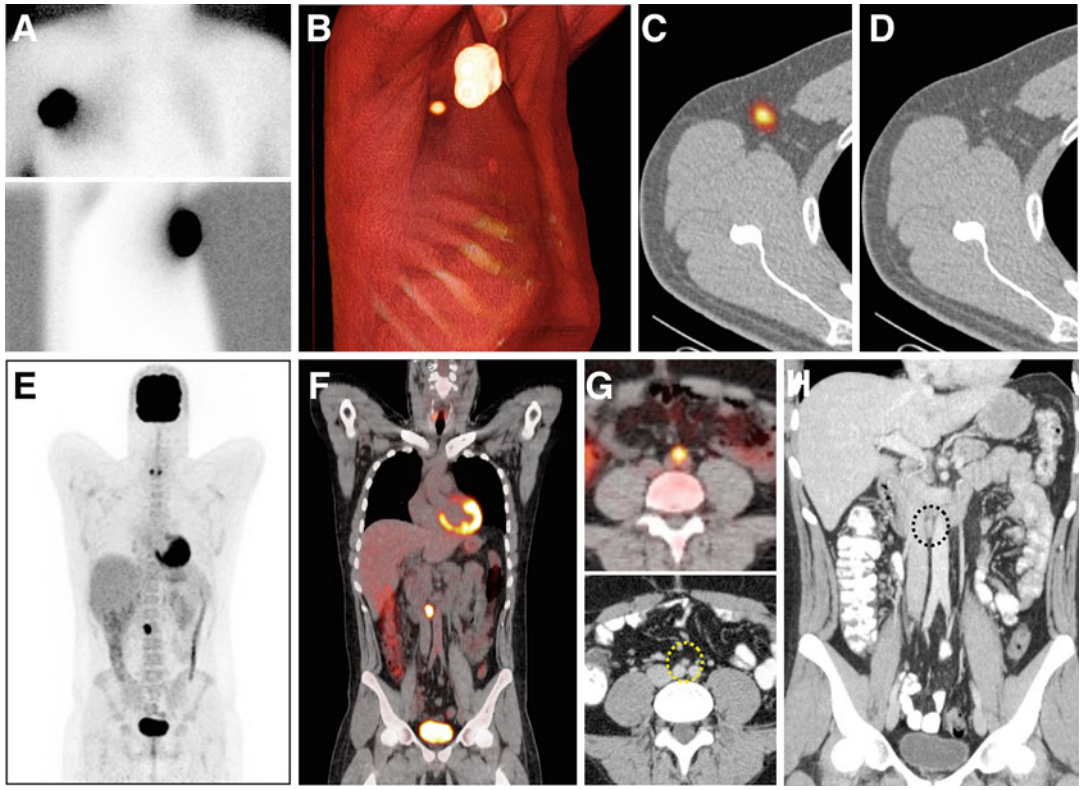

Fig. 2 Interventional molecular hybrid imaging leading to radioguided surgery. In *upper* row, planar images show no drainage to the axilla (**a**), whereas SPECT/CT (**b**–**d**) is able to depict an axillary sentinel lymph node near the injection site. In *lower* row, coronal PET (**e**) and PET/CT (**f**) showing an [^{18}F]FDG avid lymph node metastasis between aorta and cava inferior which is further localized on transversal PET/CT and CT (**g**) as well as on coronal CT (*circles*) (h)

the anatomical localization of SLNs, and protocols for imaging are, in principle, related to this goal. This also explains why SPECT/CT is usually acquired using a low-dose CT. Acquisition of a diagnostic high-dose CT, with or without intravenous contrast, is not really necessary because the SLN procedure aims at identifying subclinical metastases smaller than 2 mm in lymph nodes that are not enlarged or altered in their morphology. PET/CT is mostly acquired using a low-dose CT protocol similar as for SPECT/CT; however, high-dose CT with intravenous contrast is preferred in some cases to characterize PET-positive lesions, which are generally associated with metastases larger than 5 mm.

SPECT/CT is usually performed in addition to lymphoscintigraphy as a preoperative phase of the SLN procedure. SPECT/CT imaging with ^{99m}Tc radiocolloids is possible thanks to the prolonged lymph node retention after phagocytosis of such radiocolloids by the macrophages, which often results in an adequate detection window. This facilitates not only the acquisition of delayed planar images and SPECT/CT but also intraoperative gamma ray-guided SLN localization.

For detection of both SLNs (when patient is scheduled for SLN biopsy) and metastatic tumor tissue (when tumor-seeking radiotracers are used), a specific requirement for localization is that the CT component of SPECT/CT needs to be of sufficient quality to provide optimal anatomical information. The second generation of SPECT/CT gamma cameras includes an improved CT component; this enables the identification and evaluation of the lymph nodes corresponding with the radioactive nodes on fused SPECT/CT

images by acquiring a low-dose (e.g., 40 mAs) CT. In superficial areas such as the groin and the axilla, 5-mm slices may provide adequate anatomical details. For more complex anatomical areas (head/neck, pelvis, abdomen), 2-mm slices may be necessary. With this approach, SPECT/CT can accurately localize SLNs in relation to the vascular structures in deep anatomical areas.

The CT component is also used to correct the SPECT signal for tissue attenuation and scattering. After these corrections, SPECT can be fused with CT [77]. For fused images a grayscale is used to display the morphology in the background image (CT), whereas a color scale is used to display the SLN in the foreground image (SPECT).

For reading/reporting purposes, SPECT/CT or PET/CT images are mostly displayed in a similar manner as that of conventional tomography. Two-dimensional display of fused images to be correlated with CT and SPECT is facilitated by multiplanar reconstruction (MPR), and the use of cross-reference lines allows for the navigation between axial, coronal, and sagittal views. In the SLN procedure, this tool enables the correlation of radioactive SLNs seen on fused SPECT/CT with lymph nodes seen on CT. Most frequently, a radioactive SLN corresponds to a single lymph node on CT, but in some cases it correlates with a cluster of lymph nodes. This information may be useful for the intraoperative procedure and the post-excision control using portable gamma cameras or probes, as additional radioactive SLNs may be detected with the high-resolution portable gamma camera at the same location, then harvested for analysis.

The use of maximum intensity projection (MIP) to display fused SPECT/CT or PET/CT images may also help surgeons to anatomically recognize and localize SLNs or radiotracer-avid metastases. MIP is a specific type of rendering in which the brightest voxels are projected into a three-dimensional image. A limitation of MIP is that the presence of other high-attenuation voxels on CT may complicate recognition of the vasculature and other anatomical structures. Furthermore, MIP is actually a two-dimensional representation, which cannot accurately depict the actual relationships of the vessels and other structures [78]. Also localization of SLNs or of tracer-avid metastases in a three-dimensional context can be supported by the application of volume rendering. In this modality different colors are assigned to anatomical structures such as vessels, the muscle, bone, and skin. This results in easily recognizable anatomical reference points of the target lesions, for instance, in relation to the vasculature. By incorporating a color display, volume rendering improves visualization of complex anatomy and 3D relationships.

Retrieving SPECT/CT and PET/CT Findings in the Operating Room

The anatomical localization of SLNs or tracer-avid lesions does transform SPECT/CT and PET/CT in interventional imaging. Surgeons can use the anatomical landmarks so provided to retrieve these targets during operation. This evolution to a 3D roadmap after the incorporation of these hybrid molecular modalities has helped to further transform the GOSTT paradigm to one of "see, open, and recognize" (Fig. 3). This approach can potentially be reinforced by the synergy of SPECT/CT and PET/CT with the portable imaging technologies [3]. For instance, high-resolution portable gamma cameras are able to reproduce SPECT/CT findings in the intraoperative localization of SLNs or parathyroid adenomas in complex or difficult anatomical areas like the head and neck [25, 42, 79, 80]. These devices have been particularly helpful to depict SLNs at a distance of at least 3 mm from the injection site when equipped with a high-resolution pinhole collimator [81]. The new generation of portable gamma cameras has been upgraded with an optical module for fused optical/scintigraphic imaging resulting in improved anatomical localization [82, 83].

Another important possibility to utilize SPECT/CT and PET/CT findings during surgery is the intraoperative real-time generation of virtual elements. These elements can be added to the surgical environment in the context of an

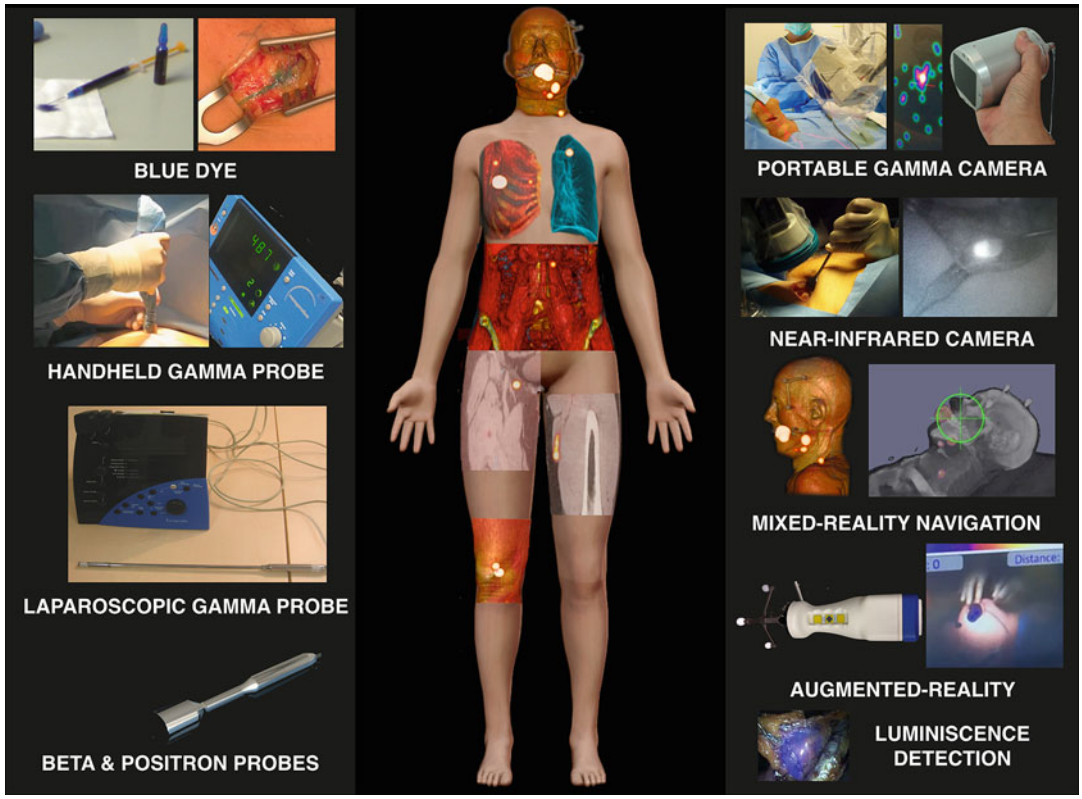

Fig. 3 Synergy of SPECT/CT and PET/CT with portable intraoperative technologies. Both sentinel lymph nodes (head/neck, axillary/intercostal, para-aortic, inguinal, popliteal) and [^{18}F]FDG avid metastases (*upper left* lung, *upper left* leg) can be preoperatively localized for further radioguided resection using conventional (*left* column) and novel (*right* column) intraoperative portable devices and modalities

augmented reality protocol. Augmented reality approaches can be considered as a part of mixed reality, but it is also an independent modality, which has been applied in radioguided surgery mainly after the introduction of the freehand SPECT technology based on a tracked gamma probe suitable for 3D image generation [84]. This device has been the basis for augmented reality experiences in SLN procedures in breast cancer [85], oral cancer [86], and melanoma [87], as well as for surgery of parathyroid adenomas [88]. The same freehand SPECT technology may be considered a helpful tool in transferring SPECT/CT, and potentially PET/CT, to the operating room using mixed reality protocols. The concept of mixed reality was introduced by Milgram and Kishino in 1994 and concerns the merging of *real* and *virtual* elements to produce new environments [89]. More related to the GOSTT approach, with the use of a tracked protocol, it has become possible today to transfer the virtual SPECT/CT images to the operating room, so that a merged environment can be created for adequate surgical navigation. This approach enabled to generate tracked 3D images of a phantom prepared with a reference target (ReT) and simulated SLNs containing ICG-^{99m}Tc-nanocolloid. After feeding the SPECT/CT images to the navigation system, optical tracking could be used to position the tip of the fluorescence endoscope relative to the preoperative 3D imaging data allowing accurate identification of the simulated

SLNs in the phantom. A similar approach was used to navigate toward the prostate and SLNs in a patient undergoing robot-assisted prostatectomy [90]. This navigation approach has been found to be feasible in areas of rigid anatomy like the retroperitoneal space and the groin [91]. However, more difficulties for SPECT/CT-based mixed reality surgery are to be expected for "non-rigid" anatomical areas. Recently, the use of freehand SPECT in combination with a mobile handheld gamma camera has been validated [92]. The freehand SPECT technology has also been used to generate intraoperative 3D navigation for single or multiple ^{125}I-seeds in RSL l [93] and ROLL [94] in breast-preserving cancer surgery.

Novel Clinical GOSTT Applications

The clinical SLN applications in breast cancer, cutaneous melanoma, and head and neck cancer are extensively discussed in other chapters of this book. This chapter mainly concerns novel clinical applications as well as the incorporation of new technologies for both preoperative imaging and intraoperative localization in existing GOSTT applications.

Head and Neck

Regional staging in the neck is performed according to the AJCC/UICC TNM staging system which differentiates seven lymph node levels in each side of the neck [95]. For GOSTT applications to localize SLNs on SPECT/CT and [^{18}F]FDG-avid metastases on PET/CT in the head and neck, the approximately 250–300 lymph nodes are divided into various nodal groups. This high lymph node density and the site of the primary lesion are the principal causes of the remarkable variations in lymphatic drainage and patterns of metastatic dissemination. For instance, scalp melanomas of the frontal zone can drain to different lymph nodes when compared with melanomas of the parietal or occipital areas. For facial and forehead melanomas, metastatic spread to different basins may occur. In the oral cavity, malignancies of the lingual apex may drain to other groups in comparison with well-lateralized lesions in the tongue or floor of the mouth. Identification of SLNs in the vicinity of periauricular melanomas may be critical. Also SLNs located near to floor-of-mouth tumors may be missed and can be accompanied by a decrease in detection rate from 97% to 80%, a decrease in sensitivity from 97% to 80%, and a reduction in the negative predictive value from 98% to 88%, respectively [96]. This has led to the conclusion that planar lymphoscintigraphy is not sensitive enough for predicting the SLN level in the neck [97]. In this scenario, SPECT/CT appears to be essential for the SLN procedure not only to accurately identify SLNs in an anatomical landscape but also to detect additional SLNs in the vicinity of the primary lesions or to personalize alternative drainage to different lymph node basins on an individual basis (Fig. 4).

In a recent study in which SPECT/CT imaging has been performed in a series of 58 patients with oral or oropharyngeal carcinoma, 11 additional SLNs were detected by SPECT/CT; one of these nodes contained metastases [98]. In another study concerning 34 patients, extra SLNs were found by SPECT/CT in 15 patients, and in seven the anatomical level of SLN location was reconsidered [99]. The superior anatomical information of SPECT/CT may lead to adjust surgical approach, as observed for 11 out of 38 patients (29%) with head and neck melanoma; in six patients of this group, SPECT/CT detected additional SLNs (16%) [46]. In another study SPECT/CT modified the surgical approach (more superficial incision or incision at other site) in 9 out of 34 (27%) patients with head and neck malignancies [100]. The surgical adjustment rate due to the additional information provided by SPECT/CT increases when SLNs are located in the periparotid areas; in 8 out of 14 patients (57%) with melanoma and drainage to the parotid region on planar lymphoscintigraphy, SPECT/CT was able to distinguish SLNs in level II of the neck from those located in or around the parotid [101]. In another evaluation in melanoma patients, SPECT/CT caused an increase of the detection rate from

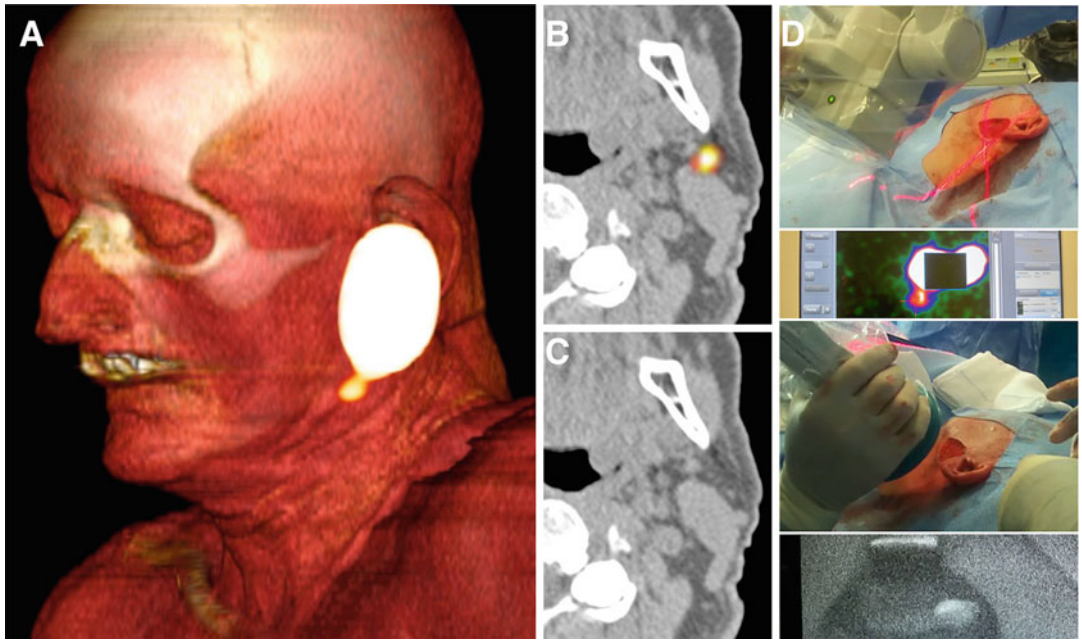

Fig. 4 SPECT/CT with volume rendering (**a**) showing drainage of ^{99m}Tc-nanocolloid to a sentinel lymph node close to the inferior border of the injection site in the left auricular area. This lymph node is further anatomically localized on SPECT/CT (**b**) and CT (**c**) to subsequently be intraoperatively recognized using a portable gamma camera and a fluorescence camera (**d**)

91% (planar scintigraphy) to 98% with a clinical impact of 63.6% [102]. The overall clinical value of the SPECT/CT anatomical information for lymph node mapping was also used to adjust super-selective prophylactic irradiation of the neck in a feasibility study including ten patients with squamous cell carcinoma of the head and neck [103]. Further GOSTT developments in the head and neck region include the hybrid tracer ICG-^{99m}Tc-nanocolloid that has been reported for oral cavity cancer [57], the use of high-resolution portable gamma cameras in addition to SPECT/CT [42], and freehand SPECT probes with 3D display [86]. The incorporation of SPECT/CT and a portable gamma camera in combination with a fluorescence camera to the SLN procedure has led to identify 26% additional SLNs [104].

Lymphoscintigraphy and SPECT/CT have also been validated for SLN identification in papillary thyroid cancer. In an initial study, SLNs were identified in 19 of 24 patients (79%); the identification rate increased to 96% during surgery using a handheld gamma probe. Multidirectional drainage to both central and laterocervical compartments was observed in 50% of the patients [105]. In another series concerning 23 clinically node-negative patients combined, visualization rate of lymphoscintigraphy and SPECT/CT was 91%. The two patients without drainage presented non-SLN positive for metastases. Most SLNs were located in levels VI (83%) and II (35%) of the neck, whereas in four patients, contralateral drainage was also noted [106].

The use of systemic administered radiotracers has been helpful to detect local regional recurrences of well-differentiated thyroid cancer; these cases were subsequently managed using radioguided surgical excision with ^{131}I-iodide in eight patients and [^{18}F]FDG in another five patients with a proven loss of iodine avidity [107]. In another study an optically tracked navigation system was used to navigate to suspected persistence or recurrence in seven patients with malignant skull base disease [108].

In the head and neck, radioguided minimally invasive surgery based on parathyroid ^{99m}Tc-sestamibi scintigraphy has been one of the classical GOSTT applications. The criteria for selection of patients for this radioguided procedure can be summarized as follows [4]:

1. Patients with primary hyperparathyroidism and rarely tertiary hyperparathyroidism
2. Scintigraphic visualization of a single site of tracer uptake
3. Good uptake of ^{99m}Tc-sestamibi by the hyperfunctioning parathyroid gland
4. Absence of concomitant solid thyroid nodules
5. Exclusion of the multiple endocrine neoplasm (MEN) syndromes

By adopting these criteria, minimally invasive radioguided surgery can be scheduled in 60–70% of the patients with primary hyperparathyroidism; in the remaining patients, it may be necessary to perform classical bilateral neck exploration. Based on preoperative ^{99m}Tc-sestamibi imaging and using a second administration of the tracer shortly before operation, even without intraoperative parathyroid hormone measurements, a 98% long-term success rate was reached in a series of 108 patients [48]. Further advances in this GOSTT application are based on the incorporation of SPECT/CT to the imaging protocol [49] and of portable imaging devices to the radioguided procedure [4]. A meta-analysis concerning 24 studies published between January 2003 and March 2014 including 1,276 patients showed a per-patient pooled sensitivity of 86% for SPECT/CT which was superior to the 74% value observed with standalone SPECT and 70% with planar scintigraphy. In this analysis the rate of ectopic parathyroid adenomas ranged between 4% and 20% with a clear added value of SPECT/CT for the localization of the ectopic sites [109]. Recently, ^{18}F-fluorocholine PET/CT has been found to perform better (92% sensitivity, 100% specificity) than ^{99m}Tc-Sestamibi SPECT/CT (49% sensitivity, 100% specificity) in localizing hyperfunctioning parathyroid tissue in 24 patients with primary hyperparathyroidism [110]. This superiority of imaging with ^{18}F-fluorocholine, mainly based on the detection of multiple lesions and hyperplasia, leads to consider this imaging modality as an indication of choice to localize parathyroid abnormal tissue in patients with negative ^{99m}Tc-sestamibi imaging (Fig. 5). This approach may lead to successfully image-guided surgery [111]. The intraoperative retrieval of ^{99m}Tc-sestamibi-avid parathyroid adenomas has been optimized using portable gamma cameras [80, 112]. An alternative to portable gamma cameras is the use of a freehand SPECT device with 3D image generation [113]. The freehand SPECT signal can be fused with real-time ultrasound when signals of both modalities are acquired in a tracked manner [114]. The potential of the tracked combination of these modalities for radioguided intervention in the head and neck area has also been illustrated by its use in targeted ultrasound-guided, fine-needle aspiration cytology of SLNs in head and neck cancer [115].

Urological Malignancies

In general, male and female urogenital malignancies located in the pelvis drain to lymphatic basins in the vicinity of the primary tumor and may follow a similar trajectory in the dissemination of regional metastases. There are different nodal groups receiving lymphatic drainage from the pelvic structures: the external iliac nodes whose medial subgroup includes the obturator nodes, the internal iliac lymph nodes, and the nodes in the trajectory of the common iliac vessels. Lymphatic spread of metastasis from malignancies of the prostate, bladder, cervix, and endometrium may frequently be found in these iliac basins. However, alternative lymphatic drainage to the para-aortic and aortocaval lymph nodes as well as to the proximity of the sacrum and anterior abdominal wall is also possible.

In penile cancer the SLN procedure was one of the first applications of SLN biopsy validated in patients with clinically negative lymph nodes, in order to select patients who can benefit from lymph node dissection. It is usually performed by intradermal peritumoral injection of the

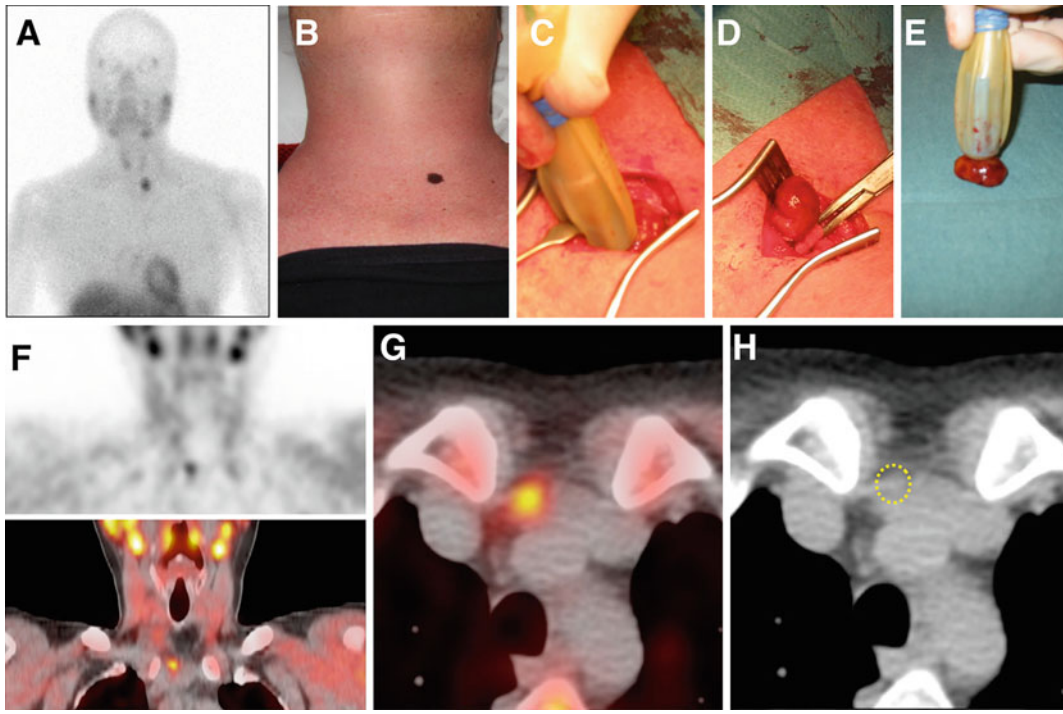

Fig. 5 Planar scintigraphy (**a**) showing increased ^{99m}Tc-sestamibi uptake near the *left lower* pole of the thyroid. Following skin marking (**b**), a parathyroid adenoma is intraoperatively localized and resected using a handheld probe (**c**–**e**). In another patient with primary hyperparathyroidism and negative ^{99m}Tc-sestamibi scintigraphy, PET/CT (F-H) using ^{18}F-fluorocholine is able to localize an ectopic parathyroid adenoma (*circle*) which is subsequently removed

radiocolloid, following the recommendation of injecting within 1 cm radius from the primary tumor, or from the surgical scar in case of prior excision of the primary tumor [116]. The SLN procedure has led to a SLN identification rate of 97% with an acceptable false negative rate of 7% [117] and to increase the 5-year survival to 91% in these patients [118]. SPECT/CT imaging has been used to optimize the procedure and to evaluate the pattern of lymphatic drainage from the malignancy by evaluating the possible implications for the extent of inguinal lymph node dissection. In a study including 50 patients, lymphatic drainage was visualized in 82 of 86 clinically node-negative groins (95%) scheduled for the SLN procedure. All SLNs were located in the inguinal zones medial superior (73%), lateral superior (8.7%), and central superior (18.3%) on SPECT/CT. No lymphatic drainage to the inferior zones of the groin was seen which suggests the possibility to exclude these zones from a subsequent inguinal lymph node dissection in the case of a tumor-positive SLN [119].

In prostate cancer, tracer administration is guided by transrectal ultrasound with usually two radiocolloid depots, one injection in each prostate lobe. Patients receive antibiotics prophylactically to prevent prostatitis. An alternative for transrectal injections is the transperineal tracer administration. Lymphoscintigraphy on the basis of 5-min planar images is performed 15 min and 2 h after injection. SPECT/CT is mostly performed subsequently to delayed planar images (Fig. 6). On early planar images, first draining lymph nodes are visualized in 88% of the cases. This visualization rate increases to more than 90% on delayed images [4]. SPECT/CT is particularly useful to anatomically localize SLNs in both the expected drainage basins of the pelvis and in alternative locations. A meta-analysis

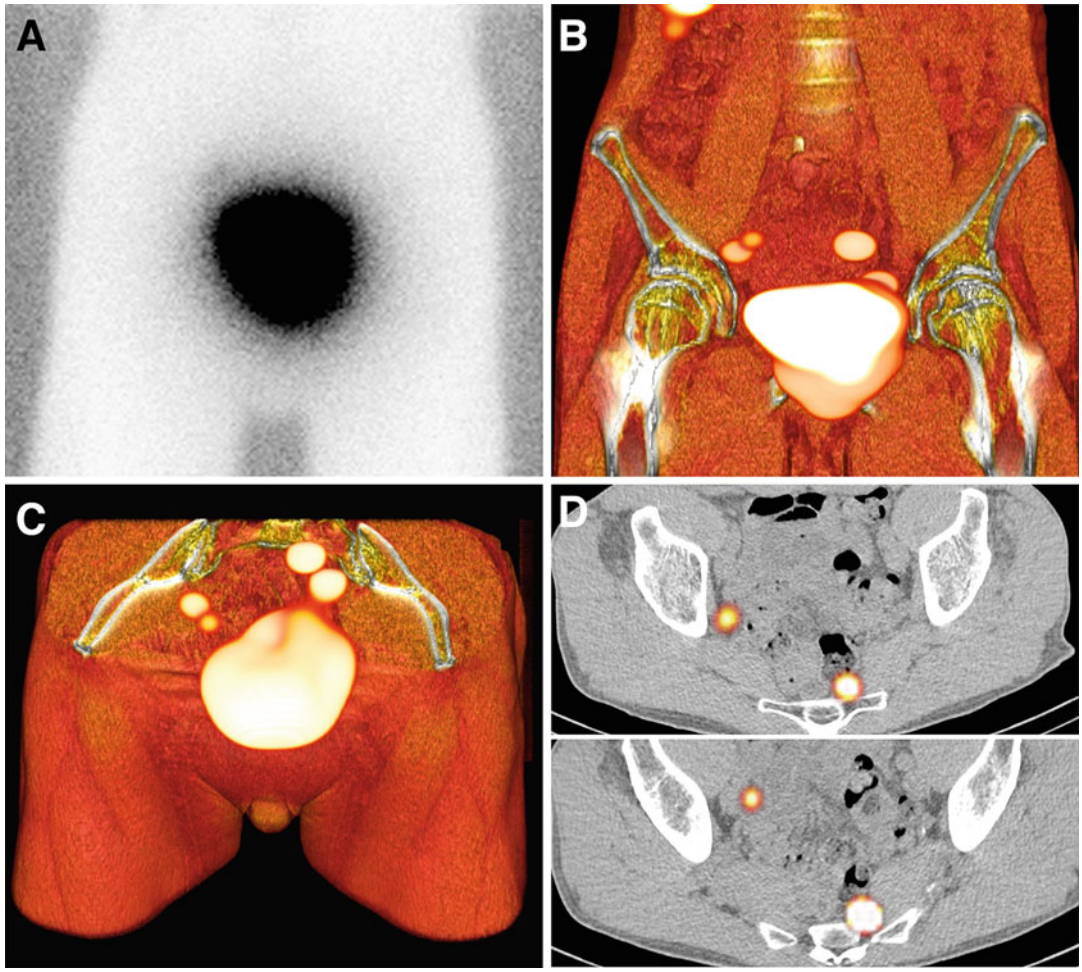

Fig. 6 Planar lymphoscintigraphy (**a**) showing some drainage to the right iliac area in a patient who has received four injections of ^{99m}Tc-nanocolloid into the prostate. By contrast on volume rendering **(b)**, bilateral drainage is observed. Volume rendering with cranial tilt (**c**) and transaxial SPECT/CT (**d**) show sentinel lymph nodes in the right iliac region and in the left presacral area

evaluating the SLN procedure included mainly prostate cancer patients with intermediate risk (clinical stage > T2b/T3, PSA >10 ng/mL, or Gleason >6); the pooled detection rate scored 93.8% and pooled sensitivity 94% [120]. Sensitivity appears to decrease to 76% in high-risk patients [121]. In recent years the role of SPECT/CT has been evaluated in various studies. SPECT/CT did increase the SLN visualization rate from 91% for planar scintigraphy to 98%. SPECT/CT also depicted more SLNs than planar images (average 4.3 vs. 2.2 SLNs) in 46 patients; 44% of the SLNs containing metastases were visualized only by SPECT/CT [43]. In another study, SPECT/CT identified SLNs outside the area of extended pelvic lymph node dissection, often used to stage the pelvis, in 37 out of 121 prostate cancer patients (31%). These SLNs were found in different locations: presacral, Cloquet's node, inguinal, para-aortic, the abdominal wall, pararectal, behind the common iliac artery, and lateral to the external iliac artery [122]. In a study involving treated prostate cancer patients, SPECT/CT

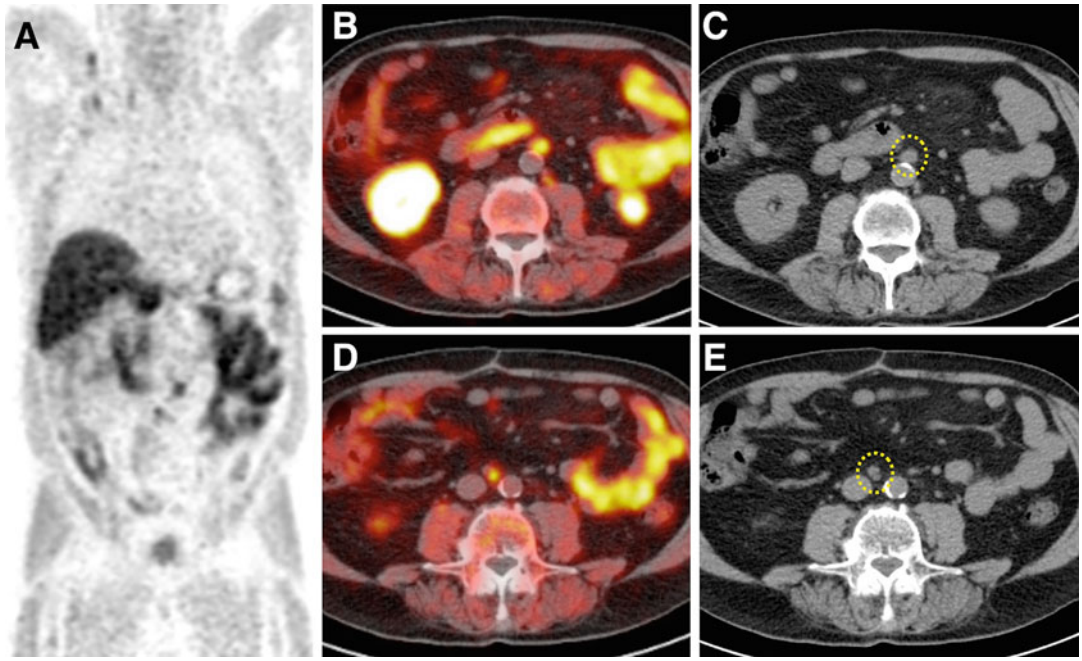

Fig. 7 Coronal PET displayed with maximum intensity projection (**a**) showing focal uptake of ^{18}F-fluorocholine in the *middle* areas of the abdomen in a prostate cancer patient with high risk of regional lymph node involvement. On fused PET/CT and CT, two radiotracer avid lymph nodes are depicted in the para-aortic area (**b**, **c**) and between the aorta and vena cava inferior (**d**, **e**). These findings led to image guided resection and histopathological confirmation of metastases

revealed a higher percentage of SLNs (80% vs. 34%) outside the pelvic para-iliac region in comparison to untreated patients [123]. In another series SPECT/CT findings led to a 25% impact of lymphatic drainage on conformal pelvic irradiation in 23 prostate cancer patients [124]. In a study designed to validate laparoscopic SLN versus hyperextended pelvic dissection for staging clinically localized prostate carcinoma, SPECT/CT identified SLNs in 191 of 203 patients (94%). Bilateral SLNs were found in 159 patients (83%) and unilateral in 32 (17%). The most frequent drainage site was the common iliac region (31%), followed by the internal iliac (20%), the obturator fossa (18%), the external iliac (15%), and the promontory/presacral area (6%) [125]. A similar presacral SLN rate (5.4%) was found in another study concerning 18 patients with prostate cancer of intermediate prognosis; in this series also para-aortic (5.4%), pararectal (5.4%), and paravesical (3.6%) SLNs were found outside the area of extended pelvic lymphadenectomy [126]. In the operating room, innovations in the SLN procedure for prostate cancer have been illustrated in recent years by the use of portable gamma camera to facilitate laparoscopic SLN biopsy [4] and the incorporation of robot-assisted SLN procedures with fluorescence/radioactivity guidance [60]. Finally, the gradual incorporation of high-risk patients for the SLN procedure has led to explore the possibility to detect macrometastases in these patients by using PET tracers before SLN biopsy (Fig. 7). This combined approach based on the use of SLN-SPECT/CT and ^{18}F-fluorocholine was found to be useful for target volume definition in high-risk prostate cancer aimed to receive radiotherapy [127]. Another PET tracer, ^{68}Ga-PSMA-ligand, has been found to be highly effective for lymph node staging in prostate cancer patients with intermediate- to high-risk prostate cancer; lymph node metastases were found in

41/130 patients (31.5%) with a patient-based accuracy of 88.5% for PET/CT increasing to 95.2% on the basis of template-based analyses [128]. The efficacy of ^{68}Ga-PSMA-ligand PET/CT has led to an innovative GOSTT approach for radioguided surgery in patients with lymph node metastases by coupling ^{111}In-PSMA-ligand with ^{68}Ga-PSMA-ligand in order to visualize PSMA-ligand-avid lymph nodes and primary tumor with SPECT/CT to enable radioguided resection [129].

In other urological malignancies, the SLN procedure has been validated only on an investigational basis in limited series of patients. In bladder cancer the imaging protocol, including lymphoscintigraphy and SPECT/CT, is similar to the one recommended for prostate cancer. Radiocolloid injection into the detrusor muscle and around the primary lesion is guided by cystoscopy [4]. Depending on the location of the primary tumor, lymphatic drainage may be unilateral or bilateral. The addition of SPECT/CT to planar lymphoscintigraphy did increase the detection rate from 33% to 83%. The negative predictive value of the SLN procedure has been found to be 92% on the basis of 156 patients reported in the literature [130]. In testicular cancer lymphatic drainage to lymph nodes along the abdominal aorta and vena cava is usually found after tracer administration with a single intratesticular injection; however, in some cases, SLNs are also found alongside the funicular vessels. SPECT/CT identified aortocaval or paracaval SLNs in five patients with right-sided testicular cancer and para-aortic SLNs in five patients with left-sided tumors; in three patients, SLNs along the funicular vessels were detected. All these SLNs were resected using a portable gamma camera [131]. Finally, in renal cell carcinoma, lymphatic drainage was seen in 14/20 patients (70%) and SPECT/CT detected 26 SLNs. The SLNs were most frequently located para-aortically, but also drainage to retrocaval, hilar, celiac trunk, and thoracic (internal mammary chain, mediastinal, and pleural) SLNs was seen [132]. The visualization of lymphatic drainage from renal cell carcinoma along the thoracic duct was further documented using SPECT/CT in 4 out 22 patients (18%) with SLN visualization [133].

Gynecological Malignancies

Gynecological GOSTT applications have been mainly limited to SLN biopsy in vulvar cancer, cervix cancer, and endometrial cancer. In vulvar cancer SLN biopsy is recommended for women with unifocal tumors <4 cm and clinically non-suspicious lymph nodes in the groin [134]. The incorporation of a radiocolloid tracer to the procedure improved the SLN detection rate to more than 95% from the 88% rate when only blue dyes were used [4]. Nevertheless, the most accepted approach is the combination of both agents with a SLN detection rate of 87% per groin, a false negative rate of 6.4%, and a recurrence rate of 2.8% according to a recent meta-analysis [134]. However, a long-term follow-up study showed a local recurrence rate at 5 years of 24.6% for patients with SLN negative and 33.2% for SLN positive [135]. The radiotracer is usually injected in three to four aliquots around the primary lesions; this is particularly important in lesions located close to mid-line, which frequently show contralateral drainage [136]. In spite of an extended validation of the SLN procedure in vulvar cancer, the role of SPECT/CT imaging in this malignancy has not been widely evaluated. In a series concerning 88 patients, SPECT/CT depicted drainage to groins not visualized on planar imaging and depicted more SLNs, but the difference was statistically not significant. However, SPECT/CT was of additional value to accurately indicate SLN location showing a 73% drainage rate to medial inguinal Daseler's zones, a 10% to the central zone around the saphenofemoral junction, and only 7% to the lateral zones. Different from drainage to the groin in penile cancer (Fig. 8), the SLN in vulvar cancer is found in 14% of the patients in the medial inferior zone; however, drainage to the lateral inferior region of the groin is only incidentally seen. Further drainage to higher-echelon lymph nodes was observed in the groin (15%) and in the pelvis (85%). SPECT/CT was found to be able to personalize lymphatic drainage and have potential use to limit extent of lymph node dissection in patients with positive SLNs [137]. Repeat SLN procedure appears to be also feasible in patients with recurrent

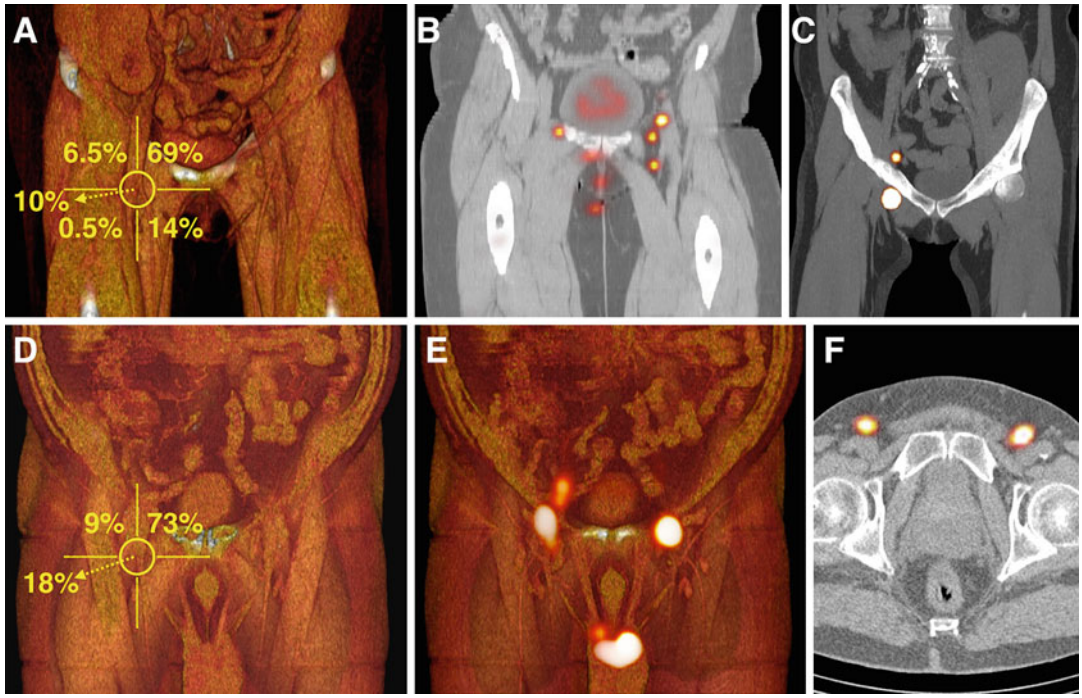

Fig. 8 Anatomical distribution (**a**) of inguinal sentinel lymph nodes according to Daseler's zones in vulvar cancer [137] showing most locations in the superior and central zones but also significant migration to the medial inferior quadrant as shown in two different patients (**b**, **c**). By contrast, in penile cancer (**d**), drainage to the inferior zones of the groin is not observed [119] as further illustrated by fused SPECT/CT images (**e**, **f**)

vulvar cancer, reaching a 78% detection rate [138]. The GOSTT concept of "see, open, and recognize" has been further explored in vulvar cancer on the basis of SPECT/CT and intraoperative SLN identification using combined NIR visualization and portable gamma devices following administration of the hybrid tracer ICG-^{99m}Tc-nanocolloid [58, 139].

Another important GOSTT application in gynecological surgical oncology concerns SLN biopsy in cervical cancer. A recent meta-analysis evaluating 67 studies resulted in a pooled detection rate of 89.2% and a pooled sensitivity of 90%; both SLN rates were related to mapping method (blue dye, radiotracer, or both) and history of preoperative neoadjuvant chemotherapy. Preoperative lymphatic mapping could also detect SLNs outside of routine lymphadenectomy areas, thus providing additional histological information important to optimize regional staging [140]. A prospective multicenter study evaluated the contribution of lymphoscintigraphy to the SLN procedure in 139 patients and concluded that, although the preoperative detection rate is lower than the intraoperative one (87.8% vs. 97.8%), the substantial proportions of SLNs in unusual drainage territories found by lymphoscintigraphy provide valuable guidance for the surgical exploration [141]. SLN visualization in preoperative lymphatic mapping can be optimized by the addition of SPECT/CT. This approach was evaluated in a meta-analysis including eight studies; the median overall detection rate was 98.6% for SPECT/CT and 85.3% for planar lymphoscintigraphy [142]. Indication for SLN biopsy in cervix cancer concerns patients with early stage (Ia2/Ib1, IIa1) and no clinical evidence of lymph node metastases. Radiocolloid administration is based on injecting peritumoral/periorificial aliquots into the four quadrants of the cervix or

pericicatricial in patients with prior conization. It is recommended to perform SPECT/CT after delayed planar imaging of lymphoscintigraphy and is crucial to assess deep lymphatic drainage and anatomical SLN localization in parametrial stations and in unusual locations [143].

In endometrial cancer a meta-analysis published in 2013 [144] resulted in a pooled SLN detection rate of 77.8% and a pooled sensitivity of 89%. The evaluation was based on 51 studies with enough information for detection rate evaluation and 35 studies providing false negative rates. The combination of blue dye and radiotracer resulted in higher detection rate and sensitivity. However, there are various approaches regarding the injection site: cervical, endometrial peritumoral, and myometrial/subserosal. Although the injection of the tracer into the four quadrants of the cervix is the easiest approach with also the highest detection rates, the other two routes appear to better reflect the drainage of endometrial cancer, with a higher incidence in drainage to the para-aortic lymph node basins [143]. SPECT/CT has been found to be helpful, and in 44 patients with high-risk endometrial cancer, SPECT/CT identified SLNs in 34 of them (77%) with a total of 110 depicted SLNs. The most frequent location was the external iliac chain (71%), but drainage to para-aortic SLNs was also common (44%). SPECT/CT was able to localize the only pelvic metastatic lymph node that was not depicted on planar images [145]. Also recently, in a study of 70 patients with endometrial cancer, SPECT/CT detected SLNs in 64 of them (91.4%). However, SPECT/CT could detect only 88.9% of the SLNs found during surgery; most of these undetected nodes on SPECT/CT had very low activity [146]. SPECT/CT SLN identification rate (94%) was significantly higher than that of planar lymphoscintigraphy (68%) in a series of 31 patients with endometrial cancer investigated after transcervical tracer injection into the isthmocervical myometrium [147].

Finally, radioguided SLN localization, without preoperative lymphatic mapping, was found to be feasible in a study including 21 patients who were at high risk of ovarian malignancy [148]; both radiocolloid and blue dye were intraoperatively injected into the proper ovarian ligament and suspensory ligament of the ovary. During open surgery the gamma probe identified SLN locations before retroperitoneal exploration; subsequently SLNs were detected in the para-aortic/paracaval regions only (67%), the pelvic region only (9%), and both the para-aortic/paracaval and the pelvic regions (24%).

Gastrointestinal Cancer

Since lymphatic drainage from the gastrointestinal tract is multidirectional and usually follows a random pattern, preoperative lymphatic mapping for SLN biopsy can be very helpful [7], considering that extensive dissection shows that metastases are found in lymph nodes nearest to the primary tumor site in, e.g., only about 60% of the gastric cancers or 40–50% of esophageal cancers. Also in lower rectal cancers, skip metastases and lateral lymph node metastases are found in a high number of the patients. However, these aggressive surgical procedures are burdened by high morbidity and even mortality.

In *esophageal cancer* the radiocolloid is administered endoscopically by injecting in the submucosal layer at the four quadrants closer to the primary lesion in the submuscosal layer, often the day before surgery. Lymphoscintigraphy is very useful to localize unexpected patterns of drainage to distant lymph nodes. In fact, in more than 80% of the cases, lymph drainage can be observed in a wide area extending from the cervical to the abdominal region. In a systematic review and meta-analysis including 23 studies of radioguided SLN mapping, the overall detection rate was 93% with a sensitivity of 87% [149].

In patients with *gastric cancer*, SLN biopsy aims at identifying clinically undetectable lymph node involvement and is generally reserved to T1 and T2 tumors (with diameter <4 cm), in which the type of resection can be modified toward function-preserving surgery whenever possible. The radiocolloid is injected endoscopically in the submucosal layers around the tumor. In a recent study involving patients with T1N0 or T2N0

operable gastric cancer [150], gamma probe in combination with blue dye identified SLNs in 372 out of 385 patients (96.6%).

Locoregional lymph node staging is an important prognostic factor for *colorectal malignancies*. In this regard, lymphatic mapping and SLN biopsy may be very important especially for identifying alternative mesenteric lymphatic drainage patterns and for detecting lymph node micrometastasis. Although at present the most popular technique is based on intraoperative subserosal injection of blue dye at the primary tumor, lymphoscintigraphy has proven definite advantages over the blue dye technique for SLNB [151]. However, evaluation of this approach in large-scale prospective investigations has not been performed. By contrast, in *anal cancer* radioguided SLN biopsy using preoperative imaging has had more acceptance; in a meta-analysis based on 16 studies including 323 patients, the best approach for SLN identification was found for the combined use of radiotracer and blue dye with a 90% detection rate [152].

GOSTT Applications in Other Malignancies

In lung cancer the GOSTT approach concerns both radioguided excision of solitary pulmonary nodules and radioguided SLN biopsy [4]. The radioguided excision has been extensively validated, and in 2012 Ambrogi et al. [153] reported radioguided video-assisted thoracoscopic surgery in 211 patients with pulmonary nodules smaller than 1 cm and/or deeper than 1 cm below the visceral pleura; the procedure was based on preoperative CT-guided administration of ^{99m}Tc-MAA into the nodule followed by lesion excision using video-assisted thoracic surgery with gamma ray probe guidance. The procedure was successful in 208 patients (98.6%) leading to histological confirmation of primary lung cancer in 113, metastases in 61, and benign lesions in 98. On the basis of a similar clinical indication and CT-guided radiotracer administration (^{99m}Tc-MAA) in or near the nodule, 112 patients underwent thoracoscopy or thoracotomy for lesion resection; in this series histology showed 14 benign lesions, 85 primary lung cancers, and 24 metastases [154]. Recently, ^{99m}Tc-sulfur colloid and a metallic clip were introduced into ground-glass opacities to enable resection; radiotracer administration was preceded by injection of cyanoacrylate that polymerizes immediately after injection into the lung parenchyma with the forming of a hard nodule enabling radiotracer retention, confirmed by SPECT/CT and easier identification during operation [155]. Concerning SLN biopsy and despite limited diffusion in surgical oncology, this GOSTT procedure has been evaluated for detection rate and sensitivity in 47 and 43 studies, respectively [156]; pooled detection was 80.6% and pooled sensitivity 87% with higher rates for the combination of radiotracer and dyes. In a pilot study, SPECT/CT has been found to be helpful in separate draining lymph nodes from the injection site of radiotracers [157].

In neuroendocrine tumors (NET) the GOSTT approach has been based on the systemic administration of radiotracers for radioguided detection and resection. In a systemic review [158], the use of the following radiotracers has been identified in various small series of radioguided surgery: ^{125}I-Tyr^3-octreotide, ^{111}In-DTPA-pentetreotide, ^{99m}Tc-somatostatin analogues, ^{123}I-metaiodobenzylguanidine, and ^{68}Ga-somatostatine analogues. Preoperative imaging has incorporated in recent years either SPECT/CT or PET/CT imaging, which has led to intervention and radioguided resection of small primary lesions, residual tumor, recurrences, and metastases (Fig. 9). The field of applications includes both pulmonary NET and gastroenteropancreatic NET.

Future GOSTT Scenarios

Current GOSTT advances open windows to new scenarios concerning clinical indications and modern technologies. In addition to the existing devices and modalities for radioguided surgery [159], some future possibilities and scenarios can be summarized as follows:

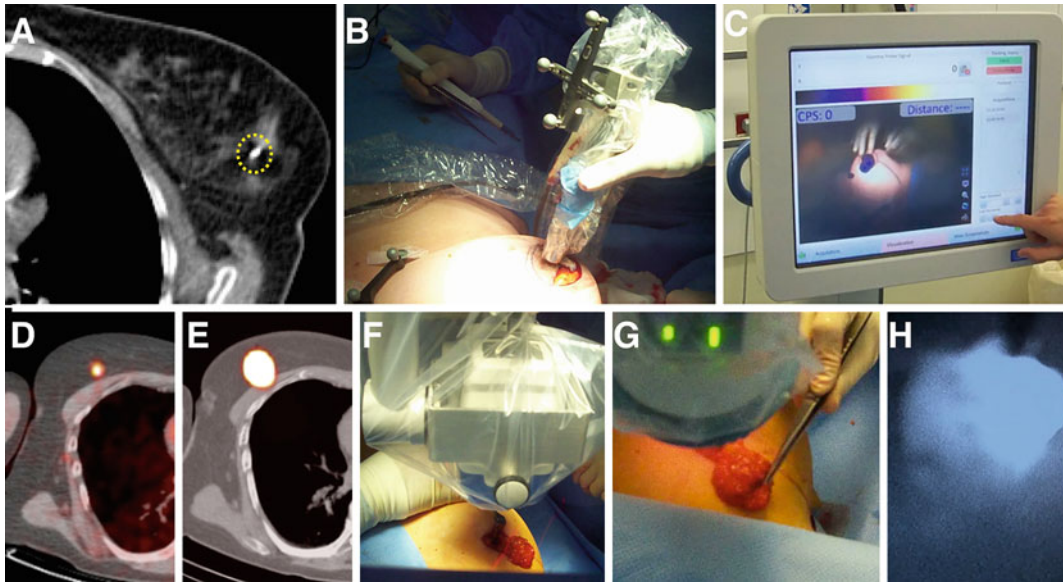

Fig. 9 Transaxial CT (**a**) showing an implanted ^{125}I-seed in the *left* breast of a patient scheduled for neoadjuvant chemotherapy. Following therapy, non-palpable residual tumor containing the radioactive seed is removed using tracked freehand SPECT (**b**, **c**). In another patient an [^{18}F]FDG-avid metastasis found on PET/CT (**d**) is subsequently removed after intralesional administration (**e**) of a hybrid tracer (ICG-^{99m}Tc-nanocolloid) using a portable gamma camera (**f**) and near-infrared camera (**g**) suitable for fluorescence detection (**h**)

1. Development of new systemic radiotracers for interventional imaging. The best example for this issue is illustrated by the recent introduction of ^{68}Ga-PSMA for prostate cancer and its interventional use in resection of lymph node metastases. The pairing of this PET tracer to ^{111}In-PSMA [129] not only enables preoperative SPECT/CT imaging but also radioguided surgery based on the more advantageous properties of ^{111}In. Similarly paired tracer use for interventional imaging and radioguided surgery can be found for iodine-based radiotracers and somatostatine analogues.
2. ROLL and SNOLL. The ROLL model can be extended to resection of recurrences, regional lymph node metastases [160], or isolated subclinical metastasis (Fig. 10). The SNOLL approach is of potential use in other malignancies like thyroid, lung, and stomach.
3. SLN-guided lymph node template resection. This model is currently discussed for prostate cancer with high-risk of regional lymph node involvement. The use of radiocolloids to guide SLN identification can help to optimize separate injection of fluorescent agents to guide lymph node resection in the basin of the SLN.
4. RSL following neoadjuvant chemotherapy. In analogy with the setting for locally advanced breast cancer and based on the practical advantages due to the long halftime of iodine-125, this approach enables seed implantation before chemotherapy and excision of residual tumor or lymph node metastasis after treatment in other local advanced malignancies scheduled for neoadjuvant therapy.
5. Mixed-reality navigation. Probably the use of new sensor technologies for tracking will help to transfer SPECT/CT, PET/CT, and PET/MRI with improved resolution to operation rooms in order to facilitate image-guided navigation to target regions.
6. Hybrid detection procedures. Portable imaging devices as gamma cameras probably will be integrated with other modalities as NIR cameras. On the other side, the integration of Cerenkov luminescence devices will extend the intraoperative applicability of PET tracers.

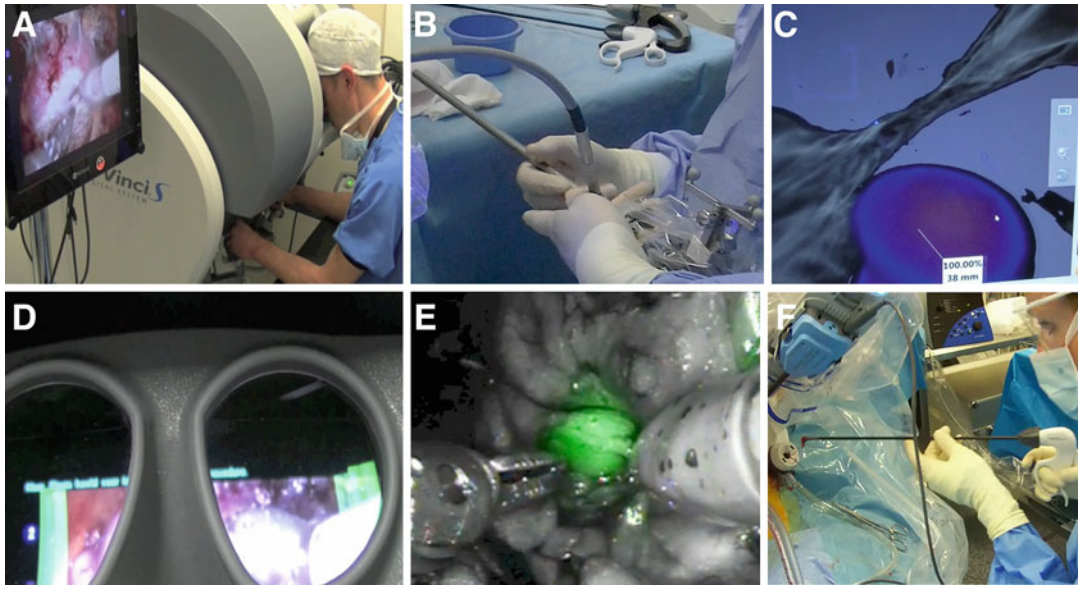

Fig. 10 Robot-assisted sentinel lymph node procedure following administration of ^{99m}Tc-nanocolloid into the prostate (**a**). A tracked laparoscopic freehand SPECT device (**b**) provides depth information for intraoperative navigation toward the sentinel lymph node, on the basis of a previous co-registered SPECT/CT (**c**). Subsequently, the integrated fluorescence signal display (**d**) enables sentinel lymph node resection (**e**, **f**)

7. Robot-assisted procedures with integrated radioguided navigation. In a similar approach as the one used for prostate cancer [60, 161], the fluorescence and probably the radioactive imaging will be integrated to robot-assisted procedures in other pelvic malignancies. Development of novel accessory devices like drop-in gamma probes [162] for insertion and residence inside the abdominal cavity using a robotic gripper will make identification of SLNs and tumor lesions during laparoscopic surgery more flexible by improving detector accessibility and geometry.

Abstract

The average age of a cancer patient is 67. Sexagenarians with cancer are likely to have comorbidities at the time of diagnosis. Cancer patients > 55 years old have an average of ~2.9 comorbidities, while cancer patients older than 75 have an average of 4.2 comorbidities.

The likelihood of coronary artery disease as an etiology of this comorbidity increases with the age of the patient. Cardiovascular comorbidity is present in ~20% of patients with neoplasm. These comorbidities increase the risk of a serious cardiovascular event during treatment. An additional risk factor is limited work capacity. If patients cannot perform 4 metabolic equivalents of work, their all cause mortality is increased. Patients with cancer and known cardiovascular comorbidity or risk factors such as diabetes, hypertension, smoking history, or limited work capacity should have medical clearance prior to invasive diagnostic procedures, major surgery, mediastinal radiation, and/or potentially cardiotoxic chemotherapy.

Medical clearance should include a detailed cardiovascular history and physical examination. This information will permit calculation of a clinical score to define the risk of adverse events as a result of a major surgical procedure, blood tests to determine hematologic and renal status, and if necessary, assessment of the patients work capacity. Stress testing with imaging should be done in patients with an intermediate risk of coronary heart disease and considered in patients with limited work capacity or advanced age. In selected patients, coronary CT angiography or coronary calcium score may be a suitable evaluation. In patients with cancer of the esophagus, breast, lung, melanoma, or lymphoma, chest-CT and PET/CT studies should be carefully evaluated to detect possible pericardial or myocardial involvement.

Chemotherapy may cause myocardial ischemia due to coronary spasm and decreased ventricular function due to irreversible or reversible myocardial damage, as well as repolarization abnormalities, which may result in fatal arrhythmia. Radiotherapy may accelerate the development of atherosclerosis of vessels in the radiation field and cause irreversible damage to myocardium in the radiation field. Myocardial perfusion imaging is useful to detect regions of acute ischemia or scar induced by therapy, while blood pool imaging is useful for serial monitoring of ventricular function.

Introduction

Cardiovascular issues in patients with cancer fall into four major categories:

1. (a) Extension of the tumor to the pericardium or myocardium (seen in cancer of the esophagus, lung, lymphoma, thymoma, and breast) or (b) a neoplasm originating in the heart or blood vessels (aside from atrial myxoma, such tumors are extremely rare).
2. Damage to the heart or blood vessels due to treatment (e.g., doxorubicin cardiotoxicity, radiation therapy where major vessels and/or portions of the heart are in the field, or severe hypertension induced by VEGF inhibitors [e.g., bevacizumab]). Cardiotoxicity is the second leading cause of long-term morbidity and mortality among cancer survivors [1].
3. Secondary effects of the neoplasm on the heart (e.g., cardiac amyloid in patients with multiple myeloma – which may occur in ~30% of myeloma patients [2]).
4. Pre-existing cardiovascular comorbidity influencing the selection of therapy (e.g., pre-existing coronary, valvular, or myocardial disease causing symptoms of ischemia or heart failure).

Since the average age of a cancer patient is 67 years, it is not surprising that about 60% of patients over the age of 65 [3] have a significant comorbidity. The Eindhoven Cancer Registry identified these comorbidities in the Dutch population as hypertension (26%), heart disease (23%), previous cancers (20%), chronic obstructive pulmonary disease (COPD; 17%), and diabetes mellitus (16%). In the United States, SEER data identified a cardiovascular comorbidity in 32% of female breast cancer patients [4], 31% of prostate cancer patients, 53% of lung cancer patients, and 41% of patients with colorectal cancer. Comorbidities in the U.S. population were different than in the Dutch population; with diabetes (16%), COPD (16%), congestive heart failure (10%), and cerebrovascular disease (6%) [5], the comorbidity of a second cancer occurred in ~19% of adult cancer patients [6] in the United States.

A cancer patient with underlying coronary artery disease has an increased risk of a serious cardiovascular event, especially if therapy involves high-risk surgery, the use of cardiotoxic chemotherapy, or mediastinal radiation. The risk is evaluated by medical clearance, which includes a detailed cardiovascular history (including the patient's work capacity. Inability to perform at least four METS (metabolic equivalents of oxygen) work (equivalent to performing light housework) is associated with increased all-cause mortality and physical examination, appropriate laboratory studies, review of a resting electrocardiogram, and cardiac imaging procedures (including echocardiogram, myocardial perfusion scan, chest film, and a chest computed tomography [CT] scan) as well as coronary calcium to calculate a clinical score (such as RCRS [revised cardiac risk score], POSSUM for severe morbidity, and Charlson [7] for comorbidity should be carried out.

Patients with a history of myocardial infarction (MI), percutaneous coronary interventions, or bypass surgery scheduled for intermediate- or high-risk procedures are candidates for stress testing with imaging. Myocardial perfusion imaging, especially using PET/CT with contemporaneous measurement of coronary calcium and coronary flow reserve, is preferred. In selected patients, stress echocardiography or coronary CT angiography may be suitable for detecting significant coronary stenosis, high-risk plaque (and vascular remodeling), as well as global and regional ventricular function at rest and stress. In patients with cancer of the esophagus, breast, lung, melanoma, or lymphoma, chest CT and/or PET/CT studies should be carefully evaluated to detect possible pericardial or myocardial metastases.

Cancer chemotherapy may cause impaired ventricular function, coronary spasm, hypertension, deep venous thrombosis, and pulmonary embolus (Table 1) [8], while radiation therapy can accelerate the development of atherosclerosis (particularly if vessels are in a radiation field) and possibly cause reversible or permanent myocyte damage with associated decrease in global ventricular function.

Table 1 Revised Cardiovascular Risk Index (RCRI)

High-risk surgery (supra-inguinal vascular, intraperitoneal, and/or intrathoracic surgery)
History of MI; history of positive exercise test; current chest pain due to myocardial ischemia; use of nitrate therapy; ECG with pathological Q waves
History of heart failure; pulmonary edema; paroxysmal nocturnal dyspnea; chest X-ray showing pulmonary vascular redistribution
History of cerebrovascular disease
Diabetes mellitus requiring insulin
Preoperative creatinine >2.0 mg/dL (177 μmol/L)

Management of Cardiac Risk in Noncardiac Surgery

Background

Worldwide there are over 200 million surgical procedures performed on patients under general anesthesia each year [9]. In the first 30 days after major noncardiac surgery, about 10 million adults (~5%) will have a major cardiac complication that may result in death. If patient demise within 30 days of surgery were to be listed as a separate cause of death in the United States, it would be the third leading cause of death [10, 11]. The likelihood of a patient with a perioperative MI dying within 6 months of the event is high. Although death occurs in only 0.01% of all patients undergoing operations, mortality increases to ~40% in cases of perioperative infarction [12].

The prevalence of coronary heart disease is 6% in men aged 40–59, ~20% in men aged 60–79, and ~32% in men older than 80 years. The prevalence in women is approximately half that of men at age 60 years and older [13]. Demographic data suggest that by the year 2055, more than 20% of the US population (and 25% of the world population) will be over the age of 65, and patients over age 65 will account for approximately 40% of all surgical procedures [[5]]. SEER statistics suggest that the lifetime risk of developing cancer is about 42% for men and 38% for women [14]. In 2015, about 1,658,370 new cases of cancer were diagnosed, and about 13,776,251 Americans had a history of cancer [15]. Based on the prevalence of cancer and of coronary disease, it is likely that a patient with cancer will have coronary disease as a comorbidity.

Events

The likelihood of a perioperative major adverse cardiac event is related to the baseline risk. Patients with a history of coronary heart disease are at much higher risk for perioperative ischemic events. In the first week after surgery, ischemic episodes occur in 24–41% of patients with a history of CAD. Although the majority of events are clinically silent [16], acute clinical events occur in approximately 5% of cases (infarction, heart failure, or cardiac death). A perioperative MI, even if clinically silent, is associated with a hospital mortality rate of 15–25%. Of the patients who have a perioperative infarct, 75% are non-transmural [17]. A study of 283 radical cystectomy patients, average age 70, average duration of surgical procedure 7 h, found coexistent coronary disease in 64 patients (23%) [18]. There were 31 patients with perioperative cardiac complications including new-onset arrhythmia in 22 and MI in ten. Of these patients, 13 (42%) had a history of coronary disease. In the infarct group, there was history of previous coronary disease in four patients. All ten MI patients had at least one other postoperative complication, such as sepsis or a major wound issue. The added stress of the complication likely caused tachycardia and possibly increased blood pressure, thereby increasing myocardial oxygen demands. Pain or other factors associated with the complication may have contributed to coronary artery spasm, reducing coronary blood flow. The mean interval between surgery and MI was 3.5 days. Preoperatively, five of the ten MI patients had normal stress test results, and two patients with abnormal stress test results had stents placed before the cystectomy.

Interval Between Stent Placement and Surgery

The interval between placing a cardiac stent and perioperative cardiac events was explored in a retrospective analysis of 1,953 patients [19]. There

were no significant differences between drug-eluting and bare metal stents (in-hospital mortality, ~0.6%; MI, ~0.9%; or postoperative ischemic cardiac events, 14%). There was a significant *increase* in the incidence of death or MI if the interval between stent placement and surgery was shorter than 42 days (42.4%), compared with 42 days to 1 year (24.5%) or longer than 1 year (11.7%).

Clinical Recognition of Perioperative Infarct

About 50% of perioperative infarcts are clinically unrecognized [20]. Typical clinical symptoms are difficult to assess owing to postoperative discomfort and the use of pain medication. In addition, electrocardiographic changes may be subtle. In a series of 65 patients undergoing head and neck surgery, troponin I was measured on postoperative day 3. Of the 65 patients, 16 (25%) had an elevated troponin level (>0.032 μg/L); only five patients had a clinically apparent infarction [21]. Myocardial damage was not related to the length of surgery (243 min in patients with elevated troponin vs. 205 min, $p > 0.2$) but it did correlate with postoperative inflammation, measured by elevated C-reactive protein (CRP) levels. The new worldwide standard definition of acute infarction includes an increase in cardiac enzymes (preferably troponin) to more than 99th percentile of normal laboratory values, new Q waves, or sudden cardiac death. This definition will help investigators identify factors associated with perioperative infarction. Cohn commented on the "diagnostic dilemma" presented by postoperative troponin surveillance [22], since 10–20% of patients have elevated troponin levels following noncardiac surgery. Patients with elevated troponin levels have an increased 30-day mortality (with higher peak troponin T levels associated with higher risk of death), often from noncardiac causes. Unfortunately, there is no proven beneficial treatment in asymptomatic patients with elevated troponin levels.

The pathophysiology of ischemia and infarction in perioperative patients is different than in patients outside this environment. Two retrospective autopsy studies evaluated the etiology of perioperative MI:

1. Dawood et al. compared fatal perioperative MI with fatal nonoperative MI [23]. The investigators evaluated the hearts of 42 patients who had elective or emergent noncardiac surgery and died of perioperative infarction within 30 days (MI occurred within 7 days in 40 patients). History of prior MI was present in 55%. Left main coronary artery disease was found in 19%, and triple-vessel disease in 59%. Plaque fissure, rupture, or hemorrhage was found in 55% of patients, and intraluminal thrombus was present in 28% (likely an underestimate, owing to autologous thrombolysis). Six patients had plaque disruption in more than one coronary artery, suggesting that there is a generalized vascular inflammation in these patients.
2. Cohen and Aretz [24] studied the hearts of 26 cases with fatal perioperative MI. Prior myocardial scar was present in 81% (compared with a clinical history in only 19%); left main coronary artery disease was present in 23%, and multivessel disease in 88%. Plaque rupture was present in 46%, and intracoronary thrombus was present in 35%. A retrospective study of 66 patients undergoing intermediate-risk noncardiac surgery, who had coronary angiography following a perioperative infarct, demonstrated demand ischemia as the predominant etiology [25].

The autopsy studies and the angiographic study confirm the importance of multivessel coronary disease as a predictor of coronary events. A clinical history of coronary disease, however, may be lacking, as demonstrated in the study by Cohen and Aretz.

An important factor in perioperative MI is an increase in myocardial oxygen requirement due to an increased heart rate, blood pressure, or both. Continuous monitoring demonstrated an average heart rate increase of ~32 bpm, often accompanied by an increase in blood pressure, resulting in multiple prolonged episodes of ST-depression ischemia. The duration of ischemic episodes was fivefold longer in patients with perioperative MI [26, 27]. These episodes likely reflect sympathetic surges. In the perioperative environment, the role

of the "vulnerable patient," for example, due to a hypercoagulable state, the presence of systemic inflammation [21], and anemia or fluid overload, is also important in the etiology of perioperative myocardial ischemia and infarction.

Perioperative and Intraoperative Management

Cancer surgical procedures frequently require hours of general anesthesia, clamping, and release of major vessels and may involve significant blood loss. These factors result in the release of inflammatory cytokines that may increase the thrombogenicity of pre-existing atheroma, leading to embolic, thrombotic, or vasospastic events. Many patients have a significant elevation of resting heart rate postoperatively, associated with the release of catecholamines due to transient hypoxia, extubation, postoperative pain, increased or decreased circulating blood volume, and transient increase in inflammatory states due to increased production/release of tumor necrosis factor, interleukin, and CRP owing to tissue injury [20]. Persistent tachycardia increases myocardial oxygen consumption, raising the likelihood that patients with moderate and severe coronary stenoses may develop ischemia. To minimize the increase in heart rate and blood pressure and reduce the likelihood of infarction, these patients should be treated perioperatively with beta-blockers [15, 19, 32] (if there is no contraindication), with the goal of maintaining a heart rate of 60 bpm or less and of minimizing surges in blood pressure.

Determination of Preoperative Risk

The following factors place the patient at risk for perioperative events:

1. A work capacity of <4 METS is associated with increased all-cause mortality [28] and increased postoperative length of stay [29]
2. Severe coronary disease
3. Recent heart failure
4. Prolonged duration of anesthesia
5. Large fluid shifts in the course of the procedure
6. Pain or other severe discomfort in the immediate postoperative and early recovery interval (up to 7 days)
7. Wound infection, sepsis, or dehiscence

A clinical scoring system focused on the cardiovascular system, the Revised Cardiac Risk Index proposed by Lee [30], considers six factors (Table 1) [31].

The rate of cardiac death, nonfatal MI, and nonfatal cardiac arrest is based on the number of risk factors [32]:

No risk factors	0.4%
One risk factor	1.0%
Two risk factors	2.4%
Three or more risk factors	5.4%

This index is useful for identifying patients at medium to high risk undergoing high-risk noncardiac surgery who could benefit from noninvasive cardiac stress testing [33].

Another clinical scoring system, P-POSSUM (Predicted mortality – Physiologic and Operative Severity Score), considers multiple factors, and online calculators are available [34]. The P-POSSUM calculator considers:

- Patient age
- The presence of heart failure and dyspnea
- Atrial fibrillation or other arrhythmia
- Blood pressure
- Hemoglobin
- White blood cell count
- Blood urea nitrogen
- Serum sodium and potassium
- Glasgow coma score
- Type of operation
- Number of procedures
- Estimated blood loss
- Chance of peritoneal contamination
- The presence of malignancy/metastasis
- Urgency of surgery

The calculator produces a score estimating morbidity and mortality. A comprehensive discussion of patient evaluation is contained in the updated

ACC/AHA guide on perioperative cardiovascular evaluation for noncardiac surgery [35]. The guidelines suggest that an MI occurring less than 90 days before surgery is associated with a postoperative 30-day mortality of 10.5%. Other factors increasing the risk of a major perioperative event include age over 62 years, history of cerebrovascular disease, the presence of heart failure, left ventricular ejection fraction (LVEF) less than 40%, elevated B-type natriuretic peptide (BNP) level, moderate or severe valvular disease, and a work capacity less than 4 METS.

Approach to the Evaluation of the Presurgical Patient with Intermediate Risk

A meta-analysis of six preoperative diagnostic tests demonstrated a sensitivity of exercise electrocardiography, MPI, and dobutamine echocardiography to be greater than 74% (confidence interval >60%) for the prediction of perioperative events [36]. Impaired left ventricular function had a surprisingly low sensitivity and poor positive predictive value for perioperative cardiac events. A direct comparison of multiple techniques suggests that CT coronary angiography and PET myocardial perfusion imaging have similar positive and negative predictive values [37]. Patients at intermediate risk for coronary events, primarily those with a score greater than 1 on the Revised Cardiac Risk Index (see Table 1), appear to be the group with the greatest benefit from preoperative testing.

Mangano and colleagues demonstrated that effective preoperative and intraoperative beta blockade can reduce the incidence of perioperative cardiovascular events particularly in low-risk patients. In addition, the investigators confirmed that preoperative revascularization does not reduce perioperative morbidity and mortality: "Coronary revascularization prior to non-cardiac surgery is only indicated in unstable patients and patients with left main disease" [38].

To assist in the selection of patients for preoperative assessment, Mukherjee and Eagle suggest utilizing MPI only on patients with clinical risk factors, such as a history of angina, MI, congestive heart failure, diabetes, and Q waves on ECG.

In a retrospective study of 271,082 patients older than 40 years undergoing intermediate- to high-risk noncardiac surgical procedures, 23,991 had preoperative noninvasive stress testing. Patients with intermediate and high risk of cardiovascular events (using the RCRI criteria) who had stress tests had improved 1-year survival and reduced length of hospital stay [39].

Preoperative testing for patients at risk of perioperative events should help identify patients at high risk for perioperative events. However, not all patients at risk of perioperative ischemia are identified on preoperative testing. Investigators compared a preoperative dobutamine echocardiogram with intraoperative transesophageal echocardiography (TEE) [40] in 54 patients scheduled for major vascular surgery. Dobutamine stress induced new wall motion abnormalities in 17 patients. Intraoperative echocardiography detected new wall motion abnormalities in 23 patients. A perioperative event occurred in 15 patients: Ten had a dobutamine-induced wall motion abnormality and a new wall motion abnormality on intraoperative TEE; in four patients, an abnormality was only detected on the intraoperative TEE, suggesting the surgery caused an added stress not inducible with dobutamine.

Myocardial Perfusion Imaging in Preoperative Assessment

MPI can be performed using single-photon or positron-emitting tracers. The most common procedures employ single-photon agents, which permit patients to be studied with exercise or pharmacologic stress. Exercise stress has the advantage of providing information about a patient's work capacity (see section "Determination of Preoperative Risk"), evidence of electrocardiographic ischemia, as well as information about the relative distribution of myocardial perfusion at rest and stress. Exercise stress is particularly useful in patients below the age of 70, with no evidence of neuropathy, orthopedic impairment, lung disease, or impaired mentation.

Patients who cannot exercise can be stressed with either intravenous administration of vasodilators (dipyridamole, adenosine, adenosine triphosphate [ATP], or regadenoson) or with catecholamine agonists (dobutamine). Vasodilator stress MPI has a sensitivity equal to exercise stress for the detection and localization of regions of decreased perfusion and has the safety advantage of intravenous aminophylline as a rapid reversing agent in the unlikely circumstance that the patient develops severe ischemia (likely from a "steal" syndrome). A major contraindication to the use of dipyridamole or adenosine, bronchospasm, can be overcome in patients who are not actively wheezing. The synthetic A2A adenosine agonist regadenoson has a low incidence of bronchospasm. Preparing the patient with inhalation of one or two puffs of albuterol before administering regadenoson reduces the likelihood of bronchospasm.

Dobutamine stress is typically a longer procedure than vasodilator stress, often requiring the addition of atropine to achieve the desired heart rate end point. Like vasodilator stress, dobutamine can be reversed pharmacologically with the short-acting intravenous beta-blocker esmolol. Atropine, however, has a half-life of ~2.5 h and in addition to dry mouth and blurred vision may cause urinary retention. To minimize these side effects, vasodilator stress MPI is overwhelmingly preferred for pharmacologic stress testing.

A retrospective review of MPI in 394 cancer patients studied for preoperative risk assessment revealed abnormal scans in 97 patients [41]. There were nine major perioperative cardiac events – all in subjects with abnormal scans. A review of stress MPI in 787 cancer patients [42] identified ischemia or scar in 36%. Ischemia or scar was seen in 36% of those stressed with adenosine, 36% of those stressed with dobutamine, and 38% of those stressed with exercise. During a 3-year follow-up, 84 patients (11%) had a cardiac event (cardiac death in 51 patients, 61% of those with a cardiac event). Cardiac events occurred in 6% of patients with a normal stress MPI and in 19% of those with ischemia, scar, or both. Ischemia on MPI was associated with a 24% likelihood of a cardiovascular event, while scar was associated with a 19% likelihood. However, the overall 3-year survival in these patients was only 44%, suggesting that ischemic heart disease played less of a role in survival than the patient's cancer.

A meta-analysis of 24 studies reporting results on 14,918 patients with known or suspected coronary disease compared the cardiac outcome of pharmacologic (dipyridamole, adenosine, or dobutamine) with exercise stress MPI [43]. Patients were followed up for 12–55 months (median 22 months for pharmacologic stress and 20 months for exercise). There were 343 cardiac deaths and 216 nonfatal MIs in the pharmacologic stress group and 180 cardiac deaths and 277 nonfatal MIs in the exercise group (total event rate = 6.8%). In the pharmacologic stress group, the annualized event rate for cardiac death and MI (hard events) for patients with normal perfusion scans was 1.78% and 9.98% for patients with abnormal images. In the exercise stress group, the pooled hard event rates were 0.65% for patients with normal images and 4.3% for those with abnormal images. These data suggest that both pharmacologic and exercise stress-gated single-photon emission CT (SPECT) myocardial perfusion scans identify patients with a significant risk of cardiac events.

PET MPI has significant technical advantages over single-photon studies thanks to the superior spatial resolution of ~3 mm for nitrogen-13 ammonia and ~5 mm for rubidium-82 versus ~11 mm for ^{99m}Tc. CT attenuation correction with PET minimizes false-positive scans due to breast or diaphragmatic attenuation, and gated CT imaging can provide information about coronary calcification. A major advantage of PET perfusion studies is the ability to measure absolute coronary blood flow and provide information about perfusion reserve. Reduced perfusion reserve occurs in patients with small vessel disease (patients with diabetes, left ventricular hypertrophy and subjects with metabolic syndrome) and may also be seen in patients with diffuse triple-vessel disease, where regional perfusion may appear normal [44]. Although oxygen-15-labeled water is the preferred tracer for determining regional myocardial perfusion, it is not widely available because of the ~2 min half-life of oxygen-15. Most PET perfusion studies are

performed with generator-produced rubidium-82 or less frequently with nitrogen-13 ammonia. After testing the generator for breakthrough of the parent strontium-82, the 75-s half-life rubidium-82 daughter is eluted from the generator directly into the patient. The short half-life permits administration of 30–50 mCi at rest during a dynamic 7–10-min data acquisition. The vasodilator (typically dipyridamole, adenosine, or regadenoson) is administered followed by a second infusion of rubidium-82 with a dynamic acquisition similar to that at rest.

As with single-photon imaging, the images are checked for appropriate registration with the attenuation correction CT, reconstructed, placed in standard cardiac orientation, and evaluated for the regional distribution of perfusion at rest and stress as well as perfusion reserve (typically with a one-compartment model) (Fig. 1). The gated perfusion images are reviewed to determine regional and global ventricular function. Recent studies suggest that hybrid imaging with PET/CT of myocardial perfusion and contrast coronary CT angiography offers the most complete noninvasive evaluation of myocardial ischemia since the vessel perfusing a specific territory and the perfusion/perfusion reserve are measured concurrently.

Myocardial and Pericardial Tumor Involvement

Primary cardiac tumors are rare: The most common primary cardiac neoplasm, accounting for 75% of cases, is a benign myxoma [45]. Malignant

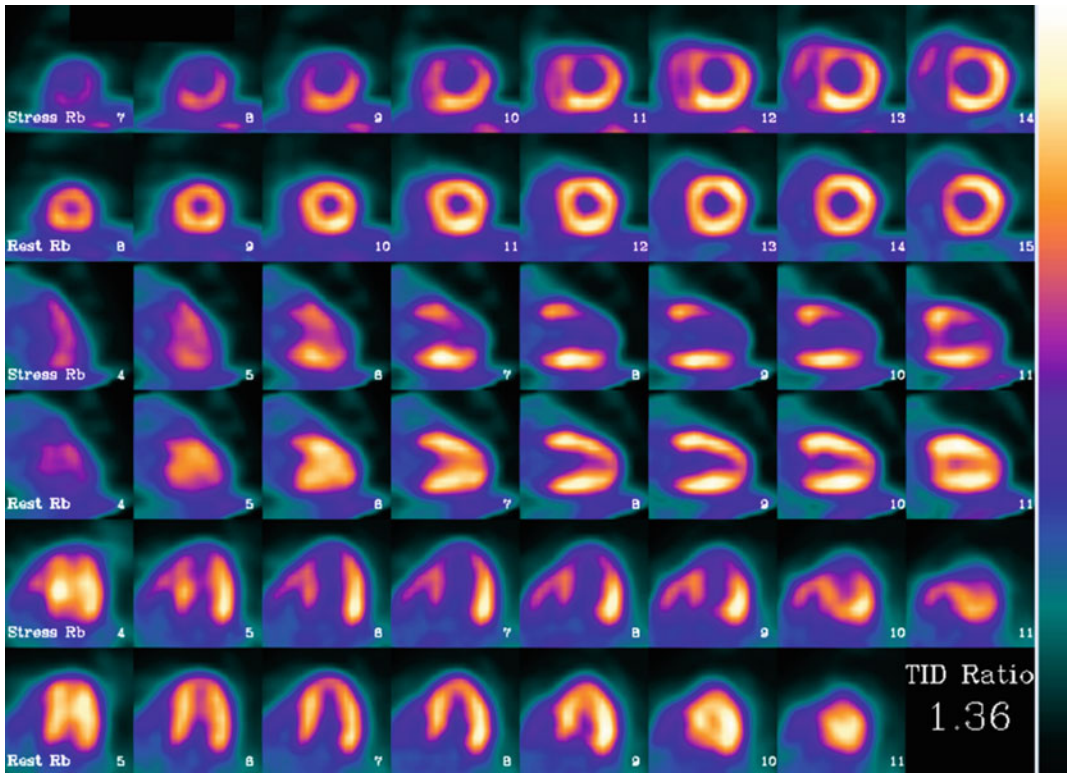

Fig. 1 Abnormal rubidium-82 PET myocardial perfusion scan at stress and rest. Short axis (*top rows*) vertical long axis (*middle rows*) and horizontal long axis (*bottom rows*) slices demonstrate severe and extensive ischemia involving the anterior, apical and septal walls. The left ventricular (*LV*) cavity is dilated on stress imaging consistent with transient ischemic dilation, a poor prognostic factor. Furthermore, on gated images (not shown), the patient's LV ejection fraction decreased from 68% at rest to 46% during stress, an additional indicator of poor prognosis. Finally, the calculated coronary flow reserve was 0.92, which is severely decreased. Cardiac catheterization performed 1 day later confirmed the presence of severe triple vessel coronary artery disease

tumors of the heart are much less common. A review of 480,331 autopsies found primary cardiac tumors in only 0.0017% [46, 47]. Sarcomas account for about 95% of primary malignant tumors, while lymphoma accounts for the remainder [48]. The lesions are usually detected and characterized with ultrasound, contrast-enhanced CT, or MRI, while radionuclide techniques such as [^{18}F]FDG PET/CT, myocardial perfusion studies, or receptor-specific imaging may contribute valuable supplementary data.

Secondary tumors occur 100–1,000 times more frequently than primary tumors [49]. Autopsy studies demonstrate that at the time of demise, ~10% of patients with metastatic tumors have myocardial or pericardial involvement. Cardiac involvement occurs by direct extension or by hematogenous or retrograde lymphatic spread [50]. Cardiac involvement impairs function in ~30% of patients. Depending on the etiology, myocardial involvement may be seen on myocardial perfusion images (usually as a focal area of deceased perfusion), on [^{18}F]FDG PET/CT (especially in patients with minimal physiologic myocardial [^{18}F]FDG uptake), as a focal region of increased [^{18}F]FDG localization (particularly in patients with metastatic melanoma or lymphoma), or with receptor agents such as ^{111}In-pentetreotide (as a focal region of increased myocardial localization) (Fig. 2). Metastatic tumors that involve the pericardium include lung cancer and breast cancer (usually by direct involvement), leukemia, melanoma, and lymphoma [51]. Pericardial involvement can result in pericardial effusion, cardiac tamponade, or less frequently constrictive pericarditis. Long-term survivors of breast cancer or lymphoma (particularly those treated with radiation) may have chronic constrictive pericarditis.

When focal [^{18}F]FDG uptake is seen in the atria, it is important to distinguish uptake in lipomatous hypertrophy of the interatrial septum (LHIS), which is a benign process [52], from metastatic tumor involvement (Fig. 3). This phenomenon on [^{18}F]FDG PET is akin to uptake within metabolically active brown fat deposits more commonly seen at other anatomic sites, such as the supraclavicular region, and the intensity of uptake may vary from scan to scan [53]. LHIS is more prevalent with obesity and advanced age and may be associated with atrial arrhythmias [54]. In patients with lung cancer, esophageal cancer, or metastatic melanoma, with lesions adjacent to the heart, additional imaging studies, such as cardiac MRI (C-MRI), may be required to distinguish between LHIS and a cardiac neoplasm.

A more frequent nonneoplastic finding that may be confused with tumor situated in or adjacent to the heart is when intense [^{18}F]FDG uptake is present within the wall of the right atrium. While physiologic [^{18}F]FDG uptake in the ventricular myocardium (left more than right) is relatively ubiquitous (albeit variable in intensity, depending on the patient's glycemic/insulinemic state), uptake is not typically seen in the myocardium of the atria in the absence of altered cardiovascular physiology. When right atrial wall uptake does occur, it is usually associated with atrial fibrillation [55, 56], paced rhythms, sinus tachycardia, or other tachyarrhythmias.

Cardiac Amyloidosis

Systemic amyloidosis is associated with significant morbidity and poor overall survival, particularly after organ-specific damage has occurred. Cardiac involvement, in particular, leads to arrhythmias and progressive cardiomyopathy. Myocardial infiltration is manifested by increased wall thickening, which is difficult to distinguish from other causes of hypertrophy (e.g., hypertension, aortic stenosis) on conventional imaging techniques. There are two main types of cardiac amyloid infiltration: monoclonal immunoglobulin light chain (AL amyloid) and transthyretin (ATTR), with the former carrying a much worse prognosis [57]. Endomyocardial biopsy is currently the gold standard for diagnosis of cardiac amyloidosis, but this invasive procedure carries inherent risks. C-MRI is an established imaging modality for detection of myocardial infiltration (extracellular matrix expansion), which is characterized by late gadolinium enhancement (LGE). However, LGE is not specific for amyloid on a

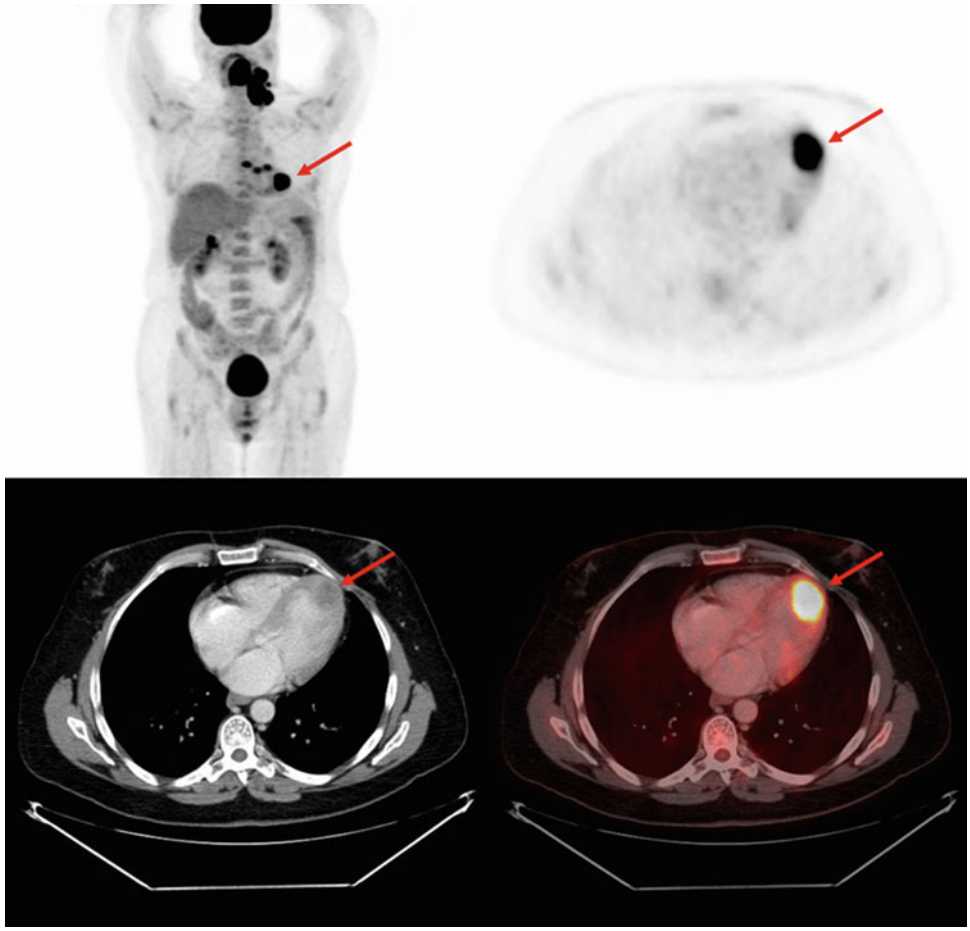

Fig. 2 Abnormal myocardial uptake of [^{18}F]FDG secondary to involvement by lymphoma. *Top left panel:* Maximum intensity projection (*MIP*) image of a patient with multiple [^{18}F]FDG-avid lymphomatous lesions in the neck and chest. *Other panels:* Axial PET, axial CT and axial fused PET/CT slices showing intense focal [^{18}F]FDG uptake at the apex of the left ventricle corresponding to a low attenuation mass in the myocardium, representing a lymphomatous deposit (*red arrows*)

molecular level, nor is it readily quantified. C-MRI currently lacks sensitivity for very early cardiac involvement and is unable to assess multi-organ involvement. A number of single-photon molecular imaging techniques suggested for the evaluation of cardiac amyloidosis have shown limited clinical promise, including ^{99m}Tc-aprotinin, a polypeptide protease inhibitor for targeting of anti-proteases within cardiac amyloid deposits [58]. ^{99m}Tc-pyrophosphate, traditionally a bone tracer, has gained traction in recent years, especially for the purpose of distinguishing between AL amyloid and ATTR [59]. Nevertheless, ^{99m}Tc-pyrophosphate is inherently limited by its lack of specificity for amyloid fibrils and difficulty in quantifying the degree of uptake, owing to the single-photon nature of the radionuclide.

PET probes with proven efficacy for detection of amyloid-beta fibril deposits in the brains of patients with Alzheimer's disease are now being evaluated for use in systemic amyloidosis. Three such tracers, ^{18}F-florbetaben, ^{18}F-florbetapir, and ^{18}F-flutemetamol, are approved by the U.S. Food and Drug Administration for use in the evaluation of Alzheimer's disease. Preliminary data suggest that these thioflavin T derivative PET tracers are not

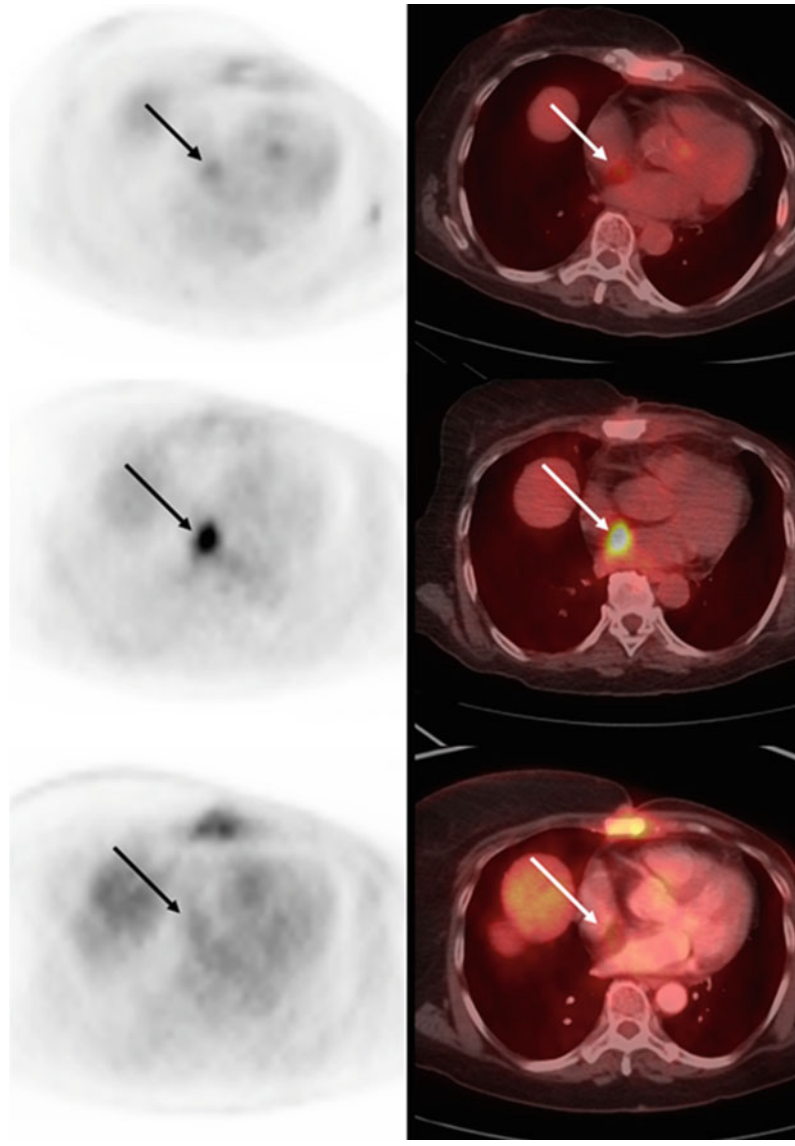

Fig. 3 Temporal variability of *benign* [^{18}F] FDG uptake associated with lipomatous hypertrophy of the interatrial septum (*LHIS*) in a patient with metastatic breast cancer. Axial PET (*left*) and axial fused PET/CT (*right*) slices of the chest at baseline (*bottom panels*), 12 month followup (*middle panels*) and 19 months followup (*top panels*) demonstrate variable levels of [^{18}F]FDG uptake in the atrial septum corresponding to a fat density structure on CT

only effective for imaging amyloid fibril deposits in brains but are also capable of binding to and imaging amyloid deposits in the myocardium.

The first in-human study demonstrating the feasibility of amyloid-avid PET imaging for cardiac amyloidosis used the tracer ^{11}C-PiB [60]. Ten patients diagnosed with systemic amyloidosis, including heart involvement of either AL or ATTR type, and five healthy volunteers were investigated. Myocardial ^{11}C-PiB uptake was visually evident in all patients 15–25 min after injection and was not seen in any control subject. A significant difference in ^{11}C-PiB retention in the heart was noted between patients and healthy controls. The authors concluded that ^{11}C-PiB and PET could be a method for studying systemic amyloidosis of type AL and ATTR affecting the heart and should be investigated further both as a diagnostic tool and as a noninvasive method for treatment follow-up.

A second study using ^{11}C-PiB PET/CT [61] demonstrated positive uptake in 13 of 15 biopsy-proven cardiac amyloidosis patients. No uptake was detected in five patients with no evidence of

cardiac amyloidosis on endomyocardial biopsy or in ten normal subjects. The maximal myocardium-to-blood cavity ratio was significantly different between patients with versus patients without cardiac amyloidosis (median 3.9 [range 1.7–19.9] vs. 1.0 [range 0.8–1.2], $p < 0.001$). Five patients who received prior chemotherapy had less uptake than did chemo-naive patients (2.3 [range 1.7–3.8] vs. median 10.4 [range 1.7–19.9] $p = 0.014$). The investigators therefore suggested that ^{11}C-PiB PET/CT may be a good surrogate marker of active light chain deposition in the myocardium warranting further investigation in a larger number of patients.

Dorbala et al. were the first to show the utility of ^{18}F-florbetapir for imaging cardiac amyloidosis [62]. They imaged five control subjects without amyloidosis and nine subjects with documented cardiac amyloidosis, transthyretin, and light chain amyloid. Left and right ventricular myocardial uptake of ^{18}F-florbetapir was noted in all the amyloid subjects and in none of the control subjects. Quantitative measures including a retention index and standardized uptake value (SUV) parameters were significantly higher in the amyloidosis subjects than in the control group.

Osborne and colleagues [63] confirmed the findings of Dorbala et al. by similarly demonstrating positive florbetapir uptake in eight amyloid patients and no uptake in three healthy controls. In addition, quantitative SUV analysis with regions drawn in the septal wall was found to be adequate in differentiating healthy controls from amyloid-positive patients in this small cohort.

The utility of ^{18}F-florbetapir for imaging cardiac amyloid was corroborated by Park et al. using human autopsy myocardial specimens [64]. They examined sections from 30 subjects with autopsy-documented AL ($n = 10$), ATTR ($n = 10$), and non-amyloid controls ($n = 10$) using ^{18}F-florbetapir and cold florbetapir compound and digital autoradiography. Diffuse or focally increased ^{18}F-florbetapir uptake was noted in all AL and ATTR samples and in none of the control samples. Compared with control samples, mean ^{18}F-florbetapir-specific uptake was significantly higher in the amyloid samples ($p < 0.001$) and, interestingly, in the AL compared with the ATTR samples ($p < 0.001$). They concluded that ^{18}F-florbetapir binds specifically to myocardial AL and ATTR deposits in humans and offers the potential to screen for these two most common types of myocardial amyloid.

Finally, Law et al. [65] recently demonstrated the efficacy of ^{18}F-florbetaben PET for detection of cardiac amyloid deposition. They studied five patients with AL amyloid, five with ATTR amyloid, and four control subjects with hypertensive heart disease. Target-to-background SUV ratio and percentage myocardial ^{18}F-forbetaben retention were noted to be higher in amyloid patients compared with hypertensive control subjects. A cutoff value of 40% was able to differentiate between cardiac amyloid patients and hypertensive control subjects. Percentage myocardial ^{18}F-forbetaben retention was an independent determinant of both global left ventricular longitudinal and right ventricular free wall longitudinal strain on echocardiogram via an inverse curve relationship.

Taken together, this small series of preliminary studies indicates that thioflavin T PET analogs are promising for detecting and quantifying amyloid deposition in the heart of patients with cardiac amyloidosis. Furthermore, these PET tracers may be able to distinguish between light chain and transthyretin deposition.

Cardiac Function

First-pass radionuclide ventriculography (RVG) and equilibrium blood pool imaging (often called MUGA for “multigated acquisition”) techniques were developed in the early 1970s [66]. Initial studies reported an excellent correlation of RVG-derived LVEF with values obtained by contrast ventriculography at cardiac catheterization [67–69]. At its inception, a major indication for RVG was the serial monitoring of cardiac function in patients with coronary artery disease. The technique was subsequently applied to the serial evaluation of patients receiving cardiotoxic therapies [70] and remains so today. Cancer patients who receive systemic chemotherapy are at risk for early and late cardiovascular complications (Table 2 [71]).

Table 2 Important cardiovascular side effects of cancer drugs

Side effect	Cancer drug	Rate/incidence	Mechanism	Reversible	Irreversible
Cardiovascular ischemia	Antimetabolites				
	5-Fluorouracil	Frequent	Vasoconstriction	+++	+
	Capecitabine	Infrequent	Vasoconstriction	+++	+

Acute manifestations of chemotherapy-related cardiotoxicity include hypertension, QTc prolongation, pericarditis and/or myocarditis-like syndromes, supraventricular and ventricular arrhythmias, and acute coronary syndromes. Acute complications can occur anytime from the onset of therapy up to 2 weeks after termination of treatment but rarely cause clinical symptoms and usually resolve spontaneously. Many of these effects are dose related and transient and are

often ameliorated by withdrawal of the drug or reduction of the dose. Chronic cardiotoxicity may occur early, within 1 year after completion of chemotherapy, or late, more than 1 year after chemotherapy. Both early- and late-onset chronic cardiotoxicity may culminate in an irreversible cardiomyopathy.

Chronic Cardiotoxicity

Two forms of chronic chemotherapy-related cardiac dysfunction (CRCD) are now recognized: type I and type II [72]. Type I CRCD is exemplified by anthracycline-associated cardiac toxicity, which is clearly dose related, generally irreversible, and associated with characteristic ultrastructural abnormalities. Type II CRCD is epitomized by the toxicity related to the monoclonal antibody trastuzumab, which does not appear to be dose related and is not associated with significant ultrastructural abnormalities. Type II CRCD also appears to be reversible, with a high likelihood of recovery.

Type I CRCD

Doxorubicin (or adriamycin [73]) and other anthracyclines are among the most effective classes of cancer therapy. Unfortunately, the benefits of anthracycline chemotherapy are tempered by potentially serious cardiotoxic effects, which were recognized shortly after the drugs were introduced in the late 1960s [74–76]. The cardiotoxic effects have a dose–response relationship, similar to the antitumor effects of the drug. Despite the medical community's vast experience with this agent, cardiotoxicity remains highly problematic and oncologists and cardiologists continue to struggle with the Hippocratic dictum, "first, do no harm" [77].

The antitumor properties of anthracyclines stem from their ability to intercalate between DNA base pairs of replicating cells, causing DNA fragmentation, inhibition of polymerases, and decreased synthesis of DNA, RNA, and proteins [78]. DNA damage is thought to be mediated in part through targeting of topoisomerase IIα [79]. Doxorubicin is also a powerful iron chelator, with iron-mediated generation of free radicals resulting in the cleavage of DNA and cell membranes. The cardiotoxicity of anthracyclines apparently results from myocyte damage due to toxic free radicals and an increase in oxidative stress, which causes lipid peroxidation of membranes, leading to vacuolization. Myocyte damage is associated with a decrease in endogenous antioxidant enzymes, such as glutathione peroxidase, that are responsible for the scavenging of free radicals [80]. Each successive dose of anthracycline results in incremental cardiac myocyte death and replacement by fibrous tissue. Eventually the compensatory mechanisms of the heart are overwhelmed and dilated cardiomyopathy ensues.

Anthracycline-induced cardiotoxicity can be directly diagnosed by endomyocardial biopsy. This is best assessed by electron microscopy, with characteristic changes that include myofibrillary bundle depletion, myofibrillar lysis, distortion and disruption of the Z-lines, mitochondrial disruption, and intramyocyte vacuolization [81]. Billingham and coworkers [82] found that morphologic damage seen on right ventricular biopsy and quantified on a four-point scale (0 = no damage, 4 = diffuse damage) was related ($r = 0.50$) to the total cumulative doxorubicin dose between 100 and 600 mg/m^2. Morphologic changes were more closely related to cumulative dose in patients who received prior mediastinal radiation ($r = 0.65$). In the same cohort, myocardial performance was preserved until a critical threshold dose of 550 mg/m^2 was reached, after which function deteriorated, echoing the findings of Lefrak et al. A study of 158 patients who underwent single or serial endomyocardial biopsies suggested that the Billingham grading system had greater sensitivity and specificity for early detection of dose-related toxicity ($p < 0.02$) than noninvasive assessment of left ventricular function by gated blood pool studies or M-mode echocardiography [83].

A postmortem study of anthracycline-treated patients similarly found histopathologic changes by light microscopy in 23 of 44 (52%) patients with no clinical signs of cardiotoxicity [84]. Although no histopathologic evidence of toxicity was

identified in seven of 20 (35%) patients who did express clinical signs of cardiotoxicity, this may be attributed to the lower sensitivity of light microscopy for detection of characteristic morphologic changes, when compared with electron microscopy techniques. These tissue-correlation studies suggest that morphologic alterations precede functional deterioration. Hence, endomyocardial biopsy with electron microscopy was given Class IIa recommendation for the assessment of suspected anthracycline-induced cardiomyopathy, based primarily on expert consensus [85].

Noninvasive Monitoring of Anthracycline Toxicity

Despite the high sensitivity and specificity of endomyocardial biopsy, it is not a practical method of patient monitoring given its invasive nature, inherent risks, and expense. Many investigators originally advocated for empiric discontinuation of anthracycline administration after reaching a threshold cumulative dose, based on population-wide data. In 1973, Lefrak et al. [86] found that clinically overt congestive heart failure (CHF) occurred only once in the 366 patients (0.27%) who were treated with less than 550 mg/m^2 of adriamycin, but ten cases were seen in 33 patients (30%) who received more than 550 mg/m^2. Consequently, an empiric restriction of 550 mg/m^2 maximum cumulative dose was recommended for all patients. In a retrospective analysis, however, Von Hoff et al. [87] estimated that 3% of patients developed CHF at a cumulative doxorubicin dose of 400 mg/m^2, 7% at 550 mg/m^2, and 18% at 700 mg/m^2, strongly suggesting an increasing risk of clinical toxicity over a continuum of cumulative doses, debunking the existence of a critical threshold. A more recent retrospective analysis of three prospective studies confirmed the nature of this exponential dose–toxicity relationship and indicated that the incidence of clinical toxicity was grossly underestimated in earlier studies. The percentage of patients with doxorubicin-related CHF was 5.0% at a cumulative dose of 400 mg/m^2, 16% at 500 mg/m^2, 26.0% at 550 mg/m^2, and 48.0% at 700 mg/m^2 [88]. The notorious unpredictability of clinical cardiotoxicity in individuals, and evidence for a $y = x^2$ dose–toxicity relationship among populations [89], has rendered empiric dose limitation obsolete. High cumulative doses, nonetheless, remain an overwhelming risk factor.

In 1979, Alexander et al. [70] reported the utility of RVG as a marker for early detection of anthracycline-related cardiotoxicity by serially monitoring of the LVEF. RVG studies were performed on 51 patients treated with doxorubicin for various types of tumors. Five developed clinical signs of heart failure at doxorubicin doses ranging from 490 to 715 mg/m^2. Absolute declines in the LVEF by more than 15% were noted prior to the development of CHF, which was clinically evident only when the LVEF declined to less than 30%. In six patients with an asymptomatic absolute decline in LVEF of 15% or less at doxorubicin doses of 460–900 mg/m^2, doxorubicin was discontinued and none developed overt heart failure. Repeat measurement of LVEF several months after stopping doxorubicin showed a modest improvement in LVEF in all patients.

In 1987, Schwartz and coworkers published guidelines for surveillance of anthracycline-induced cardiotoxicity based on their experience with RVG over a 7-year period (see Table 3) [90]. In short, baseline LVEF, absolute change in LVEF, and final LVEF were determinants. They retrospectively analyzed 282 serially monitored high-risk patients and found that heart failure developed in only two (3%) of 70 patients monitored according to these guidelines. By comparison, CHF developed in 44 of 212 high-risk patients (21%) in whom the guidelines were incompletely followed (Fig. 4). Multivariate analysis demonstrated a nearly fourfold risk reduction in development of CHF in those managed according to guidelines. In the 46 patients who developed CHF, a mean decline in LVEF of $23 \pm 14\%$ was noted versus a decline of 12 ± 10 in those who did not subsequently develop CHF ($p < 0.001$). While these guidelines have never been prospectively validated, they are still widely accepted today. These guidelines, with an updated discussion and literature review, were updated in 2016 [91].

Table 3 Guidelines for monitoring patients receiving doxorubicin

Perform baseline radionuclide angiocardiography at rest for calculation of left ventricular ejection fraction (LVEF) prior to administration of 100 mg/m^2 doxorubicin. Subsequent studies are performed at least 3 weeks after the indicated total cumulative doses have been given, before consideration of the next dose
Patients with normal baseline LVEF (≥50%)
Perform the second study after 250–300 mg/m^2
Repeat study after 400 mg/m^2 in patients with known heart disease, radiation exposure, abnormal electrocardiographic results, or cyclophosphamide therapy or after 450 mg/m^2 in the absence of arty of these risk factors
Perform sequential studies thereafter prior to each dose
Discontinue doxorubicin therapy once functional criteria for cardiotoxicity develop, i.e., absolute decrease in LVEF ≥10% (EF units) associated with a decline to a level ≤50% (EF units)
Patients with abnormal baseline LVEF (<50%)
Doxorubicin therapy should not be initiated with baseline LVEF ≤30%
In patients with LVEF >30% and <50%, sequential studies should be obtained prior to each dose
Discontinue doxorubicin with cardiotoxicity: absolute decrease in LVEF ≥10% (EF units) and/or final LVEF ≤30%

Risk Factors for Type 1 CRCD

There are many known risk factors for anthracycline-induced cardiotoxicity, in addition to cumulative dose. The pediatric population appears to be more prone to cardiotoxicity at lower cumulative anthracycline doses (250–300 mg/m^2) [92]. At the opposite end of the spectrum, patients older than 65–70 years are also more susceptible to toxicity, probably due to comorbidity of underlying heart disease and/or decreased functional reserve. In one study, after a cumulative dose of 400 m/m^2, patients older than 65 were more than three times more likely to develop CHF than patients younger than 65 (hazard ratio [HR], 3.28; 95% CI, 1.4–7.65, $p = 0.002$) [[54]]. Other drugs, such as cyclophosphamide and trastuzumab (as will be discussed), can augment the cardiotoxic effects of anthracyclines. Chest radiation, either previously or concurrent with chemotherapy probably, increases the risk of cardiotoxicity, possibly due to endothelial cell damage caused by radiation. This factor is particularly relevant for women with breast cancer who often receive radiotherapy to the chest wall or for lymphoma patients who often undergo mediastinal irradiation. Studies indicate a higher risk of toxicity in patients with left-sided breast cancer, due to the proximity to the cardiac vessels and the myocardium. One long-term study of contemporary external beam radiation techniques, however, showed that left-sided targeting is not associated with a higher risk of cardiac death up to 20 years after treatment, but is nevertheless associated with an increased rate of coronary artery disease and MI compared with right breast treatment [93]. Several risk factors were recently elucidated in a SEER data analysis of 43,338 women with breast cancer [94]. After 10 years of follow-up, 38% of women who were treated with anthracyclines at age 66–70 eventually developed CHF with a statistically significant increase in absolute risk of 5.9% and 9.7% when compared with those who received non-anthracycline regimens or no chemotherapy, respectively. This difference was not seen in women at age 71–80, possibly because of higher baseline rates of CHF in this age group because of selection bias, with the healthier women qualifying for anthracycline regimens. Specific predictors of CHF also included years elapsed since therapy (HR, 1.79 per 10 years; 95% CI, 1.66–1.93), Black race (HR, 1.40; 95% CI, 1.30– 1.50), trastuzumab treatment (HR, 1.46; 95% CI, 1.21–1.77), hypertension (HR, 1.45; 95% CI, 1.39–1.52), diabetes (HR, 1.74; 95% CI, 1.66–1.83), and coronary artery disease (HR, 1.58; 95% CI, 1.39–1.79). Left-sided radiotherapy did not confer a clearly increased risk for CHF (HR, 1.04; 95% CI, 0.98–1.11) in this cohort. Inexplicably, anthracycline-treated patients apparently had fewer cardiology visits and underwent fewer LVEF assessments with RVG or echo than other breast cancer patients ($p < 0.0001$).

Late-Onset Cardiomyopathy and the Pediatric Population

Symptomatic heart failure generally presents less than 1 year after anthracycline administration, but as suggested in the SEER data, heart failure

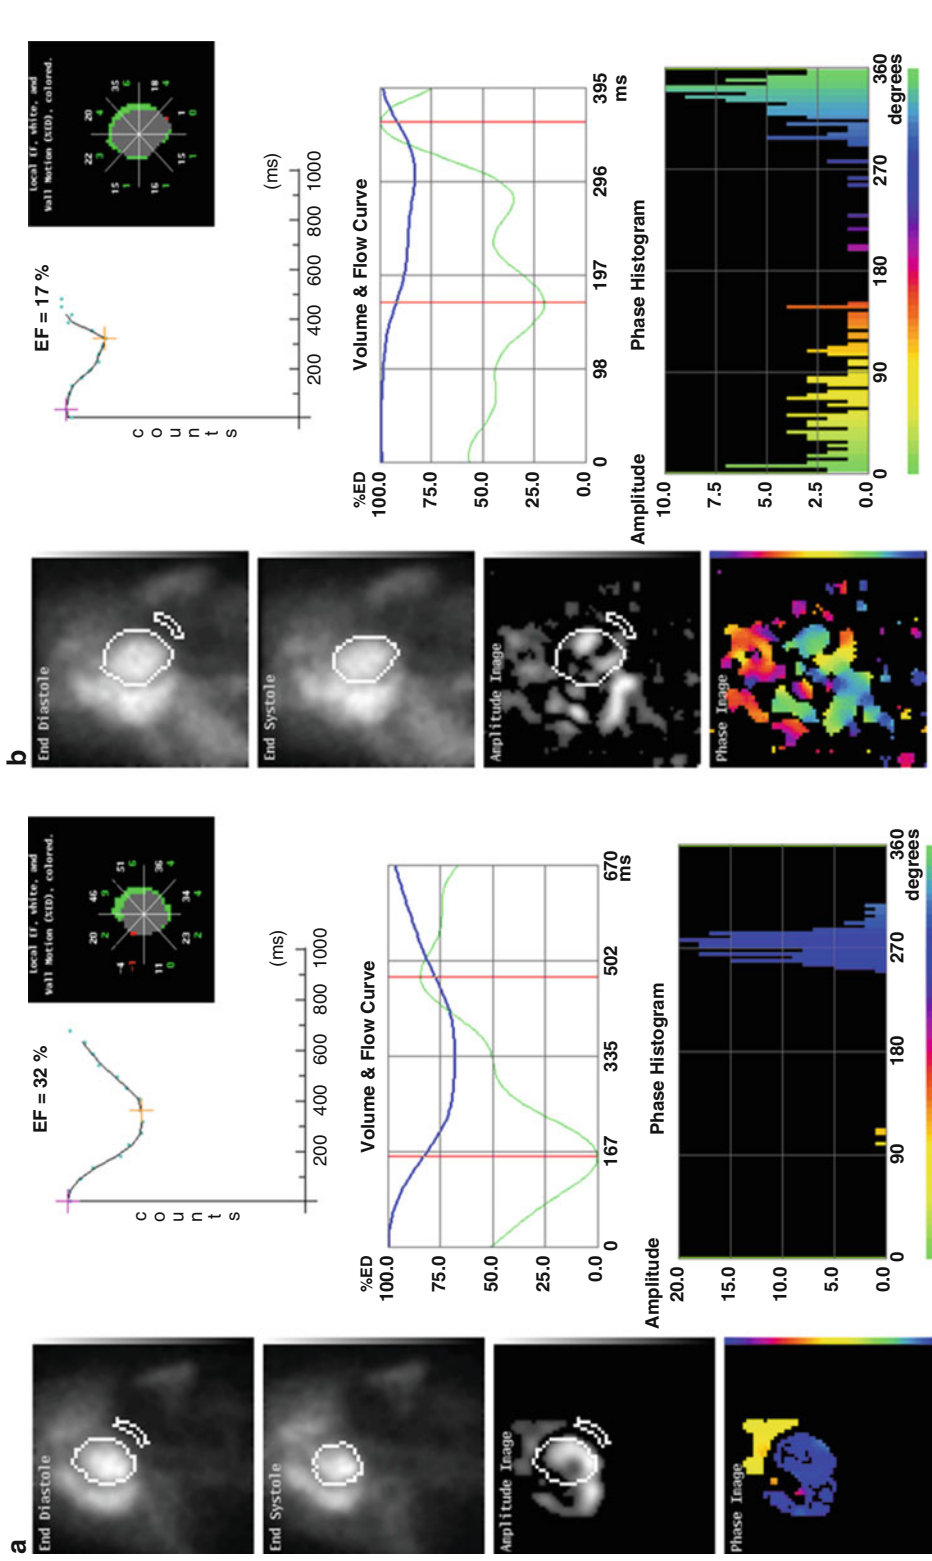

Fig. 4 Example of patient diagnosed with Hodgkin lymphoma at age 24 who developed progressive late-onset cardiomyopathy >10 years after receiving a cumulative doxorubicin dose of 200 mg/m^2 and concurrent XRT to the chest, followed by autologous stem cell transplant. (**a**) Rest RVG 13 years after doxorubicin therapy, LVEF = 32%, asymptomatic. (**b**) Rest RVG 20 years after therapy, LVEF = 17% (20% by echocardiography), NYHA Class III-IV HF

develops in a subset of patients after a latency period of more than a decade. Strong evidence for "late-late" development of cardiomyopathy is primarily derived from pediatric cancer survivors, as seen in the early 1990s [95, 96]. Recent analyses of late cardiotoxicity in childhood cancer survivors confirm that survivors are at increased risk for many cardiac complications, foremost heart failure [97]. The cumulative incidence of adverse cardiac outcomes in cancer survivors appears to continue to increase up to 30 years after diagnosis, at which point more than 7.5% of patients who received a cumulative dose of more than 250 mg/m^2 will have developed heart failure [98]. Guidelines were proposed by the Cardiology Committee of the Children's Cancer Study Group for monitoring acute and late manifestations of doxorubicin cardiotoxicity [99]. For pediatric patients, echocardiography is the preferred method of surveillance to minimize exposure to radiation, with the more reproducible RVG reserved for confirmation of LVEF decline in high-risk patients.

Type II CRCD

Trastuzumab is a humanized monoclonal antibody that targets the extracellular domain of human epidermal growth factor receptor 2 (HER2 also referred to as HER2/neu or erbB-2), a transmembrane tyrosine kinase receptor. Interaction of the antibody with the target inhibits signal transduction, resulting in decreased tumor cell growth and survival. Approximately 25% of newly diagnosed patients with invasive breast cancers overexpress HER2 and are more likely to have an aggressive form of the disease with shortened relapse-free survival and reduced overall survival [100]. In HER2-overexpressing breast cancers, treatment with trastuzumab confers a clear survival benefit in the metastatic and adjuvant settings, both as monotherapy and in combination with cytotoxic agents. Trastuzumab-associated heart failure was recognized in the initial trials of patients with metastatic breast cancer, and a small but significant risk has been repeatedly documented in the adjuvant setting. Pure type II CRCD manifests as a loss of myocardial contractility and is less likely to cause myocyte death. The underlying pathophysiologic mechanism for this dysfunction is not fully understood, but it is believed to be directly related to inhibition of HER2 signaling, which apparently plays an essential role in the heart's compensatory mechanisms following exposure to stress. Preclinical models support this notion, as *erb2* knockout mice tend to develop cardiomyopathy following induction of cardiac stress pathways [101]. Interestingly, these mutant mice are also more susceptible to anthracycline-induced cell death, suggesting a synergistic toxicity. Similarly, limited scintigraphic data indicate that myocardial HER2 expression is upregulated shortly after anthracycline-based chemotherapy, as detected by myocardial uptake on ^{111}In-DTPA-trastuzumab SPECT imaging [102]. One clinical study indicated that serum HER2 levels are increased in patients with depressed LVEF and chronic heart failure [103]. Clinically, patients who have never received anthracyclines do develop cardiac toxicity [104], but the risk is clearly higher in patients who have been treated concurrently or previously with anthracyclines and to a lesser degree with taxanes [105]. This risk of toxicity appears to decrease with longer intervals between the administration of the two drugs. Because trastuzumab has a long half-life, these synergistic effects may come to the fore even when anthracyclines are given after trastuzumab has already been discontinued.

A number of studies suggest that type II CRCD is potentially reversible, including the pivotal phase III trial of trastuzumab [106]. In one study by Ewer et al., 38 patients with HER2-positive breast cancer previously treated with doxorubicin developed cardiotoxicity after trastuzumab therapy, which generally improved after withdrawal of the drug. These patients were safely rechallenged with trastuzumab after the cardiac manifestations abated [107]. After doxorubicin but before trastuzumab, the mean LVEF was 0.61 $\pm$ 0.13, and the LVEF decreased to 0.43 $\pm$ 0.16 after trastuzumab ($p < .0001$). After withdrawal of trastuzumab, LVEF increased to 0.56 $\pm$ 0.11. Mean time to recovery of LVEF was 1.5 months and was temporally associated with medical treatment in 32 (84%) of the 38 patients but occurred without treatment in

six patients (16%). Increases in LVEF were noted in 37 of the 38 patients. Subsequently, 25 of these patients were re-treated with trastuzumab; three patients had recurrent LV dysfunction, but 22 patients (88%) did not. Importantly, in nine patients who underwent endomyocardial biopsy, no ultrastructural changes were seen.

Guarneri et al. evaluated the safety of trastuzumab therapy (median 21.3 months of administration) in 173 patients with metastatic breast cancer [108]. After a median follow-up of 32.6 months, 49 patients (28.3%) experienced a cardiac event: three patients (1.7%) had an asymptomatic decrease in the LVEF of 20%; 46 patients (26.6%) experienced grade 2–3 cardiac toxicity; one cardiac-related death was noted (0.5%). LVEF or symptoms of CHF improved in all but three patients with trastuzumab discontinuation and appropriate therapy, suggesting that toxicity is manageable and generally reversible. Interestingly, baseline LVEF was significantly associated with cardiac events (HR, 0.94; $p < 0.001$).

The HERA trial was a large three-group, randomized trial that compared 1,698 patients randomly assigned to observation and 1,703 randomly assigned to 1 year of trastuzumab treatment. The majority (94.1%) of patients had previously been treated with anthracyclines. Eligible patients had normal LVEF (defined as $\geq$55%) after completion of neo/adjuvant chemotherapy with or without radiotherapy. Trastuzumab was discontinued in 5.1% of patients owing to a cardiac disorder. At a median follow-up of 3.6 years, the incidence of cardiac end points remained low, although it was higher in the trastuzumab group than in the observation group (severe CHF, 0.8% vs. 0.0%; confirmed significant LVEF decreases, 3.6% vs. 0.6%). Roughly 80% (59/73) of those who developed cardiac end points in the trastuzumab group recovered. This important study suggests that the incidence of cardiac end points remains low even after longer-term follow-up [109].

Monitoring and Management

The optimal approach for monitoring of trastuzumab-related cardiotoxicity, as with anthracyclines, lacks complete international consensus. Proposed guidelines from MSKCC are outlined in Table 4 [110].

Similar guidelines were incorporated in the HERA trial [111].

Reducing Cardiotoxicity

Several approaches help reduce the incidence of therapy-associated cardiovascular complications. Patients should be screened for pre-existing cardiac disease, especially valvular disease and cardiomyopathy. A threshold for cumulative dose is controversial in the era of advanced monitoring techniques. Modifying anthracycline administration by prolonged infusions and liposomal formulations has met variable success. Dexrazoxane, an EDTA-like chelator, is thought to prevent anthracycline cardiotoxicity by its ability to bind iron thus preventing free radical formation. Despite the apparent cardiac benefit, the possibility of mitigating the antitumor effect has raised concern regarding the use of dexrazoxane as a cardioprotectant (ASCO guidelines 2008 [112]). Cardioactive medications, such as angiotensin-converting enzyme (ACE) inhibitors and the combined beta- and alpha-blocker carvedilol, are useful in anthracycline- and trastuzumab-induced cardiomyopathy, particularly when started early after cancer therapy [113, 114]. There is also evidence for beneficial effects of statins in this setting [115]. When appropriate, consideration should be given to alternative classes of chemotherapies, such as taxane-based therapies, or other tyrosine kinase inhibitors, for instance, lapatinib [116].

RVG Versus Other Imaging Modalities

Before discussing comparative performance of different modalities for measuring LVEF, it should be emphasized that all sequential measurements of LVEF are subject to inherent physiologic variability owing to hemodynamic, metabolic, hormonal, and pharmacologic factors, etc. One group sought to determine the limits of this variability by performing a double-blind placebo-controlled study in 39 patients who underwent two assessments separated by a 6-week placebo period, during which patients were deemed clinically stable [117]. While the total mean LEVF did not change significantly, LVEFs were quite variable on an individual basis. They determined that inherent variation in contractility is accounted for

Table 4 Proposed guidelines for the management of patients with metastatic disease who are treated with trastuzumab, based on physical status and left ventricular ejection fraction (LVEF)

Physical status[a]	LVEF	Trastuzumab	LVEF monitoring	Management
Asymptomatic	↓but normal	Continue	Repeat in 4 weeks	
	↓ >10 points but normal	Continue	Repeat in 4 weeks	Consider beta-blockers
	↓10–20 points and LVEF >40%	Continue	Repeat in 2–4 weeks Improved: monitor	Treat with medications for LV dysfunction
			Not improved: stop trastuzumab	
	↓ >20 points to <40% or LVEF < 30%	Hold	Repeat in 2 weeks	Treat with medications for LV dysfunction
			Improved to >A5%: restart trastuzumab	
			Not improved: stop trastuzumab	
Symptomatic	↓ < 10 points	Continue		Search for noncardiac pathology (e.g., anemia)
	↓ > 10 points and LVEF >50%	Continue	Repeat in 2–4 weeks	Treat for CHF
			Stable or improved: continue trastuzumab	
			Worsened: stop trastuzumab	
	↓ > 30 points	Stop		Treat for CHF

[a]Heart and body weight should be monitored weekly. Asymptomatic is defined as changes in heart rate and/or weight but without symptoms of dyspnea on exertion. Symptomatic is defined as a new, spontaneous (i.e., unsolicited) report of symptoms of dyspnea on exertion, pulmonary vascular congestion, or edema (From Keefe [110] with permission)

when the change in LVEF is greater than or equal to 7%. It was estimated that a 4% observed increase or decrease in LVEF following a medical intervention can occur by chance more than 25% of the time in individual patients.

RVG is considered more accurate and reproducible than two-dimensional (2D) echocardiography for assessment of LVEF. Advantages and limitations of RVG are listed in Table 5. The modified in vivo method for red cell labeling [118] is preferred over the in vitro and in vivo methods as it provides ease, safety, and high efficiency (92–95%) of labeling.

Normal resting LVEF by equilibrium RVG is greater than 50% as is incorporated into most clinical guidelines and as defined by the Society of Nuclear Medicine. RVG with SPECT has been shown to correlate well with planar-derived LVEF values [119]. SPECT allows for better evaluation of regional wall motion, size, and shape of the left ventricle and does not have the limitation of overlap by other cardiac chambers. Exercise stress RVG may identify a reduced contractility reserve in asymptomatic patients with normal resting LVEF [120]. Measures of diastolic dysfunction obtained on equilibrium RVG may detect toxicity earlier than changes in systolic dysfunction [121].

Advantages of echocardiography include portability, lack of ionizing radiation, and the ability to evaluate other important parameters such as valvular function, wall motion, and hemodynamics, which are better assessed by echocardiography than by RVG. The major disadvantage of echocardiography is the lower reproducibility of LVEF measurement, because of the reliance on geometric assumptions. In addition, patients with – not uncommon – poor acoustic windows are precluded from this procedure. The American Society of Echocardiography and European Society of Echocardiography have defined normal LEVF by echocardiography as greater than 55% for both men and women, although some argue that the lower limit of normal should be redefined to greater than 50% [122]. Three-dimensional

Table 5 Equilibrium radionuclide ventriculography

Advantages	Limitations
Measurements do not rely on geometric assumptions regarding shape of LV	Radiation exposure (6.2 mSv)
Functional information for all cardiac chambers	Limited information regarding structure, in particular of valves
Noninvasive	ECG gating unreliable in patients with significant arrhythmias and variability of RR interval
High accuracy and reproducibility	Limited assessment of ventricular wall thickness
Global and regional LV systolic function can be assessed	Poor technique can introduce errors in measurement
Phase analysis of segmental ventricular contraction conveys information for regional dyssynergy	
Rarely limited by body habitus	Selecting appropriate background in patients with breast prosthesis/tissue expander may be challenging
Relatively easy to perform	

(3D) echocardiography is an increasingly available modality for assessment of systolic function that takes advantage of additional spatial data to provide more accurate estimates for LVEF than two-dimensional (2D) echocardiography. C-MRI is also increasingly available and appears to accurately assess left ventricular systolic function with its high spatial and temporal resolution; however, the high cost of repeated examinations and limited availability render MRI a less-than-ideal for routine monitoring of cardiotoxicity.

Several studies suggest that ejection fraction measurements by various techniques are not interchangeable. A review of eight different studies ($n = 293$) comparing 2D echocardiography with either RVG or contrast angiography exhibited coefficients of correlation ranging from 0.78 to 0.93. Agreement analysis with Bland–Altman plots ranged from 23% to 42% around the mean ejection fraction [123]. A non-oncologic study in patients with chronic stable heart failure who underwent evaluation by M-mode echocardiography, 2D echocardiography, MRI, and RVG showed wide variability in inter-modality measurements, with the narrowest limits of agreement between MRI and RVG at 31% around the mean LVEF [124]. Gopal et al. first demonstrated that 3D echocardiography provides values comparable to RVG and more accurate than 2D echocardiography measurements [125]. A more recent head-to-head study performed in the context of trastuzumab-associated cardiotoxicity confirmed these findings, showing a high correlation ($r = \sim 0.9$) between RVG, 3D echocardiography, and MRI and a weak correlation of these modalities with 2D echocardiography ($r = \sim 0.3–0.4$) for serial LVEF assessment [126]. This suggests that 3D echocardiography and MRI may in fact be interchangeable with RVG as technology continues to improve.

Additional radiopharmaceuticals have been evaluated for the early detection of anthracycline-induced cardiac damage, including necrosis imaging with ^{111}In-antimyosin, apoptosis imaging with ^{99m}Tc-annexin-V, and imaging of cardiac innervation with ^{123}I-MIBG [127]. As of yet, none of these scintigraphic techniques have proven advantageous over imaging of cardiac function with RVG. In particular, the clinical utility of ^{123}I-MIBG is hampered by difficulty with quantifying changes on serial scans. This challenge may be overcome in the near future with the recent development of a quantifiable PET analog of benzylguanidine, ^{18}F-MFBG [128, 129], which is now undergoing evaluation for use in patients with neuroendocrine tumors.

Recommendations

RVG continues to be a widely accepted method for monitoring therapy-related cardiotoxicity in cancer patients. Baseline LVEF assessments should be obtained in all patients receiving anthracyclines and should be strongly considered in patients

receiving trastuzumab, particularly if given before, together with, or following anthracyclines. Risk–benefit ratios should be carefully weighed before initiating or withholding cardiotoxic therapies and are best assessed by dedicated onco-cardiologists or cardio-oncologists. Extreme caution is required when initiating or continuing the drug in patients with the previously specified risk factors, in symptomatic patients, or in patients who have abnormal systolic function at baseline. The lower limit of normal for LVEF by RVG is 50%; however, this value is subject to inter-institutional variability, owing to confounding factors such as the patient population tested, procedure technique and processing, software used for calculation, etc. Echocardiography may be substituted for RVG, particularly in children and those with known valvular abnormalities. The various modalities available for LVEF assessment should not be used interchangeably. Detailed algorithms for monitoring of toxicity by RVG and echocardiography have been provided; however, it should be emphasized that none of these have been prospectively validated. A rule of thumb is that a decline in LVEF of more than 10% to a level below normal (LVEF $<50\%$) is indicative of subclinical toxicity in asymptomatic patients, at which point more intensive monitoring should follow. Investigation with endomyocardial biopsy should be reserved for selective cases where the diagnosis of cardiotoxicity is unclear. In view of the limitations of RVG and echocardiography for early detection of cardiotoxicity, more efficient markers of cardiotoxicity are needed. Well-established serum markers of myocardial damage such as troponins and BNP have demonstrated a clear role in this context [130, 131] but are unlikely to replace serial monitoring of LV systolic function as a marker of toxicity. ACE inhibitors and/or beta-blockers should be considered at the earliest indication of cardiac insult, unless otherwise contraindicated. The list of drugs with potential cardiotoxic effects is increasing (Table 6). As a result, serial measurement of cardiac function is likely to increase as new drugs are developed.

Part VI

Adverse Effects of Cancer Therapy

52 Nuclear Medicine in the Assessment of Adverse Effects of Cancer Therapy in the Lung, Kidney, and Gastrointestinal Tract

Diego Alfonso López Mora and Ignasi Carrió

Abstract

Radiotherapy or chemotherapy and new drugs and strategies in oncology can produce damage in normal organs and tissues affecting the quality of life of the patient. Pulmonary toxicity is frequently seen in patients treated with bleomycin or other chemotherapeutic agents. The most common clinical form of bleomycin pulmonary toxicity is the subacute condition, which may progress to lung fibrosis and death, if not recognized and appropriately managed. The diagnosis is usually established by a combination of clinical, radiographic, and pulmonary function test abnormalities. X-ray and high-resolution CT scan findings are used to identify pulmonary fibrosis. ^{67}Ga-citrate scintigraphy has been used to detect and assess the extent of pulmonary toxicity related to bleomycin in patients who otherwise have normal chest radiographs.

Since conventional CT scanning is not able to distinguish fibrosis and active inflammation, [^{18}F]FDG-PET has been suggested as a tool to indicate the resolution of disease activity. Moreover, [^{18}F]FDG-PET could be useful to detect early preclinical pneumonitis induced by bleomycin. As pulmonary permeability can be altered by chemotherapy, ^{99m}Tc-DTPA aerosols can be used to assess a reduced epithelial permeability.

Acute radiation lung injury can occur within 1–3 months after radiation therapy of the thorax, whereas lung fibrosis can develop 6–24 months later, leading to progressive impairment of pulmonary function. Clinical manifestations, chest radiographs, and pulmonary function tests may help to establish an early diagnosis. Scintigraphic abnormalities can be demonstrated in the acute phase often before radiologic changes become apparent by ^{67}Ga-citrate scintigraphy. Moreover, ^{111}In-pentetreotide may have a role in the differential diagnosis of patients with complaints after radiotherapy and in the monitoring of the response to corticosteroid therapy. [^{18}F]FDG uptake in the irradiated region can be observed up to about 2 months following therapy. The persistence of activity beyond 8 weeks raises the likelihood of persistence of disease within the irradiated region.

Lung scintigraphy with ^{99m}Tc-DTPA aerosol or ^{99m}Tc-MAA (macroaggregates of albumin) has been performed to assess radiation-induced ventilation/perfusion changes.

Drugs for the treatment of abdominal malignancies, such as cisplatin and ifosfamide, and abdominal radiation can cause renal damage.

Chemotherapy-induced nephropathy can be identified with quantitative measurement of glomerular filtration rate. ^{99m}Tc-DTPA has become the preferred radiopharmaceutical because of availability and cost. ^{99m}Tc-

DMSA scintigraphy can be used to establish tubular dysfunction induced by nephrotoxic drugs. Nuclear medicine techniques also offer the possibility to follow the clinical evolution of radiation nephropathy. Bone scans using ^{99m}Tc-MDP can show increased kidney uptake early after radiation in patients with radiation fields including kidneys. Over the subsequent 6–12 months the uptake decreases to normal or below normal levels, associated with the loss of function. Renography with ^{99m}Tc-DTPA can be performed to assess radiation nephropathy. ^{99m}Tc-DTPA Captopril renography test has been used to investigate the relation between small vessel injury due to radiation and hypertension.

Nuclear medicine examinations can play a role in the detection of radiation-induced digestive tract damage.

In cancers of the cervix, endometrium, ovary, prostate, bladder, or rectum, radiation therapy is often required. Radiation proctitis is usually self-limiting and resolves within a month after the conclusion of therapy. Damage of the small bowel is seen in 0.5–15% of the patients. Chronic injuries to the small bowel are manifest 6 and 24 months after radiation. Ileal dysfunction is due to bile acid malabsortion, to bacterial overgrowth in the small bowel, or to the combination of both. ^{75}Se-homocholic acid conjugated with taurine (^{75}Se-HCAT) and ^{14}C-glycochol breath test can be used to differentiate between normal functioning ileum (both tests negative) and ileal dysfunction (one or both tests positive). The combination of both tests may allow the differentiation between bile acid malabsorption (^{75}Se-HCAT positive) and bacterial overgrowth (^{75}Se-HCAT negative).

These techniques may also help to document the benefit of innovative therapeutic approaches such as the use of somatostatin analogs (SOM230). In cases of radiotherapy and chemotherapy-associated liver injury, radionuclide studies can be performed using ^{99m}Tc-iminodiacetic acid or ^{99m}Tc-colloid. In patients receiving radiotherapy, the most common finding is the loss of function of the part of the liver involved in the radiation field, with a reduced uptake in irradiated areas. Recently, acute radiation-induced hepatitis has been reported as a potential cause of false-positive findings of malignancy on [^{18}F]FDG-PET scans. Moreover, esophagitis postradiotherapy can be observed on [^{18}F]FDG-PET scans.

Leucocytes labeled with ^{111}In or with ^{99m}Tc-HMPAO or [^{18}F]FDG can be used in patients with suspected radiation enterocolitis.

This chapter reviews the nuclear medicine findings in detecting organ injury and adverse effects due to cancer or cancer therapy in the lung, kidney, and gastrointestinal tract. The use of radiotherapy or chemotherapy and new drugs and strategies in order to intensify the anti-tumor effect with a curative intent can produce different types of collateral damage in normal organs and tissues affecting the quality of life of the patient. Chemotherapy acts on the parenchymal cells and radiotherapy causes inflammation both in the organ and in the major vasculature (in the direct path of the beam) and affects the microcirculation. In tissues with high proliferation rates, such as the bone marrow and GI tract, stem cells may be depleted and/or injured. Chemo- and radiotherapy can cause acute injury as well as late damage, months to years after treatment. Such damage is usually subclinical.

However, if the organ sustains an additional injury (in some cases even a minor infection), the organ dysfunction may become clinically apparent.

Lungs

Bleomycin is the most common chemotherapeutic agent associated with pulmonary toxicity. However, nitrosureas, erlotinib, cyclophosphamide, mitomycin, busulfan, and methotrexate can also cause such toxicity. At the same time, radiotherapy to lesions of the lung, breast, mediastinum, or esophagus causes initial inflammation, followed by scarring (depending on the dose). Nuclear medicine studies employing ^{67}Ga-citrate and ^{111}In-pentetreotide are able to detect acute and subacute pulmonary toxicity in patients treated either with chemotherapy or radiotherapy. When necessary, pulmonary V/Q scintigraphy can be performed to assess ventilation/perfusion changes in irradiated patients. SPECT/CT ventilation perfusion studies can be particularly helpful, since many of these patients have underlying lung disease. Following multiple courses of platinum-based chemotherapy, hypersensitivity pulmonary reactions can occur in 5–40% of patients, usually after the sixth cycle of treatment, especially when the agents are administered with paclitaxol [1].

Chemotherapy-Associated Pulmonary Toxicity

Chemotherapy-associated pulmonary toxicity is frequently seen in patients treated with bleomycin. The incidence rate of pulmonary toxicity in patients with Hodgkin's disease treated with standard AVBD chemotherapy varies between 18%

and 28% [2, 3]. The risk factors associated with bleomycin-induced pneumonitis include the cumulative dose administered, the age of the patient, and impaired renal function. The incidence and severity of bleomycin toxicity is clearly increased by previous or concomitant thoracic radiotherapy. In these patients, the risk of lethal outcome is ~4% [3, 4]. The total administered dose is clearly a risk factor, with sporadic toxicity occurring at total doses of 100–450 U and increasing incidence beyond that range. The central event in the development of bleomycin-induced pneumonitis is endothelial damage. Bleomycin causes release of cytokines and reactive oxygen species (ROS), leading to cell damage, followed by recruitment of inflammatory cells into the lung parenchyma, and subsequently of fibroblasts leading to fibrosis [4, 5]. Pulmonary fibrosis is characterized by excessive deposition of extracellular matrix components in the alveolar space, which hampers the normal transfer of oxygen. Pathophysiological enzymes, glycoprotein moieties, and matrix degrading lysosomal hydrolases are key markers and play a crucial role in the progression of fibrosis. One important pathogenic process associated with pulmonary fibrosis is injury to basement membranes by matrix metalloproteinases that are produced mainly by macrophages [6, 7].

The clinical and radiological findings in chemotherapy-associated pulmonary toxicity are nonspecific and may be difficult to detect, as they are often similar to other pulmonary syndromes [4]. Therefore, the diagnosis of chemotherapy-associated pulmonary toxicity is challenging; early detection is important to reduce lung injury and prevent pulmonary fibrosis [3–5]. Pulmonary toxicity may be short-term or permanent. The lung injury that resolves (returns to normal) after time or after the cause is removed is called acute/subacute pulmonary toxicity and the lung injury that is permanent is called chronic or late pulmonary toxicity.

The most common clinical presentation of Bleomycin-induced pneumonitis is the subacute pneumonitis, which tends to progress with time leading to lung fibrosis and death if not properly diagnosed and treated. The diagnosis of bleomycin-induced pneumonitis can be suspected with the appearance of the clinical manifestations (progressive dyspnea and nonproductive cough), the appearance of pulmonary function tests abnormalities with restrictive patterns (diminished total lung, vital capacities, and DLCO), and the appearance of common findings in chest X-ray (bilateral, lower pulmonary lobes, sometimes followed by diffuse interstitial and alveolar infiltrates) and high-resolution CT scan (diffuse areas of ground-glass opacity, interlobular septal thickening, fibrosis, or consolidation) [4, 8, 9]

Scintigraphy with ^{67}Ga-citrate has been used to detect and assess the extent of pulmonary toxicity related to bleomycin. ^{67}Ga has an atomic structure and biological behavior similar to iron (ferric ion) with the property to bind to any proteins that bind iron. ^{67}Ga circulates in plasma bound to transferrin protein. The complex ^{67}Ga-transferrin is transported to the inflammatory site due to the local increased blood flow and vascular permeability. In the inflammation site, neutrophils release large amounts of lactoferrin, which binds to ^{67}Ga. Also siderophores, compounds secreted by microorganisms such as bacteria can also bind to ^{67}Ga. Therefore, ^{67}Ga localization at the inflammation/infection site is secondary to its ferric ion-like properties [10] and allows localization, delineation of extent, and assessment of the degree of activity of the inflammatory disease [11]. ^{67}Ga scintigraphies in drug-induced pneumonitis show a bilateral diffuse lung uptake, in patients undergoing chemotherapy (including bleomycin) with normal chest X-rays (Fig. 1) [12].

Positron Emission Tomography with 2-deoxy-2-[^{18}F] fluoro-D-glucose ([^{18}F]FDG PET/CT) is a widely used molecular imaging technique in the assessment of treatment response in oncological patients [9, 13–16]. Chemotherapy-associated pulmonary toxicity is a potential cause of false-positive results in [^{18}F]FDG PET/CT of patients undergoing chemotherapy [9, 14], in particular when bleomycin is used (standard AVBD treatment for Hodgkin's disease) [4, 8, 9]. Based on the physiopathology of the inflammatory processes, a number of studies have demonstrated that a higher activation of macrophages, neutrocytes, or lymphocytes is correlated with a higher accumulation

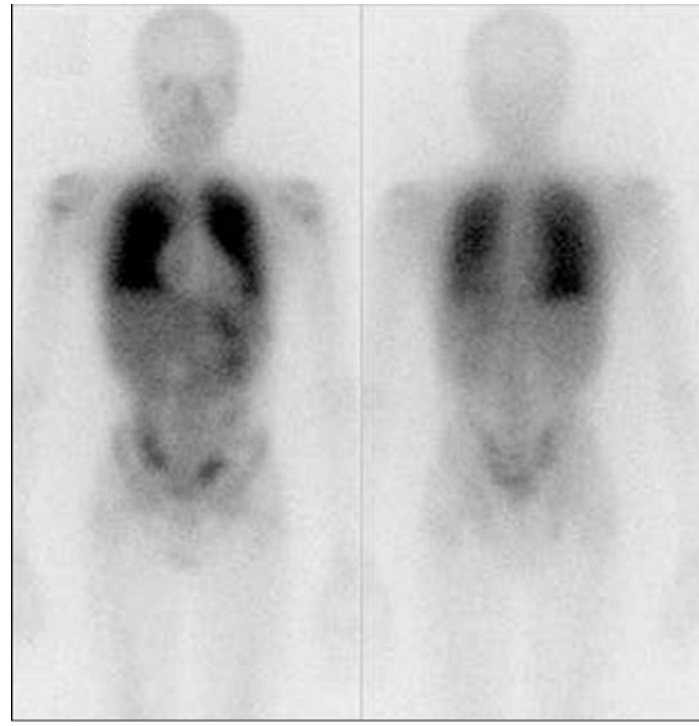

Fig. 1 Patient with Hodgkin's lymphoma treated with bleomycin. Diffuse bilateral uptake of ^{67}Ga reflects pulmonary toxicity

of [^{18}F]FDG [17–21]. Therefore, the degree of [^{18}F]FDG uptake in drug-induced pneumonitis may reflect the metabolic activity and supports its use to assess disease activity [17].

In acute drug-induced pneumonitis, the process starts with pulmonary infiltration of neutrophils, followed by morphological changes seen on high-resolution CT scan. Thus, in early stages of pulmonary toxicity, high-resolution CT scans may be unable to detect such abnormal morphological changes. In this case, [^{18}F]FDG PET/CT may be a more sensitive tool to detect early drug-induced pneumonitis, even before the onset of pulmonary symptoms and the appearance of parenchymal changes in chest X-ray and/or CT scan. Such early detection may be useful for accurate treatment to reverse the lung injury and prevent pulmonary fibrosis [22] (Fig. 2). Along this line, [^{18}F]FDG PET/CT in drug-induced pneumonitis may be used to monitor the effects of corticosteroid treatment. Von Rohr et al. [23] reported that PET scan and CT scan findings resolve after immunosuppressive therapy. Also Butchler et al [24] reported that the PET scan performed within 2 months of onset of bleomycin-induced pneumonitis demonstrated diffuse pulmonary [^{18}F]FDG uptake which resolved after corticosteroid treatment with persistence of morphological (parenchymal) changes in conventional CT scan. These data suggests that [^{18}F]FDG PET/CT may be used to distinguish between residual changes and active inflammation and that [^{18}F]FDG PET/CT may provide a tool to indicate the resolution of disease activity, even in the presence of residual pulmonary scarring [24]. Along the same line, Connerotte et al [25] have shown that PET abnormalities can resolve after cessation of bleomycin as the only intervention, suggesting that [^{18}F]FDG PET/CT could be useful to detect early preclinical bleomycin-induced pneumonitis at a stage that is fully reversible upon cessation of bleomycin. Therefore, [^{18}F]FDG PET/CT may be used in the detection of bleomycin-induced pneumonitis before clinical symptoms and possibly before significant lung function or conventional radiology alterations take place.

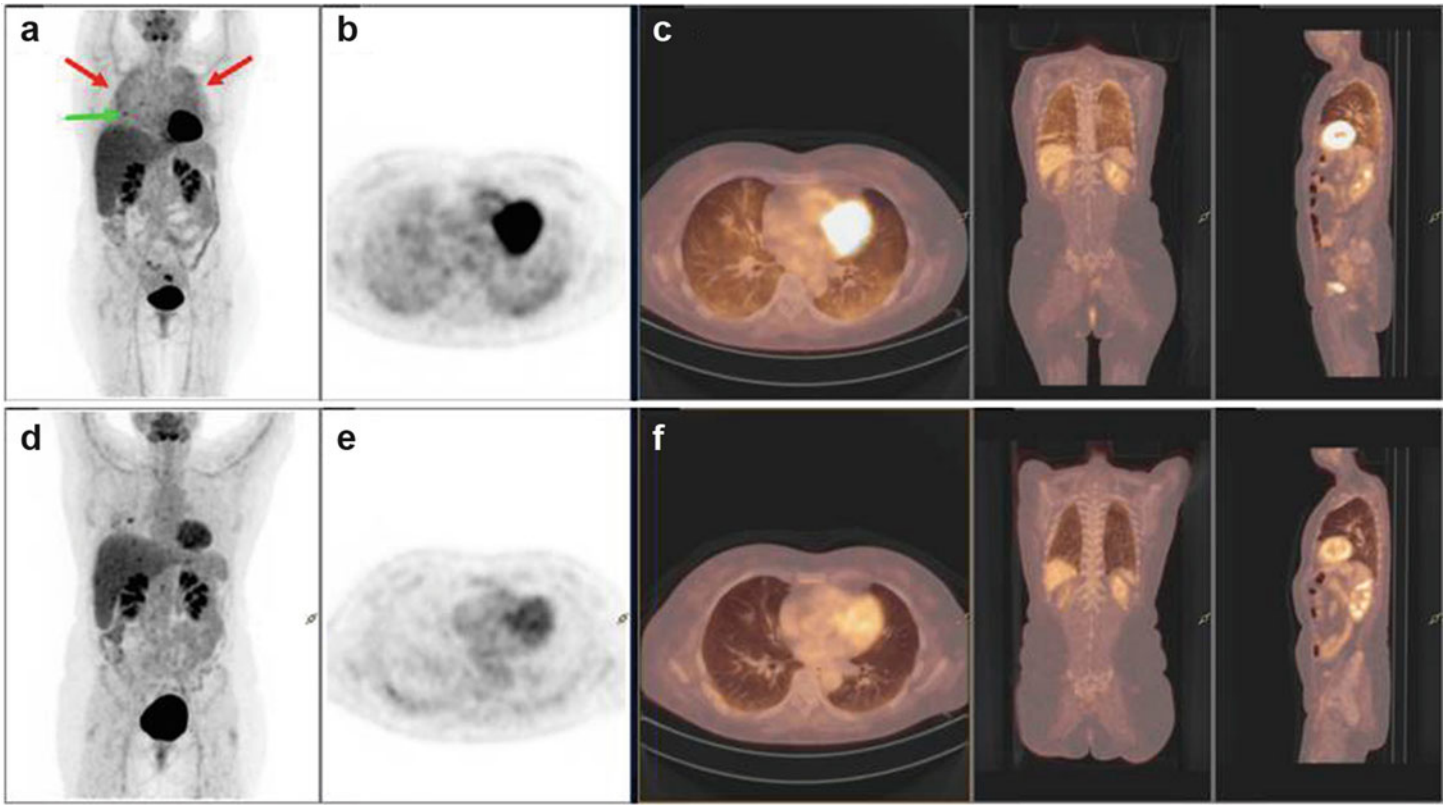

Fig. 2 Chemotherapy-associated pulmonary toxicity in a 53-year-old woman who received erlotinib/bevacizumab for metastatic non-small cell lung cancer (NSCLC). (**a**) After the third chemotherapy cycle, the MIP PET image demonstrates a diffuse [^{18}F] FDG uptake in both lungs (*red arrows*) and a focal [^{18}F]FDG uptake that corresponds to the NSCLC (*green arrow*). (**b**) Axial PET and (**c**) fused PET/CT images show hypermetabolic diffuse ground-glass infiltrates in both lungs. In the context of recent chemotherapy, these findings were consistent with chemotherapy-induced pneumonitis. The anatomical pathology of the transbronquial biopsy of the left inferior pulmonary lobe demonstrated acute inflammatory changes. (**d**) MIP PET, (**e**) axial PET and (**f**) fused PET/CT images performed 3 weeks after bevacizumab stop, reduce erlotinib dose, and steroid administration showed resolution of the hypermetabolic diffuse ground-glass lung infiltrates

Pulmonary Permeability During Chemotherapy

In chemotherapy-induced lung injury, pulmonary permeability is altered because of alveolar epithelial disruption with fluid and protein leakage into the alveolar spaces and focal necrosis of type I pneumocytes and fibrosis. Permeability can be assessed using ^{99m}Tc-DTPA aerosols. The inhalated aerosol is deposited in the alveoli, permitting the acquisition of scintigraphic images that show different patterns of ventilation. In the non-inflammed lung there is minimal permeability of the DTPA from the air space to the vasculature, hence minimal activity in the systemic circulation. The inflammed lung has greater permeability, allowing passage of the tracer from the air space to the vasculature. The clearance time decreases as epithelial permeability [26, 27] increases. In untreated patients, permeability was reduced, possibly because of tumor infiltration, while it was increased in treated patients, suggesting early injury [28, 29].

Radiation Pneumonitis

In radiation therapy of the thorax, radiation pneumonitis can appear 2–8 months after treatment. Radiation lung injury occurs in proportion to the amount of lung that is exposed to doses of >20 Gy. Symptoms vary from none, when radiation is delivered to a small region of the lung, to systemic signs and symptoms of fever, dyspnea, cough, and respiratory distress syndrome, when radiation is delivered to >20% of the total lung volume. Following lung radiation there are two phases of cytokine expression: one occurring hours to days or weeks after radiation, typically returning to normal after ~2 weeks and a second phase at 6–8 weeks, leading to pulmonary parenchymal and vascular damage [30], which may progress for 6–24 months following radiation exposure. Within 1–3 months of exposure, acute radiation lung injury can occur, manifested by dyspnea, cough, and hypoxia. Six to twenty-four months after radiation lung fibrosis can occur, leading to progressive impairment of pulmonary function. Early detection of radiation pneumonitis enables adequate treatment with a reasonable chance to prevent or limit late sequelae [31]. Clinical manifestations, chest radiographs, and pulmonary function tests may help establish an early diagnosis, but scintigraphic abnormalities can be demonstrated in the acute phase often before radiologic changes become apparent. ^{67}Ga-citrate scintigraphy is also a sensitive method for the early detection of radiation pneumonitis [32], although the delineation of lung injury may be hampered due to the physiologic ^{67}Ga uptake in sternum and thoracic spine. Pentetreotide, a synthetic somatostatin analog with strong affinity for the somatostatin receptor subtypes 2 and 5, can be labeled with ^{111}In. Somatostatin has been shown to modulate fibroblast activation and to have antifibrotic properties also [33], although the exact mechanisms of such antifibrotic action of octreotide still remains unclear. ^{111}In-pentetreotide may have a role in the differential diagnosis of patients with complaints after radiotherapy and in the monitoring of the response to corticosteroid therapy [31]. Some false-positive studies have been reported with increased pulmonary uptake in patients with neuroendocrine tumors which eventually was due to pulmonary fibrosis (Fig. 3) [34, 35]. [^{18}F]FDG-PET has also been recently proposed to detect radiation pneumonitis [36] and may be used as a predictor for acute radiation pneumonitis [37] (Fig. 4).

There may be significant [^{18}F]FDG uptake in the irradiated region up to about 2 months following therapy. Persistence of significant focal activity beyond 8 weeks raises the likelihood of persistence of disease within the irradiated region.

Ventilation/Perfusion Changes Induced by Thoracic Irradiation

Radiation-induced lung damage may lead to decreased lung perfusion, lung ventilation, and diffusion of gases in the irradiated region. A decrease in pulmonary blood flow in the irradiated areas has been reported in breast cancer patients receiving radiotherapy [38]. Lung scintigraphy with ^{99m}Tc-DTPA aerosol or ^{99m}Tc-MAA (macroaggregates of albumin) has been performed to assess abnormal ventilation/ perfusion patterns.

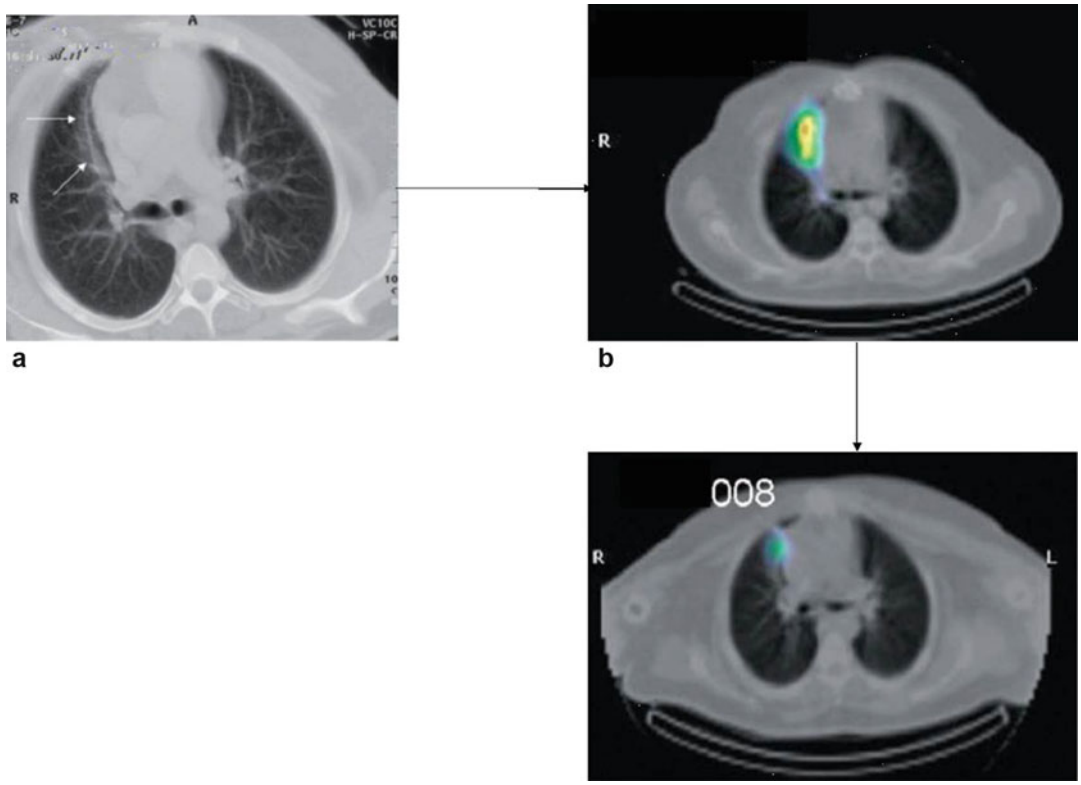

Fig. 3 Patient with a neuroendocrine tumor studied 10 months after radiotherapy. (**a**) CT. (**b**) Pulmonary fibrosis in the right paramediastinum shows ^{111}In-pentetreotide uptake on the SPECT image. (**c**) Decreased radiollabeled octreotide uptake 9 months later (Ref. [33], with permission)

A reduction in both ventilation and perfusion was observed 3 months after radiotherapy. Other radiotracers used in different studies include ^{133}Xe, ^{81m}Kr gas, or ^{131}I-MAA with reduced perfusion in the irradiated areas as the common finding [38–40].

Kidneys

Chemotherapy drugs (cisplatin and ifosfamide) can cause renal damage, while abdominal radiation in the treatment of abdominal malignancies can lead to renal nephropathy. Several radionuclide techniques have been proposed to evaluate the effect of these treatments on the kidneys.

Chemotherapy-Induced Tubular Injury

The use of nephrotoxic chemotherapeutic agents can lead to both acute and chronic toxicity, including life-threatening progressive deterioration of kidney function. Cisplatin, a frequently used chemotherapeutic agent, may cause renal toxicity in about one third of patients, usually manifest as a decrease in glomerular filtration rate (GFR). The process is initiated by proximal tubular damage followed by alterations in the GFR and in the effective plasma renal flow [41]. The decrease in GFR is closely related to the dose. Cisplatin can be given in four cycles of 20 mg/m^2 for 5 days without kidney damage, but a treatment dose of 40 mg/m^2 daily for 5 days results in the reduction

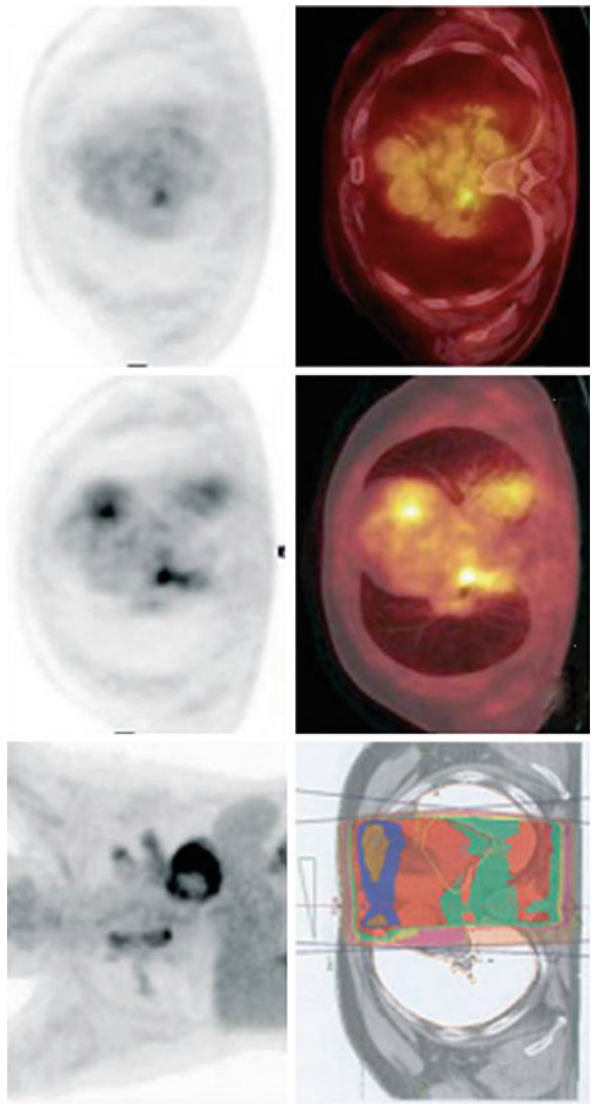

Fig. 4 Post radiotherapy pneumonitis in areas of the radiotherapy treatment field (*left* and *central* panels), with resolution on the [^{18}F]FDG PET/CT scan 2 months later (*right* panel)

of GFR and tubular function [42]. The strategies to prevent cisplatin nephrotoxicity are based on early detection and reduction of toxic effects using diuretics (mannitol and furosemide) or on the use of other platinum derivatives such as carboplatin and iroplatin which have less kidney toxicity. On the other hand, ifosfamide can induce Fanconi's syndrome, a disorder of the proximal tubule of the kidney, with increasing risk at doses exceeding 50 mg/m^2 [43].

Chemotherapy-induced nephropathy can be identified with quantitative measurement of GFR. Although the gold standard for this measurement utilized intravenous injection of ^{51}Cr-labeled EDTA, ^{99m}Tc-DTPA has become the preferred radiopharmaceutical because of availability and cost. Typically, three blood samples are obtained over 2–3 h and tracer clearance is calculated. Methods proposed to evaluate tubular function include the determination of the fractional excretion of electrolytes, the renal threshold for phosphate, aminoaciduria follow-up, and determination of low-molecular-weight proteins (beta-2 microglobulin). Results of such methods should be interpreted with caution before assuming proximal tubular damage because they are affected by excessive secretion of hormones, dependence on plasma concentration of proteins, and urine-plasma measurement. ^{99m}Tc-DMSA scintigraphy can be used to establish tubular dysfunction [44]. It binds to proximal tubular cells. Diseases affecting the proximal tubules, such as tubular acidosis, Fanconi's syndrome, or tubular dysfunction due to nephrotoxic drugs, inhibit ^{99m}Tc-DMSA uptake. In patients treated with ifosfamide, a significant correlation has been found between ^{99m}Tc-DMSA uptake and cumulative doses of ifosfamide ($p < 0.01$). Anninga et al. found that ^{99m}Tc-DMSA scintigraphy is more consistent than urine levels of beta-2 microglobulin in detecting ifosfamide-induced tubular dysfunction and concluded that the test is also able to detect subclinical injury. Other studies show that ifosfamide-induced tubular injury can be detected with ^{99m}Tc-DMSA scintigraphy [45], even before chemotherapy-associated nephrotoxicity is observed by other laboratory measurements [45–47].

Radiation Nephropathy

Radiation therapy can cause damage to the endothelial cells of the glomeruli, the parenchymal vessels, or the renal tubules leading to the radiation nephropathy [48]. Lesion progress is typically slow but resulting in complete atrophy of the irradiated renal tissue with a total loss of function. Nuclear medicine techniques offer the possibility to follow the clinical evolution of radiation nephropathy. Bone scans, using ^{99m}Tc-MDP, show abnormal uptake in the kidney of patients with radiation fields including kidneys, as for vertebral or rib malignancies. Early after radiation (over about 6–9 months) ^{99m}Tc-MDP uptake is increased. Over the succeeding 6–12 months the uptake decreases to normal or below normal levels, associated with the gradual loss of renal parenchymal function [49]. Renography with ^{99m}Tc-DTPA can be performed to assess radiation nephropathy. ^{99m}Tc-DTPA is cleared through glomerular filtration providing information about glomerular function. Simultaneous ^{99m}Tc-DTPA scans to study glomerular function and ^{99m}Tc-DMSA imaging to study tubular function show a decline in renal function at about 6 months after irradiation. Scintigraphic studies with ^{99m}Tc-DTPA and ^{99m}Tc-DMSA have been found to be more sensitive than biochemical tests to assess radiation injury. Renal toxicity has been demonstrated during treatment at radiation doses over 18 Gy. In these patients, radionuclide studies performed at regular intervals are useful for appropriate assessment of renal toxicity [49]. Some studies have described a relation between small vessel injury due to radiation and hypertension. Using ^{99m}Tc-DTPA renography with and without Captopril in patients with hypertension, it has been shown that small-vessel injury appears in hypertensive patients due to increased release of renin [50]. Other studies with ^{99m}Tc-DMSA in unilateral kidney irradiated patients have evaluated the function of each kidney. After a follow-up of 5 years, results showed that the increase of volume in the contralateral kidney was less accentuated than the increase in uptake. This suggests that the mechanism to compensate

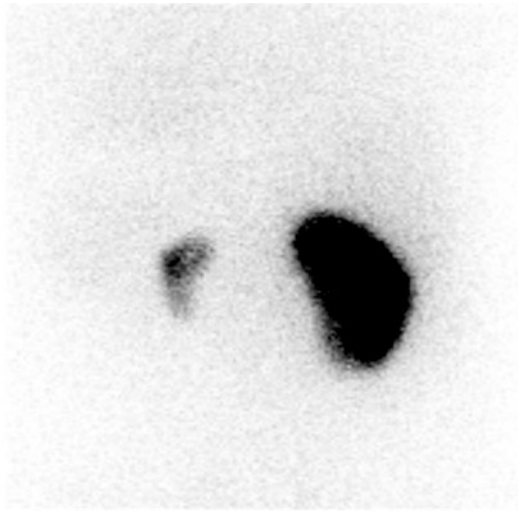

Fig. 5 ^{99m}Tc-DMSA scintigraphy in a patient who received radiotherapy involving the left kidney. Right kidney remains normal

the radiation nephropathy of the contralateral kidney would be hyperfunction rather than hypertrophy [51]. These findings underline the need to perform follow-up function studies in unilateral kidney disease (Fig. 5).

Digestive Tract

Nausea, vomiting, diarrhea, and enteritis often occur due to radiotherapy and chemotherapy. Nuclear medicine examinations can play a role in the detection of radiation-induced late injury on the small bowel.

Radiation Damage of the Small Bowel

In cancers of the cervix, endometrium, ovary, prostate, bladder, or rectum, radiation therapy is often required. In the course of radiation therapy, rectal toxicity of grade 1–2 (Radiation Therapy Oncology Group definition = grade 1 = minor symptoms requiring no treatment; grade 2 = symptoms that respond to simple management) occurs in ~70% of patients. The occurrence of radiation proctitis is related to the volume of the rectum exposed to doses >60 Gy. Radiation proctitis is usually self-limiting and resolves within a month after the conclusion of therapy. Damage of the small bowel is seen in 0.5–15% of the patients [52], and it is characterized by progressive cell depletion, collagen fibrosis, and obliterative vascular injury [53]. Small bowel radiation results in epithelial stem cell injury as an early effect and in evolving vascular injury and collagen fibrosis as late effects. Chronic injuries to the small bowel are manifest 6 and 24 months after radiation [54]. Factors predisposing to late small bowel complications include the total radiation dose, the dose per fraction, the volume of small bowel irradiated, previous surgery, age, diabetes, and chemotherapy combined with radiation therapy [53]. Ileal dysfunction is very frequent in patients with radiation damage of the small intestine, and it is due to bile acid malabsortion, to bacterial overgrowth in the small bowel, or to the combination of both. Endoscopy cannot detect radiation injury of the small bowel. Valdés Olmos et al. used ^{75}Se-homocholic acid conjugated with taurine (^{75}Se-HCAT) and [^{14}C] glycochol breath test to differentiate between normal functioning ileum (both tests negative) and ileal dysfunction (one or both tests positive) in a group of patients who received radiotherapy treatment. Unfortunately, a positive ^{14}C breath test alone cannot differentiate between bile acid malabsorption and bile acid loss due to bacterial overgrowth [51]. However, the combination of both tests may allow the differentiation of those with bile acid malabsorption (^{75}Se-HCAT positive) from those with bacterial overgrowth (^{75}Se-HCAT negative) [55]. Recent studies have proposed the use of somatostatin analogs (SOM230) to treat diarrhea and to ameliorate intestinal injury after localized irradiation in mice [56]. The results show that SOM230 increases survival, preserves mucosal surface area, and reduces bacterial translocation in a dose dependent manner and with a mechanism that likely involves reduction of intraluminal pancreatic enzymes. Nuclear medicine techniques may help to document the benefit of such innovative

approaches that can provide effective countermeasures against radiation injury of the digestive tract.

Liver Damage

The liver is also affected by radio- and chemotherapy treatments. Biopsies show nonspecific fibrosis and rarely cirrhosis, with hepatocellular necrosis and bile stasis [57]. In these cases of radiotherapy- and chemotherapy-associated liver injury, radionuclide studies can be performed using ^{99m}Tc-IDA scintigraphy or ^{99m}Tc-colloid. ^{99m}Tc-IDA has the same behavior as bilirubin. After entering the hepatocyte, it is transported into the bile canaliculi and from bile ducts to small intestine. Gallbladder filling is typically seen. In patients receiving radiotherapy, the most common finding is the loss of function of the part of the liver involved in the radiation field, with a reduced uptake in irradiated areas. A gallbladder filling defect can also be detected in gallbladder carcinomas after radiation therapy [58]. Recently, acute radiation-induced hepatitis has been reported as a potential cause of false-positive findings of malignancy on [^{18}F]FDG-PET scans. [^{18}F]FDG-PET performed 26 days after chemoradiotherapy in an esophageal cancer shows a wedge-shaped hypermetabolic area in which the degree of [^{18}F]FDG uptake is correlated with the prescribed radiation dose. Follow-up [^{18}F]FDG-PET 4 months later showed no abnormal uptake in the liver consistent with acute radiation-induced hepatitis, indicating that PET images must be carefully compared with the distribution of prescribed radiation dose [59].

Other Tracers in Injuries on the Digestive Tract

Finally, irradiation-induced odynophagia and esophageal ulcerations can be visualized by ^{99m}Tc-sucralfate, a tracer that accumulates on esophageal lesions and has shown a very good correlation with endoscopy [60]. Esophagitis postradiotherapy can be observed on [^{18}F]FDG-PET scans (Fig. 6) [36]. Esophagitis postradiotherapy occurs usually, by week 3 or 4 in patients undergoing radiotherapy, treated for thoracic nodal disease and non–small cell lung cancer [61]. Some risk factors are associated with the severity and

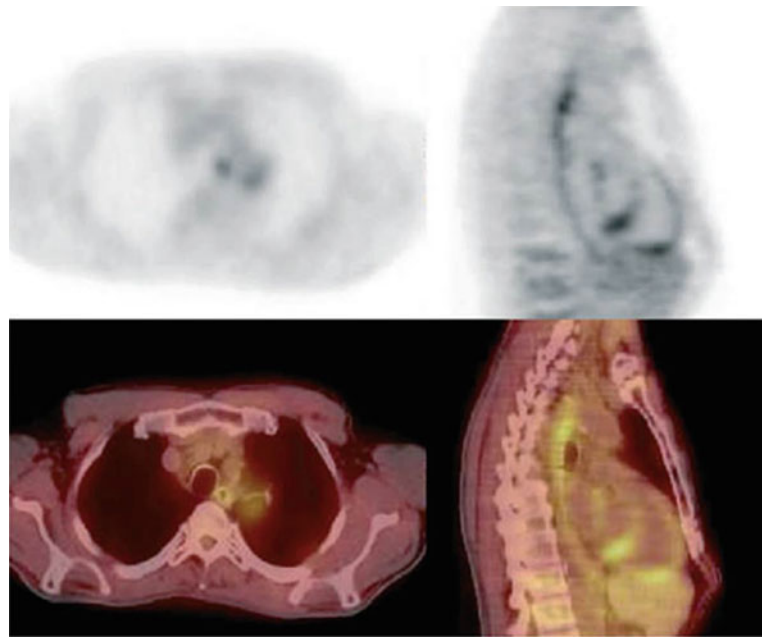

Fig. 6 Diffuse [^{18}F]FDG uptake along the esophagus with a characteristic pattern of post-radiotherapy esophagitis

incidence of esophagitis postradiotherapy such as the age of the patient, tumor type, tumor burden, concurrent chemotherapy, body mass index, and dosimetric predictors (mean esophageal dose, maximal esophageal dose, and percentage of esophagus volume that receives more than 20Gy of radiation) [62–64].

In addition, radiopharmaceuticals commonly employed to assess inflammation, such as leucocytes labeled with ^{111}In or with ^{99m}Tc-HMPAO or [^{18}F]FDG, can be used in patients with suspected radiation enterocolitis in order to localize areas of increased inflammatory activity in small bowel and colon [65].

Keywords

Hodgkin's lymphoma • Non-Hodgkin lymphoma • [^{18}F]FDG • PET/CT • PET/MRI • Diffuse large B-cell lymphoma • Burkitt lymphoma • Response to therapy

Glossary

[^{18}F]FDG	2-Deoxy-2-[^{18}F]fluoro-D-glucose
ABVD	Chemotherapy regimen based on doxorubicin bleomycin, vinblastine, and dacarbazine
AJCC	American Joint Committee on Cancer
CT	X-ray computed tomography
DLBCL	Diffuse large B-cell lymphoma
HL	Hodgkin's lymphoma
MIP	Maximum intensity projection
MRI	Magnetic resonance imaging
PET	Positron emission tomography
PET/CT	Positron emission tomography/ Computed tomography
PET/MRI	Positron emission tomography/ Magnetic resonance imaging
SUV	Standardized uptake value
SUV_{max}	Standardized uptake value at point of maximum
NHL	Non-Hodgkin lymphomas
R-CHOP	Rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone
R-COMP	Rituximab, cyclophosphamide, non-pegylated liposome-encapsulated doxorubicin, vincristine and prednisone

Diffuse Large B Cell Lymphoma

Case contributed by: V. Yerubaudi, C. Sakellis, A.D. Van den Abbeele, H. Jacene

Nuclear Medicine/PET-CT, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts, USA

Presentation

A 65-year-old man with no significant past medical history presented with night sweats, low-grade fevers, weight loss, decreased appetite, and worsening dyspnea on exertion for several months.

Findings

A CT pulmonary arteriogram obtained to evaluate for pulmonary embolism at initial clinical presentation was positive for pulmonary emboli (Fig. 1). An anterior mediastinal mass involving the pericardium and myocardium causing narrowing of the right heart chambers (Fig. 2) and completely encasing the right coronary artery without occluding or significantly narrowing the lumen (Figs. 1 and 2) was also shown.

Diagnostic CT of the abdomen and pelvis (not shown) did not show additional areas of adenopathy. A cardiac MRI better delineated tumor margins and defined the myocardial and pericardial involvement (Fig. 3). Pathology from mediastinoscopic biopsy was consistent with non-Hodgkin diffuse large B-cell lymphoma with high grade features.

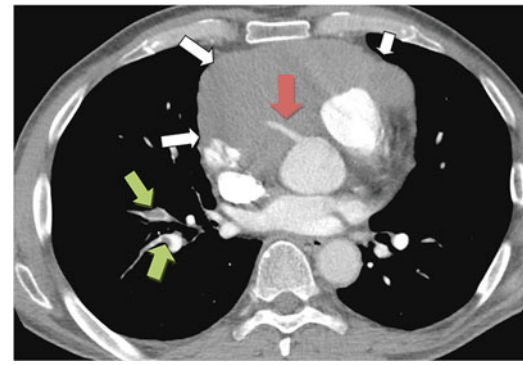

Fig. 1 CT pulmonary arteriogram showing large mass (*white arrows*) overlying the main pulmonary artery and aortic root with encasement of the proximal right coronary artery (*red arrow*). Pulmonary emboli can also be seen in the right pulmonary arteries (*green arrows*)

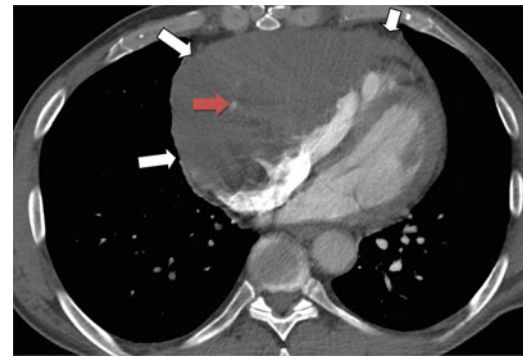

Fig. 2 CT pulmonary arteriogram showing a large pericardial/myocardial mass (*white arrows*) involving the right ventricle and right atrium with severe narrowing of the right heart chambers. Distal right coronary artery remains encased in the mass (*red arrow*)

[^{18}F]FDG PET/CT was performed prior to initiation of therapy (Fig. 4) and showed intense [^{18}F]FDG uptake in the dominant mass involving the right heart (Fig. 5) with additional sites of intense uptake in the superior mediastinum, left face adjacent to the parotid gland, and right mid-abdomen. These areas of uptake in the left face and right mid-abdomen were found to be additional sites of disease on further evaluation. These multiple areas of lymph node involvement and extranodal cardiac involvement with the presence of symptoms made the patient AJCC Stage IVB.

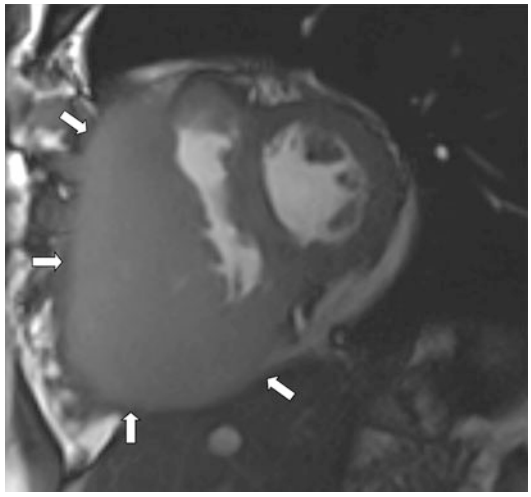

Fig. 3 Cardiac MRI EKG-gated TrueFISP sequence showing the large mass (*white arrows*) involving the right ventricular free wall in a short axis view

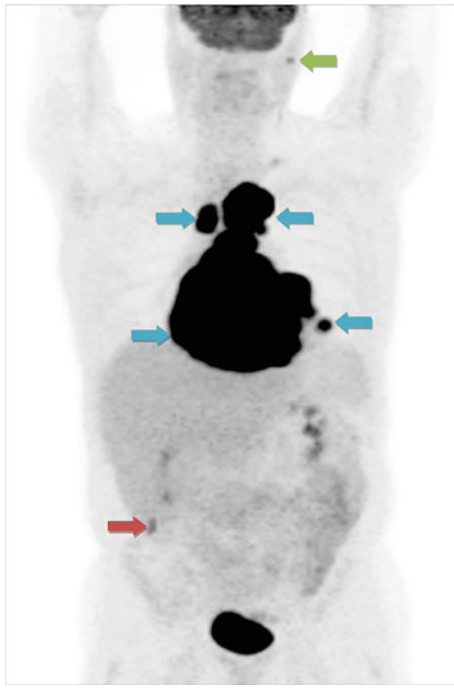

Fig. 4 PET maximum intensity projection image from the anterior view showing large mass (*blue arrows*) in the region of the right heart and superior mediastinum with additional [^{18}F]FDG-avid lymph nodes (*blue arrows*) and a separate pericardial [^{18}F]FDG-avid nodule (*blue arrows*). Small [^{18}F]FDG-avid lymph nodes were also identified in the left face (*green arrow*) and right abdomen (*red arrow*) consistent with additional sites of disease

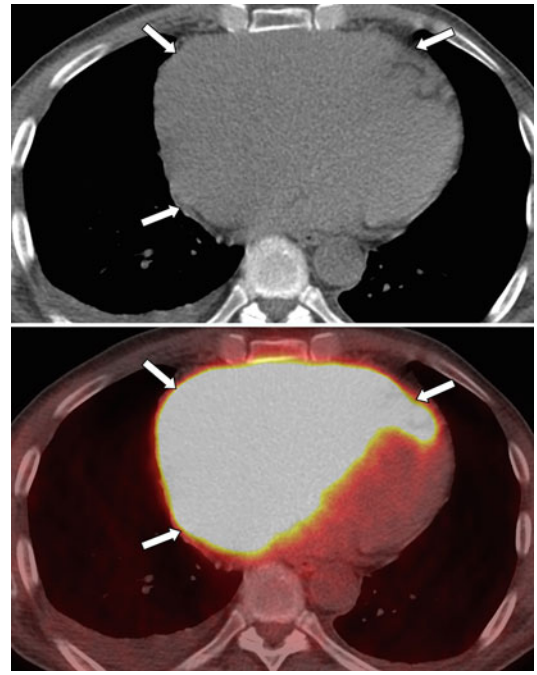

Fig. 5 Axial CT (*above*) and fused PET/CT (*below*) show intense [^{18}F]FDG uptake in the large anterior mediastinal mass with extensive cardiac involvement. Small right larger than left pleural effusions are also incidentally noted on CT

Follow-up

[^{18}F]FDG PET/CT imaging after completion of therapy with 6 cycles of R-CHOP (rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone) as well as 3 cycles of high dose methotrexate. PET/CT showed complete metabolic response to therapy with no residual [^{18}F]FDG uptake (Fig. 6).

Discussion

Systemic lymphoma with secondary cardiac involvement by lymphoma (as in this case) is more common than primary cardiac lymphoma. Initial presentation with cardiac symptoms is rare and symptoms are often non-specific. Arrhythmias, heart failure, or sudden death are some of the cardiac clinical presentations that can occur.

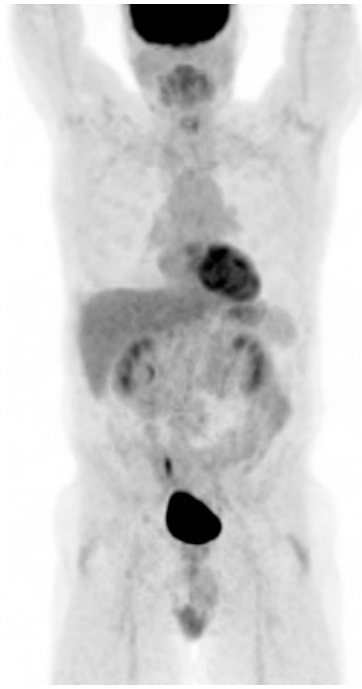

Fig. 6 PET maximum intensity projection image viewed anteriorly after the completion of therapy (6 months after diagnosis) shows complete metabolic response to therapy. No residual abnormal [^{18}F]FDG uptake is seen

This patient presented with symptoms of pulmonary embolism, likely related to thrombi developing on the mass encroaching into the right heart chambers and possibly symptoms of right heart failure as well due to the mass narrowing the lumen. Treatment of lymphoma with cardiac involvement is considered relatively urgent since cardiogenic symptoms could be potentially fatal.

Involvement of the right heart, encasement of the right coronary artery without occlusion, and mass infiltrating the myocardium are some of the characteristic features of cardiac involvement of lymphoma as demonstrated in this case.

Diffuse Large B Cell Lymphoma

Case contributed by: E. Tabacchi[1], C. Nanni[1], I. Bossert[1], A.M. Maffione[2], S. Fanti[1]

[1]Nuclear Medicine Unit, "S. Orsola-Malpighi" Hospital, Bologna, Italy

[2]Nuclear Medicine Unit, "Santa Maria della Misericordia" Hospital, Rovigo, Italy

68 year-old man with diffuse large B-Cell lymphoma localized to the right testicle and a new diagnosis of diabetes mellitus uncompensated underwent a staging [^{18}F]FDG PET/CT (Fig. 7).

[^{18}F]FDG PET/CT revealed abdominal uptake (Fig. 8) at the pancreas (SUV_{max} 13.8) (red arrows), at multiple lymph nodes above and below the diaphragm involving bilateral inguinal, paracaval, interaortocaval, hepatic hilum, peripancreatic, axillary and laterocervical lymph nodes (green arrows). In addition, there was a focal uptake in the right testicle (SUV_{max} 7.7) (Fig. 8j, k, l; orange arrows),

[^{18}F]FDG PET/CT showed increased uptake also at the right scapula, sternum, left humerus, D8, VI-VIII-IX left ribs, IX right rib, left iliac crest (SUV_{max} 5.4) (Figs. 7 and 8: yellow arrows). These findings were related to the lymphoma.

Patient underwent R-COMP regime (rituximab, cyclophosphamide, non-pegylated liposome-encapsulated doxorubicin, vincristine and prednisone) and achieved complete remission after 3 cycles of the chemotherapy.

Diffuse Large B Cell Lymphoma

Presentation

A 68-year-old woman complained about progressive sore throat, oral mass, odynophagia, dysphasia, dysarthria and reduce hearing. The patient was referred to diagnose the disease because biopsy in previous hospital was non-diagnostic.

Findings

Diagnostic CT showed heterogeneous mass in the right posterolateral nasopharynx, extending along the soft palate, deviated the airway to the left, and involvement of the masticator muscle. And bilateral enlarged level II lymph nodes were noted. Fine needle biopsy from right nasopharyngeal

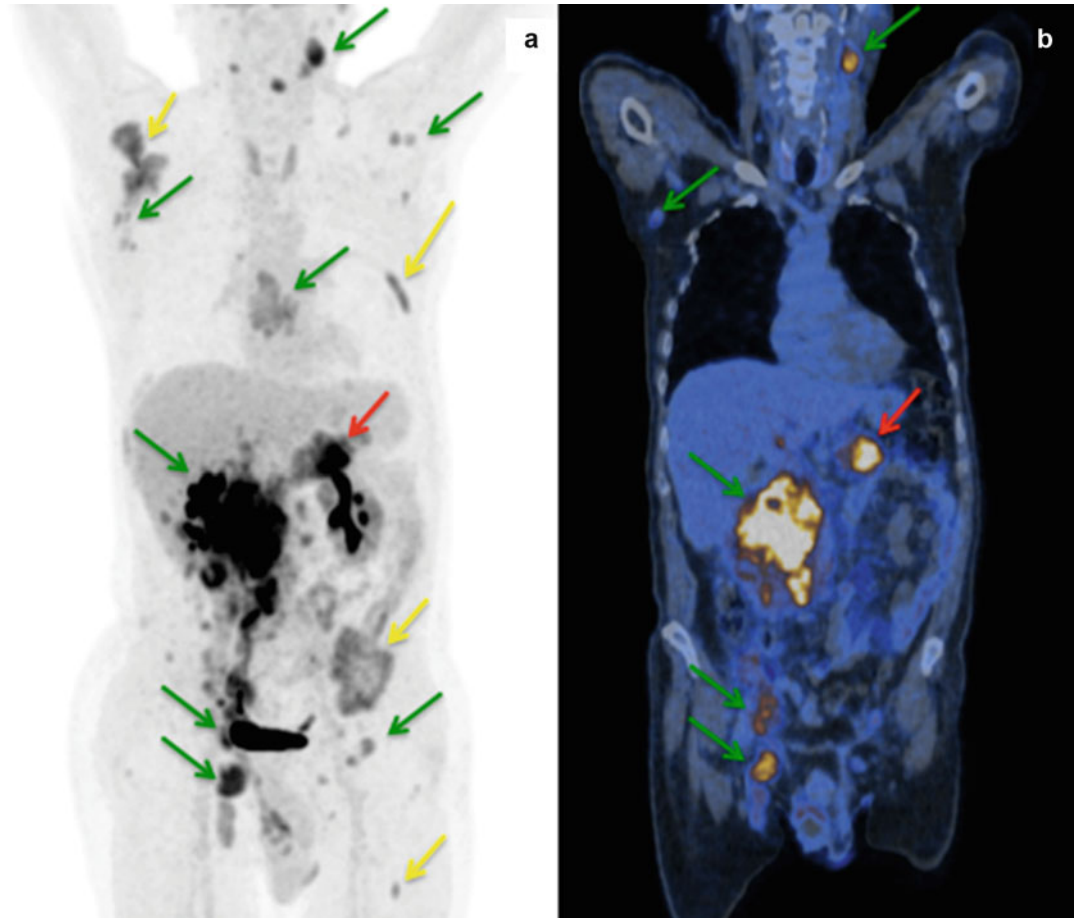

Fig. 7 (**a**): MIP; (**b**): coronal [^{18}F]FDG PET/CT; *Red arrows*: pancreas lesion, *Green arrows*: lymph nodal lesions, *Yellow arrows*: bone lesions

mass revealed diffuse large B-cell lymphoma (DLBCL) (stage II). Baseline [^{18}F]FDG PET/CT images (Fig. 9) reveal nasopharyngeal mass with lymph node metastases (A, B). Hypermetabolic bilateral neck lymphadenopathy was seen in bilateral cervical chains.

Follow-Up

After completion of therapy with 2 cycles of R-CHOP (rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone), interim [^{18}F]FDG PET/CT images (C, D) showed complete remission of DLBCL and non-hypermetabolic thickening soft tissue with air-fluid levels in the bilateral maxillary sinus. End-of-treatment [^{18}F]FDG PET/CT images (E, F) showed sustained complete remission and improved the sinusitis.

Discussion

The non-Hodgkin lymphomas (NHL) including DLBCL represent the majority of head and neck lymphomas [1]. Waldeyer's ring is one of the most

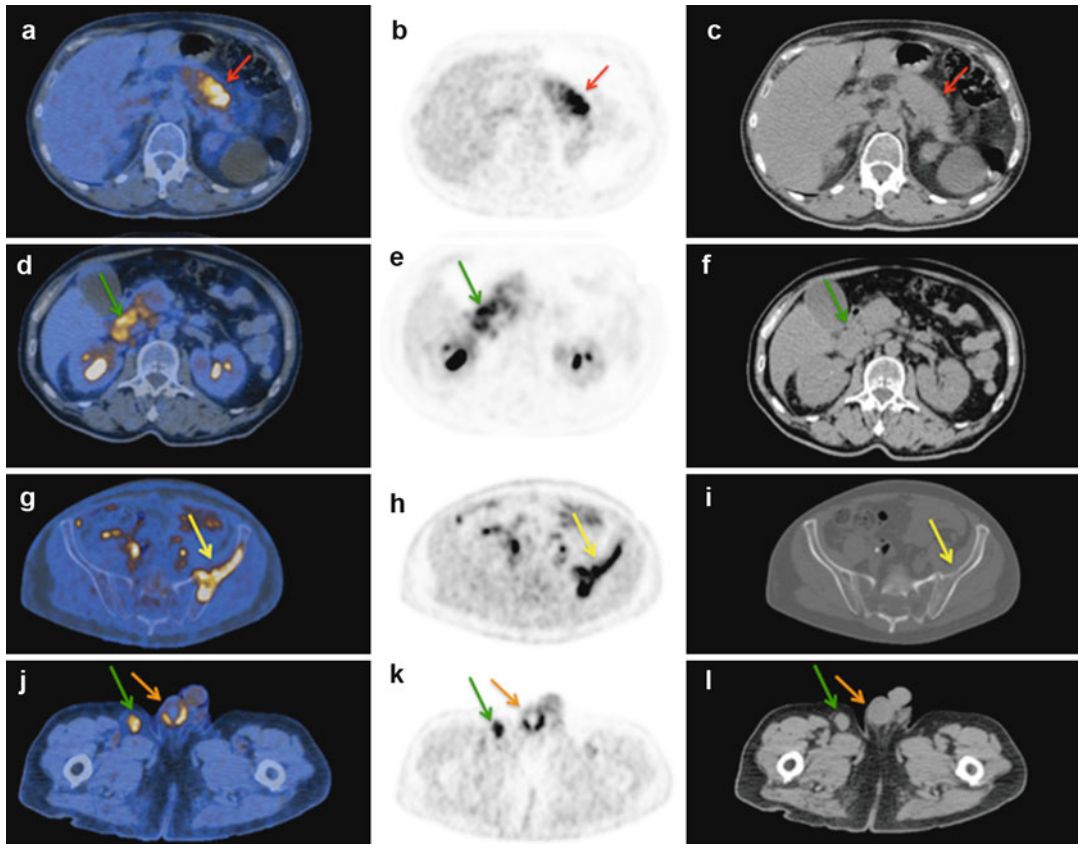

Fig. 8 (**a**, **d**, **g**, **f**): transaxial fused [^{18}F]FDG PET/CT images; (**b**, **e**, **h**, **k**): transaxial [^{18}F]FDG PET images; (**c**, **f**, **i**, **l**): transaxial CT; *Red arrows*: pancreas lesion, *Green arrows*: lymph nodal lesions, *Yellow arrows*: bone lesion; *Orange arrows*: testicular lesion

common sites. However NHL of the nasopharynx has rarely been reported.

Hodgkin's Disease

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

Newly diagnosed, bulky mediastinal Hodgkin's disease. [^{18}F]FDG PET/CT for baseline staging.

Findings

There is an intensely [^{18}F]FDG-avid bulky anterior mediastinal mass (arrow) (SUV_{max} 21.3, transverse dimension 10 cm). The mass shows heterogeneous [^{18}F]FDG uptake with focal extension of the mass into the anterior chest wall between the first and second ribs. The mass also extends to the left lung hilum and into the adjacent left lung. There is an [^{18}F]FDG-avid left supraclavicular node (arrowhead, SUV_{max} 10.8, 1.3 cm). There are further [^{18}F]FDG-avid right upper and bilateral lower paratracheal lymph nodes. The spleen is not enlarged but shows mild diffuse increased [^{18}F]FDG uptake. There is prominent diffuse skeletal [^{18}F]FDG

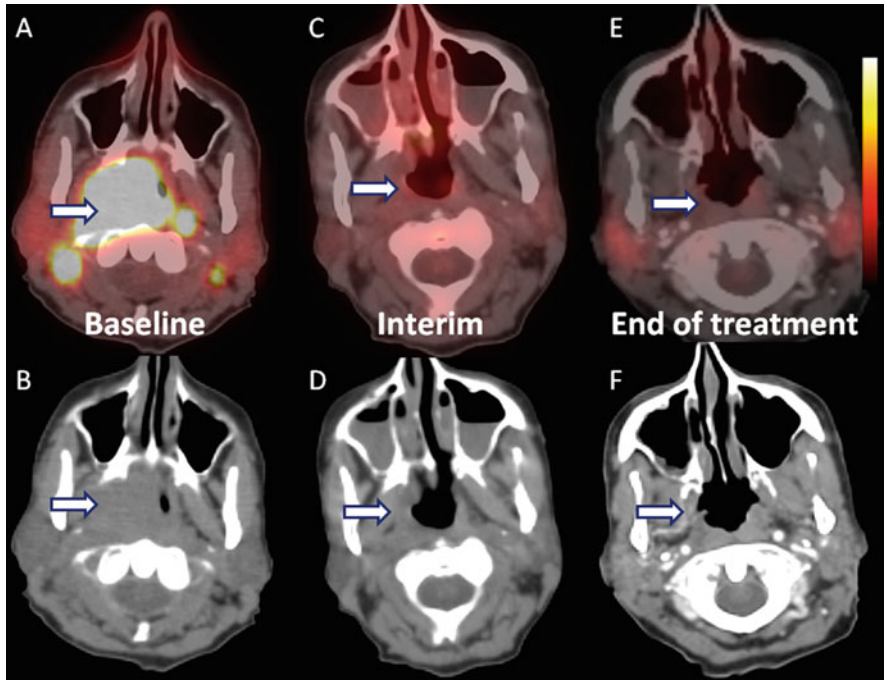

Fig. 9 (**a**) Baseline [^{18}F]FDG PET/CT and (**b**) CT axial images showed hypermetabolic large right nasopharyngeal mass extending anteriorly along the soft palate and posteriorly into the adenoid tissue and longus coli musculature C (*white arrows*) (**c**) Interim [^{18}F]FDG PET/CT fused axial image and (**d**) CT reveal complete remission of DLBCL (SUV_{max} 1.94) and non-specific fluid retention in the bilateral maxillary sinus. (**e**) End-of-treatment [^{18}F]FDG PET/CT image and (**f**) CT showed sustained complete remission of DLBCL (SUV_{max} 1.31)

activity but no focal avid lesion to suggest bone marrow involvement (Fig. 10).

Hodgkin's Lymphoma

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

Hodgkin's lymphoma. [^{18}F]FDG PET/MRI for baseline staging, interim and complete treatment scan.

Findings

There are multiple [^{18}F]FDG-avid mediastinal nodes (SUV_{max} 23.3), which show interval improvement after two cycles of treatment with doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD). There are also multiple bone lesions (arrowheads), L3 vertebral body and left iliac spine visible on the coronal views. There is complete treatment response after completion of therapy (Fig. 11).

Discussion

Staging of lymphoma is a vital pre-requisite to their appropriate therapeutic management and prognosis. This is based on the Ann Arbor classification, to which a definition of bulky disease, called the Cotswald modification, has been added. The usefulness of [^{18}F]FDG PET in the initial staging of lymphoma has been demonstrated in several studies. The main advantage over anatomical imaging techniques, such as CT, is its ability to detect metabolic changes in before the structural changes become visible. PET may upstage

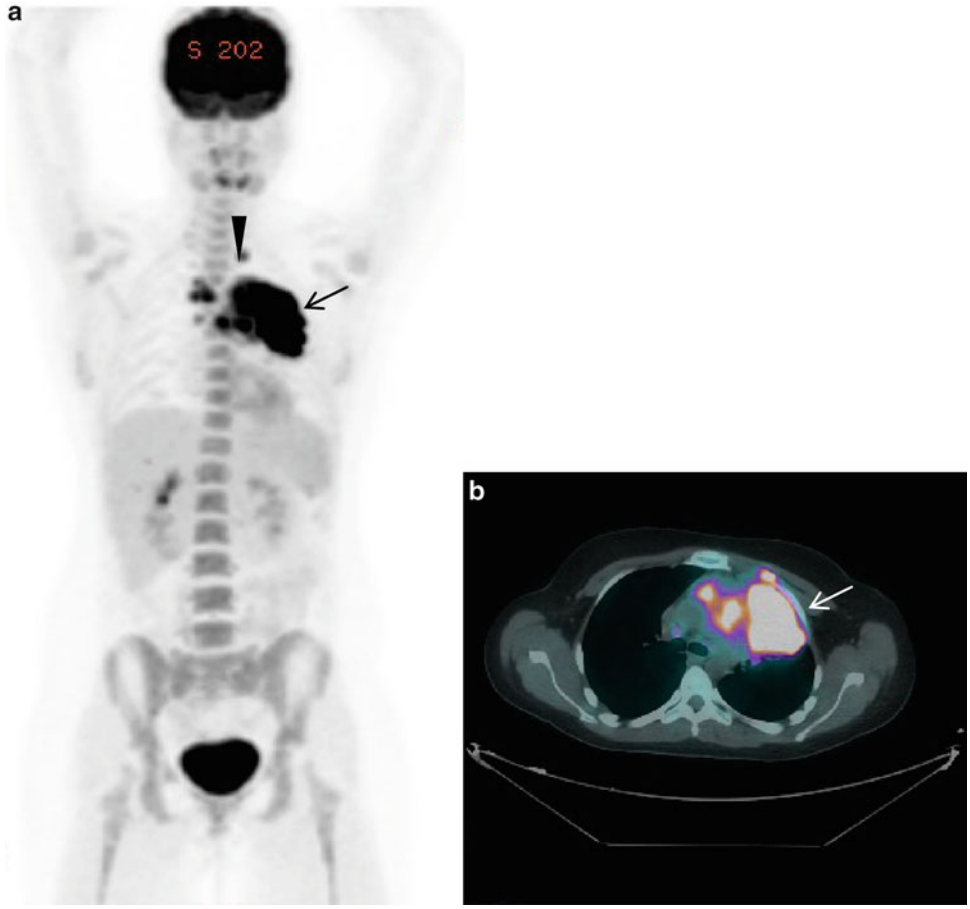

Fig. 10 (**a**) Maximum intensity projection (arrowhead, supraclavicular lymph-node); (**b**) PET/CT axial fused image (arrow, anterior mediastinal mass)

or pick up occult lesions such as splenic, bone marrow, osseous, and gastrointestinal involvement. PET scans have demonstrated high negative predictive value to exclude bone marrow involvement. This holds particularly true for early-stage Hodgkin's lymphoma (HL), and may even obviate the need for bone marrow biopsy in this group. In assessing response to therapy, the Deauville criteria, laid by a consensus committee of nuclear medicine physicians, hematologists, and oncologists recommends a 5-point scale rather than taking a binary decision (namely PET positive or negative). This is based upon visual analysis, with background uptake (mediastinum and liver) as reference. Recognition of early therapeutic response or failure enables the treatment to be adjusted accordingly. Several ongoing trials are under way to assess the impact of treatment adaptation based on early [^{18}F]FDG PET results on overall survival.

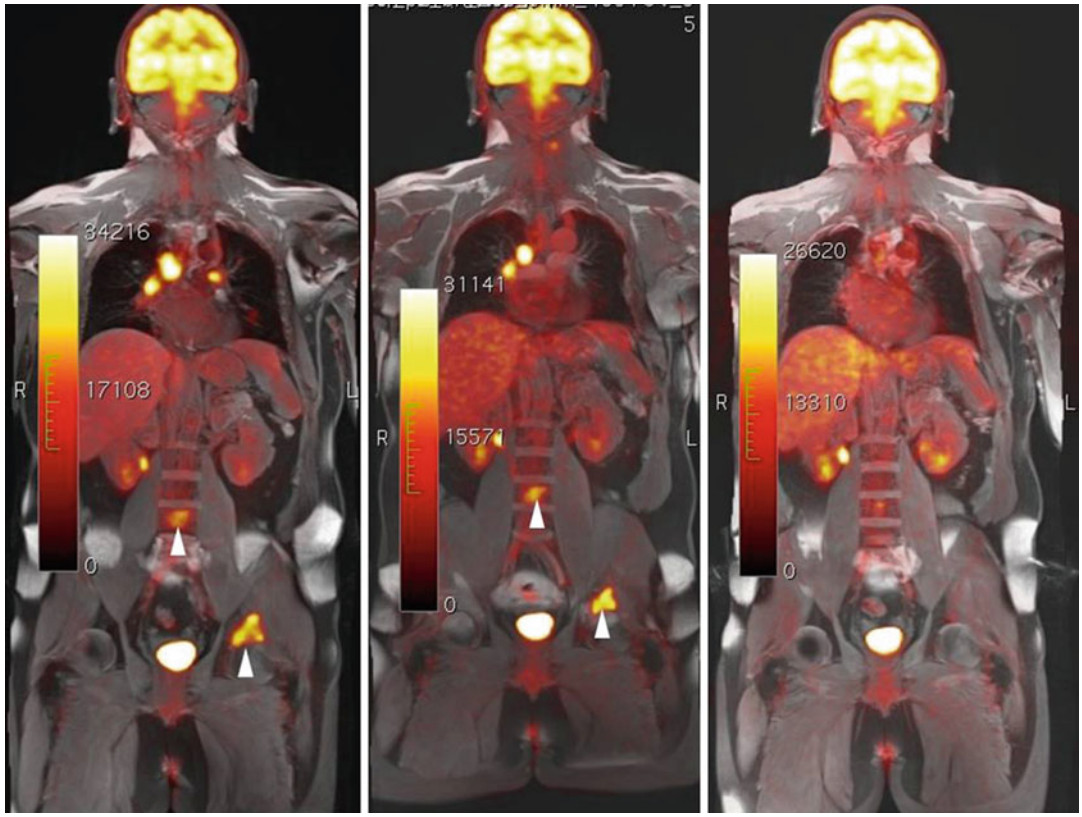

Fig. 11 Fused [^{18}F]FDG PET/MRI coronal images. Baseline and Interim PET/MRI images show hypermetabolic lesions in chest lymph-nodes, lumber vertebral body (white arrowhead), and left ilium (white arrowhead). End of treatment PET/MRI shows almost complete metabolic response

Hodgkin's Lymphoma

Presentation

A 21-year-old woman complained about persistent paroxysmal cough for 1 year. Chest X-ray at an outside hospital showed a large anterior mediastinal mass.

Findings

Ultrasound sound guided fine needle biopsy from a right neck mass showed classical Hodgkin's lymphoma (stage II). Biopsy from bone marrow showed normocellular marrow with trilineage hematopoiesis. The patient was referred for initial staging with baseline [^{18}F]FDG PET/CT. The scan showed nodal [^{18}F]FDG avid disease (Fig. 12).

Follow-Up

After 2 cycles of ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) chemotherapy, an interim [^{18}F]FDG PET/CT (Fig. 13) showed that reduced [^{18}F]FDG avid disease in a smaller

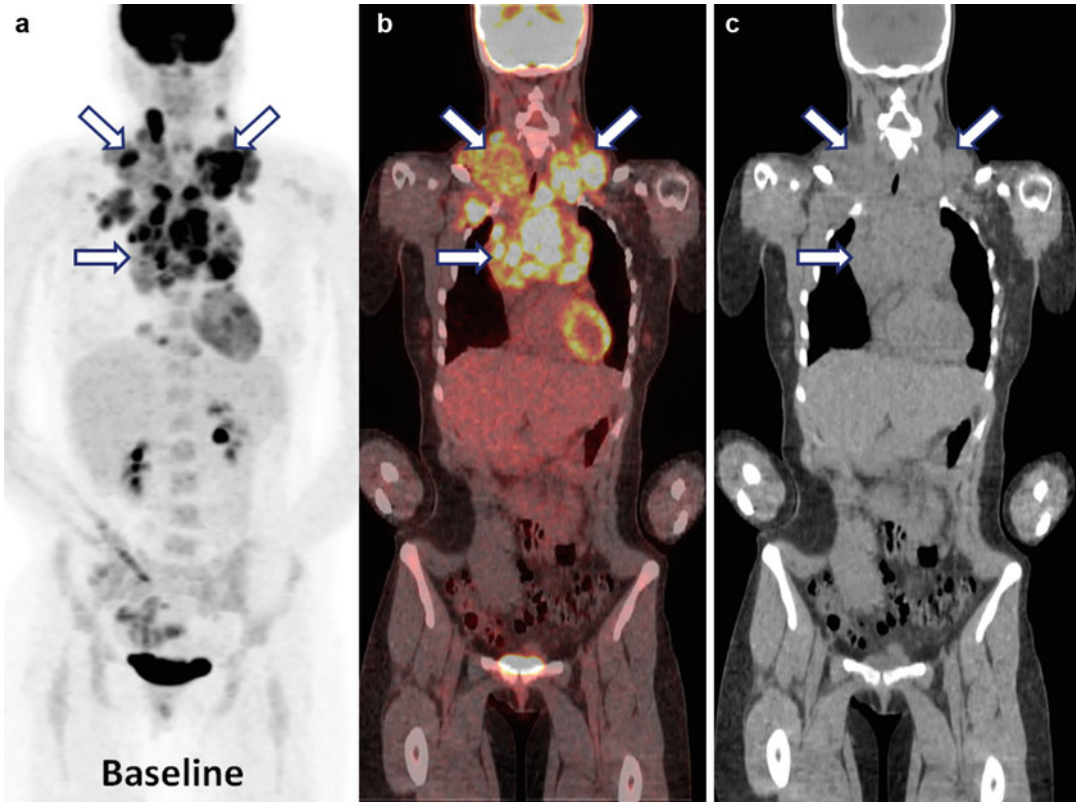

Fig. 12 (Baseline). (**a**) Maximum intensity projection (MIP), (**b**) fused [^{18}F]FDG PET/CT coronal image, and (**c**) CT coronal image show multiple hypermetabolic lesions in the mediastinum (12.5 × 4.5 cm) and subclavicular lymph nodes (*white arrows*). Conglomerate hypermetabolic anterior mediastinal lesion shows hypermetabolic uptake (SUV_{max} 14.2)

residual mass with an equivalent to blood pool activity. The patient has had no relapse for 5 years.

Discussion

In routine clinical practice, [^{18}F]FDG PET/CT plays a major role in the assessment of chemotherapy response in Hodgkin's lymphoma. Rather than pretreatment prognostic factors such as the stage of the disease, an early response to therapy assessment by means of [^{18}F]FDG PET/CT has been shown to be amore accurate predictor of prognosis [2, 3]. In this case, interim [^{18}F]FDG PET/CT showed no significant uptake, which suggested better clinical course and outcome.

Burkitt Lymphoma

Presentation

A 55 year-old-woman was referred with malignant lymphoma (stage IV). The patient complained of pain in left hip.

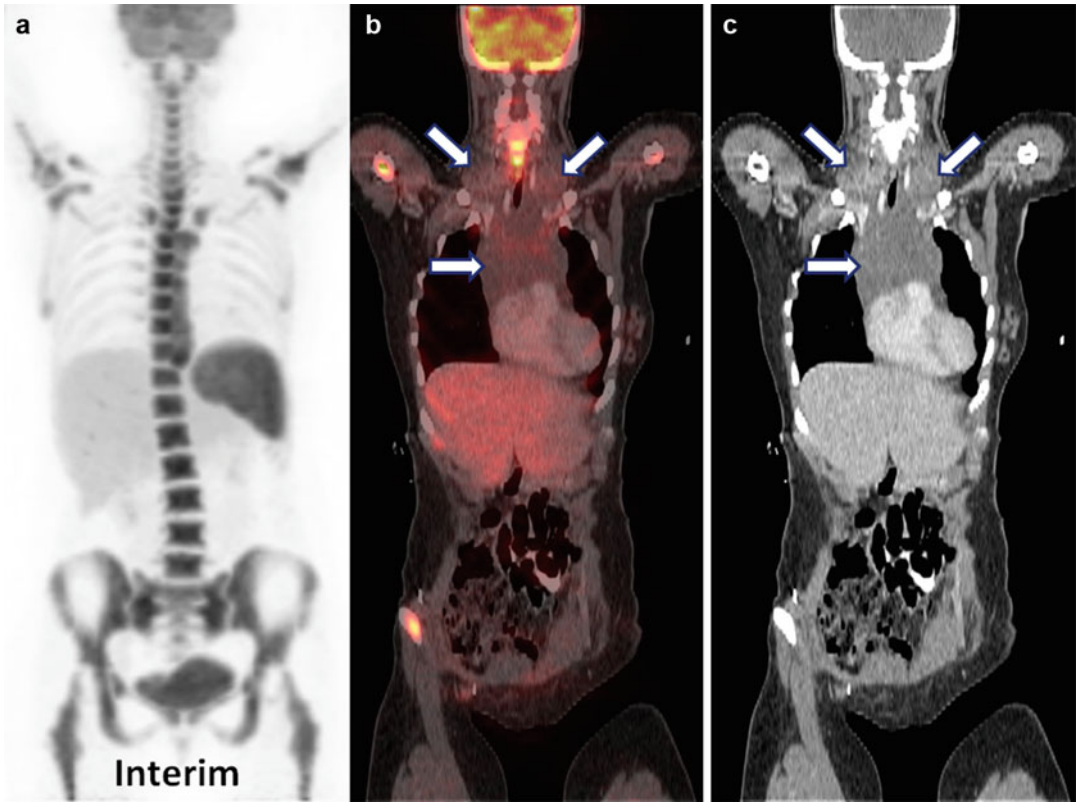

Fig. 13 (Interim). (**a**) MIP and (**b**, **c**) interim [^{18}F]FDG PET/CT images revealed complete remission with residual mass (8.5 × 4.7 cm) having slight [^{18}F]FDG uptake (SUV_{max} 2.0) in the mediastinum (*white arrows*). Diffuse metabolism in spleen and bone marrow is related to administration of granulocyte-colony stimulating factor

Findings

Diagnostic CT demonstrated soft tissue density in a right humerus and extensive marrow involvement. Open biopsy from a right humerus lesion revealed Burkitt lymphoma. [^{18}F]FDG PET/CT was performed prior to initiation of therapy. Baseline [^{18}F]FDG PET/CT (Fig. 14) showed bone marrow involvement and extranodal [^{18}F]FDG avid lesions.

Follow-Up

The patient was treated with high-dose chemotherapy with intrathecal methotrexate. End of treatment [^{18}F]FDG PET/CT (Fig. 15) clearly showed clinical remission including bone lesions. The patient was expectantly monitored until CT revealed the relapse after 6 years follow-up.

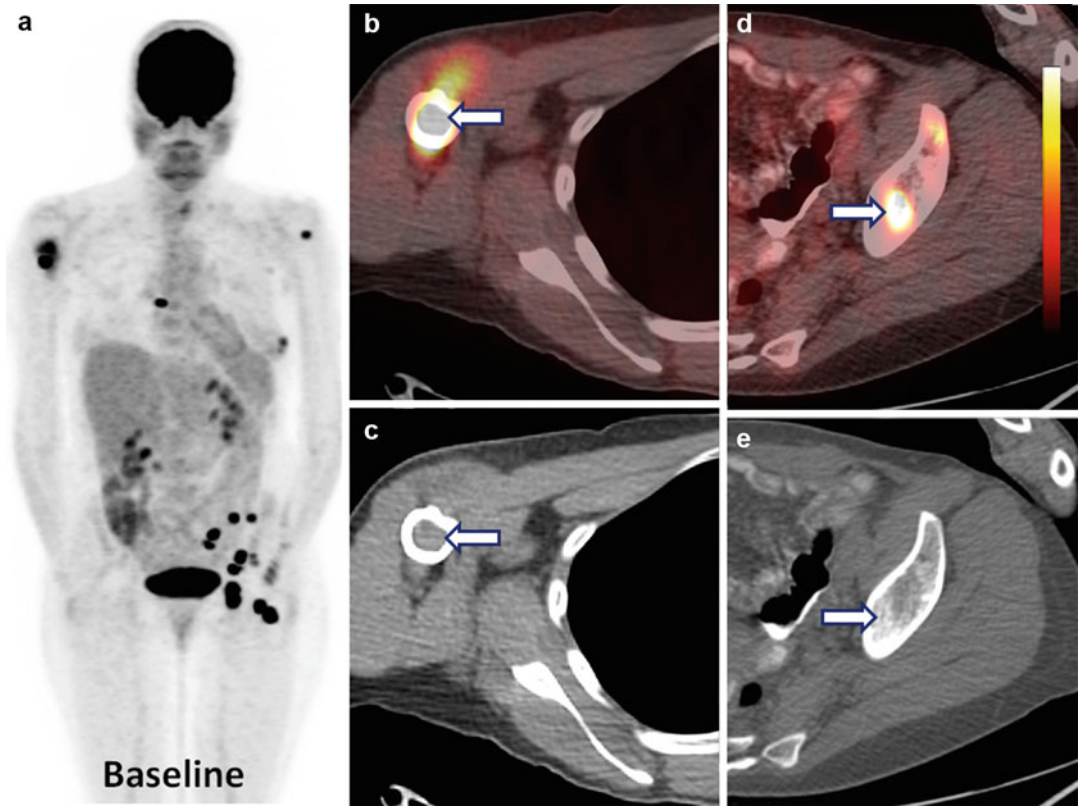

Fig. 14 (Baseline). (**a**) Maximum intensity projection (*MIP*) whole body view of the [^{18}F]FDG PET/CT shows hypermetabolic lesions in the right humerus and in the left inguinal region. (**b**, **d**) [^{18}F]FDG PET/CT fused axial images show the lesions involving the humeral bones with SUV_{max} 21.1 (*white arrow*) and the left acetabulum with SUV_{max} 17.6 (*white arrow*). Diagnostic CT images showed (**c**) the soft tissue density in the left inguinal region and (**e**) normal bone density at the left acetabulum. The lesion in the left acetabulum seems to be difficult to be detected as lymphoma lesions on diagnostic CT alone

Discussion

Adult Burkitt lymphoma is one of aggressive diseases characterized by frequent extranodal presentation, bulky disease and rapid clinical course. In this case, [^{18}F]FDG PET/CT was showed to be of value at diagnosis and completion of therapy in patients with Burkitt lymphoma [4, 5]. However diagnostic CT showed that the soft tissue density lesion still remained in the right humeral region after treatment. Comparing with diagnostic CT end-of-treatment [^{18}F]FDG PET/CT scan seems to be an attractive strategy to confirm disease activity.

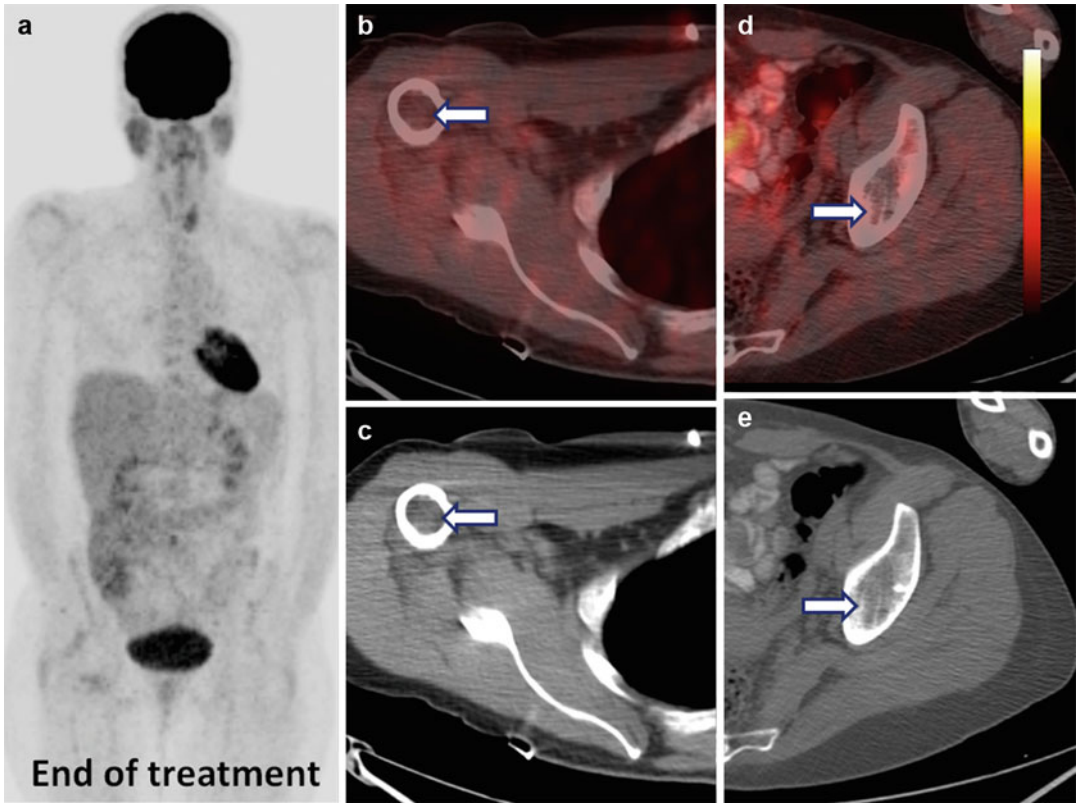

Fig. 15 (End of treatment). After completion of chemotherapy, (**a**) MIP whole body and (**b**) [^{18}F]FDG PET/CT fused axial image of the right humerus reveals complete metabolic response (SUV_{max} 1.08). However, (**c**) CT image shows the remained soft tissue density in the right humeral bone. (**d**) [^{18}F]FDG PET/CT fused axial image and (**e**) diagnostic CT image reveals that the lesions in the left acetabulum are resolved (SUV_{max} 1.16)

Presentation

A 83-year-old man presented with back pain and fatigue. He has a background of smoldering myeloma on the basis of previous bone marrow trephine showing 10% infiltration and no myeloma-defining events.

Findings

A combined [^{18}F]FDG PET/MRI study showed numerous [^{18}F]FDG-avid lesions with corresponding MR signal changes compatible with bone marrow infiltration scattered throughout the imaged body. Most of the lesions showed intensity of uptake greater than liver background activity. A larger lesion was present at L2, where there is reduction of vertebral body height. There was no [^{18}F]FDG-avid extra-osseous involvement.

Follow-Up

On the basis of compelling multifocal bone marrow lesions demonstrated on this study, progression to multiple myeloma was diagnosed. The patient was referred for kyphoplasty of L2 vertebrae to stabilize the fracture and control the pain, but he eventually required radiotherapy for symptomatic palliation (20Gy in five fractions). He was also commenced on chemotherapy (melphalan, prednisolone and Velcade) (Figs. 1, 2, and 3).

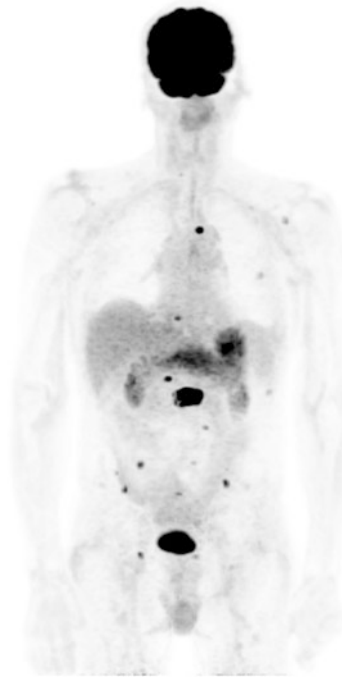

Fig. 1 The MIP image of the [^{18}F]FDG PET shows multifocal hypermetabolic lesions in the bone marrow

Case 2

Presentation

A 57-year-old woman was referred with newly diagnosed IgGκ multiple myeloma (Durie-Salmon stage IIIA).

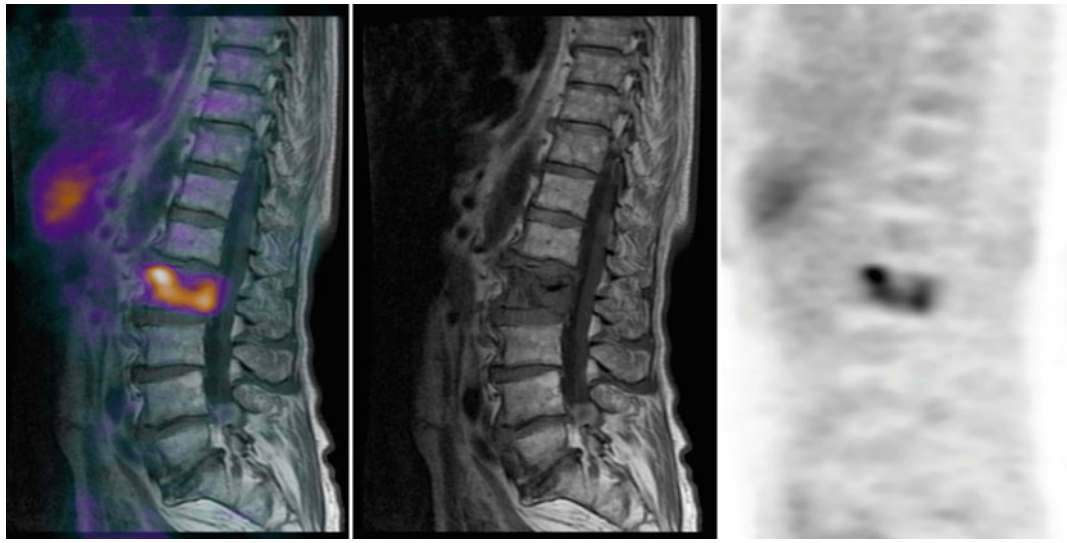

Fig. 2 Left to right: sagittal fused, T1-weighted MR and PET image of the lumbar spine. The L2 vertebrae show low T1 MR signal and heterogenous increased [^{18}F]FDG uptake in keeping with myelomatous infiltration. There is reduction of height and endplate fractures

Findings

Bone marrow biopsy showed hypercellular marrow with rich plasma cells. The patient was diagnosed with multiple myeloma after positive laboratory data and serum protein electrophoresis. Skeletal survey showed multiple osteolytic lesions (Fig. 4). [^{18}F]FDG PET/CT was performed prior to initiation of therapy. The PET/CT scan showed numerous hypermetabolic foci involving axial and appendicular skeleton with bone and bone marrow involvement (Fig. 5). The patient was treated with chemotherapy (Revlimid-Velcade-dexamethasone) and autologous stem cell transplantation.

Follow-Up

Two years after the baseline PET/CT, the patient complained of severe back pain. Restaging [^{18}F]FDG PET/CT demonstrated progression of disease with pathological compression fracture at an L1 vertebra (Fig. 6). After irradiation (total 27 Gy) for the pathologic fracture, follow-up [^{18}F]FDG PET/CT revealed lower [^{18}F]FDG uptake in the L1 vertebrae (Fig. 7) but persistent disease in other bones.

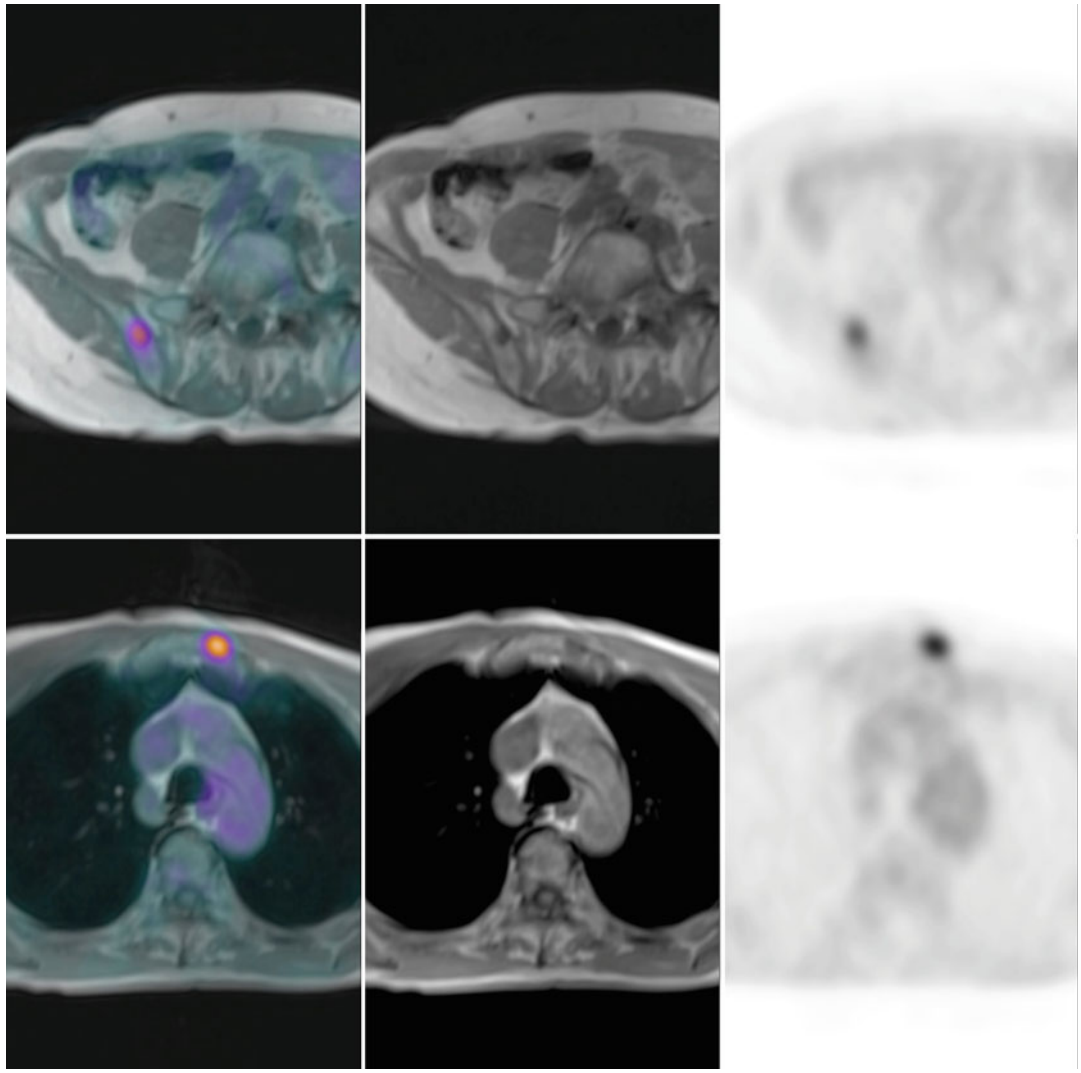

Fig. 3 Left to right: axial fused, T1-weighted and PET image at the pelvic (*upper panel*) and manubrial levels (*lower panel*). These show smaller lesions with focal hypermetabolism localizing to areas of T1 MR signal consistent with further myeloma deposits

Discussion

In this case, the initial staging and restaging [^{18}F]FDG PET/CT scans were performed during the treatment for multiple myeloma. Clinically useful applications of [^{18}F]FDG PET/CT had advantages including its utility for initial evaluation of extent and activity of disease for obtaining prognostic information.

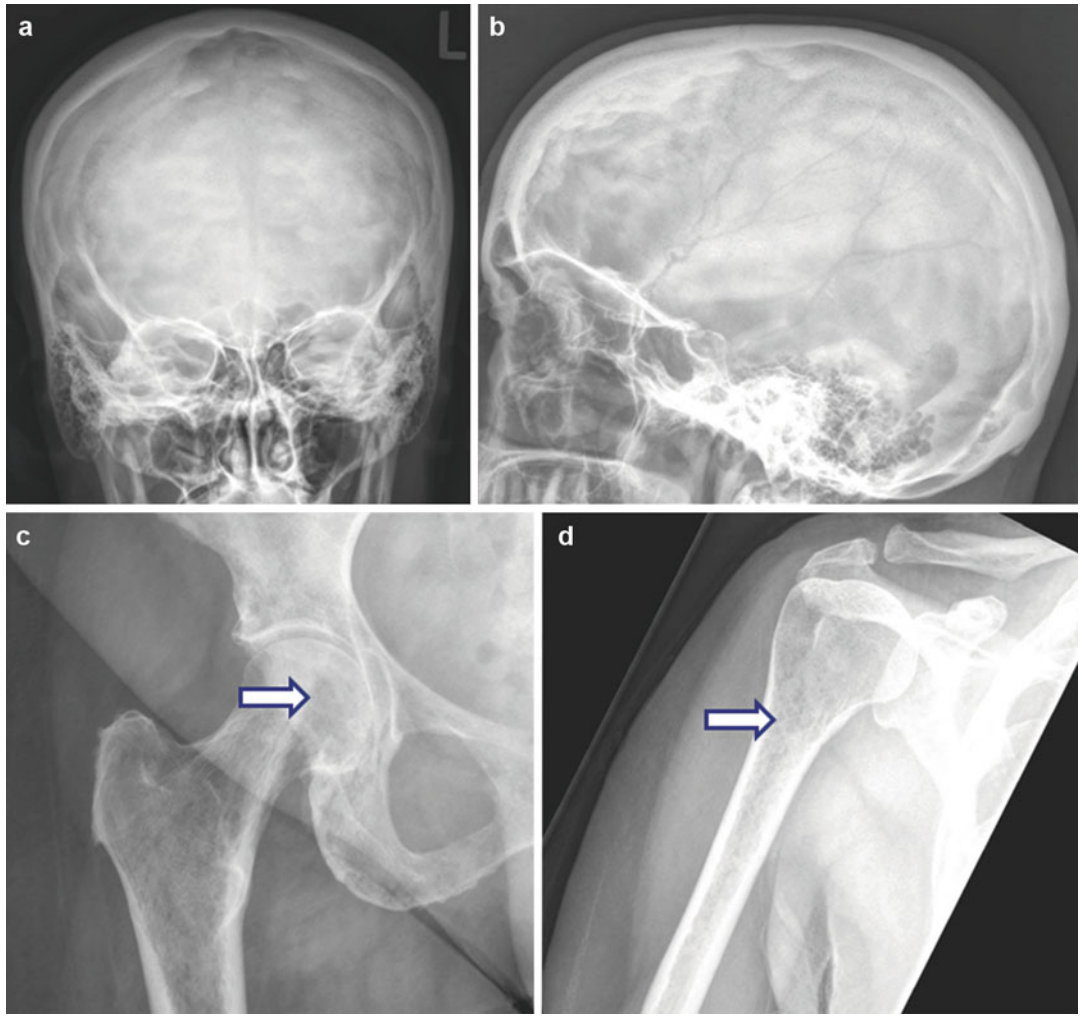

Fig. 4 Skeletal survey shows conspicuity and cortical permeation associated with multiple lytic lesions (*white arrows*). Skull bone images show inhomogeneous bone density

Case 3

Presentation

A 60-year-old woman diagnosed with plasma cell neoplasm via bone marrow core biopsy. The patient had known spinal lytic lesions and chronic back pain. Laboratory data showed elevated serum level of calcium (13.4 mg/dl).

Findings

Skeletal survey showed typical osteolytic lesions (Fig. 8). The patient underwent [^{18}F]FDG PET/CT for evaluating extent of the disease. Baseline [^{18}F]FDG PET/CT (Figs. 9 and 10) showed a few hypermetabolic foci in the bone marrow. The patient underwent chemotherapy (Revlimid-Velcade-dexamethasone) combined with bisphosphonate.

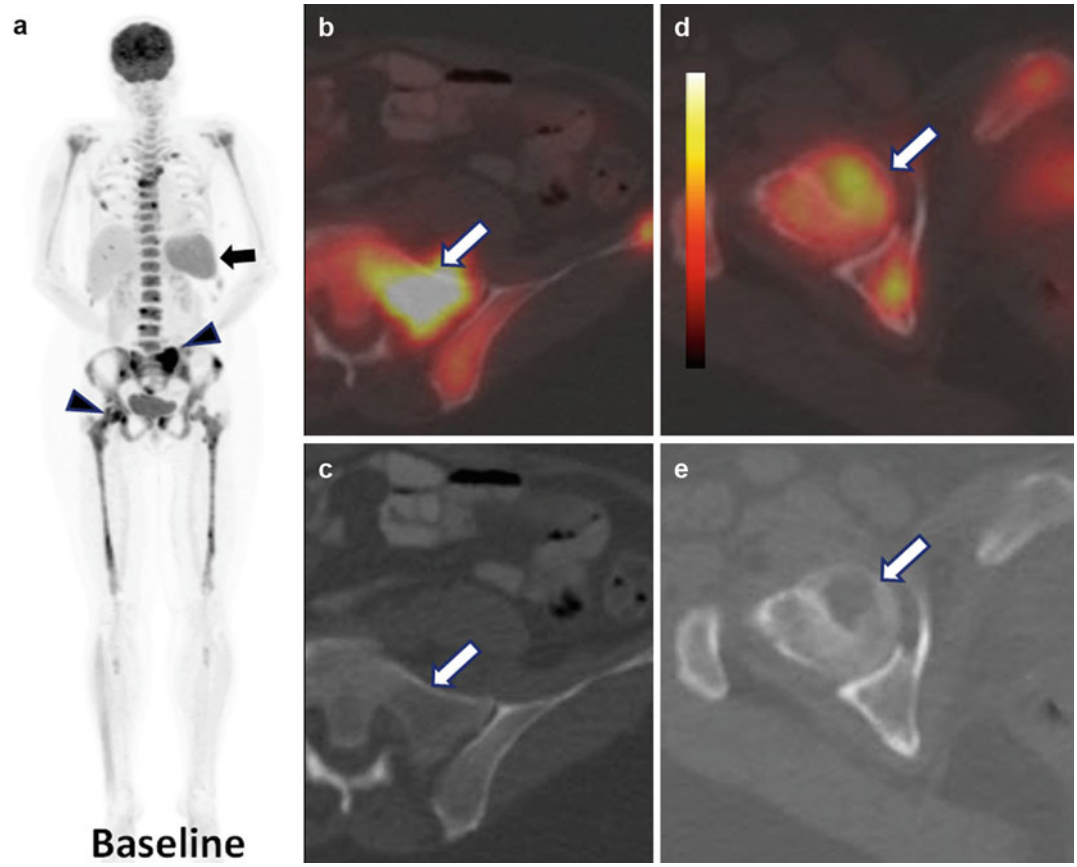

Fig. 5 (Baseline). The MIP image shows multiple hypermetabolic lesions in the bone marrow (*arrow heads*). Diffuse hypermetabolism in the spleen (*arrow*) and the bone marrow was possible myeloma involvement. [^{18}F]FDG PET/CT fused axial images revealed [^{18}F]FDG-avid lesion (SUV_{max} 15.4) at the right femoral head (*white arrow*) and the sacrum (SUV_{max} 23.7) (*white arrow*) corresponding to osteolytic lesions. Diagnostic CT scan during PET/CT was not able to detect the lesion at the left sacrum

Discussion

Multiple myeloma occurs when plasma cells form a mass in the bone marrow. A single mass or tumor detected outside the bone marrow is called plasmacytoma. However, most patients present with multiple sites of the disease, which is called multiple myeloma. [^{18}F]FDG PET/CT can be an integral part of staging and determining the extent of disease. In this case, [^{18}F]FDG PET/CT revealed a large number of bone lesions including the expansile masses [1, 2]. Early detection of expansile lesions is important to reduce risk of pathologic fractures.

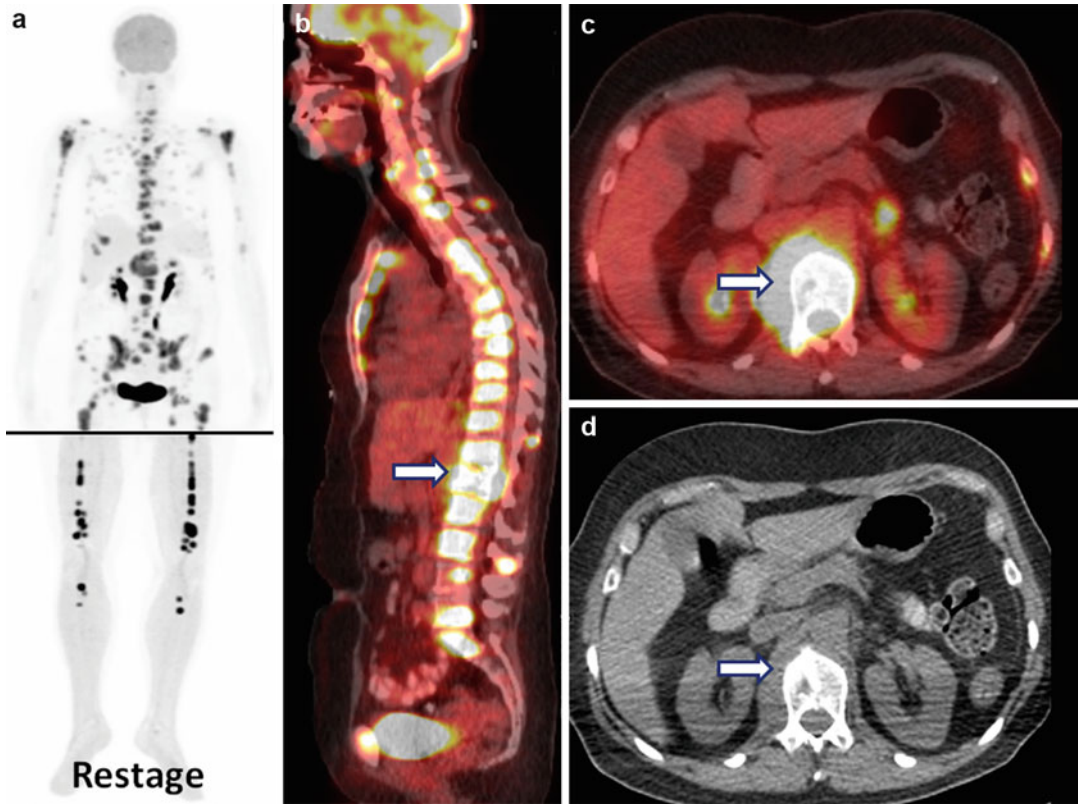

Fig. 6 (Restaging). MIP and [^{18}F]FDG PET/CT fused sagittal images show multiple hypermetabolic foci including at L1 with compression fracture (*white arrows*). Fused [^{18}F]FDG axial image shows [^{18}F]FDG-avid mass with soft tissue density (SUV_{max} 18.26) surrounding L1 vertebra

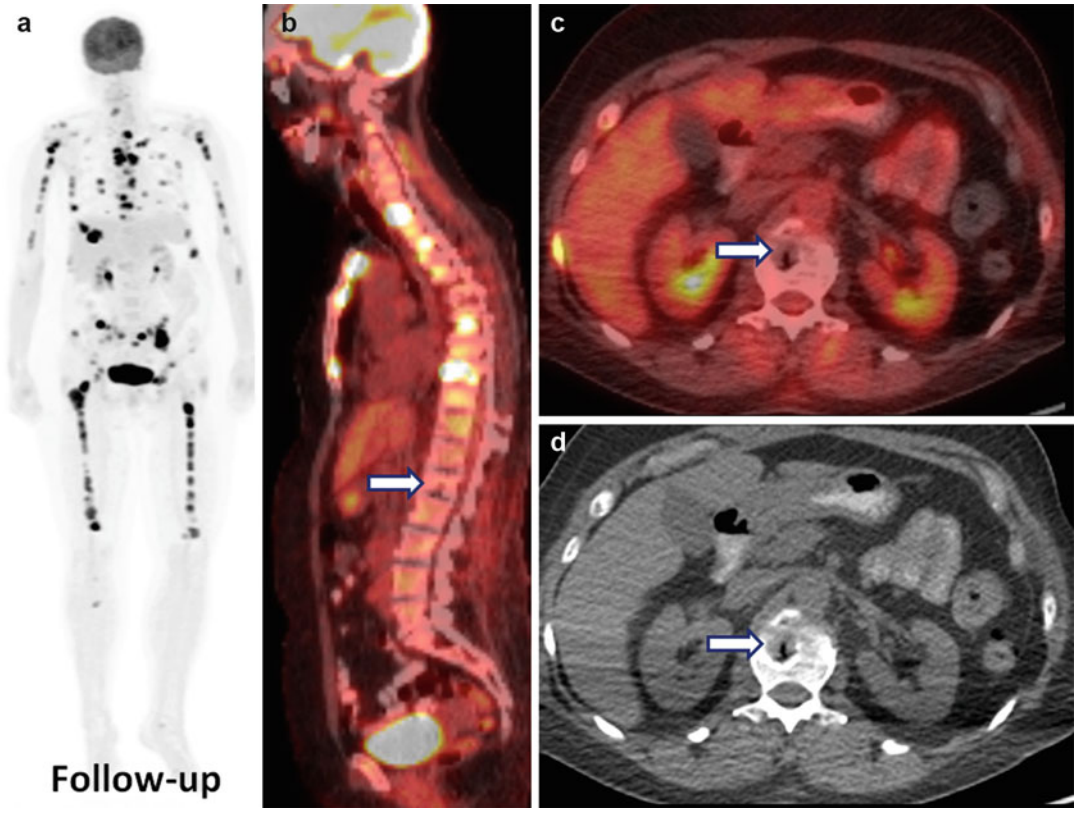

Fig. 7 (Follow-up). MIP and [^{18}F]FDG PET/CT images after radiotherapy reveal decreased uptake at the lumbar vertebrae including L1 lesion (SUV_{max} 2.34) (*white arrows*)

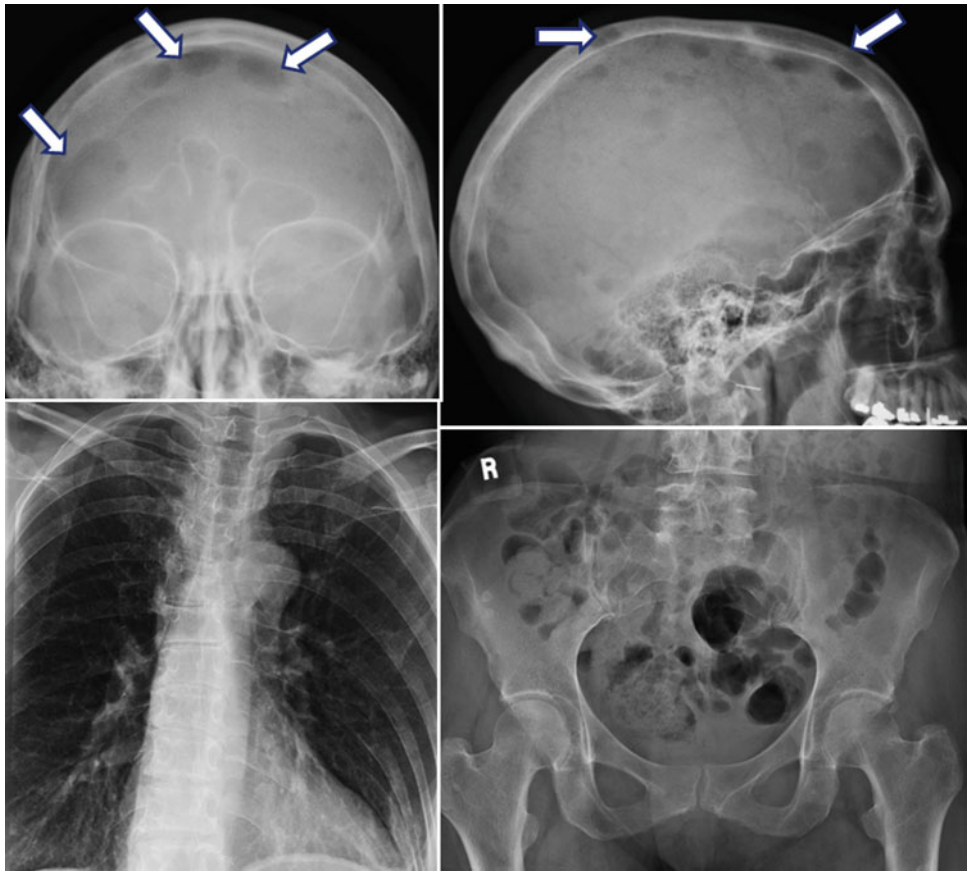

Fig. 8 Skeletal survey shows typical punched-out lesions in the skull bone (*arrows*). However, X-rays are not able to detect the osteolytic lesions in the sacrum and sternum

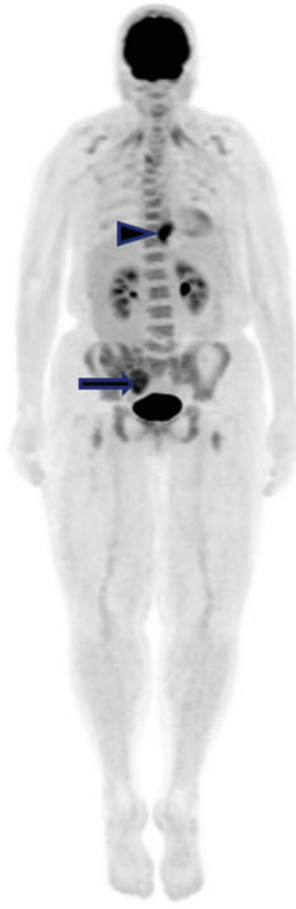

Fig. 9 MIP image reveals multiple [^{18}F]FDG-avid lesions in the sternum (*arrow*) and the right sacrum (*arrow head*)

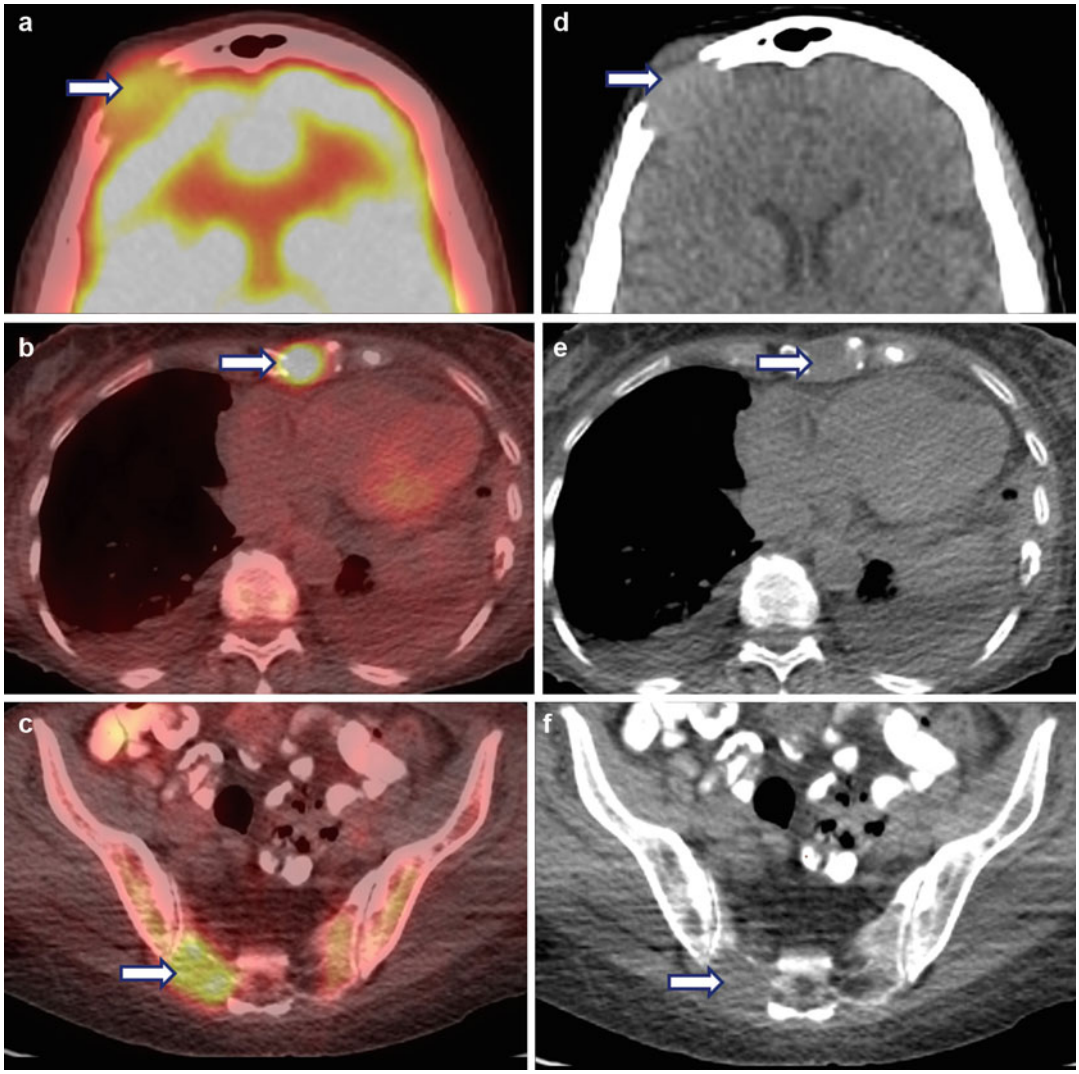

Fig. 10 Axial fused PET/CT images (**a**–**c**) and axial diagnostic CT images during PET/CT (**d**–**f**) show [^{18}F]FDG-avid expansile masses in the skull (SUV_{max} 4.4), in the sacrum (SUV_{max} 5.6), and in the xiphoid process (SUV_{max} 8.9) (*white arrows*). Additionally, there is bilateral moderate pleural effusion

Meningioma

Case contributed by*: *S. Al Shammari*, *F. Fraioli
Institute of Nuclear Medicine*, *UCLH NHS Foundation Trust*, *London*, *UK

Presentation

A forty-seven-year-old patient with meningioma treated with surgery, with residual tumor. He is a potential candidate for radiotherapy. ^{68}Ga-DOTATATE PET/MR and PET/CT are performed to assess expression of somatostatin receptors.

Findings

PET/CT (a) demonstrates a ^{68}Ga-DOTATATE-avid lesion in the left middle fossa. MR images (b) shows anatomic details. PET/MR allows visualizing the exact extent of this disease (Fig. 1). A pituitary sparing field of irradiation was chosen after precise information provided by the PET/MR scan.

Discussion

The pre- and postoperative evaluation of meningiomas may benefit by the combination of morphological and functional imaging. This tumor, although considered benign, often causes compression of important structures and, in a few cases, may show an aggressive behavior. Meningiomas located at the skull base are particularly difficult to treat because of their proximity to vital structures such as blood vessels, cranial nerves, and the brainstem, and, in such cases, a multimodal therapeutic approach is frequently necessary.

In general, surgical resection is the treatment of choice for meningiomas; nevertheless, in the adjuvant setting, radiation therapy is also highly effective. Morphological imaging methods, such as CT and MRI, are commonly used for target volume definition in radiation therapy. However, while providing anatomical detail, they demonstrate limitations for tissue characterization, i.e., distinguishing between meningioma and other tissues, such as postoperative scars, skull base, and other normal intracranial structures. Hence, there is a need for additional methods to characterize tissue

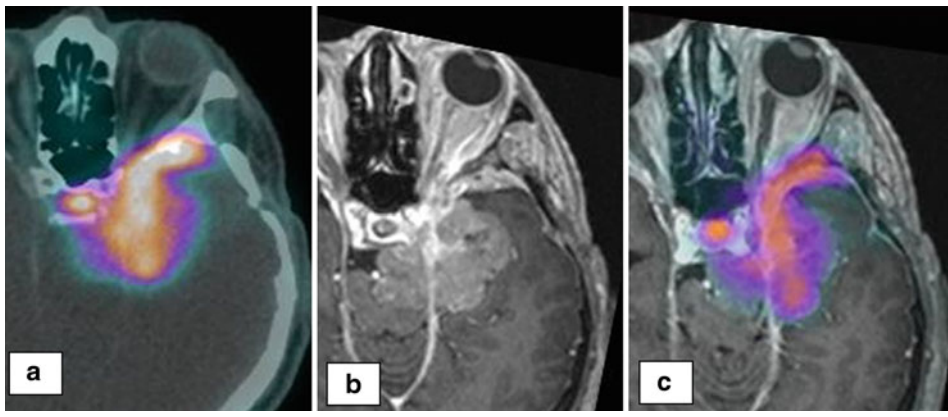

Fig. 1 ^{68}Ga-DOTATATE PET/CT (**a**) demonstrates avid lesion in the left middle fossa. MR (**b**) shows anatomic details. PET/MR allows visualizing the exact location and extent of this disease (**c**)

and more accurately determine the extent of meningioma into the neighboring anatomic structures.

PET imaging offers a solution through high levels of expression of the somatostatin receptor subtype 2 in meningiomas, which can be targeted by somatostatin receptor ligands to provide an excellent tumor-to-background signal ratio.

A PET/MRI solution combining gadolinium enhancement and somatostatin tracer uptake can improve preoperative planning and localize recurrence following therapy.

Meningioma

Case contributed by: ***L. Olivari***, ***A. Chiti***

Division of Nuclear Medicine, ***Department of Biomedical Sciences – Humanitas University***, ***Milan***, ***Italy***

Presentation

A 50-year-old woman developed a valproate-responsive generalized epilepsy. She had no history of cancer, childhood epilepsy syndromes, cerebral trauma, or vascular diseases.

Both CT and MRI of the brain showed a suspicious, slowly growing, intraventricular cystic lesion on the right side of the brain.

Findings

MRI of the brain revealed an intraventricular cystic lesion. [^{11}C]Methionine PET/CT was performed to evaluate the lesion observed at MRI (Fig. 2).

PET/CT images demonstrate no uptake in the cystic lesion, thus suggesting a nonneoplastic nature of the lesion.

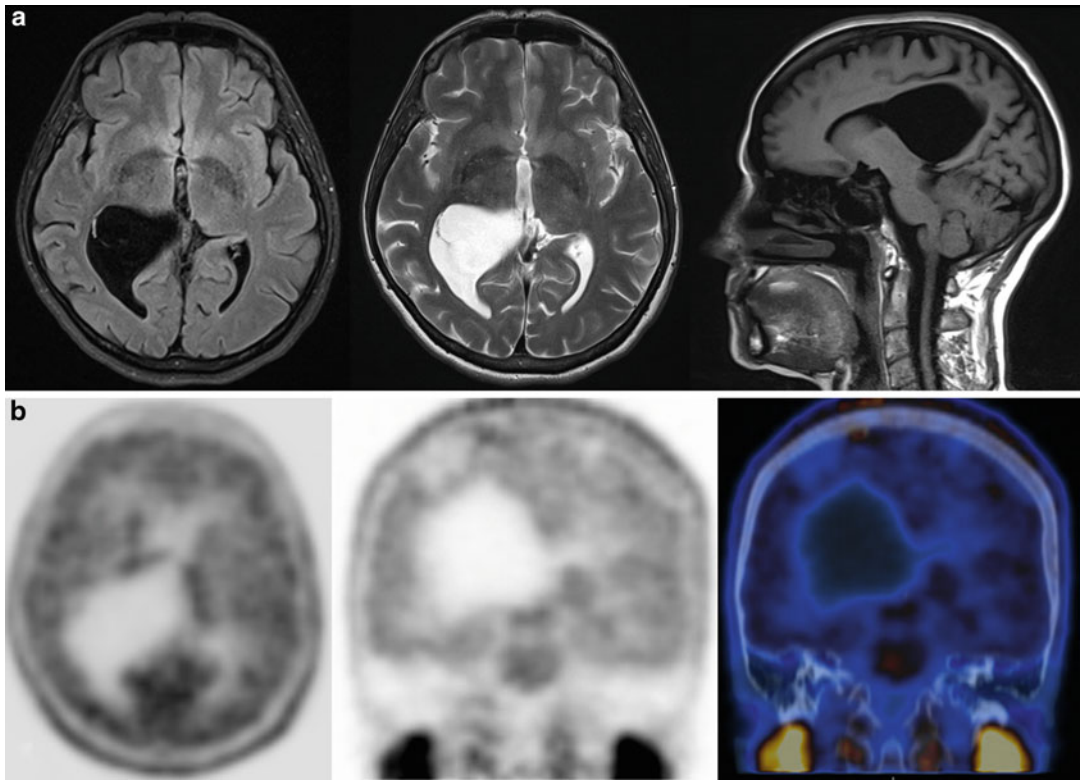

Fig. 2 Magnetic resonance imaging (*MRI*). (**a**) Showed an intraventricular cyst (sagittal, T2 FLAIR, T2 TSE; sagittal, T1 FLAIR). [^{11}C]MET PET/CT (**b**) demonstrated no pathological uptake in cyst

On the other hand, increased uptake was found in a small lesion with a rim of calcification located in the right frontal lobe (tumor-to-cerebellum ratio, 1:8). A review of the MRI images revealed an extradural lesion in the right frontal lobe hyperintense to gray matter in T2 and isohypointense in T1, compatible with meningioma. Meningioma could have been related to the patient symptoms (Fig. 3).

Discussion

This case confirms the important role on nuclear medicine imaging in the characterization of central nervous system disorders.

Different PET tracers have been explored to detect brain tumors, in particular to assess their metabolism as an index of the degree of malignancy. Radiolabeled methionine, a marker of amino acid transport and protein synthesis, shows increased uptake in meningioma (high tumor-to-cerebellum ratios) [1]. Methionine uptake correlates with meningioma volume, but it is uncertain whether it correlates with tumor aggressiveness and WHO grading; while small-series studies showed no correlation between methionine uptake and meningioma aggressiveness and WHO grading [2, 3], a more recent report found a correlation between methionine uptake and proliferative tumor activity as evaluated by the Ki-67 index [4].

Brain Tumor

Case Contributed by*: *S. Wan

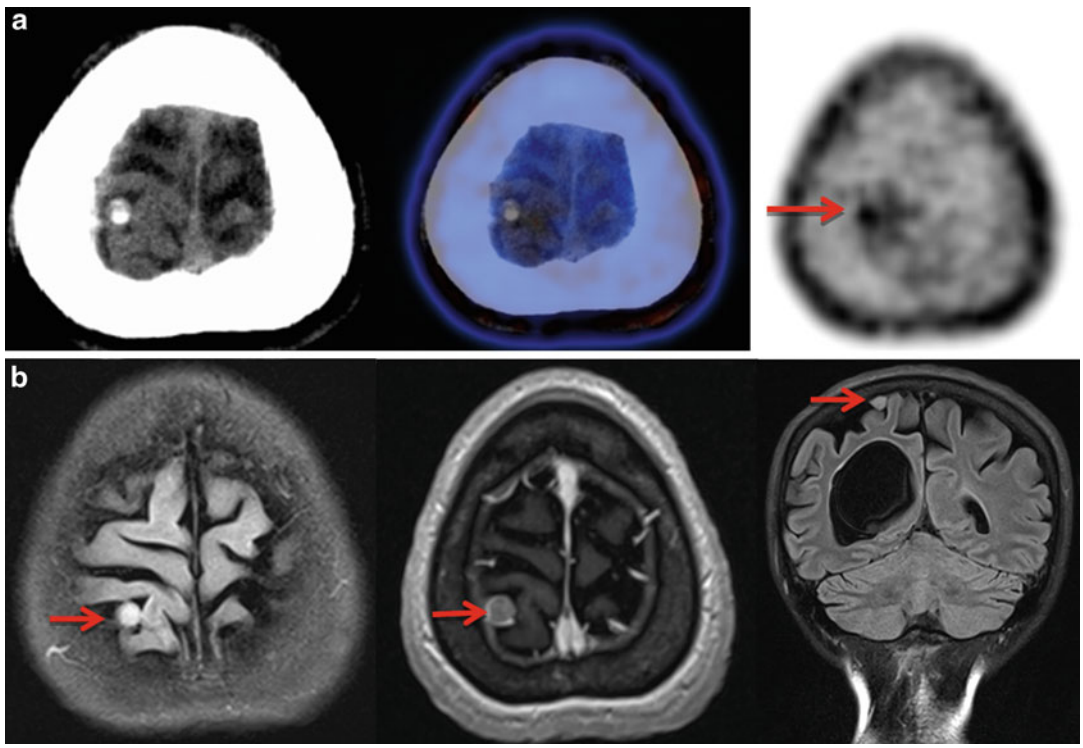

Fig. 3 [^{11}C]MET PET/CT (**a**) demonstrated an increased uptake in the right frontal lesion with a rim of calcification. Magnetic resonance imaging (*MRI*) (**b**) revealed an extradural lesion consistent with meningioma (transverse, T2wFLAIR, T2wMPRAGE; sagittal, T2 FLAIR)

Presentation

A 36-year-old man with a history of left frontotemporal anaplastic astrocytoma (initial diagnosis 5 years ago, treated with partial resection 11 months ago followed by radiotherapy completed 9 months previously) complains of increasing seizure frequency over 4 months and worsening cognitive impairment. MRI showed increasing enhancement at the site of treated tumor. MR perfusion findings were equivocal.

Findings

The [^{18}F]FDG PET/MR study showed improvement in size and enhancement compared to the previous MR studies. The enhancing lesion showed very limited [^{18}F]FDG uptake. There was diffuse hypometabolism affecting the majority of the left hemisphere, including the basal ganglia and also the right cerebellum (cerebellar diaschisis). The overall impression was that the observed MR enhancement previously was more likely due to radiation necrosis.

Follow-Up

In view of the possibility of radiation necrosis prior to the study, the patient was started on steroid treatment by the time of the PET/MR study. With the reassuring results of the study, the patient was managed expectantly. Further follow-up MRI 5 months later showed continued improvement (Figs. 4, 5, 6, and 7).

Case 3: Brain Lymphoma

Presentation

A 72-year-old woman with multifocal ductal carcinoma of the left breast treated with lumpectomy, external beam radiation therapy, and chemotherapy 5 years ago developed weakness of the right hand.

Findings

MRI of the brain revealed multiple supratentorial metastases, several of which demonstrated hemorrhage and edema. An extra-axial lesion involving the left cavernous sinus and the middle cranial fossa was also seen, representing a meningioma. [^{18}F]FDG PET/CT was performed to evaluate the extent of disease (Figs. 8 and 9). PET/CT fusion images demonstrate five hypermetabolic lesions of the brain with intense [^{18}F]FDG uptake localized,

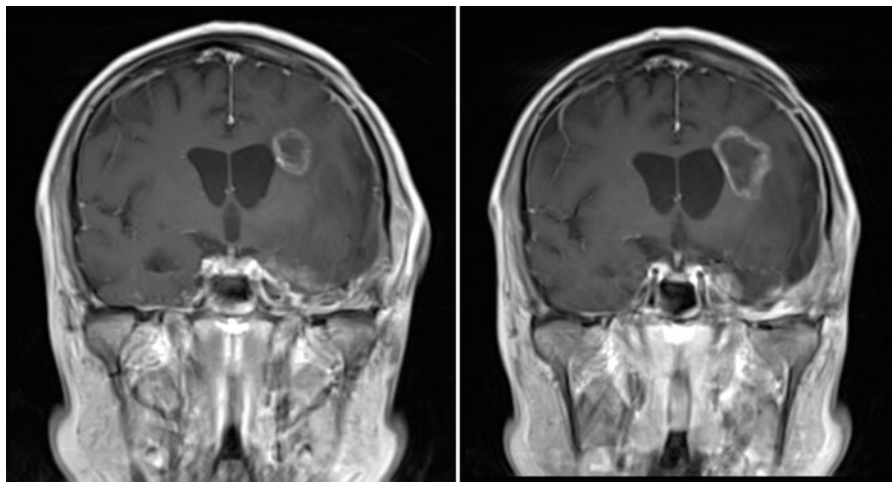

Fig. 4 Coronal T1 postcontrast images demonstrating increasing size of the enhancing cavitating area at the left corona radiate from 3 months post radiotherapy scan (*left*) to 6 months post radiotherapy scan (*right*)

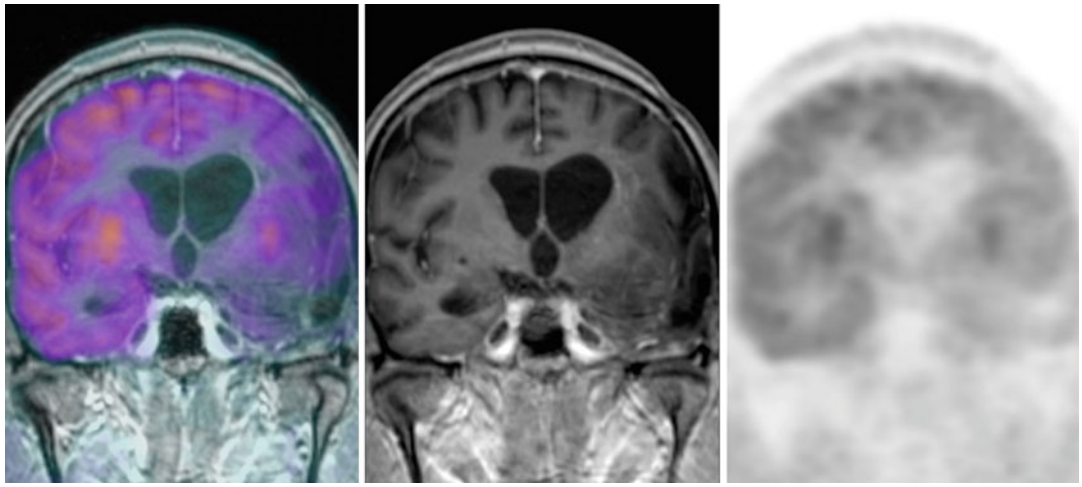

Fig. 5 From *left*: coronal fused, T1 postcontrast, and PET images from PET/MR study 9 months post radiotherapy show reduction of the enhancing area and show no significant [^{18}F]FDG uptake. Further posttreatment changes are noted over the rest of the left cerebral hemisphere

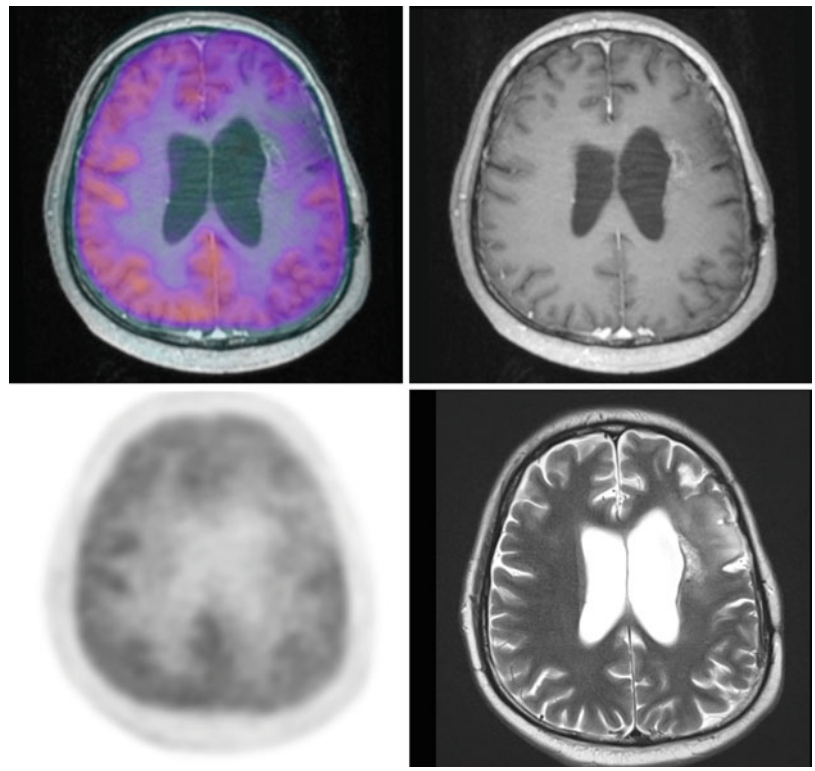

Fig. 6 Clockwise from *top left*: axial fused, T1 postcontrast, T2 weighted, [^{18}F]FDG PET images showing similar changes with regression of the enhancing area, which show no significant increased uptake. Post treatment gliosis is noted in the subcortical white matter on the T2-weighted image

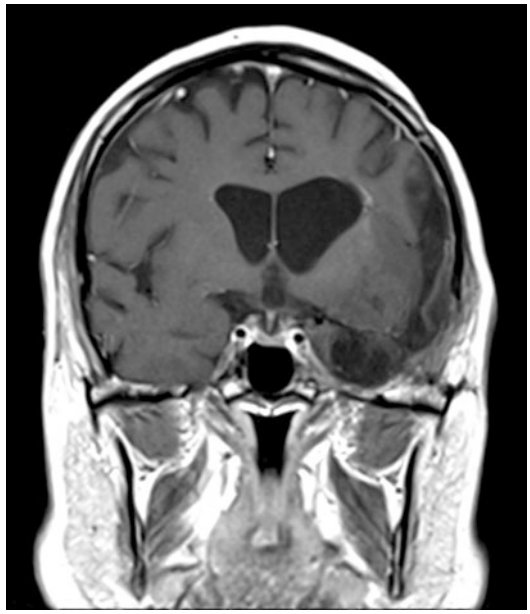

Fig. 7 Coronal T1-weighted postcontrast study showing further involution of the previously seen enhancing lesion

respectively, in the high left parietal lobe (1.7 × 1.7 cm, SUV_{max} 17), left temporo-occipital region (1.2 × 1.5 cm, SUV_{max} 15), right frontal cortex (1.3 × 1.3 cm, SUV_{max} 16), and right parietal cortex (1.6 × 1 cm, SUV_{max} (Fig. 9). These supratentorial lesions are suspicious for metastases. A large lobulated lesion (Fig. 10) in the left frontal and temporal lobe with a rim of calcification in contact to the sphenoid bone (SUV_{max} 22) is also seen, suggesting a meningioma, in correlation with MRI. [^{18}F]FDG PET/CT did not show evidence of recurrent or metastatic disease outside the brain. The patient underwent left temporal superficial brain biopsy and tumor resection which revealed diffuse large cell lymphoma with adjacent meningioma grade 1. The lumbar puncture and

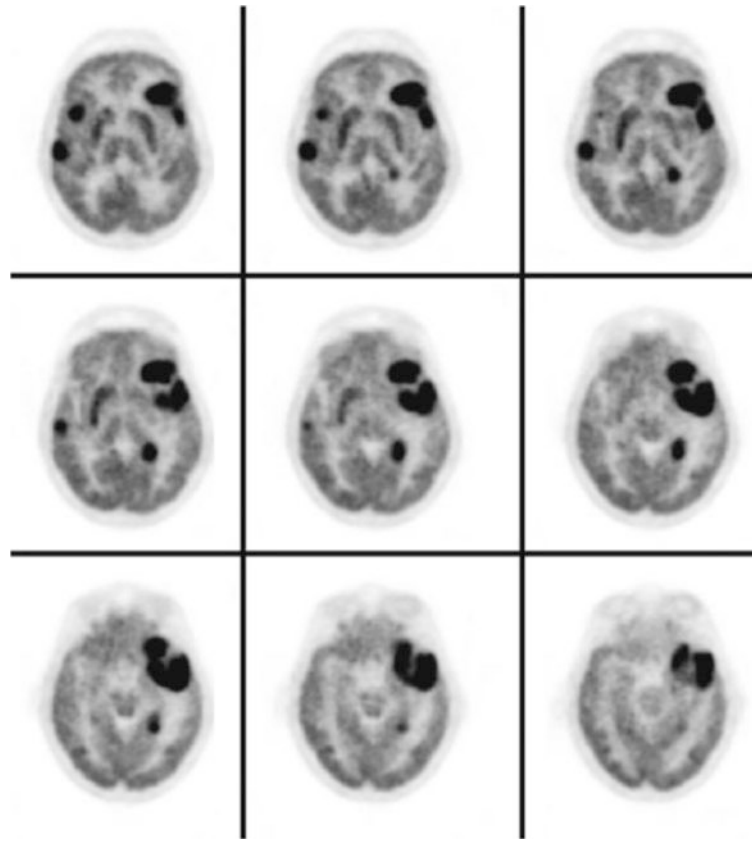

Fig. 8 [^{18}F]FDG PET axial images of the brain demonstrating five hypermetabolic lesions

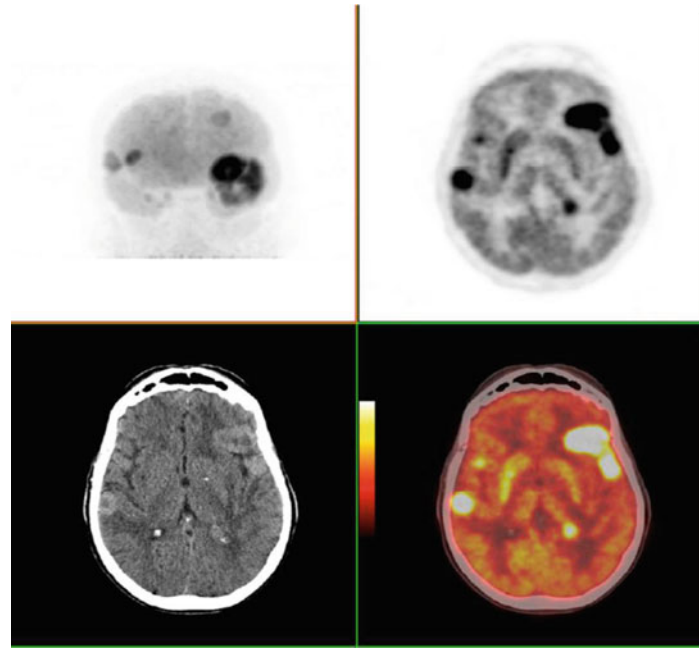

Fig. 9 [^{18}F]FDG PET/CT images: *upper left*, *MIP*; *upper right*, axial image demonstrating five lesions; *lower left*, contrast-enhanced CT; *lower right*, fused PET/CT

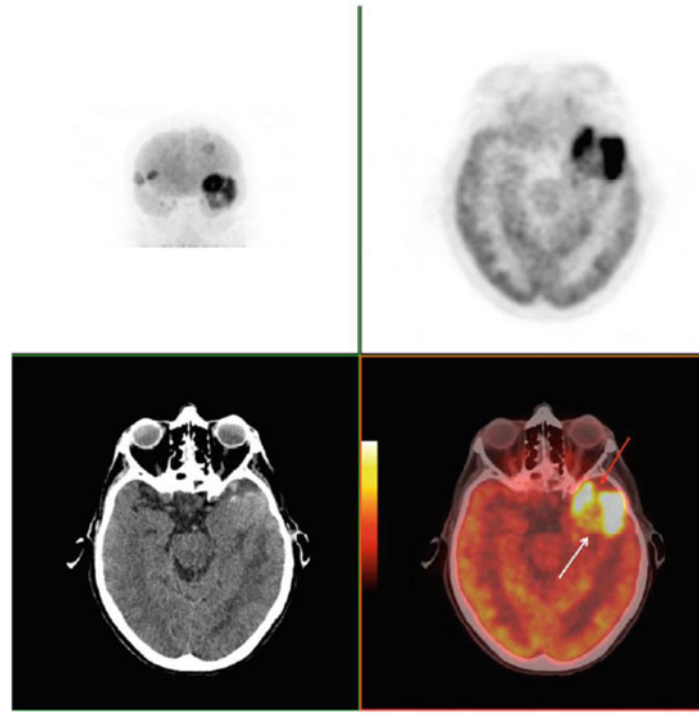

Fig. 10 [^{18}F]FDG PET/CT images of primary central nervous system lymphoma (*white arrow*) with adjacent meningioma grade 1 (*red arrow*)

bone marrow biopsy were negative for the presence of malignant cells. The patient was treated with combination chemotherapy.

Discussion

This case demonstrates the value of histologic correlation of the sites of [^{18}F]FDG localization in the evaluation of primary central nervous system lesions. In this patient with a history of treated breast cancer and a lesion with radiographic features suggesting meningioma, it is critical to determine the etiology of the lesions undergoing treatment.

Leptomeningeal Metastasis from NSCLC

Case contributed by: ***L. Olivari***, ***A. Chiti***

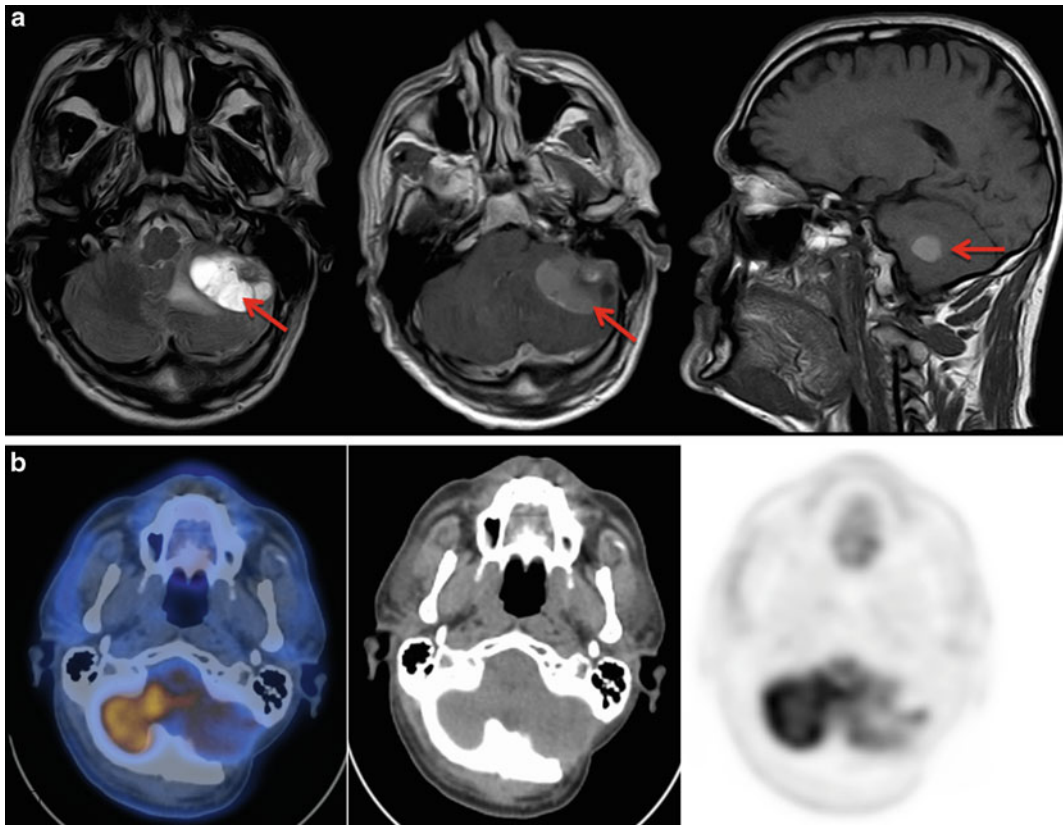

Fig. 11 Magnetic resonance imaging (*MRI*) (**a**) showed a metastasis from lung cancer in the left cerebellum lung cancer metastases, as indicated by the *red arrow* (transverse, T2wSE, contrast-enhanced T1wSE; sagittal, T1wSE). Posttreatment [^{18}F]FDG PET/CT (**b**) demonstrated no pathological uptake in the cerebellum. The *arrow* indicates the tumor

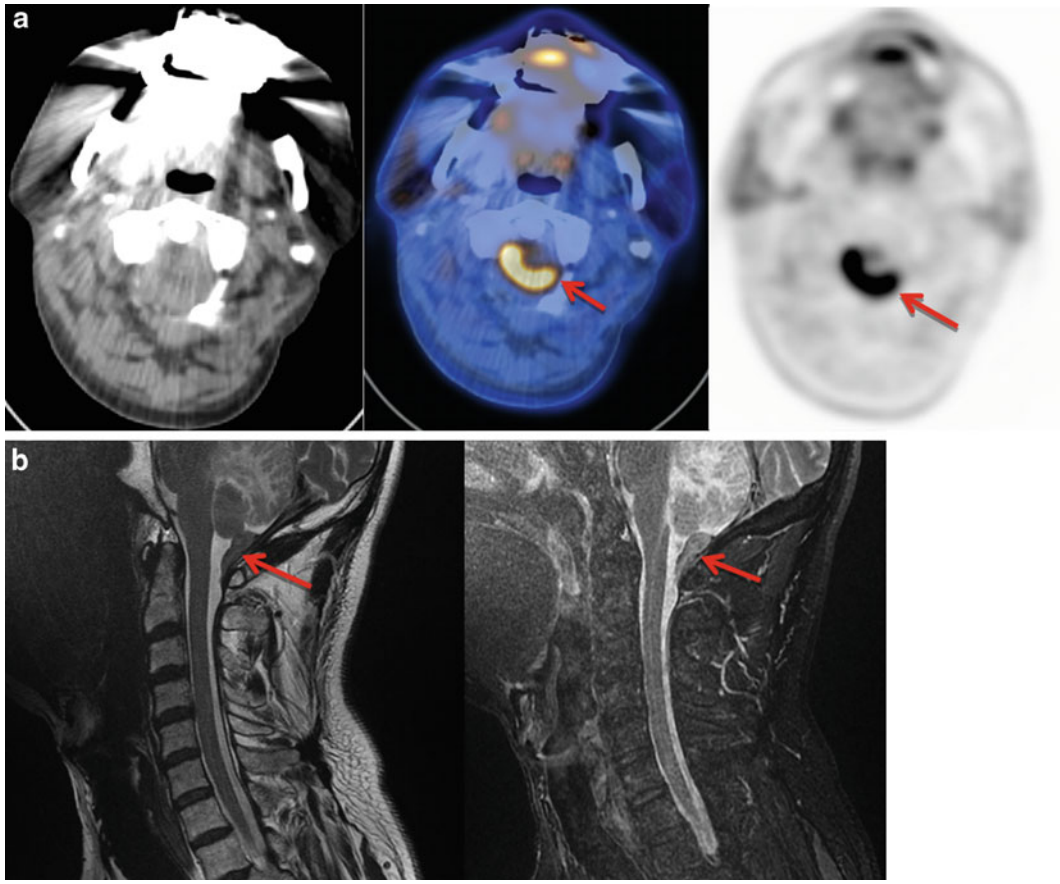

Fig. 12 Posttreatment [^{18}F]FDG PET/CT and MRI: (**a**) increased tracer uptake in leptomeninges of the foramen magnum (*red arrow*); (**b**) corresponding MRI appearance of the lesion (*red arrow*) in the sagittal plane (T2w, STIR)

Presentation

A 52-year-old man was referred to our hospital because of fatigue and severe headache not responsive to nonsteroidal anti-inflammatory drugs (NSAIDs). The patient had a prior history of non-small cell lung cancer of the apex of the left lung presenting with Pancoast syndrome (pT3N0) and had therefore been treated with chemoradiotherapy followed by surgery and intraoperative radiotherapy for the lung lesion; neurosurgery followed by radiotherapy (30 Gy) was also performed for a single cerebellar metastasis in the left hemisphere.

Findings

ceMRI of the brain revealed perilesional edema in the left cerebellar hemisphere related to previous radiotherapy treatment. No other lesions were found. Three weeks later a total body [^{18}F]FDG

PET/CT was performed for restaging. The scan showed no abnormal [^{18}F]FDG uptake elsewhere in the body except in the brain, where frankly increased uptake in the leptomeninges of the foramen magnum was observed (Figs. 11 and 12).

Follow-Up and Teaching Point

Leptomeningeal metastasis is an uncommon manifestation of non-central nervous system disease and [^{18}]FDG PET can reveal it. Even though leptomeningeal metastasis has a poor prognosis, early diagnosis is important in order to relieve symptoms, improve quality of life, and prolong survival. The patient was treated with radiation therapy.

Case 1

Case contributed by: C.M. Hoff, K. Bouchelouche
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Aarhus, Denmark

Presentation

A 52-year-old man with cancer of the tongue base. During the past 6 months the patient had noticed what he thought was a growing painful infection on his tongue. The patient had a history of smoking currently 30 cigarettes per day and accumulated 40 pack years.

Clinical examination confirmed the suspension of cancer in the tongue and floor of the mouth with spread to local right-sided lymph nodes (clinical T4a N2b Mx).

Findings

The initial [^{18}F]FDG PET/CT scan (Figs. 1 and 2) showed high [^{18}F]FDG uptake at the right side of the oral tongue, suspicious of cancer (Fig. 1b, large arrow). High [^{18}F]FDG uptake in enlarged right-sided lymph nodes, level 1B and 2, suspicious of metastatic cancer (Fig. 1c, d, small arrows) and moderate [^{18}F]FDG uptake in non-enlarged lymph nodes in the right parotid gland and level 2 and 3 on the right side, also suspicious of local metastases (Fig. 1a, small arrow).

In addition to the head and neck cancer, the [^{18}F]FDG PET/CT also showed a tumor in the rectum with high [^{18}F]FDG uptake (Fig. 2a, b, large arrow), suspicious of a second primary cancer with spread to a local mesorectal lymph node (Fig. 2b, small arrow) on the left side.

[^{18}F]FDG uptake was also seen in several cutaneous and subcutaneous processes, one of them located in the left axillary region (Fig. 2c), where inspection was recommended.

Follow-up

The squamous cell p16 negative head and neck cancer received treatment with curative intended radiation (68 Gy/34 fractions) therapy with concomitant cisplatin and nimorazole. The extent of the disease was too large for surgical intervention.

The rectal adenocarcinoma, T3 N0 M0, was treated with short-course preoperative radiotherapy (25 Gy/5 fractions) and surgical resection.

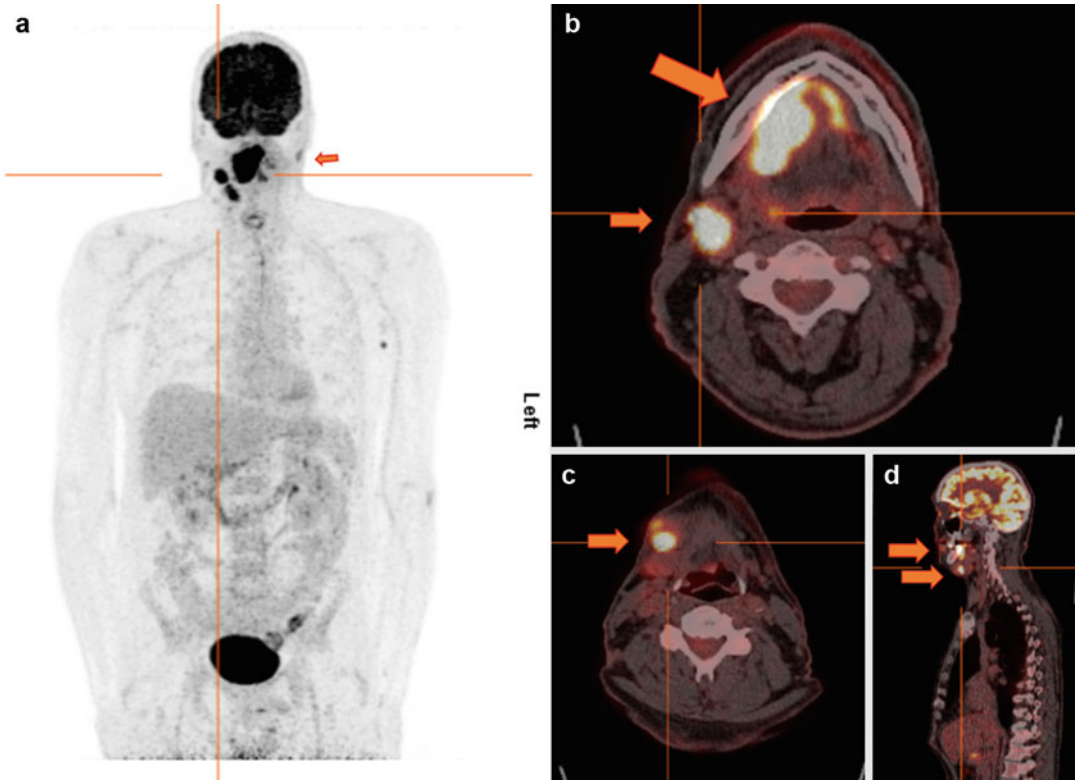

Fig. 1 (**a**) MIP, (**b**) Axial fused PET/CT image of neck, (**c**) Axial fused PET/CT image of neck, (**d**) Saggital PET/CT fusion image

In spite of aggressive therapy, residual HNSCC at both T- and N-site was suspected 2 months after treatment.

The patient had a second [^{18}F]FDG PET/CT scan (Fig. 3) performed 5 months after the initial scan. This showed high [^{18}F]FDG uptake in the right-sided level 1B lymph node (Fig. 3b), which could be both residual tumor and treatment related uptake. No sign of residual tumor at the T-site. However, the PET/CT scan showed four new sites with high [^{18}F]FDG uptake in the left lung (Fig. 3a, orange arrows and 3c), all suspicious of malignant disease. In the left axillary region (Fig. 3a, blue arrow) focal moderate [^{18}F]FDG uptake was seen, which could also represent a metastasis.

The lymph node in level 1B was removed and showed no sign of malignant disease. Biopsies from the lung metastases showed that they originated from the HNSCC.

The treatment that followed was palliative chemotherapy.

Discussion

This case demonstrates some of the diagnostic difficulties in the head and neck area. Cancers can be difficult to diagnose due to high physiological [^{18}F]FDG uptake in the area. It also demonstrates the advantage of a full body [^{18}F]FDG

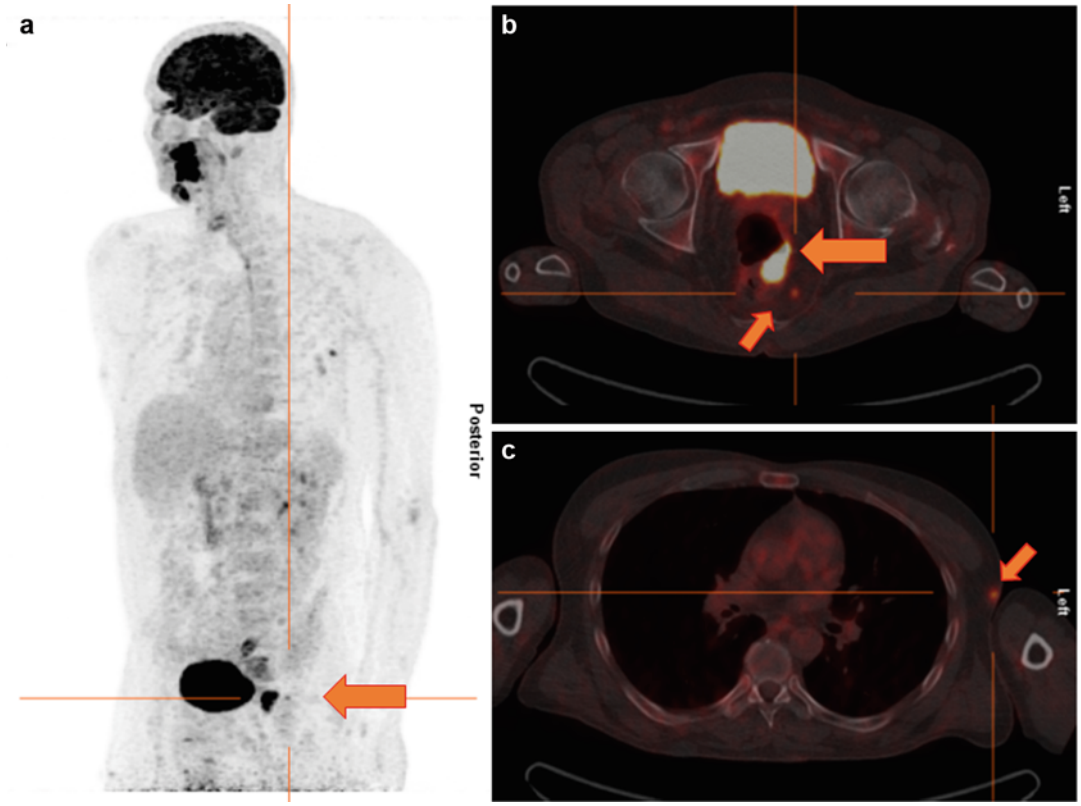

Fig. 2 (**a**) MIP, (**b**) Axial fused PET/CT image of pelvis, (**c**) Axial fused PET/CT image of chest

PET/CT scan and the possibility of diagnosing a second primary tumor. [^{18}F]FDG PET/CT is currently used for primary staging, follow-up, and treatment planning of head and neck cancers.

Case 2

Presentation

A 53-year-old man referred for oropharyngeal squamous cell carcinoma with cervical lymph node metastases (cT2N2b). The patient noticed a mass in his right upper neck 1 month before.

Findings

Ultrasound of neck showed enlarged lymph nodes in his right neck. Diagnostic CT showed the soft tissue mass on base of right side tonsil. Biopsy from the tonsil revealed poorly differentiated squamous cell carcinoma (SCC) with human papilloma virus (HPV) positive. Pathology from the enlarged lymph node was consistent with metastatic SCC. Baseline [^{18}F]FDG PET/CT scan was performed prior to initiation of chemoradiotherapy. The [^{18}F]FDG PET/CT scan shows primary tumor in the right tonsil and lymph node metastasis in the right neck (Fig. 4).

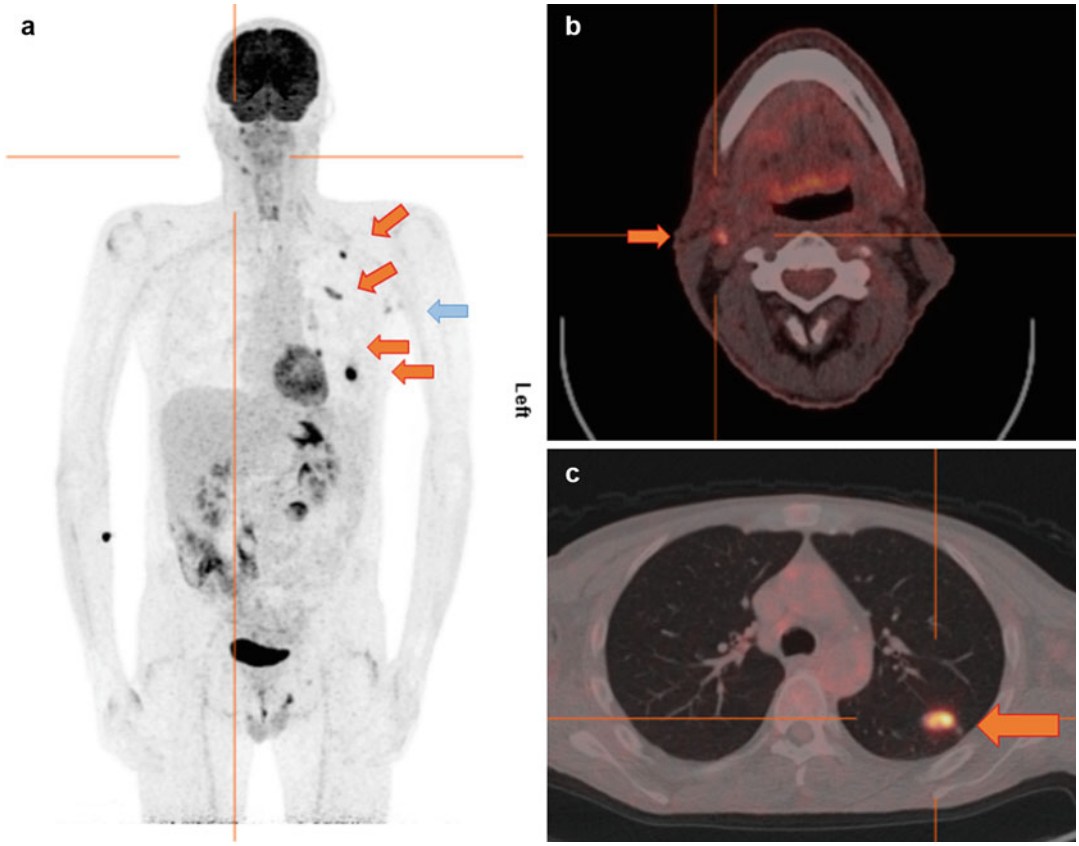

Fig. 3 (**a**) MIP, (**b**) Axial fused PET/CT image of neck, (**c**) Axial fused PET/CT image of lung

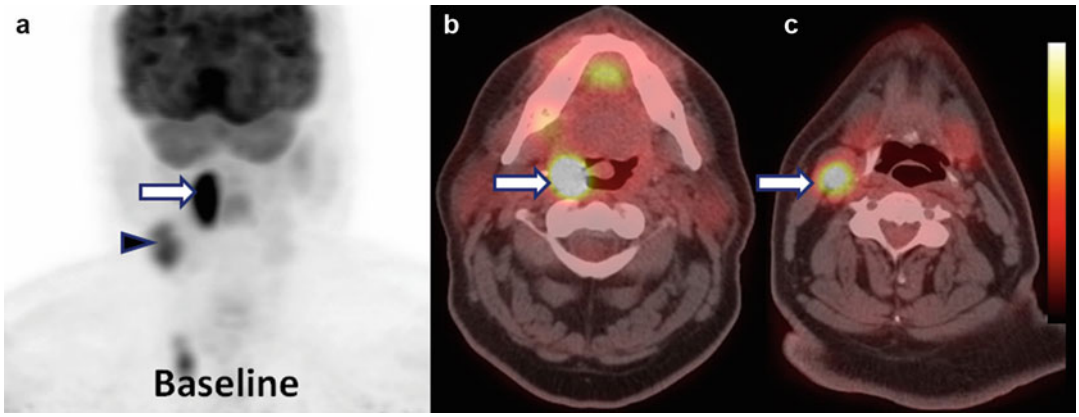

Fig. 4 (Baseline). (**a**) MIP image shows primary tumor (*white arrow*) and lymph node metastasis (*arrow head*). Fused [^{18}F]FDG PET/CT axial images showed (**b**) hypermetabolic right palatine tonsillar mass (SUV_{max} 13.0) and (**c**) hypermetabolic right supraclavicular node measuring 2.4 × 2.0 cm (SUV_{max} 7.2)

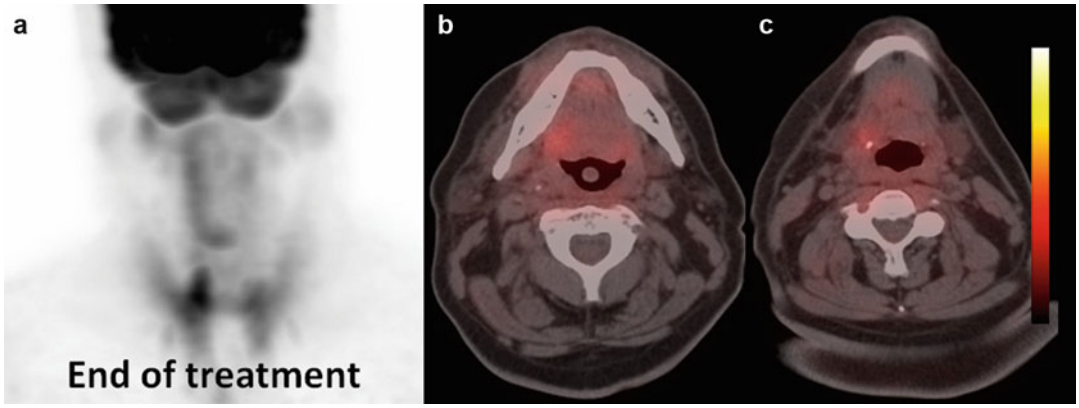

Fig. 5 (Follow-up). [^{18}F]FDG PET/CT axial images show complete metabolic response to therapy with mild physiologic muscle [^{18}F]FDG uptake of neck. (**a**) MIP and (**b**, **c**) axial [^{18}F]FDG PET/CT image shows asymmetric mild [^{18}F]FDG uptake at right tonsil (SUV_{max} 2.58) and resolved lymph node uptake measuring 0.8 × 0.8 cm (SUV_{max} 1.67)

Follow-up

The patient was treated with concurrent chemoradiotherapy (carboplatin and 5FU with radiotherapy 64 Gy). Five months after the treatment, [^{18}F]FDG PET/CT scan was repeated to evaluate response to treatment. No sites of abnormal [^{18}F]FDG uptake were seen, demonstrating complete response to therapy (Fig. 5).

Discussion

No evidence-based guidelines exist on timing and duration of PET/CT long-term surveillance after completion of therapy. It has been widely reported that a 3 months posttreatment PET/CT is able to distinguish persistent disease from treatment-related change with a high negative predictive value. In this case, [^{18}F]FDG PET/CT shows complete remission with mild physiologic muscle uptake [1–3]. It is important to understand physiologic uptake patterns of [^{18}F]FDG in the necks.

Case 3

Presentation

A 63-year-old man was referred to our hospital for tongue cancer treatment (cT2N2).

Findings

Biopsy from base of tongue showed poorly differentiated invasive squamous cell carcinoma. [^{18}F]FDG PET/CT was performed prior to initiation of chemoradiotherapy. Baseline [^{18}F]FDG PET/CT (Fig. 6a–c) showed hypermetabolic tonsillar soft tissue mass with lymphadenopathy in bilateral cervical chains and no evidence of distant metastasis.

Follow-Up

The patient underwent cisplatin-based chemotherapy and radiotherapy (70 Gy/35 fractions). Ten

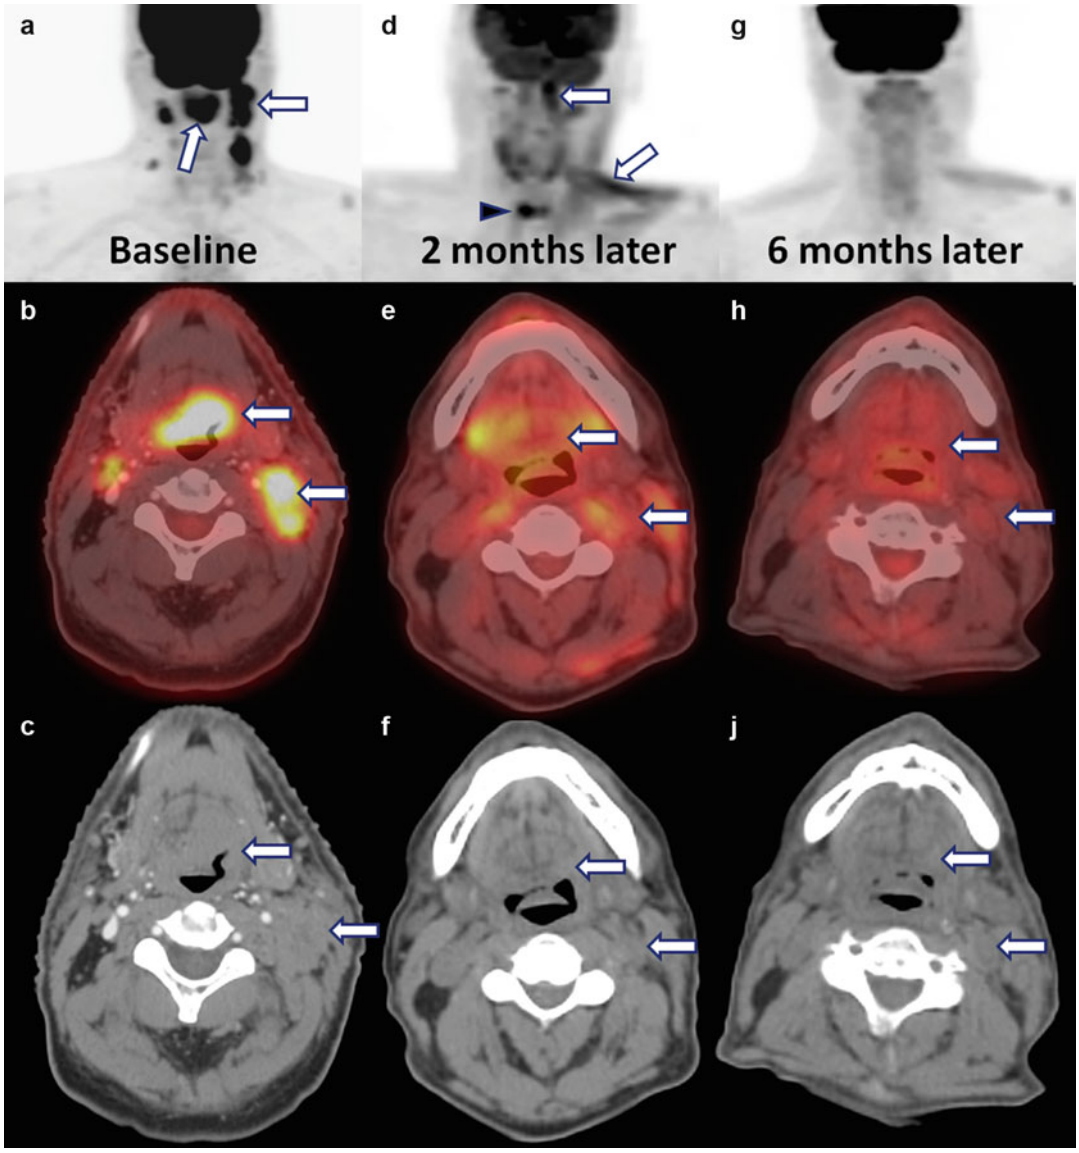

Fig. 6 (**a**) MIP image and (**b**) fused [^{18}F]FDG PET/CT axial image show primary lesion at the left tonsil with SUV_{max} 9.52 (*arrow*) and hypermetabolic metastases with SUV_{max} 10.23, measuring 3.7 × 2.4 cm (*arrows*). (**c**) CT during PET/CT revealed invasive primary tumor at the base of the tongue and lymphadenopathy in the bilateral cervical chains (*white arrows*). (**d**) MIP image of 1st follow-up PET/CT and (**e**) fused axial image show essentially resolution of abnormal uptake of primary lesions (SUV_{max} 2.83) and lymph nodes metastases (SUV_{max} 2.25), measuring 0.7 × 0.4 cm. Additionally, physiologic uptake after chemoradiotherapy appears at right vocal cord (*arrow head*) and in left trapezius muscle (*arrow*). (**f**) CT image shows residual soft tissue at the base of the tongue (*white arrow*). (**g**) MIP image of 2nd follow-up PET/CT, (**h**) fused axial image, and (**j**) CT image during PET/CT show complete remission at the base of the tongue with SUV_{max} 2.35 (*white arrow*) and left lymph node with SUV_{max} 1.5 (*white arrow*)

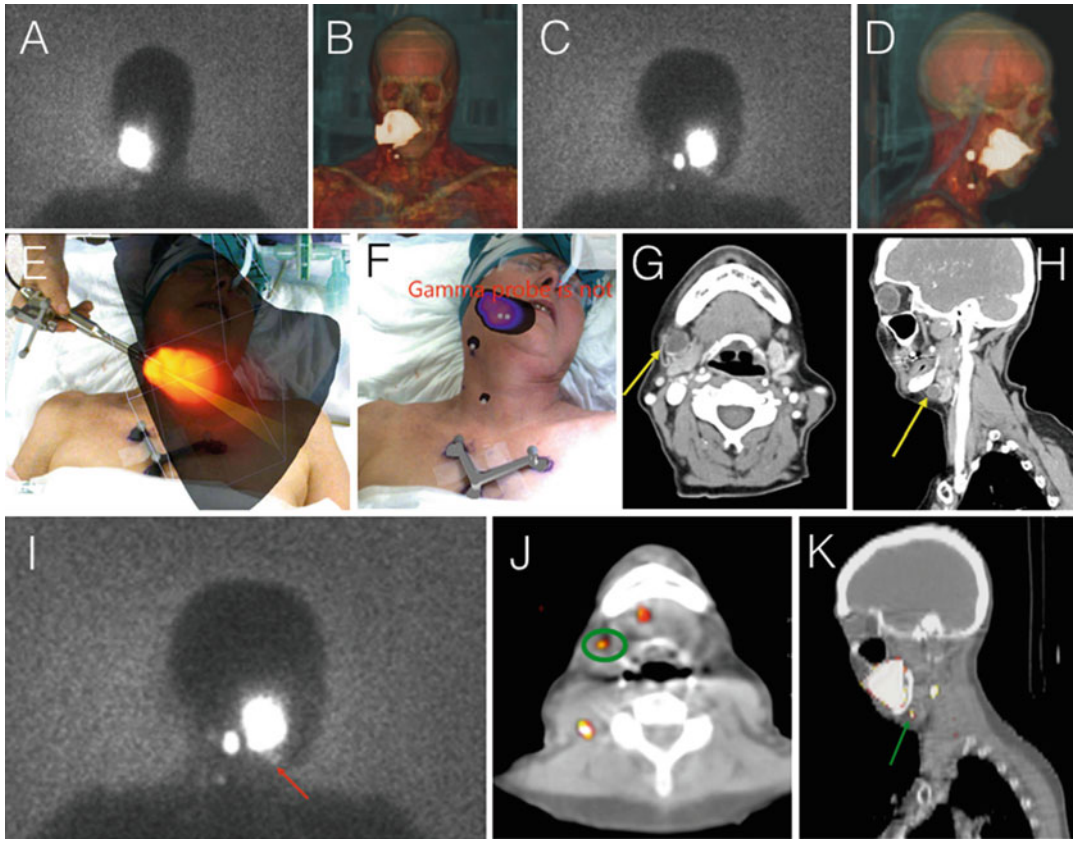

Fig. 7 (**A**) ^{99m}Tc-nanocolloidal albumin (anterior), (**B**) SPECT/CT 3D rendering (anterior), (**C**) ^{99m}Tc-nanocolloidal albumin (lateral), (**D**) SPECT/CT 3D rendering (lateral), (**E** and **F**) a free-hand SPECT probe during surgery, (**G**) Contrast enhanced axial CT image two month later showed swelling lymph-node (yellow arrow), (**H**) Contrast enhanced saggital CT image two month later showed swelling lymph-node (yellow arrow), (**I**) ^{99m}Tc-nanocolloidal albumin (lateral), (**J**) green circle showed late recurrence, (**K**) green arrow showed late recurrence

weeks later, follow-up [^{18}F]FDG PET/CT scan (Fig. 6d–f) showed complete resolution of disease. An additional follow-up scan 6 months later was also negative.

Discussion

Follow-up [^{18}F]FDG PET/CT after completion of chemoradiotherapy is scheduled 10–12 weeks after completion of treatment. Timing of follow-up [^{18}F]FDG PET/CT is important to avoid some false positive and negative findings [3, 4].

Case 4

Case contributed by: S. Vidal-Sicart
Nuclear Medicine Department, Hospital Clinic Barcelona, Barcelona, Spain

A 69-year-old lady presented with a squamous cell carcinoma in floor of the mouth, on the right side. A sentinel lymph node biopsy with the 2-day procedure was planned. After injection of 111 MBq of ^{99m}Tc-nanocolloidal albumin, dynamic, early, and delayed images showed two clear hot spots on the right side of the neck. Anterior and lateral views (Fig. 7A and C) and

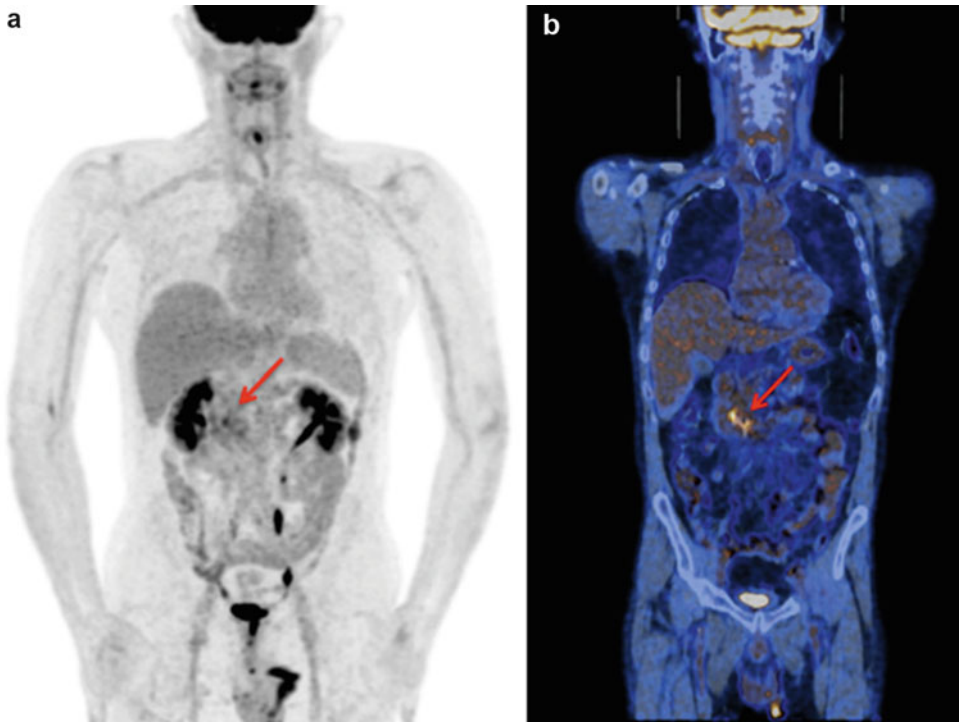

Fig. 8 (**a**) MIP, (**b**) coronal fused [^{18}F]FDG PET/CT; *Red arrows*: pancreatitis

their corresponding 3D reconstructions (Fig. 7B and D). During surgery, a free-hand SPECT device was used and similar findings were obtained (Fig. 7E and F). Two IIA level sentinel lymph nodes were resected and pathology assessment did not show metastatic involvement.

Two months later, the patient presented a palpable submandibular lymph node (Fig. 7G and H). A fine needle aspiration showed no metastasis. However, the multidisciplinary Head and Neck Cancer Committee decided to resect this node. The final pathology report indicated a macrometastatic node involvement. This situation is an example of a false negative sentinel node procedure. After a thorough reviewing of initial images, a faint uptake was considered (red arrow) and SPECT/CT slices showed a tiny uptake in the area where, lately, the recurrence was present (green circle in J and green arrow in K).

False negative results are not unfrequent in floor of mouth tumors and careful examination of all available images should be stressed.

Case 5

Case contributed by: E. Tabacchi[1], C. Nanni[1], I. Bossert[1], A.M. Maffione[2], S. Fanti[1]

[1]Nuclear Medicine Unit, "S. Orsola-Malpighi" Hospital, Bologna, Italy

[2]Nuclear Medicine Unit, "Santa Maria della Misericordia" Hospital, Rovigo, Italy

A 52-year-old man with a history of carcinoma of the soft palate treated with radiotherapy.

On serial follow-up scan 5 years later, a [^{18}F]FDG PET/CT (Fig. 8) showed thickening vocal cord with focal [^{18}F]FDG uptake (Fig. 9: brown arrows). [^{18}F]FDG PET/CT also revealed diffuse uptake in the pancreas (SUV_{max} 5.5) with some calcifications suspicious for chronic pancreatitis (red arrows).

Patient underwent biopsy of the vocal cord with diagnosis of squamous cell carcinoma and underwent endoscopic ultrasound with confirmation of chronic pancreatitis.

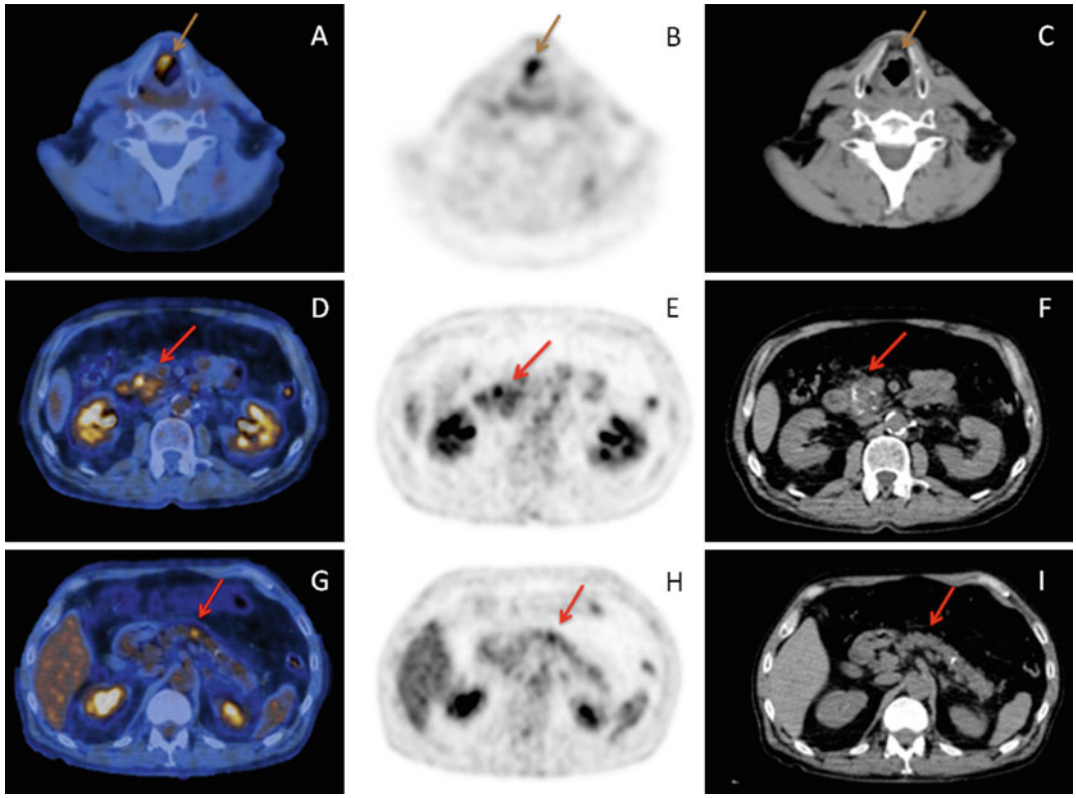

Fig. 9 (**A**, **D**, **G**) transaxial fused [^{18}F]FDG PET/CT images, (**B**, **E**, **H**) transaxial [^{18}F]FDG PET images, (**C**, **F**, **I**) transaxial CT images; *Brown arrows*: vocal cord lesion, *Red arrows*: pancreatitis

Fig. 10 (Baseline). MIP image of the [^{18}F]FDG PET showing the left nasopharyngeal lesion being the only site of disease

Case 6

Case contributed by: S. Wan
Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 15-year-old girl patient presented with 3 months history of gradually worsening headache and 2 weeks of diplopia.

Findings

Combined [^{18}F]FDG PET/MRI study showed a large soft tissue mass with the epicenter at the left nasopharynx (Figs. 10, 11, 12, and 13). There was extensive adjacent soft tissue involvement, including perineural involvement, erosion, and sclerosis of the left skull base and intra-cranial extension. There were no convincing focal avid nodal or distant metastases.

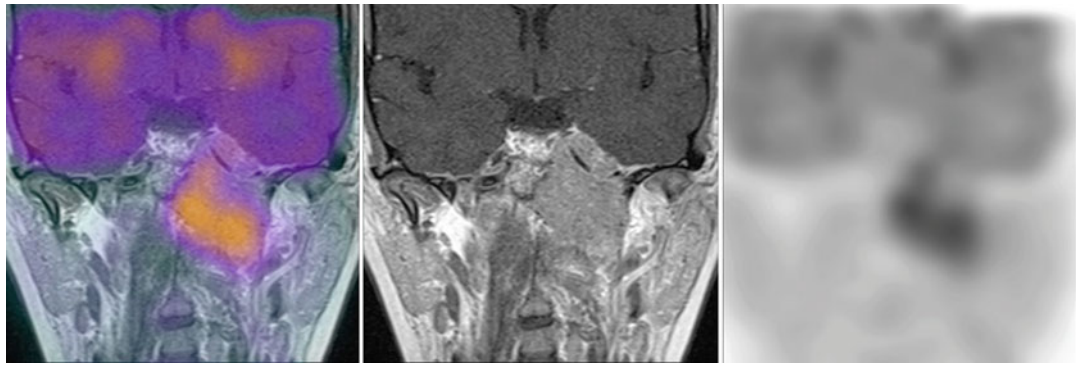

Fig. 11 (Baseline): from *left*: coronal fused, T1 postcontrast and PET image showing the extensive soft tissue mass eroding through the central and left sided skull base, with dural thickening of the left middle cranial fossa and cavernous sinus. The left internal carotid artery is encased and attenuated. There is involvement of the mandibular division of the left trigeminal nerve

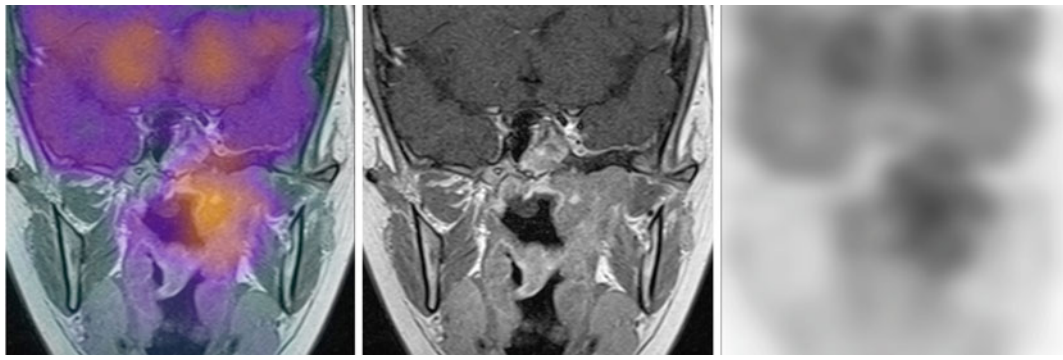

Fig. 12 (Baseline): from *left*: coronal fused, T1 postcontrast and PET image showing the extensive soft tissue mass with sclerosis as well as erosion of the left greater wing of sphenoid

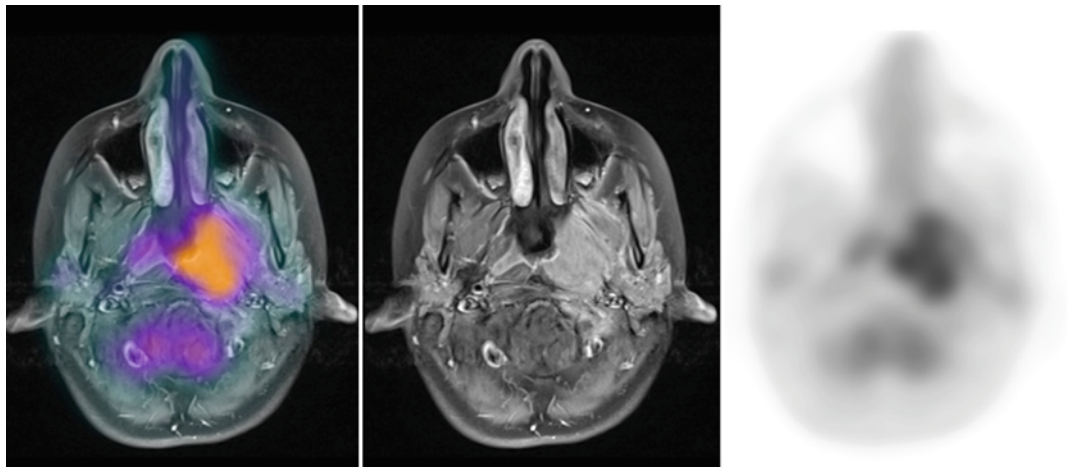

Fig. 13 (Baseline): from *left*: axial fused, T1 fat suppressed postcontrast and PET image showing the extensive left nasopharyngeal soft tissue mass involving the pterygoid muscles and plates. The prevertebral muscles are also involved

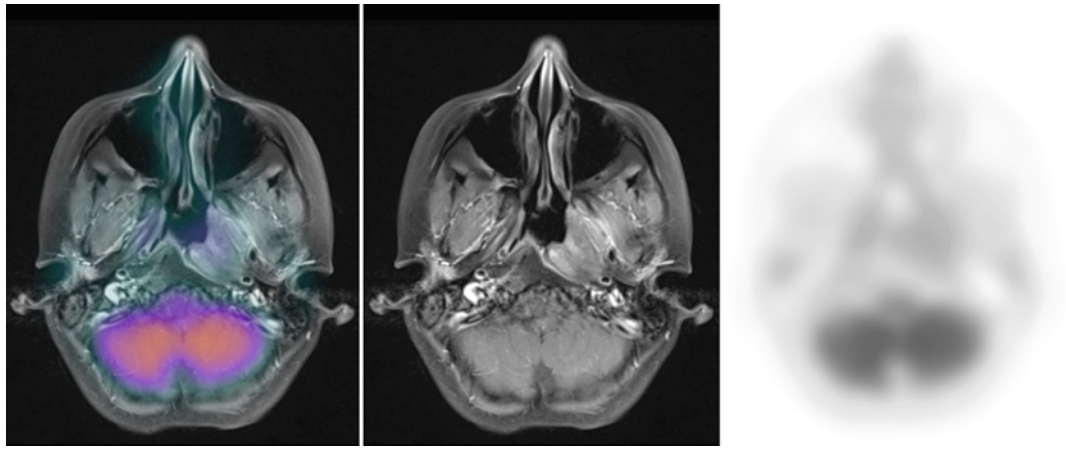

Fig. 14 (Posttreatment): from *left*: axial fused, T1 fat suppressed postcontrast and PET image restaging study showing reduction in bulk of the nasopharyngeal mass with metabolic switch off – only diffuse low grade [^{18}F] FDG uptake is evident

Fig. 15 (Posttreatment): axial T1 postcontrast MR image showing good post treatment appearance on further surveillance with no compelling evidence of relapsed disease

Follow-Up

Biopsy of the mass showed undifferentiated nasopharyngeal carcinoma (EBV positive). The patient subsequently underwent chemotherapy with 5FU/cisplatin/folinic acid and received radiotherapy. Restaging study showed good response to treatment, with further subsequent surveillance study 8 months later showing no compelling evidence of residual disease (Figs. 14 and 15).

Case 7

Presentation

A 48 year old man was referred for second line treatment of advanced squamous cell carcinoma after underwent cisplatin based chemotherapy (cT4N2c). The patient complained with recurrent sore throat and cervical lymphadenopathy.

Findings

Biopsy from the base of the tongue and right pharynx showed an SCC, HPV-positive lesion. Baseline [^{18}F]FDG PET/CT axial image showed the primary tumor on the right base of tongue and cervical lymph node metastases in the left neck (Fig. 16a, b). The patient received concurrent cisplatin based chemotherapy and radiotherapy (total 70 Gy).

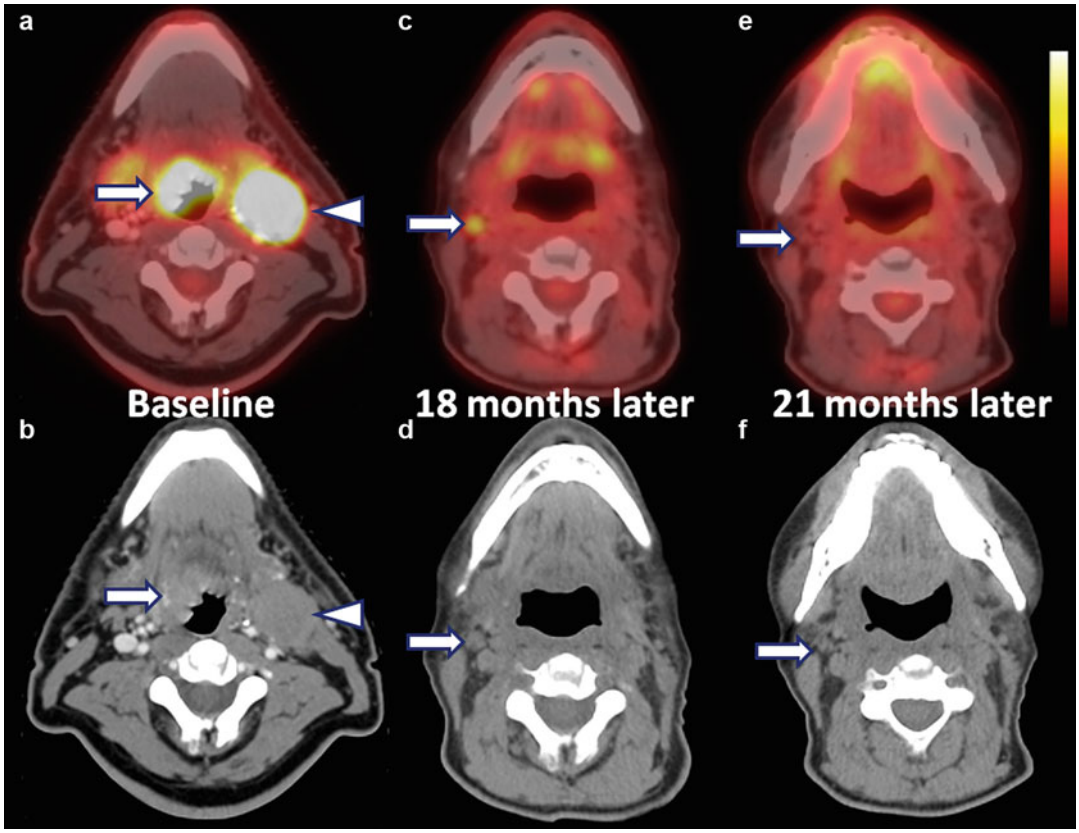

Fig. 16 (**a**) [^{18}F]FDG PET/CT fused axial image and (**b**) CT demonstrated hypermetabolic tumor at the left base of tongue with SUV_{max} 9.8 (*white arrow*) and hypermetabolic left lymph node at left level II with SUV_{max} 17.8 (*white arrow head*), measuring 2.9 × 2.8 cm. (**c**) Eighteen months after the treatment, 1st follow-up [^{18}F]FDG PET/CT fused axial image with the hypermetabolic lymph node (SUV_{max} 3.4) at right level II and (**d**) diagnostic CT scan during PET/CT shows a round lymph node measuring 0.9 × 0.8 cm (*white arrows*). Three months after the 1st follow-up PET/CT scan, (**e**, **f**) 2nd follow-up [^{18}F]FDG PET/CT shows that this finding is resolved (SUV_{max} 1.3), measuring 0.8 × 0.5 cm

Follow-Up

One and a half years after the completion of treatment, a follow-up [^{18}F]FDG PET/CT axial images showed small round lymph node with mild uptake (Fig. 16c, d). The patient was monitored expectantly. Three months later, uptake in this node completely resolved (Fig. 16e, f).

Discussion

[^{18}F]FDG PET/CT can determine the extent of the primary lesions of HNSCC with lymph node metastases. However, false positive findings of [^{18}F]FDG PET occasionally appear as [^{18}F]FDG avid lymph nodes in head and neck region after treatment due to inflammation [3–5]. In this case, the follow-up [^{18}F]FDG PET/CT performed after chemotherapy showed ambiguous findings in a small round lymph node. A watch and wait approach is often helpful to sort out such findings.

Thyroid Cancer (Papillary Carcinoma) and Malignant Struma Ovary

Case contributed by: D. Viola, L. Pieruzzi, R. Elisei
Endocrine Unit, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Presentation

A 40-year-old lady underwent a total thyroidectomy and cervical lymphadenectomy for a 2.5 cm papillary thyroid carcinoma (PTC) with lymph node metastases in the central compartment; at histology, PTC was multifocal, classical variant (T2N1aMx).

Findings

The patient was administered 3.7 GBq ^{131}I-iodide for postsurgical thyroid remnant ablation. At this time serum Tg was 157 ng/mL. The post-ablation whole-body scan (^{131}I-WBS) performed 4 days post-radioiodide administration (Fig. 1) showed frankly increased uptake not only in the neck (indicated with a circle) but also in the pelvic area (indicated with a square).

While tracer uptake in the neck was interpreted as due to a postsurgical remnant of the right thyroid lobe, uptake in the pelvis was unexpected. To better clarify the nature of this lesion, SPECT/CT was acquired, both 4 days and 7 days after administration of ^{131}I-iodide, to verify the pattern of change in uptake intensity – possibly due to non-specific ^{131}I accumulation.

As shown in Figs. 2, 3, 4, 5, and 6, uptake in the pelvis was actually represented by three different areas located as follows: (a) one close to the left anterior pelvic wall in front of the uterus, (b) one in the space between the rectum and uterus, and (c) one in the right portion of the anterior region of the sacrum. The patient underwent laparotomy and a malignant struma ovarii with local metastases was found.

SPECT/CT imaging is a powerful diagnostic tool, which is crucial for correct localization of areas of increased ^{131}I uptake, particularly when localized in the abdomen and in the chest.

Thyroid Cancer

Case contributed by: V. Yerubaudi, C. Sakellis, A.D. Van den Abbeele, H. Jacene
Nuclear Medicine/PET-CT, Dana-Farber Cancer Institute, Harvard medical School, Boston, Massachusetts, USA

Presentation

A 27-year-old man with cystic fibrosis and recently diagnosed papillary thyroid cancer with multiple cervical lymph node metastases found at the time of thyroidectomy.

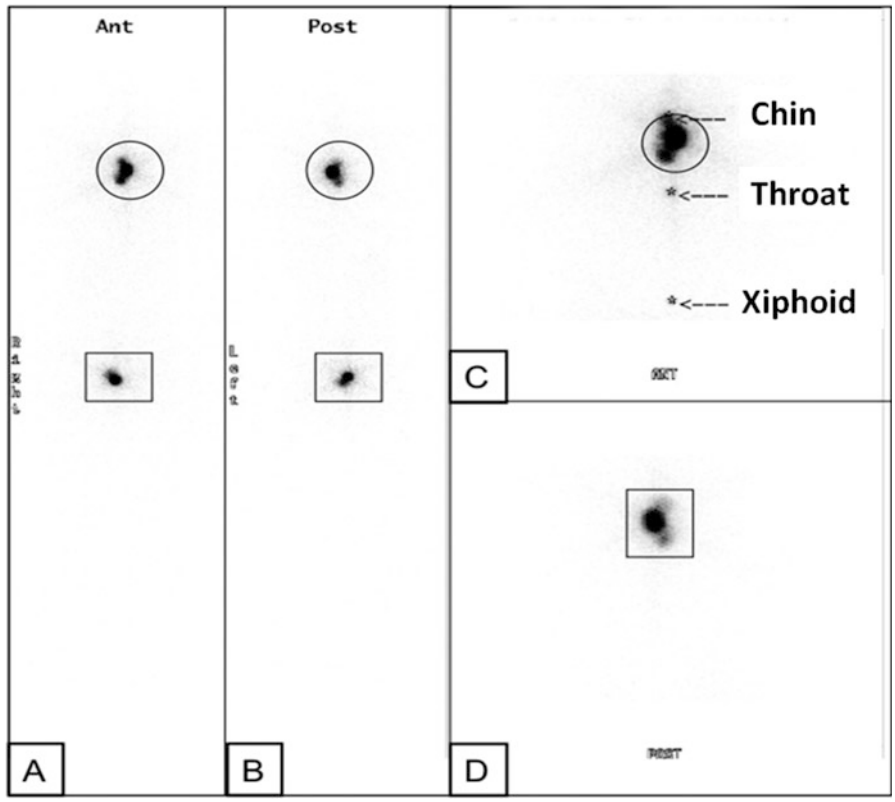

Fig. 1 Anterior (*panel A* with the spot image of the neck in *panel C*) and posterior (*panel B* with the spot image of the pelvis in *panel D*) views of the planar post-ablation ^{131}I-WBS. The area of uptake indicated with a *circle* is clearly due to the expected postsurgical thyroid remnant, while the uptake in the pelvis was unexpected and could not be topographically defined on the planar ^{131}I-WBS

Findings

Several months after surgery, a diagnostic whole-body radioiodine scan was performed 24 h after the oral administration of 107 MBq ^{123}I-iodide. The patient reported maintaining a low-iodine diet in preparation for his iodine scan, and thyroid hormone withdrawal serum TSH was 180.9 μIU/mL. Foci of uptake seen in the neck are suggestive of thyroid remnant tissue (Fig. 7). There is no evidence of abnormal iodine-avid distant foci of uptake to suggest metastatic disease (Fig. 8).

Due to a history of multiple cervical lymph nodes at surgery positive for metastatic thyroid cancer, the patient was treated with 5.5 GBq ^{131}I-iodide. A 5-day delayed post-therapy scan again demonstrated foci of uptake in the neck consistent with remnant thyroid tissue; however, there were additional findings of multiple, patchy, confluent foci of abnormal iodine uptake in the bilateral upper lung zones (Fig. 9). These areas of uptake were likely inflammatory related to patient's cystic fibrosis given the distribution; however, pulmonary metastatic disease remained a possibility. SPECT imaging was performed on this post-therapy radioiodine scan and confirmed bilateral upper lung iodine uptake. These areas of iodine uptake were not seen on the pre-therapy scan. CT chest was recommended for further evaluation.

CT of the chest was performed and images were manually fused with the SPECT previously performed at the time of the ^{131}I-iodide post-therapy scan (Fig. 10). These images

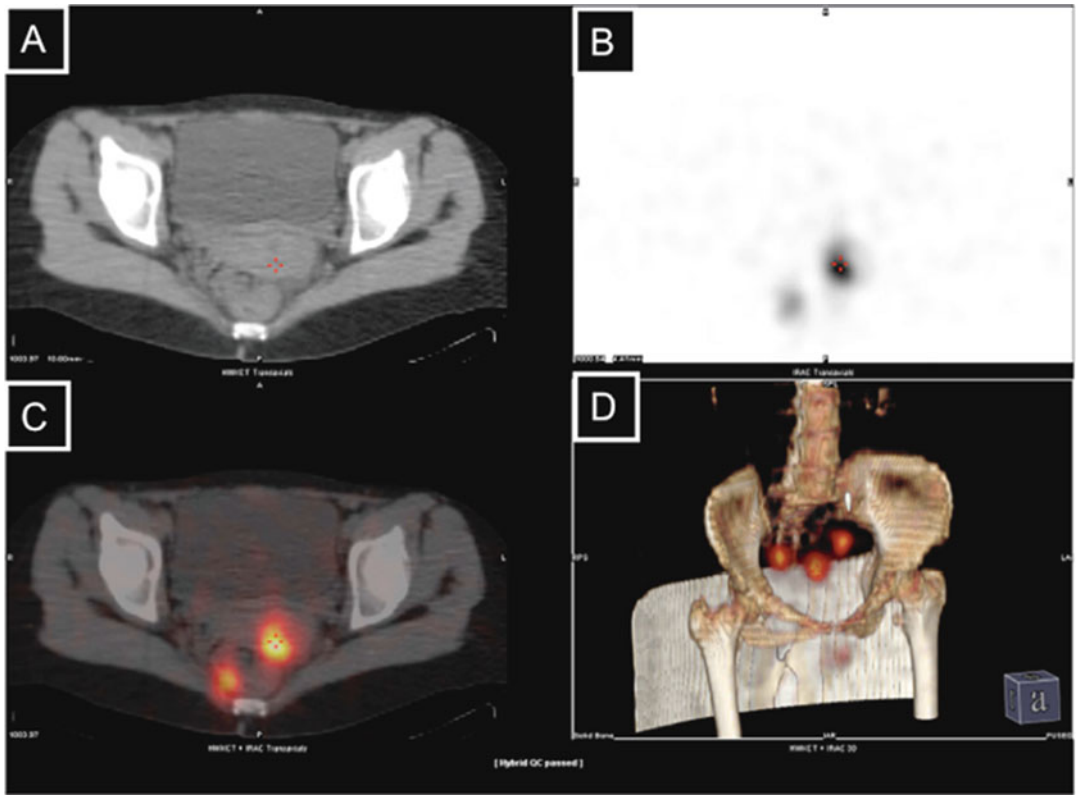

Fig. 2 SPECT/CT transaxial images of the pelvic region (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) showing several areas of ^{131}I uptake corresponding to different lesions in the pelvis; the tridimensional volume rendering (*panel D*) clearly demonstrated the presence of three distinct ^{131}I-avid lesions

demonstrated that areas of most iodine avidity in the upper lungs bilaterally corresponded with the most severe areas of bronchiectasis and bronchial wall thickening. CT findings were consistent with patient's history of cystic fibrosis, and no significant nodules/masses were seen to correspond with areas of increased ^{131}I-iodide uptake on the post-therapy scan.

Discussion

This case demonstrates that abnormal radioiodine uptake can be seen not just in well-differentiated thyroid cancer metastases but also occasionally in nontumoral areas of inflammation, infection, or bronchiectasis. Additionally, there are rare reports of radioiodine uptake in various benign and malignant non-thyroidal tumors as well. In this case, since findings are only seen in the upper lungs, and metastases would be expected to have a more random or broader distribution throughout the lungs, a nonmalignant etiology of the ^{131}I-iodide scan abnormalities should be considered. Occasionally, abnormal foci of iodine uptake are seen only on the post-therapy ^{131}I-iodide scan, and not the pre-therapy ^{123}I-iodide scan, due to the higher administered activity and/or the longer uptake period with the post-therapy scan.

If available, combined SPECT/CT may also be obtained at the time of radioiodine imaging to help localize findings on planar imaging, obviating the need for an additional visit for the patient.

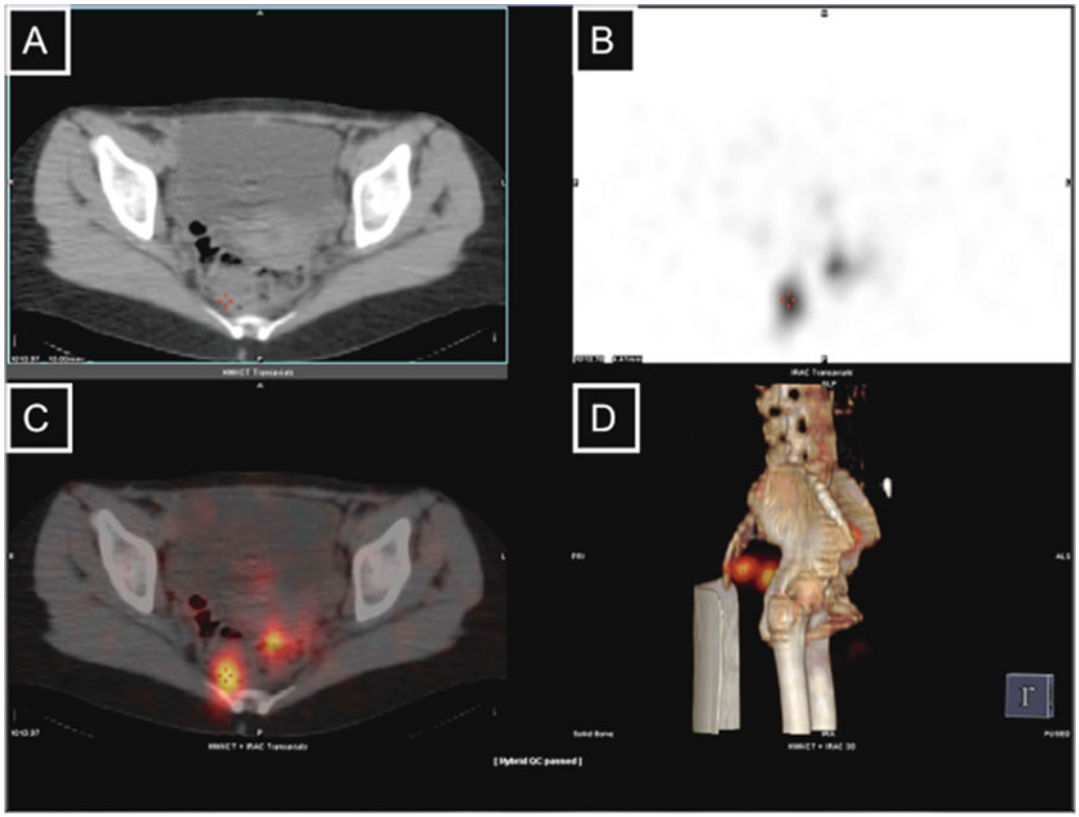

Fig. 3 *Panels A*, *B*, and *C* as in Fig. 2, but with a different tridimensional reconstruction (*panel D*), showing the spatial relationship of the ^{131}I-avid lesions with the pelvic organs and bones

Thyroid Cancer (Medullary Carcinoma)

Case contributed by: S. Wan
Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 40-year-old-man with known history of familial medullary thyroid cancer associated with a known RET oncogene mutation, was initially treated with radical resection and adjuvant chemotherapy. There was however a persistently raised calcitonin level leading to several further local resections. However, calcitonin continued to rise slowly. Conventional imaging yielded no evidence of residual disease locally or distally.

Findings

^{68}Ga-DOTATATE PET/MRI study showed no compelling evidence of somatostatin receptor-positive residual disease in the thyroid bed or cervical chain nodes. There were however a few ^{68}Ga-DOTATATE-avid bone lesions in the cervical and lumbar spine and in the pelvis.

Follow-Up

Metastatic medullary thyroid cancer was diagnosed. An expectant approach was adopted due to perceived low-volume active disease. However, a further follow-up study 6 months later showed progressive imaging findings, in parallel with calcitonin rise. The patient commenced chemotherapy with a targeted agent (Figs. 11, 12, 13, and 14).

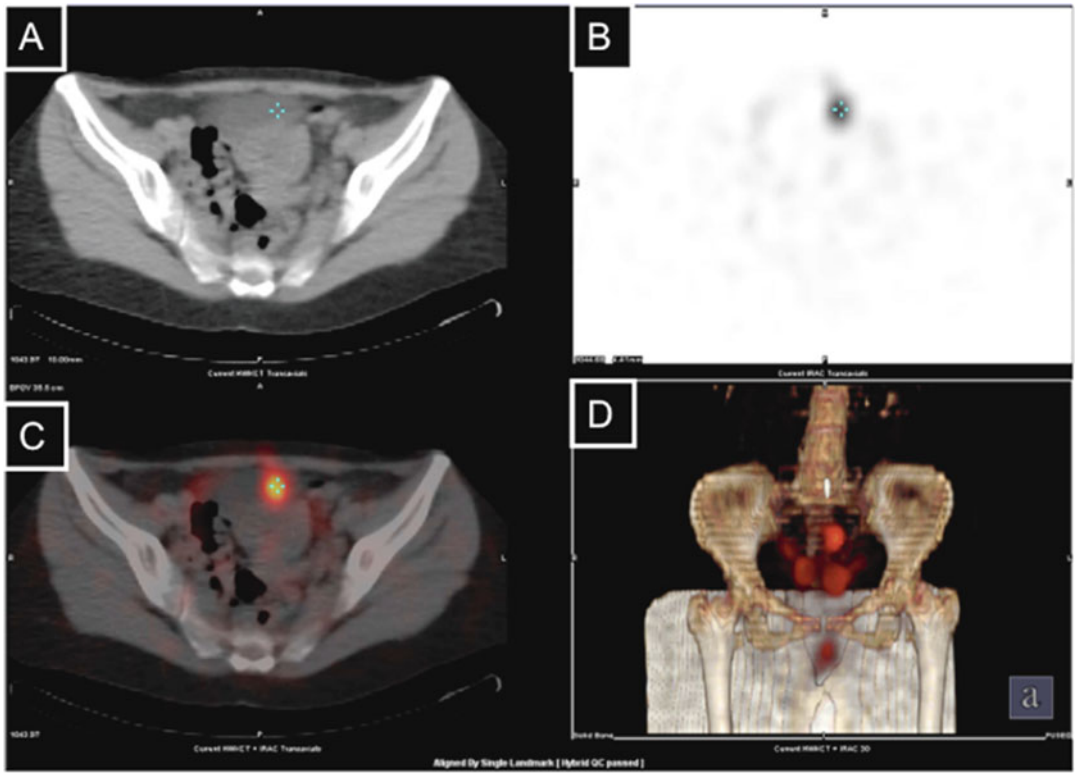

Fig. 4 SPECT/CT transaxial images of the pelvic region (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) showing the presence of a ^{131}I-avid lesion in the space between the rectus and uterus that could also be interpreted as due to ^{131}I retention in the intestinal lumen

Thyroid Cancer (Follicular Carcinoma)

Case contributed by: A. Matrone, V. Cappagli, R. Elisei

Endocrine Unit, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Presentation

A 39-year-old lady presented with a pathological fracture of the left femur. Biopsy obtained at surgery demonstrated that the fracture was due to bone metastasis from a follicular thyroid cancer.

Findings

A 2 cm thyroid nodule was found at neck ultrasound, and FNAC was suspicious for thyroid cancer. The patient underwent thyroidectomy, with histologic confirmation of follicular thyroid cancer.

After thyroidectomy, serum thyroglobulin was 481 ng/mL. Radioiodine ablation/therapy was performed by administering 7.4 GBq ^{131}I-iodide. The post-therapeutic whole-body scan (^{131}I-WBS) showed several areas of increased tracer uptake (Fig. 15). Some of them (indicated with a circle) were clearly due to metastatic lesions: left femur metastasis, lung metastasis located in the lower part of the left lung, and bone metastasis in the left iliac crest. Others (indicated with a square) were equivocal for metastatic lesions: right submandibular area and right iliac fossa.

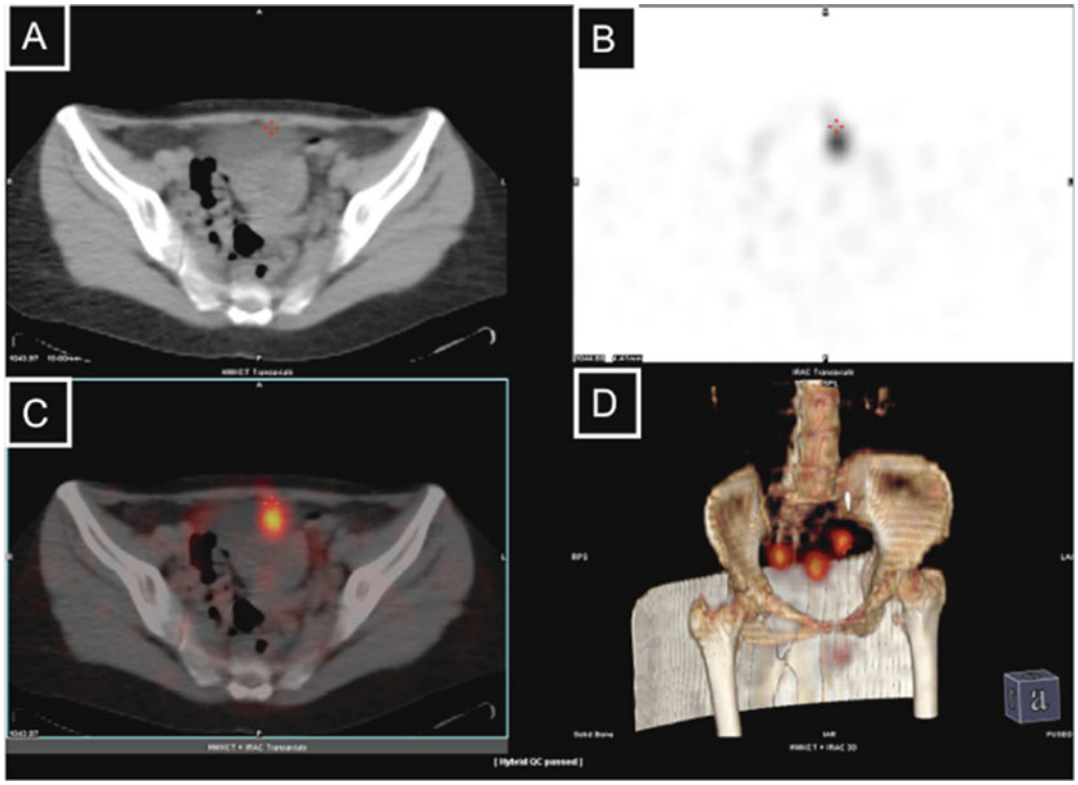

Fig. 5 The same as Fig. 4, but SPECT/CT was acquired 3 days later, showing the persistence of uptake, therefore confirming that it was not a nonspecific accumulation of ^{131}I activity

To better clarify the nature of the areas with increased ^{131}I-iodide accumulation, SPECT/CT at different body levels was acquired (Fig. 16). Uptake in the lung corresponded to a lung nodule in the CT scan. Similarly, uptake in both the left iliac crest (Fig. 17) and the left femur (Fig. 18) corresponded to bone lesions. Instead, no CT detectable lesions were found to correspond to the right submandibular area (Fig. 19) and to the right iliac fossa (Fig. 20); these were therefore interpreted as due to the physiological ^{131}I uptake in the submandibular salivary glands and to retention of ^{131}I activity in the intestine.

Hybrid SPECT/CT imaging is a powerful diagnostic tool to correctly localize the ^{131}I accumulation in the body and distinguish pathological from physiological or nonspecific areas of uptake.

Thyroid Cancer (Poorly Differentiated Carcinoma)

Case contributed by: C. Giani, E. Molinaro, R. Elisei

Endocrine Unit, Department of Clinical and Experimental Medicine, University of Pisa, Pisa, Italy

Presentation

A 52-year-old lady presented with a recently discovered and rapidly growing neck mass. At the time of the observation, the patient did not complain of any other symptoms, neither local nor systemic.

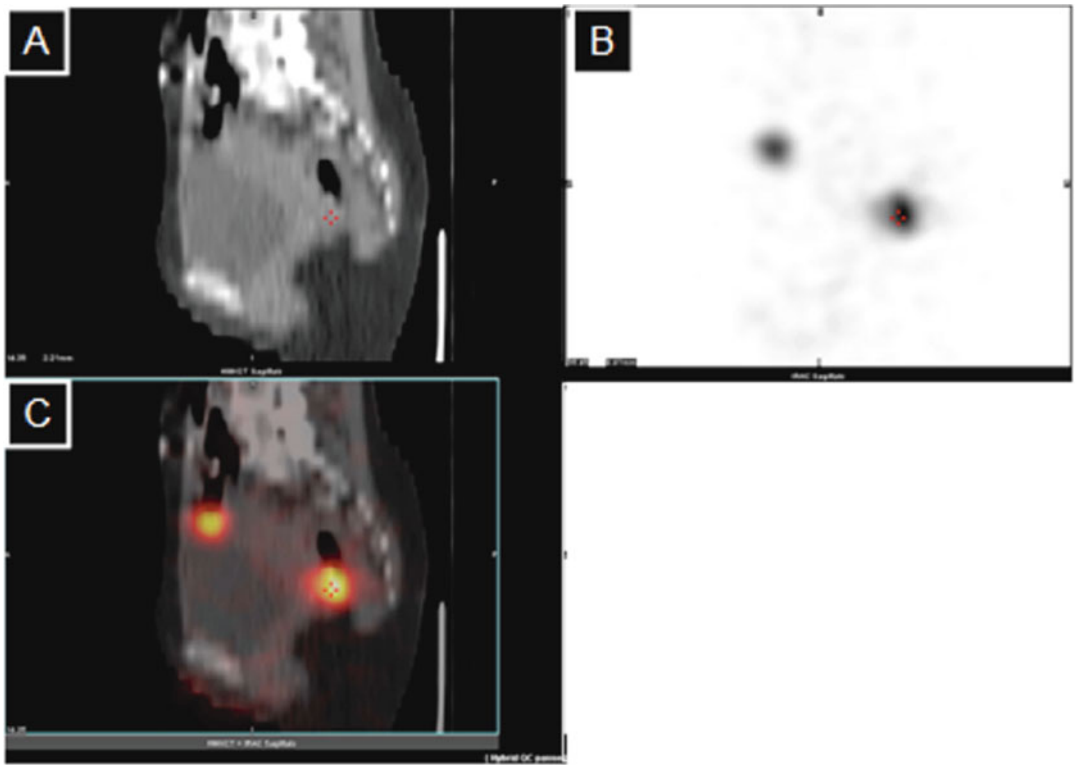

Fig. 6 Sagittal images (CT, *panel A*; SPECT, *panel B*; SPECT/CT, *panel C*) showing the topographic relationship of two of the three ^{131}I-avid lesions with the sacrum, the rectum, and the anterior wall of the pelvis

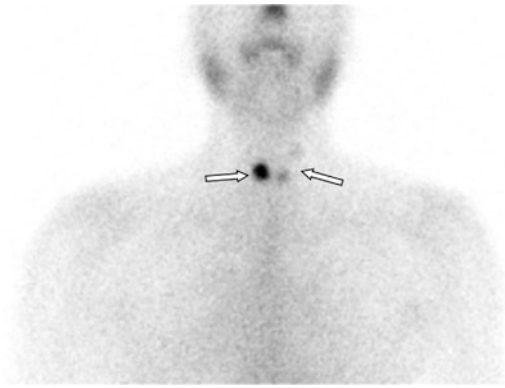

Fig. 7 Anterior neck and chest image from ^{123}I-iodide scan showing foci of uptake in the neck consistent with remnant thyroid tissue (*arrows*). Normal radioiodine distribution otherwise in the salivary glands and nasal mucosa

Findings

Neck US examination showed a large solid and hypoechoic mass in the right thyroid lobe, with features highly suspicious for malignancy (Fig. 21). Histology of a tissue sample obtained by true-cut biopsy showed poorly differentiated thyroid cancer with >30% of anaplastic areas. The CT scan showed a large mass surrounding the trachea, the lumen of which was severely restricted up to a critical point of nearly total obstruction (Fig. 22, panel A). The patient was considered not operable and therapy with a tyrosine kinase inhibitor (TKI) was immediately started as systemic therapy, despite the fact that there were no other lesions outside the

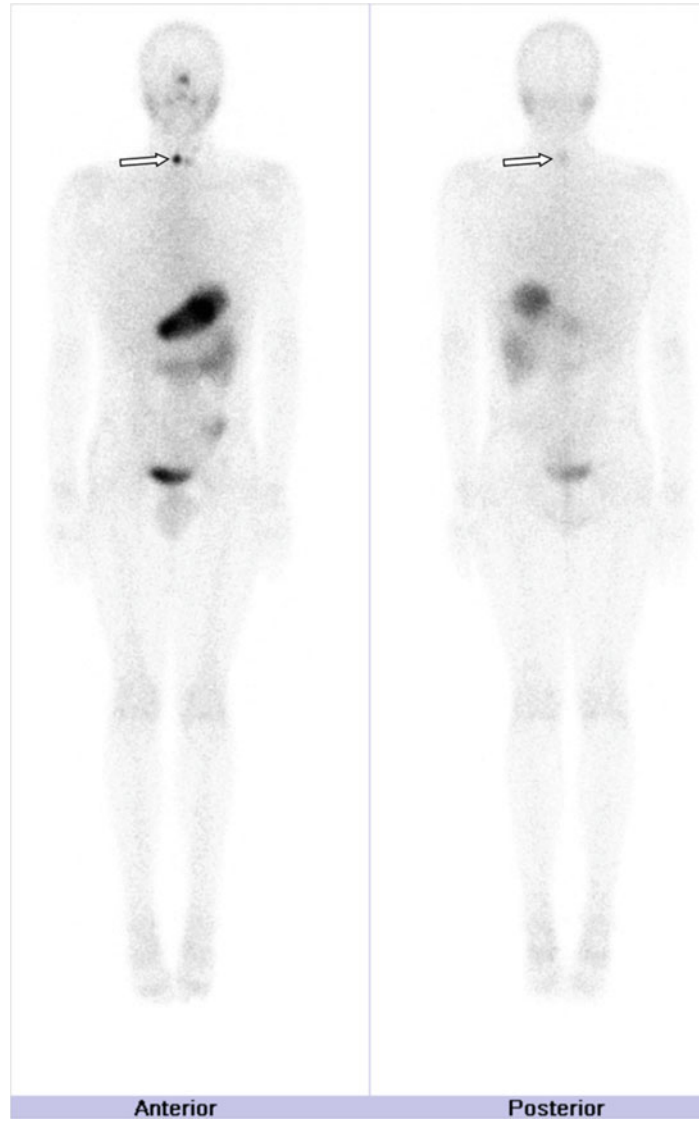

Fig. 8 Whole-body anterior (*left*) and posterior (*right*) images from ^{123}I-iodide scan again also show uptake in remnant thyroid tissue in the neck (*arrows*). Normal biodistribution of radioiodine otherwise with uptake in the nasal mucosa, salivary glands, stomach, bowel, and bladder

neck. After 4 months of TKI therapy, a 50% reduction of the thyroid mass was observed, with significant recovery in size of the tracheal lumen (Fig. 22, panel B). Radical surgery with partial laryngectomy was performed (Fig. 23), after which therapy with TKI was continued up to a total of 24 months. At this time the CT scan was negative, while [^{18}F]FDG PET/CT showed non-specific mildly increased tracer uptake in the neck located before the esophagus around the laryngectomy stoma (Figs. 24 and 25). Additional lesions with increased [^{18}F]FDG uptake were observed in the lung, but the CT scan clearly showed that these were inflammatory. TKI therapy was stopped, and

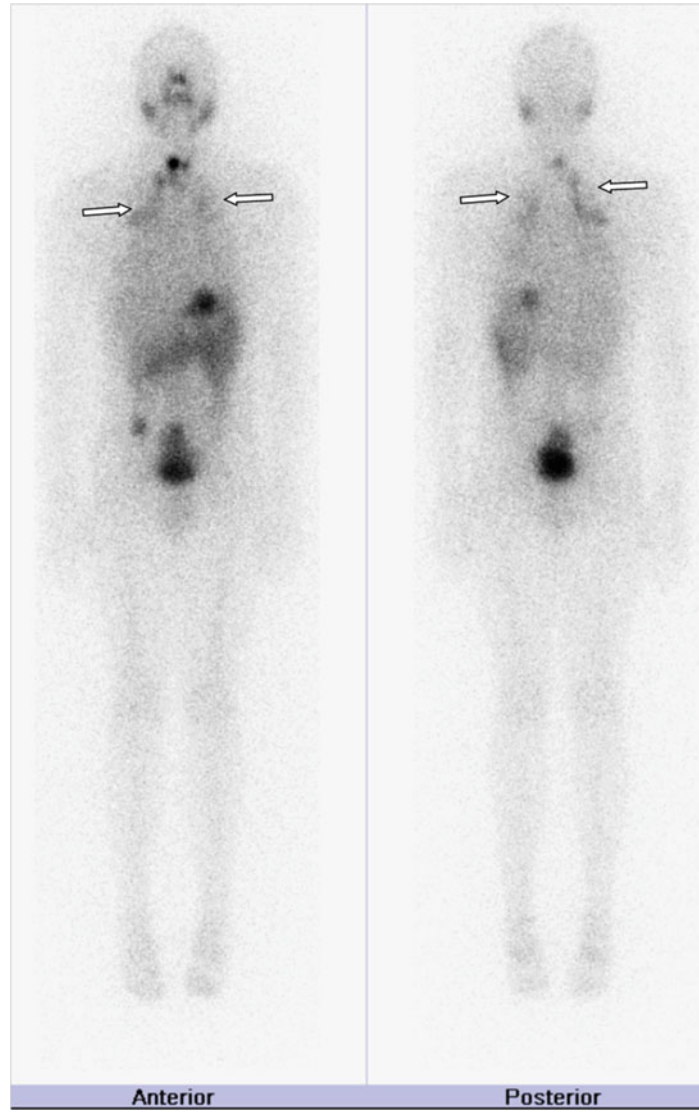

Fig. 9 Whole-body anterior (*left*) and posterior (*right*) ^{131}I-iodide gamma camera images demonstrate foci of uptake in the neck consistent with remnant thyroid tissue. Additional areas of expected biodistribution are seen in the salivary glands, stomach, bowel, and rectum. A small amount of liver uptake is seen related to metabolism of thyroid hormones. Unexpected areas of ^{131}I-iodide uptake are noted in the right greater than left upper lungs (*arrows*), not seen on the pre-therapy ^{123}I-iodide scan

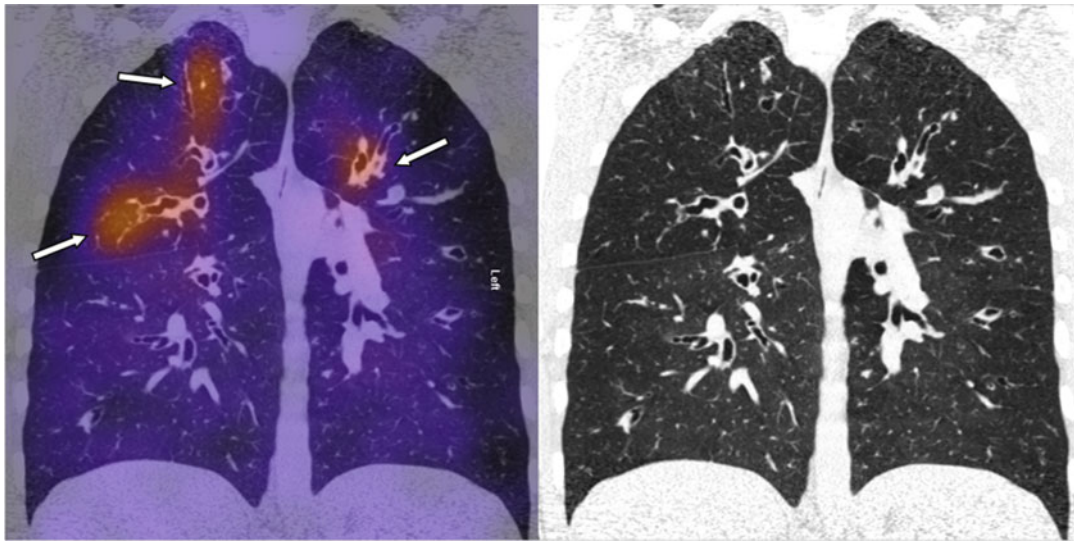

Fig. 10 Coronal fused SPECT/CT (*left*) and coronal CT (*right*) of the chest showing upper-lung-predominant bronchiectasis consistent with patient's history of cystic fibrosis. SPECT uptake is noted to correlate with areas of bronchiectasis on CT (*arrows*), notably with no significant nodules or opacities to suggest metastatic disease

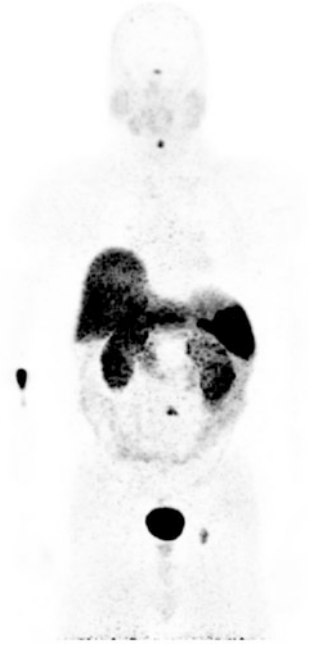

Fig. 11 Whole-body 3D maximum intensity projection (*MIP*) image of the ^{68}Ga-DOTATATE PET showing a few sites of somatostatin receptor-positive disease in the cervical, lumbar spine and in the left ischium

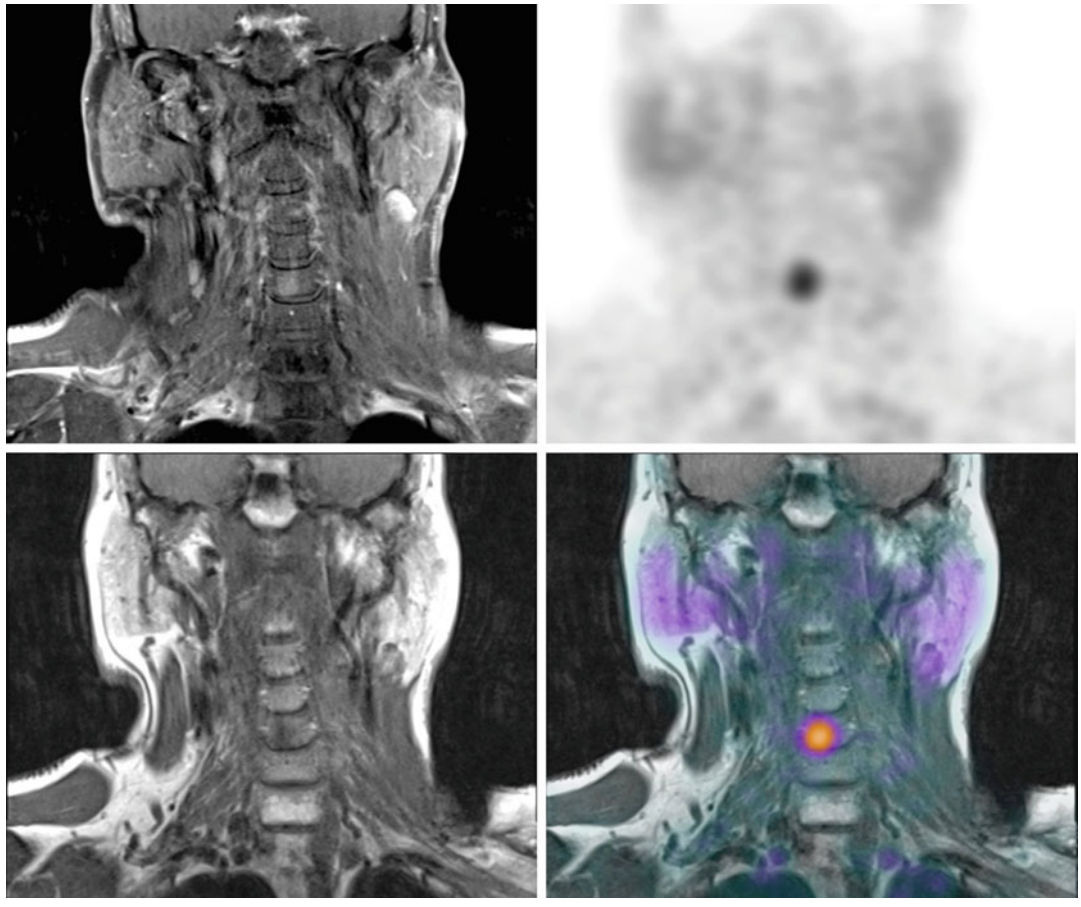

Fig. 12 Clockwise from *top left*: coronal fat-suppressed T1 postcontrast, PET, fused, T1-weighted images showing ^{68}Ga-DOTATATE-avid focus corresponding to an enhancing, low T1 signal lesion in the right side of the C5 vertebrae consistent with a metastatic deposit

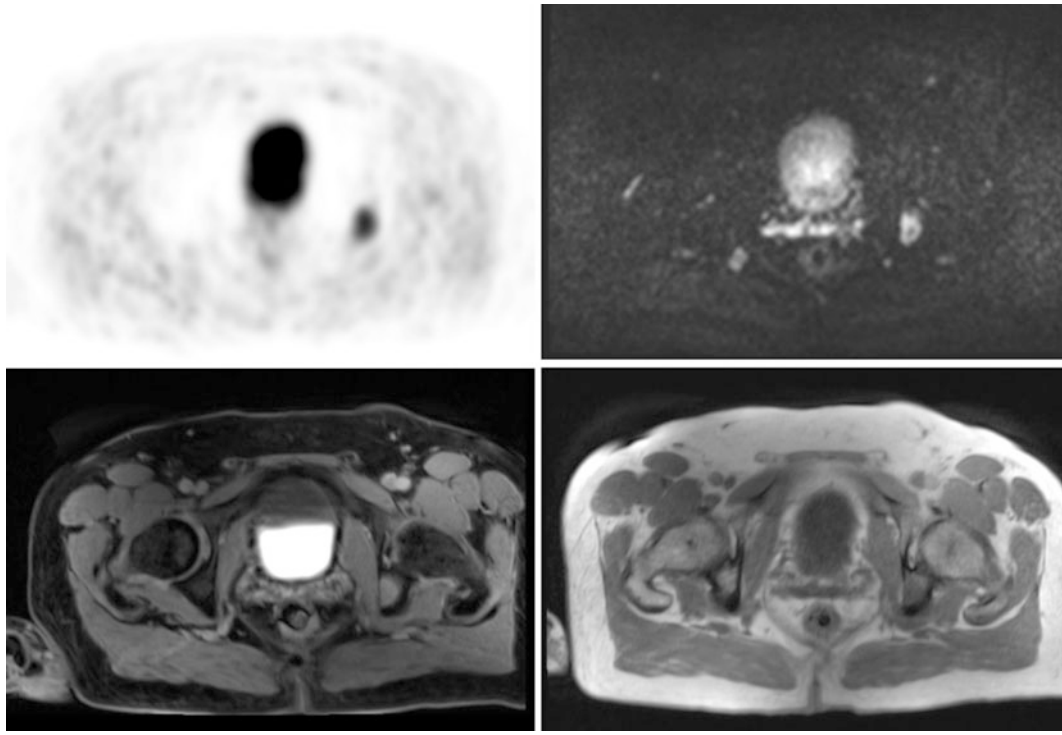

Fig. 13 Clockwise from *top left*: axial PET, high-b-value diffusion-weighted, T1-weighted, and fat-suppressed T1 postcontrast images of the lower pelvis. These show an enhancing ^{68}Ga-DOTATATE-avid lesion in the bone marrow at the left posterior acetabulum. Restricted diffusion in the lesion suggests high cellularity as expected

Fig. 14 MIP image of ^{68}Ga-DOTATATE PET 6 months later shows progressive appearance, with multiple new ^{68}Ga-DOTATATE-avid lesions now involving more of the skull, ribs, thoracic spine, and right humerus, in addition to existing lesions

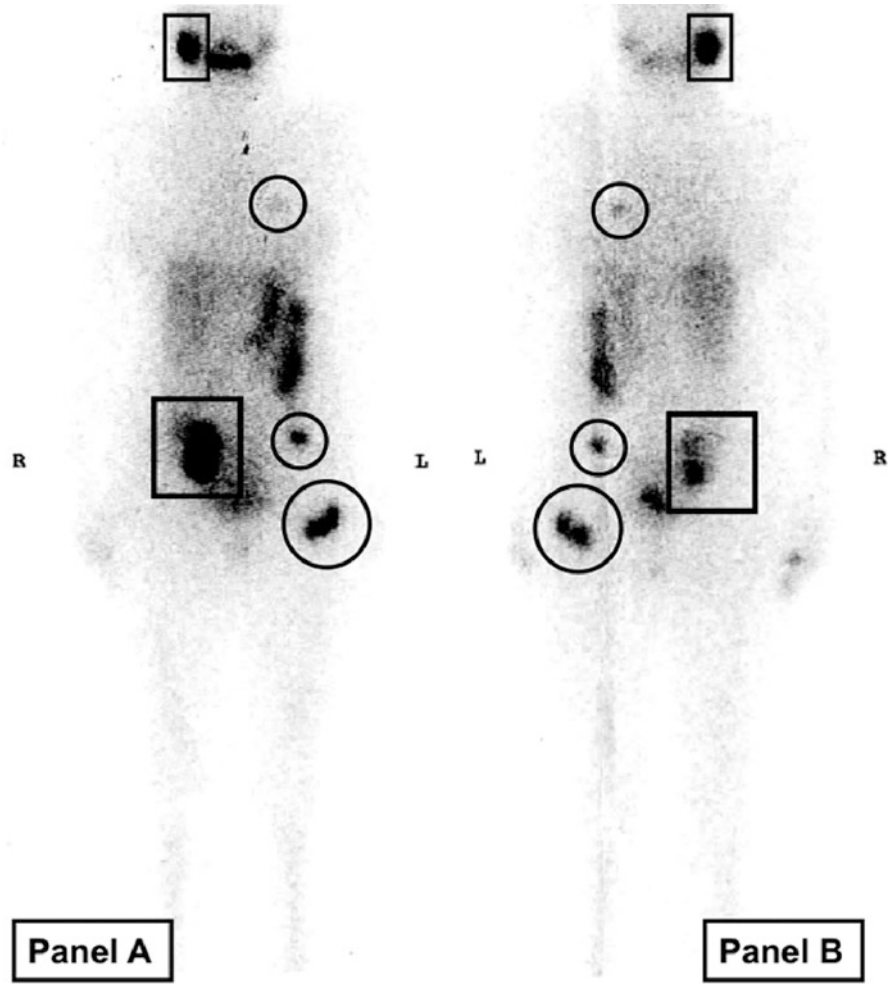

Fig. 15 Anterior (*panel A*) and posterior (*panel B*) views of the planar post-therapeutic ^{131}I-WBS scan obtained after the administration of 7.4 GBq ^{131}I-iodide. The areas of uptake indicated with a circle are due to clearly metastatic lesions, while those indicated with a square are equivocal. Planar ^{131}I-WBS cannot provide precise topographic information

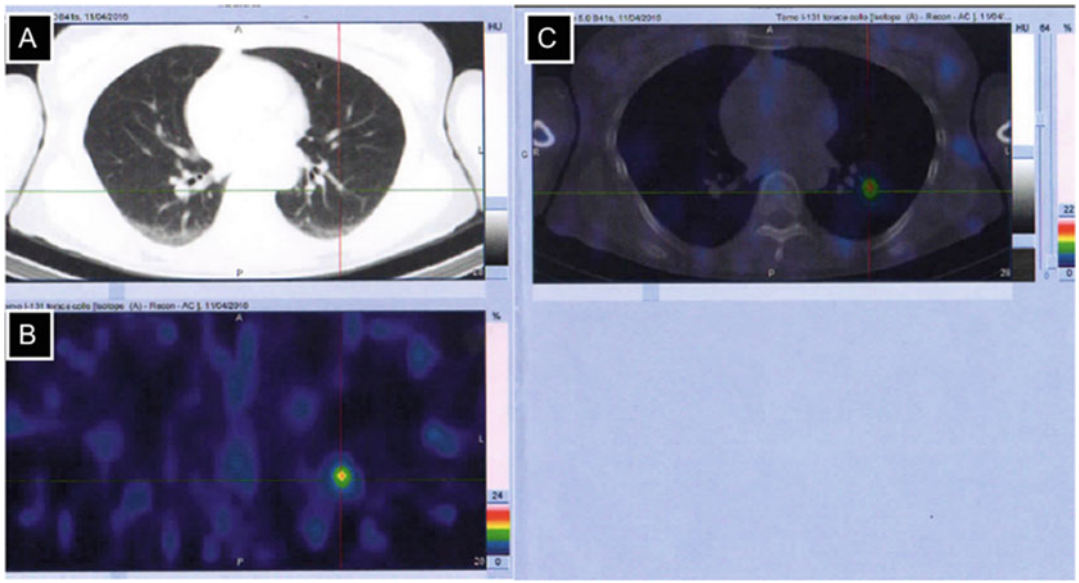

Fig. 16 SPECT/CT transaxial images of the lungs (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) demonstrated the presence of a ^{131}I-avid nodule in the left lung

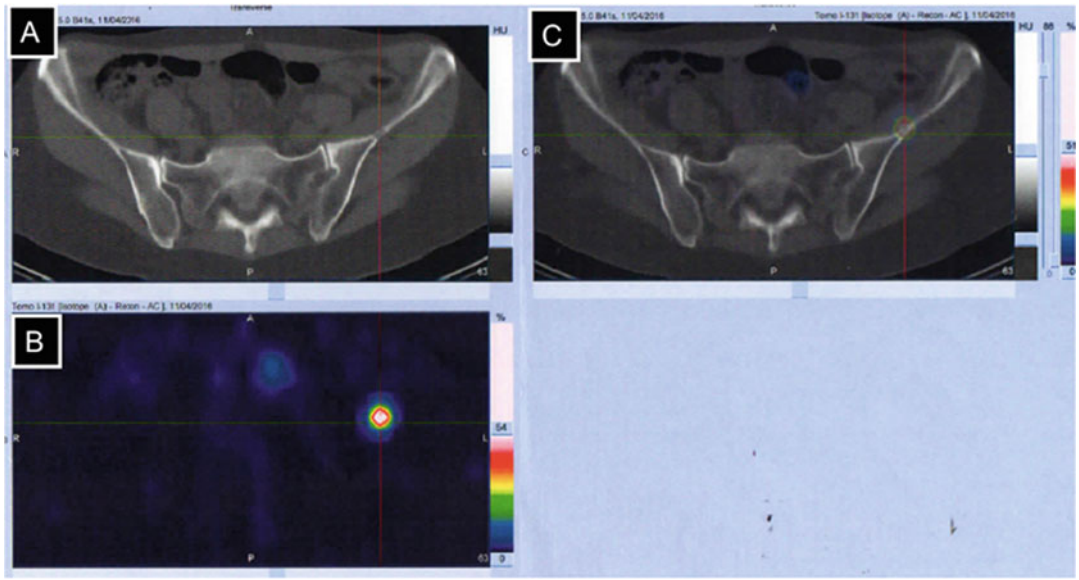

Fig. 17 SPECT/CT transaxial images of the iliac crests (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) demonstrated the presence of a ^{131}I-avid bone lesion in the left iliac crest

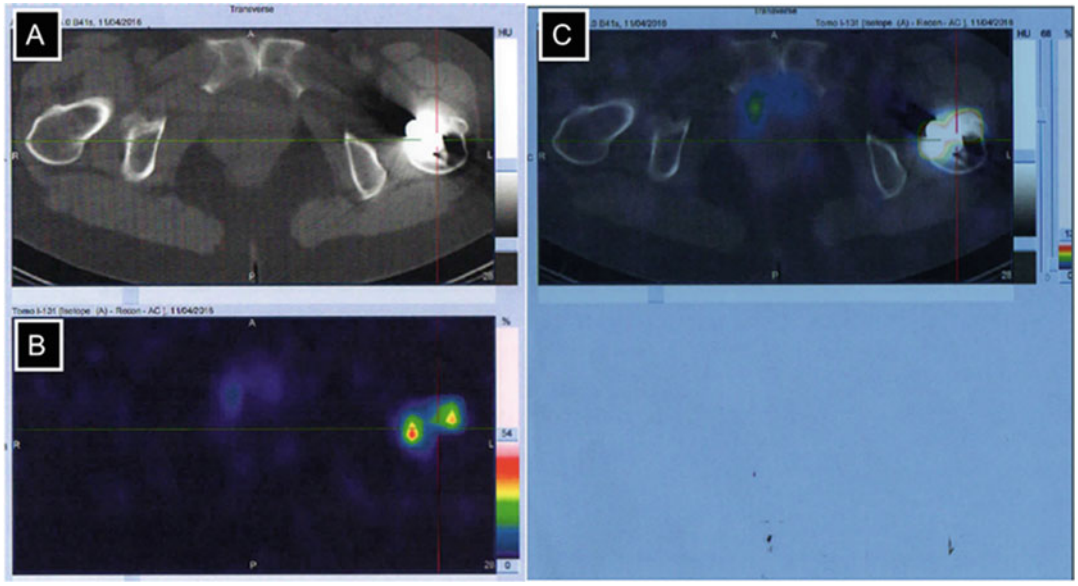

Fig. 18 SPECT/CT transaxial images of the femurs (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) demonstrated the presence of a ^{131}I-avid bone lesion in the left femur, site of the pathological fracture

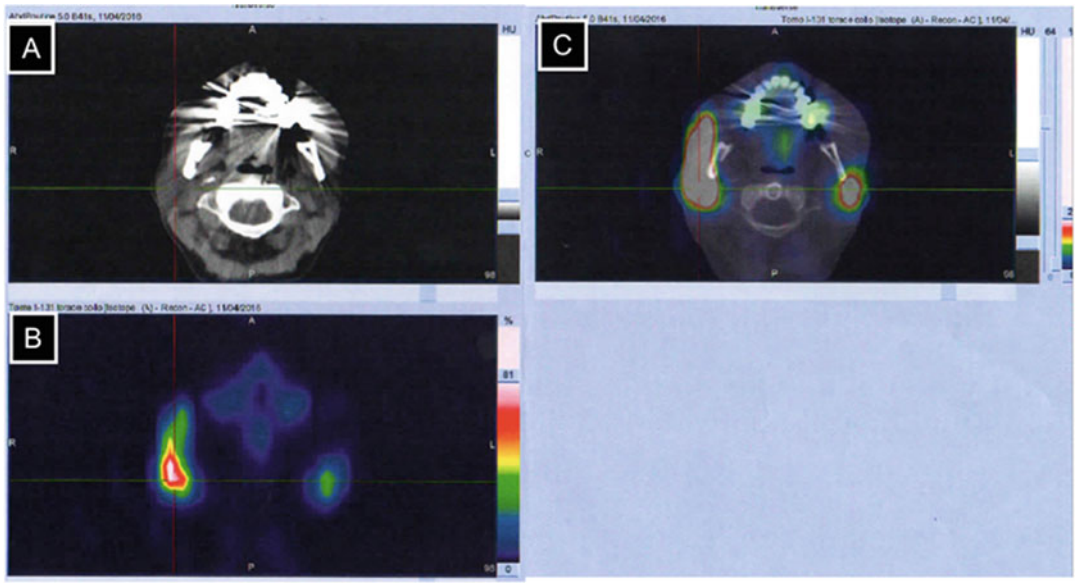

Fig. 19 SPECT/CT transaxial images of the mandibles (CT, *panel A*; SPECT, *panel B*; fused SPECT/CT image, *panel C*) demonstrated the presence of ^{131}I uptake in the right salivary gland but without any specific lesion, thus demonstrating that this uptake was due to the physiological ability of the salivary gland to take up iodine

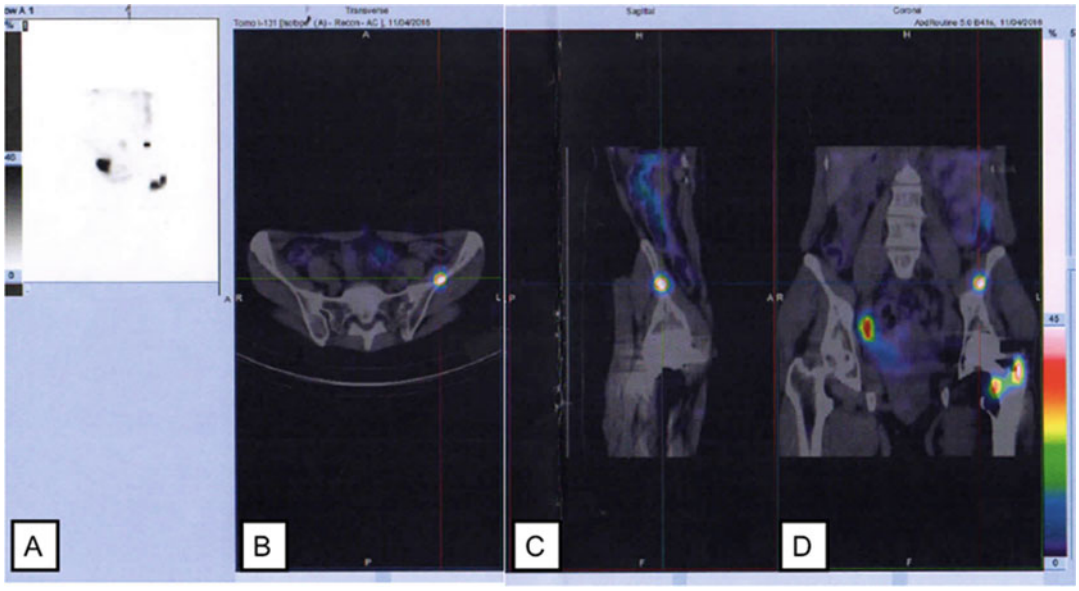

Fig. 20 Comparison of the planar ^{131}I-WBS (*panel A*) with the SPECT/CT transaxial image of the iliac crests (*panel B*) and the sagittal (*panel C*) and coronal (*panel D*) images of the abdomen and pelvis demonstrated that radioactivity accumulation in the right iliac fossa (*panel D*) had no corresponding images detected by CT (*panel B*) as it was for the left iliac crest (*panel B*) and the left femur (*panels D* and *A*), thus confirming that radioactivity accumulation in the right iliac fossa was nonspecific and most likely due to intestinal retention of ^{131}I

Fig. 21 Ultrasound appearance of the large mass in the right thyroid lobe. The lesion is solid, hypoechoic, not well defined, and with hyperechoic spots inside the mass. These features are highly suspicious for cancer

Fig. 22 *Panel A*: CT appearance of the large solid mass surrounding the trachea, whose lumen was severely reduced determining a high risk of suffocation. *Panel B*: after 4 months of TKI therapy, the same mass was greatly reduced in size, and there was a clinically important recovery of tracheal lumen

Fig. 23 CT of the neck scan after radical surgery and partial laryngectomy

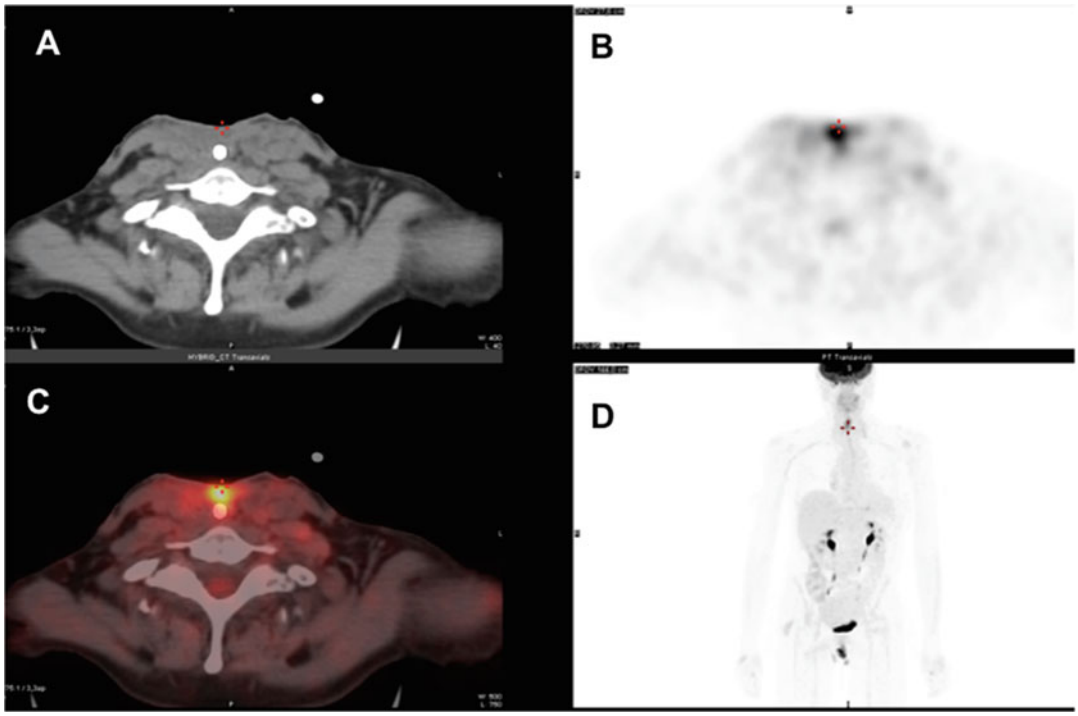

Fig. 24 [^{18}F]FDG PET/CT transaxial images of the neck (CT, *panel A*; [^{18}F]FDG PET, *panel B*; fused PET/CT fused image, *panel C*): nonspecific moderately increased tracer uptake anteriorly to the esophagus, likely due to the laryngeal stoma secondary to partial laryngectomy. *Panel D*, [^{18}F]FDG-PET MIP image, showing no other major [^{18}F]FDG-avid lesions

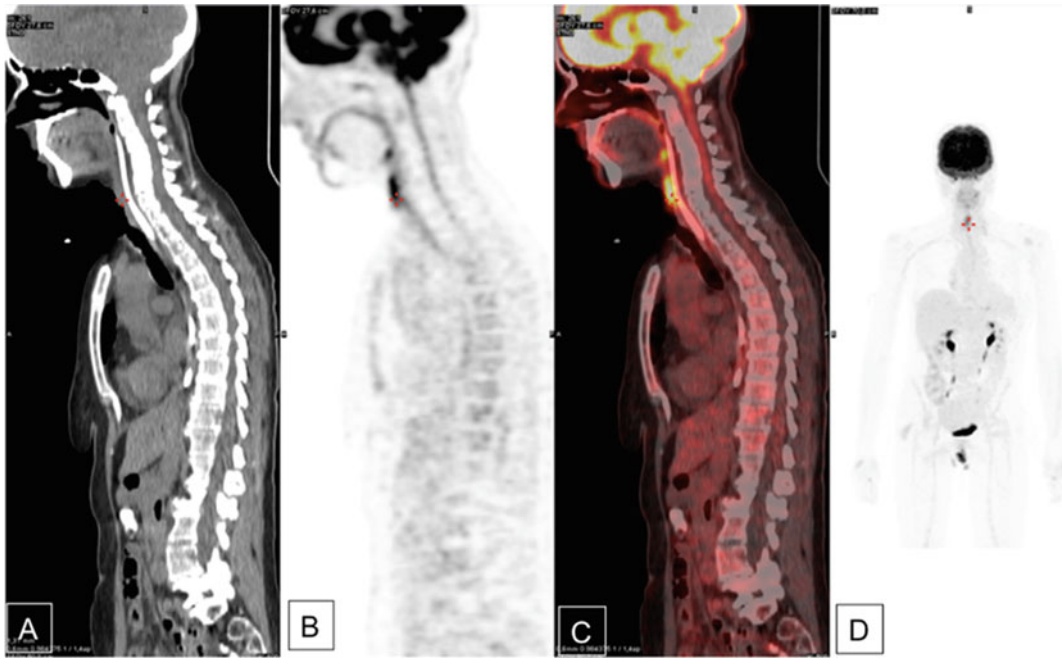

Fig. 25 [^{18}F]FDG PET/CT sagittal images (CT, *panel A*; [^{18}F]FDG PET, *panel B*; fused PET/CT image, *panel C*): nonspecific moderately increased tracer uptake anteriorly to the esophagus, likely due to the laryngeal stoma secondary to partial laryngectomy. *Panel D*, [^{18}F]FDG-PET MIP image, showing no other major [^{18}F]FDG-avid lesions

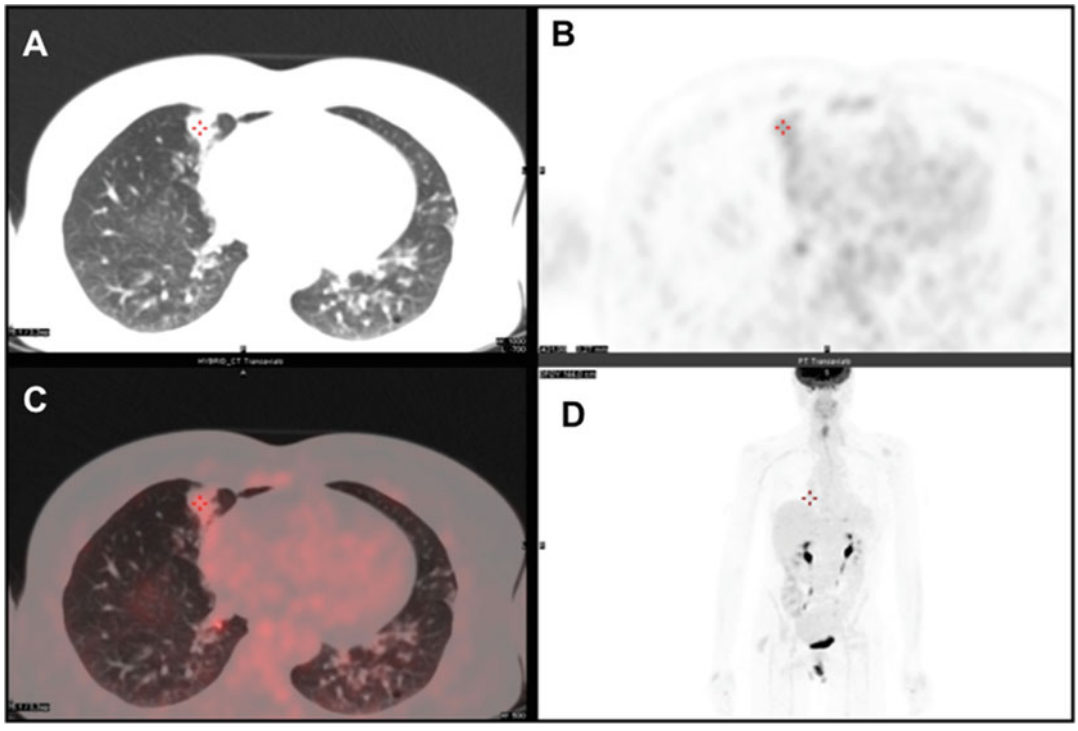

Fig. 26 [^{18}F]FDG PET/CT transaxial images of the thorax (CT, *panel A*; [^{18}F]FDG PET, *panel B*; fused PET/CT fused image, *panel C*): nonspecific mildly increased tracer uptake in the right lung, with SUV_{max} 3.5 for the largest of the two detectable areas that the CT scan demonstrates to be inflammatory lesions. Panel *D*, [^{18}F]FDG-PET MIP image, showing no other major [^{18}F]FDG-avid lesions

after 10 months later, the patient remained in good health, without evidence of recurrence (Fig. 26).

retention of this area on the delayed images (Fig. 1). Contrast-enhanced CT and MRI of the neck showed a left soft tissue lesion displacing and invading the left thyroid and likely tracheal and esophageal involvement. [^{18}F]FDG PET/CT was performed for staging and showed a [^{18}F]FDG-avid left lower neck soft tissue lesion compatible with the parathyroid carcinoma with no [^{18}F]FDG-avid nodal or distal metastases (Fig. 2).

Follow-Up

The patient underwent resection of the tumor and a left hemithyroidectomy. Histopathology confirmed the presence of a high-grade malignant tumor of parathyroid origin.

Discussion

Parathyroid carcinoma is an uncommon malignancy with an annual incidence of approximately 1.25 cases per 10,000,000. [^{18}F]FDG-PET/CT is sensitive in the detection of parathyroid carcinoma, can assess for local nodal and distant metastases, and can evaluate complications of hyperparathyroidism, i.e., abnormal calcification (renal) and bone complications (i.e., brown tumors). In this case, the absence of local nodal involvement on PET/CT allowed for less radical surgical treatment.

Paraganglioma

Case contributed by: E.D. Telenga[1], R.H.J.A. Slart[1,2], A.W.J.M. Glaudemans[1]

[1]Department of Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen, The Netherlands

[2]Biomedical Photonic Imaging Group, University of Twente, Enschede, The Netherlands

Presentation

A 48-year old man presented at a general hospital with three episodes of syncope and elevated blood pressure (>180/120 mmHg). Physical examination

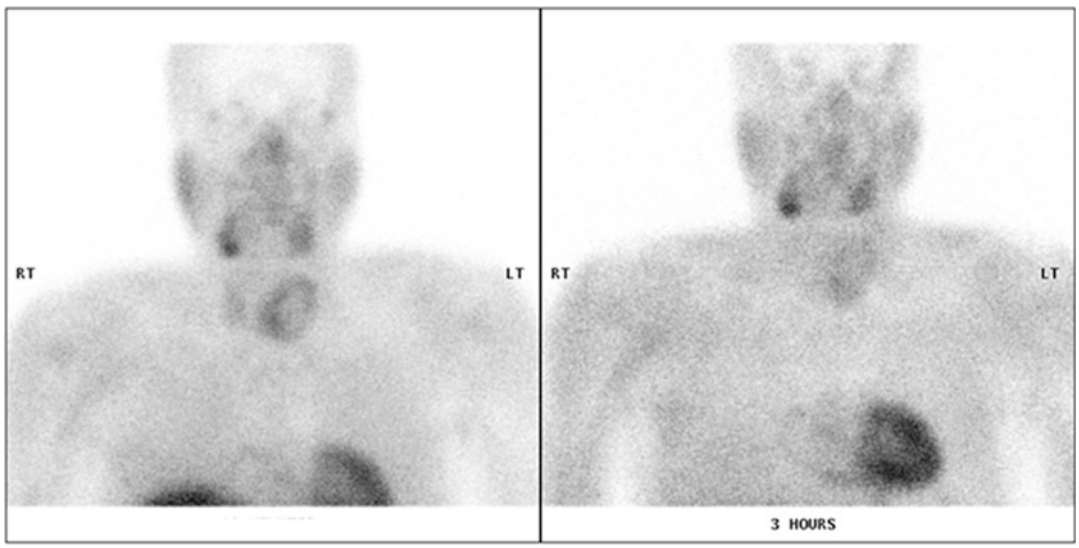

Fig. 1 Early and delayed ^{99m}Tc-sestamibi scans shows a large photopenic area of the left thyroid lobe on early imaging with subsequent faint retention of the tracer on the 3 h delayed image

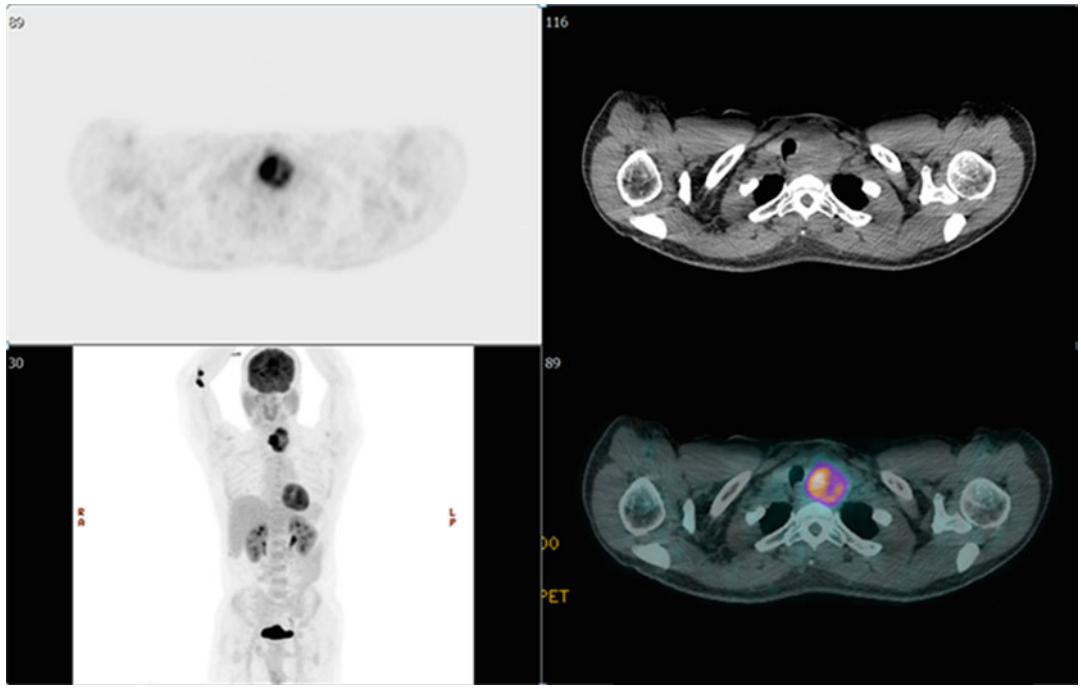

Fig. 2 [^{18}F]FDG PET/CT images: *upper left*, axial PET image; *upper right*, CT axial image; *lower left*, MIP; *lower right*, fused PET/CT demonstrating a [^{18}F]FDG-avid left upper paratracheal soft tissue lesion involving the left thyroid lobe and displacing the trachea compatible with parathyroid carcinoma

revealed a right submandibular swelling. Laboratory studies showed normal metanefrines and slightly increased normetanefrines (1.76 nmol/L, normal range 0.23–1.07 nmol/L).

Findings

MRI showed an enhancing lesion in the carotid bifurcation (right) (21 × 27 mm, Fig. 3). [^{18}F]FDG PET/CT with diagnostic CT showed intense [^{18}F]FDG uptake in the lesion in the right carotid bifurcation, as well as a smaller lesion in the left carotid bifurcation (Fig. 4). In retrospect, this lesion was already visible on the MRI. Additionally, there were two lesions more cranially in the neck left and right. The patient was referred to an academic hospital under suspicion of bilateral paraganglioma. Here, a ^{68}Ga-DOTA-TOC PET/CT was performed to evaluate somatostatin receptor expression in the

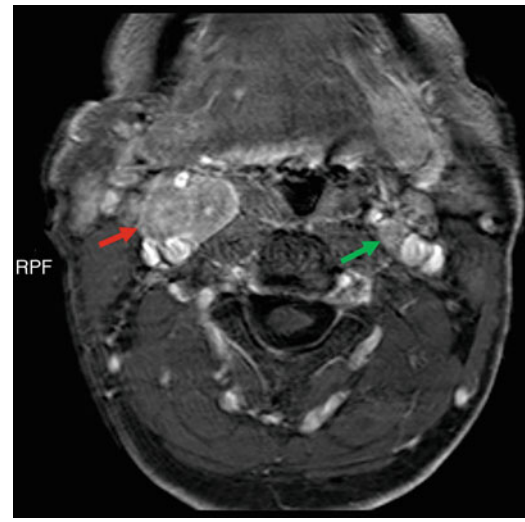

Fig. 3 T1-weighted MRI image after gadolinium showing an enhancing lesion in the right carotid bifurcation (*red arrow*). A smaller lesion can be seen in the left carotid bifurcation (*green arrow*)

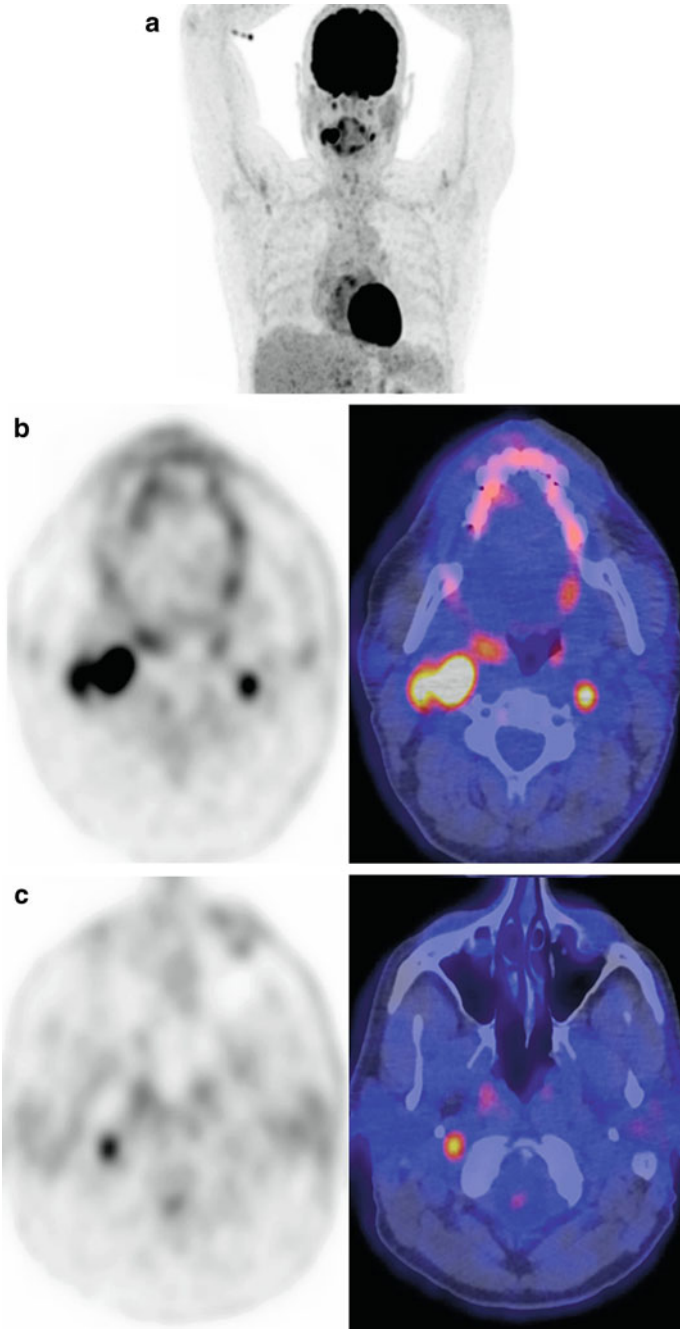

Fig. 4 [^{18}F]FDG PET/CT. (**a**) MIP image (**b**) axial reconstruction and fusion images showing intense uptake in lesions in the carotid bifurcation (*left* and *right*). (**c**) Axial reconstruction and fusion images showing a small lesion high in the neck, right side

lesions and to detect possible paraganglioma elsewhere (Fig. 5). ^{68}Ga-DOTA-TOC PET/CT showed increased uptake at the lesions previously seen on the [^{18}F]FDG PET/CT and additionally a new lesion in the left jugular foramen that was not visible on any of the earlier examinations.

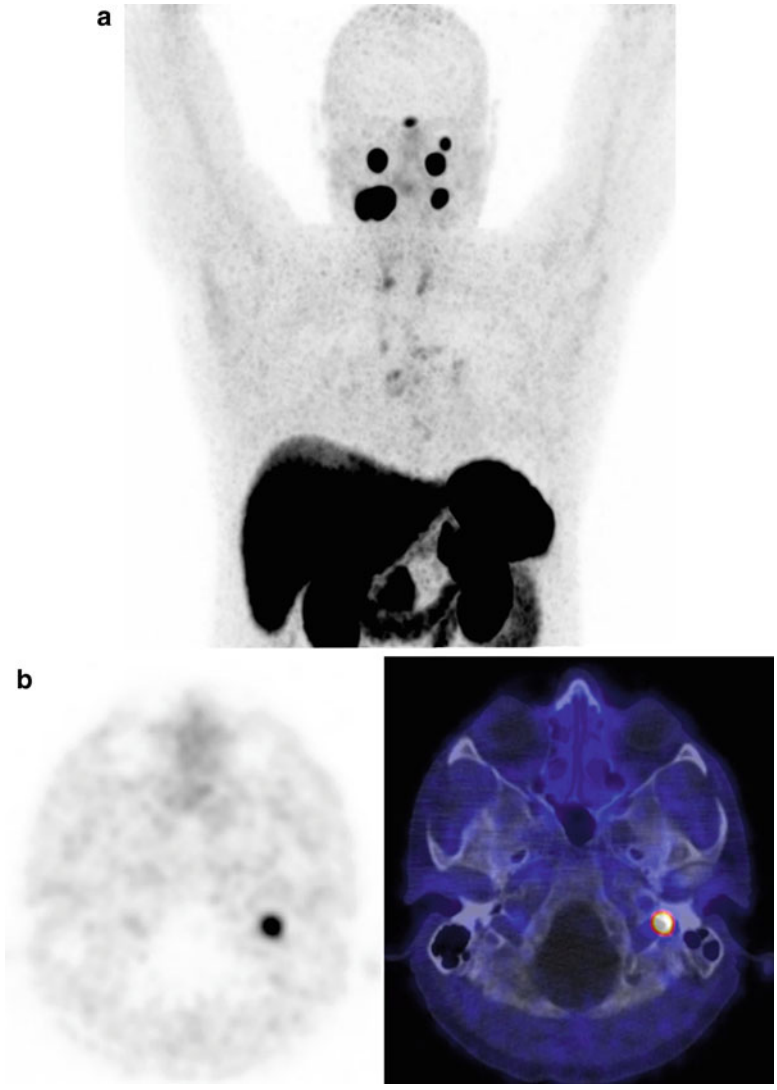

Fig. 5 ^{68}Ga-DOTA-TOC PET/CT. (**a**) MIP image showing three lesions on the left side and two on the right side. The uptake in the midline is physiologic uptake in the pituitary gland. (**b**) Axial reconstruction and fusion image showing a lesion in the jugular foramen left

The lesions were decided to be multiple paragangliomas. As the normetanefrine level was only slightly elevated, no treatment was started. Follow-up imaging will follow in 1 year.

Breast Cancer: Case No. 1

Presentation

A 76-year-old woman with a recent diagnosis of invasive ductal carcinoma of the left breast (6 cm in size) and suspected left axillary lymph node involvement was referred for [^{18}F]FDG PET/CT for staging.

Findings

[^{18}F]FDG PET/CT showed the presence of an [^{18}F]FDG-avid mass in central and lower quadrants of the left breast corresponding to the diagnosed carcinoma. Bilateral axillary nodes with high [^{18}F]FDG uptake suspicious for node involvement were also noted. Furthermore, multiple foci of [^{18}F]FDG uptake in dorsal and lumbar spine consistent with bone metastases were depicted (Figs. 1, 2, and 3).

Discussion

[^{18}F]FDG PET/CT is an important imaging modality for the detection of locoregional and metastatic spread in the appropriate patient population; while [^{18}F]FDG PET should not be used routinely for initial detection of breast cancer or for detection of axillary nodal involvement, [^{18}F]FDG PET in higher-risk populations has great value in definitive whole body initial staging.

Breast Cancer: Case No. 2

Presentation

A 58-year-old woman presented with mammographic diagnosis of tissue distortion and microcalcification of the upper outer quadrant of the left breast. The biopsy showed invasive lobular carcinoma, ER positive, PR positive, and human epidermal growth factor receptor 2 (HER2/neu) negative.

[^{18}F]FDG PET/CT was performed for staging completion before planned surgery.

Findings

[^{18}F]FDG PET/CT did not show foci of suspected glucose uptake in the upper outer quadrant of the left breast (Fig. 4). Whole body staging was negative for detection of axillary involvement and distant metastasis. Breast-conserving surgery consistent with quadrantectomy and sentinel node biopsy was performed. Histopathological analysis showed micrometastasis in sentinel node.

Discussion

The ability of PET to detect breast cancer depends on the tumor's size and histology (e.g., low [^{18}F]FDG avidity in grade 1 cancer and/or in lobular carcinoma). The sensitivity of PET has been reported to be 68% for small (<2 cm) tumors and 92% for larger (2–5 cm) tumors, and its reported overall accuracy for detecting in situ carcinomas is low (sensitivity, 2–25%).

There is also a correlation between the tumor proliferation index (Ki67 expression) and the intensity of [^{18}F]FDG uptake. [^{18}F]FDG PET has moderate accuracy for detecting axillary metastasis but often fails to detect early axillary node involvement and micrometastases.

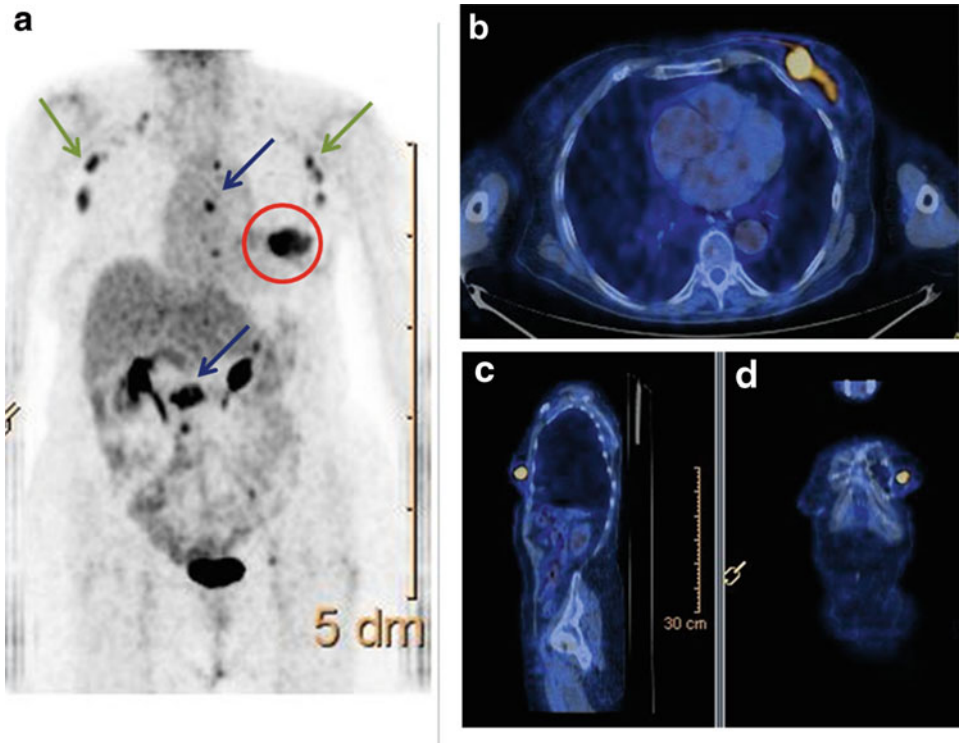

Fig. 1 Maximum intensity projection (*MIP*) (**a**, *red circle*), axial (**b**), sagittal (**c**), and coronal fused PET/CT images of the [^{18}F]FDG-avid left breast lesion. MIP image clearly demonstrated bilateral axillary lymph node involvement (*green arrows*) and bone metastases (*blue arrows*)

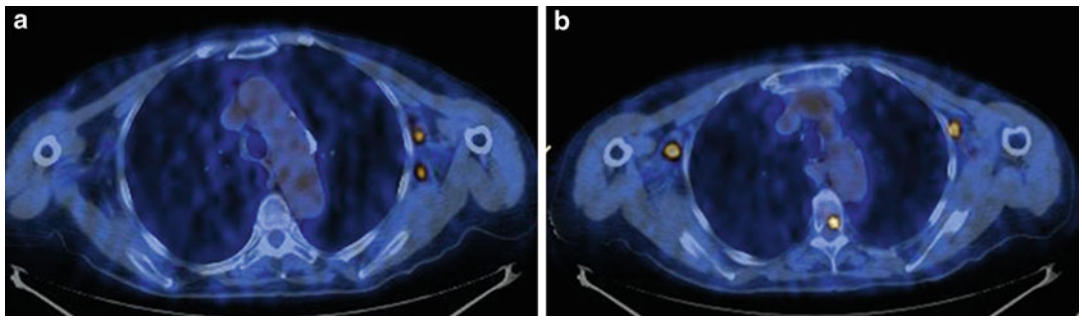

Fig. 2 Axial fused image of axillary hypermetabolic lymph nodes and focal uptake of dorsal spine consistent with skeletal metastases

Breast Cancer: Case No. 3

Case contributed by: S. Al Shammari, F. Fraioli Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK.

Presentation

A 42-year-old lady with a recent diagnosis of breast cancer was referred for [^{18}F]FDG PET/CT for staging.

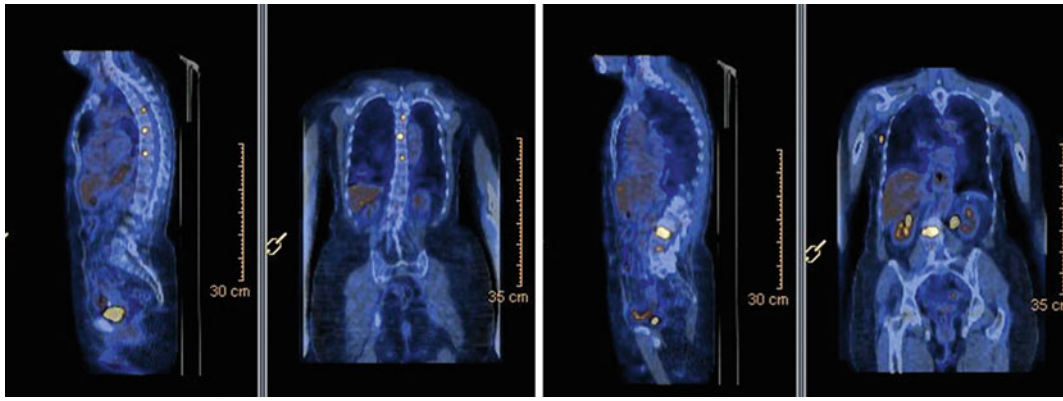

Fig. 3 Fused coronal and sagittal PET/CT images of dorsal (*left panel*) and lumbar (*right panel*) bone involvement

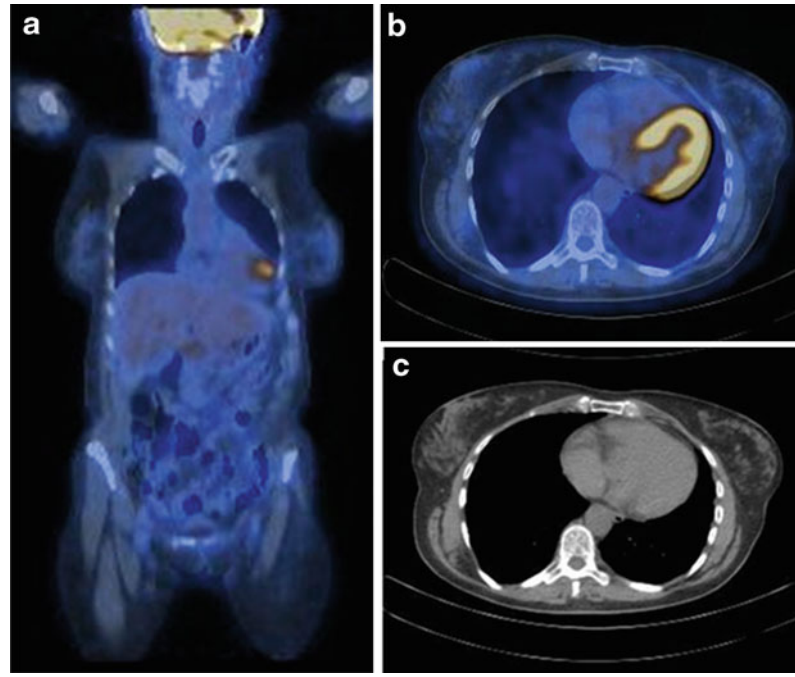

Fig. 4 Fused coronal PET/CT (**a**) and axial images ((**b**) fused PET/CT, (**c**) low-dose CT) failed to detect malignant left breast lesion

Findings

There is an [^{18}F]FDG-avid right breast lesion (measuring ~1.4 × 1 cm, SUV_{max} 7, long arrow in upper, axial PET/CT image). Furthermore, there is a mildly [^{18}F]FDG-avid level III right axillary lymph node (measuring ~7 mm with SUV_{max} 2.0, short arrow). Histopathology of the right axillary lymph node confirmed the diagnosis of nodal involvement.

Discussion

The ability of [^{18}F]FDG PET to detect breast cancer depends on the tumor's size and histology. The sensitivity of PET has been reported to be 68% for small (<2 cm) tumors and 92% for larger (2–5 cm) tumors. Overall accuracy for detecting in situ carcinomas is low (25% sensitivity). The major limitation of PET or PET/CT for breast imaging is its poor detection rate for small breast carcinomas and noninvasive breast cancers. However, PET/CT has a role to play in a group of patients, such as those with dense breasts or with implants, for determining tumor multiplicity, for localizing the primary tumor in those patients with metastasis of breast origin when the mammography is indeterminate, and for those patients where biopsy is not a desirable option. Regional lymph node assessment of the axilla, internal mammary, or mediastinum is an important factor to assess the prognosis of patients with breast cancer. PET/CT can be a valid option to localize and differentiate metastatic and reactive lymph nodes when CT shows multiple enlarged lymph nodes in the axilla. Distant metastases from breast cancer are frequently found in the lungs, liver, and bones. One advantage of whole body PET imaging over conventional imaging modalities is its ability to detect metastasis at different sites and organs during a single examination.

Breast Cancer: Case No. 4

Presentation

A 38-year-old woman with recent diagnosis of locally advanced triple negative breast cancer (TNBC) underwent [^{18}F]FDG PET for staging before scheduled chemotherapy.

Findings

[^{18}F]FDG-avid multiple left breast lesions were noted. Enlarged left axillary lymph nodes with pathological [^{18}F]FDG uptake were also shown (Fig. 5). Furthermore, a previously unknown [^{18}F]FDG-avid lymph node was clearly depicted in ipsilateral subclavicular region (Fig. 5). Patient underwent anthracycline-based regimen. After chemotherapy completion, [^{18}F]FDG PET/CT was performed to evaluate treatment response. Whole body PET/CT did not show pathological radiopharmaceutical uptake, consistent with complete metabolic response (Fig. 6).

Discussion

Triple negative breast cancer is an aggressive heterogeneous group of tumors, representing 15% of invasive breast tumors. The majority of TNBCs are aggressive basal-like subtypes presenting with larger tumors of higher grade and increased numbers of involved nodes. Patients with TNBC have a relatively poor outcome; however, this tumor has more intrinsic responsiveness to chemotherapy than estrogen receptor-positive tumors. Stratification of TNBC prognosis would be highly desired since some patients with better prognosis might benefit from appropriate targeted treatment.

[^{18}F]FDG uptake of TNBC tumor typically had higher metabolic activities than those of other phenotype breast cancers. Pretreatment [^{18}F]FDG PET/CT imaging may have a significant prognostic value for predicting survival outcome of TNBC patients. Furthermore, [^{18}F]FDG PET/CT after two cycles of neoadjuvant chemotherapy may identify poor metabolic responders who have a high risk of early relapse.

Breast Cancer: Case No. 5

Presentation

A 38-year-old woman who previously received neoadjuvant chemotherapy and curative resection of a right breast cancer was referred for sudden-onset chest pain lasting for 15 days. Right pleural effusion was demonstrated. Thoracentesis was

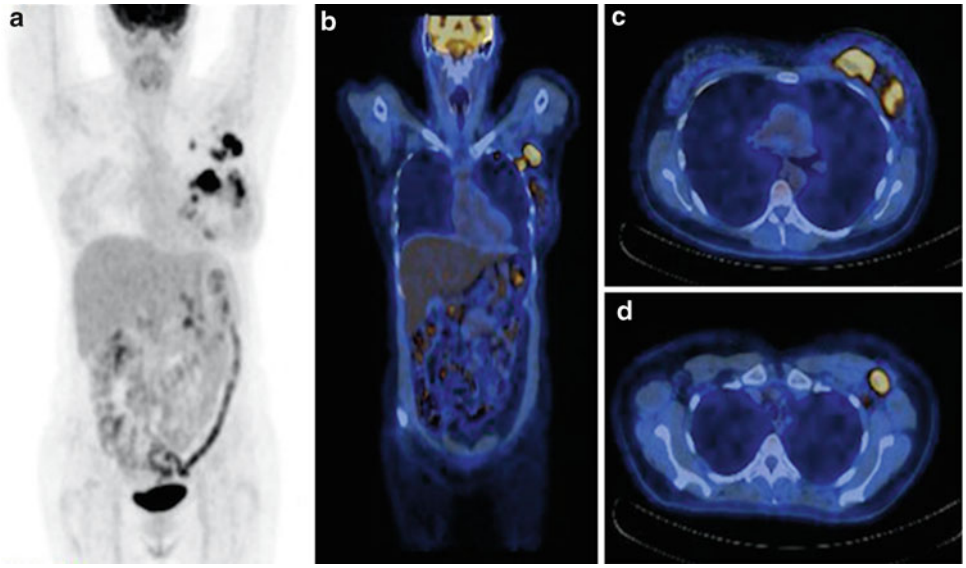

Fig. 5 Baseline whole body [^{18}F]FDG PET/CT in patient with locally advanced TNBC (**a**, maximum intensity projection). Fused PET/CT images show multifocal [^{18}F]FDG-avid primary breast tumor (**b**, **c**), pathological hypermetabolic lymph nodes in the left axillary (**b**, **d**) and in ipsilateral subclavicular region (**b**)

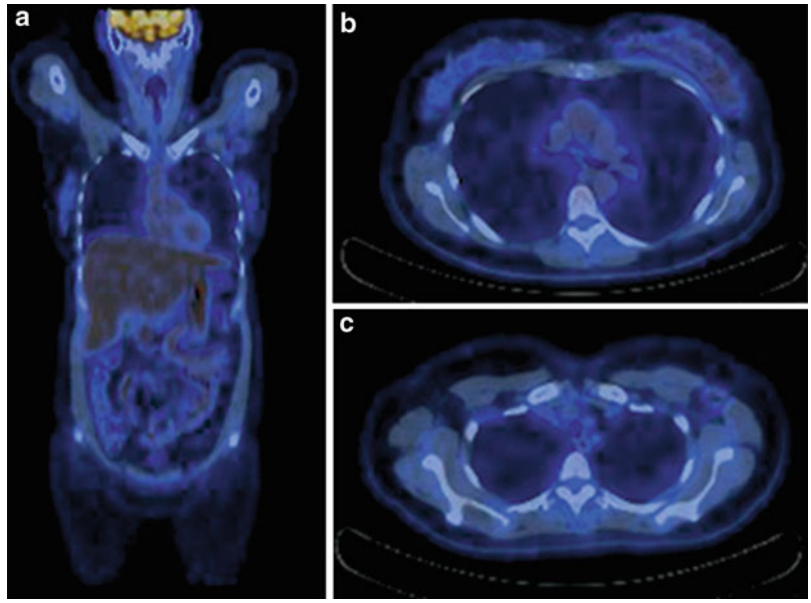

Fig. 6 Fused PET/CT images ((**a**) coronal, (**b**, **c**) transaxial) after chemotherapy completion show the disappearance of previously identified pathological [^{18}F]FDG uptake in left breast and in regional lymph nodes

performed and pleural fluid analysis showed light yellow and clear fluid with no evidence of malignancy. High values of CA 15-3 and CEA were present (65.6 U/ml and 18 ng/mL, respectively). [^{18}F]FDG PET/CT was performed for suspected recurrent breast cancer to evaluate the presence of disease.

Findings

[^{18}F]FDG PET/CT images (Figs. 7 and 8) showed diffuse intense [^{18}F]FDG uptake of the right pleura suspicious for metastatic disease. Marked focal increased metabolic activity in the segment 7 of the liver was also demonstrated consistent with hepatic metastasis. Furthermore, [^{18}F]FDG-avid abdominal para-aortic lymph node and sternal lesion were depicted. PET/CT findings clearly demonstrated stage IV recurrent breast cancer.

Discussion

Approximately 30–50% of breast cancer patients have a recurrence of disease within 10 years after diagnosis. [^{18}F]FDG PET/CT scan plays an important role in restaging breast cancer patients with rising tumor markers and negative or equivocal findings in conventional imaging techniques with high sensitivity (>90%) and a change in planned therapy in about 50% of the cases.

[^{18}F]FDG PET allows more accurate diagnosis of metastatic disease in patients with treated breast cancer and patients with rising levels of tumor

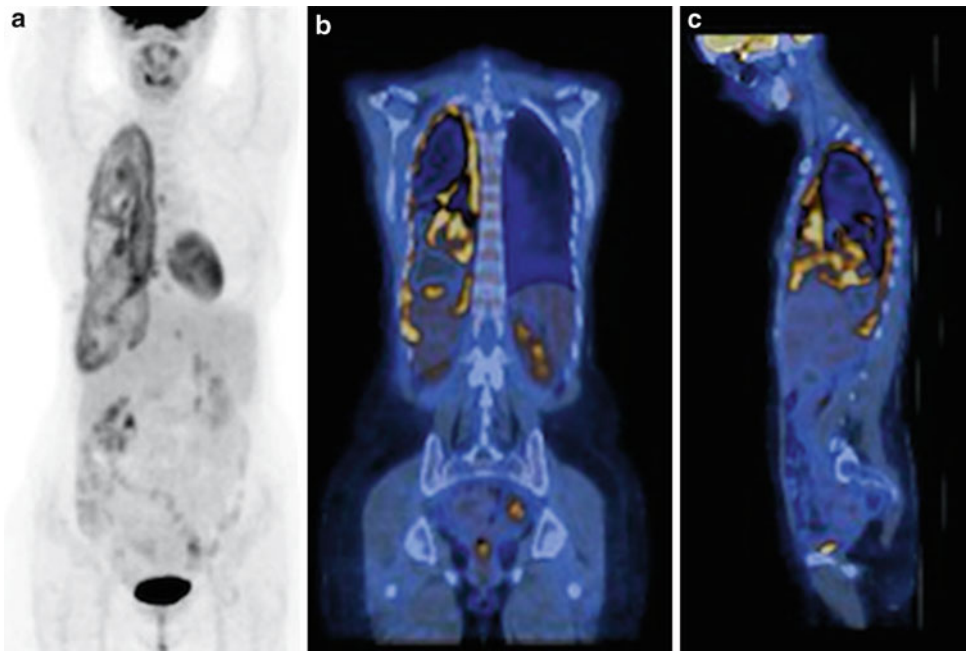

Fig. 7 Whole body [^{18}F]FDG PET/CT in patient with suspected recurrent breast cancer ((**a**), maximum intensity projection, (**b**) coronal fused PET/CT, (**c**) sagittal fused PET/CT). Diffuse intense [^{18}F]FDG uptake of the right pleura suspicious for metastatic disease is shown. Right pleura effusion without significant metabolic activity

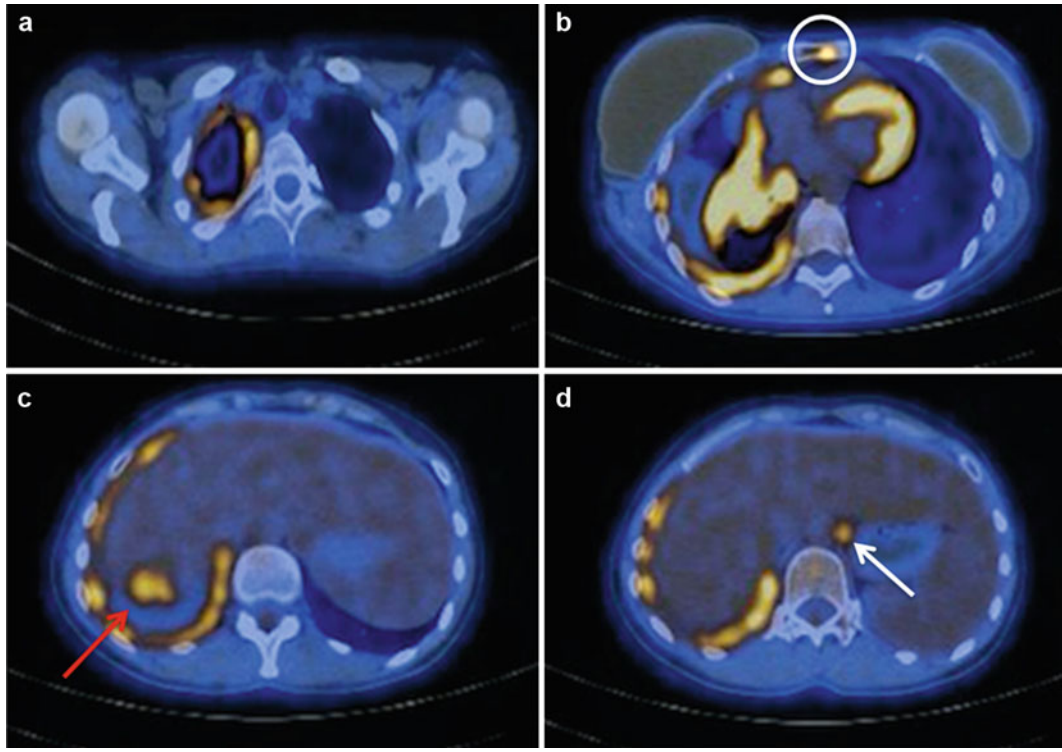

Fig. 8 Fused transaxial PET/CT images show pathological pleura [^{18}F]FDG uptake (**a**–**d**), sternal [^{18}F]FDG-avid lesion (**b**, *white circle*), liver metastasis (**c**, *red arrow*), and abdominal lymph node involvement (**d**, *white arrow*) consistent with distant recurrence of breast cancer

markers compared with CT alone demonstrating improved sensitivity, specificity, accuracy, and predictive value.

Breast Cancer: Case No. 6

Presentation

A 28-year-old woman referred with diagnosis of right breast cancer cT1N1 (CDI, G2, ER = 95%, PR = 95%, HER2 = ISH not amplified, Ki-67 = 80%) and synchronous skeletal metastases for treatment planning.

Findings

Baseline [^{18}F]FDG PET/CT was performed prior to chemotherapy. PET/CT images demonstrated small [^{18}F]FDG-avid nodule in the upper inner quadrant of the right breast corresponding to known malignancy (Fig. 9). Focal increased [^{18}F]FDG activity was noted in the right humerus, spine, pelvic skeleton, and femora (Fig. 9).

After chemotherapy, [^{18}F]FDG PET/CT was performed to evaluate treatment response. PET/CT images showed metabolic progression of the right mammary nodule (Fig. 10) and of bone disease progression (Fig. 11).

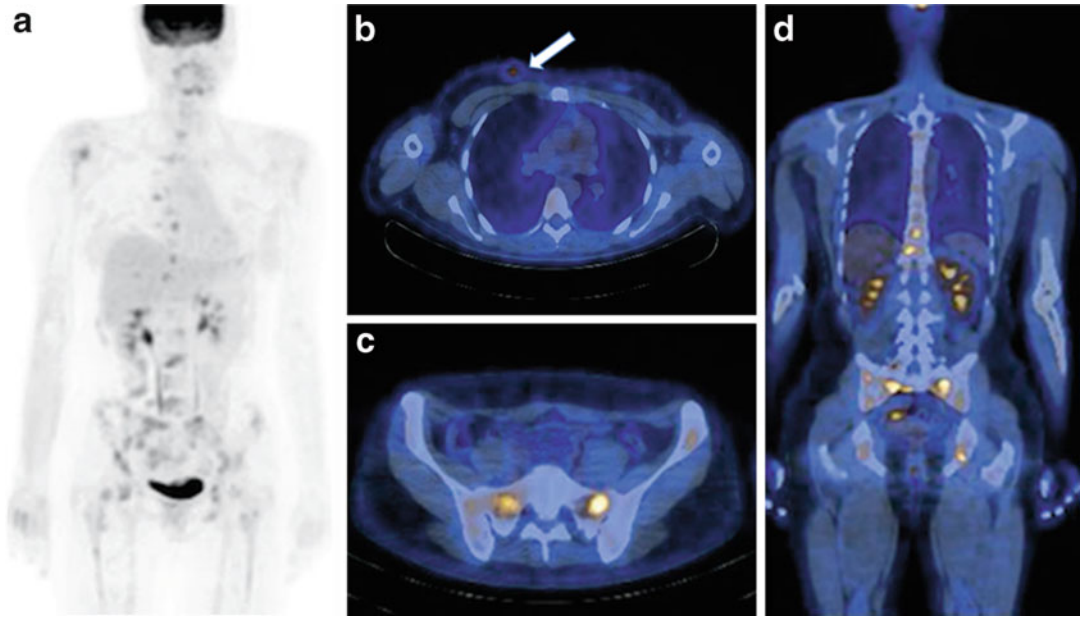

Fig. 9 Baseline [^{18}F]FDG PET/CT in patient with right breast cancer and metastatic bone lesions (**a**, MIP). Axial fused PET/CT image of [^{18}F]FDG-avid breast nodule (**b**, *white arrow*). Diffuse bone involvement consistent with multiple focal increased metabolic activity was revealed (**a**, **c**, and **d** images)

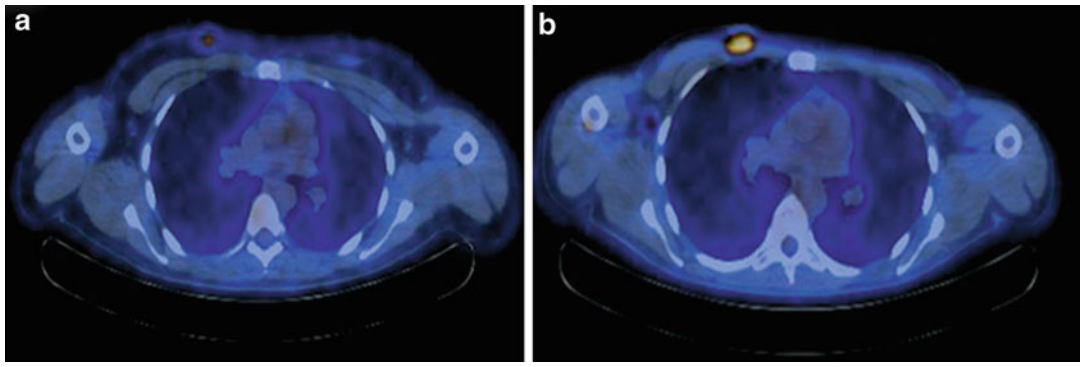

Fig. 10 Fused transaxial PET/CT images performed to evaluate treatment response show metabolic and dimensional progression of primary tumor (**a** before therapy, **b** after therapy completion)

Discussion

The treatment of breast cancer patients who have metastatic disease aims to improve survival and quality of life since the disease is generally not curable. It is therefore essential to identify patients who do not respond to chemotherapy to avoid ineffective therapies and unnecessary side effects.

Changes in tumor metabolic activity have been shown to be an important indicator of treatment

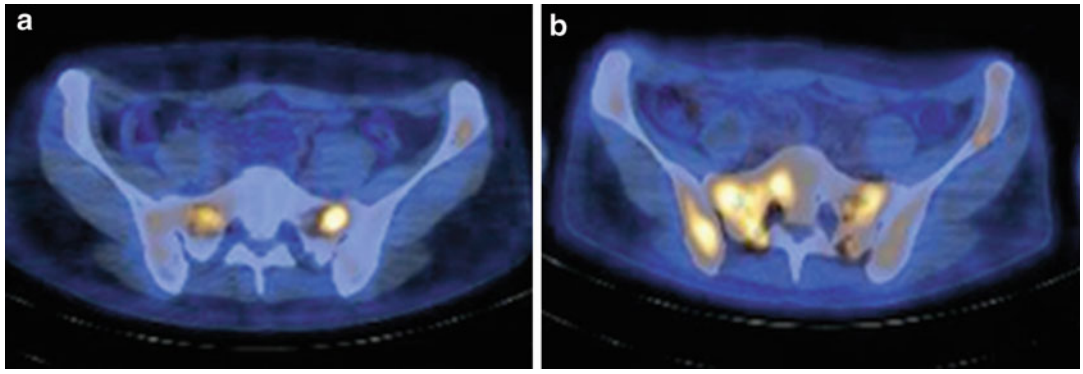

Fig. 11 Bone disease progression after chemotherapy demonstrated by [^{18}F]FDG fused PET/CT axilla images (**a** at baseline, **b** after therapy)

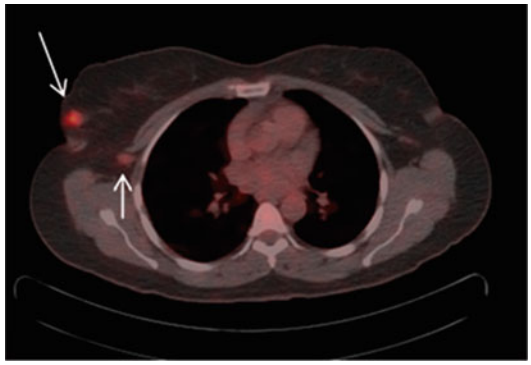

Fig. 12 Fused PET/CT tranxaxial image of FDG-avid right breast lesion and ipsilateral axillary lymph node

effectiveness for breast cancer. In patients with metastatic breast cancer, the effectiveness of chemotherapy can be evaluated earlier with [^{18}F]FDG PET than with conventional imaging. Another important finding is that PET/CT allows evaluation of response in many different metastases. Therefore, PET/CT is helpful to detect a heterogeneous response (coexistence of responding and non-responding lesions within the same patient). Furthermore, metastatic bone lesions, the most common site of breast cancer metastases, occurring in up to 80% of patients, are often difficult to assess for response by conventional imaging such as CT and bone scans. In this setting, [^{18}F]FDG PET/CT may play an important role in assessing response to therapy in bone-dominant breast cancer (Figs. 12 and 13) [1–3].

Breast Cancer: Case No. 7

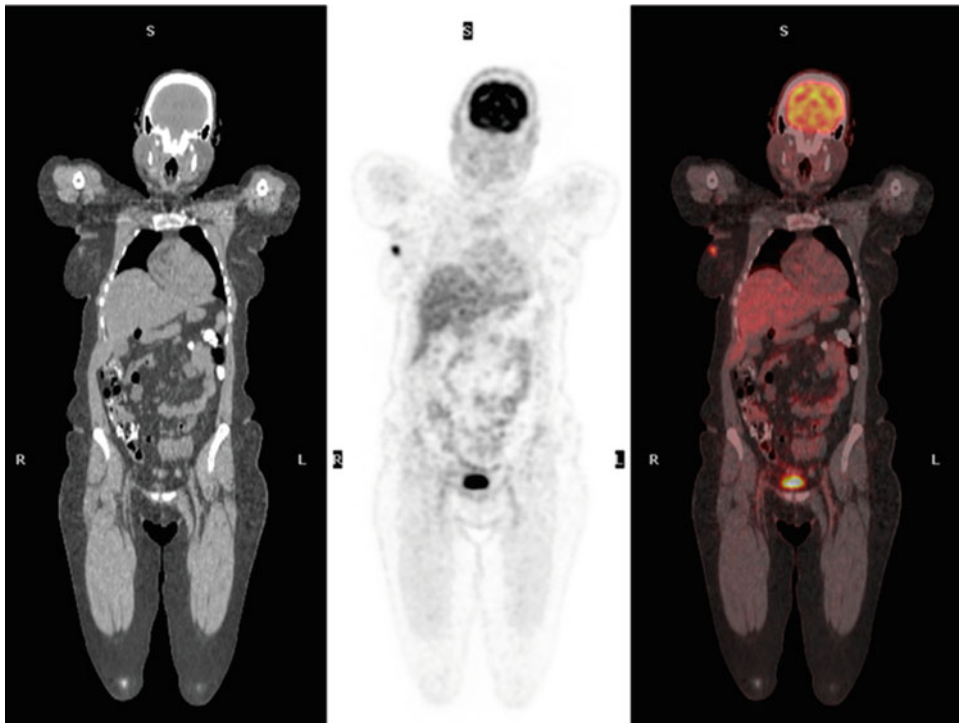

Fig. 13 Coronal image of right breast lesion

Presentation

A 72-year-old woman had been treated 13 years earlier with left-sided mastectomy and axillary lymph node dissection for an ER-positive, PR-negative breast carcinoma. Now, she presents with a lesion in the post-mastectomy scar. Biopsy showed an infiltrative lobular carcinoma, ER-positive, PR-positive, and Her2/neu-negative.

Findings

^{99m}Tc-HDP bone scintigraphy showed a small lesion in the right frontal bone as the only possible bone metastasis (Fig. 14), although a solitary bone island or hyperostosis frontalis was also considered for differential diagnosis. Because of the uncertainty about the possible solitary metastasis, the patient was accepted for curative treatment

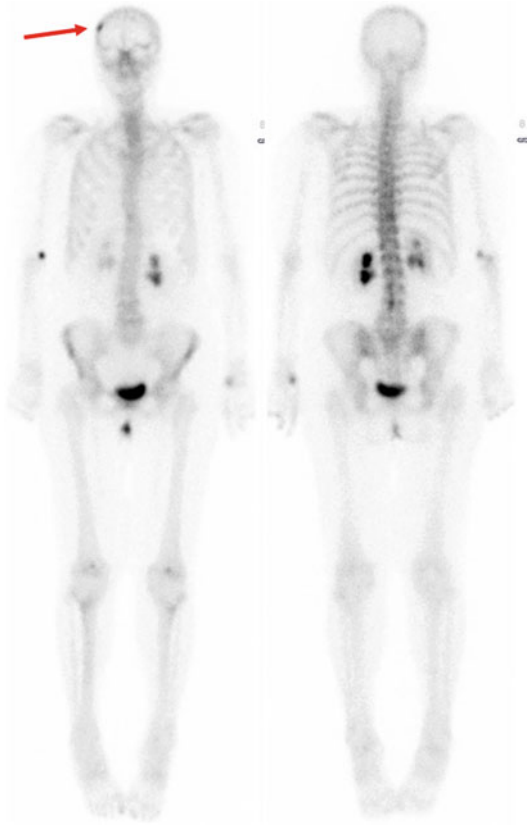

Fig. 14 Anterior (*left panel*) and posterior (*right panel*) ^{99m}Tc-HDP bone scintigraphy showing a solitary lesion in the right frontal bone (*red arrow*)

and the lesion in the left breast region was resected. Pathology showed an infiltrative lobular carcinoma (2.2 cm in maximum diameter), with residual focal tumor growth at 1 mm from the resection margin. Additional imaging was therefore performed before possible treatment with radiotherapy and hyperthermia.

[^{18}F]FDG PET/CT showed increased uptake at the left thoracic wall, consistent with inflammation due to recent surgery (Fig. 15). Furthermore, there was a small moderately intense lesion on the left side of first lumbar vertebra (SUV_{max} 4.0). On the low-dose CT, multiple sclerotic lesions

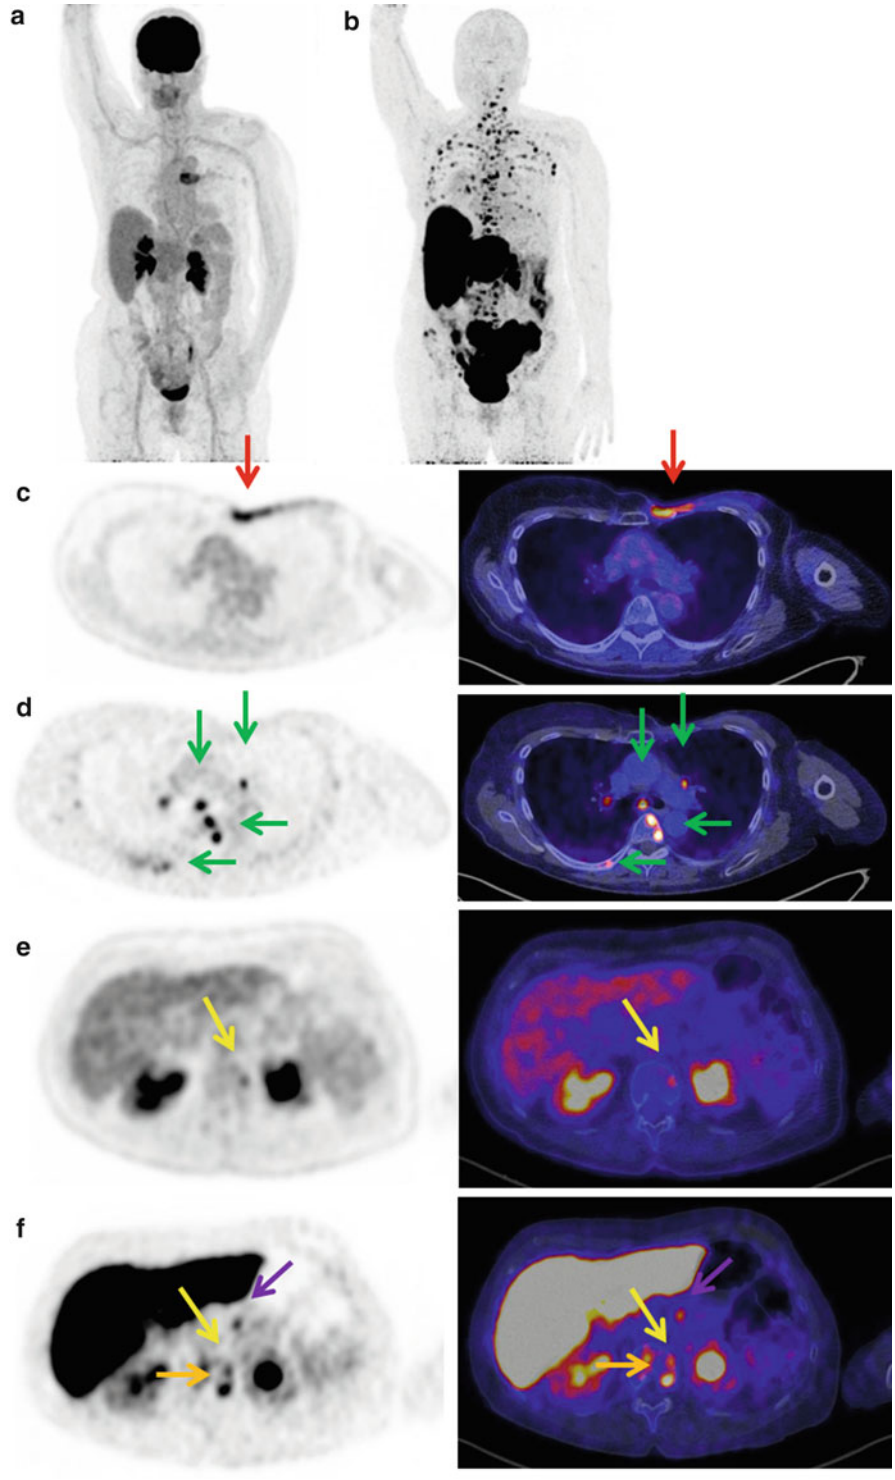

Fig. 15 (continued)

without increased uptake were seen in the frontal bone, the spine, and pelvis.

To further characterize these sclerotic lesions, the patient was referred for a PET/CT scan with ^{18}F-FES, which was performed 1 month after the [^{18}F]FDG PET/CT scan. ^{18}F-FES PET/CT showed multiple lesions with increased uptake throughout the skeleton as well as multiple ^{18}F-FES-avid axillary, mediastinal, lung hilar, and para-aortic abdominal lymph nodes (Fig. 15). The lesion seen in the first lumbar vertebra on the [^{18}F]FDG PET/CT also showed moderately intense uptake of ^{18}F-FES; however, the ^{18}F-FES PET/CT scan showed two additional lesions with intense ^{18}F-FES uptake in the same vertebral body that were not visible at all on the [^{18}F]FDG PET/CT (Fig. 15e, f). The sclerotic lesion in the frontal bone was negative on both scans.

Follow-up

Based on the ^{18}F-FES PET/CT findings, it was concluded that the patient had extensively metastatic breast cancer. Therapy with aromatase inhibiting drugs was therefore started and the patient was referred for further palliative care.

Lung Cancer: Case No. 1

Presentation

A 63-year-old patient with biopsy-proven adenocarcinoma of the left lung was referred for [^{18}F]FDG PET/CT for staging.

Findings

[^{18}F]FDG PET/CT showed an intensely avid mass in the left lower lobe with multiple avid mediastinal lymph nodes (Fig. 1). The patient was treated with chemotherapy. Post-therapy [^{18}F]FDG PET/CT showed complete metabolic response. It also revealed the appearance of small speculated nodule in the upper lobe of right lung with mildly [^{18}F]FDG uptake suspicious for malignancy (Fig. 2). Radiotherapy was performed. Post-radiation therapy PET/CT showed complete response of treated small nodule and the recurrence in the left lower lobe (Fig. 3).

Discussion

[^{18}F]FDG PET/CT imaging is helpful in staging lung cancer to determine the most suitable treatment modality and to evaluated therapy response.

Lung Cancer: Case No. 2

Presentation

A 52-year-old man presented with suspected hypertrophic pulmonary osteopathy and hippocratic fingers. Contrast-enhanced CT of the thorax showed a mass of the lower left lobe (LLL) (35 mm in size) and bulky hilar adenopathy. Biopsy of the mass indicated the presence of non-small cell lung cancer (NSCLC).

[^{18}F]FDG PET/CT was performed for staging.

Findings

PET/CT showed an [^{18}F]FDG-avid LLL mass and bulky left hypermetabolic hilar adenopathy (stage IIIA) (Fig. 4a). Patients underwent neoadjuvant platinum-based chemotherapy.

Posttreatment [^{18}F]FDG PET revealed no metabolic response of the lung mass and concomitant hilar adenopathy (Fig. 4b). Furthermore, PET/CT images demonstrated the appearance of moderate focal uptake in right adrenal gland suspicious for metastatic lesion (Figs. 5 and 6). Contrast-enhanced CT of the abdomen confirmed adrenal metastases.

Discussion

In selected patients, there may be a role for neoadjuvant therapy for locally advanced, potentially resectable NSCLC. The ability of [^{18}F]FDG PET to provide predictive and prognostic information regarding the response to initial therapy is well documented. This case confirms the utility of [^{18}F]FDG PET in response to the assessment of patients treated for NSCLC.

Lung Cancer: Case No. 3

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 50-year-old patient was referred for [^{18}F]FDG PET/CT for the evaluation of a lung lesion in the right lower lobe (Fig. 20).

Findings

Non-[^{18}F]FDG-avid right upper lobe nodule measuring ~2.8 × 2 cm. The mass appears speculated with pleural tethering (arrow). Biopsy of the mass showed bronchoalveolar cancer.

Discussion

[^{18}F]FDG PET/CT is being used more and more to differentiate benign from malignant focal lesions in the lung. Accurate diagnosis can reduce unnecessary thoracotomies in patients with benign diseases. However, [^{18}F]FDG is not a cancer-specific agent, and false positive findings in benign diseases have been reported. Infectious diseases (mycobacterial, fungal, bacterial infection), sarcoidosis, radiation pneumonitis, and postoperative surgical conditions have shown intense uptake on PET scan. On the other hand, due to low glycolytic activity, bronchoalveolar carcinoma shows significantly lower peak standardized uptake values than do other lung carcinomas. Thus, bronchoalveolar carcinoma can be a potential cause of false-negative findings of malignancy on [^{18}F]FDG PET scans. Other tumors with low glycolytic activity such as adenomas, carcinoid tumors, low-grade lymphomas, and small-sized tumors (<1 cm in diameter) can yield false negative findings on PET scan as well. Familiarity with these false positive and negative findings will help to interpret PET scans more accurately.

Lung Cancer: Case No. 4

Case contributed by: D. Neriman, J.P. Connelly, K. Al-Riyami

Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 67-year-old man presented with 6-week history of shortness of breath. The patient was found to have right lung collapse. Bronchoscopy revealed a lesion in the right main bronchus which was biopsied. An [^{18}F]FDG PET/CT was performed as part of the work up.

Findings

[^{18}F]FDG PET/CT showed an intensely avid mass (SUV_{max} >21) in the right lower lobe hilum with right lower lung collapse, mediastinal shift, and avid ipsilateral and contralateral lymph nodes (Fig. 7). In the abdomen, there was increased metabolic activity (SUV_{max} 12.3) in bulky adrenal glands bilaterally and of multilevel para-aortic and paracaval nodes in keeping with metastatic disease.

Follow-Up

Biopsy confirmed squamous cell carcinoma and the patient subsequently underwent chemoradiation. [^{18}F]FDG PET/CT has been proven to be more accurate than CT in the nodal and metastatic disease staging of non-small cell lung cancer (NSCLC) by demonstrating unsuspected sites of disease. It is recommended in patients being considered for curative treatment, as it delineates areas of metabolically active tumor from areas of atelectasis and consolidation and can therefore help guide biopsy.

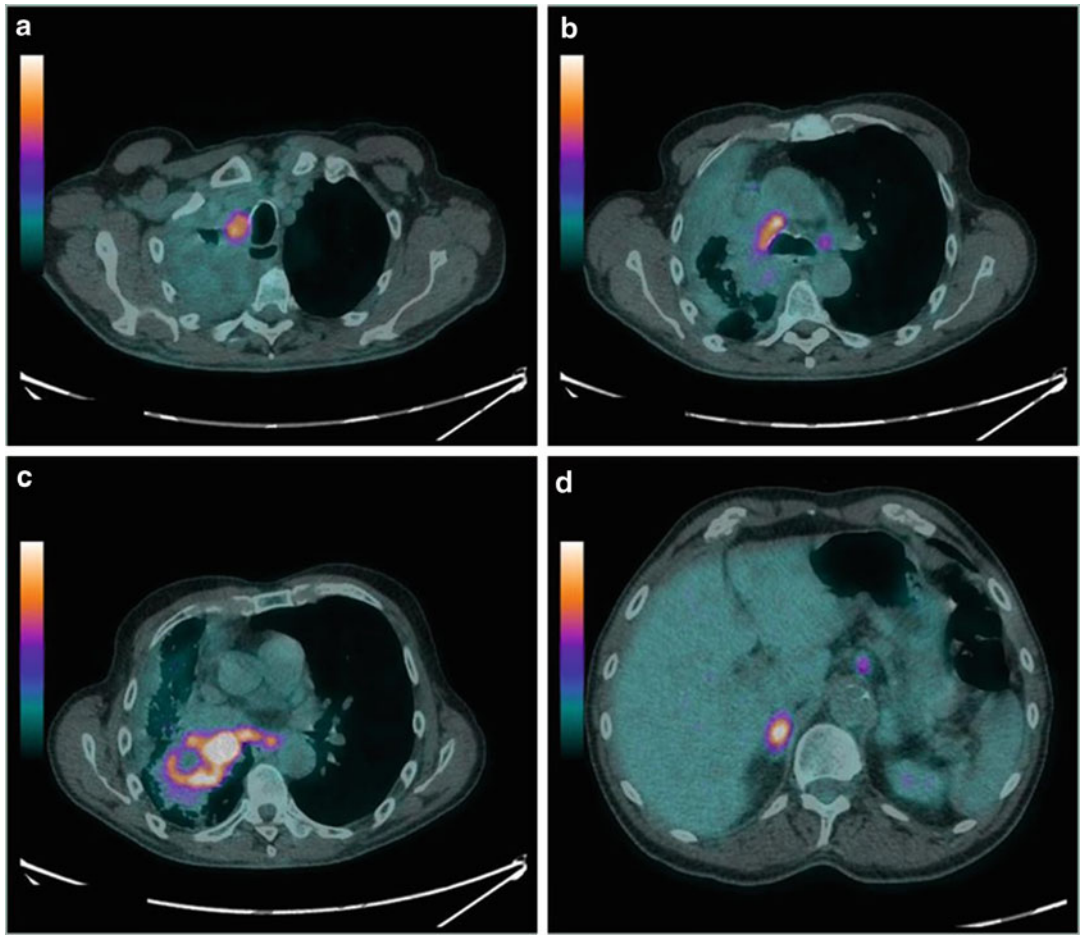

Fig. 7 Fused axial [^{18}F]FDG PET/CT images show tracer avid right paratracheal and AP window mediastinal lymph nodes. Avid uptake is seen in the mass in the right lower lobe, celiac lymph node, and right adrenal gland uptake

[^{18}F]FDG PET/CT is also useful for assessing adrenal pathology, both in terms of [^{18}F]FDG uptake and assessing fat content on the unenhanced CT.

Lung Cancer: Case No. 5

Case Contributed by: S. Wan
Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

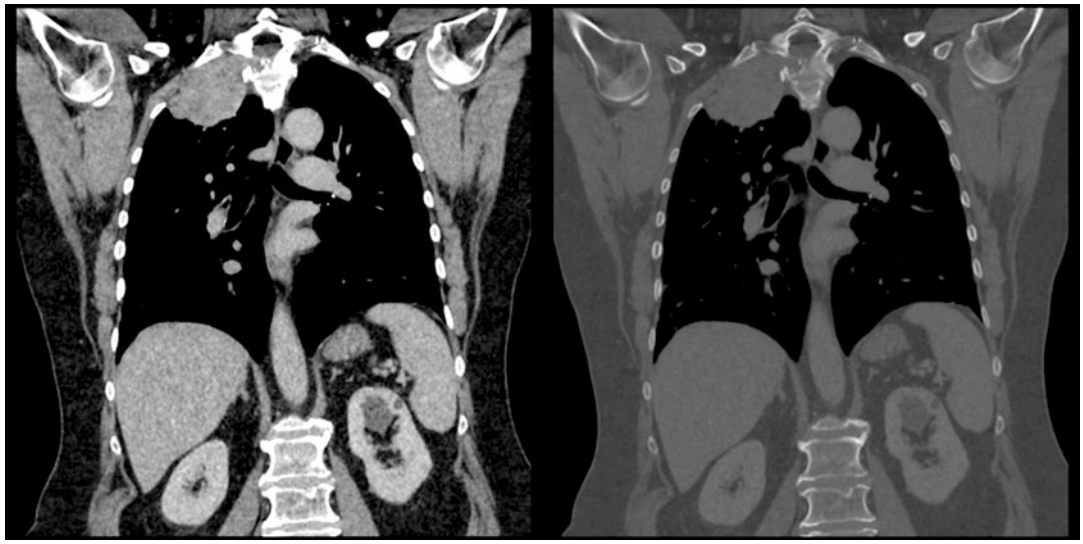

Fig. 8 Coronal CT demonstrating the mass with its epicenter at the right lung apex (*left*). There is clear destruction of the T1 vertebral body (*right*) on bone window display

Presentation

A 77-year-old woman was found to have a chest lesion on radiograph, as a work up for right-sided back pain and Horner's syndrome. CT chest showed right apical lung lesion with adjacent destruction of T1 vertebral body, compatible with a Pancoast tumor.

Findings

A combined PET/MRI study showed the lesion to have a degree of [^{18}F]FDG uptake with a more avid component clearly invading into the spinal canal and compression the spinal cord at this level. Destruction of T1 vertebrae was also evident. Despite the large size and locally advanced stage, there was no [^{18}F]FDG-avid supraclavicular, hilar, or mediastinal lymphadenopathy. There was no [^{18}F]FDG-avid distant metastases.

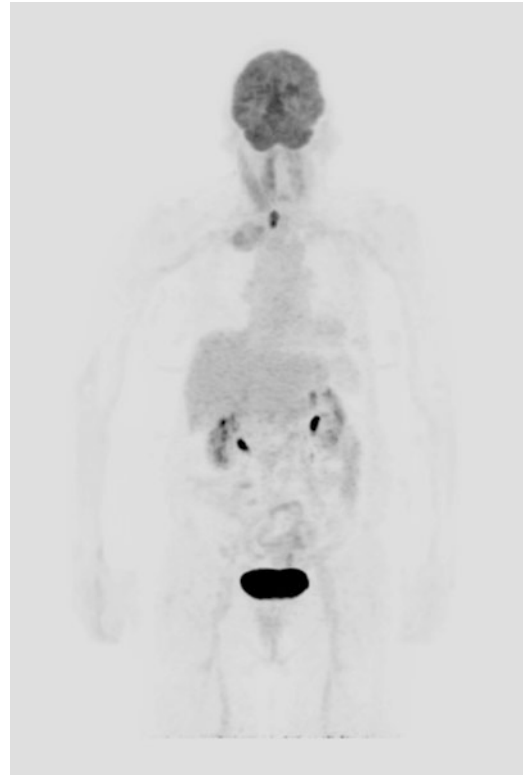

Fig. 9 3D maximum intensity projection of the [^{18}F]FDG PET showed most of the lesion to be moderately avid but with a more intense component medially. No further [^{18}F]FDG-avid disease was seen in the nodes and distally

Follow-Up

CT-guided biopsy of the lesion showed a biphasic tumor comprising nests of large epithelial cells

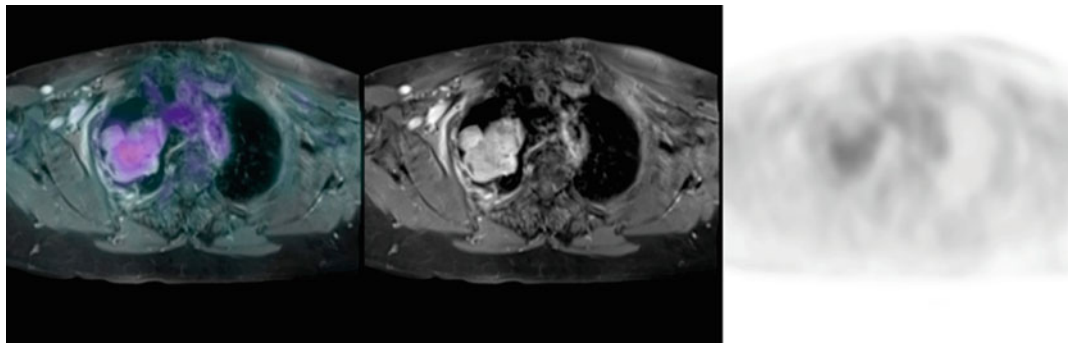

Fig. 10 (Axial), from *left*: fused, fat suppressed T1 post contrast, [^{18}F]FDG PET images showing the lesion clearly extending into the spinal canal and compressing the cord to the *left*

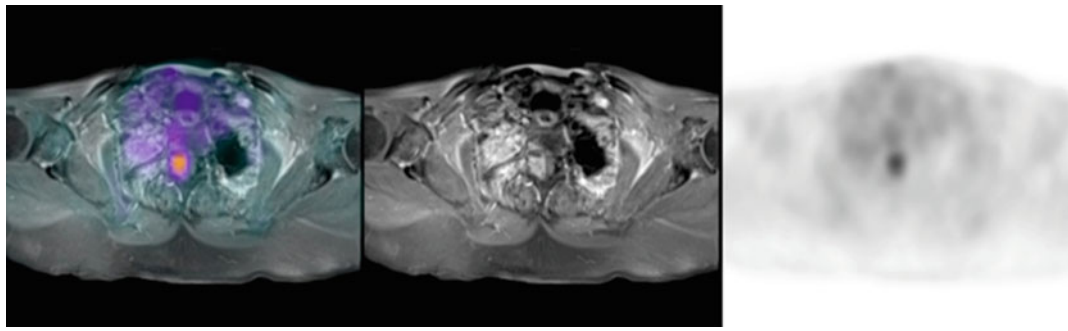

Fig. 11 (Axial), from *left*: fused, fat suppressed T1 post contrast, [^{18}F]FDG PET images showing the lesion clearly extending into the spinal canal and compressing the cord to the *left*

and fascicles of monomorphic spindle cells set in a fibrous stroma. Clinical imaging and pathological correlation concluded carcinosarcoma being the favored diagnosis. The patient proceeded to receive high-dose palliative radiotherapy (30 Gy in 12 fractions) and chemotherapy (carboplatin/gemcitabine) but unfortunately progressed despite treatment (Figs. 8, 9, 10, 11, 12, 13).

[c]Section of Medical Physics, «Maggiore della Carità» University Hospital, Novara, Italy

Presentation

A 69-year-old woman with incidental finding of a solitary pulmonary nodule in the left lung.

Findings

An [^{18}F]FDG PET/CT demonstrated intense tracer uptake in the nodular lesion in the upper lobe of the left lung (SUV_{max} 11.7), with associated increased uptake in the left hilar lymph nodes (Fig. 14).

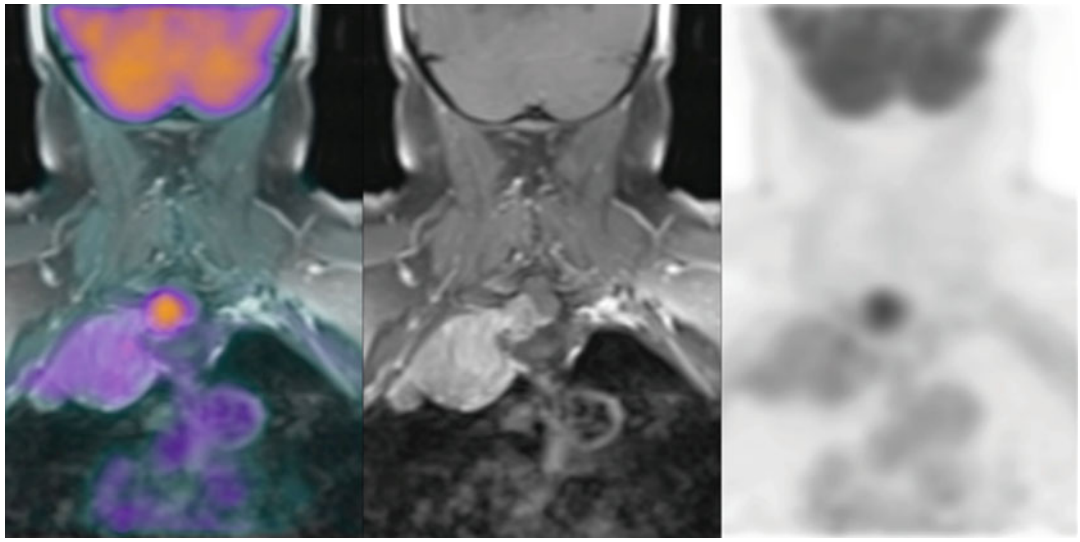

Fig. 12 (Coronal): from *left*: fused, fat suppressed T1 post contrast, [^{18}F]FDG PET images showing the lesion clearly extending into the spinal canal and compressing the cord to the *left*

Fig. 13 Further follow-up MRI of the spine demonstrates new enhancing nodules associated with the conus and cauda equina, consistent with intradural progression despite treatment

Image-guided biopsy confirmed the presence of a small cell lung cancer (SCLC); stage was defined as IIA. In this case, [^{18}F]FDG PET/CT upstaged the patient, who was initially presumed to have more limited disease.

Discussion

The case was discussed in a multidisciplinary meeting with surgeons, radiation oncologists, and medical oncologists, and the patient was recommended for radio-chemotherapy.

The patient underwent two cycles of carboplatin and etoposide, with concomitant radio-chemotherapy.

An intensity-modulated radiotherapy (IMRT) was performed to the lesion of the upper left lobe and at the level of hilar and peribronchial lymph nodes to a total dose of 60 Gy, with daily fractions of 2 Gy (Figs. 15 and 16).

Mesothelioma: Case No. 1

Presentation

A 68-year-old man presented with dyspnea and chest pain. Chest radiography showed right pleural effusion. Contrast-enhanced CT on the thorax demonstrated suspected right nodular pleural thickening and interlobar fissure thickening.

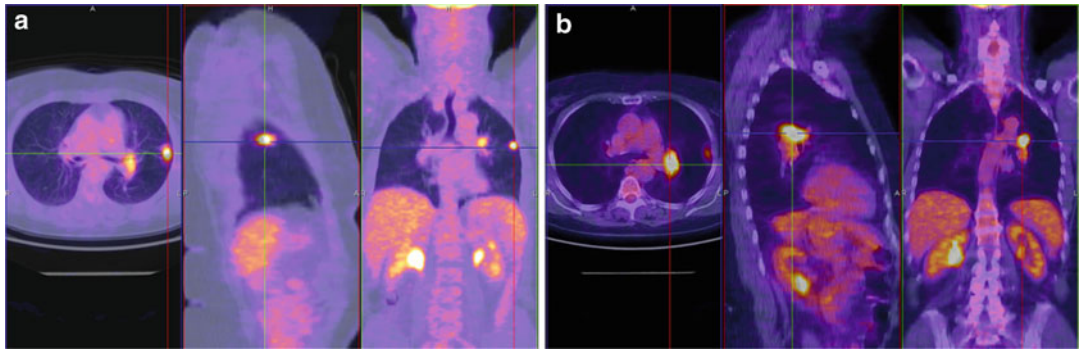

Fig. 14 Transaxial, sagittal, and coronal fused [^{18}F]FDG PET/CT images showing high-tracer uptake in the primary tumor (**a**) and in hilar and peribronchial lymph nodes (**b**)

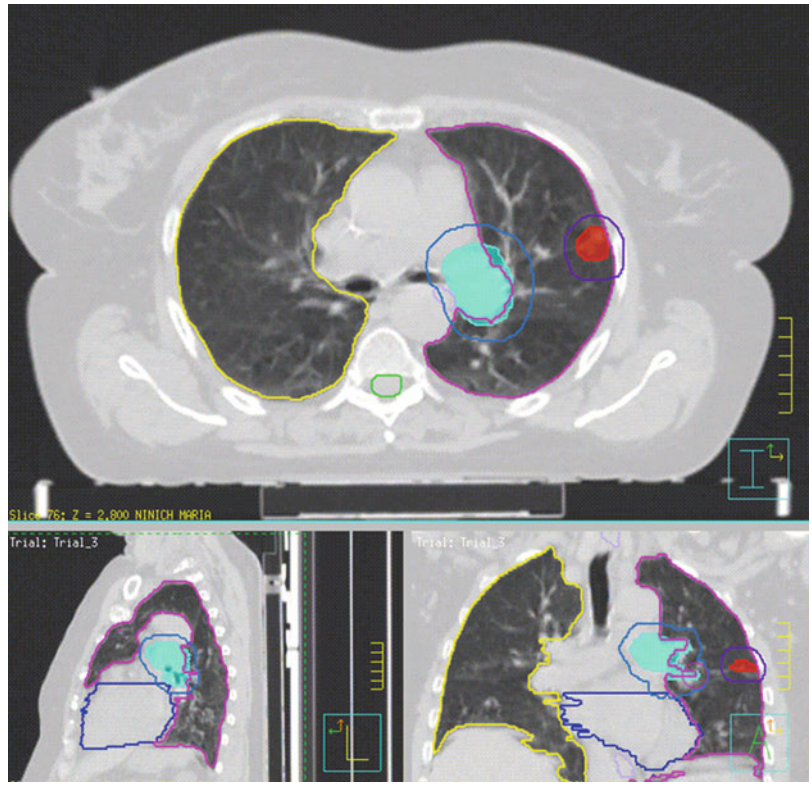

Fig. 15 Axial, coronal, and sagittal images of the simulation CT. Different colors are used to highlight the contours of the treatment volumes. *Light blue*: clinical target volume of involved hilar and peribronchial nodes (CTV-N); *red*: clinical target volume of the primary lesion (CTV-T). The prescribed dose to both CTV-N and CTV-T was 60 Gy, with daily fractions of 2 Gy

Biopsy confirmed the diagnosis of malignant pleural mesothelioma (MPM).

[^{18}F]FDG PET/CT was performed to complete staging.\

Finding

[^{18}F]FDG PET/CT images demonstrated diffuse [^{18}F]FDG uptake of the right pleura suspicious for malignancy and a focal area of increase [^{18}F]FDG

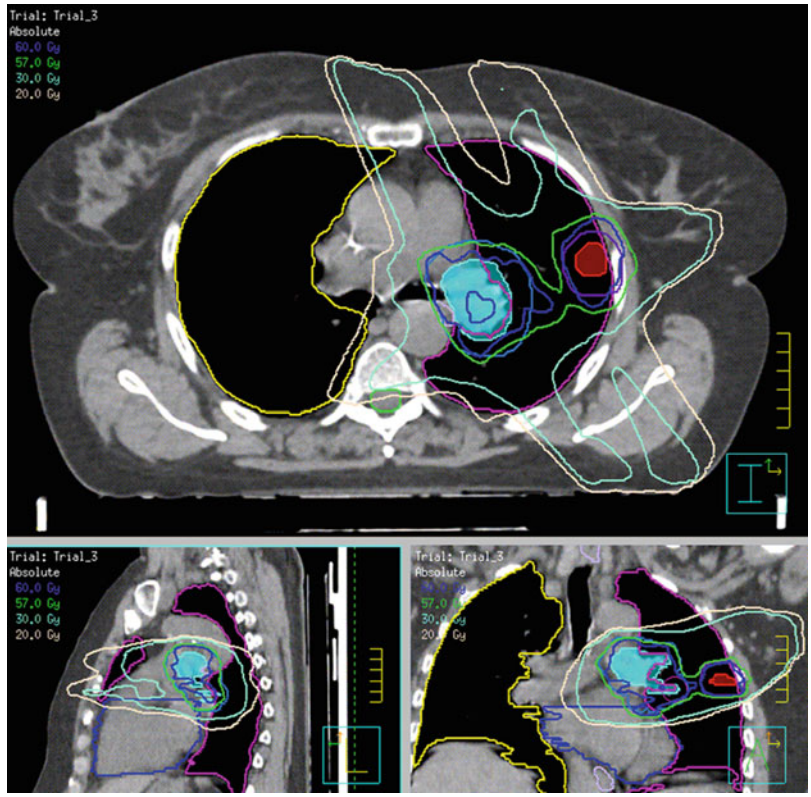

Fig. 16 Transaxial, coronal, and sagittal view of the RT treatment planning. Images show the dose distribution performed by IMRT treatment plan. Around the target volumes, the doses fall down sharply, thus reducing the dose to the organs at risk. In *green* the isodose of 57 Gy (corresponding to 95% of the prescribed dose of 60 Gy), and in white the isodose of 20 Gy

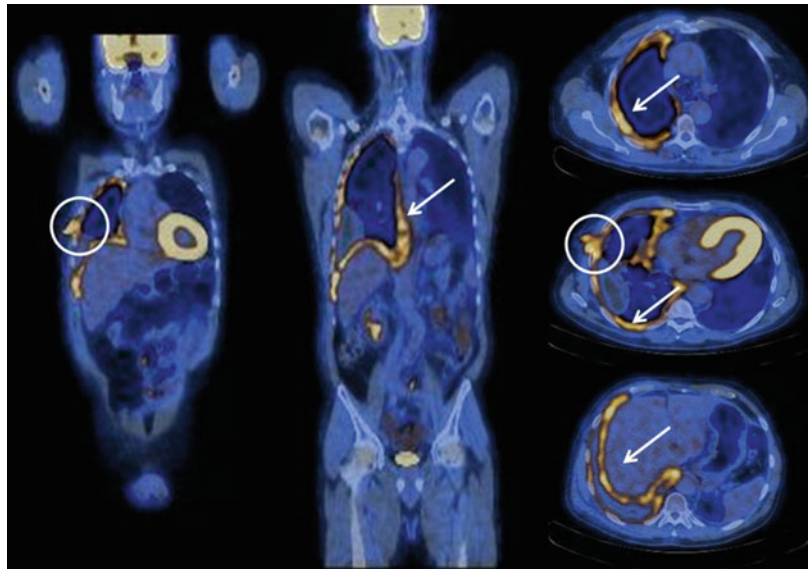

Fig. 17 Fused PET/CT images of pathological [^{18}F] FDG uptake of the right pleura (*white arrows*) and the disease extent into chest wall (*white circle*) after positioning of chest tube

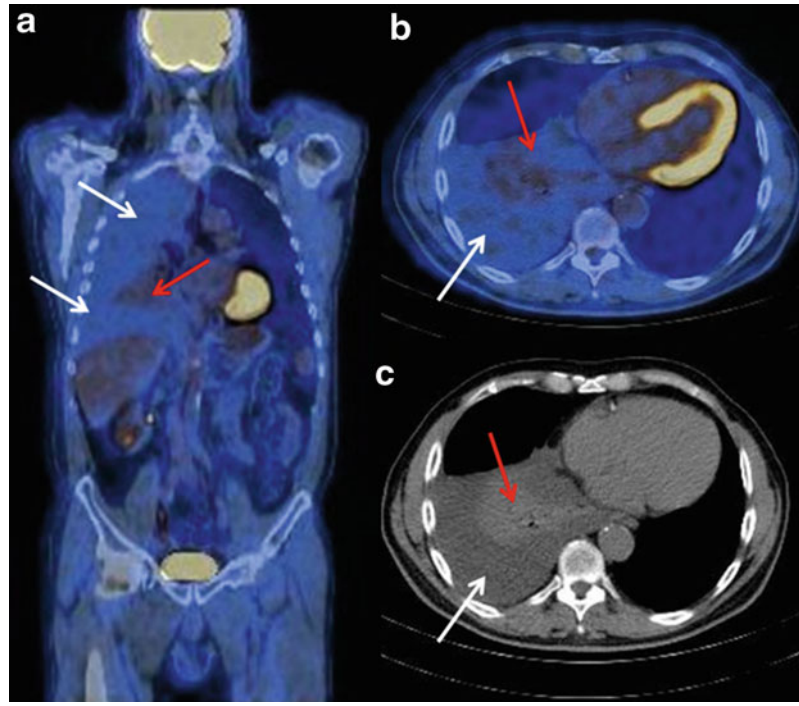

Fig. 18 Fused PET/CT (**a** coronal, **b** axial) and axial low-dose CT (**c**) images show large pleural effusion without significant [^{18}F]FDG uptake (*white arrows*) and mildly [^{18}F]FDG-avid lung atelectasis (*red arrows*)

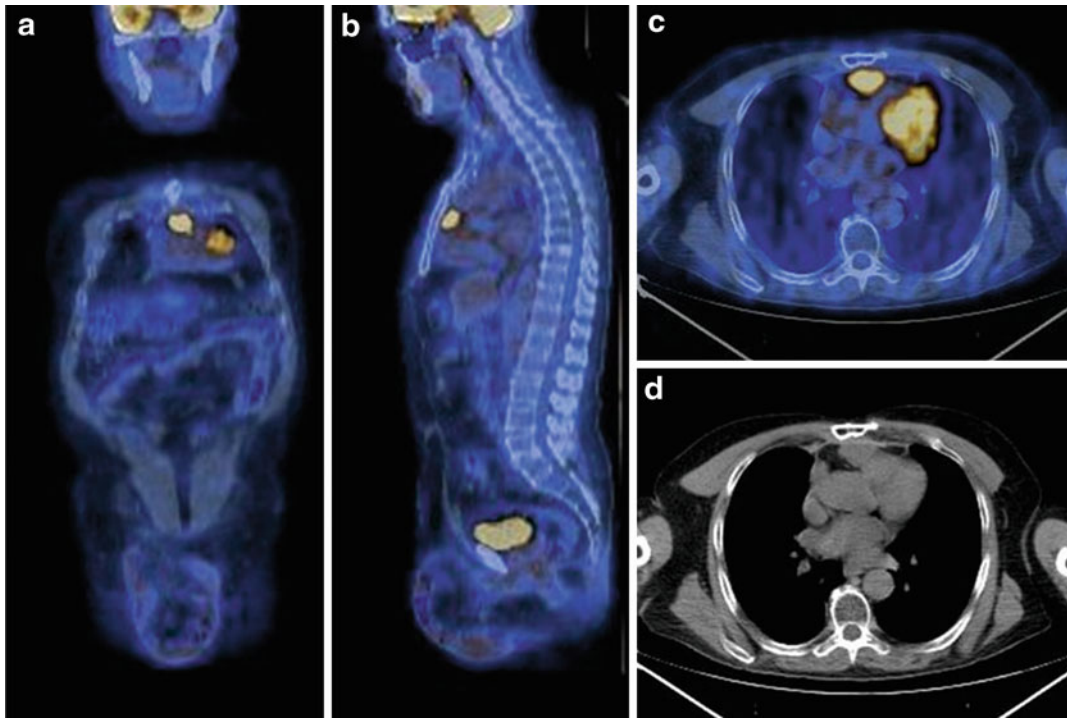

Fig. 19 Fused [^{18}F]FDG PET/CT images (**a** coronal, **b** sagittal, and **c** axial) and axial low-dose CT (**d**) show hypermetabolic mediastinal mass consistent with thymoma recurrence

Fig. 20 Non-[^{18}F]FDG-avid right upper lobe nodule

metabolism into the lateral chest wall (fifth intercostal space) possibly due to mesothelioma extension via chest tube tract (Fig. 17). Pleural effusion did not show significant metabolic activity.

Discussion

Distinguishing MPM from benign pleural disease is a challenging issue. [^{18}F]FDG PET/CT has high accuracy in identifying malignant disease, usually characterized by a unilateral circumferential or near-circumferential pleural and fissural thickening that shows [^{18}F]FDG avidity. Furthermore, increasing evidence suggests that volume-based PET parameters, such as the metabolic tumor volume or total lesion glycolysis, are important prognostic factors in mesothelioma. Staging is crucial in selection of patients for aggressive surgical procedures and multimodality therapy. PET/CT may aid in determining the extent of tumor invasion, localizing involved lymph nodes, and identifying distant metastases.

Mesothelioma: Case No. 2

Presentation

A 77-year-old man presented with a 2-month history of dry cough and dyspnea. Right pleural effusion and thickening were demonstrated. Biopsy showed well-differentiated epithelial mesothelioma.

Patient underwent [^{18}F]FDG PET/CT for staging completion.

Findings

[^{18}F]FDG PET/CT showed large right pleural effusion non-[^{18}F]FDG- avid and mild-[^{18}F]FDG uptake corresponding to right pulmonary atelectasis. No [^{18}F]FDG uptake in the pleural thickening was observed.

Discussion

[^{18}F]FDG PET has an important role in the differential diagnosis of pleural disease. This case demonstrates a false-negative [^{18}F]FDG PET result in a patient with well-differentiated mesothelioma (Fig. 18).

Thymoma: Case No. 1

Presentation

A 74-year-old man referred for a mediastinal mass, approximately 3 cm in diameter, revealed during a chest CT examination. Approximately 10 years previously, he presented with invasive type B3 thymoma infiltrating into the left lung according to the WHO classification. He underwent extended thymectomy with combined resection.

Findings

[^{18}F]FDG PET/CT revealed intense [^{18}F]FDG uptake in the retrosternal mass consistent with recurrent disease (Fig. 19). The anterior mediastinal tumor was diagnosed as poorly differentiated squamocellular carcinoma of thymic origin following percutaneous needle biopsy.

Discussion

Recurrence rates after resection of thymomas range from 5% to 50% and are related to the initial clinical stage. The pattern of recurrence of resected thymomas includes local recurrence, pleural implants, and distant metastases. [^{18}F]FDG PET/CT may highlight recurrent metastatic thymoma and is effective for estimating histopathological malignancy and staging in the diagnosis of thymic epithelial tumors (Fig. 20).

Increased physiologic [^{18}F]FDG uptake by a normal or hyperplastic thymus is not infrequent; thus, in the evaluation of malignancy, a potential pitfall is mistaking normal uptake within the thymus for disease.

Esophageal Cancer: Case No. 1

Case contributed by: D. Neriman, J.P. Connelly, K. Al-Riyami

Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK.

Presentation

A 34-year-old man presented with dysphagia and was investigated as per guidelines with endoscopy, contrast CT, and [^{18}F]FDG PET/CT.

Findings

CT of the chest, abdomen, and pelvis revealed thickening at the GEJ and cardia with a local subcentimeter paraesophageal lymph node. Initial endoscopy showed no malignancy.

[^{18}F]FDG PET/CT for staging showed [^{18}F]FDG-avid thickening at the gastroesophageal junction with an [^{18}F]FDG-avid paraesophageal lymph node (Fig. 1). Further focal uptake was seen in segment 6 (Fig. 2) of the liver correlated to an 11-mm ill-defined low-attenuation lesion, which was missed on the initial staging CT (Fig. 3). Repeat endoscopic biopsy showed adenocarcinoma.

Follow-Up

The patient subsequently underwent chemoradiotherapy.

Teaching Points

The advantage of [^{18}F]FDG PET/CT over conventional imaging is in detection of lymph node involvement and distant metastases. Distant metastatic disease has a significant impact on patient management as these patients are no longer eligible for surgical resection. [^{18}F]FDG PET has a reported sensitivity of 69–100%, a specificity of 84–90%, and an accuracy of 84–91% for the evaluation of distant metastases, with the sensitivity of CT for distant metastases being reported as lower. [^{18}F]FDG PET imaging can also exclude metastatic disease at sites considered abnormal on conventional imaging. [^{18}F]FDG PET/CT is also helpful in visualizing the primary tumor that can be difficult to delineate on contrast CT and guide biopsy.

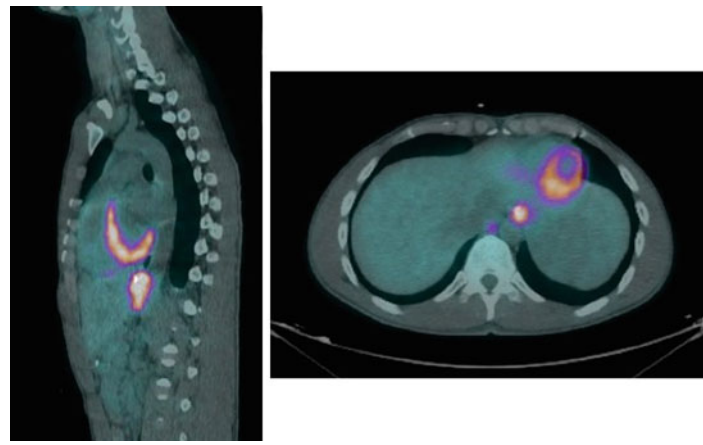

Fig. 1 [^{18}F]FDG fused sagittal and axial PET/CT showing focal uptake in the proven malignancy at the gastroesophageal junction and tracer-avid right paraesophageal lymph node

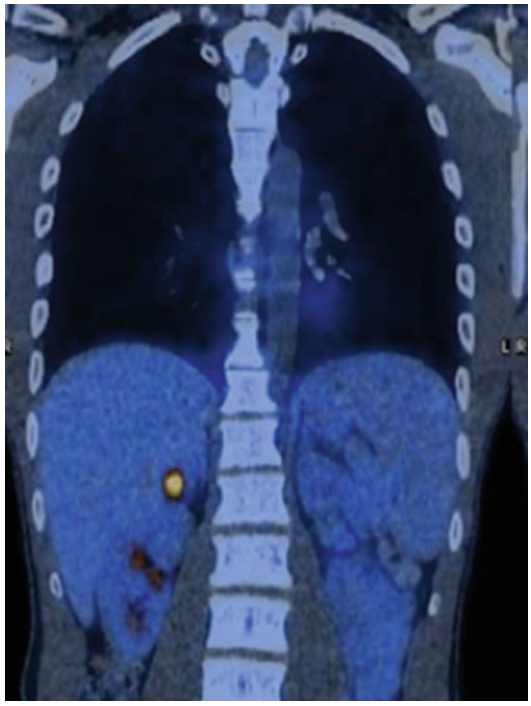

Fig. 2 Coronal [^{18}F]FDG fused PET/CT demonstrating uptake in the segment 6 of the liver (metastasis)

Esophageal Cancer: Case No. 2

Presentation

A 59-year-old man presented with dysphagia underwent endoscopy that revealed a cancer lesion at the level of the distal esophagus. The patient was initially staged with ceCT.

Findings

CT confirmed a gross vegetating lesion at the level of the distal esophagus which extends in the cranio-caudal direction for about 7 cm up to the cardias, with axial diameters of 4 × 4 cm. The mass presented irregular and progressive contrast enhancement with signs of subocclusion and distension of the upstream esophagus (Fig. 4). No locoregional lymphadenopathies nor other pathological supra- and subdiaphragmatic lymph nodes were observed. There were no distant metastases within liver and lungs. The patient underwent an [^{18}F]FDG PET/CT to complete staging and in preparation for chemotherapy and radiation

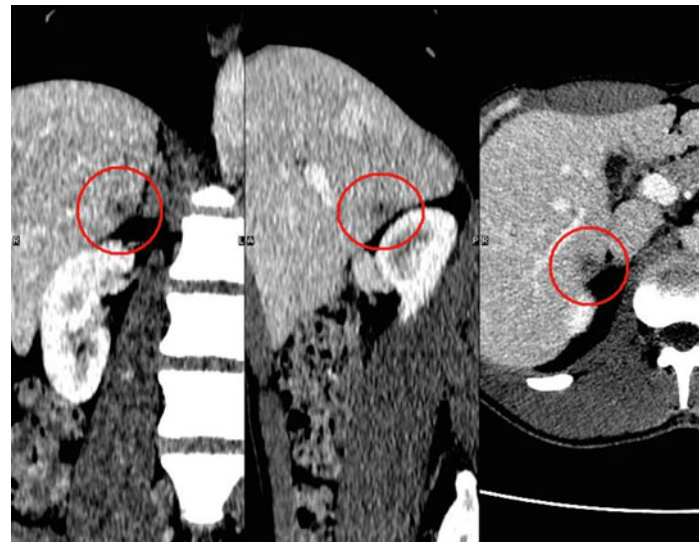

Fig. 3 Coronal and axial post contrast CT demonstrating an 11-mm ill-defined low-attenuation liver lesion compatible with metastasis

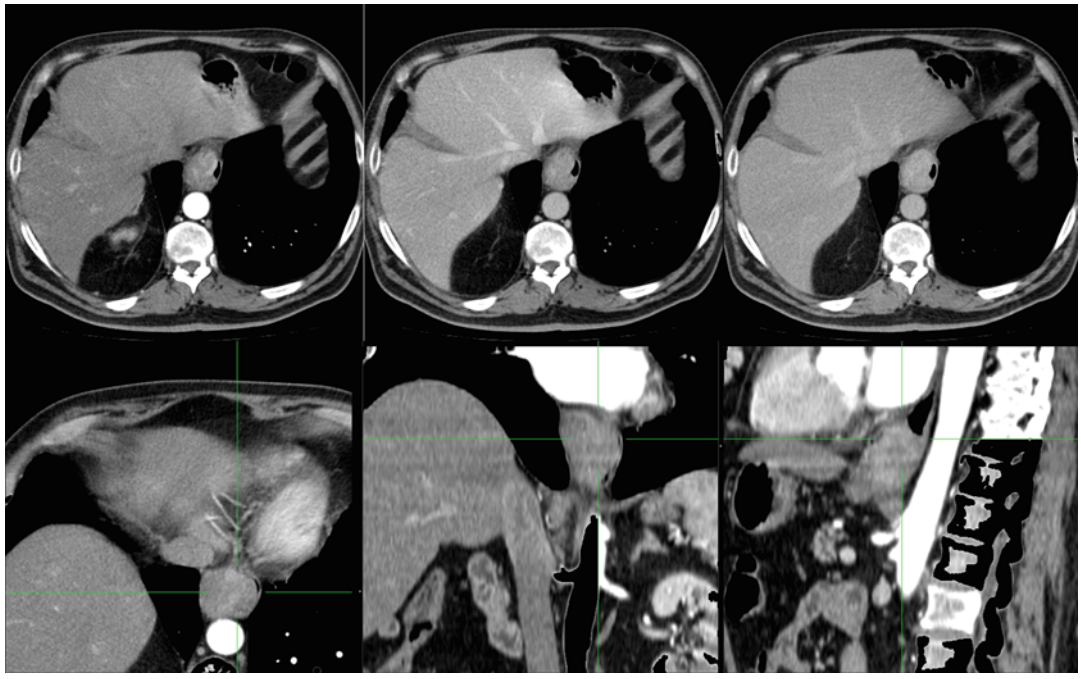

Fig. 4 Contrast-enhanced CT. On *top panels*, ceCT axial slices in the arterial, venous, and late phase showing a gross vegetating lesion of the esophagus, with progressive contrast enhancement. On *bottom panels*, orthogonal MPR showing the lesion of the distal esophagus extending in the cranio-caudal direction up to the cardias. The mass produces subocclusion with the distension of the upstream esophagus

treatment. PET/CT confirmed a gross vegetating [^{18}F]FDG-avid lesion (SUV_{max} 27.2) of the distal esophagus. No hyperactive lymphadenopathies nor distant metastases were observed (Fig. 5).

Follow-Up

After the patient had carried out chemotherapy and external-beam radiation therapy, he was subjected (1 month later) to a PET/CT monitoring. [^{18}F]FDG PET/CT disclosed a clear metabolic response of the esophageal mass (SUV_{max} 6 versus 27.2) which also presented a significant reduced size (Fig. 6).

The patient has then undergone surgery.

Teaching Point

[^{18}F]FDG PET/CT has a role in the staging of locally advanced esophageal carcinoma. In fact, due to its high sensitivity, it can rule out the presence of distant metastases. Moreover, PET/CT plays an important role in monitoring neoadjuvant chemoradiation treatment efficacy.

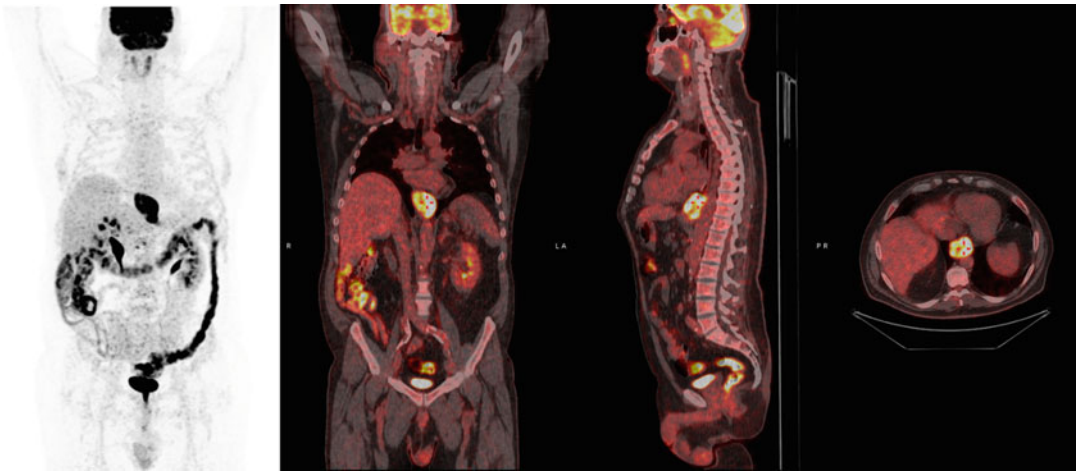

Fig. 5 [^{18}F]FDG MIP and fused coronal, sagittal, and axial PET/CT show a gross [^{18}F]FDG-avid lesion (SUV_{max} 27.2) of the distal esophagus. No other significant hypermetabolic areas

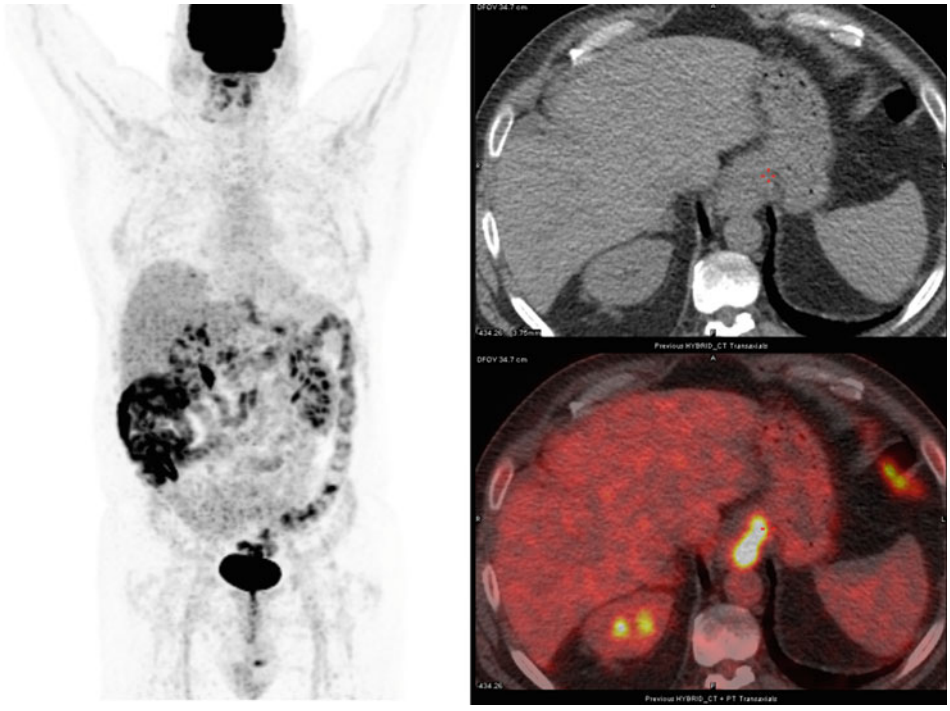

Fig. 6 Post-chemoradiation [^{18}F]FDG PET/CT shows a very significant response of the esophagus lesion that presents markedly reduced size and metabolic activity

Esophageal Cancer: Case No. 3

Presentation

A 60-year-old man with a proximal esophageal carcinoma and severe dysphagia underwent a chemoradiation treatment for primary palliative purpose. [^{18}F]FDG PET/CT was planned to be performed at staging and for monitoring treatment efficacy.

Findings

The first PET/CT before therapy disclosed a [^{18}F]FDG-avid lesion (SUV_{max} 27.2) of the proximal esophagus with a gross hyperactive right paraesophageal node (Fig. 7). Since the patient presented an increasingly severe dysphagia, he underwent percutaneous endoscopic gastrostomy (PEG) during treatment. After chemoradiation was completed, [^{18}F]FDG PET/CT showed a response to therapy of both the lesion of the proximal esophagus and the paraesophageal lymphadenopathy that presented a significant reduced size and metabolic activity (Fig. 8).

Follow-Up

It was decided to follow up the patient and to perform a new PET/CT evaluation after 3 months. Follow-up PET/CT disclosed a disease progression by revealing an increased size and metabolic activity of the primary esophagus lesion (SUVmax 14 versus 9) and of the paraesophageal lymphadenopathy. Moreover, several right superior paratracheal and right supraclavicular [^{18}F]FDG-avid nodes were found. Diffuse uptake of [^{18}F]FDG was detectable within the left clavicle related to a recent traumatic fracture (Fig. 9). A subsequent ceCT confirmed the local and nodal progression of the disease.

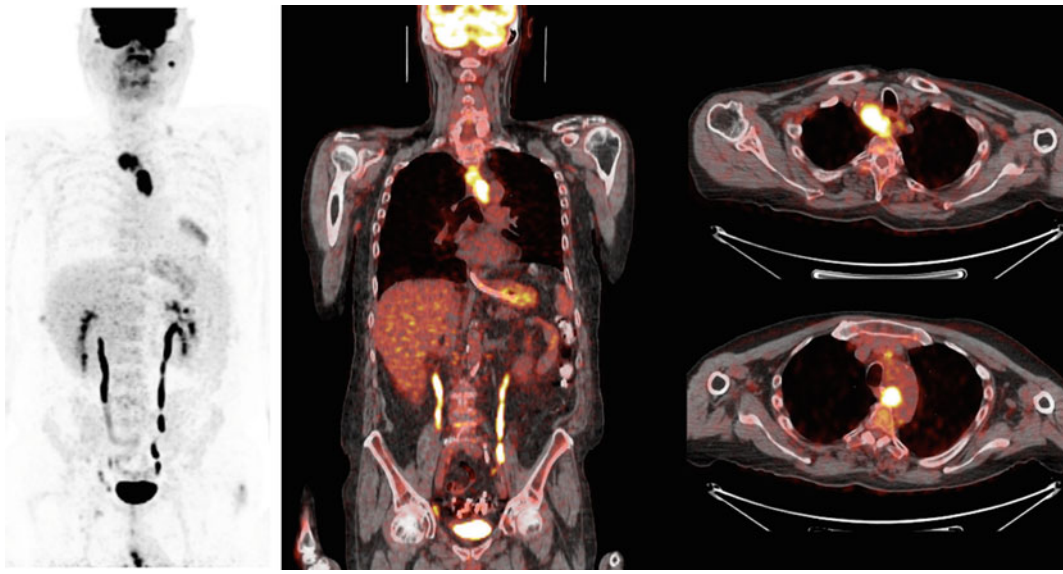

Fig. 7 [^{18}F]FDG MIP and fused coronal, sagittal, and axial PET/CT show a proximal esophagus lesion with a high [^{18}F]FDG uptake. Moreover, a right paraesophageal node [^{18}F]FDG can be observed in MIP and fused coronal and axial slices. An area of focal hyperactivity consistent with a left submandibular lymphadenopathy can be also observed

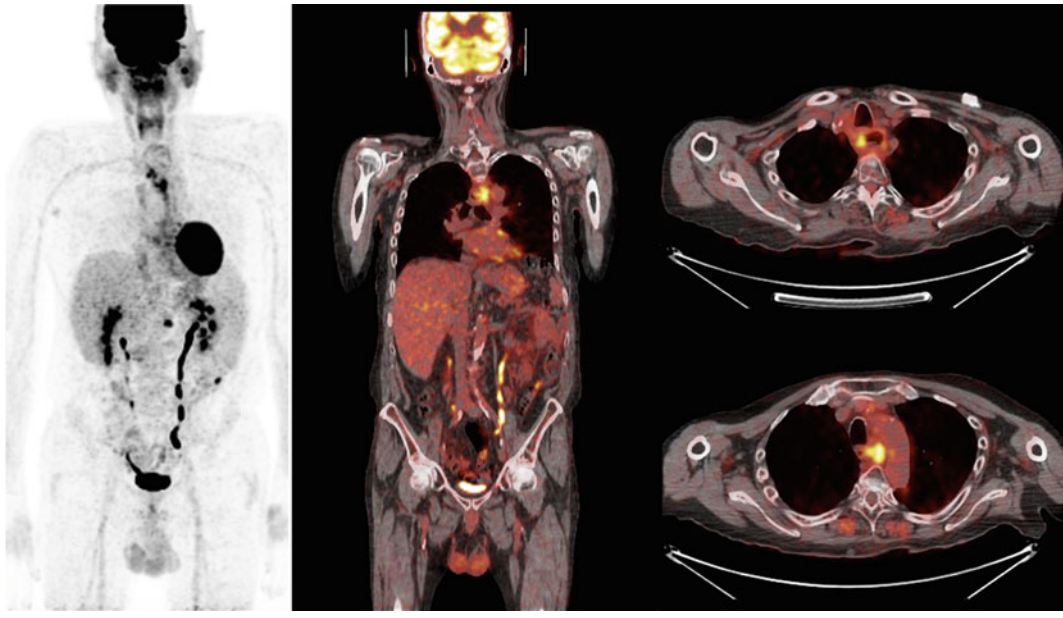

Fig. 8 [^{18}F]FDG MIP and fused coronal, sagittal, and axial PET/CT show a good response to chemoradiation with reduced size and metabolic activity of both the esophagus lesion and the paraesophageal lymphadenopathy. No submandibular lymphadenopathy is detectable. The epigastric area of hyperactivity consistent with recent positioning of PEG

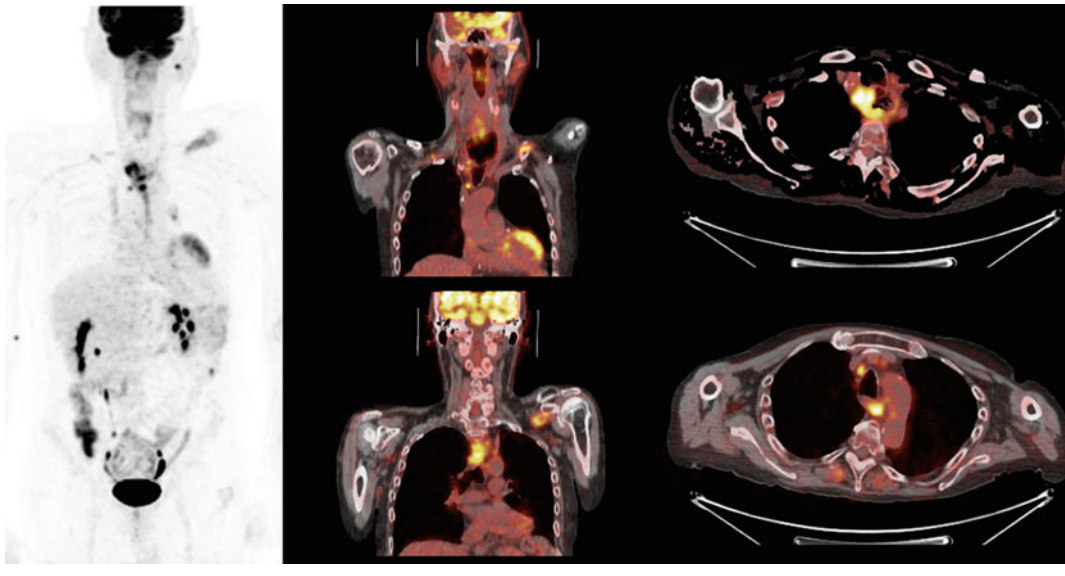

Fig. 9 [^{18}F]FDG MIP and fused coronal, sagittal, and axial PET/CT show increased size and metabolic activity of both the proximal esophagus lesion and the paraesophageal lymphadenopathy. Fused coronal and axial slices reveal right superior paratracheal and right supraclavicular small [^{18}F]FDG-avid nodes. Fused coronal slices show [^{18}F]FDG within the left clavicle related to a traumatic fracture. MIP image shows the recurrence of the left submandibular lymphadenopathy

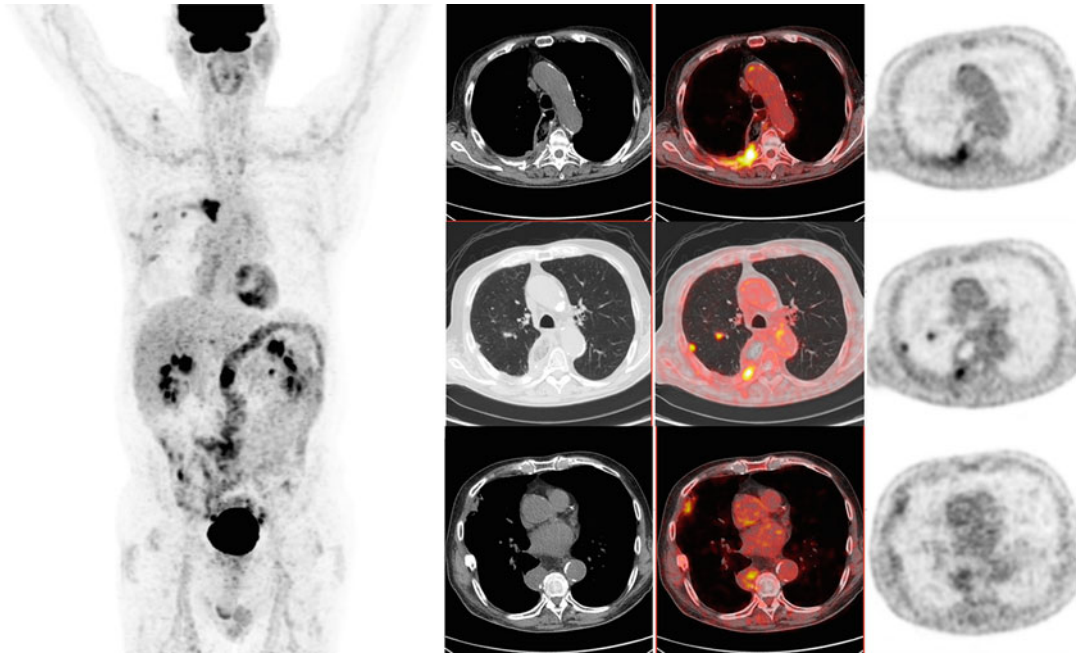

Fig. 10 PET/CT performed 3 months after surgery. [^{18}F]FDG MIP and CT, fused and PET axial slices show some [^{18}F]FDG-avid thickenings of the pleura. The most evident area is detectable on *top* axial slices within the *right* costovertebral space. Middle axial slices show two lung nodules in the *right* lung

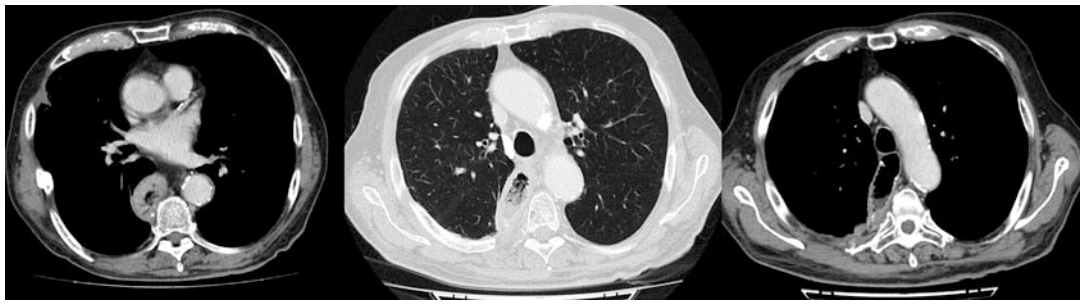

Fig. 11 Contrast-enhanced CT axial slices do not show any finding consistent with disease relapse. Axial slice on the *left* shows a small pleural perifissural thickening

Teaching Points

In this case [^{18}F]FDG PET/CT has been successfully used for staging, therapy monitoring, and following up a patient with advanced esophageal carcinoma.

Esophageal Cancer: Case No. 4

Presentation

A 73-year-old man with an early stage distal esophageal carcinoma already submitted to surgery.

Findings

After 3 months from esophagectomy, restaging PET/CT disclosed [^{18}F]FDG hyperactivity at the level of some thickening of the pleura, the most evident in the costovertebral space, and of some lung nodules in the medium and right inferior lobes (Fig. 10). These findings of uncertain interpretation suggested a subsequent investigation with a ceCT. CT was performed 1 month later and showed the regression of most of the PET/CT findings (Fig. 11).

Fig. 12 Follow-up contrast-enhanced CT. Axial slices confirm no finding consistent with disease relapse

Fig. 13 On *top panels*, CT shows multiple lymphadenopathies within the neck, mediastinum, and abdomen, most of them less than 1 cm. On *bottom panels*, axial, coronal, and sagittal CT slices, a circumferential thickening of the distal esophagus consistent with a primary esophageal cancer

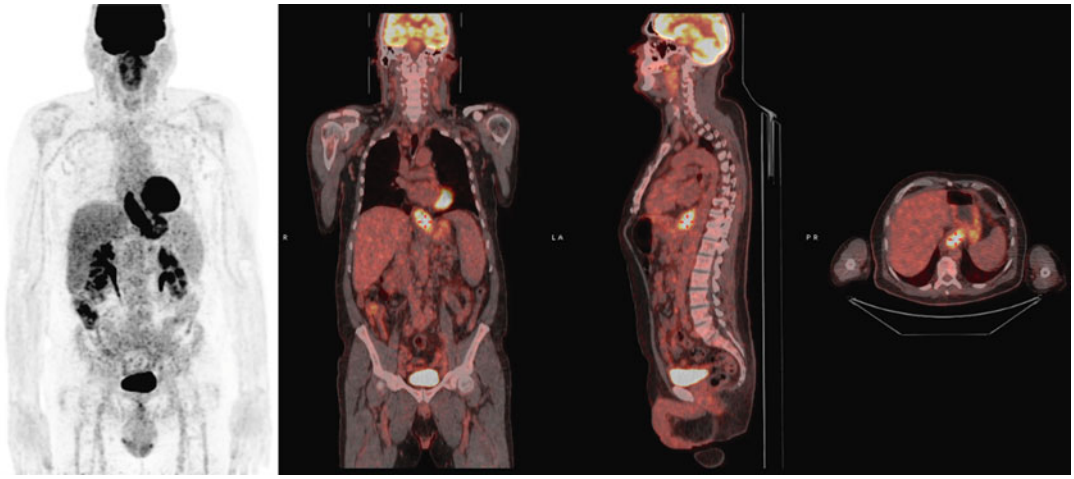

Fig. 14 [^{18}F]FDG MIP and fused coronal, sagittal, and axial PET/CT show a [^{18}F]FDG avid involving the distal esophagus

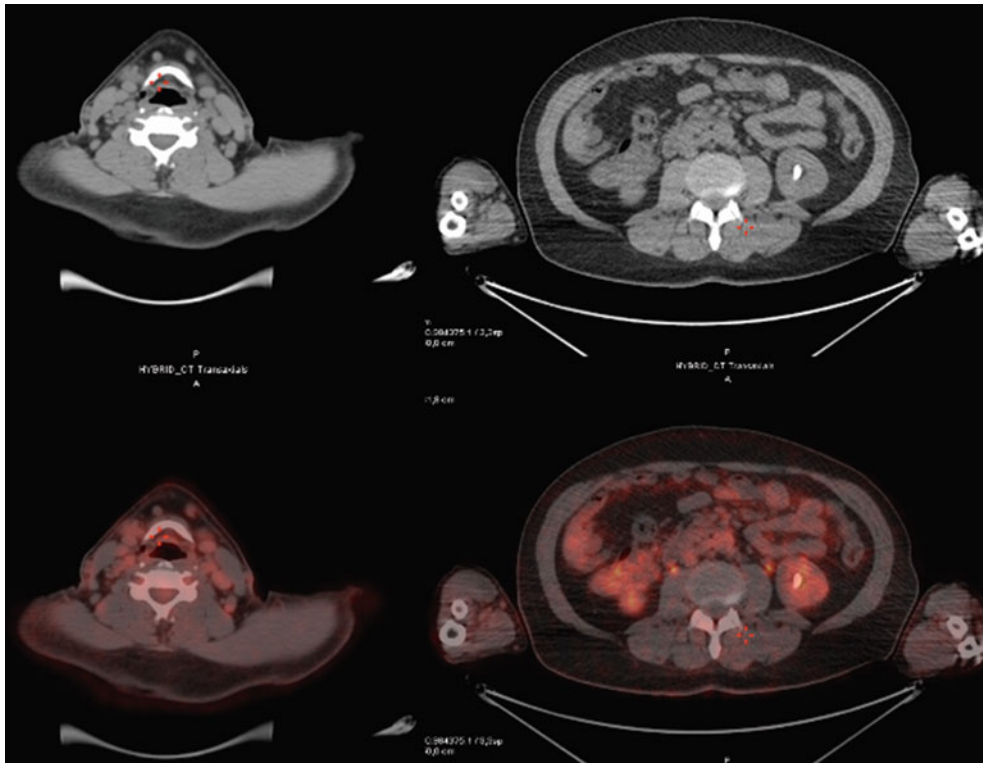

Fig. 15 CT and fused [^{18}F]FDG PET/CT axial slices multiple laterocervical and abdominal lymph nodes with low-grade tracer uptake

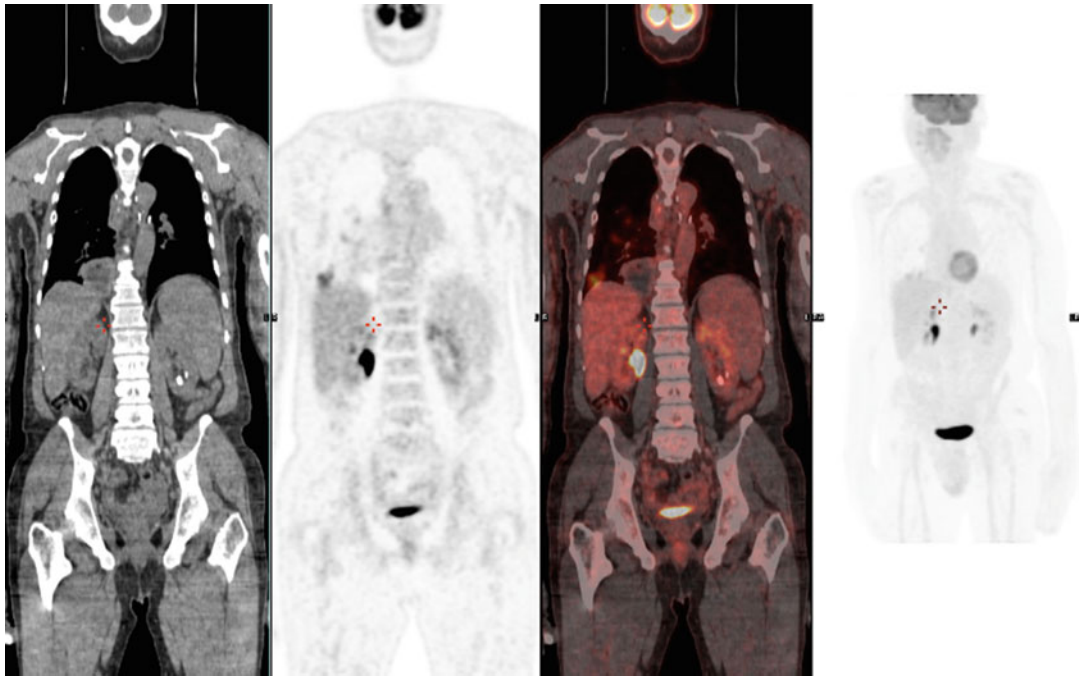

Fig. 16 PET/CT performed after esophagectomy. [^{18}F]FDG MIP image and coronal CT, fused PET/CT, and PET slices showing no hypermetabolic lesions within the residual esophagus. Moreover, no [^{18}F]FDG-avid lymph nodes nor liver lesions are detectable

Follow-Up

After 3 months the patient underwent a new CT evaluation that confirmed the complete disappearance the findings interpreted as postoperative sequelae. CT did not show any other abnormalities within the pleura, mediastinum, and lungs (Fig. 12).

Teaching Points

Esophagectomy may be the initial treatment in early stage esophageal cancers. In the period following this major surgery, phlogistic sequelae can occur producing possible false-positive results at [^{18}F]FDG PET/CT. For this reason there must be cautious interpretation of findings.

Esophageal Cancer: Case No. 5

Presentation

A 59-year-old man with a suspected lymphoproliferative disease underwent a whole body ceCT.

Findings

CT showed the presence of multiple lymphadenopathies within the neck, mediastinum, and abdomen, many of them with size less than 1 cm. As unexpected finding, a circumferential thickening of the distal esophagus was observed consistent with a primary tumor of the esophagus (Fig. 13).

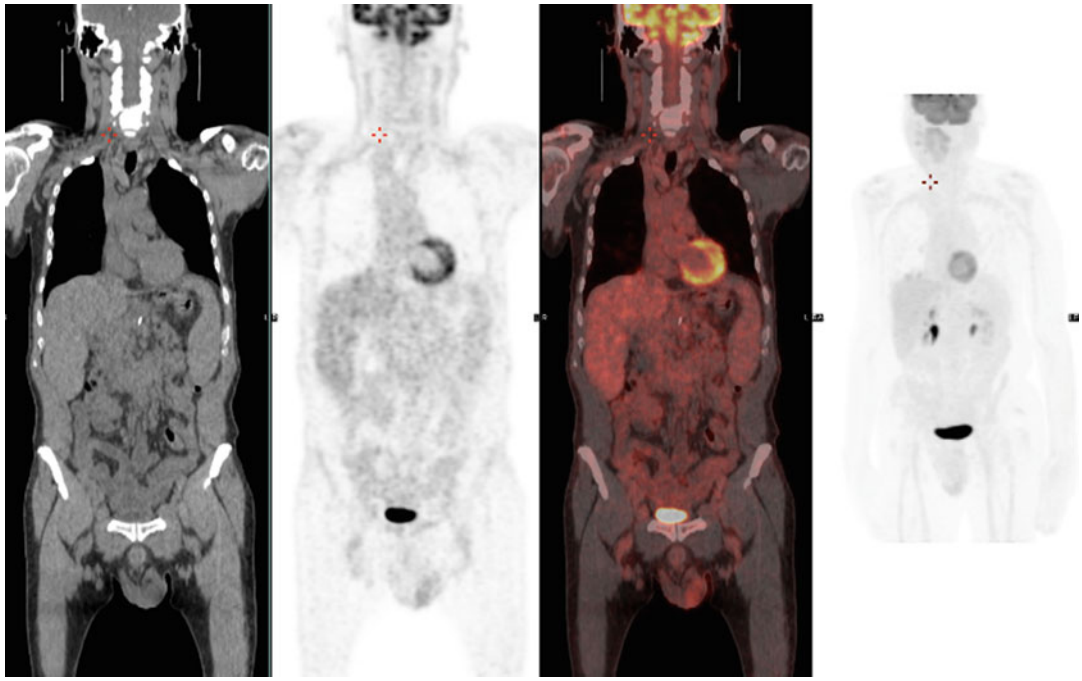

Fig. 17 PET/CT performed after esophagectomy. [^{18}F]FDG MIP image and coronal CT, fused PET/CT, and PET slices showing supra- and subdiaphragmatic non-[^{18}F]FDG-avid lymph nodes consistent with stable CLL/SLL

Follow-Up

The patient underwent lymph node and bone marrow biopsy that revealed a chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL). Moreover, EGDS confirmed the presence of a neoplasia of the distal esophagus that at pathology resulted in a squamous cell carcinoma. A PET/CT was performed to complete the staging of the esophageal carcinoma and an assessment of the CLL/SLL.

PET/CT disclosed a gross [^{18}F]FDG-avid lesion (SUV_{max} 17.7) that involved the distal esophagus (Fig. 14). Multiple supra- and subdiaphragmatic lymph nodes were observed with a very low grade of [^{18}F]FDG uptake (Fig. 15).

The patient underwent esophagectomy and after 6 months repeated a PET/CT investigation.

No hypermetabolic lesions were observed within the residual esophagus, and no [^{18}F]FDG-avid lymph nodes nor liver lesions were found. Some areas of mild hyperactivity were seen within the right pleura as surgery outcome (Fig. 16). Multiple supra- and subdiaphragmatic non-[^{18}F]FDG-avid lymph nodes were substantially unchanged compared to the first PET/CT evaluation (Fig. 17).

Teaching Points

A second primary may occur. In this case while the esophageal carcinoma was highly [^{18}F]FDG avid, as expected, CLL/SLL presented a low uptake of [^{18}F]FDG which is usually related to a slow disease progression.

Gastric Cancer: Case No. 1

Presentation

A 55-year-old man presented with abdominal discomfort over the last 5 months.

Findings

CT scan of the abdomen revealed no abnormalities. Further evaluation with esophago-gastroduodenoscopy revealed a gastric ulcer in the lesser curvature. Biopsies showed a poorly differentiated adenocarcinoma of the stomach with signet-cell rings. [^{18}F]FDG PET/CT scan was performed as a part of initial staging (Fig. 1). PET/CT images demonstrate the presence of a metabolically active mass in the body of the stomach, consistent with a primary carcinoma. Hypermetabolic lymph nodes are seen medially

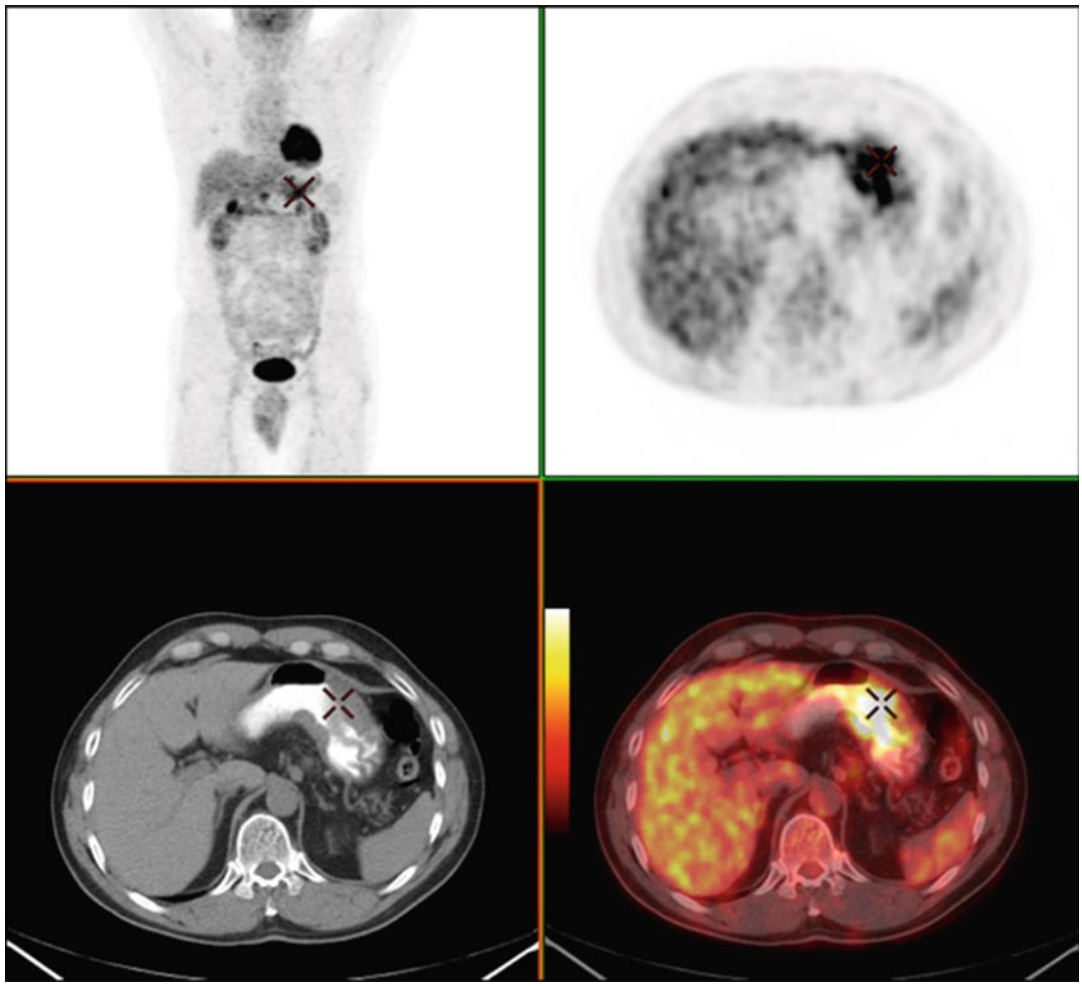

Fig. 1 [^{18}F]FDG PET/CT images demonstrate hypermetabolic lesion in the stomach body (marked by the *red cross*). MIP (*left upper*), [^{18}F]FDG axial (*right upper*), CT axial (*left lower*), and PET/CT fused images (*right lower*)

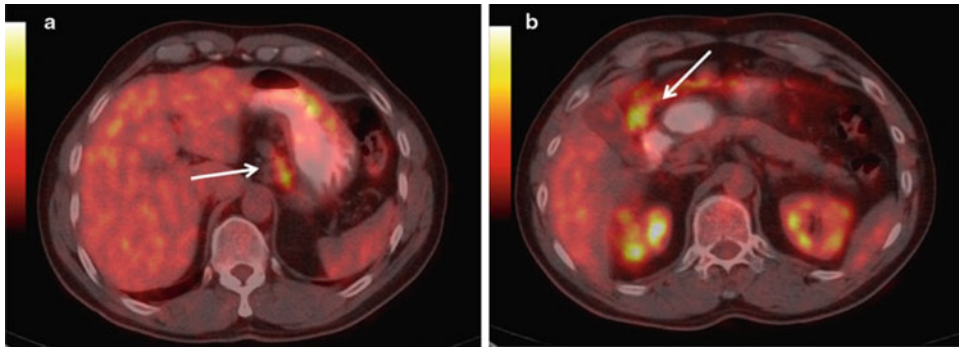

Fig. 2 [^{18}F]FDG PET/CT transaxial fused images. (**a**) Metabolically active lymph nodes medial to the stomach (*white arrow*). (**b**) Hypermetabolic peritoneal nodule (*white arrow*)

to the stomach (Fig. 2a). [^{18}F]FDG-avid peritoneal nodules adjacent to the left lobe liver and medial to the gallbladder (Fig. 2b) are also seen. Laparoscopy confirmed the presence of a locally advanced gastric tumor with regional lymph node involvement and peritoneal disease (TNM Stage IV). The patient was treated with chemotherapy.

Follow-Up

Follow-up [^{18}F]FDG PET/CT at 3 months after chemotherapy demonstrated a reduced SUV_{max} (2.9 versus 5.8) and reduced size of the gastric lesion (Fig. 3a). No [^{18}F]FDG uptake was seen in lymph nodes or peritoneal disease (Fig. 3b).

Teaching Points

Although the sensitivity of [^{18}F]FDG PET/CT is reduced in many mucinous tumors of the stomach, poorly differentiated tumors are often [^{18}F]FDG avid. This case demonstrates the usefulness of [^{18}F]FDG PET/CT both at initial staging (which showed metastatic disease in lymph nodes and peritoneum) and for monitoring the efficacy of therapy.

Gastric Cancer: Case No. 2

Presentation

Male patient 67 years old suffering from a stage III gastric cancer undergoing neoadjuvant preoperative chemotherapy (last cycle completed since about 20 days)

Findings

The patient underwent a ceCT that disclosed diffused thickening of the gastric walls with involvement of the perigastric adipose tissue where fine micronodules were clearly visible. Findings were consistent with *linitis plastica* (Fig. 4).

The patient had an [^{18}F]FDG PET/CT scan which showed diffuse metabolic hyperactivity that affects all the gastric walls and the perigastric adipose tissue (SUV_{max} 6.4). No additional significant findings were detected (Fig. 5).

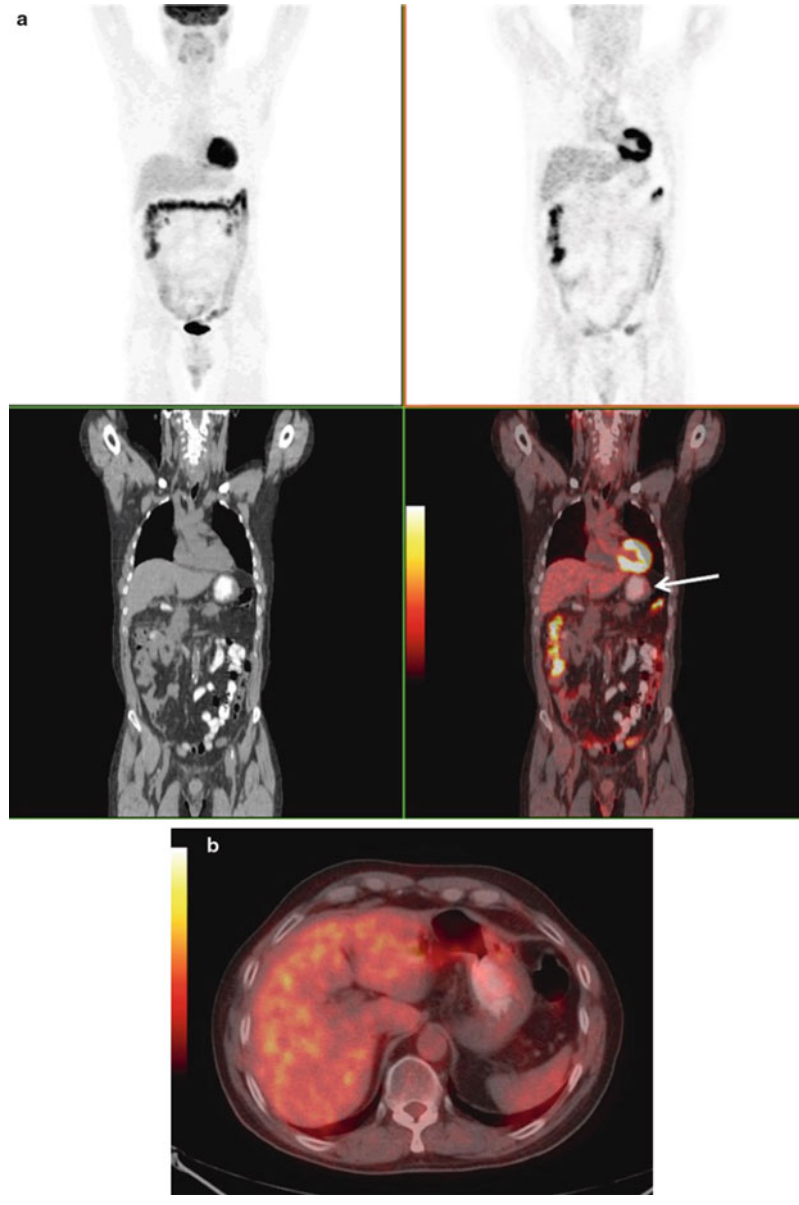

Fig. 3 (**a**) [^{18}F]FDG PET/CT (MIP and coronal images) shows reduction of the radiotracer uptake (*white arrow*) in gastric lesion after chemotherapy (*left upper* MIP, *right upper* PET, *left lower* CT, *right lower* PET/CT fused image). (**b**) Fused axial PET/CT image centered on the gastric body

Management

A second-line chemotherapy regimen was started.

Teaching Points

[^{18}F]FDG PET/CT can be used to assess the metabolic response of gastric cancer to neoadjuvant or adjuvant chemotherapy. In case of locally advanced stages, PET/CT is considered a very sensitive tool for detecting distant metastases.

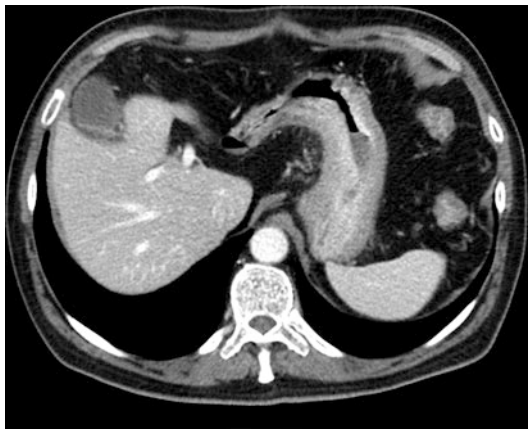

Fig. 4 Axial slice of ceCT shows diffuse thickening of the gastric walls (1.5 cm) that present contrast enhancement persistent in the late phase. Thickened perigastric adipose tissue with small micronodules is detectable

Gastric Cancer: Case No. 3

Presentation

Patient with gastric cancer treated with subtotal gastrectomy. Two years later, appearance of a bone metastasis treated with radiotherapy. After 6 months the patient underwent an [^{18}F]FDG PET/CT for restaging.

Findings

[^{18}F]FDG PET/CT showed multiple areas of hyperactivity within several bone segments (spine, sternum, scapula, ribs, pelvis, humeri, and femurs) (Fig. 6). Moreover, a focal area of increased [^{18}F]FDG uptake was found in the abdomen, close to the enteric anastomosis (Fig. 7). Findings were consistent with diffused secondary bone involvement and with the suspected presence of locoregional recurrence.

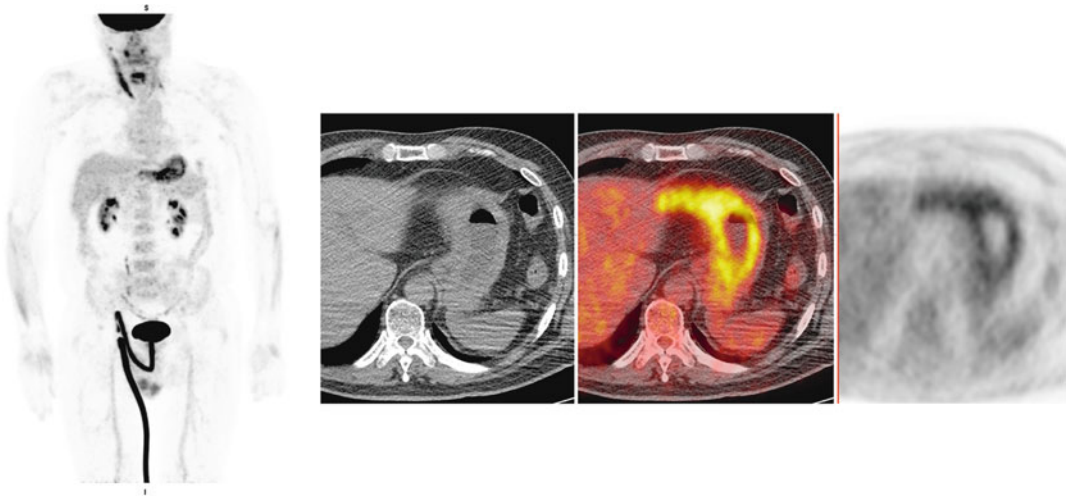

Fig. 5 [^{18}F]FDG PET/CT (MIP and axial slices) shows diffused metabolic hyperactivity of the stomach walls that appear clearly thickened (SUV_{max} 6.4). Moreover, [^{18}F]FDG increased uptake extends to the perigastric adipose tissue. MIP (on the *left*) does not show any other significant [^{18}F]FDG-avid site consistent with the presence of metastases

Fig. 6 [^{18}F]FDG PET/CT MIP image showing multiple areas of hyperactivity referable mainly to metastases of the spine, sternum, scapula, ribs, pelvis, humeri, and femurs

After 4 days the patient underwent a ceCT in emergency for acute anemia. CT confirmed multiple bone metastases, but did not disclose any significant finding in the abdomen, nor site of bleeding (Fig. 8). On the next day a gastrointestinal bleeding scintigraphy with red blood cells labeled in vivo with ^{99m}Tc was performed. Planar and SPECT/CT images disclosed a focal accumulation of activity in the upper-left abdominal quadrant, consistent with bleeding in the first tract of small bowel (Fig. 9).

Follow-Up

The patient underwent endoscopy that confirmed the anastomotic leakage with intraluminal bleeding. However, no recurrent disease was found at that level.

Teaching Point

A focal uptake of [^{18}F]FDG is not always due to the presence of tumor. In this case the focal accumulation of [^{18}F]FDG was related to an anastomotic leakage with intestinal bleeding, most likely also associated with chronic inflammation of the surrounding tissues.

Gastric Cancer: Case No. 4

Presentation

A 53-year-old man with a recent history of epigastric pain underwent an esophago-gastroduodenoscopy that revealed a cancer of the pyloric antrum of the stomach. A ceCT was performed for the staging.

Findings

ceCT showed thickening of the gastric pyloric antrum wall, associated with the presence of a lymph node (short axis 9 mm) within the immediately adjacent adipose tissue, on the right inferior side (Fig. 10). No liver nor lung nor bone metastatic disease was found.

One week later the patient underwent [^{18}F]FDG PET/CT that confirmed the presence

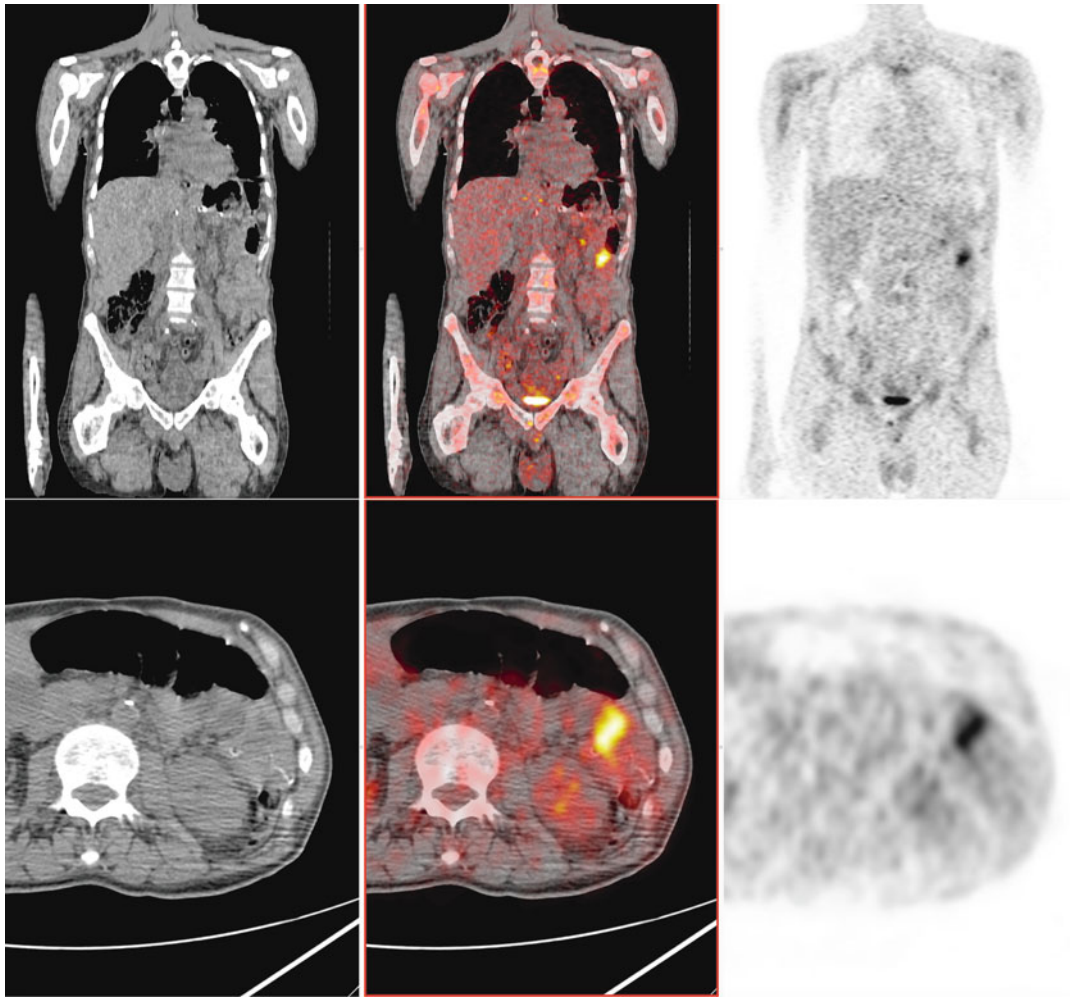

Fig. 7 [^{18}F]FDG PET/CT coronal slices (*top*) and axial slices (*bottom*) show a focal area of [^{18}F]FDG uptake close to the enteric anastomosis

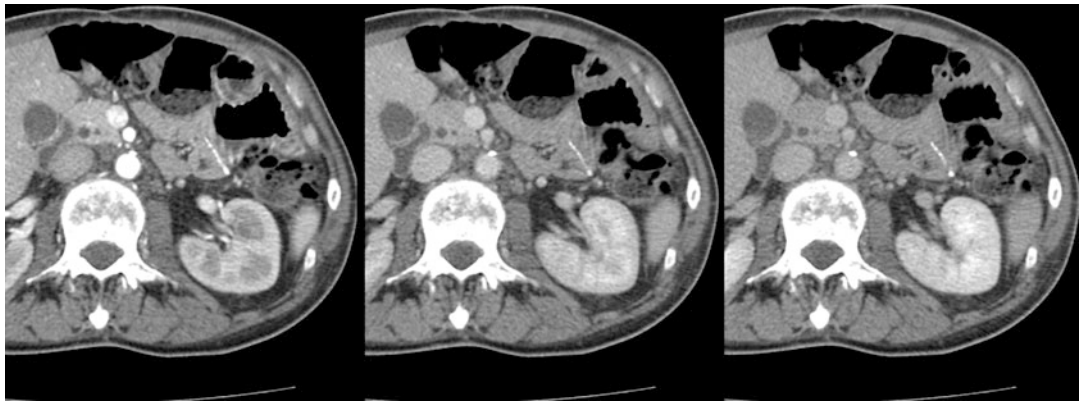

Fig. 8 CT axial slices (arterial, venous, and late phases) showing the enteric anastomosis do not disclose any finding consistent with disease relapse

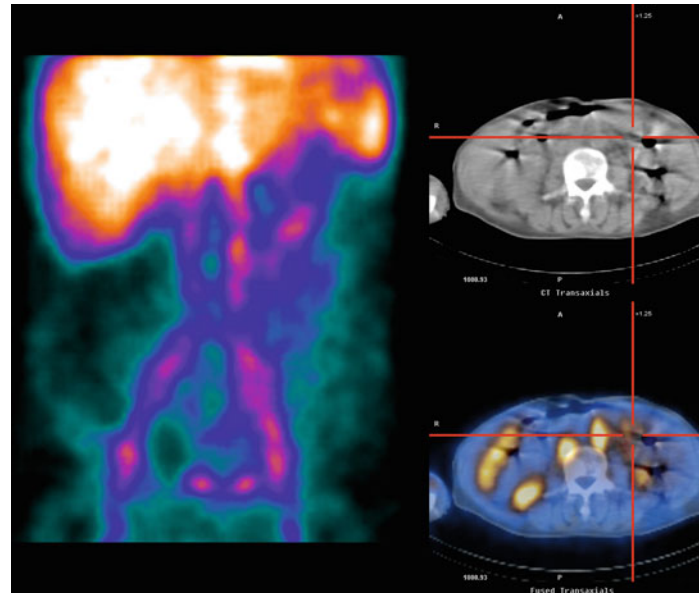

Fig. 9 ^{99m}Tc-labeled red blood cell scintigraphy reveals activity accumulation in the upper abdominal quadrant (on the *left*). SPECT/CT images (on the *right*) are consistent with low-degree bleeding from an upper small bowel loop

Fig. 10 CT axial slice (*top* panel) shows a contrast-enhanced wall thickening of the gastric pyloric antrum consistent with the presence of primary tumor. CT slice (*bottom* panel) discloses the presence of a lymph node with a short axis of 9 mm within the adipose tissue close to the right inferior side of the gastric cancer

of a hyperactive lesion (SUV_{max} 6.5) at the gastric pyloric antrum. Moreover, PET/CT found frankly increased tracer uptake (SUV_{max} 8.5) within the subpyloric lymph node disclosed by ceCT, thus confirming the presence of regional nodal disease (Fig. 11). No other [^{18}F]FDG-avid lesions in the whole body were detected.

Follow-Up

Neoadjuvant chemotherapy was started. After 3 months [^{18}F]FDG PET/CT was repeated to assess response to therapy. PET/CT disclosed a reduction in size of the gastric lesion, which however continued to exhibit high metabolic activity (SUV_{max} 6.9). However, the perigastric lymphadenopathy resulted to be completely resolved (Fig. 12).

Teaching Points

In this case PET/CT was useful to complete the staging by confirming the presence of lymph node disease in a small perigastric lymph node. [^{18}F]FDG PET/CT was also useful to assess response to chemotherapy.

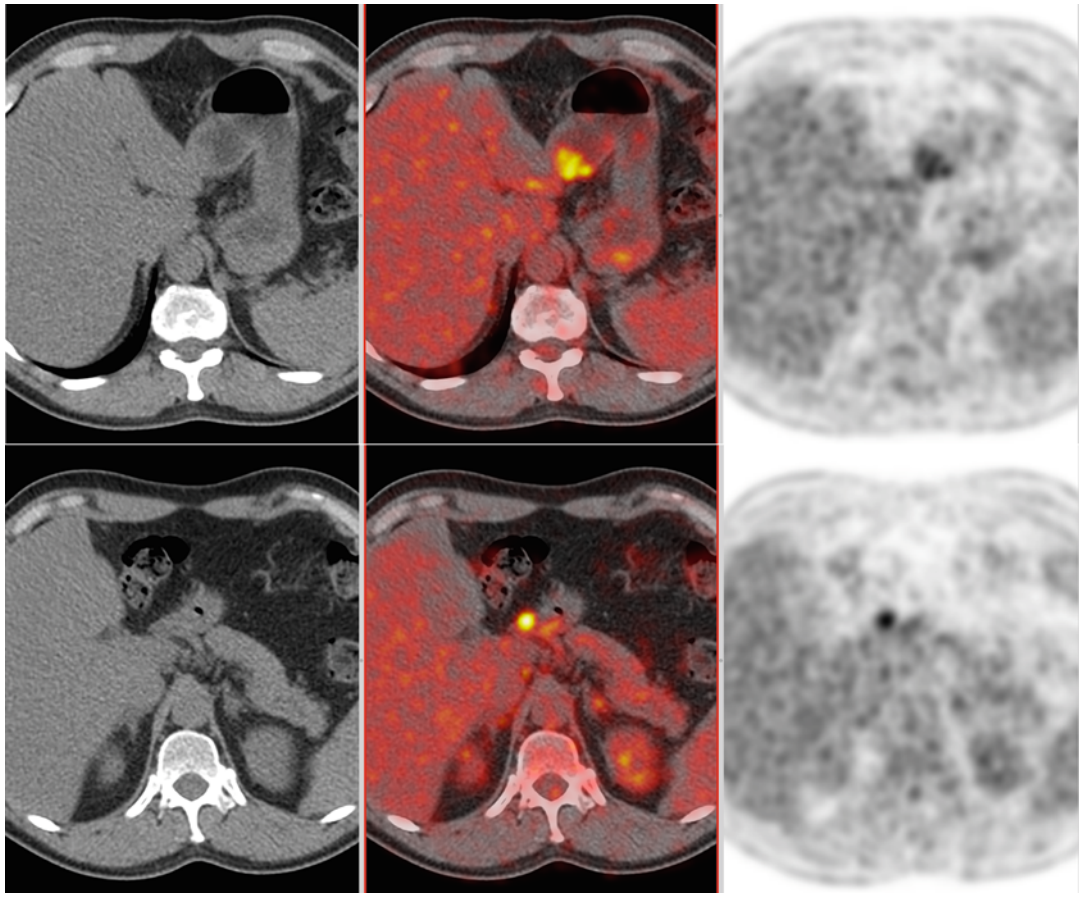

Fig. 11 [^{18}F]FDG PET/CT at staging. CT, fused [^{18}F]FDG PET/CT, and [^{18}F]FDG PET axial slices (*top* panels) show the presence of a clear hyperactive lesion (SUV_{max} 6.5) within the wall of the gastric pyloric antrum. CT, fused [^{18}F]FDG PET/CT, and [^{18}F]FDG PET axial slices (*bottom* panels) identify a significantly [^{18}F]FDG-avid subpyloric lymph node (SUV_{max} 8.5)

Gastric Cancer: Case No. 5

Presentation

A 62-year-old man complaining of heartburn, acid regurgitation, and retrosternal pain underwent esophago-gastro-duodenoscopy that revealed an adenocarcinoma of the esophagogastric junction. The patient underwent [^{18}F]FDG PET/CT for staging the disease.

Findings

PET/CT disclosed a large-size, intensely [^{18}F]FDG-avid mass (SUV_{max} 13) partially extending

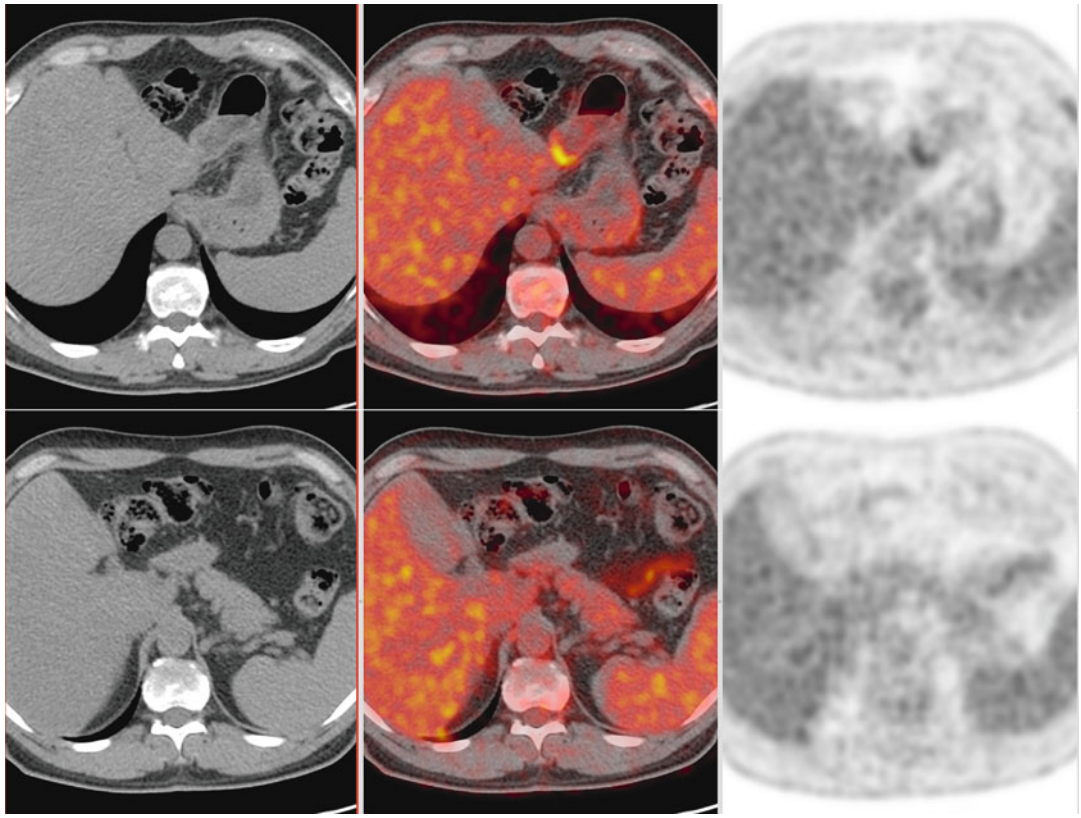

Fig. 12 [^{18}F]FDG PET/CT after neoadjuvant chemotherapy. CT, fused [^{18}F]FDG PET/CT, and [^{18}F]FDG PET axial slices (*top* panels) show the dimensional reduction of the gastric lesion which continues to present metabolic hyperactivity (SUV_{max} 6.9). No [^{18}F]FDG-avid lymph nodes are observed on CT, fused [^{18}F]FDG PET/CT, and [^{18}F]FDG PET axial slices (*bottom* panels) in the perigastric adipose tissue

from the esophagogastric junction to the lesser curvature. No abdominal nor mediastinal lymph nodes with significant [^{18}F]FDG uptake were observed, and sites of distant metastasis were not detected (Fig. 13).

Follow-Up

Although no locoregional nor distant disease was disclosed by PET/CT, nevertheless preoperative neoadjuvant chemotherapy was started, mostly based on the intense uptake of [^{18}F]FDG in the tumor lesion.

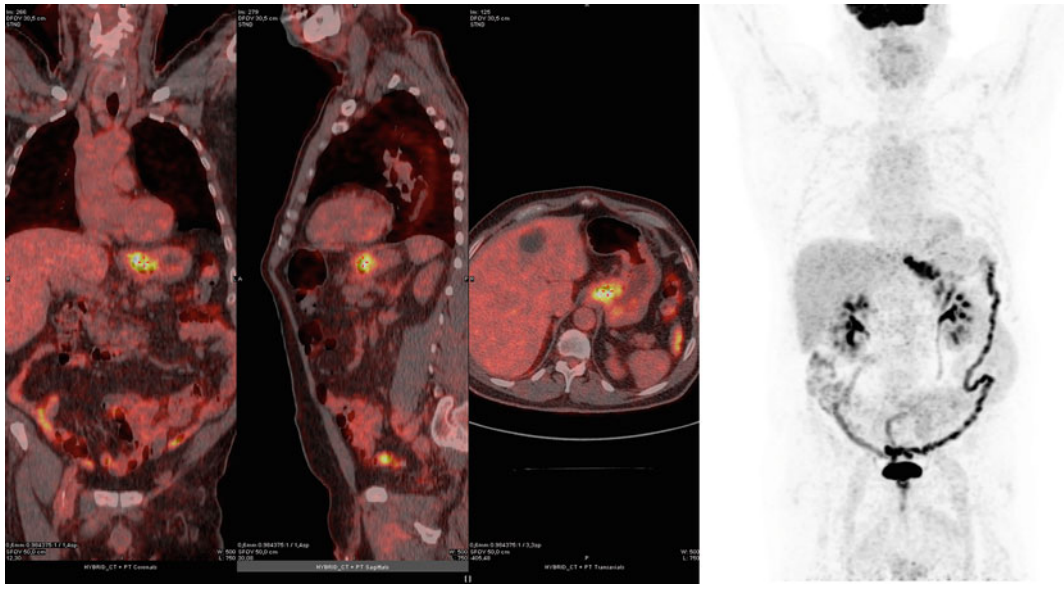

Fig. 13 [^{18}F]FDG fused PET/CT coronal, sagittal, and axial slices on the *left*. PET MIP image on the *right*. An avid mass (SUV_{max} 13) partially extending from the esophagogastric junction to the lesser curvature is clearly visible. No abdominal nor mediastinic lymph nodes nor distant metastases with significant [^{18}F]FDG uptake

Teaching Point

The standard primary treatment for junction and gastric cancer is surgical resection. Since the rate of locoregional and distant recurrences is high, multimodal neoadjuvant therapy is often suggested before surgery. [^{18}F]FDG PET/CT is considered a sensitive and specific tool for the preoperative staging of the esophagogastric junction cancer, especially for distant metastases. The intensity of [^{18}F]FDG uptake has a definite prognostic value and can be the basis for choosing the most appropriate initial management of the disease.

Small Bowel Tumors: Case No. 1

Presentation

A 40-year-old woman suffering from abdominal pain underwent US which disclosed a gross mass in the pelvis. An MRI was then performed which showed a mass with polylobate morphology, 12 × 7.7 × 6.5 cm, occupying the pelvic cavity, localized above the bladder, in front of the uterus, and displacing some loops of small intestine. Such tumefaction showed inhomogeneous signal for the presence of fat inhomogeneous component and coarse calcified formations in its context suggesting a teratoma (Fig. 1). The patient underwent surgery and pathology revealed a GIST originating from the small bowel. After 4 months a disease relapse was suspected, and the patient underwent a [^{18}F]FDG PET/CT for restaging.

Findings

Positron emission tomography/computed tomography (PET/CT) showed the presence of two gross [^{18}F]FDG-avid masses (SUV_{max} 7–8) within the pelvis. The first tumefaction resulted more anterior in the left iliac fossa and the other one between the rectum and uterus (Fig. 2). As PET/CT confirmed the disease relapse, the patient was started to therapy with a tyrosine kinase inhibitor.

After 15 days a second PET/CT was performed to assess therapy response.

PET/CT during therapy revealed a significant reduction of tracer uptake (SUV_{max} 4) within the mass in the left iliac fossa that however did not present change in size. A more inhomogeneous [^{18}F]FDG uptake was also found also in the mass located between the rectum and uterus that appeared to present a softer aspect (Fig. 3).

Management

The patient continued treatment with tyrosine kinase inhibitor.

Teaching Points

[^{18}F]FDG PET/CT is well known to be a sensitive tool in detecting early response to tyrosine kinase inhibitors in GIST.

Small Bowel Tumors: Case No. 2

Presentation

Patient with acute episode of pancreatitis and suspected mesenteric fibromatosis. MRI detection of mesenteric nodule in the right quadrants of the abdomen. Patient underwent [^{18}F]FDG PET/CT.

Findings

PET/CT images showed an [^{18}F]FDG-avid mesenteric lesion in the lower right paramedian mesogastric region (SUV_{max} 5.6). Some peritoneal nodule without significant accumulation of [^{18}F]FDG was found. No other significant areas of [^{18}F]FDG hyperactivity were observed in the whole body (Fig. 4).

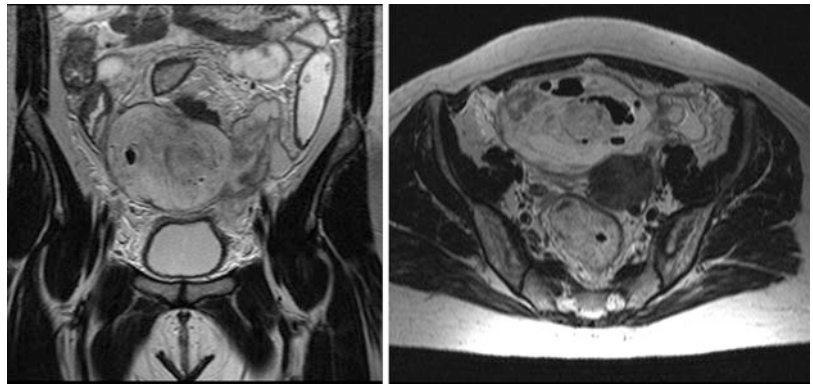

Fig. 1 MRI coronal and axial slices show a gross mass occupying the pelvic cavity, localized above the bladder, in front of the uterus, and displacing some loops of small intestine. Such tumefaction showed inhomogeneous signal for the presence of fat inhomogeneous component and coarse calcified formations

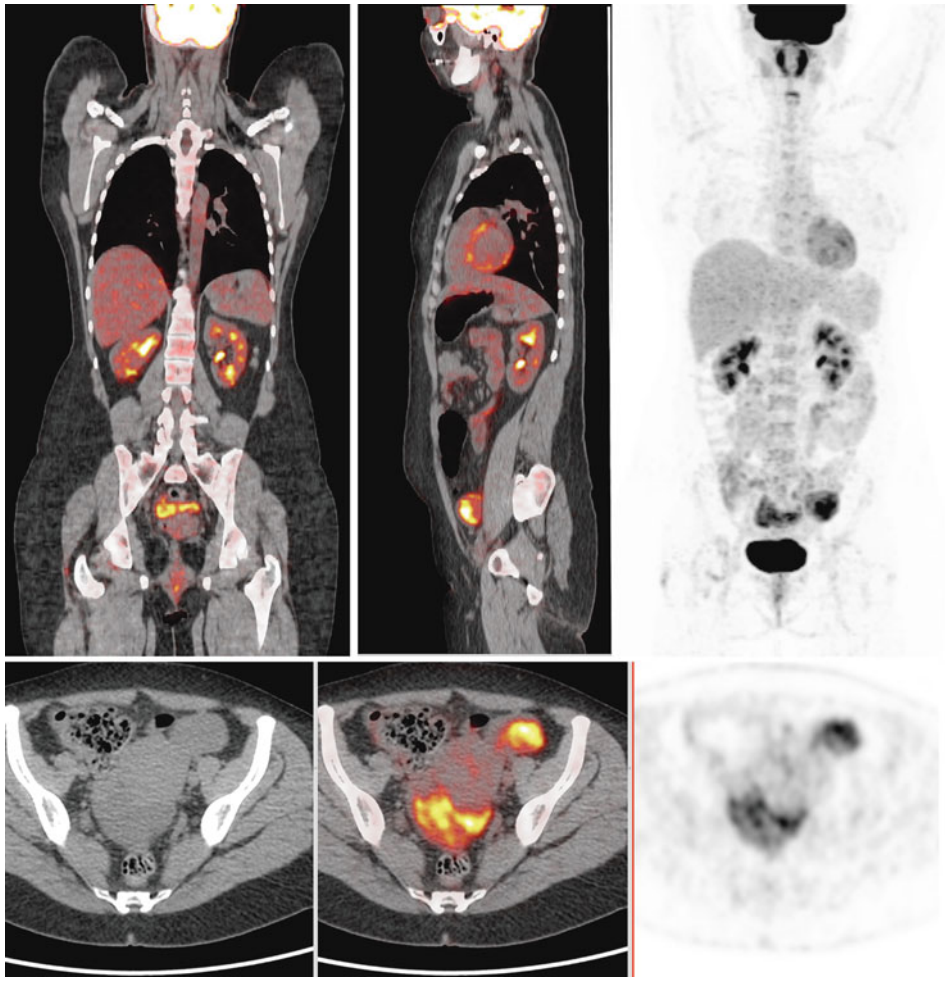

Fig. 2 Coronal and axial CT, fused PET/CT, and PET slices show two gross [^{18}F]FDG-avid masses within the pelvis. The first tumefaction results in the left iliac fossa and the other one between the rectum and uterus

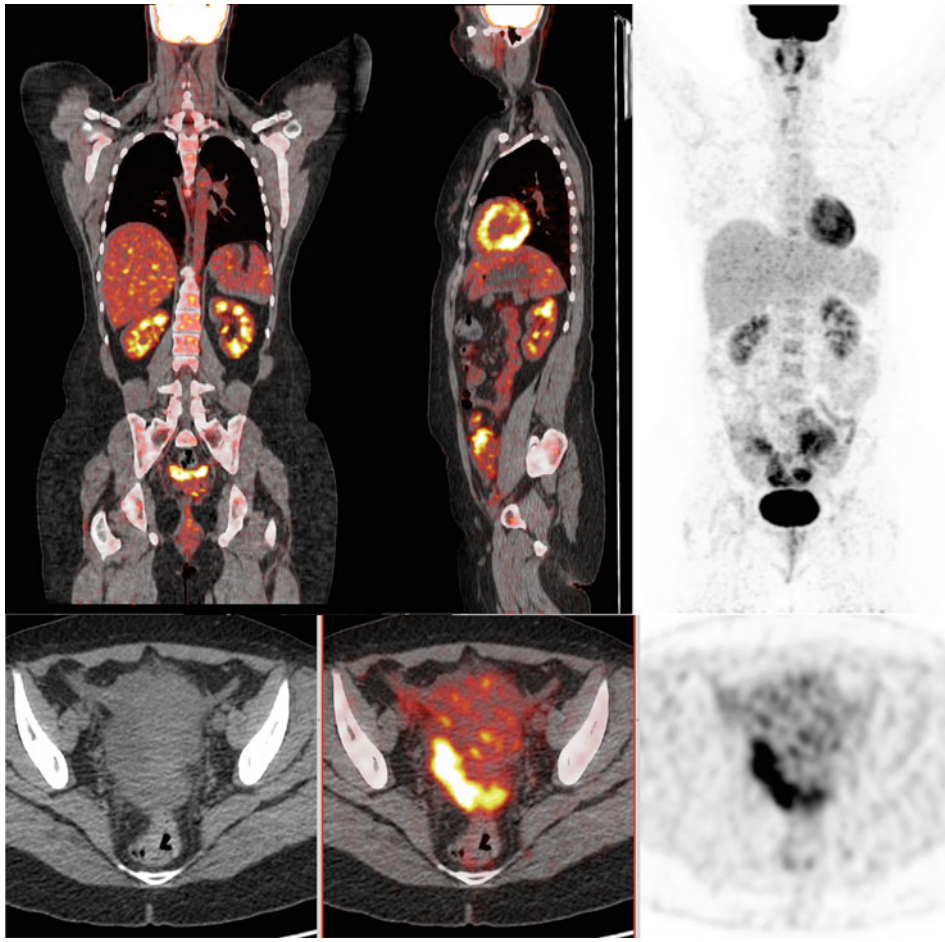

Fig. 3 Coronal and axial CT, fused PET/CT, and PET slices show a significant reduction of tracer uptake within the mass in the left iliac fossa without significant change in size. A more inhomogeneous [^{18}F]FDG uptake is detectable in the other pelvic lesion

Follow-Up

The patient underwent surgery and had a pathological diagnosis of small bowel neuroendocrine carcinoma, with nodal and peritoneal involvement.

Then the patient underwent somatostatin receptor scintigraphy with octreoscan in order to assess if persistent disease could express somatostatin receptors.

Scintigraphy showed four peritoneal nodules with a high degree of tracer uptake, one within the mesentery, one within the omentum, and two in the adipose tissue of the pelvic cavity (Fig. 5).

Teaching Points

Although neuroendocrine carcinoma tends to differentiate showing [^{18}F]FDG uptake, some lesions can preserve the expression of somatostatin receptors that can be proved by receptor scintigraphy. These information are useful for subsequent therapeutic management of patients.

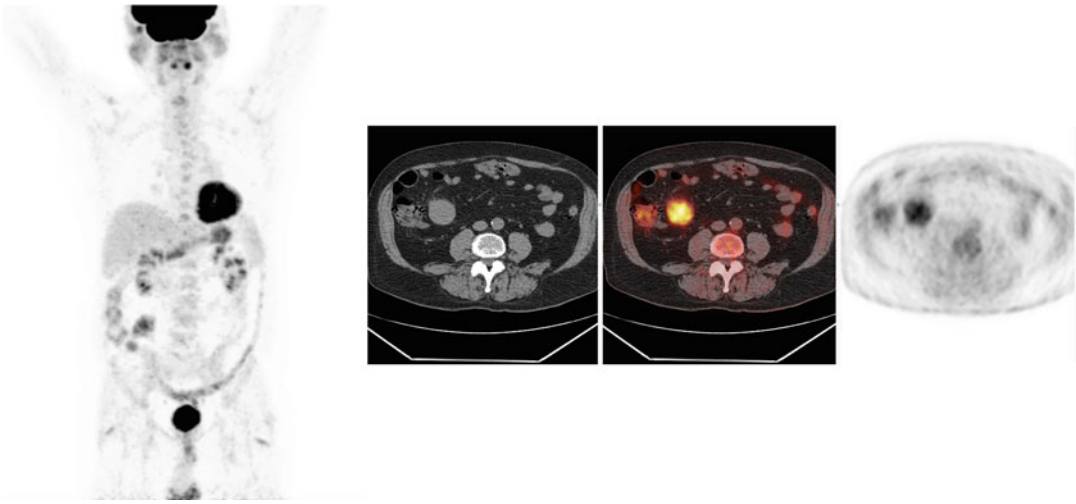

Fig. 4 [^{18}F]FDG MIP image and axial CT, fused PET/CT, and PET slices show a [^{18}F]FDG-avid mesenteric lesion in the lower right paramedian mesogastric region. No other significant areas of [^{18}F]FDG uptake can be observed

Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK.

Presentation

[^{18}F]FDG PET/CT for evaluation of tumor burden in a 56-year-old patient with small bowel gastrointestinal stromal tumor (GIST).

Findings

There is a large (8×9 cm) [^{18}F]FDG-avid abdominal mass (SUV_{max} 8.2) just left of the midline. Note is made of focal increased [^{18}F]FDG uptake in the right retromandibular region in keeping with a benign parotid tumor (arrow). The distribution of tracer elsewhere was within normal limits (Fig. 6).

Discussion

Gastrointestinal stromal tumors (GISTs) constitute approximately 0.1–3.0% of all gastrointestinal tract neoplasms and 6% of all sarcomas. GISTs are usually asymptomatic when less than 5 cm in their longest dimension and become symptomatic when they grow to more than 5 cm. The tumors most often arise in the stomach (70%), followed by the small intestine (20%), large intestine (5%), and esophagus (<5%). Seventy percent of GISTs are benign, and 30% are malignant. It was discovered that GIST cells of origin are probably related not to smooth muscle cells but to the cells of Cajal. Both GIST cells and cells of Cajal have been shown to express the cell surface receptor C-kit, which functions as a tyrosine kinase. A mutation of the C-kit protooncogene that activates tyrosine kinase in the absence of a stem cell factor leads to uncontrolled cell proliferation. Imatinib mesylate (Gleevec; Novartis Pharmaceuticals Corp.) acts as a tyrosine kinase inhibitor and resulted in an impressive response.

Teaching Points

[^{18}F]FDG PET helps in initial staging of malignant GISTs and early evaluation of response to therapy. Therefore, [^{18}F]FDG PET is able to predict response to imatinib mesylate therapy earlier than CT.

Small Bowel Tumors: Case No. 4

Case contributed by: S. Al Shammari and F. Fraioli

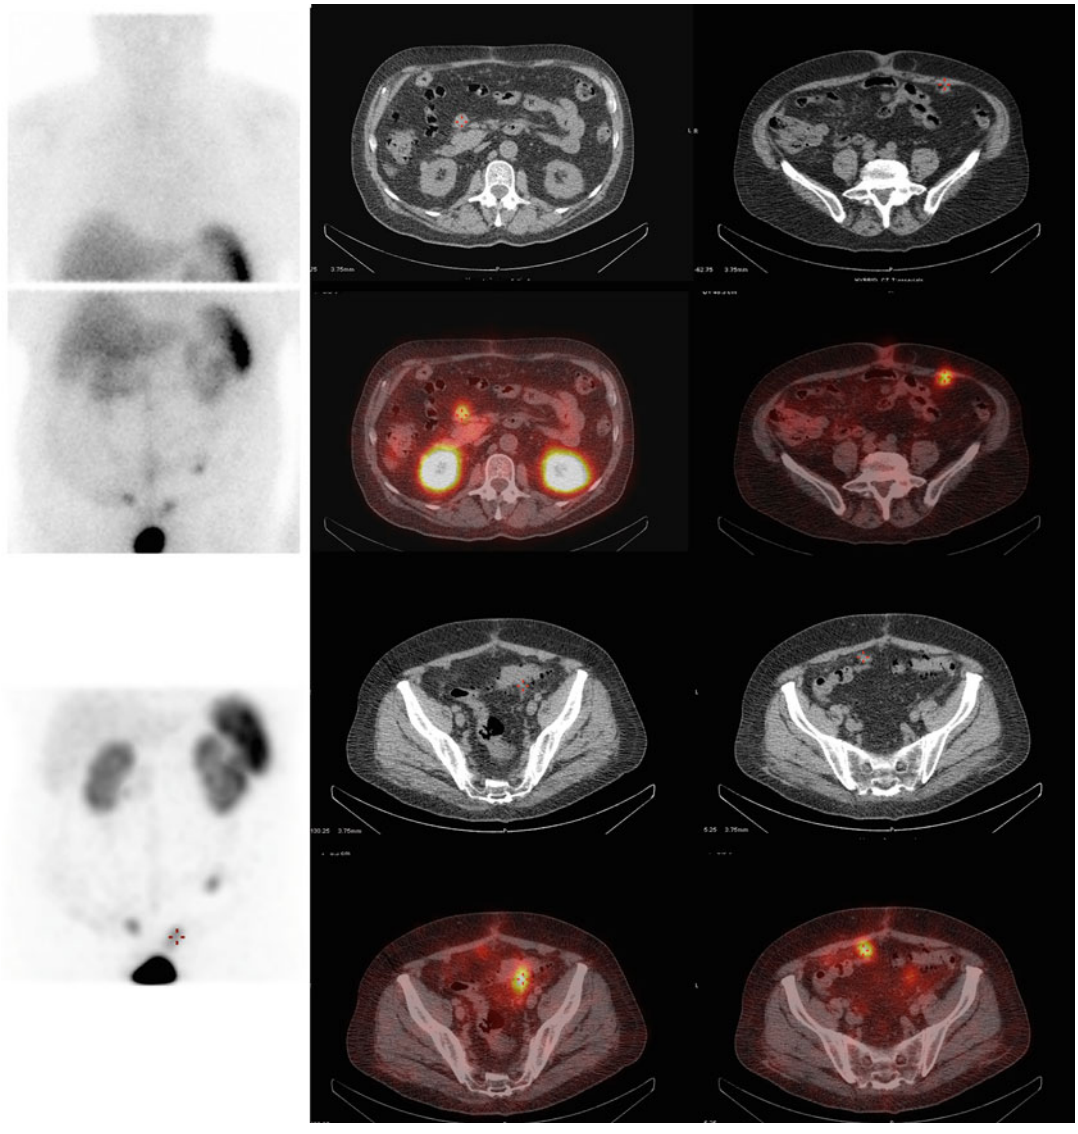

Fig. 5 Scintigraphy with Octreoscan®. Planar images and MIP image on the left. On the right axial CT and fused SPECT/CT. One nodule within the mesentery, one within the omentum, and two nodules in the adipose tissue of the pelvic cavity with a high degree of ^{111}In-pentetreotide uptake are detectable

Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

Fifty-three-year-old patient suspicious of midgut NET.

Findings

A 64-year-old man with small focus of uptake in the third portion of the duodenum.

MR post contrast images clearly show the enhancing lesion, with corresponding intense uptake at the fused ^{68}Ga-DOTATATE image (Fig. 7 a, b). PET/CT for comparison also identifies the focus of uptake (Fig. 7c).

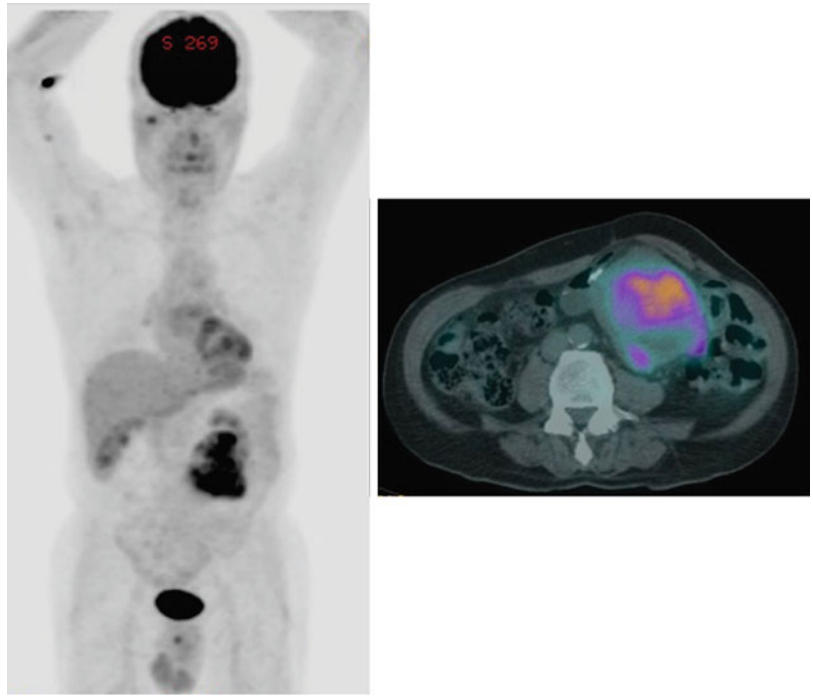

Fig. 6 [^{18}F]FDG MIP image and fused PET/CT axial slice show a large ([^{18}F]FDG-avid abdominal mass just left of the midline. A focal increased [^{18}F]FDG uptake in the right retromandibular region in keeping with a benign parotid tumor (*arrow*). Distribution of tracer elsewhere within normal limits

Discussion

The positron emitter ^{68}Ga has been linked to short peptide analogues of somatostatin analogues via bifunctionalchelate, usually 1,4,7,10-etraaza-cyclododecane-1,4,7,10-tetraacetic acid (DOTA). ^{68}Ga-DOTA-peptides have higher affinity for SSTRs as compared to conventional ^{111}In-pentetreotide. Furthermore, the relatively easy synthesis process and long half-life of the mother radionuclide ^{68}Ge (270.8 days) make it possible to use the generator for approximately 6–12 months. Positron emission tomography with ^{68}gallium (^{68}Ga)-labeled somatostatin analogues is performed for localizing and confirming the primary tumor, evaluating disease extension, monitoring treatment effects, and determining the receptor status as a predictor of response in selected patients undergoing targeted radionuclide therapy. Combined positron emission tomography/magnetic resonance imaging (PET/MRI) is a relatively new technique that has shown similar performance to positron emission tomography/computed tomography (PET/CT).

A PET/MRI solution combining gadolinium enhancement and somatostatin tracer uptake could have the potential to further improve preoperative planning and to better monitor and localize recurrence following therapy.

Small Bowel Tumors: Case No. 5

Case contributed by: V. Yerubadi, C. Sakellis, A.D. Van den Abbeele, and H. Jacene

Nuclear Medicine/PET/CT, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts, USA

Presentation

A 73-year-old woman with type 2 diabetes and neurofibromatosis presented with weight loss and abdominal fullness.

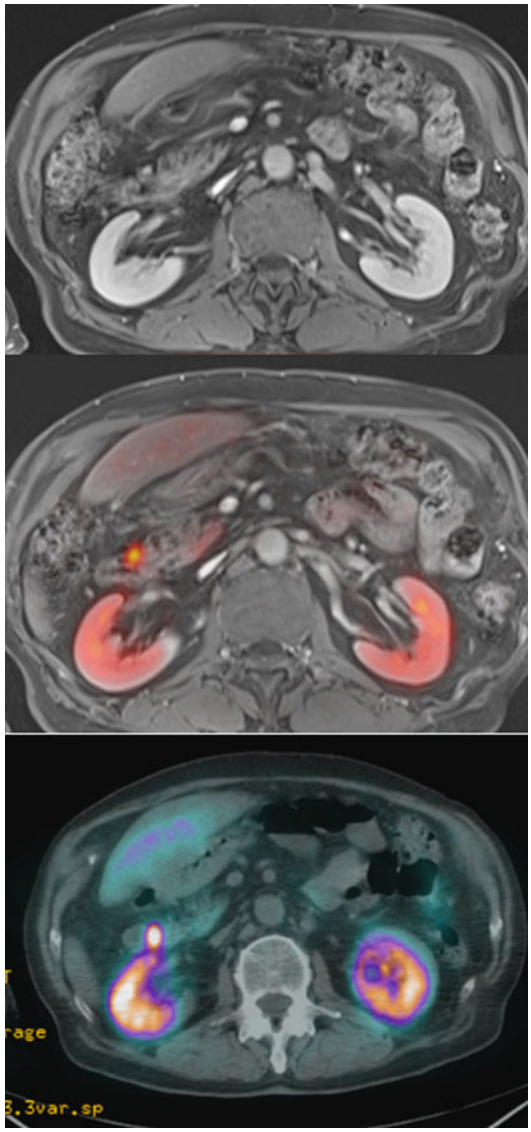

Fig. 7 CT of the head shows multiple exophytic cutaneous lesions (*arrows*) consistent with neurofibromas in a patient with known history of neurofibromatosis

Findings

CT of the head shows multiple exophytic cutaneous lesions consistent with neurofibromas in a patient with known history of neurofibromatosis (Fig. 8).

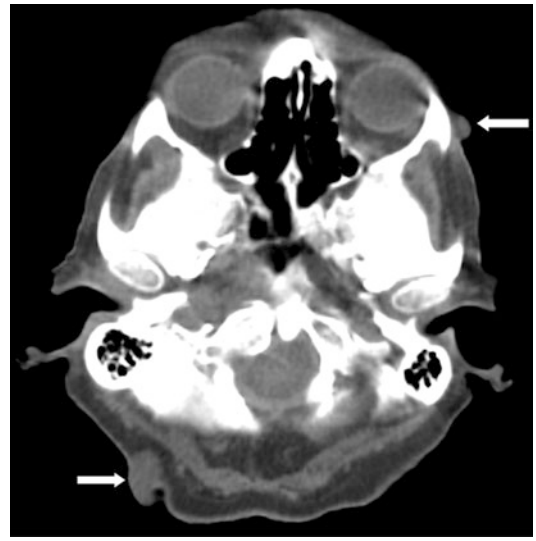

Fig. 8 CT of the head shows multiple exophytic cutaneous lesions (*arrows*) consistent with neurofibromas in a patient with known history of neurofibromatosis

CT of the abdomen and pelvis with oral and intravenous contrast demonstrates a peripherally avidly enhancing, centrally necrotic mesenteric mass associated with the small bowel that displaces the bowel anteriorly without causing obstruction (Fig. 9).

[^{18}F]FDG PET/CT performed for further evaluation (Fig. 10) demonstrates a peripherally moderately [^{18}F]FDG-avid mass corresponding to the enhancing portion of the mass and central photopenia corresponding to central necrosis seen on prior CT. Additionally, there is a focus along the left lateral aspect of the mass that is more focally intensely [^{18}F]FDG avid (SUV_{max} 5.7). Incidental note of the distal small bowel and diffuse colonic [^{18}F]FDG uptake is consistent with history of metformin use.

A trial of imatinib therapy was instituted to attempt to reduce the size of the mass prior to surgical resection, and a short-term follow-up PET/CT was performed 3 weeks later. The follow-up PET/CT demonstrates the original dominant mass is slightly increased in size with

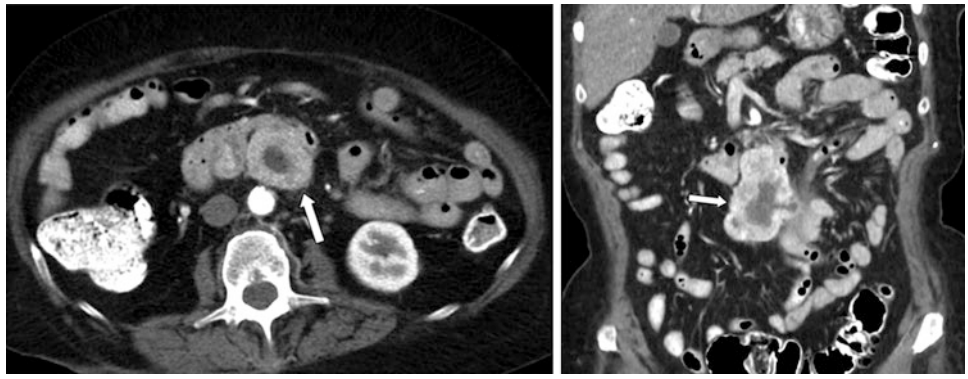

Fig. 9 On the left, axial image from a CT of the abdomen and pelvis with oral and intravenous contrast demonstrates a peripherally avidly enhancing, centrally necrotic mesenteric mass (*arrow*) associated with the small bowel that displaces the bowel anteriorly without causing obstruction. On the right, coronal reconstructed image from a CT of the abdomen and pelvis with oral and intravenous contrast demonstrates the full extent of the mesenteric mass (*arrow*) and its relationship with the adjacent small bowel

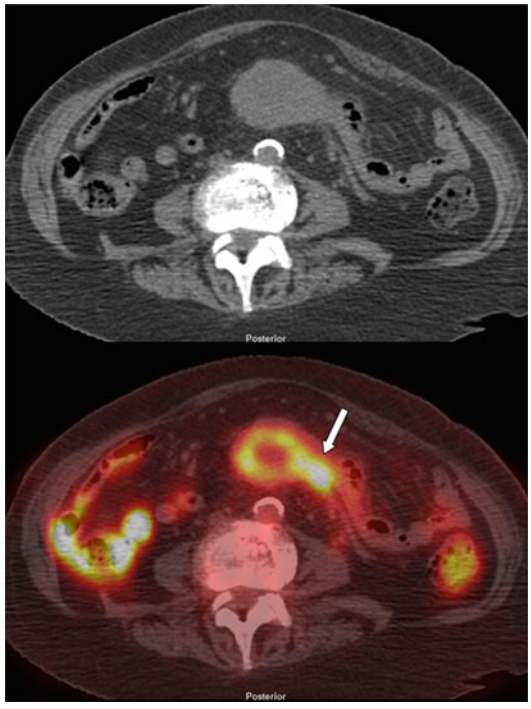

Fig. 10 Axial CT (*above*) and fused [^{18}F]FDG PET/CT (*below*) prior to therapy showing the peripherally [^{18}F]FDG-avid mesenteric mass with a more [^{18}F]FDG-avid focus along its left lateral aspect (*arrows*)

no change in peripheral [^{18}F]FDG uptake; however the left lateral intensely [^{18}F]FDG-avid focus has rapidly increased in size and [^{18}F]FDG uptake (SUV_{max} 10.5) and is also centrally necrotic (Figs. 11 and 12). Findings are consistent with disease progression on therapy.

Follow-Up

Due to lack of response to therapy, imatinib was discontinued, and the patient was scheduled for surgical resection.

Discussion

Gastrointestinal stromal tumors (GISTs) occur with an increased frequency in patients with neurofibromatosis type 1 (NF1). GISTs in this population are different from sporadic GISTs in many ways. Genetically, they are less likely to have a c-Kit mutation compared to sporadic GISTs. Since GISTs in the NF1 population do not typically have a c-Kit mutation, they proliferate independent of the c-Kit pathway, and therefore imatinib is not

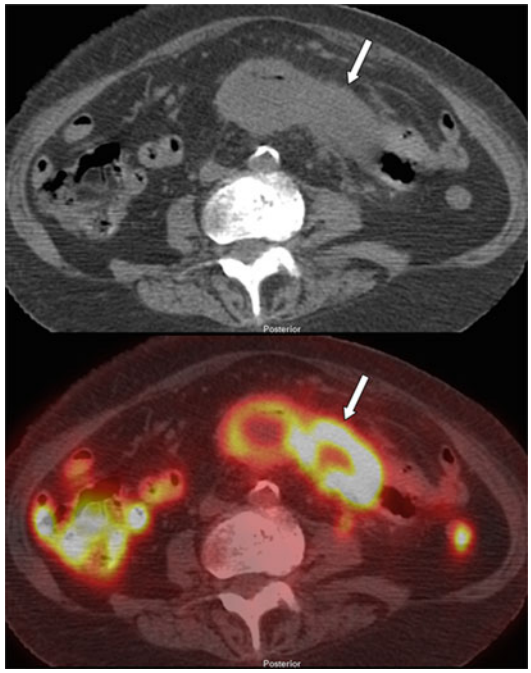

Fig. 11 Axial CT (*above*) and fused [^{18}F]FDG PET/CT (*below*) after therapy showing unchanged [^{18}F]FDG uptake and minimal increase in size of the original central mass; however the lateral more-intense [^{18}F]FDG-avid focus markedly increased in size and [^{18}F]FDG uptake (*arrows*) after 2 weeks on imatinib therapy

typically an effective therapy in these c-Kit-negative GIST cases. Additionally, GISTs in NF1 patients are more likely to be associated with the small bowel, as in this case, and there can be multiple separate GIST tumors in these patients.

Small Bowel Tumors: Case No. 6

Presentation

A 73-year-old man with suspected carcinoid syndrome and increased serotonin serum levels (1520 ng/mL) underwent a somatostatin receptor scintigraphy with Octreoscan®.

Findings

Scintigraphy showed a large area of increased uptake of ^{111}In-pentetreotide at the level of an intestinal loop of the small bowel, in the mesogastric region. This finding was consistent with the intestinal neuroendocrine lesion associated with perienteric and celiac lymphadenopathies (Fig. 13). Moreover, whole-body scan and SPECT/CT images disclosed an inferior left laterocervical lymphadenopathy with high expression of somatostatin receptors (Figs. 13 and 14).

The patient underwent resection of the small bowel loop, mesenteric lymphadenectomy, right hemicolectomy, and left laterocervical lymphadenectomy plus therapy with somatostatin analogues. Pathology confirmed the presence of a neuroendocrine tumor (grade II, atypical carcinoid) of the small bowel with mesenteric and laterocervical nodal involvement.

Follow-Up

After 8 months the patient began again to present clinical symptoms. He underwent a second somatostatin receptor scintigraphy with Octreoscan®.

Scintigraphy showed the persistence of an area of ^{111}In-pentetreotide uptake within a small bowel loop, in the same region of that seen in the first scan (Fig. 15). The findings were consistent with the persistence of disease.

Teaching Points

Somatostatin receptor scintigraphy is able to disclose neuroendocrine tumors that express somatostatin receptors of gastro-entero-pancreatic origin. As reported in this case, grade II tumors usually express somatostatin receptors and so they can be controlled by somatostatin analogue treatment. In this case scintigraphy was useful in the follow-up of the patient assessing the presence and the extension of the disease. SPECT/CT acquisitions increase the accuracy of scintigraphy by adding important anatomic information.

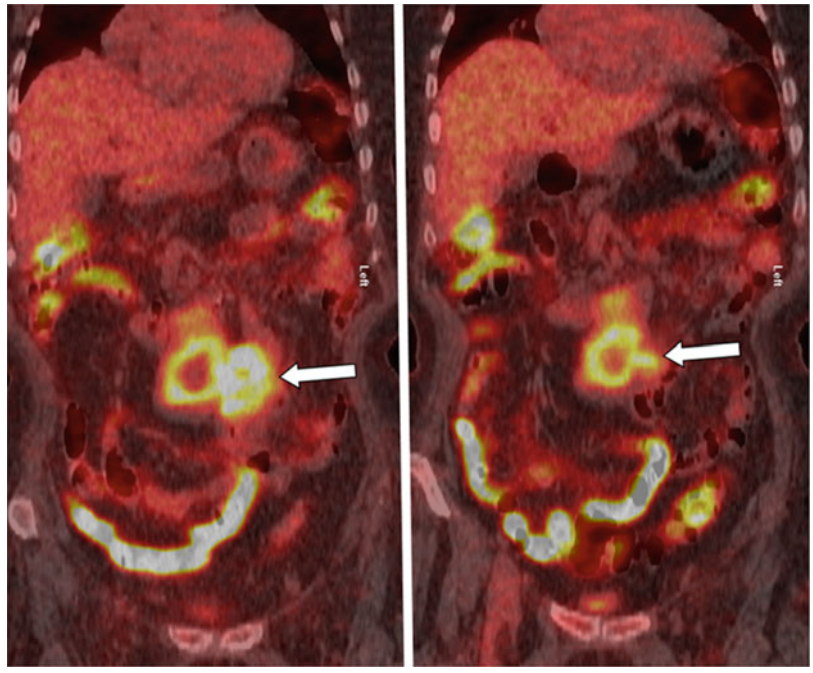

Fig. 12 Coronal fused [^{18}F]FDG PET/CT images after therapy (*left*) and before therapy (*right*). The full extent of the increase in size and [^{18}F]FDG uptake of the left lateral portion of the mass (*arrows*) is seen to better advantage in this side-by-side comparison. Findings are consistent with progression of disease on therapy

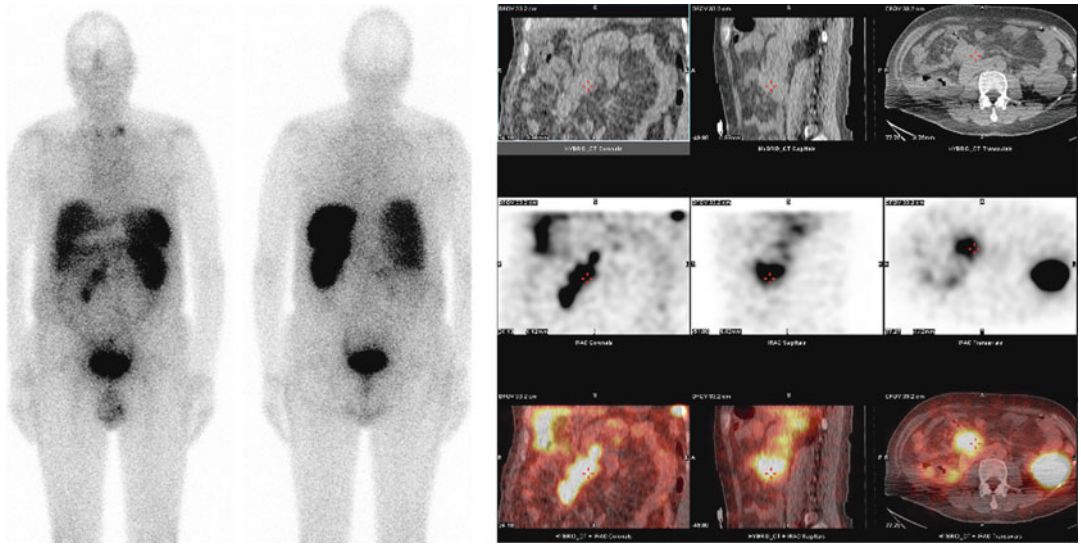

Fig. 13 Scintigraphy with ^{111}In-pentetreotide. Whole-body images on the left and axial, coronal, and sagittal SPECT/CT slices show a large area of increased tracer uptake within an intestinal loop of the small bowel, in the mesogastric region, consistent with an intestinal neuroendocrine lesion associated with perienteric and celiac lymphadenopathies

Fig. 14 Scintigraphy with ^{111}In-pentetreotide. Axial SPECT/CT slices show an inferior left laterocervical lymphadenopathy with high tracer uptake detectable also on the whole-body images

Small Bowel Tumors: Case No. 7

Presentation

A 75-year-old man with small bowel neuroendocrine tumor with a liver metastasis treated surgically (resection of the small bowel and liver nodule). Currently in treatment with octreotide but with progressive disease.

Findings

The patient underwent a PET/CT with ^{18}F-DOPA that showed multiple metastases with pathological hyperactivity within both liver lobes, the most evident located in the VI/VII segment and IV segment, respectively. Moreover, it was also clearly detectable in a tissue thickening with highly ^{18}F-DOPA avid in the small intestine, at the site of the previous surgery level. At last, multiple hyperactive lymphadenopathies were also found in several sites of the abdomen (celiac, mesenteric, portocaval, retrocrural, and subphrenic) and in the mediastinum (paraesophageal site) (Fig. 16).

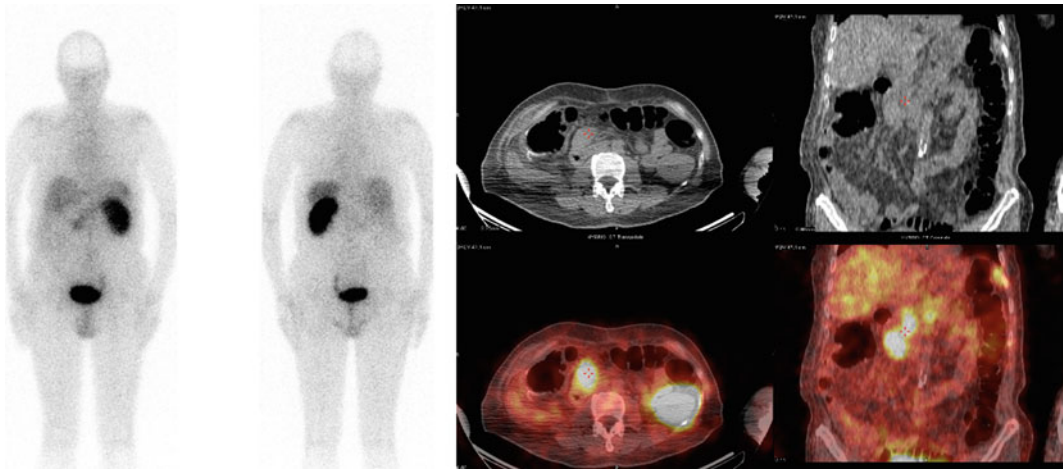

Fig. 15 Follow-up scintigraphy with ^{111}In-pentetreotide showing the persistence of an area of tracer uptake within a small bowel loop, in the same region of that seen in the first scan

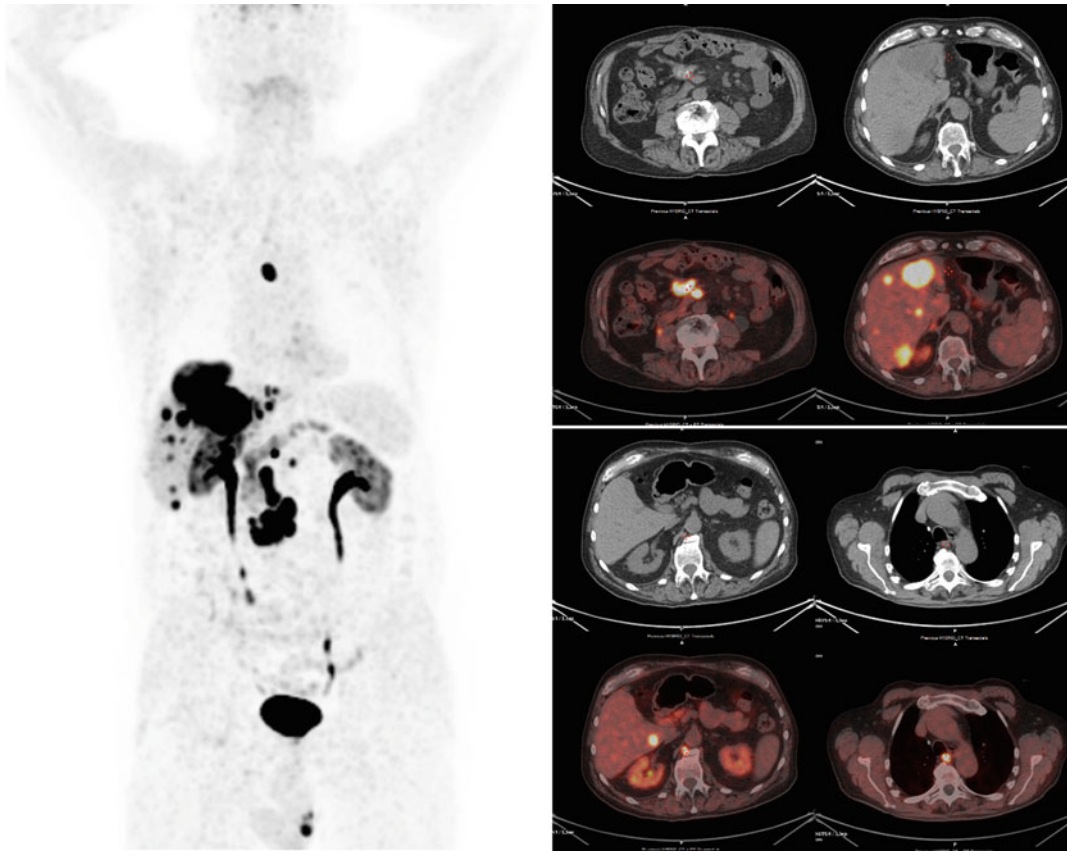

Fig. 16 PET/CT with ^{18}F-DOPA. MIP and PET/CT axial slices show multiple metastases with ^{18}F-DOPA hyperactivity within both liver lobes (the most evident located in the VI/VII segment and IV segment). A clearly detectable ^{18}F-DOPA-avid tissue thickening can be seen in the small intestine, at the site of the previous surgery level. Multiple hyperactive lymphadenopathies can be observed in several sites of the abdomen and in the mediastinum

Follow-Up

The patient was then started to a new therapy with lanreotide (1 I.M. administration/14 days).

After 6 months the patient repeated a PET/CT with ^{18}F-DOPA. PET/CT scan revealed substantial stability of the multiple liver metastases (slight increase of the largest lesions), of the small bowel lesion, and of the abdominal and paraesophageal lymphadenopathies (Fig. 17).

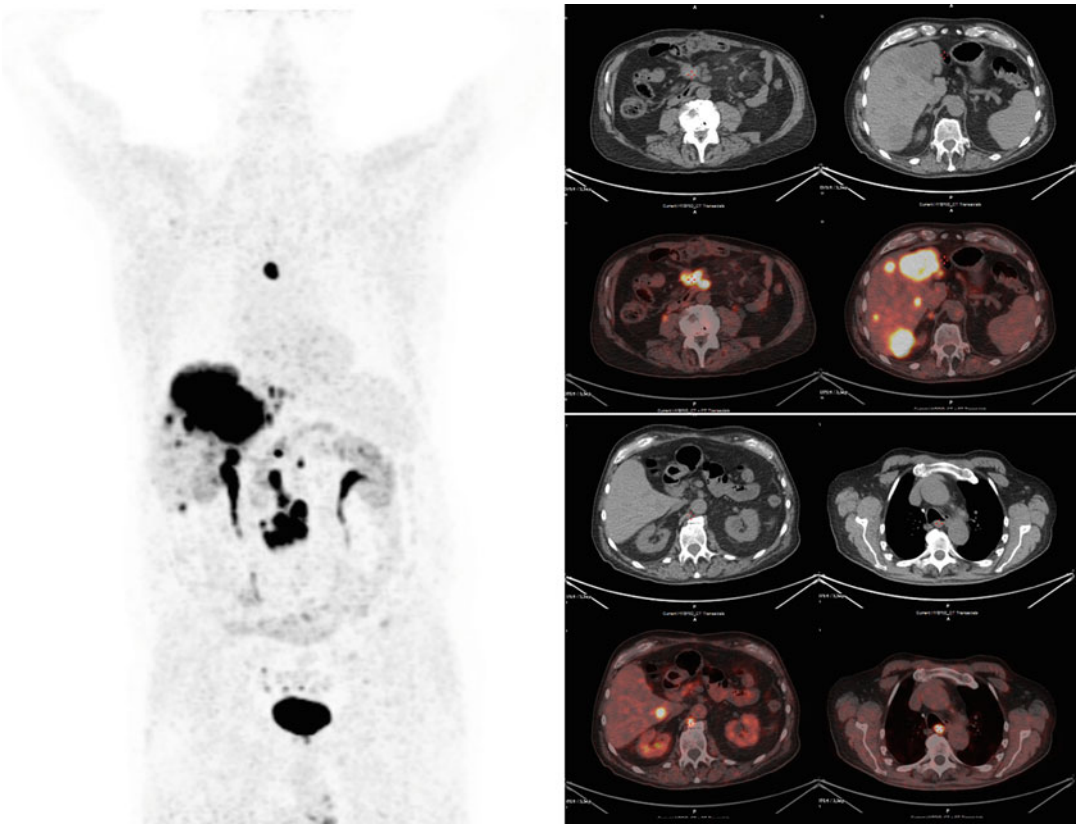

Fig 17 PET/CT scan revealed substantial stability of the multiple liver metastases except for a slight increase of the largest lesions. Substantially unchanged also the small bowel lesion and the abdominal and mediastinic lymphadenopathies

Teaching Point

PET/CT with ^{18}F-DOPA, not as a first option, can be used in the evaluation of gastro-entero-pancreatic neuroendocrine tumors with negative or inconclusive findings at conventional radiological imaging and somatostatin receptor imaging. ^{18}F-DOPA findings in this case played a major role in the management and in the follow-up of the patient.

Hepatocellular Carcinoma: Case No. 1

Case contributed by: L. Olivari, A. Chiti
Division of Nuclear Medicine, Department of Biomedical Sciences – Humanitas University, Milan, Italy.

Presentation

A 77-year-old man presented at our hospital after hemoptysis, mild serotine fever, and fatigue. Bronchoscopy was negative. Ultrasonography (US) of the abdomen demonstrated a large liver lesion, while a subsequent MRI demonstrated a 20 cm liver lesion with nonunique features, occupying the posterior area (Fig. 1). No relevant abnormalities were found at EGDS. The tumor-associated markers CEA and AFP were negative, and there was no history of alcohol abuse. HCV and HBV serology was negative. The patient had had cholecystectomy for gallstones 10 years earlier, at which time US of the abdomen was negative for liver lesions. A prior total body CT demonstrated a 10 cm liver lesion described as a hemangioma.

Findings

[^{18}F]FDG PET/CT showed a large, partially necrotic hepatic lesion (Fig. 1). Some small lung nodules observed in the CT portion of the scan exhibited no uptake, most likely because of their small size. [^{11}C]Methionine PET/CT demonstrated a large hepatic lesion characterized by nonhomogeneous increased uptake. The hepatic lesion features were compatible with hepatocellular carcinoma (HCC). While no uptake was found in the small lung nodules, there was increased uptake of [^{11}C]methionine in the right cardiac ventricle. Further evaluation with cardiac US and MRI was then performed.

Cardiac MRI demonstrated that the abnormally increased uptake observed in the [^{11}C]methionine PET/CT scan was a cardiac localization of the hepatic disease (Fig. 2).

Follow-Up

Fine needle biopsy of the hepatic lesion confirmed the clinical suspicion of HCC, and the patient started sorafenib treatment.

Teaching Point

[^{11}C]Methionine promises to be useful for PET imaging of HCC. In this patient [^{11}C]Methionine

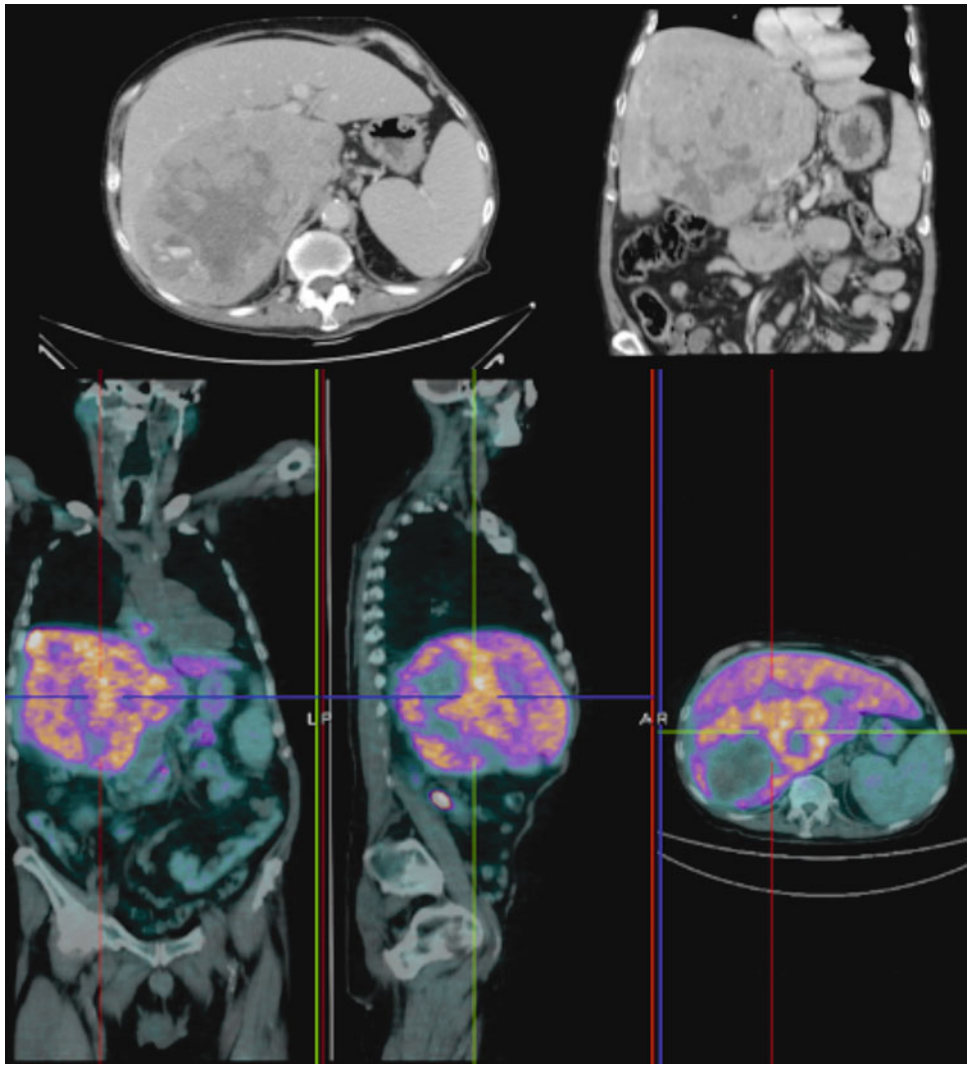

Fig. 1 Magnetic resonance imaging (*MRI*): (*top*) large liver lesion, consistent with HCC. [^{18}F]FDG PET/CT: (*bottom*) heterogeneously increased uptake in the lesion

PET/CT was also of paramount importance for disclosing an unusual site on metastasis in the myocardium.

Hepatocellular Carcinoma: Case No. 2

Case contributed by: ***H.A. Jacene***
Nuclear Medicine/PET-CT, ***Dana-Farber Cancer Institute***, ***Harvard Medical School***, ***Boston***, ***Massachusetts***, ***USA***.

Presentation

An 82-year-old man with newly diagnosed hepatocellular carcinoma (HCC) with questioned abnormalities identified in the left adrenal gland and lumbar spine on recent liver MRI. [^{18}F]FDG PET/CT was performed for further evaluation of these extrahepatic abnormalities.

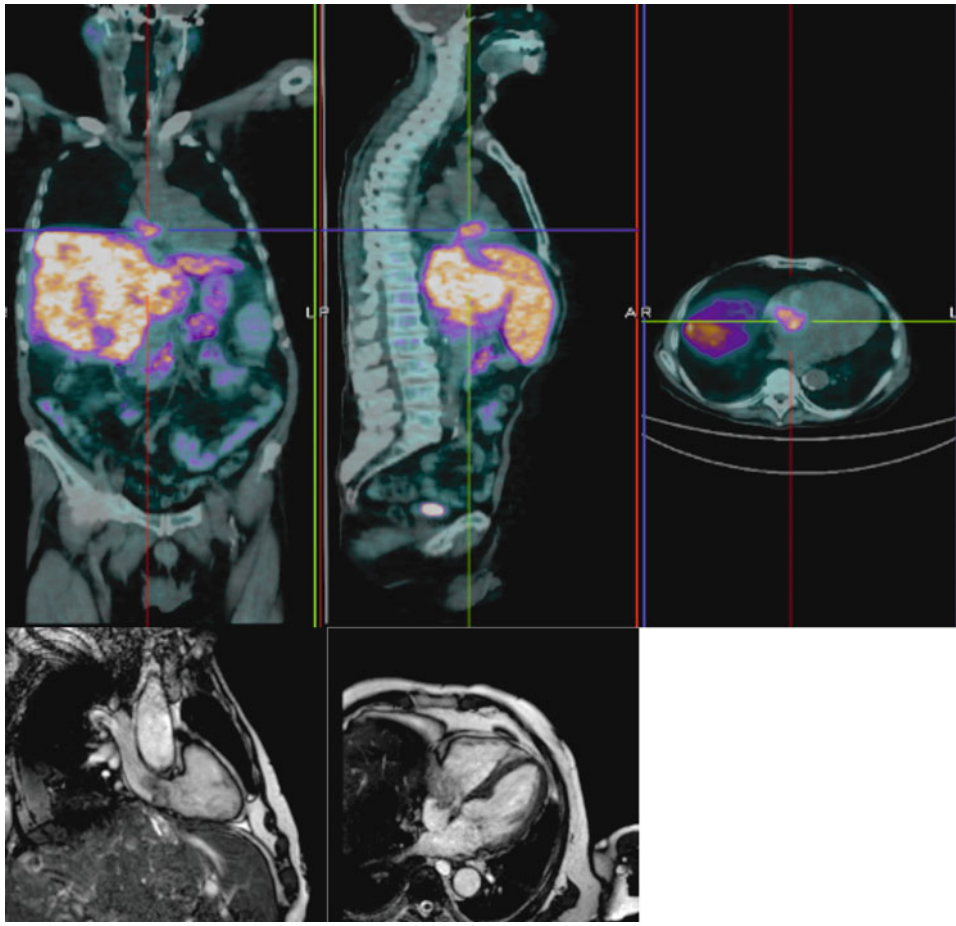

Fig. 2 [^{18}F]FDG PET/CT: (*top*) increased uptake in the myocardium. Magnetic resonance imaging (*MRI*) (*bottom*) confirmed the pathologic lesion shown in the PET/CT scan as a metastatic lesion from HCC

Findings

Subtle increased heterogeneous [^{18}F]FDG uptake is seen in the hepatic dome on the PET maximum intensity projection image (Fig. 3). Otherwise, the liver and the remainder of the PET appear unremarkable (Fig. 4).

MR images demonstrate a 20 cm heterogeneous mass with diffuse mild T2 hyperintensity (Fig. 5) and more focal rounded areas of more intense T2 signal. These foci of more intense T2 signal also have high intrinsic T1 signal and are nonenhancing, consistent with areas of necrosis/cystic degeneration. Internal proteinaceous material or hemorrhage is the likely etiology of the intrinsic high T1 signal. The mass also demonstrates arterial phase hyperenhancement (Fig. 5), contrast washout relative to the background liver on a delayed post-contrast image, and hepatobiliary phase hypointensity on a further delayed post-contrast image (Figs. 6 and 7). All of these MRI findings are characteristic of HCC.

Coronal CT and fused PET/CT images (Fig. 8) demonstrate the full extent of this large HCC with very little abnormality identified on PET. Additionally, no PET abnormalities were identified in the adrenal gland and lumbar spine, thought likely to reflect adrenal hyperplasia and degenerative changes.

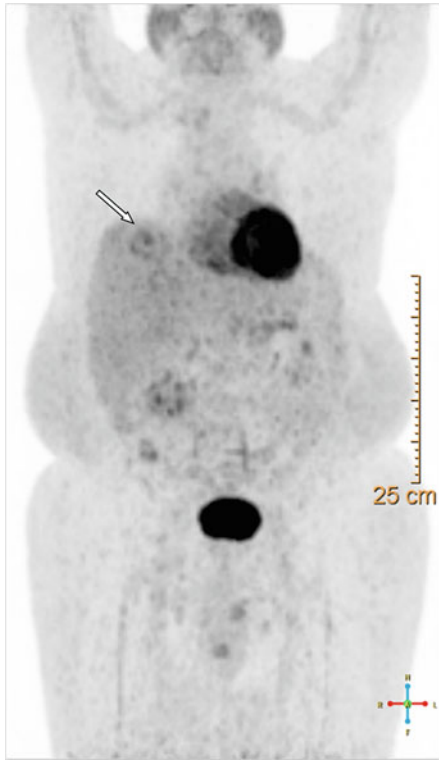

Fig. 3 PET MIP image viewed anteriorly demonstrates mild increased [^{18}F]FDG uptake in the hepatic dome (*arrow*)

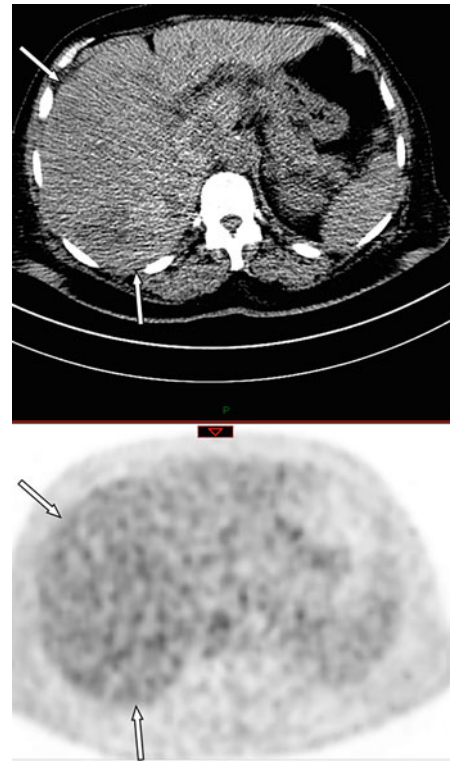

Fig. 4 Axial CT (*above*) and axial PET (*below*). CT shows heterogeneous attenuation in the right lobe of the liver (*arrows*); however, the PET shows [^{18}F]FDG uptake virtually identical to background liver parenchyma in the same area (*arrows*)

Teaching Point

Variable [^{18}F]FDG uptake has been reported in HCC resulting in variable reported sensitivities for detection of this tumor by PET/CT. The variable [^{18}F]FDG uptake is thought to be due to different glucose transporters present in the liver and HCC as well as increased levels of phosphatase activity, which prevent [^{18}F]FDG from being trapped in the cells. The effect is more prominent in well-differentiated compared to poorly differentiated HCC. This case demonstrates this variable uptake – an example of nearly identical [^{18}F]FDG uptake compared to adjacent background liver except for a small area of heterogeneity in the hepatic dome. This small amount of increased uptake in the hepatic dome may reflect a focal area

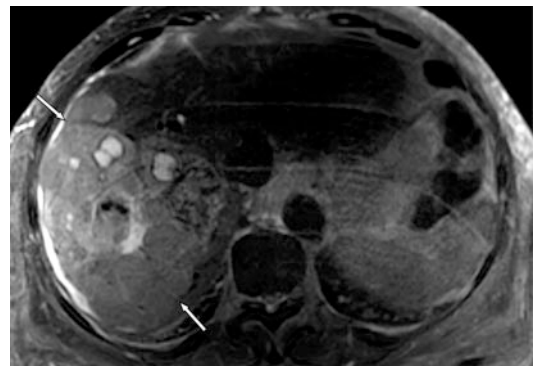

Fig. 5 Axial T2 FSE demonstrates heterogeneous mild increased signal intensity compared to adjacent background liver throughout the mass (*arrows*) with some focal rounded areas of higher intensity signal that represent areas of necrosis/cystic degeneration

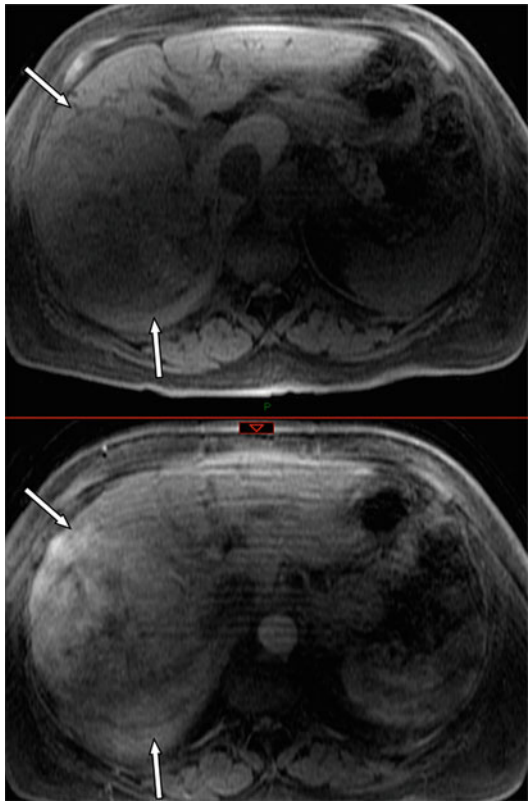

Fig. 6 Axial T1 LAVA pre-contrast (*above*) and arterial phase post-contrast (*below*). Prior to the administration of contrast, the area of the mass (*arrows*) is shown to be hypointense compared to adjacent background liver parenchyma and demonstrates arterial phase hyperenhancement compared to background liver on the post-contrast image

of higher grade of tumor, noted to be adjacent to the areas of focal necrosis within the tumor.

Cholangiocarcinoma: Case No. 1

Presentation

A 76-year-old woman with history of cholangiocarcinoma treated with right hepatectomy and cholecystectomy and adjuvant chemotherapy.

Findings

[^{18}F]FDG PET/CT was performed to assess the presence of residual liver disease and for global

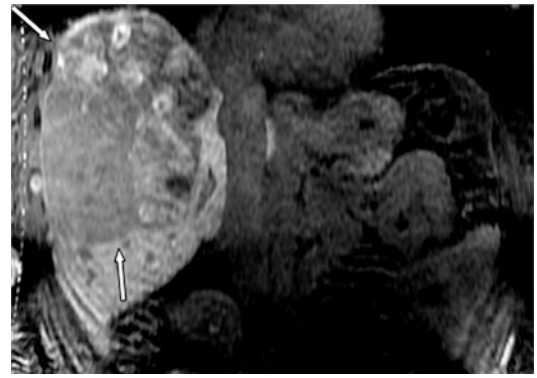

Fig. 7 Coronal T1 LAVA 17 min post-contrast (gadoxetate disodium contrast). On delayed hepatobiliary phase post-contrast imaging. The large mass (*arrows*) is hypointense relative to the adjacent background liver. Areas of intrinsic high T1 signal are noted in rounded areas of necrosis/cystic degeneration

restaging. PET/CT disclosed moderate [^{18}F]FDG uptake within two metastases in the III and IV segment of the liver (Fig. 9). Then the patient underwent second-line chemotherapy and a new [^{18}F]FDG PET/CT scan was repeated to evaluate the efficacy during treatment. [^{18}F]FDG uptake in the liver lesion was increased with respect to baseline (without significant reduction in size), thus demonstrating poor response to chemotherapy (Fig. 10).

Follow-Up

One month later new multiple secondary lesions were found in the liver parenchyma. The patient was then submitted to digital subtraction angiography (DSA) in order to evaluate the patient as a possible candidate to radioembolization therapy with ^{90}Y-microspheres. Nevertheless, at DSA the arteries afferent to lesions were found to be thin, twisted, and with a marked spasmophilia; radioembolization with ^{90}Y-microspheres was therefore deemed not to be technically feasible. The patient was subsequently started on a hypofractionated radiotherapic treatment of the liver lesions.

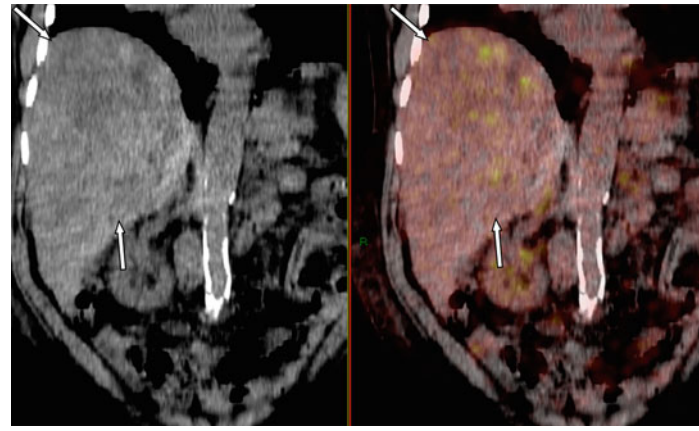

Fig. 8 Coronal CT (*left*) and fused PET/CT (*right*). Heterogeneous attenuation in the right lobe of the liver on CT (*arrows*) with the large tumor almost non-identifiable on PET aside from a few small areas of focal increased tracer uptake in the superior portion of this mass

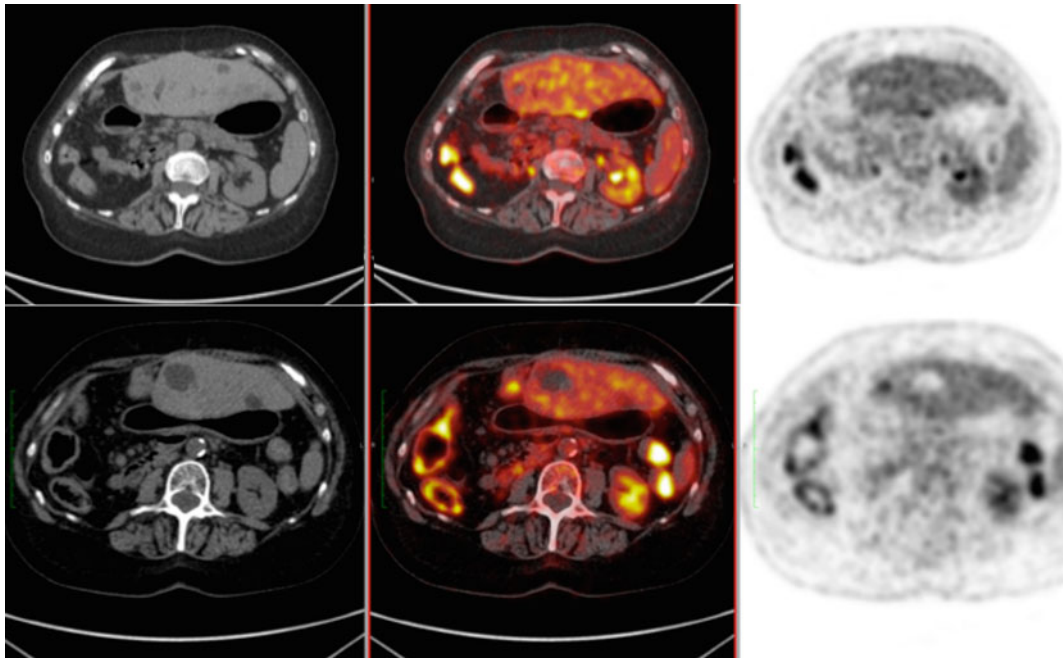

Fig. 9 Axial CT (*left*), fused PET/CT (*middle*), and PET (*right*) slices. Two small focal areas of increased [^{18}F]FDG activity are located in III and IV segment. On CT multiple low-density areas corresponding to cystic lesions in the left and right liver lobe

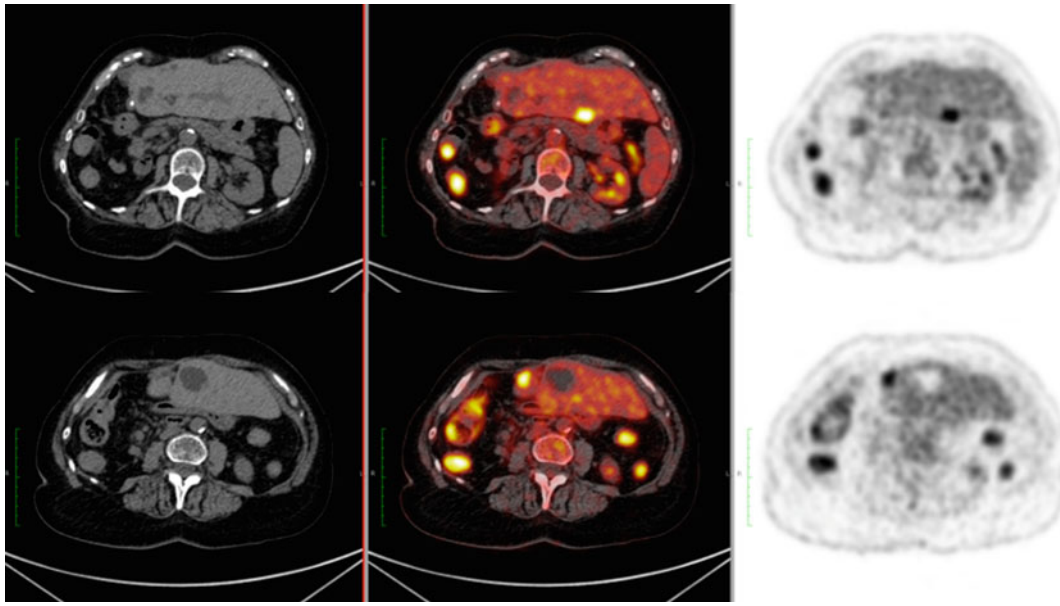

Fig. 10 [^{18}F]FDG PET/CT during chemotherapy. Axial CT (*left*), fused PET/CT (*middle*), and PET (*right*) slices showing increased uptake of the liver lesions and indicating a bad response of the ongoing treatment

Teaching Point

This case confirms the value of serial [^{18}F]FDG PET/CT scans in treatment monitoring of patients with metastatic cholangiocarcinoma.

Cholangiocarcinoma: Case No. 2

Presentation

A 65-year-old male patient was referred to the department of nuclear medicine for an [^{18}F]FDG PET/CT after chest X-ray, and CT had revealed a 18 × 16 mm nodule within the lower lobe of the left lung (Fig. 11).

Findings

PET/CT showed intense [^{18}F]FDG uptake (SUV_{max} 4.9) within the left lung nodule. Moreover, the whole body scan disclosed a focal area of hyperactivity >3 cm at the level of the IV/VIII hepatic segment. In addition, multiple hypermetabolic lymph nodes were located at the retrocrural, celiac, and lombo-aortic sites. Finally, multiple lytic bone lesions with increased [^{18}F]FDG uptake were disclosed within the scapula, sternum, and pelvis (Fig. 12).

Follow-Up

The patient underwent a biopsy of a hypermetabolic lytic lesion of the right ileum, which proved to be metastasis from cholangiocarcinoma.

Teaching Point

It is known that [^{18}F]FDG PET/CT is an effective tool for disclosing unknown primary tumors. Moreover, PET/CT-guided biopsy enables to achieve in this patient a final diagnosis of advanced primary cholangiocarcinoma with lymph node involvement and multiple metastatic lesions (T3N2M1, stage IV).

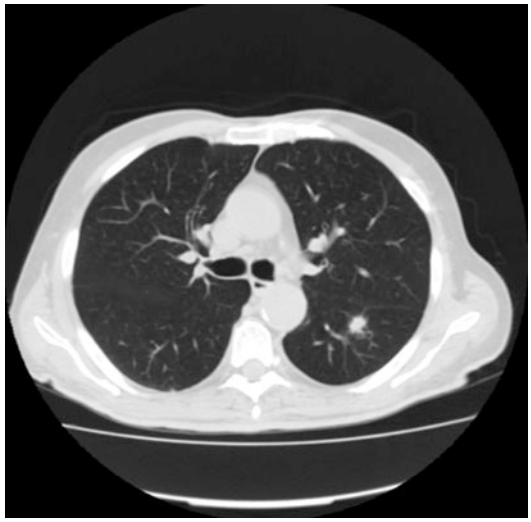

Fig. 11 Axial CT: suspicious *round-shaped* nodule in the left lower lobe

Cholangiocarcinoma: Case No. 3

Presentation

A 71-year-old man developed itching and jaundice 2 months ago.

Findings

CT scan revealed intrahepatic bile duct dilatation and a lesion in the tail of the pancreas measuring 5 × 3 cm. ERCP confirmed stricture of the common bile duct with intrahepatic dilatation that was treated with stent placement. The probable diagnosis was Klatskin tumor, but a benign lesion or a sclerosing cholangitis could not be excluded.

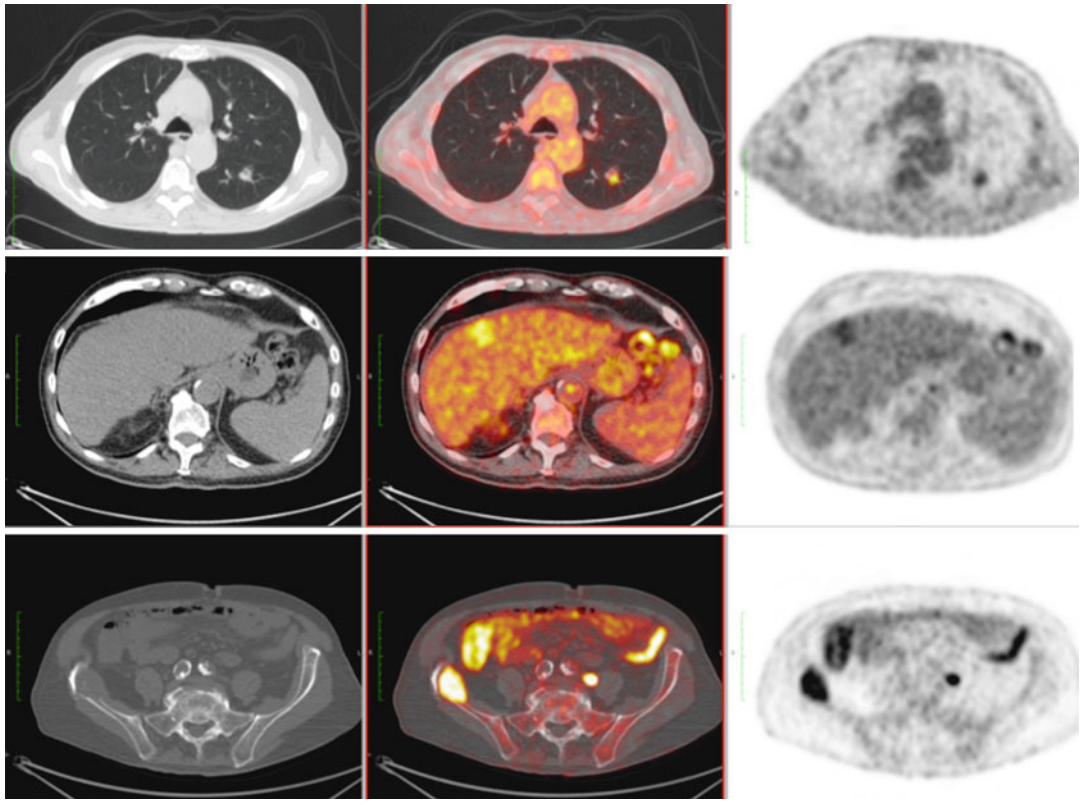

Fig. 12 Axial CT (*left*), fused PET/CT (*middle*), and PET (*right*) slices. (*Top row*) Images show an increased [^{18}F] FDG uptake within the left lung nodule. (*Middle row*) Axial slices reveal a focal area of increased metabolic activity located in the IV segment of the liver. (*Bottom row*) Area of markedly increased hyperactivity in the right iliac bone characterized by bone disruption on CT

[^{18}F]FDG PET/CT scan was performed (Fig. 13). PET/CT shows focal [^{18}F]FDG uptake at the portal vein bifurcation (SUV_{max} 5) with extension of metabolic activity in right lobe of the liver (Fig. 14). Focal [^{18}F]FDG uptake is seen at the tip of the stent due to inflammation. Multiple anterior and posterior peripancreatic hypermetabolic lymph nodes are shown. Several mesenteric foci of [^{18}F]FDG uptake are demonstrated in splenic flexure, pararenal fascia, and pelvis (Fig. 15).

Follow-Up

Surgical therapy included hepatic trisegmentectomy and cholecystectomy. Histology confirmed cholangiocarcinoma and chronic inflammation of the pancreas. This case demonstrates the value of [^{18}F]FDG PET/CT in pretreatment staging of cholangiocarcinoma, despite the possible confounding factor represented by coexistent pancreatitis.

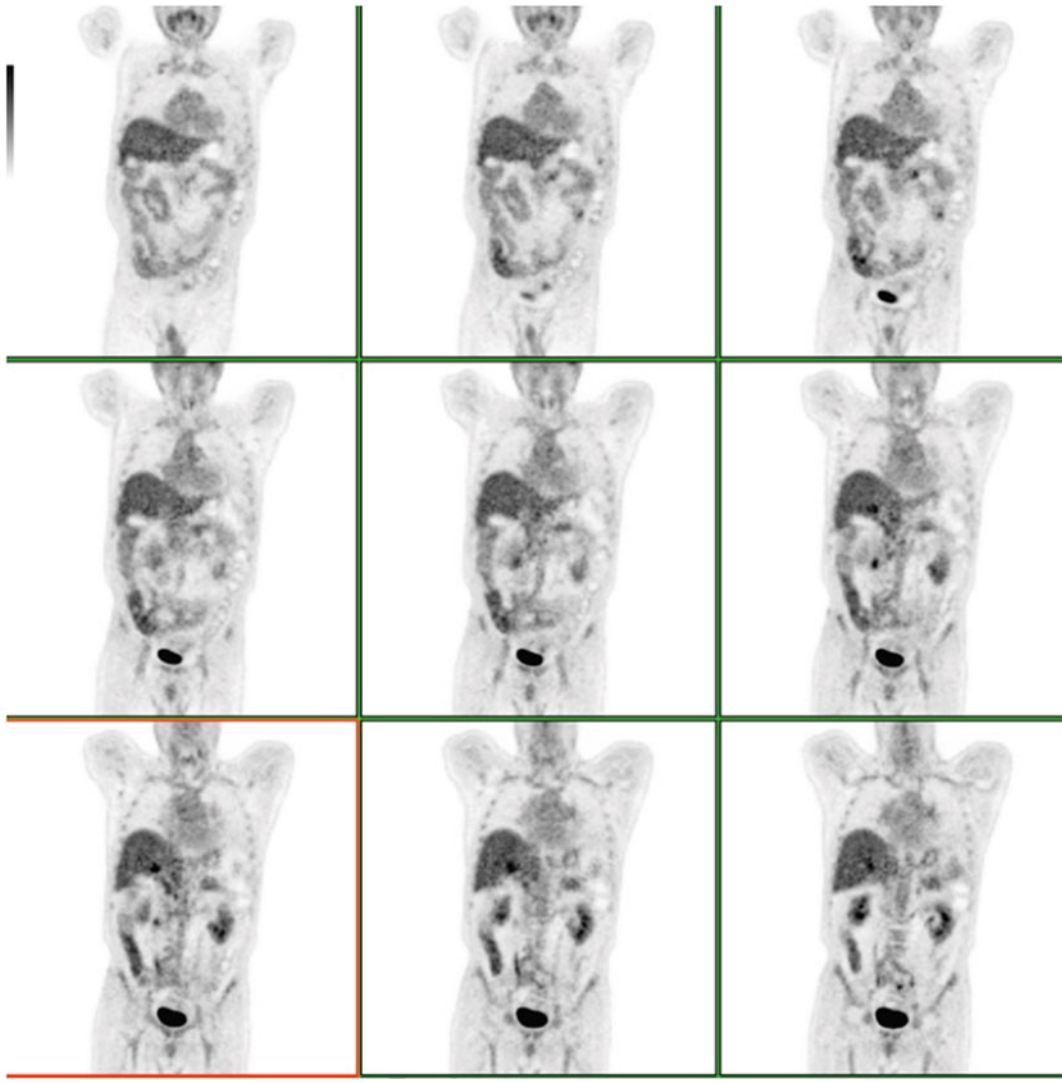

Fig. 13 [^{18}F]FDG PET coronal images demonstrate focal uptake in the hepatic hilum

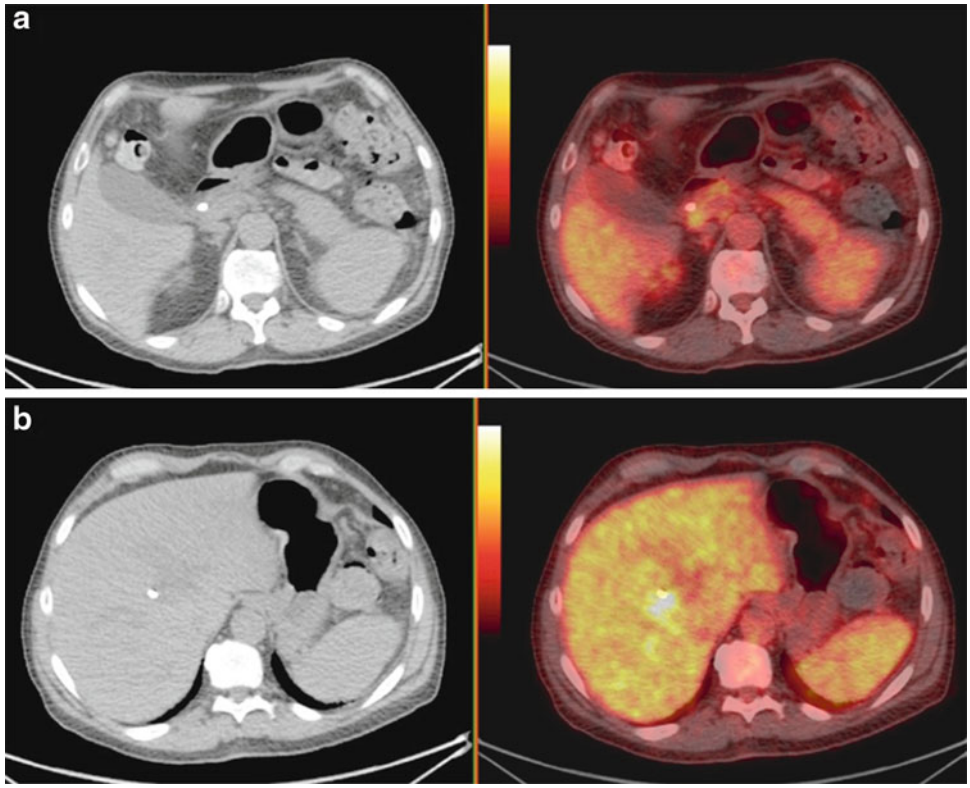

Fig. 14 PET/CT images at two levels (CT *left*, fused PET/CT *right*). (**a**) Diffuse uptake in pancreatic tail without evidence of focal activity corresponding to the lesion revealed on CT. (**b**) [^{18}F]FDG uptake at the tip of the stent due to inflammation

Liver Metastasis from Colorectal Cancer: Case No. 1

Presentation

A 41-year-old man with transverse colon cancer and multiple liver metastases already submitted to surgery (3 months earlier followed by adjuvant chemotherapy).

Findings

[^{18}F]FDG PET/CT scan for restaging confirmed the persistence of the already known multiple irregular hepatic lesions which demonstrate intense [^{18}F]FDG uptake, with a doughnut-like pattern (Fig. 16).

Follow-Up

The patient underwent digital DSA in order to evaluate the possibility of transarterial radioembolization therapy with ^{90}Y-microspheres. DSA showed a regular course of the hepatic arteries and transarterial injection of ^{99m}Tc-MAA showed good perfusion of the metastatic lesions. The lung shunt fraction was low (4%) and no splanchnic or nontarget flow was observed (Fig. 17). Two weeks later, the patient underwent a two-stage procedure of transarterial radioembolization, first on the right and subsequently (after another 3 weeks) on the left liver lobe (Fig. 18). Dosimetric estimates predicted an administered activity of 0.86 GBq of ^{90}Y-microspheres to the left and 0.57 GBq to the right liver lobe. Treatment was well tolerated without any complications.

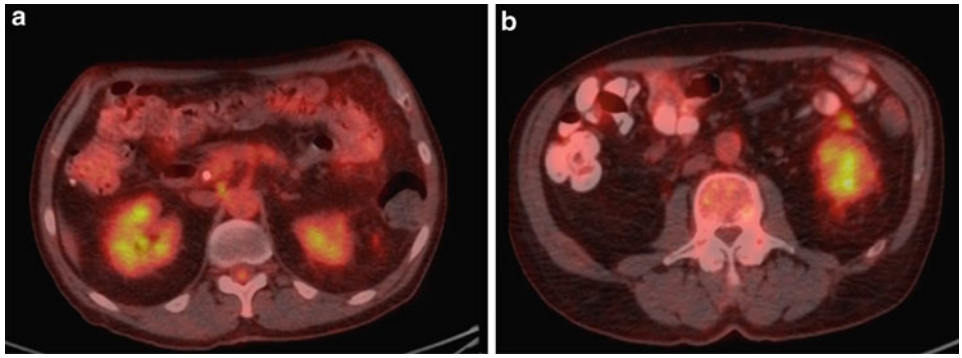

Fig. 15 PET/CT images. (**a**) Peripancreatic hypermetabolic lymphadenopathy. (**b**) Hypermetabolic mesenteric lymph nodes of the pararenal fascia

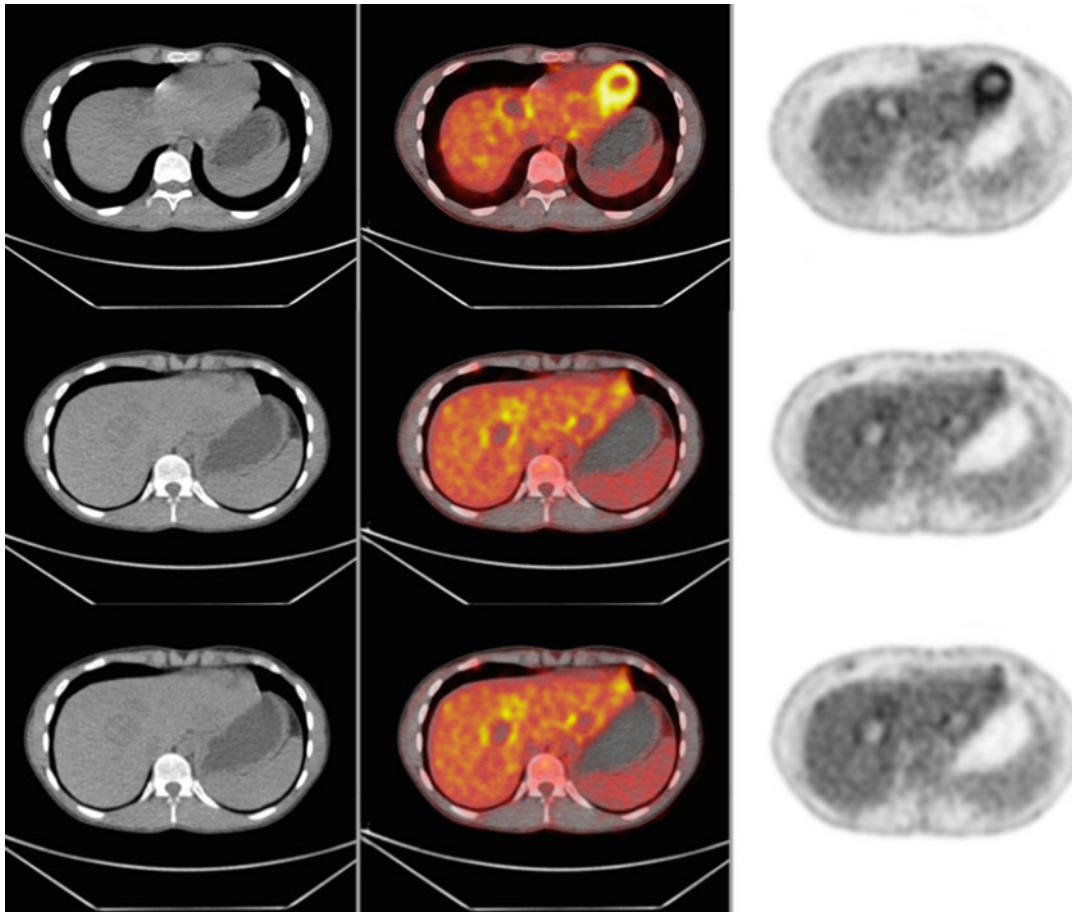

Fig. 16 [^{18}F]FDG PET/CT. Axial CT (*left panels*), fused PET/CT (*middle panels*), and PET alone (*right panels*) The lesions within the right and left lobe result hypodense, with central necrosis, areas of sclerosis, and with a [^{18}F]FDG uptake at the rim

[^{18}F]FDG PET/CT performed 6 months after therapy showed excellent objective response to transarterial radioembolization with ^{90}Y-microspheres (Fig. 19).

Teaching Point

The role of radioembolization of liver tumors is highly promising. This treatment has been shown to be safe and effective also in patients with

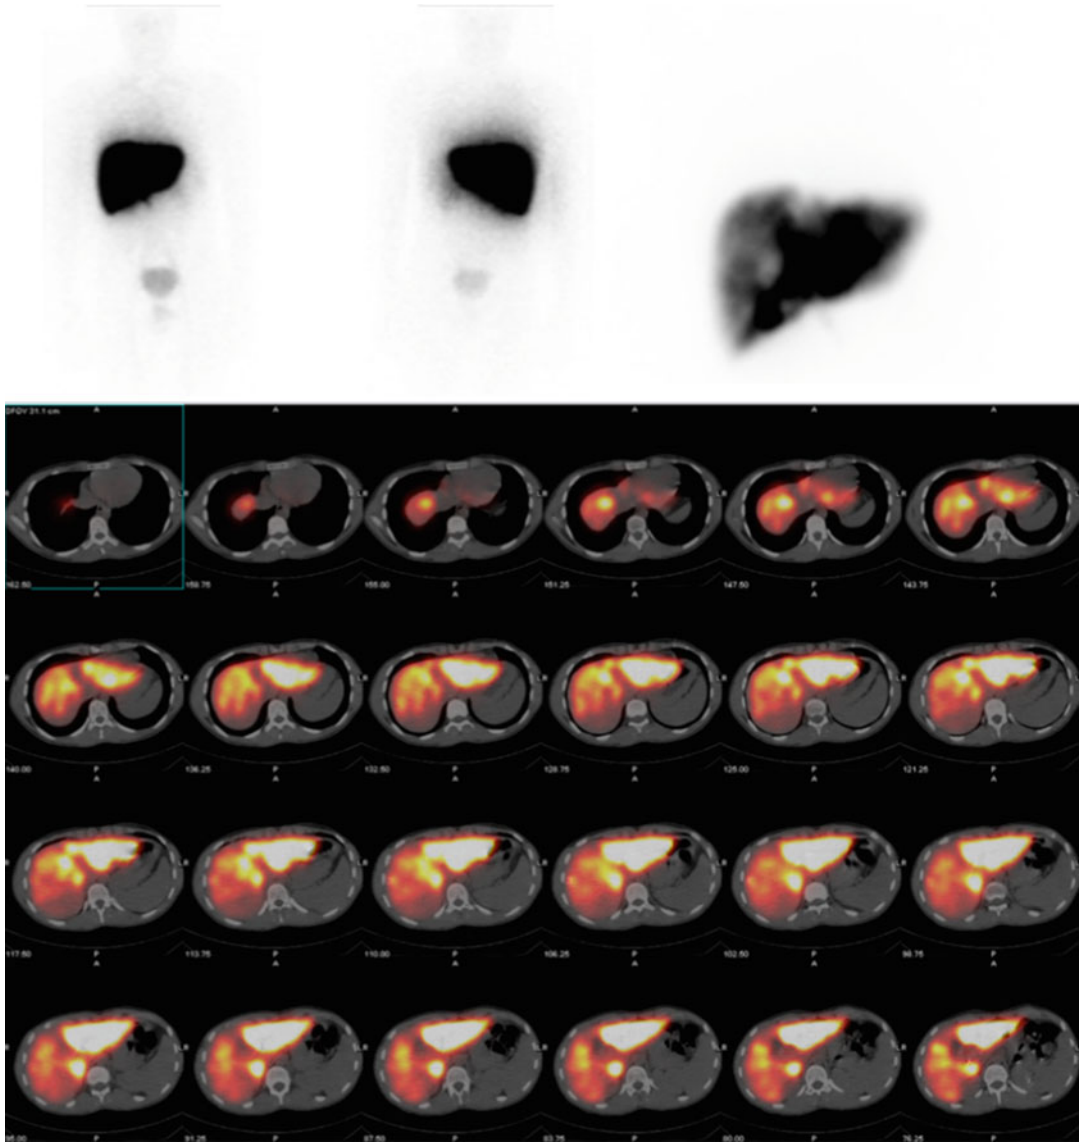

Fig. 17 Whole-body, planar, and SPECT/CT imaging after transarterial injection of ^{99m}Tc-MAA. On *top panel*, whole body and static imaging showing a normal distribution of the radiotracer with a high accumulation of the radiotracer in the liver and low activity in the lung. The lung shunt fraction was 4%. On *bottom panel*, fused SPECT/CT axial slices assessing the distribution of ^{99m}Tc-MAA in the both lobes of the liver, without the evidence of any gastrointestinal shunts

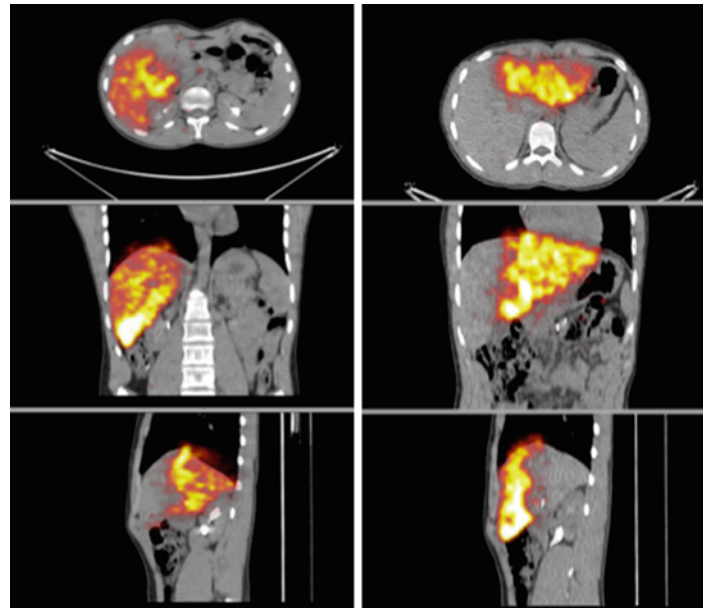

Fig. 18 Posttreatment PET/CT imaging based on the positron emission of ^{90}Y, confirming localization of the ^{90}Y-microspheres in the right lobe (*left panels*) and in left lobe (*right panels*)

metastatic liver tumors from a variety of primary tumors. Pretreatment angiography is an important step before the procedure of radioembolization; meticulous mapping of the vascular anatomy helps the interventional radiologist, when performing the procedure, to identify the vascular supply of the tumor and to identify and coil-embolize vessels that may lead to aberrant deposition of ^{90}Y-microspheres. To this purpose, an important role is played by imaging protocols implementing the use of SPECT/CT acquisition during evaluation of perfusion with ^{99m}Tc-MAA. [^{18}F]FDG PET/CT can be an important tool for treatment monitoring of transarterial radioembolization.

Liver Metastasis from Colorectal Cancer: Case No. 2

Presentation

Sixty-five-year-old man with rectal cancer undergoing initial staging assessment.

Findings

The [^{18}F]FDG PET/CT scan performed for initial staging confirmed the presence of an [^{18}F]FDG-avid rectal cancer. Moreover, PET/CT showed increased tracer uptake in a left parasacral lymph node and multiple doughnut-like lesions with intense [^{18}F]FDG uptake in the liver (Fig. 20).

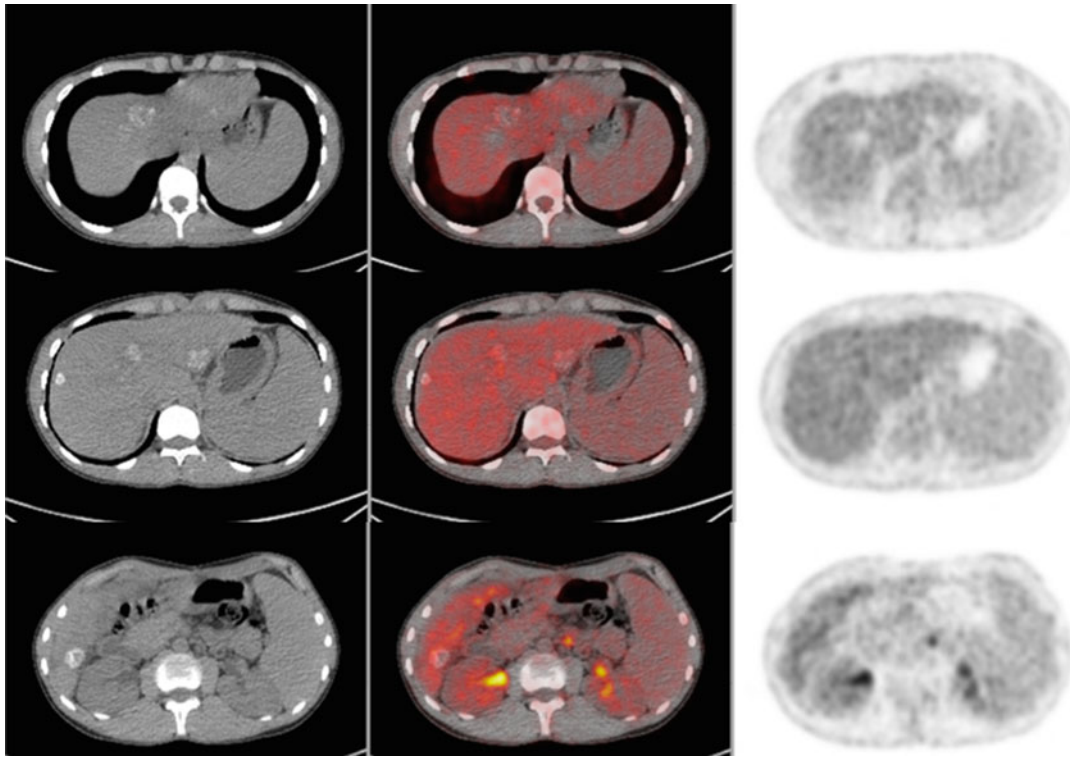

Fig. 19 [^{18}F]FDG PET/CT. Axial TC (*left panels*), fused PET/CT (*middle panels*), and PET alone (*right panels*) showing a clear metabolic response of the liver metastases treated with radioembolization

Follow-Up

One week later, the patient underwent MRI with paramagnetic contrast (Gd-EOB-DTPA) that confirmed the presence of multiple liver metastases. In particular, the MRI scan showed on the arterial phase, and a thin rim of hyperintensity was observed at the edge of the lesion in the arterial phase, which turned hypointense in the portal-venous phase. This pattern is typical of hypovascular metastases (Fig. 21).

Management

Since the patient presented with stage IV disease with multiple liver metastases, neoadjuvant chemotherapy was chosen as first treatment strategy.

Teaching Point

In patients with rectal cancer, accurate staging is of paramount importance, and it is essential also to correctly detect liver metastases in order to

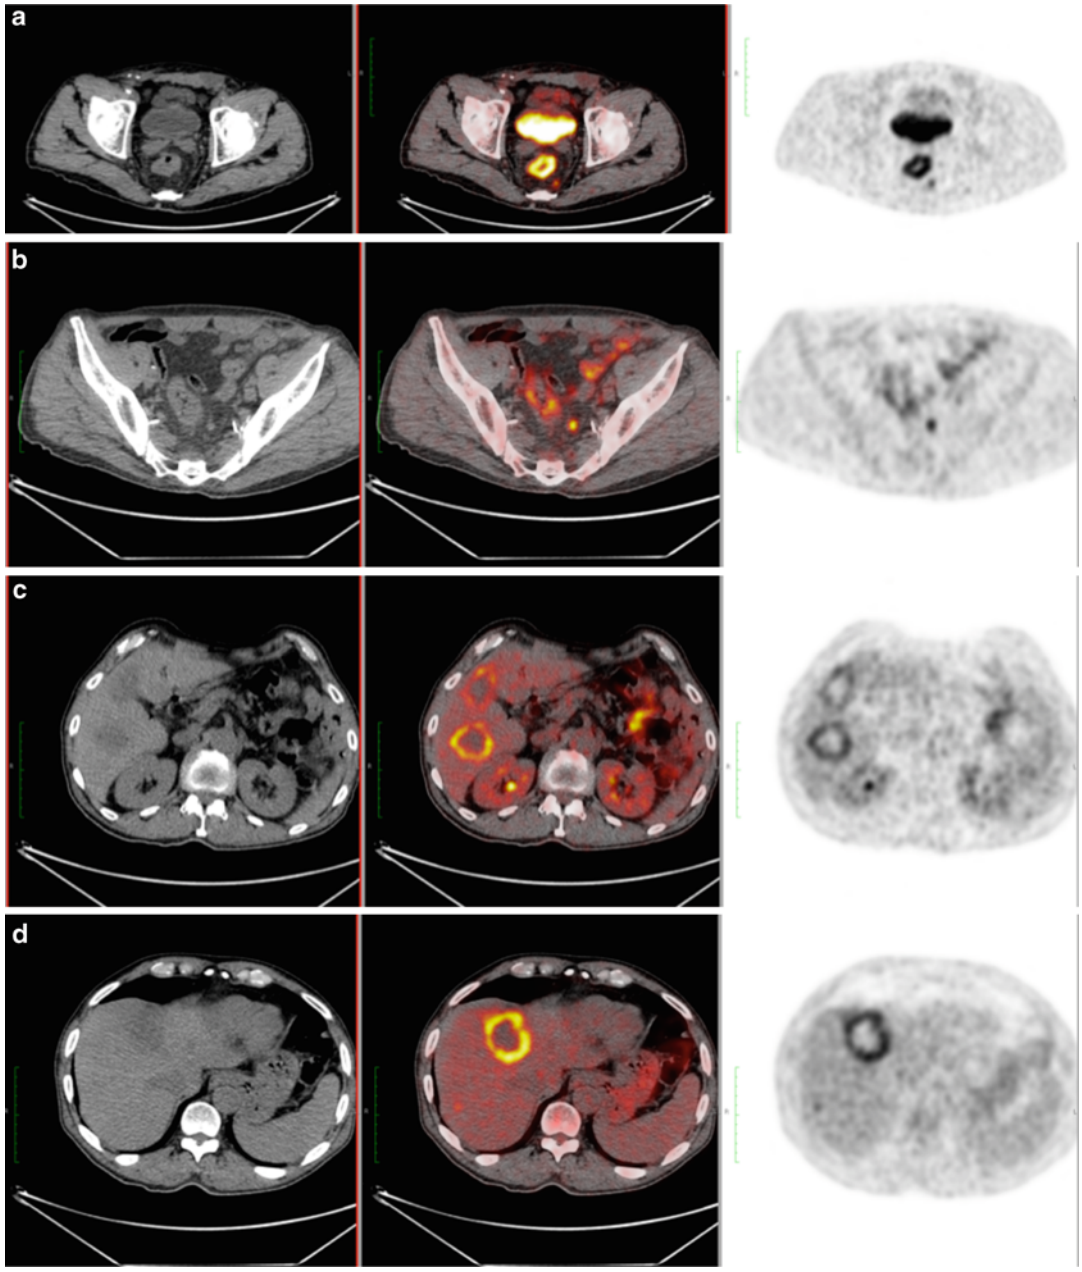

Fig. 20 (**a**) Axial CT, fused PET/CT, and PET images show markedly increased [^{18}F]FDG uptake in the thickened rectal wall, corresponding to the rectal carcinoma. (**b**) Axial CT, fused PET/CT, and PET images demonstrate the area of focal [^{18}F]FDG uptake corresponding to a left parasacral lymph node. (**c**, **d**) The axial CT image shows heterogeneous attenuation due to lesions in both the right and the left lobe of the liver, while the fused PET/CT and PET images demonstrate frankly increased tracer uptake in the peripheral rim of multiple liver metastases

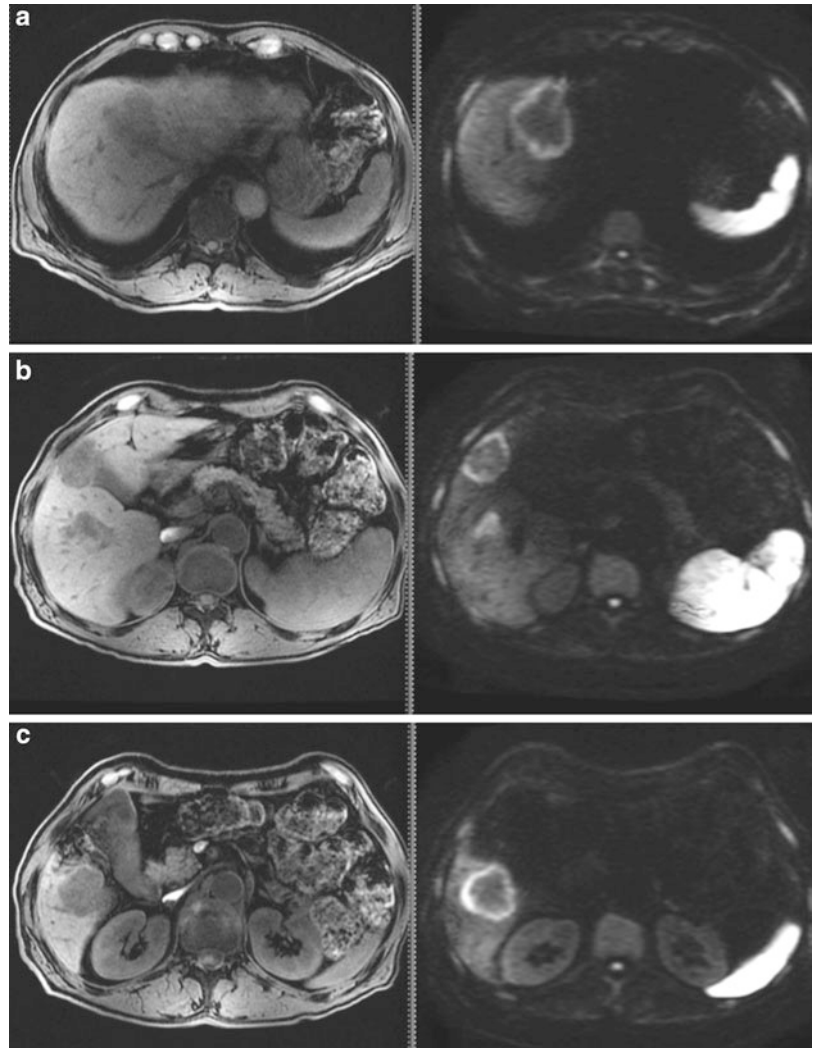

Fig. 21 MRI axial images corresponding to the lesions detected at PET/CT. Water LAVA flex MR on the *left* and DWI Ax on the *right*. (**a**–**c**) Liver metastases appear hypointense on LAVA sequences, while at DWI, a thin hyperintense rim can be observed at the periphery of the lesions

identify those patients that can be treated surgically with curative intents. [^{18}F]FDG PET/TC along with MRI can provide important information about the presence of lymph node metastases, as well as about the site and number of distant metastases. Contrast-enhanced MRI is recommended for characterization of suspected liver metastases from colorectal cancer, since its diagnostic performance is superior to contrast-enhanced ultrasound and CT. The use of hepatobiliary contrast media may further improve the detection rate of liver metastases.

Pancreatic Cancers: Case No. 8 1713
Presentation 1714
Findings 1714

Pancreatic Cancers: Case No. 1

A 73-year-old woman presented with abdominal pain radiating to the back and weight loss over the past 3 months. A contrast-enhanced CT showed low-attenuating enhancing mass in the head of the pancreas (max diameter 36 mm), suggestive of malignancy; suspected liver lesion of the VIII hepatic segment was also shown. An endoscopic ultrasound (EUS) was performed to guide fine-needle biopsy of the pancreatic lesion which demonstrated poorly differentiated adenocarcinoma.

Findings

[^{18}F]FDG PET/CT is performed as a part of initial staging.

Intense area of [^{18}F]FDG uptake is shown in the pancreatic head corresponding to malignant mass.

[^{18}F]FDG-avid pathological hepatic lesion with central photopenic area corresponding to necrotic center is also demonstrated in the VIII segment. In addition, a hypermetabolic peritoneal nodule in presacral space is seen.

[^{18}F]FDG PET/CT confirms stage IV disease also showing peritoneal implant misdiagnosed on diagnostic CT. The patient was treated with chemotherapy.

Discussion

[^{18}F]FDG PET/CT detection of distant metastases or unexpected lesions in pancreatic cancer may change patient management excluding patient from surgical intervention and thus avoiding unnecessary procedure. The spread into peritoneum is not uncommon but often missed on conventional anatomical imaging (Figs. 1, 2, and 3).

Pancreatic Cancers: Case No. 2

[2]Nuclear Medicine Unit, "Santa Maria della Misericordia" Hospital, Rovigo, Italy

Presentation

A 72-year-old woman with a history of hyperparathyroidism and osteoporosis was diagnosed with a lesion in the uncinate process of the pancreas with an associated liver lesion.

Findings

Patient underwent [^{18}F]FDG PET/CT for staging that showed increased uptake (SUV_{max} 17.5) at the head-isthmus of the pancreas suspicious for cancer (Fig. 4a) and focal uptake at the liver (IV segment, SUV_{max} 9) and at some para-aortic (SUV_{max} 6.8), epiphrenic (SUV_{max} 8.2), and left laterocervical lymph nodes (SUV_{max} 8.5) suspicious for metastasis (Figs. 4b and 5).

Discussion

The main objective of pancreatic cancer staging is to depict local and distant spread, which may preclude surgery. [^{18}F]FDG PET may play an important role in this clinical decision.

Pancreatic Cancers: Case No. 3

Presentation

An 83-year-old man, hospitalized for significant weight loss, had an ^{18}[F]FDG PET/CT that showed heterogeneous uptake of the radiopharmaceutical in the body-tail of the pancreas (SUV_{max} 5.2), with a central necrotic area (Fig. 6).

Histology showed biliopancreatic adenocarcinoma (pT3N0M0) and patient underwent distal splenopancreatectomy.

Follow-Up

One year after surgery, his medical condition worsened and Ca19.9 was 99.8 U/mL.

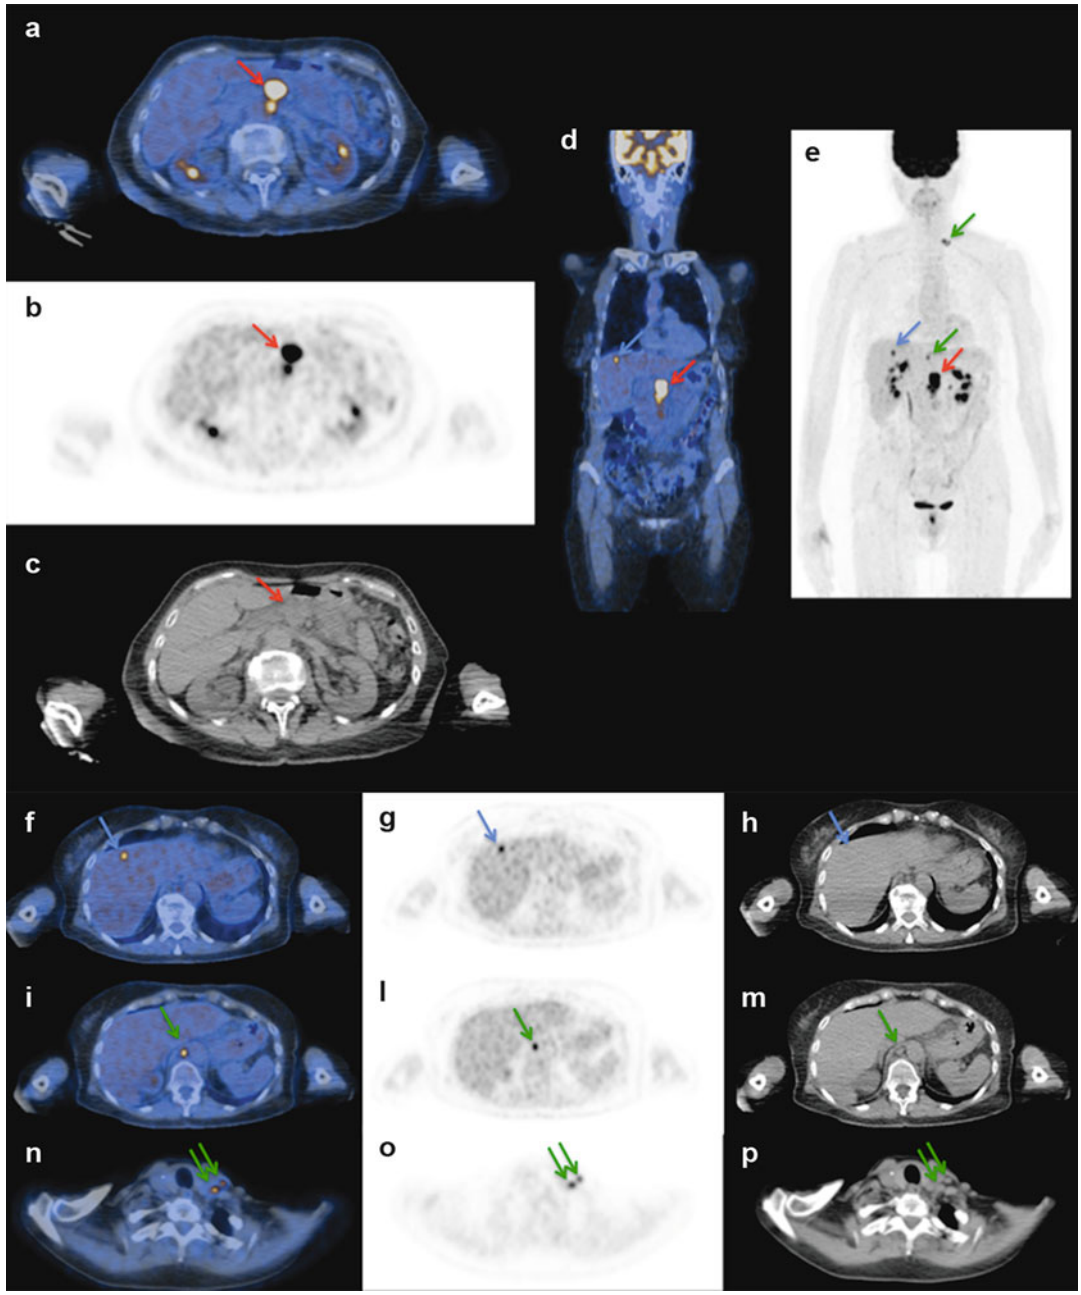

Fig. 4 (**a**) *A* Transaxial [^{18}F]FDG PET/CT; *B* transaxial [^{18}F]FDG PET/CT; *C* transaxial CT; *D* coronal [^{18}F]FDG PET/CT; *E* MIP; *red* flag, pancreatic finding; *green* flag, lymph nodal finding. Fig. 6 *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding

A subsequent [^{18}F]FDG PET/CT showed uptake (SUV_{max} 9.5) in the head and body of the pancreas, near the surgical clips. This finding was suspicious for recurrent disease (Fig. 7).

The patients condition deteriorated, and about one month later a repeat [^{18}F]FDG PET/CT that showed an area of increased uptake in the head-body of the pancreas (SUV_{max} 8.5) next to the rear wall of the gastric antrum (Fig. 8).

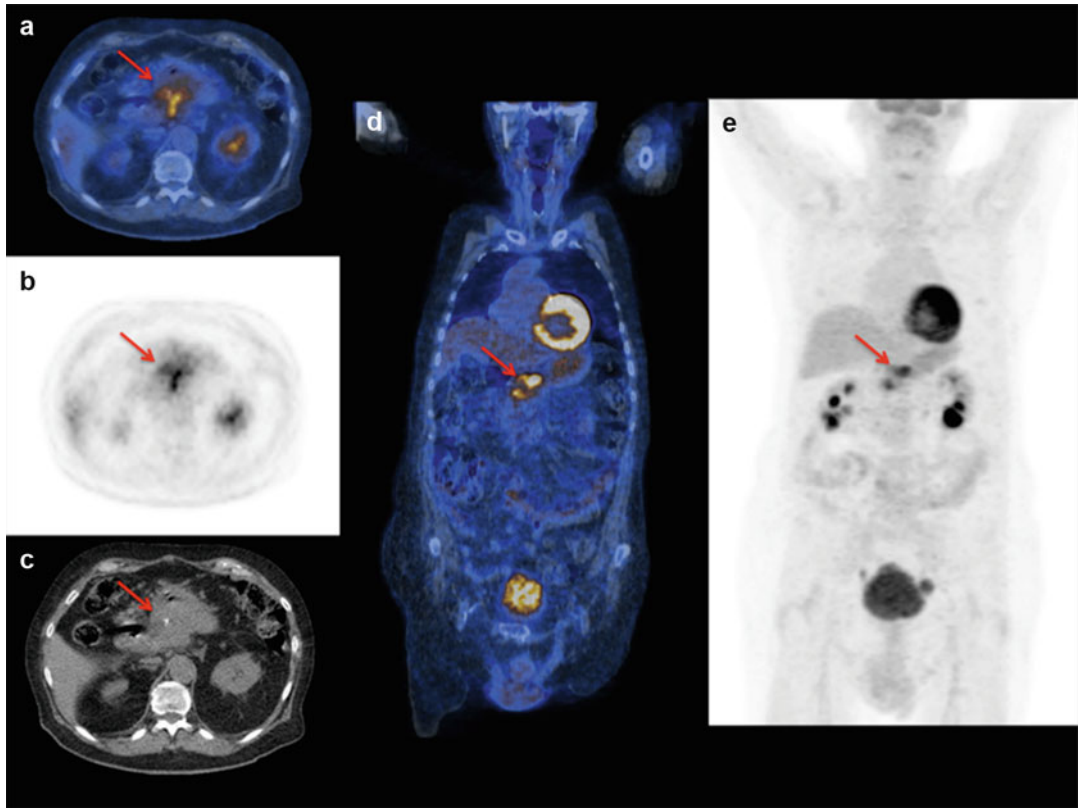

Fig. 7 *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding

Presentation

A 63-year-old woman with inoperable pancreatic cancer underwent chemotherapy.

Findings

After six cycles of chemotherapy, she underwent [^{18}F]FDG PET/CT to assess response to therapy. [^{18}F]FDG PET/CT revealed focal uptake at the head-uncinate process of the pancreas ($SUV_{max} = 5.3$) (Fig. 9a: red flags) and to some metastatic areas in the liver, respectively, to the dome of the liver ($SUV_{max} = 6.9$), between the II and III segment ($SUV_{max} = 6.7$) and between the II and IV segment ($SUV_{max} = 7.7$) (Fig. 9a: *E*, blue flag and Fig. 9b: *F*, *G*, *H*, blue flags).

The patient continued chemotherapy, and after 4 months, she underwent another [^{18}F]FDG PET/CT that revealed an increased uptake to the pancreas ($SUV_{max} = 7.3$), to many hepatic

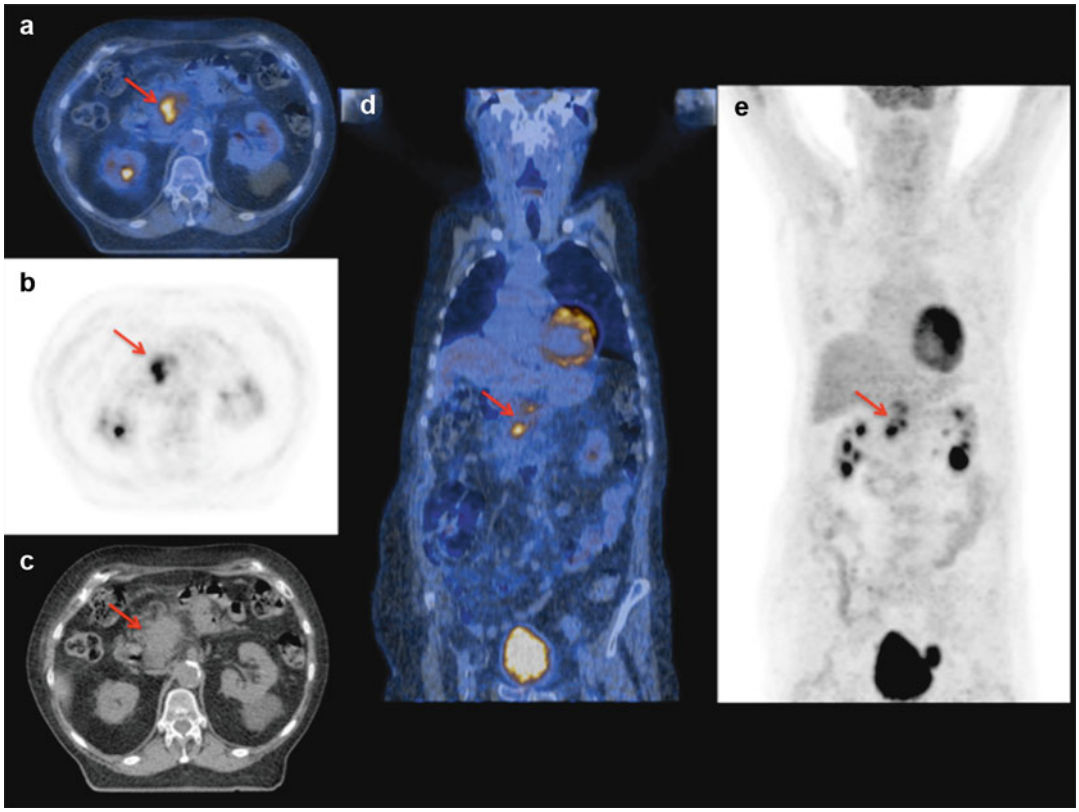

Fig. 8 *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding

lesions (SUV_{max} = 7.8) (Fig. 10a: *D*, *E*, blue flags and Fig. 10b: *F*, *G*, *H*, blue flags), to some sites in the abdomen suspicious for peritoneal carcinomatosis (Fig. 10a: *E*, pink flags), and to some right inguinal lymph nodes (SUV_{max} = 6.6) (Fig. 10a: *E*, green flag).

Widespread skeletal uptake compatible with medullary rebound after chemotherapy is observed (Fig. 10a: *E*).

Presentation

A 62-year-old man with dyspepsia had a CT scan that revealed severe gastrectasia probably due to neoplastic duodenal obstruction.

Findings

[^{18}F]FDG PET/CT demonstrated peripheral uptake at the head of the pancreas (SUV_{max} = 7.8) (Fig. 11a: red flags) suspected to be a tumor.

[^{18}F]FDG PET/CT also revealed uptake in peripancreatic lymph nodes and to many sites in the liver especially to the right lobe (IV–VIII

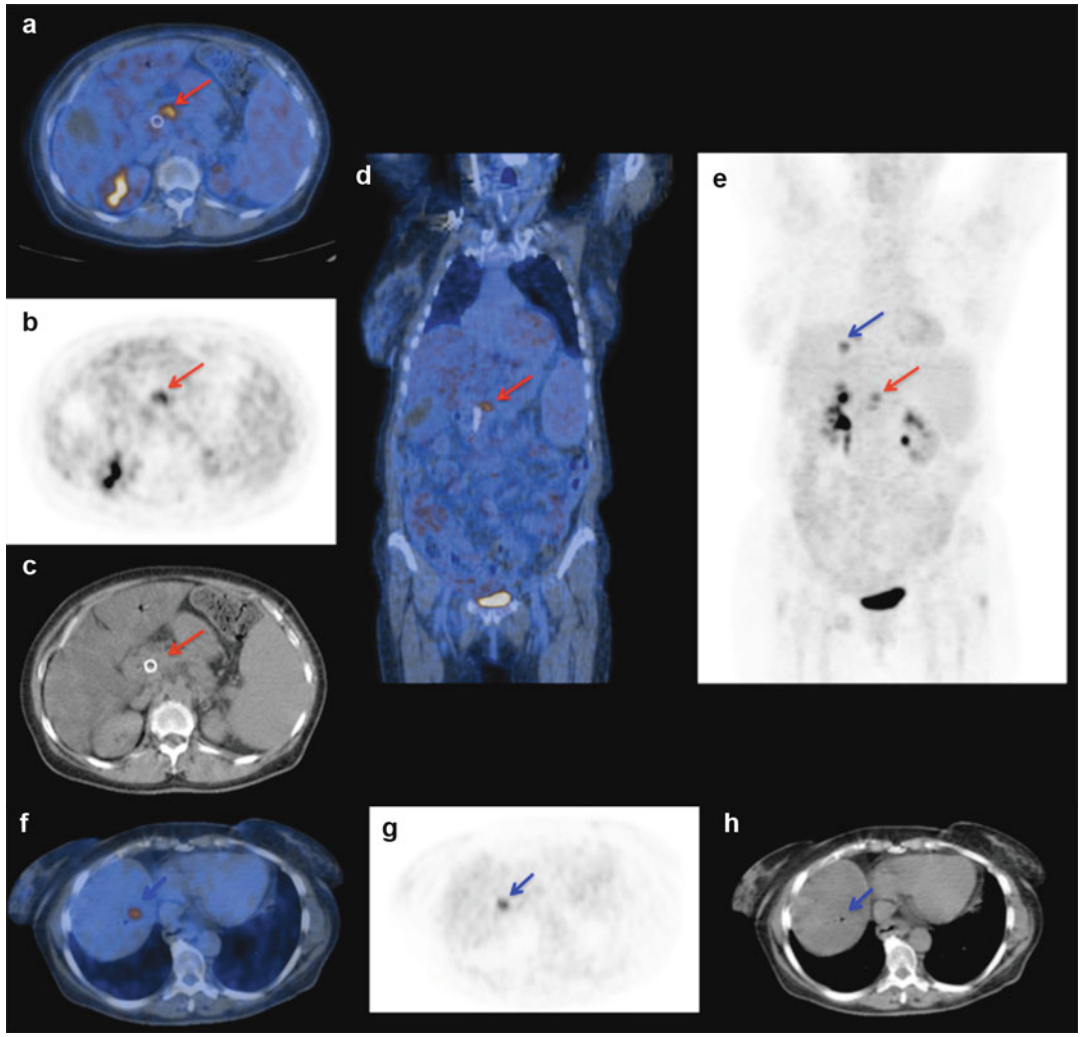

Fig. 9 (**a**) *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding; *blue* flag, hepatic finding. (**b**) (*F* transaxial [^{18}F]FDG PET/CT, *G* transaxial [^{18}F]FDG PET, *H* transaxial CT; *blue* flag, hepatic finding)

segments with $SUV_{max} = 9.9$ and VII–VIII segments with $SUV_{max} = 8$) suspected to be metastasis (Fig. 11a: blue flags).

Pancreatic Cancers: Case No. 6

Presentation

A 71-year-old woman was hospitalized for persistent pain in the abdomen (lasting since

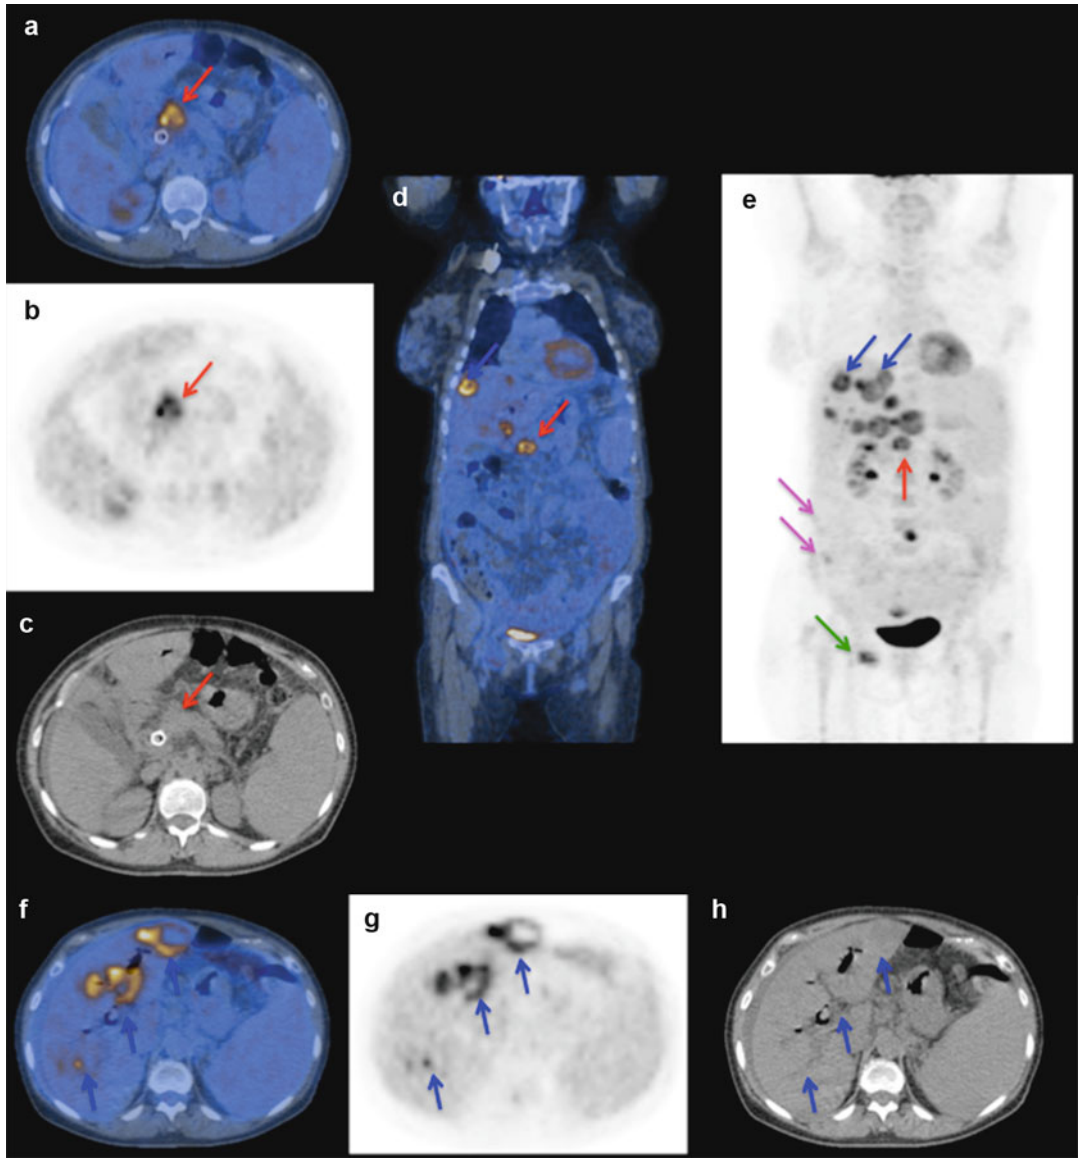

Fig. 10 (**a**) *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding; *blue* flag, hepatic finding; *violet* flag, muscular finding. (**b**) (*F* transaxial [^{18}F]FDG PET/CT, *G* transaxial [^{18}F]FDG PET, *H* transaxial CT; *blue* flag, hepatic finding)

6 months), weight loss, and intestinal sub-obstruction from suspected malignancy of sigma/extrinsic compression. Ca.19.9 was >10.000 U/mL.

Colonoscopy showed a critical stenosis of the descending colon.

Contrast-enhanced CT demonstrated a lesion at the tail of the pancreas, liver metastases, and an extensive pelvic mass.

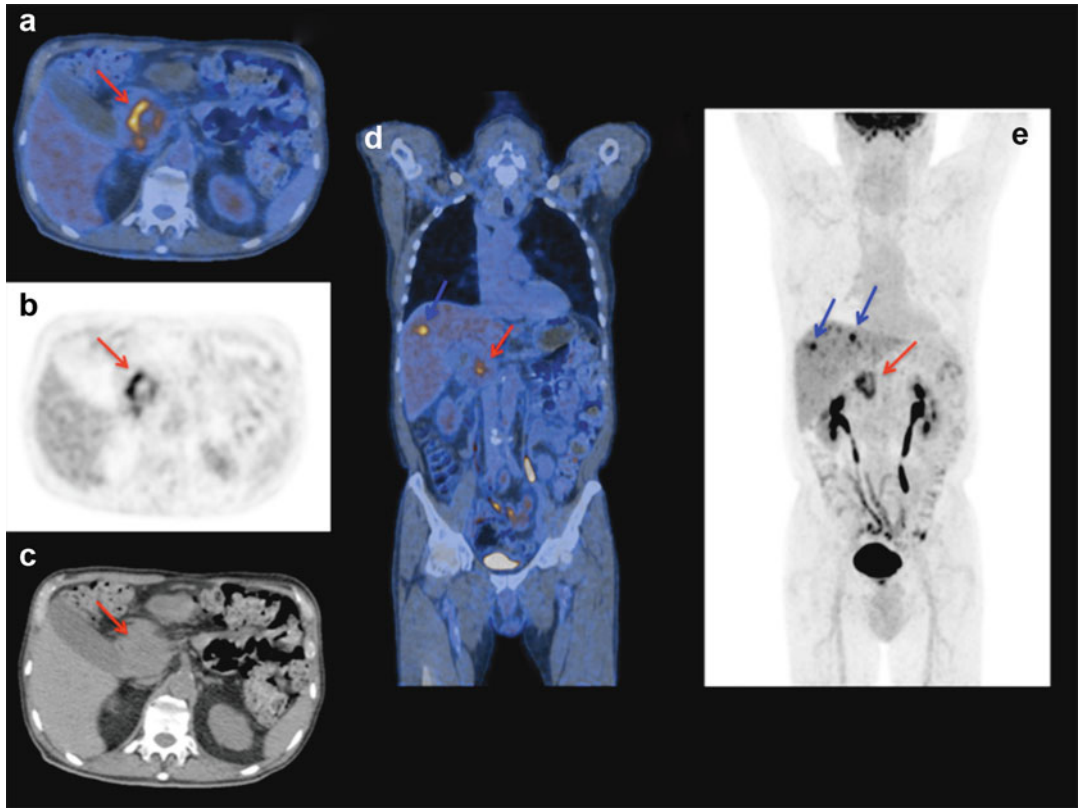

Fig. 11 *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding; *blue* flag, hepatic finding

Findings

The patient underwent [^{18}F]FDG PET/CT that showed an extensive uptake at the body of the pancreas ($SUV_{max} = 10.9$) (Fig. 12a: red flags), at least five hepatic lesions (the greater at the VII segment $SUV_{max} = 9$; the IV segment $SUV_{max} = 12.3$) (Fig. 12b: *F*, *G*, *H*, blue flags), hypermetabolic peritoneal nodules in the left iliac fossa (Fig. 12b: *I*, *L*, *M*, pink flags), and pathological uptake of the sigma ($SUV_{max} = 15.7$) (Fig. 12b: *N*, *O*, *P*, pink flags).

The patient underwent exploratory surgery. The histological examination demonstrated the presence of pancreatic adenocarcinoma (CK7+, CK20+, CDX-, Ca125-).

The patient started chemotherapy with 5-fluorouracil and folinic acid.

Pancreatic Cancer: Case No. 7

Presentation

A 70-year-old man otherwise in overall good conditions had a recent diagnosis of prostate cancer. The patient was eligible for radical prostatectomy. During preoperative staging, ultrasound (US) of the abdomen revealed a small hypo-isoechoic round mass near the pancreas. ceCT confirmed the US findings and described a 2 cm exophytic,

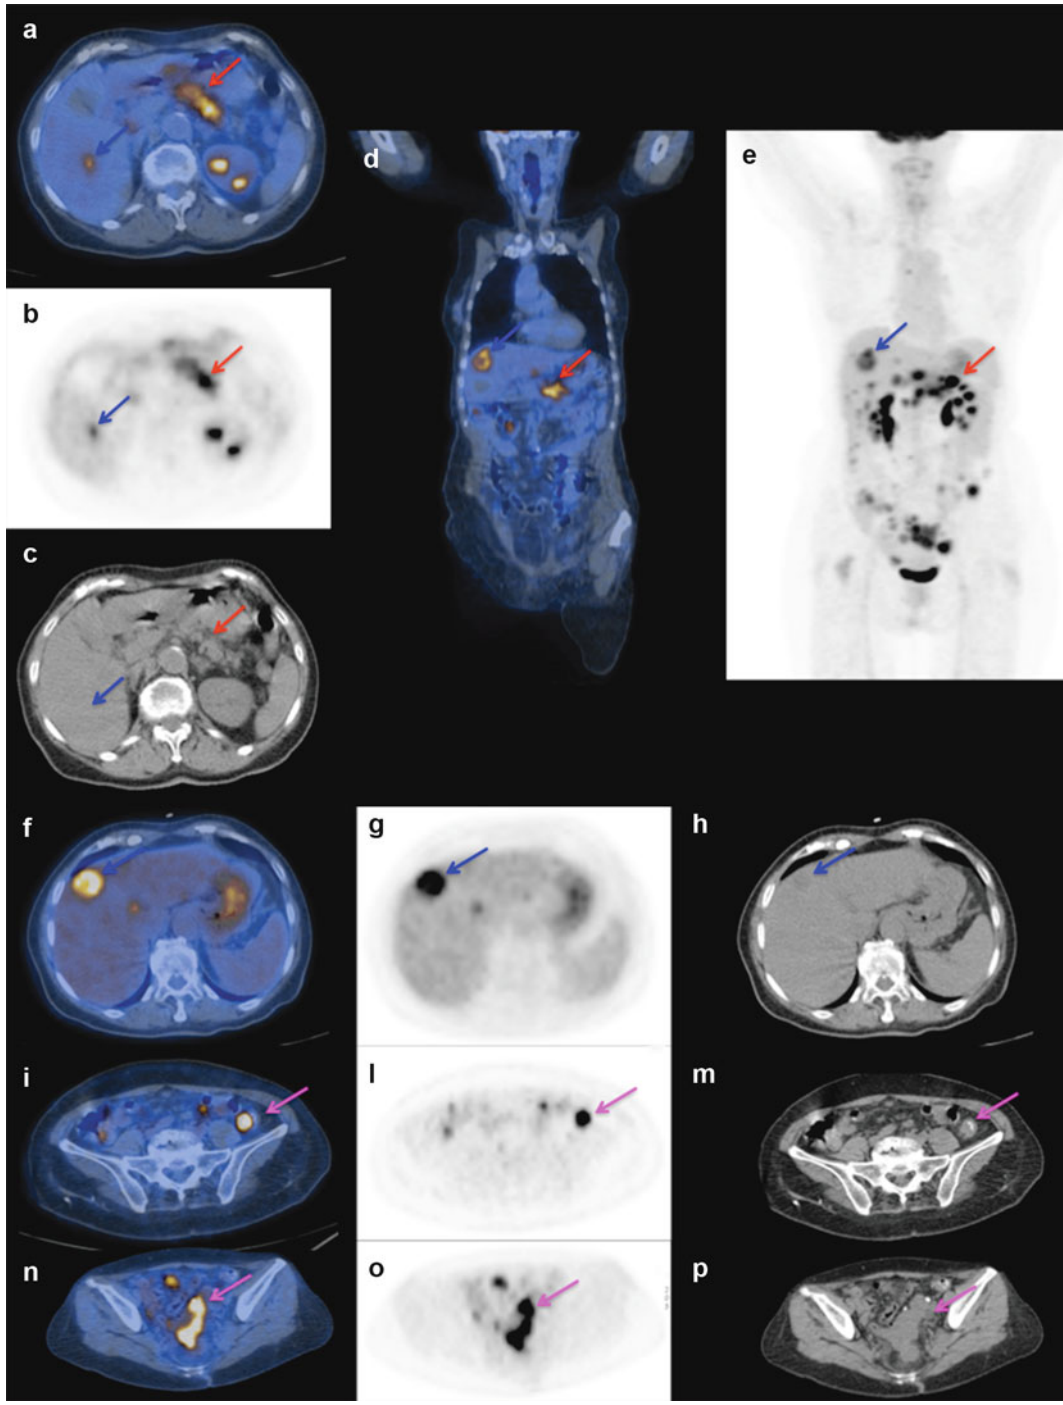

Fig. 12 (**a**) *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP; *red* flag, pancreatic finding; *blue* flag, hepatic finding. Fig. 14 (**a**) *A* Transaxial [^{18}F]FDG PET/CT, *B* transaxial [^{18}F]FDG PET, *C* transaxial CT, *D* coronal [^{18}F]FDG PET/CT, *E* MIP. (**b**) (*F* transaxial [^{18}F]FDG PET/CT, *G* transaxial [^{18}F]FDG PET, *H* transaxial CT)

hypervascular nodule on the right side of the body of the pancreas.

Findings

A SPECT/CT scan with ^{99m}Tc-nanocolloidal albumin was performed to differentiate possible ectopic spleen tissue from neuroendocrine tumor. SPECT/CT revealed no uptake in the pancreatic lesion, thus confirming the suspicion of a lesion pertaining to the pancreas.

^{68}Ga-DOTATOC PET/CT showed intense tracer uptake in the pancreatic lesion (Fig. 15). No other lesions were found. EUS fine-needle aspiration

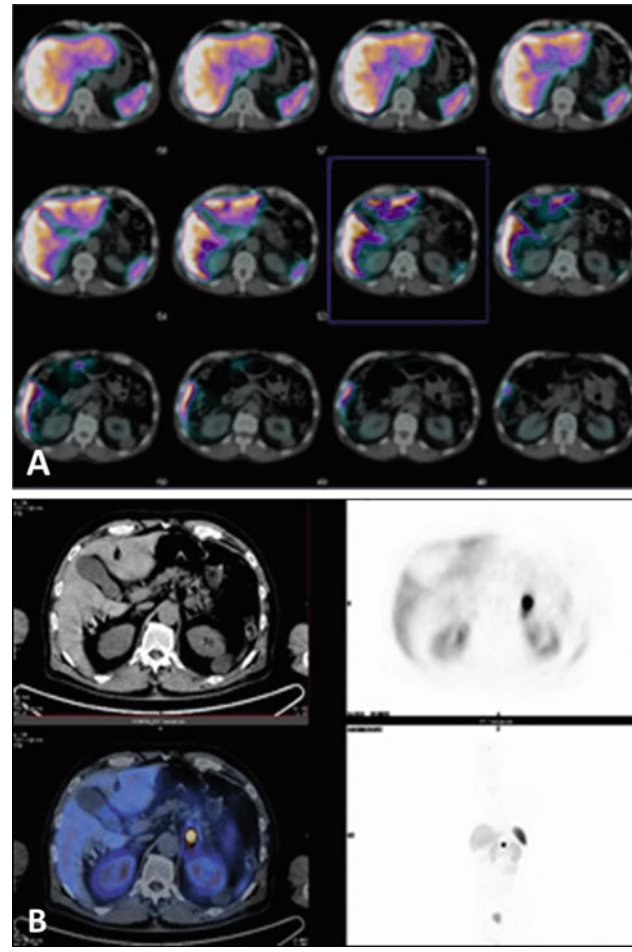

Fig. 15 Axial SPECT/CT images with ^{99m}Tc-nanocolloidal albumin (A) reveal no uptake in the pancreatic lesion. ^{68}Ga-DOTATOC PET/CT showed intense tracer uptake in the pancreatic lesion

biopsy confirmed the presence of neuroendocrine tumor.

Teaching Point

Intra-pancreatic accessory spleen, or "splenule," is an uncommon congenital abnormality of the spleen with an incidence of around 2%; this abnormality can coexist with a normal spleen and can mimic a pancreatic neuroendocrine tumor (PNET). PNETs are characterized by high signal intensity on MRI T2-weighted images, and they are typically a hyperdense, spherical lesion on the ceCT arterial phase. Both intra-pancreatic accessory spleen and PNETs show increased ^{68}Ga-DOTATOC uptake. ^{99m}Tc-colloid SPECT/CT should be performed in suspicious pancreatic lesions in order to prevent unnecessary surgery, as this radiopharmaceutical shows increased uptake in an intra-pancreatic accessory spleen but no uptake in PNETs.

Pancreatic Cancers: Case No. 8

Case contributed by: E. Tabacchi[1], C. Nanni[1], I. Bossert[1], A. M. Maffione[2], S. Fanti[1]

Presentation

A 64-year-old man, treated about 7 years before with a duodenocefalopancreasectomy for adenocarcinoma of the ampulla of Vater, underwent [^{18}F]FDG PET/CT for an increasing back pain.

Findings

[^{18}F]FDG PET/CT revealed an increased uptake at some vertebrae like D9 (SUV_{max} = 6.5) and D11 (SUV_{max} = 6.4) (Fig. 13b: yellow flags) in correspondence of lithic areas and a focal uptake (SUV_{max} = 8) at the front edge of the body of the pancreas (Fig. 13a: red flags).

At first the suspect was recurrence of the pancreatic cancer with bone metastases but after a reevaluation of the CT images and seeing the negativity of tumor markers, it was decided to proceed with the biopsy of the iliac wing. The diagnosis was of plasmocitoma.

Patient started first-line chemotherapy with gemcitabine and zoledronic acid.

After 6 months a repeat [^{18}F]FDG PET/CT was negative (Fig. 14a, b). The previous pancreatic uptake was therefore attributed to a nonspecific/inflammatory finding.

Discussion 1723

Colorectal Cancer: Case No. 1

Presentation

A 71-year-old woman presented with abdominal and lumbar pain lasting for 2 months. No abnormality was demonstrated by esophagogastroduodenoscopy. Abdominal contrast-enhanced CT demonstrated a lesion of the pancreatic body (4 cm in size) with involvement of the splenic artery, celiac trunk, and superior mesenteric artery (Fig. 1). EUS-guided biopsy showed biliopancreatic adenocarcinoma of the pancreas body.

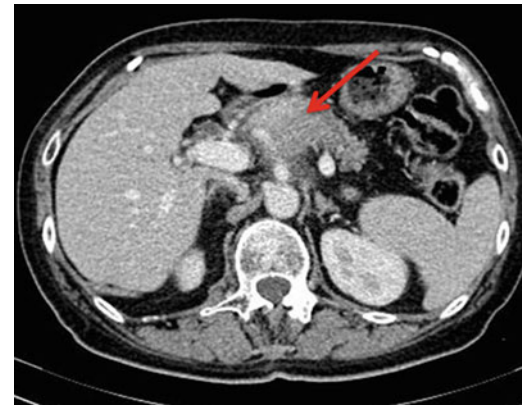

Fig. 1 Contrast-enhanced CT of pancreatic adenocarcinoma (*red arrow*)

Findings

[^{18}F]FDG PET/CT was performed to complete the staging of the locally advanced pancreatic cancer.

PET/CT confirmed the presence of hypermetabolic pancreatic lesion consistent with malignancy (Fig. 2). In addition, prominent [^{18}F]FDG-avid area associated with wall thickening on CT was noted in the transverse colon (Figs. 2 and 3). MRI of the abdomen showed the known pathologic pancreatic lesion and a suspected mass of the transverse colon.

Colonoscopy confirmed the PET/CT finding and demonstrated the presence of substenosing vegetant lesion of the colon, histologically diagnosed as moderately differentiated adenocarcinoma.

Discussion

Incidental colonic [^{18}F]FDG uptake often is observed in patients who undergo PET/CT studies. The presence of an incidental focal [^{18}F]FDG uptake in the colon justifies a colonoscopy to detect the presence of a possible premalignant or malignant lesion. Focal and multifocal high [^{18}F]FDG uptake in the colon is predictive of pathologic findings, which may include malignancy. A diffuse colonic [^{18}F]FDG uptake pattern, regardless of the degree, is predictive of normal findings at colonoscopy, whereas a segmental high uptake may imply an inflammatory condition that warrants follow-up diagnostic studies.

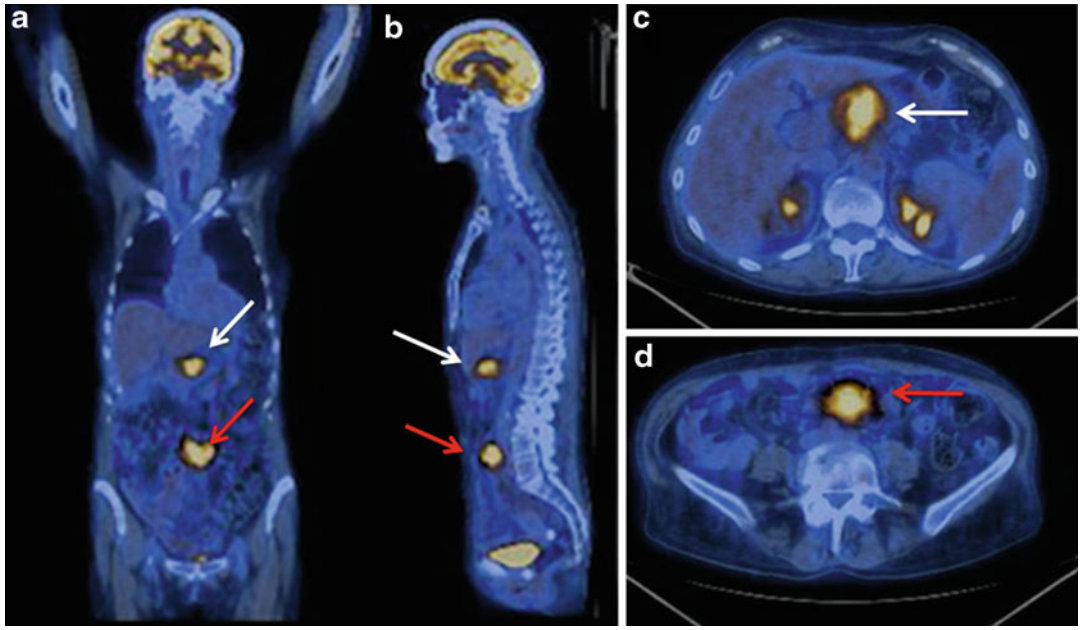

Fig. 2 Fused [^{18}F]FDG PET/CT images (**a** coronal, **b** sagittal, **c**, and **d** axial) of the pancreatic lesion (*white arrows*) and suspected hypermetabolic colonic mass (*red arrows*)

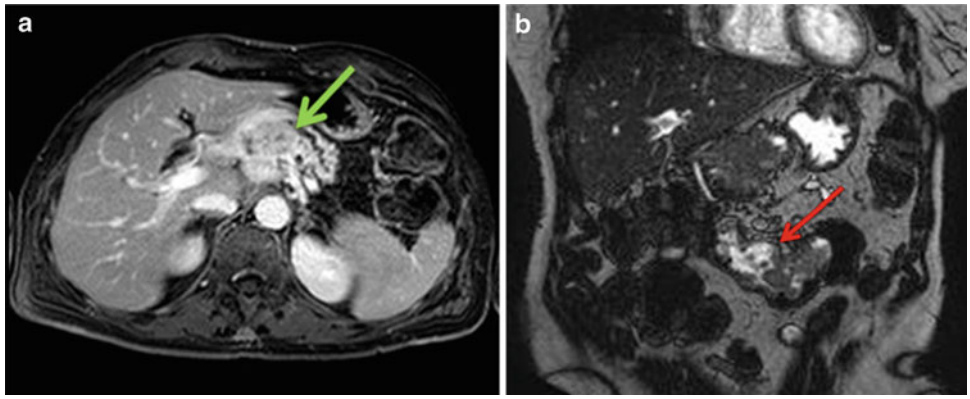

Fig. 3 Abdominal MRI shows the presence of pancreatic lesion (*green arrow*) and the suspected mass of the transverse colon (*red arrow*)

Colorectal Cancer: Case No. 2

Presentation

A 62-year-old man presented with recently diagnosed biopsy-proven colorectal cancer. Colonoscopy showed the presence of an ulcerated circumferential mass of the left colon with malignant obstruction of the lumen, which precluded a full colonoscopy.

[^{18}F]FDG PET/CT was performed as a part of preoperative staging.

Findings

[^{18}F]FDG PET/CT demonstrates focal [^{18}F]FDG uptake in the descending colon corresponding to the known colic mass. Intense focal uptake of the radiopharmaceutical is also noted in the ascending colon in proximity of the hepatic flexure. The patient was treated surgically. Histology demonstrated moderately differentiated adenocarcinoma (pT4aN0) in the descending colon and moderately differentiated adenocarcinoma in the ascending colon (pT3N0). The patient was subsequently treated with adjuvant chemotherapy. At the 3-year follow-up, he has no evidence of disease.

Discussion

Staging with [^{18}F]FDG PET/CT resulted in the detection of synchronous colorectal cancer, a relatively rare condition (2–3% of the cases) that should be considered during staging of colorectal cancer (Fig. 4).

Colorectal Cancer: Case No. 3

Presentation

A 39-year-old man presented with substenosing colorectal cancer. CT colonography (CTC) with computer-aided detection was performed. CTC confirmed the presence of the known mass of the descending colon, and a hypodense lesion of uncertain origin in the sixth segment of the liver (included in the upper limit of the scan).

[^{18}F]FDG PET/CT was performed to characterize the doubtful hepatic lesion.

Findings

PET/CT shows intense [^{18}F]FDG uptake in the descending colon corresponding to known malignancy (Fig. 5). Multiple [^{18}F]FDG hepatic lesions were also demonstrated consistent with synchronous metastatic liver involvement (Fig. 6). The patient was treated with chemotherapy.

Discussion

[^{18}F]FDG PET/CT is not routinely used for initial staging of patients with colorectal cancer (CRC). It may be used to clarify equivocal findings on conventional imaging in preoperative staging and evaluating apparently limited metastatic disease before intervention. Limited literature data has shown that [^{18}F]FDG PET/CT may change treatment plan in 3–30% of the newly diagnosed CRC.

Colorectal Cancer: Case No. 4

Presentation

A 68-year-old man with previously treated for rectal cancer presented with recent increase of serum CEA level (28.1 ng/mL). [^{18}F]FDG PET/CT was performed to evaluate the extent of disease.

Findings

[^{18}F]FDG PET showed markedly avid lesion corresponding to abnormal tissue of the rectal region consistent with recurrent disease (Fig. 7). In the right lower lung, a small nodule with moderate [^{18}F]FDG uptake was also seen, suspected for pulmonary metastases (Fig. 8).

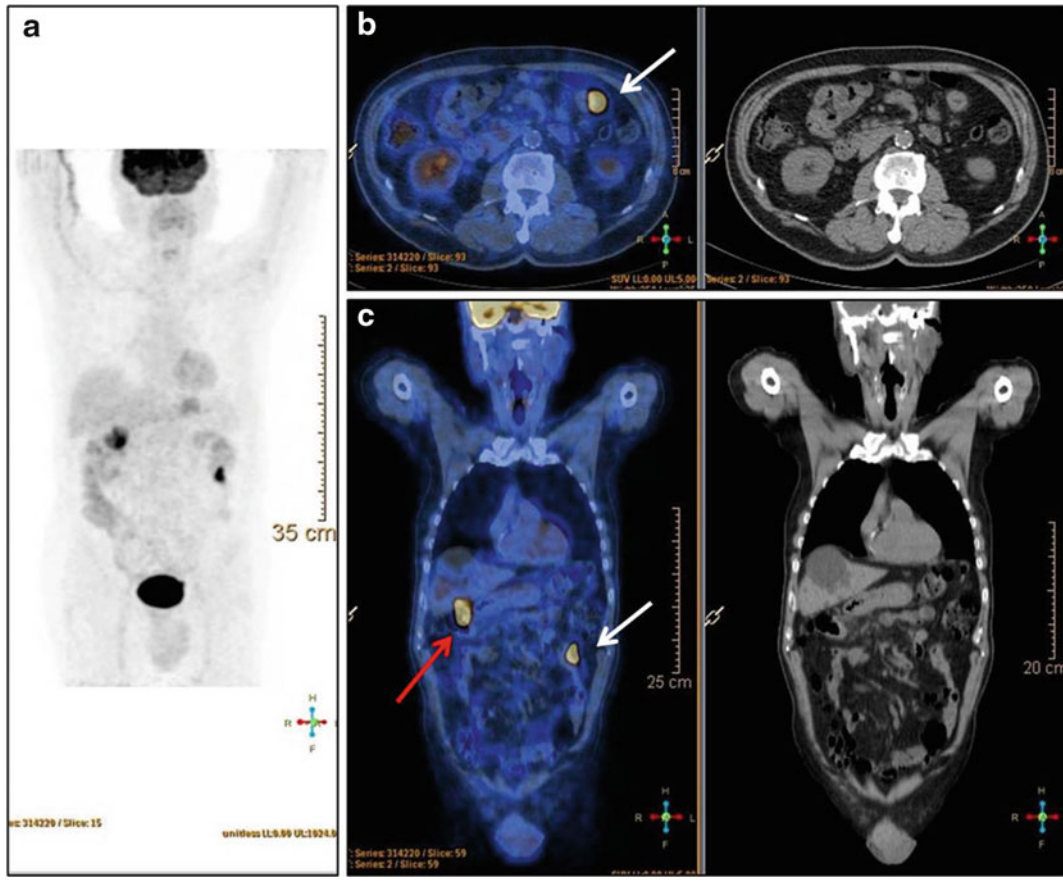

Fig. 4 [^{18}F]FDG PET/CT images (panel **a** MIP image; panel **b** axial fused image on the left and axial CT image on the *right*; panel **c** coronal fused image on the *left* and coronal CT image on the *right*) show synchronous moderately differentiated colorectal cancer in the descending colon (*white arrow*) and in the ascending colon (*red arrow*)

Discussion

In cases of rising serum markers during follow-up colorectal cancer of [^{18}F]FDG PET may be useful to detect local or distant recurrence.

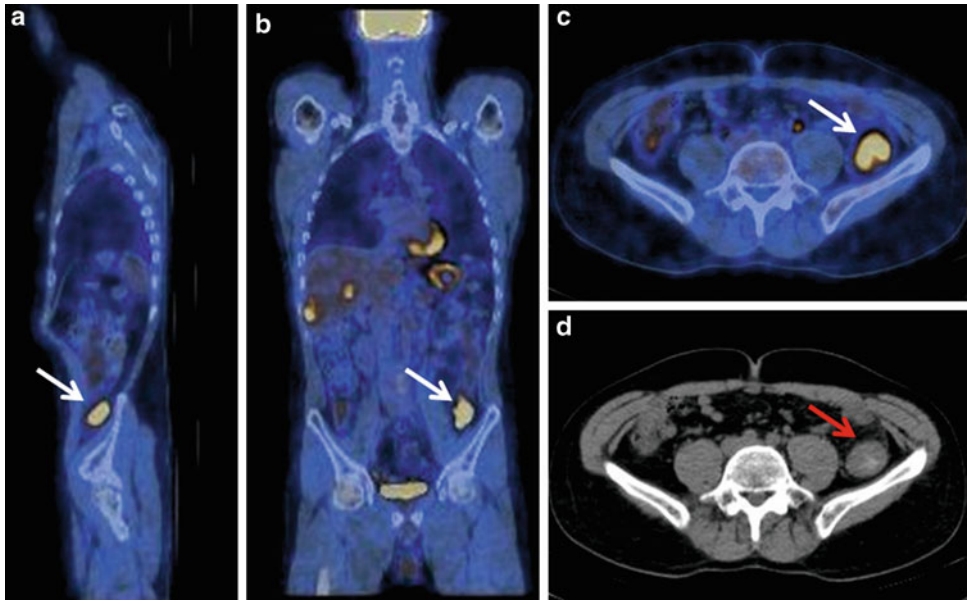

Fig. 5 Fused PET/CT sagittal (**a**), coronal (**b**), axial (**c**), and axial low-dose CT (**d**) images clearly show focal [^{18}F]FDG intense uptake in the descending colon corresponding to known malignancy (*white* and *red arrows*). Fused PET/CT coronal image (**b**) also demonstrated hepatic involvement

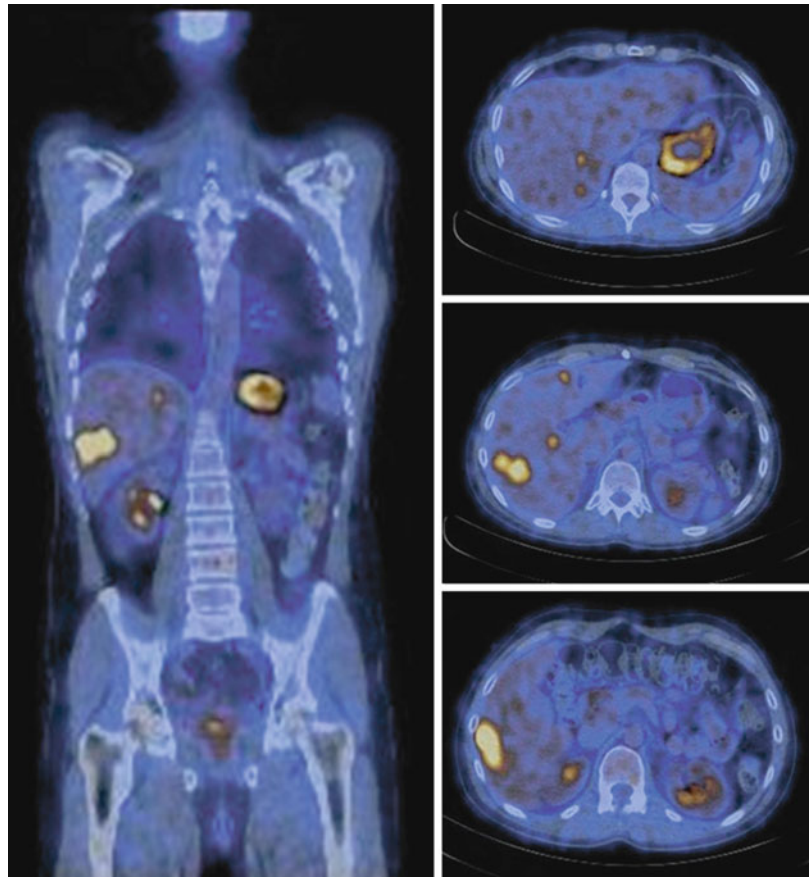

Fig. 6 Fused PET/CT coronal (*left panel*) and axial (*right panel*) images show multiple hepatic [^{18}F] FDG-avid metastases

Presentation

A 70-year-old patient with anal canal cancer.

Findings

There is intense [^{18}F]FDG activity (SUV_{max} 16.7) at the level of the anal canal extending to the lower rectum (arrows). [^{18}F]FDG-avid left inguinal lymph nodes (arrowheads) are also noted (Fig. 13).

Colorectal Cancer: Case No. 6

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 65-year-old patient with anal canal cancer.

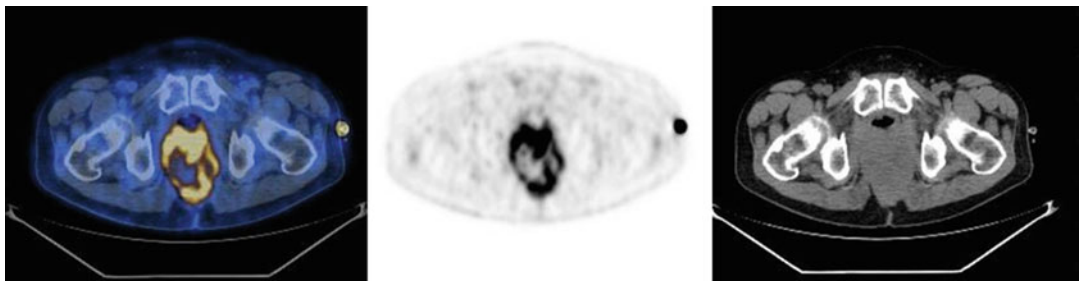

Fig. 7 Axial low-dose CT/PET and fused PET/CT images of rectal local recurrence, [^{18}F]FDG avid

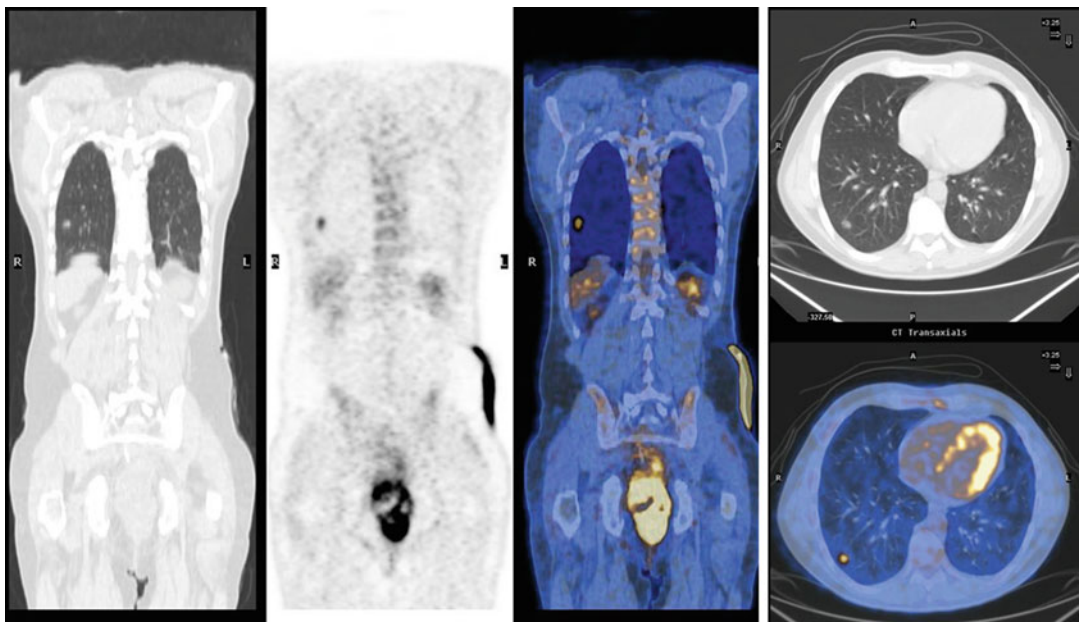

Fig. 8 Coronal low-dose CT/PET and fused [^{18}F]FDG PET/CT images (*left panel*) and axial image (*right panel*) show local recurrence and lung lesion. Radioactive urine in nephrostomy tube is seen along the left flank

Findings

On the PET/MRI scan, there is intense [^{18}F]FDG activity (SUV_{max} 16.7) at the level of the anal canal extending from the anal verge up to the lower rectum (A). The mass abuts the internal sphincter muscle (arrows). The DWI sequence (C) and corresponding ADC maps (D) show restricted diffusion at the level of the lesion (arrows) (Fig. 14).

Discussion

Although MR is the established reference standard, the role of [^{18}F]FDG PET/CT in anal cancer is becoming increasingly important. The National Comprehensive Cancer Network (NCCN) guidelines currently recommend the use of CT or MRI for initial imaging and PET for patients with T3–T4N0 disease or for patients with N+ disease. [^{18}F]FDG PET can detect the primary site of disease more frequently than CT, is sensitive for nodal and metastatic spread, and alters staging in a significant number of patients. PET/CT is beneficial for radiation planning and therapy assessment. Metabolic activity of primary anal cancer at presentation is a potential biomarker for predicting prognosis, treatment response assessment, and survival. [^{18}F]FDG-avid primary malignancy is associated with a higher incidence of disease spread. Metabolic response in post-therapy monitoring scan is associated with improved survival. The recent introduction of simultaneous hybrid PET/MR allows a multiparametric assessment and an all-in-one exam.

Colorectal Cancer: Case No. 7

Case contributed by: L. Deantonio[1], F. Orsini[2], R. Matheoud[3], M. Krengli[1], G.M. Sacchetti[2]

[2]Section of Nuclear Medicine, "Maggiore della Carità" University Hospital, Novara, Italy

[3]Section of Medical Physics, "Maggiore della Carità" University Hospital, Novara, Italy

Presentation

A 56-year-old man with a biopsy-proven primary squamous cell G2 of the anal canal presented with anal bleeding. Tumor size was determined by clinical examination that showed a 6 cm lesion along the posterolateral wall of the anal canal. In these cases efficacy of treatment relies on accurate staging of the primary tumor and regional lymph nodes, which is based on imaging studies; MR is considered the gold standard.

Findings

Pelvic MRI confirmed the locoregional extension and no lymphatic involvement (Fig. 9). Final staging was cT3N0 according to the American Joint Committee on Cancer (AJCC).

The case was discussed in a multidisciplinary meeting including gastroenterologists, surgeons, radiation oncologists, and medical oncologists. The patient was a candidate for chemoradiotherapy with curative intent.

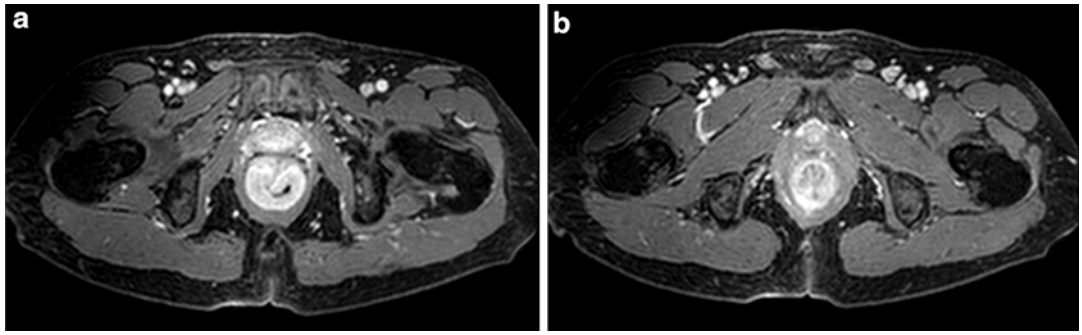

Fig. 9 Transaxial MR study using a THRIVE sequence with contrast enhancement demonstrating a lesion of the posterolateral wall of the anal canal (**a**) and no abnormal inguinal lymph nodes (**b**)

Chemotherapy was delivered with three cycles of 5-fluorouracil and mitomycin C. Planning of radiation therapy (RT) was performed including the identification of the clinical target volume (defined as the gross tumor volume) plus the potential microscopic spread to the surrounding tissues and to the regional lymph nodes based on clinical presentation and imaging.

The recently updated clinical practice ESMO guidelines for anal cancer include PET as an "optional but often recommended" modality in the workup of patients.

Thus, [^{18}F]FDG PET/CT was performed for both tumor staging and target identification. After whole-body imaging, extra bed positions were acquired in the RT decubitus with longer emission scan duration (5 min) and reconstructed on a bigger frame (2.6 mm/pixel) to ensure better definition of the target during contouring for RT planning.

[^{18}F]FDG PET/CT confirmed the anal lesion and showed increased uptake in the left inguinal lymph node, not identified by MRI (Fig. 10).

Discussion

The use of [^{18}F]FDG PET/CT can play an important role in the treatment strategy and lead to modification of RT treatment planning. An [^{18}F]FDG-positive inguinal lymph node will receive a boost of the radiation dose (54–59.4 Gy), while [^{18}F]FDG-negative lymph nodes only receive a prophylactic dose (39.6–45 Gy).

Fine-needle aspiration cytology of the left inguinal lymph node was negative for tumor cells;

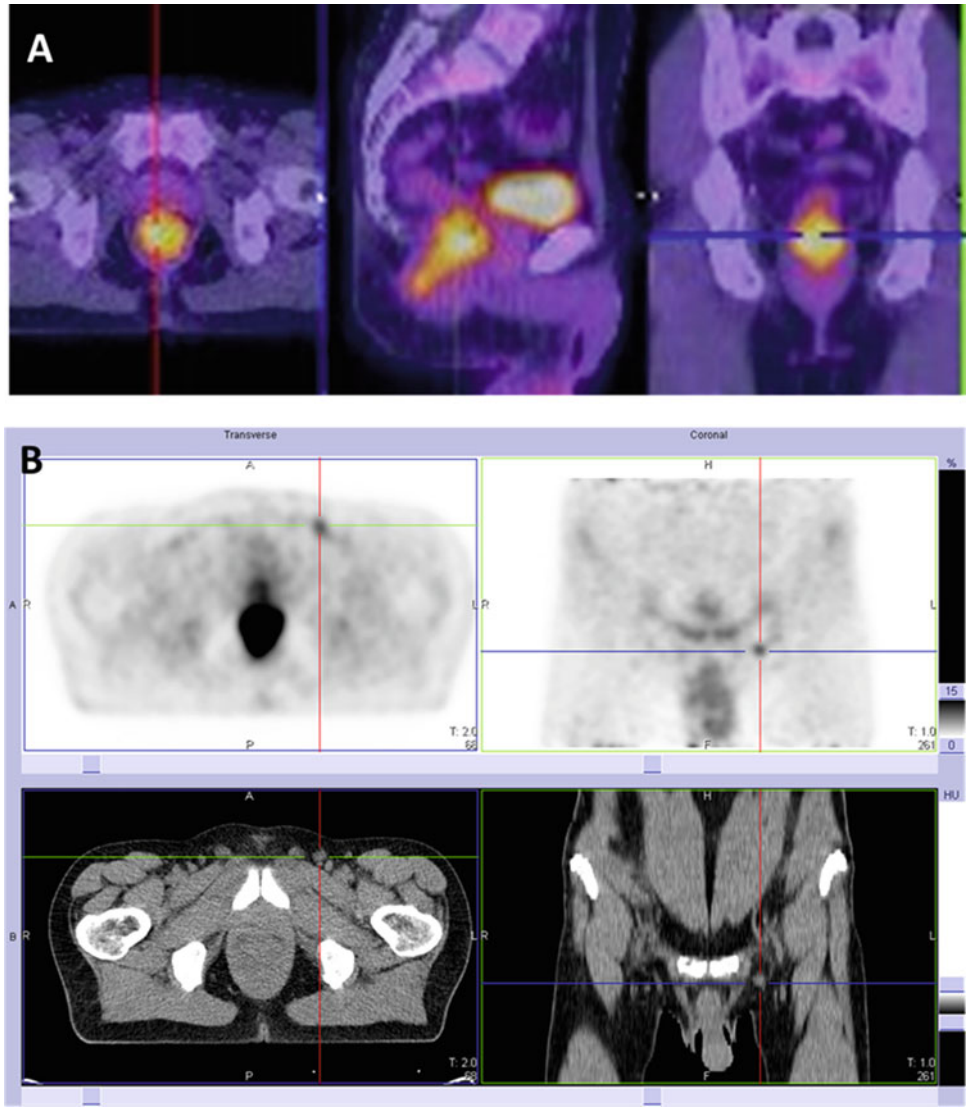

Fig. 10 Transaxial, sagittal, and coronal fused [^{18}F]FDG PET/CT images showing high tracer uptake in the primary anal canal cancer (**a**). Axial and coronal [^{18}F]FDG PET and CT images showing high [^{18}F]FDG uptake in the left inguinal lymph node (**b**)

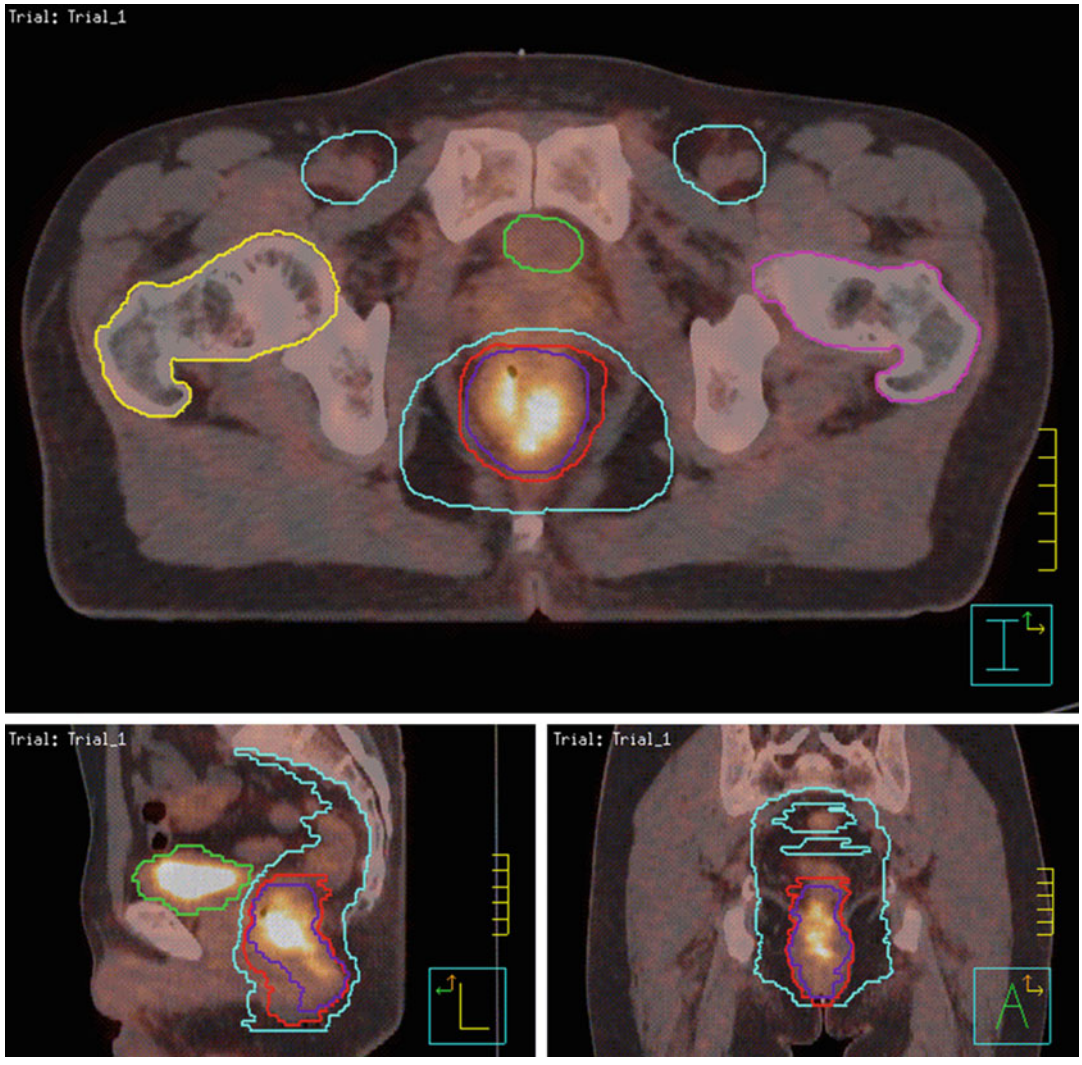

Fig. 11 Transaxial, sagittal, and coronal view of the simulation CT and fused with PET/CT. Different colors are used to highlight contours of the treatment volumes. *Purple line*: gross tumor volume (*GTV*). *Red line*: high-risk CTV represented by the canal anal. *Light blue*: low-risk CTV represented by bilateral inguinal, external, and internal iliac, perirectal, and presacral lymph nodes

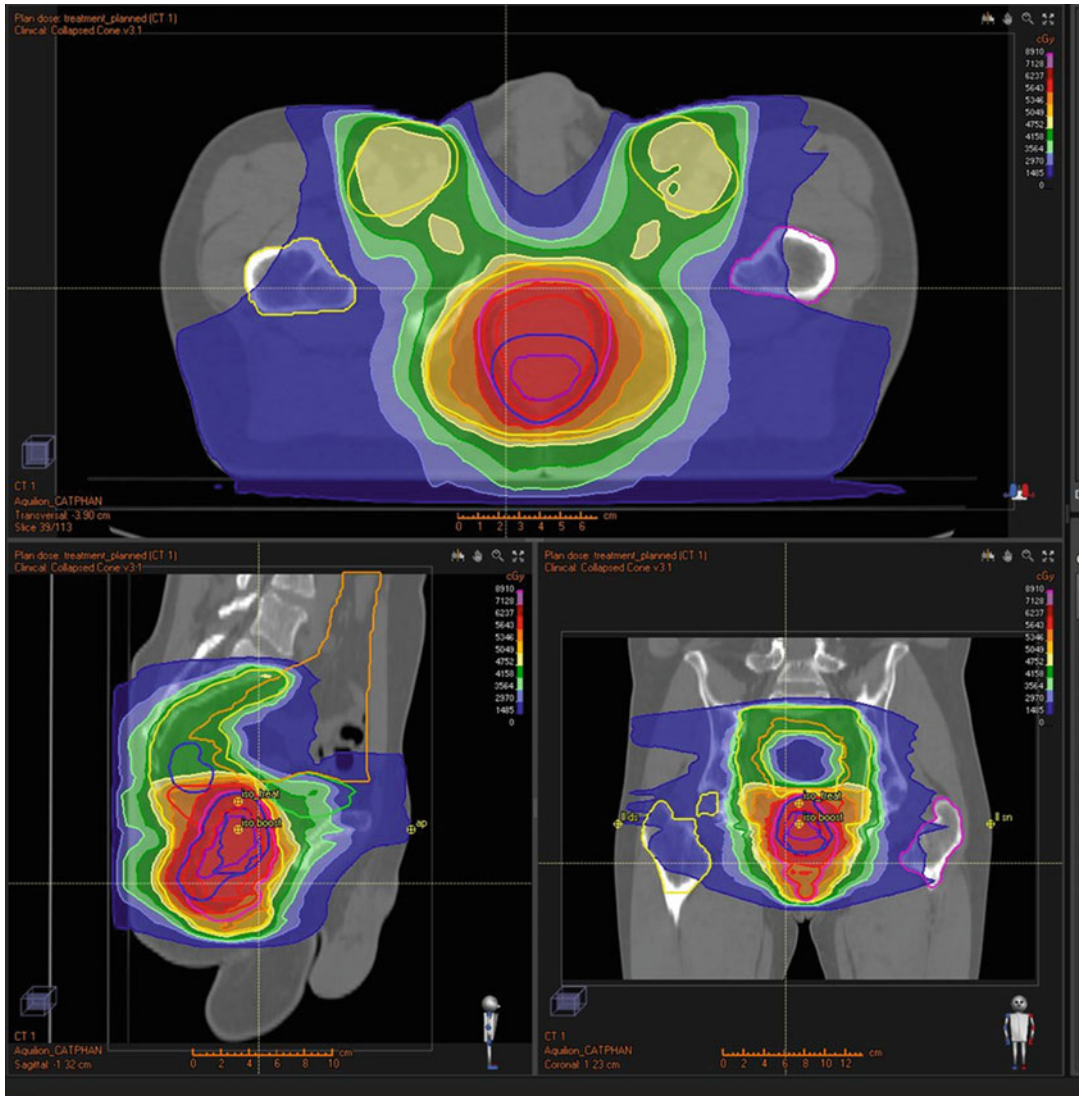

Fig. 12 Transaxial, coronal, and sagittal view of the RT treatment plan. Images show the high conformation of dose distribution performed by VMAT-SIB treatment plan. Around the target volumes, the doses decrease rapidly, thus reducing the radiation dose to the organs at risk. In *red* the 95% isodose and in *blue* the 25% isodose of the 59.4 Gy prescribed dose

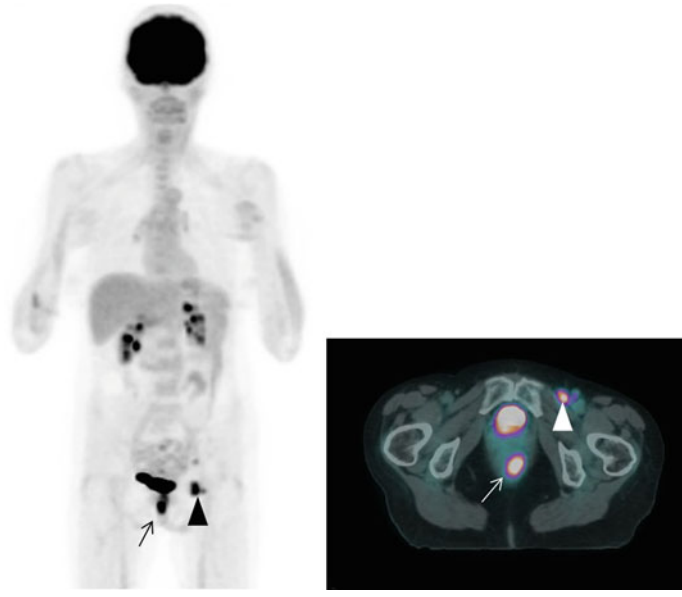

Fig. 13 PET MIP image and axial fused PET/CT image show pathological [^{18}F]FDG activity at the level of the anal canal extending to the lower rectum (arrow) and [^{18}F]FDG avid left inguinal lymph nodes (arrowheads)

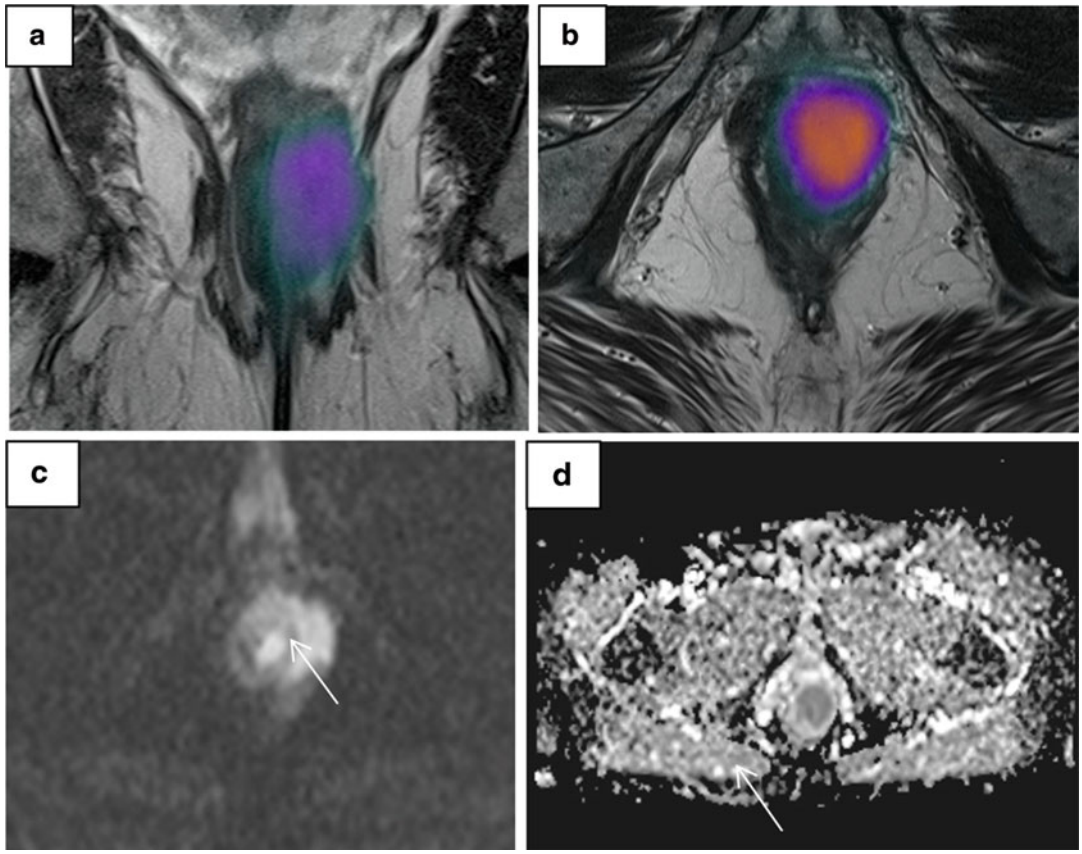

Fig. 14 PET/MRI shows intense [^{18}F]FDG activity at the anal canal extending from the anal verge up to the lower rectum (**a**). The mass abutts the internal sphincter muscle (arrows). The DWI sequence (**c**) and corresponding ADC maps (**d**) show restricted diffusion at the level of the lesion (arrows)

nevertheless, cytology of aspirates from lymph nodes has a relatively low sensitivity. Therefore, inguinal lymph nodes were included in the prophylactic clinical target volume (CTV) (Fig. 11).

A volumetric-modulated arc therapy-simultaneous integrated boost (VMAT-SIB) treatment plan was performed to a total dose of 59.4 Gy with daily fraction of 2 Gy to the macroscopic disease and to a dose of 45.0 Gy with daily fraction of 1.8 Gy to the potentially microscopically invaded regions and locoregional lymph nodes (Fig. 12).

Neuroendocrine Tumors: Case No. 1

Case contributed by: V. Duce, A. Ciarmiello
Nuclear Medicine Unit, "S. Andrea" Hospital, La Spezia, Italy

Presentation

A 66-year-old man presented with chronic diarrhea and abdominal pain. CT showed the presence of a liver lesion in segment 8. An ultrasound-guided core needle biopsy of the liver lesion demonstrated that it was a metastasis from a GEP-NET. ^{68}Ga-DOTATOC PET/CT was performed for localization of the primary tumor and evaluation of disease burden.

Findings

PET/CT images demonstrate two areas of focal ^{68}Ga-DOTATOC uptake in the terminal ileum (close to the ileocecal valve) as the primary tumor site (Fig. 1). In addition, moderate tracer uptake is seen in segment 8 of the liver, corresponding to the CT finding (Fig. 2). The small bowel lesion and the liver metastasis were surgically removed. The histopathology and immunohistochemistry analysis confirmed the diagnosis of NET.

Discussion

This case confirms the value of ^{68}Ga-DOTATOC PET/CT for identifying unknown primary neuroendocrine tumors.

Neuroendocrine Tumors: Case No. 2

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 70-year-old patient with suspicious liver lesions on MRI was referred for further characterization of these lesions.

Findings

The [^{18}F]FDG PET/CT scan (Fig. 3) did not reveal any uptake (upper row). ^{68}Ga-DOTATATE

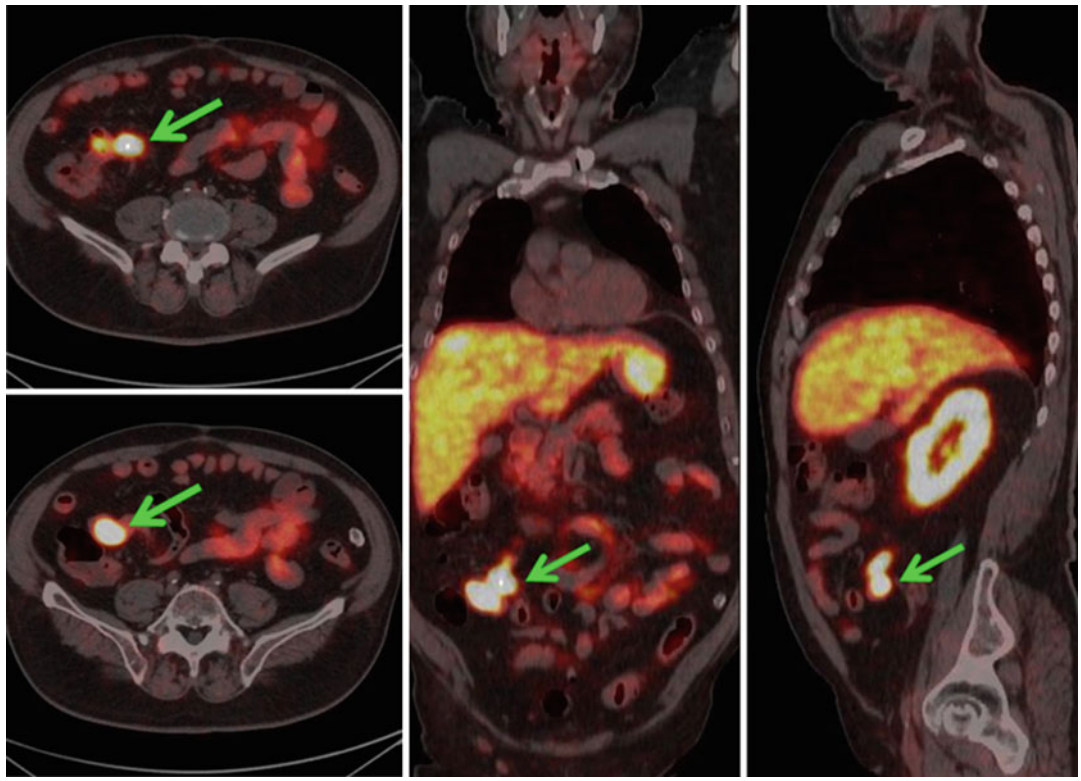

Fig. 1 Axial (*left*), coronal (*center*), and sagittal (*right*) fused ^{68}Ga-DOTATOC PET/CT images show two areas of focal tracer uptake in the terminal ileum close to the ileocecal valve (*green arrows*)

PET/CT (bottom) revealed multiple areas of increased tracer uptake within both lobes of the liver. The patient underwent liver biopsy which revealed grade 1 (G1) carcinoid tumor metastasis. The patient was treated with peptide receptor radionuclide therapy with ^{90}Y-DOTA-tyr^{3}-octreotide.

Discussion

Neuroendocrine tumors (NETs) are a heterogeneous group of malignancies ranging from well-differentiated and slowly growing tumors to poorly differentiated and malignant neoplasms, which are less frequent and display aggressive behavior. PET/CT with ^{68}Ga-DOTA-peptides was reported to present a higher sensitivity for the detection of well-differentiated, less aggressive NET than CT and octreoscan. On the other hand, [^{18}F]FDG PET/CT is preferred for more aggressive, less-differentiated NETs as the emerging evidence shows that the presence of increased glucose in NETs highlights an increased propensity for invasion and metastasis and overall poorer prognosis. The case demonstrates the value of ^{68}Ga-DOTATATE in the evaluation of a well-differentiated neuroendocrine tumor.

Neuroendocrine Tumors: Case No. 3

Case contributed by: S. Al Shammari, F. Fraioli
Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

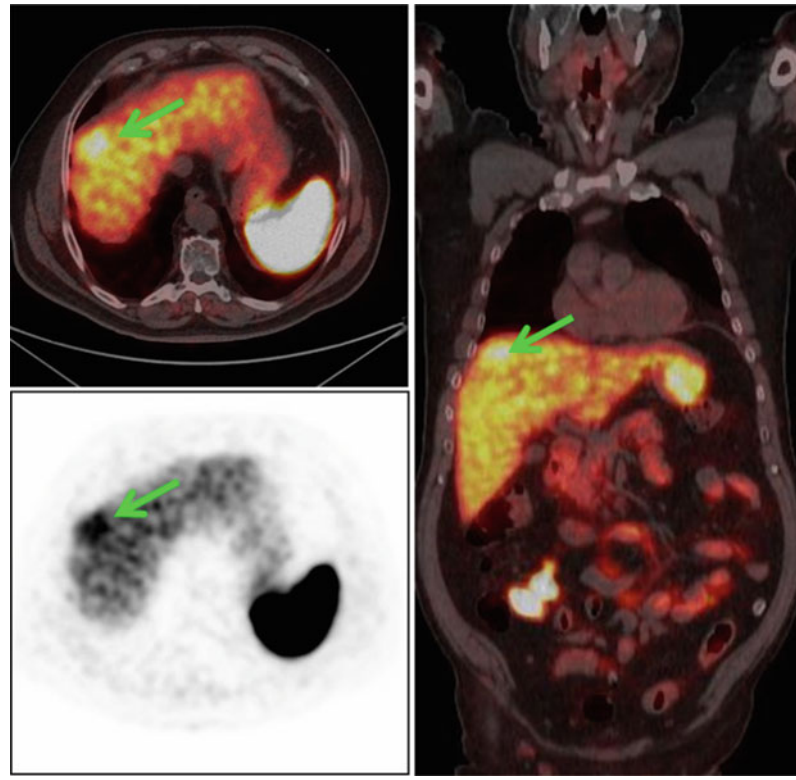

Fig. 2 Axial PET (*left lower*), axial (*left upper*), and coronal (*right*) fused PET/CT images show an area of moderate ^{68}Ga-DOTATOC uptake in segment 8 of the liver (*green arrows*)

Presentation

A 53-year-old patient with suspicion of midgut NET, referred to ^{68}Ga-DOTATATE PET/MRI for staging and baseline evaluation

Findings

Small focus of ^{68}Ga-DOTATATE uptake in the third portion of the duodenum (Fig. 4). MR postcontrast images clearly show the enhancing lesion, with corresponding intense uptake at the fused ^{68}Ga-DOTATATE image (arrows). PET/CT for comparison also identifies the focus of uptake.

Discussion

The positron emitter ^{68}Ga has been linked to short peptide analogues of somatostatin analogues via bifunctional chelate, usually 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA). ^{68}Ga-DOTA-petides have higher affinity for SSTRs as compared to conventional ^{111}In-octreotide. Furthermore, the relatively easy synthesis and long half-life of the parent radionuclide ^{68}Ge (270.8 days) make it possible to use the generator for approximately 6–12 months. Positron emission tomography with ^{68}Ga-labeled somatostatin analogues is performed for localizing and confirming the primary tumor, evaluating disease extension, monitoring treatment effects, and determining the receptor status as a predictor of response in selected patients undergoing targeted radionuclide therapy. Combined positron emission tomography/magnetic resonance imaging (PET/MR) is a relatively new technique that has shown similar performance to positron emission tomography/computed tomography (PET/CT).

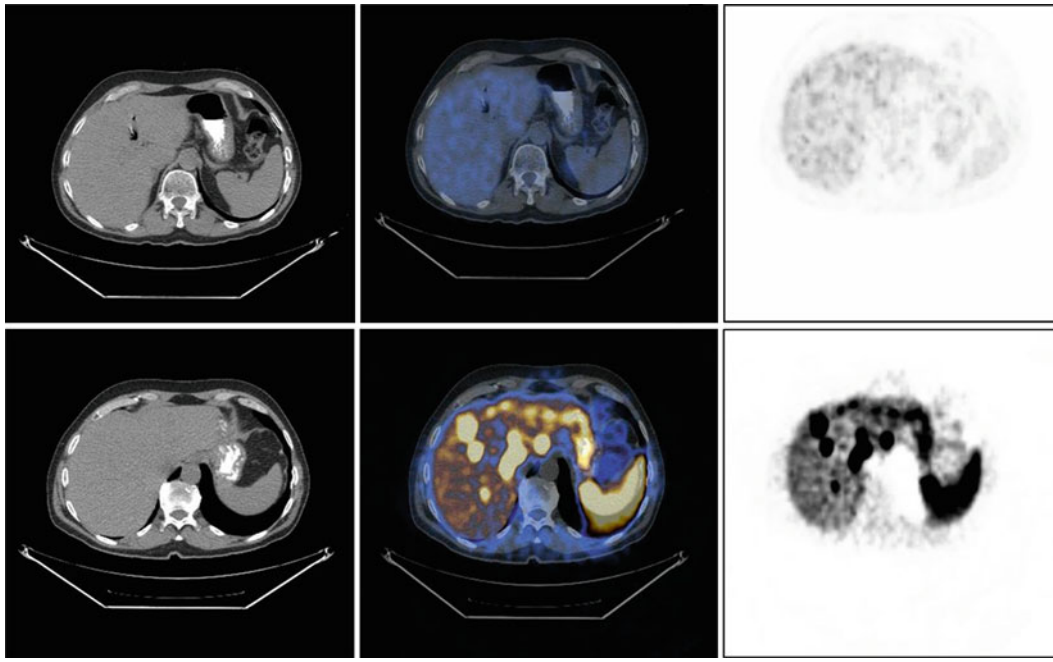

Fig. 3 [^{18}F]FDG PET/CT did not reveal any uptake (upper row). ^{68}Ga-DOTATATE PET/CT (bottom) revealed multiple areas of increased tracer uptake within both lobes of the liver

Neuroendocrine Tumors: Case No. 4

Case contributed by: T. Boshomane, M. Sathekge
Nuclear Medicine, University of Pretoria & Steve Biko Academic Hospital, Pretoria, South Africa

Presentation

A 47-year-old male patient with a history of cecal carcinoma; biopsy after hemicolectomy and lymphadenectomy confirmed large-cell neuroendocrine carcinoma, with Ki67 >20%.

Now presents with worsening dyspnea and ascites

Findings

CT showed right-sided pleural effusion with associated consolidation, multiple lymph nodes (retrosternal, costophrenic, paratracheal lymph nodes, axillary, mesenteric, and para-aortic). A ^{68}Ga-DOTATE PET/CT performed to evaluate for possible peptide receptor radionuclide therapy (PRRT) demonstrated lesions with less intense uptake than in the liver on visual analysis and $SUV_{max} = 1.48$ on axillary lymph nodes (pancreatic head $SUV_{max} = 7.78$). The pleural effusion and other lymph nodes detected on CT were not ^{68}Ga-DOTATE avid (Fig. 6).

A decision was made to perform an [^{18}F]FDG PET/CT 2 days later with the following findings: avid lymph nodes (retrosternal $SUV_{max} = 10.75$, mesenteric $SUV_{max} = 4.82$, para-aortic $SUV_{max} = 7.23$, paratracheal $SUV_{max} = 4.04$) and diffuse uptake on the omentum and peritoneal fluid (Fig. 7).

Teaching Point

The case highlights the value of tracer selection in the patient with a dedifferentiated neuroendocrine

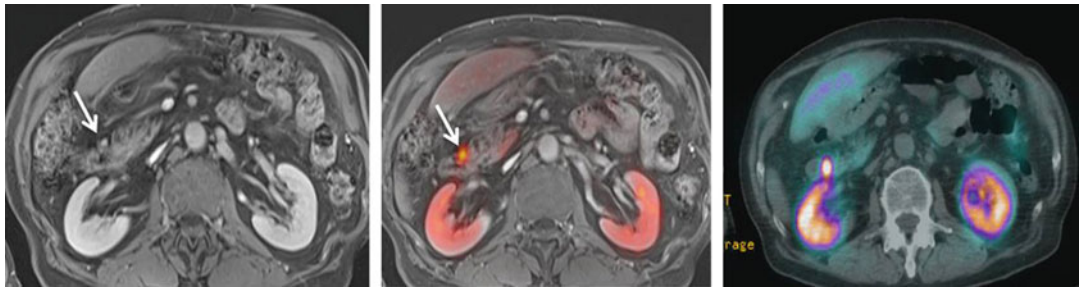

Fig. 4 Comparison of ^{68}Ga-DOTATATE PET/MRI clearly shows focal uptake in the third part of the duodenum (arrow)

carcinoma. Based on these serial imaging with two different molecular probes, i.e., ^{68}Ga-DOTATATE and [^{18}F]FDG, a treatment decision can be made, i.e., the patient is not a candidate for PRRT. Thus, alternative therapy can be sought (Figs. 5, 6, 7, and 8).

Neuroendocrine Tumors: Case No. 5

Case contributed by: G. Manfrinato, A. Chiti
Division of Nuclear Medicine, Department of Biomedical Sciences – Humanitas University, Milan, Italy

Presentation

A 54-year-old-man with chronic liver disease (HBV-HCV related) evolving toward cirrhosis underwent an abdominal ultrasound that revealed previously unsuspected hepatic lesions.

Blood chemistry showed mildly elevated serum levels of the tumor-associated markers CEA (6.7 ng/mL) and AFP (12 ng/mL), while the value of Ca 19.9 was completely normal.

Findings

A CT scan showed multiple metastatic lesions in all liver segments and a large mass (6 × 3 × 7 cm) originating from the uncinated process of the pancreas, associated with locoregional lymphadenopathy (hepatic hilum, celiac, and inter-aortocaval regions).

The patient underwent a PET/CT scan with [^{18}F]FDG that showed focally increased uptake in the uncinate process of pancreas, better outlined, however, in a subsequent scan with ^{68}Ga-DOTATOC (Fig. 9), as well as in multiple abdominal lymphadenopathy (peripancreatic region, hepatic hilum, and inter-aortocaval region), and in thoracic lymphadenopathy (subclavian region, right axilla, and left clavicular region). The liver lesions also showed increased [^{18}F]FDG uptake (Fig. 10); finally, there were also numerous areas of increased tracer uptake throughout the skeleton (Fig. 11).

One month later, a PET/TC scan with ^{68}Ga-DOTATOC showed the same lesions previously observed in the PET/TC scan with [^{18}F]FDG; nevertheless, the scan revealed other new areas of increased uptake in the skeleton (right portion of the D12 body, right pedicle of L5, left ilium, right acetabulum, and right portion of the frontal bone) (Figs. 12 and 13).

Ultrasound-guided biopsy of one hepatic lesion showed hepatic localization of neuroendocrine tumor, G3, with a Ki67 index of 85%.

Follow-Up

The patient started a chemotherapy protocol and RT treatment on bone lesions, with reduction of the extent of hepatic, lymphatic, and skeletal disease.

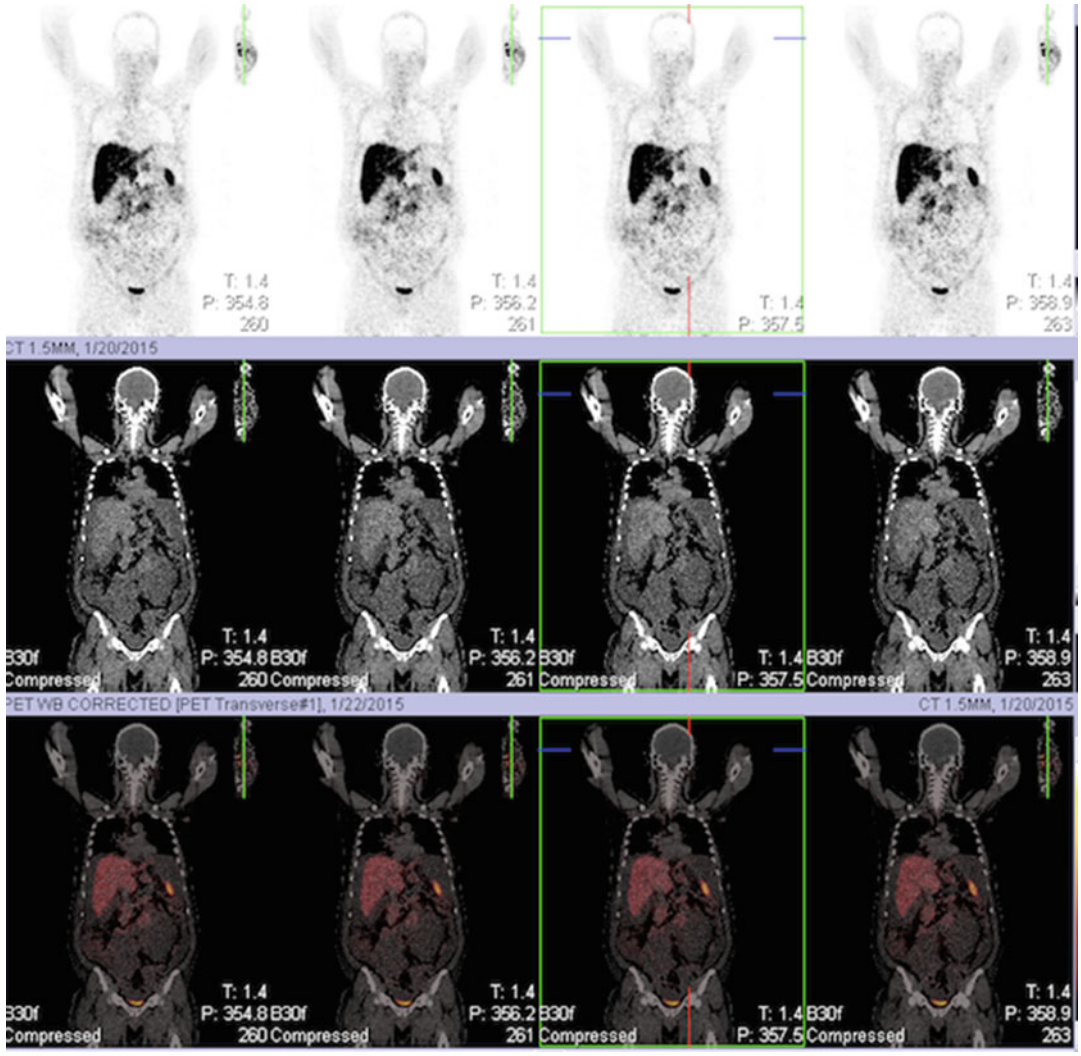

Fig. 5 *Top row*: ^{68}Ga-DOTATATE PET coronal section demonstrating no uptake in the chest and abdominal intensity less than liver and spleen. *Middle row* is the coronal CT images showing pleural effusion. *Bottom row* coronal section of the fused PET/CT images

Neuroendocrine Tumors: Case No. 6

Case contributed by: E. Tabacchi[1], C. Nanni[1], I. Bossert[1], A.M. Maffione[2], S. Fanti[1]

[1]Nuclear Medicine Unit, "S. Orsola-Malpighi" Hospital, Bologna, Italy

[2]Nuclear Medicine Unit, "Santa Maria della Misericordia" Hospital, Rovigo, Italy

A 54-year-old man, with polyuria, polydipsia, dysuria, weight loss (10 kg), and recent diagnosis of diabetes, underwent CT scan that revealed hepatic lesions, splenic vein thrombosis, and bilateral adrenal hyperplasia. Laboratory test showed hypokalemia (2 mEq/L) and hypercortisolemia. The patient was hospitalized, and a ^{68}Ga-DOTANOC PET/CT with diagnosis of neuroendocrine tumor of the pancreas with hepatic

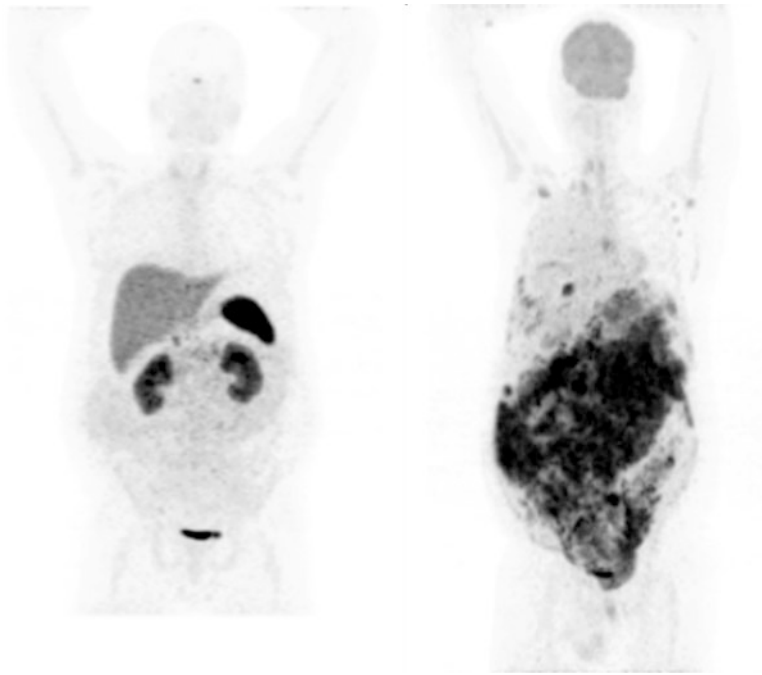

Fig. 6 MIP comparison of ^{68}Ga-DOTATATE PET (*left*) and [^{18}F]FDG PET (*right*) of the same patient with metastatic neuroendocrine tumor demonstrating dedifferentiation

metastasis and ACTH secreting was performed (paraneoplastic Cushing syndrome). Indeed ^{68}Ga-DOTANOC PET/CT revealed focal uptake at the body-tail of the pancreas ($SUV_{max} = 17.3$) (Fig. 14a, red flags; Fig. 14b, red flags) and multiple areas of uptake at the liver (the greater at the segment 6/7 with $SUV_{max} = 16.7$) (Fig. 14a, b: blue flags) compatible with lesions with moderate expression of somatostatin receptors (types: 2, 3, 5).

During hospitalization the adrenal glands were surgically removed and the patient started therapy with octreotide and lanreotide.

After almost 1 year, the patient underwent another ^{68}Ga-DOTANOC PET/CT that showed an increase in size of the area of uptake at the body-tail of the pancreas ($SUV_{max} = 40.1$) (Fig. 15a: red flags) with an increase in size and uptake in the multiple hepatic lesions ($SUV_{max} = 44$ at the segment 6/7 and $SUV_{max} = 68$ at the segment 2) (Fig. 15a, b: blue flags). PET/CT revealed the appearance of uptake to other hepatic lesions, for example, at the dome of the liver ($SUV_{max} = 33$).

The patient started therapy with Ipstyl and underwent therapy with ^{90}Y-DOTA-peptide (five cycles). After 3 months he underwent ^{68}Ga-DOTANOC PET/CT to assess response to therapy that showed stability for size and uptake at the body-tail of the pancreas ($SUV_{max} = 44.7$) (Fig. 16a: red flags) and stability at the hepatic lesions ($SUV_{max} = 34$ at the segment 6/7 and $SUV_{max} = 38$ at the segment 2) (Fig. 16a, b: blue flags) with appearance of necrosis in the middle of the lesion.

no enlarged mesenterial or retroperitoneal lymph nodes. In the liver were multiple round, hypodense lesions that were too small for further characterization. Patient was referred to an academic hospital for a pylorus-preserving pancreaticoduodenectomy with portal vein reconstruction, removal of the inferior mesenteric vein, and splenectomy with partial autotransplantation. Pathologic examination of the mass showed a low-grade neuroendocrine tumor. The resection margins were tumor-free and there were no tumor cells present in all 18 removed lymph nodes. The tumor was staged as a T3N0Mx neuroendocrine pancreas tumor. No additional treatment was given, and follow-up was started with six-monthly ultrasound of the abdomen.

After 1 year, at the second ultrasound, a hypoechoic lesion of 3.3 cm was seen in the

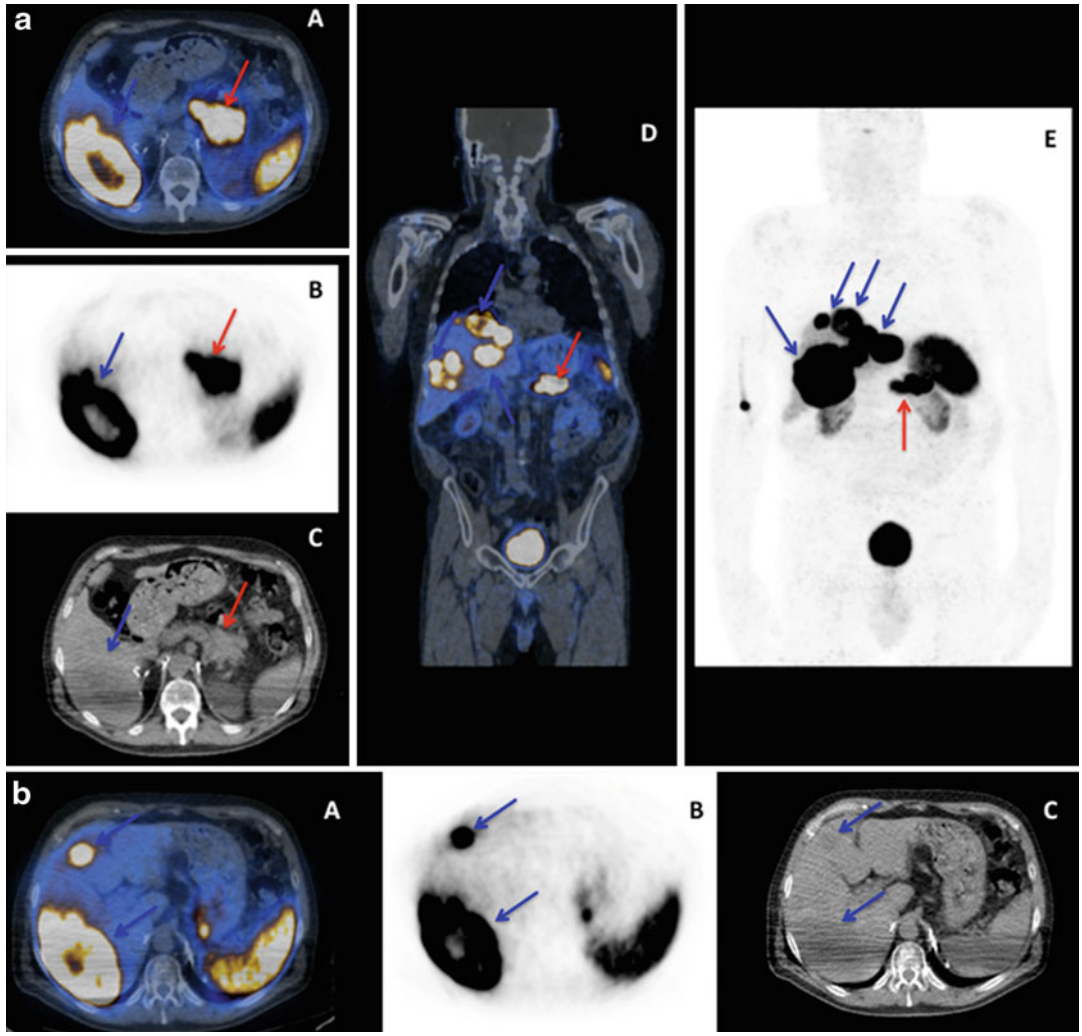

Fig. 15 (**a**) (*A*, transaxial ^{68}Ga-DOTATOC PET/CT; *B*, transaxial ^{68}Ga-DOTATOC PET; *C*, transaxial CT; *D*, coronal ^{68}Ga-DOTATOC PET/CT; *E*, MIP; *red* flag, pancreatic finding; *blue* flag, hepatic finding). (**b**) (*F*, transaxial ^{68}Ga-DOTATOC PET/CT; *G*, transaxial ^{68}Ga-DOTATOC PET; *H*, transaxial CT; *blue* flag, hepatic finding)

liver on the right side of the falciform ligament (Fig. 18). Subsequently, a whole-body ^{18}F-dihydroxyphenylalanine (^{18}F-DOPA) PET/CT with a three-phase (noncontrast, arterial, and portal venous phase) diagnostic CT of the liver was performed (Fig. 19). The ^{18}F-DOPA PET/CT showed no pathologic uptake and the lesion visible on the ultrasound could not be reproduced on the diagnostic CT. The small hypodense lesions throughout the liver were unchanged in comparison to the preoperative CT. It was determined that the lesion on the ultrasound was most likely an artifact. Normal follow-up was resumed.

On the following ultrasound, the earlier lesion was not seen. However, the ultrasound 2 years after surgery, showed a new hypoechoic lesion of 1.9 cm in segment 6 of the liver (Fig. 20). A three-phase CT of the liver showed four hypodense lesions with enhancement in the arterial phase (segment 8, 3.7 cm; segment 8, 2.4 cm;

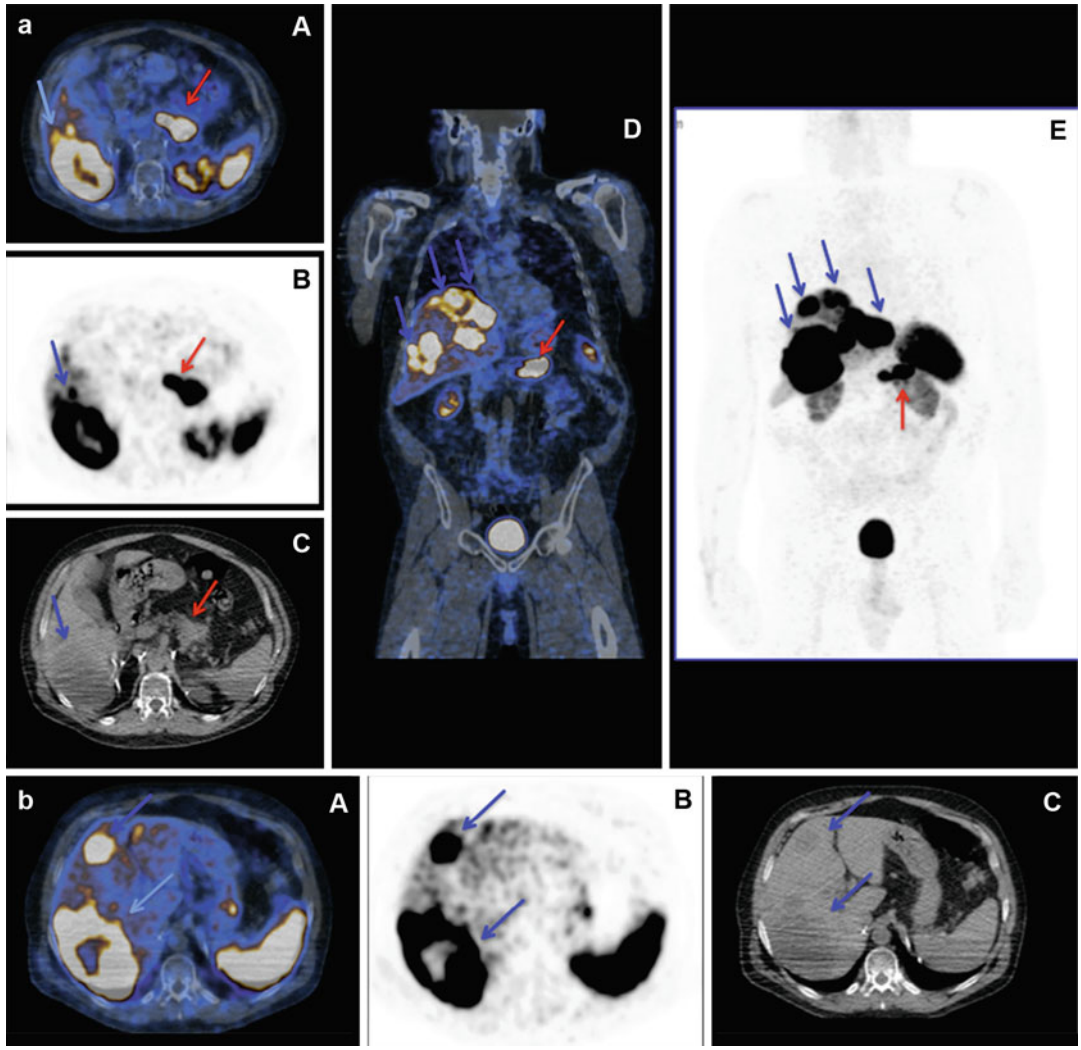

Fig. 16 (**a**) (*A*, transaxial ^{68}Ga-DOTATOC PET/CT; *B*, transaxial ^{68}Ga-DOTATOC PET; *C*, transaxial CT; *D*, coronal ^{68}Ga-DOTATOC PET/CT; *E*, MIP; *red* arrow, pancreatic finding; *blue* arrow, hepatic finding). (**b**) (*F*, transaxial ^{68}Ga-DOTATOC PET/CT; *G*, transaxial ^{68}Ga-DOTATOC PET; *H*, transaxial CT; *blue* arrow, hepatic finding)

segment 1, 2.0 cm; and segment 6/7, 1.4 cm) and several prominent lymph nodes in the mesenterium and the retroperitoneum (Fig. 21). The liver lesions were highly suspicious for liver metastases of the neuroendocrine tumor. The prominent lymph nodes were also suspicious for metastases, but were also very likely to be reactive lymph nodes.

To further evaluate the properties of the liver lesions and the lymph nodes, a [^{11}C]5-hydroxy-L-tryptophan ([^{11}C]HTP) PET/CT was performed (Fig. 21). The [^{11}C]HTP PET/CT showed increased uptake in the liver lesion, but no increased uptake in the lymph nodes or elsewhere.

Follow-Up

Based on the diagnostic CT and the [^{11}C]HTP PET/CT, it was determined that the patient had a

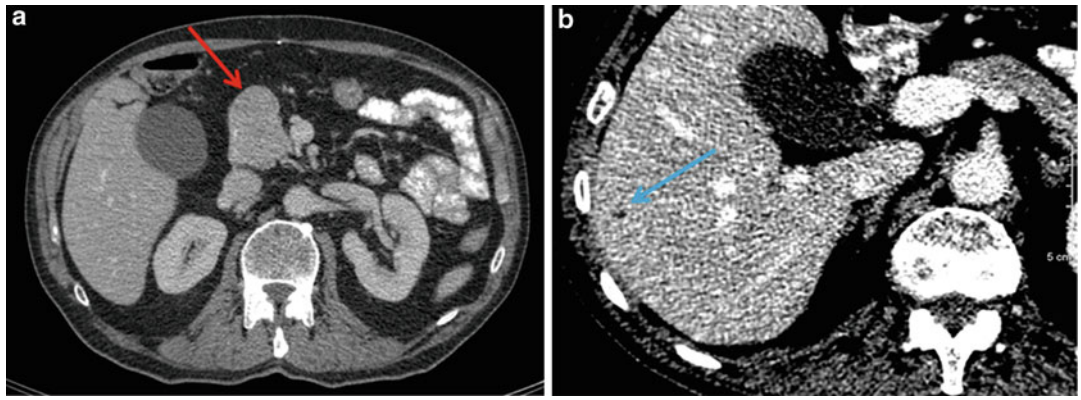

Fig. 17 Preoperative abdominal CT showing: (**a**) a mass near the head of the pancreas (*red arrow*); (**b**) small hypodense lesions in the liver (*blue arrow*)

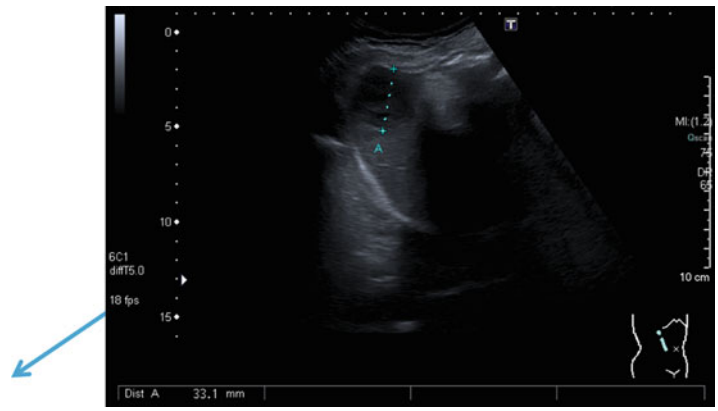

Fig. 18 Ultrasound of the liver 1 year after surgery, showing a hypoechoic lesion of 3.3 cm on the right side of the falciform ligament (*blue dotted line*)

metastasized neuroendocrine tumor with lesions in the liver, but not in the mesenteric and retroperitoneal lymph node stations. As the patient had relatively few symptoms, it was decided in agreement with the patient to treat the disease noninvasively, especially since an operation would be difficult and accompanied with high risk of complications. Patient started with subcutaneous octreotide injections once every 4 weeks. One year later the patient developed a radicular syndrome due to a metastasis in the first and second lumbar vertebrae for which radiotherapy was started.

Neuroendocrine Tumors: Case No. 8

Presentation

A 56-year-old man was diagnosed 19 years ago with malignant thymoma with predominant spindle cells. He was referred for suspected recurrence.

Findings

[^{18}F]FDG PET/CT showed hypermetabolic anterior mediastinal mass consistent with recurrent disease (Fig. 22). The CT-guided biopsy of the

Fig. 19 Maximum intensity projection of the ^{18}F-DOPA PET/CT, showing no pathologic uptake

mass revealed B3 spindle cell thymoma as the former. Thymectomy was performed, and histology demonstrated neuroendocrine tumor (NET) with spindle cell solid-lobular architecture constituted by poorly differentiated NET and atypical carcinoid.

Routine follow-up 9 months postsurgery CT of the thorax showed mediastinal lymph node enlargement and pleura thickenings of suspected origin.

^{68}Ga-DOTATOC PET/CT clearly showed left supra-infraclavicular and mediastinal lymph nodes with pathological tracer uptake and multiple thickenings of the left pleura with intense DOTATOC uptake.

Discussion

Thymic NETs are very uncommon malignant tumors of the thymus. This case demonstrates the value of both ^{68}Ga-DOTA-peptides and [^{18}F] FDG PET/CT in a rare case of combined poorly differentiated NET and atypical carcinoids of the thymus (Fig. 23).

Kidney and Bladder Cancers: Case No. 1

Case contributed by: M. Kirienko, A. Chiti

Division of Nuclear Medicine, Department of Biomedical Sciences – Humanitas University, Milan, Italy

Presentation

A 65-year-old man affected by adenocarcinoma of the prostate (pT3bN1), Gleason score 3 + 5 = 8, PSA 43 ng/mL, who had undergone radical prostatectomy 3 years earlier and hormonal therapy and salvage radiation therapy 1 year earlier, was referred to perform [^{11}C]choline PET/CT (PET/CT-1) for restaging because of biochemical relapse. PSA before the PET/CT-1 examination was 2.52 ng/mL, and the scan was negative for prostate cancer relapse. Seven months later, because of rising PSA values, another [^{11}C]choline PET/CT scan (PET/CT-2) was performed. PSA before PET/CT-2 was 6.84 ng/mL.

Findings

[^{11}C]choline PET/CT-2 images (Fig. 1) showed no tracer uptake related to prostate cancer relapse, although a huge left renal mass was seen (Fig. 2) that was confirmed also on contrast-enhanced CT (Fig. 3). Retrospectively, PET/CT-1 images were reevaluated, and a renal lesion was already identifiable, in particular, on unenhanced low-dose CT (Fig. 4a–c).

The patient underwent left nephrectomy. The lesion resulted to be a renal cell carcinoma, sarcomatoid chromophobe variety, pT4 N0 R1. Additionally, three out of three lymph nodes at the renal hilum resulted to be positive for prostate cancer metastasis. Four months later, PSA levels rose to 7.55 ng/mL, and [^{11}C]choline PET/CT showed multiple abdominal [^{11}C]choline-avid lymph nodes.

Fig. 1 The fused axial [^{11}C]choline PET/CT-2 image shows no focal uptake areas related to prostate cancer relapse

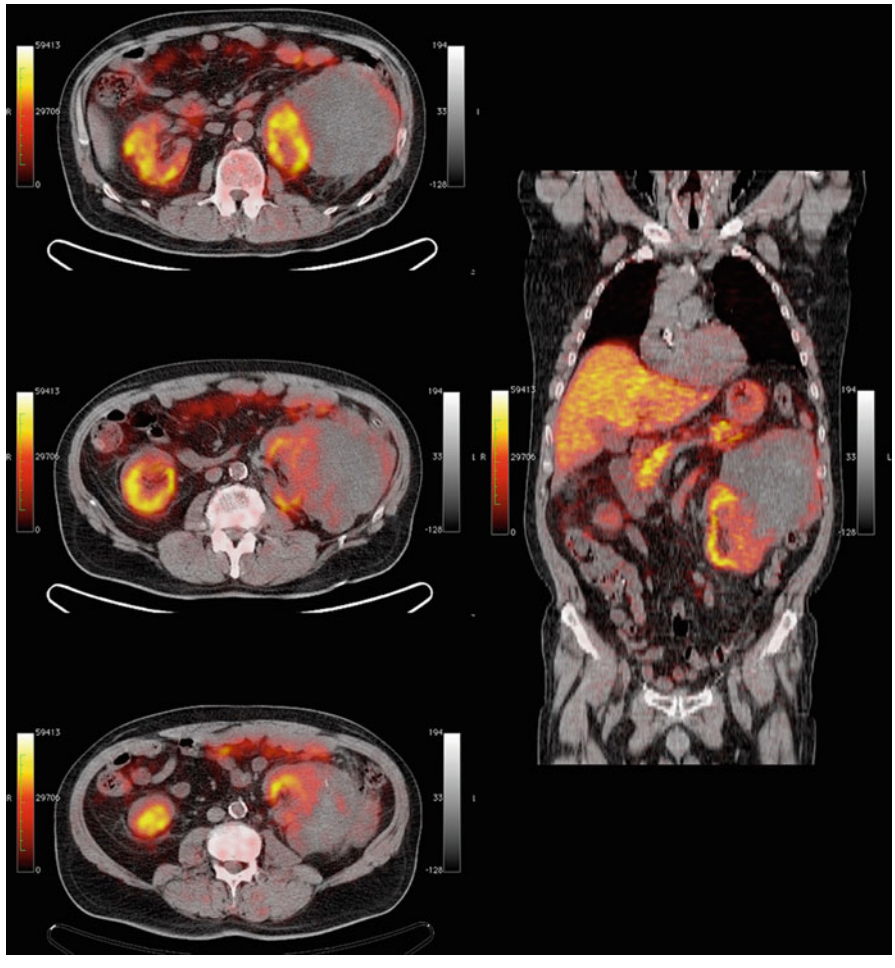

Fig. 2 The fused axial (*left*) and coronal (*right*) [^{11}C]choline PET/CT-2 images show a large left kidney mass, displaying peripheral tracer uptake with central photopenia corresponding to necrosis

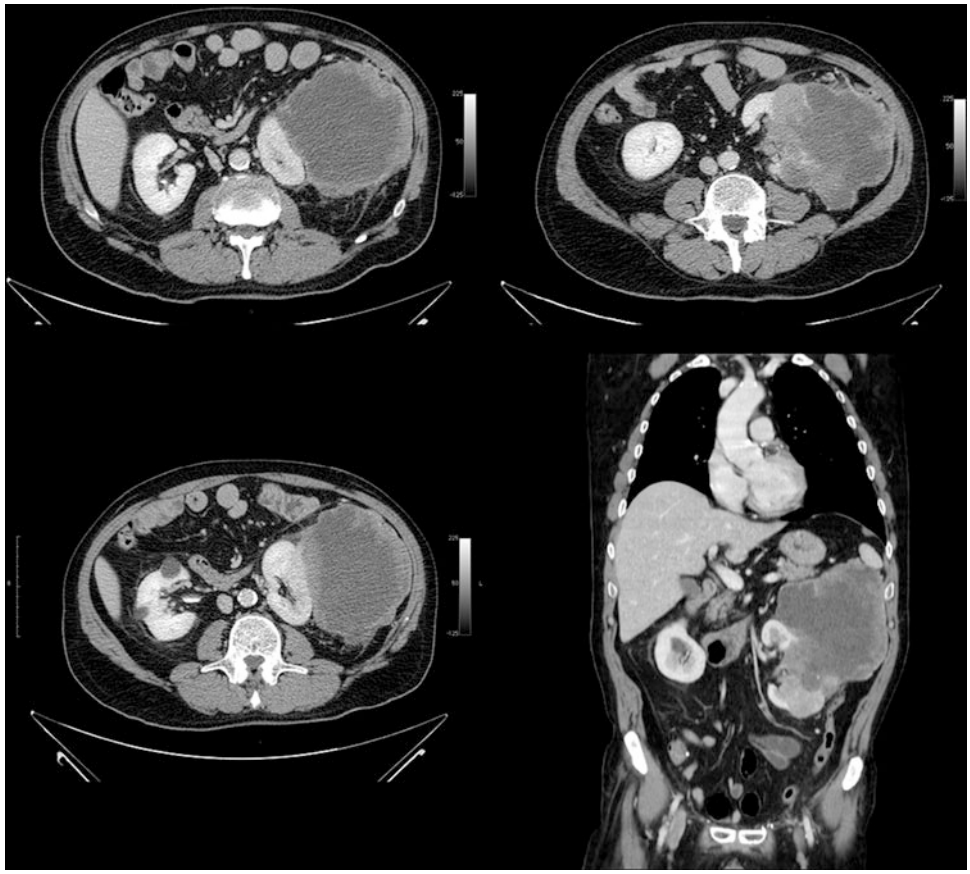

Fig. 3 The fused axial (*left* and *top right*) and coronal (*bottom right*) contrast-enhanced CT images show the left kidney mass

Discussion

[^{11}C]choline PET/CT is not specific for prostate cancer and other malignant and benign lesions can concentrate the tracer. Lesions without significant radiopharmaceutical uptake or uptake intensity equal to background (e.g., in the liver or kidneys) may also occur. Careful evaluation of all the districts is mandatory both on PET and CT image series in order not to miss lesions characterized by a low uptake.

Kidney and Bladder Cancers: Case No. 2

Case contributed by: M.A. Pedersen
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark

Presentation

A 63-year-old man presented with hemoptysis.

Findings

A CT scan showed enlarged lymph nodes in mediastinum station 2R and hydronephrosis of the left

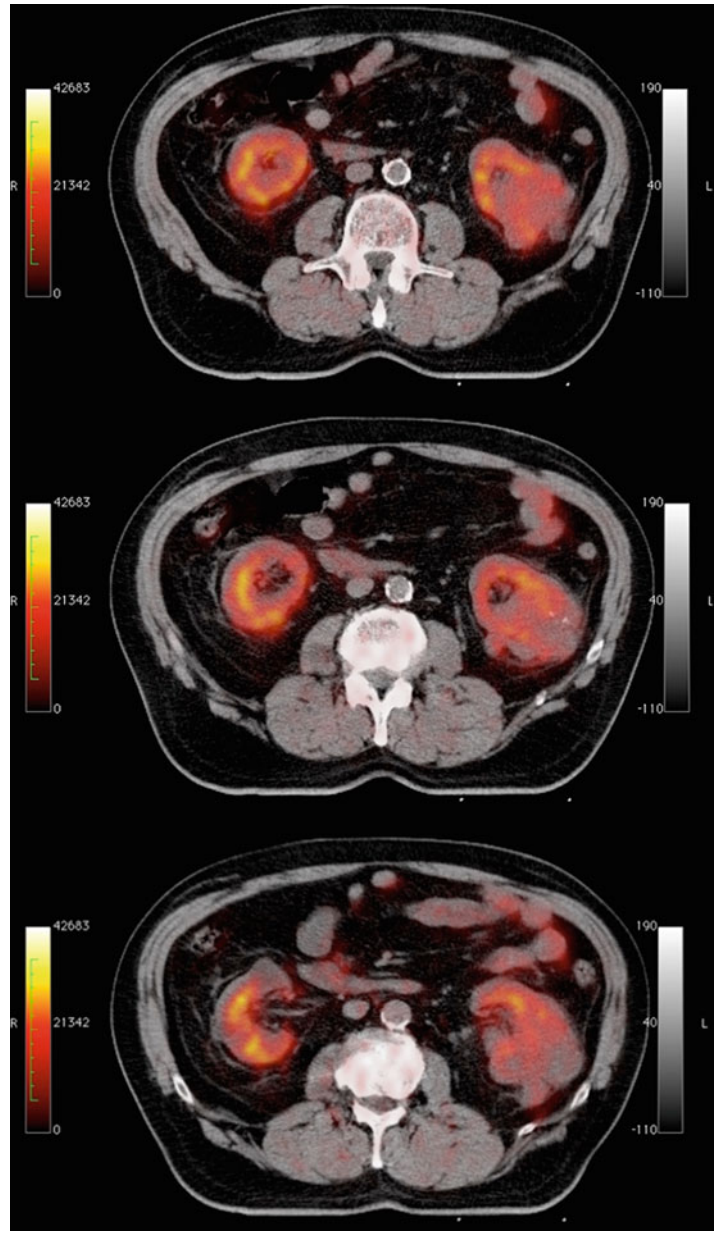

Fig. 4 The fused axial [^{11}C]choline PET/CT-1 images show an exophytic renal lesion displaying faint [^{11}C]choline uptake

kidney. Due to these findings, the patient was referred for an [^{18}F]FDG PET/CT scan with the suspicion of lung cancer.

The [^{18}F]FDG PET/CT showed a single enlarged lymph node in mediastinum station 10R with moderately increased [^{18}F]FDG uptake. The scan also confirmed hydronephrosis and minimal parenchyma in the left kidney (Fig. 5, red arrow). In addition, [^{18}F]FDG activity was observed in the distal part of the left ureter (Fig. 5, yellow arrow) which was interpreted as urinary [^{18}F]FDG accumulation in the ureter.

Follow-Up

Because of the hydronephrosis, a CT urography was performed. This revealed a possible tumor in

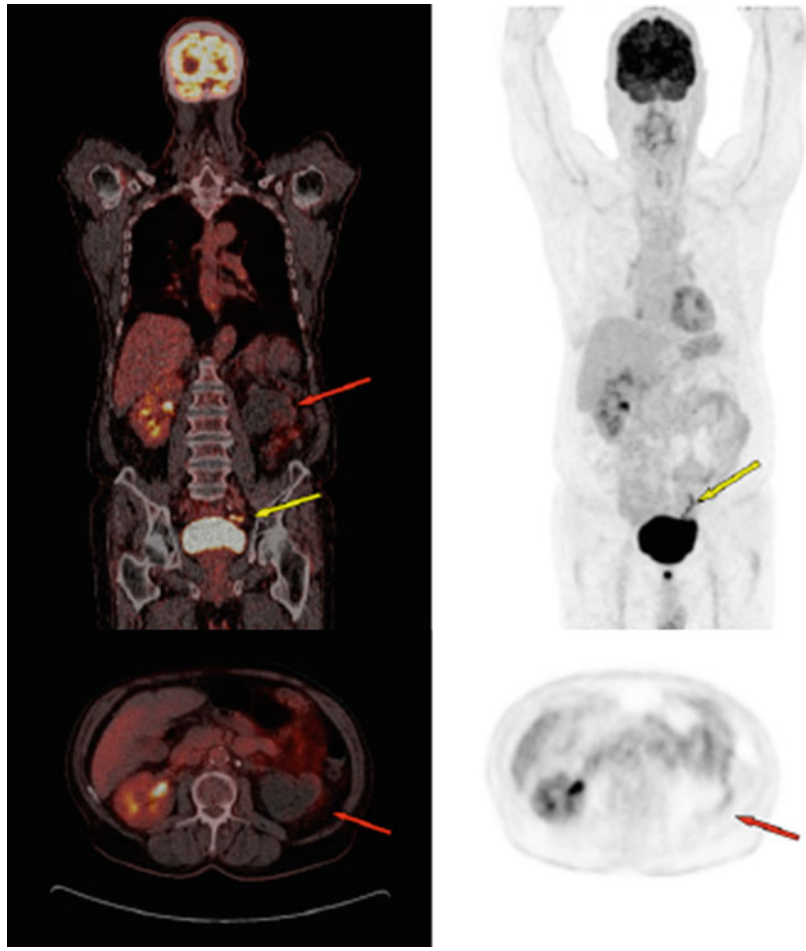

Fig. 5 The [^{18}F]FDG PET/CT scan also revealed, as previously described, hydronephrosis and minimal parenchyma in the left kidney (Figs. 1a and 2a, b, *red arrow*). In addition, [^{18}F]FDG activity was observed in the distal part of the left ureter (Fig. 1a, b, *yellow arrow*) which was interpreted as urinary [^{18}F]FDG activity in the ureter

the distal left ureter and no excretion from the left kidney. Subsequent ureteroscopy with biopsy revealed urothelial cancer with low malignancy in the distal left ureter. The patient was treated with left nephroureterectomy.

The suspicion of lung cancer was later abandoned.

Discussion

This case shows that it can be difficult to interpret [^{18}F]FDG PET/CT scans when it comes to malignancies in the urinary tract system, due to urinary excretion of [^{18}F]FDG. Special attention should be paid when a kidney shows signs of distress (e.g., hydronephrosis, loss of parenchyma) and focal [^{18}F]FDG activity in the ureter which may be due to malignancy.

Kidney and Bladder Cancers: Case No. 3

Presentation

A 57-year-old with a history of left back pain and macrohematuria underwent US examination which did not disclose any lesion at the level of all urinary pathways and the bladder. Since the patient had experienced a previous severe adverse reaction against iodinated contrast agent, he was started to

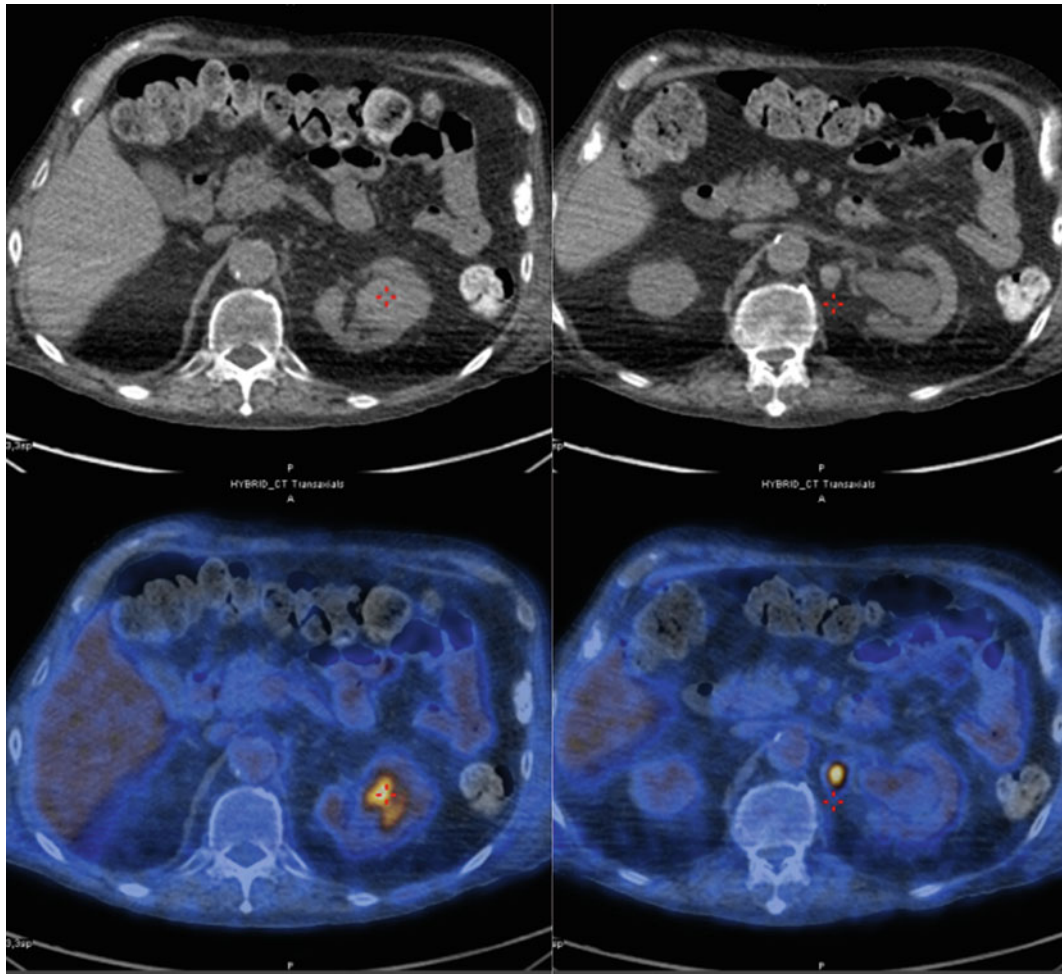

Fig. 6 [^{18}F]FDG PET/CT axial slices (CT and fused images) show a lesion accumulating [^{18}F]FDG within the pelvis of the left kidney and nodule consistent with a pathological perirenal lymphadenopathy

an abdominal MR study which revealed a T1-weighted hypointense mass with contrast enhancement within the left pelvis. A lymphadenopathy in the perirenal space, posteriorly to the renal vein, was also disclosed. An advanced urothelial carcinoma was then suspected.

Findings

In order to complete the staging, the patient underwent also a whole-body [^{18}F]FDG PET/CT study. PET/CT confirmed the presence of a hypermetabolic lesion within the pelvis of the left kidney as well as a perirenal hypermetabolic lymph node. No other pathologic hyperactive foci were observed (Fig. 6). A subsequent MR scan confirmed PET/CT findings (Fig 7).

Follow-Up

The patient underwent surgery, and pathology confirmed the presence of a transitional carcinoma arising from the renal pelvis with lymph node involvement.

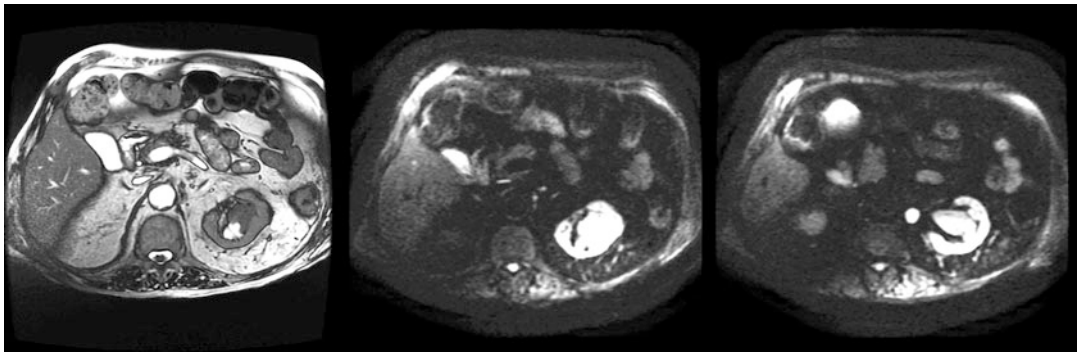

Fig. 7 T1- and T2-weighted MR axial slices confirm [^{18}F]FDG PET/CT findings

Teaching Points

Only a limited number of studies have investigated the utility of PET in the assessment of the staging of renal carcinoma. However, some renal carcinomas like those arising from urothelial cells usually show a high grade of uptake of [^{18}F]FDG.

Kidney and Bladder Cancers: Case No. 4

Presentation

A 59-year-old woman had previously undergone left nephrectomy due to a papillary renal cell carcinoma. Since the patient was suffering from osteoporosis, she experienced multiple vertebral fractures treated with a neurosurgical vertebral fixation procedure with permanent rigid titanium prosthesis.

Findings

At restaging, due to the presence of artifacts produced by the metal device on CT images, the patient underwent a PET/CT with [^{18}F]FDG to better explore the lumboaortic region. PET/CT disclosed the presence of several hypermetabolic lymph nodes which were not visualized by diagnostic CT (Fig. 8).

Management

Due to the extensive lymph node involvement seen on PET/CT, the patient was started to chemotherapy.

Teaching Points

Papillary renal cell carcinoma is usually avid of [^{18}F]FDG, and PET/CT can be used in selected cases for the restaging of patients, usually when they cannot undergo a ceCT or when CT findings are not conclusive. Moreover, PET/CT can be useful for lymph node metastases which can often be falsely negative using the CT size criteria.

Kidney and Bladder Cancers: Case No. 5

Presentation

A 69-year-old woman with a history of smoking underwent a chest X-ray that disclosed a consolidation within the upper right lobe.

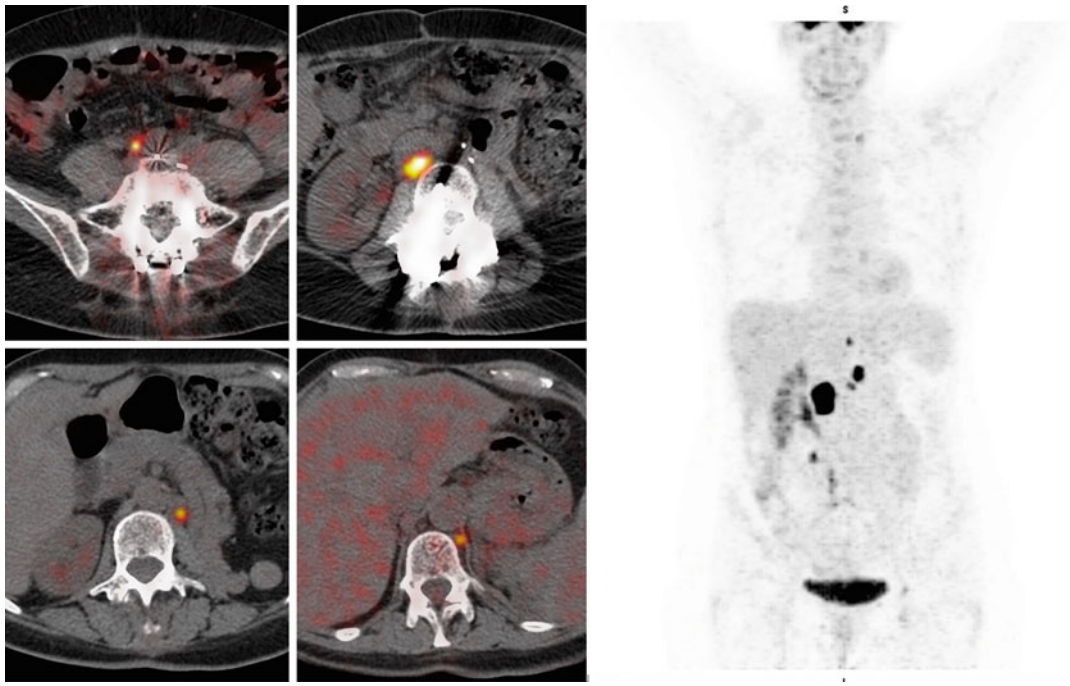

Fig. 8 On the *left*, four fused [^{18}F]FDG PET/CT images showing four different foci of hyperactivity consistent with secondary lymphadenopathies of both left and right lumboaortic stations and of left retrocrural site. The two axial images on top show the presence of artifacts that affect CT due to the vertebral metal devices. On the *right* panel, [^{18}F]FDG whole-body PET MIP image demonstrating the high uptake of [^{18}F]FDG within the lymphadenopathies

Findings

A chest CT confirmed the presence of a mass-like consolidation of the upper right lobe with interstitial infiltrates and bronchogram and another peripheral nodule in the middle lobe with blurred contours, close to the pleura (Fig. 9). A PET/CT with [^{18}F]FDG was suggested in order to metabolically characterize the pulmonary lesions described by the CT. At PET/CT, both lung lesions presented a moderate uptake of [^{18}F]FDG. Moreover, the whole-body acquisition of PET/CT allowed to observe the presence of a left kidney with a distorted renal parenchyma outline at the upper pole, with a hypermetabolic tissue surrounding the perirenal space (Fig. 10).

Follow-Up

The patient underwent a ceCT of the abdomen which confirmed the presence of a large perirenal plaque lesion inseparable from the adjacent renal parenchyma of the upper pole of the left kidney (Fig. 11). The final diagnosis was B-cell lymphoma.

Teaching Points

Incidental renal lesions can be encountered on PET/CT imaging. They are difficult to detect because of the excretion of [^{18}F]FDG via the urinary tract as well as the significant variability in the uptake of [^{18}F]FDG. Perirenal masses are

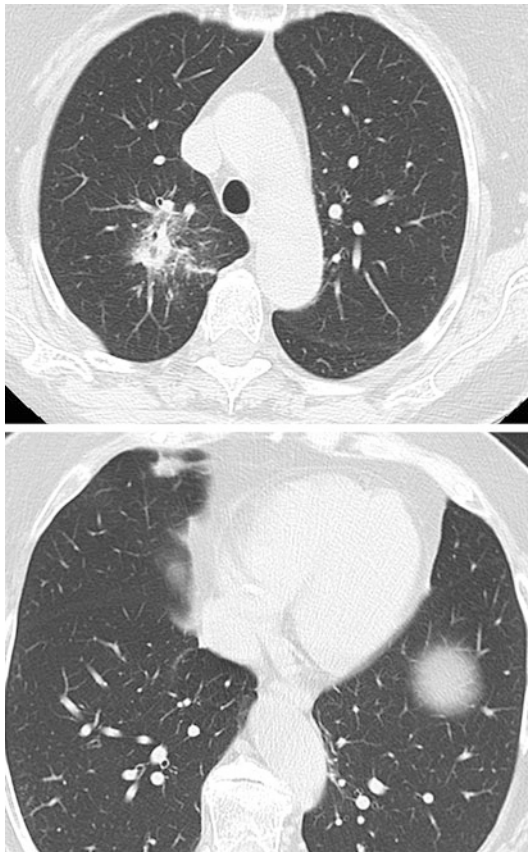

Fig. 9 Chest CT showing the consolidation of the *upper right* lobe with interstitial infiltrates and bronchogram and a peripheral nodule in the *middle lobe*

one of the more typical patterns of renal lymphoma which can be easily identified on metabolic imaging, as an intensely [^{18}F]FDG-avid lesion.

Kidney and Bladder Cancers: Case No. 6

Case contributed by: K. Bouchelouche
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark

Presentation

A 69-year-old man with a clear cell RCC of the right kidney was treated with partial nephrectomy. Control CT 2 years later demonstrated right renal vein thrombus but no signs on local recurrence in the kidney.

Findings

The patient was referred to [^{18}F]FDG PET/CT that showed local recurrence in the right kidney. Furthermore, axial PET/CT showed malignant venous tumor thrombus in the right renal vein (Fig. 12).

Teaching Points

In this case, PET showed local recurrence in the right kidney which was not seen on CT. Clear cell RCC often invades the renal vein and the cava vein, which often can be seen on PET/CT since there is no interference with [^{18}F]FDG activity in urine.

Kidney and Bladder Cancers: Case No. 7

Case contributed by: K. Bouchelouche
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark

Presentation

A 71-year-old woman with a clear cell RCC of the right kidney was treated with radical nephrectomy. Four years later, control CT demonstrated a process in the right suprarenal gland. A biopsy showed metastasis from clear cell RCC.

Findings

The patient was referred for [^{18}F]FDG PET/CT to complete restaging. PET/CT showed modest [^{18}F]FDG uptake in the known metastasis in the right suprarenal gland. No other metastases or local recurrence was found (Fig. 13).

A benign simple cyst without [^{18}F]FDG uptake was seen on axial PET image (B) and on axial CT image in the left kidney (Fig. 14).

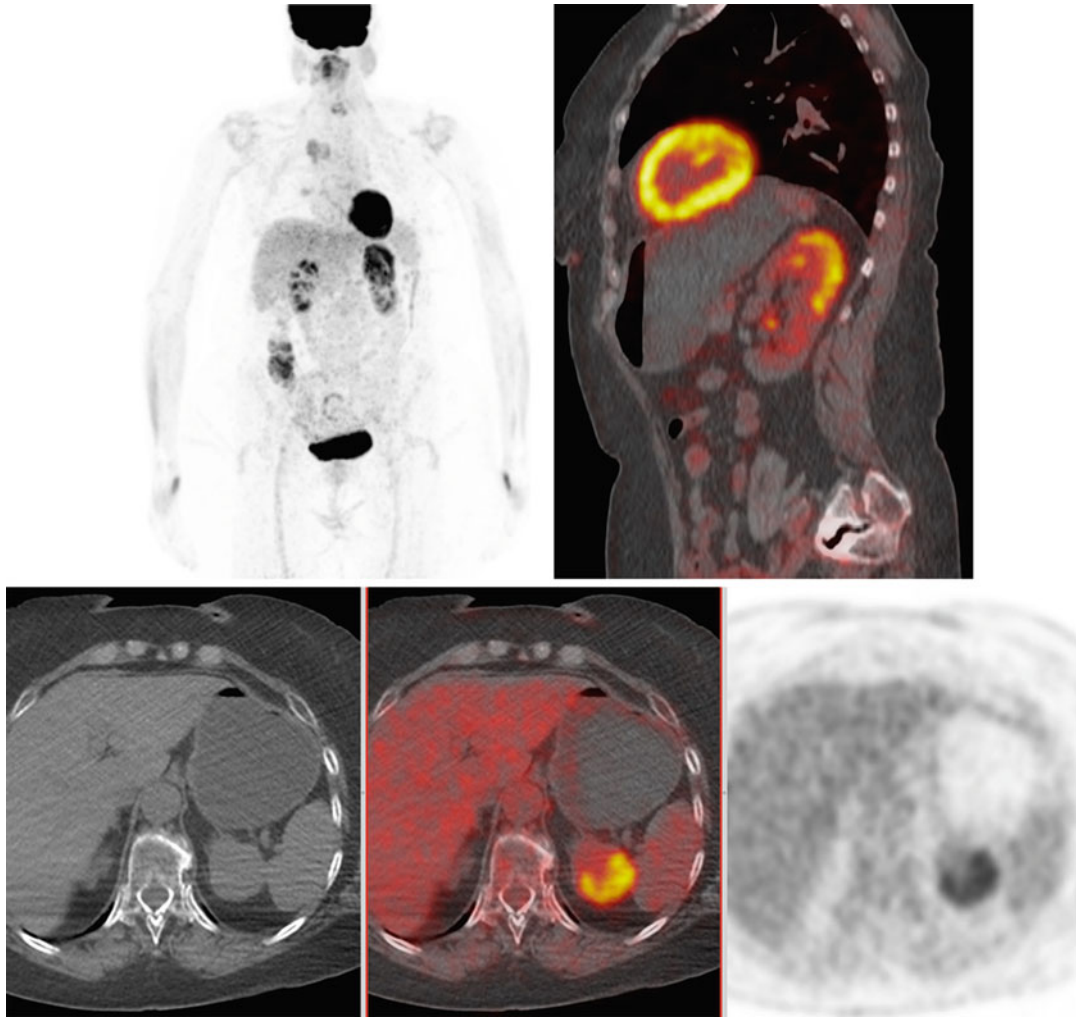

Fig. 10 [^{18}F]FDG MIP image shows two foci of moderate hyperactivity within the right lung corresponding to the lesions disclosed by CT (*top left*). Moreover, an area of high metabolic activity is surrounding the upper pole of the left kidney (*top right*). CT, fused PET/CT, and PET axial slice clearly demonstrating increased [^{18}F]FDG perirenal uptake of the left kidney

Follow-Up

Right adrenal metastasis from RCC was confirmed by pathology after surgery.

Teaching Points

[^{18}F]FDG PET/CT can be used for the detection of distant metastases during restaging of RCC. Incidental findings of benign simple cysts without [^{18}F]FDG uptake are often seen on [^{18}F]FDG PET/CT scans. If [^{18}F]FDG uptake is seen in cysts in the kidneys, it is clearly suspicious of malignancy.

Kidney and Bladder Cancers: Case No. 8

Case contributed by: K. Bouchelouche
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark

Fig. 11 ceCT image demonstrates the perirenal plaque lesion inseparable from the adjacent renal parenchyma of the upper pole of the left kidney

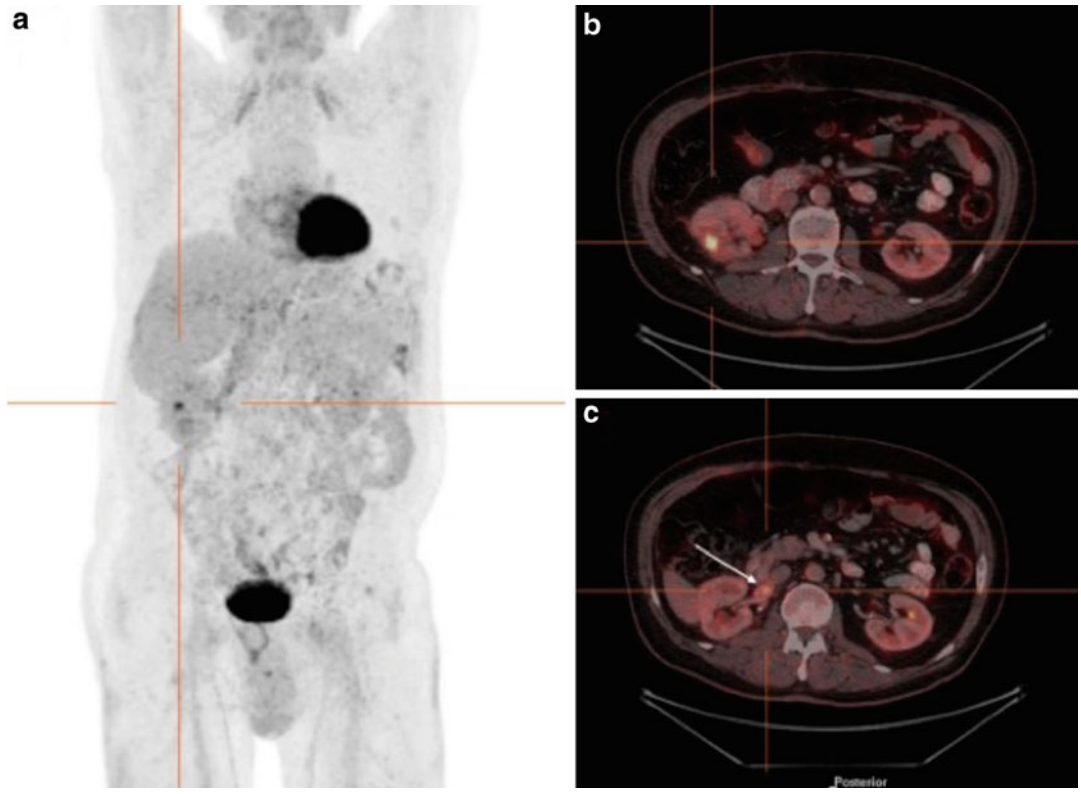

Fig. 12 MIP and fused [^{18}F]FDG PET/CT slice (*top right*) show a focal area of hyperactivity within the right kidney parenchyma. Moreover, an area of moderate uptake of [^{18}F]FDG can be observed at the level of right renal vein consistent with a venous tumor thrombus (*bottom right*)

Presentation

75 years-old woman with newly diagnosed urothelial carcinoma in the right renal pelvis was referred to [^{18}F]FDG PET/CT for staging.

Findings

PET/CT confirmed the presence of the tumor in the right renal pelvis. Moreover, several metastases with high grade of [^{18}F]FDG uptake were clearly seen located in enlarged lymph nodes medial to the right kidney, in the liver, and in the bone (the spine, pelvis bone, left femur, right humerus, and right scapula) (Fig. 15).

Management

On the basis of the advanced stage disclosed by [^{18}F]FDG PET/CT, the patient has been started on chemotherapy.

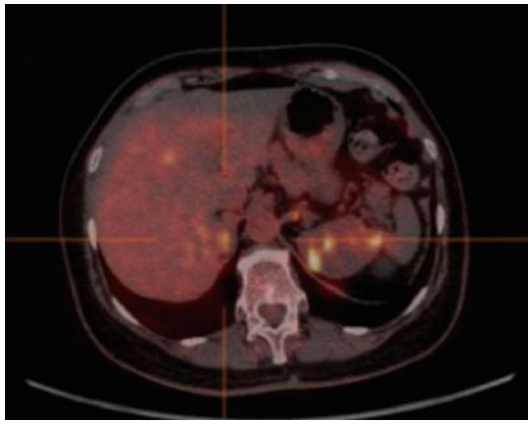

Fig. 13 PET/CT axial slice shows mild [^{18}F]FDG uptake within the known metastasis in the right suprarenal gland

Teaching Points

The case illustrates that urothelial carcinoma in the pelvis and the metastases are normally [^{18}F]FDG avid. Sometimes, it is not possible to see primary tumor in the pelvis, because urinary excretion may mask the tumor, but in this case, the tumor is clearly seen. The metastases are normally detected by [^{18}F]FDG PET/CT. Thus, [^{18}F]FDG PET/CT can be used for NM staging of urothelial malignancies located in the renal pelvis.

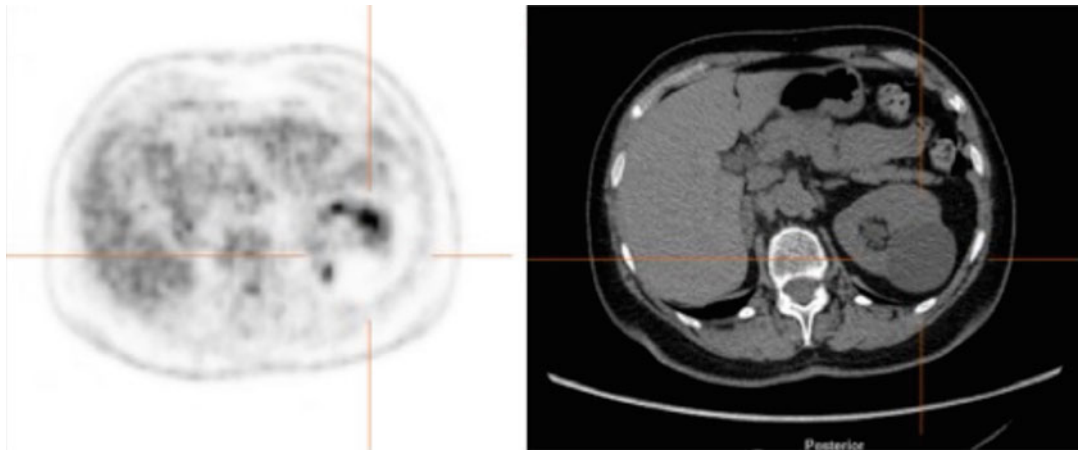

Fig. 14 PET/CT axial slices (PET on the *left* and CT on the *right*) show in the left kidney a large cyst without significant [^{18}F]FDG uptake

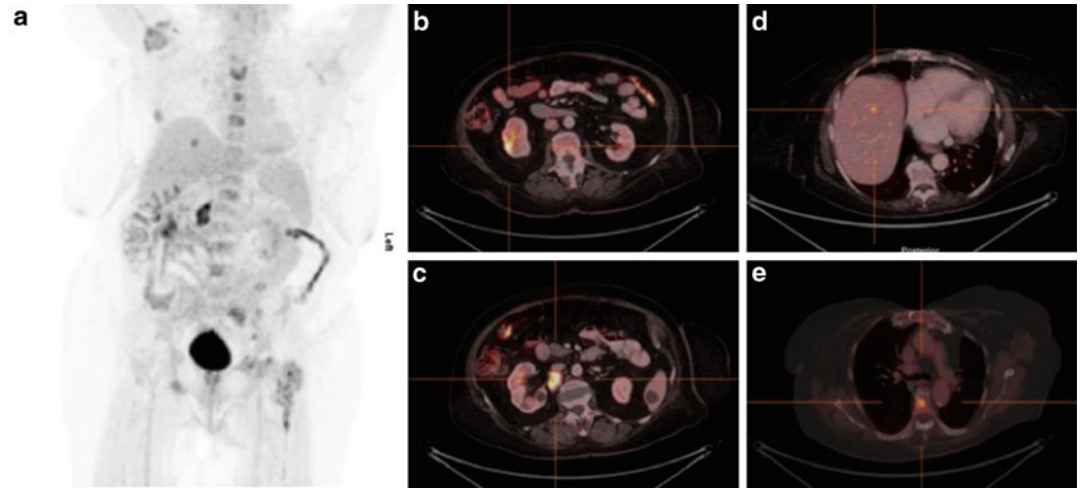

Fig. 15 PET/CT shows multiple areas of [^{18}F]FDG hyperactivity on the MIP image (**a**). A lesion with enhanced uptake of [^{18}F]FDG can be seen in the right renal pelvis on the axial fused PET/CT slice (**b**). Several metastases are clearly seen on the axial PET/CT images located in enlarged lymph nodes medial to the right kidney (**c**), in the liver (**d**), and in the spine (**e**). Bone metastases were also located in the pelvic bone, left femur, right humerus, and right scapula (**a**)

Kidney and Bladder Cancers: Case No. 9

Case contributed by: K. Bouchelouche
Department of Nuclear Medicine and PET Centre, Aarhus University Hospital, Denmark

Presentation

A 75-year-old woman with newly diagnosed multifocal muscle-invasive bladder cancer was referred to a [^{18}F]FDG PET/CT scan for staging.

Findings

PET/CT did not disclose the bladder tumor due to urinary excretion of [^{18}F]FDG. However, PET/CT was able to assess the tumor infiltration along the distal right ureter which presented high [^{18}F]FDG activity. Moreover, a lymph node metastasis was found medial to the tumor infiltrating the right ureter. Three lung metastases were also observed. At last, it was clearly visible an area of high [^{18}F]FDG activity within the vagina and the cervix clearly suspicious of malignancy (Fig. 16).

Follow-Up

Biopsy showed cervical cancer (second primary).

Histology of the lymph node metastases shown in image (C) was from urothelial cancer.

Teaching Point

PET/CT can be useful in the staging of bladder cancer. In this case, it was able to correctly identify tumor infiltration along the right ureter, abdominal lymph node involvement, and lung metastases. Urinary excretion of [^{18}F]FDG limits the assessment of the bladder. It is well known that not unfrequently, PET/CT can disclose a second primary tumor.

Kidney and Bladder Cancers: Case No. 10

Presentation

A 55-year-old woman presented with locally advanced urothelial bladder cancer, treated with radical cystectomy, hysterectomy, and construction of a neobladder.

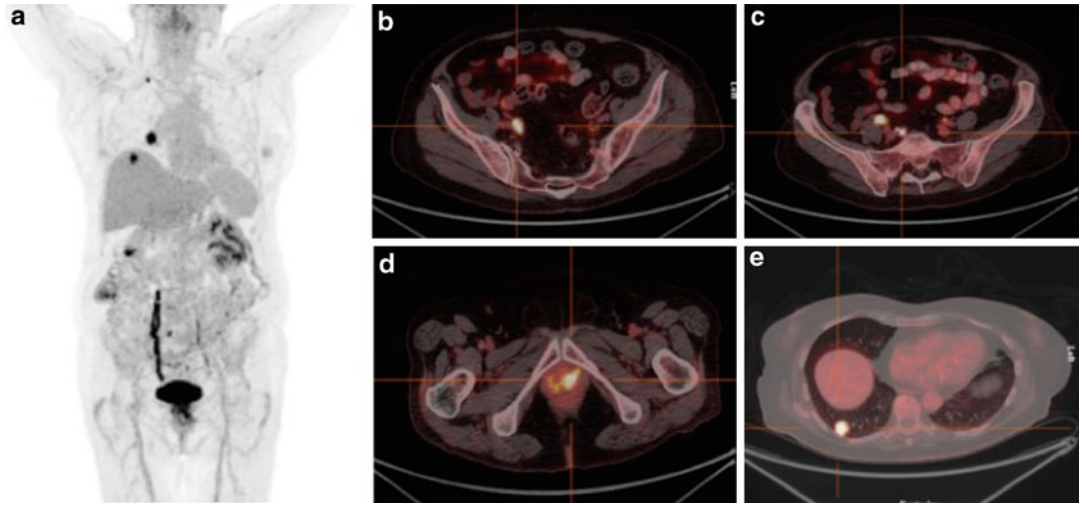

Fig. 16 Bladder tumor is not visible on PET due to urinary excretion of [^{18}F]FDG (**a**). In the distal right ureter, tumor infiltration with high [^{18}F]FDG activity is seen on MIP (**a**) and on axial PET/CT images (**b**, **c**), and a lymph node metastasis is seen medial to the tumor-infiltrated right ureter (**a**, **c**). Three lung metastases are seen on MIP (**a**) and fused PET/CT (**e**). Furthermore, high [^{18}F]FDG activity is seen within the vagina and portion of the cervix clearly suspicious of malignancy (**d**)

Findings

Post-surgery [^{18}F]FDG PET/CT was performed (Fig. 17) to determine the extent of residual disease. [^{18}F]FDG uptake (SUV 7.5) is seen in a left common iliac lymph node (max diameter 13 mm) (Fig. 18). Physiological [^{18}F]FDG is seen in brown fat of the neck bilaterally. The patient was treated with radiation and chemotherapy.

Follow-Up

Six months after treatment, [^{18}F]FDG PET/CT was performed to evaluate treatment response (Fig. 19). Para-caval and para-aortic hypermetabolic lymph nodes (SUV 8) are seen (Fig. 20). The previously visualized [^{18}F]FDG-avid node in the common iliac region is no longer seen. Multiple lesions (SUV 7) are seen in the skeleton, including the ribs bilaterally, right scapula, left ilium, left pubis, and right femur (Fig. 21). In addition, increased [^{18}F]FDG uptake is present in both enlarged adrenal glands (SUV 12) (Fig. 22).

Teaching Point

In this case, [^{18}F]FDG PET/CT was able to demonstrate a surprising lack of response to therapy in urothelial cancer.

Kidney and Bladder Cancers: Case No. 11

Presentation

A 76-year-old man with history of clear cell renal carcinoma 385 (RCC) treated with right nephrectomy presents with 4-month history of increasing left hip pain.

Findings

X-ray of the pelvis shows an osteolytic lesion of the left ilium. [^{18}F]FDG PET/CT is performed for restaging (Fig. 23). [^{18}F]FDG PET/CT shows a lesion of the right humeral head (SUV_{max} 7.2) (Fig. 24) and confirms the presence of an [^{18}F]

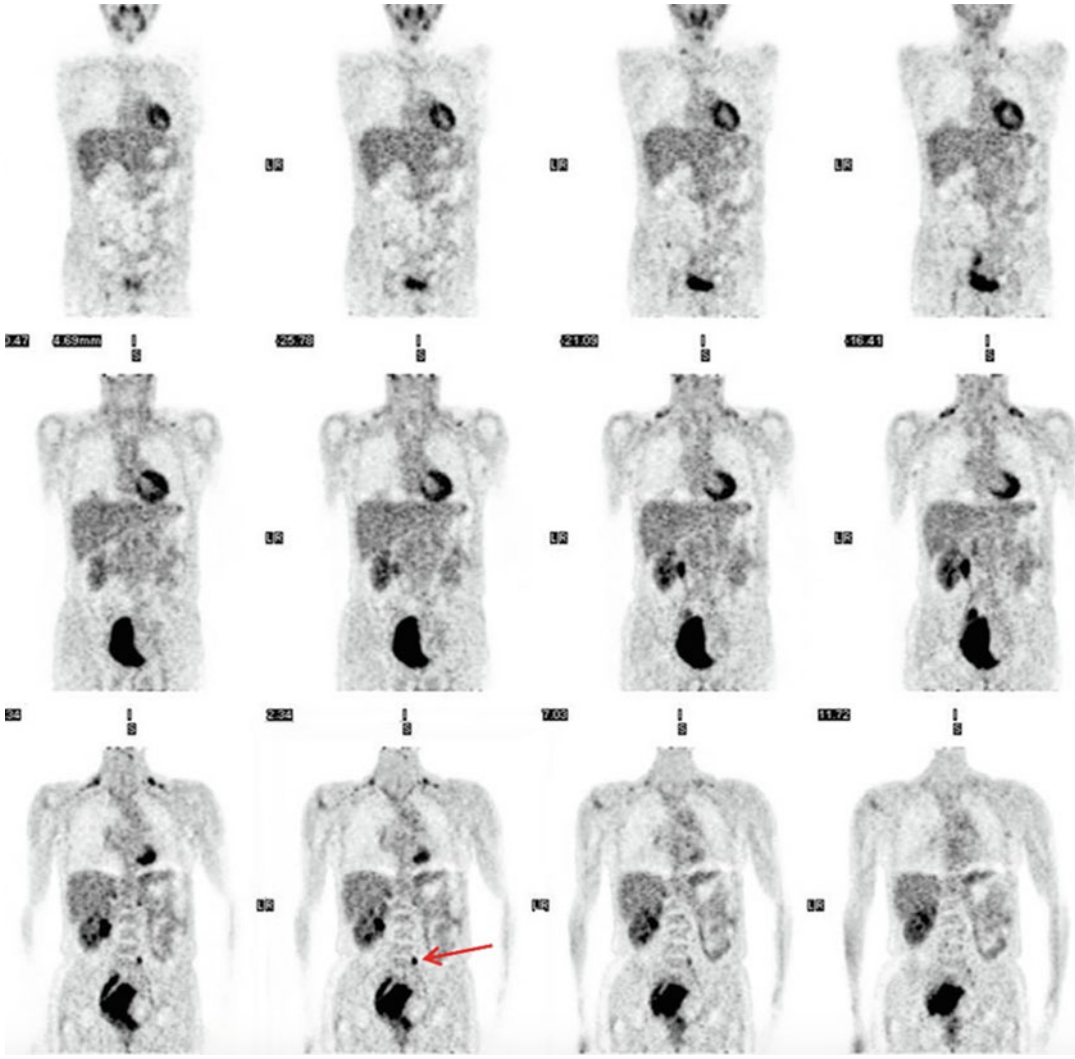

Fig. 17 [^{18}F]FDG PET images (coronal section) show hypermetabolic lymphadenopathy in the left iliac region (*red arrow*). Physiological radiotracer accumulation is in the neck bilaterally, corresponding to brown fat

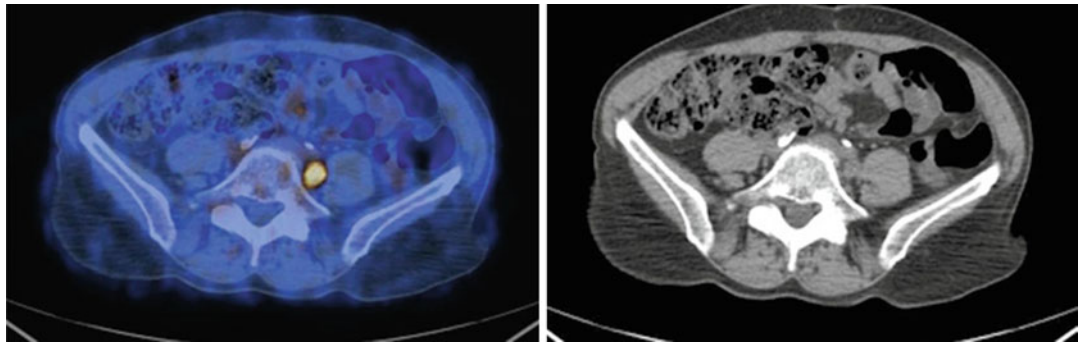

Fig. 18 PET/CT transaxial image demonstrates metabolically active adenopathy localized in the left common iliac region (PET/CT fused image in the *left panel*, CT in the *right panel*)

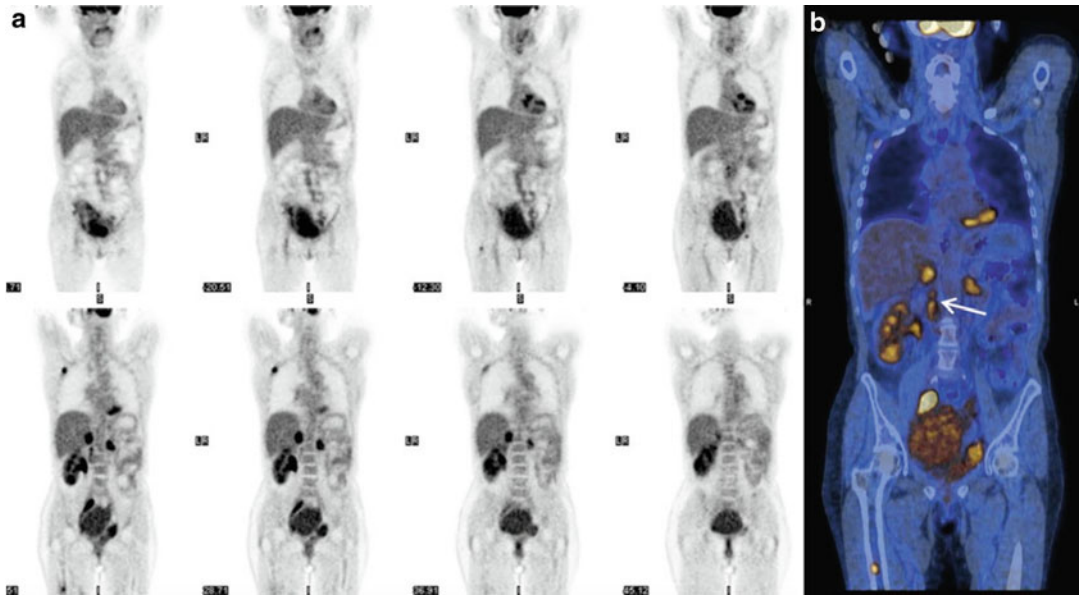

Fig. 19 [^{18}F]FDG PET coronal image (**a**) demonstrates pathological uptake in adrenal glands and [^{18}F]FDG-avid skeletal lesions (the second right rib and right femur). PET/CT coronal fused image (**b**) also shows hypermetabolic lymphadenopathy in para-caval and para-aortic regions (*white arrow*)

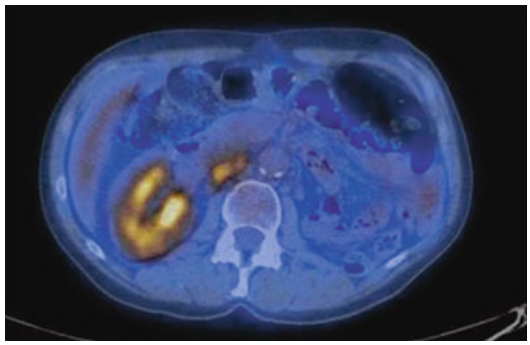

Fig. 20 PET/CT fused transaxial image demonstrates hypermetabolic adenopathy in para-caval region

FDG-avid osteolytic lesion of the left ilium (SUV_{max} 8.5). In addition, [^{18}F]FDG PET/CT images show numerous hypermetabolic lymph nodes in the mediastinum (SUV_{max} 8.6) (paratracheal, paraesophageal, subcarinal, and hilar nodes) (Fig. 25) and in the abdomen (SUV_{max} 15) (retrocrural, celiac, portocaval, and para-aortic nodes) (Fig. 26). Skeletal metastases were treated with external beam radiation therapy. The patient also received systemic antiangiogenesis therapy with sunitinib.

Follow-Up

[^{18}F]FDG PET/CT did not demonstrate significant reduction in [^{18}F]FDG uptake of hypermetabolic lymphadenopathy. However, a reduction in [^{18}F]FDG uptake in the right humeral head is seen, while no pathological uptake is shown in the ilium (Fig. 27). Subsequent imaging showed lymph node progression, liver involvement, and cutaneous metastases.

Discussion

This case demonstrates that [^{18}F]FDG PET is useful to assess the lack of metabolic tumor response to therapy.

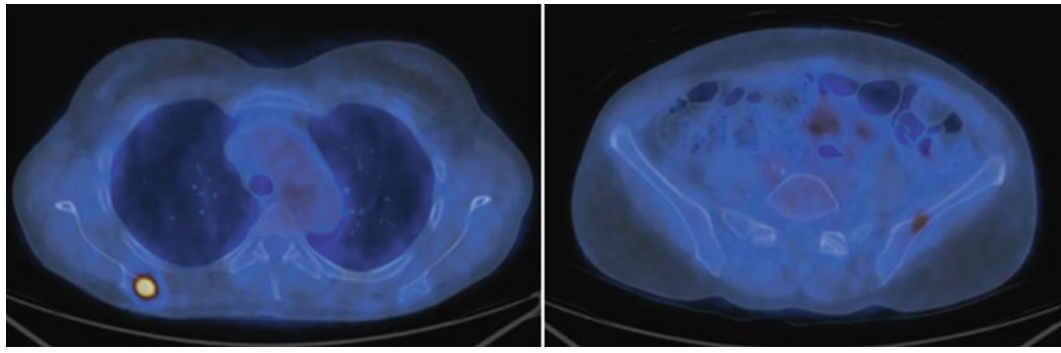

Fig. 21 PET/CT fused transaxial image of [^{18}F]FDG-avid lesions in the right scapula (*left panel*) and left ilium (*right panel*)

Prostatic Cancer: Case No. 1

Case contributed by S. Al Shammari, F. Fraioli Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK.

Presentation

A 60-year-old man diagnosed with prostate cancer in 2014. Treated with radiotherapy. Raising PSA with suspicion of local recurrence. PET/CT with ^{68}Ga-PSMA-ligand for restaging.

Findings

PET/CT showed a focal ^{68}Ga-PSMA-ligand uptake at the right posterolateral peripheral zone of the prostate, extending at least from the mid-gland down to the apex (Fig. 1). No tracer activity was observed in the seminal vesicles. No other suspicious focal lesions were found in the whole body.

Discussion

Positron emission tomography (PET) with choline tracers has been used for years for the diagnosis and follow-up of prostate cancer. Prostate-specific

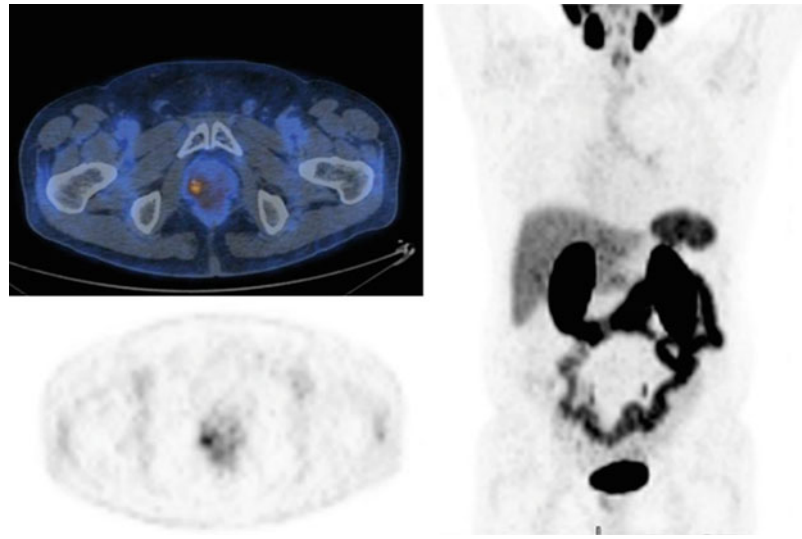

Fig. 1 Focal ^{68}Ga-PSMA ligand uptake at the right posterolateral peripheral zone of the prostate extending at least from the mid-gland down to the apex

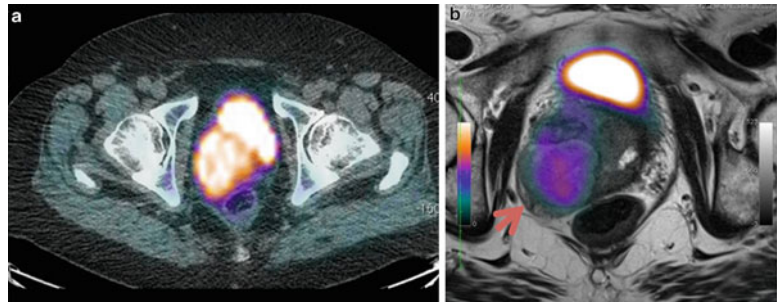

Fig. 2 ^{18}F-choline PET/MRI in patients with prostate cancer (*arrow*) allows exact correlation of elevated focal choline uptake to suspicious T2-weighted prostate lesion. Anatomical detail provided coupling PET with MRI (**a**) is much superior to PET/CT stand-alone (**b**)

membrane antigen (PSMA) is overexpressed in most prostate cancers. Therefore, a ^{68}Ga-labeled PSMA-ligand was found to be superior to choline tracers due to the high contrast. Preliminary results of PET with ^{68}Ga-PSMA-ligand have shown encouraging results particularly in the recurrent prostate cancer setting.

Physiological distribution is noted in the lacrimal gland, parotid gland, submandibular gland, liver, spleen, duodenum, colon, and kidney. Unspecific uptake was reported in gynecomastia, lymph nodes with fat hilum, and Wegener's granulomatosis. Additional faint uptake of ^{68}Ga-PSMA-ligand was also reported in tumors such as thyroid, breast, and non-small cell lung cancer.

Prostatic Cancer: Case No. 2

Case contributed by S. Al Shammari, F. Fraioli

Presentation

A 72-year-old man with known prostate cancer referred for staging with ^{18}F-choline PET/MRI.

Fig. 3 ^{99m}Tc-MDP whole-body bone scan showing a single focus of highly increased activity in the parietal bone on the left side (*arrow*)

Findings

^{18}F-choline PET/MRI allowed exact correlation of elevated focal choline uptake to suspicious T2-weighted prostate lesion. The patient underwent also a PET/CT scan that provided a worse anatomical detail than PET coupled with MRI (Fig. 2).

Discussion

PET imaging in prostate cancer is providing a reasonable option to identify the location of primary or recurrence prostate cancer in this setting.

The use of radiolabeled choline for imaging prostate cancer is based on increased phosphorylcholine levels and an elevated phosphatidylcholine turnover in prostate cancer cells. After uptake into the tumor cell through a high-affinity transporter system, choline is metabolized by choline kinase – which is the first step of the Kennedy pathway – and is incorporated into the phosphatidyl membrane. Key enzymes of the choline metabolism, like choline kinase, are upregulated in prostate cancer cells. Additionally, an increased expression of choline transporters and an elevated choline transportation rate have been described. While CT imaging has its place in the staging of prostate cancer, MRI, especially using multiparametric imaging including diffusion-weighted sequences, is the most sensitive morphological imaging method for local staging; hence, hybrid PET/MRI imaging appears to provide the best option for the future.

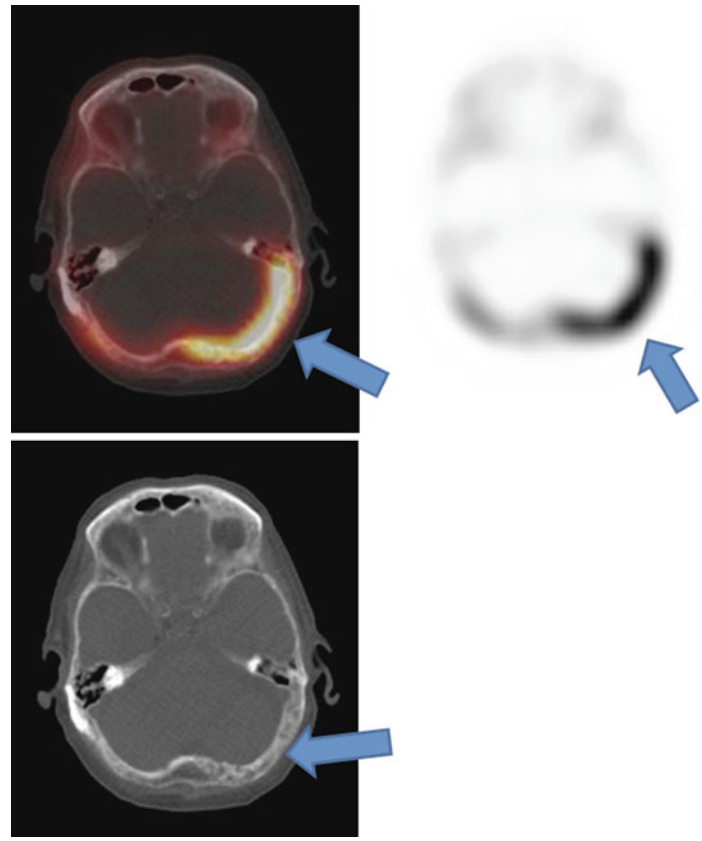

Fig. 4 At ^{99m}Tc-MDP SPECT/CT, the cortex of the bone was pathologically thickened and irregular (*D, arrow*) with highly increased activity especially in the inner cortex (*B, C, arrows*)

Prostatic Cancer: Case No. 3

Case contributed by M.R. Jochumsen

Department of Nuclear Medicine & PET Centre, Aarhus University Hospital, Aarhus, Denmark.

Presentation

An 87-year-old man who was recently diagnosed with high-risk prostate cancer (Gleason 10, and PSA 5.6 ng/mL). The patient had no symptoms from the skeleton.

Findings

In the primary staging, a ^{99m}Tc-DPD planar bone scan and SPECT/CT were performed, presenting a single focus of highly increased activity in the parietal bone on the left side (Figs. 3 and 4). The cortex of the bone was pathologically thickened and irregular with highly increased activity especially in the inner cortex. The extent of the pathology was all of the parietal bone but without involving other cranial bones. In conclusion, the findings are characteristic of Paget's disease and very uncharacteristic of a sole metastasis from prostate cancer. The most common locations of bone metastasis from prostate cancer are the pelvis, vertebrae, costae, and femora. The areas with increased activity in the lumbar spine were of benign degenerative etiology.

Follow-Up

Because of the lack of symptoms and the age of the patient, no treatment was initiated.

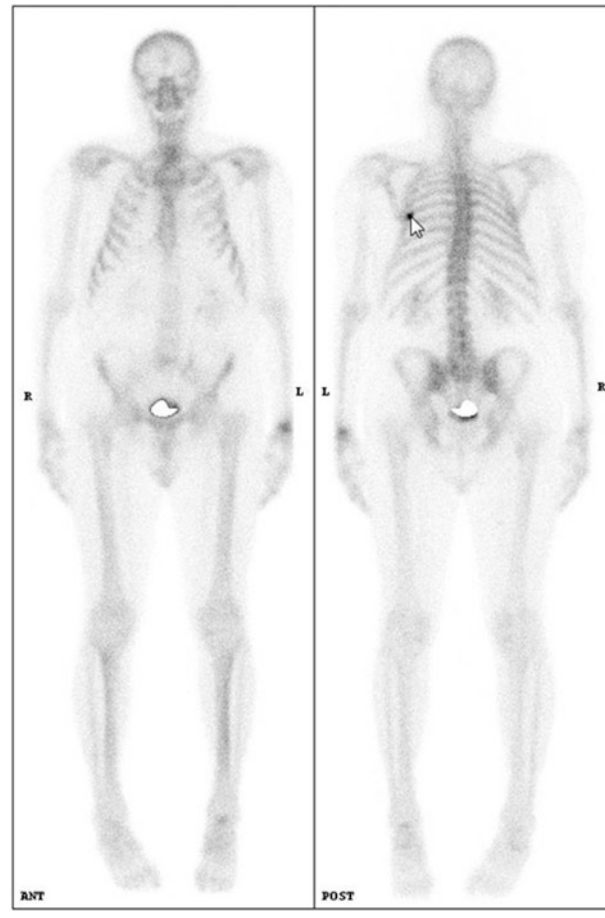

Fig. 5 ^{99m}Tc-MDP bone scan shows two metastatic foci in the ribs and one in the left scapula (*white arrow*)

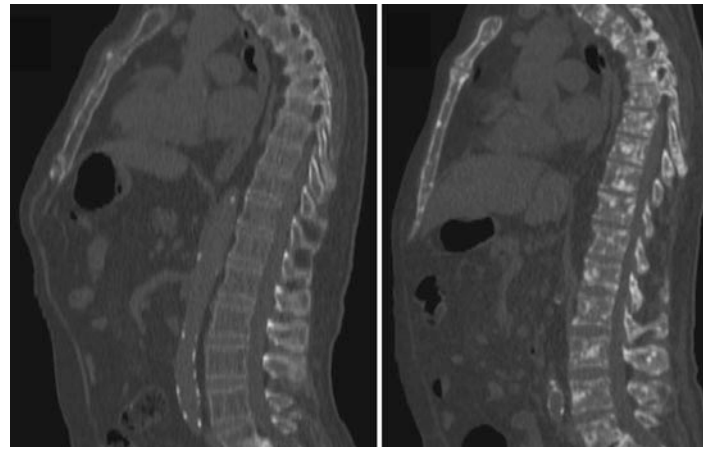

Fig. 6 On the *left*: CT sagittal slice showing no findings in the spine at the time of the first ^{99m}Tc-MDP bone scan. On the *right*: CT performed 3 months later showing multiple sclerotic and lytic bone metastasis

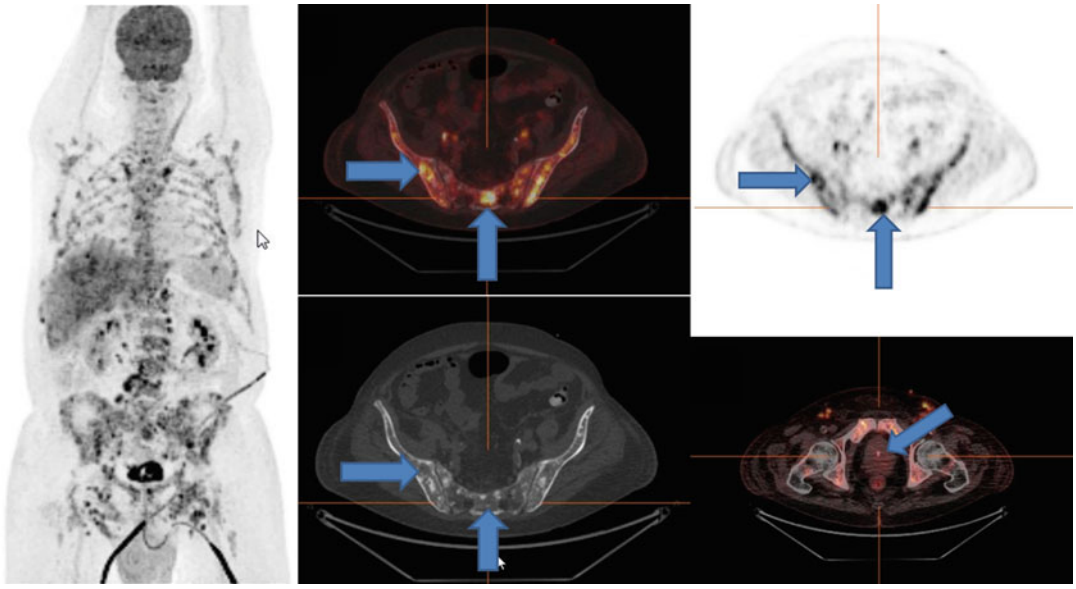

Fig. 7 [^{18}F]FDG PET/CT. On the *left*, MIP showing multiple foci with highly increased [^{18}F]FDG activity in almost the whole axial skeleton. Axial slices including the iliac bones show no increased [^{18}F]FDG uptake in most of the sclerotic areas in the skeleton, illustrating that sclerotic bone metastasis tend to metabolically "burn out" at some point. Furthermore, low [^{18}F]FDG uptake was seen in the prostate gland (*bottom right* panel, *arrow*), which indicates that the primary tumor had low metabolism at the time of the scan

Discussion

Paget's disease is caused by excessive and uncoordinated osteoclastic and secondarily osteoblastic activity, resulting in thickened and weakened bone structure. Complications of the disease are pain, warmth, fractures, bone deformities, loss of hearing, nerve compression, hypercalcemia, and urolithiasis. In most patients the disease can either be controlled with medical treatment or need no treatment at all. In rare cases the disease can develop into the highly malignant Paget's sarcoma.

Prostatic Cancer: Case No. 4

Case contributed by M.R. Jochumsen

Department of Nuclear Medicine & PET Centre, Aarhus University Hospital, Aarhus, Denmark.

Presentation

A 74-year-old man with castrate-resistant prostate cancer (CRPC). The Gleason 10 cancer had been well controlled through 2 years of hormone treatment with low prostate-specific antigen (PSA).

Findings

At the time of castrate resistance, a ^{99m}Tc-MDP bone scan was performed, the PSA was 38 μg/L. At this point two metastatic foci in the ribs and one in the left scapula were identified (Fig. 5).

No findings were observed in the spine confirmed also by a CT scan (Fig. 6).

Follow-Up

In spite of further medical treatment, the disease exploded, and 3 months later the PSA was

Fig. 8 Three-dimensional [^{11}C]choline PET/CT image demonstrates inhomogeneous hypermetabolic mass in the pelvis and [^{11}C]choline-avid pelvic and abdominal lymph nodes

536 ng/mL and the alkaline phosphatase had risen from normal to 200. At this point a CT scan was performed showing multiple sclerotic and lytic bone metastasis, especially in the spine (Fig. 6), furthermore, multiple hepatic and lymph node metastasis.

About 3 months later, the condition of the patient was declining, and he was admitted to the hospital because of fluctuating fever and C-reactive protein (CRP) of 300. An [^{18}F]FDG PET/CT scan was performed under suspicion of an abscess. But no infectious foci were found, making cancer associated fever the most likely explanation. The [^{18}F]FDG PET scan demonstrated further development in the metastatic status, revealing multiple foci with highly increased [^{18}F]FDG activity in almost the whole axial skeleton (Fig. 7).

Discussion

This case demonstrates the sudden aggressive development of a prostate cancer, illustrating the variable biology of the disease. [^{18}F]FDG PET/CT is not used for primary staging of prostate cancer, since most cancers have low metabolism resulting in low [^{18}F]FDG uptake. However, advanced and more aggressive prostate cancer including metastases may be seen on [^{18}F]FDG PET/CT.

Prostatic Cancer: Case No. 5

Case contributed by M. Kirienko, A. Chiti
Division of Nuclear Medicine, Department of Biomedical Sciences – Humanitas University, Milan, Italy.

Presentation

A 73-year-old man affected by adenocarcinoma of the prostate, Gleason score $4 + 5 = 9$, PSA >600 ng/mL, with negative bone scan, receiving LHRH analog was referred to perform [^{11}C]choline PET/CT for staging and radiation treatment

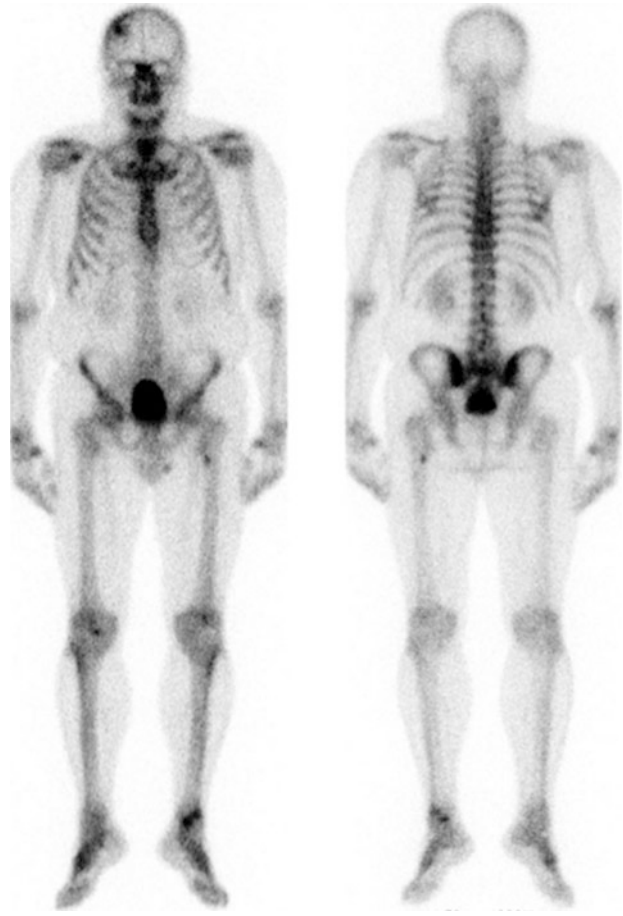

Fig. 13 Anterior (*left image*) and posterior (*right image*) ^{99m}Tc-HDP bone scintigraphy showing moderately increased uptake in the lesser trochanter of the left femur, suspect for bone metastasis. It also shows increased uptake right in the frontal bone of the skull after burr hole trephination and increased uptake in the left ankle, considered to be caused by degenerative changes

planning purpose. PSA before the examination was 108 ng/mL.

Findings

[^{11}C]choline PET/CT (Fig. 8) showed tracer uptake in the known primary lesion with inhomogeneous tracer distribution within the lesion (Fig. 9). Additionally, [^{11}C]choline-avid lymph nodes were seen: pararectal (Figs. 10 and 11), internal iliac (Fig. 11), external iliac (Figs. 10 and 11), and para-aortic (Fig. 12).

Follow-Up

Due to the pattern of diffuse metastatic disease revealed by the [^{11}C]choline PET/CT scan, the patient was not considered for radiation treatment and was scheduled to receive hormonal therapy.

Discussion

[^{11}C]choline PET/CT can be useful in the initial evaluation of patients with high-risk prostate cancer allowing to identify nodal and distant metastases. It has been also proposed to guide radiation

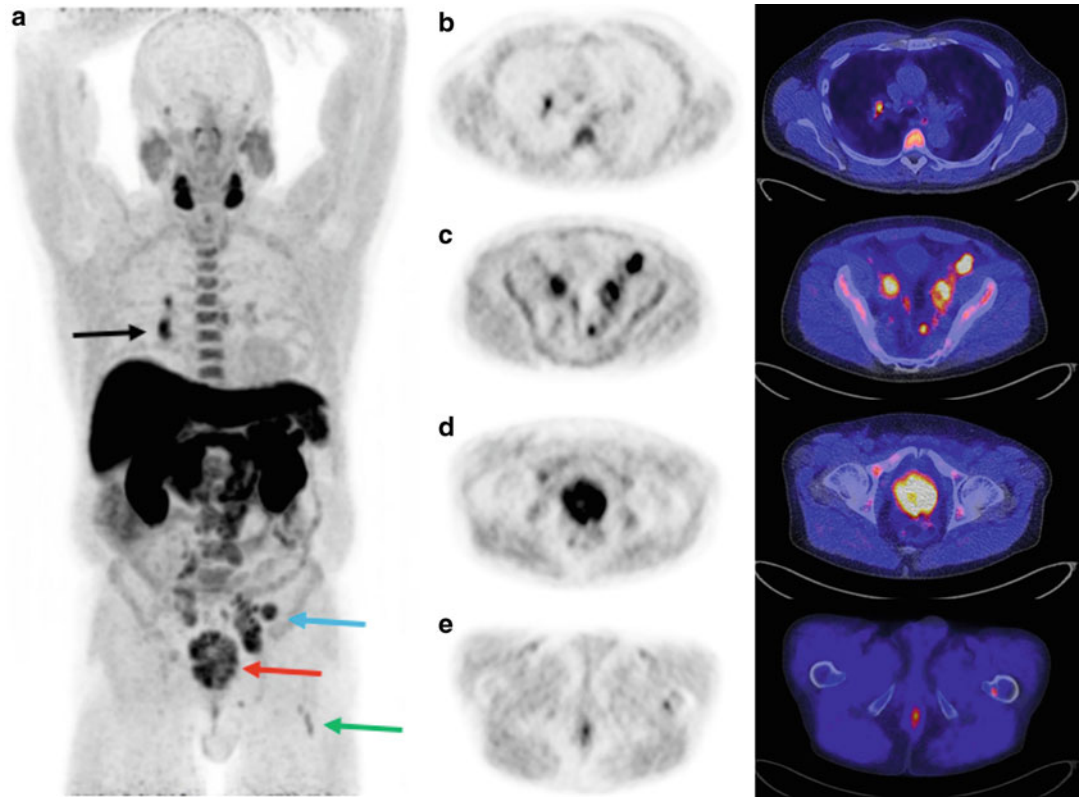

Fig. 14 [^{11}C]choline PET/CT. (**a**) Maximum intensity projection (*MIP*) showing increased uptake in the enlarged prostate (*red arrow*), multiple lesions in the pelvis (*blue arrows*), in the lesser trochanter of the left femur (*green arrow*), and in the lung hilum left and right (*black arrow*, considered reactive lymph nodes). Axial reconstructions and fusion images showing (**b**) increased uptake in a hilar lymph node, considered to be reactive; (**c**) increased uptake in multiple enlarged para-iliac lymph nodes, considered to be metastases; (**d**) increased uptake in the enlarged prostate in the known prostate carcinoma; (**e**) moderately increased uptake in the lesser trochanter of the left femur, considered to be a metastasis

treatment. In the present case, moreover, it has been useful to choose the most appropriate treatment strategy switching from radiotherapy to medical treatment because of the abdominal node disease localization.

Prostatic Cancer: Case No. 6

Case contributed by E.D. Telenga[a], A.W.J.M. Glaudemans[a], R.H.J.A Slart[a,b]

[a]Department of Nuclear Medicine and Molecular Imaging, University of Groningen, University Medical Center Groningen, The Netherlands

[b]Biomedical Photonic Imaging Group, University of Twente, Enschede, The Netherlands.

Presentation

A 74-year-old man with a history of melanoma, hypertension, heart failure, a cerebrovascular accident, and a subdural hematoma treated with burr hole trephination presented at his general physician with hematuria. Digital rectal examination revealed an irregular and enlarged prostate. The PSA level was elevated: 89.5 ng/mL. Prostate biopsies showed adenocarcinoma in all biopsies (Gleason score $5 + 5 = 10$) with perineural growth.

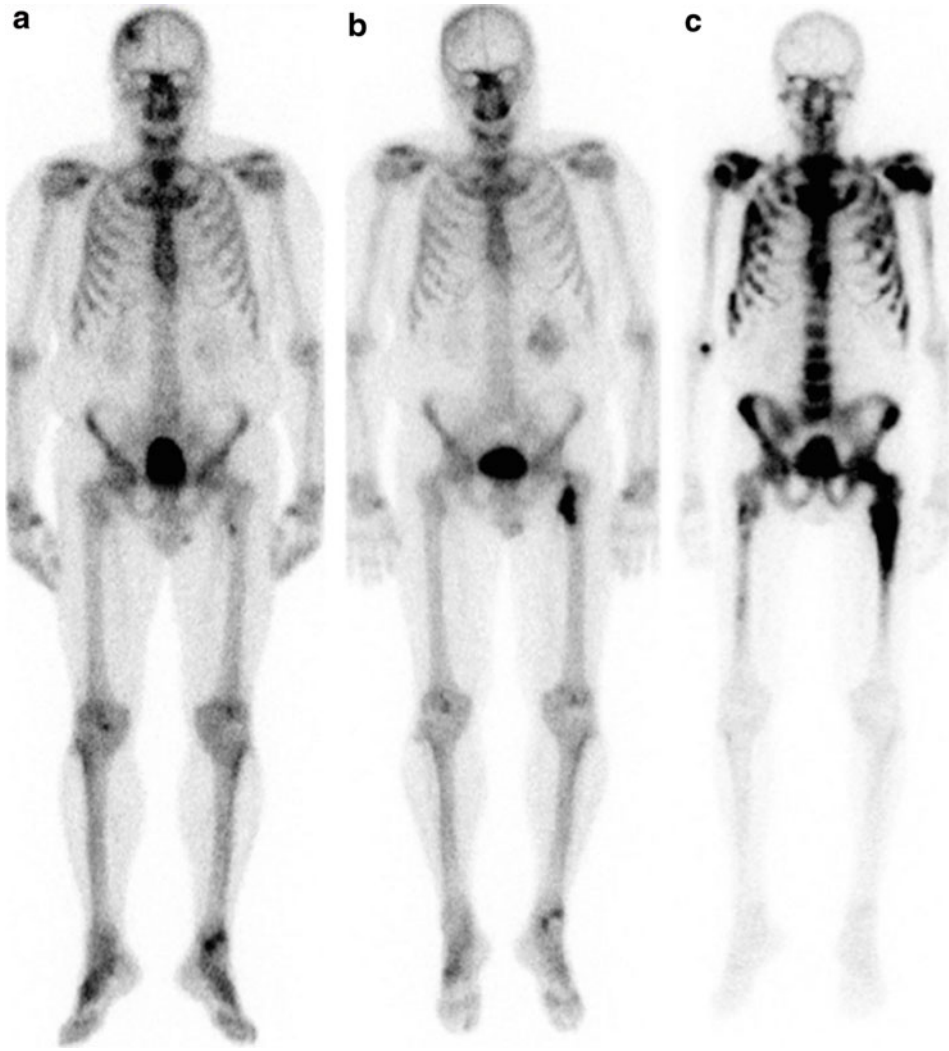

Fig. 15 ^{99m}Tc-HDP bone scintigraphy. (**a**) At presentation (see Fig. 1). (**b**) After 1 year with increased uptake at the left lesser trochanter and a new lesion in the left proximal femur. (**c**) After 2 years with intense uptake in nearly the complete axial skeleton and no excretion by the kidneys

Findings

Because of the total Gleason score of 10, a ^{99m}Tc-HDP bone scintigraphy was performed for dissemination purposes (Fig. 13). It showed moderately increased uptake in the lesser trochanter of the left femur. This lesion was suspected to be a sclerotic bone metastasis; however, a solitary bone cyst or another benign bone lesion was also considered. Additionally, it showed increased uptake in the frontal bone of the skull at the right side, which was considered to be due to the burr hole trephination in the past. Finally, it showed increased uptake in two lesions in the left ankle, which were considered to be degeneration.

To further determine the lesion in the lesser trochanter and to evaluate if there were lymph node metastases, a [^{11}C]choline PET/CT was performed (Fig. 14). It showed clearly increased uptake in the prostate and in multiple enlarged para-aortal and para-iliac lymph nodes. There was also moderately increased uptake in the lesser trochanter of the left femur with sclerotic changes on the low-dose CT. There were no other lesions

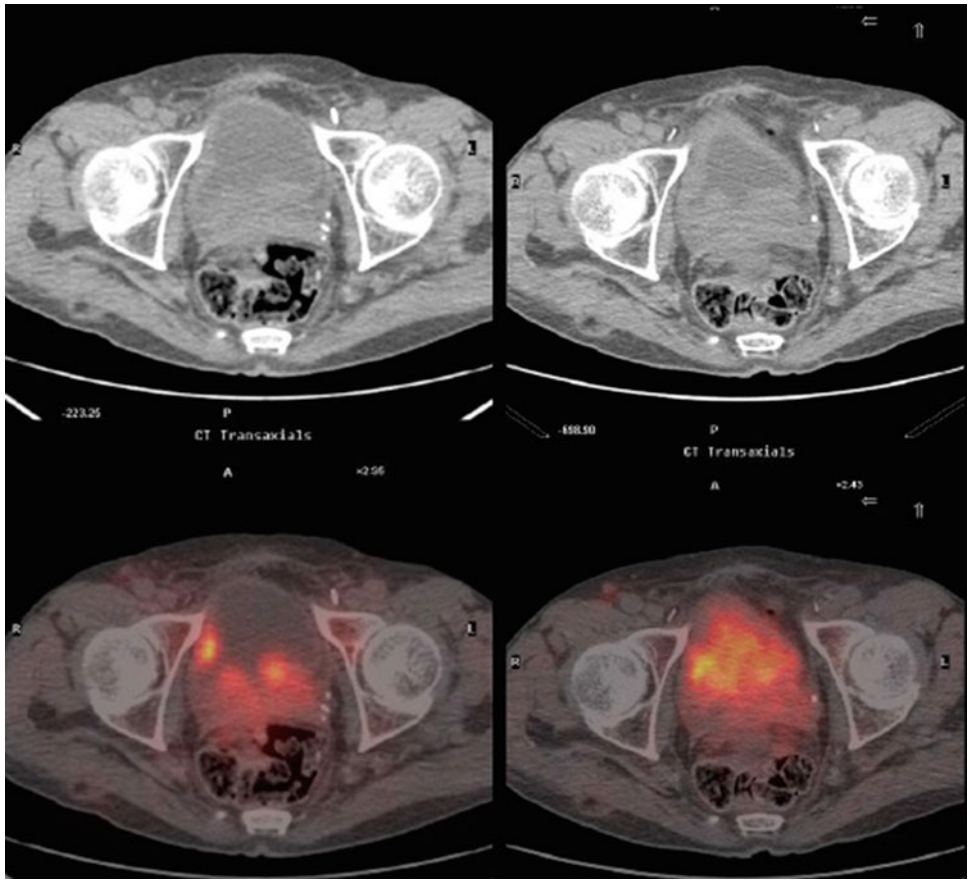

Fig. 16 On *left* panels, LD-CT and fused PET/CT axial images showing the presence of disease with high ^{18}F-choline uptake within lesions involving vesicles and the posterior wall. The uptake within the lesions can be clearly distinguished by the bladder which appears to be distended and does not contain any radioactive urine. On right panels the same LD-CT and fused PET/CT axial images obtained with the late whole-body acquisition. The identification of the lesions appears more difficult because of the radioactive urine excreted within the bladder

in the skeleton. Finally, it showed increased uptake in lymph nodes in the lung hilum bilaterally. These lymph nodes were considered to be reactive.

Follow-Up

It was concluded that the patient had prostate carcinoma with multiple lymph node metastases and one skeletal metastasis. Treatment was started with the GnRH analog leuprorelin. ^{99m}Tc-HDP bone scintigraphy performed 1 year later showed increase of the uptake in the left lesser trochanter and a new small lesion in the left proximal femur (Fig. 15). After 2 years, patient presented with progressive pain in multiple sites in the skeleton and increasing PSA (626 ng/mL) and alkaline phosphatase (982 U/L). ^{99m}Tc-HDP bone scintigraphy showed intense uptake in nearly all of the axial skeleton and no excretion by the kidneys, also known as a superscan. Patient passed away 1 month later.

Teaching Point

^{99m}Tc-HDP bone scintigraphy and [^{11}C]choline PET/CT are essential tools for the management of patients with high-risk prostate carcinoma.

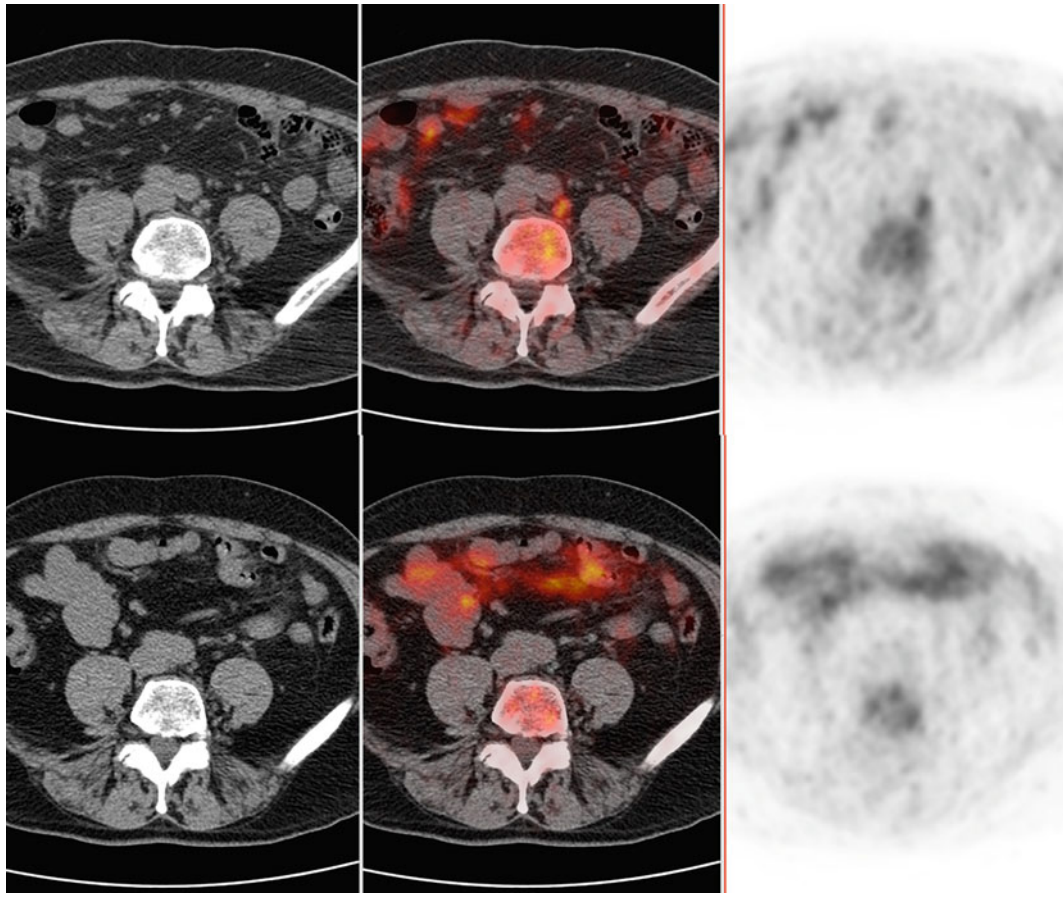

Fig. 17 On *top* panels: CT, fused PET/CT and PET axial slices showing two left para-aortic lymph nodes which accumulate ^{18}F-choline. On *bottom* panels the same slices of the PET/CT study performed 9 months before with PSA levels of 0.81 ng/mL and resulted negative. In the CT axial image (*left*), two 4 mm lymph nodes can be disclosed, but without any tracer uptake

Prostatic Cancer: Case No. 7

Presentation

A 74-year-old man with a prostate carcinoma with serum PSA 22 ng/mL and a Gleason score at biopsy of 6 (3 + 3). At staging CT did not disclose enlarged lymph nodes within the pelvis and the whole abdomen, and bone scintigraphy resulted negative for metastases. The patient underwent a radiation treatment with intensity-modulated radiotherapy (IMRT, 68 Gy) on the prostate bed. Three months after the end of treatment, PSA decreased to 0.6 ng/mL. No hormonal therapy was undertaken.

Findings

During follow-up PSA rose up to 2.7 ng/mL. CT did not localize the presence of recurrent disease. After 4 months PSA reached a level of 4.1 ng/mL, and the patient underwent a PET/CT scan with ^{18}F-choline. The PET/CT study was conducted with an early one-bed list-mode acquisition of 8 min after tracer administration (3 MBq/kg body weight) and a late (after 60 min) whole-body acquisition. Early images obtained from the first 4 min of acquisition, before radioactive urine reached the bladder, showed the presence of disease involving the seminal vesicles and the posterior wall of the bladder (Fig. 16). No other

sites of recurrence were disclosed by PET/CT at the late whole-body acquisition.

Follow-Up

The patient was then started to antiandrogen therapy.

Teaching Points

Due to high urine excretion rate of ^{18}F-choline, sites of locoregional disease close to the bladder could be difficult to be clearly seen with the only late acquisition. Thus, when locoregional recurrence is suspected, an early acquisition after tracer administration can help in identifying sites of disease that have a fast uptake of ^{18}F-choline before urinary tracer excretion reaches the bladder.

Prostatic Cancer: Case No. 8

Presentation

A 75-year-old man (a technical laboratory technician and former hospital employee) suffered by prostate carcinoma, with a PSA of 13 ng/mL and Gleason score of 7 (3 + 4). He underwent radical prostatectomy (pT2N0M0). After 2 years of follow-up without hormonal therapy, initial biochemical relapse was observed, with a PSA of 0.42 ng/mL. After 3 months PSA rose to 0.81 ng/mL.

Findings

A biopsy of the prostate bed resulted negative for the presence of local disease. The US and CT scans did not show suspected lymphadenopathies within the pelvis. Due to the rate of increase serum PSA, the urologist referred the patient for an ^{18}F-choline PET/CT scan. The PET/CT study was conducted with an early one-bed list-mode acquisition of 8 min after tracer administration (3 MBq/kg body weight) and a late (after 60 min) whole-body acquisition. Neither early nor late images showed a clear site of relapse.

Follow-Up

After 9 months serum PSA suddenly rose up again, to reach the level of 2.69 ng/mL. The patient underwent a second ^{18}F-choline PET/CT whole-body scan, which discloses the presence of two lymph nodes with a pathologically increased tracer uptake (Fig. 17).

Teaching Points

PET/CT with radiolabeled choline is considered a very sensitive technique for the localization of the relapse of prostate carcinoma. However, its sensitivity is lower in case of low levels of serum PSA. In particular, a PSA value between 1 and 2 ng/mL is considered a reasonable cutoff value below which does not perform ^{18}F-choline PET/CT.

On the other hand, high PSA velocity, or short PSA doubling time, is highly predictive of PET/CT positive findings. A PSA doubling time between 0 and 6 months predicts the appearance of distant metastases.

Prostatic Cancer: Case No. 9

Presentation

A 63-year-old man with a PSA of 12.8 ng/mL underwent a prostate biopsy, which revealed a high-risk prostate carcinoma with a Gleason score of 9 (4 + 5).

Findings

CT did not disclose sites of disease within the pelvis and the abdomen, while bone scintigraphy with ^{99m}Tc-MDP was negative. The patient was therefore submitted to radical prostatectomy with pelvic lymphadenectomy (pT3aN0M0), and

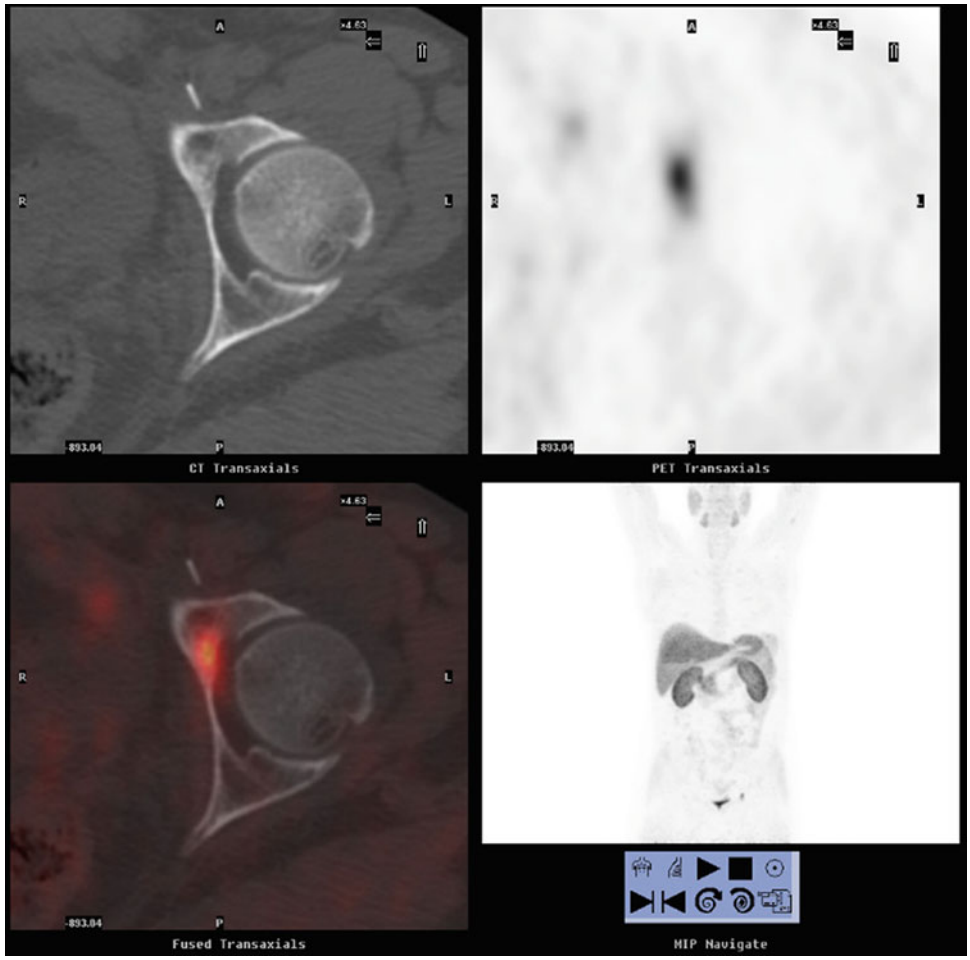

Fig. 18 PET/CT with ^{18}F-choline shows the presence of an area of hyperactivity within the left iliac bone in proximity if the acetabulum consistent with a secondary lesion

subsequently adjuvant antiandrogen hormone therapy was started. During the whole treatment with triptorelin, serum PSA levels always resulted under the sensitivity limit of detectability.

Follow-Up

About 6 months after discontinuing triptorelin, serum PSA increased reaching a value of 1.04 ng/mL. Since the US and CT scans were negative, the patient underwent an ^{18}F-choline PET/CT scan. A 60 min whole-body acquisition was performed after the injection of ^{18}F-choline (3 MBq/kg body weight). Images revealed the presence of a single site of metastasis within the iliac bone (Fig. 18).

Teaching Points

In case of a suspected recurrence of prostate carcinoma, a high Gleason score at diagnosis can be associated with a positive finding of ^{18}F-choline PET/CT in case of biochemical relapse, even with serum PSA levels not particularly high.

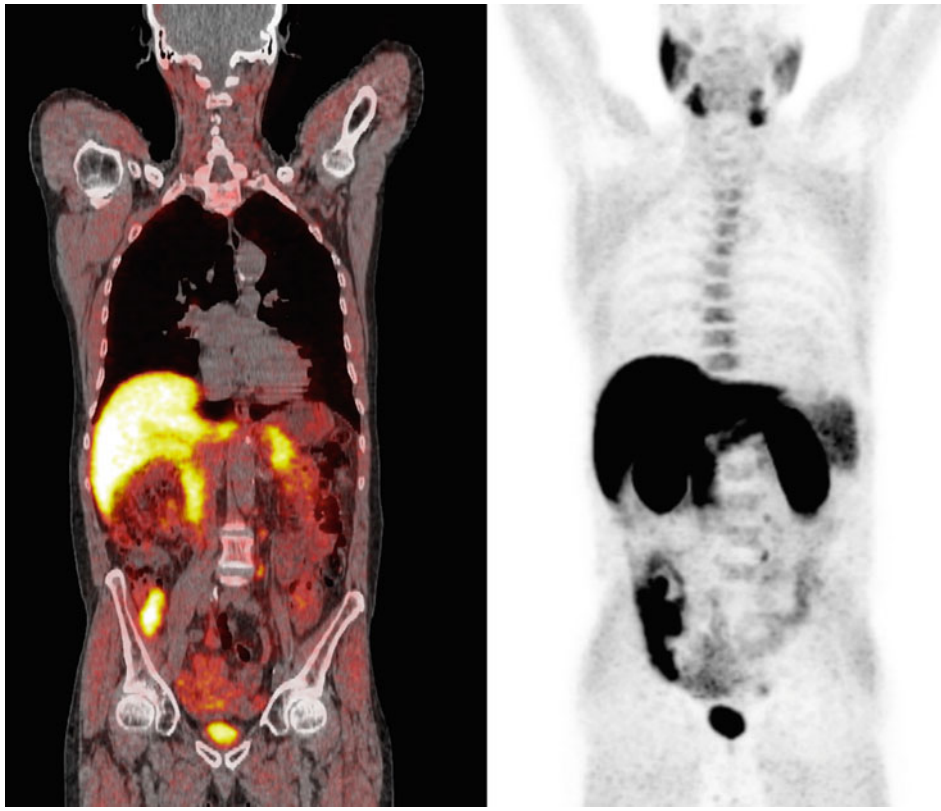

Fig. 19 PET/CT with ^{18}F-choline in patient with serum PSA level of 5.68 ng/mL. Fused PET/CT coronal slice and MIP image show two left para-aortic hyperactive lymphadenopathies

Prostatic Cancer: Case No. 10

Presentation

A 71-year-old man underwent radical prostatectomy plus external beam radiotherapy and pelvic lymph nodes dissection for an advanced prostate cancer with Gleason score 3 + 4. After 16 months of follow-up serum levels of PSA rose to 5.68 ng/mL.

Findings

The patient underwent a first PET/CT with ^{18}F-choline, which disclosed recurrent disease within two left para-aortic lymph nodes (Fig. 19). Then, the patient started an antiandrogen hormone therapy with triptorelin. After 6 months of such treatment, PSA levels had further increased up to 44.0 ng/mL. A second PET/CT with ^{18}F-choline was performed, without discontinuing triptorelin. This PET/CT scan showed progression of the disease that was limited to several para-aortic and caval-aortic lymph nodes and two left inferior latero-cervical nodes (Fig. 20).

Follow-Up

After other 4 months of antiandrogen treatment in combination with an LHRH agonist, serum PSA rose up even further to 84.1 ng/mL. Recurrent disease diffused to lymph nodes, including mediastinal nodes, and to a vertebra was demonstrated by a third PET/CT with ^{18}F-choline (Figs. 21, 22, and 23).

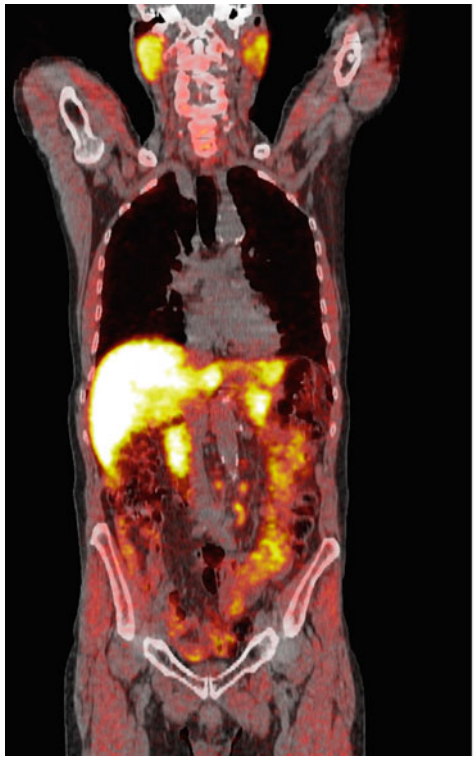

Fig. 20 PET/CT with ^{18}F-choline in patient with serum PSA level of 44.0 ng/mL. Multiple lombo-aortic hyperactive nodes have been clearly disclosed. Moreover, fused PET/CT coronal slice and MIP image show two supraclavicular lymphadenopathies

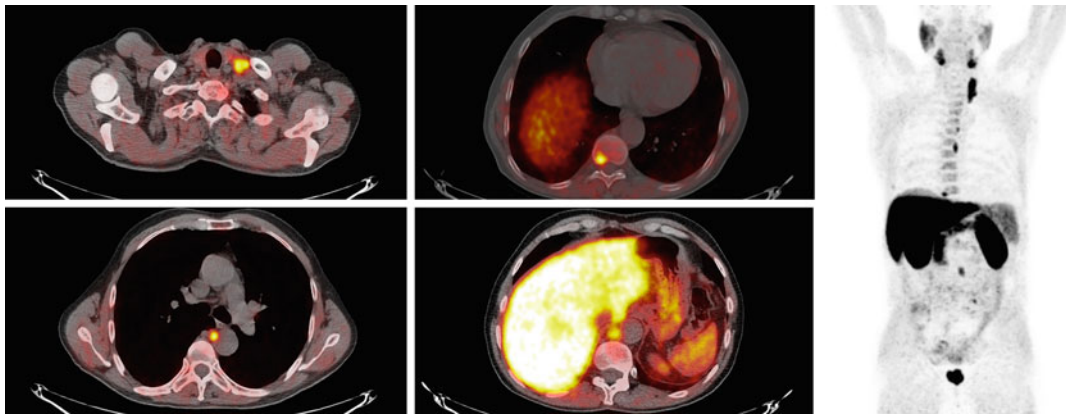

Fig. 21 Fused PET/CT axial slices and MIP image show the progression of the disease which involves multiple lymph nodes and a thoracic vertebra

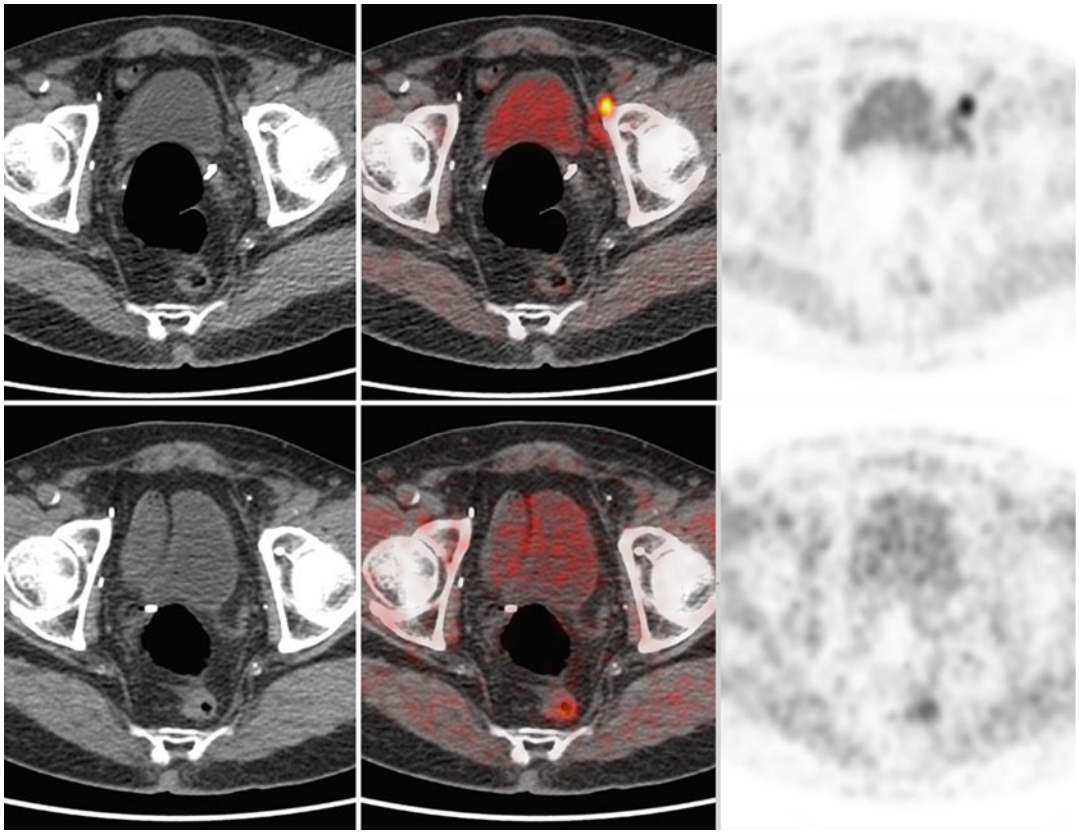

Fig. 22 On *top* panels CT, fused PET/CT and PET axial slices show the presence of a hyperactive left inguinal lymphadenopathy. On *bottom* panels the same axial slices of the patient after radiotherapy which demonstrate the disappearance of the lymphadenopathy

Teaching Points

In patients with hormone-refractory prostate cancer, PSA levels tend to rise despite treatment. For the same reason, PET/CT with ^{18}F-choline in these patients results to be positive despite the ongoing hormonal treatment, which is unable to control the disease.

Prostatic Cancer: Case No. 11

Presentation

A 74-year-old man underwent radical prostatectomy for an intermediate-risk prostate cancer with Gleason score 3 + 4. After a negative follow-up of more than 2 years, biochemical relapse with increased levels of serum PSA was observed.

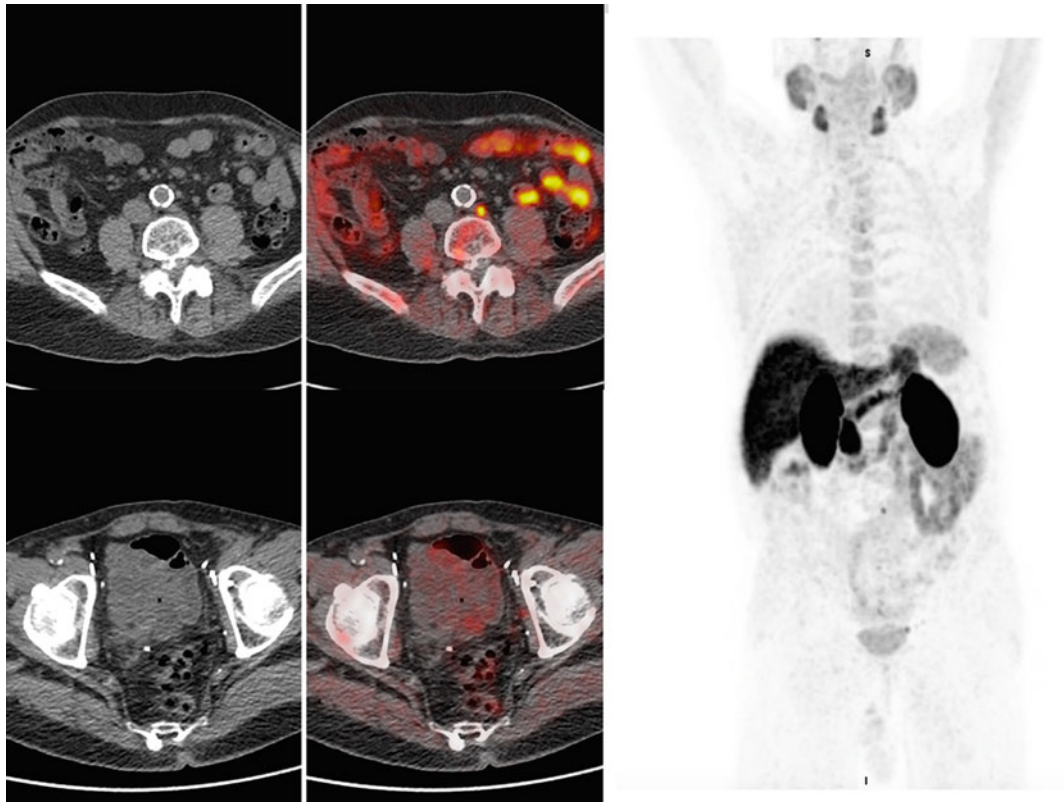

Fig. 23 PET/CT images after the new increase of PSA levels show a different site of disease within a para-aortic lymphadenopathy

Findings

PSA levels rose up to 1.56 ng/mL and the patient underwent a PET/CT with ^{18}F-choline. The whole-body scan revealed two areas of increased tracer uptake within an inguinal lymph node basin. PET/CT images were used to target subsequent external beam radiation therapy.

Follow-Up

Three months later, PSA levels decreased below 0.1 ng/mL. The patient underwent a second PET/CT, which confirmed the disappearance of the inguinal lymphadenopathy. One year later the patient presented a new increase of serum PSA up to 2.84 ng/mL. PET/CT with ^{18}F-choline revealed the presence of a new site of recurrence within a para-aortic lymph node, and the patient started hormonal antiandrogen therapy.

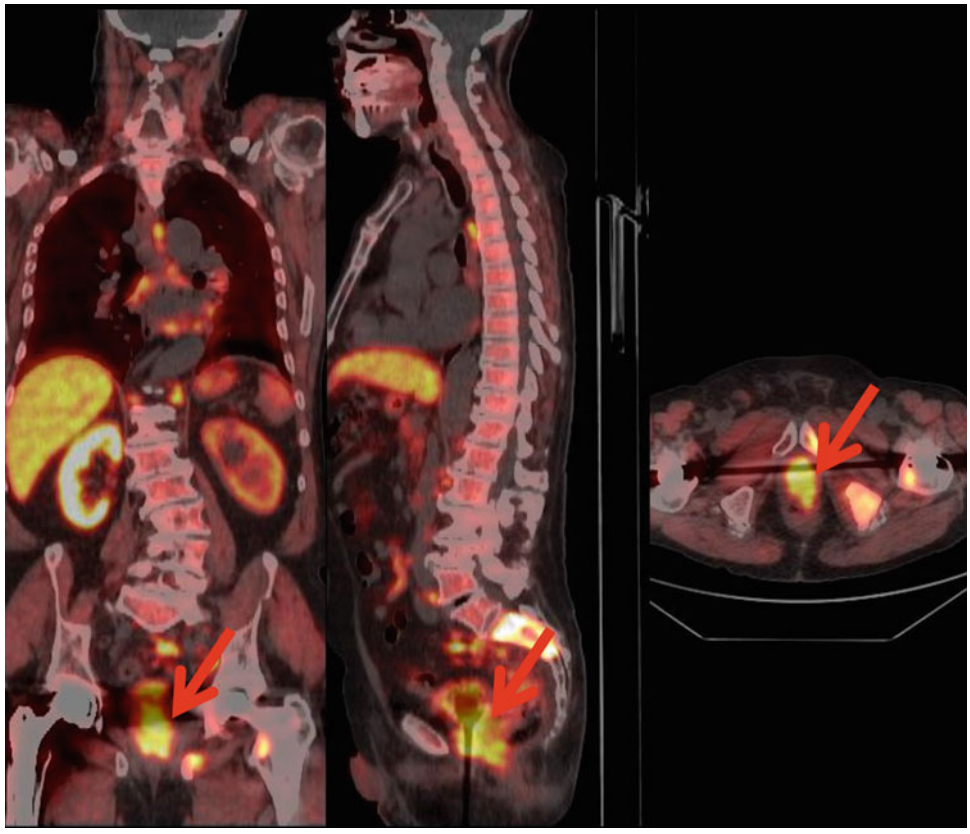

Fig. 24 Coronal (*left*), sagittal (*center*), and axial (*right*) fused PET/CT images show diffuse and intense tracer uptake in the prostate, seminal vesicles, and periprostatic adipose tissue (*red arrow*)

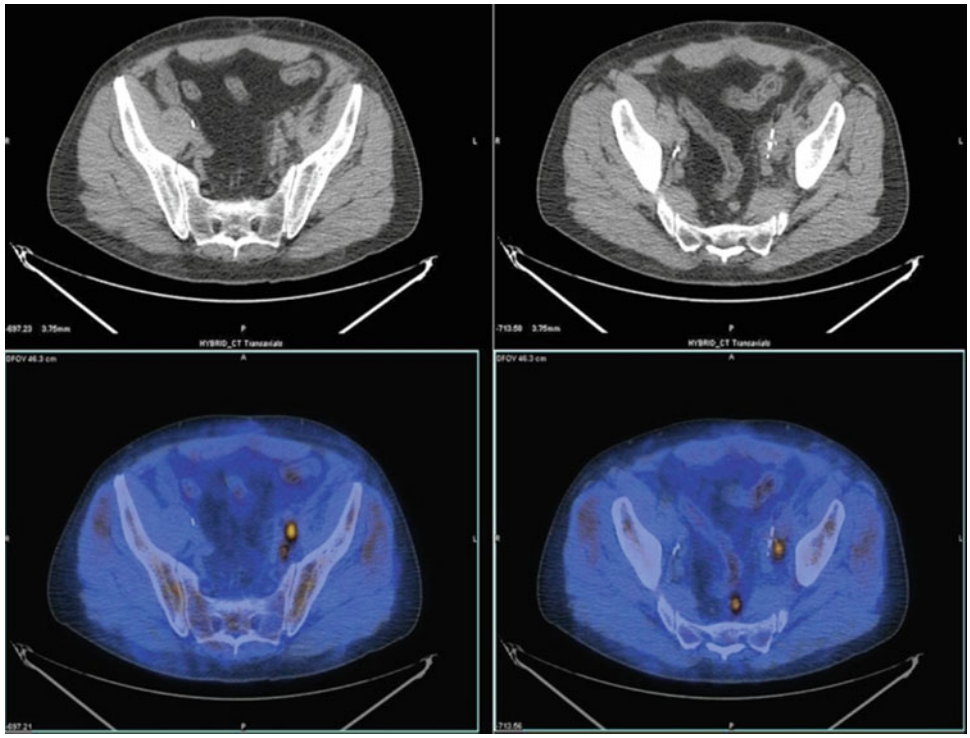

Fig. 29 Axial ^{18}F-FCH PET/CT images at two levels showing lymph node lesions. CT (*upper panels*) and fused images (*lower panels*)

Teaching Points

Although there is no firm evidence to suggest as a clinical standard the opportunity of a local treatment, to date an increasing number of patients are initiated to surgery or radiotherapy in the presence of limited clinical recurrence of disease. PET/CT with ^{18}F-choline could become one of the most effective imaging techniques to select patients for local treatments and to target radiotherapy.

Prostatic Cancer: Case No. 12

Case contributed by V. Duce, A. Ciarmiello
Nuclear Medicine Unit, "Sant'Andrea" Hospital, La Spezia, Italy.

Presentation

An 82-year-old patient with advanced prostate cancer (Gleason 9) treated with androgen deprivation therapy (LHRH agonists + antiandrogens). ^{18}F-choline PET/CT was performed to evaluate the extent of disease (restaging).

Findings

^{18}F-choline PET/CT fused images (coronal, sagittal, and axial views) show diffuse and intense tracer uptake in the prostate, seminal vesicles, and periprostatic adipose tissue (Fig. 24). Furthermore, the PET/CT scan shows numerous

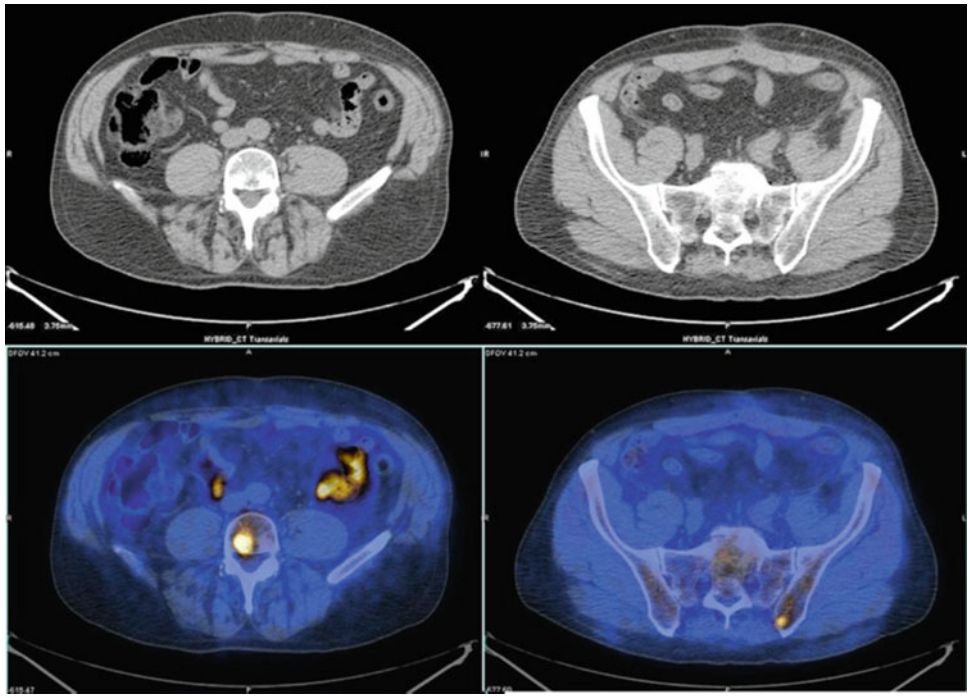

Fig. 30 Axial ^{18}F-FCH PET/CT images of skeletal metastases (CT, *upper image*, and PET/CT fused, *lower image*)

^{18}F-choline-avid lymphadenopathies in the pelvis (common iliac, external iliac, obturator, and paracolic nodes), in the abdomen (retrocrural, paraaortic, intercavoaortic, and paracaval nodes), and in the mediastinum (paratracheal, subcarinal, and paraesophageal nodes) (Fig. 25).

Lesions with increased ^{18}F-choline uptake are seen also in pelvic bones (including sacrum, ilium bilaterally, left ischium, and left pubis) and in the left femur (Fig. 26).

Discussion

This case confirms the value of ^{18}F-choline PET/CT in patients with prostate cancer for the evaluation of locoregional and metastatic disease.

Prostatic Cancer: Case No. 13

Presentation

A 64-year-old man with Gleason 9 prostate cancer with bilateral extracapsular extension and lymph node involvement (pT3bN2), previously treated with radical prostatectomy and bilateral pelvic lymphadenectomy presents with rising PSA 8 months after surgery. ^{18}F-choline PET/CT was performed to evaluate the extent of disease (Fig. 27).

Findings

Axial ^{18}F-choline PET/CT fused images show multiple sites of focal uptake in the prostate bed around the surgical clips (Fig. 28). Several foci of

^{18}F-choline uptake, corresponding to metastatic lymph nodes, are seen in common iliac region, in left external iliac, in obturator region, and in presacral nodes (Fig. 29). In addition, focal uptake in the lumbar spine and posterior left ilium suggest metastatic skeletal disease (Fig. 30).

Discussion

This case demonstrates the value of ^{18}F-choline PET/CT in patients with relapsed prostate cancer for the simultaneous evaluation of locoregional, lymph nodal, and distant recurrences.

Seminoma

Case contributed by: S. Al Shammari, F. Fraioli Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 23-year-old man with history of metastatic seminoma. [^{18}F]FDG PET/CT prior to start chemotherapy.

Findings

There is a large heterogeneous [^{18}F]FDG-avid left-sided retroperitoneal mass extending from the lower border of T12 to lower border of L4 vertebral body (measuring 8 × 7 × 12 cm, SUV_{max} 20 at the level of renal hilum) (upper row, arrows).

On follow-up study after chemotherapy (lower row), there is interval improvement in size and activity of the left para-aortic lymphadenopathy (arrow) measuring 4 × 3 × 6 cm with SUV_{max} 4.0 (Fig. 1).

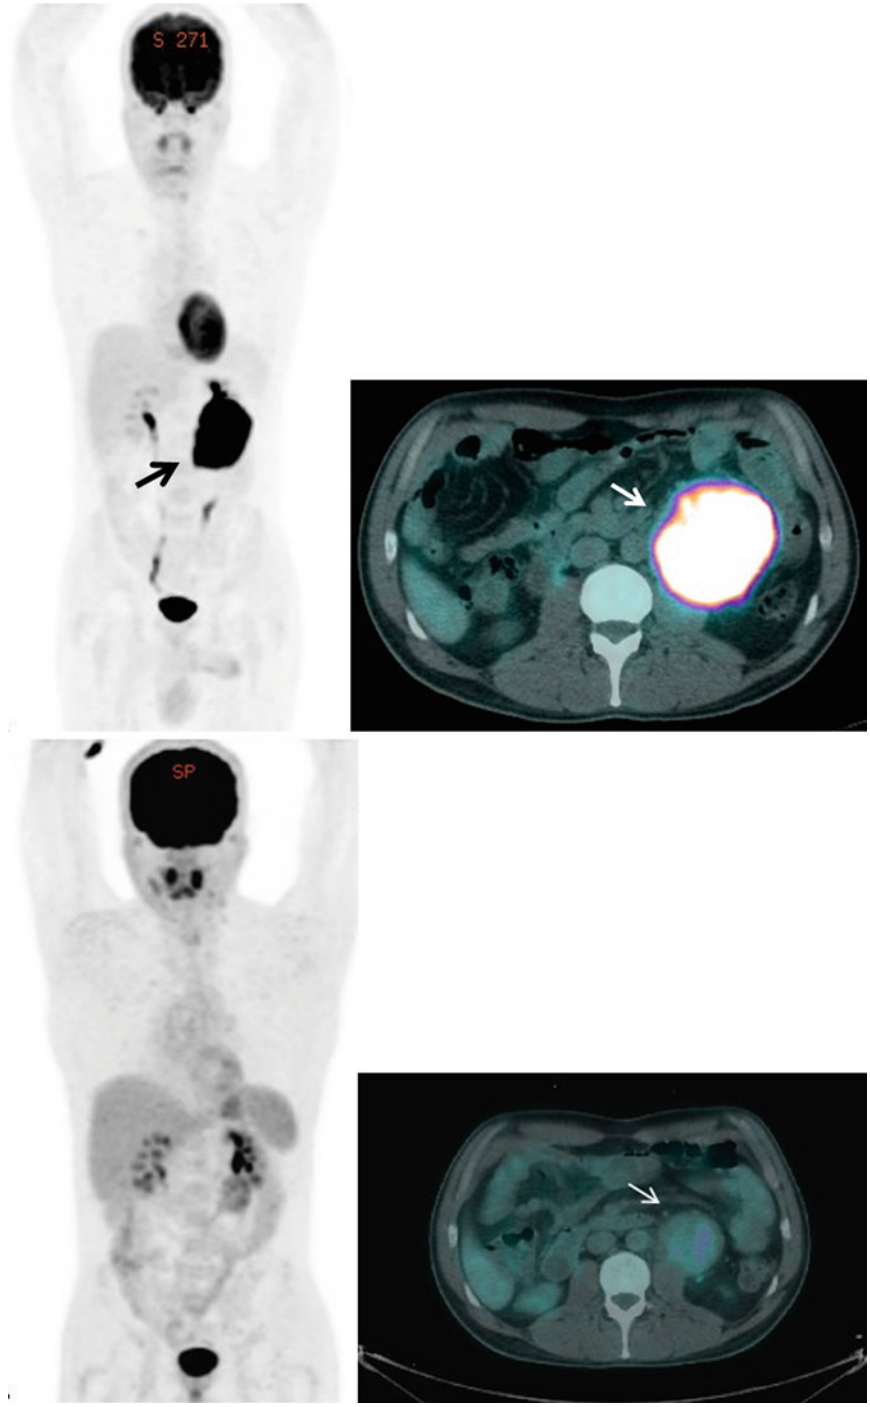

Fig. 1 MIP and axial images of [^{18}F]FDG PET/CT shows the left hypermetabolic mass (arrows at upper figures). [^{18}F]FDG PET/CT after treatment shows the hypometabolic residual mass (arrow at lower axial image)

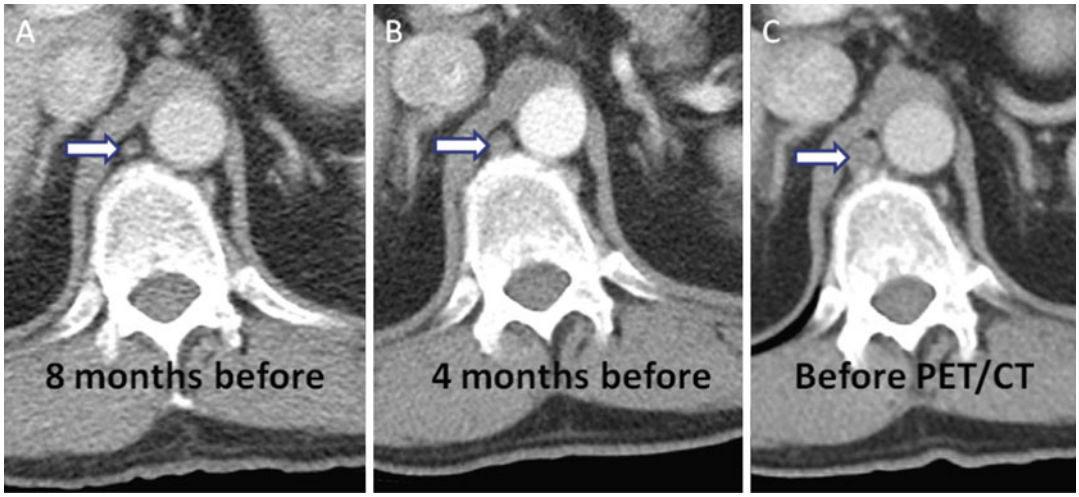

Fig. 2 Abdominal CTs after the therapy showed slowly increasing size of a retrocrural node: (**a**) 0.5 × 0.5 cm (8 months before PET/CT), (**b**) 0.6 × 0.6 cm (4 months before PET/CT), and (**c**) 1.1 × 0.9 cm (just before PET/CT)

Discussion

The limited accuracy with which testicular cancer is staged using conventional imaging modalities has led to the use of PET as an alternative staging tool. Another diagnostic challenge in the management of testicular cancer is the post-chemotherapy evaluation of a residual mass in the retroperitoneum. The differentiation between residual tumor, fibrosis, and teratoma can play a significant role in guiding further therapy. Unfortunately, by providing purely anatomic images of the retroperitoneum, CT does not adequately differentiate between these entities. Studies evaluating PET in this setting have demonstrated sensitivities ranging from 79% to 87% and specificities from 90% to 94%. In multiple studies, PET was limited by its low sensitivity for detecting mature teratoma, which has a low glucose metabolic rate. Studies have demonstrated that PET accuracy may be compromised if the scan is performed too soon (within 2 weeks) after chemotherapy, with reported false-negative findings due to early suppression of metabolic activity immediately

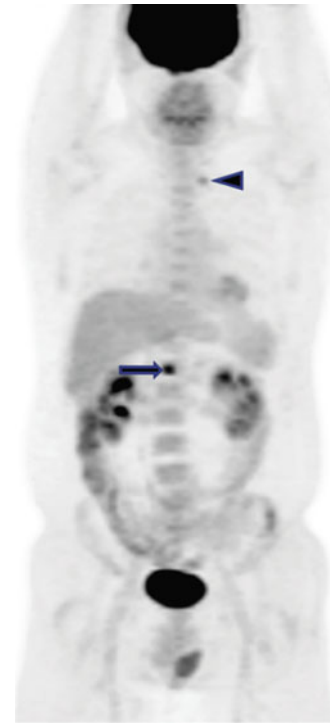

Fig. 3 MIP image of [^{18}F]FDG PET/CT shows the right hypermetabolic retrocrural node (*arrow*) and a subclavicular node (*arrowhead*)

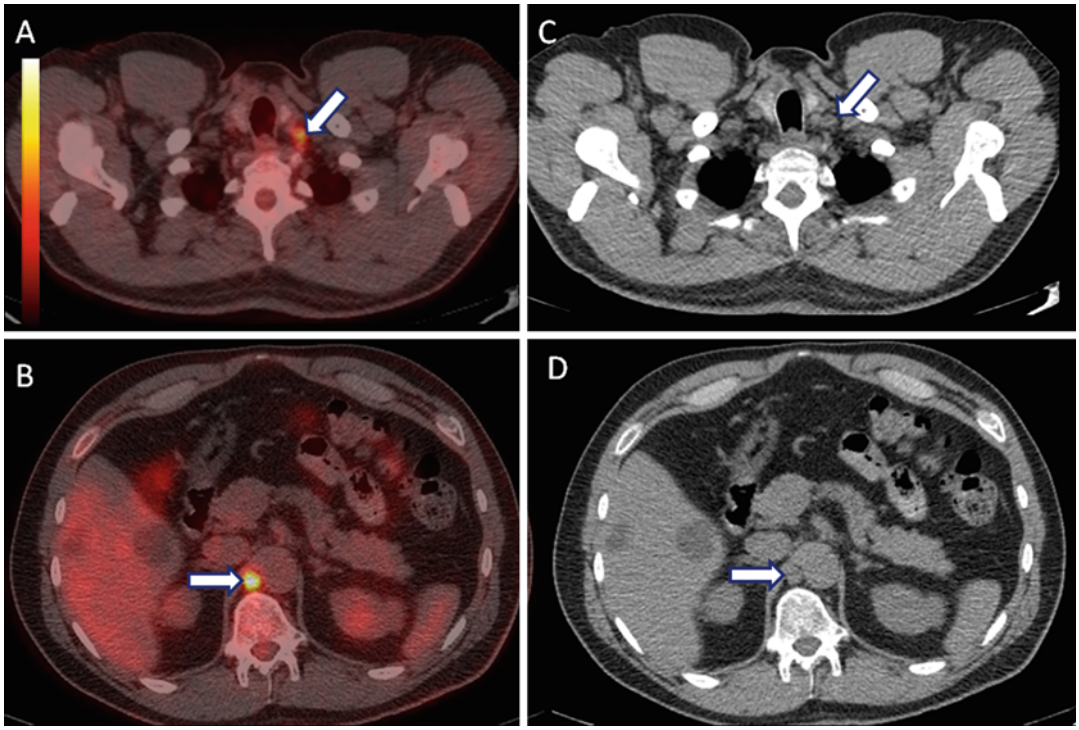

Fig. 4 Fused [^{18}F]FDG PET/CT axial images (**a**, **b**) show hypermetabolic right retrocrural lymph node (SUV_{max} 6.6) (*white arrows*) and subclavicular node (SUV_{max} 2.9) (*white arrows*). Diagnostic CT images during PET/CT (**c**, **d**) show that these lymph nodes are almost within normal limits

after chemotherapy and false-positive findings due to increased macrophage activity in absorption of necrotic tissue, respectively. As a result, PET should not be used until at least 2 weeks following chemotherapy.

Testicular Cancer (Nonseminomatous Tumor)

Presentation

A 51-year-old man with surgical history of high orchidectomy for mixed germ cell tumor. A follow-up CT showed slight enlargement of a swelling retrocrural lymph node, although serum alpha-fetoprotein was within normal limits (4.0 ng/mL, reference range 0.0–6.1 ng/mL).

Findings

Histopathology of the primary tumor in his right testicle showed mixed germ cell tumor containing embryonal carcinoma and yolk sac tumor. Follow-up abdominal CT scans (Fig. 2) demonstrated slightly increasing size of a right retrocrural node. The patient was referred for follow-up extent of disease assessment. [^{18}F]FDG PET/CT was performed to evaluate for metastatic disease (Figs. 3 and 4).

Discussion

Testicular cancers are divided into major categories (seminoma or nonseminomatous tumor). Overall, approximately two-thirds of patients have clinical

stage I disease at the time of diagnosis [1, 2]. Delayed metastases commonly occur in the para-aortic, iliac, and inguinal lymph nodes. [^{18}F]FDG PET/CT has benefit in the staging and restaging of the testicular cancers. Ambrosini et al. reported that [^{18}F]FDG PET/CT showed high sensitivity (92%) and specificity (84%) for seminoma [3]. However, [^{18}F]FDG PET/CT characteristics were lower for nonseminomatous tumors, with a sensitivity of 77% and a specificity of 99%. The study indicates the potential usefulness of [^{18}F]FDG PET/CT for patients with testicular tumors. In this case, [^{18}F]FDG PET/CT was able to clearly detect the metastatic lymph nodes and questionable finding on follow-up CT.

Case 1

Case contributed by: F. Reyneke, M. Sathekge
Nuclear Medicine, University of Pretoria & Steve Biko Academic Hospital, Pretoria, South Africa

Presentation

An 81-year-old man was referred with penile cancer for which surgery was done. He complained of pain in his left shoulder.

Findings

A biopsy taken from the penile mass revealed poorly differentiated squamous cell carcinoma.

[^{18}F]FDG PET/CT for initial staging showed mild diffuse tracer uptake in the penis including the tip of the surgical stump with regional inguinal nodal involvement (SUV_{max} 25.27) (Figs. 1 and 2). Furthermore, a mass was noted posterior to the apex of the left lung. It had a large soft tissue component with adjacent bony erosion of the vertebral bodies of T2 and T3 (SUV_{max} 33.5) (Fig. 3). This was most likely a second primary tumor and had the appearance of a Pancoast tumor.

Discussion

In this case, the restaging [^{18}F]FDG PET/CT performed after surgery for the penile cancer resulted in the incidental detection of a lung mass that was completely asymptomatic.

Case 2

Case contributed by: M. R. Jochumsen
Department of Nuclear Medicine & PET Centre, Aarhus University Hospital, Aarhus, Denmark

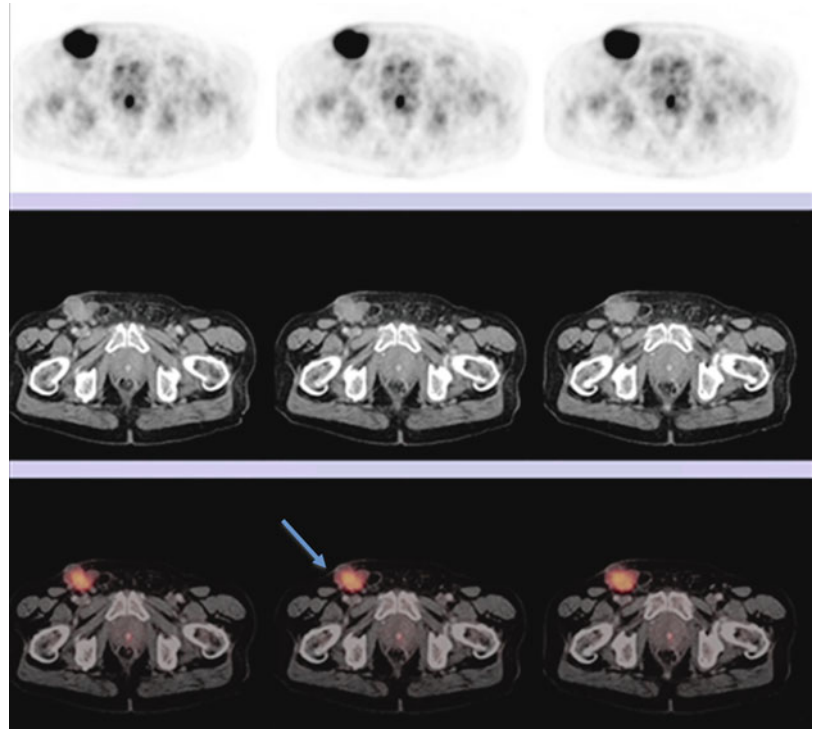

Fig. 2 [^{18}F]FDG PET/CT axial images demonstrating the penile stump

Presentation

An 87-year-old man with no previous medical history presented with a large tumor located on the penile glans. Additional clinical findings were multiple palpable lymph nodes in the right inguinal region.

Findings

A biopsy from the tumor showed a planocellular carcinoma, and the patient was referred for primary staging with [^{18}F]FDG PET/CT. The scan showed highly increased [^{18}F]FDG uptake in the primary penile tumor (A, yellow arrow) and in a lymph node conglomerate in the right inguinal region (A, dark blue arrow) and in two lymph nodes in the left inguinal region (A, red arrow). Furthermore, a focus of highly increased [^{18}F]FDG activity was seen in the left lung (A, green arrow).

Following intradermal injections of ^{99m}Tc-nanocolloidal albumin around the tumor (B, C and D, yellow arrows), lymphoscintigraphy showed a sentinel lymph node with high activity in the left inguinal region (B and C, red arrows), a secondary node superior of the sentinel node (B and C, purple arrows), and a sentinel node with very low activity in the right inguinal region (B and D, light blue arrows) in close relation to the lymph node conglomerate (D, dark blue arrow) (Fig. 4).

Follow-Up

A total penectomy was performed with simultaneous lymph node resection on the right side and gamma probe guided removal of sentinel node/suspicious lymph nodes in the left inguinal region. Histology showed that the primary tumor was a pT3 planocellular carcinoma with metastasis and perinodal growth in the lymph nodes from both sides. Later on, lymph node resection on the left side was performed and the patient was referred to chemotherapy. The tumor in the lung turned out to be a small primary lung cancer, and not a metastasis.

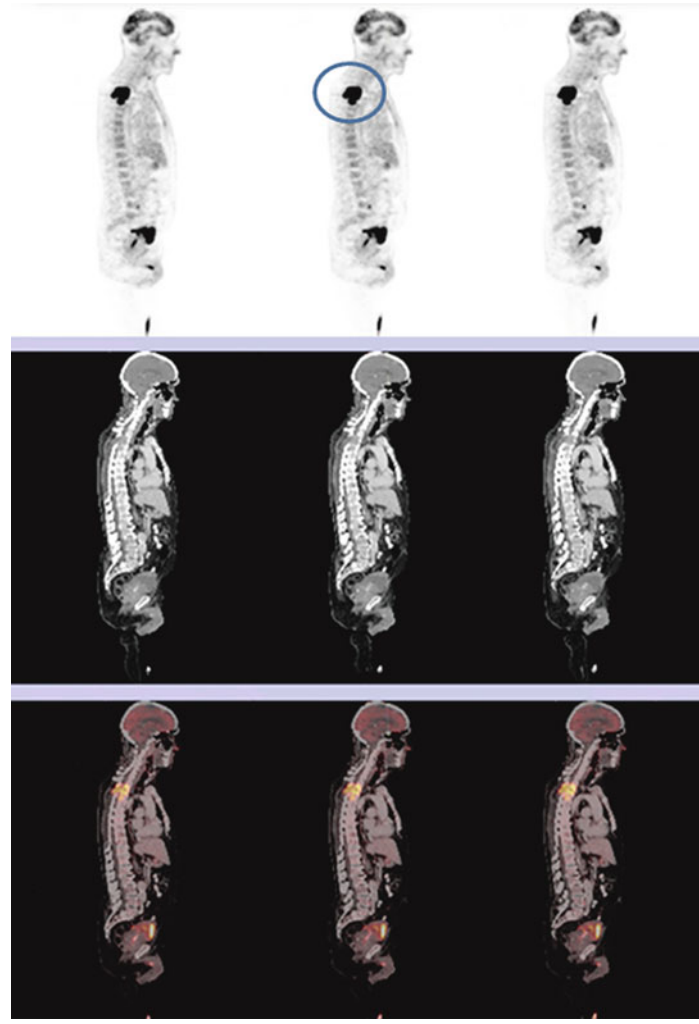

Fig. 3 [^{18}F]FDG PET/CT sagittal images showing the mass posterior to the apex of the left lung

Discussion

In this case, the significant tumor masses in the lymph nodes in the right groin almost did not appear on the lymphoscintigraphy, which illustrates that tumor infiltration of the lymph nodes can block the lymph drainage and complicate the interpretation of the lymphoscintigraphy [1]. The tumor in the lung was not a metastasis from penile cancer but instead a primary lung cancer. Thus, the case also illustrates the importance of histology of other relevant lesions suspicious of malignancy.

Case 3

Case contributed by: A. H. Dias
Department of Nuclear Medicine & PET Centre, Aarhus University Hospital, Aarhus, Denmark

Presentation

A 39-year-old man who 4 year earlier underwent partial penectomy for a pT1a squamous cell penis cancer, with negative sentinel node involvement.

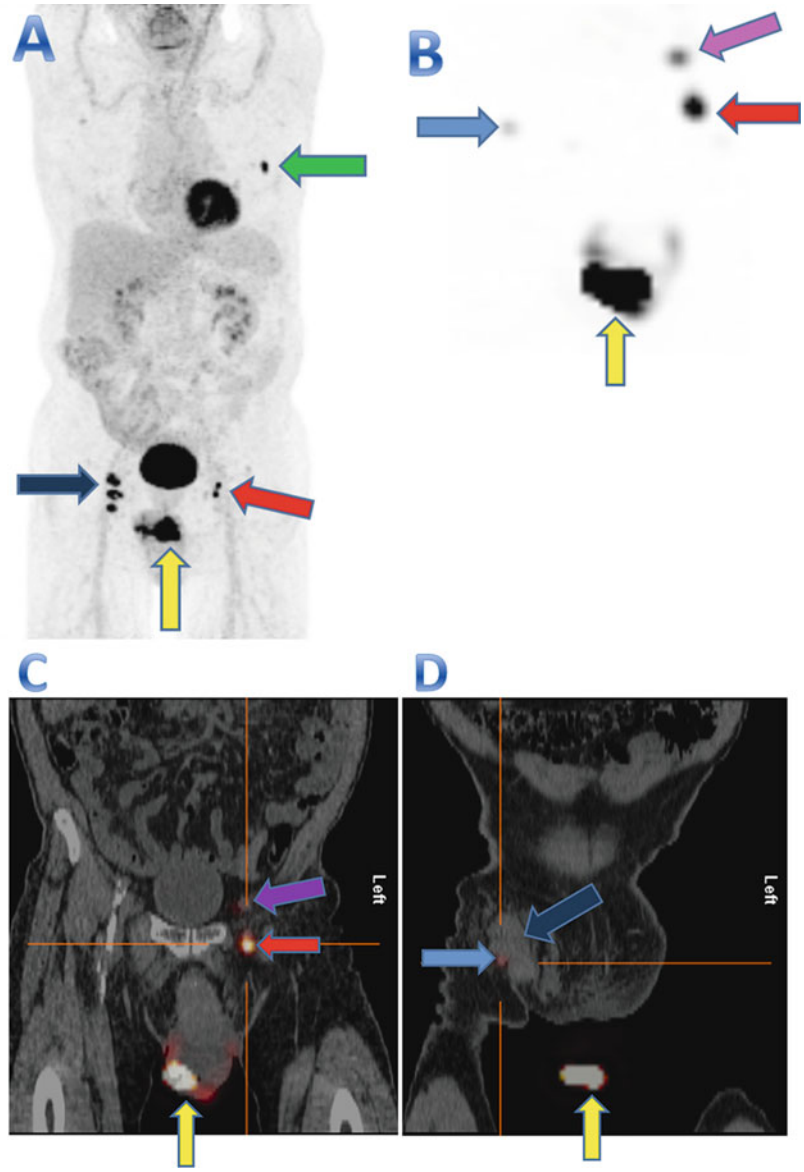

Fig. 4 Yellow arrows: penile tumor, Blue arrows: right inguinal lymph node metastases, Red arrows: left inguinal lymph node metastases, Green arrow: left lung lesion, Purple arrows: lymph node above sentinel node, (**A**) MIP image of [^{18}F]FDG PET, (**B**) ^{99m}Tc Nanocoll image, (**C** and **D**) Coronal fused SPECT/CT images

Referred to [^{18}F]FDG PET/CT scanning for restaging after a local relapse (pT2) was found in the penis stump.

Findings and Follow-Up

SCAN 1

[^{18}F]FDG PET/CT showed a small area of increased tracer uptake in the penis (arrow 1), probably because of the recent surgical excision (or small area of remaining tumor) as well as a single lymph node in the right groin with moderately increased uptake (arrow 2), suspect for possible lymph node metastasis.

A new penectomy was planned together with new sentinel lymph node procedure and excision of nodes from the right groin. Pathology results reported a 3 mm lymph node positive for squamous cell penis cancer. Patient subsequently underwent extensive right groin resection, which

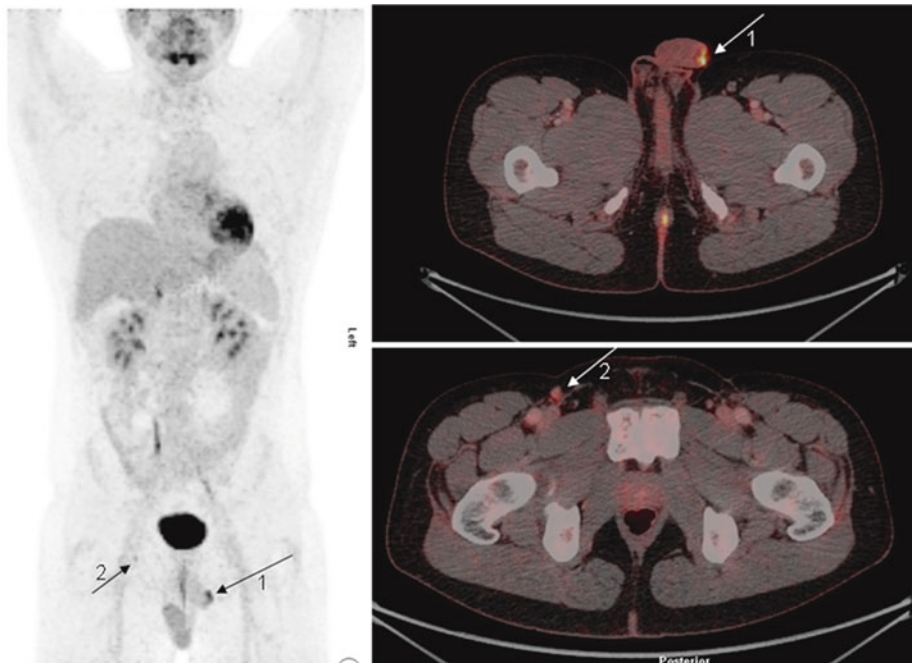

Fig. 5 MIP and axial fusion images. Arrows shows lymph nodes metastases

found no other metastases. Imaging control with 3 months interval was decided.

The 6-month control of the area showed local edema and inflammatory signs in the right groin, and a subsequent MRI of the pelvis showed possible signs of relapse in the region.

Patient was referred to a new restaging [^{18}F] FDG PET/CT (Fig. 5).

SCAN 2

This scan showed edema of the soft tissue of the right thigh and fluid collection in the right groin, possible sequelae to the surgery procedure, with associated abscess/infection.

The scan also found multiple foci in the right groin (arrows), with increased tracer uptake, suspect for new lymph node metastases.

A new surgical approach to the groin was performed to drain the local abscess and to remove these nodes. Pathology showed once again multiple nodular metastasis of low-differentiated squamous cell penis cancer.

Due to verified relapsing disease the patient was referred to chemo-/radiotherapy treatment but showed a poor response to treatment with new signs of relapse in the right groin. The disease developed locally over 1 year until a control CT discovered a new subcutaneous process on the right hip. Excision of this area found cutaneous spreading of squamous cell penis cancer. A new [^{18}F]FDG PET/CT was requested (Fig. 6).

SCAN 3

This scan showed a large multifocal tumor in the right groin (arrows 1) with severely increased [^{18}F]FDG uptake and signs of central necrosis.

Two foci in the left groin with severely increased [^{18}F]FDG uptake (arrows 2), suspect for new nodal metastasis.

Multiple subcutaneous/muscular foci with severe increased [^{18}F]FDG uptake, located in left upper arm, right hip, and right thigh (arrows 3) – suspect for subcutaneous/muscular spreading.

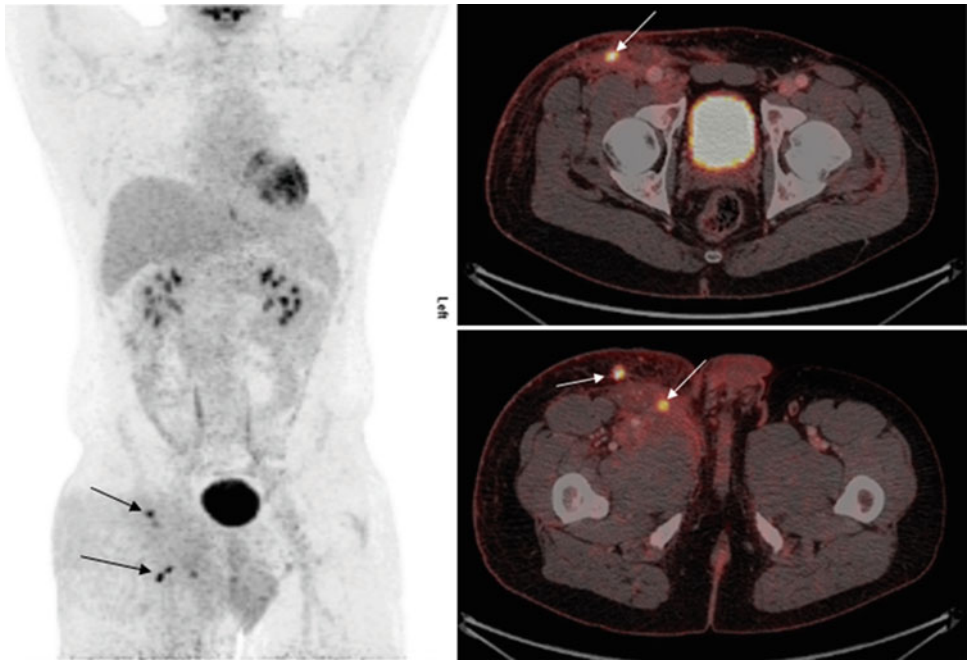

Fig. 6 MIP and axial fusion images. Arrows shows lymph nodes metastases

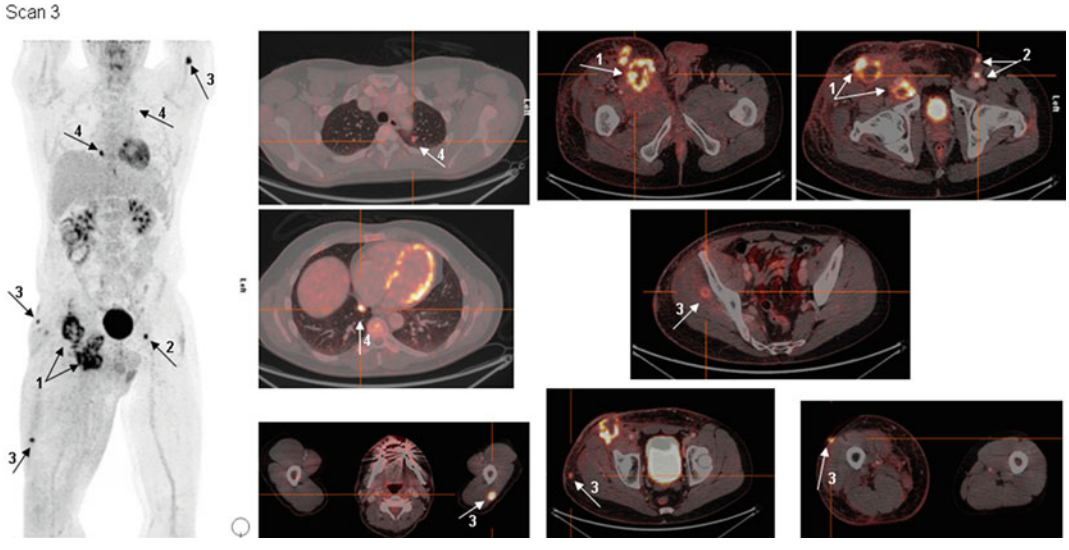

Fig. 7 MIP and axial fusion images. Arrows shows lymph nodes metastases

Bilateral foci in the lunges suspect for lunge metastasis (arrows 4).

Due to the unusual spreading behavior shows in the scan, particularly in regard to subcutaneous sites, a surgical exploration was performed in right thigh and in the left upper arm to verify the etiology of these foci. Pathology results found once again metastasis of squamous cell penis cancer at both sites (Fig. 7).

Discussion

This case exemplifies a case of severely aggressive behavior of a low-differentiated squamous cell penis cancer in a young patient, starting with a simple pT1aN0M0 tumor that evolved very poorly with multiple local relapses with no response to various treatment modalities including local surgical excision together with chemotherapy and radiotherapy and that eventually spread to the lungs and to multiple subcutaneous and muscular sites [2, 3].

Vulvar Cancer: Case No. 1

Presentation

A 62-year-old woman previously treated with vulvectomy and inguinofemoral lymphadenectomy for squamous vulvar cancer presented with biopsy-proven recurrent disease. [^{18}F]FDG PET/CT was performed to assess the extent of disease.

Findings

[^{18}F]FDG PET/CT shows focal uptake in the right vulvar region consistent with recurrent disease (Fig. 1). Hypermetabolic retroperitoneal bilateral adenopathy was also demonstrated suspicious for lymph node involvement (Fig. 2).

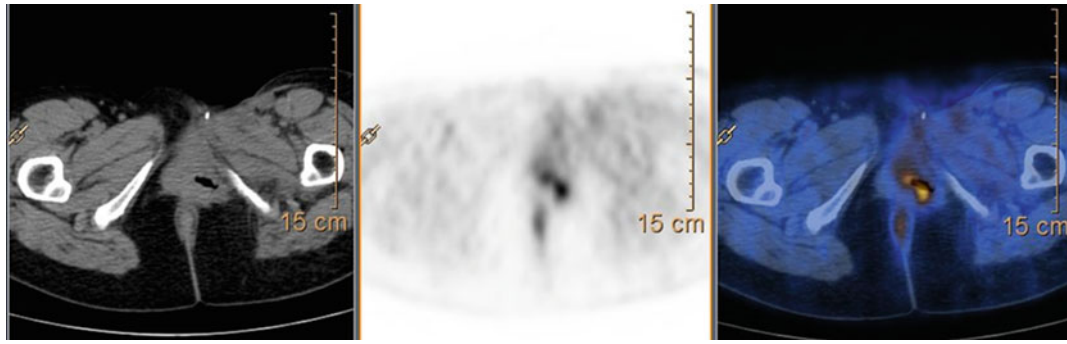

Fig. 1 Axial low-dose CT (*left*), PET, and fused [^{18}F]FDG PET/CT (*right*) images identify recurrent vulvar cancer

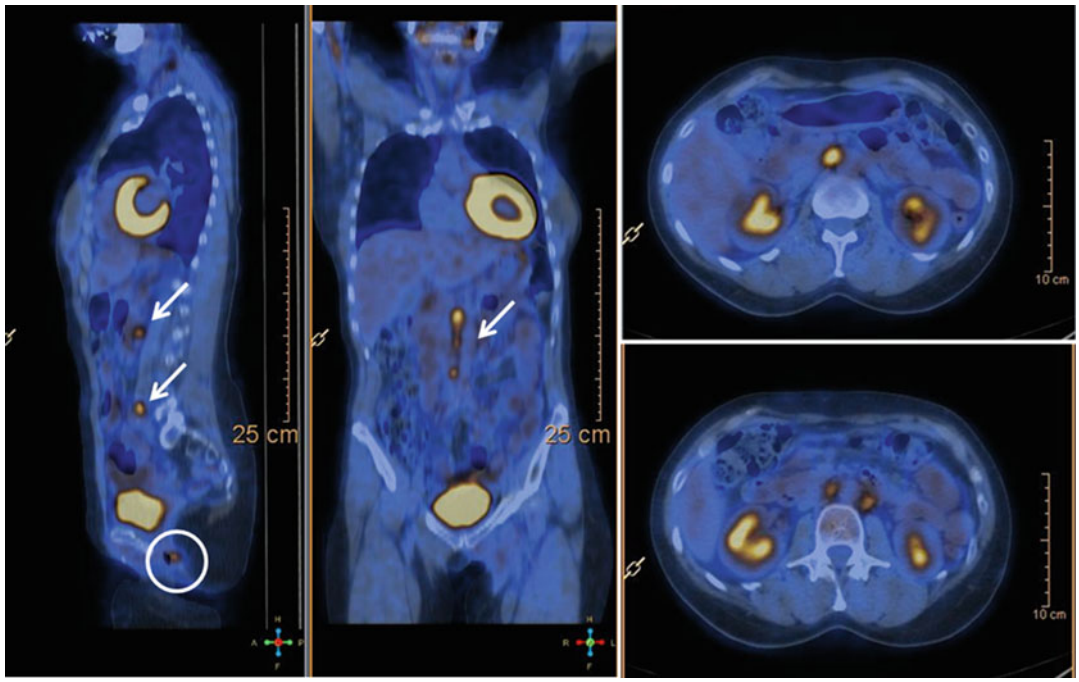

Fig. 2 Fused [^{18}F]FDG PET/CT images show recurrent vulvar cancer (*white circle*) and multiple retroperitoneal pathologic adenopathy (*white arrows*)

Discussion

Vulvar carcinoma is a rare malignancy and it is seen to recur in 30–50% of patients within the first 2 years. The majority of these are local recurrences; however, one third of recurrences are in the groin, associated with a poor prognosis. Accurate evaluation of the disease extent with the identification of distal recurrent disease and lymph node metastases is important to guide which patients may benefit from chemoradiation.

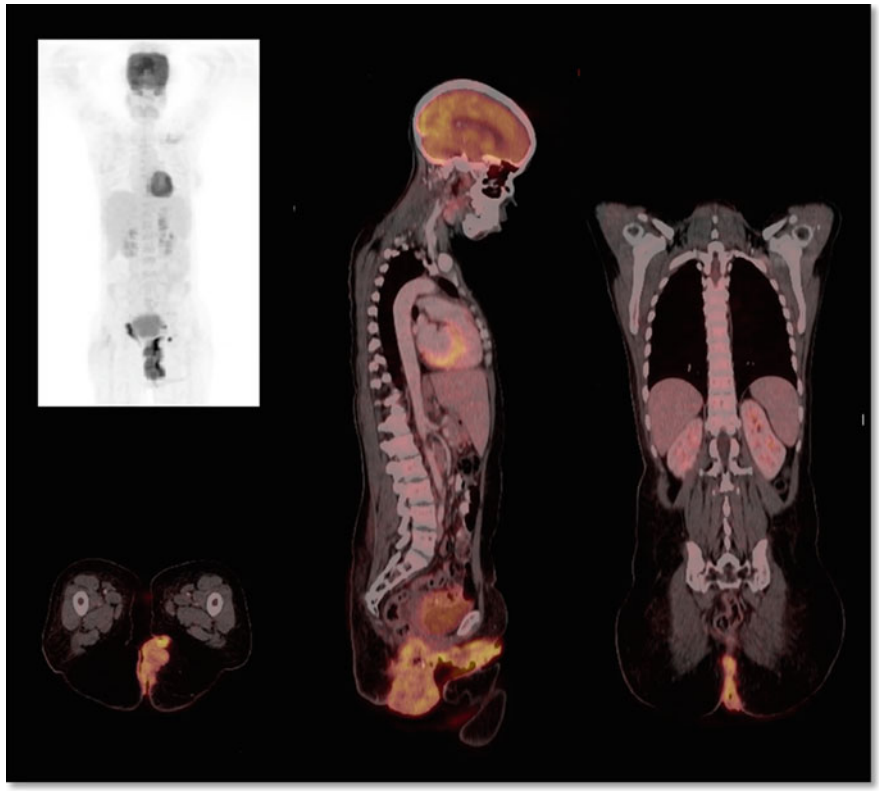

Fig. 3 *Upper left*, [^{18}F]FDG PET/CT MIP image. *Lower left to right*, fused axial, sagittal, and coronal PET/CT images. The images show the [^{18}F]FDG-avid vulvar mass infiltrating the vagina and anal canal

Vulvar Cancer: Case No. 2

Case contributed by: F. Reyneke, M. Sathekge
Nuclear Medicine, University of Pretoria & Steve Biko Academic Hospital, Pretoria, South Africa

Presentation

A 40-year-old woman referred with vulvar carcinoma. She is RVD reactive and on antiretroviral treatment.

Findings

A biopsy taken from the vulvar mass revealed squamous cell carcinoma.

[^{18}F]FDG PET/CT was performed for initial staging of the cancer. [^{18}F]FDG uptake was noted in the fungating vulval mass infiltrating the vagina and anal region (SUV_{max} 12.73) (Figs. 3, 4, and 5) with involvement of bilateral inguinal lymph nodes (SUV_{max} right 11.52, left 10.26) (Fig. 6).

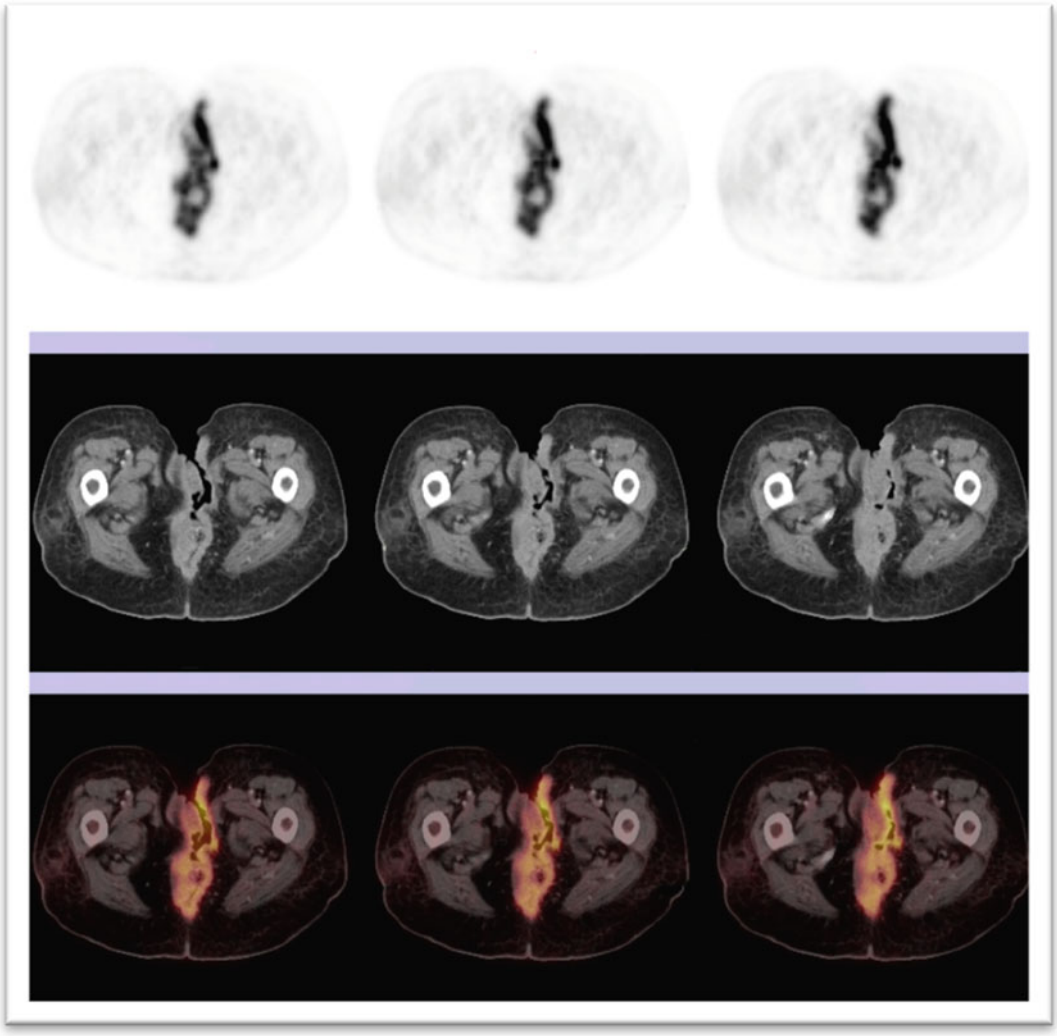

Fig. 4 [^{18}F]FDG PET/CT axial images demonstrating the vulvar mass

Discussion

[^{18}F]FDG PET/CT is a useful imaging modality in the management of vulvar carcinoma, mainly in the identification of nodal metastases. It may affect both surgical planning and clinical management of the patient.

Vulvar Cancer: Case No. 3

Case contributed by: F. Reyneke, M. Sathekge
Nuclear Medicine. University of Pretoria & Steve Biko Academic Hospital, Pretoria, South Africa

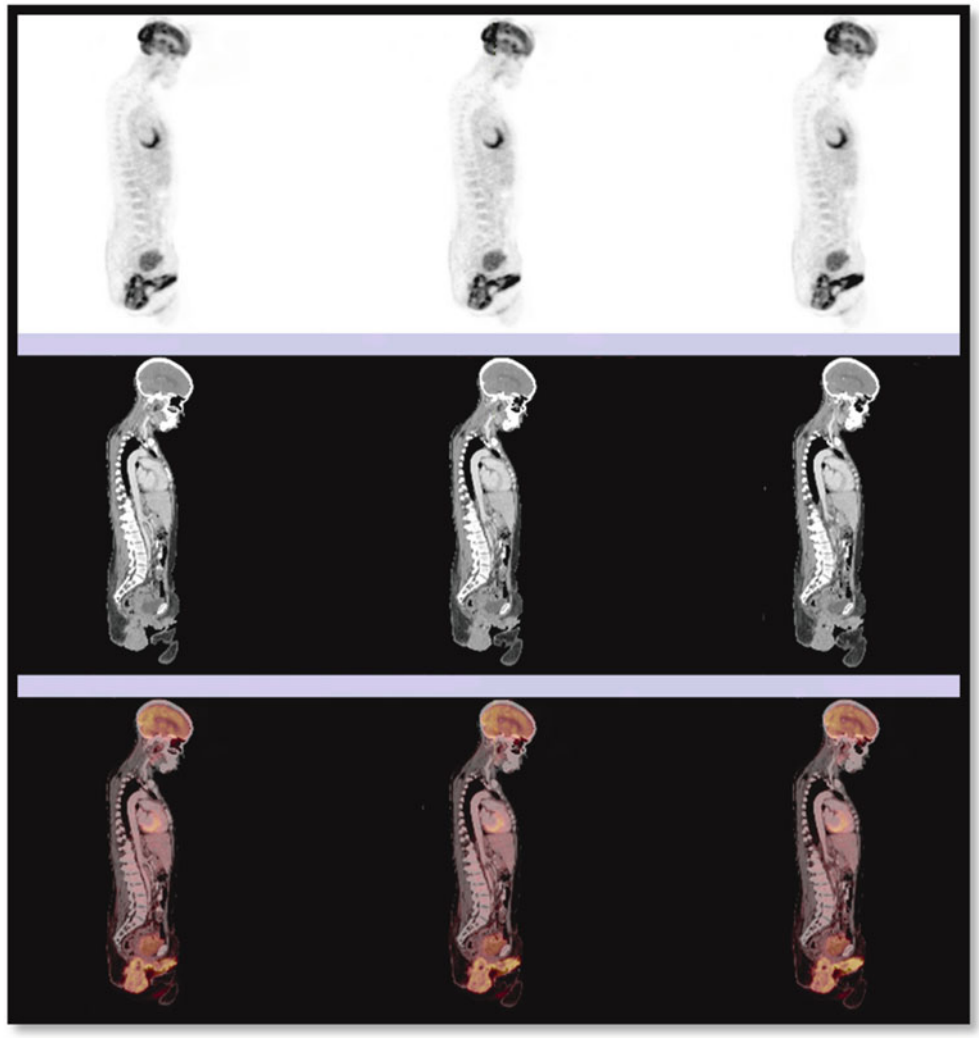

Fig. 5 [^{18}F]FDG PET/CT sagittal images demonstrating the extent of the vulvar mass

Presentation

A 72-year-old woman referred with vaginal carcinoma. The treatment history includes pelvic radiotherapy. She presented with urinary retention post radiotherapy which necessitated the insertion of a suprapubic catheter.

Findings

A biopsy taken from the vaginal mass revealed invasive moderately differentiated keratinizing squamous cell carcinoma.

[^{18}F]FDG PET/CT was performed for restaging post pelvic radiotherapy. [^{18}F]FDG

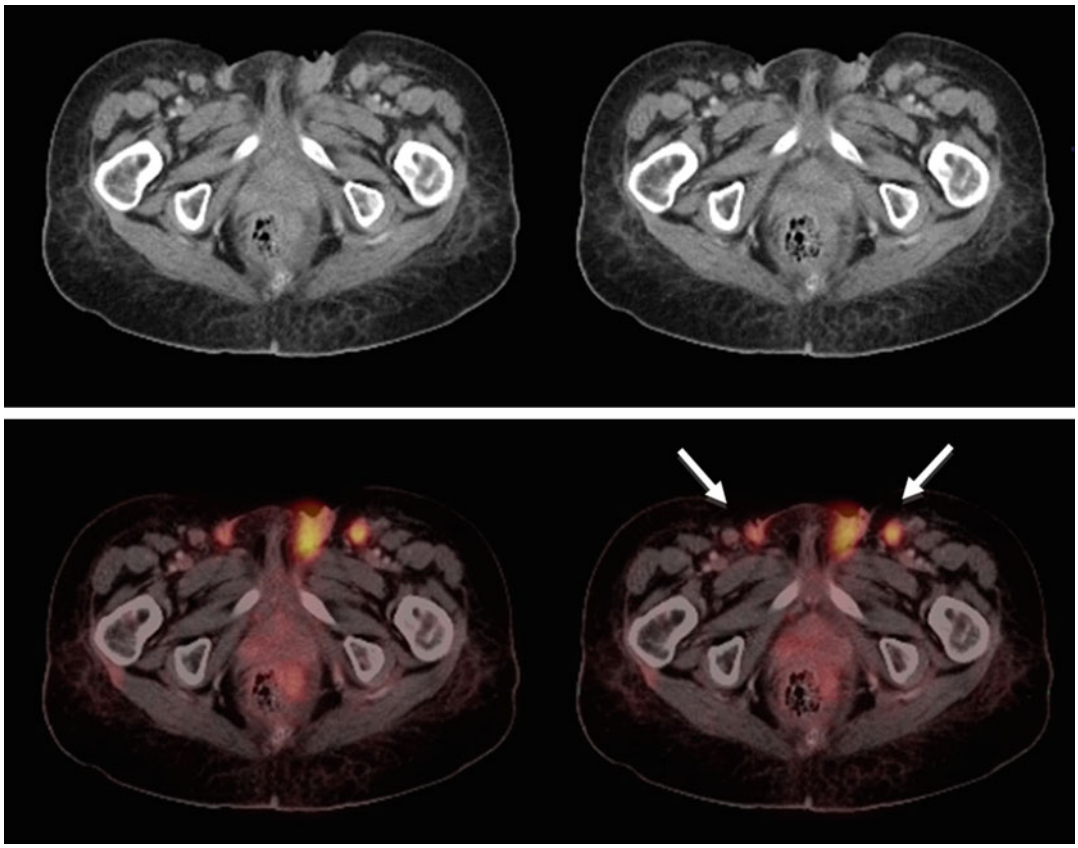

Fig. 6 [^{18}F]FDG PET/CT axial images show bilateral inguinal node involvement

uptake was noted in the vaginal vault extending from the cervix to the labia.

(SUV_{max} 22.28) (Figs. 7, 8, and 9) with multifocal uptake in the cervix (SUV_{max} 56.66) (Fig. 10).

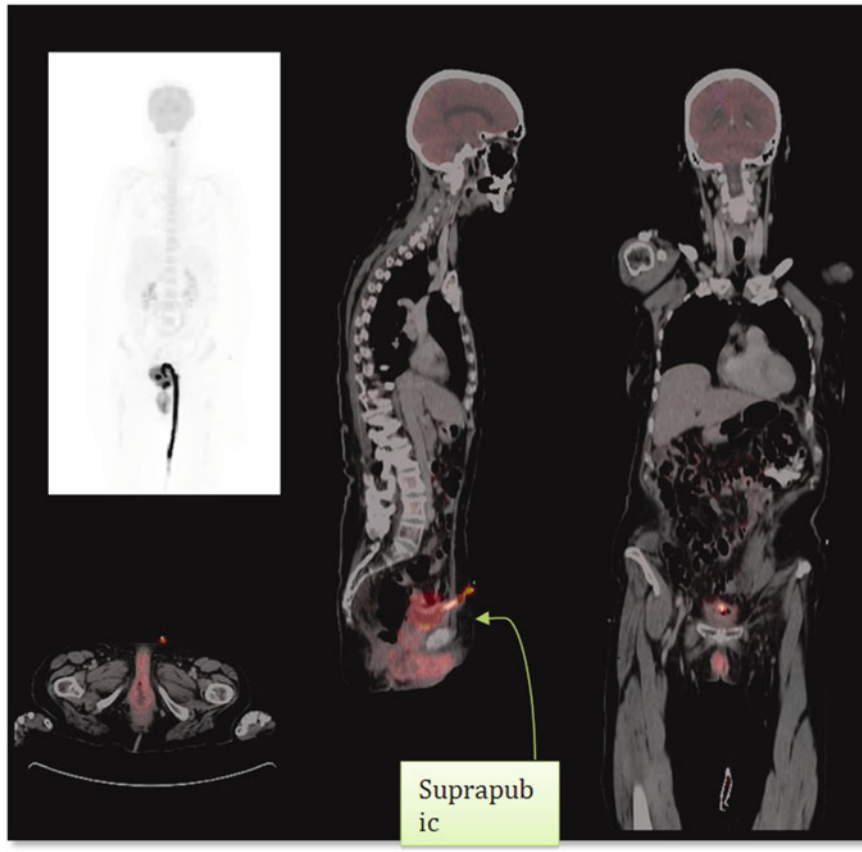

Fig. 7 *Upper left*, [^{18}F]FDG PET/CT MIP image. *Lower left to right*, fused axial, sagittal, and coronal PET/CT images. The images show the [^{18}F]FDG-avid vaginal mass extending to the cervix and labia

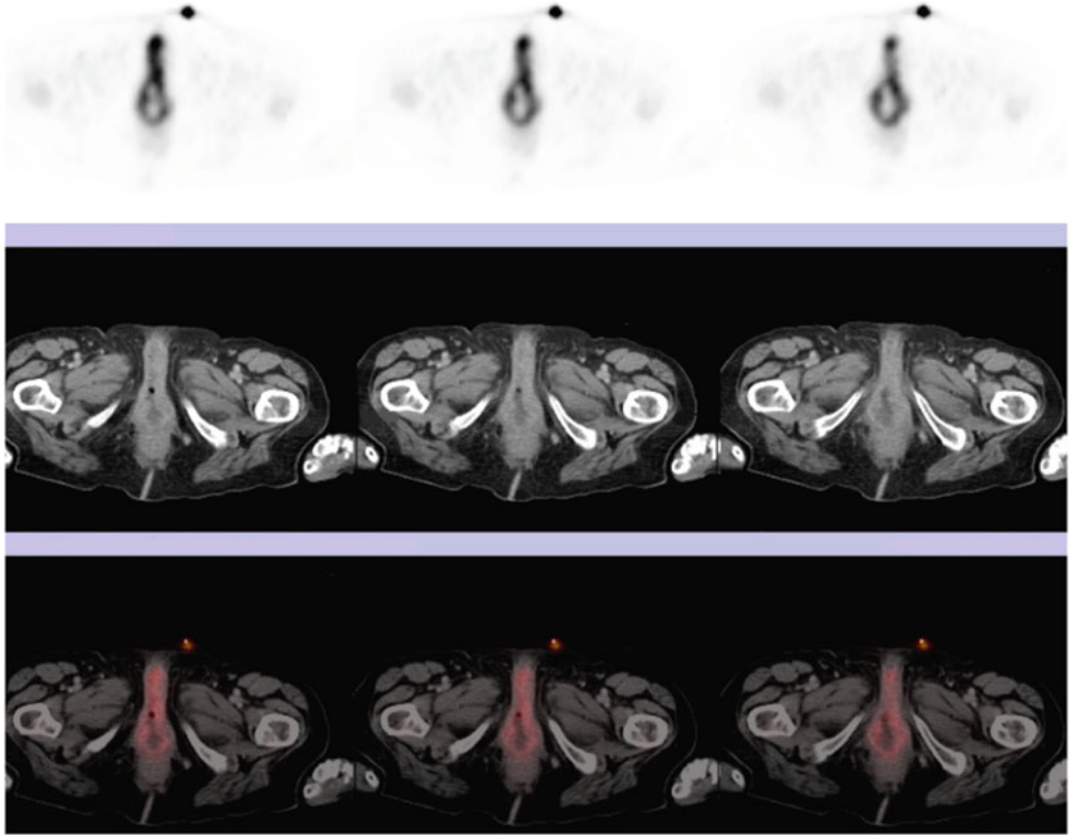

Fig. 8 [^{18}F]FDG PET/CT axial images demonstrating the vaginal mass

Fig. 9 [^{18}F]FDG PET/CT sagittal images demonstrating the extent of the vaginal mass

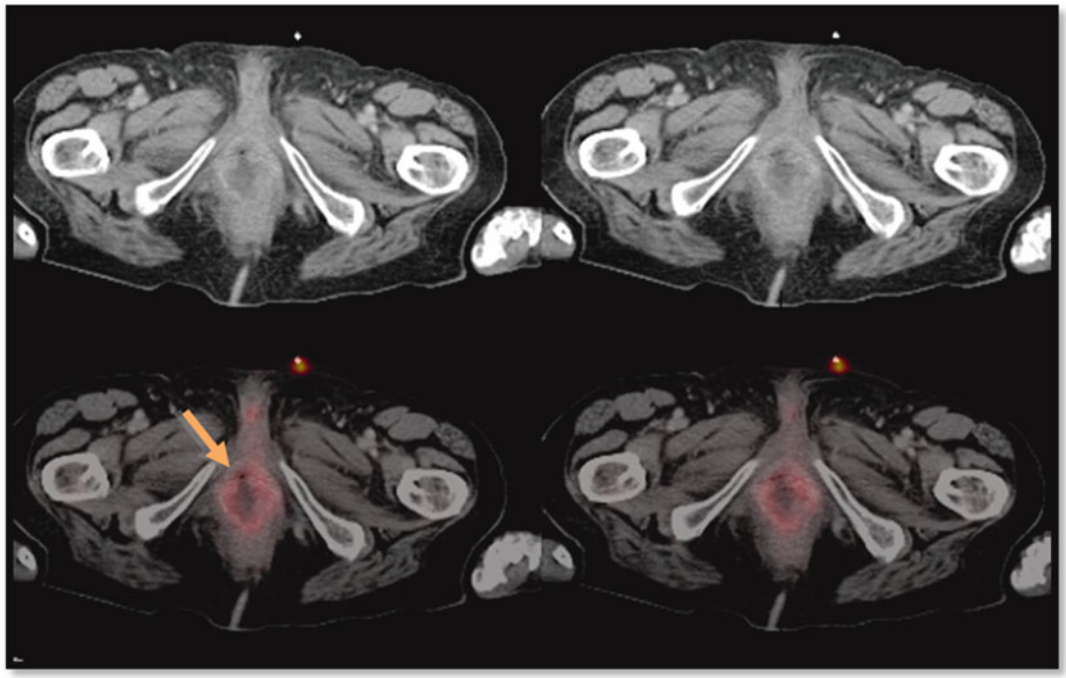

Fig. 10 [^{18}F]FDG PET/CT axial images demonstrating the multifocal uptake in the cervix

Discussion

[^{18}F]FDG PET/CT plays an important role in the management of vaginal carcinoma. It should be considered in the restaging of patients following therapy.

Uterine Cancers: Case No. 1

Presentation

A 38-year-old woman with recently diagnosed locally advanced cervical carcinoma referred for [^{18}F]FDG PET/CT staging.

Findings

PET/CT confirms the presence of hypermetabolic cervical lesion and [^{18}F]FDG-avid pelvic lymph nodes (Fig. 1). In addition, hypermetabolic para-aortic, intercavo-aortic, mediastinal, and retro-clavicular lymphadenopathy was seen (Fig. 2).

Discussion

[^{18}F]FDG PET may be useful in staging cervical cancer due to the ability to detect local pelvic and distant nodal status.

Uterine Cancers: Case No. 2

Presentation

A 42-year-old woman with metastatic cervical squamous cell carcinoma referred after chemotherapy completion to evaluate treatment response.

Findings

[^{18}F]FDG PET/CT at baseline showed intense [^{18}F]FDG pathological uptake in the cervical mass (Fig. 3a). Multiple hypermetabolic lymph nodes were seen in para-uterine, common, and internal iliac regions (Fig. 4a). Focal [^{18}F]FDG uptake was noted in segment 6 of the liver consistent with hepatic metastases (Fig. 5a). In addition, skeletal hypermetabolic lesion was demonstrated in the left ischiopubic ramus (Fig. 4a).

[^{18}F]FDG PET/CT after chemotherapy showed metabolic response of the cervical mass (Fig. 3b) and pelvic lymph nodes (Fig. 4b). Partial metabolic response was observed in liver metastases. No [^{18}F]FDG uptake was demonstrated in the left ischiopubic branch after therapy. However, the appearance of focal [^{18}F]FDG uptake consistent with skeletal metastases was noted in the right hemisacrum (Fig. 6).

Discussion

[^{18}F]FDG PET is useful in the post-therapy assessment of response in patients with advanced and metastatic cervical cancer. [^{18}F]FDG PET is an important diagnostic tool also to predict response early during the course of chemotherapy. Furthermore, literature data show that [^{18}F]FDG response to therapy may permit an accurate prediction of patient survival.

Uterine Cancers: Case No. 3

Presentation

A 69-year-old woman presented with pelvic pain and vaginal bleeding. Physical examination revealed tumor growth confined to the cervix with no signs of extension to the vagina. A cervical biopsy showed moderately differentiated (tumor grade II) large-cell nonkeratinizing squamous cell carcinoma of the cervix uteri. MRI of the pelvis shows T2 hyperintense pathological mass involving the right posterolateral cervix (Fig. 7).

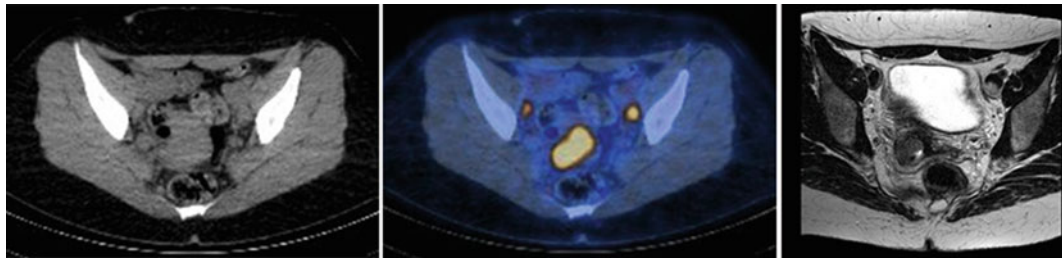

Fig. 1 [^{18}F]FDG-avid lesion of the cervix and bilateral pelvic lymphadenopathy. MRI (*right panel*) of primary tumor

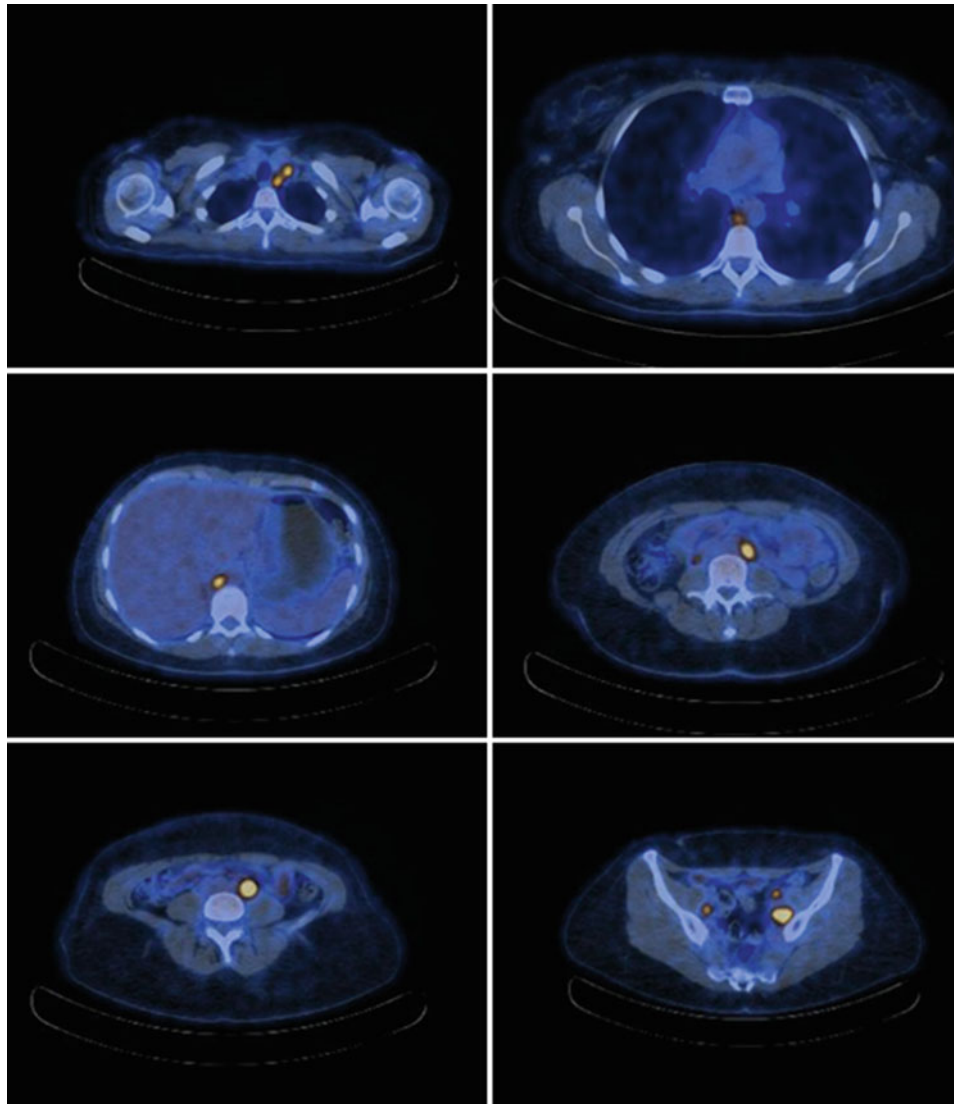

Fig. 2 Transaxial fused [^{18}F]FDG PET/CT image of hypermetabolic lymphadenopathies of the pelvis, abdomen, and thorax

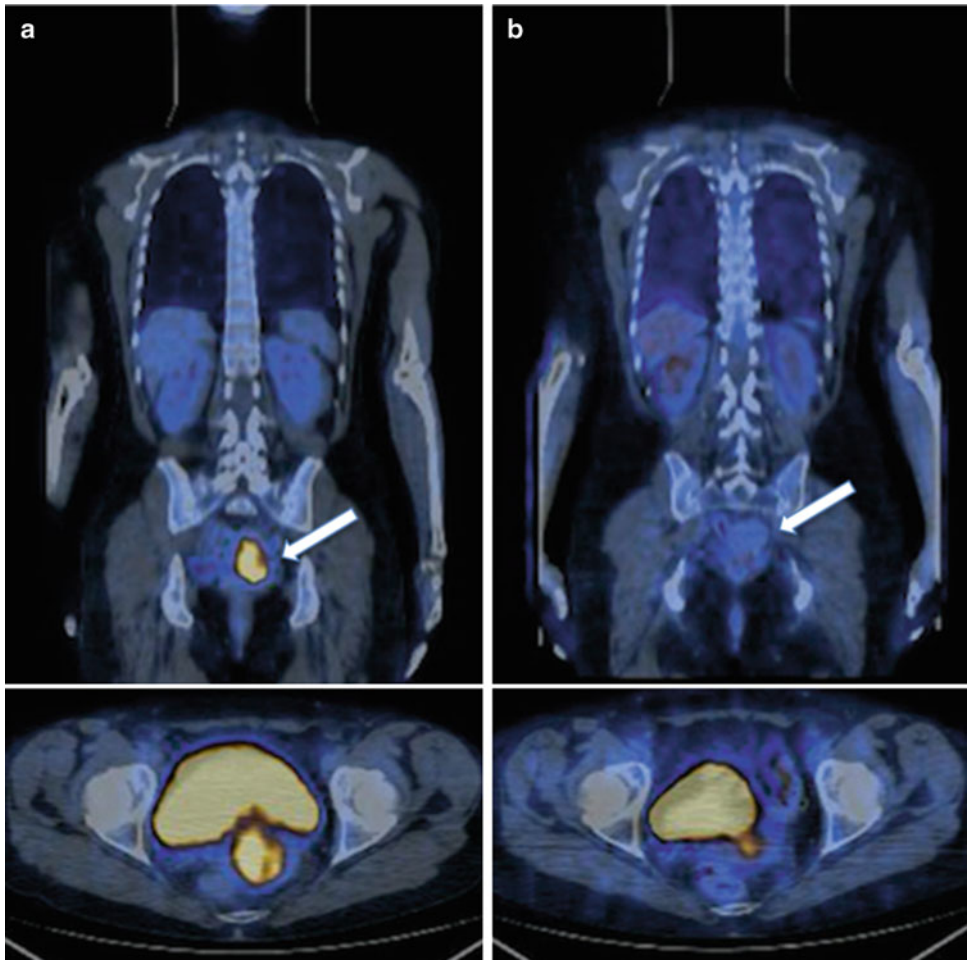

Fig. 3 Fused [^{18}F]FDG PET/CT images of hypermetabolic cervical tumor before (**a** *white arrow*) and after chemotherapy (**b** *white arrow*)

[^{18}F]FDG PET/CT was performed to assess disease extension.

Findings

[^{18}F]FDG PET/CT images showed area of increased [^{18}F]FDG uptake in the cervix corresponding to malignant tumor (Fig. 8). No other foci of [^{18}F]FDG uptake were shown in the pelvic region. A mildly [^{18}F]FDG-avid focus was noted in the left breast (Fig. 9).

Mammogram showed a spiculated 1-cm opacity highly suspicious of malignancy (BI-RADS 5) in the left equatorial external quadrant (Fig. 9).

Discussion

When an unexpected focus of [^{18}F]FDG uptake is detected in the breast during an [^{18}F]FDG examination performed for other reasons, it is prudent to characterize the lesion with additional imaging and/or biopsy, because of the high risk of malignancy of 30% [1].

Uterine Cancers: Case No. 4

Fig. 7 T2 hyperintense pathological mass involving the cervix on pelvis MRI (*red arrow*)

Presentation

A 69-year-old woman with cancer of the cervix managed with pelvic radiotherapy 30 years ago.

Patient presented with vesicovaginal fistula a year ago, and biopsy demonstrated infiltrating moderately differentiated adenocarcinoma with focal neuroendocrine differentiation.

Repeat biopsy 1 year later demonstrated no evidence of malignancy.

Findings

An [^{18}F]FDG PET/CT scan was performed for follow-up. [^{18}F]FDG PET/CT images demonstrated local recurrence (SUV_{max} 12.4) with liver metastases and widespread nodal metastases (inguinal, obturator, para-aortic, retrocrural, mediastinal, and left supraclavicular).

Discussion

This case demonstrates that [^{18}F]FDG PET/CT can be useful in the assessment of patients with suspected cervical cancer recurrence.

Fusion images demonstrating liver metastases. CT images demonstrating the liver metastases.

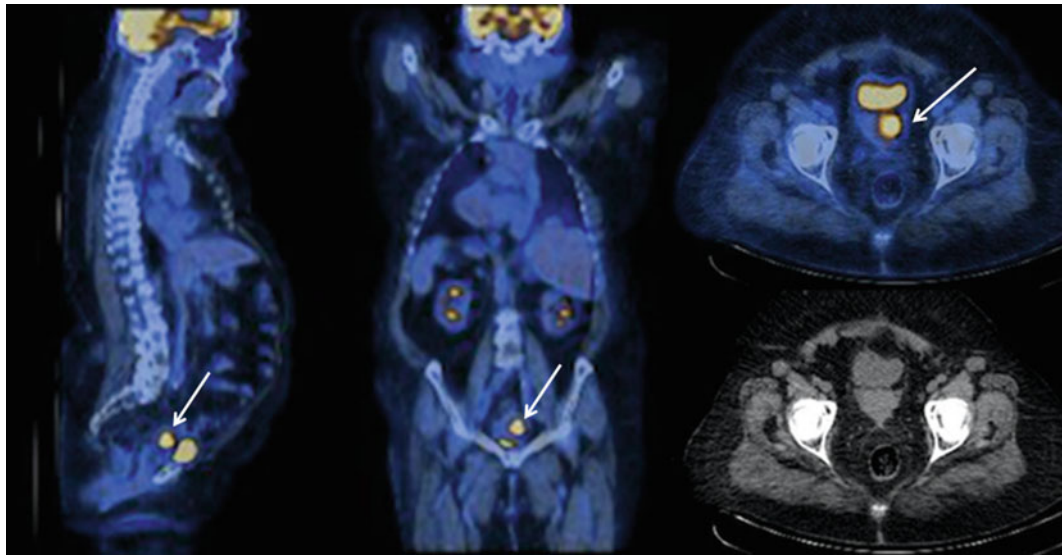

Fig. 8 Coronal (*left*), sagittal (*middle*), axial (*upper right*) fused [^{18}F]FDG PET/CT and axial low-dose CT (*lower right*) images show hypermetabolic cervical lesion

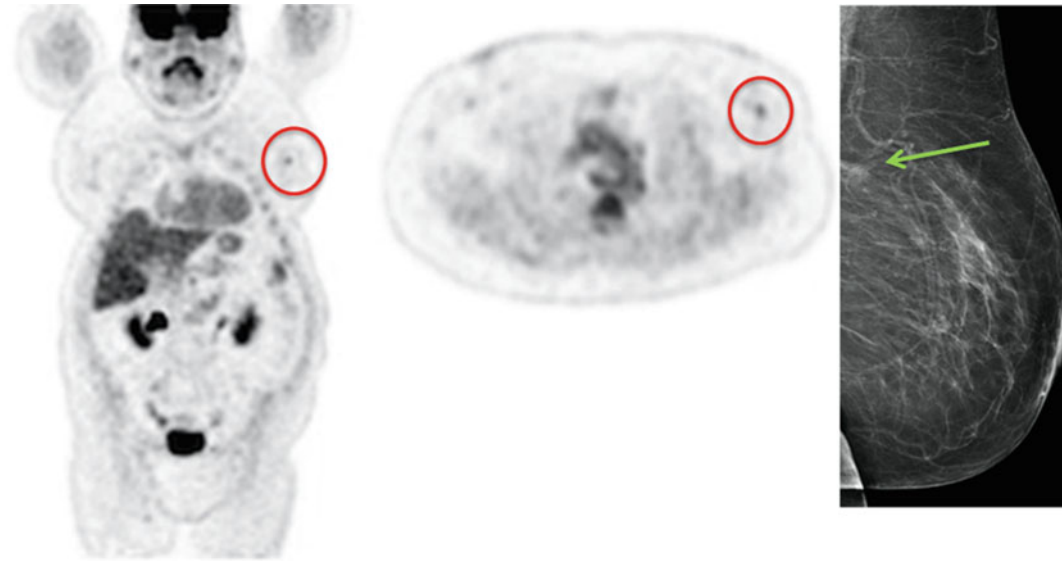

Fig. 9 Sagittal (*left*) and axial (*middle*) PET images identify small area of mild [^{18}F]FDG uptake in the left breast (*red circle*). Mammogram of the left breast (*right*) depicts opacity highly suspicious of malignancy (BI-RADS 5) (*green arrow*)

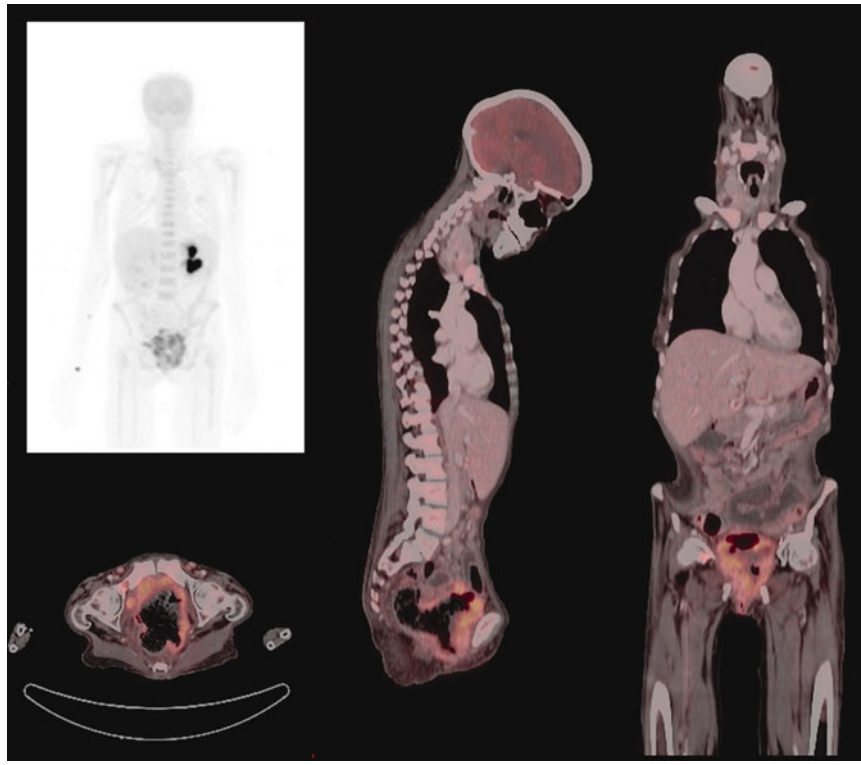

Fig. 10 *Upper left*, [^{18}F]FDG PET/CT MIP image. *Lower left to right*, fused axial, sagittal, and coronal PET/CT images. The images show the [^{18}F]FDG-avid mass involving the distal vagina infiltrating the vulva, bladder, and rectum

[^{18}F]FDG PET images demonstrating supraclavicular node and para-aortic nodes.

Uterine Cancers: Case No. 5

Case contributed by: F. Reyneke, M. Sathekge
Nuclear Medicine, University of Pretoria & Steve Biko Academic Hospital, Pretoria, South Africa

Presentation

A 59-year-old woman presented with a fungating vaginal mass and a rectovaginal fistula. She was diagnosed with cervical cancer 9 years earlier for which a radical hysterectomy was done followed by radiotherapy.

Findings

A biopsy taken from the lateral vaginal wall revealed invasive keratinizing squamous cell carcinoma grade II (presumed recurrence).

[^{18}F]FDG PET/CT was performed to detect suspected recurrence. [^{18}F]FDG uptake was noted in the irregular soft tissue mass involving the distal vagina with infiltration of the bladder, rectum, and vulva, with SUV_{max} 10.1 (Fig. 10). Regional lymph nodes and bones were also involved. In addition, minimal [^{18}F]FDG uptake was noted in the right kidney with hydronephrosis and a hydroureter secondary to extensive cervical tumor infiltration (Fig. 11).

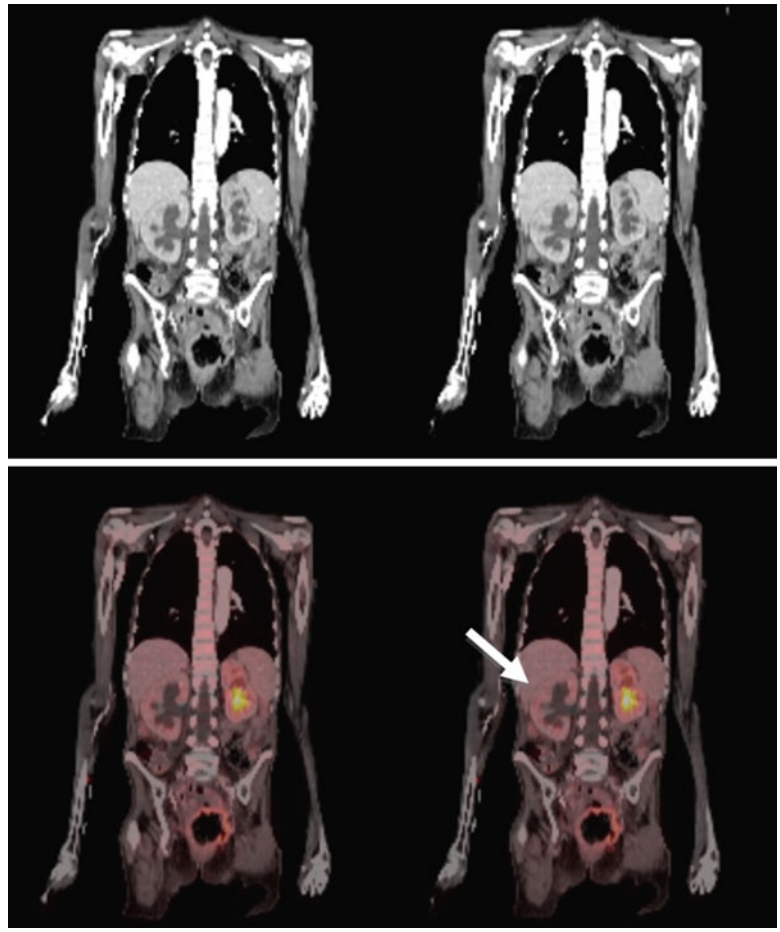

Fig. 11 [^{18}F]FDG PET/CT coronal images demonstrating reduced [^{18}F]FDG uptake in the right kidney associated with hydronephrosis and hydroureter

Discussion

This case confirms the value of [^{18}F]FDG PET/CT in the management of suspected recurrence of cervical cancer.

Uterine Cancers: Case No. 7

Presentation

A 73-year-old woman presented with vaginal bleeding and pelvic discomfort. Hysteroscopy showed endometrial lesion with cerebroid aspect. Endometrial biopsy demonstrated adenocarcinoma grade III with 60% Ki67 proliferation index. Pelvic MRI showed large lesion (74 mm in size) with myometrial infiltration. [^{18}F]FDG PET/CT was performed as part of initial staging before planned surgery.

Findings

[^{18}F]FDG PET/CT demonstrates increased uptake in the entire uterus consistent with endometrial cancer and [^{18}F]FDG-avid lymph nodes in internal-external iliac right regions (Fig. 12). In addition a small hypermetabolic nodule was noted in the gastrosplenic region consistent with peritoneal implant.

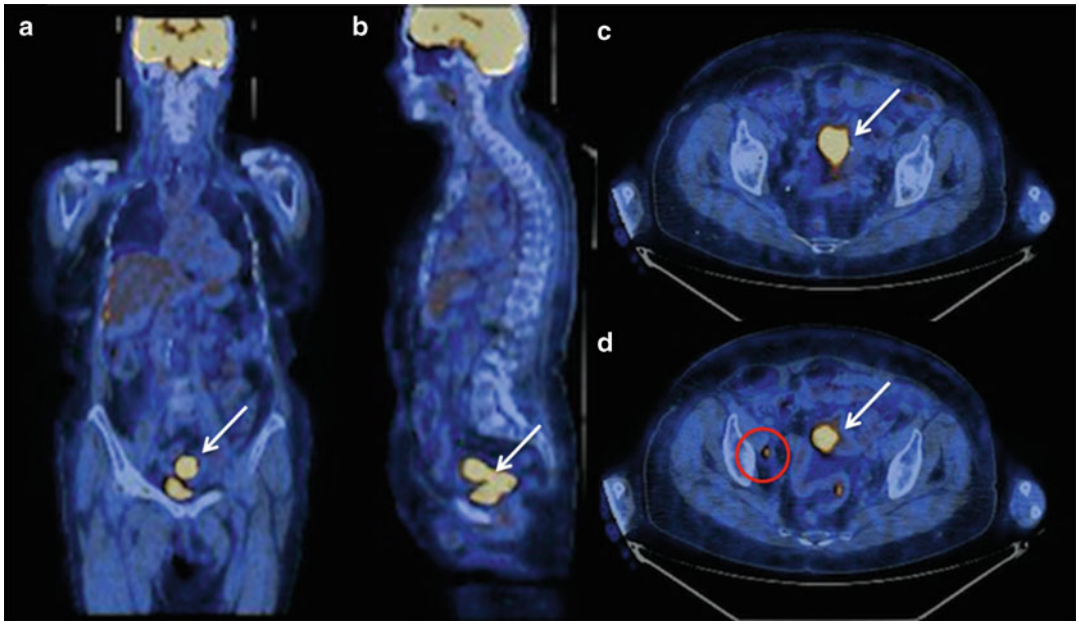

Fig. 12 Fused PET/CT images demonstrate increased uptake in the entire uterus consistent with hypermetabolic malignancy (*white arrow*). In addition focal [^{18}F]FDG-avid pelvic lymph node is seen (*red circle*)

The patient underwent hysterectomy and bilateral salpingo-oophorectomy, multiple peritoneal and lymph node biopsies, and peritoneal washing. Histology obtained after surgery confirmed the [^{18}F]FDG-PET findings.

Discussion

This case confirms the value of [^{18}F]FDG-PET/CT for detecting lymph node involvement and distant metastases (Fig. 13).

Uterine Cancers: Case No. 7

Presentation

A 69-year-old woman previously treated for stage II endometrial cancer referred for suspected vaginal cuff recurrence.

Findings

[^{18}F]FDG PET/CT images demonstrated intense [^{18}F]FDG uptake in the vagina cuff consistent with recurrent disease (Fig. 14). Also prominent [^{18}F]FDG-avid area in the retroperitoneal left para-aortic region consistent with lymph node metastases (Figs. 14 and 15). The patient was treated with chemotherapy.

Discussion

[^{18}F]FDG PET/CT is a highly sensitive (72–95%) and specific (91–96%) modality for detecting recurrence in post-therapy patients with endometrial cancer and identifying locoregional and metastatic disease.

Uterine Cancers: Case No. 8

Institute of Nuclear Medicine, UCLH NHS Foundation Trust, London, UK

Presentation

A 72-year-old woman presented with vaginal bleeding. She had a past medical history of FIGO stage I endometrial cancer (serous papillary) which was treated with hysterectomy, oophorectomy, and omentectomy. An [^{18}F]FDG PET/CT was performed as part of the surgical workup to assess the extent of recurrent and metastatic disease.

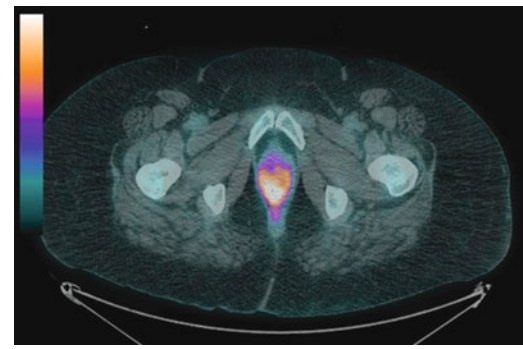

Fig. 16 Axial fused [^{18}F]FDG PET/CT showing intense uptake in the vaginal vault consistent with recurrence

Findings

[^{18}F]FDG PET/CT showed an avid mass within the vaginal vault (SUV_{max} 11.0) with no local or distant disease, in keeping with recurrent tumor (Fig. 16); biopsy revealed carcinosarcoma. The patient subsequently underwent upper vaginectomy and resection of vault recurrence.

Fig. 17 Axial contrast CT showing enhancing lesion in the right pelvis (resection bed)

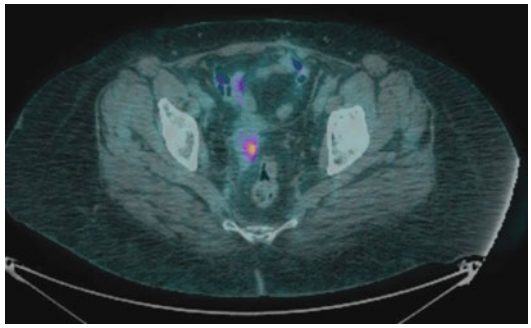

Fig. 18 Axial fused [^{18}F]FDG PET/CT showing heterogeneous [^{18}F]FDG-avid uptake in the resection bed lesion

Follow-Up

Thirteen months following chemotherapy and radiotherapy, the patient developed abnormal liver function tests. Contrast CT and [^{18}F]FDG PET/CT were repeated to assess for liver metastases and restage the disease. Contrast CT shows an enhancing lesion in the right pelvis (Fig. 17).

[^{18}F]FDG PET/CT shows this lesion to be heterogeneously [^{18}F]FDG avid (SUV_{max} 6.7) (Fig. 18) with associated hydronephrosis and hydroureter (Figs. 19 and 20). There is no [^{18}F]FDG activity in the dilated right pelvicalyceal system, with most of the tracer remaining in the renal parenchyma, compatible with acute obstruction. There was no other [^{18}F]FDG-avid disease or liver metastases.

Fig. 19 Coronal [^{18}F]FDG PET/CT showing right hydronephrosis and ureter secondary to pelvic recurrence

Fig. 20 Coronal [^{18}F]FDG MIP showing right hydronephrosis and ureter secondary to pelvic recurrence

[^{18}F]FDG PET/CT has an important role in evaluating recurrence postoperatively in endometrial cancer patients, with the extent of lymph node involvement affecting treatment options.

[3]Section of Medical Physics, «Maggiore della Carità» University Hospital, Novara, Italy

Presentation

A 65-year-old woman with squamous cell cervical cancer presents with vaginal bleeding.

Findings

For cervical cancer, staging is largely performed by clinical evaluation, which revealed a tumor with left parametrial invasion stage IIB according to the International Federation of Gynecology and Obstetrics (FIGO) surgical staging system.

Pelvic CT confirmed a cervical lesion (5.5 cm) and enlarged pelvic lymph nodes (Fig. 21). MRI was not performed because the patient was claustrophobic.

After a multidisciplinary meeting with the surgeon, radiation oncologist, medical oncologist, and radiologist, a combination of radiation and chemotherapy was recommended.

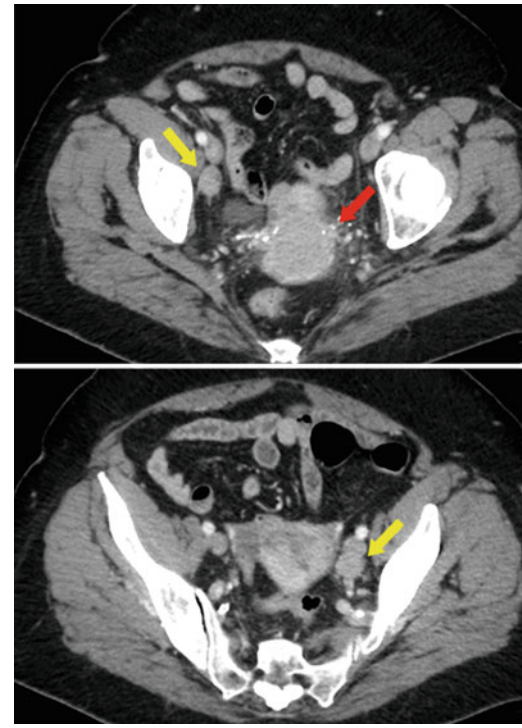

Fig. 21 Pelvic CT in axial view demonstrating the primary tumor (*red arrow*) and bilateral enlarged lymph nodes (*yellow arrows*)

Discussion

[^{18}F]FDG PET/CT was performed in radiation treatment planning position to better define target volumes and evaluate the presence and extension of disease (Fig. 22). PET/CT in cervical cancer is useful for defining lymph node volume for RT coverage. In particular, [^{18}F]FDG PET/CT uptake demonstrates metabolically active lesions not only in the uterus but also in para-aortic and intercavo-aortic lymph nodes (Fig. 23).

Given diffusion of the disease beyond the pelvis, we considered as CTV not only the cervix, uterus, parametria, vagina, and regional lymph

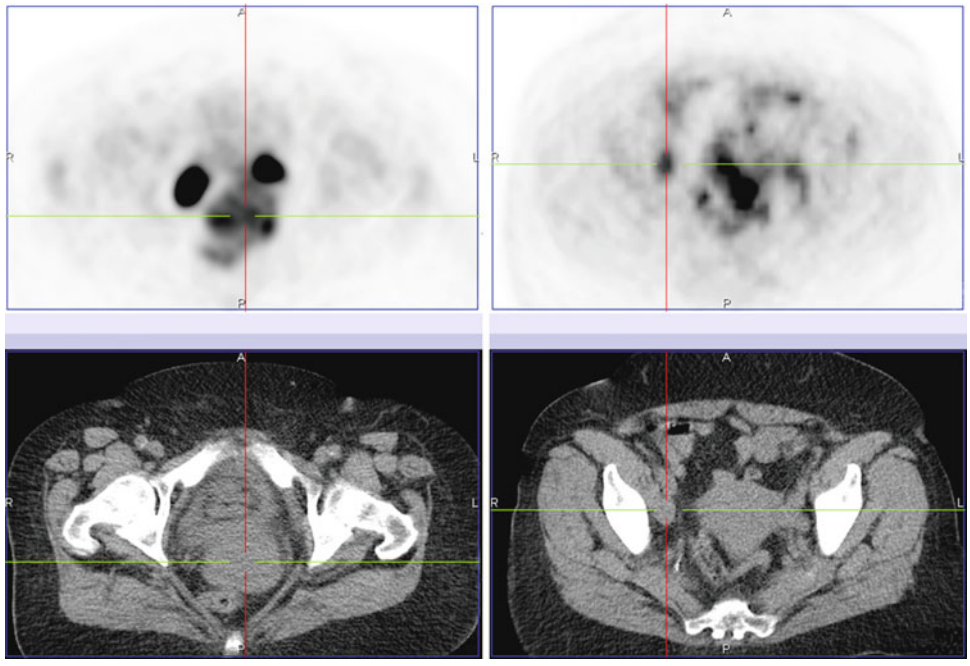

Fig. 22 [^{18}F]FDG PET/CT images (axial sections) showing high tracer uptake in the primary tumor (*left panel*) and in metastatic pelvic lymph nodes (*right panel*)

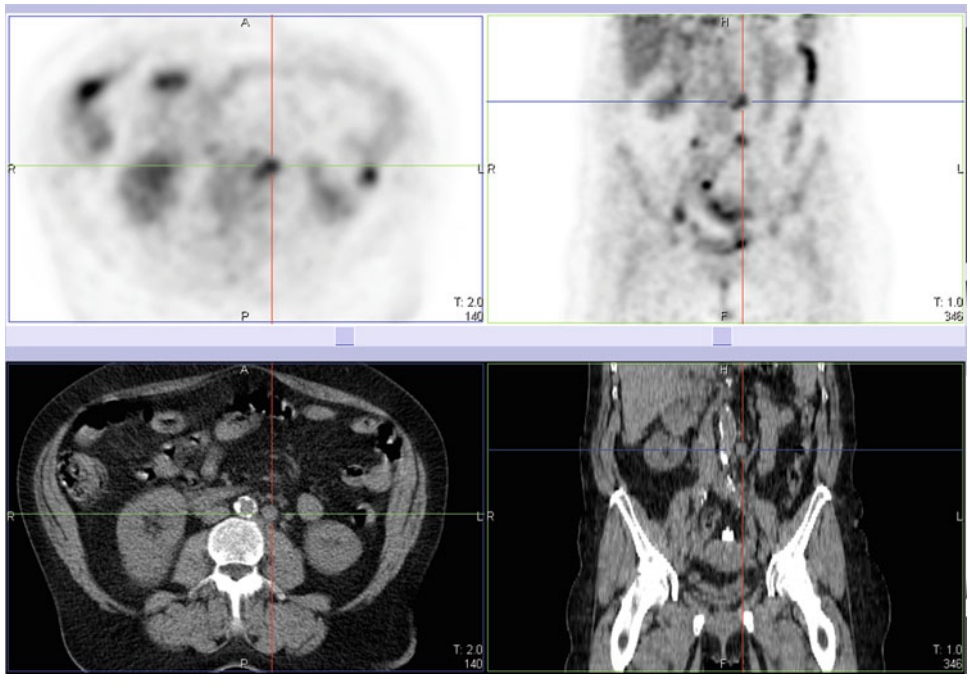

Fig. 23 [^{18}F]FDG PET/CT images (axial and coronal sections) showing high tracer uptake in the lombo-aortic pelvic lymph nodes

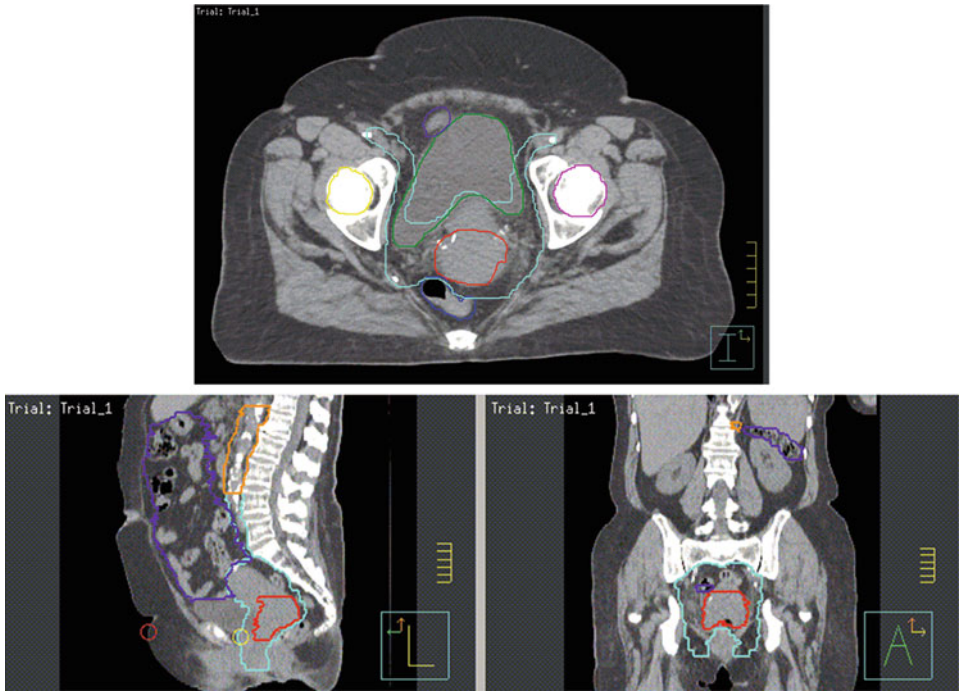

Fig. 24 Transaxial, sagittal, and coronal view of the simulation CT. Different colors are used to highlight the contours of the treatment volumes. *Red line*: gross tumor volume (*GTV*) represented by cervical cancer plus parametrial and vaginal extension; light-*blue line*: pelvic CTV represented by the uterus, parametria, vagina, and regional and para-aortic lymph nodes; *orange line*: intercavo-aortic lymph nodes CTV. *Purple line* delineates the peritoneal cavity defined as one of the organs at risk

nodes but also the para-aortic lymph nodes (Figs. 24 and 25).

A volumetric-modulated radiotherapy-simultaneous-integrated boost (VMAT-SIB) treatment plan was performed to a total dose of 50 Gy with daily fraction of 2 Gy to the macroscopic disease and to a dose of 45.0 Gy with daily fraction of 1.8 Gy to the potentially microscopically invaded regions and locoregional lymph nodes. After the external beam RT, the treatment was completed by a brachytherapy boost to the cervix and parametria (Fig. 26).

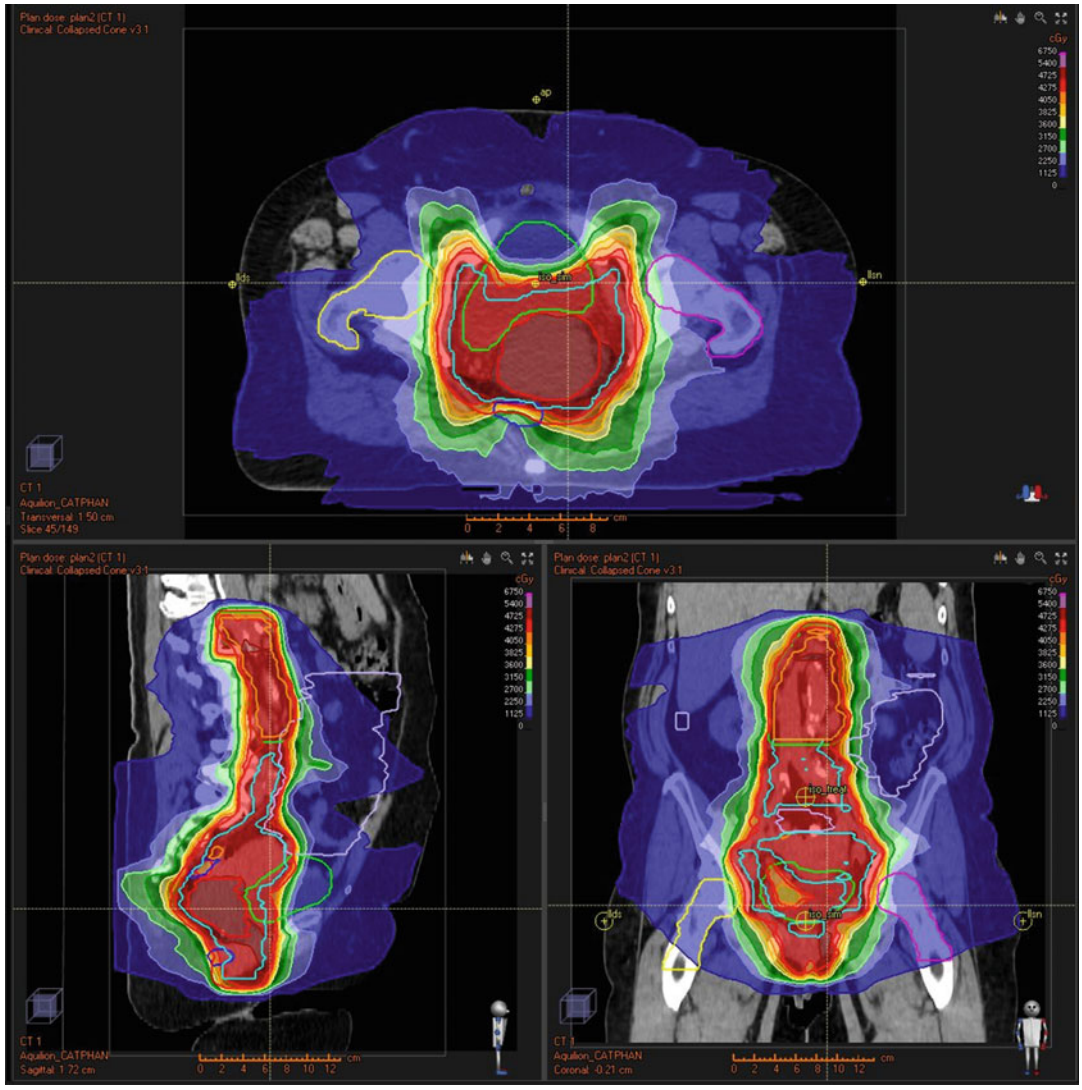

Fig. 25 Transaxial, coronal, and sagittal view of the RT treatment planning. Images show the high conformation of dose distribution performed by VMAT-SIB treatment plan. Around the target volumes, the doses fall down sharply, thus reducing the dose to the organs at risk. In red the 95% isodose of the prescribed dose of 45 Gy

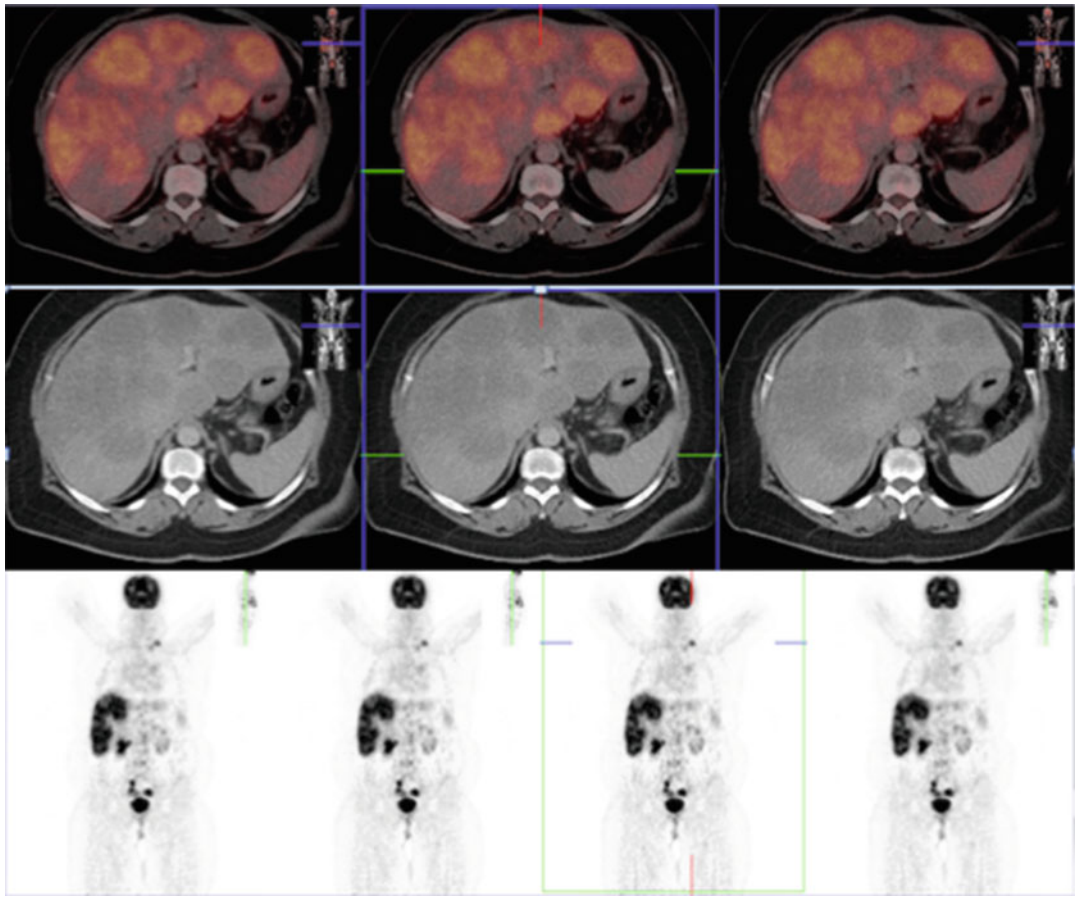

Fig. 26 Fusion images demonstrating liver metastases. CT images demonstrating the liver metastases. [^{18}F]FDG PET images demonstrating supraclavicular node and para-aortic nodes

Ovarian Cancer: Case No. 1

A 66-year-old woman presented with lower abdominal discomfort and elevated serum CA125 (260 U/mL). The presence of large right pelvic mass suspicious for ovarian malignancy was diagnosed with pelvic ultrasound.

Findings

[^{18}F]FDG PET/CT was performed as a part of initial staging to evaluate the extent of disease.

PET/CT image demonstrated metabolically active pelvic right mass corresponding to suspected ovarian lesion; also a prominent [^{18}F]FDG-avid

A. Lorenzoni (✉) • A. Alessi • F. Crippa

area was shown in the mass-like omental cake consistent with extensive omental involvement (Fig. 1). In addition, pathologic multiple [^{18}F]FDG-avid peritoneal implants were demonstrated in the abdomen and pelvis (Figs. 2 and 4).

[^{18}F]FDG PET/CT images showed two focal areas of radiotracer uptake, in the subglissonian region of hepatic segments VIII and VII consistent with liver involvement (Figs. 3 and 4).

The patient was treated with debulking surgery, hysterectomy and bilateral salpingo-oophorectomy, omentectomy, diaphragmatic peritonectomy, and sigma resection.

The histology obtained after surgery confirmed high-grade ovarian serous carcinoma stage IV FIGO.

Following surgery, the patient was treated with platinum-based chemotherapy.

Discussion

This case confirms the important contribution of [^{18}F]FDG PET/CT in abdominal and extra-abdominal stage of advanced ovarian cancer.

PET/CT pretherapy imaging may change patient management or help direct surgical planning, thus aiding optimized cytoreduction.

Ovarian Cancer: Case No. 2

Presentation

A 53-year-old postmenopausal woman presented with pelvic discomfort. Ultrasound revealed a 6 cm complex right adnexal mass. The CA125 level was 123 U/mL.

[^{18}F]FDG PET/CT was performed in order to characterize the ovarian mass before the scheduled surgery.

Findings

Fused PET/CT images (Fig. 5) showed a large right pelvic mass with a large photopenic area indicative of either cystic, necrotic, or mucinous components. The mass did not demonstrate increased [^{18}F]FDG uptake. Laparotomy revealed clear cell carcinoma of the right ovary. Postoperatively the patient received six cycles of carboplatin- and paclitaxel-based chemotherapy.

Discussion

Clear cell carcinomas of the ovary are extremely rare, accounting for less than 5% of cases. These

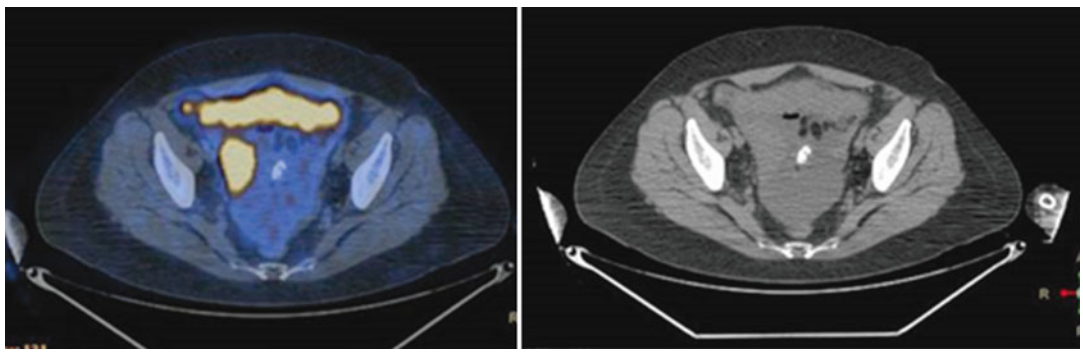

Fig. 1 Metabolically active pelvic right mass corresponding to suspected ovarian lesion (**a**); a prominent [^{18}F]FDG-avid area was shown in the mass-like omental cake consistent with extensive omental involvement

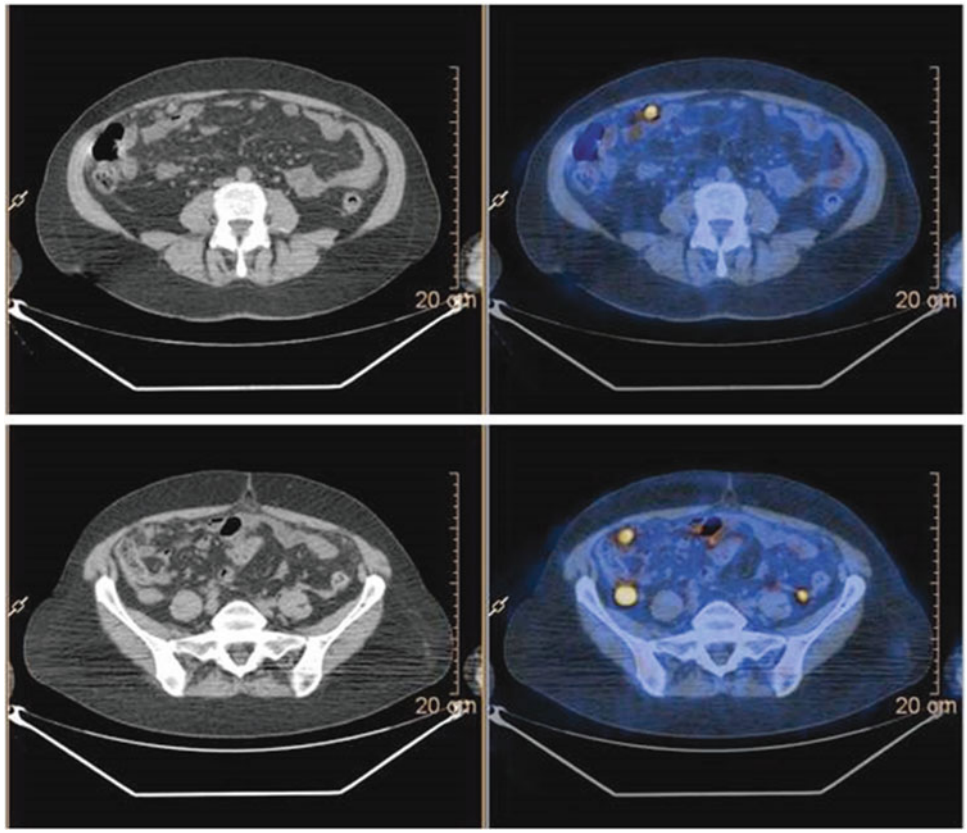

Fig. 2 Low-dose CT (*left*) and fused PET/CT (*right*) axial images show multiple [^{18}F]FDG-avid peritoneal nodules

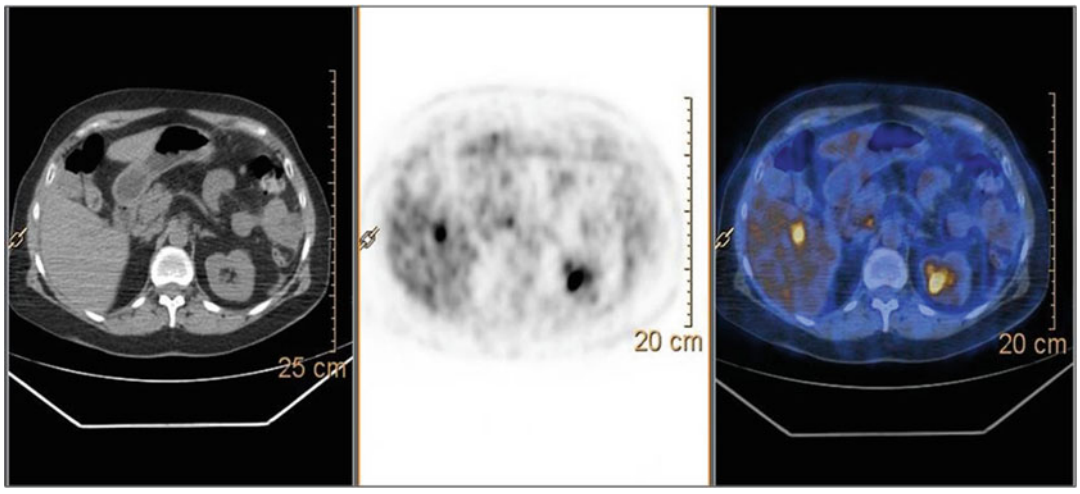

Fig. 3 [^{18}F]FDG focal uptake in VII hepatic segment consistent with metastatic liver disease

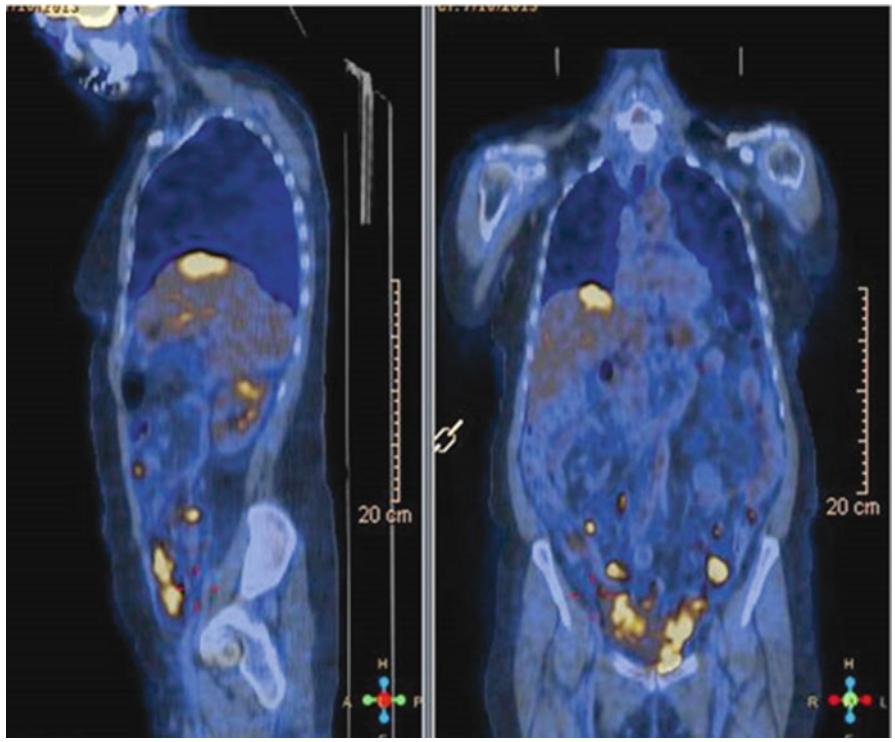

Fig. 4 Sagittal and coronal fused PET/CT images demonstrate liver metastases and multiple [^{18}F]FDG-avid peritonal implants

tumors have a very poor prognosis in terms of survival and response to chemotherapy.

[^{18}F]FDG PET/CT sensitivity and specificity to discriminate between benign and malignant tumors ranges from 70% to 100% and 77% to 100%, respectively. Ovarian carcinoma includes a variety of histological subtypes with different biological characteristics; in particular clear cell and mucinous carcinomas show a variable [^{18}F]FDG uptake. [^{18}F]FDG PET/CT does not appear to have a well defined role in the characterization of epithelial ovarian cancer and its use remains controversial. Conversely [^{18}F]FDG PET/CT may identify nodal involvement and distant metastases.

Ovarian Cancer: Case No. 3

Presentation

A 58-year-old woman presented with large pelvic mass suspicious for ovarian malignancy. [^{18}F]FDG PET/CT was performed as a part of initial staging.

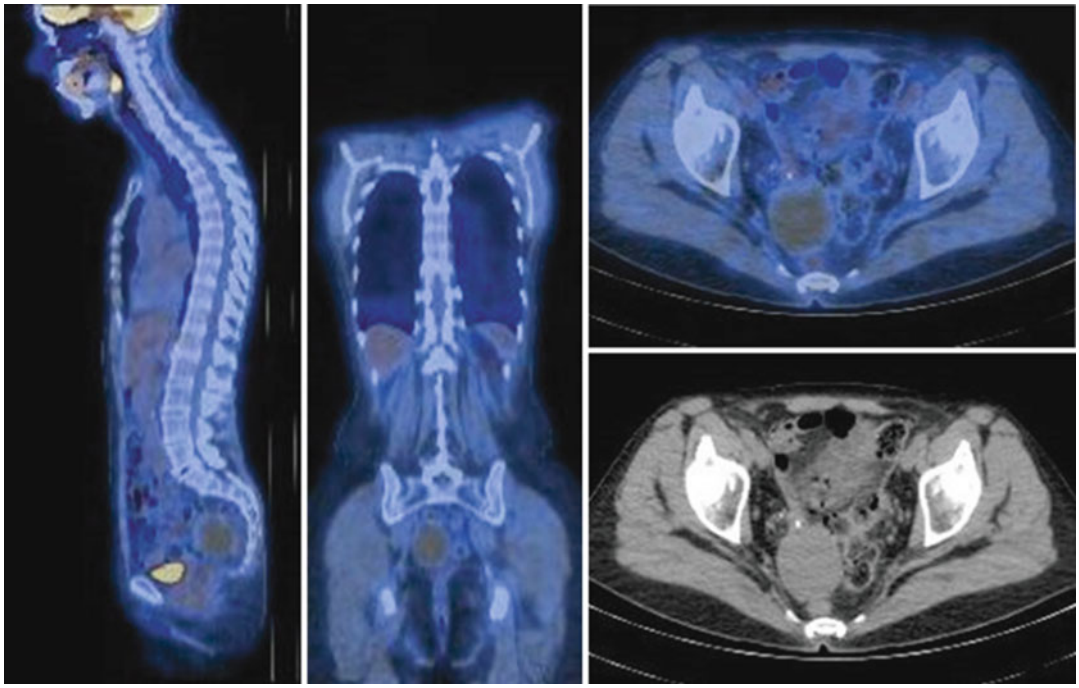

Fig. 5 Coronal (*left*), sagittal (*middle*), axial (*upper right*) fused [^{18}F]FDG PET/CT and axial low-dose CT (*lower right*) image showed pelvic ovarian mass characterized by large photopenic area

Findings

PET/CT demonstrated a large pelvic mass with heterogeneous [^{18}F]FDG uptake corresponding to the ovarian lesion. In the left common iliac region, a prominent [^{18}F]FDG-avid area was shown consistent with lymphadenopathy (Fig. 6). In addition, in the left pericolic gutter a small [^{18}F]FDG-avid nodule was noted suspicious for peritoneal implant.

The patient underwent primary debulking surgery. Histopathology showed serous epithelial ovarian cancer at the sites identified by PET/CT. No other area of tumor spread was identified. The results of PET/CT were concordant with the final pathological staging.

Discussion

[^{18}F]FDG PET/CT is an accurate imaging modality for staging ovarian cancer. Furthermore preoperative intratumoral [^{18}F]FDG uptake heterogeneity in patients with epithelial ovarian cancer has been shown to be significantly associated with recurrence.

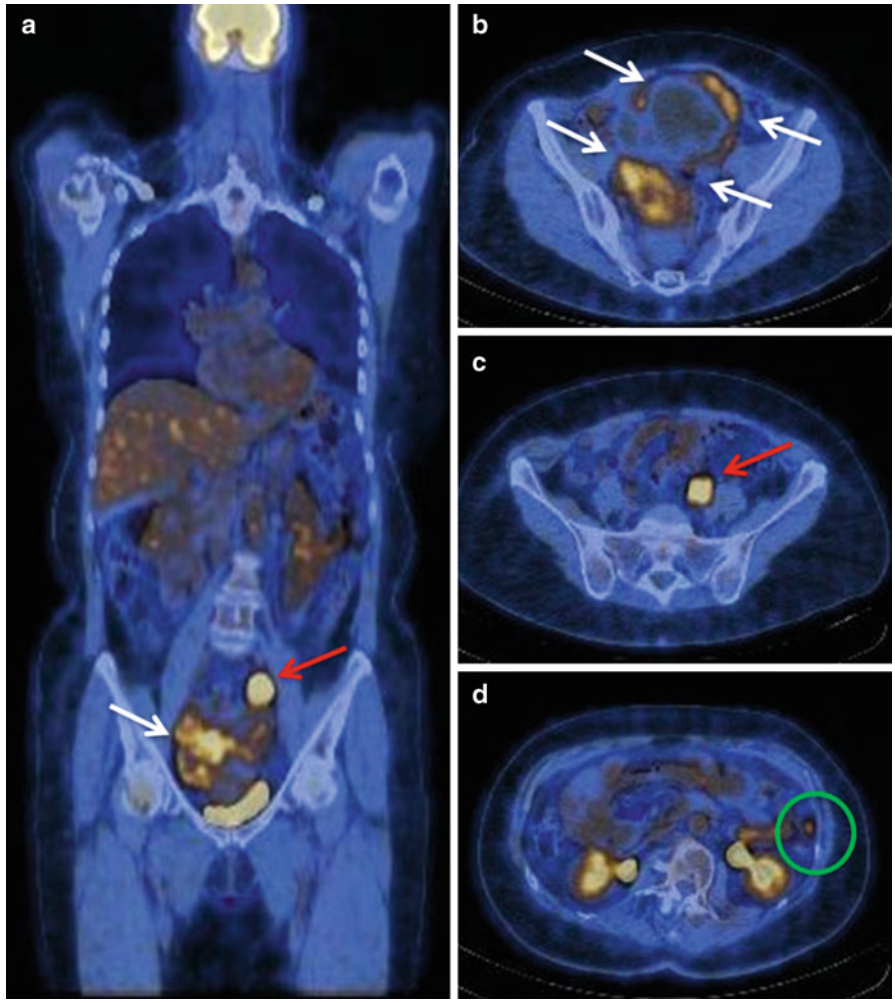

Fig. 6 Fused PET/CT images show large pelvic mass with heterogeneous [^{18}F]FDG uptake corresponding to the ovarian lesion (**a** coronal image, **b** axial image, *white arrows*). Hypermetabolic adenopathy is depicted in the left iliac common region (**a** coronal image, **c** axial image, *red arrow*). Small [^{18}F]FDG-avid nodule consistent with peritoneal implant is seen in the left parietocolic gutter (**d** axial image, *green circle*)

Ovarian Cancer: Case No. 4

Presentation

A 64-year-old woman with a history of surgery for epithelial ovarian cancer presented with rising serum CA125 level (186 U/mL). Abdominal contrast-enhanced CT was negative for the presence of recurrence. The patient underwent [^{18}F]FDG PET/CT to identify suspected ovarian cancer recurrence.

Findings

[^{18}F]FDG PET/CT identified two foci of [^{18}F]FDG uptake, one in the right internal iliac region and the second in the presacral region suspicious for pelvic recurrence of ovarian cancer (Fig. 7).

Discussion

PET/CT is an important diagnostic tool to detect recurrence in the setting of a rising CA125 and

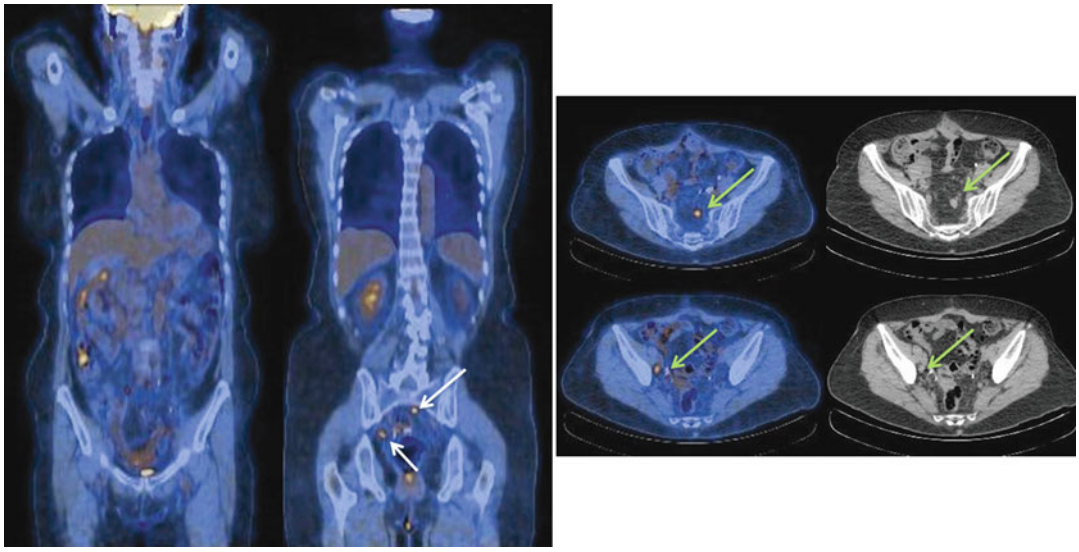

Fig. 7 Coronal fused [^{18}F]FDG PET/CT images (*left panel*) and axial images (*right panel*) show pelvic recurrence of ovarian cancer (*white* and *green arrows*)

negative conventional imaging studies in patients with epithelial ovarian cancer, detecting tumor relapse in a higher percentage than CT. In addition, [^{18}F]FDG PET/CT may be useful in patients where recurrence is suspected, even when the tumor marker CA125 is in the normal range.

Sarcomas: Case No. 1

Presentation

A 34-year-old man presented with a 4-week history of sudden-onset, nontender mass in the left leg.

Anatomic imaging was concerning for a large soft tissue sarcoma (7 cm in size). Percutaneous biopsy confirmed high-grade sarcoma with myogenic differentiation.

Neoadjuvant chemotherapy followed by radical surgery and radiotherapy was performed.

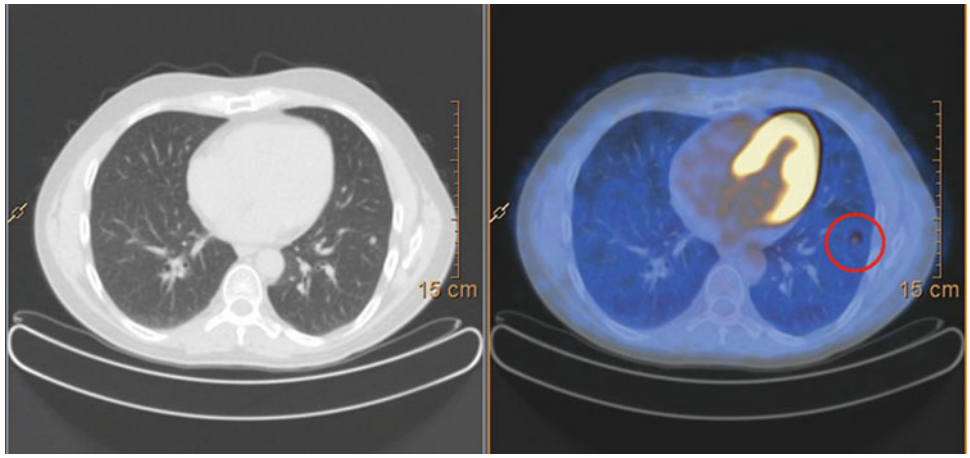

Fig. 1 [^{18}F]FDG PET/CT transaxial images demonstrated mild focal uptake (*red circle*) corresponding to suspected small nodule in the left lung

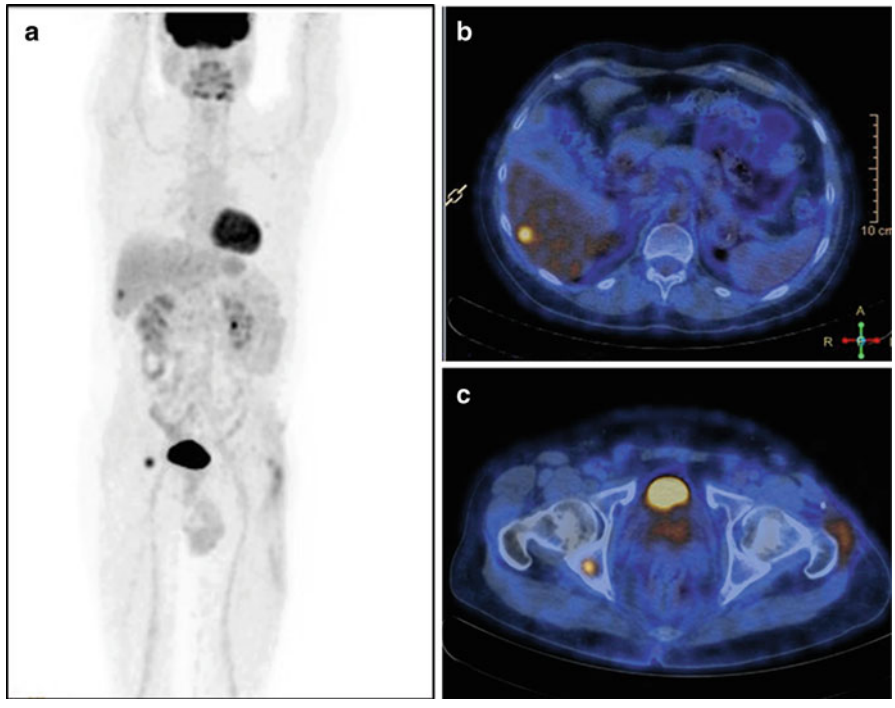

Fig. 2 Maximum intensity projection (*MIP*) (**a**) and axial fused PET/CT (**b**, **c**) images show hypermetabolic hepatic nodule and right acetabular hypermetabolic lesion. Mild uptake of [^{18}F]FDG is demonstrated in soft tissue of the left trochanteric region consistent with inflammation (unrelated to tumor)

Fig. 3 [^{18}F]FDG-PET sagittal and coronal fused PET/CT (*left*) images clearly depict skeletal lesions (*white arrows*); MRI of the spine and pelvis confirms the pathological findings (*red arrows*)

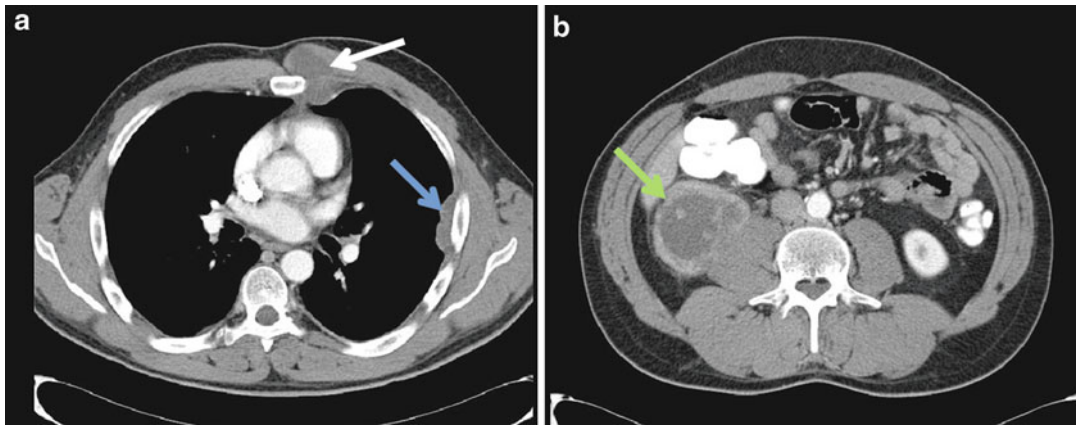

Fig. 4 Contrast-enhanced CT of suspected metastatic myxoid liposarcoma in chest wall (**a**, *white arrow*), pleura (**a**, *blue arrow*), and retroperitoneum (**b**, *green arrow*)

Post-therapy CT of the thorax showed the appearance of small nodule in the left lung suspicious for metastatic disease.

The patient was a candidate for left lung resection.

Findings

[^{18}F]FDG PET/CT was performed as a part of completion staging prior thoracic surgery.

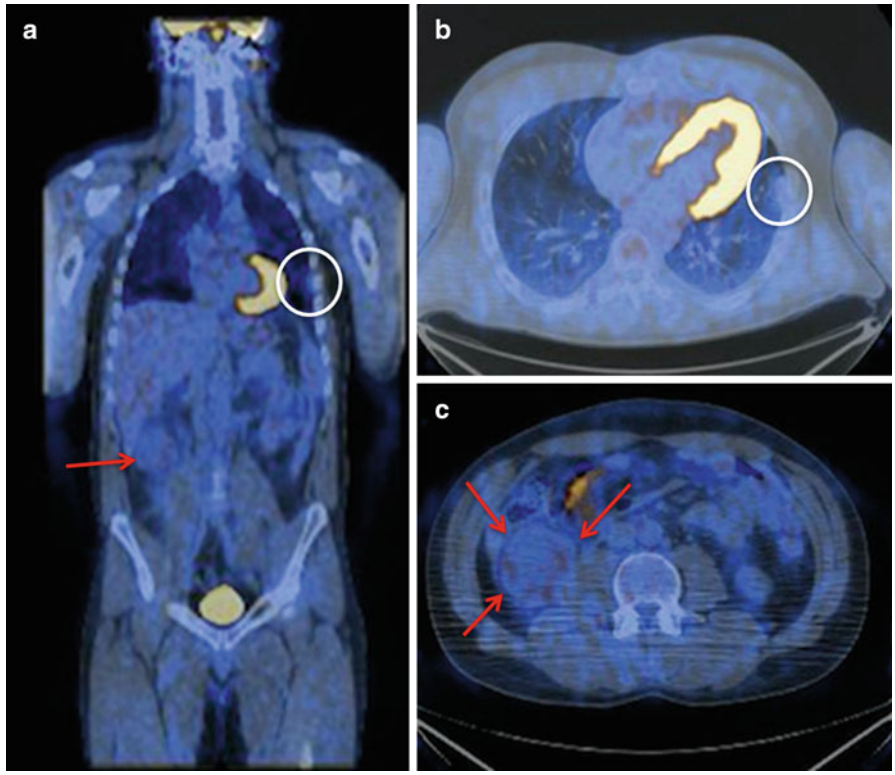

Fig. 5 Fused PET/CT images of metastatic myxoid liposarcoma mass without significant [^{18}F]FDG uptake of the pleura (**a** coronal and **b** axial images, *white circle*) and retroperitoneum (**a** coronal and **c** axial images, *red arrows*)

PET/CT demonstrated mild focal [^{18}F]FDG uptake in the left lung corresponding to suspected nodule (Fig. 1). An [^{18}F]FDG-avid hepatic lesion was also demonstrated in segments V–VI of the right lobe (Fig. 2).

[^{18}F]FDG also revealed the presence of skeletal focal [^{18}F]FDG uptake consistent with bone metastases in the right acetabulum and in the dorsal spine (Fig. 3). MRI confirms PET skeletal findings.

Discussion

[^{18}F]FDG-PET has been increasingly used in bone and soft tissue sarcomas and provides advantages in the initial tumor staging, tumor grading, therapy assessment, and recurrence detection.

Accurate detection of metastatic lesions is thus important for accurate staging and selection of appropriate therapy.

This case demonstrates the diagnostic benefit of [^{18}F]FDG-PET in sarcoma staging to guide optimal therapeutic strategy.

Sarcomas: Case No. 2

Presentation

A 42-year-old man with past history of myxoid liposarcoma in the left thigh presented with painful swelling in the right flank of 3-month duration. Intravenous and oral contrast-enhanced CT of the thorax and abdomen showed a large inhomogeneous mass of low density in the right retroperitoneal region laterally to the right psoas muscle consistent with soft tissue sarcoma localization. In addition metastatic mass was noted in the chest wall and pleura (Fig. 4).

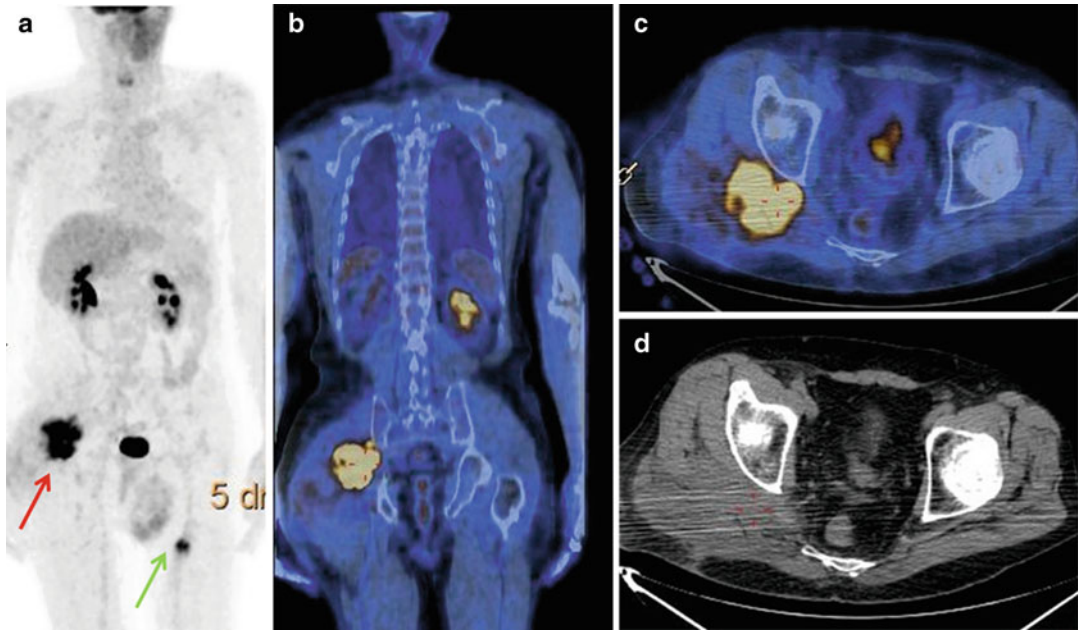

Fig. 6 Maximum intensity projection (*MIP*) image (**a**), fused PET/CT (**b** coronal, **c** axial), and axial low-dose CT images of hypermetabolic mass in the right gluteal region (*red arrow*). MIP image demonstrates also focal [^{18}F]FDG uptake in the left thigh consistent with malignancy (*green arrow*)

[^{18}F]FDG PET/CT was performed to complete the evaluation.

Findings

[^{18}F]FDG PET/CT did not show significant [^{18}F]FDG activity of metastatic myxoid liposarcoma mass in the chest wall, pleura, and retroperitoneum (Fig. 5).

Sarcomas: Case No. 3

Presentation

A 57-year-old man with soft tissue sarcoma in the right gluteal region was referred for [^{18}F]FDG PET/CT staging.

Findings

PET/CT demonstrated a large mass with intense heterogeneous [^{18}F]FDG uptake in the right gluteal muscles corresponding to known soft tissue sarcoma (Fig. 6).

PET/CT also revealed the presence of unknown hypermetabolic lesion in the anterior compartment of the left thigh (Figs. 6 and 7).

Discussion

The detection of additional multifocal sarcoma lesions is important during the initial diagnosis to plan subsequent treatment. This case demonstrates the utility of [^{18}F]FDG PET/CT in the initial staging of soft tissue sarcoma.

Sarcomas: Case No. 4

Presentation

A 21-year-old man presented with a painless mass in the right forearm. MRI showed a large lesion, approximately 14 cm in diameter, in the flexor digitorum profundus muscle. The biopsy revealed

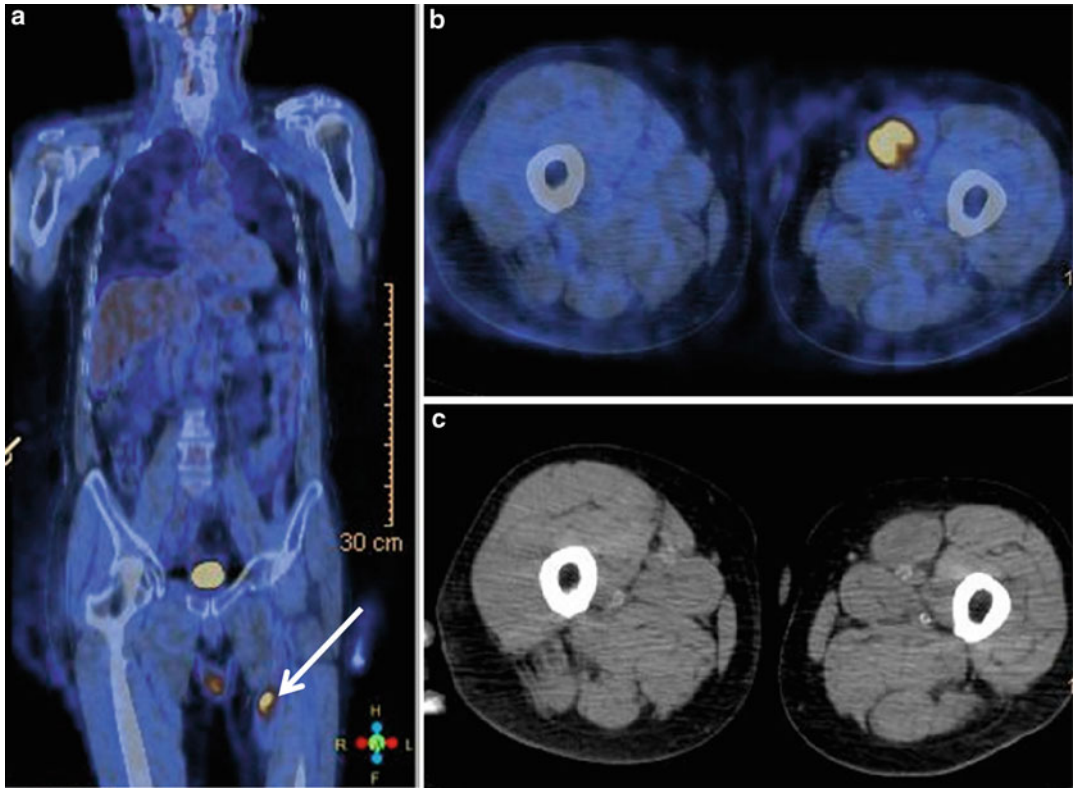

Fig. 7 Fused [^{18}F]FDG PET/CT images (**a** coronal, **b** axial) and axial low-dose CT (**c**) of the unknown hypermatabolic lesion in the left thigh (*white arrow*)

alveolar rhabdomyosarcoma. Contrast-enhanced CT of the thorax and abdomen did not show metastatic disease.

Findings

[^{18}F]FDG PET/CT was performed as a part of initial staging.

[^{18}F]FDG-PET confirmed the presence of large hypermetabolic mass in the right forearm. Focal [^{18}F]FDG-avid lesions were also detected in the soft tissue of the right arm (Fig. 8). In addition pathological [^{18}F]FDG-avid lymph nodes were noted in the ipsilateral axilla and in the supraclavicular fossa (Figs. 8 and 9).

The patient was treated with chemotherapy and subsequent surgery.

Discussion

Rhabdomyosarcomas represent more than 50% of soft tissue sarcomas occurring in childhood and adolescence. The presence of metastatic disease at the time of diagnosis decreases the chance of survival to 20% approximately. [^{18}F]FDG PET/CT can be useful in staging and restaging pediatric rhabdomyosarcoma, especially for assessing lymph nodes, soft tissue spread, and distant metastases.

Sarcomas: Case No. 5

Case contributed by T. Lengana and M. Sathkege
Nuclear Medicine, University of Pretoria, and Steve Biko Academic Hospital, Pretoria, South Africa

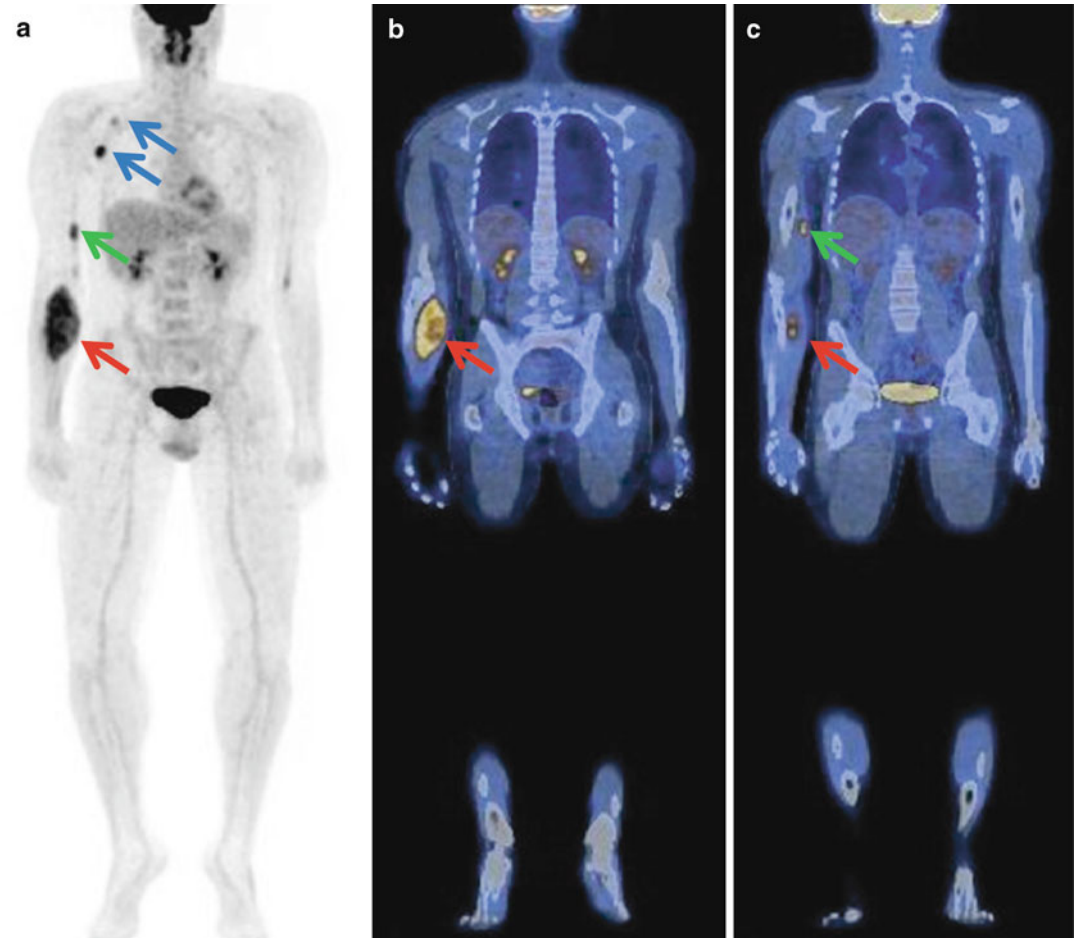

Fig. 8 Maximum intensity projection (*MIP*) image (**a**) in patient with alveolar rhabdomyosarcoma of the right forearm (*red arrow*), soft tissue localization (*green arrow*), and lymph node involvement (*blue arrows*). Coronal fused [^{18}F]FDG PET/CT (**b**, **c**) shows hypermetabolic mass in the right forearm (*red arrow*) and soft tissue spread in the ipsilateral arm (**c**)

Presentation

Twenty-six-year-old male patient presented with rhabdomyosarcoma of the right orbit. Treatment history included enucleation of the right orbit in 2010 and completion of radiotherapy in 2012.

The patient was complaining of history of neck swelling.

Findings

An [^{18}F]FDG PET/CT scan was done for suspected recurrence. [^{18}F]FDG PET/CT images demonstrated a large [^{18}F]FDG-avid mass in the right mandibular angle region measuring 5.2 × 4.3 cm (SUV_{max} 6.94). No other site of hypermetabolic uptake was noted (Figs. 10 and 11).

Patient was treated with radical parotidectomy and lymph node dissection; histology revealed embryonal rhabdomyosarcoma.

Discussion

This case demonstrates that [^{18}F]FDG PET/CT can be useful in the assessment of patients with suspected recurrence of rhabdomyosarcoma.

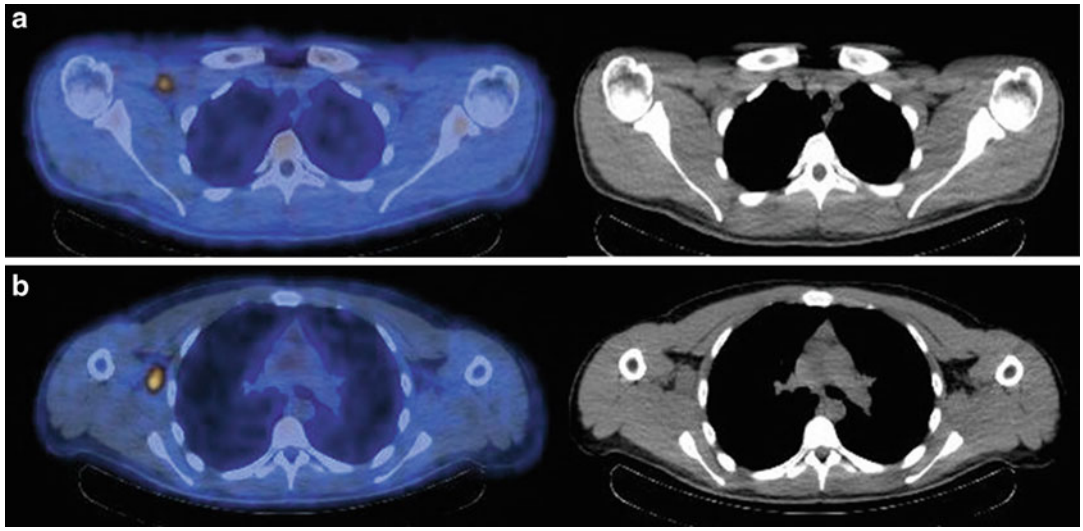

Fig. 9 [^{18}F]FDG PET/CT axial images of the hypermetabolic supraclavicular (a fused PET/CT *left panel*, low-dose CT *right panel*) and axillary (a fused PET/CT *left panel*, low-dose CT *right panel*) lymph node consistent with metastases

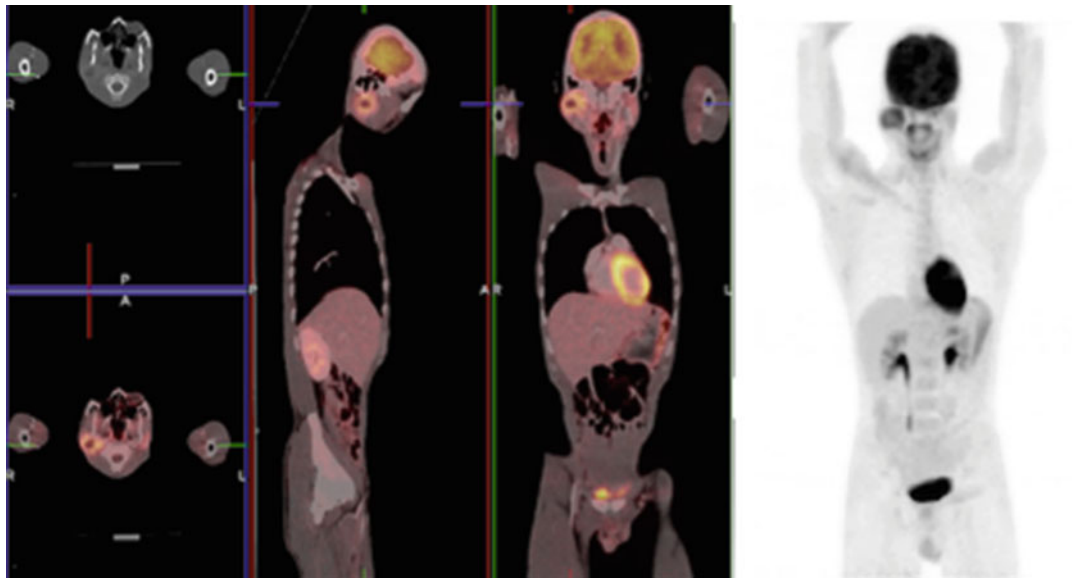

Fig. 10 Maximum intensity projection (MIP) image demonstrating uptake only limited to the parotid region

Case No. 6: Ewing's Sarcoma

Presentation

A 21-year-old woman presented with a large left scapular mass.

Findings

CT-guided biopsy revealed a round blue cell malignant neoplasm suspicious for Ewing's sarcoma. MRI of the shoulder showed a large T1 isointense/T2 hyperintense mass (12 × 11 cm) that extends superiorly encasing the supraspinatus

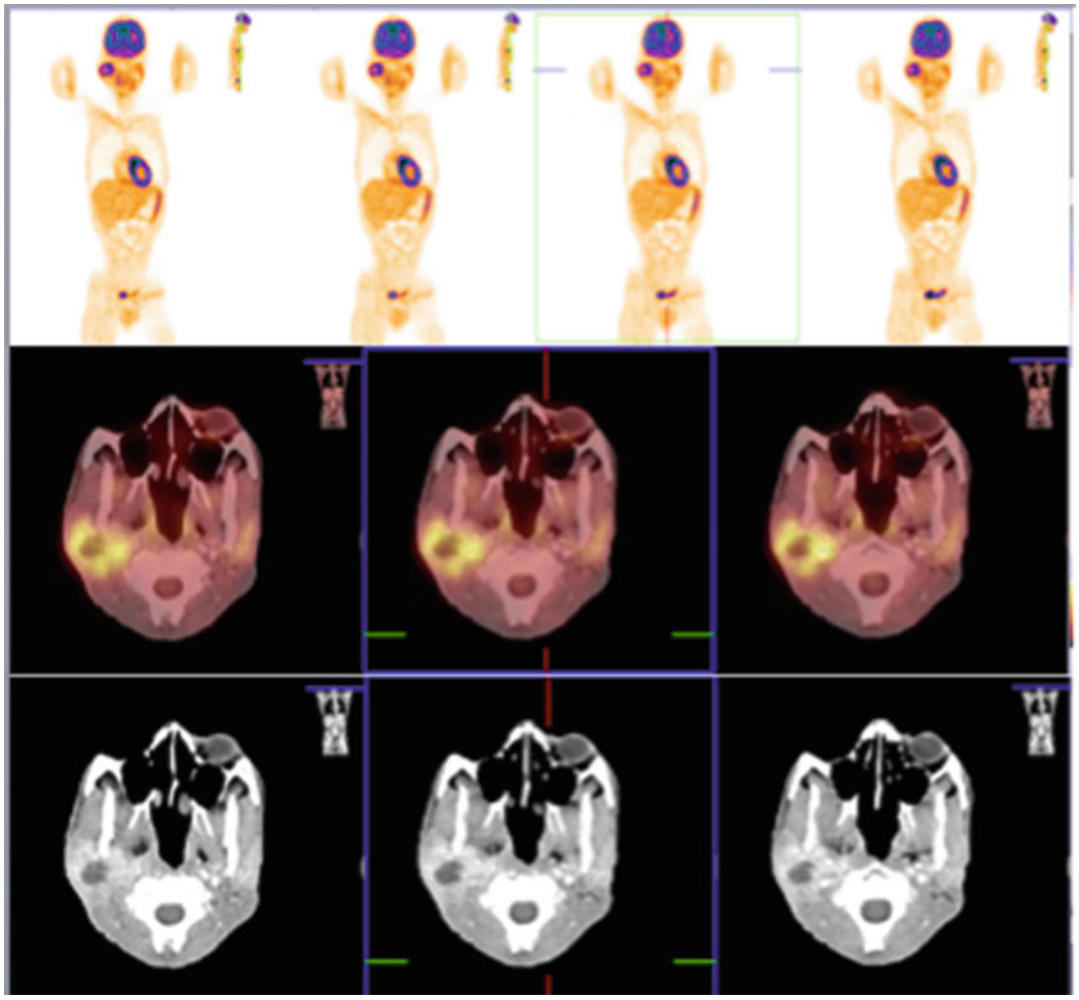

Fig. 11 Fusion coronal images demonstrating parotid mass. Fusion axial and CT images demonstrating parotid mass with necrotic center

muscle (Fig. 12). CT scan demonstrated permeative destructive changes of the scapula and left supraclavicular adenopathy. Bone scintigraphy with ^{99m}Tc-MDP demonstrated slightly increased tracer uptake in the left superior scapula, acromion, coracoid processes, and head of the left humerus (Fig. 13). [^{18}F]FDG PET/CT showed a large [^{18}F]FDG-avid mass invading the left scapula (SUV_{max} 7) (Fig. 14) without evidence of hypermetabolic lymphadenopathy or distant metastases. Increased radiotracer accumulation in the neck bilaterally and supra- and infraclavicular regions (Fig. 15) is due to metabolically active brown fat, a physiologic variant.

Follow-Up

Restaging [^{18}F]FDG PET/CT performed after three cycles of chemotherapy showed decreased [^{18}F]FDG uptake (SUV_{max} 2.1) and reduced extent of the mass, consistent with disease remission (Fig. 16). Subsequently, the patient was treated with total left scapulectomy. Histological examination demonstrated negative margins of resection, absent lymph node involvement, and a residual mass with 70% necrosis. The prior chemotherapy protocol was completed. Further follow-up imaging evaluations ([^{18}F]FDG PET/CT and CT) did not show active disease.

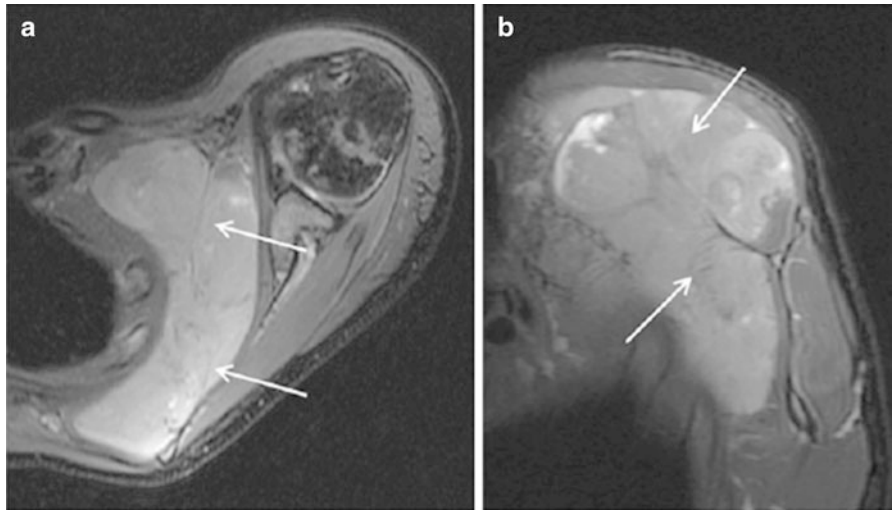

Fig. 12 MRI of the left shoulder: T2 hyperintense large mass, (**a**) axial view, (**b**) sagittal view

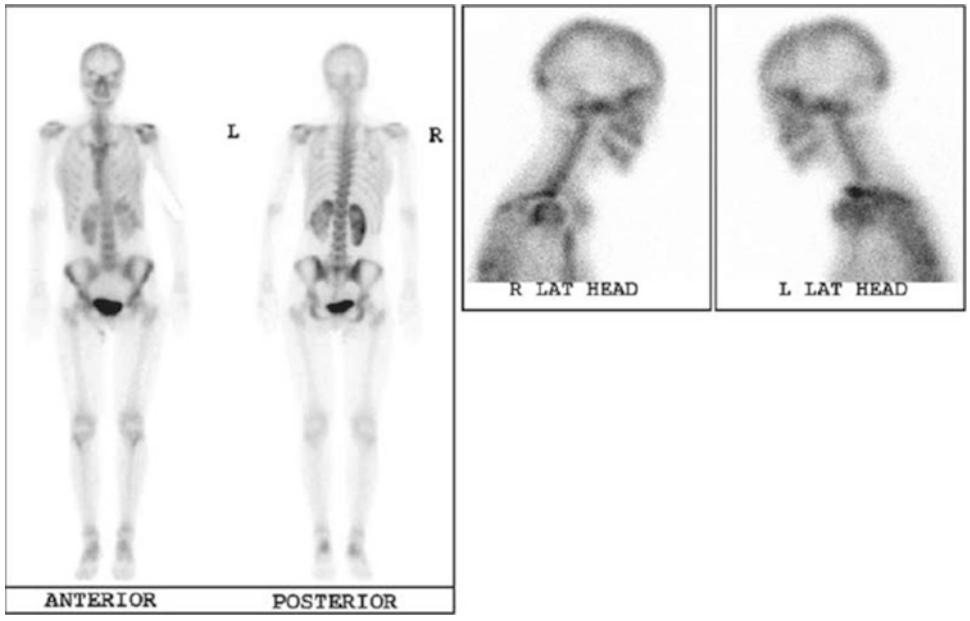

Fig. 13 Bone scintigraphy with ^{99m}Tc-MDP shows mildly increased tracer accumulation in the left scapula and proximal humerus

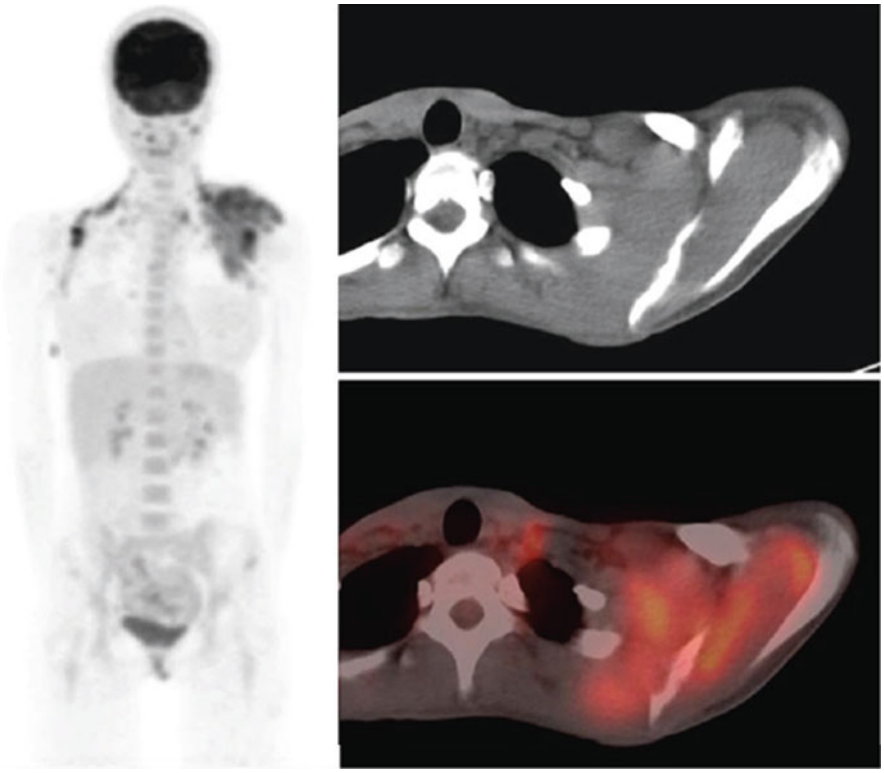

Fig. 14 [^{18}F]FDG PET/CT MIP and axial images show a large [^{18}F]FDG-avid soft tissue mass that involves the left supraclavicular, supra- and subscapular regions, and subpectoral region invading the left upper scapula

Discussion

This case demonstrates the advantage of [^{18}F] FDG PET/CT over conventional bone scan for the evaluation of both the primary lesion and the ability to detect metastases in Ewing's sarcoma.

Case No. 7: Metastatic Osteosarcoma

Presentation

A 45-year-old man with recurrent osteogenic sarcoma of the right fibula previously treated with surgical resection presents with right calf discomfort.

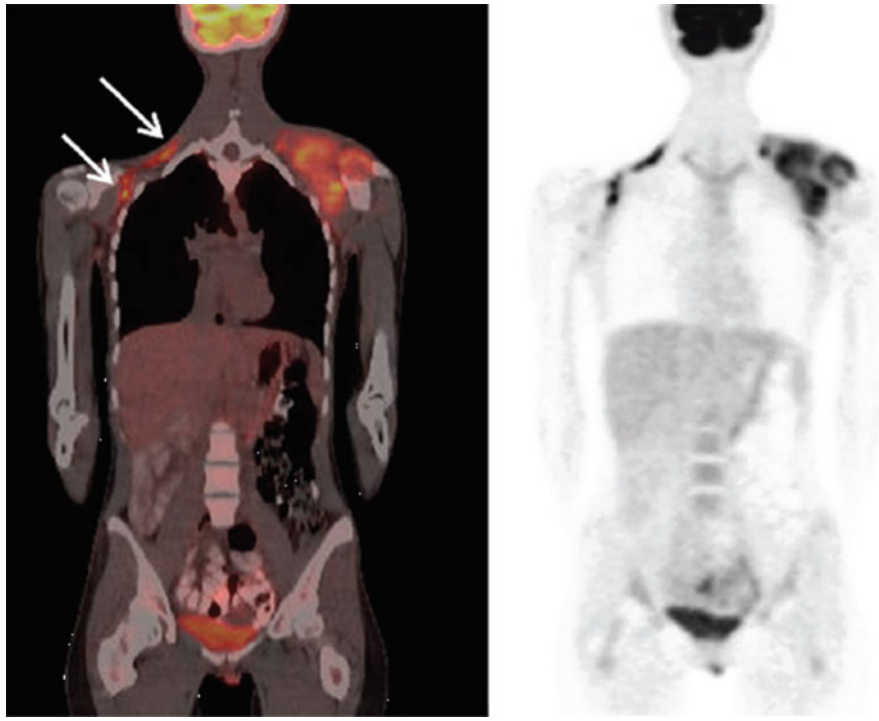

Fig. 15 [^{18}F]FDG PET/CT coronal images show multiple foci of [^{18}F]FDG uptake in the neck bilaterally and supra-infraclavicular regions (*white arrows*) corresponding to metabolic activation of the brown fat

Findings

MRI demonstrated a suspicious mass adjacent to the proximal resection margin of the fibula in the region of the peroneus longus and brevis muscles. [^{18}F]FDG PET/CT was performed for restaging.

[^{18}F]FDG PET/CT images show hypermetabolic nodules in the muscles of the proximal and midportion of the right calf, some of them calcified, with diffuse [^{18}F]FDG uptake in the post-surgical bed (Fig. 17). A calcified mass with mild [^{18}F]FDG uptake is noted in the left atrium (Fig. 18) compatible with metastatic disease. Several partially calcified nodules are also identified in the anterolateral region of the left gluteus medius muscle, of the right adductor muscle, and in the right lower neck posteriorly (Fig. 19).

Follow-Up

Follow-up [^{18}F]FDG PET/CT at 4 months after chemotherapy demonstrated no [^{18}F]FDG uptake in the left atrial mass and a mild reduction of activity in previous detected lesions.

This case demonstrates the value of [^{18}F]FDG PET/CT to assess the metabolic response to treatment in calcified metastatic lesions from osteosarcoma.

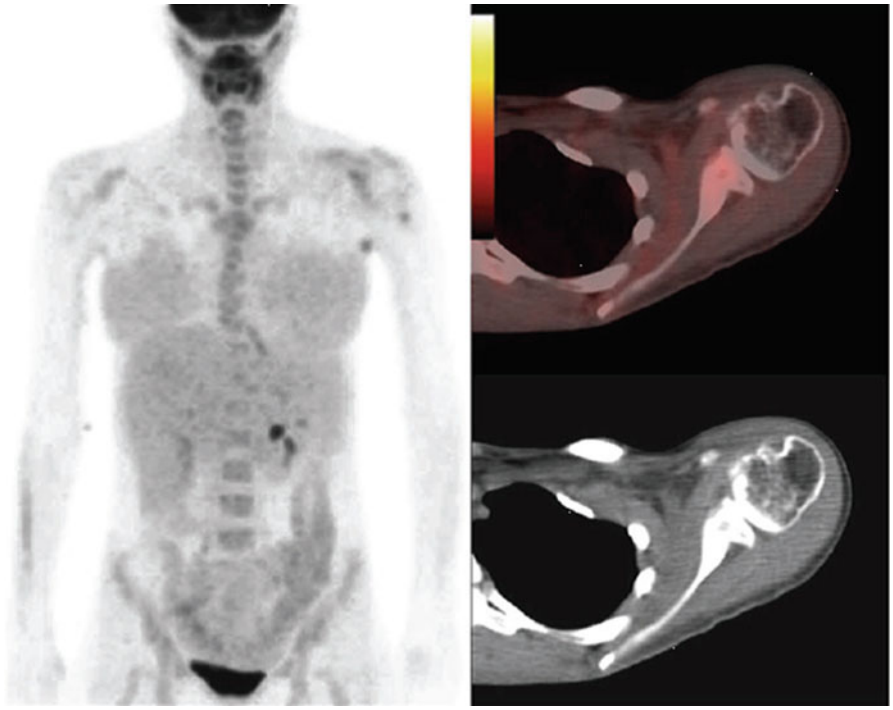

Fig. 16 [^{18}F]FDG PET/CT chemotherapy (MIP and axial images) demonstrates markedly reduced [^{18}F]FDG uptake and size of the scapular mass

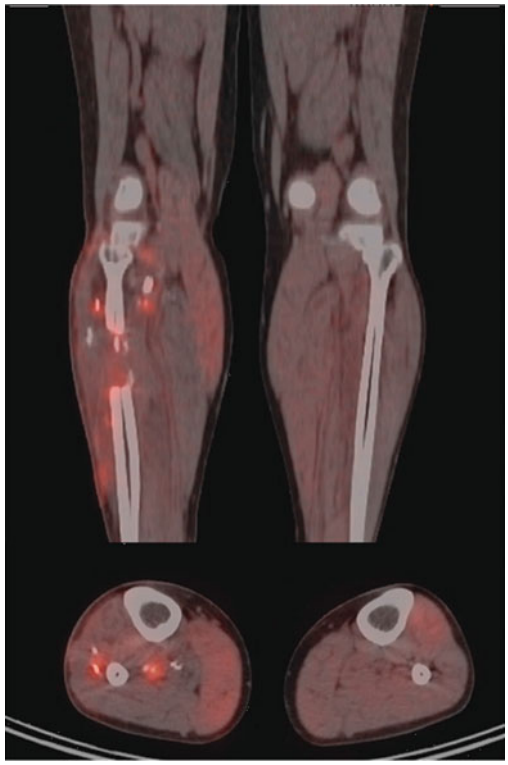

Fig. 17 Coronal and axial [^{18}F]FDG PET/CT fused images (coronal view *upper*, transaxial view *lower*) of the legs show hypermetabolic areas in the right calf, some of which are partially calcified lesions

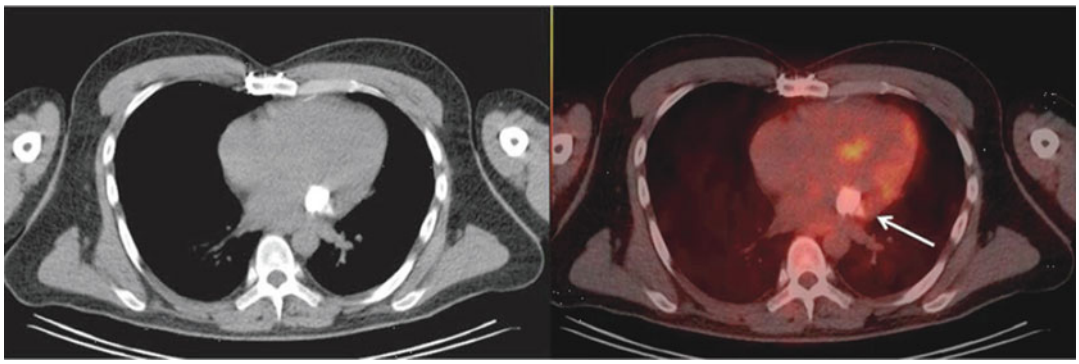

Fig. 18 Axial PET/CT image of the chest (CT, *left panel*, and PET/CT fused, *right panel*) showing the calcified left atrial mass which only demonstrates mild [^{18}F]FDG uptake

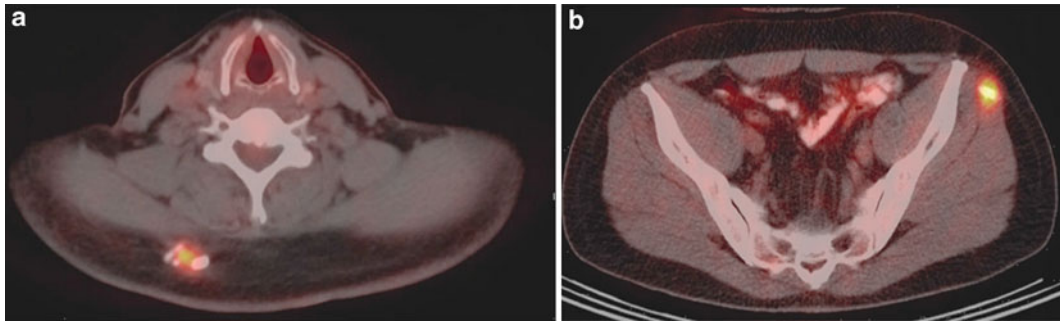

Fig. 19 [^{18}F]FDG PET/CT transaxial fused images of the neck (*upper panel*) and the pelvis (*lower panel*) show subcutaneous and muscle hypermetabolic nodules, (**a**) subcutaneous partially calcified nodule in the right lower neck, (**b**) calcified nodule in the anterolateral region of the left gluteus medius muscles

Melanoma: Case No. 1

Presentation

A 37-year-old man with dorsal melanoma and left axillary lymph node metastases treated with surgery 6 months earlier was referred for [^{18}F]FDG PET/CT for follow-up.

Findings

PET/CT examination revealed intense [^{18}F]FDG uptake in the gallbladder suspicious for malignancy (Figs. 1 and 2). Contrast-enhanced CT of the abdomen confirms the presence of multiple enhancing lesions (Fig. 2). Small [^{18}F]FDG-avid subcutaneous nodules consistent with melanoma localization were also identified in the neck and in the dorsum (Fig. 3).

Discussion

[^{18}F]FDG PET/CT may be helpful during melanoma follow-up for the assessment of recurrent and metastatic disease. Gallbladder metastasis is a rare but possible occurrence; thus, a careful evaluation in case of [^{18}F]FDG uptake in the gallbladder may correctly identify this rare occurrence.

Melanoma: Case No. 2

Presentation

A 52-year-old man with previously treated left lumbar melanoma with micrometastases in inguinal sentinel node underwent [^{18}F]FDG PET/CT during follow-up period.

Findings

PET/CT revealed the presence of multiple hypermetabolic mediastinal and bilateral hilar lymph nodes and bilateral [^{18}F]FDG-avid pulmonary nodules (Fig. 4). The differential diagnosis includes disseminated malignancies from granulomatous and inflammatory diseases. Symmetrical hilar [^{18}F]FDG uptake may be related to a benign, but the characteristics of hilar [^{18}F]FDG uptake in patients with granulomatous disease can be similar to those in patients with metastatic disease. Mediastinoscopic biopsy of lymph nodes was performed, and it revealed non-caseating giant cell granulomas, consistent with sarcoidosis. Steroid treatment was performed.

A repeat PET scan showed a decrease in the activity levels of hypermetabolic lymph nodes and pulmonary nodules (Fig. 5). These findings suggest a positive therapeutic response.

Discussion

Inflammatory lesions in the lungs, such as sarcoid, may lead to false-positive diagnosis of malignancy.

Melanoma: Case No. 3

Presentation

A 56-year-old man underwent [^{18}F]FDG PET/CT for follow-up 1 year after resection of a Stage IIIA melanoma of the left scapula.

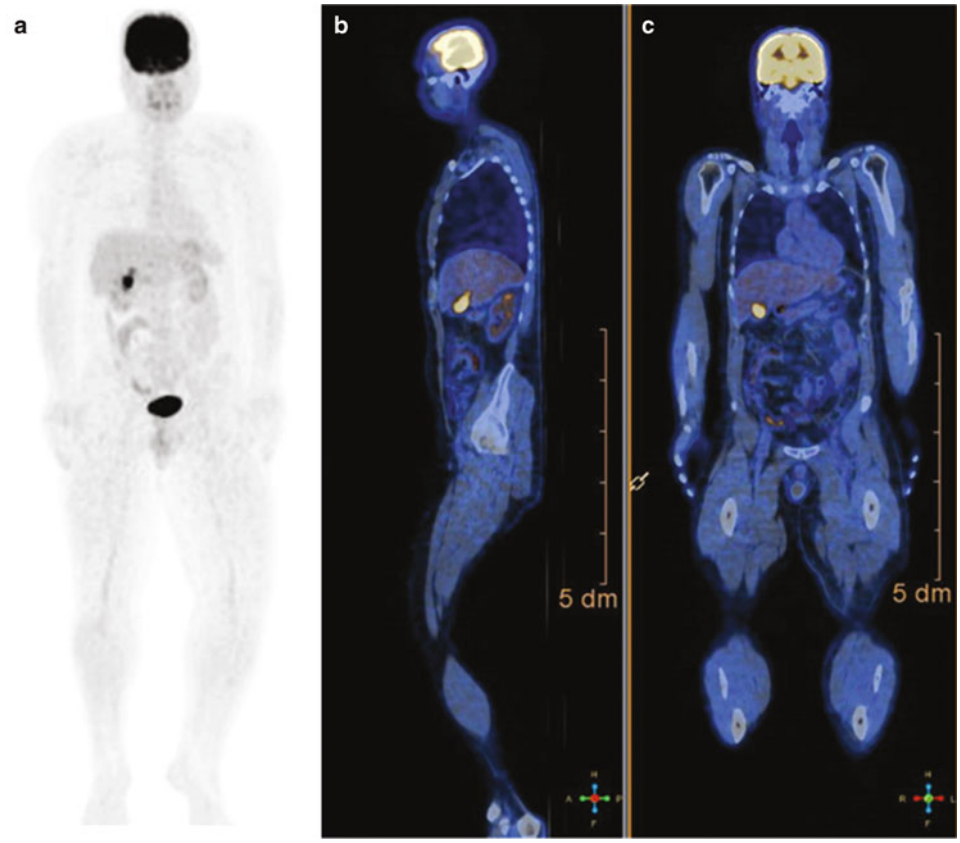

Fig. 1 Maximum intensity projection (**a**) and fused [^{18}F]FDG PET/CT images (**b** sagittal, **c** coronal) show intense FDG uptake in the gallbladder

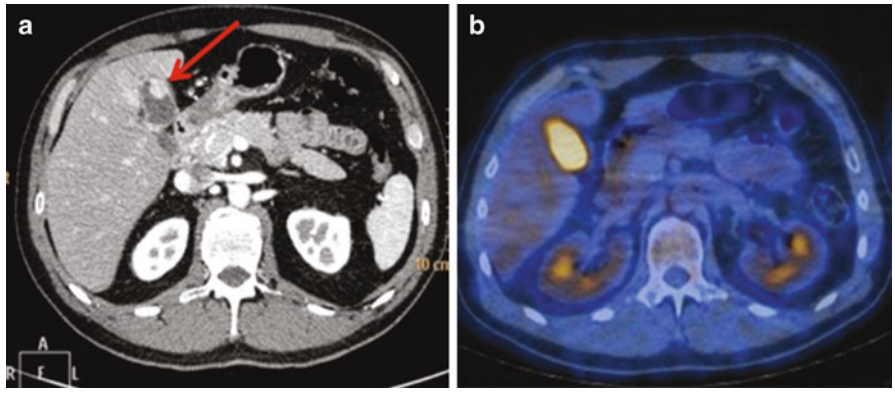

Fig. 2 Contrast-enhanced CT of the abdomen depicts the presence of gallbladder lesions consistent with metastases (panel **a**, *red arrow*) corresponding to focal [^{18}F]FDG uptake on PET/CT (panel **b**, transaxial fused PET/CT image)

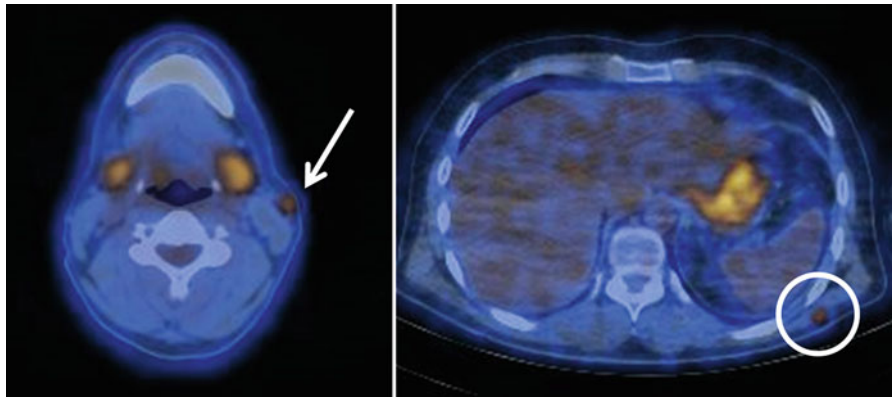

Fig. 3 Axial fused [^{18}F]FDG PET/CT images of subcutaneous lesion in the neck (*left panel*, *white arrow*) and in the dorsum (*right panel*, with *circle*)

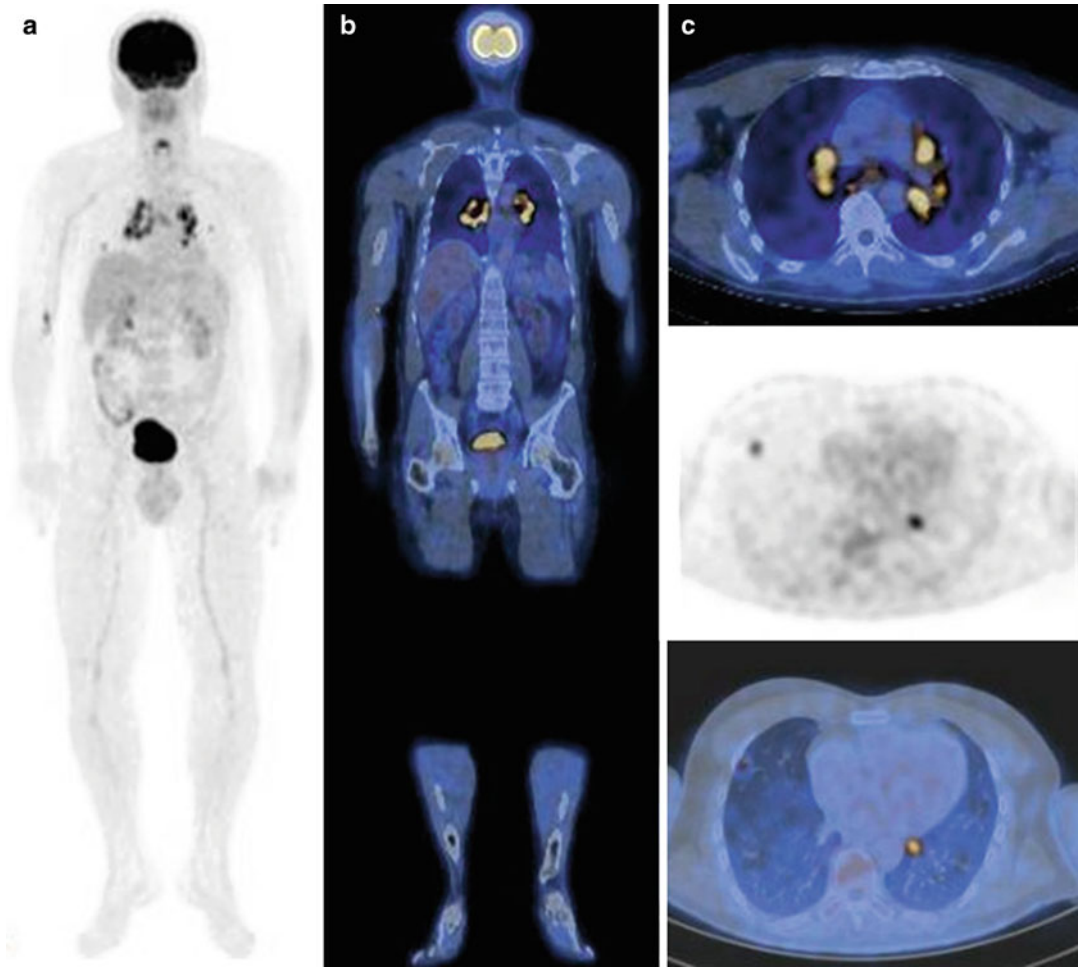

Fig. 4 Maximum intensity projection (MIP, **a**), coronal fused PET/CT (**b**), axial fused PET/CT, and axial PET images (**c**) show hypermetabolic mediastinal and hilar lymph nodes and [^{18}F]FDG-avid pulmonary nodules

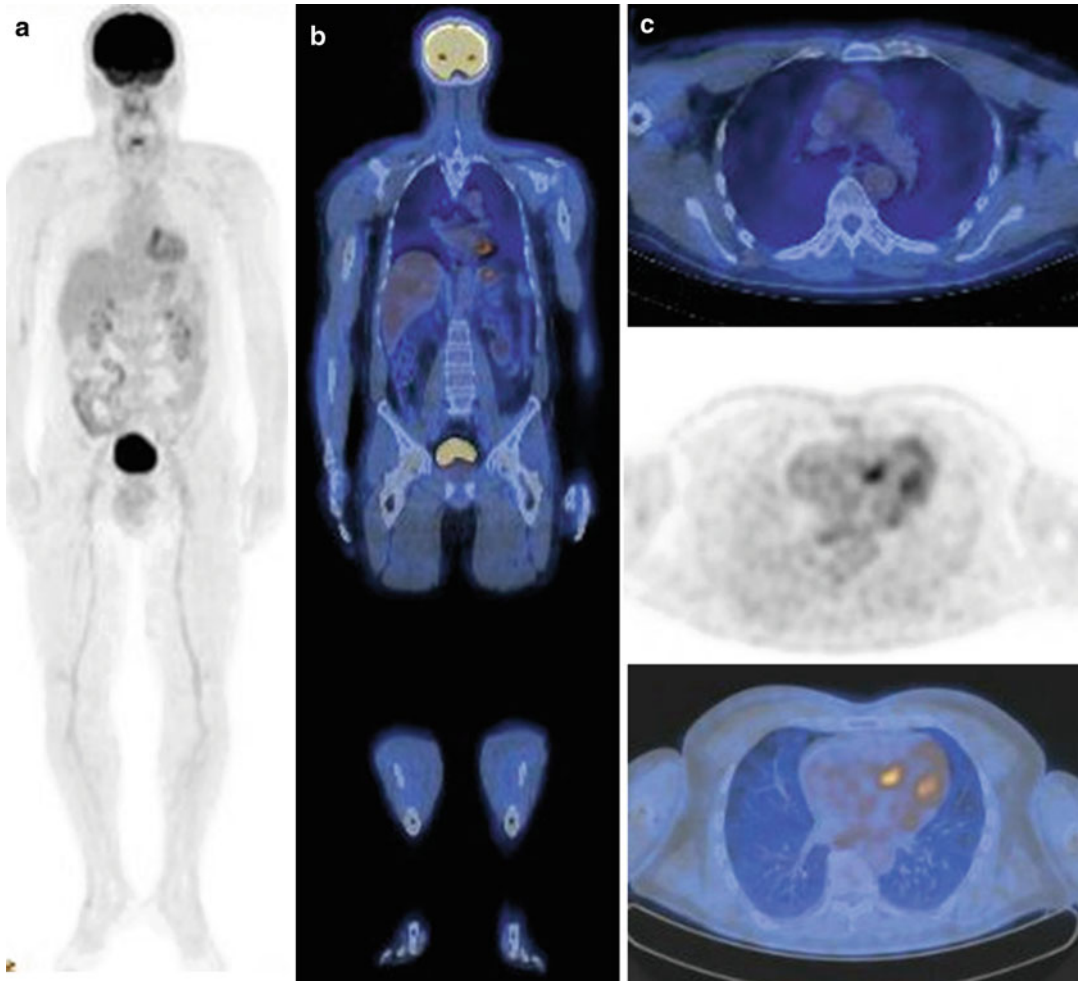

Fig. 5 Maximum intensity projection (MIP, **a**), coronal fused [^{18}F]FDG PET/CT (**b**), axial fused PET/CT, and axial PET images (**c**) show positive therapeutic response

Findings

PET/CT images revealed numerous visceral metastatic disease involving the lungs, liver, and spleen in the asymptomatic patient. Furthermore, multiple [^{18}F]FDG-avid bone lesions and soft tissue disease were noted (Fig. 6).

Discussion

At present there is no consensus on the optimal frequency of follow-up visits in asymptomatic patients with resected primary melanoma.

The National Comprehensive Cancer Network (NCCN) recommends routine imaging to monitor Stage IIB to IV melanoma chest x-ray, computed tomography (CT), and/or positron emission tomography (PET) scans every 3–12 months and annual magnetic resonance imaging (MRI) scans of the brain. However, routine follow-up radiologic imaging is not recommended for Stage IA to IIA melanomas.

In the American Academy of Dermatology (AAD) guidelines, imaging studies are not recommended in asymptomatic patients, although imaging studies can be considered in patients with high risk for recurrence. The European Society for

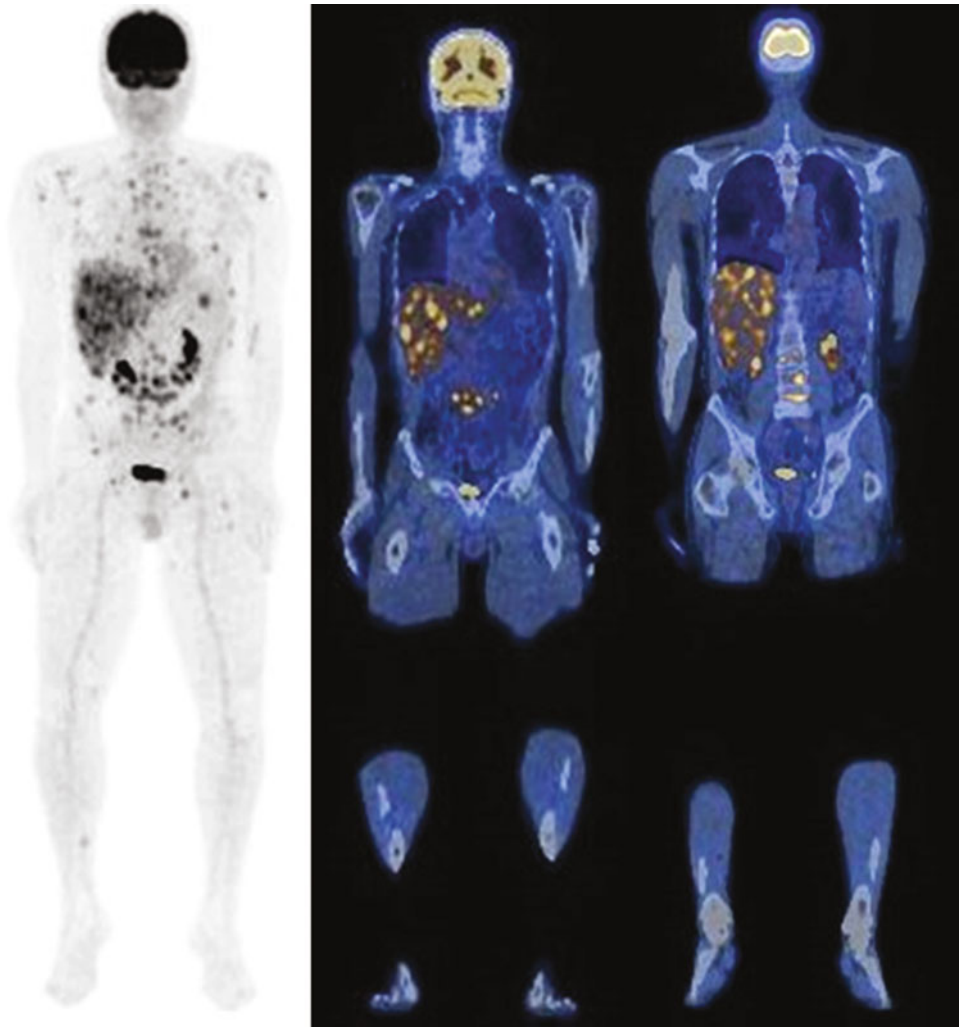

Fig. 6 Massive metastatic disease in previously treated melanoma discovered by [^{18}F]FDG PET/CT during follow-up

Medical Oncology (ESMO) guidelines provide general recommendations for monitoring patients at risk for recurrent and new disease. In high-risk patients (i.e., those with thick primary tumors or recent tumor resection), CT and/or PET scans are recommended for earlier detection of relapse.

[^{18}F]FDG PET/CT has a sensitivity of 96% and a specificity of 92%.

Melanoma: Case No. 4

Presentation

A 32-year-old man with previously surgically treated dorsal melanoma underwent [^{18}F]FDG PET/CT as a part of routine follow-up.

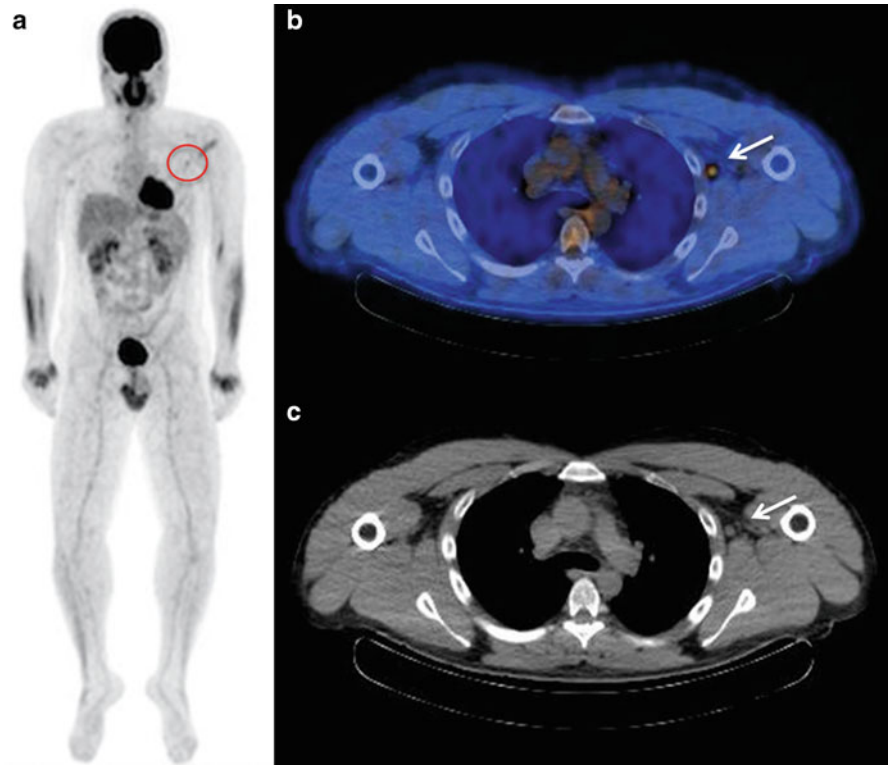

Fig. 7 Maximum intensity projection (**a**), axial fused PET/CT (**b**) and axial low-dose CT (**c**) show small lymph node in the left axilla with moderate [^{18}F]FDG uptake of uncertain origin

Findings

[^{18}F]FDG PET/CT demonstrated equivocal centimetric adenopathy with moderate [^{18}F]FDG uptake in the left axilla. Subsequent ultrasound of the axilla showed doubtful hypoechogenic lymphadenopathy.

Lymph node biopsy was performed and follicular hyperplasia was demonstrated.

Discussion

Reactive lymphadenopathy is well known as a principal cause of false-positive findings on PET/CT for nodal evaluation; when the etiology is unclear, biopsy may be necessary for diagnosis.

Melanoma: Case No. 5

Presentation

A 68-year-old man with a history of subscapular right melanoma (Stage IIA) was referred for routine physical examination. A painless, non-tender, subcutaneous nodule in the right scapula region suspicious for melanoma metastases was identified. [^{18}F]FDG PET/CT was performed to complete evaluation before planned surgical removal.

Findings

[^{18}F]FDG PET/CT confirmed the presence of hypermetabolic subcutaneous nodule in the right

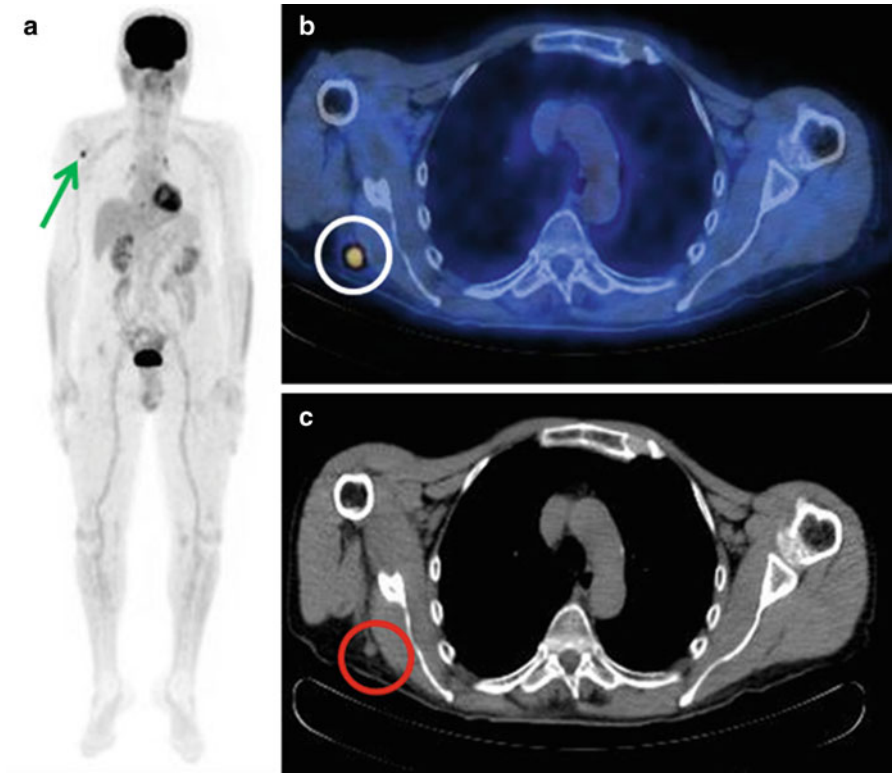

Fig. 8 Maximum intensity projection (MIP) (panel **a**) and axial images (**b** fused [^{18}F]FDG PET/CT; **c** low-dose CT) showed hypermetabolic small subcutaneous nodule in the right scapular region consistent with metastatic disease (**a** *green arrow*, **b** *white circle*, **c** *red circle*)

scapular region consistent with a pathological lesion (Fig. 8). Furthermore, an exophytic mass with soft tissue attenuation on low-dose CT images and moderate [^{18}F]FDG uptake in the left kidney was noted.

Further investigation demonstrated renal cell carcinoma.

Discussion

Findings of incidental primary renal lesions are common on [^{18}F]FDG PET/CT. Non-metabolically active pathology can be missed without close attention to the CT portion of the examination, whereas metabolically active pathology can be missed on [^{18}F]FDG PET due to physiologic accumulation of tracer in the renal collecting system. Therefore, close attention to both the PET and CT portions of the study is needed to identify renal lesions and guide the further diagnostic approach.

[^{18}F]FDG PET/CT cannot discriminate between renal cancer and oncocytoma, and furthermore complex or infected cysts can be [^{18}F]FDG-avid (Fig. 9).

Melanoma: Case No. 6

Presentation

An 84-year-old man with multiple subcutaneous nodules on the left leg in previously treated melanoma of the calf underwent [^{18}F]FDG PET/CT before planned isolated chemotherapeutic perfusion of the limb.

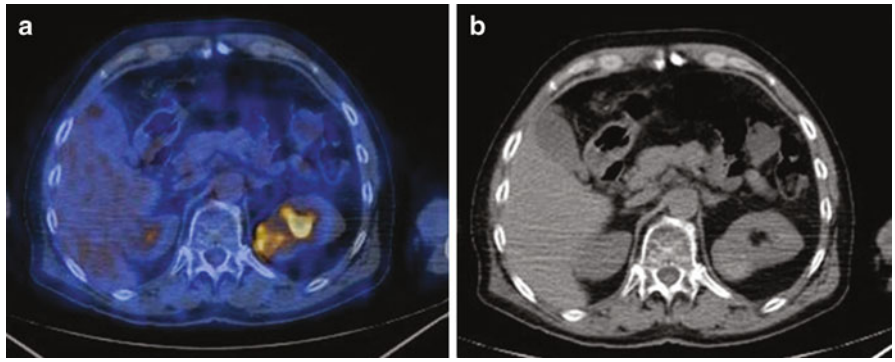

Fig. 9 Right renal [^{18}F]FDG-avid lesion on PET/CT (**a** axial fused PET/CT image; **b** axial low-dose CT)

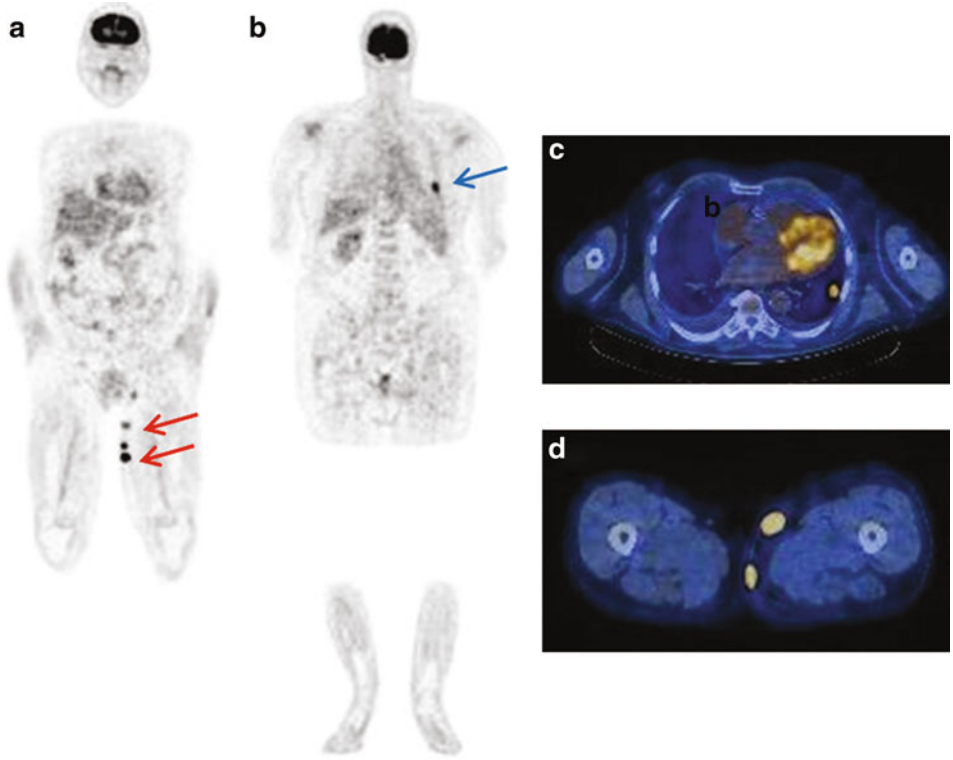

Fig. 10 Coronal PET (**a**) and axial fused PET/CT (**b**) images show hypermetabolic subcutaneous nodules in the left limb. [^{18}F]FDG-avid left lung lesion is also demonstrated (**b** PET coronal image and **c** axial fused PET/CT image)

Findings

[^{18}F]FDG PET/CT showed multiple hypermetabolic pathological subcutaneous nodules in the medial region of the left limb (Fig. 10). In the basal region of the left lung, a small [^{18}F]FDG-avid nodule was also depicted consistent with lung metastases. Bilateral Pleural effusion with mild [^{18}F]FDG uptake was shown. Systemic approach was considered to treat the patient.

Discussion

[^{18}F]FDG PET/CT can detect unexpected metastases resulting in a change in patient management.

PET scanning is extremely sensitive (91–95%) and very specific (83–92%) for identifying metastatic melanoma, particularly in soft tissues, lymph nodes, and the liver. False-negative scans in the presence of metastases are rare (<5%).

Melanoma: Case No. 7

Presentation

A 42-year-old woman previously treated for melanoma referred for suspected lymph node metastases (1 cm in size) in the left axilla detected by US. Fine-needle aspiration biopsy (FNAB) was performed, and cytology confirmed the presence of melanoma metastases. The patient underwent [^{18}F]FDG PET/CT before planned axillary lymph node dissection.

Findings

PET/CT depicted a lymph node in the left axilla which showed moderate [^{18}F]FDG uptake corresponding to biopsied lesion. A small subcutaneous nodule with mild [^{18}F]FDG uptake suggested melanoma metastasis in the left clavicular region. In addition an [^{18}F]FDG-avid lytic lesion in the sternum consistent with skeletal metastases was detected.

Patient was treated with surgery followed by external beam radiotherapy of the sternum.

Discussion

This case demonstrates that [^{18}F]FDG-PET/CT may have an additional value in the staging of recurrent melanoma (Fig. 11).

Melanoma: Case No. 8

Case contributed by H.A. Jacene

Nuclear Medicine/PET-CT, Dana-Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts, USA.

Presentation

A 49-year-old woman with metastatic melanoma, restaging examination with [^{18}F]FDG PET/CT.

Findings

On the PET maximum intensity projection image viewed anteriorly (Fig. 12), multiple [^{18}F]FDG-avid pulmonary nodules and a left pelvis mass are seen. In the region of the right kidney, the expected excreted urinary [^{18}F]FDG contour of the right renal pelvis appears to have an abnormal configuration. When the MIP image is rotated and viewed from a right anterior oblique projection (Fig. 12), it is apparent that there is an [^{18}F]FDG-avid mass anterior to the right kidney. On further evaluation of the axial PET and CT images, an [^{18}F]FDG-avid mass is seen in the neck of the gallbladder (Fig. 13). On a coronal contrast-enhanced diagnostic CT image performed on a separate date, a 3.4 cm

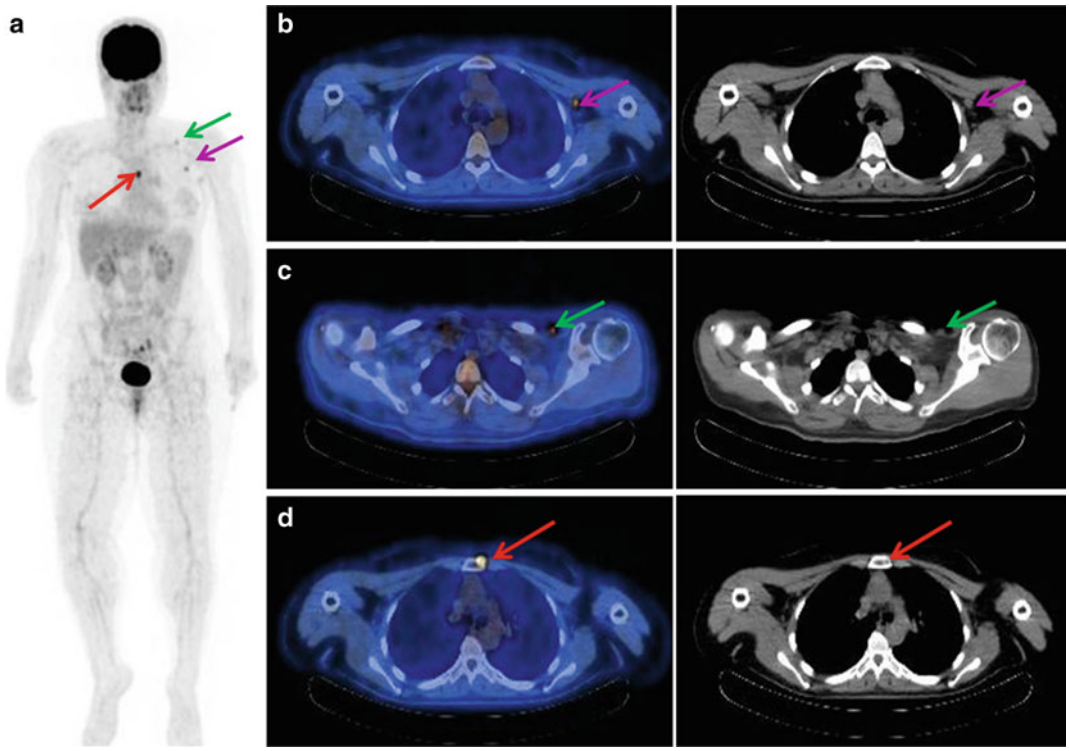

Fig. 11 Maximum intensity projection (*MIP*) image (**a**) in patient with metastatic melanoma. Axial fused [^{18}F]FDG PET/CT (*left panel*) and low-dose CT (*right panel*) show left axillary lymph node involvement (**a**, **b** *pink arrow*), subcutaneous [^{18}F]FDG-avid lesion (**a**, **c** *green arrow*), and hypermetabolic lytic sternal lesion (**a**, **d** *red arrow*)

enhancing mass within the gallbladder can be seen (Fig. 14).

Discussion

Metastases to the gallbladder are unusual for any malignancy, but are most often seen with metastatic melanoma compared to other malignancies. Metastases from other primary carcinoma origins such as renal cell carcinoma, the breast, and the stomach among others are seen, but are less common. Usually, metastases to the gallbladder are asymptomatic and however occasionally do present clinically with acute cholecystitis or common bile duct obstruction.

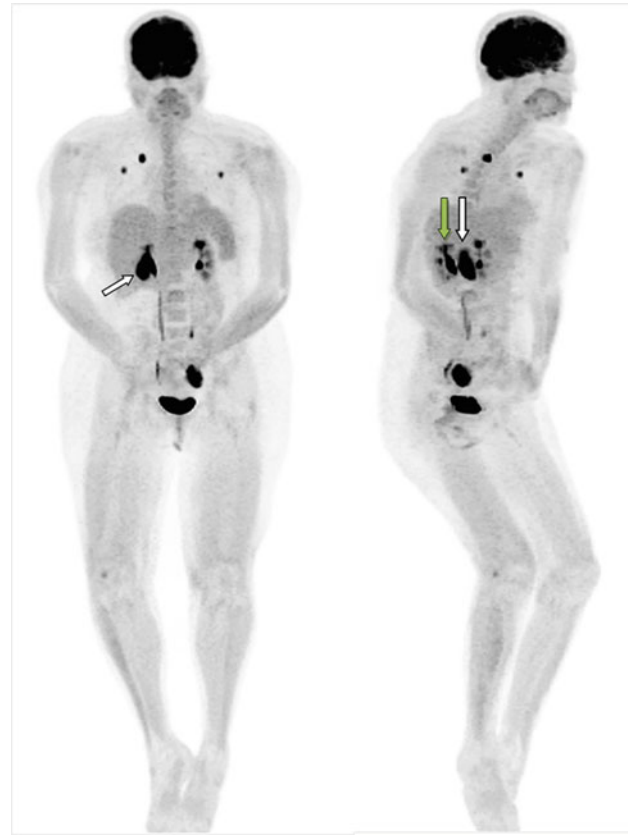

Fig. 12 PET maximum intensity projection image viewed anteriorly (*left*) and from a right anterior oblique view (*right*) shows multiple [^{18}F]FDG-avid pulmonary nodules and an [^{18}F]FDG-avid left pelvic mass. On the anterior view, in the expected location of the right kidney, there is an asymmetry and contour abnormality of the [^{18}F]FDG activity (*white arrow*). On the right anterior oblique view, this abnormality in the region of the right kidney is seen to actually be due to a mass (*white arrow*) anterior to the more posteriorly located right kidney (*green arrow*)

Melanoma: Case No. 9

Presentation

A 77-year-old woman presented with erythema and induration of the right hand. She was initially treated with local antibiotics without resolution.

Findings

A biopsy showed a malignant melanoma greater than 4 mm with ulceration.

Following intradermal injections of ^{99m}Tc-nanocolloidal albumin around the lesion, lymphoscintigraphy showed sentinel lymph nodes in the axilla and supraclavicular region (Fig. 15).

Fig. 13 CT (*above*) and PET (*below*) images of the gallbladder neck demonstrate an intensely [^{18}F]FDG-avid round mass in the gallbladder (*arrows*)

The patient had surgical excision of the lesion on the hand and sentinel node biopsies. Histological examination confirmed a malignant melanoma (Breslow 4 mm, Clark IV) with metastasis to an axillary sentinel node (Stage III). Right supraclavicular node was negative.

Fig. 14 Coronal image from a contrast-enhanced diagnostic CT demonstrates a round enhancing 3.4 cm mass in the gallbladder neck (*arrow*)

Follow-Up

[^{18}F]FDG PET/CT performed to evaluate the extent of disease after surgery did not show pathological uptake (Fig. 16). Follow-up [^{18}F]FDG PET/CT at 12 months demonstrated widespread metastases in uptake in the right neck lymph nodes (SUV_{max} 6.2) (Fig. 17) and multiple hypermetabolic foci (SUV_{max} 11) in the axial and appendicular skeleton (Fig. 18a) involving the scapulae, humeri (Fig. 18b), pelvis (Fig. 18c), spine (Fig. 18d), femora, and right tibia.

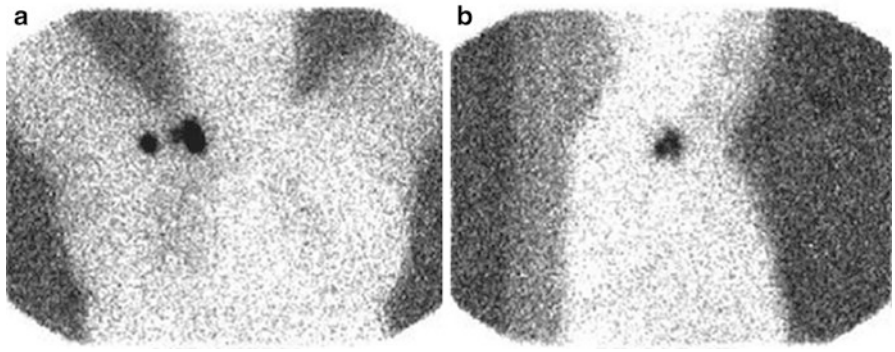

Fig. 15 Sentinel node lymphoscintigraphy. Static images of the neck and thorax show uptake accumulation in the right neck and supraclavicular region, (**a**) anterior projection, (**b**) right lateral projection

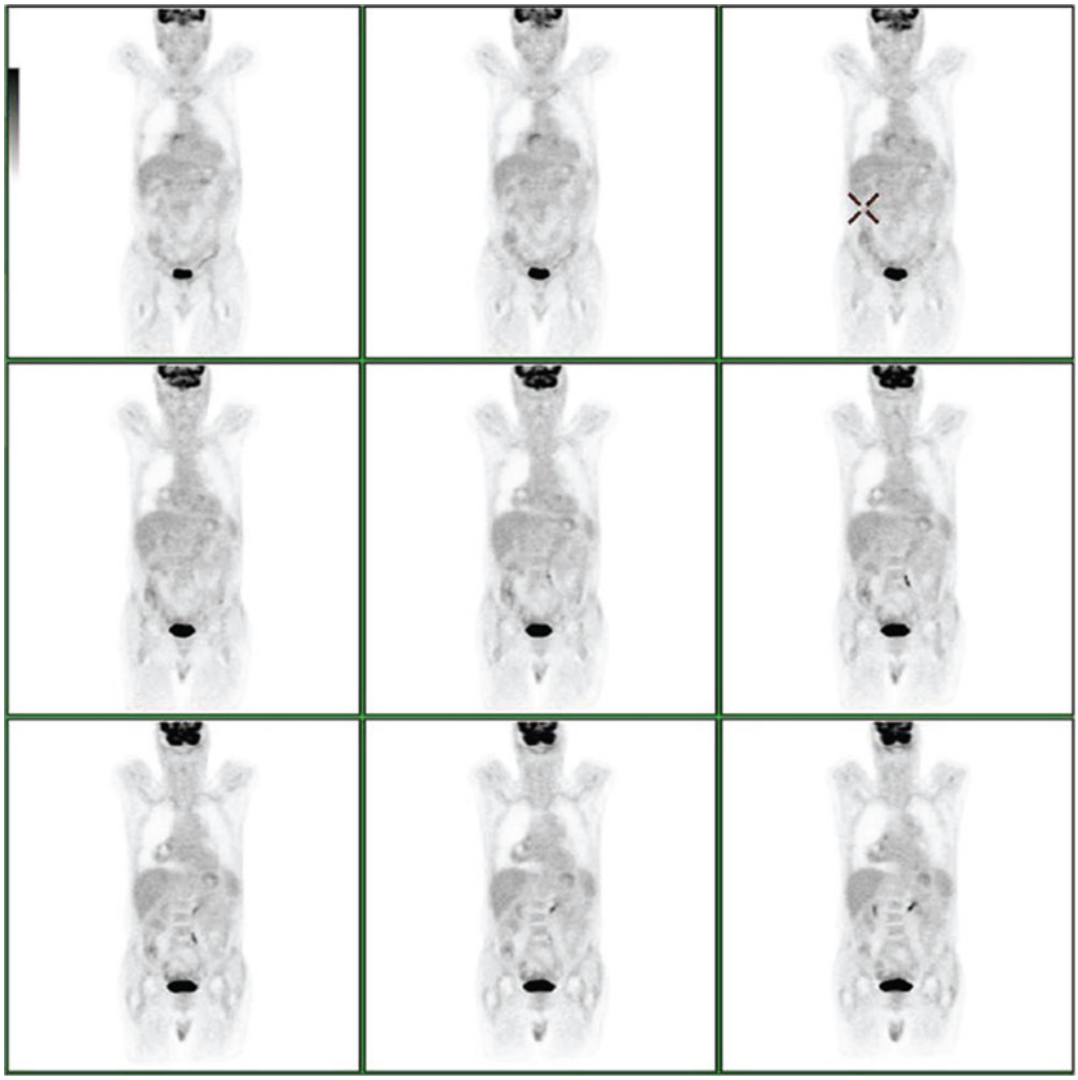

Fig. 16 Postsurgical [^{18}F]FDG PET/CT showing no abnormal sites of uptake

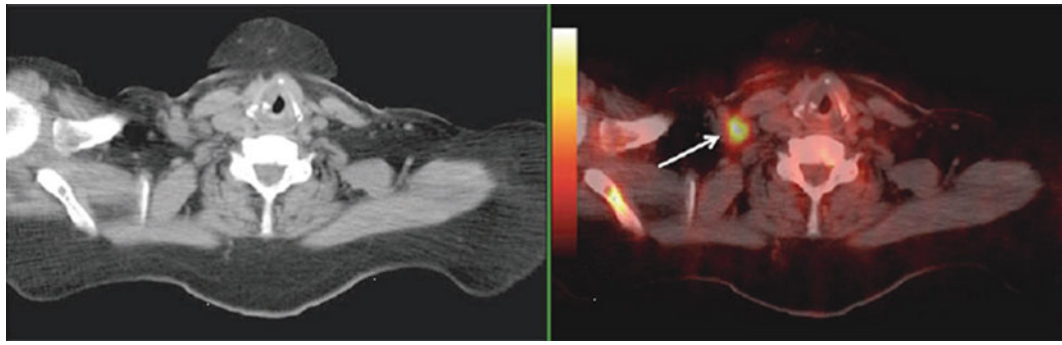

Fig. 17 CT and fused [^{18}F]FDG PET/CT axial images showing hypermetabolic right neck lymph node

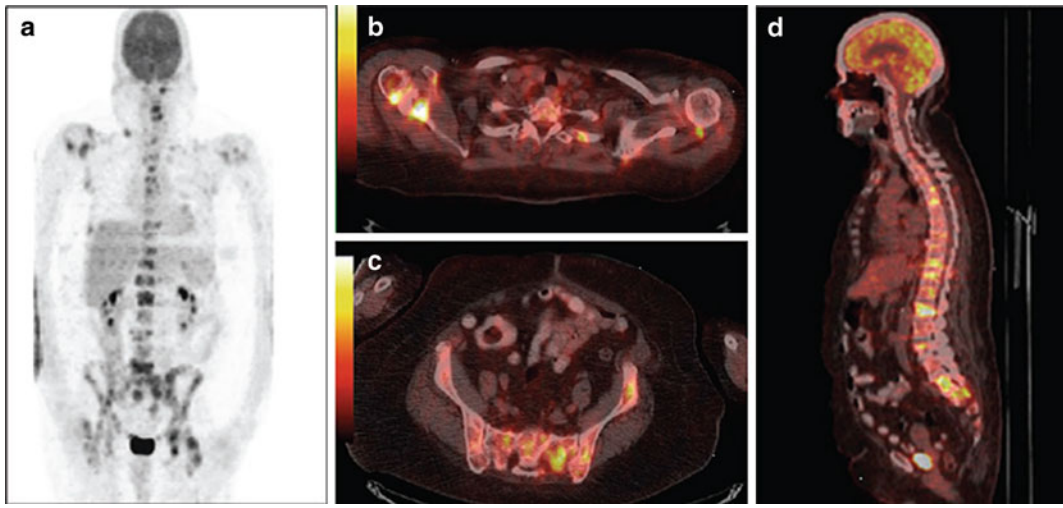

Fig. 18 (**a**) MIP image of metastatic skeletal melanoma, (**b**) axial fused image of pathological uptake in the right scapula and humerus, (**c**) axial fused image of pelvic skeletal, and (**d**) sagittal fused image show spine involvement

Discussion

The preoperative SUV_{max} of the primary lesion in patients with ulcerated lesions is a potent predictor of recurrence in patients with cutaneous melanoma. Although a preoperative [^{18}F]FDG scan was not performed in this patient, the histologic characteristics of the lesion and the presence of metastatic disease following surgery place this patient in the high risk of recurrence category of this aggressive disease.

Neuroblastoma: Case No. 1

Presentation

A four-year-old girl with high-risk neuroblastoma (stage IV, MYCN amplified). Treated with induction chemotherapy (modified N7 protocol), with partial response (persisting 5–10% positive bone marrow cells on bilateral trephines). Second-line induction chemotherapy with TVD, with some improvement, but still about 5% positivity on bone marrow trephines. Further treatment with bevacizumab and temozolomide, with good response. Surgery, with 80% tumor removal and left nephrectomy (tumor invasion of the left renal hilum).

Findings

Persisting disease on reassessment [^{123}I]MIBG (Fig. 1). The child has subsequently been treated with experimental therapies including monoclonal antibodies and modified T-cells. MRI scan after fifth cycle of monoclonal antibody treatment disclosed a splenunculus (Fig. 2). A [^{123}I]MIBG scan was performed 5 days after the MRI scan. There were two persisting foci of [^{123}I]MIBG avid disease in the left side of the abdomen (Fig. 3). The intensity of uptake is significantly reduced in comparison to the previous MIBG study after surgery. The SPECT/CT study raises the possibility that the splenunculus may be MIBG-avid (Fig. 3). Contrast-enhanced CT scan, performed the day after the [^{123}I]MIBG scan, showed the splenunculus and a further soft tissue nodule just below it, corresponding to the [^{123}I]MIBG avid nodule and compatible with residual disease (Fig. 4). Moreover, residual disease in the retroperitoneum only minimally [^{123}I]MIBG avid was clearly seen on contrast-enhanced CT (Fig. 5).

Follow-Up

The child was discussed at the multidisciplinary team meeting, with the view to proceed to further surgery that seemed feasible based on the imaging studies.

Teaching Point

The [^{123}I]MIBG SPECT/CT study has been critical in identifying the additional nodule of [^{123}I]MIBG avid disease below the splenunculus. Comparison with contemporaneous cross-sectional imaging has also been essential for a proper interpretation of the MIBG findings. Surgical planning has included resection of that nodule, clearly separate and different from the splenunculus. Without proper comparison with other imaging, the focal area of abnormal [^{123}I]MIBG uptake could have been interpreted as representing the splenunculus, with the possible risk of resecting an accidental normal finding and leaving in place a nodule of [^{123}I]MIBG avid neuroblastoma.

Neuroblastoma: Case No. 2

Presentation

A five-year-old boy, diagnosed with stage IV neuroblastoma (widespread skeletal disease) at the age of 2.5 years (Fig. 6). Treated with induction chemotherapy (rapid COJEC) to complete remission on MIBG and surgical resection of the primary tumor. Three months later, recurrent disease with a brain metastasis in the right parietal lobe; this was resected, with subsequent radiotherapy and adjuvant chemotherapy. Subsequent relapse in the skeleton (right tibia and femur) few months later, treated with second-line chemotherapy (TVD), topotecan, [^{131}I]MIBG therapy, and high-dose chemotherapy, followed by antibody therapy. In complete remission on [^{123}I]MIBG scintigraphy and X-ray as a result (Fig. 7). After 1 year, he presents with acute onset of left knee pain.

Findings

The patient underwent a MRI of the left femur that showed a focal abnormality in the distal

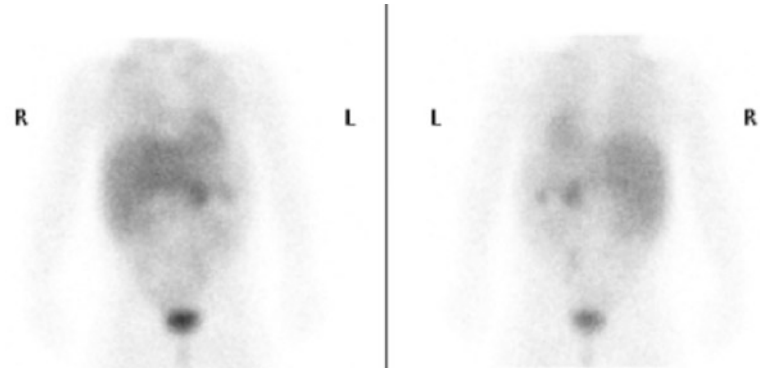

Fig. 1 Reassessment [^{123}I]MIBG shortly after surgery (anterior and posterior planar images): two focal areas of [^{123}I] MIBG avid disease in the left side of the abdomen are seen

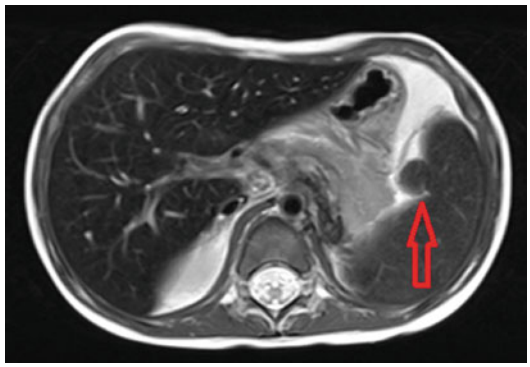

Fig. 2 MRI scan, T2 weight images, after fifth cycle of monoclonal antibody treatment and several months after surgery (axial view): there is a splenunculus

diaphysis, with abnormal signal and enhancement of the periosteum and the bone marrow, highly suspicious for recurrence (Fig. 8). One week later, [^{123}I]MIBG scintigraphy resulted completely negative with no evidence of abnormal uptake in the left femur (Fig. 9). A subsequent ^{68}Ga-DOTATATE whole body PET/CT scan found a highly increased somatostatin analogue uptake in the distal left femur, compatible with recurrent malignant disease (Fig. 10).

Follow-Up

The child was treated with three courses of ^{177}Lu-DOTATATE molecular radiotherapy, with improvement in the left femoral metastasis.

Teaching Point

This case illustrates that previous [^{123}I]MIBG avid neuroblastoma can relapse as MIBG negative disease. Neuroblastoma, although detected with high sensitivity by [^{123}I]MIBG, is [^{123}I]MIBG negative in about 5% of cases. Also, [^{123}I]MIBG positive primary neuroblastoma can show clones of [^{123}I]MIBG negative cells. And a patient with mainly [^{123}I]MIBG positive metastatic lesions can show [^{123}I]MIBG non-avid lesions. [^{123}I]MIBG is a marker of the norepinephrine active uptake-1 transport mechanism and is taken up by neuroblastoma only if this mechanism is still functional.

Neuroblastoma: Case No. 3

Presentation

A five-year-old boy, with a diagnosis of high-risk neuroblastoma (poorly differentiated Schwannian stroma poor, stage IV, widespread skeletal metastatic infiltration on [^{123}I]MIBG) at the age of 2 (Fig. 11).

Findings

He was treated with induction chemotherapy (rapid COJEC) with excellent response (resolution of all skeletal metastatic lesions with the exception of a lesion in the sternum) (Fig. 12).

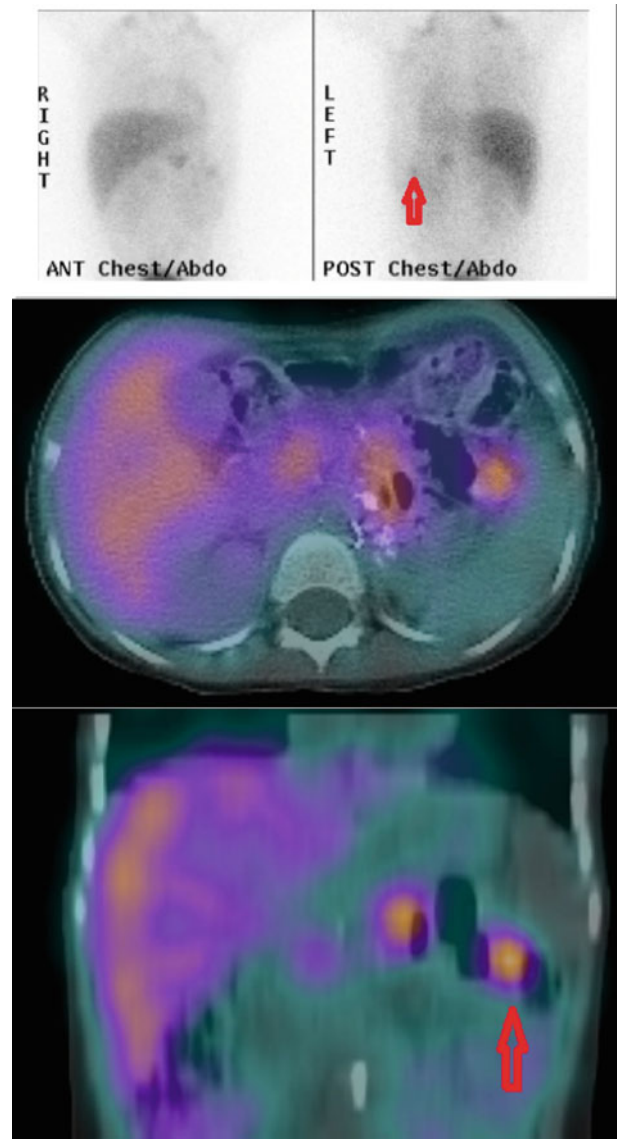

Fig. 3 [^{123}I]MIBG scan, performed 5 days after the MRI scan. Reassessment after five courses of monoclonal antibody treatment. There are two persisting foci of [^{123}I]MIBG avid disease in the left side of the abdomen on planar images (*top panel*). The intensity of uptake is significantly reduced in comparison to the previous [^{123}I]MIBG study after surgery. The SPECT CT study (axial views) raise the possibility that the splenunculus may be [^{123}I]MIBG avid (*middle* and *bottom panel*). However, it is noted that there is no [^{123}I]MIBG uptake in the spleen, and this would be very unusual

He also received high-dose chemotherapy with busulfan and melphalan and stem cell rescue, achieving complete remission on [^{123}I]MIBG (Fig. 13). He had abdominal radiotherapy at the site of the primary tumor, cis-retinoic acid, and immunotherapy with anti-GD2 monoclonal antibodies. During immunotherapy he relapsed with a focal area of abnormal [^{123}I]MIBG uptake in the manubrium of the sternum, exactly at the same site of the previous disease (Fig. 14). This was treated with cyclophosphamide and topotecan and external beam radiotherapy, with no significant change on [^{123}I]MIBG SPECT/CT scanning and ^{68}Ga-DOTATATE PET/CT (stable disease) (Fig. 15). An excision biopsy after 13 cycles of chemotherapy showed ganglioneuroblastoma with extensive differentiated elements and no evidence of undifferentiated cells (Fig. 16).

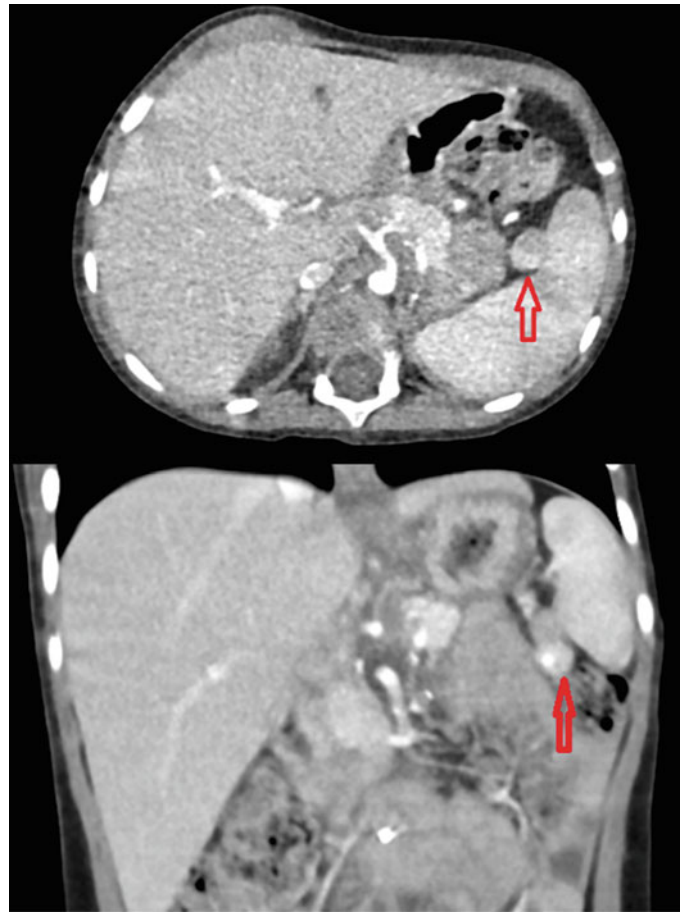

Fig. 4 Contrast-enhanced CT scan, performed the day after the [^{123}I]MIBG scan. This shows the splenunculus and a further soft tissue nodule just below it, best seen on the coronal views (*bottom panel, arrow*): this is likely to correspond to the [^{123}I]MIBG avid nodule and is compatible with residual disease

Follow-Up

In view of the completely excised well-differentiated ganglioneuroblastoma and the absence of undifferentiated cells, the cytotoxic chemotherapy based on cyclophosphamide and topotecan has been withdrawn.

Teaching Point

This case illustrates the possible differentiation of a highly malignant poorly differentiated neuroblastoma into a much more benign well-differentiated ganglioneuroblastoma variant following chemotherapy. [^{123}I]MIBG scanning could not differentiate between these histological variants.

Neuroblastoma: Case No. 4

Presentation

A five-month-old baby girl diagnosed with a poorly differentiated neuroblastoma with very elevated VMA/HVA urinary levels.

Findings

An MRI at diagnosis showed a large intra-abdominal mass lesion arising from the right adrenal, with skin and liver metastases (Fig. 17). Her [^{123}I]MIBG scan showed skeletal metastatic involvement (Fig. 18). However, her bone marrow aspirate was negative for metastatic

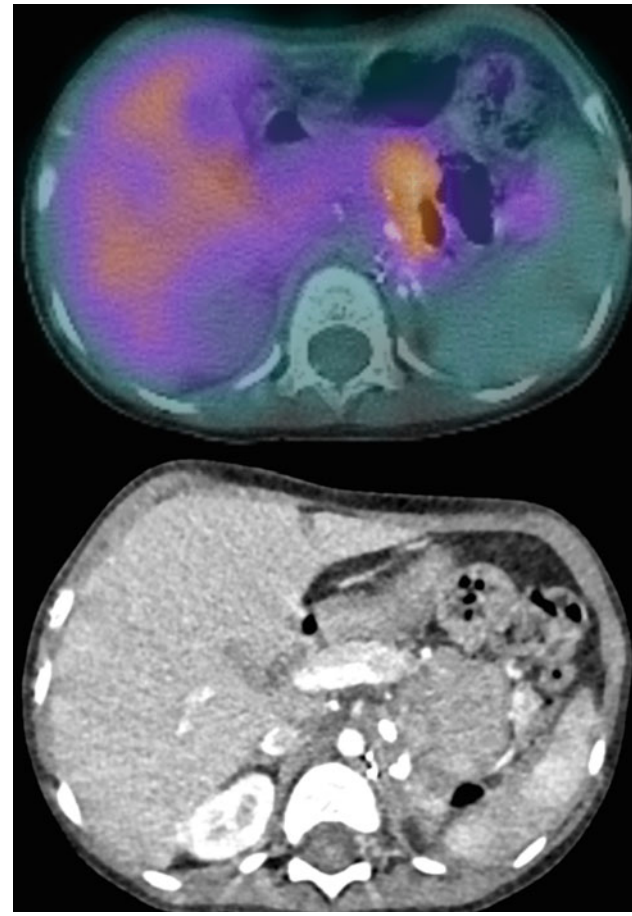

Fig. 5 [^{123}I]MIBG SPECT/CT scan (*top panel*) and contrast-enhanced CT (*bottom panel*). Residual disease in the retroperitoneum, only minimally [^{123}I]MIBG avid on SPECT/CT and clearly seen on contrast-enhanced CT

infiltration. The molecular analysis from the biopsy of her abdominal tumor did not show MYCN amplification (and no segmental chromosomal abnormality). Consequently she was considered as having intermediate rather than high-risk disease. The investigations of her disease at staging suggest a pattern of stage IV disease rather than IVs.

Management

On the basis of her stage (IV rather than IVs), this girl has been commenced on chemotherapy (carboplatin and etoposide), in line with European guidelines.

Teaching Point

This is a very interesting and unusual case. The age of the child (5 months) would raise the possibility of a IVs neuroblastoma; however, the nature of the primary tumor (crossing the midline, encasing vessels, extending to the retrocrural space) and the pattern of metastatic infiltration (focal rather than diffuse hepatic metastatic infiltration, no bone marrow disease, cortical bone metastases) are consistent with stage IV disease. However, in view of the favorable tumor biology (MYCN non-amplified, no chromosomal abnormalities) and of her age (<18 months), her neuroblastoma can be classified as intermediate rather than high risk. On the other hand, as she has stage IV disease, she has

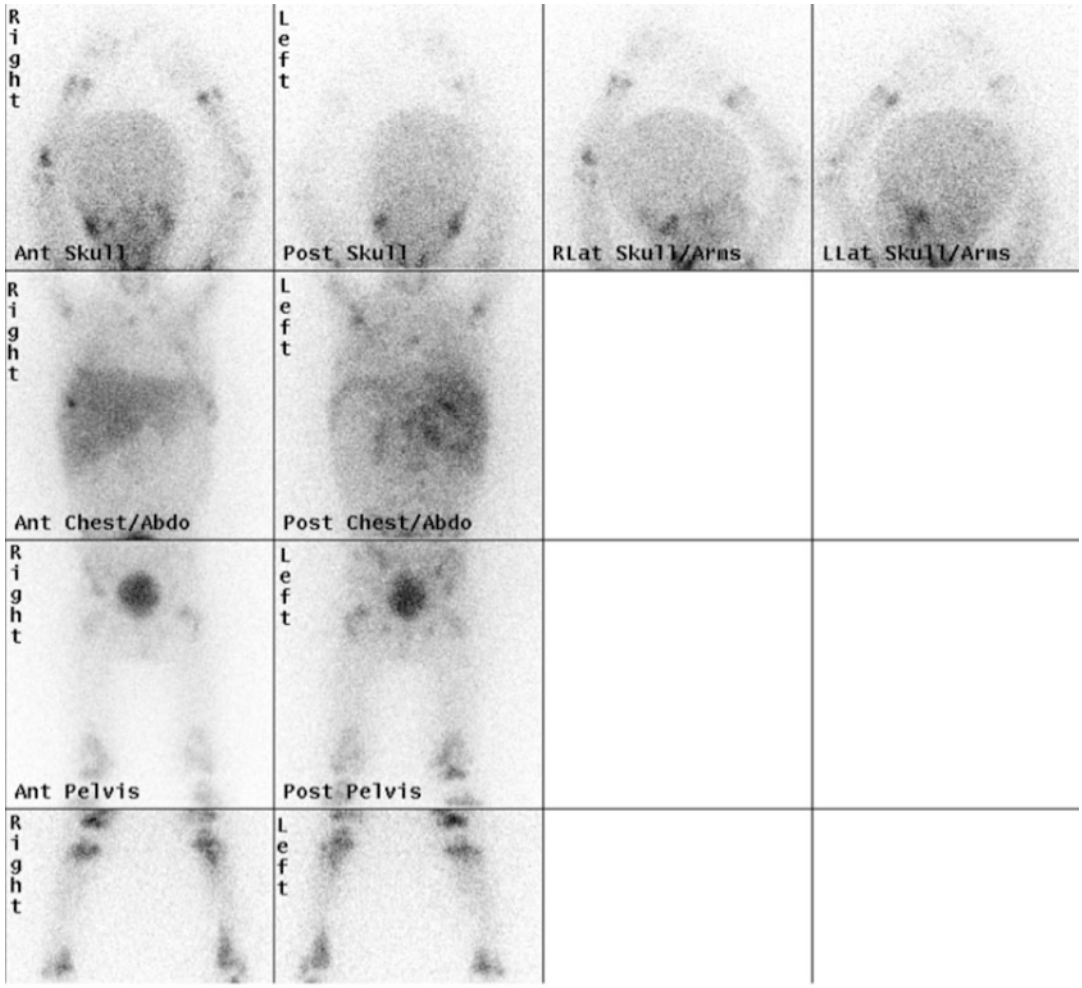

Fig. 6 [^{123}I]MIBG at diagnosis (aged 2.5 years): the primary neuroblastoma in the right suprarenal region shows a rim of [^{123}I]MIBG avid disease surrounding a central area with lower grade uptake. There are widespread [^{123}I]MIBG avid skeletal deposits, consistent with bone and bone marrow metastatic infiltration

been started on chemotherapy. The [^{123}I]MIBG scan successfully shows the skeletal metastases but fails to distinguish between bone and bone marrow disease (the bone marrow aspirate excluded bone marrow involvement). Also, the [^{123}I]MIBG scan showed low sensitivity for liver metastases, due to the normal hepatic [^{123}I]MIBG uptake.

Neuroblastoma: Case No. 5

Presentation

A two-month-old baby boy presenting with a 3-day history of vomiting, diarrhea, and increasing abdominal distension.

Fig. 7 X-ray of the left knee 2.5 years after diagnosis, when the child was in complete remission: there is a focal area of sclerosis in the medial aspect of the distal left femur, very similar to a previous X-ray, possibly compatible with a healed metastasis

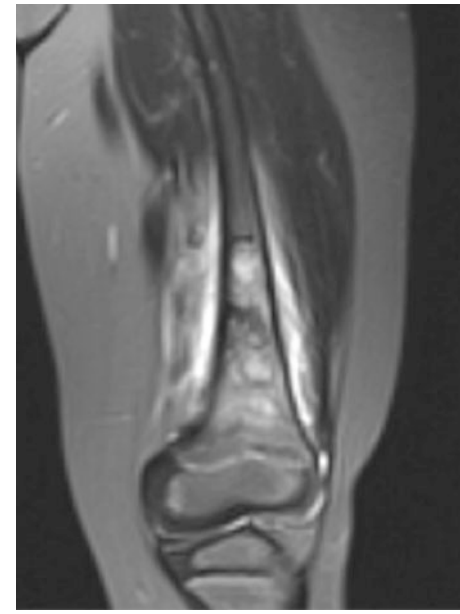

Fig. 8 MRI left femur 1 week later: focal abnormality in the distal diaphysis of the left femur, with abnormal signal and enhancement of the periosteum and the bone marrow, highly suspicious for recurrence

Findings

His MRI scan at diagnosis showed a massive hepatomegaly with multiple nodules of disease. In addition, there was a right adrenal mass lesion, which on percutaneous biopsy was demonstrated to be a poorly differentiated neuroblastoma (Fig. 19). [^{123}I]MIBG at diagnosis showed no evidence of significantly increased tracer uptake (Fig. 20).

Management

Clinically and radiologically, this baby boy had IVs neuroblastoma. However, molecular analysis on the biopsy specimen showed MYCN amplification. Therefore, in view of the unfavorable biology, he was upstaged to high risk and treated with rapid COJEC induction chemotherapy.

Teaching Points

A neuroblastoma can be [^{123}I]MIBG entirely negative in approximately 5% of cases. Therefore, [^{123}I]MIBG cannot be used to follow up these tumors. PET tracers, such as [^{18}F]FDG, ^{18}F-DOPA, ^{68}Ga-DOTATATE, or DOTANOC can be tried.

IVs neuroblastoma usually has a good prognosis and is treated with mild chemotherapy. However, in approximately 10% of cases, a IVs neuroblastoma can have amplification of the MYC oncogene; in this case it has a much worse prognosis and is treated with the aggressive form of chemotherapy used for high-risk stage IV disease.

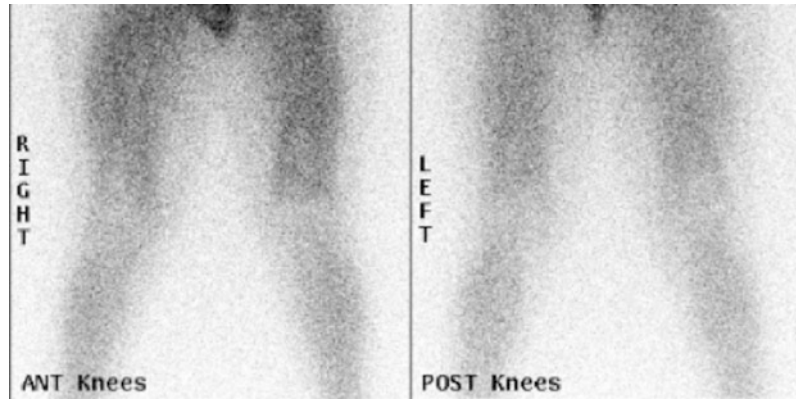

Fig. 9 [^{123}I]MIBG 1 week after the MRI: no evidence of abnormal uptake in the left femur

Fig. 10 ^{68}Ga-DOTATATE whole body PET scan 1 week later: there is highly increased somatostatin analogue uptake in the distal left femur, compatible with recurrent malignant disease (Image courtesy of Dr J. Bomanji, Institute of Nuclear Medicine, University College London Hospital)

Neuroblastoma: Case No. 6

Presentation

A two-year-old girl, presenting with jaundice. She was found to have a large abdominal mass, which on biopsy, following ultrasound and MRI, turned out to be a poorly differentiated, Schwannian stroma poor, neuroblastoma.

Findings

MRI and [^{123}I]MIBG showed localized disease in the mid-upper abdomen (Figs. 21 and 22).

Management

Based on the bone marrow trephine result (Fig. 23), this is stage IV neuroblastoma, high risk (also considering the patient's age and the unfavorable histopathology). The child was commenced on induction chemotherapy based on rapid COJEC (no vincristine due to raised bilirubin).

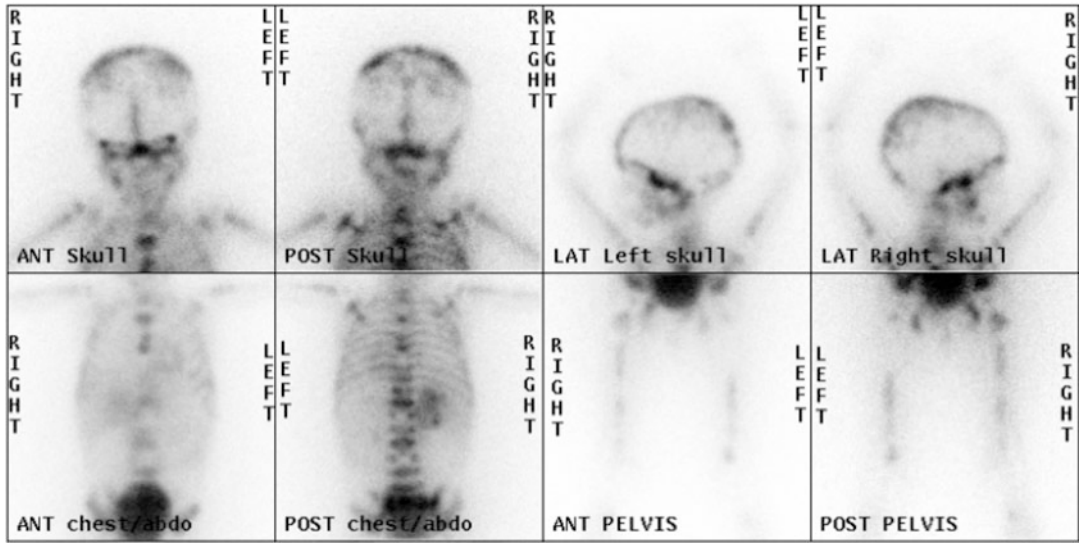

Fig. 11 [^{123}I]MIBG scan at diagnosis: there is increased tracer uptake within in the primary neuroblastoma in the right suprarenal region, with widespread metastatic infiltration in the skeleton

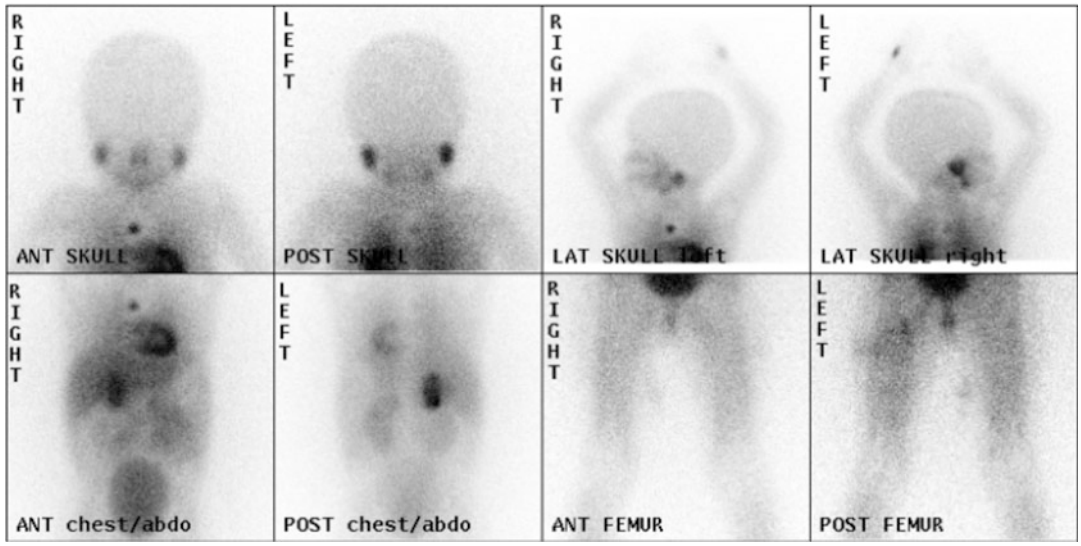

Fig. 12 [^{123}I]MIBG scan at the end of induction chemotherapy: there has been an excellent response, with resolution of all the previously demonstrated metastatic lesions, with the exception of a lesion in the manubrium of the sternum

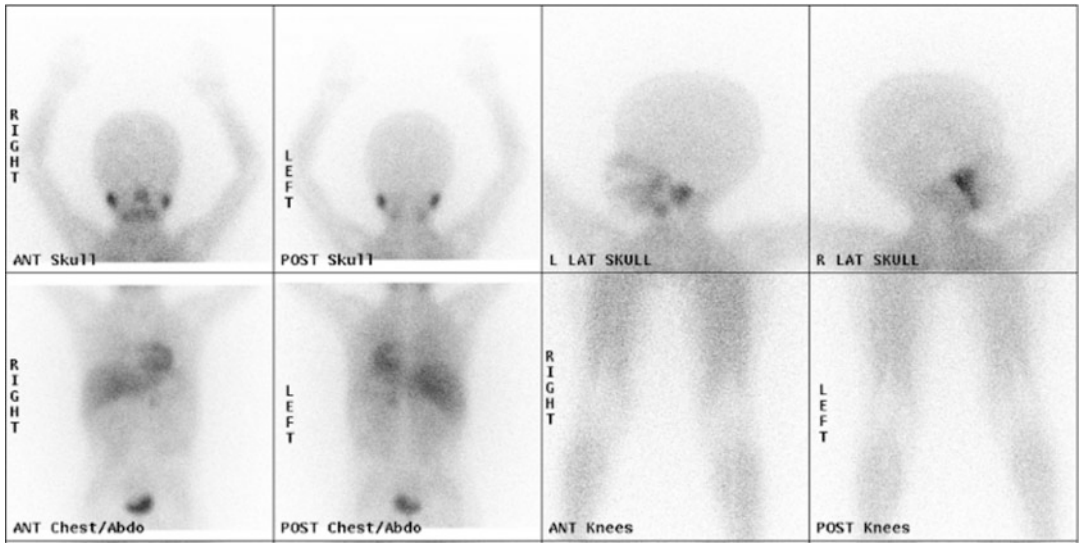

Fig. 13 [^{123}I]MIBG scan after high-dose chemotherapy: there is resolution of the previously seen metastatic lesion in the manubrium of the sternum; normal findings elsewhere. Complete remission

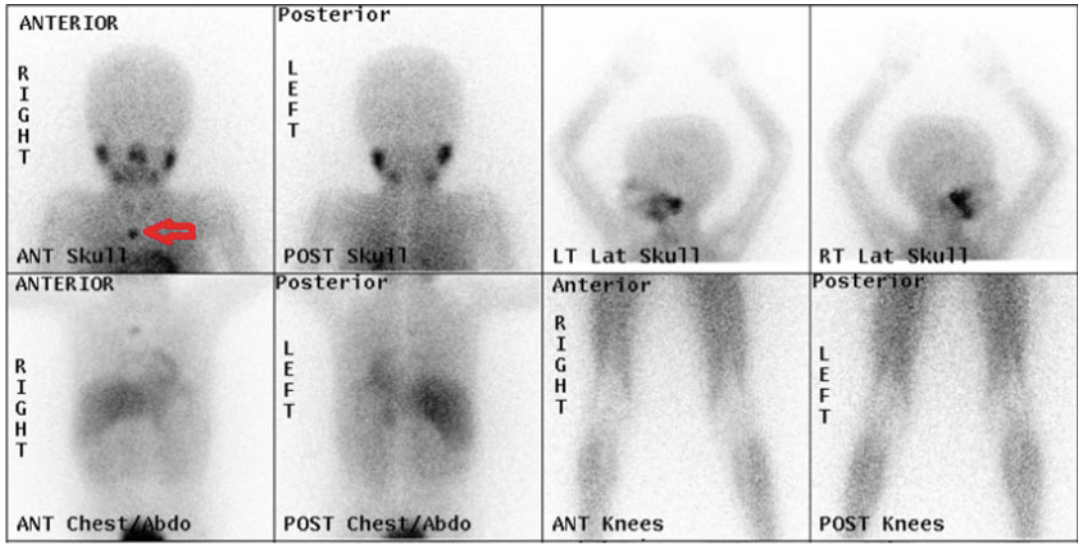

Fig. 14 [^{123}I]MIBG at relapse: a focal area of intense [^{123}I]MIBG uptake is seen in the manubrium of the sternum, exactly at the same site of the previously demonstrated disease

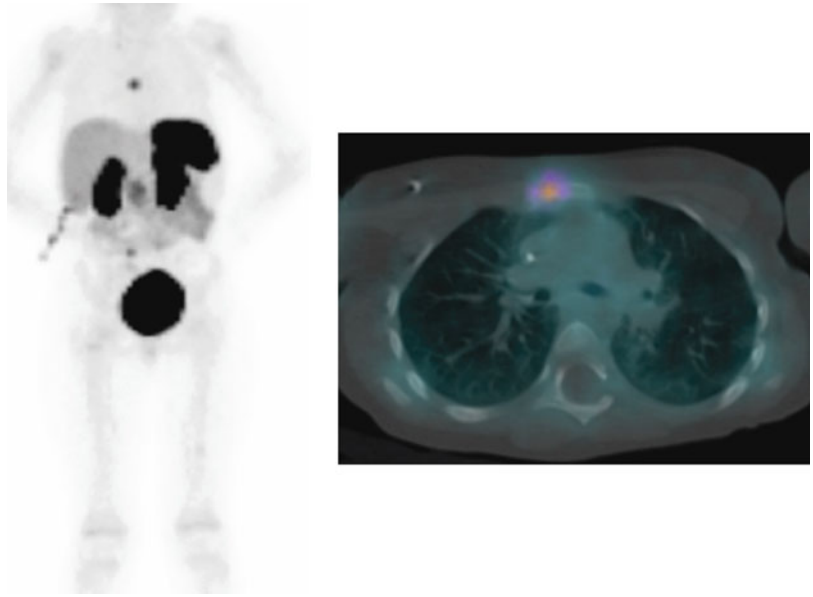

Fig. 15 ^{68}Ga-DOTATATE PET/CT scan showing highly increased tracer uptake in the manubrium of the sternum, corresponding to the abnormal [^{123}I]MIBG uptake (Images courtesy of Dr J Bomanji, Institute of Nuclear Medicine, University College London Hospital)

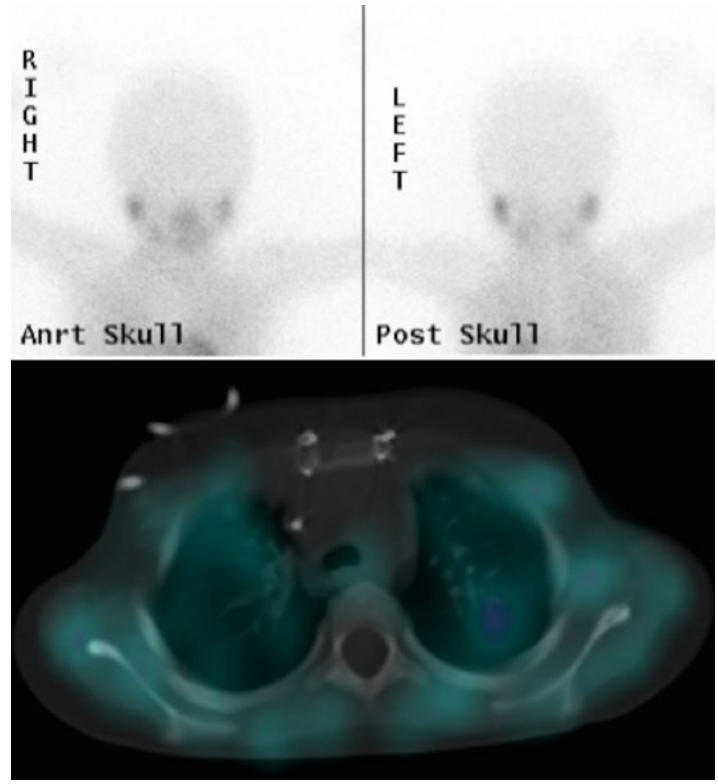

Fig. 16 [^{123}I]MIBG scan with SPECT/CT after excision biopsy: no evidence of residual abnormal [^{123}I]MIBG uptake in the sternum or elsewhere. Complete remission

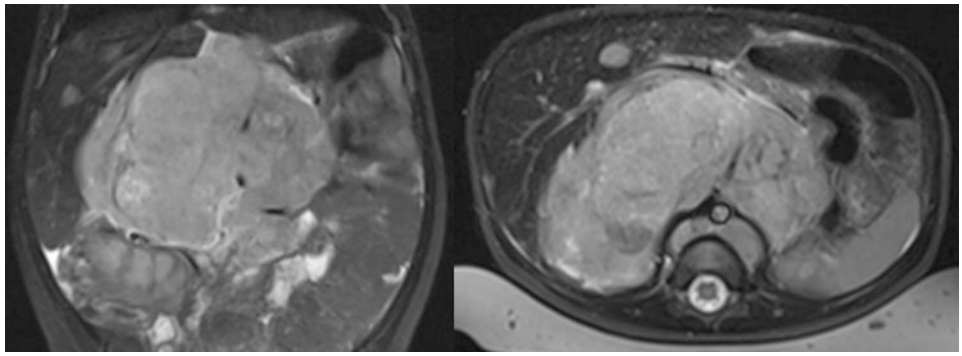

Fig. 17 MRI scan at diagnosis, STIR coronal (*left panel*) and T2 axial view (*right panel*): there is a large central abdominal mass lesion, measuring 8 × 11 × 5 cm, encasing the entire splanchnic circulation, extending into the retrocrural space bilaterally, and displacing the right kidney inferiorly. There are multiple liver metastases

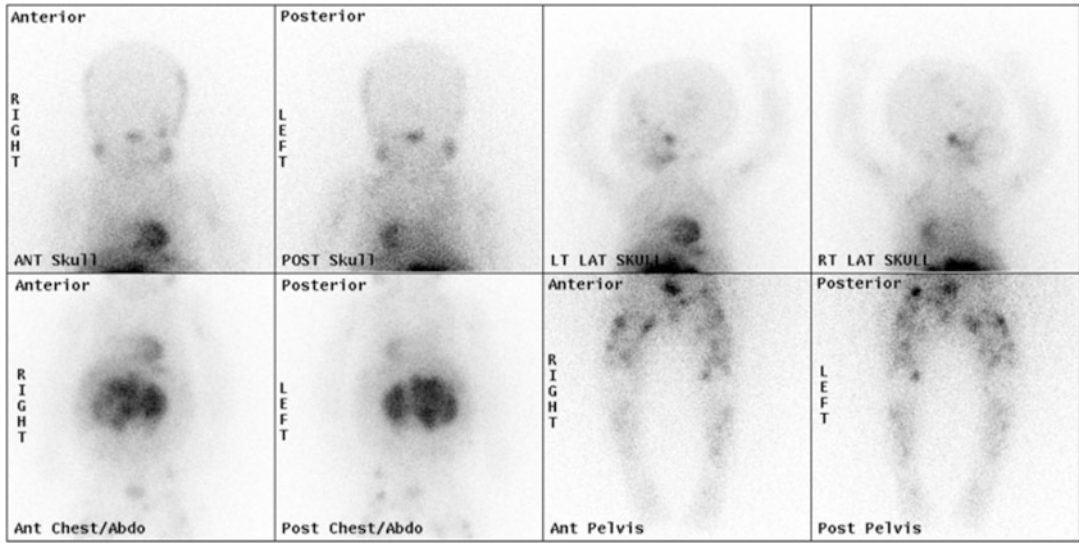

Fig. 18 [^{123}I]MIBG scan at diagnosis (planar images): the primary neuroblastoma shows intense [^{123}I]MIBG uptake. There are multiple skeletal metastases in the skull vault, left orbital region, base of the skull, both humeral shafts, both femora and tibiae. Some of the metastatic liver deposits show [^{123}I]MIBG uptake. There are also numerous skin nodules in the lower limbs

Teaching Points

The [^{123}I]MIBG scan show localized disease; however, low-grade but definite bone marrow metastatic infiltration was present, demonstrated on both right and left bone marrow trephines. Bone marrow infiltration cannot be excluded on an MIBG scan that shows localized disease. Bone marrow trephines are always necessary as a staging investigation.

Neuroblastoma: Case No. 7

Presentation

A two-year-old boy, presenting to the local hospital with a palpable abdominal mass, abdominal distension, constipation, reduced appetite, and general lethargy. An abdominal ultrasound confirmed a 12 × 6 cm mass, arising presumably from the

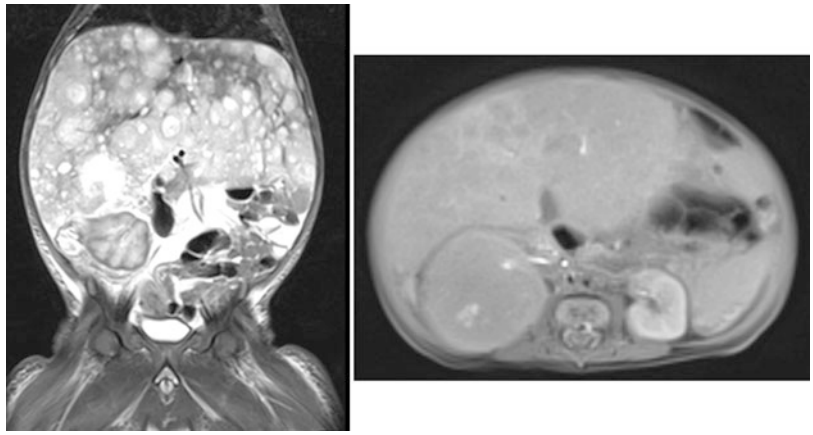

Fig. 19 MRI scan at diagnosis, STIR coronal image, and T1 axial scan: there is a right adrenal mass lesion measuring 4.4 × 4.7 × 6.1 cm. The liver is enlarged with multiple nodules of variable size scattered in both lobes, which show peripheral enhancement after i.v. contrast. No abdominal lymphadenopathy. No ascites. Appearances are suggestive of a right adrenal neuroblastoma with multiple liver metastatic deposits (likely stage IVs on MRI)

right kidney, along with central abdominal lymphadenopathy. Therefore a CT scan was performed: this showed a large partly calcified suprarenal mass lesion which invaded the right kidney and extended across the retroperitoneum. The aorta was encased by tumor. The mass extended from the right suprarenal position to the aortic bifurcation, amounting to a craniocaudal dimension of at least 16 cm. There was a 2-cm left supraclavicular calcified lump in keeping with a metastasis. Percutaneous biopsy result showed a poorly differentiated neuroblastoma with amplification of the MYCN oncogene and chromosomal abnormalities (high risk).

Findings

The [^{123}I]MIBG scan disclosed a large mass lesion with heterogeneous tracer uptake, extending from the right side of the abdomen into the retroperitoneum medially and inferiorly and crossing the midline. Moreover, a focal area of increased tracer uptake, compatible with a metastatic left supraclavicular lymphadenopathy, was found (Fig. 24). MRI showed a 11 × 8 × 8 cm heterogeneous right suprarenal mass invading the right kidney and encasing the upper abdominal vessels and both renal arteries and the involvement of multiple lymph nodes (Fig. 25).

Following completion of dose-intensive induction chemotherapy (rapid COJEC), MRI showed a residual 6-cm mass lesion in the right suprarenal region (Fig. 26). The [^{123}I]MIBG scan resulted negative (Fig. 27).

Management

The residual right adrenal mass was surgically resected. No viable neuroblastoma was demonstrated within the right adrenal mass lesion, which showed necrosis and post-chemotherapy changes. However, within a resected surrounding lymph node, there was a nodule of differentiating and viable neuroblastoma; other nodules with post-chemotherapy changes contained scattered differentiating neuroblastoma cells.

Teaching Point

An MIBG negative primary neuroblastoma following induction chemotherapy cannot exclude residual viable neuroblastoma cells.

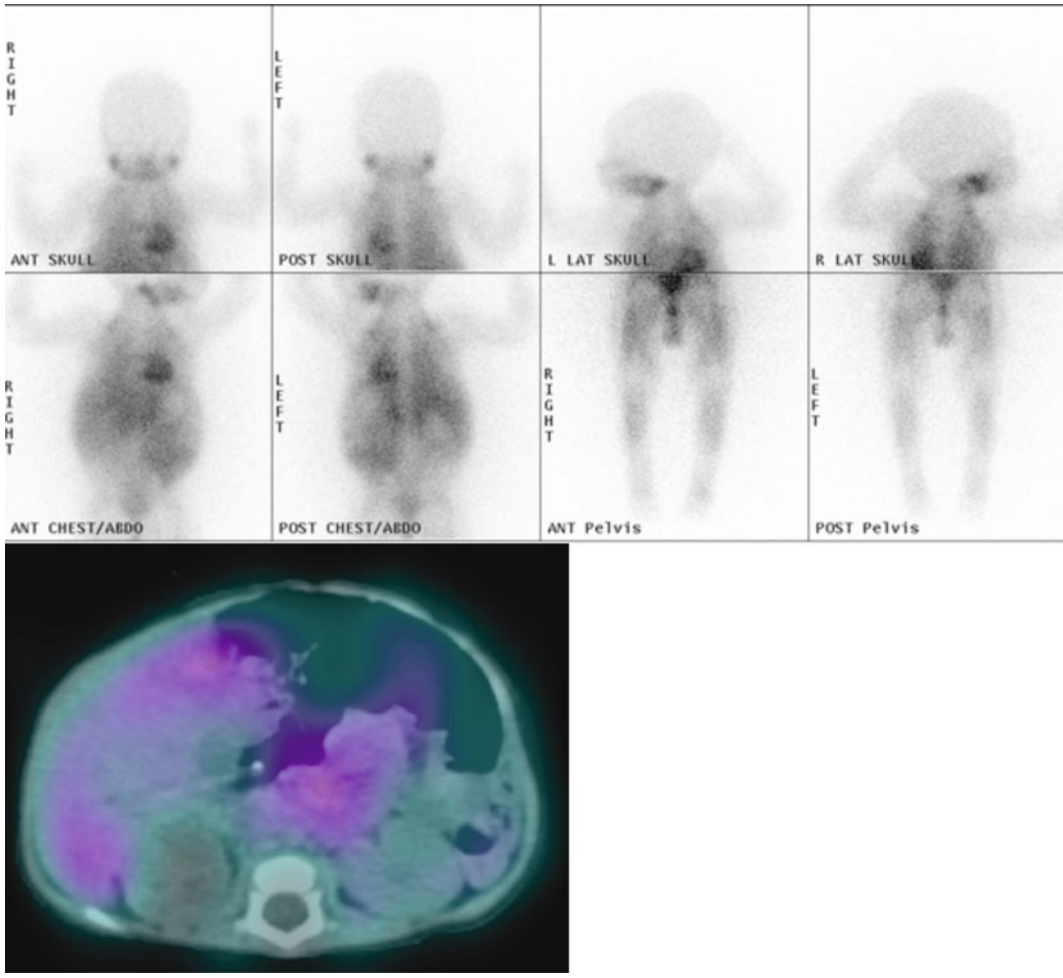

Fig. 20 [^{123}I]MIBG at diagnosis: the right adrenal primary tumor is not [^{123}I]MIBG avid. The liver is enlarged. However, it only shows background activity, with no evidence of significantly increased tracer uptake. The findings are compatible with an [^{123}I]MIBG negative neuroblastoma; the metastatic lesions are also [^{123}I]MIBG negative

Neuroblastoma: Case No. 8

Presentation

An eight-year-old boy, presenting to the local hospital with a 2-week history of right-sided flank pain and constipation, associated with intermittent fevers. In addition, he experienced night sweats, poor appetite, and increasing lethargy.

Findings

An ultrasound and an MRI at the local hospital demonstrated a right-sided abdominal mass (Fig. 28). Biopsy of the mass lesion showed a differentiating neuroblastoma. Molecular biology showed a non-amplified MYCN and chromosomal abnormalities. Staging was completed with [^{123}I]MIBG (Fig. 29).

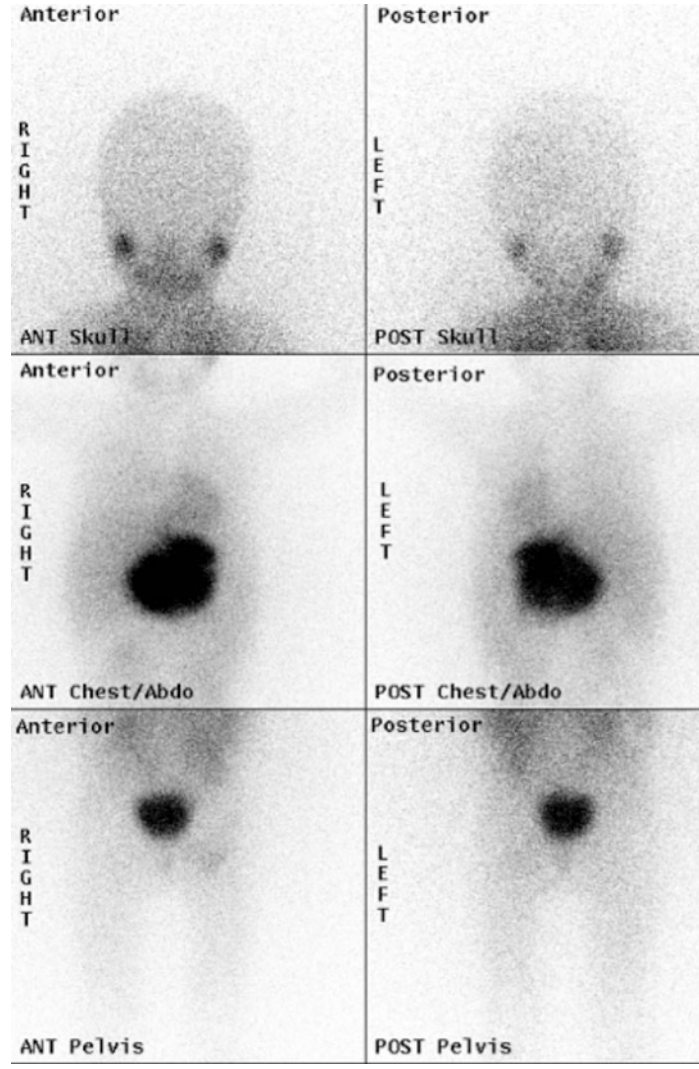

Fig. 21 [^{123}I]MIBG at diagnosis: there is a highly [^{123}I]MIBG avid mass lesion in the mid-upper abdomen, with no evidence of regional or distant metastatic spread

Chemotherapy based on carboplatin and etoposide was started. At the end of chemotherapy, the tumor was resected, and histopathology confirmed a differentiating neuroblastoma. Cis-retinoic acid was then administered for 6 months. [^{123}I]MIBG at the end of treatment showed a soft tissue nodule on the retrocaval area and is suspicious for recurrent disease within a retrocaval lymph node (Fig. 30). MRI confirmed the presence of a retrocaval area of moderately restricted diffusion and heterogeneous enhancement (Fig. 31).

Management

The nodule was surgically excised and it was confirmed to represent a retrocaval metastatic lymph node. In addition, the child was referred

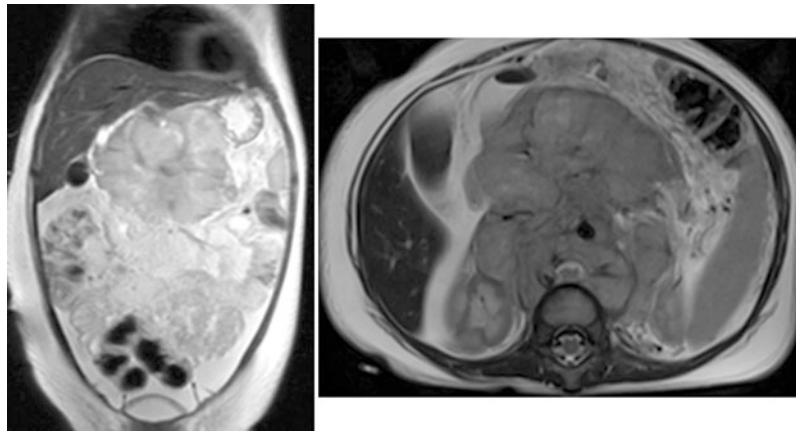

Fig. 22 MRI scan at diagnosis: there is a retroperitoneal mass lesion in the upper abdomen measuring approximately $8.3 \times 8.7 \times 9$ cm. It is centered in the retroperitoneum and involves the head of the pancreas and the majority of the body. The common bile duct is compressed by the mass, and there is common bile duct and intrahepatic ductal dilatation. There is a retrocrural component extending to T9. A further component extends to the porta hepatis but does not infiltrate the liver. There is significant abdominal pelvic ascites and subcutaneous fluid. No discrete bony lesion demonstrated

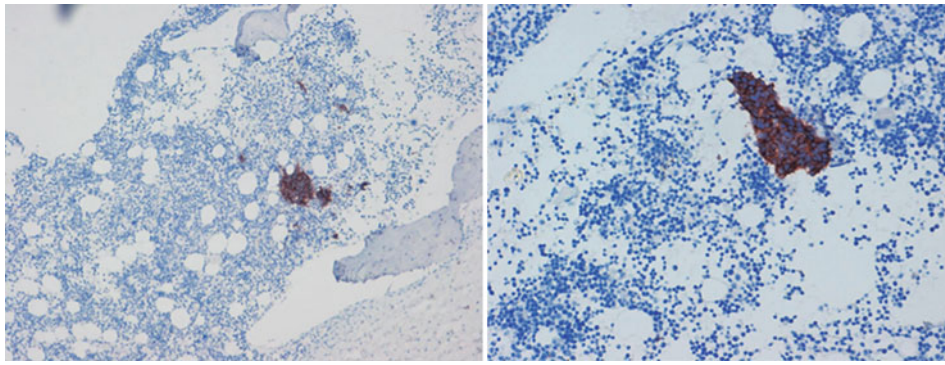

Fig. 23 Bone marrow trephines: there are small scattered groups of abnormal cells, positive for MAP2, NSE, and synaptophysin. These features are those of metastatic neuroblastoma

for radiotherapy to the para-aortic lymph nodes and the original tumor bed.

Teaching Point

SPECT/CT was critical in raising the suspicion of a focal area of recurrence. The [^{123}I]MIBG scan with SPECT/CT in neuroblastoma is now standard of care, especially for lesions deep in the abdomen/pelvis.

Neuroblastoma: Case No. 9

Presentation

A 9-month-old girl presented with bilateral periorbital ecchymosis, right side exophthalmos, and abdominal distension.

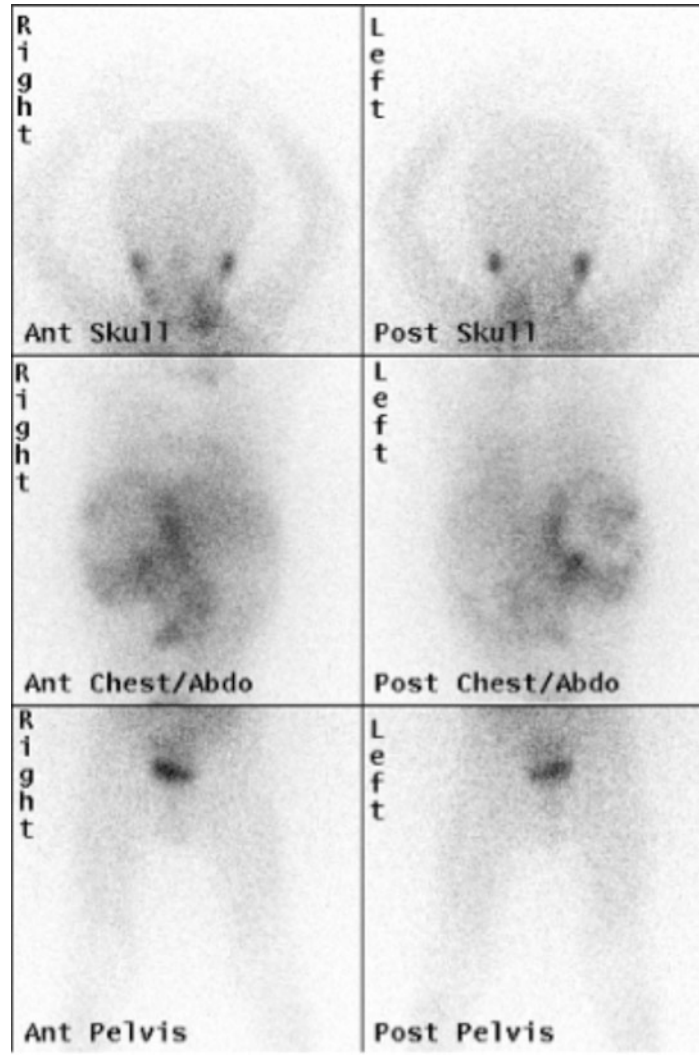

Fig. 24 [^{123}I]MIBG at diagnosis: there is a large mass lesion with heterogeneous tracer uptake, extending from the right side of the abdomen into the retroperitoneum medially and inferiorly and crossing the midline. There is a focal area of increased tracer uptake in the left supraclavicular region, compatible with a metastatic lymphadenopathy. No abnormal tracer uptake noted in the skeleton

Findings

CT revealed a renal mass (8 × 8 cm), retroperitoneal lymphadenopathy, as well as multiple hepatic and pulmonary lesions. CT of the head showed widespread osseous metastases and right exophthalmus. Biopsy confirmed neuroblastoma (stage IV). [^{123}I]MIBG planar and SPECT/CT images (Fig. 32) show a large partially calcified left abdominal mass with pathological radiopharmaceutical uptake, representing the site of primary tumor of adrenal origin. Abnormal foci of [^{123}I]MIBG uptake are present in both lobes of the liver, corresponding to hepatic metastasis. Multiple foci of pathological uptake in the axial and the appendicular skeleton are also seen. Bilateral lung nodules do not show focal radiotracer accumulation.

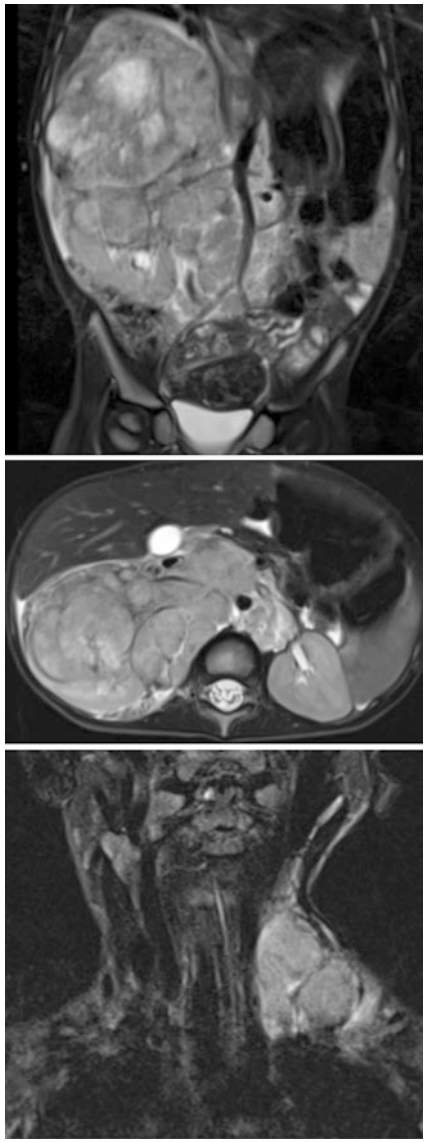

Fig. 25 MRI of the abdomen, coronal STIR (*top*), and axial T2-weighted (*middle*) images. There is a 11 × 8 × 8 cm heterogeneous right suprarenal mass invading the right kidney and encasing the upper abdominal vessels and both renal arteries. The IVC is patent but displaced anteriorly. No intraspinal invasion. There is a left-sided conglomerate lymph node measuring 3.5 × 1.9 cm. There is evidence of retrocrural disease. MRI of the neck (coronal STIR *bottom*) shows left supraclavicular lymphadenopathies

As a part of initial staging [^{18}F]FDG PET/CT was performed: images demonstrate low [^{18}F]FDG uptake in the bone marrow of the pelvis and distal femurs and proximal tibiae (Fig. 33). The known abdominal mass and liver metastases do not show abnormal uptake. Bone marrow involvement was confirmed by bone marrow biopsies that revealed the presence of neuroblastoma without *MYC*-gene amplification.

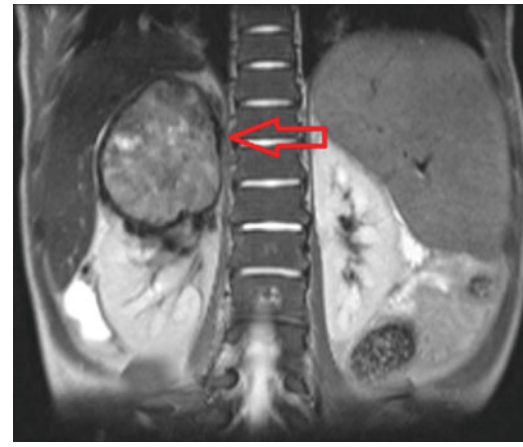

Fig. 26 Abdominal MRI after induction chemotherapy, T2-based sequence, coronal view: there is a residual mass lesion in the right suprarenal region, measuring 6 cm in maximum axial dimension

Follow-Up

The patient was treated with neoadjuvant chemotherapy and surgery (left adrenalectomy and retroperitoneal lymphadenectomy). Follow-up evaluation after adjuvant chemotherapy showed stable disease. [^{123}I]MIBG scan demonstrates abnormal uptake in the axial and the appendicular skeleton and in the liver (Fig. 34). This case demonstrates that [^{18}F]FDG PET/CT is not as sensitive as [^{123}I]MIBG imaging in many patients with neuroblastoma.

Ewing Sarcoma

Presentation

An eighteen-year-old patient with heaviness at the left inguinal region and left sciatica during prolonged sitting. After 3 months occasional finding of left inguinal swelling, of hard consistence,

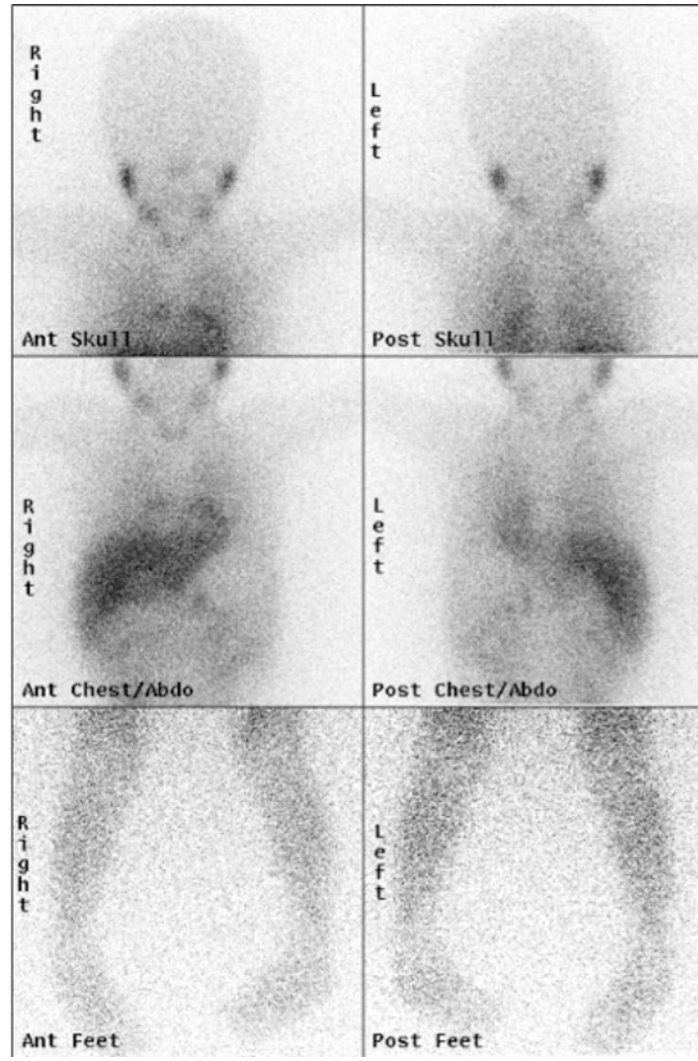

Fig. 27 [^{123}I]MIBG after induction chemotherapy: there is no evidence of abnormal tracer uptake. In particular, the residual mass lesion demonstrated on MRI is MIBG negative

painless nor tender on palpation. On the advice of the general practitioner, an abdominal and pelvic ceCT was performed showing the presence of a pelvic mass (17 × 10 × 15 cm) with parenchymatous structure, infiltrating the viscera and pelvic walls, with manifestation within the inguinal canal and the root of the left thigh. The left pubic bone branch had increased density, probably with reactive meaning. MRI confirmed the large mass showing maximum diameters in the pelvis and in the left thigh, with a global extension of about 24 cm. Biopsy of the left inguinal mass drove to the diagnosis of an Ewing sarcoma CD99 positive.

Findings

The mass presented inhomogeneous hypermetabolic activity, as disclosed by [^{18}F]FDG PET/CT (Fig. 35). Neoadjuvant chemotherapy was undertaken. PET/CT after chemotherapy showed a net response of the mass confirmed also by MRI. External beam radiotherapy of the pelvic mass (50 Gy) and other cycles of chemotherapy were then performed. CT of the lungs and PET/CT became completely negative. The patient underwent surgery with the exeresis of the pelvic mass along with the resection of the left iliopubic and ischium-pubic branches. At that level,

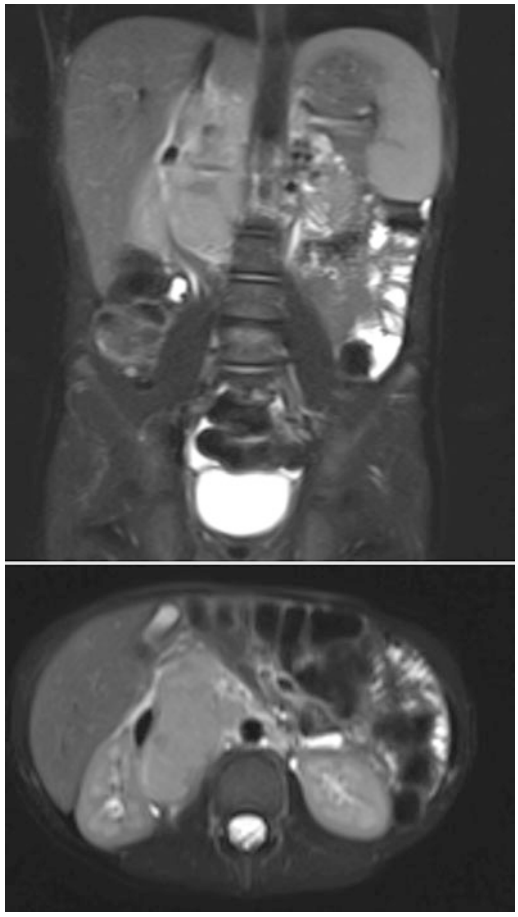

Fig. 28 (**a**, **b**) MRI at diagnosis, coronal and axial HASTE T2-based images: there is a mass lesion in the aortocaval area displacing the IVC to the *right*. The mass extends to the level of the porta hepatis, displacing and abutting the hepatic artery. The largest component of the mass is at the right renal hilum, with the left renal vein and the right renal artery encased by tumor. The infiltrating nature of this mass lesion favors a neuroblastic tumor

postsurgery PET/CT showed an area of hyperactivity with craniocaudal development and central hypoactivity, referred in the first hypothesis to surgical outcomes. Moreover, some hypermetabolic lymphadenopathies were seen in the groin and the right external iliac region (Fig. 36). Within the lungs PET/CT indicates the presence of a paracardiac hypermetabolic nodule in the lingula. CT demonstrated other micronodules within the lungs consistent with secondary lesions (Fig. 37).

Follow-Up

The patient underwent high-dose chemotherapy which determined the disappearance of lung disease. After 1 year the patient is still disease free.

Teaching Point

[^{18}F]FDG PET/CT is an effective tool for monitoring the efficacy of therapy. However, false-positive findings can be due to inflammatory or infectious processes, frequently occurring after surgery or radiotherapy. Since the lungs are a frequent site of metastasis of all sarcomas, [^{18}F]FDG PET/CT must be performed along with a diagnostic CT which is more sensitive in detecting secondary micronodules.

Lymphoma: Case No. 1

Presentation

A 14-year-old boy with pain and tenderness in the distal portion of the right femur. He underwent a MR scan of the right knee that showed an aggressive bone lesion with initial infiltration of soft tissues and a popliteal lymphadenopathy, that needed a differential diagnosis between lymphoma and sarcoma (Fig. 38).

Findings

A total body ceCT was performed which shows a not pathological enlargement of the thymus. Then [^{18}F]FDG PET/CT was performed that highlighted a focal hypermetabolism glucose within the lesion of the distal femur (SUV_{max} 8.5) and the right wing thymus (SUV_{max} 19.2) (Fig. 39).

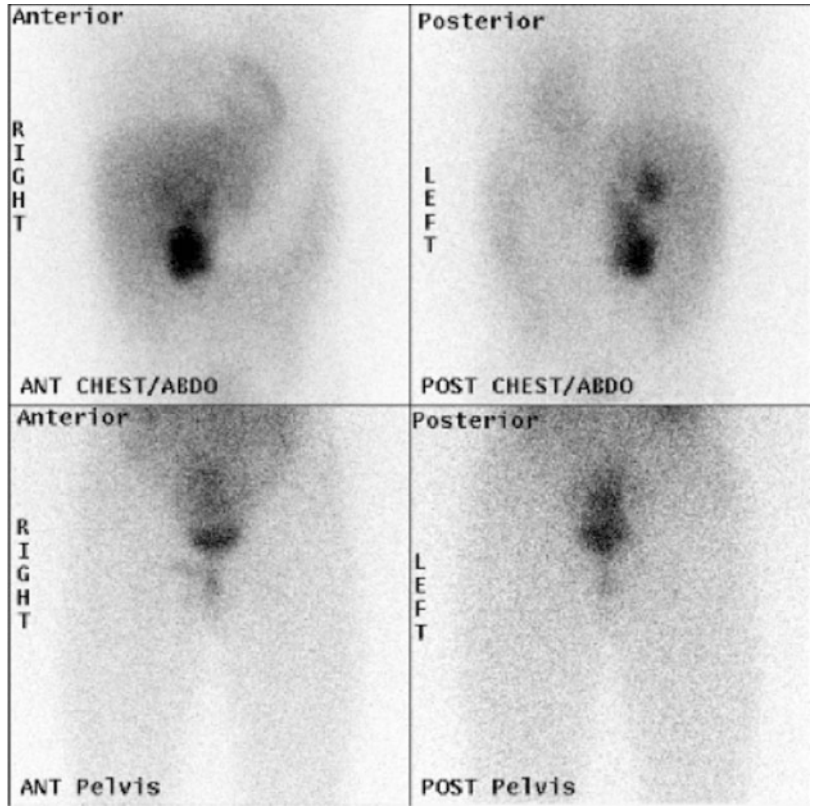

Fig. 29 [^{123}I]MIBG at diagnosis: the mass lesion demonstrated on MRI shows intense, [^{123}I]MIBG uptake. No evidence of regional or distant metastatic spread. This finding, together with the MRI and the molecular biology, makes an intermediate-risk neuroblastoma

The reassessment of the ceCT stated the presence of an anterior mediastinal mass cleaving to the right portion of the thymus. Since bone marrow biopsy resulted negative, an excisional biopsy of the lesion of the distal portion of the right femur was performed. Pathology reported lymphoma derived from peripheral B lymphocytes, large cells, and bone primitive. Chemotherapy according to the NCCN protocol for the diffuse large B-cell lymphoma (DLBCL) at stage IV was started. At the interim reassessment after two cycles, PET/CT showed complete metabolic response of the anterior mediastinum lesion, almost complete resolution of the hypermetabolic lesion of the femur (Fig. 40).

Follow-Up

At the end of the treatment, MRI showed net reduction of the intraosseous extension of the lesion, normalization of MR signal, and the reduction of contrastographic enhancement (Fig. 41).

Teaching Point

PET/CT, by identifying the hypermetabolic mass within the mediastinum, oriented the diagnosis to lymphoma and contributed to the disease staging. Moreover, the early response during chemotherapy showed by PET/CT predicted the response at the end of treatment.

Lymphoma: Case No. 2

Case contributed by: F. Reyneke, M. Sathekge Nuclear Medicine, University of Pretoria, and Steve Biko Academic Hospital, Pretoria, South Africa

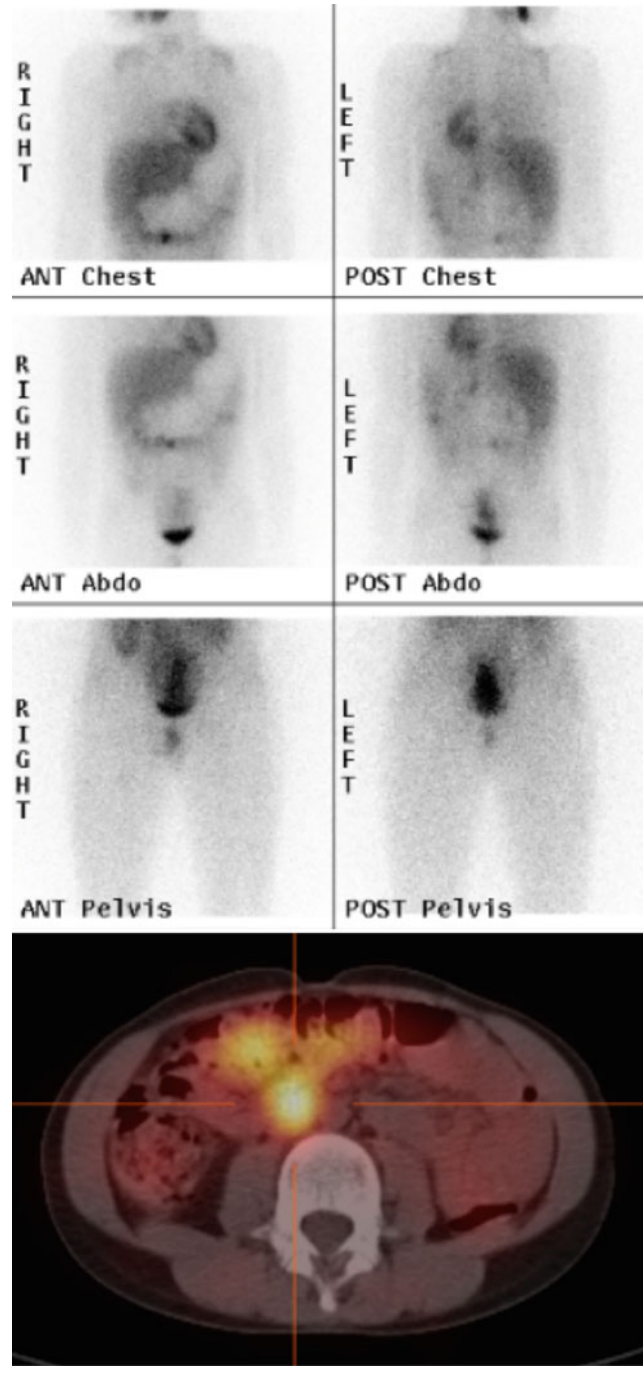

Fig. 30 (**a**, **b**) [^{123}I]MIBG at the end of treatment. The planar images (**a**) show a focal area of more prominent tracer uptake in the region of the transverse colon on the midline. On SPECT/CT (**b**), this localizes to a soft tissue nodule on the retrocaval area and is suspicious for recurrent disease within a retrocaval lymph node

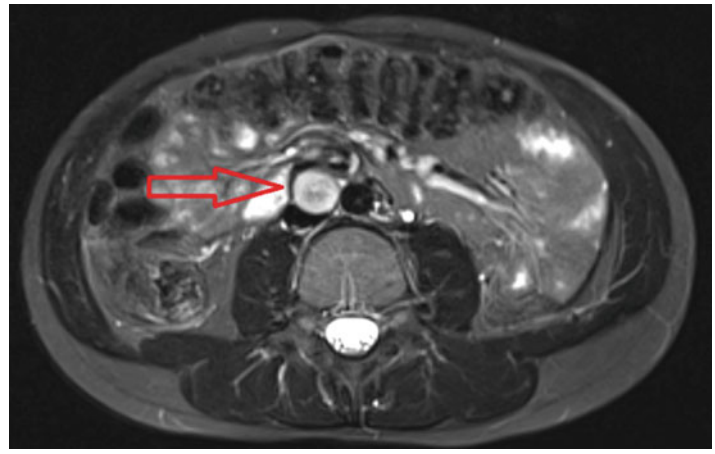

Fig. 31 MRI following suspicion of relapse, axial STIR image: there is a 1.5 × 1.5 cm area of moderately restricted diffusion and heterogeneous enhancement: this corresponds to the area of abnormality demonstrated on [^{123}I]MIBG SPECT/CT. The area of recurrence is inferior to the previously located tumor and was not present previously

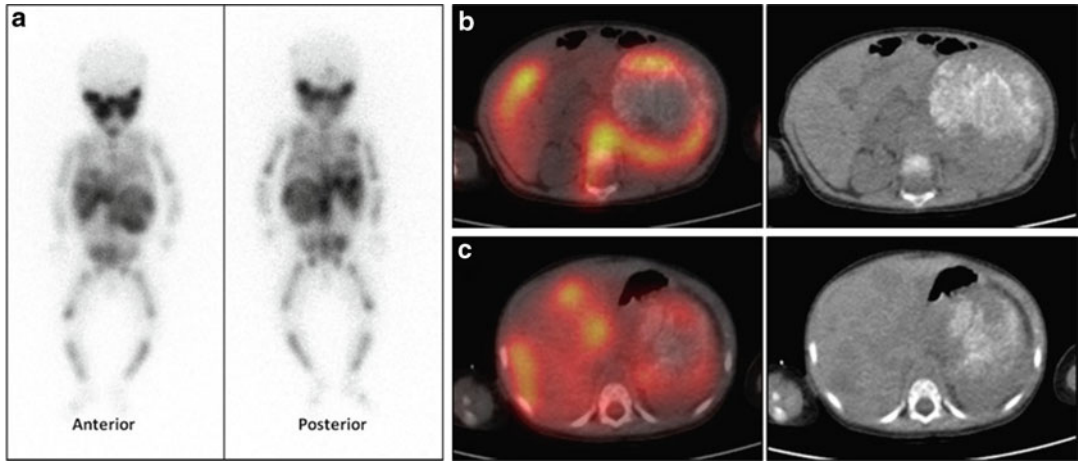

Fig. 32 [^{123}I]MIBG scan. (**a**) Whole body image (anterior and posterior view) shows increased radiotracer uptake in the axial and appendicular skeleton. (**b**) Axial SPECT/CT image (fused image in the *left panel* and CT image in the *right panel*) of large partially calcified left abdominal mass. (**c**) Axial SPECT/CT image (fused image in the *left panel*, CT image in the *right panel*) of hepatic metastasis

Presentation

A 10-year-old boy presented with a painless mass in the left side of his neck.

Findings

A biopsy taken from a left cervical lymph node revealed classical Hodgkin's lymphoma (mixed cellularity subtype).

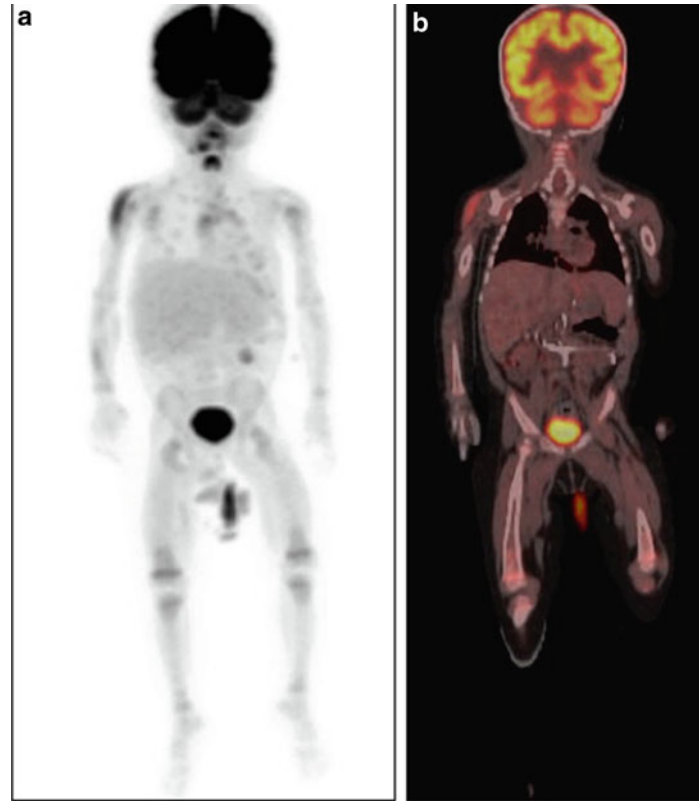

Fig. 33 (**a**) [^{18}F]FDG MIP image demonstrates low uptake in the bone marrow of the pelvis and distal femurs and proximal tibiae. (**b**) [^{18}F]FDG PET/?CT fused coronal image: no abnormal uptake is seen in the known abdominal tumor or in the liver

[^{18}F]FDG PET/CT for initial staging showed a conglomerate of lymph nodes in the left cervical region (involving all the lymph node groups) extending into the infraclavicular region – SUV_{max} 10.5 (Figs. 42 and 43).

Follow-Up

Following chemotherapy, [^{18}F]FDG PET/CT was repeated to monitor response during therapy. Increased [^{18}F]FDG uptake was still noted in cervical lymph nodes in levels II, III, and IV (SUV_{max} 8.16) with significant reduction in size demonstrating a good response to therapy (Figs. 44 and 45).

Teaching Point

[^{18}F]FDG PET/CT is highly sensitive in the detection of Hodgkin's lymphoma and can also accurately evaluate the effectiveness of therapy. This should be done 6–8 weeks after therapy to minimize false-negative and false-positive results.

Lymphoma: Case No. 3

Case contributed by: T. Boshomane, M. Sathekge Nuclear Medicine, University of Pretoria, and Steve Biko Academic Hospital, Pretoria, South Africa

Presentation

A fifteen-year-old girl with histologically confirmed lymphoma (Hodgkin's, clinical stage II with no other risk factors) and treated with chemotherapy (ABVD).

She presented to her oncologist >3 months post-chemotherapy complaining of unintentional weight loss and increasing fatigue.

Fig. 34 [^{123}I]MIBG study (whole body image) performed after chemotherapy shows the persistence of pathological uptake in the skeleton and liver

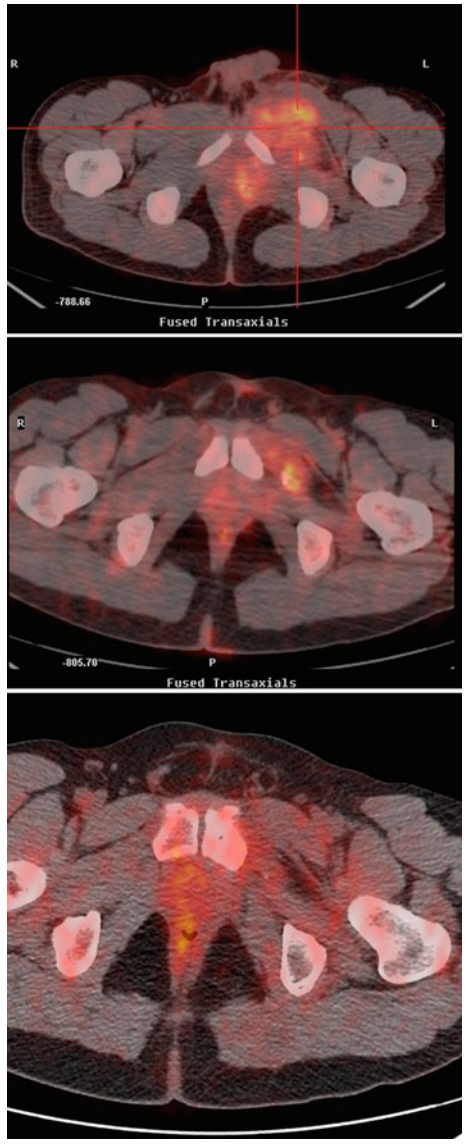

Fig. 35 [^{18}F]FDG PET/?CT scans performed at staging (*top panel*), after chemotherapy (*middle panel*) and after chemoradiotherapy (*bottom panel*), show the progressive response of the left inguinal?mass

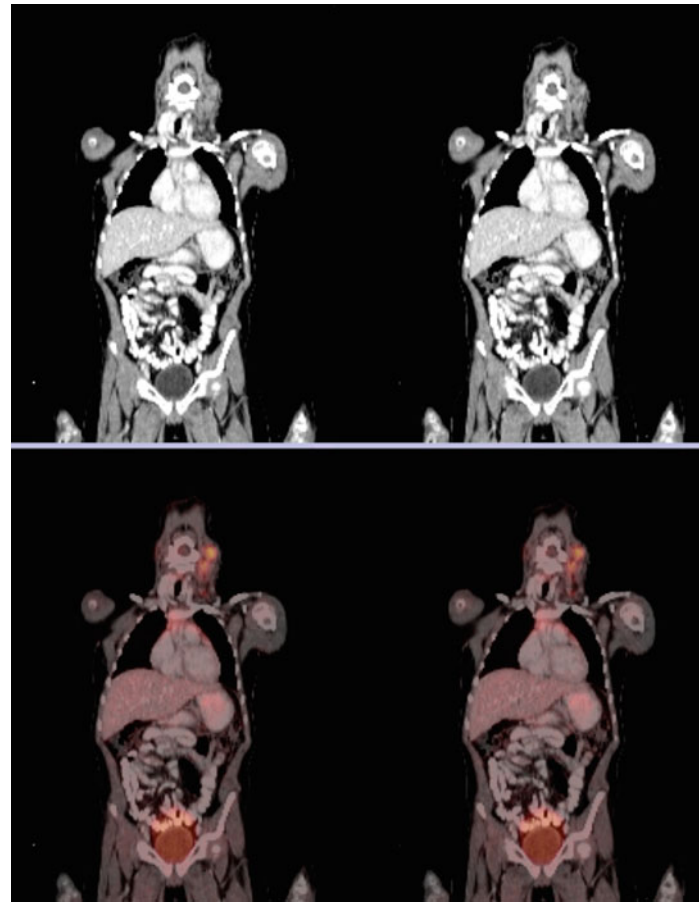

Fig. 44 [^{18}F]FDG PET/?CT coronal images demonstrating residual lymph nodes in the cervical region (reduced SUV_{max} and significant reduction in size compared to previous study)

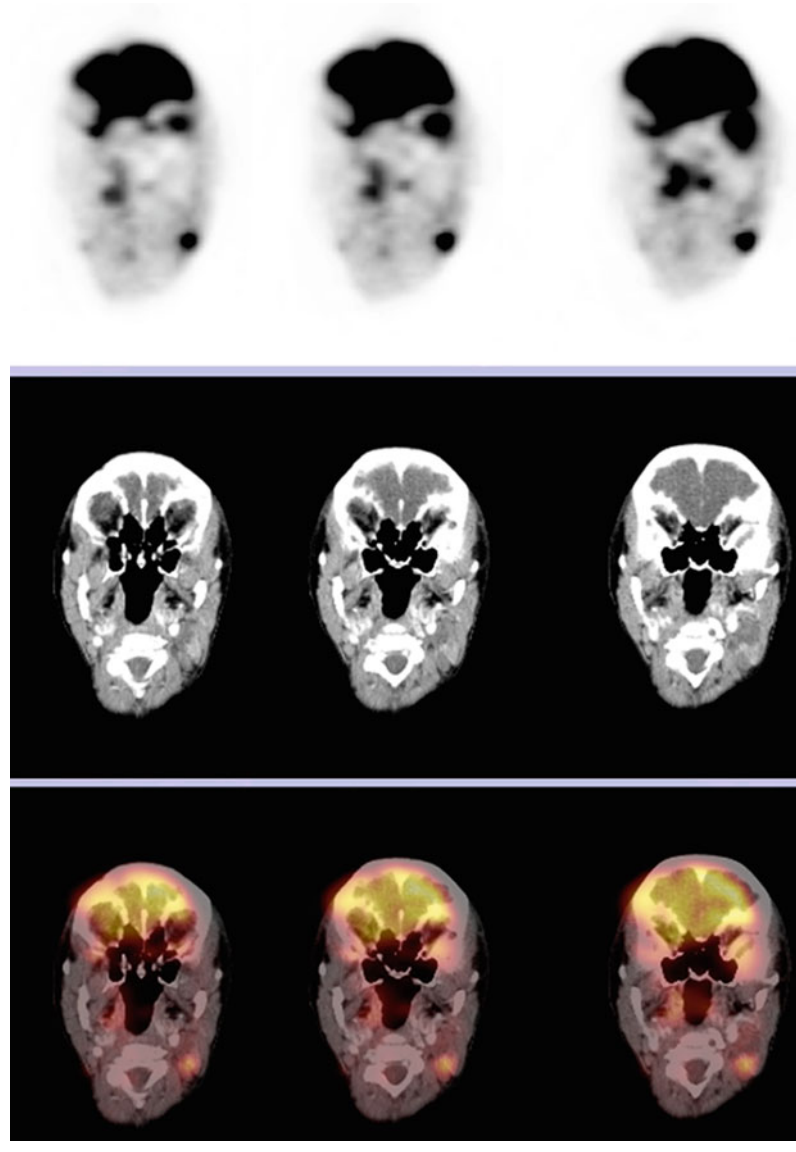

Fig. 45 [^{18}F]FDG PET/?CT axial images demonstrating a good metabolic response to chemotherapy

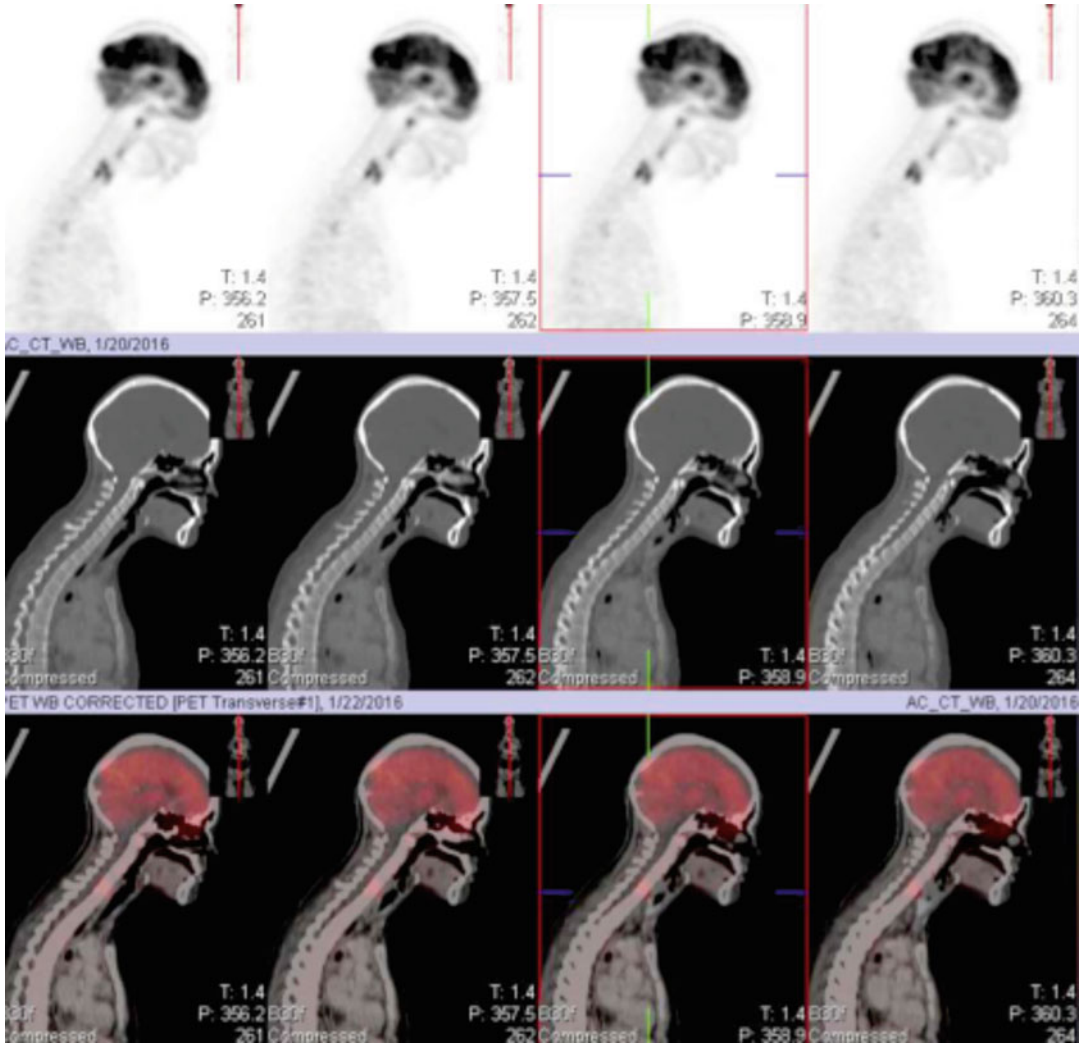

Fig. 46 *Top row*: sagittal images of metabolic activity noted on [^{18}F]FDG PET, which was not appreciated on the CT images (*middle row*). *Bottom row*: fused PET/?CT demonstrating the T2 lesion

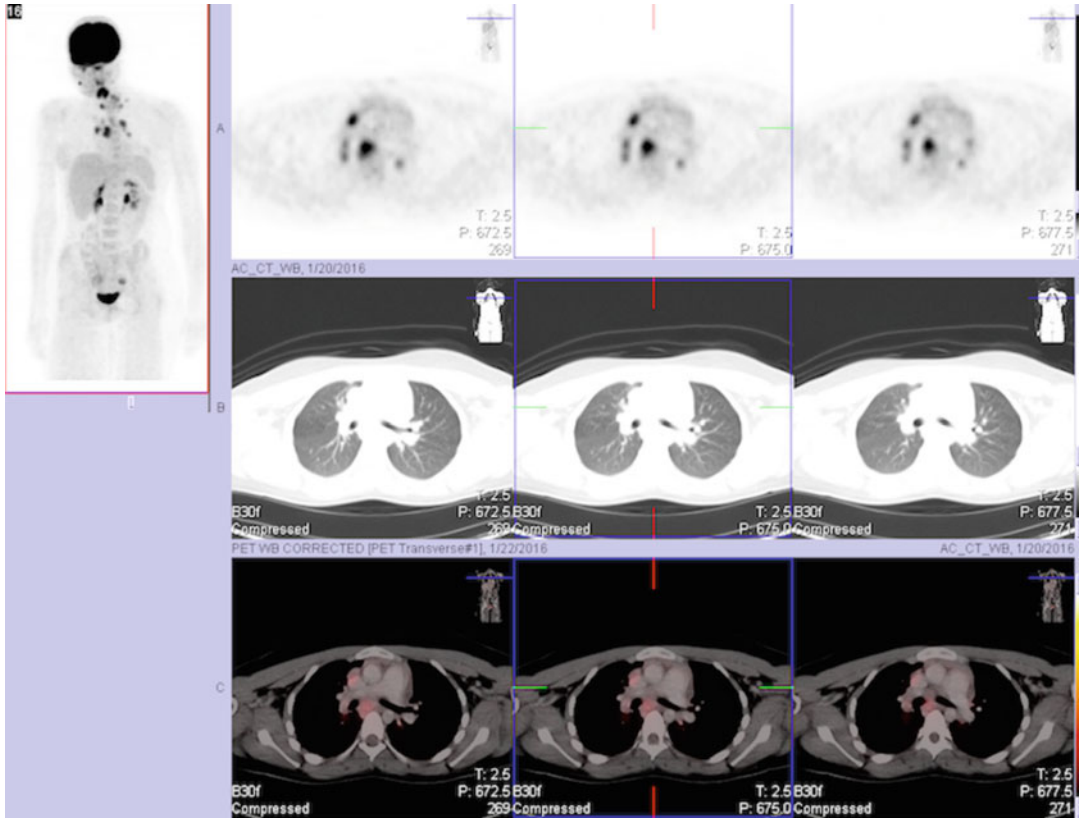

Fig. 47 Axial images. *Top row*: metabolically active mediastinal lymph nodes demonstrated on [^{18}F]FDG PET. *Middle row*: CT images showing the lung fields and mediastinum. *Bottom row*: fused PET/?CT demonstrating the mediastinal lymph nodes. The side image is the MIP images showing the supradiaphragmatic disease but involving bone [adnexal activity was non-?lymphomatous]

Findings

CT noted mediastinal lymphadenopathy (aortopulmonary, carinal, anterior to SVC, and paraoesophageal) with no skeletal changes. [Previously only left cervical lymph nodes were seen].

Fused [^{18}F]FDG PET showed metabolic activity in the mediastinal lymph nodes (SUV_{max}: 9.9 aortopulmonary, 5.9 hilar, 10.0 in the posterior mediastinum) and T2 vertebra (SUV_{max} 8.6) (Figs. 46 and 47).

Teaching Point

Given the high sensitivity of [^{18}F]FDG PET/CT for detecting bone marrow involvement, this case highlights the importance of this modality when available. An invasive procedure is averted as PET detects lymphomatous involvement of the skeleton therefore upstaging the disease. The indication of the PET scan in this study was restaging after chemotherapy.

Introductory Background

Cardiovascular disease is a frequent comorbidity in cancer patients. Ischemia occurring during therapy, especially perioperative ischemia, is a serious event, associated with increased morbidity and mortality (see ▶ Chap. 51, "Imaging the Heart in the Cancer Patient" of this book). Detecting ischemia in patients at intermediate risk of a cardiovascular event is a major indication for myocardial perfusion imaging

in cancer patients. Many patients referred for myocardial perfusion imaging are frail and cannot exercise. These patients usually undergo stress testing with pharmacologic agents. Although pharmacologic stress can be performed with agents that increase myocardial oxygen consumption, such as dobutamine, these agents have largely been replaced by vasodilator agents, such as adenosine (adenosine triphosphate in Japan) or the synthetic adenosine A_{2A} agonist, regadenoson, because of their relative safety. Adenosine infusion or regadenoson administration causes a generalized vasodilatation, often associated with a slight decrease in blood pressure, and may also be accompanied by a pounding sensation in the head and a feeling of abdominal fullness. The coronary vasodilatation during infusion of adenosine (0.14 mg/kg/min) increases coronary blood flow velocity by more than 3.5-fold over baseline [1]. Regadenoson, on the other hand, raises coronary flow about 2.5-fold within approximately 2 min of IV administration, and it remains over twofold increased for about 10 min [2]. Both adenosine and regadenoson also cause vasodilatation of splanchnic blood vessels, increasing splanchnic flow, which in turn increases subdiaphragmatic activity that may interfere with the evaluation of inferior wall perfusion on stress-injected images. To minimize activity in the splanchnic bed, it is helpful to combine pharmacologic vasodilator stress with low-level exercise (if technically and clinically feasible). Walking, even at 1–2 mph with 0% grade, is sufficient to reduce splanchnic perfusion. The following cases illustrate some of the clinical and technical issues that arise in the performance and interpretation of these studies.

Case 1

A 70-year-old man with a 60-pack-year smoking history, chronic obstructive lung disease, dyslipidemia, and a family history of early coronary artery disease was referred for a myocardial perfusion study prior to a Whipple procedure for pancreatic cancer.

Procedure: Rest and stress myocardial perfusion PET/CT scan.

Radiopharmaceutical:

Rest: 9.5 mCi ^{13}N-ammonia IV

Stress 10.9 mCi ^{13}N-ammonia IV (20 min after rest tracer injection)

Technique: A prospectively gated CT was recorded for coronary calcium scoring, followed by a low-dose CT (20 mA) for attenuation correction.^{13}N-ammonia was administered as a bolus IV and gated list-mode data were acquired for 10 min to determine myocardial perfusion and left ventricular function at rest.

A pharmacologic stress test was then performed using regadenoson 0.4 mg IV, administered over 20 s, followed about 30 s later by the administration of the stress dose of ^{13}N-ammonia. Gated list-mode data were acquired for 10 min to determine myocardial perfusion and left ventricular function during vasodilator stress.

Following regadenoson administration, the patient experienced mild chest discomfort, without associated ECG changes. Oxygen saturation (SpO_2) was 98% during the rest acquisition, but decreased to 82% during the episode of chest discomfort. The chest discomfort gradually increased over the next 3 min. Aminophylline 50 mg was administered intravenously to reverse the residual effects of regadenoson. Within 2 min of aminophylline administration, the chest discomfort cleared, and SpO_2 increased to 95%.

Hemodynamics:

Baseline: heart rate (HR) 93 bpm; blood pressure (BP) 151/91 mmHg

Peak stress: HR 96 bpm; BP 148/90 mmHg

Image findings:

Left ventricular size: The left ventricular cavity is dilated at stress compared with rest, suggesting transient ischemic dilatation.

Perfusion: There is a large, moderate-to-severe reduction in perfusion at stress that was not present at rest, consistent with ischemia involving the anterior, lateral, and distal septum (Fig. 1).

Gated images: There is mild hypokinesis of the anterior and lateral walls at stress, which was not seen at rest.

Left ventricular ejection fraction (LVEF): 71% at rest, *decreasing* to 63% at stress.

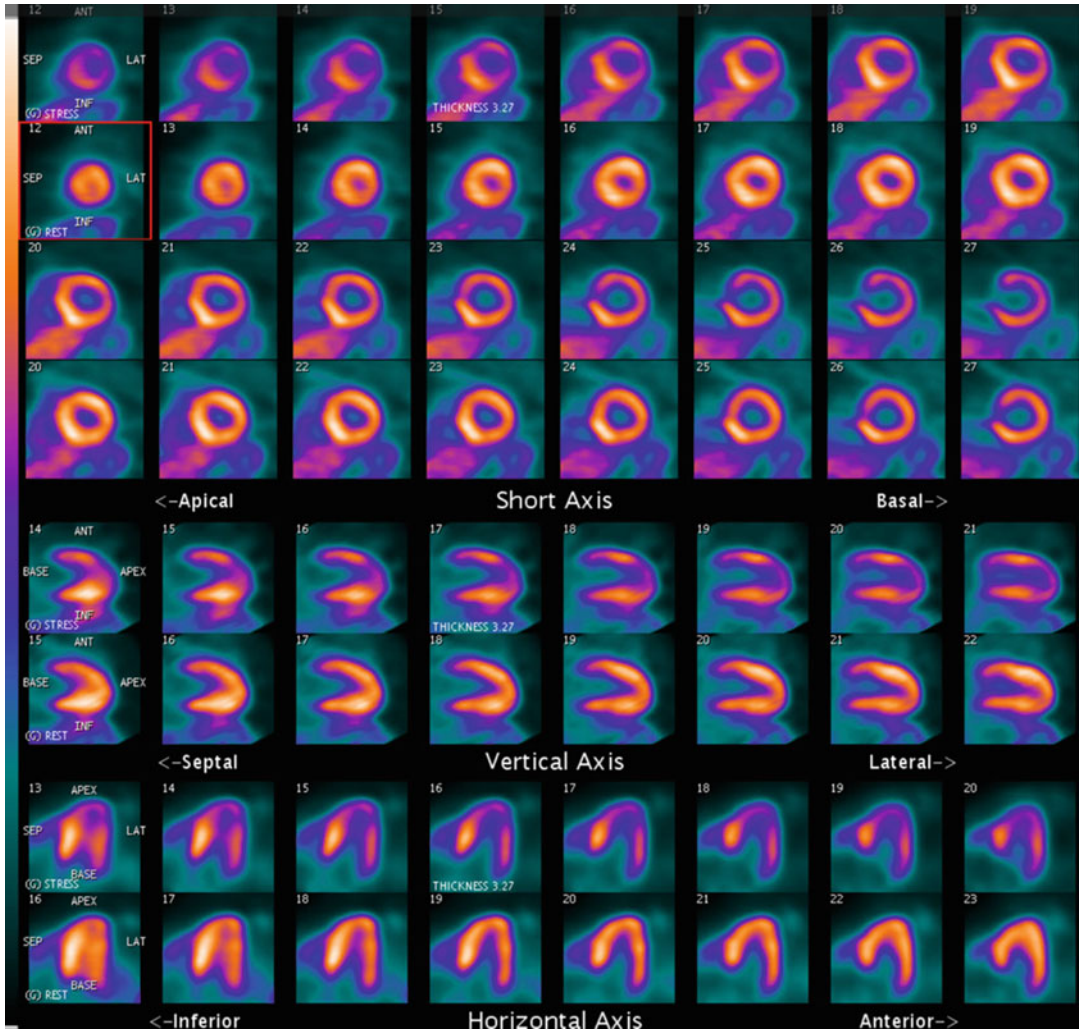

Fig. 1 Summed list-mode images of ^{13}N-ammonia following injection at stress (*upper row*) and at rest (*lower row*) in the short axis, vertical long axis, and horizontal long axis. The stress images demonstrate cavity dilatation, associated with a decline in global ventricular function (LVEF at rest was 71%, decreasing to 63% at stress). Regional perfusion is normal at rest. At stress, there is a significant decrease in perfusion to the distal septum, the entire lateral wall, and the entire anterior wall, suggesting the presence of left main coronary artery disease

Coronary calcium score: 398 (68th percentile).

Impression: Markedly abnormal, high-risk, myocardial perfusion study, consistent with a large area of severe stress-induced ischemia. Findings were discussed with the referring physician.

Comments: The scan demonstrates a pattern of ischemia consistent with a high risk for a coronary event in the following 12 months. This scan indicates a conundrum of care by raising the need for coronary revascularization prior to high-risk cancer surgery. Coronary revascularization performed with percutaneous techniques with a bare metal stent should delay surgery for at least 4–6 weeks or preferably 6 months to minimize the risk of a perioperative coronary event [3, 4]. Recent recommendations suggest that the interval between coronary bypass surgery and elective surgery should be at least 6 weeks. Given the size of the patient's pancreatic cancer, and the fact that the disease was

limited to the location of the mass, the surgeon recommended performing the cancer surgery as expeditiously as possible without prior revascularization. Medical therapy was optimized to maximize pain control and minimize myocardial oxygen demand in the perioperative interval. In light of the patient's known obstructive lung disease, careful titration of the beta blockade is critical. It is helpful to have the perioperative cardiac monitoring managed by both a cardiologist and an experienced anesthesiologist.

Outcome: The patient had a successful Whipple procedure. In spite of the high-risk imaging findings, there were no major acute coronary events during the perioperative interval.

In addition to the specific imaging findings, there were two other indications that the patient was at high risk for a perioperative event:

1. There was a blunted heart rate response following injection of regadenoson [5]. Subjects with <25% increase in heart rate over baseline have an increased risk of cardiac events.
2. There was a decrease in LVEF from rest to stress. Normally, LVEF increases with vasodilator stress on PET/CT myocardial perfusion imaging, where data are recorded immediately after injection of the stress agent [6]. An increase of >5% in LVEF has a high negative predictive value for the presence of triple-vessel or left main coronary artery disease.

Case 2

A 50-year-old man with a family history of accelerated coronary artery disease was referred for myocardial perfusion imaging. His mother died at age 45 of a "heart attack" and a younger sibling died suddenly at age 40. Genetic evaluation of the patient and his immediate family confirmed the diagnosis of homozygous familial hypercholesterolemia, with marked elevation of low-density lipoprotein cholesterol. The patient had sustained a myocardial infarct at age 40. Catheterization at the time of the infarct demonstrated moderate-to-severe stenosis in the left anterior descending artery (LAD), treated with multiple drug-eluting stents. About 1 month before presentation he noted a mass in his left breast. He was referred for evaluation for possible stress-induced myocardial ischemia prior to left breast biopsy and possible mastectomy.

Procedure: Rest and stress PET/CT myocardial perfusion scan.

Radiopharmaceutical:
Rest: 7.2 mCi ^{13}N-ammonia IV
Stress: 12.1 mCi ^{13}N-ammonia (20 min after rest injection)

Technique: Calcium scoring was not performed because of prior stent placement. Low-dose CT (20 mA) was performed for attenuation correction. ^{13}N-ammonia was administered IV, and gated list-mode data were acquired for 10 min to determine myocardial perfusion at rest.

A pharmacologic stress test was then performed using regadenoson 0.4 mg IV over 20 s, followed by the administration of the stress dose of ^{13}N-ammonia. Gated list-mode data were acquired for 10 min to determine myocardial perfusion with vasodilator stress.

Following regadenoson administration, the patient had no symptoms. There were no ST changes on ECG.

Hemodynamics:
Baseline: HR 70 bpm; BP 135/85 mmHg
Peak stress: HR 90 bpm; BP 152/90 mmHg

Image findings:

Left ventricular size: Upper limits of normal at rest and stress.

Perfusion: There is a large, moderate-to-severe reduction in perfusion at rest in the septal, distal anterior, inferior, and lateral walls, extending to the apex. The regions of decreased perfusion are worse at stress, suggesting superimposed ischemia (Fig. 2).

Gated images: There is hypokinesis of the distal inferior and lateral walls and systolic anterior motion of the septum at rest (likely due to the prior infarction). The findings were unchanged at stress.

LVEF: 58% at rest; 59% at stress.

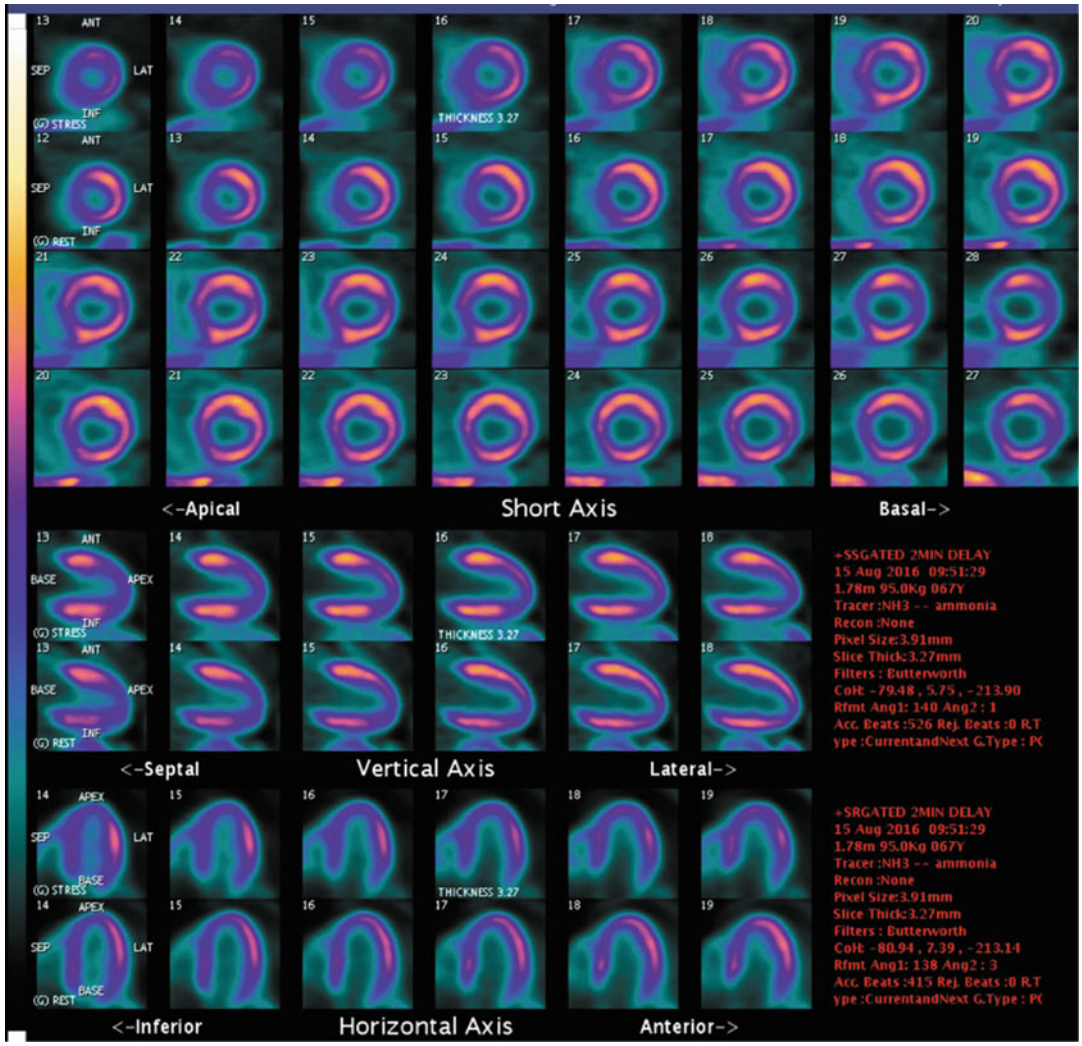

Fig. 2 (**a**) Summed list-mode images of ^{13}N-ammonia following injection at stress (*upper row*) and at rest (*lower row*) in the short axis, vertical long axis, and horizontal long axis. There is a large, moderate-to-severe reduction in perfusion at rest in the septal, distal anterior, inferior, and lateral walls as well as the apex, consistent with scar. The regions of decreased perfusion, especially in the distal anterior wall, are slightly worse at stress, suggesting peri-infarct ischemia

Impression: Abnormal myocardial perfusion scan, demonstrating moderate-sized regions of decreased perfusion in the septal, distal anterior, and inferior walls, worse at stress than at rest, suggesting myocardial scar and ischemia.

Comments: The patient with genetic predisposition has severe coronary artery disease evidenced by prior myocardial infarction and stent placement, as well as scan findings suggestive of superimposed ischemia. Medical therapy with lipid-lowering agents, although not fully effective in this genetic disease, should be maintained. In the absence of contraindications, beta-blocker therapy should be instituted and maintained through the course of hospitalization. Although breast surgery is not a high-risk procedure, the patient should be

monitored frequently to avoid surges in blood pressure and/or episodes of prolonged tachycardia that may cause ischemia. Postoperatively, pain should be minimized to avoid catechol surges that may cause coronary spasm.

Case 3

An 80-year-old man with biopsy-proven Hürthle cell thyroid carcinoma, chronic atrial fibrillation, and right bundle branch block was referred for myocardial perfusion imaging to detect possible stress-induced myocardial ischemia prior to thyroidectomy.

Procedure: Rest and stress SPECT/CT myocardial perfusion scan. Owing to difficulty with balance (use of a cane), the patient was stressed with a combination of low-level exercise (1.7 mph and 5% grade) and 0.4 mg regadenoson IV over 20 s.

Radiopharmaceutical:

Rest: 4 mCi ^{201}Tl-chloride IV
Stress: 30 mCi ^{99m}Tc-sestamibi IV

Image findings:

Careful inspection of the rotatogram reveals an extracardiac focus of abnormal uptake in the left lung (white arrow on selected rotatogram images at rest and stress).

Attenuation corrected myocardial perfusion images at stress and rest show a short septum (likely an anatomic variant) and relatively increased tracer uptake in the anterobasal wall on the rest images (likely due to scatter from activity below the diaphragm), with no significant change from rest to stress. There is no definite evidence of ischemia or scar (Fig. 3).

Impression:

1. No evidence of myocardial ischemia or scar.
2. Focal extracardiac tracer uptake in the left lung, corresponding to a lung nodule on CT (Fig. 3).

Comment: The rotatogram should be carefully inspected for evidence of abnormal extracardiac activity in all patients. In this case, a pulmonary metastasis from Hürthle cell thyroid cancer was incidentally detected.

Case 4

A 59-year-old woman with a history of vulvar cancer and a new pulmonary nodule was referred for myocardial perfusion imaging because of a recent treadmill test with positive findings on ECG (Fig. 4). The patient was asymptomatic during the stress test and had no history of coronary disease. The patient exercised to stage 2 of the Bruce protocol, reaching a heart rate of 155, 96% of the predicted maximum for age.

Comments: In view of the severity of the ECG changes despite the normal imaging findings, a debate ensued about the necessity of an anatomic study to confirm the absence of coronary disease. Although a coronary CT arteriogram was considered, the attending physician decided a selective coronary arteriogram was required. The selective coronary arteriogram demonstrated no significant arterial narrowings. One of the first applications of rest and stress myocardial perfusion imaging was the identification of patients with a false-positive ECG response to exercise [7].

Comment: Display of myocardial perfusion images in monochrome was the standard prior to the general acceptance of SPECT images. Displaying data in color adds additional contrast to the display, in some cases resulting in false-positive interpretations. When in doubt about a subtle lesion, it is helpful to review the rotatogram and the reconstructed images in monochrome.

Case 5

A 51-year-old woman with a history of bilateral breast cancer was treated with surgery and radiation therapy. Tumors recurred in both breasts 5 years after her initial therapy. The recurrent lesions were treated with surgery and doxorubicin. She was referred for myocardial perfusion imaging owing to increasing shortness of breath on exertion and a persistent resting tachycardia of 110 bpm. She had a long history of cocaine abuse.

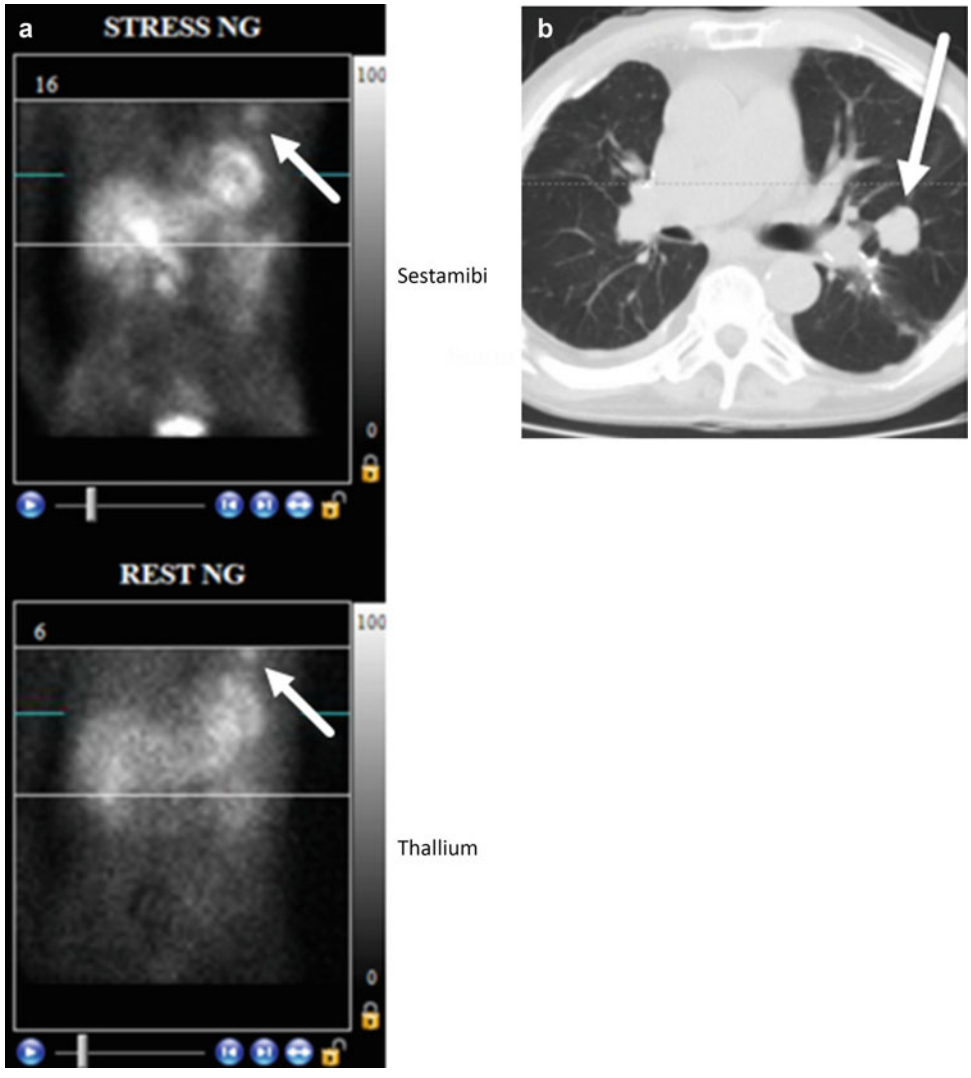

Fig. 3 (continued)

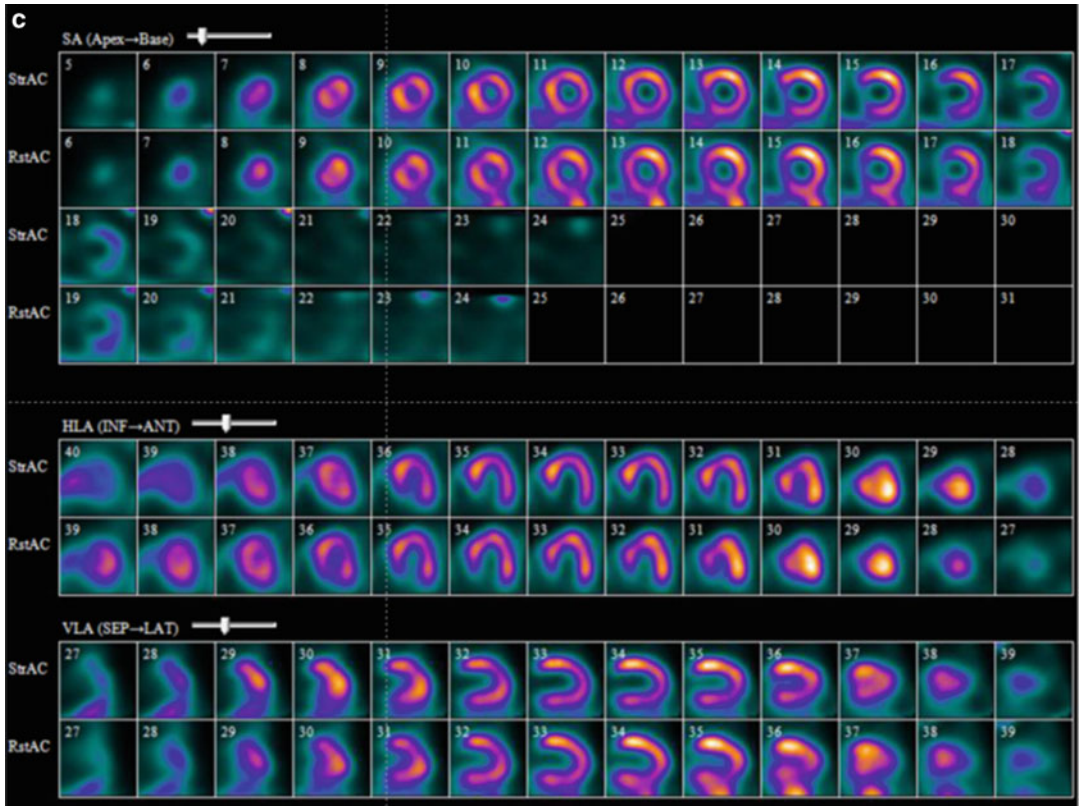

Fig. 3 (**a**) Single frames of the SPECT rotatogram at stress (*top*, sestamibi) and at rest (*bottom*, thallium) demonstrate a focus of uptake superior and lateral to the anterior wall (*arrow*). (**b**) Selected slice of CT scan demonstrating a 2-cm left lung metastasis (*arrow*), corresponding to the focal uptake seen on the perfusion scans. (**c**) Attenuation corrected myocardial perfusion images at stress (*top rows*, *StrAC*) and rest (*bottom rows*, *RstAC*). The scans show a short septum (likely an anatomic variant) and relatively increased tracer uptake in the anterobasal wall on the rest images (likely due to scatter from activity below the diaphragm), with no significant change from rest to stress. There is no definite evidence of ischemia or scar. An extracardiac focus is seen in the *left upper corner* on the basal axial slices corresponding to the left lung focus on the rotatogram

Procedure: Rest and stress myocardial perfusion SPECT/CT scan. The patient underwent stress testing with treadmill exercise. The patient exercised for 6 min, reaching stage 3 of the Bruce protocol. Poststress SPECT/CT images were acquired 20 min after the stress tracer injection.

Radiopharmaceutical:

Rest: ^{201}Tl-chloride 3.5 mCi IV

Stress: ^{99m}Tc-sestamibi 30 mCi IV

Hemodynamics:

Rest: HR 105 bpm; BP 110/70

Peak stress: HR 143 bpm (100% of predicted maximum for age); BP 150/90

Image findings:

There is a moderate-sized lesion in the apex where perfusion is absent on both the rest and stress images, suggesting myocardial scar (Fig. 5).

Regional wall motion at rest and stress demonstrates akinesis of the apex and distal septum, corresponding to the region of decreased perfusion.

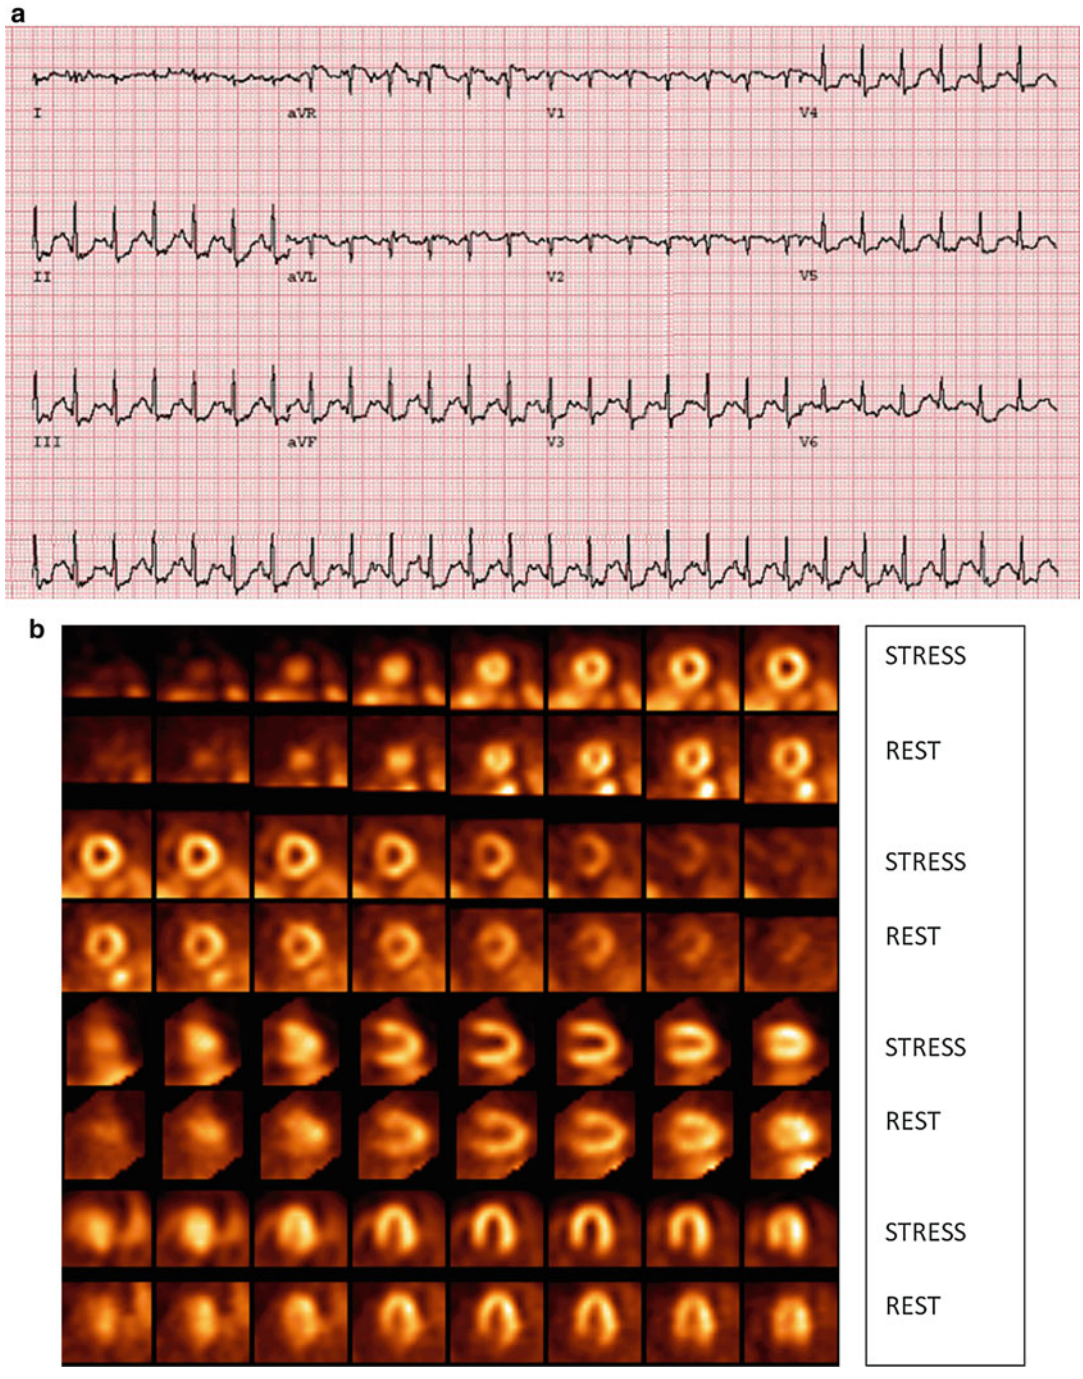

Fig. 4 (**a**) ECG at peak stress demonstrates significant ST depression in leads III, aVF, and V_3–V_5. (**b**) Myocardial perfusion SPECT scan at stress (*ST*) and rest *(RE*), demonstrating a homogeneous distribution of perfusion in the LV myocardium at rest and stress. The study was interpreted as an abnormal ECG and a normal perfusion scan, likely a false-positive ECG

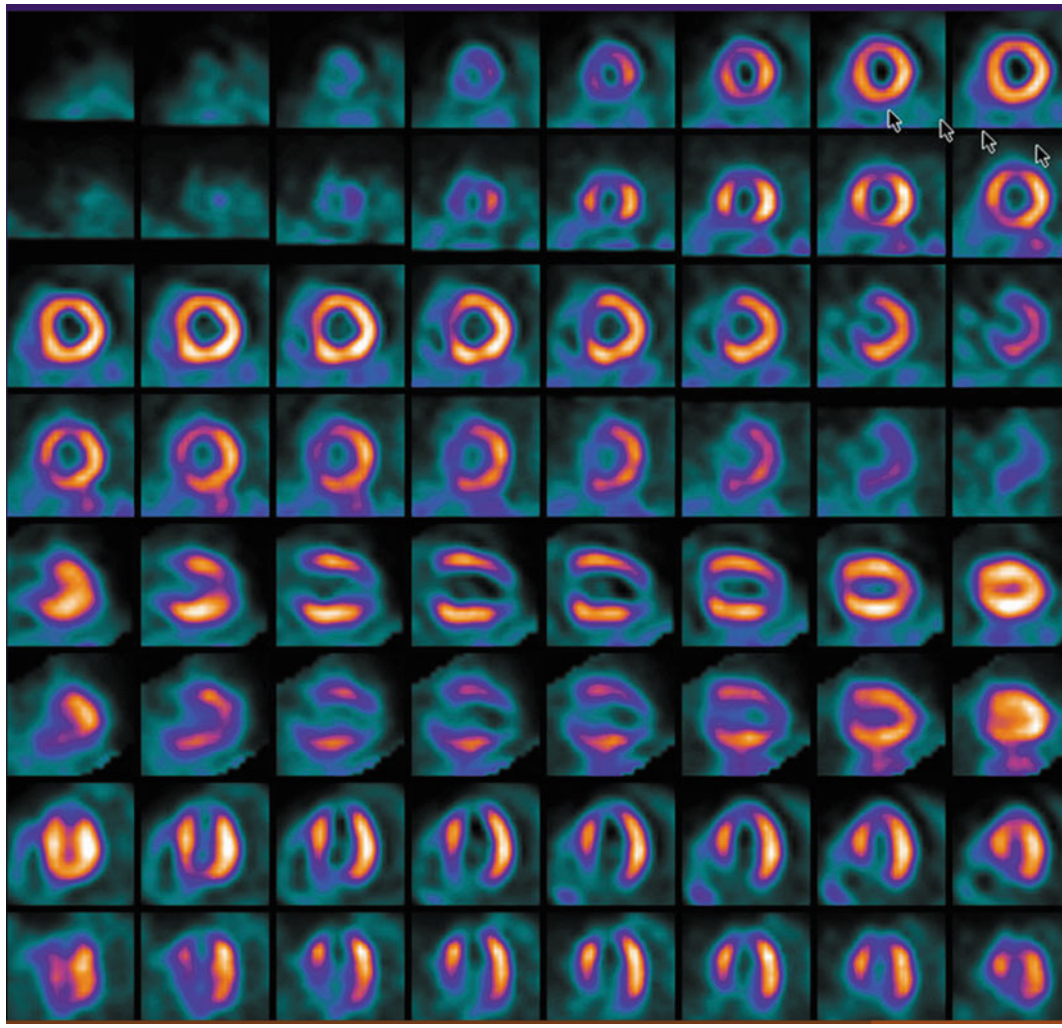

Fig. 5 (**a**) Myocardial perfusion scan at rest and stress

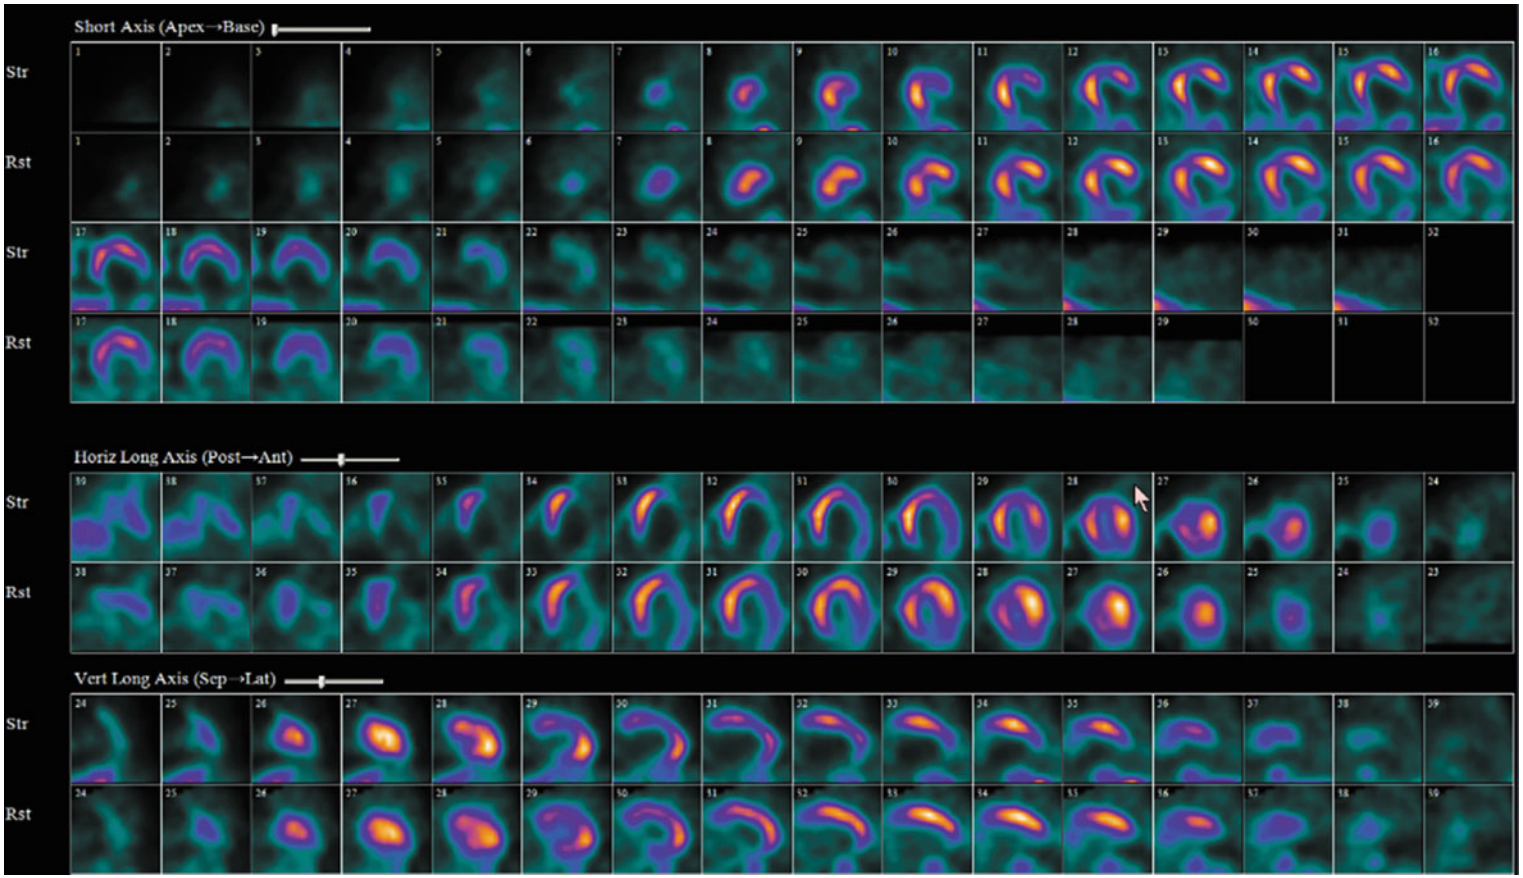
LVEF: 55%

Impression: Abnormal scan, demonstrating myocardial scar in the apex. No evidence of ischemia.

Comment: In view of the history of cocaine abuse, it is possible that the region of decreased perfusion is due to an area of infarction secondary to cocaine-induced coronary spasm. An alternative, although less likely explanation, is that the lesion may be due to radiation-induced coronary disease. To determine if the lesion is due to radiation, the radiation treatment plan was reviewed to establish whether the apex was exposed to over 30 Gy, the threshold dose for myocardial damage [8]. The treatment plan did not include the left ventricular myocardium in the radiation field.

Case 6

A 76-year-old man with a history of bladder cancer, scheduled for cystectomy, was referred for rest and stress myocardial perfusion imaging. He had a history of type 2 diabetes treated with oral hypoglycemics and hyperlipidemia treated with statins. His medical history also included acute



he scan demonstrates a large region of markedly decreased/absent perfu-
ferior wall at both rest and stress suggesting myocardial scar. There is a

Poststress images were recorded 30 min after completion of the stress test. The left ventricular cavity is enlarged. There is akinesis of the inferior wall, severe hypokinesis

myocardial infarction 11 years before the current presentation. At the time of his infarction, coronary arteriography demonstrated triple-vessel disease. He was treated with three-vessel coronary bypass surgery. The patient had a second myocardial infarction 1 year after CABG. No additional revascularization was done. At an examination 5 years before his current presentation, there was evidence of ischemia on a myocardial perfusion scan and a reduced LVEF of 30%. Based on the LVEF of 30% and the extent of the myocardial scar, the patient was treated with an implanted cardiac defibrillator. A pharmacologic stress myocardial perfusion SPECT/CT scan was performed.

Procedure – rest: ^{99m}Tc-sestamibi 10 mCi IV, followed about 30 min later by rest SPECT/CT acquisition. About 2 h after rest imaging, pharmacologic stress was performed with 0.4 mg regadenoson IV. About 1 min after regadenoson, 30 mCi ^{99m}Tc-sestamibi was administered IV. The patient was asymptomatic and there were no changes on the ECG during the stress procedure.

Hemodynamics:

Baseline: HR 80 bpm; regular; BP 110/70

Peak stress: HR, 100 bpm; BP 100/60 (Fig. 6).

Comments: The imaging findings suggest that the patient is at high risk of a perioperative event in the course of the cystectomy, an operation that is definitely considered high-risk surgery. In view of the patient's prior revascularization and implantation of an automatic implantable cardioverter-defibrillator, coupled with the aggressiveness of his tumor, it was decided to proceed with surgery. Beta-blocker therapy was started before surgery to maintain a heart rate of < 60 bpm and minimize surges in blood pressure. The patient had no cardiovascular events in the perioperative interval.

Takeaway In the evaluation of patients with a history of coronary disease, or individuals at intermediate risk for myocardial ischemia, myocardial perfusion imaging remains a useful clinical procedure. The 2012 appropriate use criteria for coronary revascularization focused update [9] defines high risk as a 3% incidence of a major cardiovascular event in the next year. Based on this definition, the odds of a patient with a high-risk scan surviving for the year favor the patient. When it is acceptable to caregivers and the patient to delay a major cancer therapeutic intervention while waiting for recovery from stent placement or bypass surgery, revascularization should be performed. On the other hand, as we describe in two patients with high-risk scans, when cancer therapy cannot be delayed, medical therapy and intensive monitoring can help patients survive high-risk procedures.

Urothelial carcinoma, 1755, 1758
Uterine cancer
  cervical carcinoma, 1824–1830
  endometrial cancer, 1831–1833
  metastatic cervical squamous cell carcinoma, 1824
  squamous cell cervical cancer, 1836–1840

V
Vaginal cancer, 1815
Vapreotide, 148
Vascular endothelial growth factor (VEGF)
  bevacizumab, 9
  blockade of, 1076
  expression, 1069
  neovasculature, 9
Vascular endothelial growth factor receptors 1–3 (VEGFR1–3), 715
Vasoactive intestinal peptide receptor scintigraph, 766
Vemurafenib, 1074, 1168
  vs. ipilimumab, 1076
V600E mutation, 25
Vertebroplasty, 1182
Visual analog scale (VAS), 177
Vitamin D receptors (VDR), 588
Volumetric-modulated arc therapy-simultaneous integrated boost (VMAT-SIB) treatment, 1728, 1838–1839
von Hippel-Lindau (VHL) protein, 28–29
Vulvar cancer
  AJCC classification, 963
  diagnosis of, 963
  environmental factors and genetic predisposition, 960–961
  [^{18}F]FDG PET imaging, 963–967
  histopathologic categories of, 961–962
  incidence of, 960
  median age for, 960
  nuclear lymphoscintigraphy, 967–974
  radiopharmaceutical imaging, 964
  recurrent, 1813–1814
  staging and prognosis, 962
Vulvar mass, 1816, 1817

W
Warburg effect, 18, 19, 481
WBLD-CT. *See* Whole-body low-dose CT (WBLD-CT)
WB-MDCT. *See* Whole-body multidetector computed tomography (WB-MDCT)
WBS. *See* Whole-body scan (WBS)
Whipple procedure, for pancreatic cancer, 1916
WHO classification
  acute myeloid leukemia, 453, 454
  leukemias, 440
  lymphoma, 360
Whole-body low-dose CT (WBLD-CT), 408–409
Whole body-MRI (WB-MRI), 647
Whole-body multidetector computed tomography (WB-MDCT), 408
Whole-body scan (WBS), 315–316
Wilms' tumor, 1119–1120

X
^{127}Xenon, 78
^{133}Xenon, 77–78
X-rays, 203, 406–407

Y
^{90}Y, bremsstrahlung imaging, 45
^{90}Y-DOTATOC
  chemical structures of, 1250
  efficacy, 1256–1259
  PRRT with, 1249, 1255
  vs. ^{77}Lu-DOTATATE, 1262
^{90}Y-glass spheres, 112
^{90}Y-HuM195, 1174
^{90}Y-ibritumomab tiuxetan, 111
  clinical efficacy and safety, 1147
  clinical experience with, 1148
  with CLL, 1164
  consolidation therapy, 1144
  general eligibility and dosing for, 1146

^{90}Y-ibritumomab tiuxetan (*cont.*)
for initial therapy, 1149
maximally tolerated dose of, 1149
with recurrent NHL, 1142
regimens for, 1146
^{90}Y-images, 318–319, 321
^{90}Y-microspheres
administration, 1347
methods, 1345
posttreatment assessment of, 1347
radioembolization with, 1345, 1348–1351
types of, 1341
^{90}Y-microspheres, tansarterial, 790–791
^{90}Y-resin, 112, 206
Ytterbium-175 (^{175}Yb), 187
Yttrium-90 (^{90}Y), 43, 188–189

Z
Zevalin®, 1147
Zirconium-89, 9
^{89}Zr, 132
^{89}Zr-desferrioxamine B (DFO), 48–49
^{89}Zr-J591, 157
Zr, trans-chelation of, 49
^{89}Zr-trastuzumab PET/CT, 630
