Marked reductions in brain matter density are also associated with T1DM. Compared with a group of healthy individuals without diabetes, young adults with a childhood onset of diabetes manifested ~5% less gray matter in the right superior temporal gyrus, and in several left hemisphere regions, including the temporal gyrus, angular gyrus, medial frontal gyrus, inferior parietal lobule, and thalamus [217]. These structures are especially important for attention, memory, and language processing. The strongest predictor of gray matter density reduction was degree of chronic hyperglycemia; higher lifetime HbA_{1c} was consistently correlated with lower gray matter density.

A case–control study reporting similar findings, demonstrating that individuals with diabetic proliferative retinopathy manifest small reductions in gray matter density in the left middle frontal gyrus, the right inferior frontal gyrus, the right occipital lobe, and the left cerebellum. By contrast the gray matter values of people with diabetes without retinopathy were comparable to adults without diabetes [218]. Reductions in white matter volume have also been noted, with effects being greatest amongst adults with a longer history of chronic hyperglycemia and microvascular complications [219].

Retinopathy as a risk factor for CNS abnormalities

A long history of chronic hyperglycemia and the occurrence of microvascular complications is a robust risk factor for neurocognitive abnormalities. In a longitudinal study that followed a group of young and middle-aged adults with a childhood onset of T1DM over a 7-year period [220], those who had clinically significant proliferative diabetic retinopathy at baseline, or who developed retinopathy during the course of the follow-up period, showed a significant decline in psychomotor efficiency, compared to demographically similar people without diabetes. In contrast, those without retinopathy at either time showed no evidence of psychomotor slowing. The risk of cognitive change was predicted by four variables: the presence or development of proliferative retinopathy, the presence of autonomic neuropathy, elevated systolic blood pressure, and longer duration of diabetes. The resulting statistical model identified, with 83% accuracy, those who showed significant cognitive decline and explained 53% of the variance.

Cross-sectional studies of young adults have similarly demonstrated that background retinopathy is associated with white matter abnormalities on MRI and poorer performance on measures of attention, fluid intelligence, and information-processing speed [221]. Abnormal brain activation patterns during the performance of a working memory task have also been identified in people with clinically significant retinopathy [222]. Other microvascular complications, particularly peripheral neuropathy, are also associated with changes in brain function and structure [212, 214, 223, 224].

Given that middle-aged adults without diabetes who have retinal microaneurysms also show a pattern of cognitive decline that is characterized by psychomotor slowing [225], retinopathy may serve as a general marker of cerebral microangiopathy [181, 226]. This is quite plausible, given the well-known homology between the retinal and cerebral microvascular systems [227]. In those with clinically significant diabetic retinopathy, the resulting microangiopathy could lead to cerebral hypoperfusion

and thereby contribute to the development of abnormalities in brain structure and function by interfering with the efficient delivery of glucose and other key substances to neural tissue [181, 218]. The relationship often reported between peripheral neuropathy and brain dysfunction in individuals with diabetes may simply reflect the fact that microvascular complications tend to appear contemporaneously and have a common origin [228]. That is, microvascular disease may be the primary mechanism underlying the development of neurocognitive dysfunction in young and middle-aged adults [183].

Hyperglycemia and neurocognitive dysfunction in people with diabetes

Chronic hyperglycemia and the subsequent development of microvascular disease contribute to cognitive dysfunctions in people with T1DM or T2DM. Both T1DM and T2DM are associated with mental and motor slowing, and also with decreases in attention and executive functioning [229] and also with neural slowing, increased cortical atrophy and microstructural abnormalities in white matter tracts. In a meta-analysis, Biessels et al. studied the association between diabetes and incident dementia, using 14 longitudinal population-based studies. The incidence of "any dementia" was higher in individuals with diabetes, compared to those without diabetes. This elevated risk included both Alzheimer's disease and vascular dementia. These mechanistic studies suggest that vascular disease and also changes in glucose, insulin, and amyloid metabolism may underlie the pathophysiology [230].

HbA_{1c} is the best (albeit imperfect) predictor of impairment in older people with diabetes, although other diabetes-related conditions, (including hyperinsulinemia [231, 232] and hypertension [233]) are important. Many people with T2DM are beset with multiple medical problems or diabetic complications, some of which (e.g. cerebral atherosclerosis) may contribute to cognitive decline. Nevertheless, it is clear that factors other than vascular disease must play a part in the etiology of these cognitive impairments because they can be identified in otherwise healthy adults with T2DM who have no clinically apparent vascular complications.

Conclusions

One of the greatest problems facing people with diabetes is the failure, or inability, of many clinicians to empathize with how challenging it is to live with the daily self-care demands of a condition like diabetes, to identify those experiencing psychological distress quickly and provide appropriate support. From this chapter, it is clear that people with diabetes have a remarkable level of psychological resilience but, like anyone else, they may experience psychological distress, made more likely by having to cope daily with the demands of living with a chronic condition. Furthermore, it is evident that the behavioral change is unlikely if the person lacks the pre-requisite information, motivation and/or behavioral skills, and is unsustainable if such changes cannot be incorporated into the person's lifestyle (or if they compromise their quality of life). It is incumbent on all members of the healthcare team to recognize the psychological impact of diabetes and to continue to develop better ways of delivering healthcare and support in order to alleviate distress, improving both biomedical health outcomes and quality of life.

57 Psychiatric Disorders and Diabetes

Richard I.G. Holt[1] and Leslie Citrome[2]

[1] Human Development and Health Academic Unit, Faculty of Medicine, University of Southampton and University Hospital Southampton NHS Foundation Trust, UK

[2] Department of Psychiatry and Behavioral Sciences, New York Medical College, Valhalla, NY, USA

Key points

- The interactions between diabetes and psychiatric disorders are complex: physical illness raises the risk of psychiatric disorder, but mental illness and its treatment with certain psychotropic medications also impact on the risks and outcomes of diabetes.
- Since mental health problems are more common among people with diabetes, heightened levels of awareness and knowledge are vital for the health professionals who work with them.
- Screening for mental health problems should form part of the holistic care of people with diabetes.
- The prevalence of diabetes is increased two- to threefold among those with mental illness, including depression and psychotic illnesses.
- The mechanisms underlying the association between diabetes and mental illness are multifactorial and include genetic and environmental factors as well as effects of the illness and its treatment.
- The presence of comorbid mental illness worsens the diabetes outcomes; the rates of microvascular and macrovascular complications, acute metabolic dysregulation and diabetes-related deaths are all higher in people with mental illness.
- The availability of mental health expertise in the settings where people with diabetes are treated is generally poor and should be improved.
- Tailored lifestyle interventions have been shown to reduce body weight in people with psychotic illness and are likely to reduce the incidence of diabetes.
- Effective diabetes management, incorporating primary care, diabetes services, and mental health teams, is essential to reduce the poorer health outcomes and current inequity experienced by people with mental illness and diabetes.

Introduction

The greatest challenge facing medicine in the 21st century is multimorbidity, defined as the co-occurrence of two or more diseases in the same individual. Whilst diabetes healthcare professionals are used to managing this increasingly common challenge, given the effects of diabetes on many body systems, the comorbidity of diabetes and mental illness is less well appreciated despite it being common and worsening the outcomes of both conditions. Psychiatric illness hinders an individual's ability to undertake the diabetes self-management that is central to the maintenance of health and prevention of complications and premature mortality. Therefore an understanding of the complex interaction between mind and body is crucial to the management and outcome of people with diabetes.

Both diabetes and psychiatric disorders are common conditions, and therefore a degree of co-occurrence would be expected purely by chance. There is considerable evidence, however, that diabetes is associated more frequently than expected with a range of psychiatric morbidity. In particular, it appears that people with mood and psychotic disorders are at increased risk of developing diabetes [1, 2], whilst those with diabetes go on to develop a range of psychological problems at increased rates compared to people without diabetes [1]. This was noted over a century ago; Henry Maudsley said in his celebrated textbook *Pathology of Mind*,

> *"Diabetes is a disease which often shows itself in families in which insanity prevails. Whether one disease predisposes in any way to the other or not, or whether they are independent outcomes of a common neurosis, they are certainly found to run side by side, or alternately with one another more often than can be accounted for by accidental coincidence or sequence" [3].*

Unfortunately in most countries, services are poorly equipped and organized to deliver good quality care for both the physical and psychological needs of patients in the same setting [4]. Clinicians need to be aware of the increased risks of comorbidity, and the need for screening. Diabetes healthcare professionals should be able to provide "first response" management, and recognize the needs of more complex patients for whom specialist management is essential. The topic of comorbidity has attracted interest from researchers, and considerable progress has been

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Table 57.1 DSM-5 "Major" Depressive Episode.

A Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood, or (2) loss of interest or pleasure.
- Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g. feels sad or empty) or observation made by others (e.g. appears tearful).
- Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
- Significant weight loss when not dieting or weight gain (e.g. a change of >5% of body weight in a month), or decrease or increase in appetite nearly every day.
- Insomnia or hypersomnia nearly every day.
- Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
- Fatigue or loss of energy nearly every day.
- Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
- Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
- Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B The symptoms cause clinically significant distress or impairment in social, occupational or other important areas of functioning.

C The symptoms are not due to the direct physiological effects of a substance (e.g. a drug of abuse, a medication) or a general medical condition (e.g. hypothyroidism).

made in understanding the epidemiology and psycho-biological mechanisms involved. Efforts targeting psychiatric care providers have increased awareness of diabetes and metabolic problems in general, and have led to initiatives to increase routine screening and referrals for diabetes care, with varying degrees of success.

This chapter will provide an overview of the relationship between diabetes and mental illness, in particular focusing on the association with depression, psychotic illness (schizophrenia and bipolar illness), and eating disorders. Within each section, the epidemiology of the comorbidity, mechanisms underlying the association, and clinical implications will be considered.

Mood disorders

The association between diabetes and depression has been recognized for many years. In the 17th century, Thomas Willis described how "*diabetes is a consequence of prolonged sorrow*" [5]. Nevertheless it is a frequently ignored component of holistic diabetes care. Until the last decade, any discussion of mood disorders and diabetes would have concentrated solely on the increased rates of depression in people with diabetes, and is likely to have viewed such comorbidity as an "understandable" reaction to the difficulties resulting from living with a demanding and life-limiting chronic physical illness. We now understand that the relationship between the two conditions is more complex than this:

- At least in the case of type 2 diabetes (T2DM), the relationship between diabetes and depression is bi-directional as depression is a risk factor for the development of diabetes [6–8].
- Biological aspects of diabetes may contribute to the development of depression and vice versa.
- Other antecedent factors, such as the early nutritional environment or neighborhood, may contribute to the risks of both conditions [1].

Given the large numbers of people with diabetes and mental illness, approximately 8.3% and 10% of the total world's population, respectively, and the twofold higher rates of depression in people with diabetes [9], the comorbidity of these two conditions presents a major clinical challenge as the outcomes of both are worsened by the presence of the other. Quality of life is worse, diabetes self-management is impaired, the incidence of complications is increased and life expectancy is reduced [1]. The costs of treatment increase significantly for both individual patients and health economies but these costs do not necessarily result in significant improvements in disease or quality of life outcomes [10].

Case definition

Depressive symptoms exist on a continuum of severity. Standard definitions of "clinical" depression are based on symptom count and duration; the most widely used diagnostic criteria in current practice are those of the American Psychiatric Association DSM-5 "Major" depression [11] (Table 57.1). This definition approximates to a level of symptomatology which is associated with significant disability and dysfunction but it is important to note that depressive symptoms of lesser severity may still compromise self-care and outcomes in people with diabetes.

The clinical category of mood disorders includes both unipolar depression and bipolar (previously known as "manic-depressive") illness. This section will focus on unipolar depression; bipolar illness will be included in the section on psychotic disorders.

Epidemiology

Depression is common, affecting between 3–5% of the general population at any time. Its prevalence appears to be increasing and is predicted to become the second leading global cause of disability (after heart disease) by 2020 [12].

Considerable variability of measurement and use of terminology have contributed to heterogeneity and inconsistency in studies examining diabetes and depression [1]. The meaning of the term

depression spans relatively minor, occasional negative mood states (which should more accurately be termed *depressive symptoms*) to incapacitating and treatment-resistant disorders that fulfil all diagnostic criteria for depression. Many self-rating scales do not acknowledge the overlap between symptoms of diabetes and those of depression (e.g. fatigue, weight loss), leading to overestimates of the prevalence of "depression" in those with diabetes [13]. The "gold standard" for ascertainment of case status is a research diagnostic interview; at most rating scales can only give a probabilistic estimate of caseness. A further confounding factor is the construct of "diabetes-related distress" which captures the emotional distress associated with living with diabetes [14]. Diabetes-related distress correlates modestly with depressive symptoms with ~30% overlapping variance but remains distinct from depression in its association with self-management and glycemic control.

Studies have tended to ignore the heterogeneity of diabetes, studying mixed populations of different forms of diabetes (e.g. T1DM and T2DM). It is important to distinguish between these groups for several reasons:

- People with T2DM are generally older and depression prevalence varies with age
- Pathological mechanisms may differ
- The rates of diabetic complications and other comorbid conditions (e.g. obesity, heart disease) differ
- Management demands are different.

Studies have often been based on "convenience" samples of patients, usually drawn from specialist diabetes clinics, where referral patterns and the effect of other biases in sample composition, such as ethnicity, were unknown.

Finally the studies often had low or unknown response rates, and since the presence of depressive symptoms may reduce the likelihood of responding in such studies, this biases prevalence estimates further.

More recent studies, using better methods, and meta-analyses, have tended to report lower estimates of prevalence, with significant depressive symptoms affecting approximately 1 in 3–4 adults with T1DM and T2DM while a formal diagnosis of depressive disorders is made in approximately 10–15% of people with diabetes [9]. One review of the prevalence of comorbid depression in T1DM [15] concluded that clinical depression was present in 12%, compared with 3.2% in people without diabetes. Excluding studies without control groups and interview ascertainment led to a fall in estimated prevalence to 7.8%, a figure which was no longer statistically significantly different from healthy controls (OR 2.4; 95% CI: -0.7–5.4). A meta-analysis of 10 studies that included 9028 people with T2DM and 42,272 adults without diabetes found that rates of self-reported depression were significantly elevated in those with diabetes (18% vs. 10%) [16]. Recently the course of depression has been studied in 2460 people with T2DM in a primary care setting [17]. Over a 3-year period, 26% met the criterion for depression on at least one occasion, with incident depression present in 14%. Recurrence or persistence of depression was evident in 66% of those with baseline depression. Depression was more common in women and those with low education, non-cardiovascular chronic diseases, stressful life events, or a self-reported history of depression.

The association between diabetes and depression appears to be similar across many countries; in a study including 231,797 adults from 47 countries, people with diabetes were 2.36-fold more likely to have experienced an episode of depressive symptoms than those without (Figure 57.1) [18]. Similar associations were found in South America, Asia, and Europe but not Africa where case ascertainment may be less complete.

A meta-analysis of 11 cohort studies including ~50,000 people with T2DM but without depression at baseline indicated that the incidence of depression is 24% higher in people with diabetes [7] while another meta-analysis of 13 studies found incident depression was increased by 15% in people with diabetes at baseline [8]. The discrepancy between prevalence and incidence rates may be explained by greater persistence of depression and higher relapse rates in people with diabetes.

Although there have been few studies in children and adolescents with either T1DM or T2DM, depression rates (9–26%) also appear elevated [1].

Who is likely to develop depression?

Risk factors for depression in otherwise healthy individuals, including female sex, marital status, childhood adversity and social deprivation, operate equally in people with diabetes and much depression in people with diabetes may be "independent" of the presence of the disease. However, there are both treatment- and diabetes-specific risk factors associated with depression. The use of insulin in T2DM is associated with higher rates of depression compared to non-insulin medications or dietary and lifestyle interventions alone [19, 20]. It seems unlikely that insulin causes depressive symptoms per se but insulin is associated with increased treatment demands and is generally used in people with more advanced disease. Recurrent hypoglycemia and poor glycemic control are both risk factors for depression and insulin therapy is usually associated with greater glycemic variability than other treatments. The intensive self-monitoring of blood glucose required with insulin therapy may also adversely affect depressive symptoms [20].

There is a well-recognized association between cardiovascular disease and depression but the development of microvascular complications, particularly sexual dysfunction and painful peripheral neuropathy, are also associated with depression [21]. In a specialized outpatient clinic, the presence of two or more complications more than doubled the risk of depression in people with T2DM, with neuropathy and nephropathy showing the strongest association with depression [22].

Depressive disorders as a risk factor for diabetes

A meta-analysis of nine cohort studies found that adults with depression had a 37% increased risk of developing T2DM [23] after accounting for factors common to both disorders including sex and body mass index. There is heterogeneity across studies which in part could be ascribed to ascertainment bias as people

	OR	95% CI
World	2.36	1.91–2.92
Africa	0.86	0.54–1.37
South America	1.98	1.46–2.68
Asia	2.16	1.38–3.37
Europe	2.47	1.73–3.52

Figure 57.1 Depressive episodes in people with and without diabetes. Odds ratios (OR) of an episode of depressive symptoms according to diabetes presence with 95% confidence intervals. Source: Data from Mommersteeg et al. 2013 [18].

with depression may be more likely to be screened for diabetes than those without.

Proposed mechanisms linking depression and diabetes

Several psychological, sociological and biological models have been proposed to explain the association between diabetes and depression. While there may be specific reasons why one condition pre-disposes to the other, recent research has also considered common antecedents to both (Figure 57.2) [1].

Common antecedents

An adverse intrauterine environment may predispose individuals to both T2DM and depression. There is a J-shaped relationship between birth weight and plasma glucose, insulin concentrations and T2DM while some but not all studies have shown that fetal under-nutrition is associated with adult depression [1]. One possible mechanism is programming of the hypothalamic-pituitary adrenal (HPA) axis as both depression and diabetes are associated with HPA dysfunction [24]. Adverse environmental factors in postnatal life, ranging from childhood adversity to neighborhood environment and poverty may also influence the predisposition to depression and diabetes.

Why diabetes may increase the risk of depression

The traditional view holds that depression is an understandable reaction to the challenges of living with a demanding chronic physical illness that is associated with disabling complications and premature mortality. This is supported by studies that found no increase in depression rates amongst those with undiagnosed diabetes or impaired glucose metabolism [25]. As depression rates only increase following a diagnosis of diabetes, this suggests that the knowledge of the diagnosis and the burden of managing the condition and its complications are important in the etiology of depressive symptoms; consequently healthcare professionals need to convey the diagnosis of diabetes sensitively and provide psychosocial support to mitigate against this effect.

The psychological model does not preclude other biological mechanisms and it is well recognized that both hypoglycemia and hyperglycemia affect brain function in areas of cognition and mood. Animal studies of diabetes have shown loss of hippocampal integrity and neurogenesis, which may contribute to mood symptoms while in humans, MRI studies have shown hippocampal atrophy. Prefrontal glutamate-glutamine-gamma-aminobutyric acid levels are increased in people with T1DM in a way that correlates with mild depressive symptoms [26].

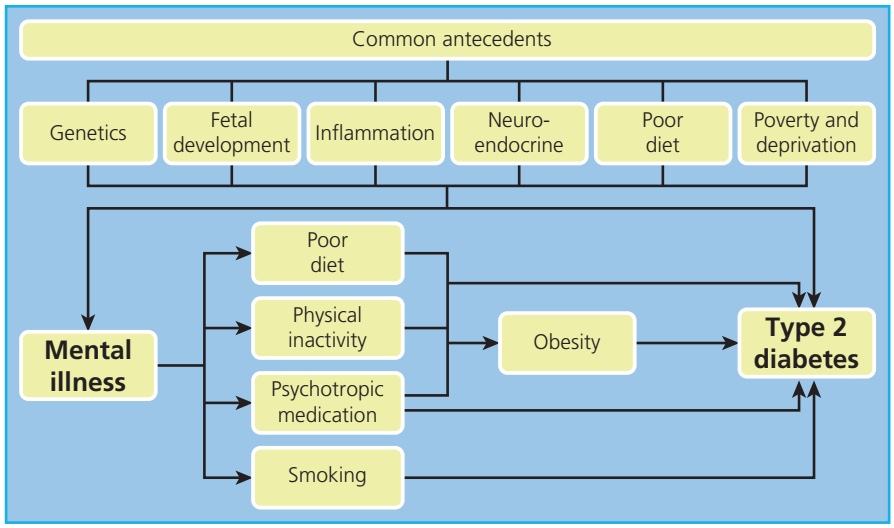

Figure 57.2 Mechanisms that explain why mental illness may predispose type 2 diabetes. There are a number of common antecedents that increase the risk of both conditions. Once an individual develops mental illness, further lifestyle changes may occur, which together with the effects of psychotropic medication may increase the risk of diabetes, either directly or indirectly through the development of obesity. Source: Adapted from Holt and Mitchell 2015 [2]. Copyright 2015 Nature Publishing Group.

Why depression may lead to diabetes

People with depression tend to be more sedentary and eat diets that contain more saturated fats and refined sugars and less fruit and vegetables than the general population [27, 28]. Other self-care behaviors may also be relevant; a meta-analysis found that people with depression were significantly less likely to follow diabetes treatment recommendations including missed medical appointments, medication use, glucose monitoring, and foot care [29]. This could lead to a vicious cycle whereby poorer self-care management leads to hyperglycemia which in turn worsens depressive symptoms and consequently contributes to decreased adherence to diabetes self-care. Depression is associated with disrupted sleep patterns [30], which may increase insulin resistance and risk of T2DM [31].

Pharmacological treatment of depression has also been implicated in the development of diabetes; some antidepressants may cause significant weight gain which may worsen insulin resistance [32]. Case reports and observational studies have shown a consistent association between the use of antidepressants and diabetes while randomized controlled trials have reported both hyperglycemic and hypoglycemic effects [33]. It is uncertain whether any or all antidepressants cause diabetes as their use may be a marker of individuals at high risk of diabetes.

Consequences of depression in diabetes

Comorbid depression adversely affects diabetes outcomes and decreases quality of life [34–36]. This is not explained by poor glycemic control as rather surprisingly and in contrast to diabetes-related distress, no consistent association between depressive symptoms and HbA_{1c} has been found [37–39]. Nevertheless treatment studies suggest that improved glycemic control may accompany a reduction of depressive symptoms.

Depression is associated with worsened severity of many diabetes complications although the direction and mechanisms that underlie this association are not fully understood [21]. The evidence that depression increases the risk of developing complications is less strong, although the associated impaired self-care would lead to this expectation. In one 10-year cohort study of individuals with childhood-onset diabetes, retinopathy severity was predicted by increasing duration of diabetes, with length of time spent in poor control and with overall proportion of time depressed [40]. Similar results have been seen in people with T2DM; in one longitudinal study, those with high depression scores at both baseline and 6-year follow-up were more likely to progress to diabetic retinopathy and to proliferative diabetic retinopathy than those with low depression scores [41].

One complication that may be particularly associated with depression is painful peripheral neuropathy. Recent studies suggest that not only is chronic pain a risk factor for depression, but the presence of depression may itself worsen the experience of pain [42].

Depression, even if mild, is also associated with premature overall and cardiovascular mortality [43]; in one study the annual mortality rate for those with diabetes and depression was 8%, 2.5-fold higher than those without either condition [44].

Management of people with diabetes and depression

The main aims of treatment are to reduce depressive symptoms and to improve self-care, glycemic control and diabetes outcomes. A major difficulty for most clinics is the lack of readily available specialist mental health input, and this has been a disincentive for services to engage actively in tackling this important clinical problem [45]. By contrast, guidelines now include psychological well-being. Most clinics should be able to provide "first response" management for simple depressive disorders, although specialist help will still be required for more complex cases, where there is diagnostic uncertainty, lack of response to initial treatment or suicide risk.

Screening and diagnosis of depression

The first step to the effective management of depression is its recognition and diagnosis. At present, screening and case finding

are not part of the routine management of people with diabetes; however, given the high prevalence of comorbid depression in people with diabetes, this seems worthwhile and healthcare professionals should ensure they have appropriate skills to diagnose mood disorders.

A formal diagnosis of depression requires a time-consuming validated interview and so quick and cheaper screening methods are needed for primary and secondary care settings [46]. Although there are many short questionnaires that screen for depressive symptoms, it is important to use one that has been evaluated adequately in people with diabetes because of the overlap of symptoms between diabetes and depression, such as lethargy, irritability, or weight change [13]. Questionnaires that rely heavily on these symptoms tend to overestimate the likelihood of depression.

The most widely used and validated questionnaire in T2DM is the Patient Health Question-9 (PHQ-9). It is also the shortest, containing nine questions and can be easily completed by the patient alone. The cut-off for major depression is ≥10 in primary care populations but it has been suggested that a higher cut-off of ≥12 points in people with diabetes may improve the discrimination between diabetes-related symptoms and depressive symptoms [47]. Other well-validated questionnaires for people with diabetes include the Beck Depression Inventory, the Center for Epidemiologic Studies Depression Scale, and the Hospital Anxiety and Depression Scale (HADS). These questionnaires should not be used to diagnose depression but to identify those who should undergo a diagnostic interview.

Another straightforward approach that can be used by diabetes healthcare professionals is to ask two simple questions:

- "During the past month, have you been bothered by having little interest or pleasure in doing things?"
- During the past month, have you been bothered by feeling down, depressed, or hopeless?"

If the answer to either is "yes," the person with diabetes should be asked if they want help with this problem. If the answer to this is also "yes," then the patient should be assessed by a diagnostic interview and offered appropriate referral and treatment.

While a necessary first step, screening alone is insufficient to improve clinical outcomes [46]. A Cochrane meta-analysis reported that depression screening in the general population had little or no impact on the detection and management of depression if used alone and recommended screening strategies could not be justified without organizational changes to ensure appropriate treatment if needed [48]. The importance of this for diabetes was demonstrated in a Dutch randomized controlled trial which investigated the benefits of depression screening [49]. Following screening, although written feedback was provided to both the person with diabetes and doctor neither utilization of mental health services nor depression scores improved. Furthermore without links to treatment, screening could lead to harm, including the stigma associated with depression, the risk of labeling transient distress as illness, and societal discrimination by insurance companies [50]. Several reasons might explain the observed low effectiveness of screening for depression in people with diabetes including a low acceptance of screening and subsequent referral to further care by people with diabetes, failure to screen those at highest risk of depression, reluctance by healthcare professionals and generally poor quality of depression care in primary care systems [50].

Treatment of depression in people with diabetes

Knowledge of appropriate counselling techniques and appropriate drug therapy is important for diabetes healthcare professionals, as well as an awareness of the need for prompt referral to specialists when psychological difficulties continue to interfere significantly with well-being or diabetes self-management.

Previously people with diabetes were specifically excluded from trials of depression treatment and so consequently, there were relatively few studies examining antidepressant and psychological treatment of depression in this population until recently. Nevertheless studies published over the two decades have clearly indicated that treating depression with either psychological therapies or antidepressant medication is effective [50].

Psychological treatment

A variety of psychological treatments, including cognitive behavioral therapy, problem-solving and psychodynamic techniques have been used to treat depression in people with diabetes. These have been delivered in a variety of settings both in primary and secondary care by different members of the healthcare team [50]. Others have used web-based and telephone contacts. The trials have a preponderance of people with T2DM and no trials have been conducted with only people with T1DM. Given the heterogeneity of interventions, varied levels of effectiveness were found making it difficult to compare trials. Nevertheless the consensus is that such interventions improve psychological distress, with a moderate to large effect size (standardized mean difference (SMD) ranging from -0.14 to -1.47). There is more debate about the effect on glycemic control with one systematic review reporting a reduction in HbA_{1c} of ~0.6% (6 mmol/mol) [51] while another reported a less pronounced and overall non-significant improvement in glycemic control (SMDs from 0.40 to –1.40) [52]. Four recent trials on psychological interventions found an improvement in glycemic control (SMD -0.25 to -0.68) [50]. Although web-based psychological therapies may be effective in treating depression in people with diabetes, they appear to have limited effects on glycemic outcomes.

The best response to psychological interventions occurs when these are combined with education that provides diabetes self-management skills as well as the psychological support to use these effectively. In these situations the boundary between educative approaches and formal psychotherapy can become blurred.

Pharmacotherapy

Effective and well-tolerated antidepressants are widely available and affordable and form an integral component of management for many people with depression. People with diabetes respond to antidepressants as the general population with amelioration of

depressive symptoms. Formal efficacy trials in people with diabetes are limited to a relatively small group of antidepressants, including nortriptyline, fluoxetine, buproprion, sertraline, paroxetine, and citalopram [50], leaving substantial gaps in the evidence for effectiveness, both depression and glycemic control, and safety for many commonly prescribed antidepressants. All antidepressants studied appear to have similar efficacy in terms of depression outcomes as long as adequate doses are used with effect sizes of -0.61 SMD [52] but no trial has reported the medium- and long-term sustainability of pharmacological interventions after treatment cessation.

The treatment of choice depends largely on the side-effect profile, patient preference, and individual response. Selective serotonin reuptake inhibitors (SSRIs) are less cardiotoxic than tricyclic antidepressants, are safer in overdose and consequently are widely used as first-choice agents. There are important drug–drug interactions between some members of this class and oral hypoglycemic agents through inhibition of the cytochrome P450 3A4 and 2C9 isoenzyme. For example, the use of fluoxetine may potentiate the effect of sulfonylureas precipitating hypoglycemia [53]. Some antidepressants, including mirtazapine, paroxetine and some tricyclic antidepressants, may cause undesirable weight gain [32]. By contrast, buproprion, which is available in the USA, is associated with weight loss. Furthermore, unlike SSRIs, it does not appear to worsen sexual function and therefore may have advantages for people with diabetes [54]. Several new antidepressant medications have been approved including vilazodone, vortioxetine, and levomilnacipran [55]. Differentiating these from most of those already available include a more benign weight gain profile for all three, fewer problems related to sexual functioning for vilazodone and vortioxetine, and potential relief of the cognitive dysfunction that can be associated with depression as demonstrated with vortioxetine. None of these drugs has been tested specifically in people with diabetes.

The clinical trials demonstrate a modest improvement in glycemic control with SSRIs (SMD -0.38). However, older studies have shown a mixed effect on glycemic control ranging from hyperglycemic effects with tricyclic antidepressant medications to euglycemic or slightly hypoglycemic effects with SSRIs and serotonin–noradrenaline reuptake inhibitors. Consequently the findings of improved glycemic control with certain antidepressants should not be extrapolated to other untried antidepressants [50].

Most guidelines recommend that there should be complete remission of depressive symptoms. To achieve this, treatment must be sustained at an adequate dose for at least 4–6 months after remission has been attained to consolidate recovery and reduce the risk of relapse and recurrence.

In addition to possible direct pharmacological effects, it should be remembered that treating depression may lead to a change in the patient's behavior and routine which may require adjustment of diabetes self-management. For example, if the patient's appetite improves, insulin requirements may increase; if the patient becomes more active, they may decrease.

Models of care

In most healthcare systems, depression is managed mostly within primary care and many diabetes healthcare professionals feel ill equipped to manage depression. In the United States, a case management model known as "collaborative care" has been developed, whereby a multidisciplinary team works together to identify and treat depression within primary care settings. The model incorporates identification of high-risk cases, problem-solving therapy delivered by trained nurse case managers, and pharmacological treatments using a stepped-care approach. The first study to evaluate this approach was the PATHWAYS study which showed improvements in depression symptoms but no change in glycemic control [56]. Subsequently, greater attention was paid to intervention strategies for diabetes resulting in improved glycemic and blood pressure control as well as improved depressive symptoms [57]. As well as being clinically effective, these models of care are also highly cost-effective [58, 59].

Psychotic disorders

Psychotic disorders include schizophrenia, psychotic depression and bipolar disorder and are often known as "Severe (and Enduring) Mental Illness" (SMI). The presence of psychotic symptoms, which include delusions and hallucinations, has a profound effect on well-being and functioning of many aspects of daily life. When they co-occur with a chronic physical illness, they create significant management challenges, and such patients are amongst the most complex that healthcare systems encounter.

Case definitions

Schizophrenia is characterized by psychotic symptoms (delusions, hallucinations), disorganization of speech and other behavior, and so-called "negative" symptoms which include loss of drive and blunting of affect (Table 57.2). Schizophrenia is also associated with cognitive decline. The illness tends to run a chronic clinical course, and most people with the condition will be under the long-term care of specialist mental health services.

Although bipolar disorder is often thought to be a disease whose hallmark is the occurrence of one or more episodes of mania (elevated mood; criteria for a manic episode are shown

Table 57.2 DSM-5 Schizophrenia.

1	Two or more of the following symptoms, at least one of these must be i, ii, or iii:
	i Delusions
	ii Hallucinations
	iii Disorganized speech
	iv Grossly disorganized or catatonic behavior
	v Negative symptoms (affective flattening, alogia, or avolition)
2	Social/occupational dysfunction
3	Features continuously present for at least 6 months

Table 57.3 DSM-5 Manic Episode.

1 A distinct period of abnormally and persistently elevated, expansive or irritable mood, and abnormally and persistently increased goal-directed activity or energy, lasting at least 1 week.
2 During the period of mood disturbance, three or more of the following symptoms have persisted (four if mood only irritable):
- i Inflated self-esteem or grandiosity
- ii Decreased need for sleep
- iii More talkative than usual or pressure to keep talking
- iv Flight of ideas or subjective experience that thoughts are racing
- v Distractibility
- vi Increase in goal-directed activity or psychomotor agitation
- vii Excessive involvement in pleasurable activities that have high potential for painful consequences (e.g. spending, sexual activity)

3 Marked impairment in occupational functioning or in usual social activities or relationships with others, or need for hospitalization to prevent harm to self or others, or psychotic symptoms.

in Table 57.3), bipolar disorder can be conceptualized as a predominantly depressive disorder, based on the amount of time people with bipolar disorder have depressive symptoms [60]. On average, the ratio of the number of depressive episodes to manic or hypomanic episodes is 3 : 1 for bipolar I disorder, and the ratio of depressive episodes to hypomanic episodes is 39 : 1 for bipolar II disorder. In addition, the strict diagnostic criteria for bipolar disorders are complex, and there is a degree of overlap with schizophrenia, such that some people may be diagnosed as having a "schizo-affective" disorder [61].

Epidemiology

Schizophrenia is estimated to have a point prevalence of between 1–7 per 1000 in the general population, with an annual incidence of 13–70 per 100,000, and a lifetime risk of 1–2%. There is little variation in incidence across the world. The clinical course of the illness is variable, ranging from a single brief episode (rarely) to a lifelong illness with marked deterioration over time. There are many theories about the causation of schizophrenia; it has a marked genetic risk profile, but is also associated with early cerebral insults (e.g. birth anoxia) and environmental stress.

Bipolar disorder is much less common than unipolar depression, with an estimated lifetime prevalence of 1% for bipolar I disorder and another 1% for bipolar II disorder. Again genetic factors are thought to play an important role in the etiology of bipolar disorders, which are among the most heritable of psychiatric disorders.

People with SMI have standard mortality rates that are approximately two- to threefold higher than the general population, equating to a loss of 10–20 years of life [62]. The average life expectancy for men and women with schizophrenia in the UK is 62.8 years and 71.9 years respectively [63]. While suicide and trauma account for the highest relative risk of death, the commonest causes of death are from physical illness, principally cardiovascular disease. Over the last 30 years, while the life expectancy of the general population has improved, this has not been experienced by people with SMI leading to a widening health inequality gap.

Diabetes and severe mental illness

It is challenging to obtain precise diabetes prevalence rates in people with SMI because of the high prevalence of undiagnosed diabetes, which is estimated to be up to 70% of all cases [2]. Nevertheless there is a general consensus that the prevalence of diabetes is two- to threefold higher than in the general population. A meta-analysis of 41 studies including 161,886 people found that the overall prevalence of diabetes was 9.0% with an odds ratio for diabetes among those with multiple episodes of psychosis of 1.99 [64]. The increased prevalence is driven by an excess of T2DM as there is no evidence of enhanced pancreatic autoimmunity. The incidence of diabetes is higher and the onset of diabetes appears to be 10–20 years earlier than in the general population [65] (Figure 57.3). As diabetes is uncommon in young healthy adults, the increased relative risk of diabetes is greatest in adolescents and young adults with SMI [2].

Although subtle metabolic abnormalities have been found in people with a first episode of psychosis, the majority of studies show that metabolic abnormalities develop rapidly after treatment initiation and two recent meta-analyses found no appreciable increase in diabetes in people prior to the initiation of antipsychotic treatment [64, 66].

People with SMI experience higher rates of microvascular and macrovascular complications, acute metabolic dysregulation and three- to fourfold more diabetes-related deaths [2]. In one study from Denmark, among those aged ≤50 years, 15.0% died within 7 years of a diagnosis of diabetes; the corresponding figures for those aged 50–69 years and ≥70 years were 30.7% and 63.8%, respectively. A third of deaths from physical causes were attributed to diabetes while 14% of deaths were attributed to the interaction between diabetes and SMI [67].

Why psychotic disorders are linked to diabetes

Unlike depression, there is no evidence that diabetes predisposes to psychotic illness but it has been noted for over a century that people with SMI are at increased risk of glucose abnormalities. An interest in the physical health of those with SMI was stimulated following the introduction of first-generation antipsychotics that for the first time allowed people with SMI to achieve reasonable control of their psychotic symptoms and live independently. Following concerns about metabolic side effects of the second-generation antipsychotics around the turn of the millennium, further effort was made to understand the link between SMI and diabetes and a greater understanding of the highly complex inter-relationship between the person with SMI, their treatment and environment and risk of diabetes has been gained. Although concerns about the side effects of antipsychotics triggered the resurgent interest in diabetes, to blame the antipsychotics alone for the increased risk of diabetes in people with SMI misses the

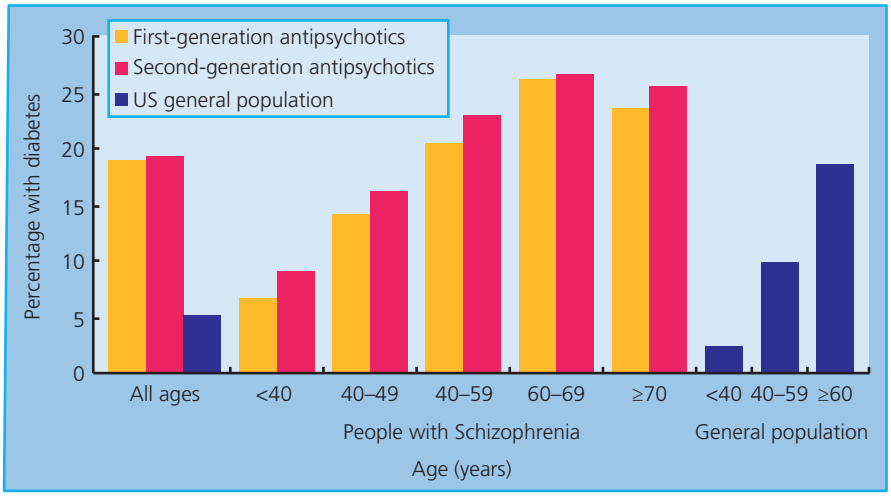

Figure 57.3 Age-specific prevalence rates of diabetes in people with schizophrenia, separated by treatment, compared with the general US population. full picture and may hinder attempts to prevent and treat diabetes in this population.

Genetics

Both schizophrenia and T2DM are highly heritable disorders and it is conceivable that there may be genes that increase the risk of both conditions. Many schizophrenia genes are expressed in the brain and include those involved in glutamatergic neurotransmission and D_2 dopamine receptor (*DRD2* gene) while T2DM is associated with polymorphisms in genes that influence hepatic and peripheral insulin resistance, adipogenesis, and pancreatic β cell mass and function (see Chapter 14). Recent studies have identified at least 37 common genes that increase the risk of both T2DM and schizophrenia [68]. It is estimated that approximately 11% and 14% of these risk genes for T2DM and schizophrenia, respectively, may account for the risk of the other disease. Several candidate genes that may affect the risk of both conditions have been identified (Table 57.4) [68].

In addition to affecting an individual's risk of T2DM directly, genetic polymorphisms in various genes, including the promoter region of the 5-hydroxytryptamine$_{2C}$ receptor, leptin, methylenetetrahydrofolate reductase (*MTHFR*) and *MC4R* genes, appear to modify the risk of antipsychotic-induced weight gain [69]. Polymorphisms in the *HRH1*, *BDNF*, *NPY*, *CNR1*, *GHRL*, *FTO*, and *AMPK* genes may also affect the risk of weight gain.

Environment and biological effects of the illness

Many of the environmental factors that mediate the association between diabetes and depression are also relevant for the links between diabetes and SMI, including intra-uterine environment, adult lifestyle (diet and lifestyle), neighborhood environment, and poverty (Figure 57.2) [2]. A number of inflammatory and neuroendocrine changes, including HPA dysfunction, also occur in SMI.

Antipsychotic medication

Antipsychotics are an integral element of SMI treatment that comprises multidisciplinary psychological, social, and rehabilitation interventions. They are frequently taken over a long period to prevent relapse and hospitalization and to decrease mortality [70]. The first generation of antipsychotics was introduced in the 1950s but their use was blighted by a high incidence of a range of unwanted side effects, including hypotension, weight gain, sexual dysfunction, and sedation and extra-pyramidal side effects. In order to reduce the likelihood of these movement disorders, second-generation antipsychotics (also known as atypical

Table 57.4 Genes that have been linked to both diabetes and schizophrenia [2].

Gene	Function
Glycogen synthase kinase 3 (*GSK3*)	Regulates both glucose metabolism and cognitive function
Serine–threonine protein kinase *AKT1*	Reduced expression in lymphocytes and the frontal cortex in schizophrenia. Mediates insulin signaling and glucose metabolism; reduced action leads to diminished phosphorylation of its substrates, including *GSK3*.
Dopamine D_2 receptor (*DRD2*) gene	Implicated in obesity and T2DM, through alteration of insulin sensitivity and secretion. Affects risk of schizophrenia
Tyrosine hydroxylase gene	Associated with insulin resistance and schizophrenia
TCF7L2 gene	Encodes for a transcription factor involved in Wnt/beta-catenin signaling that has a role in pancreatic β cell function and is a susceptibility gene for T2DM. Wnt signaling pathway plays a role in CNS development and is associated with schizophrenia

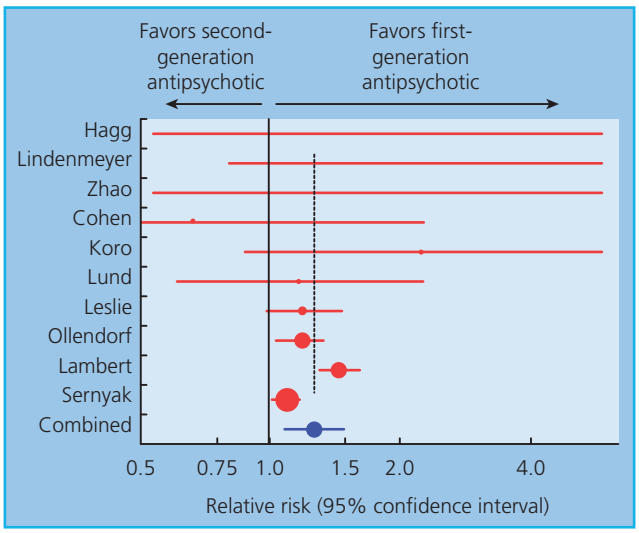

Figure 57.4 Forest plot of relative risks and 95% CIs for diabetes in patients with schizophrenia receiving first-generation antipsychotics compared with second-generation antipsychotics. Source: Adapted from Smith et al. 2008 [72].

antipsychotics) were developed. Although the second-generation antipsychotics are generally better tolerated, an association with weight gain and other metabolic abnormalities rapidly became apparent [2, 71].

Large pharmaco-epidemiological database studies reported that antipsychotics were associated with more diabetes than no treatment while treatment with a second-generation antipsychotic is associated with a small 32% (15–51%) increase in diabetes risk compared with first-generation antipsychotics (Figure 57.4) [72]. Overall the risk, however, appears to be low with the NNH estimates ranging from 19 to 333 for clozapine, 22 to 3333 for risperidone, 21 to 747 for olanzapine, and 24 to 500 for quetiapine (Figure 57.5) [73]. Although the risk of diabetes for the latest second-generation antipsychotics is widely believed to be lower, this has not always been apparent in pharmaco-epidemiology studies. For example, aripiprazole and ziprasidone were not associated with lower rates of diabetes than olanzapine, quetiapine, and risperidone in a pharmaceutical claims database [74], perhaps because of channeling bias whereby persons at higher risk for diabetes are prescribed antipsychotics that are perceived to be safer.

Although pharmaco-epidemiological studies are able to assess small risks in large populations who may be followed for a longer period of time than clinical trials, by design, they have a number of

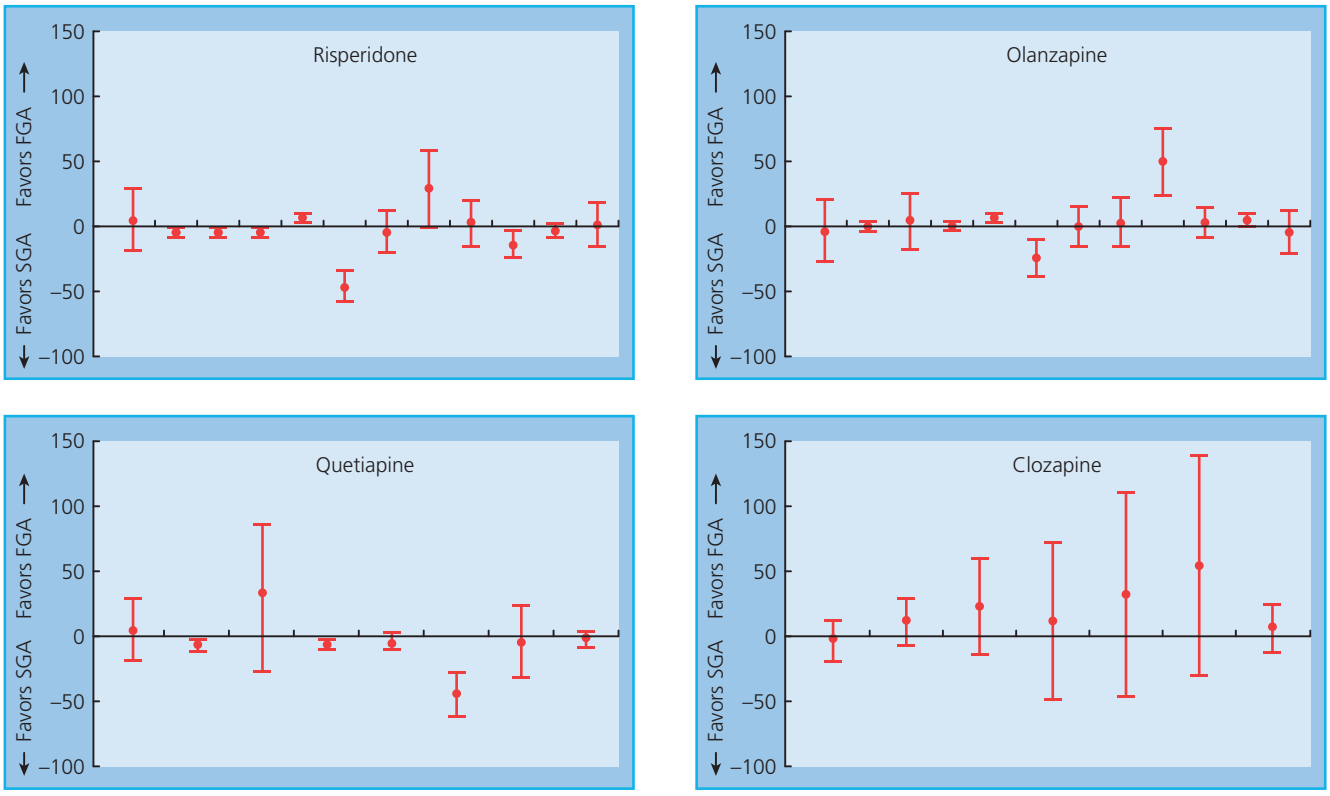

Figure 57.5 Number of cases of diabetes estimated to occur beyond those expected with first-generation antipsychotics (FGA) per 1000 patients treated with a second-generation antipsychotic (SGA), 95% CI. Source: Adapted from Citrome et al. 2007 [73].

methodological flaws that can affect the interpretation of results. They rely on data from administrative databases with inherent problems of data quality, such as convenience reporting of adverse effects, prescriber bias and omission of important confounding diabetes risk factors [75]. Furthermore individuals with either undiagnosed diabetes or those treated with lifestyle interventions alone will not be recorded in prescription databases.

Treatment assignment is not randomized and so differences in diabetes rates may be explained by factors other than the treatment. For example, clozapine is usually reserved as a second-line antipsychotic because of its risk to cause agranulocytosis, requiring ongoing monitoring of the white blood cell count. As a result, it is used in people with the most serious mental illness who are resistant to treatment with at least two other antipsychotics. By virtue of their illness, these individuals may be at higher risk of diabetes and so higher rates of diabetes among people treated with clozapine may reflect the person receiving the antipsychotic rather than treatment per se. Another potential reason for the observed increase with clozapine is "screening bias." People receiving second-generation antipsychotics, particular those receiving clozapine, are much more likely to be screened for blood glucose abnormalities than individuals receiving first-generation antipsychotics [76, 77]. Since there are high rates of undiagnosed diabetes in people with SMI, increased screening will inevitably result in an increased detection of diabetes without the need to invoke a causal relationship between drug and diabetes.

Randomized controlled trials (RCTs) are considered the gold standard when assessing the effect of an intervention but antipsychotic trials are under-powered to detect changes in incident diabetes and consequently most RCTs have reported no differences in incident diabetes [78]. Examining blood glucose changes is a more sensitive way of assessing an antipsychotic's metabolic effects and a systematic review of 48 head-to-head comparison studies found that a greater, albeit small, increase in glucose following treatment with olanzapine compared with amisulpride, aripiprazole, quetiapine, risperidone, and ziprasidone [79]. There were no differences in glucose changes between the other antipsychotics studied. Another systematic review found similar increases in glucose following treatment with the newer antipsychotics, asenapine, iloperidone, and paliperidone [80]. In the European First-Episode Schizophrenia Trial, which examined treatment effects in treatment naïve people with first episode psychosis, the mean change in glucose over a year ranged between 0.2–0.5 mmol/L with no differences between drugs [81]. Albeit small, these increases in glucose concentration may translate into meaningful differences in incident diabetes with the long duration of treatment needed to treat SMI.

There are several mechanisms by which antipsychotics increase the risk of diabetes. All antipsychotics may be associated with weight gain [71]; however, the effect size is markedly heterogeneous, with weight gain being less problematic for haloperidol, ziprasidone, and lurasidone in contrast to large effects observed with olanzapine, zotepine, and clozapine [82]. Overall 15–72% of people taking antipsychotics experience more than 7% of body weight gain in the first year of treatment [83]. From the short-term pivotal trials of the different antipsychotics, NNH versus placebo for weight gain of ≥7% from baseline ranges from 6 for olanzapine and quetiapine immediate-release to 67 for lurasidone [84]. Weight gain is most marked in people naïve to antipsychotics where weight gain is up to three- to fourfold greater than in those with chronic illness [85]. Most weight gain occurs early in treatment although people can continue to gain weight for at least 4 years after treatment initiation albeit at a slower rate gradually reaching a plateau.

Weight does not explain all the excess diabetes risk as some individuals develop diabetes without being overweight or gaining weight. Furthermore, as weight gain is likely to increase diabetes risk through increased insulin resistance, it does not explain why some people develop diabetic ketoacidosis which occurs as a result of markedly impaired insulin secretion. Through their interaction with multiple receptors, antipsychotics may affect insulin secretion by the β cells of the pancreas. Blockade of α_2 receptors may increase basal insulin secretion while blockade of 5-HT_{1a} and 5-$HT_{2a/c}$ receptors may decrease pancreatic β cell responsiveness to blood glucose (Figure 57.6). Central control of glucose homeostasis may also be affected by antipsychotics [86].

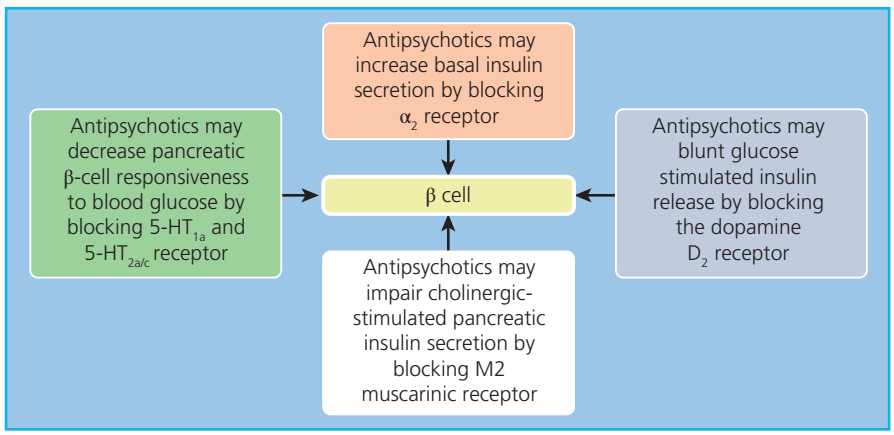

Figure 57.6 Possible pharmacological effects of antipsychotics on β-cell function.

In addition to these pancreatic effects, *in vitro* work suggests that antipsychotics may directly impair insulin action by inhibiting insulin-mediated glucose uptake and glycogen synthesis.

Contribution of different mechanisms

Given the complex pathophysiology of T2DM, it is perhaps unsurprising that multiple mechanisms are involved in the association between SMI and diabetes. It is also likely that the contributions of these risk factors operate differently between individuals. Overall, it appears that an excess of traditional diabetes risk factors, such as obesity, poor diet, physical inactivity, and family history, convey a higher risk than treatment, but this does not discount the possibility that antipsychotics are the major contributor to the development of diabetes in certain individuals, particularly where the onset of diabetes is rapid after treatment initiation and other risk factors are absent [2].

Screening of diabetes in those with severe mental illness

Given the large numbers with undiagnosed diabetes, there have been moves to screen at risk individuals in the general population for diabetes. As people with SMI constitute a high-risk group, several national and international guidelines have recommended regular screening for diabetes, regardless of treatment [87–90]. Although there are differences in detail, all guidelines recommend screening before the start or change of treatment, several months later to identify the few who develop diabetes rapidly after antipsychotic initiation and annually thereafter. Although the oral glucose tolerance test has been implemented successfully in some settings, this test is no longer widely used in the general population and measurements of fasting or random glucose, or glycated hemoglobin (HbA_{1c}) are more practical alternatives. There is a debate about the relative sensitivity and specificity of each of these tests but a pragmatic view should be taken; both random glucose and HbA_{1c} are more convenient and this probably outweighs any small loss of sensitivity. One caveat about HbA_{1c} is that it may be falsely negative if glucose concentrations are rising rapidly as may happen shortly after treatment initiation. In the setting, combining HbA_{1c} and glucose is a sensible option.

Despite clear guidance and potential benefit, screening has not been implemented into routine clinical practice (Figure 57.7) [90, 91], perhaps because people with SMI may be less likely to undergo opportunistic health screening. Professional barriers to screening including inertia or prejudice, lack of clarity about whose responsibility it is, lack of understanding about the most appropriate test and its interpretation and lack of access to necessary equipment may also be responsible for the poor screening rates within mental health settings [92].

Prevention of diabetes

There have been no specific diabetes prevention studies in people with SMI, but randomized control trials have shown that lifestyle interventions that aim to treat or prevent obesity, which encompass similar principles to diabetes prevention are

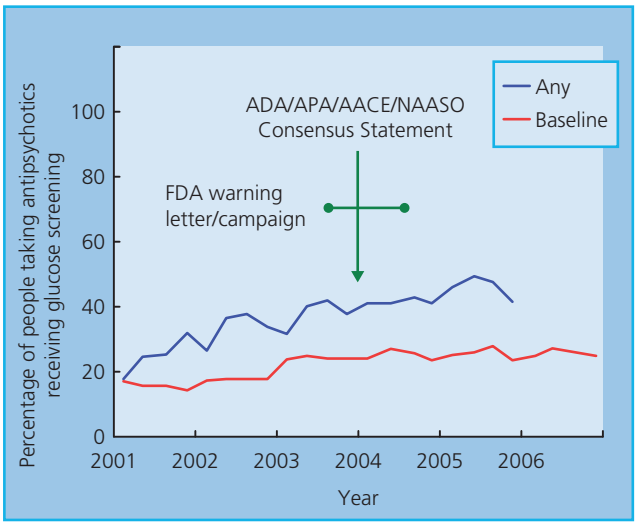

Figure 57.7 The effect of the American Diabetes Association; American Psychiatric Association; American Association of Clinical Endocrinologists; North American Association for the Study of Obesity consensus statement and U.S. Food and Drug Administration guidance on glucose testing in people receiving antipsychotic medication. Source: Adapted from Morrato et al. 2009 [91], Figs 1 and 2.

feasible in people with SMI. A meta-analysis of lifestyle interventions reported a mean reduction in weight of 3.12 kg over a period of 8–24 weeks with commensurate reductions in waist circumference and improvements in cardiovascular risk factors [93]. The interventions, which employed a variety of techniques including cognitive behavioral therapy and nutritional interventions, were beneficial in both individual or group settings and weight reductions were seen irrespective of duration of mental illness and treatment. Outpatient interventions appeared more effective than inpatient settings. The few studies with long-term outcomes suggest that benefits may persist for up to 1 year after the program's end, although others suggest that long-term behavior change may be difficult to maintain [94].

Several longer observational studies of weight management programs suggest that sustained weight loss can be achieved [2]. An 8-year observational study of a group intervention in well-motivated participants found that mean weight and BMI reduced progressively throughout follow-up [95]. The mean weight loss at 1 year was ~10% (~10 kg), with nearly two-thirds of participants achieving a 7% weight loss. By the end of the program, 92% had lost some weight with the only predictor of weight loss being the number of sessions attended.

A tailored and flexible program design of the intervention, outreach delivery in familiar locations, and effective inter-agency working are all important facilitators of behavior change while barriers include literacy difficulties, transient participant populations, low prioritization of diabetes prevention, and cost [96].

No pharmacological diabetes prevention trials in people with schizophrenia have been reported but short-term trials have shown that both metformin and orlistat reduce weight or

Metformin
Betahistine
Fluoxetine
Reboxetine (not available in the USA)
Sibutramine (withdrawn because of safety concerns)
Exenatide
Orlistat (approved for the management of obesity)
Lorcaserin (approved for the management of obesity in the USA)
Phentermine topiramate combination (approved for the management of obesity in the USA)
Naltrexone bupropion combination (approved for the management of obesity in the USA)
Liraglutide (approved for the management of obesity)

attenuate weight gain in people with schizophrenia receiving antipsychotics and improve insulin resistance (Table 57.5) [97]. A systematic review of studies to attenuate weight gain or promote weight loss reported that the mean difference between metformin and placebo was -3.17 kg [97]. In practice, orlistat is difficult to use because of its gastrointestinal side effects and so metformin is a more practical option. More research is needed to determine the long-term effectiveness of metformin but in the meantime, it can be considered for those who are unable or unwilling to make lifestyle changes or for those whose glucose concentrations continue to deteriorate despite lifestyle change.

Several other drugs, including d-fenfluramine, sibutramine (now withdrawn), topiramate, and reboxetine, have a modest effect on weight but there are insufficient data about efficacy or safety to recommend their use outside clinical trials (Table 57.5) [98]. Newly approved weight-loss agents such as lorcaserin, phentermine topiramate combination, naltrexone bupropion combination, and liraglutide have not yet been systematically studied among persons with SMI [99, 100].

Given the different propensities to weight gain and metabolic disturbance between antipsychotics [71], it is reasonable to consider whether switching antipsychotics may reduce the subsequent risk of diabetes. There is a lack of high-quality data to support this strategy but a Cochrane review of four studies including 636 participants showed that body weight reduced by a mean of 1.94 kg when people switched from olanzapine to either aripiprazole or quetiapine [101]. In addition there was a small but significant reduction in fasting blood glucose (0.1 mmol/L) reported in two trials. Any decision to switch antipsychotic must take account of the potential to affect the mental health of the patient.

Management of those with diabetes

The management of diabetes in people with SMI should follow currently available treatment algorithms for the general population but agents that induce less weight gain or promote weight loss, such as incretin-based therapies or SGLT-2 inhibitors, may have advantages given the high prevalence of obesity in people with SMI. Although the GLP-1 receptor agonists must be given by injection, the development of once-weekly preparations may allow these to be administered by mental health teams when the individual is unable to self-administer the injection.

Diabetes self-management is a key skill to achieving good control of diabetes and there are concerns that SMI may interfere with the lifestyle changes, regular monitoring and self-medicating that make up diabetes self-management. Consequently it is reassuring that a systematic review reported adherence rates among those with mental illness of between 51–85% with two studies finding higher rates of adherence than in the general population [102].

It is important that healthcare professionals, both in primary care and in mental health teams, ensure that people with SMI are not disadvantaged with regard to their diabetes care. Despite increased contact with primary care, there is increasing evidence that people with mental illness receive less education about diabetes, are less likely to be examined for retinopathy or diabetic foot complications, and are less likely to be screened for HbA_{1c} and other cardiovascular risk factors [4].

When an individual develops diabetes, while receiving an antipsychotic, it is important to assess what role this is likely to have played in the onset of diabetes in this individual. Under some circumstances, it may be appropriate to switch to an alternative antipsychotic if the patient's mental state will not be adversely affected [87].

Eating disorders

Case definitions

There are three main forms of eating disorder commonly diagnosed in adults [11].

- Anorexia nervosa (AN)
- Bulimia nervosa (BN)
- Binge eating disorder (BED).

Eating disorders exist on a continuum of severity, and there is a lack of good evidence on which to establish a formal boundary or cut-off for "clinical" significance. When an eating disorder co-occurs with a chronic disease such as diabetes, its significance may be increased by the potential for harm resulting from impaired self-care and glycemic control; thus eating disorders, which may be seen as "mild" in an otherwise healthy individual take on increased clinical importance. Because eating disorders are commonest in adolescents and young adults, there has been more research on the co-occurrence of eating disorders and T1DM; far less is known about such problems in the larger population with T2DM [103].

Diagnostic criteria for the common forms of eating disorder [11] are given in Table 57.6.

Table 57.6 DSM-5 Diagnostic criteria for Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder.

Anorexia Nervosa

Restriction of energy intake relative to requirements, leading to a significantly low body weight in the context of age, sex, developmental trajectory, and physical health. Significantly low weight is defined as a weight that is less than minimally normal or, for children and adolescents, less than that minimally expected.

- Intense fear of gaining weight or becoming fat, even though underweight.
- Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight.

Bulimia Nervosa

- Recurrent episodes of binge eating. An episode of binge eating is characterized by (1) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances; and (2) a sense of lack of control over eating during the episode.
- Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as: self-induced vomiting; misuse of laxatives, diuretics, enemas or other medications; fasting or excessive exercise.
- The binge eating and inappropriate compensatory behaviors both occur, on average, at least once a week for 3 months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of anorexia nervosa.

Binge Eating disorder

- Recurrent episodes of binge eating. An episode of binge eating is characterized by (1) eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances; and (2) a sense of lack of control over eating during the episode.
- The binge eating episodes are associated with three (or more) of the following: (1) Eating much more rapidly than normal. (2) Eating until feeling uncomfortably full. (3) Eating large amounts of food when not feeling physically hungry. (4) Eating alone because of feeling embarrassed by how much one is eating. (5) Feeling disgusted with oneself, depressed, or very guilty afterward.
  - Marked distress regarding binge eating is present.
  - The binge eating occurs, on average, at least once a week for 3 months.
  - The binge eating is not associated with the recurrent use of inappropriate compensatory behavior as in bulimia nervosa and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa.

Clinical features

Anorexia nervosa (AN)

The hallmark of AN is weight loss, usually achieved by a combination of extreme dieting, exercise and, less commonly, self-induced vomiting. Misuse of laxatives and other weight-reducing substances (e.g. diuretics, thyroxine) may also occur. People with AN experience a characteristic set of attitudes and values concerning body shape and weight, which include intense feelings of fatness and extreme fear of loss of control over eating and consequent weight gain. Their body image is distorted and they express a level of dissatisfaction with their shape and weight, which is far beyond that seen in the general population. There is a tendency to judge their self-worth almost solely in terms of weight, shape, and ability to control food intake. AN is commonly regarded as being "egosyntonic," as individuals are unable to recognize that there is anything wrong and have little insight into the seriousness of their low body weight.

Anorexia nervosa usually begins in adolescence, although prepubertal and adult onset may occur. For some the natural body changes of adolescence appear to be a risk factor; weight loss associated with a diagnosis of T1DM and then commencement of insulin treatment and subsequent weight gain may act as a trigger.

The low weight of people with AN gives rise to the physiological and psychological features of starvation, including ritualized eating habits, cognitive rumination about eating, irritability, poor concentration, constant feelings of cold and misery, and decreased activity. Social withdrawal and isolation is common, and anxiety, obsessional features and suicidal thoughts sometimes occur. "Fattening" foods are typically avoided and the diet contains an average daily intake of calories in the region of 600–900 kcal per day, with very low fat and mineral intake. Most people with anorexia continue to feel hungry, and as such the term "anorexia" is a misnomer.

Common physical symptoms include gastrointestinal complaints (constipation, fullness after eating, bloating, and abdominal pain), lack of energy, reduced libido, early waking, and postural dizziness. Amenorrhea is often present, with infertility and osteopenia a significant risk. Those with pre-pubertal onset are often small in stature and show failure of breast development. Bradycardia, hypotension, and peripheral neuropathy are also reported, and a range of endocrine abnormalities may be found, including low sex hormone and tri-iodothyronine levels (with normal thyroxine and TSH), and raised growth hormone and cortisol.

Bulimia nervosa (BN)

Bulimia nervosa is characterized by recurrent episodes of binge eating in which large amounts of food are consumed (typically

≥2000 kcal) during which the individual feels unable to control the eating. This behavior is accompanied by a range of "compensatory" behaviors designed to prevent weight gain, including dietary restriction, vomiting, exercise, and laxative or diuretic misuse. People with BN have broadly the same set of attitudes and beliefs to those seen in AN. Although most individuals fall within the normal weight range, some have a past history of underweight, and may have previously met the diagnostic criteria for AN, while others are overweight. The vicious cycle of dieting, bingeing, purging, and fear of weight gain invariably has a detrimental impact on other aspects of functioning, such as work and social relationships, and can have financial implications resulting from the cost of the food. For some, binge eating seems to serve an important function by regulating unpleasant emotional states. Some sufferers have other impulse control problems and a history of interpersonal difficulties. Depression and self-harming behaviors such as cutting, overdosing or substance misuse may occur.

Physical complications of BN include enlargement of the parotid glands, erosion of dental enamel, and hypokalemia from vomiting, laxative or diuretic misuse.

Binge eating disorder (BED)

The cardinal feature of BED is regular episodes of binge eating. In the DSM-5, it is defined by recurrent episodes of binge eating (eating in a discrete period of time an amount of food larger than most people would eat in a similar amount of time under similar circumstances and a sense of lack of control over eating during the episode), occurring on average at least once a week for 3 months, and associated with marked distress. Binge episodes are also associated with ≥3 of the following:

- eating rapidly,
- eating until feeling uncomfortably full,
- eating large amounts of food when not feeling physically hungry,
- eating alone because of feeling embarrassed by how much one is eating,
- feeling disgusted with oneself, depressed, or guilty afterwards.

Unlike those with BN, persons with BED do not regularly engage in compensatory behaviors. Although many people with BED are obese, more than half have a BMI <30 kg/m^2, including 19% whose weight is normal [104].

Epidemiology

Binge eating disorder is the commonest eating disorder with an estimated lifetime prevalence of 2.6% among US adults, more than the prevalence for bulimia nervosa and anorexia nervosa combined, with a gender ratio that is far less skewed [104, 105]. In contrast, it is thought that about 1 in 250 females and 1 in 1000 males will experience AN, usually during adolescence or early adult life. BN is thought to be commoner with 0.5–1% of young women being affected in community studies. Longitudinal studies have shown that eating disorder diagnoses are often unstable over time, and cross-sectional studies underestimate the proportion of the population affected in the long term. Incidence rates in adolescent and young adults are higher than previously estimated.

Diabetes as a risk factor for the development of an eating disorder

Early case reports in the 1970s and 1980s highlighted the fact that people with T1DM omit insulin as a further means of weight control and there has been a strong clinical impression for many years that eating disorders are over-represented in people with diabetes. However, studies have produced conflicting results depending on the study population and eating disorder studied. There seems to be no difference in the prevalence of AN [106] but BN is 2.4-fold commoner in people with T1DM [107]. Intentional insulin omission occurs remarkably frequently increasing from 2% among girls aged 9–13 years, to 11% among girls aged 12–19 years, to 34–40% among young women aged 16–30 years old [108]. Such "self-induced glycosuria" is common but not universal, and is not confined to people with a frank eating disorder, being more widely observed as an occasional phenomenon in a range of weight-conscious individuals, more commonly women. As a means of weight control, the behavior produces rapid but often unsustainable weight loss, the main effect being via acute dehydration.

Some clinical features of disordered eating may persist into middle and later life and may be seen in people with T2DM. BED is often associated with obesity and is the most likely condition to occur.

Etiology

The causes of eating disorders are incompletely understood but dieting appears to be an important risk factor, although only a small proportion of all those who diet go on to develop a disorder. Other known risk factors include female gender, early puberty, a history of obesity or gaining weight, peer and cultural influences and certain personality traits including perfectionism and low self-esteem. Family relationships are often disturbed, although this may be either a cause or consequence of the disorder, or both. Several of these factors may be magnified by the demands of the diagnosis or management of T1DM. People with T1DM are encouraged to make dietary changes including restriction of high calorie fatty and sugary foods; this can lead to a preoccupation with food and body weight. Instead of relying on physiological cues related to hunger and satiety, food intake is brought under cognitive control; this can lead to feelings of low self-esteem and depression if self-imposed targets are missed. This in turn may drive further dietary restraint with a greater likelihood of subsequent failure, thereby causing a vicious cycle.

On average, people with T1DM are heavier than their peers and this may trigger dieting, weight preoccupation and altered body image perception. Furthermore there is a conflict between optimal diabetic and body weight control as weight tends to increase as HbA_{1c} comes down. Insulin treatment itself can lead to weight

gain and adjustment of insulin dose during puberty is notoriously difficult.

In contrast, there may also be protective factors; most notable of these is close medical and family surveillance during the period of highest risk of behaviors, such as vomiting and bingeing. However, in dysfunctional families, omission of insulin may be a tool used by the adolescent.

Impact on diabetes outcomes

Eating disorders, especially if persistent, are a major cause of poor outcome in people with diabetes [109]. In the short-term severe hypoglycemia, diabetic ketoacidosis, and hospital admission are all commoner in those with eating disorders [110]. Rates of serious micro- and macrovascular complications and mortality are significantly increased, even if the eating disorder is relatively short-lived. However, the incidence of long-term complications increases with the duration of insulin omission. Eighty-six percent of girls with T1DM and severe eating disorders developed retinopathy after 4 years compared to 24% of those without eating disorders [111]. In a 10-year follow-up study of females with T1DM, a quarter of those who reported insulin omission had nephropathy, compared with 10% of those who did not [112]. Mortality rates in girls with T1DM are increased nearly 16-fold in those with an eating disorder compared to those with diabetes alone (34.6 vs. 2.2 per 1000 person-years) in girls with T1DM [113].

Management of eating disorders

Detection

- Although some people with diabetes may volunteer information about eating problems, many will be secretive as a result of factors including denial, guilt, or shame. Thus an essential first step in management is successful detection of the problem. It is important to note that, although eating disorders are generally associated with poor self-care and erratic glycemic control, alternating periods of hypo- and hyperglycemia may be undetected by HbA_{1c}. Warning symptoms include:
- Marked weight fluctuation or loss.
- Symptoms of hyperglycemia (thirst or tiredness).
- Frequent episodes of ketoacidosis (often requiring hospital admission) or hypoglycemia leading to loss of consciousness.
- Growth retardation and pubertal delay may be seen in younger people with T1DM.

Most of these features are not specific for eating disorders and are only indicative of poor self-care. The only way to establish a diagnosis of an eating disorder is by a clinical interview, although brief self-report scales may be a useful means of screening.

General diagnostic questionnaires for detecting eating disorders are inappropriate for individuals with T1DM, as they do not identify features that are unique to T1DM, such as insulin omission. Furthermore some aspects of normal diabetes management may be viewed as disturbed eating in the general population. The revised Diabetes Eating Problem Survey (DEPS-R) is a 16-item diabetes-specific self-report measure of disordered eating that was designed specifically for people with diabetes [114] while the mSCOFF questionnaire is a simple five-item screening tool that is reliable, well validated, and can easily be used by diabetes healthcare professionals [115].

Treatment of eating disorders

There is a lack of primary research to guide the treatment of people with an eating disorder and diabetes, and advice is therefore based on existing guidelines for people without diabetes [116]. Dietary counselling by a dietician or specialist nurse may be a helpful first step, especially for those with milder disorders, but most cases will require specialist help. Guided self-help appears to be a viable option as a first step for people with bulimia. In all cases close liaison between the therapist managing the eating disorder and the diabetes team will be required. Eating disorder treatment needs to be enhanced with attention to:

- insulin or medication use
- glycemic control
- diabetes-related dietary restrictions
- relationships with family and medical staff
- feelings about having diabetes.

Although most people can be managed on an outpatient basis, the risk of impaired physical health necessitating inpatient admission is increased in those with diabetes. Regular physical monitoring is needed to manage the high risk of complications and mortality [117].

Anorexia nervosa

The evidence base for the treatment of AN with comorbid diabetes remains surprisingly weak but is likely to involve both psychosocial and biological aspects requiring a multidisciplinary team. A necessary first step for all patients is restoration of weight towards normal levels. During this process it is usually necessary to accept realistic rather than tight glycemic control. Diet should focus on healthy foods with a high satiety index. Severe hypo- or hyperglycemia must be avoided; as it is necessary to consume calories to prevent or treat hypoglycemia, this can cause patient anxiety. There is preliminary evidence that insulin pumps may decrease abnormal eating behavior and improve glycemic control because their use is associated with less weight gain and hypoglycemia [118]. As the insulin dose and blood glucose levels will change with eating habits and weight, it is essential that the eating disorder therapist understands the principles of diabetes treatment.

Bulimia nervosa

Treatment for BN, particularly by means of cognitive-behavioral therapy (CBT), is widely accepted, although there has been less study of its suitability for people with diabetes. The coexistence of diabetes with bulimia inevitably complicates management. Successfully engaging people in treatment may be more difficult, and approaches such as motivational interviewing may play a role [119]. Modification to standard treatment approaches includes the monitoring of self-care behaviors; again it is desirable that the

eating disorder therapist has knowledge and experience of the usual management of diabetes. Conflict may arise between the modifications to eating behavior advocated for BN treatment (promoting a more flexible approach to eating) and the dietary advice often given for diabetes management (regular controlled eating and avoidance of certain food groups). The development of structured education which offer a more person-centered approach may help this dilemma [120].

Other forms of treatment for BN include interpersonal psychotherapy, and the use of antidepressants. Fluoxetine has been approved for acute and maintenance treatment of binge-eating and vomiting behaviors in people with moderate to severe BN. A group educational program for people with bulimia and T1DM was better than "standard care" in improving eating behavior, but did not lead to improved glycemic control [121]. Inpatient treatment also appears to be successful, although the applicability of this approach in most healthcare systems remains to be tested.

Binge eating disorder

For the management of BED, psychological treatments such as cognitive behavioral interventions are recommended as first line and supported by meta-analytic reviews [122]. At present, only lisdexamfetamine, a stimulant that was originally approved for the treatment of attention deficit hyperactivity disorder, has been approved for the treatment of moderate to severe BED [123]. Treatment approaches for BED with comorbid diabetes have not been extensively studied but in one small study in T2DM, no significant difference was found in HbA_{1c} between those with and without BED [124].

Acknowledgments

We acknowledge Professor Robert Peveler, who was the first author of this chapter in the previous edition of the *Textbook of Diabetes*. We would also like to acknowledge Alex Mitchell, Sherita Golden, and Mary de Groot who were co-authors of RIGH for two reviews on which this chapter heavily draws [1, 2].

58 Social Aspects of Diabetes

Brian M. Frier[1] and Mark W.J. Strachan[2]

[1] BHF Centre for Cardiovascular Science, The Queen's Medical Research Institute, University of Edinburgh, Edinburgh, Scotland, UK

[2] Metabolic Unit, Western General Hospital, Edinburgh, Scotland, UK

Key points

Driving

- Potential hazards facing the driver with diabetes include hypoglycemia, visual impairment, and disability from severe neuropathy or leg amputation.
- Hypoglycemia can severely disrupt driving skills by causing cognitive dysfunction and mood changes. Motor skills and judgment can become impaired when blood glucose falls below 3.8 mmol/L, often without inducing hypoglycemic symptoms. Impaired awareness of hypoglycemia is a relative contraindication to driving. Drivers with diabetes must take precautions to avoid hypoglycemia and know how to treat it if it occurs while driving.
- Corrected visual acuity that is worse than 6/12 in the better eye precludes driving in the general population. People with diabetes may fulfil this criterion, but still have significant visual impairment (e.g. field loss, poor night vision and perception of movement) secondary to retinopathy, laser treatment, or cataracts.
- In many countries, drivers with diabetes are legally required to declare the diagnosis for their driving license and motor insurance. Failure to do this will invalidate insurance claims.
- Driving licenses are often issued for fixed terms and only renewed following satisfactory medical review. In many countries, insulin-treated drivers are debarred from driving passenger-carrying vehicles and large goods vehicles, but the regulations have been changed in the European Union to allow this.

Employment

- Diabetes is not a bar to most occupations, and people with diabetes are protected in many countries by legislation against discrimination on the grounds of disability.
- People with insulin-treated diabetes are barred from certain occupations because of the risk of hypoglycemia. These include the armed forces, emergency services, commercial pilots, prison and security services, and jobs in potentially dangerous areas (e.g. at heights, underwater, and offshore).
- Severe hypoglycemia in the workplace is uncommon and shift work seldom compromises glycemic control. Depressive illness and poor glycemic control are associated with higher unemployment and sickness absence in people with diabetes.

Prison and custody

- Glycemic control may be suboptimal in prison because of restrictions in diet, exercise, and blood glucose monitoring. Intercurrent illness and metabolic abnormalities may not be recognized or treated promptly.
- Input from a diabetes specialist may improve the quality of care. Knowledge of diabetes among prison officers and staff of short-term custodial units is often limited and may be improved by liaising with local diabetes specialist services.

Insurance

- Diabetes should be declared to insurers, who may impose higher premiums or limited coverage. Many insurers' decisions are based on outdated actuarial data or misconceptions about the current prognosis of diabetes. National diabetes organizations can provide details of insurance brokers who do not weight policies against people with diabetes.
- Life expectancy in type 1 diabetes (T1DM) can be modeled from age, sex, and the presence of proliferative retinopathy and nephropathy. As the latter is a major determinant of survival, life insurance premiums should be reduced for all those who reach the age of 50 years without renal impairment.

Alcohol

- The association between excessive alcohol consumption, chronic pancreatitis, and secondary diabetes is well established. Alcohol excess is also associated with central obesity and poor adherence with medication; both could increase the risk of type 2 diabetes (T2DM) and compromise control of established diabetes. Most epidemiologic studies, however, have demonstrated a J-shaped relationship between alcohol consumption and diabetes, with moderate intake being associated with a lower risk of diabetes.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

- In T2DM, moderate alcohol consumption is associated with a 35% reduction in total mortality and lower risk of cardiovascular disease compared to abstinence. Excessive alcohol consumption is associated with hypertriglyceridemia and resistant hypertension; affected individuals have an increased vascular risk.
- Ethanol inhibits hepatic gluconeogenesis and increases the risk, severity, and duration of hypoglycemia. Alcohol obscures the ability, both of the individual and of observers, to recognize and treat hypoglycemia, and intoxication can simulate hypoglycemia.

Recreational drugs

- Approximately one-third of young people with diabetes use recreational drugs at some time. The most common class of drug taken is cannabis, but amfetamine-type stimulants (including "ecstasy"), cocaine, and opiates are also used.
- Recreational drug use is associated with a sixfold higher risk of death from acute metabolic complications of diabetes. Intravenous drug use is uncommon but is dangerous and is associated with omission of insulin therapy, frequent hospital admissions (usually with diabetic ketoacidosis), and high mortality.
- Cocaine and amfetamine-type stimulants can have profound hemodynamic effects through sympatho-adrenal activation. In addition to an increased risk of cardiac arrhythmias and myocardial ischemia, the sympathetic activation antagonizes the action of insulin and can precipitate diabetic ketoacidosis.

Travel

- Diabetes is not a bar to traveling, but changes in meals, physical activity, and antidiabetes drug treatment en route and after arrival all need careful consideration. Important issues include travel insurance, medical identification, supplies and storage of medication and monitoring equipment and immunizations.
- During long flights, blood glucose should be monitored frequently and glycemic control relaxed to avoid hypoglycemia. Insulin injection schedules may require in-flight adjustment, especially if the time-shift exceeds 4 hours.

Leaving home

- In the Diabetes UK Cohort Study, "living alone" was associated with a more than fourfold increase in risk of death from acute metabolic complications of diabetes.
- Leaving home is potentially a period of high risk for young people with diabetes; particular concern has been expressed about the welfare of university students with T1DM.

Introduction

Diabetes influences many aspects of daily life, principally through the effects of treatment and its potential side effects, particularly hypoglycemia. The development of diabetic complications, such as neuropathy and retinopathy, can also affect everyday activities, particularly when these are severe with clinical manifestations, or require time-consuming treatment such as dialysis for chronic renal failure.

Driving

Driving is an everyday activity that demands complex psychomotor skills, visuospatial coordination, vigilance and satisfactory judgment. Although motor accidents are common, medical disabilities are seldom responsible. Diabetes is designated a "prospective disability" for driving because of its potential to progress and cause complications, while side effects of treatment (principally hypoglycemia) can affect driving performance. In most high-income countries, the duration of the license of a driver with diabetes is period-restricted by law, and its renewal is subject to review of medical fitness to drive. The problems associated with diabetes and driving and the limitations of relevant research data have been reviewed [1, 2].

The main problems for the driver with diabetes are hypoglycemia and visual impairment resulting from cataract or retinopathy. Rarely, peripheral neuropathy, peripheral vascular disease, and lower limb amputation can present mechanical difficulties with driving (Table 58.1), but these problems may be overcome by adapting the vehicle and using automatic transmission systems.

Despite these challenges, drivers with diabetes do not appear to be involved in more accidents than their counterparts without diabetes [3]. Population studies have shown no excess in accident rates among drivers with diabetes in Northern Ireland [4], Scotland [5], England [6], Germany [7], Iceland [8], or Pittsburgh in the USA [9], while a large survey of over 30,000 drivers in Wisconsin, USA found only a modest increase [10]. In most surveys, however, incidents were self-reported and probably underestimated, while fatal accidents (in which a diabetes-related cause, such as hypoglycemia, could have had a role) were excluded. Accident rates may also have been lowered by regulatory authorities

Table 58.1 Reasons for drivers with diabetes to cease driving.

Newly diagnosed people with diabetes, especially insulin-treated, should not drive until glycemic control and vision are stable
Recurrent daytime hypoglycemia (particularly if severe)
Impaired awareness of hypoglycemia, if disabling
Reduced visual acuity in both eyes (worse than 6/12 on Snellen chart)—note use of mydriatics for eye examination will affect visual acuity
Severe sensorimotor peripheral neuropathy, especially with loss of proprioception
Severe peripheral vascular disease
Lower limb amputation

Table 58.2 Advice for drivers with diabetes.

Inform licensing authority* (statutory requirement) and motor insurer of diabetes and its treatment
Do not drive if eyesight deteriorates suddenly
Check blood glucose before driving (even on short journeys) and at intervals on longer journeys
Take frequent rests with snacks or meals; avoid drinking alcohol
Keep a supply of fast-acting and complex carbohydrate in the vehicle for emergency use
Carry personal identification to indicate that driver has diabetes (and is prone to hypoglycemia)
If hypoglycemia develops, stop driving, switch off engine, leave the driver's seat and then treat with carbohydrate
Do not resume driving for 45 minutes after blood glucose has returned to normal (delayed cognitive recovery)

* In the UK, the licensing authority is the Driver and Vehicle Licensing Agency (DVLA), Swansea, SA99 1TU, UK.

debarring high-risk drivers and by drivers with advancing diabetic complications who stop driving voluntarily [4, 5]. Practical advice for drivers with diabetes is given in Table 58.2.

Hypoglycemia

Drivers with insulin-treated diabetes often experience hypoglycemia while driving [4, 5, 11] and this can interfere with driving skills by causing cognitive dysfunction, even during relatively mild hypoglycemia that does not induce symptoms. Studies of people with T1DM using a driving simulator showed that driving performance often became impaired at blood glucose concentrations of 3.4–3.8 mmol/L, and deteriorated further at lower levels [12]. Problems included poor road positioning, driving too fast or too slow, inappropriate braking and causing "crashes" by stopping suddenly. Alarmingly, most did not experience hypoglycemic symptoms or doubt their competence to drive; only one-third treated the hypoglycemia, and only when blood glucose had fallen below 2.8 mmol/L [12]. In the UK, the Driver and Vehicle Licensing Agency (DVLA) does not distinguish between type of diabetes, and the restrictions are based on the use of insulin as therapy, as this can cause hypoglycemia in any person using this treatment. The risk of hypoglycemia in insulin-treated T2DM rises with duration of insulin therapy.

Judgement and insight become impaired during hypoglycemia, and some drivers with diabetes describe episodes of irrational and compulsive behavior while at the wheel [11, 12]. Hypoglycemia also causes potentially dangerous mood changes, including irritability and anger [13]. In addition, asymptomatic hypoglycemia impairs visual information processing and contrast sensitivity, particularly in poor visibility [14, 15], which may diminish driving performance.

Poor perception of hypoglycemia is also potentially dangerous. Many drivers with diabetes subjectively overestimate their current blood glucose level and feel competent to drive when they are actually hypoglycemic [16]. Impaired awareness of hypoglycemia, often associated with more frequent severe episodes, is potentially hazardous and is a common reason for revocation of the driving license. It is not an absolute contraindication to driving if it can be demonstrated, by frequent self-monitoring, that there is prolonged freedom from hypoglycemia [17].

Hypoglycemia is a recognized cause of motor vehicle accidents, but its true frequency and causal relationship to a particular incident are often difficult to ascertain. Blood glucose is seldom estimated immediately after a road traffic accident, and evidence for preceding hypoglycemia is often circumstantial. Hypoglycemia was the main cause of non-fatal motor vehicle accidents in the Diabetes Control and Complications Trial (DCCT); hypoglycemia was three times more common in the intensively treated participants, but the rate of major accidents was no higher, perhaps because of better precautionary advice [18]. Other studies have found that the frequency of hypoglycemic episodes during driving correlates with the total number of accidents [4, 5] and hypoglycemia-related driving mishaps are related to the frequency of severe hypoglycemia in the preceding year [19]. The frequency of hypoglycemia-related accidents is substantially lower than those caused by alcohol and drugs.

Avoiding and treating hypoglycemia while driving

General measures to avoid hypoglycemia are discussed in Chapter 35. All drivers with insulin-treated diabetes should keep some fast-acting carbohydrate in the vehicle; disturbingly, some do not [20, 21]. Each car journey, no matter how short, should be planned in advance to anticipate possible risks for hypoglycemia, such as traffic delays. It is advisable to check blood glucose before and during long journeys, and to take frequent rest and meals. Unfortunately, these measures are seldom undertaken [22]. Driving expends energy and—as with other forms of exercise—prophylactic carbohydrate should be taken if the blood glucose is <5.0 mmol/L and driving should be avoided if <4.0 mmol/L [23].

If hypoglycemia occurs during driving, the car should be stopped in a safe place, and the engine switched off before consuming some glucose. In the UK, the individual should vacate the driver's seat and remove the keys from the ignition, as a charge can be brought for driving while under the influence of a drug (insulin) even if the car is stationary. Driving should not be resumed for at least 45 minutes after blood glucose has returned to normal, because cognitive function is slow to recover after hypoglycemia [13].

Many features of hypoglycemia resemble alcohol intoxication, and mentally obtunded hypoglycemic drivers with diabetes are sometimes arrested on the assumption that they are drunk. Drivers with insulin-treated diabetes should therefore carry a card or identity bracelet stating the diagnosis. Individuals with newly diagnosed insulin-treated diabetes may have to stop driving temporarily until their glycemic control is stable.

Insulin secretagogues, the sulfonylureas and glinides, are the only oral antidiabetes drugs that may cause hypoglycemia while driving, and people treated with these agents should be informed

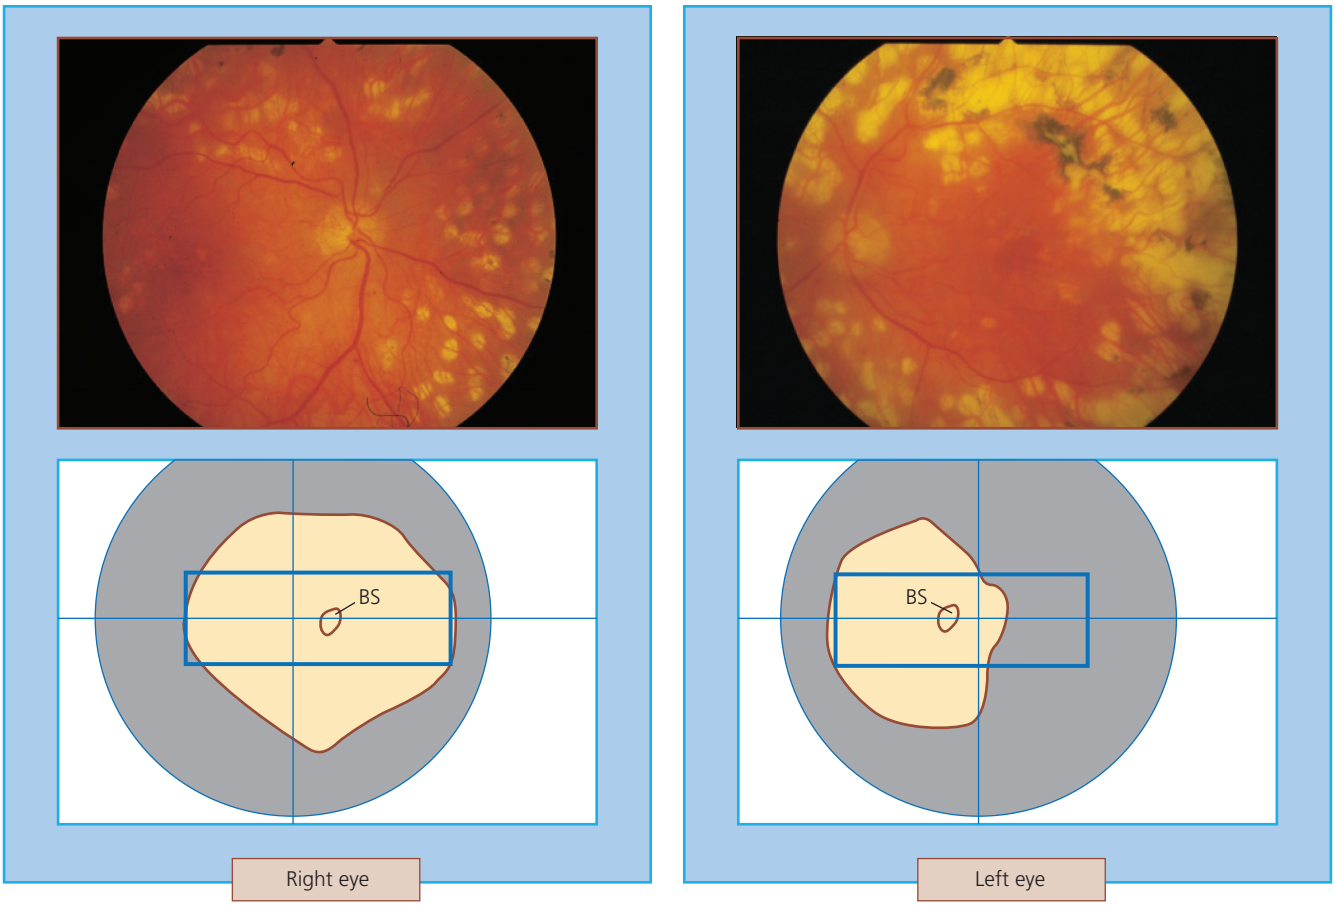

Figure 58.1 Visual field loss caused by photocoagulation. This 60-year-old man with diabetes needed extensive laser photocoagulation to the temporal retina of the left eye, causing nasal visual field loss which caused this eye to fail the standard test for driving. The right eye required less intensive laser treatment and the visual field was adequate for driving. BS, blind spot. Blue rectangle: minimum area recommended for safe driving. Source: Courtesy of D. Flanagan, Addenbrooke's Hospital, Cambridge, UK.

of this possibility. While GLP-1 receptor agonists alone are not associated with a risk of hypoglycemia, this may be a problem when used in combination with a sulfonylurea. Blood glucose testing in relation to driving is not a requisite for drivers with Group 1 driving licenses (see below), but may be required for holders of Group 2 driving licenses who are taking this treatment combination.

Visual impairment

In the UK, monocular vision is accepted for driving, provided that the person meets the minimum legal requirement, that is, to be able to read a number plate with letters 8.9 cm (3.5 inches) high at a distance of 30 m (75 feet), wearing spectacles if necessary. This corresponds to a distance visual acuity of approximately 6/10 on the Snellen chart. The number plate test has deficiencies: it is poorly reproducible under clinical conditions and does not assess visual fields, night vision, or the ability to see moving objects. All of these may be severely reduced by retinal ischemia in preproliferative retinopathy [24], while visual field loss can be caused by extensive laser photocoagulation for diabetic retinopathy [25, 26] or macular edema (Figure 58.1) [27]; careful containment of laser burns can preserve vision [28]. Cataracts often accentuate glare from headlights, and in such cases driving in the dark should be avoided.

Previous surveys have identified very few drivers with diabetes who would fail the standard eyesight test. Impaired vision is an uncommon reason for the driving license to be refused or revoked, although many people stop driving voluntarily because their eyesight is deteriorating. Worsening vision from diabetic (or other) eye disease should be reported by the individual to the licensing authority.

Eye screening is a crucial part of assessing medical fitness to drive. Pupillary dilatation for fundoscopy or retinal photography temporarily reduces visual acuity, particularly if the usual binocular visual acuity is 6/9 or worse [29]. Patients should be told not to drive for at least 2 hours after the use of mydriatics. The driving regulatory authorities require perimetry to assess the visual fields of people who have had photocoagulation (Figure 58.1).

Statutory requirements for drivers with diabetes

In most developed countries, drivers with insulin-treated diabetes are required by law to declare their diabetes to the relevant

regulatory authority (in the UK this is the DVLA). The statutory requirements for ordinary and vocational (professional) driving licenses vary considerably around the world; the national licensing authority should be contacted for details. Licensing restrictions have been criticized as being draconian and discriminatory against people with diabetes, but the civil rights of the person with diabetes have to be balanced against the need to safeguard public safety.

European driving licenses

Ordinary driving licenses (Group 1)

The European Union (EU) member states all use the same classification for driving licenses but this is not applicable to other parts of the world. In the UK, the DVLA must be informed when a person with insulin-treated diabetes applies for, or renews, a driving license, or if insulin dependence develops in a driver with diabetes. Failure to do this constitutes "concealment of a material fact," which can incur a fine, but more importantly can invalidate a claim to the motor insurers; professed ignorance of the law is not accepted as an excuse. The onus to declare rests with the individual driver, but doctors who provide diabetes care, including general practitioners, have a responsibility to inform their patients of this legal requirement, and should offer practical advice (Table 58.2). Drivers with diabetes who are treated with diet alone or with oral antidiabetes medications do not have to notify the DVLA unless they have visual impairment or other diabetes-related problems that could affect medical fitness to drive. In the UK, a driving license is "period-restricted" and is usually issued for a maximum of 3 years, and is renewed after completion of a medical questionnaire. The DVLA request further medical reports in some cases, and always when an applicant reports a medical problem that may seriously affect driving (e.g. recurrent hypoglycemia). GLP-1 receptor agonists (given by injection) can be used without restriction, other than when used in combination with a sulfonylurea for drivers with Group 2 (vocational) licenses, when this must be notified to the DVLA and requires assessment of medical fitness to drive.

The member states of the EU have an agreed policy on restrictions on driving licenses for people with insulin-treated diabetes, and these were changed after publication of the Third Directive on driving (Annex III to European Directives 91/439/EEC and 2006/126/EC: Driving Licence Standards for Diabetes) in 2006 and implemented thereafter. The main provisions are:

1 The interval between regular medical reviews should not exceed 5 years; stricter rules (3-yearly review in the UK) are allowed.

2 A driver must not experience more than one episode of severe hypoglycemia within the preceding 12 months. The time of day has not been specified, and so nocturnal episodes of severe hypoglycemia occurring during sleep are presently included but are to be ignored in future as this requirement is to be amended following legislation that will take effect in January 2018. This criterion raised concerns that it may lead to deliberate concealment of severe hypoglycemia by insulin-treated drivers, which has been suggested by a Danish study [30].

3 A driver must not have impaired awareness of hypoglycemia. No definition of this syndrome was given, and so its interpretation has been left to the discretion of individual states. In the UK it has been defined as "an inability to detect the onset of hypoglycemia because of a total absence of warning symptoms," which is rare in clinical practice.

Vocational driving licenses (Group 2)

It is extremely difficult to estimate the risk and likely outcome of a motor accident as many factors can be involved. Professional drivers have a much higher annual mileage than ordinary car drivers and a higher rate of driving mishaps overall. In the absence of scientific evidence, risk and hazard are gauged by the size of vehicle being driven, which is perhaps not unreasonable, given the potential consequences of a hypoglycemic person losing control of a large heavy vehicle. Before 2010 drivers with insulin-treated diabetes could not be issued with a Group 2 vehicle driving license except in (undefined) "exceptional circumstances," subject to (unspecified) authorized medical opinion and were debarred from driving Group 2 vehicles, with the exception of C1 vehicles (3.5 to 7.5 tonnes). However, in some European countries "exceptional cases" appeared to be the norm and the inconsistent application of EU regulations, inadequacy of assessment of medical fitness to drive, and lack of harmonization between states were very unsatisfactory. As these professional drivers were able to cross state borders and drive in countries with much stricter regulations for Group 2 driving licenses, this was politically unacceptable. The EU Regulations on driving have been relaxed and now allow all drivers with insulin-treated diabetes to apply for a Group 2 driving license, provided they meet strict criteria including having no episodes of severe hypoglycemia, normal hypoglycemia awareness, and undertaking frequent blood glucose monitoring at times relevant to driving (Annex III to European Directives 91/439/EEC and 2006/126/EC).

Oral antidiabetes medication is not a bar to holding a vocational driving license in the UK. In practice, however, many public transport companies restrict the employment of drivers with T2DM who take sulfonylureas; metformin or treatment with GLP-1 receptor agonists is not a contraindication, but medical assessment is usually necessary. Progression to insulin therapy usually terminates the employment of bus and train drivers. Taxi, ambulance and police pursuit drivers are not covered by the statutory regulations. In the UK, taxi licenses are issued by local authorities, which vary considerably in how medical fitness to drive is assessed, although many have now adopted Group 2 licensing standards. The employment of insulin-treated drivers in these other categories is determined by employers who usually seek advice from occupational health physicians.

Driving outside Europe

Outside Europe, the regulations in different countries range from a complete ban to no restriction other than a medical

examination for prospective or current drivers who require insulin [31]. Differences in approach between countries are influenced by the level of economic development and the prevalence of insulin-treated diabetes; many low- and middle-income countries impose no restriction on vocational driving licenses for people with insulin-treated diabetes [31]. The American Diabetes Association has published a position statement with valuable practical recommendations about how to evaluate risks to driving associated with diabetes in individuals, and how these should influence licensing decisions in the USA [32]. Drivers with insulin-treated diabetes are prohibited from driving commercial motor vehicles across state borders in the USA, but within most states, drivers with insulin-treated diabetes can drive commercial vehicles with the exception of lorries transporting hazardous materials and passenger-carrying buses [33].

In most other countries, insulin treatment alone is targeted by legislation, even though hypoglycemia can occur with other glucose-lowering drugs. A Canadian survey of crashes involving truck and commercial vehicle drivers with diabetes revealed an increase in risk for drivers with T2DM treated with sulfonylureas [34], the presumption being that unsuspected hypoglycemia is a causal factor. Similarly, an insurance-based study in the USA of people with T2DM treated with (unspecified) non-insulin therapies showed that those who had made claims for hypoglycemia had greater rates of motor vehicle accidents requiring hospital treatment [35], indicating that hypoglycemia-related mishaps also occur in people with T2DM who are not being treated with insulin.

Aircraft pilot licenses

Pilots with insulin-treated diabetes have been employed for several years by a Canadian commercial airline without any incidents, but in Europe pilots on insulin are not allowed to fly commercial aircraft. However, the UK Civil Aviation Authority, in collaboration with the Republic of Ireland Aviation Authority, is currently using an agreed protocol to certify individual pilots with insulin-treated diabetes to fly commercial aircraft, provided they meet strict medical fitness criteria and fly along with a co-pilot without diabetes. This trial will provide data for further consideration by the European Aviation Safety Agency, with the possibility of allowing certification of insulin-treated pilots in other EU countries. Private pilot licenses can be issued to individuals with diabetes treated with sulfonylureas (provided that they have a safety license endorsement), but not with insulin. People with insulin-treated diabetes cannot work as air traffic controllers.

Employment

With a few provisos, people with diabetes can successfully undertake a wide range of employment. There remains some prejudice against people with diabetes, but employment prospects in the UK and many other countries have improved with the introduction of legislation that makes it unlawful to treat a disabled person less favorably.

The main concern when considering people with diabetes for employment is the risk to safety associated with the condition or its treatment. Employers often fail to make the crucial distinction between a "hazard" (something with the potential to cause harm) and a "risk" (the likelihood that such harm will occur). The potential problems of diabetes relevant to employment are the hazards of acute hypoglycemia related to insulin and sulfonylureas, poor control of diabetes, and the development of serious diabetic complications that may affect ability to work or interfere with performance at work.

Employment is generally restricted where hypoglycemia could be hazardous to the worker with diabetes, their colleagues, or the general public. Employment-related issues, however, are not confined to people with T1DM. The rising prevalence of T2DM in the population of working age, along with the increasing use of insulin, has become an issue for occupational health assessment. Access to employment may be limited through discriminatory employment practices and restrictions posed by companies (rather than by legislation) because of perceived problems associated with diabetes or to job-sensitive issues related to the potential risks of hypoglycemia or to visual impairment. Diabetes can also affect employment through increased sick leave and absenteeism and by adversely influencing productivity. Diabetes in general has a negative long-term influence on the economic productivity of the individual; health-related disabilities can cause work limitations, especially in older employees in whom early retirement is more common on medical grounds.

A prospective survey in Edinburgh of 243 people with insulin-treated (mainly type 1) diabetes in full-time employment found that hypoglycemia occurred uncommonly at work (14% of all severe episodes) and had few adverse effects [36]. The study cohort, however, may have been subject to selection bias in terms of occupational diversity and many had suboptimal glycemic control; surprisingly few participants had impaired awareness of hypoglycemia. An internet survey of the effects of non-severe hypoglycemia in people with T1DM and T2DM in employment has suggested that work time and productivity are lost by around one in five people when hypoglycemia occurs at work, though such an uncontrolled study may be open to over-estimation of the magnitude of the problem [37].

For some occupations (e.g. train drivers) any risk of hypoglycemia is considered unacceptable. Elsewhere, the case for employment restrictions may be less clear-cut. Jobs that restrict the employment of workers with insulin-treated diabetes are listed in Table 58.3. People treated with insulin are not usually permitted to work alone in isolated or dangerous areas, or at unprotected heights. Shift-work is not necessarily a contraindication: one study in a car assembly plant found no difference in glycemic control between day and night-shift workers with diabetes, although control deteriorated if shift rotas were changed frequently [38].

In one British survey, the prevalence of diabetes in the workforce was 7.5 per 1000, including a lower-than-anticipated rate of

Table 58.3 Forms of employment from which people with insulin-treated diabetes are generally excluded in the UK.

Vocational driving
Large goods vehicles (LGV)
Passenger-carrying vehicles (PCV)
Locomotives and underground trains
Professional drivers (chauffeurs)
Taxi drivers (variable; depends on local authority policy)
Civil aviation
Commercial pilots and flight engineers (licensing currently under trial)
Aircrew (as above)
Air-traffic controllers
National and emergency services
Armed forces (army, navy, air force)
Police force
Fire brigade or rescue services (some exceptional cases)
Merchant navy
Prison and security services
Dangerous areas for work
Offshore: oil-rigs, gas platforms
Moving machinery
Incinerators and hot-metal areas
Work on railway tracks
Coal mining
Heights: overhead lines, cranes, scaffolding

Source: Data from Waclawski [38] and Waclawski and Gill [56].

2.6 per 1000 for people treated with insulin [39]. Employment is generally debarred in the armed forces, emergency work such as fire-fighting, civil aviation, jobs in the off-shore oil industry, and in many forms of commercial driving [39]. Workers with diabetes seldom conceal their medical condition from their employers, and any blanket policy that debars workers with diabetes from a specific occupation may be inappropriate or even discriminatory. Individual assessment is crucial, as employment regulations may not differentiate between different types and treatments of diabetes. Some bureaucratic regulations have been successfully challenged on medical grounds: for example, active fire fighters in the UK and a US air traffic controller were reinstated following appeals against dismissal.

In some cases, entering or persevering with a specific occupation may not always be in the individual's long-term interests (e.g. with the advance of disabling complications). This is clearly a difficult issue, which may require sympathetic medical counseling because of possible repercussions on the individual's income, self-esteem, future quality of life, and the financial support of dependants.

Unemployment, sickness and diabetes

According to a British survey, employers do not generally believe that diabetes per se limits employment prospects, because most workers with diabetes have few medical problems and can tackle a wide range of occupations [40]. Discrimination by employers, however, may affect hiring practices. Some British and Dutch surveys reported no apparent excess of unemployment among people with diabetes as compared with the general population [41–44], but other studies in the UK [45, 46] found that relatively more people with diabetes were not earning because of inability to work, intercurrent illness, early retirement or by being housewives. Although in many cases there was no apparent reason why an individual with diabetes could not obtain employment [46], depressive illness is strongly associated with unemployment and difficulties with work performance [47]. Adolescents with diabetes appear more likely than their peers without diabetes to lose jobs, or to fail to follow their desired occupation or cope with shift-work [48]. Reduced employment and income in workers with diabetes in North America have been related to disability, which was seven times more common than among a sibling control group, was mainly related to diabetic complications [49, 50], and was associated with lower employment income [51, 52]. Sickness absence rates among employees with diabetes are moderately to substantially higher than in workers without diabetes [53–56], which has economic and social consequences. Workers with insulin-treated diabetes and good glycemic control had fewer sickness absences than those with poor control [57]; poor control itself (HbA_{1c} >86 mmol/mol, 10%) is associated with a high rate of sickness absence [58].

Prison and custody

Imprisonment and short-term custody are unusual but troublesome life situations that can interfere with the management of diabetes. Hypoglycemia can occur if food is withheld after arrest, and may be confused with intoxication by alcohol or drugs. Diabetes is generally managed badly in prison because of the unsuitability of prison diets, lack of exercise, and the practical difficulty of using some insulin regimens (e.g. basal bolus); also, self-monitoring may be prohibited, and glucose to treat hypoglycemia may be unavailable during long "lock-up" periods. Most prison medical personnel have no specialist knowledge of diabetes and there may be no access to specialist supervision during custody.

Some prisoners with diabetes deliberately manipulate their treatment (e.g. by omitting insulin to induce ketoacidosis to have themselves removed to hospital which arguably offers a more amenable environment [59]). By contrast, treatment of intercurrent illness may be delayed by prison staff, who think that the prisoner is "misbehaving."

In some cases, withdrawal of alcohol, better dietary adherence and weight loss may actually improve glycemic control while in prison, and structured diabetic care can be provided effectively by an attending specialist physician [60, 61]. Facilities for people with diabetes in police custody are generally limited, with an inability to measure blood glucose, treat diabetic emergencies or to provide insulin and appropriate meals [62]. A Scottish liaison initiative between a specialist diabetes department and the local police force identified and successfully addressed deficiencies in

their custody facilities, including the provision of glucose monitoring equipment and the training of police staff [62]; this has been assisted by the development of a forensic nursing service.

Insurance

In many societies, insurance is viewed as essential to protect individuals and their families from the financial risk of unexpected events or illness, and insurance is often necessary to secure a financial loan, as for house purchase. People with diabetes are sometimes refused insurance or have to accept higher premiums and limited coverage, because the disorder is associated with reduced life expectancy, the risk of complications, and greater use of healthcare services. Several factors are important for insurance underwriting, including the severity and duration of the diabetes, the extent of diabetic complications and other concurrent medical disorders. It is reasonable for an insurer to be cautious in dealing with applicants who have poorly controlled long-standing diabetes and established complications.

There is wide variation in insurance terms and premiums among different European countries [63], in the USA [64] and even within the UK [65], which suggests that insurers work from assumptions about diabetes rather than using scientific evidence from actuarial studies. The presence of T1DM may be the only factor considered by insurers [64], and many still base potentially discriminatory decisions on outdated information that reflects the poor outcome of diabetes diagnosed and treated decades ago. There are no standardized guidelines, nor is there any uniformity in the approach to diabetes and insurance [65], although risk classifications for life insurance have been published [66]. Some companies do not accept applicants with diabetes, while others do so without financial penalty. People with diabetes seeking insurance cover should therefore request quotations from several companies, and should be supported by a medical assessment from a physician who is competent in the specialty. Many national patient organizations have negotiated favorable terms with insurance brokers and will provide details on request.

The prognosis of people with diabetes (particularly T1DM) has improved considerably during the last 50 years, and the impact of this on life insurance for people with T1DM has been analyzed in Scandinavia [67]. In the last 30–40 years, median life expectancy has increased by over 15 years, largely because of substantial reductions in diabetic nephropathy. It has therefore been suggested that life insurance in T1DM should focus entirely on the risk of developing diabetic nephropathy [68], and a model to calculate insurance terms has been proposed, based on current age, age at diagnosis, sex, presence of nephropathy or proliferative retinopathy and other pre-existing disease [67]. As the risk of developing new nephropathy falls after 25 years of diabetes, all people who reach the age of 50 years without nephropathy should have their insurance premium reduced. This approach has been adopted by most insurance companies in the Nordic countries, and by some in other European countries. To avoid penalizing people with diabetes, there must be regular updating of mortality and life expectancy data, and this information must be transmitted to actuarial advisers and insurance underwriters.

People with diabetes also face higher premiums for accident insurance, which is unjustified because there is no evidence that they have more accidents or permanent disability than the general population [69]. Neither is there any rationale for higher motor insurance premiums [64, 65, 70], particularly for those not treated with insulin, because no excess in road traffic accidents has been demonstrated (see earlier). A US study of the insurance cost of employees with diabetes showed that while healthcare expenditure was three times higher than all healthcare consumers, it was not more expensive than other chronic illnesses such as heart disease, asthma, and cancer [71].

Diabetes must always be disclosed to the insurer: concealing the diagnosis constitutes the withholding of a material fact, which nullifies the contract with the insurer and thus the insurer's liability in the event of a claim.

Alcohol

Many people enjoy drinking alcohol and diabetes should not be a barrier to social drinking. Accumulating data suggest that moderate alcohol consumption not only reduces the risks of developing T2DM but improves metabolic control and restricts diabetic complications. By contrast, alcohol can promote hypoglycemia and chronic excessive consumption may be deleterious both to long-term diabetes management and general health.

Alcohol consumption and risk of diabetes

Chronic high consumption of alcohol can predispose to the development of secondary diabetes. Alcohol has a direct toxic effect on the pancreas resulting in both acute and chronic pancreatitis. Diabetes complicates about 45% of cases of chronic pancreatitis (see Chapter 21). Insulin treatment is usually required to control hyperglycemia in people with chronic pancreatitis, although diabetic ketoacidosis is rare. This may be because the pancreatic damage also destroys the α-cells that secrete glucagon, which is an essential factor in ketogenesis (see Chapters 15 and 36). Insulin therapy can be particularly challenging in this situation, as many individuals with alcohol-related chronic pancreatitis have chaotic lifestyles, with poor diet and ongoing excess alcohol consumption. A heavy alcoholic binge, with concomitant low food intake, can result in alcoholic ketoacidosis.

By contrast, modest alcohol consumption appears to protect against T2DM, reducing risk by up to 30% [72, 73]. A J-shaped relationship has been observed between alcohol consumption and risk of T2DM (Figure 58.2). Moderate alcohol consumption is associated with enhanced insulin sensitivity, which may in part explain the relationship. The pattern of drinking behavior also appears to be important, with binge drinking associated with an increased risk of T2DM [74].

Alcohol and glycemic control

Hypoglycemia

Ethanol has marked metabolic effects on the liver, which metabolizes over 90% of an alcohol load. Gluconeogenesis is suppressed, even at blood alcohol levels that are not usually associated with intoxication [75–77], while the processes of recycling carbon as glucose and lactate between hepatic gluconeogenesis and muscle glycolysis [76] and fatty acid oxidation are also inhibited by alcohol. Thus, alcohol has the potential both to predispose to hypoglycemia and to inhibit glucose recovery. In individuals without diabetes, total hepatic glucose production is not reduced by alcohol, despite the inhibition of gluconeogenesis [77], and alcohol-induced hypoglycemia only occurs if hepatic glycogen stores are already depleted; for example, by fasting for at least 36 hours [78].

In people with diabetes, alcohol consumption may impede recovery from insulin-induced hypoglycemia. This effect is often delayed, occurring up to 24 hours after alcohol ingestion and may occur during the night or the following day [79]. Those with a deficient glucagon response to hypoglycemia (see Chapter 35) may be at greater risk, because they are unable to increase hepatic gluconeogenesis. The signs of hypoglycemia may be missed or mistaken for those of alcohol intoxication by the individual or by observers and even moderate alcohol consumption increases the cognitive impairment that occurs during hypoglycemia [80]. People with insulin-treated diabetes should be advised not to drink *any* alcohol before driving.

Overall, alcohol is an important contributory factor to many episodes of hypoglycemia in people with diabetes—an estimated 20% in one study [81]. Hypoglycemia-induced brain damage is rare, but when it occurs, it is often preceded by excessive alcohol consumption, which presumably promotes protracted neuroglycopenia. Severe hypoglycemia caused permanent neurologic damage after binge drinking in five alcoholic patients with insulin-treated diabetes, two of whom died [82].

Hyperglycemia

Excessive alcohol consumption is associated with central obesity [83], which may be a consequence of the adverse lifestyle factors that tend to accompany high alcohol intake. It should also be noted that alcohol provides 7 kcal energy per gram (1 unit = 10 g alcohol) in an easily consumable form and can therefore provide a substantial caloric intake, particularly as beer and lager. This is a commonly overlooked source of calories in obese, middle-aged men with T2DM, who are having difficulty in achieving weight loss by dietary means. The caloric content of spirits is much lower but may be augmented by adding sugar-rich mixers to drinks. Low-carbohydrate beers and lagers (such as Pilsner) have been marketed as being suitable for people with diabetes but should not be recommended because of their high alcohol content.

Heavy drinking has also been linked with poorer adherence to medications, outpatient follow-up, and self-blood glucose monitoring [84, 85]. Despite this, and the association with increased central obesity, excessive alcohol consumption does not appear to be associated with poorer glycemic control. Indeed, in most studies, there is a linear inverse relationship between glycemic control and alcohol consumption [74, 86]. However, people with very heavy alcohol consumption tend to be underrepresented in such studies.

Alcohol and diabetic complications

Moderate alcohol consumption in people with T2DM is associated with a 35% reduction in total mortality compared with non-drinkers (i.e. a similar magnitude to the effect of moderate alcohol on the risk of developing T2DM) [87] (Figure 58.3). These favorable effects of alcohol consumption may be a consequence of enhanced insulin sensitivity, lower blood pressure, and favorable changes in lipids and hemostatic factors [74]. These observations again do not include data on substantive numbers of very heavy drinkers and it is well established that excessive alcohol consumption increases serum triglyceride concentrations in

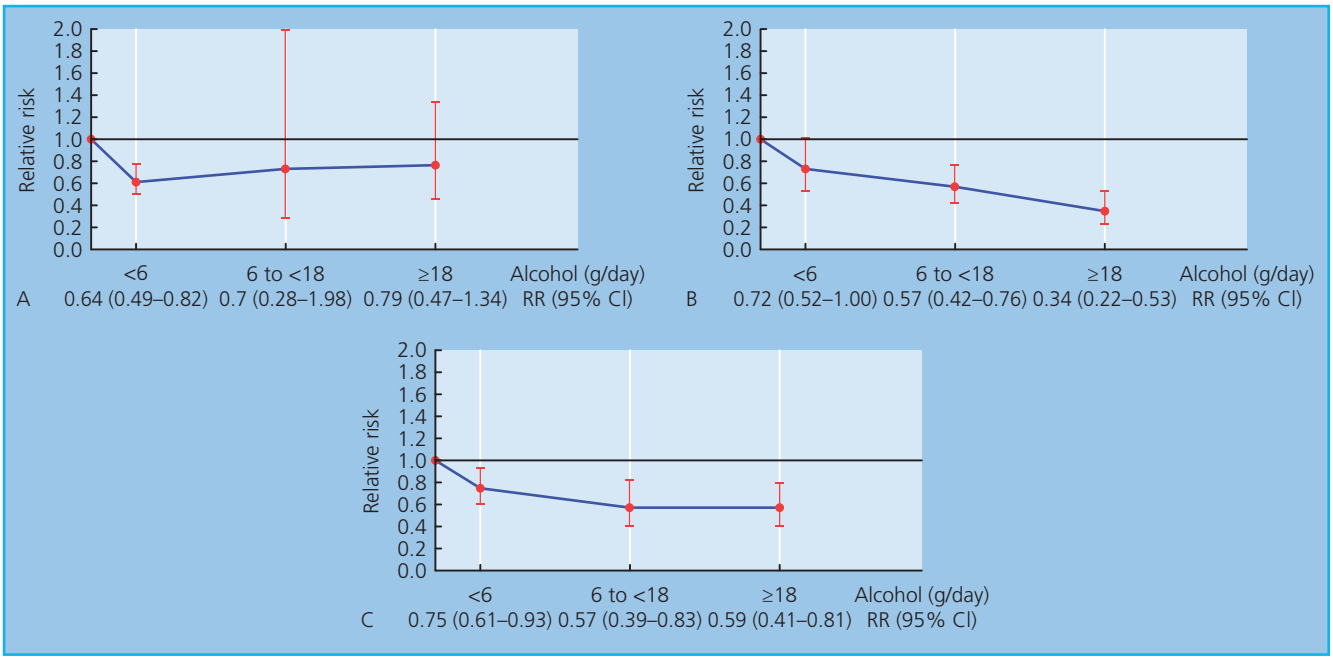

Figure 58.3 Pooled relative risk estimates (with 95% confidence intervals) of: (a) total mortality; (b) coronary heart disease mortality; and (c) coronary heart disease incidence for three alcohol consumption categories, with non-drinkers as the reference. susceptible individuals and raises blood pressure; excess alcohol consumption is an important cause of hypertension failing to respond to treatment (see Chapter 42). In the ADVANCE trial, mortality and risk of cardiovascular events was indeed higher in people with T2DM who drank more than the UK-recommended limits [88].

With regard to microvascular complications, a J-shaped relationship is observed between risk and alcohol consumption [89]. Moderate consumption (30–70 g/week) is associated with a 40% reduction in risk of proliferative retinopathy and neuropathy in T1DM, and over 60% reduction in risk for macroalbuminuria. Conversely, chronic excessive consumption of alcohol in people with diabetes is associated with peripheral neuropathy and exacerbation of neuropathic symptoms, erectile dysfunction, and increased risk of foot ulceration [90]. This may be in part a direct toxic effect of alcohol on the nervous system, though acute alcohol intoxication also impairs erectile function, while poor self-care and hygiene behaviors may contribute to the association between alcohol and foot ulceration.

Recommended alcohol intake

Recommendations for average alcohol intake in people with diabetes are comparable with advice given to the general population, that is, women with diabetes should drink no more than 2 units of alcohol per day and men no more than 3 units. General advice from Diabetes UK given to people with diabetes regarding alcohol is summarized in Table 58.4.

Recreational drugs

Use of recreational drugs is a serious problem in the general population, but can pose particular difficulties for people with diabetes [91]. The main classes of drugs involved are cannabis, amfetamine-type stimulants (including "ecstasy"), cocaine and opiates, with cannabis being the most commonly used drug by far.

Regulation

In the UK, drugs that are associated with dependence or misuse are regulated under the Misuse of Drugs Act, 1971. This Act specifies a classification system for drugs according to harm associated with misuse and specifies controls over manufacture, supply, and possession (Table 58.5). The list of drugs within each class can be amended by order of the Home Secretary. The Misuse of Drugs Regulations, 2001 define the classes of individuals who are authorized to supply and possess controlled drugs and lay down the conditions under which these activities may be carried out. Drugs are classified under five schedules, which specify the requirements governing import, export, production, supply, possession, prescribing, and record keeping. Cannabis and lysergide (LSD) are classified as Schedule 1 as they have no medicinal use, while opiates, cocaine and amfetamine are classified as Schedule 2 and are subject to full controlled drug requirements.

Table 58.4 General advice on alcohol for people with diabetes.

Moderate amounts of alcohol can be drunk shortly before, during or soon after a meal without affecting short-term blood glucose control and can be beneficial for the heart
Alcohol should never be drunk on an empty stomach as the alcohol will be absorbed too quickly
Alcoholic drinks should not be substituted for usual meals or snacks as this may cause hypoglycemia
Severe hypoglycemia can occur with larger quantities of alcohol, particularly when taken by people treated with insulin and especially if insufficient carbohydrate has been eaten
Hypoglycemia may occur up to 16 hours after heavy drinking
A hypoglycemic episode can be confused with being drunk. Tell people you have diabetes and wear some form of diabetes identification.
Check your blood glucose levels regularly; take treatment for hypoglycemia with you and have a starchy snack before going to bed.
Continuous heavy drinking can lead to raised blood pressure
All types of alcoholic drinks contain calories and may contribute to weight gain or failed dietary effort
Drinking alcohol can worsen neuropathy and aggravate associated symptoms
Drinking low carbohydrate beers and cider offer no benefit because of their higher alcohol content
Low alcohol wines are often higher in sugar than ordinary ones, so intake should be restricted
Mixer drinks should be "diet" or "sugar-free" such as diet tonic water and diet cola
Drinking and driving should be avoided.

Table 58.5 Classification of controlled drugs.

Class A includes:*
Cocaine
Diamorphine (heroin)
Methadone
Methylenedioxymethamfetamine (MDMA, "ecstasy")
Morphine
Opium
Pethidine
Class B includes:
Oral amfetamines
Barbiturates
Codeine
Cannabis
Ketamine
Class C includes:
Most benzodiazepines
gamma-Hydroxybutyric acid (GHB)
Cathinone (Khat)
Zolpidem
Androgenic and anabolic steroids

Source: Data from UK Misuse of Drugs Act 1971.
* Includes Class B substances when prepared for injection.

Prevalence of recreational drug use

On a global scale, it is estimated that in 2012 between 3.5–7% of the world population aged 15–64 years (162–324 million people) had used illicit drugs at least once in the preceding year [92]. In England and Wales in 2013–2014, 8.8% of adults aged 16–59 years had taken an illicit drug in the preceding year, but this figure rose to 18.9% in adults aged 16–25 years [93]. Approximately one-third of adults have used recreational drugs at least once in their lifetime [93]. Trends in recreational drug use have changed over the years with a decline in the use of LSD and solvents and an increase in the use of amfetamine-type drugs and ketamine, particularly associated with the night-club and "rave" culture. Cannabis and powder cocaine remain the most commonly used illicit drugs in the UK. The Internet, and in particular the so-called "dark-net," has facilitated the manufacture, sale, and distribution of a plethora of new psychoactive chemicals. The rapid proliferation of these chemicals is a challenge for authorities, not the least in determining which should be subject to legal controls. Other legal drugs are also being used increasingly for their psychoactive properties, including nitrous oxide and salvia.

Data specifically about the use of recreational drugs by people with diabetes are sparse. Two uncontrolled questionnaire surveys of young adults with T1DM, one from the USA and one from the UK, have reported a similar prevalence and pattern of recreational drug use to that observed in the general population [94, 95]. In the UK survey, approximately 30% of respondents had used recreational drugs, with cannabis (28.2% of respondents), amfetamine-type stimulants (13%), and cocaine (12%) being used most commonly [95]. Many (15% of respondents) used more than one drug. A report from Chile has suggested that use of recreational drugs was lower in school-aged adolescents with T1DM than in the general population (9.6% vs. 22.2%), although this difference disappeared during later years at school [96]. In all studies examining prevalence of recreational drug use, underreporting by respondents is highly likely, related in part to fear of retribution.

Impact of recreational drug use on diabetes

In the Diabetes UK Cohort Study, acute metabolic complications (diabetic ketoacidosis and, to a lesser extent, severe hypoglycemia) were the most common causes of death in adults with T1DM under the age of 30 years, closely followed by accidents and violence [97]. In that study, a history of previous drug abuse was associated with a nearly sixfold increase risk of death from acute complications. More than 50% of young adults presenting with diabetic ketoacidosis to a tertiary referral hospital admitted to using recreational drugs; a history of recreational drug use was volunteered by only 20% on initial questioning [98]. Drug misuse has also been identified as a major cause of death in young people with T1DM [99]. Substance abuse co-occurring with mental illness is associated with a particularly high mortality [100].

Intravenous drug abuse

Recreational drug use often disrupts normal lifestyle and a person with diabetes may abandon the daily routine of regular meals

and insulin injections. Recreational drug use may also be only one aspect of a chaotic lifestyle associated with other high-risk behaviors. This can result from the use of any recreational drug, but intravenous drug abuse (particularly of opiates, but also amfetamines) is particular damaging and is strongly associated with poor social support, criminality, and mental illness. Intravenous drug use is uncommon in people with diabetes (as it is in the general population), but is associated with omission of insulin therapy, frequent admissions to hospital and high mortality, both from diabetic ketoacidosis and deliberate or accidental opiate overdose [101]. Unsurprisingly, intravenous drug abusers with diabetes may also present with complications related to the route of drug administration: deep venous thrombosis and abscesses at groin or limb injection sites. Intravenous drug abusers often default from outpatient clinic attendance (this may be associated with imprisonment) and maintaining contact with such individuals is usually difficult.

Cocaine and amfetamines

Cocaine and amfetamine-type stimulants can have dramatic effects on the cardiovascular system through activation of the sympathetic nervous system [102]. Cocaine is a sympathomimetic that inhibits reuptake of norepinephrine and dopamine at sympathetic nerve terminals. Amfetamine and ecstasy potentiate the release of norepinephrine, dopamine, and serotonin from the central and autonomic nervous systems. Cocaine toxicity may be potentiated by cannabis, while amfetamine toxicity is enhanced by alcohol. Drug-induced sympathetic activation leads to tachycardia, vasoconstriction and hypertension. Myocardial ischemia and infarction, supraventricular and ventricular tachyarrhythmias, and severe hypotension can all occur. Prolonged use can result in a dilated cardiomyopathy. The sympathetic activation produced by these drugs antagonizes the action of insulin and cocaine use has been identified as an independent risk factor for diabetic ketoacidosis [103]. The risk of diabetic ketoacidosis may be increased by the omission of insulin before discos and parties to avoid the potential risk and embarrassment of hypoglycemia.

Ecstasy is also associated with severe hyponatremia, secondary to a combination of inappropriate secretion of antidiuretic hormone, polydipsia, and a proximal renal tubulopathy [95, 98].

Ketamine

Ketamine acts as an N-methyl-D-aspartate receptor antagonist and so reduces excitatory neurotransmission. It induces a state of relaxation and dissociation ("K-land"), but hypertension, hyperthermia, tachycardia, and seizures can occur in severe intoxication. Ketamine can precipitate diabetic ketoacidosis, with a metabolic acidosis that is severe and disproportionate to the degree of ketosis. It can also be associated with metabolic acidosis without ketoacidosis and rhabdomyolysis [98].

Cannabis

Cannabis is not known to affect glucose metabolism but its effects on the central nervous system may increase appetite and impair recognition of hypoglycemia. Use of cannabis in low doses is associated with sympathetic activation and tachycardia; at high doses, parasympathetic activation may predominate, resulting in bradycardia and hypotension. In the absence of any structural heart disease, these effects are usually well tolerated.

Hypoglycemia

While the association between recreational drug use and diabetic ketoacidosis is well established, there are few data suggesting any association with hypoglycemia. Such drugs, however, are often taken in conjunction with alcohol and may be associated with poor oral intake of carbohydrate both of which will increase the risk of hypoglycemia. Moreover, amfetamine-like stimulants can induce frenetic behavior at night clubs and raves which can induce hypoglycemia in people treated with insulin [104]. The hallucinatory, or central nervous system, depressant effects of recreational drugs may impair an individual's ability to recognize and treat hypoglycemia. Furthermore, the sympathomimetic effects of cocaine and amfetamine-type stimulants may mimic the autonomic signs and symptoms of hypoglycemia.

Advice on recreational drug use in diabetes

Recreational drugs cause significant morbidity and are hazardous for people with diabetes. Their dangers must be emphasized to people with T1DM (particularly teenagers and young adults), but advice must be given in a sensitive and non-judgmental manner. When exposed to recreational drugs and alcohol, modest reductions in insulin dosage and regular consumption of carbohydrate-based snacks or non-alcoholic sugary drinks are required, particularly if strenuous dancing is to be undertaken. In such situations, significant dehydration can occur and water should be regularly consumed. Music festivals are increasingly popular and the ready availability of alcohol and recreational drugs pose additional risks due to the more prolonged nature of the events over several days, poor sanitation, limited food choices, and the potential for significant peer pressure. People with T1DM attending such events should be advised of the potential hazards and the need to moderate consumption of alcohol and recreational drugs, while maintaining a regular intake of food and non-alcoholic beverages. Regular monitoring of capillary glucose should be strongly advised, although the reality is that frequent monitoring is likely to fall by the wayside during the excitement of the event.

Travel

Diabetes should not be regarded as a bar to short- or long-distance travel, although careful planning may be required to avoid metabolic disturbances and other problems of diabetes that could have particularly serious consequences away from home. Diet and an adequate fluid intake may be disrupted while travelling or staying abroad, and local differences in climate, food, endemic diseases, and medical facilities may compromise

diabetes control. Blood glucose levels should be monitored frequently during travel and holidays, and people with diabetes must be able to take a pragmatic approach to deal with contingencies (e.g. loss of insulin, delays during travel) that could perturb their diabetes. Occasionally, specific diabetic complications or other medical disorders such as uncontrolled hypertension or ischemic heart disease can jeopardize health and safety during travel and periods away from home.

Preparation for travel

Personal identification

Travelers with diabetes should carry a doctor's letter stating the diagnosis and treatment, and ideally some other form of identification such as medical identification jewelry or tags (these contain personalized medical information and are recognized worldwide). These should also allay the suspicions of airline security, immigration and customs officials who discover syringes and drugs in luggage. Many national diabetes associations provide an identification card that shows the person's photograph, doctor's name and contact telephone number.

If a prolonged stay abroad is intended, it is useful to carry a prescription letter listing all medications (with generic names, as brand names often vary between countries), insulin-injection devices, and blood-testing items.

Insurance and medical care abroad

Comprehensive medical insurance is essential to cover accidents and illness that require medical assistance, and loss of medical equipment and drugs. The insurance policy must cover diabetes and other pre-existing medical conditions, as claims relating to these may otherwise be rejected. Most travel policies contain exclusions, which frequently include diabetes; a person with diabetes may not be covered for conditions such as a stroke or myocardial infarction for which diabetes is a recognized risk factor. When appropriate, insurance must be adequate to cover any dangerous sporting activities (when hypoglycemia could be particularly hazardous), and the costs of emergency air transport home in the event of a serious accident or illness.

Most countries in the EU provide emergency medical attention free or at reduced rates to visitors from other member states, although immediate payment for treatment may be demanded in some countries, such as France. Travelers from the EU can obtain a European Health Insurance Card (EHIC) in their home country, which confirms their entitlement to this scheme, although full medical travel insurance is still recommended. Some non-EU countries (e.g. Australia and Russia) offer free or reduced-rate medical care for EU members. In the USA, emergency medical treatment can be extremely expensive, and insurance premiums are correspondingly high. A list of insurers who do not load premiums against people with diabetes can be obtained from national diabetes associations.

Irrespective of medical insurance cover, it should be appreciated that emergency medical care available in some countries is suboptimal or even potentially dangerous for a diabetes-related emergency. In some parts of the world, insulin is not readily obtainable and intravenous fluids are in short supply. These considerations may influence the choice of holiday destination for people with diabetes.

Table 58.6 Checklist of essential items for travelers with insulin-treated diabetes.

Health checks
Diabetes "annual review"—if prolonged travel
Vaccinations
Visit GP for prescriptions, including possible antibiotics and anti-diarrheal agents
Documents
Diabetes identity card/bracelet
Document stating diagnosis and treatment; letter from insulin pump company regarding X-ray machines and scanners
Copy of repeat prescription
Medical insurance and EHIC
Insulin pump company care-line number
Insulin pump settings
Equipment
Insulin vials or cartridges (also required by those on pump therapy)
Syringes and needles/pens and spare pen needles
Flask or cool bag for insulin storage
Blood glucose meter; spare meter and batteries; ketone meter (if used)
Finger pricking device and spare lancets; container for used needles
Spare insulin pump, batteries and consumables
Hypoglycemia treatment
Quick-acting carbohydrate:
Glucose drinks (screw-top container; no more than 100 mL if flying)
Glucose tablets/confectionery
Slow-acting (complex) carbohydrate:
Biscuits or cereal bars

Drugs and equipment

Essential items for the traveler with diabetes are listed in Table 58.6.

- *Immunization.* Routine recommendations should always be followed for the relevant destination. Occasionally, a severe reaction to a vaccine may cause a temporary rise in insulin requirements.
- *Medication.* Air travelers treated with insulin should carry an ample supply in their hand luggage. Preferably, another supply of medication should be carried by a relative or friend in case of loss or theft. When travelling by air, medication and blood monitoring equipment should not be consigned to the hold, because of the risk of losing luggage and the deleterious effects of extremely low hold temperatures on the insulin. During travel, insulin can be carried in an insulated cool bag. Treatment for hypoglycemia should also be carried in the hand luggage; this is best in the form of dextrose tablets or sweets as the regulations on the amount of liquid that may be carried through airport security may pose difficulties.

- *Insulin pumps.* People using continuous subcutaneous insulin infusion should carry spare batteries for their pump, vials of long-acting insulin and syringes (or pens) as a back-up in case of pump failure and the contact details of the pump manufacturer so that a replacement can be ordered. Some insulin pump manufacturers will provide users with the temporary loan of a spare pump for a holiday. It is important that insulin pump users carry a written note of their insulin pump settings, including basal rates, bolus ratios, sensitivity factor, blood glucose targets, and active insulin time, as well as the consumable types and the pump serial number. Some insulin pumps should not be passed through X-ray security or body scanners as these may interfere with the electronic software in the pump; pump manufacturers will provide an explanatory letter, which can be shown to security staff. Insulin pumps can pass safely through security metal detectors. The delivery of insulin from a pump may be increased if the atmospheric pressure is reduced suddenly because bubble formation displaces insulin from the cartridge, and may provoke hypoglycemia. If cabin depressurization is severe, this could increase insulin delivery by as much as 8 units [105]. Even during normal ascent and descent, there can be slight increases and decreases respectively in the amount of insulin administered. Insulin pumps can also be targets for theft, as they may be mistaken for mobile phones or other electronic devices; it is important to check that travel insurance covers theft of the insulin pump.
- *Blood glucose and ketone monitoring.* Extremes of temperature and high altitude can disable some blood glucose meters and affect the accuracy of blood glucose test strips, although the cabin pressure of passenger aircraft (equivalent to an altitude of up to 8000 feet) should not pose problems [106]. While on holiday, it is sensible to carry a spare glucose meter (and blood ketone meter if used), test strips, and a replacement meter battery. If a new glucose meter is purchased overseas, it is important to remember that its default display could be in different units to the standard for an individual's home country, that is, mg/dL instead of mmol/L. Continuous glucose monitoring systems use wireless technology to link with a monitor or insulin pump device. This can be an issue for some airlines and current advice is that people with diabetes should discuss any medical devices that they intend to take on board an airplane with their airline.
- *Other considerations.* Those prone to motion sickness should take an anti-emetic to prevent nausea and vomiting from disrupting glycemic control. Antidiarrheal agents and a broad-spectrum antibiotic should be carried, particularly if travelling to regions with a high risk of acquiring gastroenteritis. People with peripheral sensory neuropathy should take comfortable and appropriate footwear for travel and for holiday use, as foot ulceration may be caused by wearing ill-fitting sandals or walking barefoot across rocks or even hot sand.

Long flights and crossing time zones

These pose several potential problems, ranging from the timing and composition of airline meals to ensuring that insulin dosages will cover the flight and adjust to local time on arrival.

Meals

Times of serving in-flight meals after take-off can usually be obtained from the airline. In-flight meals can be supplemented with a personal supply of suitable carbohydrate, but it is impractical to carry large quantities, not least because of the limits of what foods may be imported into many countries. Allowance may have to be made for delayed flights or long intervals between meals, while fatigue or travel sickness may blunt appetite.

Alcohol

Drinking alcohol before and during air travel is best avoided because of the risk of hypoglycemia; also, the diuretic effects of alcohol favor dehydration, which has been implicated in deep venous thrombosis and pulmonary embolism during long-haul flights (although diabetes does not appear to confer greater risk) [107]. Water or non-alcoholic sugar-free drinks should be drunk liberally.

Blood glucose

Blood glucose levels should be monitored frequently while in transit and when changing time zones. It is often safer to allow in-flight blood glucose values to be slightly higher than usual to avoid the risk of hypoglycemia.

Insulin treatment

There is no evidence-based information on how to adjust insulin dosages during flights that cross several time zones, and this probably accounts for the variability in the advice that is given [108]. Each case should be discussed individually, taking into account the duration of the flight and the change in time zone, the usual insulin preparations and dosages, the size and timing of meals, and the results of glucose monitoring. Some general guidelines are suggested in Table 58.7 and Figure 58.4.

Guiding principles are:

- Do not aim for strict blood glucose control while flying. A few hours of mild or moderate hyperglycemia will do no harm and, as long as glucose levels are monitored regularly, it is safer to reduce usual insulin dose and use small additional insulin dosages rather than risk hypoglycemia.
- Blood glucose levels should be checked every 2–3 hours.

Table 58.7 Management of diabetes during long-distance air travel.

Obtain advice from the diabetes clinic before traveling
Obtain essential information, including the local time of departure, flight duration, and local time of arrival
Inform the airline that you have diabetes, especially if treated with insulin
Carry extra supplies of carbohydrate
Anticipate that delays may occur
Time zone travel may necessitate two consecutive morning or evening insulin doses, before and after the flight
Ensure that you can monitor your blood glucose frequently during travel
Do not strive for meticulous control of blood glucose while traveling
Adjust insulin doses if necessary

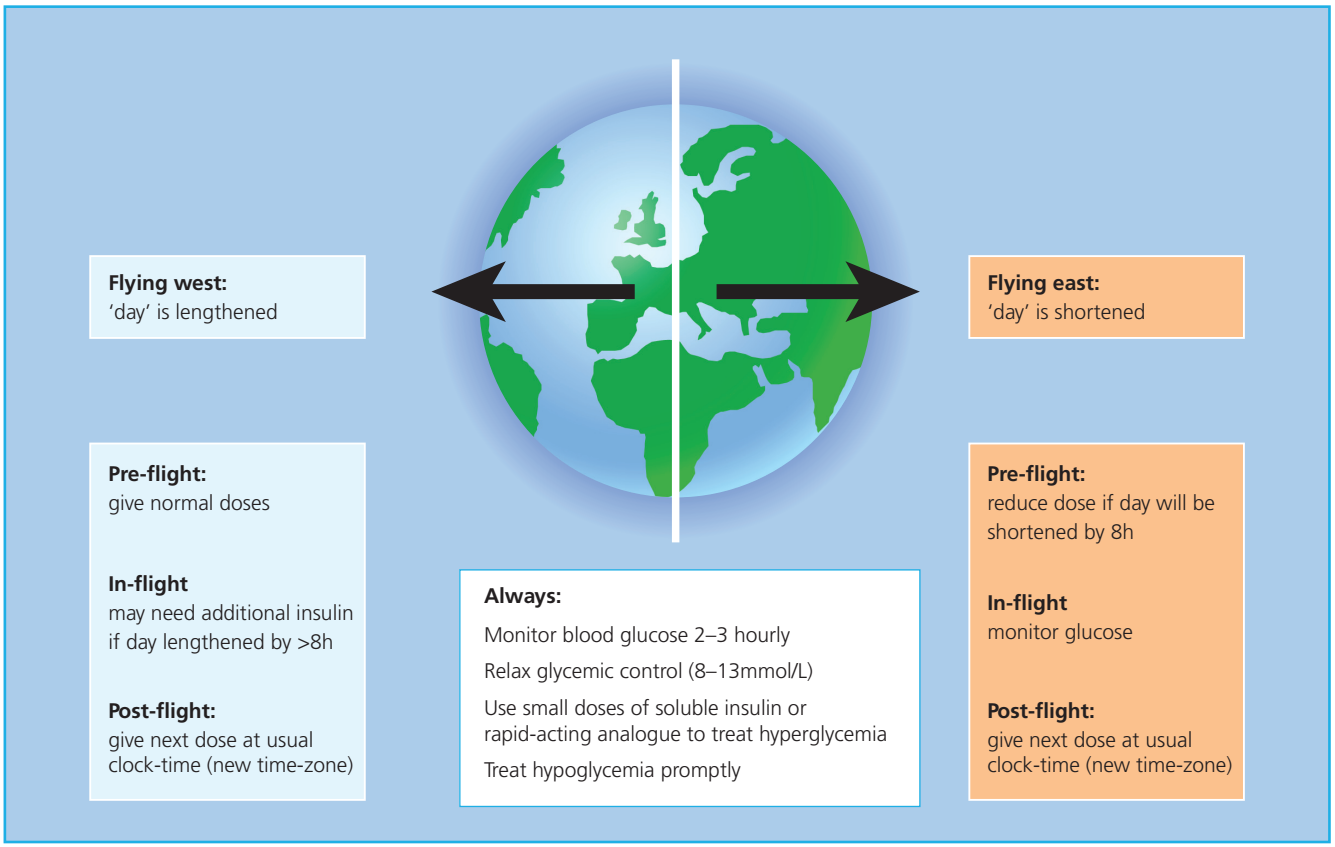

Figure 58.4 Scheme for adjusting insulin dosages during flights that cross time zones.

- Time changes of less than 4 hours in either direction usually need no major adjustment of the usual insulin schedule: simply give the next dose of insulin at its usual clock time, using the destination's time zone.
- Westward flights lengthen the "day." Give the next dose of delayed-acting or premixed insulin at its usual clock time (using the destination's time zone). If this injection is delayed by more than 12 hours, then additional insulin with food will be needed in the interim. The most convenient way to do this is with small doses (usually a few units) of soluble insulin or a rapid-acting analog, injected every 4 hours or so on the basis of blood glucose measurements.
- Eastward flights shorten the "day." The next dose of delayed-acting or premixed insulin should again be given at its usual clock time (destination time zone), but because this injection will effectively be earlier than usual, the previous dose of delayed-action insulin should be reduced if the interval between the injections is less than 12 hours.
- Extremely long flights with a time shift of 12 hours or more may require two "morning" or two "evening" insulin dosages to be injected consecutively, before and after the flight.
- Any additional insulin needed to fill in long gaps between delayed-action injections or to correct hyperglycemia is best given as small doses of soluble or a rapid-acting analog, ideally using a pen injection device.
- Travelling across time zones is generally easier to manage when using insulin pump therapy. The "temporary basal" feature can be helpful, depending on the length of the flight and activity levels, and it is easier to administer correction boluses. It is important to adjust the clock time on the pump to the local time, to ensure that the correct basal rates of insulin are being administered [109].

Oral antidiabetes agents

Additional doses are not usually required to cover an extended day.

Insulin treatment in hot climates

An individual's insulin requirements may change markedly in different countries, the main factors being differences in diet and daily physical activity. Subcutaneous insulin absorption can be accelerated by high ambient temperatures, such as in a sauna (see Chapter 29), and this effect has variable clinical significance in very hot climates.

Modern formulations are quite stable, but sometimes denature if exposed to high temperatures and shaken; in this case, discolored particles or a granular appearance (distinct from the normal cloudiness of delayed-action preparations) may be seen when the insulin is resuspended. Sometimes, there are no visible changes, but the insulin appears to lose its effect, with the usual dosages failing to lower blood glucose. Particularly in hot countries, insulin is

best stored in a refrigerator; if one is not available, insulin can be protected by a damp flannel or a porous clay pot containing some water or wet sand, placed in a cool part of the room. Even these measures may be unnecessary, as most insulin preparations can survive being kept at 25 °C or more for up to 6 months, and will retain most of their biologic activity [110].

Food and drink

When traveling abroad, it is essential to know the basic form of carbohydrate that is eaten locally, and useful to learn to judge quantities of foods such as pasta or rice. Items selected from local menus can be supplemented with bread, biscuits, or fruit. Sugar-free drinks are difficult to obtain in many countries but bottled water is safe and usually available.

Quick-acting carbohydrate to treat hypoglycemia should always be carried and stored appropriately: dextrose tablets may disintegrate or set hard in hot and humid climates unless wrapped in silver foil or stored in a suitable container, while the temperature-dependence of chocolate is well known. Cartons of fruit juice cannot be reused once opened; a plastic bottle with a screw top is preferable. Sealed packets of powdered glucose may be the best option for hot damp climates.

Traveling companions should carry a supply of quick-acting carbohydrate (and glucagon) for emergency use, and should know how to test the blood glucose and how to treat hypoglycemia.

Intercurrent illness

Any intercurrent infection should be treated promptly and appropriately, with adequate replacement of fluids and carbohydrate in the form of drinks if possible. Insulin therapy must never be discontinued and dosage may have to be increased, and blood glucose should be checked every 3–4 hours, with testing for urinary ketones if possible. The "sick-day" rules described in Chapter 29 should be followed.

Recreational activities

The impact of physical exercise and sport on diabetes is discussed in Chapter 26. People need advice about strenuous and unaccustomed exercise during holidays, such as beach sports or prolonged and vigorous dancing. Swimming alone should be avoided. The risks of alcohol and recreational drugs have been described earlier.

Leaving home

As a child with diabetes grows up, inevitably parental input to the day-to-day management of diabetes is reduced with increasing autonomy of the adolescent. In teenage years this is often manifest by a deterioration in glycemic control (Chapter 60). Even in adolescence, parents or guardians still have a very important role with the provision of regular meals and in the recognition and treatment of hypoglycemia, particularly at night. Therefore, the eventual move away from the parental home can pose problems, especially if the individual with T1DM is living alone and if they move to another town. Social isolation may exist until new friends are made and access to alcohol and recreational drugs may increase, with the attendant risks that have been highlighted. Sexual activity may commence or increase, introducing issues of sexual health and pregnancy, and novel forms of exercise may be more readily available. On leaving the parental home, individuals often become removed from the familiar support of the healthcare professionals in their local diabetes center and initially do not have the similar contact and immediate access to advice from doctors and nurses about diabetes, precisely at a time it may be most needed. It is a disturbing fact that "living alone" was associated with a more than fourfold increase risk of mortality from acute metabolic complications of diabetes in the Diabetes UK Cohort Study [98].

Students with diabetes

Particular emphasis has been placed on the welfare of students with T1DM who have left home to attend university or college. In part, this has been because of high-profile instances where individuals with T1DM have died shortly after commencing university [111]. Several surveys have suggested that students find diabetes more difficult to manage, although this does not necessarily translate into a rise in glycated hemoglobin concentrations [112–117]. Barriers to diabetes control include fear of hypoglycemia, diet, irregular schedules, lack of parental involvement, limited finances, recreational drugs, and alcohol. There is a natural desire for students with diabetes not to appear different from their peers and this may lead them to assign a lower priority to diabetes management than they would normally and to undertake potentially high-risk activities [118].

Diabetes services need to be responsive to the needs of adolescents and young adults who are leaving home. Such individuals are often poorly informed about the inherent risks associated with, for example, alcohol and drugs [95, 117] and these and other needs may not be addressed in the context of a routine diabetes consultation [116]. Before the individual leaves home, a formal re-education program should be offered in which alcohol, drugs, exercise, sex, and sick-day management are discussed [119]. Individuals leaving home need to think about their mealtimes; it can be difficult for someone living alone to motivate themselves to prepare substantial meals and many adolescents have limited cooking skills. Regular meals are provided in university halls of residence, but the nature and content of the food, particularly the carbohydrate content, may not be ideal. Students should be advised to monitor blood glucose levels frequently during examination periods. Many students report that studying and undertaking examinations can cause marked fluctuations in glucose levels; this may partly be associated with stress or varying carbohydrate intake. Both acute hypoglycemia and hyperglycemia impair cognitive function and can cause mood changes and may affect examination performance adversely. Therefore, students should try to optimize glucose control during examinations and ensure that a supply of rapid-acting carbohydrate is available during an examination.

Many students may prefer to remain under the care of their "home" diabetes team, but it is important that they know how to contact local specialist diabetes services in the university town for advice or assistance. Medical practitioners in university health services have a duty to ensure that students with diabetes are offered regular diabetes follow-up. The student should be encouraged to confide at an early stage with a reliable friend or colleague about their diabetes and the potential problems that may arise [119]. It may cause embarrassment talking to recent acquaintances about having diabetes. University authorities have a pastoral responsibility for students with diabetes [112].

11 Diabetes in Special Groups

59 Diabetes in Childhood

Shideh Majidi, Christine M. Chan, and Marian Rewers
Barbara Davis Center for Childhood Diabetes, School of Medicine, University of Colorado Denver, Aurora, CO, USA

Key points

- An estimated 700,000 children have diabetes worldwide; 100,000 new cases are diagnosed annually; the incidence has been increasing by up to 5% annually, over decades.
- Type 1a (autoimmune) diabetes mellitus (T1aDM) accounts for almost all cases in children younger than 10 years, for >90% among older children of European ancestry, and for 20–70% of diabetes in children older than 10 years from other ethnic groups.
- The presence of two or more of the islet autoantibodies predicts the development of diabetes in those less than 10 years, in most cases; despite enormous research effort, prevention of T1aDM is still elusive.
- Diabetes in children is diagnosed based on polyuria, polydipsia, weight loss, fatigue, and random blood glucose >200 mg/dL (11.1 mmol/L). Oral glucose tolerance testing is rarely needed.
- Diabetic ketoacidosis (DKA) in a thin dehydrated child with Kussmaul breathing, abdominal pain, vomiting, and impaired neurologic status is present at diagnosis in fewer than 30% of cases in high-income countries today.
- There are significant differences in management of DKA in children, compared with adults, with the primary focus on prevention of cerebral edema.
- After diagnosis, childhood diabetes is managed in the outpatient setting by a team including a pediatrician specializing in diabetes, a diabetes nurse educator, a dietitian, a pediatric social worker, and/or a pediatric psychologist trained in childhood diabetes.
- In-depth initial and continuing education of parents and children in the self-management of diabetes is the cornerstone of lowering the risk of acute and long-term complications.
- Insulin pump or basal bolus multiple daily injections are the standard of insulin therapy in children.
- Nutrition planning should be based on carbohydrate counting or exchange system; the macronutrient and micronutrient composition of the diet is similar to that for healthy children without diabetes.
- While regular exercise is recommended for all children with diabetes, it requires careful planning of insulin and nutritional management to prevent severe hypoglycemia.
- Severe hypoglycemia is largely preventable, but is still the most common serious complication of childhood diabetes.
- Healthcare providers should equip families with the tools necessary to avoid dehydration, uncontrolled hyperglycemia or DKA, and hypoglycemia during routine infections.
- HbA_{1c} levels below 58 mmol/mol (<7.5%) are the target currently recommended and achievable by most children and adolescents; the gap between recommended and actual HbA_{1c} levels is the widest among adolescents.
- Age-specific psychologic care should include screening for and treatment of family dysfunction, developmental maladjustments, and communication problems, disordered eating and sleep patterns, as well as psychiatric disorders both in the children and their care providers.
- All children with diabetes should be screened at an appropriate age and duration of diabetes for dyslipidemia, microalbuminuria, elevated blood pressure, retinopathy, celiac, thyroid and Addison disease.

Spectrum of diabetes in children

In Europe and North America, 1 in 300 children develops diabetes by the age of 20 years. While the rates are lower elsewhere, there are an estimated 700,000 children with diabetes worldwide and 100,000 new cases are diagnosed annually. Diabetes is a heterogeneous disease at any age. Newborn babies and infants rarely develop the disease (1 in 250,000 in those younger than 6 months) and the etiology is not autoimmune, but usually monogenic (see Chapter 18). From the age of 9 months to 10 years, almost all diabetes is caused by islet autoimmunity (see Chapter 10). With the increasing prevalence of obesity in the general population, a significant proportion of children with T1aDM present with a phenotype that masquerades for T2DM. Measurement of autoantibodies to insulin, GAD_{65}, IA-2, and ZnT8 at diagnosis, C-peptide after the initial metabolic stabilization and HLA-DR,DQ typing may be necessary to assess appropriate long-term treatment.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

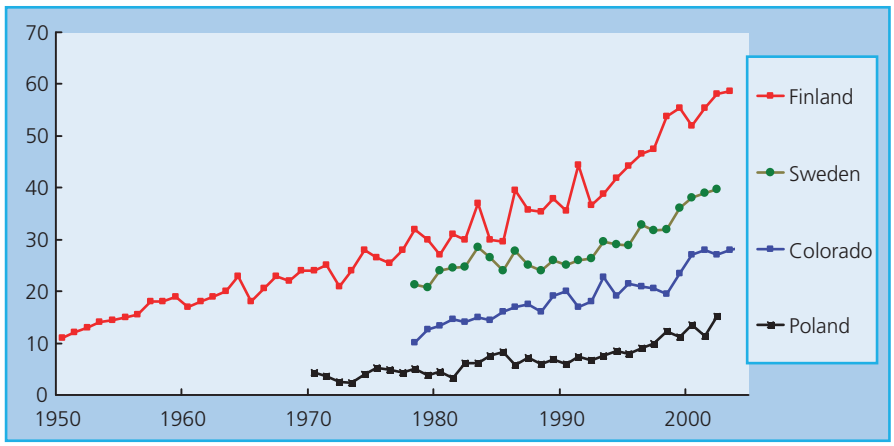

Figure 59.1 Incidence of T1DM has been rising about 3–5% per year.

This chapter focuses on the practical aspects of the management of T1aDM in children, while Chapter 60 addresses management of diabetes in adolescents and transition to adult care. For type 1b diabetes (clinical presentation as in T1aDM, but absent islet autoantibodies) and monogenic diabetes see Chapters 11 and 18, respectively. The epidemiology and etiology of T1aDM are addressed in Chapters 3 and 10, respectively. Briefly, T1aDM is caused by the interplay of genetic and environmental factors. The initial step—development of islet autoimmunity marked by the presence of islet autoantibodies—is believed to be driven by one or more environmental triggers [1]. Over the past 40 years, the incidence of childhood T1DM worldwide has increased by 3–5% annually (Figure 59.1). Elimination of the environmental trigger(s) responsible for this epidemic would be the most efficient approach to primary prevention; however, there is lack of consensus about which environmental factors initiate and promote islet autoimmunity. Efforts to prevent T1DM have been recently reviewed elsewhere [2]. After the initiation of islet autoimmunity, most people have a long preclinical period that offers an opportunity for secondary prevention of the progression to clinical diabetes. The presence of more than one of the autoantibodies combined with susceptibility HLA-DR,DQ genotypes identifies those at high risk of developing diabetes. There may be a "point of no return" in the autoimmune destruction of the islets, rendering some interventions effective only at the earlier stages of the process. Once tolerance is broken to more than one of islet autoantigens, most individuals progress to diabetes within 10 years. A period of mild asymptomatic hyperglycemia, detectable by oral glucose tolerance testing (OGTT) [3] or HbA_{1c} [4], may precede by months or years overt insulin dependence among those with islet autoantibodies. Intervention at this "dysglycemic" stage may also theoretically preserve endogenous insulin secretion and prevent the acute and long-term complications of T1DM. Preservation or regaining of residual insulin secretion after diagnosis of diabetes might also help, but the immunomodulatory agents used so far in tertiary prevention carry unacceptable long-term risks.

Manifestation, diagnosis, and initial treatment

Clinical presentation and diagnosis

The cardinal symptoms at the diagnosis of diabetes include polyuria (96% of children, often with nocturia or bed-wetting), polydipsia, weight loss (61%), and fatigue [5]. The classic presentation of diabetic ketoacidosis (DKA) in a thin dehydrated child with Kussmaul breathing, abdominal pain, vomiting, and impaired neurologic status affects fewer than 30% of cases presenting in high-income countries today [5, 6]. With the increasing community recognition of diabetes, most children present with milder hyperglycemia of shorter duration; however, 75% of the children (63% below age 5 years) have the symptoms for more than 2 weeks, suggesting that the diagnosis could be made earlier in many cases. A young child may have a less specific presentation, for example, with vomiting or rapid breathing during the course of an infection. Diabetes should always be considered in ill children; urine or blood testing for glucose and ketones leads to an early diagnosis and may prevent DKA and hospitalization. Nearly all children admitted with severe DKA have been seen hours or days earlier by healthcare providers who missed the diagnosis.

While most children do not require intravenous fluids or insulin infusion at the diagnosis of diabetes, many are hospitalized for a few days. These hospitalizations could be avoided if safe outpatient alternatives and adequate reimbursement existed for this initial care. For instance, the availability of a US outpatient care center has helped to decrease hospitalization at diagnosis from 88% in 1978–1982 to 46% in 1998–2001, with the proportion of hospitalizations secondary to DKA increasing from 44% to 63% [6].

The diagnostic criteria are the same in children and adults (see Chapter 2); however, most children are quite symptomatic and do not require an extensive work-up. In a symptomatic child, plasma glucose ≥11.1 mmol/L (200 mg/dL) at any time of day, without regard to time since the last meal, or fasting plasma glucose ≥7.0 mmol/L (126 mg/dL) is diagnostic. Blood glucose results

obtained using a glucose meter should be immediately confirmed in a laboratory, before the initiation of insulin treatment. By contrast, if marked hyperglycemia and blood or urinary ketones are present, treatment is urgent; waiting another day to confirm the diagnosis may be dangerous if DKA is allowed to develop. In a well child, the diagnosis must not be based on a single plasma glucose test or borderline results obtained using a glucose meter. In such cases, the authors check the HbA_{1c} level; if this is normal, further monitoring of the fasting and/or 2-h postprandial blood glucose is recommended for several days. In children progressing to overt diabetes, hyperglycemia after dinner is usually the initial abnormality detectable by self-monitoring of blood glucose at home. OGTT should not be performed if fasting, random, or postprandial criteria are met as it is unnecessary and excessive hyperglycemia can result.

Hyperglycemia detected incidentally or during acute infection, trauma or other illness may be transient, especially if typical symptoms of diabetes are absent or equivocal. Children with transient hyperglycemia may be more likely to develop diabetes, but the reported progression rates vary from 0% to 32%. Testing for islet autoantibodies helps to rule in diabetes in cases with mild presentation; however, it is important to consider that the quality of commercial assays for islet autoantibodies varies widely and testing for at least three autoantibodies (to insulin, $GAD_{65,}$ and IA-2) provides 80% predictive value.

The possibility of other types of diabetes should be entertained in children who have negative diabetes autoantibodies and any of the following features:

- diagnosis at <6 months of age,
- autosomal dominant family history of diabetes,
- mild fasting hyperglycemia which does not progress,
- associated syndromic features, or
- a history of exposure to drugs known to cause β-cell toxicity or insulin resistance [7].

Impaired glucose tolerance (IGT) and impaired fasting glucose (IFG) may also be detected in a child with islet autoimmunity progressing to overt diabetes [3]. OGTT is rarely needed in prepubertal children, however, except to reassure the family that a metabolic decompensation is not imminent. In older children, especially obese teenagers with equivocal symptoms, the OGTT may have a role in the earlier diagnosis of T2DM, IGT, and IFG.

Diabetic ketoacidosis

The clinical presentation of DKA includes abdominal pain, nausea, and vomiting which can mimic an acute abdomen. The children are mildly to moderately dehydrated (5–10%), may have Kussmaul respiration and become progressively somnolent and obtunded.

DKA results from absolute or relative deficiency of circulating insulin and a corresponding increase in the levels of counter-regulatory hormones, such as catecholamines, cortisol, glucagon, and growth hormone (see Chapter 36). This combination leads to a catabolic state with increased glucose production by the liver and kidneys, increased lipolysis, ketogenesis with ketonemia, and metabolic acidosis. Absolute insulin deficiency occurs in children with previously undiagnosed T1DM or in those with an established diagnosis through omission of or inadequate insulin regimens. Relative insulin deficiency occurs during acute illness and stress if the increase in counter-regulatory hormones is not balanced by an appropriate increase in insulin dosage. The severity of DKA is categorized by the degree of acidosis:

- Mild: venous pH 7.2–7.3 or bicarbonate <15 mmol/L
- Moderate: venous pH 7.1–7.2 or bicarbonate <10 mmol/L
- Severe: venous pH <7.1 or bicarbonate <5 mmol/L.

Diabetic ketoacidosis at diagnosis of diabetes

In the USA, in those diagnosed with T1DM and T2DM younger than 20 years, 29% and 10% of the cases, respectively, presented in DKA [6]. In Europe, the rates for T1DM cases ranged 15% to 67% correlating inversely with the local incidence of T1DM [8]. DKA is more often found among younger children and in children with lower socioeconomic status who encounter barriers in accessing medical care [6]. Intensive community intervention to raise awareness of the signs and symptoms of childhood diabetes among school teachers and primary care providers may help to reduce the prevalence of DKA at diagnosis [9].

Diabetic ketoacidosis in children with established T1DM

In a large cohort of children with established T1DM, on average, eight per 100 developed DKA every year [10]; however, nearly 60% of the DKA episodes occurred in 5% of children with recurrent events. Recurrent DKA was predicted by omission of insulin, poor metabolic control, intercurrent gastroenteritis with dehydration, psychiatric and eating disorders, difficult family or social circumstances or limited access to medical care, peripubertal/adolescent girls, and insulin pump therapy.

Treatment of ketoacidosis

Children with DKA should ideally be cared for in a unit with nursing staff trained in management of DKA in children, written guidelines for DKA management in children and access to a laboratory capable of providing frequent and timely biochemical results. Hydration status should be assessed and fluid deficit and osmolality calculated to help guide fluid and electrolyte replacement. Serum electrolytes, glucose, blood urea nitrogen, creatinine, calcium, magnesium, phosphorous and blood gas testing should be repeated every 2–4 hours or more frequently in severe cases. The calculations are shown in the Box 59.1.

Children with DKA have a 5–10% deficit in extracellular fluid volume which has developed slowly. Avoid rapid or overzealous fluid replacement. Initial volume expansion should occur over the first 1–2 hours with intravenous (i.v.) infusion of 10–20 mL/kg normal saline (0.9%) or Ringer solution. The bolus rarely needs to be repeated and should not exceed a total of 40 mL/kg over the first

Box 59.1 Calculations of Anion gap, corrected sodium and serum osmolality

Anion gap = $Na - (Cl + HCO_3)$

Corrected Na = measured Na + [(plasma glucose − 100 mg/dL)(1.6)/100]

Serum osmolality = 2(Na + K) + glucose/18 + Blood urea nitrogen/2.8(mOsm/L)

4 hours of treatment. Subsequent fluid deficit replacement should occur over the next 48 hours using $^1/_2$ to $^3/_4$ normal saline, in addition to electrolytes (see Box 59.2).

Once blood glucose concentrations reach 250 mg/dL (14 mmol/L), 5–10% dextrose should be added to the i.v. solution to maintain the blood glucose concentration between 150 and 250 mg/dL (8–14 mmol/L) and avoid saline overload and hyperchloremic acidosis.

Continuous i.v. insulin infusion (typically consisting of diluted regular insulin) at a dose of 0.05–0.1 units/kg/h should commence after the child has received initial volume expansion. An i.v. bolus of insulin is unnecessary and may increase the risk of cerebral edema [11]. The insulin infusion should allow for a gradual decrease in blood glucose concentration by 50–100 mg/dL/h. If the blood glucose levels decrease too quickly or become too low before acidosis has resolved, i.v. dextrose concentration may be increased to 12.5% to prevent hypoglycemia while continuing to correct the metabolic acidosis with insulin. Unless the child is truly hypoglycemic, the insulin infusion rate should not be decreased to less than 0.05 units/kg/h as this is likely to prolong the time needed to suppress ketogenesis. Bedside monitoring of blood ketones (β-hydroxybutyrate) is more helpful than blood gases in adjusting insulin and glucose infusion rates.

Total body potassium is usually depleted, but serum levels at presentation may be normal or high secondary to efflux of intracellular potassium into the extracellular space in the presence of acidosis. Once the serum potassium is found to be normal or low, and urine output is confirmed, i.v. fluids should include 20–40 mEq/L potassium in the form of K acetate, K_2HPO_4, or a combination of these. No more than half of the potassium replacement should be given as K_2HPO_4 because excessive phosphorous administration may result in hypocalcemia following the suppression of parathyroid hormone.

Similar to serum potassium levels, serum phosphorus levels may be initially elevated only to fall rapidly during treatment of DKA. Clinical problems resulting from low phosphorus levels have not been substantiated; however, severe hypophosphatemia (<1 mg/dL) should be treated. If hypocalcemia develops, administration of phosphate should be decreased or stopped.

Severe acidosis is reversible with fluid and insulin replacement. Bicarbonate therapy may paradoxically cause CNS acidosis and hypokalemia from rapid correction of acidosis and is a risk factor for cerebral edema. Bicarbonate therapy is not recommended unless the acidosis is profound (pH < 6.9) and likely to interfere adversely with the action of epinephrine during resuscitation. If bicarbonate is considered necessary, 1–2 mmol/kg can be cautiously administered over 60 min.

Box 59.2 Estimate of 24-hour maintenance fluid volume

Estimation based on age:
- 0–2 years = 80 mL/kg
- 3–5 years = 70 mL/kg
- 6–9 years = 60 mL/kg
- 10–14 years = 50 mL/kg
- >15 years = 35 mL/kg

Estimation based on body weight:
- 100 mL/kg for the initial 10 kg body weight, plus
- 50 mL/kg for the next 10 kg body weight, plus
- 20 mL/kg for each additional kg body weight

For example, a child weighting 30 kg needs 1000 + 500 + 200 = 1700 mL maintenance water for 24 hours or 70 mL/h, not counting past or ongoing losses

Cerebral edema

Cerebral injury is the major cause of morbidity and mortality in children with cerebral edema accounting for 60–90% of all deaths due to DKA while up to 10–25% of survivors have significant residual morbidity [11]. Neurologic status must be monitored at frequent and regular intervals. Subclinical cerebral edema occurs in most children with DKA. Severe clinical edema affects 0.5–1% of the children and is fatal in over 20% [12]. Typically, cerebral edema occurs at 4–12 hours, but has been reported as late as 24–28 hours, after the initiation of i.v. fluid treatment. Potential risk factors for symptomatic cerebral edema in children include:
- More profound dehydration, hyperventilation, and acidosis at presentation;
- Bicarbonate therapy;
- Excessive and rapid fluid administration, especially if initial serum osmolality is >320 mOsm/L;
- Failure of serum sodium to rise as hyperglycemia resolves; and
- Initial i.v. insulin bolus or too early initiation of insulin infusion.

Signs and symptoms of cerebral edema include headache, change in mental status or behavior, incontinence, focal neurologic findings, sudden normalization of heart rate in a previously tachycardic dehydrated child, or a worsening clinical course in a child with improved laboratory values. Bradycardia, hypertension and irregular respiration (Cushing triad) are signs of greatly increased intracranial pressure. Early intervention is essential. Treatment includes administration of mannitol (1 g/kg over 30 min), decreasing fluid rate to 75% or less of maintenance rate, and elevation of the head of the bed. Mannitol therapy may need to be repeated. Intravenous hypertonic saline has also been used as an alternative to mannitol. However, a recent 11-year retrospective cohort study suggests that hypertonic saline as a sole agent may be

associated with an increased risk of mortality [13]. Radiographic studies (such as head CT), if necessary, should be obtained after rather than during treatment of cerebral edema.

Frequent monitoring of blood glucose levels should prevent hypoglycemia. For acute hypoglycemic episodes while on continuous insulin infusion, the insulin infusion may be temporarily discontinued for up to 15 min if necessary.

Transition to subcutaneous insulin regimen

Children may be transitioned to an appropriate subcutaneous insulin regimen once DKA has resolved and they are able to eat. To prevent rebound hyperglycemia, the insulin infusion should not be discontinued until 15–30 min after the first subcutaneous injection of rapid-acting insulin has been administered. Long-acting insulin analogs achieve therapeutic levels able to replace insulin infusion 4–6 hours after the subcutaneous injection. Bedside monitoring of blood ketones helps to titrate insulin dose and prevent a relapse.

Hyperglycemic hyperosmolar syndrome

Hyperglycemic hyperosmolar syndrome (HHS) can occur in children, primarily in the setting of T2DM and is defined as:

- Plasma glucose concentration 600 mg/dL (>33.3 mmol/L);
- Venous pH > 7.25 or arterial pH > 7.30;
- Serum bicarbonate >15 mmol/L;
- Small urine ketones or absent to small blood ketones;
- Serum osmolality >320 mOsm/kg.

Presentation of HHS can have a more insidious onset than DKA, and polyuria and polydipsia may continue until profound dehydration occurs, with approximately 50% of cases having altered consciousness or seizures. Compared to DKA, children with HHS need greater amounts of fluids to avoid intravascular collapse, which contributes to the mortality seen in HHS.

Goals of HHS treatment include:

- Gradual decrease of sodium concentration, often by titrating the sodium content in fluids.
- Decrease in glucose of 90 mg/dL per hour (5 mmol/L per hour) or less, after first few hours of therapy (initial treatment with bolus fluids causes a greater fall in glucose initially, but this should not persist).
    - Insulin therapy is delayed until glucose is falling less than 50 mg/dL (3 mmol/L) per hour and should be initiated at 0.025–0.05 units/kg/h and adjusted to maintain a decrease in serum glucose of 50–75 mg/dL per hour (3–4 mmol/L).
- Monitor potassium every 2–3 hours and phosphate and magnesium every 3–4 hours. Treat hypokalemia, hypophosphatemia, and hypomagnesemia if they are present.
- Check creatine kinase every 2–3 hours to monitor for rhabdomyolysis.

Complications of HHS include venous thrombosis associated with use of central venous catheters, rhabdomyolysis, and malignant hyperthermia. Cerebral edema is rarely seen. Children can have a mixed picture of DKA and HHS, and in these cases typically more fluids are given than usual for DKA, and insulin is started sooner than in HHS, but treatment should be based on the individual clinical presentation [14].

Pediatric ambulatory diabetes care

Diabetes is primarily managed in the outpatient setting by a team including a pediatrician specializing in diabetes, a diabetes nurse educator, a dietitian, a pediatric social worker trained in childhood diabetes and/or a pediatric psychologist with knowledge of childhood diabetes and chronic illness. In communities with low population density and low prevalence of childhood diabetes, such a care team may not be available and care will primarily be provided by the child's primary care physician. In these instances, these physicians should work closely with and have access to a regional diabetes care team. When available, telemedicine utilizing two-way video-computer technology and local medical staff offers a way for more efficient and effective care from afar.

Healthcare providers and the diabetes care team must always be cognizant of and sensitive to the cultural needs and barriers to care that may arise with minority children of recent immigrants. Interpreters should be utilized when needed.

Initial education

Initial education should provide a basic understanding of the pathophysiology of diabetes and its treatment to ensure that families feel confident in providing diabetes care at home (Table 59.1) [15].

At many institutions, initial education at time of diagnosis occurs in an inpatient setting regardless of whether or not the child presents acutely ill in DKA. In some centers with appropriate outpatient resources, initial diabetes education and initiation of insulin therapy can occur in the ambulatory setting, which has been shown to be cost effective.

Continuing education

In the first 6 months following diagnosis, close contact in the form of frequent outpatient visits, home visits, telephone communication and other methods of communication is essential for

Table 59.1 Initial education curriculum.

An explanation of how the diagnosis was made and reason for symptoms
Discussion regarding normal blood glucose levels and targets, the need for immediate insulin treatment and its mechanism of action
Practical skills including how to draw up and administer insulin, blood glucose testing, blood and urine ketone testing
Basic dietary guidelines
Simple explanation of symptoms and management of hypoglycemia
Diabetes at school
Importance of medical alert identification
Psychologic adjustment to the diagnosis
Emergency telephone contacts

Table 59.2 Continuing education curriculum.

Insulin types, actions, and adjustments based on self-monitoring of blood glucose
Monitoring and treatment goals
Mechanisms for coping with and adjusting to the diagnosis of diabetes
Nutrition, including carbohydrate counting
Management of diabetes during illness
Management of hyperglycemia and ketosis and prevention of DKA
Prevention, recognition, and management of hypoglycemia
Exercise, travel and holiday planning
Microvascular and macrovascular complications of diabetes and their prevention
Up-to-date information on research in diabetes and new therapies and technologies in diabetes care
When age-appropriate, discuss diabetes and driving, smoking, alcohol, drugs, college, and employment

DKA, diabetic ketoacidosis

addressing the frequently changing requirements during this time (Table 59.2) [15].

Diabetes education is a continuous process and must be repeated to be effective. It must be adapted and appropriate to the age of the child. Infants and toddlers often have unpredictable eating and activity patterns. There is often more difficulty in distinguishing normal behavior from mood swings related to hypoglycemia or hyperglycemia. Needle phobia can present a significant issue with the perception of pain inflicted by the caregiver. Hypoglycemia is more common in this age group and the prevention, recognition, and management of hypoglycemia is a priority. School-aged children will have increased understanding and involvement with their diabetes management. Providers should address school-aged children directly in addition to speaking with their parents or care providers. Education includes monitoring of blood glucose levels and injections at school, particularly during meal times, exercise and extracurricular activities. There should be increased recognition and awareness of hypoglycemic symptoms. Education should also focus on age-appropriate stepwise handover of diabetes responsibilities. This becomes particularly important in adolescence during which there is a critical balance between promoting independent responsible management of diabetes while maintaining parental involvement.

Once established, it is common practice for children to be seen in the ambulatory setting at least every 3 months; visits should be more often if the child does not meet the treatment goals or intensifies treatment, for example, if insulin pump treatment is initiated. During these visits, overall health and well-being is assessed, growth and vital signs are monitored, and a physical examination is performed. There should be routine screening for diabetes-associated complications and comorbidities. Blood glucose records, including a check of HbA_{1c}, medications and school plans are reviewed. This will allow the insulin doses to be adjusted and provide a template for continued diabetes education. Age appropriate diabetes-specific knowledge should be assessed and reviewed.

The dietitian may review dietary habits and provide ongoing nutrition education as needed. The social worker or psychologist assesses and monitors psychosocial problems and family dynamics and the impact of diabetes care. At the conclusion of these visits, an individualized plan should be developed for each child and their family and a written copy of this plan should be provided.

The advent of new technology including downloadable glucometers, insulin pumps and continuous glucose sensors, and electronic smartphone apps has made it increasingly possible for the diabetes care team to gain insight into home management of diabetes; however, this should not replace self-monitoring and regular review of blood glucose data at home by the child and their family.

Diabetes management in school

Children with diabetes spend a significant portion of their day in school; therefore, diabetes management in school is a critical portion of their diabetes management plan [16]. The child has the right to receive adult support for diabetes care from school personnel during school hours, outdoor school activities and school-sponsored events away from school. School personnel must be trained to provide or supervise all diabetes care prescribed by the diabetes team, be supportive of providing diabetes care and encourage diabetes management during school hours, including:

- Insulin administration by injection or with an insulin pump;
- Testing blood glucose in young children and older, newly diagnosed children and adolescents until they are capable of performing the task independently; and
- Identification and treatment for hypoglycemia, both mild–moderate and severe.

Children with diabetes should have a school health plan in place. The health plan should include contact information for the child's family as well as their diabetes care providers. It should also contain information regarding routine management of diabetes (blood glucose monitoring, insulin administration and dosing, snack times) and an emergency plan for management of hypoglycemia and hyperglycemia. Issues specific to insulin pumps include remembering to activate insulin bolus with food, disconnecting the pump during vigorous exercise or in the event of severe hypoglycemia, pump failures, and pump alarms.

Extracurricular activities are an important component of a child's school experience and children with diabetes should be allowed to participate and their needs accommodated accordingly. Field trips, field days and overnight trips often require advanced planning, but a child's diabetes should never be a cause for exclusion from any school-sanctioned activity.

Insulin treatment

The overarching goal of insulin replacement is to provide just enough insulin at an appropriate time to provide sufficient basal

insulin levels as well as higher insulin levels after meals [17]. The choice of insulin regimen depends on the individual's age, duration of diabetes, dietary and activity patterns, ability to cope, and metabolic targets. Patient and family preferences should also be respected.

Subcutaneous insulin injection regimens

Injections regimens, in order of worsening HbA_{1c} outcomes, include:

- Basal bolus regimen: 40–60% of the total daily dose as basal insulin analog (e.g. glargine, detemir) in 1–2 doses a day with rapid-acting insulin analog 10–15 min before each meal; soluble human insulin is less preferable and requires administration at least 20–30 min prior to each meal.
- Intermediate-acting human insulin twice daily and soluble human insulin 20–30 min prior to each meal.
- Two injections daily of a mixture of short- or rapid- and intermediate-acting insulin before breakfast and before the evening meal.
- Three injections using some variation of the following: a mixture of short- or rapid- and intermediate-acting insulin before breakfast, rapid or soluble human insulin before the afternoon snack or evening meal, and intermediate or basal/long-acting insulin before bed.

Basal insulin analogs, include glargine, which lasts for 20–24 hours and detemir, which lasts between 6–23 hours and is often given as twice daily injections (see Chapter 29). Longer acting insulins include degludec, which can last up to 72 hours [18] and is currently only approved for adults in the USA. In Europe insulin degludec is licensed for children with diabetes aged 1–17 years old. Intermediate-acting insulins include NPH, which is often given twice daily, and have greater inter- and intra-individual variability than the long-acting insulin analogs. Common rapid-acting insulin analogs include aspart, lispro, and glulisine, which are given before a meal and to treat hyperglycemia. Regular human insulin is a short-acting insulin that has a longer onset of action and later peak of action, but is still used commonly in many places around the world.

Intermediate-acting insulins, such as NPH, are often mixed with soluble human (regular) or rapid-acting analogs (aspart, lispro, or glulisine). If children are using needles and syringes, in place of insulin pen devices, they and their families should be taught how to mix the insulin properly to avoid contamination. It is generally taught to draw up the clear (regular or short-acting) insulin before drawing up cloudy insulin (NPH). As per the manufacturer's instructions, glargine or detemir insulins should not be mixed with any other insulin.

Premixed insulins contain a mixture of regular (or rapid-acting) insulin and NPH insulin in various fixed ratios. These preparations may be useful for children who do not want to draw insulin from separate vials prior to injecting. They may also be useful in reducing the number of injections when adherence is an issue, especially among teenagers. Premixed insulins are also available for use in pen injector devices. The main disadvantage to using premixed insulin preparations is the lack of flexibility in adjusting the separate insulin doses, which is often necessary with varied food intake or during illness or exercise.

Insulin pump therapy

Insulin pump therapy is the best way to restore the body's physiologic insulin profile. The pump delivers a variable programmed basal rate that corresponds to the diurnal variation in insulin needs. Prepubertal children require a higher basal rate in the early part of night, while post-pubertal adolescents who experience the "dawn phenomenon" require higher rates in the morning.

The user initiates bolus doses before meals and to correct hyperglycemia. Most pumps can receive wireless transmission of test results from glucose meters, but the child or caregiver must still manually enter the amount of carbohydrate being consumed. The pump calculates the amount of insulin needed for a meal or correction based on previously entered variables, which include: insulin : carbohydrate ratios, insulin sensitivity factor, glycemic target, and duration of insulin action (set at 2–8 h to protect from accumulating too much insulin). The user may accept or override the suggestion.

Rapid-acting insulin analogs perform better in pumps than soluble human insulin, both in terms of mimicking the first-phase insulin release after meal and avoidance of postprandial hypoglycemia. Even with the analogs, however, insulin has to be administered at least 10–15 min before meal to reach effective levels in time. A longer lead time may be needed if pre-prandial blood glucose is higher than 150 mg/dL. Young children, picky eaters and those with lack of organization may struggle with these requirements. In addition, children are often unable to predict the size of the meal. In these cases, one may administer half of the usual meal bolus in advance, with the other half, if needed, after meal. Adherence problems include infrequent blood glucose testing, not reacting to elevated blood glucose, incorrect carbohydrate counting or missing boluses altogether.

Children and their families must be instructed on troubleshooting and treatment of hyperglycemia, particularly if ketones are present, as this may be an indication of a pump malfunction. If the flow of insulin becomes interrupted, ketonemia will develop within 4 hours; this is particularly dangerous at night as there is no long-acting insulin on board. Syringes or insulin pens should always be available so that insulin may be administered via injection in the event of a pump failure.

Most clinical trials have demonstrated better HbA_{1c} and less severe hypoglycemia with pump therapy, compared with multiple daily injections. Pump therapy can improve the quality of life in children who have trouble with injections or who desire greater flexibility in their lifestyle (e.g. with sleeping in, sports, or irregular eating). Insulin pumps can be particularly helpful in young children or infants who have multiple meals and snacks and require multiple small doses of rapid-acting insulin. The newer generation of insulin pumps can deliver as little as 0.025 units/hour, but higher rates using diluted insulin may be needed for uninterrupted flow.

Currently, the most frequent complications of insulin pump treatment include failures of insulin delivery because of a displaced or obstructed infusion set, local skin infections, and DKA. Insulin pump treatment is significantly more expensive than regimens based on injections. For some children, pumps may be too difficult to operate or follow the multiple testing and carbohydrate counting requirements, or may be unacceptable because of body image issues or extreme physical activity (e.g. swimming, contact sports) [16].

Continuous glucose monitors (CGM) have been used in children with pumps and on multiple daily injection therapy (see "Monitoring and goals of diabetes management" section later in this chapter). Sensor-augmented pump therapy linking CGM to pumps is currently available, and an automatic shut-off of a pump overnight to prevent hypoglycemia was recently approved and is in use. Fully "closed-loop" systems, allowing the insulin pump to be directed automatically by a continuous glucose sensor with minimal human input, are being tested [19].

Nutrition

Nutritional management in children with diabetes remains a key component of diabetes care and education; if available, a pediatric dietitian should be a part of the diabetes care team. A key strategy should be prevention of overweight and obesity. The management does not require a restrictive diet, just a healthy dietary regimen from which the children and their families can benefit. Current guidelines target optimal glycemic control, reduction of cardiovascular risk, psychosocial well-being, and family dynamics [20, 21]. A thorough dietary history should be obtained including the family's dietary habits and traditions, the child's typical meal times and patterns of food intake.

Weight loss or poor weight gain may be a sign of illness (such as infection, celiac disease, or hyperthyroidism), insulin omission, or disordered eating [22].

Insulin pump and multiple daily injections therapy utilize carbohydrate counting in which the grams of carbohydrate to be eaten are counted and a matching dose of insulin is administered. This plan allows for the greatest freedom and flexibility in food choices, but it requires expert education and commitment and may not be suitable for many families or situations (e.g. school lunches, teenagers). Books and apps are now available to help calculate carbohydrate intake more accurately. Exchange planning teaches that it is not necessary to count precise grams. Exchanges are taught as either 10- or 15-g servings of carbohydrate. The exchange plan can enable a more consistent daily intake of carbohydrate. The constant carbohydrate meal plan was used often in the past with insulin regimens based on NPH and regular insulin, where carbohydrate intake and the amount of insulin were kept relatively constant from day to day. It has been perceived as too restrictive and a potential source of conflict.

The use of the glycemic index has been shown to provide additional benefit to glycemic control (see Chapter 25). Low glycemic index carbohydrate foods, such as wholegrain breads, pasta, temperate fruits, and dairy products may lower postprandial hyperglycemia. A glycemic load approach to predicting the postprandial blood glucose response, based on the glycemic index of the food and the portion size, has not been fully explored in children. Regardless of which meal plan is chosen, helpful principles are shown in Table 59.3.

Table 59.3 Principles of dietary planning in children with diabetes.

1. Eat a well-balanced diet, with daily energy intake distributed as follows:
   - Carbohydrate 50–55% (sucrose intake up to 10% total energy)
   - Fat 30–35% (up to 20% monounsaturated fat; <10% polyunsaturated fat; <10% saturated fat and trans fatty acids; n-3 fatty acids 0.15 g/day)
   - Protein 10–15%.
2. Eat meals and snacks at the same time each day, if possible.
3. Use snacks to prevent and treat hypoglycemia, but avoid overtreatment:
   - Young children often have a mid or late morning snack
   - Most people will have a mid or late afternoon snack
   - Many children require a bedtime snack, particularly if the bedtime blood glucose is below 130 mg/dL (7 mmol/L) or if they have been active during the day.
4. Gauge energy intake to maintain appropriate weight and body mass index:
   - Overinsulinization, "forced" snacking and excess food intake to prevent or treat hypoglycemia promote excessive weight gain and should be avoided
   - Eating disorders are common in teenagers with diabetes, particularly girls.
5. Recommended fiber intake for children older than 1 year: 3.3 g/MJ; children older than 2 years should eat = (age in years + 5) g/day fiber.
6. Avoid foods high in sodium that may increase the risk of hypertension; target salt intake to less than 4 g/day (sodium chloride).
7. Avoid excessive protein intake (athletes should not require protein supplements).
8. Children with diabetes have the same vitamin and mineral requirements as other healthy children; however, hypovitaminosis D is common and screening and supplementation are recommended.
9. There is no evidence of harm from an intake of artificial sweeteners in doses not exceeding acceptable daily intakes.
10. Specially labelled diabetic foods are not recommended because they are not necessary, are expensive, are often high in fat and may contain sweeteners with laxative effects. These include the sugar alcohols such as sorbitol.
11. While alcohol intake is generally prohibited in youth, teenagers continue to experiment with and sometimes abuse alcohol. Alcohol may induce prolonged hypoglycemia in young people with diabetes (up to 16 hours after drinking). Carbohydrate should be eaten before, during and/or after alcohol intake. It may be also necessary to lower the insulin dose, particularly if exercise is performed during or after drinking (e.g. dancing).
12. Approximately 10% of children with type 1 diabetes have serologic evidence of celiac disease. Those with positive intestinal biopsy or symptomatic have to be treated with a gluten-free diet. Products derived from wheat, rye, barley, and triticale are eliminated and replaced with potato, rice, soy, tapioca, buckwheat, and perhaps oats. While most of the children are asymptomatic, the long-term consequences of untreated celiac autoimmunity may warrant a gluten-free diet.

Age-specific advice

Breastfeeding in infants should be encouraged. Insulin pump therapy should be considered, particularly in children who require very small doses of insulin. Toddlers are often picky eaters and are more likely to eat frequent smaller meals throughout the day; their insulin regimen should match this eating pattern. Food refusal can be a significant source of distress, particularly if an insulin dose has already been administered. In school-aged children, meal plans may need to be adjusted depending on the school schedule. Food intake among teenagers is often chaotic. Breakfasts are skipped and binges may happen at any time of day or night. Weight loss or failure to gain weight may be associated with insulin omission for weight control and may be indicative of a disordered eating behavior. While insulin pump or multiple daily injections treatment may help some, simplification of the management plan to avoid extreme mismatches between food intake and insulin are sometimes the only viable option.

Exercise

Children with diabetes derive the same health and leisure benefits from exercise as children without diabetes and should be allowed to participate with equal opportunities and equal safety [23]. Physiologically, during exercise in children without diabetes, there is a decrease in pancreatic insulin secretion and an increase in counter-regulatory hormones resulting in an increase in liver glucose production (see Chapter 24). This matches skeletal muscle uptake of glucose during exercise, maintaining stable blood glucose concentrations under most conditions. In children with T1DM, there is no pancreatic regulation of insulin in response to exercise and there may be impaired counter-regulation. These factors combine to increase the risk of hypoglycemia and hyperglycemia during exercise. It is helpful to keep an exercise record noting the most recent insulin dose, timing and type of exercise, blood glucose levels before and after exercise, snacks eaten and the time of any episode of hypoglycemia.

Factors affecting a child's response to exercise include:

- Duration, type, timing and intensity of activity;
- Overall metabolic control and ambient blood glucose level;
- Type and timing of insulin injections and its absorption;
- Type and timing of food;
- Muscle mass and conditioning; and
- Degree of stress/competition [23].

Preventing hypoglycemia

Blood glucose levels should be checked before, during, and after the exercise. Children should consume carbohydrates prior to exercise, with the amount depending on the blood glucose level prior to exercise and the duration and intensity of exercise. For short duration activity, sports drinks with simple sugars provide optimal absorption and usually prevent hypoglycemia for the next 30–60 min. For activity of longer duration, solid foods containing carbohydrates are digested more slowly and should be consumed in addition to a liquid with simple sugars. Extra snacks should always be available to the child during exercise. The child's coaches and teammates or other responsible adults and peers should be aware of the signs and symptoms of hypoglycemia. Often, children will require adjustments to their insulin dosing when exercise is anticipated. The site of insulin injection should also be taken into account. Exercise increases blood flow in the part of the body being used, increasing insulin absorption if that area is where the insulin injection was administered. For example, prior to running the insulin dose should not be administered in the legs.

Insulin adjustments

For exercise anticipated within the first hour after eating, the dose of rapid-acting insulin before the meal may need to be decreased by 25–75% (depending on the intensity of the exercise). For evening exercise, reduction of the evening meal rapid-acting insulin by 25–75% as well as ingesting 10–15 g of fast-acting carbohydrate before the activity can help avoid hypoglycemia. For day-long activities (such as camps, hiking, or skiing), consider a 30–50% reduction in the long-acting insulin dose (or in the basal rate if using an insulin pump) the night before and on the day of the activity. For children using insulin pumps, there are numerous options for insulin adjustments with exercise. If the pump will be worn during exercise, a reduction of the basal rate by 20–50% starting 90 min before activity and lasting until the end of exercise can help to avoid hypoglycemia. For day-long activities, the basal rate can be reduced by 30–50% during the day of and the night after activity [23]. For some types of activities (e.g. contact sports), children may need to disconnect from the pump and do one of the following:

- Bolus part of the basal insulin to be missed prior to exercise (particularly if the pre-exercise blood glucose level is elevated) and the remainder after exercise;
- Bolus half of the insulin missed while disconnected after exercise;
- Bolus all of the insulin missed while disconnected after exercise.

In general, the pump should not be disconnected for longer than 2 hours. If necessary, the pump should be reconnected briefly and a bolus administered prior to disconnecting again.

New technologies with low glucose suspend may help with decreasing risk of hypoglycemia during and after activity.

Delayed hypoglycemia

Hypoglycemia can occur up to 24 hours after exercise secondary to increased glucose transport into the skeletal muscle, the late effect of increased insulin sensitivity, and the delay in replenishing liver and muscle glycogen stores. Blood glucose levels must be monitored for several hours following exercise, at bedtime and sometimes during the night on days with strenuous exercise. Consider a longer lasting snack (containing a solid carbohydrate, protein, and fat) at bedtime and reducing the insulin dose as discussed earlier.

Ketones and exercise

In situations of poor insulin intake or increased insulin resistance, whether it be from poor glycemic control or from illness, exercise may be dangerous because of the effect of uninhibited action of the counter-regulatory hormones. Children with diabetes should not participate in strenuous exercise if the pre-exercise blood glucose level is high (250 mg/dL, >14 mmol/L) and urine ketones (small or more) or blood ketones (≥0.5 mmol/L) are present. Treat ketones and postpone exercise until ketones have cleared.

Hypoglycemia

Hypoglycemia is the most common acute complication in the treatment of T1DM and responsible for a significant proportion of deaths in people with diabetes aged under 40 years of age (see Chapter 35) [24]. Blood glucoses of <60–70 mg/dL (<3.3–3.9 mmol/L) are considered to place an individual with T1DM at risk of severe hypoglycemia. A threshold value of 70 mg/dL (<3.9 mmol/L) is used as the value for identifying and treating hypoglycemia in children with diabetes because of the potential for glucose levels to drop further [24]. Severe hypoglycemia happens to one in five children every year on average, but 80% of the events occur among the 20% of children who have recurrent events [6]. Younger age, longer diabetes duration, barriers in access to care, and presence of psychiatric disorders or chaotic family environment increase the risk. While lower HbA_{1c} is generally a risk factor for hypoglycemia, appropriate intensive insulin treatment can lower the risk by improving timing of insulin in relationship to food intake and exercise [25].

Signs and symptoms

- *Autonomic signs and symptoms:* shakiness, palpitations, sweatiness, pallor.
- *Neuroglycopenic signs and symptoms:* difficulty concentrating, blurred or double vision, disturbed color vision, difficulty hearing, slurred speech, poor judgment and confusion, problems with short-term memory, dizziness and unsteady gait, loss of consciousness, seizure, death.
- *Behavioral signs and symptoms:* irritability, erratic behavior, nightmares, inconsolable crying.
- *Non-specific symptoms:* hunger, headache, nausea, tiredness.

Early warning signs and symptoms of hypoglycemia are much more difficult to identify in young children.

Treatment

In mild or moderate symptomatic hypoglycemia, after documenting a blood glucose of ≤70 mg/dL (3.9 mmol/L):

- Provide immediate oral, rapidly absorbed 5–15 g glucose or sucrose: glucose tablets, "Smarties" or 4 oz (100 mL) of sweet drink (juice, soda).
- Retest blood glucose in 10–15 min, if no response or inadequate response—repeat as above.

As symptoms improve and euglycemia is restored, ingest solid snack or meal (e.g. fruit, bread, cereal) to prevent recurrence.

- Retest blood glucose in 20–30 min to confirm that target glucose has been maintained.

In severe hypoglycemia, where the child has an altered mental status and is unable to assist in their care, may be unconscious and/or seizing, urgent treatment with parenteral glucagon or dextrose is required.

Glucagon

Glucagon is given intramuscularly or subcutaneously (10–30 μg/kg body weight):

- 0.5 mg for those <12 years
- 1 mg for those older than 12 years or heavier than 100 lb (45 kg).

Glucagon injection may be repeated in 5–10 min, if response was inadequate; however, it is likely to be ineffective after prolonged fasting. Side effects include vomiting and tachycardia.

Dextrose

Dextrose can be given intravenously by trained medical staff if glucagon is unavailable or recovery is inadequate in a hospital setting or by paramedics:

- Intravenous dextrose should be administered slowly over several minutes (e.g. dextrose 10% at 2–3 mL/kg).
- Rapid administration or higher concentration may result in an excessive rate of osmotic change, phlebitis and extensive tissue damage, if extravasated.

Close observation and monitoring of blood glucose is essential because vomiting is common and hypoglycemia may recur. Severe headache and transient paresis lasting up to 24 hours are not uncommon but generally do not require radiologic work-up.

Hypoglycemia unawareness

Hypoglycemia unawareness occurs when there is reduced awareness of the onset of hypoglycemia. A single hypoglycemic episode can lead to hypoglycemia unawareness secondary to a decrease in counter-regulatory responses, but it is usually seen in children who have multiple periods of blood glucose <70 mg/dL. Avoiding subsequent hypoglycemia for 2–3 weeks may reverse this loss of awareness.

Prevention

Hypoglycemia occurs more frequently

- when the treatment regimen or lifestyle is altered (increased insulin, less food, more exercise);
- in younger children;
- with lower HbA_{1c} levels;
- with previous severe hypoglycemia;
- when there is hypoglycemia unawareness;
- during sleep; or
- after alcohol ingestion.

Children and families should be aware of the above risk factors so that glucose monitoring and insulin regimens can be changed accordingly. There is an increased risk for hypoglycemia during,

immediately after, and up to 24 hours after exercise. Untreated celiac disease and Addison disease may also increase the risk of hypoglycemia.

Nocturnal hypoglycemia is often asymptomatic and should be suspected if the morning blood glucose is low and/or there are episodes of confusion, nightmares, or seizures during the night, or if there is impaired thinking, altered mood or headaches upon awakening. Nocturnal hypoglycemia can be confirmed with blood glucose monitoring during the night and may be prevented by including more protein and fat in the bedtime snack. Care should be taken that this does not occur at the expense of high overnight blood glucose levels.

Studies have shown an association between hypoglycemia and decrease in cognitive functioning in children with T1DM, particularly in children diagnosed before the age of 5–6 years. Recurrent severe hypoglycemia has been associated with worsened long-term memory, attention, and verbal IQ, but studies have been inconsistent. Severe hypoglycemia can increase parental and patient's worry, poor sleep, emergency room visits, hospitalizations, excessive lowering of insulin doses and subsequent worsening of glycemic control. Long-term follow-up of the Diabetes Control and Complications Trial (DCCT) participants has been reassuring that there was no evidence for permanent neurocognitive changes related to hypoglycemia in adolescent and young adult individuals, suggesting that the effect of severe hypoglycemia on long-term neuropsychological functioning may be age-dependent [26].

Ultimately, hypoglycemia is frequently predictable and should be prevented. Children and their caregivers must be taught to recognize the symptoms of hypoglycemia and treat this immediately and appropriately. Children with diabetes should always carry around a source of rapid-acting glucose and should wear identification noting that they have diabetes. The diabetes care provider should be notified if a child is having recurrent episodes of symptomatic hypoglycemia or if there is hypoglycemia unawareness. This will facilitate discussions to adjust insulin regimens, food intake patterns, blood glucose goals and monitoring. Continuous glucose monitoring helps to detect and to avoid hypoglycemia.

Sick-day management

Children with diabetes in good metabolic control should not experience more illness or infections than children without diabetes; however, they will go through their share of routine infections, which can be challenging for their caregivers. The influenza vaccine and other routine childhood immunizations are recommended for all children with diabetes. When children with diabetes become ill, the underlying precipitating illness should be treated promptly.

Healthcare providers should equip families soon after diagnosis with the tools necessary to avoid dehydration, uncontrolled hyperglycemia or ketoacidosis, and hypoglycemia. Face to face education and written instructions are important, but most parents require telephone advice when first facing sickness in their child and some may need repeated support. Over time, most parents should be able to manage sick days independently as well as identify appropriate times when to seek help from their diabetes provider or emergency services. Children and their families should immediately seek medical attention if:

- blood glucose concentrations continue to rise despite extra insulin;
- blood glucose concentrations remain persistently below 70 mg/dL (3.5 mmol/L);
- blood ketones are higher than 1.5 mmol/L or ketonuria is severe and persistent; or
- the child becomes exhausted, confused, dehydrated, or develops difficulty in breathing, severe abdominal pain, or a severe hypoglycemic reaction.

Missed insulin injection, inactivated insulin or interruption of insulin delivery from pump may lead to "sick days" as well, especially in older children. While treatment is essentially the same as for hyperglycemia in the course of an infection, the differential diagnosis is important for prevention of recurrent events.

Hyperglycemia is seen in many illnesses, particularly those associated with fever, as a result of elevated levels of stress hormones, which promote gluconeogenesis and insulin resistance. Severe illness increases ketone body production secondary to inadequate insulin action or insufficient oral intake of carbohydrates. By contrast, illnesses associated with vomiting and diarrhea can lead to hypoglycemia secondary to decreased food intake, poor absorption, and slower gastric emptying.

In general, during illness, blood glucose concentrations must be monitored more frequently—at least every 3–4 hours and more often when blood glucose concentrations are outside the target range (e.g. 80–200 mg/dL). Urinary or blood ketones must be checked at least twice daily and always when blood glucose concentration exceeds 300 mg/dL (17.6 mmol/L). If available, the authors recommend testing blood ketones (β-hydroxybutyrate, using, for example, Precision Xtra/Exceed meter) over urine ketone testing as a more specific and timely marker of ketosis:

- The presence of ketones when blood glucose concentrations are persistently elevated above 200 mg/dL (11.1 mmol/L) indicates the need for supplemental insulin and fluids.
- The presence of ketones when blood glucose concentrations are low or normal, especially during gastrointestinal illness, indicates insufficient oral intake of carbohydrates (starvation ketones). In this case, ketones do not reflect insulin deficiency, but rather a physiologic response and may protect the child patient from severe hypoglycemia as β-hydroxybutyrate is the only alternative fuel to glucose for the brain. Supplemental insulin is contraindicated as it will likely cause hypoglycemia; the correct treatment includes fluids with glucose.

Insulin therapy must never be stopped during a sick day, although the dose may need to be decreased if the child is vomiting or eating less than usual. A fasting child still requires approximately 40% of the usual daily insulin dose, as long-acting

basal insulin, to cover basic metabolic needs and prevent ketoacidosis; however, infections associated with normal food intake often require an increase of basal insulin by 10–15%. In addition, extra doses of rapid-acting insulin are usually needed to correct hyperglycemia, prevent ketoacidosis and avoid hospital admission. These doses may be repeated every 2–4 hours as needed based on the results of blood glucose and ketone monitoring.

With blood glucose concentrations greater than 200 mg/dL (11.1 mmol/L), the authors recommend:

- Usual high blood glucose correction (e.g. 1 unit of rapid-acting insulin for each 50 mg/dL above 100 mg/dL, if blood ketones <0.6 mmol/L or urine ketones negative/small;
- Injection of rapid-acting insulin in the amount of 10% of the total daily dose, if blood ketones 0.6–1.5 mmol/L or urine ketones are moderate or large;
- Injection of rapid-acting insulin in the amount of 10–20% of the total daily dose if blood ketones >1.5 mmol/L or urine ketones are moderate or large;
- As acidosis is present in most children with hyperglycemia and blood ketones >3.0 mmol/L, this warrants referral to an emergency department.

Children using insulin pumps who develop hyperglycemia and moderate or large urine ketones (or ≥1.0 mmol/L blood ketones) must always take into consideration the possibility of an interruption in insulin delivery. If blood glucose levels do not decrease appropriately after an insulin bolus from the pump, the correction bolus of short-acting insulin should be given as injection by pen or syringe and the pump infusion set should be changed. A temporary increase in the basal rate by 20% or more may be required until blood glucose concentrations begin to normalize and ketones clear.

If hypoglycemia <70 mg/dL (<3.9 mmol/L) persists and the child is unable to tolerate any oral intake, an injection of low-dose glucagon may reverse the hypoglycemia and enable oral fluid intake to resume. Glucagon is mixed as usual but given using an insulin syringe with the dose being one unit per year of age up to 15 years [27]. Upon mixing with water, glucagon remains stable for at least 48 hours at 4 °C. The small dose of glucagon can be repeated every 2–4 hours; however, it is likely to be less effective with prolonged fasting. This dose of glucagon is not to be used for the emergency treatment of severe hypoglycemia.

Hydration status must be followed closely. Fever, hyperglycemia with osmotic diuresis, and ketonuria all increase fluid losses. Households should maintain a supply of sugar and electrolyte-containing fluids:

- Oral water is sufficient to prevent dehydration in uncomplicated cases of hyperglycemia.
- If there is an ongoing fluid loss from diarrhea or vomiting, hydration liquids should contain salt in addition to water (e.g. Pedialyte, Rehydralate). These preparations contain 25–30 g/L glucose, 45–90 mEq/L sodium, 30 mEq/L bicarbonate, and 20–25 mEq/L potassium. Oral rehydration fluid can be made at home by mixing half of a flat teaspoon of salt (~3 g of NaCl = ~50 mEq sodium), 7 teaspoons of sugar (28 g), and (optionally) 100 mL (4 oz) of orange juice into 1 L water.
- If there is difficulty eating or keeping food down and the blood glucose is falling below 200 mg/dL (11.1 mmol/L), sports drinks should be administered. They contain less electrolytes but higher amounts of glucose (e.g. Gatorade contains 255 g/L glucose, 20 mEq/L sodium, 3 mEq/L bicarbonate, and 3 mEq/L potassium).
- If the blood glucose is falling below 100 mg/dL (5.6 mmol/L), fluids with higher concentration of sugar are recommended (e.g. juice or non-carbonated regular soda containing approximately 70 g glucose per 100 mL). These fluids contain almost no sodium and are not appropriate in large amounts for children with diarrhea.

The required volume of oral fluid replacement is the sum of maintenance volume, deficit and ongoing losses. In practical terms, infants and toddlers with diabetes who vomited more than twice or have multiple loose stools should be referred to an emergency department for evaluation and intravenous fluids. Those with milder symptoms can be given oral fluid therapy at home using small amounts (5 mL) of cold fluids every 5 minutes. Most children with vomiting can be successfully orally rehydrated with persistent gentle encouragement of parents.

Antiemetic medication at home is generally contraindicated, especially in young children, as it may mask acute abdominal processes such as appendicitis, volvulus or intussusception and may have significant adverse effects. Ondansetron can be used to contain vomiting in children properly evaluated by a physician and selected older children presenting without abdominal pain.

Monitoring and goals of diabetes management

Glycated hemoglobin (HbA_{1c}) is the only measure of mid- to long-term glycemic control for which robust outcome data are available (see Chapter 27). Elevated HbA_{1c} predicts long-term microvascular and macrovascular complications but has its limitations. In the DCCT, an HbA_{1c} of 53 mmol/mol (7.0%) corresponded to a higher average blood glucose concentration (measured seven times a day) of 192 mg/dL in the conventionally treated participants compared with 163 mg/dL in those in the intensively treated group. Consequently, the same HbA_{1c} level conferred significantly higher risk of microvascular complications and hypoglycemia in the conventionally treated group compared with the intensively treated group [19]. HbA_{1c} is only one of the measures of optimal glycemic control, with other measures including documented hypoglycemia, type of treatment, patient's age, and quality of life. Ideally, there should be four to six measurements per year in younger children and three to four measurements per year in older children.

Self-monitoring of blood glucose (SMBG) provides immediate and daily documentation of hyperglycemia and hypoglycemia, helps to determine immediate and daily insulin requirements and detects hypoglycemia and assists in its management. Blood

glucose is best measured during the night, after the overnight fast, before meals, 2 hours after a meal—typically 4–6 times a day. Blood glucose should also be measured in association with illness, exercise, and prior to driving a car. The frequency of SMBG is associated with improved HbA_{1c} in people with T1DM [19]. Patient acceptance of SMBG may be enhanced by including the opportunity for testing alternative sites in addition to the fingertips (e.g. the palm of the hand or the forearm); however, as alternative sites may be slower to reflect falling blood glucose, the fingertips should be used if there is concern for hypoglycemia based on symptoms or its presence using alternative sites for measurement.

A logbook or some type of electronic memory device has to be used to record patterns of glycemic control and adjustments to treatment. The record book is useful at the time of consultation and should contain time and date of blood glucose reading, insulin dosage, together with a note of special events (e.g. illness, parties, exercise, menses, hypoglycemic episodes, and episodes of elevated blood or urine ketones).

At present, the safest recommendation for glycemic control in children is to achieve the lowest HbA_{1c} that can be sustained without severe hypoglycemia, frequent moderate hypoglycemia, or prolonged periods of significant hyperglycemia where blood glucose levels exceed 250 mg/dL (14 mmol/L). Each child should have targets individually determined. Targets for HbA_{1c} and SMBG recently proposed by the International Society for Pediatric and Adolescent Diabetes (ISPAD) [19] are summarized in Table 59.4.

Table 59.4 Biochemical targets of glycemic control. These targets are intended as guidelines, each child should have their targets individually determined.

Level of control	Optimal	Suboptimal	High risk
HbA_{1c}			
DCCT standardized (%)	<7.5	7.5–8.9	≥9.0*
IFCC (mmol/mol)	<58	58–74	≥75
SMBG mmol/L (mg/dL)			
Fasting or pre-prandial blood glucose	4–8 (70–145)	>8 (>145)	>9 (>162)
Postprandial blood glucose	5–10 (90–180)	10–14 (180–250)	>14 (>250)
Bedtime blood glucose	6.7–10 (120–180)	<6.7 (<120) or >9 (>162)	<4.4 (<80) or >11.1 (>200)
Nocturnal blood glucose	4.5–9 (80–162)	<4.2 (<75) or >9 (>162)	<4.0 (<70) or >11.1 (>200)

DCCT, Diabetes Control and Complications Trial; IFCC, International Federation of Clinical Chemistry; SMBG, self-monitoring of blood glucose.
* DCCT conventional adult cohort had a mean HbA_{1c} value of 8.9% (74 mmol/mol), both DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) have shown poor outcomes with this level.

Continuous glucose monitoring

Sensors are available and in development that measure interstitial fluid glucose every 1–5 min (i.e. "continuously"). Currently, these devices are expensive, may not be available in many countries, and insurance coverage is limited. Over time, it is anticipated that these devices will become the standard of care in children with T1DM. The continuous glucose results are available to the user in real-time and are stored in the receiver device or pump for downloading to a computer at a later time. The download allows the child and healthcare professional to review the results and make appropriate and educated insulin dosage adjustments. This much more sophisticated approach to SMBG may allow targets to be determined so that an alarm will alert the wearer to a glucose value projected to fall below or above the preset target and inform insulin delivery from a pump. As continuous glucose monitoring becomes more widely used, decreased blood glucose targets may be more safely achieved in children with diabetes.

The average HbA_{1c} is lowest in the youngest age group, perhaps reflecting the more complete caregiver involvement at younger ages. Of all age groups, adolescents are currently the farthest from achieving HbA_{1c} <58 mmol/mol (<7.5%), reflecting the diabetes mismanagement that frequently accompanies the increased independence in diabetes care during the adolescent years, as well as the effect of psychological and hormonal challenges of adolescence. Goals that are too ambitious may lead to an unwarranted sense of failure and alienation of the teenager with diabetes. As diabetes technology improves, especially continuous glucose monitoring, recommended target indicators for glycemic control will likely decrease to reflect a new balance of benefits and risks.

Healthcare providers should be aware that achieving an HbA_{1c} consistently below the target range without extensive personal and national healthcare resources and outside of a clinical trial structure may be very difficult. As a benchmark, intensively treated adolescents in the DCCT achieved a mean HbA_{1c} of 65 mmol/mol (8.1%), compared to 54 mmol/mol (7.1%) in adults. Older well-educated DCCT participants with excellent access to the newest diabetes technology maintained HbA_{1c} of 62–66 mmol/mol (7.8–8.2%) during 12 years of follow-up in the Epidemiology of Diabetes Interventions and Complications (EDIC) study [28].

Psychological care

The diagnosis of T1DM changes the lives of affected families and poses lifelong challenges. Children with T1DM are at risk for adjustment disorder during the initial period after diagnosis (Chapter 56). Those with adjustment disorder are also at increased risk for continued psychological concerns. Young people with T1DM are more frequently diagnosed with and treated for psychiatric disorders, disordered eating, neurocognitive and learning problems, family dysfunction and poor coping skills than the

Table 59.5 Psychologic care recommendations for families of children with T1DM.

1	Resources should be made available to include professionals with expertise in the mental and behavioral health of children and adolescents within the interdisciplinary diabetes healthcare team. Mental health specialists include psychologists, social workers, and psychiatrists.
2	Mental health professionals should be available to interact not only with children and families at clinic visits to conduct screening and more complete assessments of psychosocial functioning, but also to support the diabetes team in the recognition and management of mental health and behavior problems.
3	There should be easy access to consult psychiatrists for cases involving severe psychopathology and the potential need for psychotropic medications.
4	All mental and behavioral health specialists should have training in diabetes and its management.
5	The interdisciplinary diabetes healthcare team should maintain regular, consistent and uninterrupted contact with children and their families. When clinic visits are missed or not frequent, other modes of contact such as phone, texting, or e-mail should be made available
6	Assessment of developmental progress in all domains of quality of life (i.e. physical, intellectual, academic, emotional and social development) should be monitored routinely.
7	Routine assessment should be made of developmental adjustment to and understanding of diabetes management, including diabetes-related knowledge, insulin adjustment skills, goal-setting, problem-solving abilities, regimen adherence, and self-care autonomy and competence. This is especially important during late childhood and prior to adolescence when in many families the child may take on diabetes management responsibilities without adequate maturity for effective self-care.
8	Identification of psychosocial adjustment problems, depression, eating disorders and other psychiatric disorders should be performed at planned intervals and by appropriately trained mental health professionals. These assessments are particularly important in young people not achieving treatment goals or who exhibit chronically poor metabolic control.
9	The interdisciplinary team should assess general family functioning needs (conflict, cohesion, adaptability, and parental psychopathology) and diabetes-related functioning (communication, parental involvement and support, and roles and responsibilities for self-care behaviors) especially when there is evidence of cultural, language, or family problems.
10	The interdisciplinary team should aim to provide preventative interventions for patients and families (including training parents in effective behavior management skills) at key developmental times, particularly after diagnosis and prior to adolescence. These interventions should emphasize appropriate family involvement and support (i.e. teamwork) in diabetes management, effective problem-solving and self-management skills, and realistic expectations about glycemic control.
11	Evidence-based psychosocial, behavioral, or psychiatric interventions should be made available for patients or families exhibiting conflict, disordered communication, behavioral or psychiatric difficulties, or adherence problems affecting glycemic control. Developmental needs of children and adolescents should be considered while planning interventions incorporating social, emotional, and tangible support.
12	In counselling young people and parents regarding advances in diabetes management, and encouraging the intensification of insulin regimens, motivational interviewing may be useful. This may help in clarifying patient and parental goals and resolve ambivalence about regimen intensification. Patients should not be denied access to regimen intensification based on perceptions of limited competence, as even youth with low self-management competence have been shown to improve with intensive insulin therapy.
13	Adolescents should assume increasing responsibility for diabetes management tasks but with continuing, mutually agreed parental involvement and support. The transition to adult diabetes care should be discussed, negotiated, and carefully planned with adolescents, their parents, and the adult diabetes team well in advance of the actual transfer to adult care.

general population. The psychological care recommendations of the ISPAD [29] are summarized in Table 59.5.

Screening and early treatment of risk factors for complications and associated conditions

Dyslipidemia

Cardiovascular disease (CVD) is a leading cause of morbidity and mortality in adults with T1DM. Preclinical atherosclerosis often starts in childhood. While children with T1DM generally have a favorable lipid profile, this remains a major modifiable CVD risk factor in this population. Screening for dyslipidemia in children with T1DM should commence after diagnosis, once glycemic control has been established, in those older than 10 years of age. Screening should start at the age of 2 years if there is a family history of hypercholesterolemia or CVD or if family history is unknown. Lipids should be repeated every 5 years thereafter if normal [30].

Approved therapies for children include bile acid sequestrants and statins [31]. Bile acid sequestrants are not well tolerated and therefore adherence is poor. Several short-term trials of statins have confirmed their safety and efficacy in children and adolescents with familial hypercholesterolemia. Per ISPAD guidelines [32], children with low density lipoprotein (LDL) levels >100 mg/dL ($\geq$2.6 mmol) should obtain glucose control, and dietary and lifestyle interventions. If LDL is 130 mg/dL ($\geq$3.4 mmol/L) and has one or more CVD risk factors, then statin therapy is recommended for children greater than 10 years of age. Target LDL level is 100 mg/dL (<2.6 mmol/L). Target high density lipoprotein (HDL) is >35 mg/dL (>1.1 mmol/L) and triglycerides 150 mg/dL (<1.7 mmol/L). ADA guidelines state that after 10 years of age, if LDL is >160 mg/dL and does not respond to lifestyle therapy or if the child has additional risk factors (i.e. family history of early CVD) and LDL >130 mg/dL that has not responded to lifestyle therapy, statin therapy should be considered. If therapy with statins is undertaken, regular monitoring of liver function and screening for symptoms of

rhabdomyolysis should occur. Appropriate contraceptive advice should be given to girls receiving statins.

Microalbuminuria

Microalbuminuria is the first clinical manifestation of diabetic nephropathy and may be reversible with diligent glycemic and blood pressure control. Microalbuminuria is defined as any of the following:

- Albumin excretion rate 20–200 μg/min, or 30–300 mg/24 h in 24-hour urine collections.
- Albumin concentration 30–300 mg/L (in early morning urine sample).
- Albumin : creatinine ratio 2.5–25 mg/mmol or 30–300 mg/g (spot urine) in males and 3.5–25 mg/mmol in females (because of lower creatinine excretion).

Screening for microalbuminuria with a random spot urine sample should occur annually in children once they are 10 years of age and have had diabetes for more than 5 years. If values are increasing or borderline, more frequent screening should occur. Abnormal results should be repeated. The diagnosis of microalbuminuria requires documentation of two abnormal samples out of three samples over a period of 3–6 months. Once persistent microalbuminuria is confirmed, non-diabetes-related causes of renal disease should be excluded and treatment started. Persistent microalbuminuria is associated with end-stage renal disease and increased risk of macrovascular disease. Treatment with an angiotensin-converting enzyme (ACE) inhibitor should be started in the setting of persistent microalbuminuria, even if the blood pressure is normal. Children and their families should be counselled about the importance of glycemic control and smoking cessation if applicable, and appropriate contraceptive advice should be given to girls receiving ACE inhibitors [32]. Angiotensin receptor blockers are not approved for use in children but are occasionally used off-label.

Elevated blood pressure

Hypertension in adults with diabetes is associated with the development of both micro- and macrovascular disease. Treatment of blood pressure is critical in reducing these complications in adults and presumably in children and adolescents as well. Blood pressure should be checked and reviewed at each clinic visit. Hypertension is defined as systolic or diastolic blood pressure (measured on at least three separate days) above the 95th percentile for the child's age, sex and height and target blood pressure is <90th percentile. Care should be taken to ensure use of the appropriate-sized cuff in children to avoid inaccurate readings. If elevated blood pressure is confirmed, non-diabetes causes of hypertension should first be excluded. Treatment includes lifestyle interventions and ACE inhibitors if lifestyle fails [32].

Retinopathy

Adolescents have a higher risk of progression to severe non-proliferative or proliferative retinopathy compared to adults with diabetes [33]. The first dilated ophthalmologic examination should be obtained by an ophthalmologist, optometrist, or other healthcare professional trained in diabetes-specific retinal examination once the child is ≥10 years old or puberty (if this is earlier) and has had diabetes for 2–5 years [34]. The frequency of subsequent examination is generally every 1–2 years, depending on the individual risk profile and advice of an eye care provider [32].

Celiac disease

The prevalence of biopsy-confirmed celiac disease in children with T1DM ranges from 1–10%, compared to <1% in the general population [35]. The risk is greatest in children diagnosed before age 5 years. Many children with diabetes are asymptomatic but are positive for specific serologic markers of celiac disease such as autoantibodies to tissue transglutaminase. Most of the children with diabetes and celiac disease still remain undiagnosed, despite intestinal symptoms and/or short stature in about half of the cases.

Clinical manifestations of celiac disease are diverse, vary with age and may overlap with functional disorders. Some of the manifestations, such as delayed growth and puberty, decreased bone mineralization, abdominal pain and abnormal liver function tests, may overlap with those of poorly controlled diabetes. Therefore, physicians and other healthcare providers need to consider celiac disease in the differential diagnosis and many have argued for a routine transglutaminase screening in children with T1DM.

T1DM and celiac disease share HLA and non-HLA susceptibility genes. The prevalence of transglutaminase autoimmunity is highest in those with the HLA-DR3, DQB1∗0201 haplotype. One in four children with diabetes homozygous for this haplotype and 12% of the heterozygotes are positive for transglutaminase autoantibodies.

Most children with T1DM with celiac disease are transglutaminase-autoantibody-positive at the initial screening, although new cases develop during follow-up. All children should be screened for immunoglobulin A (IgA) transglutaminase-autoantibodies at onset of diabetes and, if negative and asymptomatic, rescreened every other year. If the transglutaminase-autoantibodies are negative, but the child has symptoms and/or signs consistent with celiac disease, other causes (e.g. poor glycemic control, or intolerance of milk, soy or salicylates) should be explored. HLA-DQB1 typing and total IgA level measurement may be helpful; if DQB1*0201 is present, IgA <10 mg/dL and, if symptoms persist, biopsy is recommended. Celiac disease is unlikely if both HLA-DQ2 and HLA-DQ8 are negative. Positive transglutaminase autoantibody findings have to be confirmed on another occasion, because transglutaminase autoantibody levels can fluctuate. If transglutaminase autoantibodies are strongly and persistently positive (radioimmunoassay index >0.5 or ELISA >60), biopsy is recommended even in a completely asymptomatic child. By contrast, children with low to moderately positive transglutaminase autoantibody levels may have false-negative biopsy and may be falsely reassured that they do not have celiac disease and forego further follow-up. The authors recommend repeating transglutaminase autoantibody testing every 3–6 months as

long as the levels are positive. Recent guidelines suggest that celiac disease can be diagnosed without biopsy in symptomatic children with elevated transglutaminase autoantibodies provided the endomysial IgA is also positive and either HLA-DQ2 or HLA-DQ8 is present.

Untreated celiac disease may pose problems with diabetes management, including increased risk of hypoglycemia and chronic diarrhea that is difficult to differentiate from that caused by autonomic neuropathy in adults. It is an open issue whether treating silent celiac disease improves diabetes-related outcomes. To date, results suggest small benefit in growth and bone mineralization, excess weight gain but no diabetes control benefit, or a slight decrease in HbA_{1c}. Gluten-free diets may prevent some of the episodes of hypoglycemia. The benefit of early detection and treatment remains unproven, but is the subject of ongoing investigation.

Thyroid disease

Hypothyroidism is present in 3–8% of children with T1DM. Long-term follow-up suggests that as many as 30% of people with T1DM develop autoimmune thyroiditis [36, 37]. The presence of hypothyroidism has been associated with thyroid autoantibodies, which are observed more frequently with increasing age and diabetes duration and female gender. With follow-up of 20 years, 80% of people with T1DM and thyroid peroxidase (TPO) autoantibodies develop hypothyroidism. Hyperthyroidism is less common than hypothyroidism in people with T1DM, but still more common (3–6%) than in the general population.

The presence of autoimmune thyroiditis in the population with T1DM has the potential to affect growth, weight gain, diabetes control, menstrual regularity, and overall well-being. All children with T1DM should be screened for elevated levels of the thyroid-stimulating hormone (TSH) after stabilization at onset of diabetes and every 1–2 years thereafter, or sooner if symptoms of hypothyroidism or hyperthyroidism are present. We also recommend measuring TPO and free T4 at the time of TSH screening. Those with positive TPO autoantibodies and normal thyroid function should be screened on a more frequent basis (every 6–12 months). Treatment of thyroid disease in children with T1DM is the same as that for the general population.

Addison disease

Addison disease affects approximately 1 in 10,000 of the general population and in 1% of people with T1DM [36]. The autoimmune process resulting in Addison disease can be identified by the detection of autoantibodies reacting to 21 hydroxylase (21-OH). The presence of this autoantibody in the general population is very rare, in contrast to 1–2% in people with T1DM. Of those with positive antibodies but as yet free of Addison disease, 15% develop Addison disease within a few years. Progression to adrenal insufficiency begins with elevated plasma renin activity and then progresses to increased adrenocorticotropic hormone, decreased stimulated cortisol, and eventually abnormalities of basal cortisol. The authors' current practice is to screen all children with T1DM for the presence of 21-OH autoantibodies. Those positive are followed for adrenal insufficiency by plasma renin activity and adrenocorticotropic hormone stimulation testing. Most children who develop disease are mildly symptomatic with decreasing insulin doses and HbA_{1c}.

60 Adolescence and Emerging Adulthood: Diabetes in Transition

Rebecca K. Snelgrove,[1,2] Dayna E. McGill,[2] and Lori M.B. Laffel[1,2]

[1] Pediatric, Adolescent and Youth Adult Section, Joslin Diabetes Center, and Harvard Medical School, Boston, MA, USA
[2] Clinical, Behavioral and Outcomes Research Section, Joslin Diabetes Center and Harvard Medical School, Boston, MA, USA

Key points

- The time period of adolescence and young adulthood involves significant physical, social, and emotional growth, and presents unique challenges to those with diabetes.
- The intensive treatment required for consistent and effective diabetes care, especially for type 1 diabetes, can be time-consuming and challenging for young adults with diabetes, but it can be especially challenging as adolescents move toward adulthood. The degree of independence and responsibility adolescents accept for their diabetes care ideally increases as they enter older adolescence and young adulthood.
- Empowering emerging adults with a sense of self-efficacy with respect to their capacity to care for diabetes effectively is crucial to ensuring success during this transition phase and in establishing consistent self-care habits for life.
- As the emerging adult is likely to leave the home, the supportive role originally assumed by parents and family members can be taken on by close friends and significant others.
- The process of transition followed by the actual transfer from pediatric diabetes care to an adult practice can be challenging for emerging adults with diabetes. It is imperative that parents and the pediatric diabetes team members provide the necessary training and preparation for self-care to support the transfer to an adult practice. It is recommended that parents continue to support their teenager's diabetes care during this tumultuous developmental stage.
- Parents of teenagers and their healthcare professionals should monitor and attempt to prevent teenage burnout from diabetes care. Inclusion of diabetes educators and mental health clinicians on the teenager's and emerging young adult's diabetes team can help reduce the likelihood of burnout and help overcome barriers to self-care acquisition.

Introduction

Although this chapter focuses on the adolescent and young adult with type 1 diabetes (T1DM), the commonest type of diabetes affecting this age group, many of the issues also apply to young persons with type 2 diabetes (T2DM). Thus, this chapter will describe the process of transition that begins during adolescence and culminates in the transfer from a pediatric care team to an adult diabetes or endocrinology practice for young persons with diabetes, either T1DM or T2DM. This period of transition is impacted by multiple developmental changes that teenagers undergo between the ages of 13–18 years with additional developmental issues arising during the stage of emerging adulthood, between the ages of 18–25 and 25–30 years. The chapter will examine the psychosocial and physical changes experienced by adolescents as well as the special challenges teenagers and emerging young adults with diabetes encounter as they transition from adolescence into early adulthood.

The process of transition requires the growing and developing adolescent to take on the responsibilities for diabetes self-care previously managed by the youth's parents. This process should be gradual with sharing of diabetes management between parents and teenagers initially, followed by the ultimate transfer to self-care that should precede the time when the older adolescent or emerging young adult leaves the pediatric diabetes team and receives care from a medical team that specializes in adult diabetology or endocrinology.

There is no exact age at which the young person with diabetes should perform all self-care; rather this is a process that needs to be individualized, depending on development stage, maturity, family support, family expectation, education from the healthcare team, as well as other factors. Acquisition of self-care can begin for some youngsters in the higher primary grades or during the middle school years while the youths are under the supervision of adults for diabetes management tasks, such as checking blood glucose levels, assessing the carbohydrate content of meals or

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

snacks or reading the values on food packages, and participating in calculating insulin doses. Participation in these management tasks are generally encouraged by parents and the pediatric diabetes team with decreasing supervision by parents and other adults from around the ages of 12 or 13 years [1]. Direction and support provided by members of the pediatric diabetes medical team is imperative to promote the gradual transfer of these self-care tasks to the teenager with the goal to maintain treatment adherence in order to maximize the opportunities to achieve target HbA_{1c} values and reduce the likelihood of acute and chronic diabetic complications [2]. As youth differ in their cognitive capacity to perform diabetes tasks with increasing independence, it is imperative that healthcare professionals, parents, and the young person with diabetes work together to establish realistic goals. Helping the growing and developing teenager to develop a sense of self-efficacy in performing diabetes self-management tasks with increasing independence is critical, certainly prior to the transfer to adult diabetes clinics, where healthcare providers expect independence in diabetes care. The eventual goal is for the adult with diabetes to have the capacity and to possess the skills to engage in full and effective diabetes self-care, having traversed adolescence without diabetes burnout [3].

Demographic information about diabetes

There appears to be a significant increase in the occurrence of T1DM and T2DM in youth between the ages of 13 and 18 years. According to the SEARCH for Diabetes in Youth study in the United States, more than 190,000 youth were estimated to have physician-diagnosed diabetes in 2009 [4]. The US Centers for Disease Control and Prevention and the American Diabetes Association (ADA) report that an estimated 208,000 Americans under the age of 20 years have been diagnosed with diabetes, which represents approximately 0.25% of that population. Although this statistic does not differentiate between T1DM and T2DM, the report notes that between 2008 and 2009, the annual numbers of diagnosed diabetes in youth was estimated at 18,436 for T1DM and 5089 for T2DM [5]. The SEARCH study indicated that there has been an overall increase by 21.1% and 30.5% in the number of estimated cases of diabetes of T1DM and T2DM, respectively, between 2001 and 2009 [4].

Physical changes during adolescence

At the same time that there is an expectation for the teenager to take on increasing responsibility for diabetes self-management, the young teenager undergoes substantial physical, developmental, behavioral, and emotional changes, many of which substantially impact insulin needs. The major change in diabetes management results from the recognized insulin resistance associated with pubertal growth and development [2, 6] (See Chapter 59). Regardless of the age at diagnosis of diabetes, this period of adolescence requires great vigilance to assess diabetes needs and direct management due to physical and lifestyle changes. This vigilance entails frequent blood glucose monitoring, attention to carbohydrate intake, physical activity that becomes as much therapeutic as recreational in nature, and, of course, careful attention to insulin delivery both in terms of amount and timing. Shortly after diagnosis, persons with T1DM generally experience a time-limited phase known as "the honeymoon" stage during which the pancreatic β cells continue to produce a small amount of insulin. As time progresses, the pancreas produces less insulin and persons with T1DM experience increasing needs for exogenous insulin as the honeymoon wanes. This intensification of T1DM can be particularly apparent for the growing and developing adolescent whose insulin needs usually increase rapidly during puberty by up to 50% or even more [2].

In order to manage insulin effectively for an adolescent, parents and the pediatric diabetes team need to pay close attention to changes related to puberty, weight gain, and linear growth. Insulin doses need to be increased to help ensure that the HbA_{1c} remains within the target range of <7.5% (<58 mmol/mol). Thus, while teenagers with diabetes experience increasing independence in many aspects of their lives related to school and social life, the period of pubertal growth and development requires ongoing parental involvement in diabetes management to ensure that glycemic control does not deteriorate. Indeed, teamwork in diabetes management between the parents and the teenagers is recommended at this stage. Furthermore, frequent consultation with members of the pediatric diabetes team regarding insulin adjustments, appropriate nutrition, stress management, and exercise also reduces the likelihood of uncontrolled diabetes and the development of acute complications [2, 6].

Developmental stages

This section of the chapter will describe the normal developmental stages of adolescence and emerging adulthood with a focus on various transitions and recommendations for optimal family management of diabetes (Table 60.1). Key developmental changes that may impact the ability of the youth with diabetes to engage in self-care tasks independently will be reviewed (Figure 60.1). There will also be a section on empiric evidence for specific intervention and care strategies for adolescents and emerging adults with diabetes. Lastly, novel technology platforms to support optimal diabetes management will be discussed.

Adolescence (ages 13–18 years)

Along with rapid physical growth, cognitive development, and pubertal maturation, adolescence is a time of increased attention to body image and sexuality. Youth within this age range are also forming their identities, a process that can lead to increases and decreases in taking on and accepting greater responsibility for a variety of school and home-related tasks. Furthermore, relationships with same-age peers have a powerful influence on an adolescent's behavior [7–9].

Table 60.1 Developmental stages and major developmental tasks during adolescence and emerging adulthood.

	Typical development	Diabetes-specific development	Psychosocial challenges
Early adolescence (ages 13–15 years)	• Rapid growth • Sexual maturation • Body image concerns • Changing physical activity level • Social / friend interactions • Interest in technologies • Ongoing cognitive development • Emerging alcohol and drug experimentation	• Frequent alterations in glucose levels • Expanding needs for self-care and sharing diabetes responsibilities between teens and parent • Body image concerns related to wearing diabetes devices • Concerns regarding peer awareness and comments about diabetes • Understanding exercise and diabetes needs	• Diabetes family conflict • Disordered eating • Depressive symptomatology • Fear of hypoglycemia / hyperglycemia • School staff knowing what to do in an emergency • Family planning
Later adolescence (ages 16–18 years)	• Identity formation • Sexual activity • Body image concerns • Changing physical activity level • Social / friend interactions • Interest in technologies • Ongoing cognitive development • Emerging alcohol and drug experimentation	• Balancing T1DM care with schoolwork and social interests • Greater independence / need of adult support related to diabetes care • Body image concerns related to wearing diabetes devices • Concerns regarding peer awareness and comments about diabetes • Understanding exercise and diabetes needs	• Diabetes family conflict • Disordered eating • Depressive symptomatology • Fear of hypoglycemia / hyperglycemia • School staff knowing what to do in an emergency • Family planning • Driving a motor vehicle
Early phase emerging adulthood (ages 19–24 years)	• Education and career training • Moving away from family home • Dormitory / apartment roommates • Changes in emotional and financial ties with parents • Wider friendship group	• Possible gaps in medical insurance • Making time for T1DM when with friends • Negotiating performing diabetes tasks at first job or while at college • Remembering to re-fill / re-order prescriptions • Recreational substance use • Negotiating self-advocacy	• Diabetes family conflict • Disordered eating • Depressive symptomatology • Fear of hypoglycemia / hyperglycemia • Professors / co-workers knowing what to do in an emergency • Family planning
Later phase emerging adulthood (ages 25–30)	• Interest in marriage, starting a family • Further career advancement • Expanding social, emotional, and financial independence	• Increasing awareness of the impact of diabetes care on significant others, family planning, and career development • Recreational substance use • Negotiating self-advocacy • Remembering to re-fill / re-order prescriptions	• Diabetes family conflict • Health roles of close friends / significant others • Professors/ co-workers knowing what to do in an emergency • Family planning

A tremendous number of physical, social, and emotional changes occur during the period of adolescent growth and development, often challenging the management of diabetes for youth, their parents, and healthcare providers. The ADA and the International Society of Pediatric and Adolescent Diabetes (ISPAD) along with other organizations recommend a glycated hemoglobin goal of <7.5% (<58 mmol/mol) for persons under 18 years old and <7% (53 mmol/mol) for persons 18 and older [10–12]. However, the maintenance of HbA_{1c} within this range is an elusive goal for most adolescents [13]. Along with the impact of pubertal development, physical growth, and emotional stress that most adolescents experience, diabetes, and especially T1DM, when compared to other chronic illnesses of childhood, requires the teenager to perform management tasks multiple times each day, day in and day out without any break. In addition to checking blood glucose levels, attending to food intake, administering insulin, understanding the impact of exercise on glucose levels, youth with diabetes and their families also must navigate the impact of acute

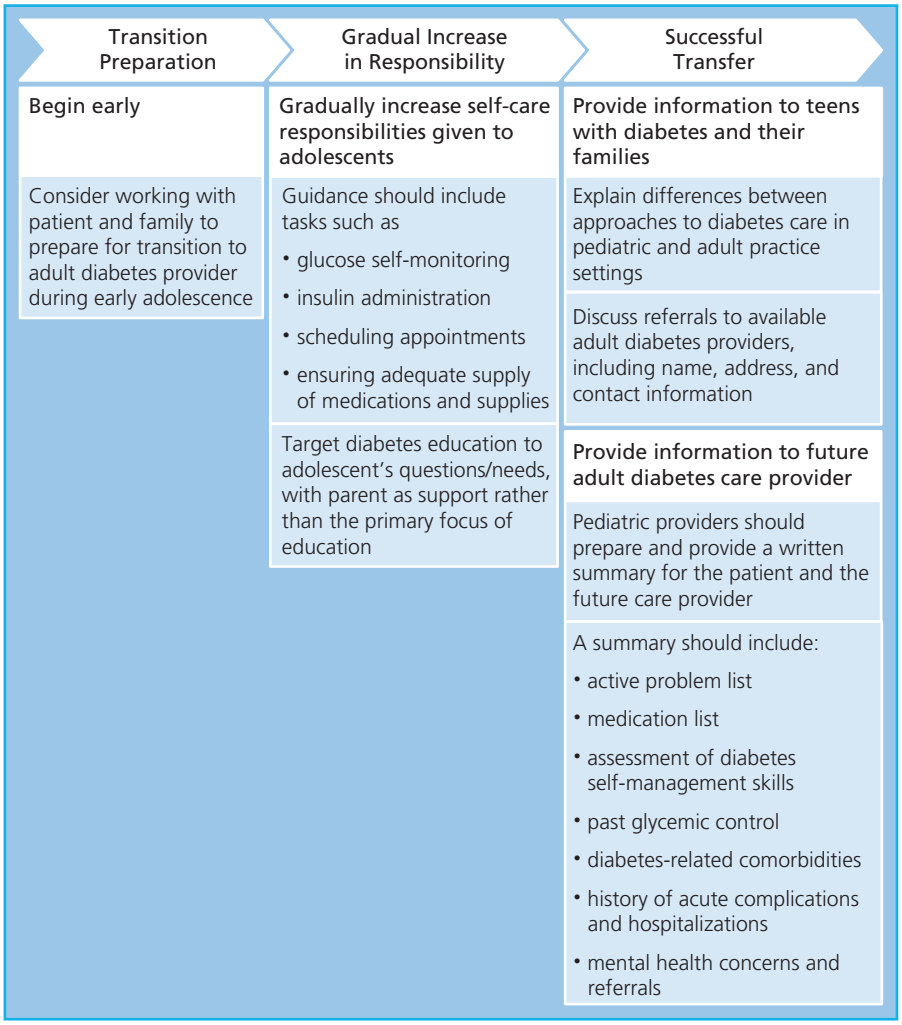

Figure 60.1 Trajectory of transition preparation, self-care acquisition, and transfer to adult care.

illness on their diabetes management needs [1]. Teenagers develop emotional maturity and the ability to take on diabetes responsibilities with independence at varying rates and at various ages. However, some teenagers do not possess the emotional maturity to sustain tasks of daily self-care and some may experience gaps in medical care, which can lead to adverse health outcomes [14].

Family support, family involvement in diabetes management, and low levels of diabetes-specific family conflict are associated with smoother transitions for adolescents as they acquire and accept more responsibilities of T1DM self-care [15–17]. While adolescents with diabetes learn to adapt to fewer adult prompts to engage in and perform self-care tasks accurately and consistently, parents are encouraged to remain involved in sharing management responsibilities. The roles and responsibilities that parents keep versus those that they pass on to the adolescent will differ depending on the adolescent's cognitive capacity and willingness to engage in care activities. As these factors are rarely static due to ongoing maturation and situational stressors experienced by the adolescent and/or family, the roles parents and teenagers fill during this transition will frequently need to be re-negotiated. Members of the adolescent's diabetes team can serve as an excellent resource in problem-solving the division of responsibilities and ensuring teenagers with diabetes are provided with a realistic amount of self-care tasks. The ultimate goal is for the adolescent to possess a sense of self-efficacy and the capacity to accept and treat diabetes optimally [1].

Additional important factors for an optimal transition of diabetes management from parents to the adolescent include the establishment of self-efficacy and self-advocacy for the teenager, especially in the context of developmental and social needs. Teenagers with a strong belief and confidence that they can perform self-care and advocate for themselves in particular situations are more likely to overcome barriers to diabetes self-care. Teenagers should be empowered to speak up for their diabetes self-management needs in public settings, such as school or athletics, and have confidence in doing so. Setting alarms on a smartphone can help increase the likelihood that teenagers will check blood glucose levels and respond in a timely manner. There are improved outcomes when there is acceptance of self-care leading to improved glycemic control [18–20]. In a study conducted

by Wiebe et al. (2014), the investigators found that youth who reported a decrease in parental involvement for T1DM care and a high sense of self-efficacy were better able to maintain treatment adherence than those with a lower sense of self-efficacy [21]. Youth who possessed a lower sense of self-efficacy had better glycemic control only when a parent played a greater role in establishing self-care skills [22]. These findings support the need for the adolescent's diabetes team to consider the level of self-efficacy an adolescent possesses when increasing their self-care independence.

In addition to the impact of pubertal insulin resistance, other factors can lead to deterioration in glycemic control. Target glycemic control can be challenging when teenagers have competing preoccupations, for example, with athletics, academic studies, and social distractions, which can detract from self-management, leading to lower adherence and poorer glycemic control [6,17,23–25]. Only 23% of more than 6000 adolescents with T1DM (ages 13–<18 years) in the T1D Exchange Clinic Registry had HbA_{1c} levels in the target range of <7.5% [24,26]. Hilliard et al. (2013) analyzed predictors of deterioration in glycemic control in 150 adolescents with T1DM over a period of 18 to 24 months [27]. Approximately two-thirds of participants did not meet the requirement to check blood glucose values ≥4 times daily and did not achieve the target HbA_{1c} of <7.5%. There were a variety of modifiable and non-modifiable factors related to the suboptimal management and glycemic outcome. Non-modifiable factors included ethnic minority status and unmarried care-giver status. The authors highlighted that diabetes healthcare professionals should identify these non-modifiable factors in order to assess a patient's risk and provide timely support. The modifiable factors associated with deteriorating T1DM care and glycemic control included injection-based insulin regimens as well as diabetes-specific family conflict [27]. This latter finding emphasizes the importance of including behavioral and mental health assessments as part of adolescent diabetes care visits in order to assess and intervene for stressful parent–teenager interactions around diabetes management and transitions in self-care to the teenager.

As mentioned earlier, social context can have an important impact on an adolescent's diabetes self-management. Borus et al. (2013) conducted a study where, over a 14-day period, adolescents with T1DM, aged 14–18 years, carried handheld devices that prompted them to report social context variables related to self-monitoring of blood glucose. Despite concern that many adolescents with T1DM do not check their blood glucose as often as recommended, the study demonstrated an increased likelihood of the youth checking blood glucose levels when the teenagers expressed a strong desire to blend in with peers and a lower likelihood of checking blood glucose levels when the teenagers wanted to impress others. The authors suggested that these findings could help providers to encourage teenagers to check their glucose levels more frequently as monitoring allows teenagers to identify out-of-range glucose values in a timely manner, thereby allowing them to avoid possible embarrassment as a result of sudden unexpected hypoglycemia or symptomatic hyperglycemia [28].

There have been a variety of family-based behavioral interventions aimed at optimizing glycemic control during adolescence. Ellis et al. (2012) performed a 6-month behavioral intervention using multi-systemic family therapy in youth with poor glycemic control. This group was compared to a second group of participants who only received telephone support. Results indicated that teenagers in the multi-systemic family therapy group experienced a significant reduction in HbA_{1c} at the post-treatment time point and 12 months after the intervention [29]. Wysocki et al. (2006) conducted a 6-month behavior intervention using Behavioral Family Systems Therapy for Diabetes (BFST-D). Participants exposed to this intervention were compared with two comparison groups (educational support and standard care); teenagers in the BFST-D group demonstrated greater treatment adherence at follow-up compared to the comparison groups [30].

Another series of studies focused on cost-effective, clinic-based interventions utilizing "care ambassadors" [31–33]. The "care ambassadors" do not possess medical training but they provide support to patients and families between medical visits, ensuring timely follow-up, which is particularly important when the competing needs of adolescence may impede routine diabetes visits. Those with T1DM receiving care ambassador support compared to standard care demonstrated increased outpatient visits, reduced hospitalizations and emergency room visits, and reduced occurrence of severe hypoglycemia. Furthermore, those youth with T1DM with poor control at study entry who were assigned to receive care ambassador support compared with standard care demonstrated a decrease in HbA_{1c} [31–33].

Motivational interviewing has also demonstrated usefulness in regard to bolstering an adolescent's willingness to increase self-management. Motivation interviewing involves collaborative communication between a member of the pediatric diabetes team and the adolescent in an effort to strengthen the teenager's personal motivation for change and commitment toward achieving a specific goal [34]. Channon et al. (2011) designed and implemented a randomized controlled trial that studied the impact of motivational interviewing during clinic visits in 66 teenagers with T1DM, aged 14 and 17 years [35]. Findings of the 12-month study showed that, compared to control participants, those who received the motivational interviewing intervention had lower mean HbA_{1c}. Furthermore, this improvement was maintained a year after the intervention ended. Motivational interviewing may serve a role during transition as a means to motivate support for the acquisition of self-care tasks among teenagers with diabetes.

A number of studies have examined the use of mobile technologies to assist adolescents in their transition to diabetes self-care. Text-messaging has been studied as means to offer reminders to adolescents for self-care when they are away from their parents and other adult care providers. Markowitz et al. (2014) conducted a study where adolescents and young adults with diabetes received text-messages that promoted a general healthy lifestyle and diabetes self-care [36]. Messages were tailored to assisting study participants attain personal goals regarding diabetes adherence. While self-efficacy and glycemic control did not change during the 3-month pilot study, results indicated that text-messaging was highly acceptable to participants and could be expanded in future studies [36]. A Scottish study entitled, "Sweet Talk," sent

daily automated text-messages that reinforced goals that adolescent study participants had set during their diabetes clinic visit [37]. The intervention did not demonstrate consistent improvement in participants' HbA_{1c}. However, results suggested that the adolescent participants developed a stronger sense of self-efficacy related to their ability to care for T1DM. Considering the popularity and ubiquitous nature of cell-phone text-messaging among adolescents, text-messaging may prove to be a useful and cost-effective means to support and promote adolescent self-care during transition.

Emerging adulthood

To add to the challenges of transition to self-care during adolescence, another development stage, termed emerging adulthood, demands the attention of both pediatric and adult diabetes care providers in their efforts to support the young person with diabetes. This developmental stage of young adulthood has been popularized over the past 20 years in the United States and other high-income countries [38]. The period of emerging adulthood is marked by the observation that many individuals in their late teens and early 20s are delaying tasks that had been traditionally associated with this age, such as marriage, parenthood, and work. These life events now occur for many in their late 20s and early 30s. The period between ages 18 and 30 years is now referred to as "Emerging Adulthood" by some developmental theorists and psychologists [38]. This post-adolescent period can be separated into an early phase and later phase. Notably, health insurance coverage for young adults with diabetes has generally not been a problem in countries with universal coverage but young adults in the United States had been at risk for gaps in health insurance coverage until reforms such as the Patient Protection and Accountable Care Act in the USA mandated coverage under parents' policies until the age of 26 years [13].

The early phase of emerging adulthood corresponds to the years immediately after high school, ages 18 through 24 years. During this phase, the emerging adult may be moving physically away from home and beginning to change the degree and nature of emotional and financial ties with parents, although the emerging adult is not yet fully independent. During this phase, the young adult experiences tremendous pressures related to academic studies, occupational choices, and social commitments, while separating from the family [13]. Thus, it is not surprising that these competing needs for time, energy, and effort often detract from diabetes self-care, leading to further deterioration in adherence and glycemic control. Indeed, data from the Type 1 Diabetes Exchange Clinic Registry in the United States indicate that HbA_{1c} reaches its highest level of 9.2% (77 mmol/mol) during this phase of development [3,24]. Thus, pediatric and adult healthcare professionals working with these emerging young adults must be aware of these competing demands and help to ensure that young adults with diabetes receive reinforcement for self-care behaviors, along with ongoing education and training in self-management, including how to fill prescriptions and make diabetes follow-up appointments [39].

During the later phase of emerging adulthood, usually occurring between the ages of 25 to 30 years, the young adult starts to assume more traditional adult roles [38]. An increasing sense of maturity leads many emerging young adults in the second phase to realize the importance of monitoring their health. Interest in getting married, raising children, and establishing a career lead many individuals to invest more effort to improving self-care and achieving better glycemic control [13]. Considering the young person's increased awareness of self-care needs and health outcomes, this period is an ideal time for the diabetes healthcare professional team to bolster diabetes management habits. As transfer from pediatric to adult providers likely occurs during this developmental stage, both pediatric and adult healthcare professionals should be well versed in these issues [13].

Changes in family involvement

Family involvement is a critical component of diabetes management during childhood and adolescence. Additionally, parents and family members as well as members of the pediatric diabetes team play significant roles in helping adolescents and young adults transition to taking on the primary role of managing their diabetes. Interestingly, the perceptions of parents may contrast at times with that of the pediatric diabetes team with respect to a youth's capacity to engage independently and effectively in self-care and to sustain adherence to tasks. Wysocki et al. (1992) had parents and members of pediatric medical diabetes teams complete surveys that measured their estimates of the self-care independence of youth with T1DM [40]. This study, which was conducted across multiple T1DM centers, found that compared to parents, healthcare professionals characterized young children and those in elementary school as being less capable of independently monitoring and treating T1DM without the supervision of an adult care-taker. Parents of these children, however, reported earlier mastery of skills by their children related to motor activities (e.g. self blood glucose monitoring) and the capacity to take care of T1DM events with immediate consequences (e.g. preventing or treating hypoglycemia). Additional results indicated that many parents of adolescents, however, reported lower levels of self-care and competence for critical skills involving executive functions. These self-care activities included planning, anticipation, and self-regulation (e.g. preventing hyperglycemia or adjusting insulin doses) [40].

Prior to 1986, no guidelines existed for the family sharing of T1DM management activities or what tasks were appropriate at different ages and stages of development of youth. Research conducted by Ingersoll et al. (1986) found that as youth grew older, responsibility for T1DM tasks shifted from the parent to the growing teenager [41]. This finding matches the general developmental expectation that adolescents will require less guidance, in general, from teachers, for example, to write down homework assignments and fewer prompts from parents to complete homework. However, when parental involvement in diabetes management tasks decreased, specifically regarding adjusting insulin, Ingersol

et al. (1986) reported that adolescents did not increase their independence and effectiveness in the self-care management of T1DM. However, youth who took over more responsibility for insulin adjustments were at "advanced levels of cognitive maturity and had a stronger personal sense of control over diabetes" [41]. These findings launched a critical body of research related to family teamwork during adolescence, which has changed the paradigm of care during this stage of development, and continues to highlight the need to individualize approaches based upon the individual's cognitive, emotional, and social development.

As parent involvement in T1DM care declines over time, roles of the child or teenager and family in diabetes management rarely remain static; the growing and developing youth goes from a stage of dependence upon parents or other adults, to sharing tasks or a state of interdependence, prior to emerging with full independence in self-care during later adolescence and young adulthood. In order to provide optimal care, pediatric diabetes providers are encouraged to be well-versed in the ebb and flow of the roles of the youth and family members during the course of adolescent development. Normal developmental tasks of childhood and adolescence call for slowly increasing the youth's acquisition of responsibilities, personal decision-making, and self-care (Figure 60.1) [10]. Division of T1DM management roles within the family is often directed by the multi-disciplinary diabetes care team, which ideally provides ongoing education and psychological support for youth with T1DM and their families, with a need to direct diabetes education and support from the parent to both the youth and parent. Healthcare team members can provide anticipatory guidance and realistic expectations related to the roles of the youth and family members [2].

It is also important to recognize that adolescents and emerging adults will likely differ in their capacity to perform diabetes self-management independently. The ability to manage diabetes responsibilities can be impacted by executive functioning challenges, such as attention-deficit/hyperactivity disorder (ADHD) as well as short-term and working memory difficulties [42]. A number of recent studies have focused on the impact that hypoglycemia and hyperglycemia may have on a cognitive ability and executive functioning skills [43, 44]. The findings have been mixed, and deeper examination of these studies is beyond the scope of this chapter. Nonetheless, it is important to consider the impact ADHD, short-term/working memory, executive functioning, and organizational skills on an adolescent's or emerging adult's capacity to perform diabetes self-care independently, consistently, and effectively. The individual may benefit from carrying a discrete, step-by-step checklist or by utilizing mobile phone alarms as reminders or aides to perform diabetes tasks as the young person acquires increasing independence in self-care. Depending on the skill level of the teenager or young adult, the checklist or reminder can include instructions for what to do when blood glucose levels are out of range, either low or high.

To increase the likelihood that adolescents and young adults with diabetes will experience success in self-care, it is imperative that parents and members of the pediatric diabetes team monitor and take action to prevent or intervene on diabetes burnout. Research has suggested that a variety of factors, including low self-efficacy, low self-esteem, complex treatment regimens, and longer duration of the disease contribute to burnout [45, 46]. Burnout in adolescents becomes evident when teenagers reduce their frequency of blood glucose monitoring and glycemic control subsequently deteriorates [47]. Members of the adolescent's diabetes team, specifically diabetes educators and mental health counselors, can help parents and teenagers identify and manage diabetes burnout and ensure parents remain in supportive roles when the adolescent experiences this challenge during transition to greater self-care.

Diabetes technologies

Despite the burgeoning of new technologies to assist in managing diabetes, especially T1DM, over the past 20+ years, consistent and effective use of devices, such as insulin pumps and continuous glucose monitors (CGM), can be challenging for persons with diabetes across the age range. Insulin pumps can simplify insulin delivery throughout the day and night and CGM devices can enable persons with diabetes to monitor trends in glucose levels and to receive alerts and alarms when glucose values fall out of range [48, 49]. However, none of these devices is fully automated and all require input and vigilance to ensure proper functioning. Thus, the additional effort needed to use these advanced diabetes technologies may impede uptake or lead teenagers and emerging adults to stop using them. The healthcare team can help by providing families, adolescents, and emerging adults with realistic expectations and ongoing education and support regarding the use of these technologies to maximize their uptake and durability of use. This support should include discussions regarding optimal timing of initiation of these devices. It is likely that similar approaches will be needed for soon-to-be-available "closed-loop" systems that will provide automated or semi-automated insulin delivery in an "artificial pancreas" as human input will remain critical for proper functioning and surveillance of such systems.

Type 2 diabetes in adolescence and transition

Unlike T1DM, where pancreatic β cells cease to produce insulin, the pancreas of individuals with T2DM still produces insulin but there is peripheral resistance to insulin action [50]. T2DM is generally considered a disorder associated with middle or older age. However, the increased occurrence of childhood obesity over the past few decades has led to an increase in the number of youth diagnosed with T2DM [51]. This is particularly problematic in minority populations, including Afro-Caribbean, Hispanic, Asian/Pacific Islander and Native American youth, between the ages of 10 and 19 years, where T2DM can represent more than half of the newly diagnosed cases of diabetes [52]. Furthermore, youth diagnosed with T2DM are at increased risk for developing

comorbid complications, such as hypertension, hyperlipidemia, and diabetes complications at an early age [53]. Although obesity is the hallmark of T2DM, in North America there are increasing rates of childhood overweight and obesity in the general population, and, as a result, more children with T1DM are overweight or obese today. This can make it challenging, at times, to distinguish between the two types of diabetes [54].

The Treatment Options for Type 2 Diabetes in Adolescents and Youth (TODAY) Study is the largest clinical trial examining the management of youth with T2DM [55]. This study enrolled 699 participants, age 10–17 years old, with recent-onset T2DM. After a run-in period during which metformin was used to attain an HbA_{1c} of <8%, participants were randomized to treatment with metformin alone, metformin with a lifestyle intervention, or metformin with rosiglitazone. About half of the participants experienced the primary outcome of loss of glycemic control (defined as $HbA_{1c} \geq 8\%$ for 6 months or metabolic decompensation requiring treatment with insulin) over an average follow-up of about 4 years. Loss of glycemic control occurred at approximately equivalent rates in the metformin alone and metformin plus lifestyle groups while the group receiving rosiglitazone in addition to metformin had superior outcomes, with an approximately 25% reduction in the proportion of participants randomized to that group reaching the primary outcome. This highly important finding underscores the need for treatment of young persons with T2DM with more than one antidiabetes agent; however, rosiglitazone and other thiazolidinedione drugs are not FDA-approved for use in children. The transfer of older teenagers and emerging adults to adult diabetes care may offer a unique opportunity to overcome clinical inertia and to re-visit a young adult's diabetes treatment regimen by adding a second medication to the care plan. Similar to the young person with T1DM, this transition period can also be a time full of multiple changes in the young adult's life, and the provider must take special care to continue to integrate the needs of the young adult with diabetes and their family into the holistic model of care.

Studies of T2DM medical care have focused on including a short-term diabetes educational component. The TODAY study provided "standardized diabetes education" during which teenagers with T2DM received education not only about pathophysiology, how medications work, and lifestyle guidelines, but also about how to improve their diabetes self-care with focused goal setting. Participants were closely monitored with regard to dosages of injected medication and/or oral medication(s) for diabetes. As this chapter is about ensuring the transition from pediatric diabetes care to adult care and increasing the likelihood that adolescents and emerging adults will establish consistent self-care practices, it is important to acknowledge that all participants in the TODAY study had to complete a 2–6 month run-in period successfully prior to randomization. During this period, which could include a minimum of 6 to a maximum of 12 clinic visits, participants were required to demonstrate ≥80% medication adherence for at least 6 weeks, miss no more than two run-in visits and maintain an HbA_{1c} of <8% for at least 2 months [52]. In order to fulfill these requirements, participants were provided with a significant amount of support, including appointment reminders and follow-up phone calls or text messages from study staff. Despite this support, 24% of the young adults who were screened for the study failed to fulfill the requirements of the run-in period and thus were excluded from randomization into the main trial.

It is also important to consider inclusion of a family-based behavioral lifestyle intervention with the focus on weight loss or prevention of continued weight gain during the transition process and even upon transfer from pediatric to an adult diabetes medical practice. Hannon and Arslanian (2015) reviewed the importance of a multidisciplinary team that could include the patient, family, physician, nurse educator, dietician, behavioral specialist, and personnel from the adolescent's school [50]. Although the authors did not go into detail regarding the emerging adults' transition from pediatric to adult diabetes care, they emphasized that the focus should be geared toward individualized therapy, family-based interventions, and pharmacotherapy with the objective of weight loss or prevention of continued weight gain while optimizing diabetes management and glycemic control [50, 56].

Van Walleghem and colleagues from Canada consider transitions in care for children with T2DM [57]. The Diabetes Education Resource for Children and Adolescents (DER-CA) in Winnipeg, Manitoba, Canada, follows children from diagnosis to age 18 years in a "… coordinated, family centered integrated program of care" [57]. The numbers of youth with T2DM referred to the service increased from four new cases in 1986 to 67 in 2010 and T2DM was cited as accounting for more than 50% of the children with new-onset diabetes. As of 2012, DER-CA was following 207 youth with T2DM, leading to their interest and focus on T2DM transition [57].

The number of children at the DER-CA transitioning from pediatric to adult care has also increased from 8 in 2001 to 42 in 2009. While Van Walleghem and colleagues acknowledged that youth with T2DM and T1DM experience similar challenges during the transition process and with transfer from pediatric to adult care, the authors emphasized differences due to "… the clinical complexity, the different cultural and social characteristics, and the aggressive progression of life-threatening complications in emerging adult life for T2DM" that "require[s] a different approach to transition" [57]. The authors proposed a "life-cycle approach" to care, education, and support along with further research related to T2DM. The authors have examined a model of care similar to the "care ambassador" approach described earlier for T1DM, by utilizing a patient navigator in the "Maestro Project" [57]. The Maestro Project aims to increase the rate of medical follow-up and reduce morbidity and mortality from acute and chronic complications of diabetes. The authors emphasized that medical systems must respond quickly and creatively to meet the needs of adolescents and young adults with T2DM who are transitioning from pediatric to adult care [57].

Many studies in youth and adults with T2DM have found a high prevalence of other cardiovascular risk factors, encapsulated in the metabolic syndrome. The TODAY study found a very

high prevalence of metabolic syndrome (75.8%) at baseline, and this did not differ in those with excellent glycemic control ($HbA_{1c} < 6\%$) or improve with treatment [58].

Family planning and the possibility of pregnancy are also of major importance in women with diabetes, and the transition and transfer to adult care presents a unique opportunity for exploration of this topic. As part of the TODAY study of youth with T2DM, all female participants received counseling on birth control, and in fact were required to use some form of contraception (including abstinence) in order to participate in the study. Despite that, 10% of female participants became pregnant during the study. Of the pregnancies that were not electively terminated, 26.4% ended in miscarriage, stillbirth, or intrauterine demise, and 21.5% of the live-born infants had major congenital anomalies [59].

Acute and chronic complications in young adults diagnosed with diabetes in childhood

Youth with T2DM are at risk of acute complications, such as diabetic ketoacidosis and hyperosmolar hyperglycemia [53]. Youth with T2DM are also at increased risk for a variety of chronic complications and comorbidities including hypertension, dyslipidemia, nephropathy, retinopathy, non-alcoholic fatty liver disease, polycystic ovary syndrome, depression, and binge eating [53]. The TODAY study found that hypertension, dyslipidemia, and microalbuminuria were present at baseline, and increased by the end of the study [60].

The commonest acute complication for adolescents and young adults with T1DM are hypoglycemia and diabetic ketoacidosis. The ADA recommends assessment of the history of acute complications, along with continued education on prevention of recurrence of acute complications [10]. Adolescents and young adults with T1DM are also at risk for various psychiatric disorders, including depression and eating disorders, and providers should attempt to identify and intervene for such problems to avoid worsening, particularly at the sensitive time of transition. Finally, chronic vascular complications, such as retinopathy, nephropathy, neuropathy, and cardiovascular disease, can begin in childhood and continue or worsen in young adulthood. The ADA and other national and international organizations regularly publish guidelines regarding the screening for such complications and the most recent ADA screening recommendations can be found in the 2016 Standards of Medical Care in Diabetes [12].

What is transition?

Transition is the re-orientation that people experience in response to a change. While change is situational, such as moving to a new town or changing jobs, transition is the way in which people respond to the changes they encounter in their lives [61]. Transition is the movement people make through such a disruptive life event in order to continue to live with a coherent, albeit evolving, sense of themselves [62]. Transfer refers to the physical change in the ministration of responsibilities from one individual to another; in this case, the pediatric endocrinologists or diabetologists end their relationships with youth diagnosed with diabetes and the person with diabetes begins meeting with an adult physician. As noted, transition is a process in which the adolescent or young adult with diabetes prepares for self-care and the future change in providers, while transfer is the actual transfer event. If these activities are managed poorly, failure to engage with adult services decreases the likelihood of regular attendance at diabetes medical centers [63].

Within pediatric healthcare, transition has often been defined as the time when an adolescent or young adult makes a purposeful, planned movement from pediatric to adult care services. The goal is to optimize health and well-being. To accomplish this, a number of factors need to be met. These include:

- transition preparation,
- engagement in chronic disease management, and
- the actual transfer of healthcare from pediatric to adult systems [63].

The moment of transfer requires a hands-off approach between providers. Successful transition from pediatric to adult services involves the family, is impacted by demographic characteristics, diabetes history, glycemic control, self-management, and a sense of self-efficacy and transition preparation [64]. Transition is considered to be successful when an emerging adult demonstrates the ability to self-manage diabetes, meet with members of the diabetes healthcare team at recommended intervals, maintain glycemic control, and avoid acute complications [63]. See Figure 60.1 for a schematic of tasks during the period of transition and for the ultimate transfer between providers.

Problems with transition

Emerging adults with diabetes and their healthcare providers encounter a variety of issues during the transition from a specialized pediatric diabetes clinic to an adult endocrinology, diabetology, or primary care practice (Box 60.1). Notably, the topic of transition has recently garnered substantial interest from the diabetes clinical and research communities for a number of reasons; first, there are more young persons with T1DM and T2DM who need to undergo transition and, second, there is a deficiency of intervention research aimed at guiding the transition process and optimizing health outcomes of emerging adults with diabetes [13, 63, 65].

One difficulty with transition is that the emerging adult must part with a long-term, familiar relationship with a group of pediatric healthcare providers. In addition, there are some fundamental differences in healthcare delivery between pediatric and adult settings [13]. The relationship with the pediatrician is family-centered and holistic with respect to pediatric and adolescent developmental needs. Adult visits tend to be shorter in duration and tend to focus more on medical treatment [13]. Adult medical providers tend to focus the visit almost exclusively on the young

Box 60.1 Challenges for older teenagers and young adults with diabetes during the transitional period.

- Diabetes self-care often loses priority to competing demands related to social, emotional, educational, and occupation interests and needs.
- Emerging adults with diabetes are at high risk for poor glycemic control.
- Mental health issues (i.e. depression, anxiety, disordered eating behaviors) are common at this age.
- Issues around sexual and reproductive health become paramount.
- Risk-taking behaviors around alcohol, smoking, and drug abuse often increase in this age group.
- There is increased risk of acute complications (i.e. DKA and severe hypoglycemia) for transitioning youth.
- There is a risk of missing screening opportunities for eye and kidney complications and CVD risk factor identification.
- Pediatrics and adult providers employ different approaches to diabetes care.
- Loss to follow-up is a common problem at time of transition / transfer.
- Developing chronic complications of diabetes may present in older adolescence and young adulthood and may go under-detected and untreated.

DKA, diabetic ketoacidosis; CVD, cardiovascular

adult, rather than the family, with the belief that the individual is capable of making independent decisions regarding care and treatment [13]. Adult care providers often assume that the person with diabetes possesses the skills and capacity to perform diabetes care independently, which could be problematic if the emerging adults were ill-prepared by the pediatric team to assume the necessary responsibilities for their diabetes self-care. In turn, the emerging adult may feel unsupported and vulnerable following the transfer [64]. In some instances, young adults may choose to reject adult care, limiting their openness to the medical provider's recommendations. These factors contribute to the frequent loss to follow-up care experienced by many emerging adults [13]. Furthermore, more than one third of older teenagers and emerging adults transferring care between pediatric and adult providers experience gaps in care exceeding 6 months [13]. These gaps in care and loss to follow-up can lead to acute complications and the emergence of chronic complications that go undetected and untreated.

Unsuccessful transition is more likely to occur when emerging young adults lack skills for independent decision-making, especially when they do not feel ready to handle such responsibilities [3, 13]. Furthermore, there are many age-appropriate social, emotional, educational, and work-related activities that compete for the attention of older teenagers and emerging adults, often superseding self-care and attendance at healthcare visits [64]. Many older teenagers and young adults may also feel uncomfortable disclosing their chronic medical condition to others, especially when entering a new school or work environment, making it challenging for those with diabetes to perform management tasks consistently. The successful balance of diabetes self-care demands with these competing needs requires self-efficacy and self-advocacy. Transition preparation should include attention to these areas.

Gaps in care or loss to follow-up care results in poor glycemic control and places the emerging adult at increased risk for medical complications in both the short and long term [66]. The short-term complications are related to extreme glucose fluctuations (i.e. severe hypoglycemia or hyperglycemia) and can lead to emergency room hospitalizations, especially in the absence of routine care. Further, persistent hyperglycemia with uncontrolled diabetes increases the risk for long-term microvascular and macrovascular complications [67]. Transition preparation from the pediatric team should include discussion of chronic diabetes complications, pregnancy planning, and routine screening for clinical evidence of early kidney and eye changes as well as risk factors for macrovascular complications. Otherwise, some emerging young adults may opt to avoid follow-up adult care rather than be suddenly faced with discussions regarding complications when they have been ill-prepared [3].

There are a number of behavioral, psychosocial, and psychiatric challenges that can confront the older teen and emerging adult with diabetes during the transition; these include diabetes distress, fear of hypoglycemia, fear of hyperglycemia, burnout, depressive symptoms, depression, anxiety, and disordered eating behaviors, among others. These challenges can interfere with effective self-care and consistent diabetes follow-up, leading to a vicious cycle of discouragement and burnout, which, in turn, may further diminish attention to diabetes self-care. Data in teenagers and emerging adults with T1DM identify psychosocial and socioeconomic risk factors associated with reduced diabetes self-management and burnout [25, 68–70].

The coexistence of psychiatric conditions (Chapter 57), specifically depression and anxiety, brings considerable challenges to the management of diabetes during adolescence and emerging adulthood, substantially impacting self-care and consistent follow-up with medical providers [3]. Although such conditions are common in the general population, rates of depression and anxiety are higher in those with diabetes especially during these developmental stages [71]. Collaborative care from professionals, including psychologists, social workers, and psychiatrists, versed in depression and anxiety disorders, including their impact on diabetes, is necessary to aid in the management of these conditions. Depressive symptoms and frank depression, associated with reduced motivation, often lead to reduced attention to diabetes self-care, yielding hyperglycemia. Further, the symptoms of depression and persistent hyperglycemia can overlap with intensification of fatigue. Anxiety disorders also complicate living with and managing diabetes, in particular, related to fear of needles/injections or fear of extremes of glucose levels. Fear of hypoglycemia is more common than fear of hyperglycemia but some may fear the latter

due to extreme concerns about the development of diabetes complications. Extreme anxiety can trigger panic attacks. Additionally, symptoms of hypoglycemia and anxiety can also overlap, at times, further complicating management and generally leading to poor control [13].

Disordered eating behaviors and eating disorders, especially common in females, also complicate diabetes management, especially during the period of transition [13]. A unique manifestation of eating disorders in diabetes is the purposeful restriction or omission of insulin. The deliberate under-dosing of insulin serves as a very potent but dangerous weight-loss strategy [72]. Many specific elements of T1DM and its treatment have been linked to the development of disordered eating behaviors. Specifically, the following have been linked to the occurrence of disordered eating and eating disorders:

- the initial loss of weight at the onset of the disease followed by weight gain upon initiating insulin replacement;
- occasional weight gain associated with intensive insulin therapy;
- a focus on diet as part of the diabetes treatment plan; and
- the need to eat often without hunger due either to peaking insulin action or hypoglycemia [73, 74].

Furthermore, disordered eating and eating disorders, particularly with insulin restriction or omission, lead to deterioration in glycemic control and subsequent complications, and even premature mortality [75–77]. It is crucial that teenagers and emerging adults with disordered eating behaviors or eating disorders receive specialized care, often coordinated by the diabetes treatment team; however, this can be problematic if care for the affected person falls between the pediatric and adult healthcare systems [13].

In addition to the challenges enumerated above, there is a lack of empirically validated programs to promote transition readiness, well-defined criteria to determine transition readiness, and methods to ensure a smooth transfer between pediatric and adult healthcare systems. Thus, it is not surprising that many older teenagers and young adults with diabetes experience gaps in care upon transfer, deterioration of glycemic control, and increased risk for acute complications and the unrecognized emergence of chronic complications. Finally, there may be a component of reticence and even ambivalence regarding transition and transfer on the part of pediatric providers. Many pediatric diabetes providers have known their patients for years and may have difficulty discharging their patients to adult providers, as they worry about how their patients will adjust to different models of care. Thus, there is a need for coordinated efforts between pediatric and adult providers to ease the transition and transfer for patients and families as well as for the providers.

Existing transition programs and interventions

Currently, some transition programs exist in the USA and in other countries. However, there is no documented "gold standard" approach that has been empirically proven to yield optimal outcomes with respect to engagement, follow-up, medical outcomes, and psychosocial outcomes. The literature includes descriptions of structured and unstructured transition programs, with structured programs generally reporting better outcomes. The following section will describe published approaches to transition programs along with suggestions for future directions.

There are three main approaches to developing transition programs: clinics dedicated solely to emerging young adults, clinics focused on transition planning, and clinics that incorporate care coordinators (care ambassadors or patient navigators) to ensure timely follow-up. In dedicated young adult clinics, there are generally specific days and times reserved for the care of young adults within diabetes clinics. These focused clinics tend to be staffed by adult providers who possess particular interests in the care of emerging young adults.

Outcomes resulting from care in young adult clinics have been variable, with some studies yielding no effect on glycemic control [78], while others have demonstrated superior outcomes with lower HbA_{1c} levels and reductions in hospital admissions [79, 80]. The different results may reflect variations in design and features of each of the programs.

The second kind of transition program relates to transition preparation, which provides pediatric diabetes teams, patients, and families with a more structured and purposeful approach to transition planning aimed at creating a successful transfer. In 2009, Cadario and colleagues [81] retrospectively examined two groups who were transferred from pediatric to adult diabetes care in different ways. The first group received a letter with information about their medical history and a scheduled appointment with an adult provider. The second group participated in a structured transition program, which included transition planning during the last year of pediatric care and discussions about what to expect following the transfer. Additionally, both pediatric and adult physicians participated in the last pediatric clinic appointment and first adult clinic appointment, with the pediatrician providing a medical summary to the patient and adult doctor at the last pediatric appointment. The second group had more optimal outcomes, with a shorter time between last pediatric and first adult clinic appointments, better clinic attendance in the first year post-transfer, and improved HbA_{1c}. Furthermore, the second group reported satisfaction with the transition process [81]. More rigorous, prospective studies are needed.

The third type of transition program utilizes a care coordinator who works closely with the older teenagers or young adults as they transition from pediatric to adult diabetes care. Van Walleghem and colleagues [82] evaluated an intervention called the Maestro Project, which assigns a care coordinator to maintain consistent contact and ensure access to diabetes care for patients during the transition process. In addition to the care coordination, this program provided a website, newsletter, group meetings, and educational events. The authors reported that patients in the program had greater retention in care. Further, the coordinator helped recapture patients who had been previously lost to

follow-up care. Other studies of care coordination have shown varied results; one demonstrated improved glycemic control and reduced hospitalizations [79] while another study comparing usual care with outreach by phone revealed no difference in outcomes [83]. Again, varying results may reflect differences in program features or implementation.

British researchers performed a systematic review of care transition among many chronic diseases of childhood and compared the effectiveness of different transition programs by evaluating the reported health outcomes [84]. The evaluation of outcomes varied according to the study design and included comparisons of transition programs with control conditions as well as pre- and post-intervention designs. Three categories of intervention were studied. The first was directed toward the patient and consisted of educational programs and skills training. The second focused on staff and involved care coordinators and joint pediatric and adult clinics. The third involved healthcare service delivery and after-hours phone support with intensive follow-up specifically directed at the young adults. Results indicated the most successful programs included patient education and transition clinics directed either to young adults within adult healthcare settings or including both pediatric and adult providers, all of which included people with diabetes [84]. From this report, it remains clear that there is a need for more prospective, longitudinal research.

In addition to the transition programs housed within either pediatric or adult diabetes clinics described above, there may be opportunities to support older teenagers and young adults within a support group setting. Our team at the Joslin Diabetes Center in Boston recently examined the utility of monthly support groups for young adults with T1DM and found that after 5 months of participation, self-reported diabetes burden decreased, two-thirds of participants had improved HbA_{1c}, and there was a trend for improved self-care [85]. Another report described a program that combined aspects of many of the clinical centers listed earlier [86]. Vidal and colleagues implemented a program that included transition planning, coordinated transfer visits, an extended intake appointment with adult diabetes staff, and support group sessions [86]. They found that those who participated in this program had improved HbA_{1c}, decreased hypoglycemic episodes, and greater diabetes-specific knowledge compared to those who received standard care. A number of investigations are ongoing worldwide to design, implement, and evaluate transition programs, given the increasing numbers of older teen and emerging adults with diabetes in need of improved systems of care and improved health outcomes.

Summary

Significant physical, social, and emotional growth occurs during the adolescent years. The extra burden of diabetes adds further challenges at this time. Teenagers with diabetes have often developed a strong relationship with their pediatric diabetes care team, and the transfer to a new adult diabetes care team disrupts an established bond. Adolescents and young adults must develop increasing independence and responsibility for their diabetes care. This could be a time of crisis or a time of opportunity. By approaching this transition equipped with information about normal developmental stages and the unique challenges of diabetes self-care at this time, parents and diabetes healthcare providers can help older adolescents and emerging adults make this transition, and empower them to negotiate the transition and transfer as seamlessly as possible to preserve health and prevent the emergence of diabetes complications.

61 Diabetes in Pregnancy

Tim Cundy
Department of Medicine, Faculty of Medical and Health Sciences, University of Auckland, Auckland, New Zealand

Key points

- The main risks to pregnancy in women with diabetes are an increased rate of congenital malformations, an increased risk of intrauterine death in late pregnancy, and complications during delivery and in the postnatal period resulting from fetal overgrowth (macrosomia).
- By improving glycemic control in late pregnancy, remarkable reductions in perinatal mortality in women with diabetes were achieved in the middle of the 20th century, but rates of late intrauterine death remain 3–5-fold higher than in non-diabetic pregnancies.
- Less progress has been made in reducing the rate of congenital malformations, which are the consequence of exposure of the fetus to hyperglycemia in the first 6–8 weeks of pregnancy. A wide range of congenital malformations are associated with diabetes, but complex conotruncal cardiac anomalies are the most common.
- Metabolic changes in pregnancy facilitate nutrient transfer to the fetus. Maternal insulin resistance, which increases significantly from about 24 weeks' gestation, helps divert glucose to the fetus. Women with pregestational diabetes require increasing insulin doses during pregnancy. Women without diabetes before pregnancy become glucose intolerant in pregnancy if they have insufficient insulin reserve.
- Fetal insulin is an important fetal growth factor. Accelerated fetal growth occurs in many diabetic pregnancies as a consequence of maternal hyperglycemia causing fetal hyperinsulinemia. In later pregnancy, this metabolic environment may render the fetus susceptible to hypoxia and acidosis and ultimately stillbirth. It also increases the risk of neonatal hypoglycemia.
- The outcome of pregnancy can be improved by good prepregnancy care, the main components of which are folic acid supplementation, achieving good glycemic control, avoiding potentially embryotoxic drugs, and optimal control of diabetic complications before discontinuing contraception and attempting pregnancy.
- The proportion of women with diabetes who receive good prepregnancy care is disappointingly low, and it remains a major challenge to ensure that more women with diabetes are properly prepared for pregnancy.
- Diabetic retinopathy may deteriorate in pregnancy and in the months following birth, sometimes to the point where laser treatment is required. Those at greatest risk are women with pre-existing retinopathy who come into pregnancy with poor glycemic control that then rapidly improves.
- Diabetic nephropathy is a risk factor for pre-eclampsia, intrauterine growth retardation, and preterm birth, but pregnancy does not seem to affect the long-term outlook of renal disease.
- Antenatal management should focus on achieving maternal glucose levels as near normal as is safely achievable, and close maternal and fetal surveillance for medical and obstetric complications. A number of national evidence-based clinical guidelines for diabetes in pregnancy have been published.
- Secular trends towards having fewer children later in life and increasing levels of obesity impact on fertility and obstetric management.
- The increasing prevalence of obesity has seen a marked rise in the prevalence of type 2 diabetes in pregnancy. Obesity itself has a significant impact on maternal and fetal pregnancy outcomes, and is associated with stillbirth, macrosomia, and hypertension in pregnancy. Rising obesity levels are also contributing to the increasing number of women developing glucose intolerance during pregnancy.
- Excessive gestational weight gain is an important cause of macrosomia, hypertension in pregnancy and fetal morbidity in women with established and gestational diabetes.
- Testing for gestational diabetes is undertaken at 24–28 weeks' gestation when maternal insulin resistance is increasing. There is continued debate on how gestational diabetes is best diagnosed, the thresholds for treatment, and the risks, costs, and benefits of intervention.
- Dietary modification, physical activity, and limiting gestational weight gain are the mainstays of treatment of gestational diabetes, with insulin or oral antidiabetes therapy added if glucose values cannot be normalized.
- Intervention trials in mild gestational diabetes have shown that treatment makes babies 2–3% lighter (so lowering the incidence of macrosomia), and reduces the incidence of shoulder dystocia and hypertensive disorders of pregnancy. It is not clear if these effects are primarily due to lower maternal blood glucose values or to less maternal weight gain.
- Both metformin and glibenclamide are effective in reducing maternal glycemia, but fetal outcomes appear to be poorer with glibenclamide.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

- A proportion of women diagnosed with gestational diabetes actually have previously unrecognized diabetes. These pregnancies have the same risks as those of women with known diabetes, and there is increased interest in diagnosing such cases early in pregnancy, by either screening or risk factor-based testing.
- The majority of newly recognized diabetes cases will have type 2 diabetes, but the onset of type 1 diabetes in pregnancy is not uncommon.
- Women with pregestational and pharmacologically treated gestational diabetes should be offered induction of labor at 38 completed weeks to reduce the risk of a late stillbirth and the risk of birth injury from a large for gestational age infant.
- Insulin requirements fall to prepregnancy values in the immediate postpartum period.
- Early breastfeeding reduces the risk of neonatal hypoglycemia. All mothers with diabetes should be encouraged to breastfeed within 30 min of birth and then every 3–4 h, until a regular feeding pattern is established.
- Women who have had gestational diabetes should be screened for diabetes postpartum and then annually and receive lifestyle advice to lessen their long-term risk of future diabetes.

Introduction

The dramatic improvement in the outcome of pregnancy for women with diabetes that occurred in the middle decades of the last century was one of the outstanding medical achievements of the age. Before the discovery of insulin, the chances of a woman with diabetes dying in pregnancy were very high and those of delivering a live, healthy baby were negligible. The discovery of insulin transformed the life expectancy of women of child-bearing age, and its use also restored fertility, previously affected by the disease and its treatment [1]. Maternal mortality dropped very sharply, but the prognosis for the fetus remained dismal. As late as 1953, even centers specializing in diabetes pregnancy were recording perinatal mortality rates of 20–25% [2]. The major cause of perinatal mortality was the late intrauterine death of overgrown or "macrosomic" fetuses, but birth trauma, early neonatal death (particularly from severe hypoglycemia), and major congenital anomalies also took their toll. Over the following two decades, advances pioneered at centers such as the Joslin Clinic in Boston, King's College Hospital in London, and the Rigshospitalet in Copenhagen established that good glycemic control in mid- and late pregnancy, coupled with early delivery, could substantially reduce perinatal mortality and morbidity [2]. These results were soon replicated around the world as the need for intensive integrated care was recognized, and units specializing in diabetes pregnancy were established. It is worth remembering that these remarkable improvements in pregnancy outcome were achieved well before the development of technologies such as glycated hemoglobin measurement, insulin pens and pumps, self-blood glucose monitoring, and obstetric ultrasound on which much of current practice relies.

Until the 1980s, type 2 diabetes mellitus (T2DM) was largely confined to middle-aged and older people and so its occurrence in pregnancy was rare, but the epidemic of obesity has seen not only a great increase in the number of people with T2DM, but also a reduction in age at its onset. The UK National Diabetes Pregnancy Audit of 2013 reported that the proportion of women with established diabetes who have T2DM increased from 27 to 45% in 10 years [3], and in many countries the number of women with T2DM in pregnancy now exceeds that of women with type 1 diabetes mellitus (T1DM). This change has brought its own set of problems and challenges, as the majority of women with T2DM are overweight, and obesity is itself strongly associated with adverse obstetric outcomes [4–8].

Maternal overweight and obesity are also central to the issue of gestational diabetes. Observations in the 1930s and 1940s suggested that women who later developed what we now call T2DM had reproductive histories with a high incidence of large babies and fetal loss, raising the possibility that a prediabetic state existed that was harmful to the fetus [9]. The concept of gestational diabetes was developed in the 1960s, but the diagnostic criteria initially proposed were based on the ability of the glucose tolerance test in pregnancy to predict future diabetes in the mother, rather than fetal outcomes [10]. As discussed later, the diagnostic criteria and the value of treatment remain the subject of much current debate.

Changes in glucose metabolism in pregnancy

Maternal metabolism changes significantly during pregnancy. From about 8 weeks' gestation fasting glucose concentrations decrease, and reach a nadir by the end of the first trimester. The sensitivity of muscle and adipose tissue to insulin changes little in early pregnancy, but decreases significantly after about 22 weeks' gestation, by 33–78%, depending on the method by which it is assessed. The degree of insulin resistance may be even greater than this, as the methods of assessment do not capture (the non-insulin-requiring) glucose utilization by the placenta and fetus. As a consequence of increased insulin resistance, postprandial glucose levels are increased. There is a concomitant increase in fasting insulin, but hepatic glucose production, which would normally be suppressed by the increase in insulin, is also increased, indicating decreased hepatic insulin sensitivity.

The precise mechanism underlying the insulin resistance of late pregnancy is uncertain, but it appears to be related to a combination of increased hormone concentrations (human placental lactogen, progesterone, estrogen, prolactin, and cortisol), increased free fatty acid concentrations, and changes in various cytokines secreted by the placenta, such as tumor necrosis factor-alpha (TNF-α), adipocyte fatty acid-binding protein, and leptin [11]. The degree to which insulin resistance is increased is also related to maternal weight gain. Non-obese women gain 3.5 kg of

fat on average during a normal pregnancy; subcutaneous deposits increase and provide a ready source of calories for the fetus and mother, but increased visceral deposits contribute to insulin resistance.

For glucose tolerance to be maintained, maternal β cells compensate for the fall in insulin sensitivity by increasing first- and second-phase insulin responses approximately threefold by the last trimester [12]. Increased insulin secretion is associated with morphological changes in the pancreas, including marked β-cell hypertrophy and hyperplasia [13].

In teleological terms, pregnancy-related maternal insulin resistance benefits fetal growth, since a rise in postprandial glucose concentration aids glucose transfer to the fetus ("facilitated anabolism") [14]. Maternal to fetal glucose transfer in the fasting state is also enhanced by maternal lipolysis, which occurs in late pregnancy, with free fatty acids becoming the main maternal fuel substrate with diversion of glucose to the fetus. The ability of insulin to suppress lipolysis via inhibition of hormone-sensitive lipase in adipose tissue is impaired in late pregnancy, when maternal free fatty acid release and fatty acid oxidation are increased in parallel with reduced carbohydrate oxidation [15–17]. This process of enhanced lipolysis [18] is attributed to the actions of human placental growth hormone and other placental hormones [19–24]. All of these metabolic changes facilitate the transfer of glucose and amino acids to the fetus. The increase in hepatic glucose output in late pregnancy resulting from hepatic insulin resistance ensures that maternal glucose is available to the fetus between meals [25]. The main changes in glucose and lipid metabolism in pregnancy are summarized in Table 61.1. Increased insulin resistance induced by the fetoplacental unit reverses within a few hours of delivery, although of course any increase related to excessive maternal weight gain in pregnancy persists.

Table 61.1 Changes in glucose metabolism and lipids in normal pregnancy.

	Early pregnancy	Late pregnancy
Basal metabolism		
Fasting glucose	Decreased	Decreased (×0.9)
Fasting insulin	Unchanged	Increased (×1.6)
Hepatic metabolism		
Hepatic glucose production	Unchanged	Increased (×1.3)
Hepatic insulin sensitivity	Unchanged	Decreased
Insulin metabolism		
First-phase insulin response	Increased (×2)	Increased (×3)
Second-phase insulin response	Increased (×1.5)	Increased (×3)
Peripheral insulin sensitivity	Decreased (×0.7)	Decreased (×0.4)
Plasma lipids		
Triglycerides	Unchanged	Increased (×3)
Total cholesterol	Unchanged	Increased (×1.5)
HDL cholesterol	Unchanged	Increased (×1.2)
LDL cholesterol	Unchanged	Increased (×1.7)
Free fatty acids	Unchanged	Increased (×1.6)

HDL, high-density lipoprotein; LDL, low-density lipoprotein.
Source: Data summarized from Catalano et al. 1999 [12], Sivan et al. 1999 [15], Homko et al. 1999 [16], and Sivan et al. 1997 [17].

Gestational diabetes mellitus (GDM) is defined by the presence of glucose concentrations that are at the upper end of the population distribution and first detected in pregnancy. In most cases it arises from a relative failure to increase insulin secretion in the face of chronic insulin resistance (primarily related to obesity) that worsens in pregnancy and is often compounded by excessive gestational weight gain. Most studies of women who have had GDM reveal decreased β-cell function compared with women maintaining normal glucose tolerance in pregnancy [26–28]. The mechanism is therefore essentially the same as that occurring in T2DM, and so from this perspective GDM can be considered as simply a specific subtype of prediabetes.

Glycated hemoglobin (HbA_{1c}) values are lower in normal pregnancy than in the non-pregnant state, probably because of reduced fasting blood glucose levels and shortened erythrocyte survival [29]. Suggested upper limits of the reference range are 36 mmol/mol in the first and second trimesters and 40 mmol/mol in the final trimester [30, 31]. The small increase in HbA_{1c} in late pregnancy could be the consequence of developing iron deficiency [32].

Classification of diabetes in pregnancy

Diabetes in pregnancy encompasses those women known to have diabetes before pregnancy (sometimes called "pregestational diabetes") of various types, and those with hyperglycemia first detected in pregnancy ("gestational diabetes"). The latter category includes some women who have diabetes that was undetected before pregnancy, in whom pregnancy outcomes may be particularly poor [33–35]. Recent classifications have attempted to distinguish this group by glucose tolerance test or glycated hemoglobin-based criteria [36, 37]. A rather confusing terminology has resulted, the group with suspected undetected diabetes being termed "diabetes in pregnancy" (World Health Organization [WHO]) or "overt diabetes in pregnancy" (International Association of Diabetes and Pregnancy Study Groups [IADPSG] and American Diabetes Association [ADA]). The WHO further suggested that the label "gestational diabetes" be restricted to women with hyperglycemia first detected in pregnancy who do not have "diabetes in pregnancy" (Table 61.2).

New-onset T1DM in pregnancy

Most women diagnosed with "overt diabetes in pregnancy" will have previously unrecognized T2DM. The onset or detection of T1DM in pregnancy is, however, not uncommon. The finding of unusually high blood glucose results with or without ketonuria in a woman who is not obese should prompt consideration of the diagnosis. Serological tests for islet cell autoimmunity are usually strongly positive. Between 3 and 10% of women with newly recognized diabetes in pregnancy prove to have T1DM [38, 39].

It has been suggested that the incidence of T1DM in pregnancy exceeds the expected rate [40]. This at first seems unusual, given

Table 61.2 Recent proposals for the classification of diabetes in pregnancy.

Type of diabetes	Also called
Known diabetes	*Pregestational diabetes*
Type 1 (T1DM)

that with most other autoimmune disorders disease activity is suppressed in pregnancy. However, it is likely that the increased insulin resistance of pregnancy in the context of declining β-cell function overcomes any such effect (70% of such women are diagnosed in the third trimester). Most of these women have modest hyperglycemia detected by screening for GDM, but presentation with diabetic ketoacidosis can occur: the latter presentation is associated with a high perinatal mortality rate [41]. After delivery, a high proportion of women in this category can stop insulin and may even lose their diabetes, but with time relapse occurs in almost all cases [41].

Fulminant-onset T1DM

This entity was first described in Japan in 1987, but has since been observed in women in or originating from other East and South-East Asian countries. Women present abruptly with severe diabetic ketoacidosis, often preceded by flu-like symptoms and abdominal symptoms. Serum pancreatic enzymes are commonly elevated and whereas blood glucose levels are very high, glycated hemoglobin levels are normal, emphasizing the acuteness of onset [42]. The disease seems to have a particular predilection for late pregnancy (or immediately postpartum): 21% of cases in women in the 13–49-year-old age group occurred in pregnancy [43] and again, emphasizing its acute nature, many cases had tested negative for GDM just a few weeks beforehand. The perinatal mortality rate with this condition is very high [44].

New-onset T2DM in pregnancy

The majority of cases of diabetes detected for the first time in pregnancy have T2DM. A proportion of these women will have had GDM in earlier pregnancies or be known to have had prediabetes, and almost all will have some other features of the metabolic syndrome, such as truncal obesity, acanthosis nigricans, hypertension, dyslipidemia, and fatty liver. The frequency with which this condition is seen depends largely on the prevalence of obesity in the community. In Auckland, New Zealand, where obesity is prevalent amongst Māori and Pasifika communities, for every three cases of known T2DM in pregnancy a further two were detected for the first time in pregnancy; 13% of cases of GDM had previously undetected T2DM (as defined by early postpartum glucose tolerance testing) [35]. Women with previously unrecognized T2DM have higher rates of perinatal mortality and congenital malformation than those with lesser degrees of GDM, and the same as those with known T2DM [33–35]. The recognition that this is a high-risk condition has prompted the interest in detecting it by early pregnancy screening.

Cystic fibrosis-related diabetes and pregnancy

Survival into adulthood is now common amongst people with cystic fibrosis, so that pregnancy is becoming an issue for these women. The incidence of cystic fibrosis-related diabetes increases with prolonged survival; in the 20–30-year-old age group about one-third will have developed diabetes (see Chapter 21). Women with cystic fibrosis who become pregnant actually have better survival than those who do not, but this is because the ones who have children are less ill: they have better pulmonary function, higher body mass index (BMI), and a lower prevalence of diabetes [45]. Women with cystic fibrosis-related diabetes have a higher incidence of premature delivery than those without diabetes, but this is likely in part to be iatrogenic [46].

Monogenic diabetes

Diabetes is a heterogeneous condition and although most women with pre-gestational diabetes will have T1DM or T2DM, a few will have genetic diabetes (most commonly due to *GCK* or *HNF1A* mutations, or mitochondrial diabetes). Pregnant women are younger than the average adult with diabetes and so the pregnant population has a relatively high proportion of women with genetic forms (with diabetes presenting from birth in the case of *GCK* mutations, or from the teenage years to the 20s in the case of *HNF1A* mutations). The same considerations apply to women with "overt diabetes in pregnancy" discovered as result of screening for GDM. Pregnancy may thus be the first time that asymptomatic forms of monogenic diabetes are diagnosed. The clues to identifying such women lie in attaining accurate family histories and phenotyping (see Chapter 18). Recognition is important because of the impact of certain forms of monogenic diabetes on fetal growth.

Effects of diabetes on pregnancy

Fertility and conception

Fertility is usually normal in women with T1DM, although delayed menarche in girls diagnosed before puberty is common, especially if diabetic control is poor [47, 48]. Although the age at menopause in women with T1DM is normal [49], fertility declines

with age and, in common with the general population, women with T1DM now often choose to delay having children. Other potential causes of infertility in women with T1DM are eating disorders (prevalent among young women with T1DM; see Chapter 57) that are commonly associated with anovular cycles and amenorrhea [50]. Rarely, autoimmune premature ovarian failure can be associated with T1DM [51].

The degree to which polycystic ovarian syndrome is expressed clinically is strongly related to obesity and, indeed, polycystic ovaries may be regarded as a component of the metabolic syndrome. Women with T2DM are usually overweight and there is a strong association between glucose intolerance and polycystic disease [52]. Subfertility due to polycystic disease responds to weight loss and metformin treatment. Other insulin sensitizers may also improve fertility but should be avoided because of their potential adverse effects on the developing fetus.

Miscarriage

Spontaneous miscarriage rates among women with diabetes are broadly similar to those in the general population (12–15%), although the risk is increased when diabetic control is poor [53–55].

Early fetal loss in non-diabetic pregnancies is often attributable to lethal chromosomal abnormalities. Fetal trisomy is more common with advancing maternal age, hence the association of the latter with an increased miscarriage rate. Diabetic pregnancies are not at increased risk of chromosomal abnormalities, but nonviable congenital malformations are more common than in nondiabetic pregnancies and probably contribute to the increased early miscarriage rate in women with poorly controlled diabetes.

Maternal obesity is associated with poorer success with *in vitro* fertilization and may also be a risk factor for first-trimester miscarriage. Not all studies concur, but a threefold increase in recurrent early miscarriage (defined as more than three successive miscarriages before 12 weeks) was found in a United Kingdom study of pregnant obese women (BMI >30 kg/m^2) compared with age-matched women of normal weight [56]. As more older and obese women with T2DM are now becoming pregnant, miscarriage rates may well rise.

Congenital anomalies

The risk of major fetal congenital anomalies is increased in women with diabetes, irrespective of the type of diabetes. Abnormally high glucose levels in maternal blood, transported to the embryo, are responsible for the teratogenic effect. To have such an effect, fetal exposure to hyperglycemia must occur at the earliest stages of pregnancy (6–8 weeks), during which organogenesis occurs. Major fetal anomalies (detected by ultrasound in early pregnancy) are common reasons for elective termination of pregnancy and an important cause of perinatal morbidity and mortality. As many women do not present for care until after the critical first 8 weeks, it is unsurprising that it has been difficult to reduce the proportion of diabetic pregnancies complicated by major congenital anomalies.

The most prevalent abnormalities are neural tube defects (including anencephaly and encephalocele), which are increased fourfold, and congenital heart disease, which is increased threefold [57]. Although no cardiac anomaly is specific to diabetes, severe conotruncal anomalies are more common than simple anomalies. Transposition of the great arteries, tricuspid atresia, and truncus arteriosus are at least 15 times more prevalent in infants of mothers with diabetes [58].

A wide variety of other defects are commonly seen either singly or in combination (Figure 61.1, Table 61.3). Again none are exclusive to diabetes, although caudal dysgenesis (sacral agenesis) is relatively specific to diabetic pregnancy [59]. Many anomalies are components of the VACTERL association (vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities). One model for the clustering of these features is the idea of the "developmental field defect," in which malformations that occur in blastogenesis tend to result in polytopic anomalies, affecting multiple organ systems [60]. It has been suggested that tissue-specific developmental control genes are regulated at specific times in embryonic development by glucose metabolism or that maternal diabetes, possibly through epigenetic changes, reduces the precision of gene regulation [61, 62].

The risk of a fetus having a major congenital anomaly is clearly related to maternal glycemia around the time of conception [63, 64]. The absolute risk is ~3% when the periconceptional HbA_{1c} is 50 mmol/mol, and 10% when it is 100 mmol/mol. However, the 95% confidence intervals (CIs) around these estimates are very wide (Figure 61.2), so there is no certainty of prediction, suggesting that whether or not a fetus is affected is a stochastic event.

Fetal morbidity

Macrosomia

Maternal hyperglycemia increases placental fetal transfer of glucose. In response to this, fetal insulin secretion is increased; immunoreactive insulin is detectable in the human fetal pancreas by the seventh week after conception, with evidence of functional fetal β cells by the end of the first trimester [65]. The diabetic intrauterine metabolic environment promotes abdominal fat disposition and visceral growth, notably in the liver and heart. The infant of a mother with diabetes is thus "growth promoted" [66]. Maternal diabetes, particularly when it is poorly controlled, is therefore a potent cause of accelerated growth. In women with T1DM, birth weights are typically 1.3–1.4 standard deviations above the population norm, with twice as many babies with birth weights >90th centile as normal [67, 68]. There is increasing recognition that maternal obesity and gestational weight gain are also important causes of fetal overnutrition and macrosomia. Along with rest of the population, there is a secular trend to increasing BMI in women with T1DM, which may contribute to persistently high rates of macrosomia [69].

Macrosomia has variously been defined as a birth weight >90th or >95th centile, for general or population-specific norms; or a birth weight of >4 or >4.5 kg. Higher maternal age, height, parity,

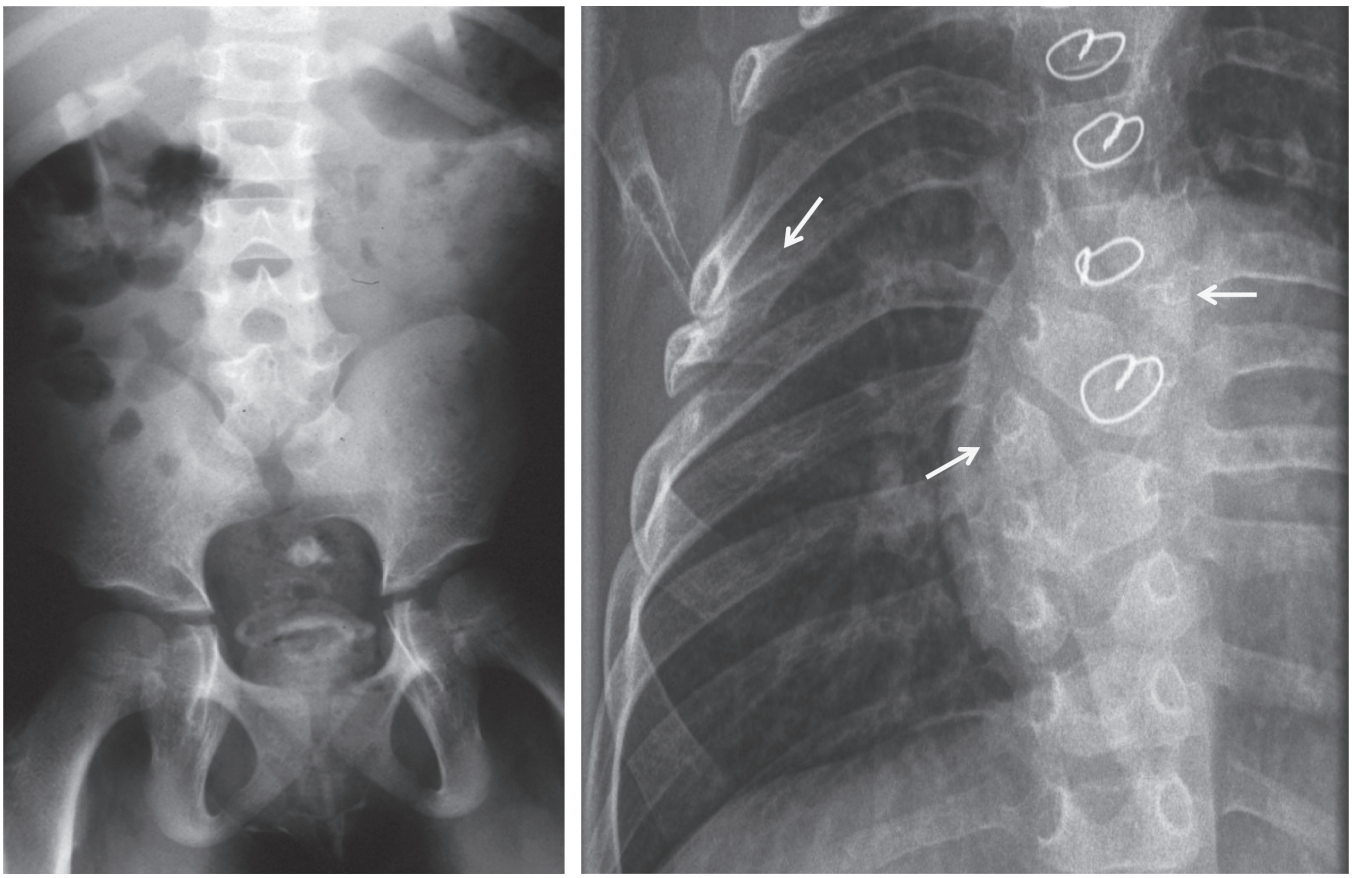

Figure 61.1 Examples of diabetic embryopathy. Left: sacral agenesis in a child whose mother had poorly controlled T2DM at conception. Affected children can have spina bifida-like features with difficulties walking and bowel and bladder dysfunction. Right: chest radiograph from an infant of a mother with T1DM. The child had cardiac surgery at age 7 months for double outlet right ventricle. Note also the two hemivertebrae and the fused ribs (arrowed).

BMI, presence of diabetes, gestational age at delivery, and male fetal sex are all significantly related to macrosomia [70]. Although simple to measure and almost universally recorded, birth weight is a fairly crude measure; a long, thin newborn can weigh the same as a short, fat child, but the *in utero* exposures and neonatal risks are not necessarily the same.

Accelerated growth can be detected on routine clinical ultrasound as a relative increase in the abdominal circumference

Table 61.3 Absolute and relative frequencies of congenital malformations in diabetic pregnancy.

Type of defect	Approximate frequency (%)	Relative frequency
Congenital heart disease	21	3×
Central nervous system	18	3×
Renal and urinary defects	12	4×
Lower spine defects	12	39×
Upper spine/rib defects	11	26×
Caudal dysgenesis	5	53×

measurement after about 28 weeks' gestation (Figure 61.3) [71]. Although characteristic of the diabetic pregnancy, this finding again is not specific, as it can result from maternal obesity and excess gestational weight gain. Fetal liver length measurements may be more specific to hyperglycemia [72], but are technically challenging.

Many other factors influence fetal growth, including placental size and function, uterine blood flow, hypertension, and smoking. Genetic factors are also important. This is most graphically illustrated by the effects of *GCK* and *HNF4A* mutations (Table 61.4), which can differ according to whether the mother and fetus have the same or are mismatched for the disease-associated mutation [73–77]. Genome-wide association studies have identified mutations and polymorphisms in other genes that are associated with fetal growth patterns [78].

The potential consequences of accelerated growth *in utero* include an increased risk of shoulder dystocia, birth trauma and birth asphyxia. Emergency cesarean section and some neonatal morbidities are also linked to fetal overgrowth. The increase in subcutaneous fat distribution in these infants combined with their high hematocrit gives them a typical "macrosomic" appearance with plethoric features and an obese body (Figure 61.3).

Shoulder dystocia and brachial plexus injury

Shoulder dystocia occurs when, after delivery of the fetal head, the baby's anterior shoulder becomes stuck behind the mother's pubic bone. If this happens, the remainder of the baby does not follow the head out of the vagina as easily as during normal delivery. There is no agreed definition; some suggest that shoulder dystocia should be diagnosed only when there is some time delay (1 min is often quoted) between the delivery of a baby's head and shoulders. Others suggest that shoulder dystocia is present any time that the midwife or obstetrician finds that the shoulders cannot be delivered with the normal amount of downward traction on the fetal head. Still others have suggested that the definition of true shoulder dystocia requires that special maneuvers have to be employed in order to deliver the shoulders. Hence there is always some degree of subjectivity in the reports of its incidence.

The Confidential Enquiry into Maternal and Child Health (CEMACH) study reported that 8% of babies of mothers with established diabetes had shoulder dystocia, compared with 3% in a general maternity population. The risk of shoulder dystocia was clearly related to birth weight, increasing from <1% in babies weighing <2.5 kg to 43% of babies weighing >4.5 kg [79]. The incidence of brachial plexus injury (Erb palsy) was increased 10-fold but remained an infrequent event (<0.5%). Another study of women with T1DM reported an incidence or Erb palsy of 2% [80]. Although most babies suffering brachial plexus injuries recover without long-term sequelae, the most serious damage tends to occur in the largest babies [81, 82].

Shoulder dystocia also affects maternal morbidity, in particular increasing the risk of postpartum hemorrhage and third- and fourth-degree perineal tears [83].

Stillbirth

Stillbirth is defined as fetal loss occurring after 24 completed weeks of gestation. In women both with and without diabetes, identifiable causes of stillbirth include congenital malformations, chromosomal abnormalities, infection, and intrauterine growth restriction. Approximately one-quarter of all cases are unexplained [84]. The risk of stillbirth in diabetic pregnancies is approximately fivefold higher than for non-diabetic pregnancies [85–87]. In the CEMACH audit, there were 63 stillbirths in 2536 births in one calendar year, representing a 4.7-fold greater risk than that of the general UK antenatal population (5.7 per 1000 births). There was no difference in the stillbirth rate between T1DM (25.8/1000) and T2DM (29.2/1000). A similar stillbirth rate of 25 per 1000 births was seen in an audit of T1DM pregnancies in northeast England between 1990 and 1994 [88]. The CEMACH audit and other studies have identified poor glycemic control throughout pregnancy as a risk factor for stillbirth [79, 89]. Other identifiable risk factors include diabetic nephropathy, smoking, and lower socioeconomic status [90].

It is important to recognize that obesity and increasing maternal age are also risk factors for stillbirth in women both with and without diabetes. This may explain why, in obstetric units that serve extremely obese women with T2DM, the stillbirth risk may be higher for T2DM than T1DM [35, 91].

A proportion of stillbirths in diabetic pregnancies cannot be explained by congenital malformations or other identifiable causes. The etiology remains uncertain, although chronic fetal hypoxia and acidosis may be contributory factors [92]. Fetal

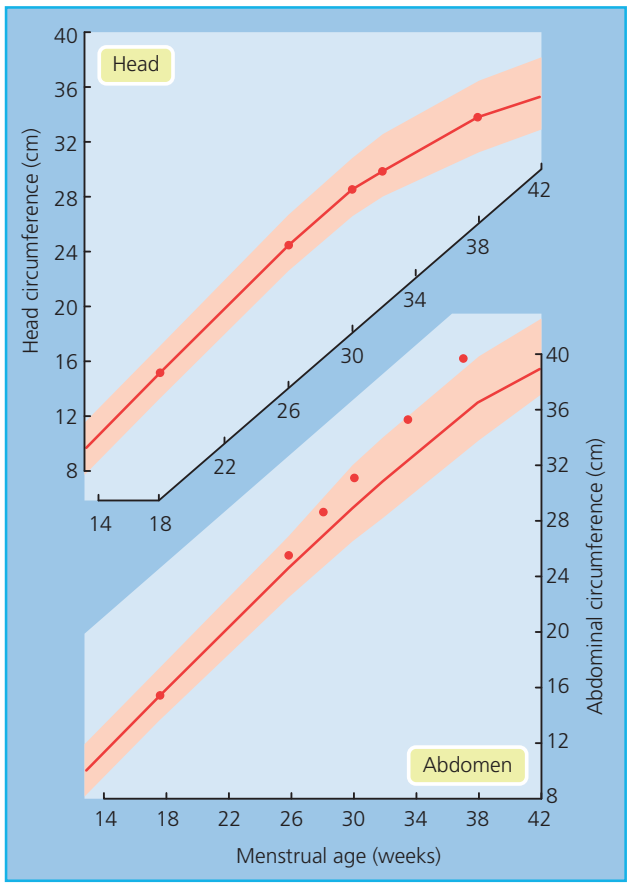

Figure 61.3 Macrosomia. Left: accelerated fetal growth, manifested as a progressive increase in abdominal circumference (lower panel), while head circumference remains on the 50th centile (upper panel). The red line represents the 50th centile and the shaded area represents the 3rd to 97th centile. The accelerated growth in abdominal circumference is not specific to maternal diabetes. It can also result from maternal obesity and excessive gestational weight gain. Right: a macrosomic baby born to a mother with diabetes, with a normal-weight baby born to a mother without diabetes for comparison.

hyperinsulinemia combined with the availability of excessive fuel substrate increases oxygen demand in insulin-sensitive tissues and it is postulated that this may eventually exceed placental oxygen supply [93]. Human and large animal studies suggest that the fetuses of diabetic pregnancies may be more susceptible to acidosis than those of a non-diabetic pregnancy [94, 95]. Amniotic erythropoietin, a marker of chronic fetal hypoxia in late pregnancy, is higher in diabetic than non-diabetic pregnancies. In one study of women with T1DM, amniotic erythropoietin levels correlated inversely with cord blood pH and pO_2 at birth [92].

Hypoglycemia

Neonatal hypoglycemia is important because if prolonged and severe it can cause brain injury and poor neurodevelopmental outcome. Although there is debate about the definition, thresholds for treatment (typically <2.2 or <2.6 mmol/L) have been established and are used in clinical practice [96]. Neonatal hypoglycemia affects as many as 5–15% of otherwise healthy babies [96, 97] and is widespread in resource-poor countries [98].

Capillary blood glucose readings are often unreliable as they commonly have poor precision at low values, and so when neonatal hypoglycemia is suspected, the plasma or blood glucose concentration should be determined immediately by using one of the laboratory enzymatic methods (e.g. glucose oxidase, hexokinase, or dehydrogenase method) [99].

Hypoglycemia is common, albeit usually transient, in infants of women with diabetes and occurs in approximately half of all diabetic pregnancies. However, it is also common after preterm birth, in small-for-gestational-age and large-for-gestational-age babies [100]. The macrosomic infants of mothers with diabetes are at risk for hypoglycemia because of postpartum hyperinsulinemia secondary to fetal β-cell hyperplasia and the inhibition of hepatic glucose production by hyperinsulinemia.

Most cases of neonatal hypoglycemia occur in the first 24 h after delivery [100]. The risk is greater if the maternal blood glucose concentration is high during labor, and can be minimized by maintaining the maternal blood glucose at <8 mmol/L during labor [101].

Early feeding reduces the risk for hypoglycemia, and so it is recommended that all mothers with diabetes be encouraged to breastfeed within 30 min of birth and then every 3–4 h, until a regular feeding pattern is established. The current National

Institute for Health and Care Excellence (NICE) guideline recommends the use of intravenous glucose to treat neonatal hypoglycemia only when there are clinical signs or a persistent blood glucose <2.0 mmol/L that cannot be raised by oral or tube feeding, or when the blood glucose is very low (1.1–1.4 mmol/L). If intravenous glucose is required, this should be continued until the glucose level is >2.5 mmol/L [102]. The prophylactic use of a glucose gel applied to the buccal mucosa of at-risk babies can reduce the incidence of neonatal hypoglycemia by half [98].

Other neonatal complications

Neonatal erythrocytosis

The infants of mothers with diabetes commonly have an elevated hematocrit. This finding (often erroneously termed "polycythemia") has been attributed to fetal hyperinsulinemia and chronic fetal tissue hypoxia [103, 104]. However, hematocrit is not strongly related to birth weight, and the relationship with late-pregnancy maternal glycated hemoglobin is fairly weak [105]. The mode of delivery has a pronounced effect: the hematocrit is lower in babies delivered by cesarean section.

Jaundice

Jaundice is more common in macrosomic babies. The cause of hyperbilirubinemia is probably multifactorial, including birth trauma, erythrocytosis, hemolysis, and immature hepatic uptake and conjugation of bilirubin.

Respiratory distress syndrome

This was considered to be common in diabetic pregnancies [106] but is likely to result from preterm birth and high rate of cesarean section rather than any underlying metabolic effect [107, 108]. Delivery before term is common in women with diabetes, and an increased incidence of respiratory distress syndrome may reflect some clinical reluctance to administer glucocorticoids to hasten fetal lung maturation, because of their effects on maternal glycemia.

Transient hypertrophic cardiomyopathy

Transient hypertrophic cardiomyopathy, characterized by ventricular septal hypertrophy and sometimes subaortic stenosis, occurs in up to 30–80% of all babies of mothers with diabetes (the more sensitive the echocardiogram the higher is the proportion apparently affected) [109–111]. Very severe cases may present with congestive cardiac failure, but this usually has a benign course, resolving within 1 month without any clinical sequelae. Echocardiograms in older children of mothers with T1DM do not show persistence of ventricular hypertrophy [112].

Other metabolic abnormalities

Both hypocalcemia and hypomagnesemia occur more frequently in the infant of a mother with diabetes, usually as a consequence of prematurity or birth asphyxia.

Effects of maternal diabetic ketoacidosis and hypoglycemia on the fetus

Diabetic ketoacidosis

Diabetic ketoacidosis is fortunately uncommon in pregnancy, but it can have serious consequences. Most cases occur in women with T1DM, but it may also occur in "atypical" T2DM. The fetus and the placenta use large quantities of maternal glucose as a major source of energy, and so with relative insulin deficiency this leads to an increase in maternal free fatty acids, which are then converted to ketones in the liver. Ketoacidosis therefore tends to develop at lower levels of blood glucose than in the non-pregnant state [113].

Ketoacidosis may be precipitated by a number of factors, including protracted vomiting and starvation, infections, poor glycemic control, poor adherence to treatment, insulin pump failure, the use of β-sympathomimetic agents for tocolysis or steroid use for fetal lung maturation (or for other medical disorders), or new-onset T1DM. Women with diabetes are particularly sensitive to the effects of vomiting and starvation, which may arise through hyperemesis, gastroparesis, eating disorders, or gastroenteritis (or other infections).

The exact mechanism by which maternal diabetic ketoacidosis affects the fetus is unknown Keto acids readily cross the placenta, but whether it is the acidosis, hyperglycemia, severe volume depletion, or electrolyte imbalance that is the most malign for the fetus is uncertain [113, 114]. Cardiotocography during diabetic ketoacidosis has shown an absence of baseline heart rate variability, persistent late deceleration, and non-reassuring biophysical profile—all indicating fetal distress. Fetal mortality rates are high, ranging from 10 to 30%, although these seem to have improved in recent years [115]. The mortality rate is particularly high in fulminant-onset T1DM (see above).

Treatment should follow standard guidelines for the management of diabetic ketoacidosis.

Maternal hypoglycemia

One of the main aims of managing diabetes in pregnancy is to try to maintain maternal blood glucose values as close to normal as possible. An inevitable consequence, particularly in women with T1DM, is more frequent hypoglycemia including asymptomatic nocturnal hypoglycemia [116, 117], and with that comes reduced hypoglycemic awareness and an increased risk of severe hypoglycemia (requiring the assistance of others to recognize and/or treat it). Those at greatest risk are women known to have hypoglycemic unawareness and to have suffered severe hypoglycemia before pregnancy [118, 119]. The risk is greatest in the first trimester [119, 120]. A recent study has suggested that this risk can be reduced by a focused intervention, including education of caregivers and women [121].

The CEMACH study documented that 61% of women with T1DM had recurrent hypoglycemic episodes during pregnancy and 25% had severe hypoglycemia [122]. Severe hypoglycemia has been implicated in maternal deaths [120]. Although women with T2DM had a lower risk for severe hypoglycemia in the CEMACH

study, 21% of the women with T2DM had recurrent episodes of hypoglycemia [122].

In the CEMACH study, neither recurrent nor severe hypoglycemia was associated with poor pregnancy outcome (odds ratio [OR] 1.1; 95% CI: 0.7–1.7 and OR 1.3; 95% CI: 0.7–2.3, respectively) [122]. It is therefore the mother who is at greatest risk from severe hypoglycemia, raising the question of exactly how tight maternal glucose needs to be in order to maximize the benefits to the fetus and minimize the risks to the mother.

Effects of pregnancy on diabetes complications

Diabetic retinopathy

Diabetic retinal disease commonly progresses during pregnancy, sometimes to the point where laser treatment becomes necessary. Two main factors determine the severity of such deterioration: the degree of pre-existing retinopathy and the degree to which glycemic control improves. The risk of progression to sight-threatening retinopathy is of the order of 20–30% for those with moderate to severe retinopathy before pregnancy but ≤2% for those with minimal disease or no retinopathy. The phenomenon of a rapid tightening of glycemic control causing an acute deterioration in retinopathy is not restricted to pregnancy [123, 124]. In the Diabetes Control and Complications Trial (DCCT), if the fall in HbA_{1c} during pregnancy was ≤17 mmol/mol (1.6%) then a similar proportion (20–30%) of women had some deterioration as had some improvement in retinopathy. If, however, the fall in HbA_{1c} during pregnancy was ≥35 mmol/mol (3.2%) then >80% had some deterioration [125].

The women at greatest risk are therefore those with pre-existing moderate to severe retinopathy who enter pregnancy with high glycated hemoglobin levels and then have very rapid improvement in glycemia. This should not preclude efforts to improve glycemic control as the benefits to the fetus outweigh the risks to the mother. Conversely, women who come into pregnancy with no retinopathy and glycated hemoglobin levels that are already low are at minimal risk. Diabetic retinopathy is commonly associated with nephropathy, and hypertension in early pregnancy is associated with an increased risk of progression, although it is not clear that intensive treatment of hypertension reduces the risk [126].

Pregnancy is associated with increased circulating concentrations of many growth factors, angiopoietic factors, and proinflammatory molecules. Current evidence points toward a critical role of placental growth factor (PGF) in increasing the susceptibility of the retina in pregnancy. PGF is a member of the vascular endothelial growth factor subfamily and is a key molecule in angiogenesis and vasculogenesis, particularly during embryogenesis. Its main source during pregnancy is the placental trophoblast, and maternal plasma concentrations of PGF increase 15–20-fold between 8 and 32 weeks' gestation. Increasing PGF concentrations in the vitreous alters the permeability of the retinal pigment epithelial cells, permitting the development of retinal and macular edema [127], and overexpression of *Pgf* in rat eyes produces a diabetic retinopathy phenotype [128]. The *Pgf*-knockout mouse is resistant to oxygen-induced retinopathy, and knockout of the *Pgf* gene in the Akita diabetic mouse model prevents diabetes-induced retinal cell death, capillary degeneration, pericyte loss, and breakdown of the blood–retinal barrier [129]. In addition, the constriction of the retinal arteries and reduction in retinal blood flow that occur in the third trimester of pregnancy are more pronounced in diabetic pregnancies [130]. This could lower the threshold for retinal ischemia and hypoxia and hence progression of retinopathy.

Retinopathy can develop *de novo* in pregnancy, although this is unlikely to progress to proliferative retinopathy [126, 131]. A characteristic feature of marked pregnancy-associated deterioration in retinopathy is the appearance of cotton-wool spots (Figure 61.4). These lesions, which are related to microinfarction in the retinal nerve fiber layer, develop in up to half of those with progression to sight-threatening retinopathy. Cotton-wool spots usually regress postpartum and may not require immediate treatment, but the overall risk of deterioration in retinopathy status may persist for up to 1 year after delivery [125], and some women may require laser treatment in the postpartum period [132]. However, the pregnancy effect does not seem to change the long-term natural history or progression of diabetic retinopathy [125]. An analysis of 59 women with T1DM before pregnancy who had annual follow-up for up to 10 years after delivery showed that baseline retinopathy status was the only independent risk factor predicting later progression of retinopathy [133].

Diabetic nephropathy

Diabetic nephropathy can have a major influence on pregnancy outcome for both mother and baby. Maternal hazards include worsening of renal failure and pre-eclampsia; fetal complications include intrauterine growth restriction, prematurity, and death. Nephropathy is a progressive disorder and the pregnancy risk increases the more advanced the disease.

During normal pregnancy, the glomerular filtration rate (GFR) increases by 50–100% compared with non-pregnant values, driven by an increase in effective renal plasma flow (ERPF), which increases by ~80% during early pregnancy but falls significantly from this new level during the third trimester. The GFR remains ~50% above the non-pregnant level throughout pregnancy. The filtration fraction (GFR/ERPF) is significantly reduced during early pregnancy but rises to a value equivalent to the non-pregnant level during the third trimester [134]. In women with nephropathy, the GFR may increase only slightly during pregnancy [135] and there can be dramatic increases in protein excretion, particularly in late pregnancy. After delivery, albumin excretion may remain high for a few weeks, but usually then falls to prepregnancy levels. For most women with nephropathy, pregnancy is not associated with any reduction in GFR, but for those with stage 3 or 4 chronic kidney disease there may be some deterioration; however, this usually reverts to prepregnancy levels in the postpartum period [136].

The development of pre-eclampsia superimposed upon the renal disease is the greatest hazard. In a prospective study of 203 women with T1DM, pre-eclampsia developed in 6%

Figure 61.4 Acute retinal changes in pregnancy. Retinal photograph from a woman with T2DM recognized for the first time in pregnancy who presented with an HbA_{1c} of 89 mmol/mol at 9 weeks' gestation. She started insulin and metformin treatment, with a rapid reduction in her blood glucose levels (by 27 weeks the HbA_{1c} was 25 mmol/mol). At 14 weeks' gestation she developed blurred vision: the retinal photograph shows numerous cotton-wool spots, which result from microinfarcts in the retinal nerve fiber layer caused by occlusion of small retinal arterioles.

of women without microalbuminuria, in 42% of those with microalbuminuria, and 64% of those with heavy proteinuria [137]. Pre-eclampsia is usually defined by the new appearance of hypertension and proteinuria in pregnancy, but this definition is problematic in women with nephropathy who have renal disease antedating the pregnancy. In this circumstance, pre-eclampsia may be defined by worsening hypertension and a doubling of proteinuria (or albuminuria), along with the other defining features (increasing plasma creatinine, platelet count $<150 \times 10^3/mm^3$, or plasma aspartate aminotransferase >40 U/L).

Early intensive hypertensive management before and during pregnancy may reduce the risks of pregnancy-induced hypertension, pre-eclampsia, and preterm birth [138–140], as may good glycemic control [141]. The antihypertensive agents of first choice for people with diabetic nephropathy are angiotensin-converting enzyme inhibitors (ACEi) or angiotensin receptor blockers (ARB). However, both are contraindicated in the second and third trimesters because they cause the fetal renin–angiotensin system blockade syndrome, characterized by renal failure and complications that include oligohydramnios, arterial hypotension, intrauterine growth retardation, respiratory distress syndrome, pulmonary hypoplasia, hypocalvaria, limb defects, persistent ductus arteriosus, cerebral complications, or death [142].

There is controversy as to whether these agents are teratogenic in early pregnancy. One study reported that infants exposed to ACEi were at increased risk of malformations of the cardiovascular system (risk ratio [RR] 3.72; 95% CI: 1.89–7.30) and the central nervous system (RR 4.39; 95% CI: 1.37–14.02), and the authors concluded that exposure to ACEi during the first trimester cannot be considered safe [143]. However, there were a number of potential confounders in this study (notably maternal diabetes) that were not accounted for, and more recent analyses suggest that exposure during the first trimester may not be hazardous. It is common practice to discontinue ACEi and ARB when pregnancy is confirmed, rather than when pregnancy is planned, as it may be more hazardous to change therapy and risk losing control of blood pressure and albuminuria. Although the fetal renin–angiotensin system blockade syndrome appears to be more common with ARB than ACEi [142], the risk of congenital malformations related to early pregnancy exposure does not seem to be increased with ARB [144].

Diabetic nephropathy, especially when the serum creatinine is raised, carries a significant risk of birth before 32 weeks' gestation, very low birth weight, and neonatal hypoglycemia [145]. The increased rate of preterm births may well explain the mild disturbances in growth and development in early childhood seen in offspring of these pregnancies [146].

Renal transplantation

The first report of successful pregnancy following a renal transplant in women with diabetic nephropathy was in 1986 [147]. Successful pregnancies are now common in the general renal

transplantation population [148, 149], with a number of national and international registries providing pregnancy outcome data. These all show some increased risk of miscarriage, stillbirth, ectopic pregnancy, preterm birth, low birth weight, and neonatal death. However, most of these registries do not document outcome according to the mother's original renal disease, and as women with diabetic nephropathy have more advanced microvascular and macrovascular disease it is probable that their outcomes are worse. In the Australian and New Zealand Dialysis and Transplant Registry report of pregnancies in renal transplant recipients, only 4% had diabetes/hypertension as the primary renal disease, suggesting that many such women choose not to become pregnant [150].

Combined renal–pancreatic transplantation

The United States National Transplantation Pregnancy Register reported outcomes in pregnancies in 38 women a mean 3.7 years after combined renal–pancreatic transplantation [151]. Although the live birth rate was 79%, problems with hypertension (75%), pre-eclampsia (34%), infection (55%), prematurity (78%), and low birth weight (63%) were common. In pregnancy, 6% had a rejection episode affecting one or both organs and 16% experienced graft loss in the 2 years after delivery, although it is not clear whether this was any higher than in the population that did not have a pregnancy.

Neuropathy

Pregnancy has no long-term impact on the progression of peripheral or autonomic neuropathy, but given their relatively poor prognosis, women who have already suffered neuropathic foot ulceration are generally advised not to become pregnant. Severe gastroparesis due to autonomic neuropathy can cause pregnancy loss and maternal malnutrition and is likewise a contraindication to pregnancy [110, 114, 152]. Gastroparesis can be a factor in hyperemesis gravidarum and a precipitant of ketoacidosis in women with T1DM [153, 154]. However, there is no evidence that hyperemesis is more prevalent in women with long-standing diabetes than in the general population.

Ischemic heart disease

Maternal diabetes, obesity, and increasing age are all known risk factors for ischemic heart disease in pregnancy [155], hence as the general antenatal population becomes more obese and more women give birth in their late reproductive years, ischemic heart disease in pregnancy is likely to become more prevalent.

Outside pregnancy, women with T1DM aged 35–45 years have a 15-fold higher risk of a major cardiovascular event and women with T2DM aged 35–54 years have a fivefold higher risk of a myocardial infarction than women without diabetes of a similar age [156, 157]. Pregnancy increases the risk of an acute myocardial infarction 3–4-fold, with the risk being greatest in the peripartum period [155]. The number of pregnant women with ischemic heart disease and maternal deaths from ischemic heart disease have both increased in recent years. Ischemic heart disease is now the most common cause of cardiac death associated with pregnancy in the UK [158]. Nevertheless, the overall mortality rates from acute myocardial infarction in pregnancy have declined [159].

Acute myocardial infarction during pregnancy in women with diabetes has a poor prognosis, but pregnancy outcomes seem to be better in women who have survived a myocardial infarction before pregnancy [160]. Women who suffer acute coronary syndromes in pregnancy should receive the same urgent and intensive management as those in the non-pregnant state and interventions should not be withheld for fear of causing fetal harm [161].

Hypertensive disorders of pregnancy

Hypertensive disorders of pregnancy are common in women with diabetes of all types, and the combination of hypertension with diabetes has a greater impact on adverse maternal and fetal outcomes than either alone [162]. There is a wide spectrum of hypertension in pregnancy defined by severity, time of onset, and associated features (Table 61.5). The impact on pregnancy is greatest with early-onset pre-eclampsia and least with gestational hypertension.

The risk factors for pre-eclampsia in the general population include chronic hypertension (adjusted OR 2.72; 95% CI: 1.78–4.13), pregestational diabetes (adjusted OR 3.88; 95% CI: 2.08–7.26), multiple gestation (adjusted OR 2.96; 95% CI: 1.74–5.03), pre-eclampsia in a previous pregnancy (adjusted OR 3.63; 95% CI: 2.29–5.73), nulliparity (adjusted OR 1.73; 95% CI: 1.26–2.38), assisted reproductive techniques (adjusted OR 1.72; 95% CI: 1.10–2.68), and being overweight or obese [163].

The majority of studies in women with diabetes have been in those with T1DM in whom hypertensive disorders of pregnancy are reported to be 2–4-fold more prevalent than in women without diabetes [163, 164]. In women with T1DM, additional risk factors for hypertensive disorders of pregnancy include a long duration of diabetes, poor glycemic control, and the presence of nephropathy or early or prepregnancy proteinuria [165–171]. Many of these characteristics are incorporated in the White classification of diabetes in pregnancy that is commonly used in North America (Table 61.6), hence there is a strong relationship between White class and the risk of hypertension in pregnancy [172].

The worst outcomes (fetal death, impaired fetal growth, premature delivery, need for cesarean section, and neonatal intensive care) are seen with severe early-onset pre-eclampsia [173], which in the context of diabetes most often arises in women with pre-existing hypertension and proteinuria due to nephropathy [168, 172, 174]. Diabetes per se is more strongly associated with late- than early-onset pre-eclampsia [173].

In many parts of the world, pregnancy in women with T2DM is now more common than in women with T1DM. Relatively few studies have examined hypertensive disorders of pregnancy in women with T2DM, but compared with women with T1DM they tend to be older and more obese, hence there is more chronic (essential) hypertension; however, their duration of diabetes tends to be shorter and they are less frequently nulliparous, and so

Table 61.5 Classification of hypertension in pregnancy and its severity.

Severity of hypertension	a. *Hypertension* Hypertension in pregnancy is defined as a systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg, or both b. *Severe hypertension* Severe hypertension in pregnancy is defined as systolic blood pressure ≥160 mmHg or diastolic blood pressure ≥110 mmHg, or both. Severe hypertension in pregnancy is considered to be a hypertensive emergency that requires urgent intervention
Classification of hypertension	a. *Chronic (pre-existing) hypertension* Chronic hypertension is defined as hypertension (systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg, or both) that is present before 20 weeks' gestation or prior to pregnancy b. *Gestational hypertension* Gestational hypertension is defined as new hypertension (systolic blood pressure ≥140 mmHg or diastolic blood pressure ≥90 mmHg, or both) presenting at or after 20 weeks' gestation without proteinuria or other features of pre-eclampsia c. *Pre-eclampsia and chronic hypertension with superimposed pre-eclampsia* Pre-eclampsia is defined as hypertension plus significant proteinuria (urine protein excretion ≥300 mg/day or a spot urine protein : creatinine ratio of ≥30 mg protein/mmol creatinine). Rarely, pre-eclampsia can occur without proteinuria, but with hepatic, hematopoietic, or other manifestations. Edema is not a specific diagnostic criterion. This category includes: *Gestational hypertension plus new onset proteinuria* *Chronic hypertension with superimposed pre-eclampsia with new or worsening proteinuria* (defined as a rapid 2–3-fold increase in proteinuria) Pre-eclampsia may be further classified into *early-onset* (<34 weeks' gestation) and *late-onset* pre-eclampsia (≥34 weeks' gestation) d. *Severe pre-eclampsia* The criteria for severe pre-eclampsia include the presence of any one of severe hypertension (systolic blood pressure ≥160 mmHg or diastolic blood pressure ≥110 mmHg, or both), cerebral or visual disturbance, epigastric or right upper quadrant pain, oliguria, pulmonary edema, cyanosis, impaired liver function, thrombocytopenia, or intrauterine growth restriction e. *Eclampsia* Eclampsia is defined as new-onset grand mal seizures in women with pre-eclampsia. Some women presenting with eclampsia do not have diagnosed pre-eclampsia, and some may present with eclampsia in the post-partum period

there is generally less pre-eclampsia. As a consequence, the overall impact of hypertensive disorders of pregnancy on pregnancy outcomes may be less for women with T2DM than those with T1DM [175]. Proteinuria is more prevalent in women with T2DM, but may reflect pathologies other than diabetic nephropathy. The predictive power for low-level proteinuria detected in early pregnancy appears to be poorer for T2DM than T1DM [175, 176].

Table 61.6 The modified White classification of diabetes in pregnancy.

Class	Onset age (years)	Duration (years)	Insulin treated	Criteria
A_1	Any	Any	No	Gestational diabetes
A_2	Any	Any	Yes	Gestational diabetes
B	>20	<10	Yes	Benign retinal and renal findings
C	10–19	10–19	Yes	Age of onset 10–19 years *or* duration 10–19 years
D	<10	>20	Yes	Age of onset <10 years *or* duration >20 years
F	Any	Any	Yes	Nephropathy (>500 mg/day protein)
R	Any	Any	Yes	Proliferative retinopathy
RF	Any	Any	Yes	Retinopathy and nephropathy
T	Any	Any	Yes	Renal transplant patient
H	Any	Any	Yes	Cardiovascular disease

The White classification performs relatively poorly at predicting hypertensive disorders of pregnancy in women with T2DM because a high proportion of women fall into a single category (B) [175].

Of relevance particularly to women with T2DM or GDM is that obesity is also a significant risk factor for pre-eclampsia (including severe pre-eclampsia). In a large community study, the adjusted OR (compared with a BMI of <25 kg/m^2) was 1.65 for BMI 25–30 kg/m^2, 2.34 for BMI 30–35 kg/m^2, 3.59 for BMI of 35–40 kg/m^2, and 6.03 for BMI >40 kg/m^2 [163]. Increasing levels of obesity in the community may help explain why blood pressure levels in pregnancy have increased in recent decades, including in women with T1DM [177].

Despite a knowledge of the risk factors that predispose to pre-eclampsia, it remains a difficult condition to predict, as there are no reliable biomarkers in early pregnancy. Nevertheless, the accurate identification of women at risk, early diagnosis, and prompt and appropriate management (e.g. antenatal corticosteroids for fetal lung maturation, treatment of severe hypertension, early delivery) may improve maternal and perinatal outcome.

Aspirin therapy

A number of studies have examined whether aspirin can prevent hypertensive disorders of pregnancy. In a Cochrane review (34 studies, 20,701 participants) [178], no statistically significant difference was found in the incidence of gestational hypertension in women receiving antiplatelet agents compared with women

receiving placebo or no antiplatelet agents (RR 0.95; 95% CI: 0.88–1.03). Pre-eclampsia was evaluated in 43 studies (32,590 participants) and the pooled analysis showed that antiplatelet agents were associated with a statistically significant reduction in the risk of pre-eclampsia (RR 0.83; 95% CI: 0.77–0.89). On this basis, NICE has recommended that women at high risk for pre-eclampsia should take 75 mg of aspirin daily from 12 weeks until the birth of the baby. "High risk" in this definition includes hypertensive disease during a previous pregnancy, chronic kidney disease, T1DM or T2DM, and chronic hypertension [179]. In addition, NICE recommends that women with more than one moderate risk factor for pre-eclampsia should to take 75 mg of aspirin daily from 12 weeks until the birth of the baby. Moderate risk factors are first pregnancy, age 40 years or older, pregnancy interval of more than 10 years, a BMI of 35 kg/m^2 or more at first visit, a family history of pre-eclampsia, or multiple pregnancy [179].

This very broad recommendation of aspirin therapy—for all women with established diabetes and some women with GDM—is somewhat at odds with the evidence concerning women with diabetes in the major clinical trials, in whom no benefit was seen [180], which may explain why this recommendation is generally not promulgated by diabetes societies.

Calcium therapy

Randomized controlled trials suggest that calcium supplementation can reduce the risk of gestational hypertension and pre-eclampsia, particularly in those women with a low calcium intake, although current guidelines stop short of recommending it [179].

Management of diabetes in pregnancy

Managing pregnancy successfully in women with established diabetes is demanding and complex, requiring the full support and commitment of a multidisciplinary team. Numerous agencies have issued management guidelines that are updated periodically. Overall there is good agreement between the various guidelines. The recommendations below are largely drawn from the NICE Guidelines that were updated in 2015 [102], with comment on where there are significant omissions or differences from other recent guidelines issued by the American Diabetes Association (ADA), the Endocrine Society (ES), and the Canadian Diabetes Association (CDA) [181–183].

Prepregnancy counseling

All the guidelines emphasize the importance of planning pregnancy and there is good evidence that prepregnancy counseling can improve outcomes. The risk of fetal or infant death is increased with higher periconception HbA_{1c}, lack of folate use, and the presence of diabetes complications [184]. A recent meta-analysis suggested that prepregnancy care is effective in reducing both congenital malformation (RR 0.25; 95% CI: 0.16–0.37); number needed to treat [NNT] 19; 95% CI: 14–24) and perinatal mortality (RR 0.34; 95% CI: 0.15–0.75; NNT 46; 95% CI: 28–115) [185]. The important elements are obtaining good glycemic control, folate administration, the management of diabetic complications, smoking cessation, withdrawal of potentially teratogenic medication, and making sure that women are well informed about the likely changes through pregnancy.

Glycemic control

The purpose of achieving good glycemic control before embarking on pregnancy is to minimize the risk of major congenital anomaly and miscarriage. NICE recommends that women with established diabetes maintain their blood glucose level at >4 mmol/L and below the following target levels, if these are achievable without causing problematic hypoglycemia: fasting, 5.3 mmol/L; 1-h postprandial, 7.8 mmol/L; and 2-h postprandial: 6.4 mmol/L. The recommended HbA_{1c} target is <48 mmol/mol (6.5%) and women with an HbA_{1c} >86 mmol/mol (10%) should be "strongly advised" not to get pregnant. The ADA recommendations differ somewhat, with a target HbA_{1c} of <53 mmol/mol (7.0%) or "as close to normal as possible" while avoiding significant hypoglycemia. For most women, achieving such targets means either starting insulin (in T2DM) or intensifying the insulin regimen, using a basal/bolus regimen or a continuous subcutaneous infusion pump, with frequent self-monitoring of blood glucose. A meta-analysis of the effectiveness of prepregnancy counseling found that an average reduction in HbA_{1c} of 13 mmol/mol (1.2%) was achieved, but at the expense of an increased risk of hypoglycemia during the first trimester (RR 1.51; 95% CI: 1.15–1.99) [185].

Folate supplementation

Folate supplementation is recommended in a daily dose of 5 mg (NICE and ES) or 0.6 mg (ADA) in order to reduce the risk of neural tube defects.

Assessment of diabetic complications

This is important for the reasons discussed above in order to identify those at risk of deterioration in retinopathy in pregnancy and the association of nephropathy with pre-eclampsia and fetal growth retardation. All guidelines recommend that any necessary treatment for retinopathy is completed and the clinical condition is stable before embarking on pregnancy.

NICE recommends that if the serum creatinine is ≥120 μmol/L, the urinary albumin : creatinine ratio is >30 g/mol, or the estimated glomerular filtration rate (eGFR) is <45 mL/min/1.73 m^2, review by a nephrologist should be considered before discontinuing contraception.

The ADA also recommends ultrasound screening for fatty liver in women with elevated serum gamma-glutamyltransferase and/or alanine transaminase enzymes, and an electrocardiogram in asymptomatic women >35 years of age (and more intensive cardiovascular investigation of symptomatic women).

Drug cessation

NICE recommends that ACEi and ARB should be discontinued before conception, or as soon as pregnancy is confirmed.

Alternative antihypertensive agents suitable for use during pregnancy should be substituted. Statins should be discontinued before pregnancy or as soon as pregnancy is confirmed. NICE makes no specific comment about smoking cessation, but the benefits for women with diabetes women are the same as those for women without diabetes.

Obesity

NICE recommends that women with diabetes with a BMI >27 kg/m^2 who are planning to become pregnant should be advised to lose weight.

Autoimmune disease

Up to one-third of women with T1DM have serological evidence of autoimmune hypothyroidism, and up to half of these develop postpartum thyroiditis [186]. The ES and ADA recommend pre- or early pregnancy screening of women with T1DM with thyroid-stimulating hormone and thyroid antibody tests, with consideration also of testing for vitamin B_{12} deficiency. NICE makes no specific recommendation.

Achieving preconception recommendations

The recommendations for prepregnancy care—particularly the glycemic targets—are demanding to fulfill, and so it is perhaps not surprising that many women do not achieve the ideal. The sociological dimension should not be ignored. The studies that have demonstrated benefit from prepregnancy counseling have all been observational, and so the groups with and without counseling are self-selected. It is difficult to control for confounding factors such as social class, level of education, patient motivation, smoking, maternal age, obesity, parity, and complications of diabetes. Risky behaviors cluster together, and so women with poorly controlled diabetes tend also to be those who are irregular in the use of contraception, have unplanned pregnancies, are smokers, present late to diabetes pregnancy clinics, and have more diabetes complications [79, 187–190]. Thus the paradox of Tudor Hart's "inverse care law" prevails: those who would probably benefit most from rigorous prepregnancy counseling may be the least likely to receive it [191]. From this perspective, the problem is less of what to do (which is largely known), but rather how to reach those women who would benefit most.

Management of T1DM in pregnancy

Glycemic targets

All the guidelines recommend tight glycemic control. The ADA suggests that the target for preprandial, bedtime, and overnight blood glucose values should be 3.3–5.5 mmol/L; peak postprandial values (1 h after eating) should be 5.6–7.2 mmol/L, the mean daily glucose <6.1 mmol/L, and a target HbA_{1c} 42 mmol/mol (6.0%). The ES recommends a fasting blood glucose of ≤5.0 mmol/L, a preprandial target of ≤5.3 mmol/L, 1-h postprandial blood glucose ≤7.8 mmol/L, and 2-h postprandial blood glucose ≤6.7 mmol/L, with a target HbA_{1c} of 42 mmol/mol (6.0%). NICE suggests that fasting blood glucose be kept between 3.5 and 5.9 mmol/L and 1-h postprandial blood glucose <7.8 mmol/L. NICE advises that HbA_{1c} should not be used routinely for assessing glycemic control in the second and third trimesters but (somewhat ambiguously) also advises that its use should be considered to assess the level of risk (Table 61.7).

For a majority of women, particularly those with T1DM, achieving such low glycemic targets is very demanding, and there is no doubt that their pursuit can induce hypoglycemic unawareness with a significantly increased risk of hypoglycemia. In one study, the rate of severe hypoglycemia episodes increased threefold in the first trimester compared with the 4 months before conception [192]. First-trimester severe hypoglycemia is independently related to a history of severe hypoglycemia before gestation, a long duration of diabetes (>10 years), and an HbA_{1c} ≤48 mmol/mol (6.5%) [193]. All the guidelines add the caveat that these targets should be relaxed if there is "undue" hypoglycemia or hypoglycemia unawareness. Reassuringly, the limited evidence from clinical trials suggests that the outcomes of moderately tight glycemic control (fasting blood sugar 5.0–6.5 mmol/L) are not inferior to those of "tight" glycemic control [194]. In a large observational study, the risk of some adverse outcomes (macrosomia, pre-eclampsia, early delivery, and neonatal hypoglycemia) were elevated only when the 26-week HbA_{1c} was ≥48 mmol/mol (6.5%) [195] (cf. ≤42 mmol/mol, 6.0%, recommended by ES and ADA).

Ketone testing is recommended by the ADA and NICE for women with T1DM who become ill or and/or hyperglycemic. Urine ketone (acetoacetate) estimation has been the traditional method of testing for ketosis, but some blood glucose meters can (with the use of special strips) also quantitate β-hydroxybutyrate in the blood. Although more expensive, these have the advantage of providing more immediate information than urine tests.

Choice of insulin

The introduction of each new insulin formulation has been followed by a period of uncertainty as to whether it is safe in pregnancy. Relatively small non-inferiority trials were undertaken for insulin detemir and aspart, but often acceptance of the use of a new insulin in pregnancy follows when observational studies of women who were using it before conception and continue it through pregnancy do not indicate harm [196]. All the guidelines now suggest that quick-acting insulin analogs such as lispro or aspart are preferred for mealtime coverage. There is less agreement about the choice of basal insulin. NICE still suggests that isophane insulin should be the first choice. The ADA suggests that women already taking insulin or glargine should be transitioned to isophane, but the ES recommends that women already using insulin detemir or glargine continue these agents through pregnancy. The so-far unproven theoretical risks of the newer long-acting insulins (which are centered on transplacental transfer and potential mitogenicity) [197] have to be balanced against the risks of losing good glycemic control during the transfer process.

Table 61.7 Comparison of guidelines on management of diabetes in pregnancy.

	Issuing group			
Parameter	**NICE 2015**	**ADA 2014**	**CDA 2013**	**Endocrine Society 2013**
Glycemic targets prepregnancy				
Preprandial (mmol/L)	<5.3	NS	NS	≤5.3
Postprandial (mmol/L)	<7.8 (1 h) <6.4 (2 h)	NS	NS	≤ 7.8 (1 h) ≤ 6.7 (2 h)
HbA_{1c} (mmol/mol)	<48 (6.5%)	<53 (7.0%)	<53 (7.0%)	<48 (6.5%)
Glycemic targets in pregnancy				
Preprandial (mmol/L)	3.5–5.9	3.3–5.5	≤5.3	
Postprandial (mmol/L)	<7.8 (1 h)	5.6–7.2 (1 h)	<7.8 (1 h) <6.7 (2 h)	<7.8 (1 h] <6.7 (2 h)
HbA_{1c} (mmol/mol)	"Consider" use—not routine	≤42	NS	≤42
Long-acting insulin	Switch glargine/detemir to NPH insulin	NPH or detemir—stop glargine	Continue detemir or glargine	
Retinal screening intervals	Booking and 28 weeks (all)	Booking and 3rd trimester (all)	Booking and as indicated	Booking and as indicated
Weight gain in pregnancy	NS	IOM guidelines[a]	NS	IOM guidelines[a]

Continuous subcutaneous insulin infusion (CSII) therapy

CSII therapy has been widely used in the management of pregnancy in women with T1DM, and to a lesser extent in women with T2DM. There may be particular women, for example with recurrent hypoglycemia, a pronounced "dawn phenomenon" or labile glycemia who benefit from the insulin delivery by CSII, but there is no evidence that in general the outcomes are any better than with the use of multiple daily injection regimens [198]. There are also some risks — of hyperglycemia or ketoacidosis in the event of pump failure — and also increased costs. However, women whose diabetes is well managed with CSII preconception usually choose to continue it through pregnancy.

Continuous glucose monitoring (CGM)

CGM has been explored in a small number of trials in women with (mainly) T1DM. One small randomized controlled trial (RCT) [199] found that HbA_{1c} in late pregnancy and mean birth weight were lower than in women using CGM (although the latter may have been influenced by the high number of twin pregnancies in the CGM group), but a larger RCT [200, 201] found no evidence that CGM was more effective than frequent self-monitoring of blood glucose. An analysis of data from both of these trials showed that women who developed large-for-gestational-age infants had higher glucose values in the early morning and afternoon in the second trimester and in the evening in the third trimester [202]. A larger study of CGM in women with T1DM (CONCEPTT) is nearing completion. One small study has suggested a possible role in managing hyperglycemia induced by steroid treatment in women at risk of preterm birth [203].

The ADA suggests that continuous blood glucose monitoring would be helpful for selected women if there are problems with hypoglycemia unawareness. NICE suggests that CGM should be considered in pregnant women on insulin therapy who have problematic severe hypoglycemia (with or without impaired awareness of hypoglycemia) or who have unstable blood glucose levels (to minimize variability), or to gain information about variability in blood glucose levels.

Insulin requirements during pregnancy

The dose of insulin required to maintain good glycemic control varies substantially through pregnancy. In the early weeks of pregnancy, insulin doses may increase (particularly if glycemic control was poor coming into pregnancy), or decrease (particularly if there is marked pregnancy-associated sickness), or remain similar to prepregnancy levels. At ~20–24 weeks' gestation, insulin requirements typically start to rise in response to increasing insulin resistance. The degree of change is very variable, averaging ~100%, but ranging from very little to a >200% increment. The degree of change is closely related to maternal weight gain,

particularly between weeks 20 and 29 [204]. On a weight-adjusted basis (U/kg), the typical increment in women with T1DM is of the order of 60–65% [205]. Insulin requirements may be higher in twin pregnancies; in one study, the weekly increase in insulin dose between 14 and 27 weeks was doubled compared with singleton pregnancies [206]. In women using continuous insulin infusion pumps, both basal and bolus doses increase, but the proportionate change is greater for the latter [207, 208].

Insulin requirements tend to peak between 32 and 36 weeks' gestation and a fall in insulin doses is not uncommon in late pregnancy. Small falls from the peak insulin dose do not seem to be of clinical significance [209, 210], but larger falls (>15%) may be associated with pre-eclampsia and placental insufficiency [211]. Very large falls in insulin requirements in late pregnancy (>35%), particularly if accompanied by severe headache, can indicate the rare event of antepartum pituitary necrosis [212]. Insulin requirements drop abruptly after delivery. In women with T1DM, doses typically average two-thirds of the prepregnancy insulin dose, or one-third of the dose at the end of pregnancy by the third postpartum day, and the same as that before pregnancy by the end of the first postpartum week [213]. If insulin treatment was first started in pregnancy, it can be stopped after delivery in almost all women with GDM and many with T2DM.

Retinal assessment

NICE guidelines (Table 61.7) suggest that retinal photographic screening be performed at booking and at 28 weeks' gestation in all women with pre-existing diabetes, with more intensive follow-up of those with any retinopathy. The ADA similarly recommends that women with no or minimal retinopathy on the initial examination should have follow-up retinal examination in the third trimester; those with mild retinopathy should be evaluated every trimester, and those with more advanced retinal disease should be evaluated at intervals determined by an ophthalmologist. The ES recommends ocular assessment soon after conception and then "periodically as indicated"—meaning more intensive follow-up in those with established retinopathy. In practice, it appears safe to omit the 28-week review in low-risk women (no retinopathy and low glycated hemoglobin levels in early pregnancy).

NICE specifically comments that the presence of diabetic retinopathy should not be considered a contraindication to rapid optimization of glycemic control in women who present with a high HbA_{1c} in early pregnancy. None of the guidelines discusses retinal screening for women presenting with GDM whose early pregnancy blood glucose or HbA_{1c} suggests that they have previously unrecognized diabetes. However, this should be considered, as retinopathy may be present (Figure 61.4).

Renal assessment

If renal assessment has not been undertaken in the preceding 12 months in women with pre-existing diabetes, NICE recommends that this is arranged at booking. If the serum creatinine is abnormal (≥120 μmol/L), the urinary albumin : creatinine ratio is > 30 g/mol, or total protein excretion exceeds 2 g/day, referral to a nephrologist should be considered. Women with known renal disease should be carefully monitored by regular measurements of blood pressure, urine albumin or protein excretion, and serum creatinine. eGFR estimates are not accurate in pregnancy, but a rising serum creatinine has serious implications. Antihypertensive agents suitable for use in pregnancy include methyldopa, nifedipine, hydralazine, and labetolol; the aim should be to keep blood pressure below 140 mmHg systolic [214]. NICE suggests that thromboprophylaxis should be considered for women with proteinuria >5 g/day.

Management of T2DM in pregnancy

T2DM in pregnancy was rare until the 1980s, but it is a problem of ever-increasing importance [3, 79]. T2DM is prevalent amongst the poor, in migrant and minority communities (including, in North America, Australia, and Aotearoa [New Zealand], marginalized indigenous peoples), and in the mentally unwell. Although, on average, the duration of diabetes is shorter and glycemic control better, there are often special difficulties that make it a challenge to achieve optimal outcomes. The challenges include language and cultural difference, poverty, low educational attainment, and obesity. These are reflected in the frequent late presentation to diabetes services and low rates of referral and attendance for prepregnancy counseling [3, 215].

The management of T2DM in pregnancy is similar to that of T1DM. Many women are taking metformin, sulfonylureas, or other antidiabetes agents at the time of conception. The great majority (>95%) of women with T2DM require insulin therapy and, because of obesity, insulin doses may be greater than in T1DM. With the exception of metformin, all the other antidiabetes agents should be stopped as their safety has not been determined. There is no trial evidence to indicate that in T2DM pregnancy the use of metformin in addition to insulin is superior to insulin alone, but it does not appear to be harmful [216, 217]. A large RCT in Canada is examining whether the addition of metformin to standard insulin treatment is beneficial.

Obstetric monitoring

Fetal ultrasound examination has become an indispensable tool, used at various stages of pregnancy. The NICE guidelines [102] outline the standard approach:

- *Scan at 7–9 weeks* (or at first presentation, if later) to confirm viability and gestational age.
- *Scan at 12–14 weeks* for nuchal translucency, if screening for trisomy 21 is being undertaken (in conjunction with β-HCG and PAPP-A serum measurements). (Note: this screening method is likely soon to be superseded by cell-free DNA analysis.)
- *Scan at 18–20 weeks* for detecting structural anomalies and examination of the four-chamber view of the fetal heart and outflow tracts. If major congenital anomalies are identified, then elective termination can be discussed with the women.

- *Scan at 28, 32, and 36 weeks* to monitor fetal growth and amniotic fluid volume. Accelerated growth of the fetus—particularly the abdominal circumference (Figure 61.3)—and polyhydramnios are common features of poorly controlled diabetes, but neither is specific. Accelerated fetal growth is common in obese women and in those with excess gestational weight gain. The normal range for amniotic fluid volume varies considerably.

Other tests advocated as routine assessments for women with diabetes in some countries include *non-stress testing* (NST) and performing a *biophysical profile* (BPP) [218]. The NST involves recording of the fetal heart rate and uterine activity for 20–40 min in late pregnancy. If the fetal heart rate baseline is 110–160 beats per minute (bpm), and has a variability of 5–25 bpm with at least two acceleration peaks of 15 bpm for > 15 s, and no concerning decelerations, the NST is called "reactive," which suggests that the baby is actively moving and is not acidemic or hypoxic. The NST is called "non-reactive" when it does not meet these criteria. A reactive NST is reassuring and over 99% of cases are expected to survive over the following week, but the value of this test in predicting late fetal death or guiding intervention in diabetic pregnancy has not been proven, and the false-positive rate is very high. This test is most valuable in pregnancies with intrauterine growth restriction. NST may be used in conjunction with the other ultrasound variables in the BPP. Four measures derived from 30-min continuous ultrasound monitoring are made: fetal breathing, gross body movement, tone (the movement from flexion to extension and back again of a fetal limb), and the depth of amniotic fluid. Each is scored from 0 to 2 points, with scores of 8–10 considered reassuring. As with NST, the value of this test in predicting late fetal death or guiding intervention is unproven in diabetic pregnancy, and its value lies mainly in the evaluation of the fetus affected by intrauterine growth retardation.

Doppler studies of the fetal umbilical artery are useful for assessing placental vascular resistance. In particular, routinely measuring the systolic/diastolic flow ratio in the umbilical artery in fetuses with intrauterine growth retardation has been shown to improve offspring outcomes by optimizing the timing for delivery (mostly by reducing induction of labor and delaying delivery), but also aiding the differentiation of the truly growth-restricted fetus from those that are constitutionally small, but with a normal umbilicoplacental circulation. Doppler velocimetry has not been shown to be effective in the surveillance of the large fetus in which the pregnancy may be complicated by problems other than those affecting the uteroplacental circulation.

Appointment scheduling additional to the ultrasound appointments outlined above should be determined on an individual basis. When easy telephone or email contact can be maintained with a woman whose glycemic control is good and there are no complications, unnecessary clinic attendance should be avoided, but visits will become more frequent closer to the end of pregnancy when monitoring for pre-eclampsia and decisions about the timing and mode of delivery are needed. Women with difficult-to-manage glycemic control, diabetic complications, or fetal growth abnormalities need more frequent visits.

Labor and delivery

NICE and other expert bodies recommend that women with T1DM or T2DM and no other complications should have an elective birth by induction of labor, or by elective cesarean section between 37 weeks + 0 days and 38 weeks + 6 days of pregnancy. Birth before 37 weeks + 0 days should be considered for women if there are concerning metabolic problems or any other maternal or fetal complications [102, 219]. Women with T1DM are, on average, delivered earlier than those with T2DM. In the recent UK audit, 60% of women with T2DM had pregnancies continuing into the 39th week, compared with 39% in women with T1DM [3].

The rates of preterm birth (delivery at <37 weeks' gestation) are 2–3-fold higher among women with pregestational diabetes than among women without diabetes. The majority of this increase is due to elective preterm delivery (6–7-fold higher than in women without diabetes), but spontaneous preterm delivery is also increased (~50% higher). Rates of both elective preterm delivery at <35 weeks' gestation and spontaneous preterm delivery are also higher in women with diabetes [220]. Nulliparity, progression of nephropathy, pre-eclampsia, and HbA_{1c} ≥53 mmol/mol (7%) at delivery are all strongly associated with indicated preterm delivery [221], as is poorer maternal mental health [222]. Preterm delivery is associated with significant neonatal morbidity, particularly neonatal hypoglycemia and respiratory distress syndrome [221].

The practice of early delivery means that rates of induction of labor are high, and inevitably this means that there will be cases of failure of labor to progress and increased rates of maternal and fetal distress. This is one of the main drivers behind the high rates of cesarean section in women with diabetes, which in most series varies between 40 and 65%. Once a woman has had a primary cesarean section then the probability is high that any future pregnancy will be delivered in the same way. Several diabetes-related factors such as maternal obesity, fetal macrosomia, polyhydramnios, and microvascular complications have also been associated with an increased risk of cesarean delivery [223–226]. Cesarean section rates are similar in T1DM and T2DM [227, 228]. Secular trends towards increasing maternal age and obesity mean that it is unlikely that the high cesarean section rates can be substantially reduced.

Management of glycemia during labor

Avoiding intrapartum maternal hyperglycemia may reduce the likelihood of subsequent neonatal hypoglycemia [101]. In women using insulin in pregnancy, maternal glycemia is usually controlled during induction of labor by an intravenous infusion of regular insulin, titrated to maintain hourly readings of blood glucose at 4–7 mmol/L [102, 229]. Women having elective cesarean sections can often continue their usual insulin regimen. Women who are using an insulin pump may continue their basal infusion during labor where units are familiar with pump use.

General management

Breastfeeding

Breastfeeding is encouraged in women with diabetes, but the rates are often disappointingly low [230, 231]. One factor is that babies born early are often separated from their mothers at birth for neonatal care, and so there is difficulty establishing breastfeeding. Previous positive experience of breastfeeding and higher educational level are strong predictors of success in breastfeeding [232, 233]. In women who are breastfeeding and still taking insulin, the postpartum insulin requirements are typically ~10% lower than before pregnancy [232]. For women with T2DM, metformin, glibenclamide (glyburide), and glipizide all seem to be safe during lactation, as the levels appearing in breast milk are low [234].

Family planning

Having a baby is no small undertaking for women with diabetes, and given a natural concern for their own long-term health (particularly in those who already have diabetic complications), many women choose to limit the size of their families [235]. One of the most important conversations that physicians, midwives, and obstetricians need to have with women with diabetes concerns their long-term outlook, their future plans, and the need for contraception (see Chapter 49). This discussion should begin before delivery, particularly if a cesarean delivery is likely, as many women elect to have tubal ligation at the time of their cesarean section.

Fetal overnutrition: gestational diabetes, obesity, and gestational weight gain

The traditional view of diabetes in pregnancy has been dominated by the importance of maternal hyperglycemia in providing excess nutrition, and hence accelerating fetal growth. However, both maternal obesity and excessive weight gain in pregnancy are characterized by energy intake in excess of need and so are also important factors in fetal overnutrition. In high-income countries there has been a marked secular trend towards increasing obesity that has driven the rising incidence of T2DM. This is also reflected in the obstetric population [236]. The trend to increasing birth weight is largely explicable by increased maternal obesity and a reduction in cigarette smoking [237].

Maternal obesity is associated with an increased risk of early miscarriage [56] and late fetal death [4–8]. The risk of late fetal death is clearly related to the degree of obesity [4, 5, 8] and is particularly linked to placental diseases, hypertension, fetal anomalies, and umbilical cord abnormalities [238]. The risk of many other poor outcomes is also increased by maternal obesity. These include: pre-eclampsia, pregnancy-induced hypertension, respiratory, wound, and urinary tract infections, venous thromboembolism, large-for-gestational-age infants, shoulder dystocia, perineal tears, and increased rates of cesarean section (and operating time) and neonatal intensive care admission [8, 239–248]. Although GDM is associated with maternal obesity, the latter has a greater impact on these adverse outcomes [239, 249–251]. Interpregnancy weight gain is also associated with poorer outcomes in subsequent pregnancies [252, 253].

These same pregnancy and neonatal morbidities are also associated with excessive gestational weight gain [250, 251, 254–260] and, although GDM is associated with greater weight gain (particularly in early pregnancy [261, 262]), it is the weight gain that has the dominant effect on fetal growth [248, 249]. In an RCT of limiting gestational weight gain in obese women, the proportion of large-for-gestational-age babies was reduced by 65% in the intervention group [259]. The same effects of gestational weight gain, independent of HbA_{1c}, can also be found in the pregnancies of women with T1DM and T2DM [263–267].

The US Institute of Medicine has issued guidelines [268] suggesting targets for healthy weight gain in pregnancy, with women who were overweight or obese at the onset of pregnancy having lower targets than underweight or normal weight women (Table 61.8). These guidelines suggest that obese women limit their total pregnancy weight gain to 5–9 kg, but even lower targets (including weight loss) might be associated with better outcomes [269, 270]. Obese women who lose or gain <5 kg in weight in pregnancy have babies that are on average 190 g lighter than those with weight gain >5 kg (with a rate of small-for-gestational-age babies that matches that in the non-obese) [271].

Gestational diabetes

Background

The concept of GDM arose from observations made in the 1930s and 1940s that women who later developed what we now call T2DM were overweight and had reproductive histories with an unexpectedly high incidence of large babies and fetal losses. The term "gestational diabetes" was introduced in the 1950s for women with poor obstetric histories who, during a subsequent pregnancy, had high glucose levels (on oral glucose tolerance testing). Treating hyperglycemia in the subsequent pregnancy seemed to be associated with better perinatal outcomes [2].

In the 1960s, O'Sullivan and colleagues published a series of studies of glucose tolerance in pregnant women. These women were followed postpartum with annual glucose tolerance tests, and a significant proportion went on to develop T2DM. From these studies, diagnostic criteria for GDM were proposed on the basis of the pregnancy glucose tolerance test's ability to predict future diabetes. According to these criteria, the prevalence of GDM at that time was ~2%.

A crucial change occurred in 1979, when the US National Diabetes Data Group (NDDG) recommended that GDM be recognized as a distinct diagnostic entity [272]. The NDDG argued that recognition of GDM was important not only because of the high risk of later developing diabetes, but also because "therapy can prevent much of the associated perinatal morbidity and mortality" (although this had not been demonstrated at the time). It was recommended that all pregnancies should be screened, using a two-step testing procedure (a 50-g non-fasting glucose challenge test,

Table 61.8 Institute of Medicine weight gain recommendations for pregnancy.

Prepregnancy[a] weight category	BMI[a] (kg/m^2)	Recommended range of total weight gain (kg)	Recommended rate of gain[b] in 2nd and 3rd trimesters: mean and range (kg/week)
Underweight	<18.5	13–18	0.45 (0.45–0.59)
Normal weight	18.5–24.9	11–16	0.45 (0.36–0.45
Overweight	25.0–29.9	7–15	0.27 (0.23–0.27)
Obese (grade 1)	30.0–34.9	5–9	0.23 (0.18–0.27)
Obese (other grades)	≥35.0	<5	<0.20

followed, if positive, by a formal glucose tolerance test). The definition of GDM adopted by the NDDG was *any degree of glucose intolerance with onset or first recognition during pregnancy.* This created a problem in that it conflated into a single entity a spectrum ranging from mildly, but transiently, elevated blood glucose levels in the third trimester through to previously unrecognized (most commonly type 2) diabetes. The concept of GDM as a specific diagnostic type of diabetes was adopted by the WHO in their 1980 guidelines. The NDDG proposals were adopted in North America and elsewhere, although many countries developed individual screening protocols, testing regimens, and diagnostic criteria. As with the NDDG criteria, all were decided by expert opinion and typically yielded rates for GDM of 2–6%.

There were a number of valid criticisms of this approach. First, the diagnostic criteria were based on the mother's future risk of diabetes [10], rather than immediate maternal and fetal outcomes. Second, it was not clear whether the links between dysglycemia in pregnancy and perinatal morbidity were causal or incidental associations. Finally, there was uncertainty as to whether treatment conferred significant benefit [273, 274].

RCTs of treatment of mild GDM

Some clarity concerning the final point came from two RCTs of the treatment of mild GDM: the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) and the Maternal–Fetal Medicine Units Network (MFMU) [275, 276] (with "mild" GDM defined as levels of hyperglycemia that would not meet the diagnostic criteria for diabetes outside pregnancy). In both studies, GDM was identified using a two-step diagnostic procedure (but with different diagnostic criteria for the 2-h glucose tolerance test), and ~1000 women with mild GDM were randomized to treatment or no treatment The women in the MFMU study were somewhat less hyperglycemic than those in the ACHOIS cohort, and so fewer women in the active management group were treated with insulin in the MFMU study (8% vs. 20%). Both studies used composite endpoints as their primary outcome measure, because too great a sample size would be required to demonstrate an effect on individual components. Neither study reported the between-group difference in achieved blood glucose measurements.

In the ACHOIS study [275], the composite primary outcome of "any serious perinatal complication" was more frequent (4% vs. 1%) in the routine care group. The significance of this difference was critically dependent on the high number of perinatal deaths (five deaths, or 1% vs. 0%) in the routine care group). However, some of the deaths could not plausibly be attributed to the non-treatment of GDM; for example, one infant had a lethal congenital anomaly and another had severe intrauterine growth retardation. A number of secondary outcomes differed between the groups: maternal weight gain was less and the mean birth weight was 145 g lower in the intervention group. Consequently, there were fewer babies born weighing >4 kg (10% vs. 13%), and the rate of shoulder dystocia was reduced from 3.2% to 1.4%. The rate of pregnancy-associated hypertension was lower in the intervention group (12% vs. 18%) but the cesarean delivery rate was the same. There was a significantly increased rate of induction of labor in the intervention group (39% vs. 29%) and a higher proportion of infants in the intervention group were admitted to neonatal intensive care (71% vs. 61%), with more neonates in the intervention group developing either hypoglycemia requiring treatment or respiratory distress syndrome.

In the MFMU trial [276], there were no differences between the groups in the composite primary outcome score and so the trial produced a clear negative result. A number of secondary outcomes, however, did differ between the groups: maternal weight gain was less and the mean birth weight was 106 g lower in the intervention group, with fewer babies born weighing >4 kg (6% vs. 7%), and the rate of shoulder dystocia was reduced from 4.0% to 1.5%. The rate of pregnancy-associated hypertension was lower in the intervention group (8.6% vs. 13.6%) and the cesarean delivery rate was also lower (27% vs. 34%).

The effectiveness of GDM treatment compared with usual antenatal care in the prevention of adverse pregnancy outcomes has been the subject of two meta-analyses, which were dominated by data from the ACHOIS and MFMU trials. Both meta-analyses concluded that detection and treatment GDM defined by two-step testing were associated with a reduction in macrosomia and large-for-gestational-age infants by ~50%, with a similar reduction in rates of shoulder dystocia. There was moderate quality

evidence that treatment reduces pre-eclampsia and hypertensive disorders in pregnancy [277, 278]. In summary, the intervention trials in mild GDM (defined by two-step testing) confirmed that treatment makes babies 2–3% lighter (so the incidence of large babies is lower), reduces the incidence of shoulder dystocia, and may reduce the incidence of hypertensive disorders of pregnancy. However, it is not clear if these effects were primarily due to lower maternal blood glucose values or to less maternal weight gain.

The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study

To clarify better the association of fetal morbidity and other pregnancy outcomes with the degree of maternal hyperglycemia, a major international collaboration, the HAPO study, was established. In the study, 23,316 women had a 75-g glucose tolerance test performed at 24–32 weeks' gestation. All women who had a fasting blood glucose ≤5.8 mmol/L and 2-h values up to 11.1 mmol/L were included. The study was observational and clinicians were blinded regarding the glucose tolerance test results. The major aim was to determine a level of glycemia beyond which maternal and infant risks clearly increased, to inform the selection of scientifically valid universal diagnostic criteria for GDM.

The study had four primary endpoints: two were of direct clinical importance (primary cesarean section rate and neonatal hypoglycemia), one was an intermediate outcome (birth weight), and one a surrogate outcome (cord-blood serum C-peptide level >90th centile for gestational age) [279]. The major findings were of continuous, independent relationships between untreated maternal blood glucose (fasting, 1-h and 2-h post-glucose load) and each of the outcomes, with the cord blood C-peptide level (reflecting fetal hyperinsulinemia) and birth weight >90th centile showing the strongest association with maternal blood glucose. There was no association between perinatal mortality and blood glucose levels. The differences in mean birth weight between the lowest and highest glucose categories for the three glucose measures ranged from 242 to 305 g [279].

The International Association of Diabetes Pregnancy Study Groups (IADPSG) recommendations

In the light of the HAPO findings, the IADPSG met in 2008 to determine the glucose thresholds for diagnosing GDM. The group mainly comprised physicians, with notably little input from primary care providers, midwives, public health experts, or patient representatives. The group made four important consensus recommendations [280]:

- Screening for "overt diabetes" be undertaken at the first prenatal visit, with the diagnosis based on a fasting plasma glucose ≥7.0 mmol/L or an HbA_{1c} ≥48 mmol/mol (6.5%).
- Glucose levels associated in the HAPO study with a 1.75-fold increased risk above the mean for birth weight, cord C-peptide, and percentage body fat >90th percentile would constitute a diagnosis of GDM.
- One abnormal glucose value of three in a 75-g glucose tolerance test would suffice for diagnosis (fasting 5.1–6.9 mmol/L; 1-h value ≥10.0 mmol/L; 2-h value 8.5–11.0 mmol/L).
- A single glucose tolerance test could be adequate and that two-step testing be abandoned.

The ADA endorsed the IADPSG recommendations in 2011, and they have also been adopted by diabetes associations in several countries, including Australia, Brazil, and China. While the first recommendation—screening for undiagnosed diabetes—has been generally welcomed, there has been considerable disquiet about the others. Adoption of the IADPSG regimen and diagnostic criteria has meant that in most countries the prevalence of GDM has doubled or trebled to ~20% or more of pregnancies; in southern China it is nearly 40% [281]. Although one report has suggested that the IADPSG criteria might be effective at reducing morbidity and costs [282], several others have not [281, 283–285]. This has led to considerable debate about the wisdom and affordability of the move and concerns about overdiagnosis [286–289]. The main concerns (summarized in Table 61.9) fall into two broad categories: issues regarding the scientific validity and the undesirable downstream impact.

The key scientific concerns are as follows: (a) the reliance on a single blood glucose result, given the known high variability

Table 61.9 Concerns about the WHO/IADPSG diagnostic criteria for GDM.

Concern	Comment
Reliance on a single blood sugar result	Post-load blood glucose values are very variable, with poor reproducibility
The arbitrary 1.75 risk threshold	Relative risks derived from observational studies should be >3 for reliability [290]
Criteria not based on clinically significant outcomes	Birth weight, percentage body fat, and cord C-peptide are surrogate or intermediate outcomes
No evidence of treatment benefit	No RCT of treatment in the additional women diagnosed by the IADPSG criteria. Clinical benefits likely to be modest at best
Increased intervention	A diagnosis of GDM makes interventions more likely, irrespective of glycemia and fetal size
Cost-effectiveness	Modeling suggests criteria would be cost-effective only if cesarean section or maternal diabetes can be prevented
Resource diversion	Large number of mild "cases" diverts resources from women with pregestational diabetes who benefit most
Medicalization	Pathologizes pregnancies that were hitherto thought to be healthy

of post-load glucose values; (b) the use of surrogate measures of limited clinical significance as the main outcome descriptors; (c) the arbitrary 1.75 risk threshold, which epidemiologists regard as too low—risk ratios of 3–4 derived from observational studies are more reliable [290] (note: if the IADPSG criteria were used but requiring a high fasting *and* at least one high post-load result for diagnosis, then the risk threshold would be ~3 [291], which could resolve both the statistical and "one abnormal test" issues); and (d) the lack of any RCT data on benefits of treatment at these thresholds, given that the trials of treatment in GDM at conventional thresholds showed only modest benefit [275–278].

Despite the concerns outlined above, the WHO's committee (in which IADPSG members were prominent) adopted the IADPSG criteria in 2013 [37]. The priority of the WHO committee seemed to be the establishment of an international standard rather than strong science, admitting that the quality of evidence for the position was "very low" and the strength of their recommendation was "weak" [37].

However, the hoped-for unanimity in the diagnosis of GDM has not materialized. For example, neither the 2013 National Institutes of Health Consensus Conference nor the American Congress of Obstetricians and Gynecologists endorsed the IADPSG guidelines. Most recently, the 2015 NICE guideline opted for different diagnostic criteria [102].

A number of countries have continued to develop their own approaches. A summary of some recent international guidelines is given in Table 61.10.

The IADPSG–WHO [37] and the New Zealand criteria [292] have a distinct focus on the early detection of previously unrecognized diabetes, with all pregnancies being screened by random glucose in the former and HbA_{1c} in the latter. The current UK [102], Canadian [183], and American [293] guidelines recommend testing for unrecognized diabetes only if there are risk factors. The New Zealand approach creates a new pathophysiological "entity," that is, women with an HbA_{1c} in the prediabetes range in early pregnancy. Around one-third of women in this category will have GDM when tested later in pregnancy [294], but it is not yet

known whether earlier treatment (after detection in early pregnancy) has definite advantages over later treatment (from 24 to 28 weeks).

With regard to testing at 24–28 weeks' gestation, the UK remains the exception in recommending risk factor-based testing, whereas other countries recommend testing of all pregnancies. The NICE criteria were based on evidence derived from routine observational data sets comprising more than 40,000 pregnant women across 14 centers, including the HAPO centers in the UK and Australia, along with other UK centers. The majority of centers used risk factor-based selective screening, but just over 12,000 women had been screened by a universal screening process. NICE rejected the IADPSG criteria, deeming them to be not cost-effective based on health economic modeling in a subset (n = 18,974) of these women for whom fasting, 1-h, and 2-h glucose values were available. There are many uncertainties in such analyses. In particular, the cost-effectiveness of selective versus "universal" screening depends on the prevalence of GDM within a given community [295]. The UK glucose tolerance test 2-h threshold for diagnosis is substantially lower than those in all the other guidelines, and the differences in the fasting and 2-h criteria between the IADPSG–WHO and the NICE guidelines mean that different populations are identified as having GDM: the former include more women with mild elevations in fasting blood glucose and the latter more with mild elevations in postprandial blood glucose. The concordance rate for a diagnosis of GDM may be as low as 55%.

The continued divergence in the approach to diagnosis is confusing for healthcare practitioners and pregnant women. To add to the confusion, both the CDA and ADA guidelines suggest that the IADPSG–WHO criteria are alternatives to previously developed criteria in these countries, despite doubling the chance of being diagnosed [183, 293], and, in the USA, the 100-g glucose tolerance test has two alternative sets of diagnostic criteria [293] (Table 61.10).

GDM: disease or risk factor?

That this unsatisfactory situation persists despite a great deal of research (more than 7000 papers on GDM have been published since 2000) suggests that perhaps we have not been addressing the right questions. There seem to be two conceptual roadblocks: first, the conflation of all degrees of glucose intolerance in pregnancy into a single entity, and second, the idea (enshrined in 1979) that GDM is a distinct disease entity. We know that both the risks to the fetus and the mother's risk of later T2DM are continuously related to the degree of glycemia, and so hyperglycemia in pregnancy might be more usefully viewed as a risk factor rather than a "disease" requiring "diagnosis" [286, 289, 292]. The questions that then arise include: What is it a risk factor for? How do we quantify the risk? What are the other risk factors for these outcomes? Who benefits, and by how much, from what intervention?

At the top end of the spectrum, in women with previously undiagnosed diabetes, the risks of major congenital anomalies and perinatal mortality are comparable to those seen in women with established diabetes [33–35], hence the growing consensus that it is worth identifying such cases as early as possible in pregnancy. At the lower end of the spectrum, the risk is primarily of excessive fetal growth (macrosomia) [285], but, as discussed above, it is by no means the only risk factor. We should not forget that macrosomia itself is not a disease, but a risk factor for a number of adverse outcomes [70, 286]. As currently defined, not all women with GDM have significant risk, and only a minority benefit from treatment [296]. Perhaps future research needs to be less "glucocentric" and should concentrate on identifying those fetuses at greatest overall risk of the adverse outcomes we are trying to prevent, and determining which would benefit most from what treatment.

Management of GDM

Nutritional therapy is an integral part of the treatment of women with GDM, with the key principles being to reduce overall energy intake and limit the proportion derived from carbohydrates (see Chapter 25). Several dietary modifications can lower glucose levels effectively. These include reducing caloric intake for overweight and obese women (e.g. to ~25 kcal/kg body weight) [297] and limiting carbohydrate content to 35–40% of total calories [298] while focusing on carbohydrates with a low glycemic index. Similar lifestyle interventions implemented in early pregnancy can reduce gestational weight gain and the incidence of GDM [299].

Women with GDM are also encouraged to undertake self-monitoring of blood glucose to help decide if additional pharmacological therapy is needed. Women are usually asked to measure capillary glucose levels before breakfast and 1–2 h after breakfast, lunch, and dinner, but the optimal timing and frequency of monitoring have not been determined. One study, often cited as proof that postprandial glucose targets are more important than preprandial targets, compared rather low postprandial targets with fairly high preprandial targets [300], thus biasing the design in favor of postprandial monitoring. Treatment targets have varied among studies that have demonstrated improved perinatal outcomes. The NICE-recommended targets are fasting plasma glucose levels <5.3 mmol/L, 1-h postprandial glucose levels <7.8 mmol/L, and 2-h postprandial glucose levels <6.3 mmol/L [102]. Most other international bodies recommend a higher 2-h postprandial target of <6.7 mmol/L, a figure with support from clinical trials [274, 275]. Fasting blood glucose levels of ≥5.8 mmol/L are associated with an increased risk of preventable perinatal complications [301, 302] and are thus an indicator that pharmacological treatment is likely to be of benefit. NICE recommends that women with a fasting blood glucose level of ≥7.0 mmol/L at diagnosis of GDM should be treated with insulin in preference to oral antidiabetes drugs [202].

The major effect of treating mild GDM is to slow fetal growth to reduce fetal macrosomia. It is not clear whether fetuses that are small or normal sized benefit from treatment. Buchanan's group used fetal abdominal circumference measurements obtained by ultrasonography to help identify the substantial proportion of pregnancies that will not incur a perinatal complication in

the absence of intensified treatment. In pregnant women with a fasting plasma glucose level <5.8 mmol/L, a fetal abdominal circumference of <70th centile for gestational age between 29 and 33 weeks of gestation was associated with no excess risk of large-for-gestational-age infants or cesarean deliveries compared with that in pregnant women without diabetes [301], and intensified insulin treatment in pregnancies with a fetal abdominal circumference of >70th centile eliminated the excess of large-for-gestational-age infants [67, 301]. The peripheral blood glucose targets were fasting levels <4.4 mmol/L and 2-h postprandial levels <6.1 mmol/L. These low targets were possible because, when directed to fetuses with accelerated growth, there is virtually no risk of these offspring becoming small for gestational age [302]. None of the major guidelines have endorsed this specific targeted approach, but it has definite attraction, as it matches the major effect of treatment (slowing growth) to the most affected fetuses.

Insulin remains an important treatment option and regimens should be tailored to meet glycemic targets. Regular exercise is often recommended, and there is limited evidence that it may reduce fetal birth weight [303].

Oral antidiabetes agents in GDM

Two important RCTs have explored pharmacological options for mild GDM. One study compared glibenclamide (glyburide) with insulin in women who were deemed in need of intensified treatment on the basis of maternal self-monitored glucose level results [304]. Equivalent perinatal outcomes were observed in the two groups. Only 4% of women assigned to glibenclamide also received insulin to meet prespecified glycemic targets. The other study compared metformin with insulin [305]. Perinatal outcomes were similar in the two treatment groups, but a high proportion (46%) of women assigned to metformin received supplemental insulin to achieve glycemic targets. Unsurprisingly, supplemental insulin was required more often in the most hyperglycemic women; according to the fasting plasma glucose levels at diagnosis of GDM, 20% of those with <5.3 mmol/L, 53% of those with 5.3–6.0 mmol/L, 68% of those with 6.1–6.9 mmol/L, and 81% of those with ≥7.0 mmol/L needed additional insulin treatment.

Glibenclamide use in GDM increased considerably, particularly in the USA, following publication of the RCT in 2000 [304]. With widespread use, concern about its use as a first-line agent has grown [306]. Comparisons with metformin or insulin indicate that glibenclamide use is associated with greater risks of macrosomia and admission for neonatal care, predominantly because of respiratory distress and hypoglycemia [306–311]. The latter effect may be related to placental transfer of glibenclamide to the fetus [312].

Delivery

NICE recommends that women with pharmacologically treated GDM should be delivered before 40 weeks' gestation is reached [202]. A US modeling analysis suggested that delivery at 38 weeks' gestation may be optimal at balancing the risks of late intrauterine death and death from the consequences of prematurity [313], but in practice obstetricians estimate risk on an individual basis, and women with mild GDM well managed with diet and lifestyle, without macrosomia and with no other pregnancy complications, can safely go to near term before delivery.

Postpartum reclassification of diabetes

Women diagnosed with GDM need to be reclassified postpartum. Some will have newly recognized or incipient T1DM or genetic diabetes, but the majority will be on the metabolic syndrome spectrum and postpartum demonstrate either normal glucose tolerance, pre-diabetes, or T2DM. It cannot be assumed that all those diagnosed with "overt diabetes" in pregnancy will continue to have it postpartum, particularly if significant weight loss has been achieved. Reclassification has traditionally been on the basis of a glucose tolerance test 6 weeks after delivery, but if HbA_{1c} is being used for diagnosis, then testing should be delayed until at least 3 months postpartum.

Long-term effects of GDM

Maternal

GDM is well known to be an antecedent of T2DM, and indeed was originally defined on this basis. For women with GDM, the risk for developing diabetes is increased relative to women with a normoglycemic pregnancy, 4.7-fold within 5 years of having GDM, and 9.3-fold after 5 years or more [314]. It should be noted that this estimate is derived from studies in which GDM was identified by two-step testing, and not from studies in which women were identified by the IADPSG criteria. The risk is likely to be substantially lower if women are identified only by a single blood glucose value.

Unsurprisingly, women with the highest blood glucose levels at diagnosis of GDM, those who needed insulin treatment in pregnancy, those with impaired β-cell function, and those who are overweight and gain most weight after their GDM pregnancy tend to develop T2DM the earliest [314–316]. The identification of women with previous GDM offers a potential opportunity to intervene with modification of lifestyle risk factors to delay the development of T2DM, but there is little evidence that this is being achieved on any large scale.

All guidelines recommend periodic screening for T2DM after a diagnosis of GDM; the new NICE recommendations suggest annual screening by HbA_{1c} starting after the early postnatal (3-month) test [202], although the long-term adherence to such follow-up plans is often poor. GDM is uniquely linked to pregnancy, but in its foreshadowing of T2DM, it is best regarded as a form of prediabetes, with the same risk factors [296], and in this regard not unique to women. If one were to test all the male partners of pregnant women and stratify this population according to the degree of glycemia, then undoubtedly the same phenomenon would be found: the higher the blood glucose, the sooner diabetes will develop.

Offspring

Otherwise healthy newborn babies of women with diabetes tend to be heavier and fatter than average and it has also become evident that later in life the offspring of mothers with T2DM or GDM are at

increased risk for becoming obese and developing diabetes themselves. A widely accepted interpretation of these observations is that exposure to hyperglycemia *in utero* directly drives the development of obesity and diabetes through fetal metabolic programming [317–319]. Although this mechanism cannot be discounted, its importance may well have been overstated [320]. Longitudinal population studies indicate that the most robust risk factors for adolescent obesity are maternal BMI, paternal BMI, maternal occupation, birth weight, maternal gestational weight gain, the number of household members, and smoking habits [321], but the clinical studies claiming to demonstrate a link with maternal glucose tolerance and later obesity and diabetes in the offspring have rarely taken these factors into account. The importance of paternal BMI is emphasized by the observation that GDM in mothers also signals incident diabetes in the babies' fathers, an effect presumably mediated by shared deprivation level and ethnocultural background [322].

The most commonly cited evidence in favor of the theory that exposure to maternal diabetes *in utero* is a risk for T2DM in the offspring comes from the National Institute of Health group studying the O'odham (Pima) people of the Gila River community in Arizona [323–331]. In the Pima studies, the offspring of women with diabetes were significantly heavier than offspring of women without diabetes and women who subsequently developed diabetes [323], but obesity in the offspring was significantly related to both maternal and paternal BMI [324]. Subsequent reports related maternal diabetes status and 2-h blood glucose on a pregnancy glucose tolerance test to the incidence of T2DM in the offspring [325, 326, 331], but no adjustments were made for maternal or paternal BMI. In a study that compared offspring born to the same mother before and after her diagnosis of T2DM, mean BMI was higher in the offspring of the diabetic pregnancy than in the non-diabetic pregnancy, but again no adjustment was made for paternal or maternal BMI or inter-pregnancy weight gain [330].

Further evidence that exposure to hyperglycemia *in utero* is unlikely to be directly causative is that there is no epidemic of obesity and T2DM in the offspring of women with T1DM. Follow-up studies of children in the two large RCTs of treatment of GDM have not demonstrated any effect of treatment on offspring adiposity [332–334].

62 Diabetes in Old Age

Ahmed H. Abdelhafiz[1] and Alan J. Sinclair[2]

[1] Department of Elderly Medicine, Rotherham General Hospital, Rotherham, UK
[2] University of Aston, and Foundation for Diabetes Research in Older People, Diabetes Frail Ltd, Droitwich Spa, UK

Key points

- The prevalence of diabetes is increasing in older people because of increased life expectancy.
- The phenotype of diabetes in old age is characterized by an increased prevalence of multiple comorbidities, geriatric syndromes, and frailty.
- A comprehensive geriatric assessment should be performed at the initial diagnosis of diabetes and annually thereafter.
- A multidisciplinary team approach with a multidimensional assessment, including screening for physical and cognitive function, is important to meet the complex needs of older people with diabetes.
- Hypoglycemia is common in older people with diabetes owing to multiple comorbidities and can be less easily recognized or misdiagnosed because of reduced autonomic symptoms.
- A deterioration in glycemic control, unexplained hypoglycemia or reduced adherence to self-care should alert the clinician to the presence of dementia or depression.
- Tight glycemic control is reasonable in fit older people but a relaxed approach is more appropriate in frail elderly at risk of hypoglycemia.
- An individualized and holistic care plan is key for diabetes care in older people.
- Older people with diabetes living in care homes are particularly vulnerable and require greater specialist input.
- Quality of life should always be the focus for individualized care.

Introduction

With increasing aging of the population and urbanization of lifestyle, the prevalence of diabetes has or is likely to reach epidemic levels in most countries, especially in older people ≥75 years [1]. Aging is associated with body composition changes that lead to increased insulin resistance, glucose intolerance, and increased risk of diabetes [2]. As a result, an increasing number of older people are developing diabetes. The lifetime risk of developing diabetes is high reaching 22.4% for women and 18.9% for men from the age of 60 years [3]. Older people with diabetes are exposed to the interplay between metabolic dysfunction, vascular disease, and the aging process in combination with other age-related disorders. Geriatric syndromes and frailty are emerging as a third category of complications in addition to the traditional micro- and macrovascular disease [4]. Therefore, diabetes in old age may lead to considerable disability. Unlike other chronic conditions, diabetes care is dependent on self-management, which may be compromised by the presence of comorbidities and geriatric syndromes. Owing to the heterogeneous nature and variations in comorbidity, life expectancy and functional status, ranging from a fit individual living independently in the community to a fully dependent person living in a care home, therapeutic interventions and metabolic targets should be individualized taking into consideration individual preference while putting quality of life at the heart of the care plans. This chapter reviews the phenotype of diabetes in old age and addresses the key areas and special considerations for the care of older people with diabetes to meet their complex needs.

Epidemiology

The prevalence of diabetes rises with increasing age. Worldwide, the greatest proportional increase in the number of people with diabetes by age group is expected to occur in people aged 60–79 years [3]. For example, in France, the prevalence has increased to 14.2% in those aged 65–74 years, peaking at 19.7% in men and 14.2% in women aged 75–79 years. More than half of those with diabetes were ≥65 years [5]. In the USA, 14% of the population are estimated to have diabetes and the prevalence is highest in those aged ≥65 years; by 2050 diabetes prevalence could be as high as 33% of the whole population [6]. However, a similar number may remain undiagnosed. In the National Health and Nutrition Examination Survey the prevalence of diagnosed diabetes in those ≥75 years was 14.9% and undiagnosed diabetes based on fasting plasma glucose and 2-hour oral glucose

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

tolerance test was 13.4%, making a total prevalence of diabetes of 28.3% with undiagnosed diabetes constituting around 47%. The prevalence of "pre-diabetes" defined as either impaired fasting glycemia (IFG) or impaired glucose tolerance (IGT) was 46.7% in those aged ≥75 years. Therefore, the total prevalence of diabetes and pre-diabetes was approximately 75% in older people ≥75 years [1]. Low- and middle-income countries will have the greatest burden of diabetes, where the prevalence will increase in adults (aged 20–79 years) by 69% by 2030 compared to only 20% in higher income countries [7]. This is likely driven by the growth and aging of the population and urbanization of lifestyle in these countries. The prevalence of diabetes among older Chinese in rural Taiwan aged 72.6 years was 16.9% in 2000 and increased to 23.7% in 2005 [8]. In minority ethnic groups living in high-income countries, the incidence and prevalence of diabetes is higher than in white European populations. For example, the prevalence of diabetes in older Mexican Americans (≥75 years) has almost doubled between 1993–1994 and 2004–2005 from 20.3% to 37.2% in comparison to an increase from 10.4% to 16.4% in the general population of the same age [9]. Diabetes prevalence in care homes is also high. In 2004, 24.6% of US nursing home residents had diabetes; among residents aged 65–74, 75–84, and ≥85 years, the prevalence of diabetes was 36.1%, 29.5%, and 18.3%, respectively [10]. The prevalence of diabetes has steadily increased in US nursing homes (16.9% to 26.4% in men and 16.1% to 22.2% in women) between 1995 and 2004. A more recent survey showed a further increase in the prevalence of diabetes with 32.8% of residents living with diabetes [11]. Ethnic disparities in diabetes prevalence are also well documented in care home settings. In US nursing homes, the adjusted odds of diabetes are approximately twofold higher in African American and Hispanic residents relative to white American residents with diabetes present in 22.5% of white Americans and 35.6% of those from other ethnic groups [10].

Pathogenesis

Glucose homeostasis requires both normal insulin secretion by the pancreatic β cells and normal glucose utilization by the peripheral tissues that are sensitive to insulin. Diabetes in old age is linked to increased insulin resistance and decreased insulin secretion with a principle defect of insulin resistance in obese individuals and insulin secretion in lean ones. It is likely that both genetic and environmental factors are involved in the pathogenesis of insulin secretory dysfunction and insulin resistance. As older people are heterogeneous, the extent and rate of deterioration in glucose homeostasis is variable, leading to insignificant changes in some individuals and diabetes in others (Box 62.1).

Increased insulin resistance

Aging is associated with body composition changes that result in increased insulin resistance [12]. Increased visceral fat is associated with increased rates of lipolysis causing high levels of free fatty acids which may have a role in reducing peripheral insulin sensitivity [13]. Reduction of muscle mass or sarcopenia occurs with aging through physical inactivity and as the muscle is the main site of glucose consumption, the loss of muscle mass increases insulin resistance [12]. Accumulation of lipids within the muscles is another factor reducing insulin sensitivity. A reduction in mitochondrial function [14] may also contribute to age-related glucose intolerance by reducing oxidative metabolism, physical fitness, and oxidative capacity. Low concentrations of adiponectin, leptin, and insulin-like growth factor-I (IGF-I), and high concentrations of tumour necrosis factor alpha (TNF-α) are associated with aging and linked to increased insulin resistance and incident diabetes [14–16].

Box 62.1 Determinants of glucose intolerance in old age

- Decreased β-cell function
- Reduced β-cell mass
- Increased visceral fat
- Reduced muscle mass
- Mitochondrial dysfunction
- Low concentrations of adiponectin*
- High concentrations of tumour necrosis factor alpha**
- Reduced insulin-like growth factor-I concentration***
- Reduced leptin concentration****
- Physical inactivity
- Altered lipid metabolism

*Secreted by adipose tissue which improves insulin resistance by increasing fat oxidation.
**Induces anorexia, weight loss, and insulin resistance.
***A peptide hormone which stimulates glucose uptake.
****Secreted by adipose tissue which decreases appetite, and its decline may contribute to the increased adiposity and body composition changes seen in the elderly.

Decreased insulin secretion

Insulin secretion diminishes by 0.7% per year with increasing age because of reduced function and increased apoptosis of pancreatic β cells [17]. β-Cell autoimmunity may lead to activation of an acute phase response in older people with diabetes with hypersecretion of interleukins, C-reactive protein, and TNF-α which may reduce insulin secretion [18]. Disturbances in the physiology of the gut-derived incretins, gastric inhibitory polypeptide (GIP), and glucagon-like peptide-1 (GLP-1), may be another factor involved in β-cell dysfunction [19]. Both peptides enhance insulin secretion after meals and may have a role in maintaining β-cell growth, proliferation and inhibition of apoptosis. Aging is associated with reduced levels and function of these peptides [20].

Diabetes phenotype in old age

Diabetes in older people is associated with coexistent multiple comorbidity burden, geriatric syndromes, and frailty (Box 62.2).

Box 62.2 Diabetes phenotype in older people with diabetes

- Multiple comorbidities
- Cognitive dysfunction
- Depression
- Physical dysfunction
- Falls and fractures
- Urinary incontinence
- Polypharmacy
- Less muscle mass and poor muscle quality
- Malnutrition
- Frailty
- Nutritional need and hydration
- Irregular eating pattern especially in people with dementia
- Vulnerability to hypoglycemia

Comorbidity burden

Diabetes in older people is associated with increased atherosclerosis, premature aging, and increased disability. Older people with diabetes frequently have at least one comorbid chronic disease in addition to diabetes and as many as 40% have at least three conditions [21]. The comorbidity burden is even higher in care home residents with diabetes. For example, those with diabetes have more cardiovascular disease, visual problems, pressure sores, limb amputations, and kidney failure than residents without diabetes [22]. In a retrospective case note review of 75 nursing home residents with diabetes in the UK, significant levels of disability were shown in areas of continence, feeding, mobility, and communication. The average number of comorbidities per individual was four (range 1 to 8) [23]. The mortality rate was 34% after 1 year of follow-up indicating severe comorbidity [24]. In another study, residents with diabetes had a greater comorbidity burden (Hierarchical Condition Category 1.90 vs. 1.58), more prescribed medications, and experienced more hospitalizations (37% vs. 18%) than residents without diabetes [11].

Geriatric syndromes

Geriatric syndromes, such as cognitive and physical dysfunction, depression, falls, and urinary incontinence are common in older people with diabetes and may have subtle presentations [25]. Diabetes is associated with a twofold increased risk of being unable to perform daily physical tasks, such as walking, doing house work or climbing stairs, and 1.6-fold greater risk of difficulties performing basic personal care, such as bathing, using the toilet, dressing, and eating. Diabetes complications, such as neuropathy, arthritis, and vascular disease, are contributors to physical disability in older people with diabetes [26, 27]. The Study of Osteoporotic Fractures has shown that diabetes also increases the risk of falls (odds ratio (OR) 2.78; 95% confidence interval (CI):1.82–4.25). History of arthritis, musculoskeletal pain, depression, poor vision, and peripheral neuropathy are the main predictors of falling among older people with diabetes [28]. The risk of developing Alzheimer's disease or vascular dementia is twofold higher in older people with diabetes compared to age-matched people without diabetes [29]. In the Health, Aging, and Body Composition Study, older people (70–79 years old) with diabetes had an increased incidence of depression compared with persons without diabetes (23.5% vs. 19.0%, hazard ratio (HR) 1.31; 95% CI:1.07–1.61) [30].

Frailty

Frailty is a condition characterized by a reduction in physiological reserve and in the ability to resist physical or psychological stressors [31]. Its definition is largely based on the presence of three or more phenotypes (weight loss, weakness, decreased physical activity, exhaustion, and slow gait speed) [32]. Frailty is viewed as a wasting disease with weight loss being one of its criteria. Undernutrition, which is common in older people, seems to be a risk factor for frailty. In the USA, ~16% of elderly persons living in the community are undernourished. These figures rise to 59% in long-term care institutions and 65% in acute care hospitals [33]. Sarcopenia or muscle mass loss is a component of frailty which seems to be accelerated when diabetes is present. In a community study of 3153 participants ≥65 years, appendicular lean mass loss in men with diabetes was twice that of men without diabetes (3.0% vs. 1.5%) and in women with diabetes was 1.8 times that of those without diabetes (3.4% vs. 1.9%) over 4 years of follow-up. The mechanisms explaining these results may be related to reduced muscle protein synthesis as a result of lower testosterone and IGF-I and increased muscle protein breakdown caused by a higher rate of inflammation [34]. Diabetes also causes sarcopenia through the catabolic effect of insulin deficiency and by increasing intramyocellular lipid accumulation [35]. In another study, older persons with type 2 diabetes (T2DM) had accelerated decline in leg lean mass, muscle strength and longer sit to stand time compared to those with normoglycemia [36]. Another factor related to malnutrition and frailty may be oral health. For example, optimal nutrition may not be maintained because of poor dentition, dry mouth, reduced taste sensation, palatability, and appetite change with increasing age [37].

Clinical presentation

Diabetes can be asymptomatic in up to 50% of older people [38]. However, when symptoms are present they are mostly non-specific and may be attributed to aging. Non-specific symptoms, such as general malaise, fatigue or lethargy, are common manifestation of diabetes in old age. Geriatric syndromes, such as falls and urinary incontinence, may be the first manifestation of diabetes. Symptoms may be atypical, for example, anorexia rather than the typical polyphagia. The classic osmotic symptoms are usually less prominent because of the increased renal threshold for glucose (reducing the intensity of polyuria) and impairment of thirst sensation (reducing the intensity of polydipsia).

Box 62.3 Diagnosis and assessment of diabetes in old age-special considerations

Clinical presentation and diagnosis

- Fasting blood glucose may be normal in up to one-third of cases
- Postprandial or 2-hour oral glucose tolerance test are more reliable
- HbA_{1c} is specific but less sensitive as a diagnostic test
- Symptoms may be absent in up to 50% of patients
- Osmotic symptoms are less prominent
- Other symptoms may be non-specific such as fatigue or lethargy

Comprehensive geriatric assessment

Comprehensive geriatric assessment should be performed on initial diagnosis and annually including assessment of:

- Cognitive function
- Screening for depression
- Assessment for frailty
- Falls risk
- Activities of daily living ability
- Presence of urinary incontinence and chronic pain
- Nutritional status
- Medication adherence and polypharmacy
- Social circumstances

Hyperosmolar hyperglycemic state may be the presenting symptom or diabetes may be first diagnosed during an acute illness or following a routine blood test (Box 62.3).

Diagnosis

The diagnostic criteria for diabetes are the same irrespective of age (see Chapter 2). Clinicians should be aware that fasting glucose concentration may be normal in the early stages of diabetes and is therefore less sensitive in diagnosing diabetes in old age; however, the 2-hour OGTT appears to capture undiagnosed cases [39].

Since February 2011, glycated hemoglobin (HbA_{1c}) has been used as a diagnostic test for diabetes. However, although HbA_{1c} has high specificity (98.7%), its low sensitivity (46.8%) means that it can miss more than half of people with diabetes [40]. There are a number of pitfalls to using HbA_{1c} in older people. HbA_{1c} increases with age after adjustment for glucose suggesting that non-glycemic factors contribute to this increase. Furthermore, iron deficiency anemia, which is common in older people, is associated with an increase in HbA_{1c} independent of changes in blood glucose. Both of these factors will lead to an over-diagnosis of diabetes in older people if HbA_{1c} is used in preference to glucose. The diagnosis should be confirmed by a second laboratory test in the absence of diabetes symptoms as for younger people.

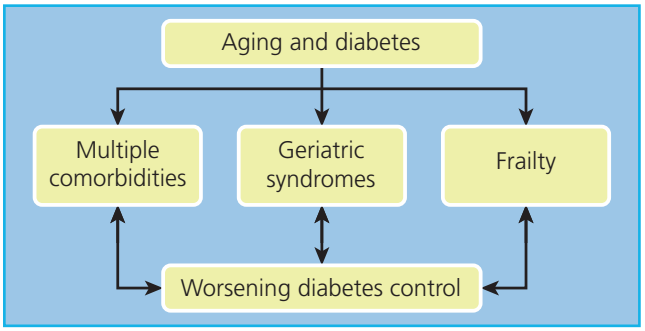

Figure 62.1 Interaction between diabetes phenotype in old age and diabetes control. The interplay between aging and diabetes leads to the development of the characteristic phenotype of diabetes in old age of multiple comorbidities, geriatric syndromes, and frailty, which in turn may lead to worsening of diabetes control setting a vicious circle.

Management

The phenotype of diabetes in old age is highly variable and affected by comorbidity, geriatric syndromes, and frailty. Therefore, the diabetes management should take into account the heterogeneous nature of the diabetes and the complex needs of the individual. A comprehensive geriatric assessment should be performed after the initial diagnosis and annually as age-related comorbidities may impair diabetes control. (Figure 62.1) Hyperglycemia should not be treated in isolation but as part of a multifactorial intervention to reduce cardiovascular risk. Cardiovascular complications remain the main cause of mortality accounting for 50–75% of all deaths in people with diabetes [41]. Management includes lifestyle modification and pharmacological interventions for hyperglycemia and cardiovascular risk factors (Box 62.4).

Lifestyle modifications

Lifestyle modification includes changes in diet, weight reduction, smoking cessation (the single most effective means of reducing mortality [42]), and regular exercise to reduce visceral obesity and improve insulin sensitivity.

Aging is associated with increased insulin resistance through the loss of skeletal muscle mass [12]. Muscle mass is dependent on a balance between muscle protein synthesis and breakdown; protein intake with exercise training synergistically increases skeletal muscle mass in older people. In one trial, protein supplementation for frail older people who were engaged in resistance training resulted in muscle hypertrophy, and increases in muscle strength, muscle mass, and performance [43]. A diet that is high in fiber and potassium and low in saturated fats and refined carbohydrates and salt may help achieve an ideal body weight as well as improving the lipid profile, significantly lowering blood pressure and reducing the overall cardiovascular risk [44]. In the Diabetes Prevention Program, lifestyle intervention including modest weight reduction, a healthy low-fat diet, and regular exercise reduced the development of diabetes and this beneficial effect persisted for up

Box 62.4 Management of cardiovascular risk factors in older people with diabetes

Lifestyle modifications

- Smoking cessation.
- Balanced diet with adequate nutrition especially in frail individuals.
- Regular exercise.
- Weight loss in overweight persons.

Hyperglycemia

- Tight control in fit or newly diagnosed people.
- Conservative approach in frail persons.
- Avoid hypoglycemia.

Hypertension

- A target systolic BP of 140 mmHg is reasonable in fit individuals but higher targets around 150–160 are appropriate in frail or very old (≥85 years) persons.
- Achieving target BP is more important than the antihypertensive drug class used and most people will need more than one drug to achieve the target.

Dyslipidemia

- Statin therapy in older people with diabetes is beneficial and should be offered unless specifically contraindicated or life expectancy is limited by frailty and comorbidities.
- The routine use of fibrate or niacin in addition to statin is not recommended.

Aspirin

- Aspirin therapy should be considered selectively in older people with diabetes and high cardiovascular risk but after assessment of their bleeding risk.

Multiple intervention

- Hypoglycemia should not be treated in isolation but as part of a multiple cardiovascular risk factors reduction.
- Statins and antihypertensive drugs have the largest effect in reducing cardiovascular events followed by hypoglycemic agents and aspirin.

Reverse metabolism

- In frail individuals targets should be relaxed because of the inverse relationship between cardiovascular risk factors and mortality.

BP, blood pressure; CV, cardiovascular.

to 10 years after the end of the study especially in older people (≥60 years) [45]. Additional benefits of exercise for older people may include increased muscle strength and improved walking balance. The Look AHEAD (Action for Health in Diabetes) study in the middle aged and older people with T2DM showed that weight loss and improved fitness lowered the risk of loss of mobility [46].

Hyperglycemia

Although the evidence in reducing microvascular disease by tight glycemic control is established, there is ongoing debate about whether reducing blood glucose to near normal levels results in lower cardiovascular events (Table 62.1) [47–50]. In frail older people, the benefit of blood glucose control diminishes in the presence of other comorbidities. In a decision analysis to assess the effects of baseline health status on prioritization of therapy, blood pressure control conferred a larger benefit than glucose control at advanced ages (75–79 years) and the expected benefits of both therapies steadily declined as the level of comorbidity and functional impairment increased [51]. Therefore, in older people who are frail with multiple comorbidities and functional impairment, tight control may be more harmful by inducing hypoglycemia. It is important to address individual goals of therapy, guided by patient preferences, life expectancy, comorbidities, and the influences of therapy on quality of life. The advantages and disadvantages of antidiabetes medications in older people are detailed in Table 62.2.

Hypertension

A target systolic blood pressure of ~140 mmHg is reasonable in older people with diabetes as maintainence of a systolic pressure between 130–140 mmHg is associated with a reduction of adverse cardiovascular outcomes in older people with hypertension and diabetes. Tighter control, however, is not warranted as this may be associated with increased adverse events. In the International Verapamil SR-Trandolapril (INVEST) study controlling systolic blood pressure to <130 mmHg was not associated with better cardiovascular outcomes than usual control of 130–140 mmHg in individuals aged ≥55 years, and it was associated with a non-significant increased risk of mortality (11.0% vs. 10.2%; adjusted HR 1.20; 95% CI: 0.99–1.45, $p = 0.06$) [52]. Tight blood pressure control (target <120 mmHg systolic) was also not beneficial and was associated with adverse outcomes in older people (40–79 years) with diabetes [53]. The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) also had similar conclusions for older individuals, mean age 66 ± 7 years, of whom 57% were aged ≥65 years [54]. Two meta-analyses of older people with diabetes did not show reduced myocardial infarction or mortality rates with systolic blood blood pressures <140 mmHg [55, 56]. In very old people (>80 years), the targets may be even more relaxed. The Hypertension in the Very Elderly Trial (HYVET) which included older people aged ≥80 years with sustained systolic blood pressure >180 mmHg, 7% of whom had diabetes, showed a significant 33.7% (HR 0.66; 95% CI: 0.53–0.82, $p < 0.001$) reduction in cardiovascular events with a target blood pressure control of 150/80 mmHg. However, the individuals included in HYVET were healthier than those in the general population with a low baseline rate of known cardiovascular disease (11.5%), myocardial infarction (3.1%), or heart failure (2.9%). Therefore, the results may not apply to all older persons, especially those with multiple comorbidities or living in care

Table 62.1 Summary of recently published trials [47–50].

	UKPDS Follow-up	ACCORD	ADVANCE	VADT
Number of participants	3277	10,251	11,140	1791
Mean (SD) age (years)	62 (8.0)	62.2 (6.8)	66 (6.0)	60.5 (9.0)
Inclusions criteria	Newly diagnosed T2DM	Age 40–79 with history of CVD, age 55–79 years with evidence of atherosclerosis, albuminuria, LVH, or two additional risk factors for CVD	Diagnosis of T2DM at ≥30 years of age or age ≥55 years or history of macro- or microvascular disease	T2DM with inadequate response to maximum dose of an oral agent or insulin therapy
History of cardiovascular disease	People with significant CVD were excluded	35%	32%	40%
Duration of diabetes on entry (years)	Newly diagnosed	10.0	8.0	11.5
Cardiovascular outcome	Benefit	Harm	No benefit	No benefit
Hypoglycemia intensive vs. standard therapy (%)	2.4% for sulfonylurea, 1.8% for insulin, and 0.7% for standard therapy.*	16.2 vs. 5.1	53 vs. 38	24.1 vs. 17.6

UKPDS, UK Prospective Diabetes Study; ACCORD, Action to Control Cardiovascular Risk in Diabetes; ADVANCE, Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation; VADT, Veterans Affairs Diabetes Trial; DM, diabetes mellitus; CVD, cardiovascular disease; LVH, left ventricular hypertrophy.
*Only rates of sever hypoglycemia reported in the intervention phase of the study.

homes [57]. In another community study of people aged ≥85 years old, there was a U-shaped relationship with a systolic blood pressure of 164.2 mmHg (95% CI: 154.1–183.8 mmHg) being associated with the lowest mortality suggesting that the optimal systolic blood pressure for this age group could be >140 mmHg [58].

Thiazide diuretics, angiotensin receptor blockers, angiotensin-converting enzyme inhibitors, and calcium channel blockers are reasonable first choice agents although higher doses of diuretics may worsen blood glucose and lipid profile. Most people will require more than one antihypertensive agent.

Table 62.2 Advantage and disadvantage of antidiabetes medications in older people.

Medication	Advantage	Disadvantage
Sulfonylureas	Suitable for those with renal impairment or low risk of hypoglycemia.	Increased risk of hypoglycemia and weight gain. Long-acting sulfonylureas should be avoided.
Metformin	Low risk of hypoglycemia, cardiovascular benefit, weight neutral.	Increased risk of lactic acidosis in those with renal impairment, heart failure, sepsis, and dehydration.
Meglitinides	Short-acting, suitable for those with erratic eating pattern.	Risk of hypoglycemia and weight gain but less than sulfonylureas.
Alpha-glucosidase inhibitors	Low risk of weight gain and hypoglycemia.	Weak hypoglycemic action, gastrointestinal side effects.
Pioglitazone	Suitable for those with renal impairment, less risk of hypoglycemia.	Fluid retention, worsens heart failure, increases fracture risk and possibly bladder cancer.
DPP-4 inhibitors*	Low risk of hypoglycemia, weight loss.	Gastrointestinal side effects, dose mostly needs to be adjusted with renal impairment.
GLP-1 receptor agonists**	Low risk of hypoglycemia, weight loss.	Injectable, weight loss in frail individuals, not suitable in renal failure, nausea is common and possible risk of pancreatitis.
Sodium glucose cotransporter 2 (SGLT2) inhibitors	Low risk of hypoglycemia, weight loss.	Not suitable for frail elderly with weight loss, heavy glucosuria increases risk of urinary tract infections, candidiasis, dehydration, and hypotension.
Insulin	Effective, tailored rapidly to changes in need, improves quality of life.	High risk of hypoglycemia and weight gain.

*DPP-4, Dipeptidyl peptidase 4
** GLP-1, Glucagon-like peptide-1.

Dyslipidemia

There are no large clinical trials of lipid-lowering interventions specifically in older people with diabetes. Post hoc analysis of the Heart Protection Study, which included participants with diabetes aged between 40 and 80 years, showed a significant 25% risk reduction of cardiovascular events [59]. A meta-analysis of 18,686 people with diabetes in 14 trials of statin therapy for primary prevention showed a similar 20% relative risk reduction in major adverse vascular outcomes in older (≥65 years) compared to younger (<65 years) people [60]. In the very elderly (>80 years), cholesterol targets are unclear. A review of observational studies including 13,622 participants showed that low total cholesterol (<5.5 mmol/L) was associated with the highest mortality rate in those >80 years old [61]. The routine use of a fibrate or niacin in addition to a statin therapy failed to reduce cardiovascular events beyond the effects of statins and is not recommended [62, 63]. Cardiovascular prevention with statins emerges fairly quickly (within 1–2 years) suggesting that statins may be offered to nearly all older people with diabetes except those with very limited life expectancy. Chronological age per se should not exclude people from receiving therapy but functional or biological age as well as the impact of long-term drug therapy on safety and quality of life should be considered.

Aspirin therapy

Aspirin reduces cardiovascular morbidity and mortality in people with a history of cardiovascular disease [64]. However, evidence for aspirin use in primary cardiovascular risk prevention is still unclear. A meta-analysis of aspirin treatment as primary prevention in people with diabetes demonstrated a trend towards a 10% reduction in the cardiovascular events but this needs to be balanced against an increased risk of hemorrhage [65]. Presence of diabetes per se does not justify aspirin use. However, most older people with diabetes have a high burden of cardiovascular risk factors and are likely to benefit from aspirin therapy. Therefore, aspirin use should be considered selectively in older individuals with diabetes and high cardiovascular risk after assessment of the risk of bleeding.

Multiple risk intervention

Cardiovascular risk factors tend to cluster in what is known as the "metabolic syndrome." Both age and diabetes increase the prevalence of metabolic syndrome. In a Norwegian study, the prevalence increased from 11.0% in men aged 20–29 years to 47.2% in men aged 80–89 years, and from 9.2% to 64.4% for women in the corresponding age groups [66]. In a population-based study of 5632 white European people (65–84 years old), the prevalence was 64.9% and 87.1% in men and women with diabetes, respectively, compared to 25.9% and 55.2% in men and women without diabetes [67]. Although metabolic syndrome is postulated as a risk factor for cardiovascular disease, in a prospective study of 1025 elderly people aged 65–74 years [68] and an analysis of the outcomes of two prospective studies in people aged over 60 years, the metabolic syndrome was shown to be a marker of cardiovascular disease but did not enhance risk prediction above and beyond the risk associated with its individual components [69].

Multifactorial interventions are appropriate and show that the use of statins and antihypertensive drugs have the largest effect in reducing cardiovascular events with antidiabetes agents and aspirin the next most important interventions [70]. More effort is needed to optimize this comprehensive approach as many older people do not receive this level of care [71].

Reverse metabolism

In frail older people, the power of traditional cardiovascular risk factors including hypertension, dyslipidemia, and hyperglycemia to predict risk of cardiovascular disease seems to diminish with age leading to a paradoxical relationship [72]. The more commonly proposed explanations include the association of low body weight and low cholesterol with increased protein energy malnutrition and increased inflammation associated with frailty [73]. In a study of 331 very old people (mean age 85 ± 7 years), low body mass index, low blood pressure, low total and high density lipoprotein (HDL) cholesterol, and high insulin sensitivity in individuals without diabetes predicted total mortality indicating a "reverse metabolism" that is probably attributable to malnutrition and chronic disorders which have a negative impact on survival [74]. Low albumin (a marker of malnutrition) and high C-reactive protein (a marker of inflammation) were associated with these cardiometabolic factors limiting their prognostic value for cardiovascular risk in older people [74]. It is important to recognize that many older people with diabetes are frail and the expected benefit of tight metabolic control declines as morbidity and functional impairment increase thus, functional status and level of comorbidity are important factors in assessing risk [51].

Special considerations in old age

Hypoglycemia

Hypoglycemia is commoner in older people with diabetes because of the associated comorbidities, geriatric syndromes, polypharmacy, long duration of diabetes and the increased prevalence of hepatic and renal dysfunction (Box 62.5). Although there is a paucity of data about the incidence of hypoglycemia in older people, the reported incidence of hypoglycemia varies in the literature owing to differences in the definition used and the age of the populations studied. In a US retrospective population-based study of 19,932 Medicaid patients, aged ≥65 years, the incidence of severe hypoglycemia was 1.23 episodes per 100 person-years for people treated with sulfonylureas and 2.76 episodes per 100 person-years in those treated with insulin [75]. However, the strict definition of severe hypoglycemia (an episode leading to fatal outcome or hospital admission) may have underestimated the true frequency of events. Also, the data collection was conducted before the publication of the evidence for the benefit of tight glycemic control in T2DM in 1998 [76]. The subsequent trends towards

Box 62.5 Hypoglycemia in older people with diabetes

Incidence

- Increased in old age due to multiple comorbidities, undernutrition, polypharmacy, long duration of diabetes, and renal or hepatic impairment.

Difficult recognition

- Non-specific symptoms.
- Misdiagnosed for stroke, vertigo, or visual disturbance.
- Misinterpreted as dementia-related symptoms such as agitation or behavior change.
- Atypical presentation, e.g. confusion or passive delirium.
- Little warning or unawareness of autonomic symptoms.
- People with dementia are unable to communicate their feelings or symptoms.

Consequences

- Acute events such as cardiac arrhythmias or stroke.
- Chronic consquences such as mental and physical dysfunction.

tighter glycemic control have resulted in more frequent hypoglycemic episodes with insulin becoming the second commonest medication associated with adverse events reported to the Federal Drug Administration with a threefold increase in reported events from 1998 to 2005 [77]. Insulin was the second most frequent medication associated with emergency department visits in older people ≥65 years; 95.4% of episodes were related to hypoglycemia, 24.1% involved loss of consciousness or seizure, and 25.1% required hospitalization [78]. More recently in a prospective study involving 3347 people, median age 66.1 years, from the DiaRegis, a multicenter registry of people with diabetes in Germany, the annual incidence of hypoglycemia of any severity was 14.1% [79]. Although hypoglycemia incidence is difficult to estimate accurately, it is likely to be higher in older than younger people. In a prospective observational study of 3810 people in primary care, 11% of participants reported at least one episode of hypoglycemia of any severity in a 12-month period. Older people (≥70 years) reported more episodes than younger (<60 years) people (12.8% vs. 9.0%, $p < 0.01$). Significant differences were also seen for symptomatic episodes without a need for help (9.2% vs. 5.6%) and symptomatic episodes with a need for medical assistance (0.7% vs. 0.1%) [80]. In care homes the incidence of hypoglycemia is likely to be much higher than in a community setting reaching up to 41.9% in one study over a one-year period (median 2, range 1–10 episodes per patient per year) because of the higher levels of comorbidities [81].

Recognition

Although hypoglycemia in older people with diabetes is common, its recognition and diagnosis can be difficult. For example, owing to the predominance of neurological rather than autonomic symptoms, hypoglycemia may present with symptoms such as dizziness or visual disturbance resulting in misdiagnosis [82]. Another diagnostic challenge is the similarity in the clinical presentation of hypoglycemia with that of dementia where people may present with agitation, increased confusion, or behavioral changes. Furthermore, symptoms of hypoglycemia tend to be less specific with increasing age. In a survey of hypoglycemia symptoms perception by older people with diabetes (age 82.3 ± 3.9 years) attending an outpatient clinic, the majority of respondents reported non-specific symptoms of being generally unwell when their blood glucose level dropped, making the recognition of hypoglycemic episodes more difficult for healthcare professionals [83]. This was also demonstrated in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study with non-specific fatigue or weakness being the commonest symptoms of hypoglycemia experienced by the participants (mean age 62.2 ± 6.8 years) [84]. In older people the threshold of autonomic symptoms of hypoglycemia occurs at a lower blood glucose concentration while cognitive dysfunction occurs at a higher level compared with younger adults. Therefore, autonomic and neurological symptoms occur almost simultaneously with little warning [85]. This is referred to as "impaired awareness of hypoglycemia" [86]. Subclinical hypoglycemia or episodes with fewer symptoms may further reduce awareness leading to a vicious cycle whereby one episode of hypoglycemia can induce further hypoglycemia [87]. Therefore, many episodes of hypoglycemia may be unrecognized and under-reported by both people with diabetes and physicians, and subsequently the frequency is likely to be underestimated.

Consequences

Older people with diabetes are likely to be at a higher risk of the adverse consequences of hypoglycemia because of the increased prevalence of comorbidities, undernutrition, and polypharmacy compared with younger people [88]. Severe hypoglycemia may lead to serious acute vascular events, such as stroke, myocardial infarction, acute cardiac failure, and ventricular arrhythmias [89, 90]. The morbidity attributed to recurrent episodes of hypoglycemia is associated with silent and chronic complications, which could lead to significant physical and cognitive dysfunction and eventually to frailty, disability, and increased mortality. In a Taiwanese study of 234 residents aged 77.5 years living in long-term care facilities, of whom 35.5% had diabetes, hypoglycemia was associated with disability and reduced function. Functional status was worse in those who experienced hypoglycemia in comparison with those with no history of hypoglycemia (mean Barthel Index score 22.5 vs. 38.2). Complete dependence, defined as Barthel Index score <30, was also commoner in people with hypoglycemia (69.2% vs. 50%) [81]. The burden of hypoglycemia leading to hospitalization is higher in old age and may contribute to increased frailty and reduced quality of life. In a US study of a 33,492 people with diabetes, aged ~60 years, accidents resulting in hospital visits occurred in 5.5% of those with hypoglycemia compared to 2.8% of those without. Hypoglycemia was associated with

significantly increased hazards for any accident (HR 1.39; 95% CI: 1.21–1.59, $p < 0.001$), accidental falls (1.36; 1.13–1.65, $p < 0.001$), and motor vehicle accidents (1.82; 1.18–2.80, $p = 0.007$) after adjustment for baseline characteristics. In an age-stratified analysis, the risk of falls was twice as high among older people, ≥65 years, compared with younger individuals and hypoglycaemia was significantly associated with a greater than 50% increase in the hazard of falls (adjusted HR 1.52; CI: 1.18–1.95) [91]. Hypoglycemia also increases the risk of fractures which may lead to disability and frailty. In a retrospective observational study of 361,210 Medicare-covered patients with diabetes ≥65 years old, those with hypoglycemic events had a significantly higher proportion of fall-related fractures compared to those without hypoglycemia (5.24% vs. 2.67%, $p < 0.001$). Hypoglycemic events increased the risk of falls and fractures by 70% (OR 1.7; 95% CI: 1.58–1.83) [92].

Dementia

Progressive decline in cognitive function leading to dementia is common in older people with diabetes. Persistent hyperglycemia increases the risk of cerebrovascular disease by inducing inflammation, endothelial dysfunction, oxidative stress, and insulin resistance leading to an increased incidence of vascular dementia [93]. Moreover, accelerated brain aging from altered amyloid metabolism, increased protein glycation and direct cerebral glucotoxicity may explain the increased incidence of Alzheimer's dementia [94]. Structural changes in the brain have been noted with diabetes and dementia. For example, cerebral atrophy and hippocampal atrophy are reported more frequently in older people with diabetes and contribute to cognitive dysfunction especially impairment in immediate memory [95]. It seems that brain insulin resistance increases in Alzheimer's disease suggesting that Alzheimer's may be caused by a cerebral manifestation of diabetes.

Risk

Among people with diabetes, the relative risk of Alzheimer's disease is 1.56 (95% CI: 1.41–1.73), while vascular dementia is increased 2.27-fold (1.94–2.66) and all types of dementia by 1.73-fold (1.65–1.82) compared to those without diabetes [96]. In a prospective study of older people (>60 years old) with diabetes, age, microvascular disease, diabetic foot, cerebrovascular disease, cardiovascular disease, acute metabolic events, depression, and education were used to develop a risk score for dementia. Over 10 years, the risk of developing dementia was 5.3% (95% CI: 4.2–6.3) for the lowest score (-1) and 73.3% (64.8–81.8) for the highest (12–19) sum scores [97]. The presence of diabetes also accelerates mortality rate in people with dementia. In a retrospective Australian study, the mortality rate for people with diabetes and dementia was almost twice that of those with dementia but without diabetes (HR 1.9; 95% CI: 1.3–2.9) [98].

Implications

Older people with diabetes and dementia experience difficulties in performing self-care tasks. In a community-based study of 1398 people with diabetes, aged 70 years, adherence to diabetes self-care tasks decreased as cognitive impairment increased, with exercise and diet adherence being the most strongly associated with cognitive impairment [99]. The combination of diabetes and dementia is likely to be associated with an increased incidence of treatment adverse events, such as severe hypoglycemia [100]. Due to erratic eating patterns associated with dementia, older people with diabetes are also at risk of malnutrition, dehydration, and worsening diabetes control. Carers of people with diabetes and dementia face extraordinary challenges to care for both conditions especially in people who develop behavior changes. Their needs should be identified early to allow for greater support from the healthcare system.

Management

Although there is an association between hyperglycemia and cognitive dysfunction, intensive glycemic control does not prevent a decline in mental function [101]. Once dementia develops diabetes self-care deteriorates and so clinicians need to check for cognitive dysfunction if non-adherence to self-care tasks occurs. Clinicians should also be aware that dementia may be associated with language impairment, disorientation, and personality changes that may mimic the symptoms of hypoglycemia [102]. The Mini Cog test is a simple screening tool for dementia which has a sensitivity of 86.4% (95% CI: 64.0–96.4%) and a specificity of 91.1% (85.6–94.6%) and takes only 3 minutes to perform [103].

Older people with diabetes and dementia have complex needs because of increased dependency and unpredictable behavioral changes as the decline in cognitive function continues. For example, hydration should be maintained because of impaired thirst sensation to avoid risk of volume depletion and hyperglycemic crises. In people treated with insulin, the new class of long-acting insulin analogs may be a good option as they reduce the risk of hypoglycemia and can be conveniently injected once daily [104]. People who have erratic eating patterns and unpredictable caloric intake could be managed with a regimen where short-acting insulin analogs are administered only after meal consumption, thus reducing the risk of hypoglycemia if a meal is missed or only partly consumed (Box 62.6).

Hypoglycemia–dementia interaction

The brain is highly dependent on glucose for its metabolism and is particularly vulnerable to hypoglycemia especially in older people. After each hypoglycemic episode major cognitive changes occur leading to post-hypoglycemic encephalopathy. Repeated episodes of hypoglycemia may contribute to cognitive dysfunction and the relationship appears to be bidirectional. History of severe hypoglycemia increases risk of cognitive dysfunction [105] and cognitive dysfunction increases risk of hypoglycemia [106]. Therefore, recurrent hypoglycemia may be associated with impaired cognitive function and development of dementia. In a retrospective study of 16,667 older people with diabetes, mean age 65 years, the risk of dementia increased by 26% (HR 1.26; 95% CI: 1.10–1.49), 80% (1.80; 1.37–2.36) and 94% (1.94; 1.42–2.64) in those with a history of one, two, and three or more

Box 62.6 Dementia in older people with diabetes

Screening
Should be performed annually or earlier if one of the following is observed:
- Less medication adherence.
- Forgetfulness in how to handle insulin injections.
- Forgetting how to recognize or treat hypoglycemia.
- Difficulties in how to interpret blood glucose results or to make decisions regarding adjusting insulin doses.
- Non-adherence with general self-care.
- Erratic eating pattern and missing meals.
- Non-adherence with dietary requirements.
- Recurrent unexplained hypoglycemia.

Screening tool (Mini-Cog)
Ask the patient to repeat three items such as lemon, key, and balloon then provide a clock face:
- Ask the patient to draw the numbers of the clock face.
- Ask the patient to draw the hands of the clock to show the time as ten to three.
- Ask the patient to recall the three items.

Give one mark for each task performed and for each item remembered. A score 0–3 out of maximum 5 defines cognitive impairment.

severe hypoglycemic episodes (defined as hypoglycemia needing hospital admission or emergency department visit), respectively independent of glycemic control, medications, and comorbidities. The attributable risk of dementia was 2.39% (1.72% to 3.01%) per year in people with compared with those with no history of hypoglycemia [105]. In an observational cohort study of 302 participants with diabetes, mean age 75.7 ± 4.6 years, a cross-sectional association between severe hypoglycaemia and cognitive function was observed. People with dementia (16% of participants) or cognitive impairment (14%) were significantly more likely to have been hospitalized with hypoglycemia than people with normal cognitive function (3.8%), $p = 0.004$ [107]. A prospective association between historical hypoglycemia and cognitive decline in a subsample of the participants without dementia was not found. However, the prospective phase of this study was limited by the small number of participants ($n = 205$) and short duration of follow-up (18 months) which may have limited the power to detect any association between incident hypoglycemia and cognitive dysfunction [100]. More recently, in the Edinburgh population-based cross-sectional study of 1066 people with T2DM, mean age 67.9 ± 4.2 years, self-reported history of severe hypoglycemia was associated with poorer late life cognitive ability. Those who reported at least one episode of severe hypoglycemia demonstrated poorer performance on tests of verbal fluency (34.5 vs. 37.3, $p = 0.02$), digit symbol testing (45.9 vs. 49.9, $p = 0.002$), letter–number sequencing (9.1 vs. 9.8, $p = 0.005$), and trail-making ($p < 0.001$) independent of diabetes duration, vascular risk factors, or vascular complications. These associations persisted after adjustment for estimated prior cognitive ability suggesting that the association may be attributable to an effect of hypoglycemia on age-related cognitive decline [108]. A linear relationship was observed between poorer general cognitive ability and increasing frequency of severe hypoglycemia over the year preceding cognitive testing supporting results of earlier studies.

Management of Diabetes

Glycemic targets

Glycemic targets should be individualized taking into consideration overall health and life expectancy.

Fit older people

For healthier older people with low prevalence of cardiovascular risk factors especially those with a new diagnosis of diabetes, tight glycemic control with an HbA_{1c} around 53 mmol/mol (7%) is reasonable as this is likely to reduce diabetes complications [47] while persistent hyperglycemia is associated with increased risk of falls [109] and mortality [110] regardless of the associated comorbidities.

Frail older people

For frail older people or those with established cardiovascular disease a safer target around 58–64 mmol/mol (7.5–8%) is appropriate. The presence of multiple comorbidities is a potential competitor for the benefit of tight glycemic control in this population. In a decision analysis to assess the effects of comorbid conditions and functional impairment, the expected benefits of tight glycemic control, HbA_{1c} 53 versus 63 mmol/mol (7% vs 7.9%), declined steadily as the level of comorbidities and functional impairment increased. One to two points were allocated for each comorbidity, according to severity, to create a mortality index score. In people aged 60–64 years with new-onset diabetes, the quality-adjusted days declined from 106 (95% CI: 97–117) days to 44 days (range 38–50) with three additional points in mortality index score, and to 8 days (range 5–10) with seven additional index points [51].

Very frail older people

For very frail older people and those residents in nursing homes and with limited life expectancy, a target HbA_{1c} of 64–75 mmol/mol (8–9%) is suitable. Tight glycemic control in this population may be harmful by inducing hypoglycemia and reducing quality of life. However, higher HbA_{1c} >75 mmol/mol (>9.0%) is associated with increased mortality [111]. Targets in this population should focus on short-term day to day blood glucose control, rather than long term HbA_{1c}, to avoid both hyperglycemia, which may lead to lethargy, dehydration, visual impairment and infections, and hypoglycemia which may lead to falls and confusion (Figure 62.2).

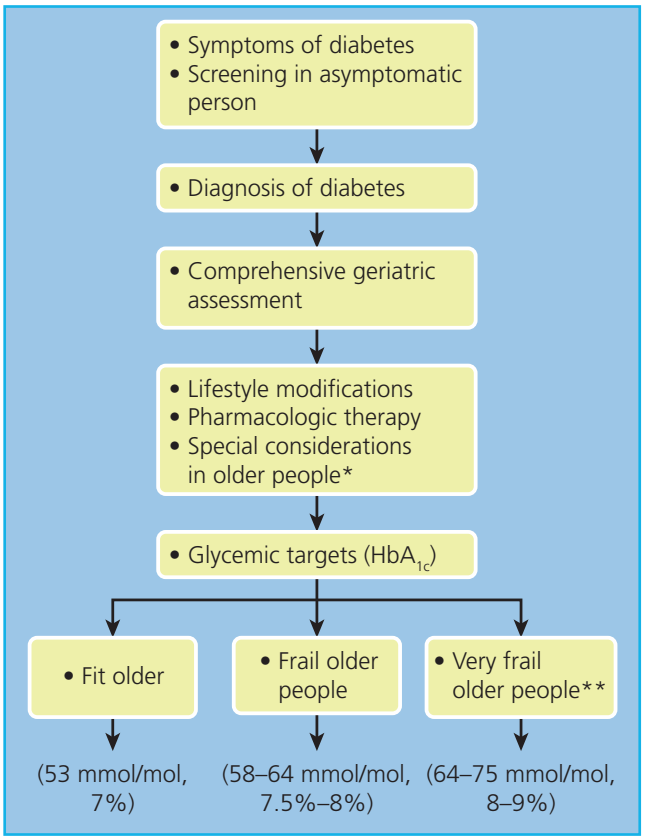

Figure 62.2 Diabetes diagnosis, management and glycemic targets. *Considerations such as risk of hypoglycemia, dementia, polypharmacy, and residents in care homes. **In very frail older people with limited life expectancy, short-term targets of blood glucose >4 but <15 mmol/L is more important than the long-term HbA_{1c} target.

Polypharmacy

Clinical guidelines are largely disease-specific, age-neutral, and driven by numerical surrogates, such as HbA_{1c} or blood pressure, but do not necessarily consider hard endpoints and outcomes relevant to older people, such as physical function, disability, or quality of life [112]. Indiscriminate application of guidelines may lead to over treatment and polypharmacy with potential harm and increased hospitalization in the elderly. For example, older people are more liable to experience adverse effects of antihypertensive medications, such as renin angiotensin system blockers leading to acute kidney injury, hyperkalemia, or hypotension with further deterioration of renal function especially in those with existing chronic kidney disease. Withdrawal of these drugs in elderly people (mean age 73.3 years) with stage 4 and 5 chronic kidney disease has been shown to improve kidney function [113]. A gradual decrease of blood pressure is an essential strategy in treating elderly people with hypertension to avoid an accelerated blood pressure drop with subsequent falls. Blood pressure should be measured both lying and standing and patients asked about orthostatic symptoms to avoid orthostatic hypotension. It is important to realize that the presence of orthostatic symptoms, such as dizziness, light headedness or faintness, is associated with an increased risk of falls (OR 8.21; 95% CI: 4.17–16.19) rather than orthostatic hypotension per se [114].

Avoidance of hypoglycemia is essential especially in those with impaired kidney or liver function which delays the clearance of antidiabetes medications [115]. Glycemic goals should be regularly reviewed and antidiabetes medications adjusted with increasing age especially in those with the onset of cognitive impairment or frailty. Declining weight, malnutrition, and frailty may lead to a reduced need for antidiabetes medications while increasing the risk of hypoglycemia. Antidiabetes medications have been safely withdrawn in a cohort of frail nursing home older people with T2DM, mean age 84.4 ± 6.8 years [116] and in another group in the community, mean age 86.5 ± 3.2 years attending outpatient clinics without a deterioration of their glycemic control [117]. The main characteristics of these individuals were significant weight loss, increased comorbidities including dementia and polypharmacy with recurrent hypoglycemia [117]. Therefore, people with these criteria appear to be suitable candidates for a trial of antidiabetes medication withdrawal. Higher doses of statins should be avoided in frail elderly people, who may be more susceptible to drug-related myopathy. Non-steroidal anti-inflammatory drugs should be used carefully in older people with diabetes especially those with chronic kidney disease because of the increased risk of acute kidney injury. Polypharmacy (taking >4 drugs) is common; in a British care home study, 84% of residents with diabetes were taking >4 drugs with a high proportion (59%) of residents prescribed drugs for cardiovascular disease prevention. This may be inappropriate in this disabled population with limited life expectancy as polypharmacy leads to increased risk of drug errors, hypoglycemia, and hospitalization. Therefore, regular medication review of care home residents with diabetes should be undertaken as it has the potential to reduce costs and minimize adverse drug reactions [118].

Care homes

Care home residents with diabetes are likely to be frail, with multiple comorbidities and limited life expectancy. Therefore short-term glycemic targets with minimal diabetes-related interventions are important to maintain quality of life. Maintaining a random blood glucose between 4–15 mmol/L (70–270 mg/dL) is reasonable as blood glucose outside this range is likely to be symptomatic and result in cognitive changes [119]. Maintaining blood glucose in this "comfort zone" may ensure "comfort care" avoiding both hyperglycemia and hypoglycemia thereby reducing malaise and improve mental function and general well-being [120] (Box 62.7).

Care plans

Care homes should have a policy for diabetes care including diabetes screening for residents on admission and an individualized care plan for residents. Care plans should be tailored to individual needs and take into consideration patients' values, preferences,

Box 62.7 Recommendation for care of older people with diabetes in care homes

On admission to care home

- Each resident should be screened for the presence of diabetes.
- Each resident with diabetes should have assessment for functional loss and interventions in place to delay disability.

During their stay at care home

- Residents should be regularly reviewed for the presence of hypoglycemic symptoms especially for those on insulin or sulfonylureas.
- Resident with diabetes should have optimal blood pressure and blood glucose regulation to help maintain cognitive and physical performance.

Good clinical practice in care homes

- All residents should have an annual screen for diabetes.
- Each resident with diabetes should have an individualized diabetes care plan.
- Care homes with diabetes residents should have an agreed diabetes care policy or protocol which is regularly audited.
- Diabetes education and training courses should be available to care home staff.
- Adoption of risk–benefit approach in the management of residents with diabetes in terms of medications, metabolic targets, and extent of performing investigations with a focus on enhancing quality of life, maintaining functional status, and avoiding hospital admission for diabetes-related complications.

life expectancy, comorbidities, and the impact of diabetes management (polypharmacy, glucose monitoring) on quality of life. Medications should be reviewed to switch those taking longer acting sulfonylureas to shorter acting agents and polypharmacy reviewed regularly. Screening for complications relevant to older people, such as cognition, physical function, and depression, should be included in their annual review.

Nutrition

Nutritional guidelines should not be too restrictive but tailored to be healthy and to reflect personal preferences. Individuals are free to exercise personal choices with respect to food selection. Diabetes treatment is then adjusted accordingly. The aims of nutritional intervention include maintenance of healthy body weight and avoidance of malnutrition.

Holistic approach

An individualized holistic care plan is recommended to address care home residents' complex needs [121]. Residents with diabetes should have an annual comprehensive foot examination to identify risk factors for ulcers and amputations. Podiatry input should be available regularly. Residents with diabetes should have an initial comprehensive eye examination and annually thereafter. Domiciliary optometric services may be an option for residents who are not able to travel.

Education

As older people are at increased risk of hypoglycemia [82, 90] and may tolerate low blood glucose with no specific symptoms due to diminished autonomic response, it is important that residents and care home staff are educated to recognize the symptoms and to treat hypoglycemia. In a study that delivered a diabetes educational program to care home staff, staff knowledge improved and was retained at 12 months and led to improved quality of care up to a year after the intervention [122].

Conclusion

Aging is associated with increased insulin resistance, due to decreased muscle mass, increased visceral fat, and decreased insulin secretion, because of diminished β-cell mass and function, leading to glucose intolerance and diabetes in genetically susceptible individuals. Through population aging and increased life expectancy, diabetes is increasingly becoming a disease of older age. The phenotype of diabetes in old age is characterized by an increased prevalence of multiple comorbidities, geriatric syndromes, and frailty. Therefore the assessment of older people with diabetes on diagnosis and annually thereafter should be comprehensive and include screening for these syndromes, especially cognitive and physical dysfunction. Older people are a highly heterogeneous population ranging from a fit person living in the community to a frail individual with multiple comorbidities living in a care home. Management should therefore be individualized with variable metabolic targets from tight control in fit individuals to a conservative approach in frail ones. More attention should be focused on optimal management of undernutrition in frail older people by improving nutrition and physical activity to maintain muscle mass and improve overall function. Quality of life should be at the center of the management plans.

Future perspectives

Although tight glycemic control will continue to be the aim for older fit and independent people with diabetes, this is not suitable for those who are frail and at a high risk of side effects due to polypharmacy [123]. A new approach to defining glycemic targets based on the level of function has recently been introduced by the International Diabetes Federation and represents the first comprehensive guidance in this area [124].

There is a need for clinical trials specifically designed for older people with diabetes to explore the real benefit of glycemic control

in this diverse group. Comprehensive geriatric assessment including physical and mental health assessment will continue to be essential in view of the epidemiological shift of diabetes towards older age. Frailty and geriatric syndromes are emerging as complications in older people with diabetes and will need interventions beyond glycemic control. There remains a lack of intervention studies that reduce disability and improve quality of life in older people with diabetes. A focus on improvements in function may be of greater clinical relevance in frail older people with diabetes than metabolic targets alone. The proposed MID-Frail study will evaluate the clinical, functional, social, and economic impact of a multimodal intervention (resistance training exercise, diet, and education) in frail and pre-frail participants aged ≥70 years with T2DM compared with usual clinical practice [125]. This may have an impact on reducing functional decline, promoting independence, and maintaining quality of life.

63 Diabetes at the End of Life

June James,[1] Jean MacLeod,[2] and Robert Gregory[1]

[1] University Hospitals of Leicester NHS Trust, Leicester, UK
[2] University Hospitals of North Tees and Hartlepool, Stockton-on-Tees, Cleveland, UK

Key points

- Although diabetes is common worldwide, only a minority of deaths in people with diabetes are directly attributable to diabetes. However, diabetes as a cause of death is underreported.
- It is estimated that 4.9 million people with diabetes died in 2014.
- Diabetes is not usually the main cause of death; the causes of death in people with diabetes are in general the same as for those without diabetes, but cardiovascular deaths (especially heart failure) and some cancers are overrepresented.
- People are approaching the end of life when they are likely to die within the next 12 months.
- Generic end-of-life guidance applies to people dying with diabetes and healthcare professionals need to be trained and competent to care for this population; however, this should be supplemented by diabetes-specific guidance.
- Glycemic targets may be relaxed in the last year of life; HbA_{1c} is not required during this time but the blood glucose should be kept between 6–15 mmol/L (110–270 mg/dL).
- Hypoglycemia in people taking insulin or oral hypoglycemic agents is predictive of mortality.
- Insulin treatment must never be stopped in dying people with type 1 diabetes.

Dying with diabetes

Diabetes is common with an overall global prevalence of 8.3% which is rising [1]. The prevalence is higher in the elderly; 10–30% of people in Europe of pensionable age have diabetes and 25% of care home residents in the UK have diabetes [2].

Although survival with diabetes has been improving, people with diabetes have reduced life expectancy compared with the general population [3–7]. The National Diabetes Audit for England and Wales in 2012–2013 revealed a standardized mortality ratio (SMR) of 134 for people with all types of diabetes. The effect was larger for people with type 1 diabetes (T1DM) (SMR 232), for younger age groups, and for women [3]. In Africa 76% of deaths occur in people aged <60 years [1].

It is estimated that globally 4.9 million people with diabetes died in 2014, which equates to one death every 6 seconds. In the United States diabetes was the seventh leading cause of death in 2010, with 69,071 death certificates listing diabetes as the underlying cause of death, and a further 234,051 death certificates listing diabetes as an underlying or contributing cause of death. This may be an underestimate as only 35–40% of recorded deaths in people known to have diabetes stated diabetes on the death certificate and only 10–15% had it listed as the underlying cause of death [8]. In England approximately 500,000 people die each year, 75,000 of whom will have diabetes [9]. There are apparent variations in mortality related to diabetes across Europe with age standardized death rates ranging from 4.0 per 100,000 in Greece to 17.9 in Portugal and even higher levels for Israel (36.1) and Armenia (46.8) [10].

Deaths attributed primarily to diabetes include ketoacidosis, severe hypoglycemia, and hyperosmolar hyperglycemic state, but these account for only 3% of all diabetes deaths. In high-income countries, the premature mortality in people with diabetes is predominantly caused by a higher prevalence of cardiovascular disease, particularly heart failure, which accounts for 75% of all deaths and is associated with a 10-year reduction in life expectancy [3, 11]. The next most common causes of death are chronic kidney disease (10%) [12] and cancer. Individuals with type 2 diabetes (T2DM) are at increased risk of developing certain cancers as both conditions share many of the same risk factors including aging, gender, obesity, physical inactivity, diet, alcohol, and smoking [7, 13].

It follows that healthcare professionals working with adults will encounter people with diabetes who are dying in various settings, and should know how to address their needs at the end of life.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

End of life

Palliative medicine is a surprisingly young specialty even in high-income countries, probably because death has been regarded as a failure of medical care. This attitude was changed by the pioneering work of those such as Dame Cicely Saunders and international declarations about the rights of the dying person. In 1976 the Parliamentary Assembly of the Council of Europe resolved that:

> *"The prolongation of life should not in itself constitute the exclusive aim of medical practice, which must be concerned equally with the relief of suffering" [14].*

The principles of care at the end of life apply to everyone who is terminally ill, and have been articulated in numerous publications, which have themselves been revised in line with evidence and experience (Table 63.1) [15]. The sensitive application of such principles tailored to the individual, and supplemented by excellent communication with them and their families, is likely to result in the best possible outcome under the circumstances.

Although self-evident, end-of-life care cannot start until it is recognized and acknowledged that an individual is nearing the end of their life. This is not intuitive, particularly when medical and nursing staff have until then been providing active management intended to bring about a cure. Guidance has been produced to assist healthcare professionals in making this diagnosis. The General Medical Council UK [16] states that "Patients are 'approaching the end of life' when they are likely to die within the next 12 months." This includes patients whose death is imminent (expected within a few hours or days) and those with:

- advanced, progressive, incurable conditions;
- general frailty and coexisting conditions that mean they are expected to die within 12 months;
- existing conditions if they are at risk of dying from a sudden acute crisis in their condition;
- life-threatening acute conditions caused by sudden catastrophic events [16].

Table 63.1 Key principles of end-of-life care.

- Provision of a painless and symptom-free death
- Tailor glucose-lowering therapy and minimize diabetes-related adverse treatment effects
- Avoid metabolic decompensation and diabetes-related emergencies:
  - frequent and unnecessary hypoglycemia
  - diabetic ketoacidosis
  - hyperosmolar hyperglycemic state
  - persistent symptomatic hyperglycemia
- Avoidance of foot complications in frail, bed-bound patients with diabetes
- Avoidance of symptomatic clinical dehydration
- Provision of an appropriate level of intervention according to stage of illness, symptom profile, and respect for dignity
- Supporting and maintaining the empowerment of the individual patient (in their diabetes self-management) and carers to the last possible stage.

Source: Based on Diabetes UK 2013 [21]. Reproduced with permission.

The Gold Standards Framework for end-of-life care developed in the UK [17] identifies three triggers that may help the healthcare professional to determine if the individual is nearing the end of life:

1 *The "Surprise Question"*: Would you be surprised if this patient were to die in the next few months, weeks, days?

The answer to this question should pull together a range of clinical, comorbidity, social, and other factors that give a whole picture of deterioration. If you would not be surprised, then it is important to consider what measures might be taken to improve the patient's quality of life now and in preparation for possible further decline.

2 *General indicators of decline—deterioration, increasing need or choice for no further active care.*

These include:

- Decreasing activity—functional performance status, declining limited self-care, in bed or chair 50% of day and increasing dependence in most activities of daily living.
- Comorbidity, which is regarded as the biggest predictive indicator of mortality and morbidity.
- General physical decline and increasing need for support.
- Advanced disease with an unstable, deteriorating complex symptom burden.
- Decreasing response to treatments.
- Decreasing reversibility.
- Choice of no further active treatment.
- Progressive weight loss (>10%) in past 6 months.
- Repeated unplanned or crisis admissions.
- Sentinel event, e.g. serious fall, bereavement, transfer to nursing home.
- Serum albumin <25 g/L.
- Considered eligible for additional financial support and benefits.

3 *Specific clinical indicators related to certain conditions.*

These relate to specific conditions. Although diabetes is not mentioned, it frequently occurs in association with those conditions that are specifically mentioned including cancer, chronic obstructive airways disease, heart disease, renal disease, general and specific neurological disease, such as motor neuron disease, Parkinson's disease and multiple sclerosis, frailty and dementia, and stroke.

The Gold Standards Framework also defines four main stages of end of life [17]:

1 Stable from diagnosis (usually lasting years);
2 Unstable, advanced disease (usually lasting months);
3 Deteriorating, exacerbations (usually lasting weeks);
4 Last days of life pathway (usually lasting days).

This model has been adapted in Canada and their guidance is separated into five stages as they included death and bereavement which is considered an integral part of care provision [12]:

1 Disease advancement
2 Experiencing life-limiting illness

3 Dependency and symptom increase
4 Decline and last days
5 Death and bereavement.

For people with diabetes who are taking insulin or β-cell secretagogues, we recommend adding hypoglycemia to the indicators that a person is at the end of life. It has long been recognized that the development of hypoglycemia in people who have not previously been prone to this is a poor prognostic sign. This is true for hospitalized patients, in whom the excess mortality is not caused by hypoglycemia per se, but by associated comorbidities [18]. It seems that this also applies to out-of-hospital hypoglycemia. An audit of the introduction of a community-based scheme in Leicestershire, UK that assessed emergency callouts for people with diabetes experiencing hypoglycemia who were treated at home by paramedics revealed that 5% of patients triaged died within *30 days* of the initial call-out, mainly from previously undiagnosed malignancies. Hypoglycemia in this context is multifactorial, arising from a reduced food intake, weight loss, and/or impaired kidney function without adjustment of the dose of hypoglycemic medication.

The management of diabetes at the end of life

The care of the dying person with diabetes is challenging, encompassing changes to glycemic targets, patient and carer expectation, reducing risk of hyperglycemia and hypoglycemia, managing the effects of other medications, such as glucocorticosteroids, and tailoring of diabetes medications depending on the stage of end of life. Planning for end-of-life care in people with diabetes is often seen as a direct choice between treating or withdrawal of treatment for diabetes [1]; in practice caring for the dying patient is more complex.

Until 2010 there was a dearth of information or guidance on care for these individuals [19, 20]. Generic end-of-life guidelines did not attempt to address the specific issues encountered by people with diabetes. In acknowledgement of this in 2010 Diabetes UK commissioned a working party to review available data and the existing guidance from around the world. The agreed aim of the working party was to summarize a consistent but high-quality approach towards end-of-life care for people with diabetes by providing guidelines and clinical care recommendations. These were developed in partnership with multiple professional groups and formed a consensus of opinion across care and professional boundaries [21]. This guidance has formed the basis of clinical recommendations by the International Diabetes Federation [1] and Diabetes Australia [22].

The key principles underlying high-quality diabetes care at the end of life are summarized in Table 63.1 [21]. The consensus recommendations addressed the major clinical problems that people with diabetes at the end of life experience, and how these could best be managed. The recommendations were aligned to the generic Gold Standards Framework for End of Life Care [17]. They included a review of the use of glucose-lowering therapies and set glycemic targets that aimed to minimize hypoglycemia and improve patient safety [21].

Algorithms were developed for specific situations, such as use of once daily steroid therapy or to treat hypoglycemia. Relevant competencies for various health professionals were suggested and care outcome metrics for assessment of care discussed. It was hoped that these documents would contribute to the development of a consistent approach in care delivery and act as a platform for future partnership working with the third sector and the public.

Glycemic targets

There have been no well-designed studies supporting or providing insight into glucose regulation, diabetes self-management, or the use of particular glucose-lowering therapies at the end of life. Maintaining appropriate metabolic control at all terminal stages of life might seem an achievable goal in most people with diabetes but the influences of the stress response to severe illness, disturbances in glucose metabolism caused by malignancy, use of steroids, and frequent infections can be challenging for clinicians tasked with providing this care. Patients dying with diabetes may have an increased frequency of symptoms such as pain, constipation, and fatigue, which can be difficult to ameliorate unless there is experience in providing tailored glucose-lowering therapy in combination with adequate pain relief including use of opiates.

No published evidence existed at the time to justify any particular glucose or HbA_{1c} target for end-of-life diabetes care management; more recently there have been suggestions that a less demanding HbA_{1c} target of 7.5% (58 mmol/mol) may be safer for some individuals [23]. Others have argued that the testing of HbA_{1c} should cease when estimated survival is only a few months, not least because the use of HbA_{1c} for diagnosis of diabetes in this situation is not validated [24, 25].

As imposed fasting is inappropriate in this context, fasting glucose readings will not always be available. It is likely that the optimal glycemic range will vary according to the stage of illness, the ability to eat and drink normally, the presence of hypoglycemia, the nutritional status, and concomitant treatments. Many people prefer not to have blood glucose estimations done frequently, particularly if they understand that the result may not have an immediate impact on management; their wishes should be respected. Some have argued for a blood glucose target range of 180–270 mg/dL or even up to 360 mg/dL (10–20 mmol/L), although this latter figure may not be appropriate because of an increased risk of ketoacidosis in people with T1DM. The consensus glycemic target recommended by Diabetes UK is 6–15 mmol/L

Box 63.1 Blood glucose targets for end-of-life care [21]

Aim 1: No glucose level less than 6 mmol/L (110 mg/dL)
Aim 2: No glucose level higher than 15 mmol/L (270 mg/dL)

Table 63.2 End-of-life medicine management: non-insulin therapies.

Metformin (standard or modified release Metformin)	Sulfonylureas (e.g. gliclazide, glipizide, glimepiride)	Pioglitazone	Gliptins (saxagliptin, sitagliptin, linagliptin, vildagliptin)	GLP-1 analogs (e.g. exenatide, liraglutide, lixisenatide)	Sodium glucose co-transporter 2 agents (SGLT2) (dapagliflozin, canagliflozin, empagliflozin)
Review dose according to changing renal function	Review if dietary intake is reduced and/or there is significant weight loss	The risk-benefit ratio for pioglitazone in people with terminal disease requires review and should be only prescribed if benefits can clearly be identified	Review doses in accordance with individual licenses if renal function deteriorates	Review if eating patterns change or significant weight loss occurs	Review dose if liver function deteriorates
Withdraw if creatinine >150 µmol/L or eGFR < 30 ml/L/1.73m^2	Review dose if renal function deteriorates and consider a switch to tolbutamide		Some gliptins can be used for all stages of renal disease	Withdraw if abdominal pain or pancreatitis develops	Review individual product characteristics for use in chronic kidney disease. Withdraw if there is evidence of dehydration, poor nutrition, and in acute illness or major surgery
Review if gastrointestinal disease is present or symptoms of nausea, heartburn, diarrhea or flatulence are making patients miserable with discomfort	Review dose if liver function deteriorates as hypoglycemia may occur	Should not be used in people with or at risk of bladder tumor or heart failure	Combination with sulfonylurea increases the risk of hypoglycemia		Use with caution in over 65 year olds (canagliflozin) Limited evidence for use in people over 75 years old

(108–270 mg/dL), and this range is one of the suggested quality metrics for end-of-life care (Box 63.1) [21].

Since people with diabetes are increasingly used to a care planning approach in which they take informed decisions about their care, everyone with capacity should continue to be involved in their care planning for as long as possible, including decisions about target setting and the frequency of monitoring.

Medicines management during the last year of life

Specific recommendations which are aligned to life expectancy are given in the UK guidelines. In general, non-insulin glucose-lowering therapies can be reduced and eventually stopped depending on other factors such as poor appetite, weight loss, and anorexia (Table 63.2). It may be necessary to discontinue insulin treatment in people with T2DM, but insulin should never be stopped in those known to have T1DM (Table 63.3).

Other medication

Once it has been recognized that a person has reached end of life a review of all prescribed medication is indicated. Many people with diabetes are taking medication intended to reduce the risk of cardiovascular events in the long term, including ACE inhibitors or angiotensin II receptor antagonists, other antihypertensives, aspirin or antiplatelet agents, statins and other lipid-lowering agents. There are significant potential side-effects associated with these medicines, and stopping some or all of them may improve quality of life. This decision should be taken in conjunction with the patient and their family to avoid giving the impression that their medical advisors are "giving up on them."

The flowchart for diabetes at end of life (Figure 63.1) provides guidance on how to manage diabetes in the dying patient. It can be reassuring for relatives and carers to know that this additional pathway of care is being followed and that the diabetes is being *managed differently* rather than being *ignored*. The flowchart has been devised to minimize symptoms of diabetes and keep invasive testing to the minimum needed to achieve that aim.

Insulin

The general principles of insulin management are summarized in Table 63.3.

Continuous subcutaneous infusion of insulin—insulin pumps

Although insulin pumps are increasingly being used to manage diabetes in an end-of-life phase, there seems limited value in extensive training of health professionals in their use as patients are likely to be well informed about adapting their pump settings

Table 63.3 End-of-life medicine management: insulin therapies.

- Doses may need to change with changes in renal function
- Equipment for insulin delivery may need to be reassessed if physical capabilities alter, vision is poor, or carers become involved in giving insulin
- Hypoglycemia risk will need to be reassessed with changes in eating patterns
- Evening isophane (Insulatard/Humulin I, or Insuman Basal) in combination with daytime oral hypoglycemic drugs may be a good first-line treatment choice
- A change of insulin regimen may be needed to match changes in activity levels
- The simplest regimen should be chosen if switching to insulin only, both once or twice daily injection can be considered

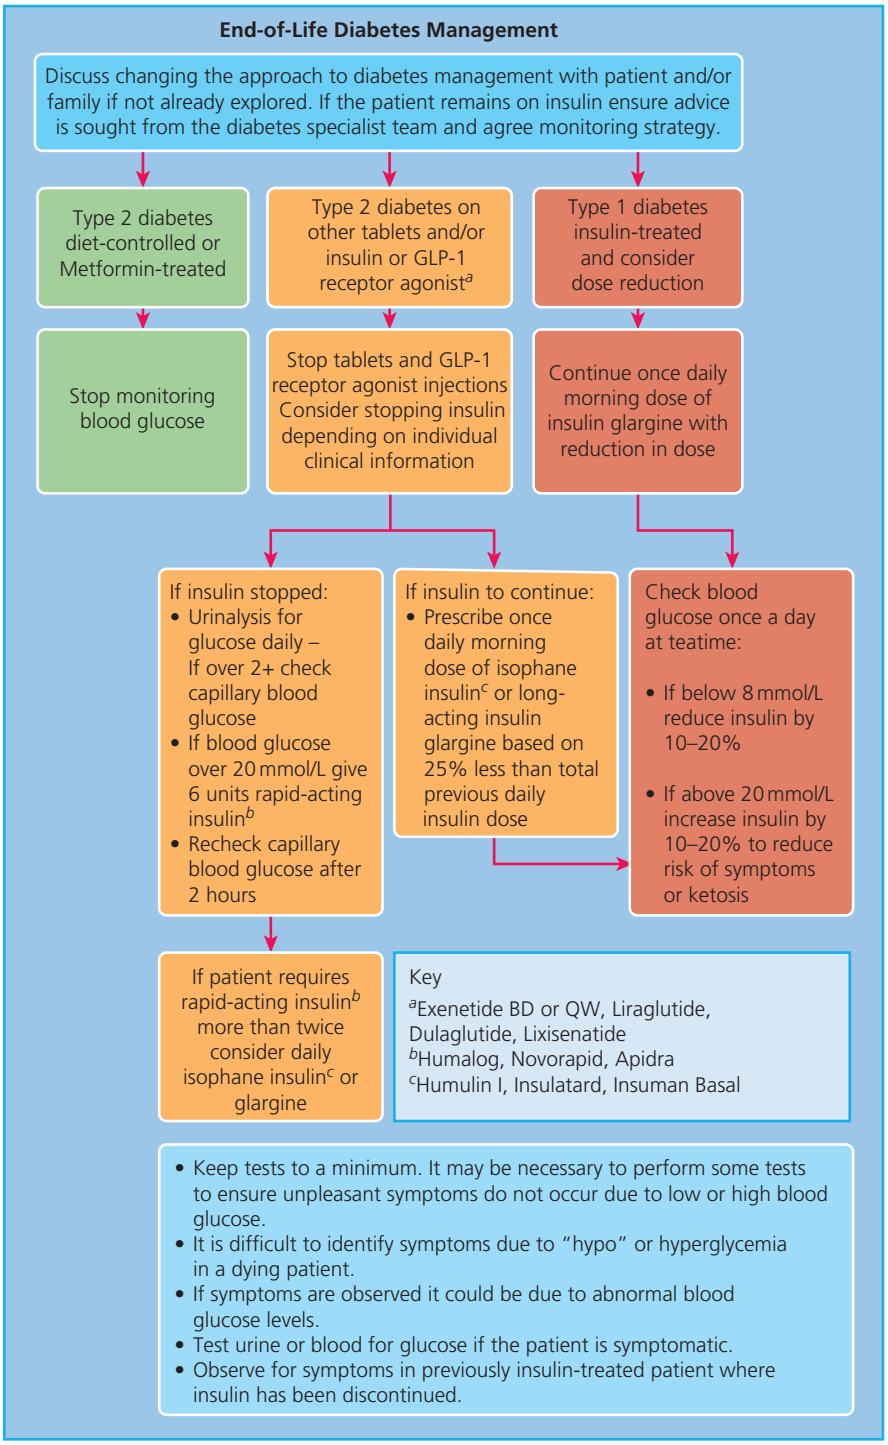

Figure 63.1 Flowchart for diabetes at end of life. Source: Adapted from Diabetes UK, *End of Life Diabetes: Clinical Care Recommendations*, 2nd edn, 2013. https://www.diabetes.org.uk/upload/Position%20statements/End-of-life-care-Clinical-recs111113.pdf.

for illness and have a good awareness of food intake in terms of carbohydrate and protein content. If the person with diabetes feels capable of using the pump, they should be encouraged to do so; however, carers may need education in pump adjustment if it is physically difficult for the person with diabetes to make setting and cannula changes. Members of the specialist team who are adept at dealing with lifestyle and appetite changes in managing pumps may need to develop their understanding of the implications of chemotherapy or radiotherapy regimens in order to give appropriate advice.

Should the person with diabetes wish to remain on their pump, the infusion rates can be adapted to cope with even the last days of life. In this situation close cooperation between diabetes specialist teams is crucial since the caring team may be unfamiliar with

the equipment. The diabetes specialist team can advise about alternative insulin regimens in situations where pump treatment is no longer considered to be appropriate or feasible, but planning ahead will minimize the understandable anxiety associated with switching. On a practical note insulin pumps may be returned to the issuing department when they are no longer required, as they can be reconditioned and re-issued.

Nutrition

It is important that people at end-of-life care are reviewed regularly to determine whether they are becoming malnourished or dehydrated. If there are concerns that an individual is not receiving adequate nutrition or hydration by mouth, even with support, an assessment of their condition, their individual requirements and consideration given to different forms of clinically assisted nutrition must be undertaken. If the individual refuses to eat or drink or has swallowing difficulties, an assessment of the underlying cause, for example depression, dry mouth, oral candidiasis, or painful mouth ulcers, and possible treatment should be offered [26].

Poor appetite or reductions in meal size along with swallowing difficulties experienced by some individuals will impact on glycemic control and may lead to hypoglycemia. People with T2DM may be taking several oral glucose-lowering therapies, which may be difficult to swallow because of tablet size, or the number of medications prescribed. In these instances, a medication review should be undertaken and treatment regimens simplified. Individuals may also prefer to take smaller meals more frequently. Avoidance of glucose-rich foods may no longer be considered appropriate and so diabetes therapies may need adjustment to reduce hyperglycemic symptoms. It is entirely appropriate to relax dietary restrictions originally designed to minimize weight gain and stabilize blood glucose control. Patients can be offered any of their favorite foods in order to tempt them to eat. Other guidance includes:

- Consider using metformin in powdered form or syrup if patients are not coping with tablets.
- Avoid long-acting sulfonylurea preparations (e.g. glibenclamide).
- If small meals are being taken, repaglinide can be useful for managing small regular meals with dose adjustments according to intake.
- Low-dose insulin may be the only option for those whose glucose levels are high despite a significantly reduced oral intake.
- People receiving insulin with poor intake will need lower doses [21].

Management of diabetes in those treated with glucocorticosteroids

The use of steroid therapy in people in end of life can alleviate symptoms, reduce fatigue and improve quality of life [27, 28].

Table 63.4 Suggested treatments for hyperglycemia when using steroids.

Regimen	Treatment
Once daily steroid therapy	Morning administration of a sulfonylurea, e.g. gliclazide, or morning isophane insulin, e.g. Insulatard, Humulin I, or Insuman Basal
Twice daily steroid therapy	Consider using a twice daily sulfonylurea (e.g. gliclazide) or isophane insulin. If hypoglycemia is a concern consider changing to a long-acting analog insulin, such as insulin glargine or insulin detemir

Source: Adapted from the Joint British Diabetes Societies Inpatient Care Guidelines 2014 [29].

They can be given using various regimens and in variable doses. The most common method is a short course of, for example, prednisolone given in the morning which will lead to raised blood glucose readings later in the day but reducing overnight. People with cancer are more frequently treated with dexamethasone twice daily which can lead to hyperglycemia throughout the 24-hour period. The commonest treatment for steroid-induced hyperglycemia is a sulfonylurea, such as gliclazide, or isophane (NPH) insulin (Table 63.4) [29]. People on very short courses of steroids (less than 3 days) may only require close monitoring. Targets should include a blood glucose concentration between 6–15 mmol/L (108–270 mg/dL) and no osmotic symptoms. Any diabetes treatments should be reduced or stopped in tandem with steroid reduction to avoid hypoglycemia.

Withdrawal of diabetes and other medication

The decision to withdraw from treatment including medication used in diabetes is difficult. Recognizing the concept of a "good death" for all people entering an end-of-life phase can be an awkward aspect of caring to communicate. Key priorities should be freedom from pain, being with family and loved ones, and being treated with dignity and respect at all times.

The use of an advanced or a living will is becoming more common; this is a legal document that needs to be signed and witnessed and enables the person with diabetes to refuse specific types of treatment at an indeterminate time in the future. Health professionals need to know if an advanced directive is in place [1, 12, 30–34]. The UK guidance [21] recognizes that any withdrawal of diabetes-related treatments warrants close liaison with the person with diabetes, the family, and the family doctor, and *must* take into account the patient's wishes, family concerns, and the presence of an advanced directive.

Treatment withdrawal can be considered:

- when the person with diabetes is entering the terminal phase of life;

- where frequent treatment-related hypoglycemia is causing distress and significant management difficulties;
- where continued treatment with insulin poses an unacceptable risk of hypoglycemia or where the benefits of stricter glucose control cannot be justified;
- where continued use of blood pressure or lipid-lowering therapy cannot be justified on health benefit considerations;
- where continued food or fluids is not the choice of the patient;
- where prescribing anti-infective therapy is unlikely to benefit the patient.

Workforce

Dissatisfaction with and complaints about care provided at end of life still occur too frequently, and are usually attributable to inadequate understanding of the complexities of the situation, a failure of communication, or both. Lack of workforce knowledge and training in end-of-life care is a common feature of professionals delivering diabetes care both in hospital and community settings [21, 33]. Conversely palliative care clinicians may lack up-to-date skills in diabetes medication and management, impacting on their ability to offer holistic packages of care. Healthcare professionals need to know where their area of responsibility lies and recognize when they need to consult with other team members and colleagues, specialist teams, social services, or voluntary organizations in order to ensure a holistic approach to care [35]. All staff caring for individuals at the end of life should have received initial and ongoing training and have been assessed for competency [21, 34].

Competency is defined as "the state of having the knowledge, judgment, skills, energy, experience, and motivation required to respond adequately to the demands of one's professional responsibilities" [34]. The competency framework from the comprehensive *Integrated Career and Competency Framework for Diabetes Nursing* illustrates the different competencies expected from healthcare professionals and unregistered practitioners involved in the care of someone with diabetes at the end of their life [36].

12 Delivery and Organization of Diabetes Care

64 The Role of the Multidisciplinary Team Across Primary and Secondary Care

Samuel I. Seidu, Kamlesh Khunti, and Melanie J. Davies
Leicester Diabetes Centre, University of Leicester, Leicester General Hospital, Leicester, UK

Key points

- The rising prevalence of diabetes coupled with increasing life expectancy makes it impossible for specialist care to cope with the demands of diabetes care, thus necessitating a shift to primary care.
- In an integrated diabetes care model, innovative collaboration between primary care and specialists can result in the creation of new healthcare organizations that can provide integrated diabetes care for their local populations.
- Care provision in community settings other than within general practices requires a collaborative unit of diabetes specialist support teams based on the needs of the local population.
- Multidisciplinary teams are essential for the care of people with diabetes from early life to end of life.
- Multidisciplinary teams are essential to manage the various complications of diabetes.
- The composition of multidisciplinary teams should span a wide range of specialties and community care workers in order to address the complexities of diabetes.

Background

Diabetes has now been recognized as an epidemic globally. In 2015, the prevalence of diabetes was estimated to be 415 million worldwide, and this is expected to rise to 642 million by 2040 [1]. It is a complex chronic disease affecting multiple organ systems, often accompanied by other comorbid conditions with an associated disease management burden for people with diabetes. The rising prevalence coupled with the increasing life expectancy makes it impossible for secondary care to cope with the demands of diabetes care, which was the case until 20–30 years ago, thus necessitating a shift to primary care (i.e. by general practitioners or family physicians) [2]. The community (i.e. outside the hospital setting) or primary care management of diabetes is therefore a logical focal point for implementing strategies that improve the care of people with diabetes [3]. Multifactorial intervention in the management of type 2 diabetes mellitus (T2DM) is known to lead to reductions in cardiovascular disease (CVD) mortality [4]. The control of the multiple strands of cardiovascular risk factors in diabetes care requires multidisciplinary teams (i.e. the coming together of health professionals to achieve a common goal). The organization of the teams needs clinicians not just to have the necessary expertise in their chosen fields but to be skilled in an interprofessional approach. The multidisciplinary approach to diabetes management (i.e. the combination of various healthcare disciplines to care for people with diabetes) is based on the premise that, on a background of a common framework, decisions on the aims of treatment should be dictated by the insight of several professions. This normally requires team building, focusing on developing a common culture and giving priority to professional and social interaction. The purpose of this multidisciplinary approach is to ensure that the activities around the complexities of screening, diagnosis, early and late management, and treatment of complications are coordinated, with the aim of ensuring an optimal individualized management plan for each person with diabetes. The patient thereby will be expected to receive a seamless integrated approach to their care in a coordinated way.

Coronary heart disease (CHD) is a frequent complication and a major cause of mortality in people with diabetes. Therefore, its presence can create added complexity for an already burdensome regimen. Individuals with diabetes also experience added burden from other, non-CVD comorbidities (e.g. osteoarthritis, chronic obstructive pulmonary disease), with only 17.6% having diabetes alone [5]. The treatment of the complications and these comorbidities requires coordination across a number of specialists. System management is therefore essential, including the flexibility to deliver personalized care and identifying and meeting the individual needs of people with complex needs. In dealing with these complexities, integration of care around the person with

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

diabetes is pivotal to delivering seamless, optimal, and effective care. Integration refers to the bringing together of people of different healthcare professional backgrounds into unrestricted association with the aim of delivering a seamless care package for people with diabetes.

Upskilling of primary or community care professionals in multidisciplinary teams

In an integrated diabetes care model (referring to a system of care worthy of emulation), innovative collaboration between primary care and specialists can result in the creation of new healthcare organizations that can provide integrated diabetes care for their local populations. With the person with diabetes at the center, delivery of care can revolve around them, with the aspiration of having an organizational structure, clinical pathways and financial planning that all align seamlessly [6]. The subsequent care pathway that is developed should be customized to the wide-ranging needs of the local population and adapted to the evolving needs and the changing national health agendas instead of a "one size fits all" model. The prime focus of the integrated diabetes service is the integration of a healthcare system and the coordination of services around a person with diabetes, bringing together primary and specialist care in a setting nearer the patient's home, where applicable.

In order to maintain successfully or even improve patient outcomes and reduce variations in care, while supporting this "left shift" of care, upskilling of general practitioners, practice nurses, and healthcare assistants and ongoing support from specialists in this field are required. This comprehensive upskilling process of healthcare professionals needs to be based on psychological theories of learning [7–9] with the necessary knowledge repertoire. It is hoped that this will equip the diabetes care workforce with the appropriate knowledge and skills to provide them the confidence to deliver the highest quality care and improve patient outcomes.

Possible areas of training could include mentorship and case management at practice level to support clinical development, training, and care planning. Not only should the education and training be available at different levels, but also they need to be provided by multiple alternative and complementary methods, including workplace-based learning, distance learning, modular format, journal clubs, and mentorship [10]. The multidisciplinary team creates an adaptable and responsive model with a feedback mechanism that encourages the improvement of the quality of care through their knowledge of local needs. Furthermore, and crucial for such an educational program's longevity, it has to be developed so that it can reflect the continually changing approaches to diabetes management in relation to new therapies and national drivers [10].

Practices that participate and engage in this training process can gain accreditations based on the breadth and level of diabetes care that they provide [10]. A stepwise and ongoing accreditation process could start from the provision of a basic core service, including screening of all individuals at risk for diabetes, diabetes prevention interventions, regular surveillance of all persons with diabetes, i.e. measuring and managing HbA_{1c} according to guidelines, blood pressure and cholesterol measurements, eye and foot examinations, reduction of CVD risk, evidence-based prescribing, auditing care provision, and evidence of referral and attendance at evidence-based patient education interventions/programs [10].

A step up on the accreditation ladder will be practices that can provide elements of an enhanced service, including the management of those with complex conditions on insulin, including in-house initiation and titration for people with T2DM, management of those with stable type 1 diabetes mellitus (T1DM), initiation and management of glucagon-like peptide 1 (GLP-1) receptor agonist therapies, high quality of care for housebound patients (including nursing/residential homes), and proactive discharge of suitable patients currently under specialist follow-up [10].

Support of multidisciplinary teams in structured patient education in diabetes

People with diabetes have to live the rest of their lives with the condition and therefore need to improve their knowledge, skills, and confidence, enabling them to take better control of their own condition through the positive improvement of their beliefs. They also have to integrate effective self-management into their daily lives. These aims can be achieved through structured patient education programs [11].

The multidisciplinary team will need to consider a range of issues in order to ensure that their patient education programs meet the expected standards. The program must have a written curriculum, and include areas such as health professional training, quality assurance, and learning needs assessment [12]. Healthcare professional training should incorporate modules around patient centeredness. Professional training in cultural diversity awareness in diabetes, self-management initiatives including motivational interviewing and other behavior change interventions, and psychosocial aspects of diabetes will help multiprofessional teams develop working plans to achieve desired goals [11]. This structured training for diabetes educators has to address the theoretical base and the underlying philosophy of structured education in diabetes. The program itself therefore has to be underpinned by the philosophy that it will be adaptable to the needs of people with diabetes and involve them in its ongoing development. It should be evidence based and have clear aims and learning objectives that are shared with people with diabetes and their carers and family. Health professionals have to plan with people with diabetes on issues around the care of their condition.

Local multidisciplinary teams have the responsibility of ensuring that there is an internal quality assurance process in place for the structured education programs. This ensures that practitioners are carrying out self-reflection during the delivery of the program with ongoing review of the biometric outcomes and patient satisfaction and experience in order to maintain standards

[13]. External reviewers will have a role in ensuring that the internal quality assurance program is robust to ensure that the center is delivering sufficient programs to maintain educator skills. They will ensure that there are organizational processes in place to guarantee that the program can be delivered according to the set philosophy and standards.

Multidisciplinary teams in diabetes care models

In developing a diabetes service, it is important to know what the components of the service ought to be and the mode of implementation required. Even though the models of care delivery in diabetes vary from country to country, the components required are broadly similar; it is the implementation that varies from place to place. The choice of implementation strategy depends on the local needs and the availability of various component resources. In many developed countries, there is usually a national strategy in delivering diabetes care.

In a generic service model, there must be integration across all levels of the service in order to provide a seamless transition for people with diabetes and to ensure that appropriate referrals take place, with clear and agreed referral criteria and clinical protocols for chronic and emergency management (Figure 64.1). Good communication links and joint working between the practice diabetes leads and specialist care teams are essential for the planning of services and to provide a framework for audit, quality assurance, and performance monitoring.

Care provision in community settings (i.e. other than within general practices) requires a collaborative unit of diabetes specialist support teams. These teams are constructed based on the needs of the local population and can comprise a collaborative team of diabetes specialist nurses, diabetes consultants, dieticians, diabetic retinopathy screening teams, and podiatrists. They can offer clinic-based care, outreach support to practices and nursing homes, rapid-access community clinics, development of agreed clinical care pathways for various aspects of diabetes care and referrals, and telephone- and web-based support for complex cases, again depending on the needs of the locality. This support should be flexible in approach and multistranded to reflect the varying gaps in knowledge of the healthcare professionals. The fundamentals of any such program should be applicable and transferable to other diabetes care providers.

These components require a coordinated approach between multiple healthcare professionals in different sectors of health and social care. For local populations, a local model of care is required, which can be developed in more detail, with roles and responsibilities clearly identified. Ideally, care should be provided within each locality to agreed care pathways, and each care provider should be clear about their role and relationship with other providers. The delivery of integrated diabetes care in any locality requires leadership and teams working through cooperation, coordination, and collaboration, working to a shared vision of healthcare, and drawing together the skills and relationships across the healthcare community. This integrated collaborative approach has been shown to be effective not only in mental illness but also in the management of people with other chronic physical multi-morbidities [14]. Specialist diabetes teams, often with extended roles, working in primary care through community consultants, form a central "hub" of expertise to support the delivery of high-quality and effective diabetes care.

In the United States, there is a drive to incorporate elements of the chronic care model into diabetes care. System redesigns, self-management, and decision support and organization of diabetes care in the community could collectively improve outcomes in diabetes and reduce costs [15]. Organizations such as Kaiser Permanente are using these components in diabetes care and have shown improvements in admission rates and outpatient clinic attendances [16].

The situation is much more challenging in developing countries such as sub-Saharan Africa, where diabetes care, largely driven by specialist care, faces competition for resources from infectious disease care. The lack of financial, infrastructural, and human resources is a major drawback for any effective service implementation in diabetes care, thus leading to a shorter life expectancy in individuals with diabetes [17].

Enhancement of multidisciplinary teams through the use of information technology

Local information technology (IT) infrastructure allowing shared records between primary, community, and secondary care and providing secure data centers to facilitate monitoring of clinical outcomes and service improvement is also required. This can assist people with diabetes, carers, and healthcare professionals in the choice of therapeutic options, understanding of the disease and its complications, and self-management [18]. Through the use of integrated IT systems, the provision of therapies and services to people with diabetes in different healthcare regions is made possible by ensuring effective responses to the needs and preferences of those with diabetes, improvements in healthcare processes and intermediate outcomes, patient–clinician communication, and access to medical information [19]. However, appropriate consideration needs to be given to potential problems with access to the IT infrastructure due to older age, low income, poor education, and cognitive impairment and also to physicians' concerns about increasing their workload.

Multidisciplinary teams in the management of complexities in CVD risk prevention

The presence of a complex health and illness profile is found to be associated with worse control of cardiometabolic risk factors independent of regimen intensity and history of CHD [20]. This is compounded by the fact that management of the major CVD risk factors in diabetes has raised questions about the benefits of

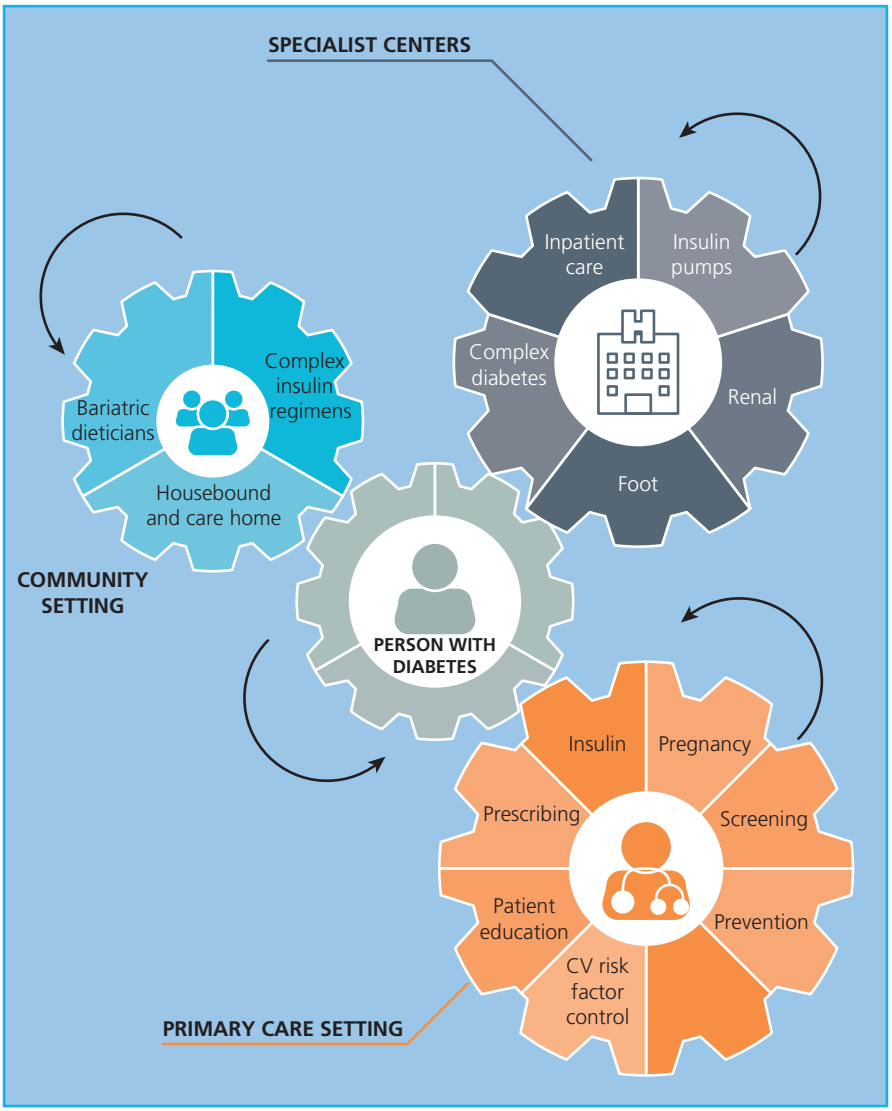

Figure 64.1 An illustration of integration of care across the levels of the service in order to provide a seamless transition for people with diabetes and ensure that appropriate referrals take place.

high risk factor control. In glycemic control, for example, although early intensive treatment in diabetes results in lasting benefit, including CVD risk reduction [21], intensive glycemic control in people with late diagnosis and background CVD does not reduce major cardiovascular events and indeed may increase mortality [22]. Similarly, even though major reductions in cardiovascular outcomes are seen in people receiving tight control of blood pressure compared with those receiving conventional control, if the baseline blood pressure was high [23, 24], tight control of systolic blood pressure among people with diabetes and CHD has not been shown to improve cardiovascular outcomes [25]. Indeed, increased mortality in intensively treated people with newly diagnosed diabetes has also been noted and caution in lowering blood pressure too aggressively is therefore recommended in these patients [26]. Regarding cholesterol, a reduction of 1 mmol/L in low-density lipoprotein leads to a 20–25% reduction in cardiovascular events (major coronary events, coronary revascularization, and ischemic stroke) [27]. However, among persons at increased risk for diabetes (those with baseline evidence of impaired fasting glucose, metabolic syndrome, severe obesity, and elevated HbA_{1c}), the risk of developing diabetes among those treated with statins appears to be raised. However, the overall cardiovascular and mortality benefits of statin therapy exceed the risk for developing diabetes [28]. Nevertheless, this finding introduces another complexity into CVD risk management in diabetes. Hence the control of the various risk factors could potentially require inputs from other team members with expertise in particular areas.

Multidisciplinary teams in renal disease in diabetes

The presence of chronic kidney disease increases the risk of CVD morbidity and mortality and increases the risk of progression to end-stage renal disease [29]. Diabetic nephropathy is progressive and its management requires the input of a number of

healthcare professionals at various stages of the disease trajectory. The primary care teams, after initial diagnosis of early disease, can reduce the progression of renal disease with the use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers [30, 31]. Specialist assessment should be available to individuals with or at high risk of renal disease through referrals by the primary care teams as the disease progresses. The late management and treatment of complications should be well coordinated, with the diabetes renal service working closely with nephrology services. Diabetes nephrology services should have appropriately trained staff and systems in place not just to organize the service effectively in a timely manner during disease deterioration but also to manage acute complications such as hypoglycemia during episodes of dialysis. Multicomponent structured patient educational interventions have been shown to be effective in predialysis and dialysis care [32]. The role of the dietician is invaluable in this group of patients not only to maintain adequate nutrition but also to prevent abnormal electrolyte excursions [33].

Multidisciplinary teams in the care of people with diabetic retinopathy

The implementation of a diabetes retinopathy service should involve a multidisciplinary team of clinicians who understand the natural history of the condition and options for early detection and treatment. The service will normally comprise permanent staff at a fixed or mobile retinal screening unit who are engaged in regular professional development updates. The aims of the service should to be to improve access to retinopathy screening, particularly for those for whom access has traditionally been limited, for example individuals who are housebound, disabled, elderly, indigenous, or from non-native-speaking backgrounds. In the pediatric and adolescent populations, it is essential to have an ophthalmologist with expertise in diabetic retinopathy and an understanding of the risk for retinopathy in the pediatric population, backed up by a team that has experience in counseling young persons and their families on the importance of early prevention and intervention [34]. The coordination and supervision of such a service requires effective leadership to identify clinical incidents, make safety assessments, and draw up proper interventions to tackle these deficiencies. The general practitioner keeps an updated register of people with diabetes for a call–recall system for retinopathy screening. This is coordinated through appropriate liaison between the hospital eye service and screening program.

Successful multidisciplinary coordinated retinal screening services should have the necessary components not just for screening but also for investigations and management. There has to be immediate access to facilities for fluorescein angiography and optical coherence tomography to allow individuals with maculopathy to be treated within 10 weeks [35] and those with new proliferative retinopathy to receive laser treatment within 2 weeks [36–38]. Patients needing urgent photocoagulation should be able to have it carried out immediately. For patient convenience, it is better to have the laser treatment carried out on the day when diagnosis of the problem is made, hence there should be sufficient laser clinics or staff available to undertake the treatment outside laser clinics. Intravitreal drug delivery facilities will be needed at any treatment center [37], but vitreo-retinal surgery, if not available locally, can be referred to a tertiary referral center. For individuals with visual impairment, appropriate counseling services should be available.

Multidisciplinary teams in the care of people with diabetic foot problems

Many people with acute diabetic foot ulcers also have other multi-morbidities including macrovascular complications, hence healthcare professionals must be mindful of these aspects [39]. Foot ulceration has been reported as the leading cause of hospital admission and amputation in individuals with diabetes [40]. Acute diabetes-related foot ulcers require multidisciplinary management and best-practice care, including debridement, offloading, dressings, management of infection, modified footwear, and management of extrinsic factors [41]. Treatment of diabetic foot ulcers varies widely, depending on the skills of the attending clinicians. Best practice is deemed to be a multidisciplinary approach, where the holistic view of the person with diabetes is sought, and a care plan developed around their individual needs. However, these multidisciplinary teams are not always available. Multidisciplinary teams ideally should include appropriately trained staff such as orthotists, podiatrists/podiatric surgeons or both, vascular surgeons, orthopedic surgeons, diabetologists, microbiologists, radiologists, diabetes specialist nurses (including a diabetes specialist inpatient nurse), ward link nurses, and consultants in pain management (with an interest in diabetic neuropathy) [41].

For individuals at no added risk, foot-care education is usually all that is required, but as they become at risk, twice-annually reviews including foot inspection, footwear assessment, and foot-care education become necessary. Those at high risk (i.e. the presence of more than two risk factors) need reviewing every 3–6 months, including foot inspection, footwear assessment, and potential need for vascular assessment or referral. Referral to a multidisciplinary foot-care team within 24 hours for management of ulcers and infection is mandatory [42]. To ensure a seamless package of care for people with foot-care problems, it is important that they are put at the center of the decision-making process, and have access to accurate information and support. The organization of care has to involve appropriate healthcare professionals, including community podiatrists who have a clear referral pathway to specialist services. The multidisciplinary specialist teams must endeavor to hold joint clinics in order for the service to be more effective and to reduce duplication of visits [43]. For the inpatient with diabetes, close observation for risk factors and prevention of foot ulceration is crucial, as this can be a vulnerable situation with increase in pressure-related ulcers.

For the seamless organization of care around the person with a diabetic foot problem, services to support the management must be readily available. Facilities for pressure area offloading include orthotic services, foot casting, and prosthetic services. Imaging facilities, including X-ray, computed tomography, and magnetic resonance imaging, and microbiological support services also need to be available.

Multidisciplinary teams in the care of women with diabetes in pregnancy

All women of child-bearing age who have diabetes should have access to preconception services [44]. This may often be in primary care. However, it is important that there is integration of care between primary, community, and specialist services. Specialist services can provide the leadership and support to raise awareness and provide education to primary and community services so that women with diabetes are aware of the need for preconception counseling and support. Through this leadership, guidance, and auditing of clear documentation of preconception counseling, pregnancy care and postpregnancy management can be carried out effectively.

The components of a multidisciplinary specialist diabetic pregnancy service should include clear signposting to different aspects of care, diet and lifestyle advice, provision of appropriate contraception, alcohol and drug counseling, higher dose folic acid supplementation, smoking-cessation support, assessment and management of diabetes complications, setting of glycemic control targets, and regular discussion of results of self-monitoring to enable the woman to achieve control that is as near to normal as possible before conception, discussion of diabetes pregnancy risks and expected management strategies, and clear documentation of care and counseling [45].

Once a woman with diabetes has become pregnant, a specialist multidisciplinary team with interest in diabetes in pregnancy, composed of an obstetrician, diabetologist, dietician, and diabetes specialist nurse and midwife, should be made accessible. The role of the specialist multidisciplinary team should be to agree an individualized care plan covering the pregnancy and postnatal period up to 6 weeks. The contents of such plans will include glycemic control targets, retinal and renal screening schedules, fetal surveillance, a plan for delivery, and a plan for immediate postdelivery diabetes care [46].

Multidisciplinary teams in the care of young people with T2DM

With recent increases in overweight and obesity, the prevalence of T2DM in the younger population is also rising. People with T2DM diabetes under the age of 45 years have a fourfold increased risk of myocardial infarction compared with those aged 45 years or more [46]. This age group will normally also include women of child-bearing age who require special care [47]. Diabetes occurring early in adult life appears to lead to more aggressive cardiovascular complications than in age-matched people without diabetes, although the absolute rate of CVD is higher in older adults [46]. These younger individuals may also have other conditions such as non-alcoholic fatty liver disease, sleep apnea and vitamin D deficiency. The implications of this are not just the development of complications for these persons, but also a tremendous knock-on effect on the economy as a whole as this is the age of maximal productivity. Hence strong leadership for the delivery and organization of services and the championing of the needs of younger people with diabetes is essential. Younger people with T2DM require tailored management strategies to engage them and manage their CVD risk factors intensively, because these risk factors are highly prevalent and insufficiently treated in this extreme phenotype of T2DM diabetes [48].

A service for young people with diabetes should include a consultant diabetologist, a diabetes specialist nurse, a specialist diabetes dietician, and a clinical psychologist with an interest in diabetes. The collaborative working of these healthcare professionals will ensure that a package of care encompassing psychological, dietary, and cardiometabolic risk control is delivered. These individuals are likely to be in active employment, so flexibility in the delivery of service at convenient times is essential to engage them. In the primary care setting, there should be adequate provision for routine care, including diagnosis, initial management, continuing care, surveillance, management of complications, and annual assessment. Access to family planning, contraception, and preconception services should be provided. In working together with consultants, there should also be an agreement for arrangements for shared access to records and ready access to specialist diabetes advice. Targeted glycemic levels can be established before any attempt at conception is considered [44]. Access to smoking-cessation and substance-abuse services should be integrated into any such service design.

Multidisciplinary teams in the care of elderly people with diabetes

Even though elderly people with diabetes have as high a risk of developing a range of macro- and microvascular complications as their younger counterparts with diabetes, their absolute risk for CVD is much higher. Older persons with diabetes suffer excess morbidity and mortality compared with those without diabetes [49]. Contributing factors to this increased risk in elderly persons with diabetes include cognitive impairment, functional disabilities, frailty, polypharmacy, depression, urinary incontinence, and persistent pain [50].

The components of a diabetes service for the elderly should be commissioned, delivered, and monitored to ensure that it is delivered as locally as possible, near to the families' homes. The multidisciplinary team staff with interest in diabetes must include a consultant geriatrician, a consultant psychiatrist for the elderly,

a diabetes specialist nurse, a consultant diabetologist, a specialist diabetes dietician, and a community pharmacist. Specific services aimed at elderly people with diabetes should include diabetes education programs aimed at healthcare professionals looking after elderly people [51]. This is particularly important for elderly individuals because of the complexities of varying targets in this population. Older people with diabetes are not a homogeneous population; rather, they may include persons who are functionally independent and residing in the community and those who may be functionally dependent with many comorbidities and are living in assisted care facilities or in nursing homes. Each group will have individualized targets for CVD risk factor control. In frail older persons with diabetes, avoidance of hypoglycemia, hypotension, and drug interactions due to polypharmacy is of great concern [52]. In addition, management of coexisting medical conditions is important, as it influences their ability to perform self-management.

Uncontrolled diabetes is associated with an increased risk for dementia, including the vascular and degenerative types. In addition, borderline and undiagnosed diabetes are related to Alzheimer disease without vascular comorbidities, which suggests a direct link between glucose dysregulation and neurodegeneration [53]. As a result, access to integrated memory clinics with psychological support and local counseling is needed for elderly patients with diabetes. Case management is best delivered by a dedicated community psychiatric nurse and a social worker who ensure that there is adequate provision for routine care, including diagnosis, initial management, continuing care, management of complications, and annual assessment. There should also be provision for rapid access to the service when needed, together with agreements with primary care for arrangements for shared access to records and 24-h access to specialist diabetes advice. It may well be that owing to the multimorbid state and frailty of these individuals, these services are delivered at home or in residential institutions.

The staff composition of a multidisciplinary diabetes team

Community pharmacists

A sustainable collaborative care approach for people with diabetes should make use of community pharmacists, a local and accessible resource that is increasingly regarded as the first port of call for patients to seek help with the management of chronic disease. By offering programs for monitoring therapeutic interventions, improving adherence with medication, and educating people about their lifestyle to improve their quality of life, community pharmacists play a vital role in managing diabetes and its complications [54, 55] On average, the community pharmacist consults with individuals with diabetes three to eight times more frequently than other persons [56]. As a result, in addition to bringing "medicines expertise" to the team-based care of people with diabetes and performing root-cause analyses of adverse events with diabetes medicines to contribute to the patient/medicine safety agenda, community pharmacists can help establish a collaborative care approach to managing diabetes and reducing associated CVD risk factors. The availability of such a collaboration can bridge the gap between a successful pharmacy screening program for diabetes and primary care follow-up of these persons [57]. This role can be extended to individuals in residential care or who are housebound.

Practice nurses

In the primary care setting, chronic disease management is increasingly being carried out by practice nurses with general practitioners intervening only in complex cases [58]. In the case of diabetes, this has become even more necessary because of the increasing prevalence and the burden of caring for people with the disease. It is known that despite the worsening of health-related quality of life and an increase in diabetes-related symptoms, practice nurses are able to achieve results that are comparable to those achieved by a general practitioners in terms of cardiometabolic risk factor reduction [58]. People being treated by practice nurses also reported as being more satisfied with their treatment than those being treated by a general practitioners [58]. The care of people with T2DM can therefore be safely delivered by practices nurses, using clinical guidelines. This makes the nursing team an important resource in a multidisciplinary primary care team. The extension of the practice nurse's role to include the initiation and titration of medications complements their other roles such as in supporting and educating people with diabetes and enabling them to manage their diabetes care, thus ensuring a holistic delivery of care closer to home. However, they can potentially overutilize insulin inappropriately, and close collaborative working between nurses and doctors can limit any potential overutilization of insulin management if it were to occur.

General or family practitioners

The use of primary care physicians (general or family practitioners) can be as good as if not better than hospital outpatient care if regular review of patients is guaranteed [3]. The enhancement of the generalist's care for people with diabetes with the use of quality improvement strategies such as audit and feedback is an effective tool for reducing the CVD risk profile [59]. The generalist's role often includes active case management of patients with multiple conditions. In these patient groups, continuity of care is of paramount importance. Multidisciplinary primary care teams, led by the generalist, therefore have a fundamental role in the prevention and identification of diabetes and also in routine care at a level that fits with their competencies. They will ensure that an accurate disease register is maintained to enable a call–recall system for annual reviews to be set up. They work cooperatively with other members of the team, seeking their views, acknowledging their contributions, and using their skills appropriately. People with poor CVD risk factor control and those with early signs of microvascular complications can be identified and referred on to more specialist centers. The generalist has a more

longitudinal relationship with patients with chronic conditions such as diabetes. They have the responsibility of coordinating the management of the patient's acute and chronic complications of diabetes over time. They have an understanding of the patient in relation to their socioeconomic and cultural background and, additionally, recognize the impact of the problem on the patient's family and carers. They will therefore use appropriate support agencies including primary healthcare team members targeted to the needs of the person with diabetes.

The pay-for-performance initiative started in the United Kingdom in 2004 is probably the most ambitious quality improvement strategy and initially yielded some obvious improvements in the care of people with diabetes [60], but these benefits reached a plateau across the population [61] and did not lead to reductions in the variations in care [62, 63]. The provision of primary care services for people with diabetes, whether traditional primary care clinics or diabetes clinics run by GPs with special interests, is effective in reducing HbA_{1c}, cholesterol, and blood pressure [64].

Diabetes specialists

The rising prevalence of diabetes coupled with increasing life expectancy makes it impossible for specialists to cope with the demands of diabetes care, which was the case until 20–30 years ago, thus necessitating a shift to primary care [50]. Hospital diabetes clinics developed historically from the need for supervision of insulin treatment. Inevitably, they also recruited large numbers of people with diabetes not managed with insulin. The work load has thus increased over the decades. With the majority of people with diabetes now being managed in primary care, the specialist's role in insulin management has become limited to the acutely ill patients with diabetes, including those with diabetic ketoacidosis, those with acute myocardial infarctions, those in intensive care, and those on renal wards who need meticulous insulin management to foster early recovery. People with T1DM or T2DM who require complex insulin regimens for the control of their diabetes, such as those needing very large doses and those needing insulin in combination with newer therapies, are managed by the specialist. Most consultants with a specialist interest in diabetes are based in acute hospitals where they also deliver general medicine, alongside training roles, general management, and research. As a result of these multiple roles, they are very well placed to provide multidisciplinary diabetes specialist teams with leadership, providing support and education to community diabetes services. In some areas, the integration of services has made it necessary to employ an increasing number of community diabetes consultants who deliver and coordinate services in a community setting only.

Dieticians

The use of dietary education has been found to improve anthropometric measures and glycemic control and the use of less prescribed medication [65]. By improving knowledge of diabetes self-managed, dietician-led diabetes management programs can be an effective strategy for glycemic control and improving dietary habits for individuals with poorly controlled T2DM [66]. Registered dieticians can therefore contribute greatly to the comprehensive care plans for persons with diabetes. They work as members of multidisciplinary teams across a variety of healthcare settings, including primary and specialist care. Their caseload might encompass working with children, adults, young people, and individuals with mental health problems. They also have an important role in the management of severely obese people with diabetes. The dietician can also offer support for those with T1DM in areas around carbohydrate counting. In primary care, their role could be in advising people at risk of diabetes and those who are newly diagnosed on the appropriate dietary requirements. In the case of patients with diabetes with complex needs requiring initialization or augmentation of insulin therapy, dietician support is normally necessary. Within a specialist care setting, they support antenatal and postnatal care of women with diabetes. They can provide dietary support before and after bariatric surgery. For patients with mental health issues such as eating disorders, dietician support to maintain weight and glycemic control can be sought. On dialysis units and inpatient wards, people with diabetes will normally need complex nutritional care such as enteral feeding. The dietician supports people with complex problems such as gastroparesis and pancreatitis.

Community health workers

Diabetes programs can include community health workers in the multidisciplinary teams in a variety of roles. They usually reside in the target community and are given special training to help bring health services, health education, and health promotion to their local communities. They also mobilize members of the community to adopt behaviors that improve their overall health and living conditions [67–69]. This important resource has to improvements in patients' knowledge and behavior and in some cases may even improve biochemical outcomes in diabetes and promote health [70]. The optimal role of peer support of community lay educators is particularly crucial in low-income, underserved populations, particularly for racial and ethnic minority communities [68, 71–73]. Their knowledge of the language, culture, and geographic background of communities can be used to coordinate care in partnership with healthcare systems [74]. Their functions include activities such as home visits, health education, and outreach activities for ambulatory care sites [69].

Conclusion

The management of diabetes through the integration of care between primary and specialist centers can result in the creation of new healthcare organizations that can provide multidisciplinary diabetes care for their local population. The multidisciplinary teams work together around various groups with diabetes, including pregnant women, adolescents, and the elderly. Other groups of patients include those with diabetic foot ulcers, kidney disease, and retinopathies. The teams comprise general or family physicians, community pharmacists, community health

advocates, podiatrists, diabetes specialist nurses, and specialist diabetes physicians, all working seamlessly in a coordinated fashion in the different sectors of a diabetes service.

Key points

- A comprehensive approach to diabetes prevention and care includes policies and activities outside the formal health sector, particularly for primary prevention.
- Integrated care refers to the need to provide care for conditions coexisting with diabetes within the same primary healthcare service.
- Continuity of care, a cornerstone of effective healthcare organization, is associated with improved outcomes.
- Prerequisites for improving outcomes include ensuring that essential medications (including insulin) are either free or highly affordable and that tests for the diagnosis of diabetes, monitoring of control, and equipment to screen for complications are available.
- Living health systems should care for, empower, and nurture their staff so that they are enabled to do the same for their patients.
- If no-one is responsible for chronic care, the tendency is for it to be overlooked.
- A respectful, open, and curious stance may help different professionals and people to understand each other better.
- Patient-centeredness improves quality of life, increases patient satisfaction, improves adherence to treatment, enhances the integration of preventive and promotive care, and improves the provider's job satisfaction.
- In low-resource settings where large numbers of patients overwhelm facilities, it may make sense to extend care into the community.
- Ideally, a systematic process for reviewing the evidence and updating guidance accordingly should be in place in all countries.
- A quality assurance program should be in place for each district in every country.
- Advances in the use of information technology and the Internet are likely to provide increasingly important contributions to diabetes care in all settings.

Introduction

Almost no community worldwide remains unaffected by diabetes. Premature mortality and the morbidity caused by diabetes complications exact considerable personal costs on individuals and families. The economic burden of diabetes remains substantial at the individual, family, health system, and societal levels. It is concerning that there has been little progress in reducing the inequities of healthcare provision for people with diabetes between countries, and also within the same country, for example in rural versus urban settings, private versus public sectors, and hospital versus community-based services. This is typified by the fact that in 2013, while diabetes accounted for 10.8% of total health expenditure worldwide, the majority of this expenditure was in high-income countries where only 20% of the people with diabetes live [1]. As the largest growth in the number of people with diabetes in the future will occur in low- and middle-income countries, where lifestyles are transitioning, the need for diabetes prevention strategies has never been more apparent, nor has the urgent need to improve management and care for those who have already been diagnosed.

The challenges facing health planners and providers, whose goal is for their health system to deliver increasing health benefit at an individual and a societal level, are enormous, especially in less resourced countries and areas. This is because of the emergence of dual or multiple disease burdens, namely traditional infectious diseases, such as tuberculosis and malaria, and also HIV/AIDS, and the emerging scourge of chronic non-communicable diseases, including diabetes, results in competition for limited resources. Further, most healthcare systems have evolved from the basis of dealing with acute medical problems (mainly infectious disease, curative and reactive) and have been or, in most instances, remain ill-equipped to provide the kind of care that people with

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

chronic diseases require. In addition, many low-income countries do not have the primary care infrastructure to cater for people with chronic conditions such as diabetes. This underscores the need for countries in the throes of the diabetes epidemic to focus on healthcare strengthening. That is not to say that well-resourced countries do not face challenges with healthcare delivery. In these countries, there are also problems in ensuring that quality healthcare is delivered in a cost-effective manner. Notwithstanding these challenges, each person with diabetes, wherever they live, should have access to the best care that can be provided in their setting and consequently have the opportunity to achieve the outcomes they seek. Unfortunately, this is not the current situation, even in well-resourced countries and settings.

Over the past 10 years, politicians have made a number of global agreements that might be expected to translate into national level actions to reduce the burden and impact of diabetes. The first was the United Nations Resolution on Diabetes in 2006. This encouraged "member states to develop national policies for the prevention, treatment and care of diabetes in line with the sustainable development of the health-care systems, taking into account the internationally agreed upon development goals, including the Millennium Development Goals" (Resolution 61/225, December 20, 2006). In 2011, the United Nations made a political declaration on the prevention and control of non-communicable diseases (NCDs) followed by the adoption by the World Health Organization (WHO) of a voluntary Global Action Plan for the same [2, 3]. The subsequent introduction of a WHO NCD progress monitor provides an assessment of member countries' implementation of their commitments to develop national responses to the NCD burden. Although many of the progress markers are difficult to measure accurately, it is a step in the right direction. The first report in 2015 indicated that only about one-third of countries have fully met the target of setting up national NCD targets and indicators and having guidelines for the management of NCDs. More recently, the sustainable development goals were launched globally to replace the millennium development goals. For the first time these include a specific target for NCDs that by 2030 we should have reduced by one-third premature mortality from non-communicable diseases through prevention and treatment, and promote mental health and well-being [4].

The International Diabetes Federation (IDF), the WHO, and the NCD Alliance need to work together in order to improve the suboptimal care and outcomes for people with diabetes. After all, it is not that a dearth of evidence exists for the effectiveness of a wide range of interventions to prevent complications associated with diabetes, but rather the reverse. Three interventions that are cost-saving and fully feasible (in terms of penetration of the target population, technical complexity, amount of capital required, and cultural acceptability), even in low- and middle-income countries, have been identified as [5]

1 improvements in glycemic control;
2 improvements in blood pressure control; and
3 delivery of effective foot care.

A fourth intervention, provision of preconception care, was found to be cost-saving, but not fully feasible because of concerns about not being able to reach all women with diabetes. The issue at hand is how to translate the evidence into practice. It also needs acknowledging that, almost without exception, health services are in need of strengthening. The specific interventions to be introduced or implemented will undoubtedly vary, depending on the healthcare structure and resources available. There is also the need to recognize that diabetes requires that people not only have access to sufficient resources, such as medication, but also the understanding, motivation, and skills to self-manage their condition. Healthcare cannot be seen in isolation, occurring as it does within a broad societal framework that places varying degrees of emphasis on ensuring that quality care is prioritized. Thus, in the first instance, for effective healthcare delivery, a positive policy environment needs to be in place, nationally and locally. The "macro" level of the WHO Innovative Care for Chronic Conditions (ICCC) framework focuses on this very issue (Figure 65.1), highlighting the components that can promote a positive policy environment [6]. Political will, building or strengthening partnerships (e.g. between community-based organizations, patient organizations, healthcare workers, and government), and ensuring consistent funding are key aspects of the process. So too is the need for an intersectoral approach or collaboration to building a healthy society, encompassing, for example, urban planning (with the provision of green areas, easy public transport, access to sports and recreation facilities), the introduction of health promotion activities within schools, and regulating the food industry.

The "meso" level in the ICCC framework relates to healthcare organization and links to the community. It is at this level that the concept of "model of care" comes into play. A healthcare model can be regarded as an overarching design for the provision of a service that is ideally underpinned by a theoretical framework, evidence base, and clearly defined standards [6]. The model has core principles and elements in addition to an agreed upon agenda for implementation and later evaluation. It is unlikely that a single healthcare model for diabetes exists that can be used effectively and efficiently in all settings—indeed, the model will take different forms or shapes in different settings. Where health systems are in transition, planners have to decide whether to pursue a diabetes-specific model of care or to incorporate multiple chronic diseases such as diabetes, hypertension, and chronic lung diseases in a common chronic care model. In many established healthcare systems, there is now active promotion of integrated models of care.

Given that type 2 diabetes mellitus (T2DM) frequently coexists with other NCDs, in particular hypertension, thus giving rise to multimorbidity, there are salient reasons for pursuing a common chronic care model and building on the commonality of aspects of care for these conditions. However, factors such as the available resources are likely to guide this decision. Regardless of the model selected, changing the value system in which healthcare is delivered, with the aim of ensuring motivated affirmed healthcare workers, is perhaps key to equipping or enabling people living with diabetes with the information, motivation, and skills to

self-manage their diabetes. There is a real need to embrace the lessons that can be learned from the successful highly active antiretroviral therapy (HAART) programs for people with HIV/AIDS, which have yielded levels of adherence to therapy that most clinicians and public health specialists can only dream of in relation to diabetes [7]. There are certain core principles for diabetes care that could be applied across all resource settings [6]. These include establishing:

- A comprehensive approach that provides for health promotion to allow prevention and early diagnosis and management of diabetes and complications when they arise and rehabilitation when needed.
- Integrated healthcare, such that conditions coexisting with diabetes can be readily managed within the same primary healthcare service.
- Continuity of care, which has a number of connotations: in terms of the relationship between healthcare worker and patient; in terms of management strategies and decision-making; and in terms of patient information.
- Access to care, which can be understood in a physical or geographic sense, but extends to access to appropriate equipment for monitoring, diagnosis, and management in addition to medication.
- Coordination of care from primary to secondary and tertiary levels, with appropriate referral strategies and role delineation. Where multiple professionals and organizations are involved in primary care, horizontal coordination of care is also important.
- Teamwork between multiple health workers, professional categories, and disciplines, even in low-resource settings, is important. Establishment of teams whose focus is on delivering and improving the quality of care permits the development of shared goals, defining and clarifying roles, reflecting on how care can be improved, and holding each other accountable for decisions. The identification of a team leader may be a major factor in the success of this element.
- Person-centeredness implies a more collaborative approach and holistic understanding of the patient that elicits, acknowledges, and addresses relevant beliefs, concerns, and expectations. This is often a paradigm shift in the mind of the health worker from the traditional biomedical, technical, and sometimes authoritarian model to a more personalized, biopsychosocial, and goal-orientated model [8].
- Family and community orientation are integral to providing support for the individual with diabetes and also to raising awareness and extending care from the health centers into the community.
- The use of evidence as far as it is available, accessible, and relevant. The evidence base for diabetes is constantly expanding and all resource settings need to look at how they access the latest and ever-changing evidence base.

We now discuss how these principles are being incorporated into care for people with diabetes across different resource settings in high-, middle-, and low-income settings, and how information technology can be embraced and harnessed

appropriately in different settings with the goal of supporting these principles.

A comprehensive approach

Taking a comprehensive approach to diabetes prevention and care implies that policies and activities are put in place to address primary prevention, early diagnosis (including screening if appropriate), management of diabetes and its complications, and rehabilitation for those affected by complications. A comprehensive approach will include policies and activities outside the formal health sector, particularly for the primary prevention of T2DM. For example, promoting healthier diets and greater physical activity could involve policies on food production, marketing, and taxation, and policies on design of local environments and public transport. The WHO's strategy on diet and physical activity provides a framework for developing national and international policies that are relevant to countries at all levels of development [9]. The best indication of a comprehensive approach is a national government-led strategy that covers primary prevention through to rehabilitation, with the caveat that the presence of a strategy does not guarantee that it has been implemented. A survey carried out through IDF member organizations in 2008 [10] found that 61% of respondents (96 respondents) indicated that their country had a national diabetes program and the majority of the remainder confirmed plans to implement and develop components of such a program. At that stage, even in regions such as Europe, over 20% of responding countries did not have a national diabetes program. Examples of national diabetes programs in countries at opposite ends of the economic spectrum include the program in Cameroon [11] and the National Service Framework for Diabetes in England [12].

Integrated healthcare

Integrated care for people with diabetes refers to the need to provide care for conditions coexisting with diabetes within the same primary healthcare service. Within most high-income countries, primary healthcare has been developed to provide a range of services covering most of the needs of people with diabetes, and indeed with other chronic conditions, and also people with multimorbidity, which are almost invariably NCDs. In low- and

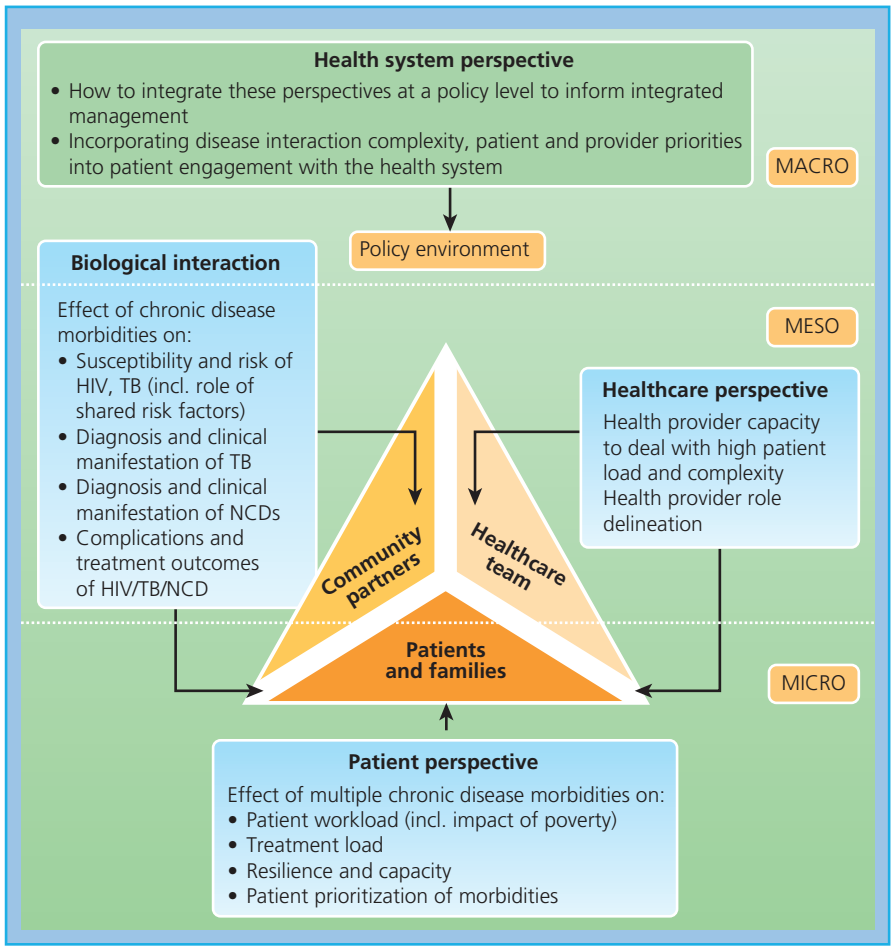

Figure 65.2 Conceptual modification of the WHO ICCC framework. The modifications are represented by the text in the three bubbles and arrows. Source: Modified from Oni et al. 2014, p. 575 [13].

middle-income countries, however, integration of care is often a challenge, as donor funding is most often given to specific disease programs such as HIV/AIDS, tuberculosis, or malaria, or large-scale government funding is allocated for specific vertical programs, such as HIV/AIDS. In these countries, however, there is increasingly an intersection between chronic non-communicable and infectious diseases, with these diseases coexisting in the same person. Hence the integrated model should enable the person with diabetes and several multimorbidities, such as hypertension and antiretroviral therapy, to receive all components of their care in a single clinic and by the same team of health workers.

The multimorbidity between these chronic non-communicable and infectious diseases may also alter typical clinical manifestations and prognosis, for example in comorbid T2DM and tuberculosis, where there may also be pharmacological interactions between the treatments for these two conditions that alter their efficacy. Therefore, the management of such cases is more complex for the health providers and the health system and more challenging for the individual. This level of complexity was not considered in the original WHO ICCC model of care and has led to a recent proposed modification of the model. The modification takes biological interactions, expectations of patients by health providers (patient workload), patients' capacity to deal with the workload, and health provider workload and capacity into consideration, and as such should be included in the thinking around setting up of integrated clinics (Figure 65.2) [13]. To highlight this complexity from the perspective of the person with diabetes, this includes the need for self-care, behavior change, adherence to numerous medications, often at different times, and multiple clinic appointments, while often having poor health literacy, a lack of family and social support, poor physical and/or mental functioning, and consequently a reduced capacity to meet these demands. It is concerning that the burden of multimorbidity is frequently higher in the poor, who often have a lower capacity to deal with ill-health and have worse outcomes.

Interestingly, although the subject of integration of care between chronic non-communicable and infectious diseases has received a great deal of attention, there are few concrete examples in the literature, other than the integrated chronic care clinic for HIV/AIDS, diabetes, and hypertension at provincial hospitals in Cambodia (Box 65.1) and a hospital-based pilot study in Ethiopia [14, 15]. There is no reason why such an approach could not be used in primary healthcare [16].

Box 65.1 Cambodia: integrated chronic disease clinics.

Chronic disease clinics for the combined care of HIV/AIDS, diabetes, and hypertension were set up in two provincial referral hospitals in Cambodia based on a number of assumptions that: a common approach is needed to respond to the needs of chronic disease patients, with the widespread acceptance that HIV/AIDS has become a chronic disease following increasing availability of antiretroviral therapy; attending a combined clinic would minimize the stigma that a specific HIV/AIDS clinic induces; and the care model should reflect estimates of disease burden. All patients were managed according to standard treatment protocols. A team of counselors promoted adherence and lifestyle changes to complement medical consultations, and peer support groups extended the efforts of the doctors and counselors.

After 2 years:

- 70.7% of people with diabetes (90% of those who attended for >3 months) and 87.7% of those on highly active retroviral therapy (HAART) remained in active follow-up.
- Median HbA_{1c} was 8.6% (70 mmol/mol), but the degree of improvement could not be assessed in the absence of a baseline measurement.
- Median CD4 count doubled in patients on HAART.

Hence integrated chronic care is not only feasible, but can produce good patient outcomes.

Continuity, access, coordination, and teamwork

These four core principles—continuity of care, access to care, coordination between different levels of care, and multidisciplinary team work—really belong together, as they concern the provision of quality healthcare for managing diabetes and preventing its complications. A particular challenge in low-resource settings is that of moving away from a focus on episodic curative care. High patient numbers, with acute infectious illness, and low numbers of trained professionals have nurtured this approach, which will tend to wait for the patient to present with gangrene of the foot rather than invest energy in identifying those at risk. Likewise, there is more focus on treating the problem than empowering the person. For example, a person presenting with an elevated blood glucose level is more likely to receive a change of prescription than a useful exchange of information about diet, physical activity, and how to overcome barriers to adherence.

Continuity of care

Continuity of care in chronic diseases is a cornerstone of effective healthcare organization and has been associated with lower mortality, better access to care, less hospitalization and referral, fewer emergencies, and better detection of adverse medical events [17, 18]. Continuity is easier to achieve when services are offered close to communities where access is easier. Care that requires visits to a distant referral hospital is unlikely to support continuity because of the costs and time involved in traveling. In many less-resourced countries and areas, diabetes care has not been part of primary healthcare offered in the community, although there is a clear drive by the WHO to change this.

Central to providing continuity of care is continuity of information, such that the status of individuals is known, in terms of when they attended their last appointment, the next appointment

due, and what was found, discussed, and prescribed at previous appointments. A diabetes register is therefore essential, providing a list of people with diabetes being treated at that facility, a record of their appointments, linked to a system to follow-up those who fail to attend for an appointment. In higher income situations, electronic diabetes registers are now the norm, and in some situations comprehensive community-based registers are maintained across all levels of care. In low-income situations, an adequate register can be kept using "pencil and paper" at the level of the facility at which most diabetes care is delivered. In addition to keeping a register of patients and their appointments, there is the need to provide continuity of relevant information between visits. In high-resource settings, electronic records linked between different levels of care can provide a state-of-the-art approach. In low-resource settings, a range of approaches have been tried (e.g. color coding of patient records, the use of annual summary sheets, and patient-retained records) [19]. A simple, but effective, approach in some settings can be a combined "paper and pencil" register and record, listing a small number of core items such as blood pressure, a measure of blood glucose control, whether feet were examined, advice given, and current medication.

Continuity of management aims to provide continuity with a specific group of healthcare providers. The challenge here is to maintain the same team of people for a reasonable period of time. Relational continuity with the same healthcare provider over time is occasionally possible and would be an ideal [20].

Access to all

Access to care, of any type at all, is still an issue in many low- and middle-income countries, particularly in more remote areas. In many urban and peri-urban areas in sub-Saharan African countries, people with diabetes receive their care from hospitals and not from the more accessible primary care services [21]. Another example is the lack of access to insulin, leading to unnecessary mortality in people with type 1 diabetes mellitus (T1DM) [22, 23]. Even when available, the cost of purchasing insulin is substantial and can be the equivalent of up to 20 days' wages for a 1-month supply of insulin. Hence addressing the supply chain for medication and ensuring that essential medication is either free or easily affordable is a prerequisite for improving outcomes, but that is not all that is required. Availability of tests for the diagnosis of diabetes, monitoring of control, and equipment to screen for complications are also essential.

A shortage of human resources is a serious barrier to providing access to care in many low- and middle-income countries, the irony being that these countries are often recruiting grounds for high-income countries seeking to staff their own healthcare systems. Given their shortage, health workers in low-resource settings often develop a broader scope of practice than their equivalents in high-resource settings and as a result need to have a wide range of skills. This is often necessitated by the absence of more highly trained professionals, particularly in rural and remote areas. Although a less qualified professional may offer lower quality care, there is also the potential for effective substitution, or task shifting, with the right training and organization. This has been well demonstrated by Gill et al. in rural Africa [24]. Using a wholly primary care-level nurse-led program, with key elements of education and drug titration by clinical algorithm and using drugs on the essential drug list, significant improvements in glycemic control were noted and maintained over an 18-month period (HbA_{1c} 11.6 ± 4.5% [103 ± 49 mmol/mol] [mean ± SD] at baseline, and 7.7 ± 2.0% [61 ± 22 mmol/mol] at 18 months). The impact of education alone was remarkable, as without any change in drug therapy the HbA_{1c} decreased from 10.6 ± 4.2% (92 ± 46 mmol/mol) at baseline to 7.6 ± 2.3% (60 ± 25 mmol/mol) at 18 months.

In primary care, well-trained nurses can offer equivalent care to doctors for routine follow-up of chronic conditions, minor illness, and preventive interventions [25]. In diabetes, this may mean the nurse conducting the consultation and reviewing results such as urinalysis, and HbA_{1c}, glucose, and cholesterol levels. The nurse may also screen the feet, take blood pressure, and calculate the body mass index (BMI). Nurses will then refer to the generalist doctor for complicated or uncontrolled patients. Patient satisfaction may even be higher as consultations are longer and contain more information. Nurses, however, may not necessarily be cost-effective as they are less productive and may not be well trained or informed [25, 26]. A range of mid-level workers such as health promoters and clinical associates/assistants may also provide effective substitution [27].

Management of diabetes and other chronic diseases involves providing access to screening and early intervention to prevent or at least limit the impact of complications [6]. In low-resource settings, some complications are easy to screen for (e.g. using a testing strip dipstick to assess for proteinuria or identifying the at-risk foot with a monofilament) provided that the necessary tools are available; however, screening for retinopathy is problematic as health providers seldom succeed in overcoming the many obstacles to effective ophthalmoscopy. Nevertheless, even in low-resource settings, appropriate technology using a fundal camera may be possible [28, 29].

Further decisions need to be made regarding the relative costs and benefits in different resource settings of macro- versus microalbuminuria screening, use (and frequency) of glycated hemoglobin versus random/fasting blood glucose, and total cholesterol versus high-density lipoprotein (HDL) and low-density lipoprotein (LDL) cholesterol measurements. Recent work in a middle-income setting in South Africa suggested that microalbuminuria testing in primary care would be cost-effective, although it is not implemented, while the current use of random blood glucose to determine control gives the wrong result in one-quarter of people with diabetes, but is used in many settings [30, 31]. Point-of-care testing is another option, for example for HbA_{1c}, which has been shown to improve glycemic control in well-resourced settings [32]. Recent work in our setting, however, suggests that clinical inertia in primary care due to high workload, inadequate training, and burnout may negate the benefits.

Coordination of care

The ideal is seamless care across the health system. This requires that care is coordinated between primary, secondary, and tertiary levels so that the full range of available therapeutic and management options is utilized. In well-financed and organized systems, this coordination includes well-developed referral pathways within health districts and regions, and well-developed systems of information exchange between the levels, and thus promotion of continuity of care. Specialist services likely to be available at a secondary level include the treatment of foot ulcers, retinal laser therapy, and the investigation and medical treatment of renal impairment. Renal dialysis and replacement are an example of services often provided at the tertiary level. In low- and middle-income settings, and even in some high-income countries where universal health insurance does not exist, access to secondary and tertiary care tends to be highly dependent on the ability to pay.

Teamwork

No single healthcare provider can engage effectively with the person with diabetes and deliver all of the many components of diabetes management. Consequently, teamwork is an essential feature of providing diabetes care. Even at the primary healthcare level, particularly in high-income settings, several professionals and disciplines can be involved in the routine care of people with diabetes, including, for example, doctor, nurse, podiatrist, and optometrist. In order to develop chronic care, the people involved in managing chronic conditions need to develop a team that meets regularly to focus on improving the quality of care [6], and one of the team should be appointed as the chronic care coordinator. If no-one is responsible for chronic care, the tendency is for it to be overlooked. For example, basic equipment, such as glucometers, monofilaments, or obese cuffs for blood pressure measurement, is not provided [19]. In addition, new ideas, initiatives, and procedures are not sustained in the absence of a leader who is present during a sufficient time period. Continuously rotating staff, such as nurses, erodes the ability to create effective teams and sustain changes. When teams meet, they should develop shared goals, clarify their complementary roles, reflect on how to improve care, and hold each other accountable for decisions. Health professionals need to be clearly aligned with the purpose of improving chronic care and not with defending professional identities. A respectful, open, and curious stance helps professionals and others to understand each other better [33].

When nurses working in a large, informal settlement in Cape Town were asked what would help improve diabetes care they replied, "caring for the carers," reminding us that building a good team begins by caring for its members. The nature of the relationship between health workers and managers, and the values embedded in the organizational culture, may be reflected in the nature of the relationship between health worker and patient and the culture of caring [34]. Organizations that operate too heavily in a mechanistic and bureaucratic model tend to treat health workers as human resources that can be used and replaced like parts in a machine [35]. Organizations should strive for congruence between individual values and behavior and organizational culture and structures. It is difficult for health workers to empower people for healthy living, motivate change, and care for patients when the organization is not congruent with the same values [36]. Wheatley [37] expressed this well when she said, "After years of being bossed around, of being told they're inferior, of power plays that destroy lives, most people are exhausted, cynical and focused only on self-protection … when obedience and compliance are the primary values, then creativity, commitment and generosity are destroyed." Living health systems should care for, empower, and nurture their staff so that they are enabled to do the same for their patients.

Patient-centered care

In low-resource settings, the need to be patient-centered is often dismissed as a luxury in the face of high workloads and sometimes broad differences in education, language, and culture between health providers and patients, although in high-resource settings patient-centered care is also difficult to achieve. Nevertheless, engaging people actively in their own healthcare improves people's experience and the quality of care, enhances health literacy, helps tailor treatment to the individual, builds a sense of partnership, promotes public health and reduces inequity, makes health systems more responsive, and reduces waste of resources [38, 39]. It does not necessarily imply a longer consultation and may improve the provider's work satisfaction. Patient-centeredness implies a more collaborative approach and holistic understanding of the patient that elicits, acknowledges, and addresses relevant beliefs, concerns, ideas, and fears [20]. It may mean balancing the evidence-based requirements of guidelines with the personal values and goals of patients, especially in the face of multimorbidity.

Patient-centeredness is in part a paradigm shift in the mind of the health worker from a biomedical, technical, public health, and sometimes authoritarian model to a biopsychosocial, holistic, personalized, and participatory model [20]. It is fundamentally a way of genuinely being with the patient. Nevertheless, a range of specific communication skills can be learnt, such as the ability to ask both open and closed questions, to make reflective listening statements, exchange information, or invite mutual decision-making [40]. Although the training of doctors has begun to include these communication skills, even in low-resource settings, the training of nurses and mid-level health workers often has not.

Supporting people in health-related behavior change is a key part of patient-centered care. Motivational interviewing is one patient-centered approach to help patients make decisions about lifestyle and behavior change [40]. Diabetes, which involves multiple changes in behavior (diet, exercise, smoking, alcohol, medication), particularly lends itself to adaptations of motivational interviewing. A challenge in low-resource settings is to see how

a range of health workers can incorporate such a guiding style into their consultations and, once this has been achieved, pivotally, how it can be sustained. Group diabetes education by mid-level healthcare workers with a guiding style has been shown to be cost-effective in a less well-resourced setting during a 12-month trial, even though the effects were less than reported on from better resourced contexts [41, 42].

In a model of care that emphasizes patient empowerment and self-care as key components [6], every consultation also needs to be seen as an opportunity for this. Health providers need to have the necessary expertise in the relevant topics, useful communication skills, and a range of educational materials appropriate to the literacy level of the community [26, 43].

A family and community orientation

Beyond the individual with diabetes is their family and community context. Clearly, family beliefs and customs and degree of social support will have an impact on the ability of an individual within that family to make lifestyle changes and cope with their diabetes. Involving family members in the consultation or educational program can strengthen the overall response to diabetes [44]. Likewise, an understanding of the individual's environment will inform discussions about appropriate changes and likely constraints.

In low-resource settings, where facilities are overwhelmed with large numbers of patients, it may make sense to extend care into the community [6]. For example, community-based support groups can be run by health promoters or local non-government organizations to offer some aspects of routine chronic care. People with diabetes can then return to the local clinic for periodic or annual review and help with complications. Support groups can also encourage lifestyle change and adherence to medication. Expert patients, an increasingly developed resource in both low- and high-income situations, may also be useful to enhance self-care, although further evaluation is required [42].

Community health workers have the potential to promote healthy lifestyle, provide home-based care, and link selected people with diabetes with the local facilities [45]. Although a number of individual studies have demonstrated that community health worker interventions were associated with improvements in glycemic control, this is not universal, as demonstrated by recent systematic reviews [46, 47].

Communities should not just be seen as additional platforms for care or targets for interventions, but representative structures or key leaders should be engaged with in order to understand how local health priorities are perceived and to elicit feedback and involvement in the planning and delivery of services [20].

Primary care workers usually have a responsibility not just for individual patients, but also for people living within specific communities or health districts [20]. Concern for the growing number of people with diabetes should lead to interventions that address the underlying determinants of obesity and reduced physical activity, for example, school-based healthy lifestyle programs, provision of green spaces in inner cities, marketing of food to children, sale of junk food on public premises, and labeling of food. Many of these require health workers to contribute to interventions in other sectors [48].

Clinical governance

Clinical governance refers to the people and processes that are put in place to ensure improvements in and maintenance of a high quality of care [49, 50]. Clinical governance activities can include some or all of the following:

- A national process for developing evidence-based guidelines, drawing on effectiveness research, relevant to the needs and context of the country. An example of such a system from a high-income setting is the National Institute for Health and Care Excellence (NICE) in the United Kingdom. This may be beyond the resources of lower income countries, but through regional cooperation, such as coordinated by the WHO, the IDF, and the World Bank, regular reviews of the evidence appropriate to different resource settings do take place.
- Financial incentives to providers for delivering processes of care and achieving targets for good clinical outcomes, for example, the UK quality outcomes framework tied to NICE guideline recommendations.
- A more local process for disseminating and implementing guidelines and integrating guidance on care for diabetes with other conditions.
- Quality improvement cycles that include audit of the technical quality of diabetes care and also the performance of the health services (e.g. continuity, coordination). Another example from the UK is the English and Welsh National Diabetes Audit, which has driven improvements in the quality of services and health outcomes for people with diabetes. The Audit addresses four questions based on the diabetes National Service Framework. These cover whether all people with diabetes diagnosed were included in a practice diabetes register. In addition, the percentage of those registered with diabetes who had the nine NICE key processes of diabetes care, the proportion who achieved NICE-defined glucose control, blood pressure, and blood cholesterol treatment targets, and the rates of acute and long-term complications (disease outcomes) are collected [51]. Incorporating patient voices in addition to the voices of health workers is also important in a comprehensive view of quality.
- Training and upskilling of health workers in terms of their clinical and communication competencies are a key part of clinical governance.
- Regular reflection on routinely collected data may also be important, for example, looking at the rational use of investigations and prescribing of medication.
- Attention to patient safety and risk management, for example, by analyzing the causes of unexpected or premature morbidity or mortality.

A model of care for diabetes should ensure that this condition is included in the approach to clinical governance.

Information technology

The widespread availability and affordability of mobile devices, increasing Internet access, and recent advances in the networking of physical objects and devices with electronics, software, sensors, and network connectivity ("Internet of things") have led to an explosion in the number of applications and programs that have been developed with the aim of improving healthcare in general and diabetes care in particular. These information technology interventions have been delivered through an ever-evolving and wide range of devices and modalities, and have been accompanied by a shift from computer-based technology and software to cloud-based computing and mobile devices, including phones, tablets, and smart watches, all with powerful computing capabilities. These advances have therefore opened up the possibility of strengthening some models of care and allowing the development of new ones.

To date, information technology has been used to support health systems, providers, and people living with diabetes at numerous levels and across multiple domains and settings, including in low- and middle-income countries where there is high mobile phone penetration and widespread telecommunication connectivity. At a health systems level, advances in electronic health records have created new and better ways for patient data to be securely shared, electronic registries have been utilized to track people with diabetes and to ensure comprehensive follow-up and monitoring, and telemedicine services have been used to provide care at a distance, including the reading of fundus images by experts when screening people for diabetic eye disease. At a provider level, clinical decision support tools have reduced errors and improved the quality of care, and online educational resources have created new training and continuous development opportunities. At a patient level, advances in sensors and mobile devices have made remote and self-monitoring easier, and online forums and health information systems have improved support among people living with diabetes and improved their access to information.

Although the use of information technology in healthcare has generated considerable enthusiasm among policy-makers, funders, healthcare providers, and patients themselves, widespread implementation and adoption of information technology have been limited by the lack of empirical evidence on the health outcomes and cost-effectiveness of these interventions and, in low- and middle-income countries, competing priorities for limited budgets available for health system strengthening [52, 53]. This section evaluates these information technology advances, summarizes the evidence where available, and highlights how these can be embraced in the different models of diabetes care. Given the large number of studies that have been undertaken in the past few years that have evaluated telemedicine, electronic health (eHealth) and mobile health (mHealth) intervention, our aim is to summarize systematic reviews and meta-analysis where available.

Electronic health records

Electronic health records (EHRs) have seen a number of advances in the past few years. Now they are often based in a cloud, can be updated and edited in real time, and can be accessed by authorized users on a range of devices, making patient information instantly and securely available across multiple facilities. These capabilities can support different models of care, by making patient data readily available to multiple providers. Although EHRs have been found to be effective in improving health system process outcomes, there is now also increasing evidence finding EHRs to be associated with improvements in the standard of diabetes care [54]. The sharing of up-to-date patient data between primary and tertiary care providers and also between the various multidisciplinary providers, such as ophthalmologists, podiatrists, dieticians, physiotherapist, and educators, is a critical component in ensuring an effective continuum and integration of care, with both models reliant on patient data being easily accessible. Privacy and data ownership laws are increasing the popularity of personal health records, where patients own their own clinical data and records [55]. Designing clinical information systems with patients at the center supports patient-centered models of care, where patients are empowered to manage, share, and use their data to access care and improve their health.

Registries

Patient registration systems facilitate tracking of patients and identification of those who are eligible for specific services. Registries enable comprehensive models of care to be developed and ensure timely follow-up [56]. Many countries, particularly high-income countries, have developed and utilized electronic diabetic registries for the management of clinical services and also for research purposes [57, 58]. These registry systems are also used to monitor people for complications of diabetes, such as diabetic retinopathy, where registers are becoming the standard for implementing national screening programs and monitoring and following up patients with this complication over time. In addition to scheduling people with diabetes due for annual screening, these systems can identify high-risk individuals who miss appointments, triggering reminders and follow-up by case managers, and also facilitate referrals for laser treatment once sight-threatening retinopathy is identified [59, 60].

Telemedicine and remote monitoring

Telemedicine refers to the use of information technologies to provide healthcare at a distance. In the past two decades, telemedicine has been used to provide education (to support self-management), for monitoring (of blood glucose), and to facilitate consultation with health providers (telephone and videoconferencing support and also to schedule follow-ups). Numerous studies and

systematic reviews have evaluated the effectiveness of remote glucose monitoring on improved glycemic control and, although telemedicine has been found to be feasible and acceptable, there is still a lack of strong evidence for its effectiveness in improving HbA_{1c} [61–63]. Further, a recent synthesis of evidence of the use of telemedicine in managing chronic diseases (including diabetes) over the past 20 years found that neither telemonitoring nor videoconferencing was superior to telephone support, and that the evidence base for the value of telemedicine in managing chronic diseases suggested that findings were inconsistent [64, 65]. A notable exception is telemedicine diabetic retinopathy screening systems, where fundus images taken at primary healthcare screening sites are transferred to central reading centers for assessment and grading of diabetic retinopathy. These telemedicine retinopathy screening systems have been shown to be both effective in identifying individuals requiring referral for treatment and cost-effective to implement across different resource settings [66]. Telemedicine interventions, whether synchronous and asynchronous, remain an important enabler of models of care that focus on providing better access, especially in resource-limited settings.

Clinical decision support tools

Information technologies are increasingly being used to provide clinical decision support in the form of electronic protocols, guidelines, and checklists. Clinical decision support tools have shown great promise for reducing medical errors and improving patient care, especially when utilized by a lower cadre of health provider. A systematic review of computer-based clinical decision support systems found that they enhance the clinical performance for drug dosing, preventive care, and other aspects of medical care, but not convincingly for diagnosis [67]. The use of a computer to generate the decision support was among the top four features of clinical decision support systems critical for improving clinical practice, with a close correlation between automatic provision and successful outcome. The other key features included providing decision support automatically as part of clinician workflow, delivering decision support at the time and location of decision making and providing actionable recommendations [68]. A number of diabetes-specific clinical decision support tools and algorithms have been developed and are used in clinical practice. Examples include algorithms that can calculate a person's risk of developing T2DM and those that can calculate a person's risk of developing complications such as cardiovascular disease or diabetic retinopathy [69–72].

Provider training and education

Access to information, via mobile devices and Internet connectivity, has created new opportunities for medical education and training of providers. Constantly available online resources and native applications create new and convenient learning opportunities for providers. Continuous medical education activities can be seamlessly incorporated into clinical practice and effortlessly recorded for accreditation and audit purposes.

Supporting self-management and behavior change

A number of information technology interventions are currently being used to make information accessible and actionable for people with diabetes and to support the domains requiring diabetes self-management. These include nutritional management, exercise and physical activity, blood glucose monitoring, and medication utilization and adherence [73, 74]. The use of the audio and video functionality of mobile devices to show educational and instructional videos has also been found to enhance counseling between providers and patients, especially in people with low health literacy. Evaluation of the effects that these technologies are having on people with diabetes has received considerable attention by researchers and in systematic reviews. These reviews have shown: (1) that computer-based interventions to improve self-management have a small beneficial effect on glycemic control, with mobile phone-based interventions having a larger beneficial effect on glycemic control [75]; (2) that behavioral interventions targeting one domain of self-management (physical activity) produced a statistically significant increase in exercise and a clinically significant improvement in glycemic control and BMI [76]; and (3) a small reduction in HbA_{1c} levels among the diabetes self-management interventions using mobile health technology-based health behavior change or disease management interventions. Understanding the specific underlying behavior change techniques being utilized in effective information technology interventions is increasingly being recognized as an important aspect when it comes to replicating or taking an intervention to scale [77]. More extensive use of behavior change theory in Internet-based interventions has been found to be associated with increases in effect size [78].

Digital glucose monitoring

Recent advances in the computing capabilities of mobile devices and in connected glucometers that can be linked to insulin pumps have created new opportunities for self-monitoring of blood glucose. In addition, novel glucose sensors, including non-invasive, continuous monitors that are capable of conducting, evaluating, storing, and transmitting glucose readings through connected mobile devices are being developed and tested [79–81]. These devices are able to detect abnormal measures and trigger an appropriate response, such as sending a message to the patient's phone or activating an emergency response number. Longitudinal data can also be stored for later review with health providers, providing better data for more informed decision-making. Personalized feedback has been shown to be an important component in remote monitoring following self-monitoring activities. A systematic review looking at remote monitoring and the impact on HbA_{1c} found significant change between groups to be associated with personalized feedback (whether it came from skilled healthcare providers or automated algorithms) [82]. Although these developments represent important advances towards fully automated glucose monitoring and control, further research is required to determine the safety and effectiveness of these technologies once integrated into clinical practice. Patient-centered

models of care and also those that are designed around access to care could benefit from remote- and self-monitoring technologies, but the likelihood of these being readily available in low-resource settings outside private or academic environments is very low.

Online health information, support groups, and social media

Healthcare providers are no longer the primary source of medical information. It is estimated that most people in high-income countries with chronic conditions such as diabetes search online for information on treatment options, tools for managing their condition, and scientific breakthroughs. This opens up the possibility of new and exciting models of care based on patient empowerment. Supporting patients by teaching them how to search for credible and reliable information or by directing them to vetted online resources may reduce the risk of misinformation. Online support groups, compared with face-to-face support groups, offer an easy and convenient way for individuals with diabetes to join a community of people with diabetes where they can compare experiences, symptoms, and treatments and also receive and give support. The number of diabetes-specific online communities has increased dramatically in the past decade, with hundreds of options available that cater for people from all walks of life and with varying needs. Social media are also being used increasingly by people to source information about diseases and services and to organize communities and groups. Family and community models of care are strengthened by the participation and engagement of friends and family. Information technologies that make it easy for communities, both on- and offline, to support people with diabetes create informed and empowered societies.

Conclusion

Although the advances in information technology described above hold immense promise in enhancing the different models of care for diabetes, embracing these technologies remains a challenge. Ad hoc implementations of information technology are likely to give way to more integrated approaches where these technologies are viewed as enabling components within the context of a health system or a specific model of care, instead of as a standalone solution.

Information technology has the potential not only to strengthen existing models of care but also to create new models of care for people living with diabetes. Mobile phones, for instance, have been used as tools for community health workers, enhancing the task shifting of health promotion and disease prevention activities in resource-limited settings [83, 84]. The uptake of text messaging between providers is improving coordination of care and creating new and simpler referral pathways, which are being further automated by clinical decision support plug-ins. Developments in non-invasive sensor technology, mobile applications capable of processing point-of-care biomedical signals and the connectivity between these devices, insulin pumps, and pharmacy drug ordering systems are likely to lead to the creation of new and more automated models of care. Although many of these information technology advances are currently unavailable and unaffordable in low- and middle-income countries, they are likely to become increasingly affordable in the future. Low- and middle-income countries will also benefit from the learning from the trials and errors of embracing these technologies and integrating them into health systems, and may have the opportunity to leapfrog high-income countries in implementing evidence-based information technologies that are both cost- and clinically effective.

13 Future Directions

66 Future Drug Treatments for Type 1 Diabetes

Jennifer L. Sherr, Eda Cengiz, Michelle A. Van Name, Stuart A. Weinzimer, and William V. Tamborlane

Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Key points

- One of the limitations of insulin therapy is the use of preparations that do not adequately reproduce the patterns of physiological insulin secretion.
- The essential need for improvement appears to be for insulin analogs with extended release, basal insulin analogs, and ultrafast-acting insulin analogs with faster absorption and action.
- The availability of newer ultrafast- and ultralong-acting insulin analogs offering efficacy in terms of glycemic control with a low risk of hypoglycemia and fewer side effects will help overcome some barriers related to treatment of type 1 and type 2 diabetes mellitus (T1DM and T2DM).
- Although initially targeted towards treatment of T2DM, adjunctive therapies including dipeptidyl peptidase 4 inhibitors, glucagon-like receptor peptide 1 agonists, and sodium–glucose co-transporter inhibitors show promise in the treatment of T1DM.
- Sensor-augmented insulin pumps with a feature that automatically suspends basal insulin for low sensor glucose levels have been demonstrated to reduce exposure to hypoglycemia without raising average glucose levels, and systems that suspend basal insulin for predicted low glucose levels are in development.
- Artificial pancreas systems consisting of an insulin pump, continuous glucose sensor, and control algorithm that dynamically regulate insulin delivery on a minute-to-minute basis have shown promise in reducing both hyperglycemia and hypoglycemia and improving overall diabetes control.
- Intranasal glucagon to treat hypoglycemia is effective and simpler to administer than currently commercially available intramuscular glucagon. An aqueous glucagon formulation has been developed and has the potential for use in a dual hormone closed-loop system.

Introduction

The dawn of the era of intensive treatment of type 1 diabetes mellitus (T1DM) in the late 1970s and early 1980s was brought about by the nearly simultaneous introduction of improved methods of monitoring glycemic control (i.e. blood glucose meter monitoring and HbA_{1c} assays) and more physiological approaches to insulin replacement (i.e. insulin pumps and multiple daily injection regimens). It was more than 10 years later that the Diabetes Control and Complications Trial (DCCT) was able to demonstrate finally the benefits of intensive treatment in delaying or preventing the early microvascular and neuropathic complications of the disease [1, 2].

There have been a number of advances in the treatment of T1DM in the more than 20 years since the end of the DCCT that include further improvements in monitoring glycemic control with continuous glucose monitoring (CGM) systems [3] and the introduction of rapid- and long-acting insulin analogs. Nevertheless, too many individuals with T1DM do not achieve target HbA_{1c} levels, while acute complications of severe hypoglycemia and diabetic ketoacidosis remain ever-present dangers [4], and the devastating long-term vascular complications can be delayed by current therapies but may not be prevented [5].

Owing to the failure of a number of clinical trials that utilized a variety of immunologically active agents to preserve residual β-cell function in new-onset diabetes and to prevent the development of T1DM in high-risk individuals, and also the limited availability of pancreas and islet transplants to cure T1DM, clinicians and people with T1DM continue to follow the same insulin-based treatment regimens, albeit with somewhat better methods. Although strict metabolic control has long been known to slow the loss of β-cell function early in the course of diabetes [6], the recent Metabolic Control Study of the DirecNet and TrialNet study groups demonstrated convincingly that we have already reached the maximum benefit from current intensive insulin treatment methods [7].

As we describe in this chapter, there has been a spate of new biosynthetic insulin analogs whose time–action profiles are faster than those of the current rapid-acting insulins and flatter and longer acting than current basal insulins. It is particularly exciting that we also appear to be on the verge of truly transformational changes in the treatment paradigms for adults and children with

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

T1DM that move beyond newer insulin preparations. Specifically, new classes of drugs for the treatment of type 2 diabetes (T2DM) in adults, such as dipeptidyl peptidase 4 (DPP-4) inhibitors, glucagon-like peptide-1 (GLP-1) receptor agonists, and sodium–glucose co-transporter (SGLT) inhibitors, are currently being tested for use as adjunctive treatment of T1DM. Although new insulins with better pharmacokinetic and pharmacodynamic characteristics with or without concomitant use of adjunctive therapies may allow more people with T1DM to achieve target HbA_{1c} levels more safely, no treatment of T1DM will be optimal until there is feedback control of insulin delivery. In this chapter, the great advances in the development of closed-loop insulin delivery systems for outpatient treatment of T1DM since the last edition of this book are summarized. New preparations of glucagon, such as intransasal delivery and stable liquid preparations for use in continuous subcutaneous delivery, are important for optimal treatment of severe hypoglycemia and integral to the development of dual-hormone closed-loop systems, which infuse both glucagon and insulin.

New biosynthetic human insulin analogs

One of the limitations of insulin therapy is the use of preparations that do not adequately reproduce the patterns of physiological insulin secretion. Insulin therapy has evolved greatly in the last 50 years, with the introduction of purified insulin analogs that are manufactured by recombinant DNA technology with improved time–action profiles. The synthesis of insulin analogs became possible by rearranging human insulin amino acid positions to modify insulin bioavailability (pharmacokinetics) and glucose-lowering action (pharmacodynamics) in a favorable way compared with human insulin. The ongoing challenge in insulin therapy is to discover new and improved insulin analogs or methods to improve time–action profiles of conventional insulin analogs. A major goal of future insulin therapy is to provide insulin coverage that more closely mimics endogenous insulin secretion while reducing hypoglycemia and postprandial hyperglycemia and improving adherence. Consequently, the essential need for improvement appears to be for insulin analogs with extended-release basal insulin analogs and ultrafast-acting insulin analogs with faster absorption and action. The following section summarizes developments in the field under three main topics: the ultralong-acting basal insulin analogs, the ultrafast-acting insulin analogs, and methods to accelerate insulin action, with a focus on the safety and the efficacy results for each group.

Ultralong-acting insulins

Basal insulin coverage to control fasting blood glucose is an important component of diabetes management. An ideal basal insulin should achieve an equilibrium between the rate of endogenous glucose production and use during the fasting state. It should provide a more physiological pharmacokinetic/pharmacodynamic profile with longer duration, low intra- and inter-patient variability, reduced day-to-day variability, and less pronounced peaks in time–action profiles. Important drawbacks of currently available basal insulin therapy, including dose-to-dose variability resulting in unanticipated blood glucose fluctuations and the need for once or twice per day therapy, have led to the search for ultralong-acting insulins with less variability and longer duration of action to improve adherence. Another important goal for the development of new ultralong-acting insulins has been the reduction or elimination of peaks of insulin action, in order to reduce late hypoglycemia, which has been partially achieved with insulin glargine and detemir. The development of new long-acting basal insulin analogs, including glargine insulin U300 and insulin degludec, offers the promise of improved opportunities for intensive insulin therapy.

Insulin degludec

Insulin degludec is produced by the removal of threonine at position of 30 of the β chain (B30) and the attachment of a 16-carbon fatty diacid to lysine at position 29 of the β chain (B29) via a glutamic spacer linker to change the human insulin amino acid sequence [8]. The phenol solution in the formulation keeps the molecule in a stable dihexameric form *in vitro*. The phenol diffuses once insulin degludec has been injected into the subcutaneous tissue, exposing free ends of the dihexameric structure, which then transforms into a soluble multihexameric structure (zinc and fatty acid side-chains). Similarly to physiological insulin synthesis and storage in the secretory granules, the presence of zinc ions promotes self-association of insulin molecules from dimers into hexamers, increases stability and prolongs insulin's absorption into the circulation. Once the zinc on the terminal ends of the molecule has diffused, the insulin slowly dissociates, resulting in slow and steady absorption of monomers, conferring an ultralong-acting profile. The presence of resorcinol with zinc determines the formation of hexamers and the presence of phenol with zinc promotes dihexamer formation. Linear multihexamers are formed by self-association of dihexamers promoted by phenol depletion after subcutaneous injection [9]. The acylation of lysine B29 contributes to albumin binding similarly to insulin detemir; however, unlike insulin detemir, this feature does not contribute to insulin degludecs prolonged time–action profile [9]. The maximum plasma concentration for insulin degludec is achieved 10–12 h after subcutaneous injection and the mean-terminal half-life is 17–25 h. The steady state is achieved after 2–3 days with once-daily administration during which the daily injected dose is equivalent to the daily eliminated amount of insulin. The pharmacokinetic profile constitutes a similar pattern in persons with T2DM. Pharmacodynamics studies employing the euglycemic clamp technique reported glycemic control that was both stable (evenly distributed across the 24–26-h evaluative periods) and reproducible, with an inter-day within-subject coefficient of variation of 20% compared with 82% for insulin glargine [10–12].

Insulin degludec has been shown to be non-inferior with regard to glycemic control compared with insulin glargine U100 in phase III studies for individuals with T1DM and T2DM.

The risk of nocturnal hypoglycemia was lower for insulin degludec based on meta-analysis of pooled data in T1DM and T2DM in comparison with insulin glargine U100 basal insulin therapy [13].

More recently, a 52-week randomized phase III trial evaluated the clinical efficacy of combining insulin degludec with liraglutide, a glucagon-like protein-1 (GLP-1) receptor agonist that decreases fasting and postprandial glucose levels, compared with insulin degludec or liraglutide separately among people with insulin-naïve T2DM [14]. IDegLir a achieved superior glycemic control to insulin degludec or liraglutide alone, indicating a synergistic effect, and also mitigated weight gain (2.1 kg) and risk of hypoglycemia (38%) compared with insulin degludec. Subsequent 26-week phase III trials among adults with insulin-naïve T2DM also reported that IDegLir a yielded superior glycemic control when tested as an add-on to previous GLP-1 receptor agonist treatment compared with unchanged GLP-1 receptor treatment [15], and also compared with placebo [16]. Notably, IDegLir a led to a 1.5–3.0 kg weight gain compared with the other treatments. Two other 26-week phase III trials tested IDegLir a among insulin-experienced participants with T2DM, and found that it yielded superior glycemic control and reduced body weight (2.7–3.2 kg) compared with both add-on insulin degludec therapy [17] and continued insulin glargine therapy [17]. Overall, the combination of insulin degludec with liraglutide appears beneficial for glycemic control, weight control, and reducing the risk of hypoglycemia.

Another agent that has been successfully combined with insulin degludec is the rapid-acting insulin aspart; the combination drug insulin degludec with insulin aspart was approved by the US Food and Drug Administration (FDA) in 2015. In the presence of zinc and phenol, the former exists as dihexamers but the latter as hexamers, thus avoiding the risk of hybrid hexamer formation. IDegAsp has been tested in six 26-week phase III trials against insulin aspart alone or insulin glargine among individuals with T1DM and T2DM, in all cases yielding equal or superior glycemic control and equal or lower rates of nocturnal hypoglycemia [18]. Despite these favorable outcomes, a meta-analysis of 16 phase III trials testing either insulin degludec or IDegAsp revealed an increased risk of major cardiovascular events versus comparator drugs [14]. The magnitude of increased risk ranged from 13 to 67% depending on the definition of the major cardiovascular event utilized. These data led to the initiation of a post-marketing evaluation dedicated to cardiovascular outcomes for insulin degludec and IDegAsp.

Insulin glargine U300

Insulin glargine is synthesized by exchanging asparagine at position 21 of human insulin for glycine, and adding two arginine residues to the B chain. Insulin glargine is a diarginylinsulin analog with an acidic isoelectric point of 5.4 that shifts to a neutral pH and precipitates once it is injected into the subcutaneous site, thereby delaying its absorption and prolonging its action. Insulin glargine U300 is a concentrated form of insulin glargine with a slower absorption profile secondary to reduction of volume and depot surface. U300 is released more gradually into the circulation with a less pronounced peak action and fluctuation (peak-to-trough ratio 1.8) and a longer duration of action extending beyond 24 h [19]. Insulin glargine U300 has lower within- and between-day variability than insulin glargine U100, with comparable risk of hypoglycemia and a similar safety profile [20]. Steady-state clamp studies of U300 demonstrated an increase in the glucose infusion rate from 2 to 16 h post-dose, followed by a slight decline at around 18 h post-dose, and then stable activity up to 36 h post-dose. Clinical trials of U300 showed a 10% reduction in nocturnal hypoglycemia and 10–17% increased insulin requirement [21]. A small attenuation of weight gain (0.2–0.6 kg) with U300 compared with U100 has been observed in some of the clinical studies, and no trial has reported differences in adverse events between groups [22, 23]. In summary the flatter, more prolonged, and more predictable pharmacokinetic profile of U300 compared with U100 appears to lead to a reduced risk of hypoglycemia and possibly reduced weight gain, although at the expense of a slightly higher dosage to achieve glycemic control.

Peglispro

Basal insulin peglispro comprises insulin lispro covalently bound to a 20-kDa poly(ethylene glycol) (PEG) at lysine B28. The attachment of a PEG chain to a protein (PEGylation) reduces degradation, prolongs exposure, and reduces immunogenicity [24]. The resulting PEGylated insulin lispro's duration of action is ~24 h [25, 26]. Peglispro has demonstrated slightly superior glycemic benefits along with a reduction in nocturnal hypoglycemia and a weight advantage compared with insulin glargine in clinical studies [27, 28]. Peglispro preferential hepatic versus peripherally binds tissue [29], which could mitigate weight gain and possibly lower dose requirements. The main side effect of peglispro of concern has been liver enzyme alanine aminotransferase (ALT) elevation among those taking peglispro in clinical trials [30, 31]. These levels decreased towards baseline about 4 weeks after discontinuation. Participants on peglispro showed elevation of triglycerides and low-density lipoprotein cholesterol and a reduction in high-density lipoprotein cholesterol, which also raised some concern [32]. Clinical studies revealed no significant differences in rates of severe hypoglycemia between the peglispro group and the insulin glargine group for people with T2DM, but those with T1DM taking peglispro had higher rates of severe hypoglycemia than those taking insulin glargine in a clinical study at 26 weeks (39.0 vs. 16.2 events per 100 patient-years) and similar rates of severe hypoglycemia in a subsequent clinical study at 52 weeks (19.7 vs. 22.5 events per 100 patient-years) [30, 33]. Additionally, liver fat as measured by MRI has been noted to be higher among a subset of participants treated with basal insulin peglispro versus insulin glargine in two clinical trials [32, 34]. The mechanism of the increased liver fat content with peglispro is unknown [30, 31, 35, 36] but these abnormalities led Lilly to announce it was ceasing development of peglispro in December 2015.

Ultrafast-acting insulins

One of the limitations of currently available rapid-acting insulins is the insufficiently rapid absorption and onset of action from the subcutaneous compartment, resulting in excessive postprandial glucose excursions. Molecular genetic techniques have allowed the synthesis of rapid acting insulin analogs with faster insulin absorption after subcutaneous injection, achieved by amino acid substitutions in the distal end of the β chain of insulin that allow for more rapid disassociation of hexamers to dimers and monomers in the subcutaneous depot. Rapid-acting insulin analogs produce higher plasma insulin levels earlier and have a shorter duration of action compared with regular insulin but behave like human insulin with regard to both insulin- and insulin-like growth factor-receptor binding. The faster onset of rapid-acting analogs facilitates greater adherence by reducing the interval between the injection and ingestion of a meal, allowing people with diabetes to inject 15 min before the meal or even immediately before the meal rather than the recommended 35 min prior.

Although current rapid-acting insulin analogs have major advantages over regular human insulin, the time–action profiles of Rapid-acting insulin analogs still do not match the rapid absorption and onset of action observed with physiological insulin secretion, which is essential to suppress the rise in postprandial blood glucose [37, 38]. The concept of ultrafast-acting insulin analogs was introduced in order to fulfill a need for faster onset and shorter duration of action than rapid acting analogs [37, 38]. Novel ultrafast-acting insulin and methods to accelerate insulin action represent promising strategies to overcome some of the shortcomings of conventional insulin therapy for optimizing glycemic control [39, 40]. Moreover, the combination of new, ultrafast-acting insulins and automated or semiautomated closed-loop artificial pancreas systems offers the potential of a new era in the treatment of T1DM, in which target glucose and HbA_{1c} levels can be achieved with greater safety and a much reduced burden on patients and clinicians [41].

Faster-acting insulin aspart

Faster-acting insulin aspart is insulin aspart in a new formulation that contains two new excipients (nicotinamide and arginine) to stabilize the insulin formulation. Both of the excipients are generally recognized as safe by the FDA [42], and result in faster initial absorption after subcutaneous injection [43]. Compared with insulin aspart, faster-acting insulin aspart is associated with a faster onset of action and increased early exposure that, in turn, leads to a significantly greater early glucose-lowering effect [43]. Furthermore, increased early exposure with faster-acting insulin aspart, compared with insulin aspart, led to improved glycemic control following a postprandial challenge in both the subcutaneous injection and continuous subcutaneous insulin infusion (CSII) settings [44].

VIAject

VIAject (Linjeta; Biodel Inc.) is an ultrafast insulin formulation with significantly faster absorption than either regular human insulin or insulin lispro [45]. VIAject uses ethylenediaminetetraacetic acid (EDTA) to chelate zinc and, therefore, destabilize insulin hexamers. Glycemic excursions were reduced with VIAject treatment compared with either regular human insulin or insulin lispro [46]. A pH-neutral formulation of this compound has since been developed that has demonstrated bioequivalence with the previous formulation and has also been shown to reduce absorption and onset of action significantly compared with insulin lispro [47]. People experienced less injection-site pain with the pH-neutral formulation than the previous formulation; however, greater discomfort with VIAject than with insulin lispro was reported by participants during the study [45]. The current formulation under development is BIOD-531, which is a U400 formulation containing EDTA, citrate, and magnesium sulfate with an intention to improve injection-site tolerability [48]. BIOD-531 is associated with a significantly faster rapid absorption and onset of effect than concentrated regular human insulin (U500) or insulin lispro.

Technosphere insulin

The search for alternative routes of insulin delivery has been driven by the desire to eliminate the discomfort and inconvenience of insulin injections. The vast surface area of the alveolar surfaces in the lung allows rapid absorption of inhaled drugs. Inhalation as a novel route of administration for insulin delivery has demonstrated faster absorption and onset of action of insulin compared with traditional subcutaneous injection. Additionally, it provides an alternative mode of insulin delivery for those who are reluctant to take injections. The ability to design insulin particles that can reach the lung and be absorbed into the circulation made inhaled insulin a possibility.

Technosphere insulin (Afrezza; MannKind Corp.) is an inhaled preparation consisting of insulin adsorbed on to highly porous microparticles [49]. It consists of recombinant human insulin and fumaryldiketopiperazine (FDKP) that self-assembles into Technosphere particles. The Technosphere particles dissolve immediately at the physiological pH of the lung, and insulin and FDKP are absorbed systemically. The systemic absorption of insulin produces rapid and high peak serum insulin concentrations that fall between the concentration times of intravenous insulin and subcutaneous regular insulin or rapid-acting insulin analog [50]. The glucose-lowering action of Afrezza peaks approximately 30 min after administration and mimics the physiological first-phase insulin response after a meal that is characteristically absent in people with diabetes. Published studies of Technosphere insulin have primarily involved individuals with T2DM and have demonstrated effective control of postprandial blood glucose levels [51]. A phase II study showed that Technosphere insulin plus basal insulin glargine multiple daily injection treatment led to dose-dependent reductions in glucose and HbA_{1c} levels [52]. A subsequent phase III study showed there was no significant difference in HbA_{1c} between treatment with Technosphere insulin plus glargine and treatment with biphasic insulin aspart 30 [53]. However, weight gain and hypoglycemic episodes were

reduced in the Technosphere insulin group. Technosphere insulin was approved for treating individuals with T1DM and T2DM by the FDA in 2014 [54]. However, Technosphere insulin carries a black-box warning advising that acute bronchospasm has been observed in persons with asthma and chronic obstructive pulmonary disease; this product should therefore not be used in such people, or cigarette smokers, because of this risk.

BioChaperone insulin

The BioChaperone platform constitutes a library of polysaccharides modified with naturally occurring molecules. The BioChaperone technology to accelerate insulin absorption relies on a polymer that forms a molecular complex with insulin to speed up insulin delivery into the circulation. The formulation of human insulin and a polymer of the BioChaperone platform, known as HinsBet, has been proven to be absorbed faster than regular human insulin from the subcutaneous tissue. As for rapid acting insulin analogs, BioChaperone Lispro demonstrated an earlier onset of action, earlier maximum action, and stronger glucodynamic effect in the first 2 h after dosing compared with insulin lispro during clamp studies in people with T1DM [55]. New studies are under way to investigate the BioChaperone polymer technology to deliver high-concentration human insulins and compound long-acting- rapid acting insulin mixtures [56].

Alternative means of accelerating insulin absorption and action

Insulin infusion and injection site-warming devices

Insulin absorption may be accelerated by increasing blood flow to a localized area by warming the skin. A pilot study showed that a site-warming device (InsuPatch; Insuline Medical Ltd.) significantly increased the maximum concentration and decreased the time to reach maximum concentration of serum insulin levels in people with T1DM receiving insulin aspart or lispro via insulin pump therapy [57]. The use of a similar device designed to warm insulin injection sites (InsuPad; Insuline Medical Ltd.) has been shown to decrease prandial bolus insulin requirements by 19% in obese individuals with T1DM and T2DM, suggesting that site warming enhances insulin bioavailability [58]. Subsequent studies have confirmed that site warming accelerates absorption and increases the action of rapid acting insulin analogs, and may enhance the performance of open- and closed-loop insulin delivery systems [39, 40].

Administration via intradermal microneedles

Intradermal administration could permit faster insulin absorption because of the skin's greater vascularity in comparison with the subcutaneous space. Studies comparing delivery of insulin lispro via conventional subcutaneous catheters and intradermal microneedles have found that intradermal delivery significantly decreased time to onset and offset of metabolic effect [59, 60]. Intradermal needles are generally well tolerated and may be less painful than subcutaneous injections or catheters; however, transient, localized wheal formation and redness have been observed at injection sites. Currently, no intradermal microneedles are commercially available.

Pretreatment of new infusion sites with hyaluronidase

Recombinant human hyaluronidase (rHuPH20) is an FDA-approved enzyme that is used to increase the absorption and dispersion of other injected drugs by breaking down the connective tissue that acts as a barrier to fluid dispersion [61]. In phase I studies of healthy volunteers, coadministration of rHuPH20 (Hylenex; Halozyme Therapeutics, Inc.) with rapid acting insulin analogs significantly reduced intra-subject variability in the pharmacokinetic response to insulin, and accelerated insulin exposure to insulin aspart, lispro, or glulisine with a faster onset and offset of action [62, 63]. In people with T1DM, rHuPH20 coadministered with either regular insulin or insulin lispro produced earlier and greater peak serum concentrations of insulin and improved postprandial glycemic control [64]. Pretreatment also reduced the rate of hypoglycemic episodes over CSII use alone. Co-mixtures or co-formulations of commercial rapid acting insulin analogs with rHuPH20 have also demonstrated benefits over insulin use alone. Although postprandial glycemic excursions did not differ between coadministered recombinant human insulin and rHuPH20 versus insulin lispro alone in individuals with T1DM [65], a separate study showed that coadministration of rHuPH20 with insulin lispro improved postprandial glycemic control in those with T2DM [66].

New generation of insulins in development

Smart insulins

The rationale behind the discovery of smart insulins is to release insulin into the circulation depending on the ambient blood glucose level, to maintain tight glycemic control. Smart insulins are small molecules containing both an aliphatic moiety and a phenylboronic acid (PBA) moiety [67]. The incorporation of PBA provides a glucose-sensing element within the conjugate. The end product is a glucose-sensing, soluble, and circulating modified insulin molecule. Animal studies have demonstrated enhanced responsiveness to glucose challenge in mice with diabetes and a reduction in hypoglycemic index in healthy mice [67]. There are plans to investigate smart insulins in human trials that can lead to their integration with insulin pumps, infusion devices, or controlled release materials to improve performance further.

Adjunctive therapies

Although insulin therapy is the cornerstone of diabetes treatment, the investigation and application of adjunctive therapies, primarily developed for T2DM, has recently allowed a multipronged

approach to afford targeted glycemic control in the T1DM population. Benefits of adjunctive therapy include the potential to achieve more targeted glycemic control, often in the setting of reduced insulin doses and weight loss. Below, the mechanism of action, currently available preparations, relevant side effects, and preliminary studies of these adjunctive agents in persons with T1DM are summarized for metformin, GLP-1 agonists, DPP-4 inhibitors, and SGLT inhibitors (see Chapter 31).

Metformin

Metformin is an oral agent commonly used in T2DM that improves glycemia by several mechanisms, including lowering hepatic glucose output and increasing peripheral uptake of glucose, especially in the muscle [68]. A recent meta-analysis showed that metformin treatment significantly reduced insulin doses but had no effect on HbA_{1c} levels in adults with T1DM, but the use of this agent in youth with T1DM has never been adequately studied. Pediatric investigators in the T1DM Exchange recently reported the results of a 6-month, multicenter, placebo-controlled randomized trial to assess the effect of the addition of 2000 mg of metformin per day to basal/bolus insulin treatment in 140 overweight/obese adolescents with T1DM with baseline mean HbA_{1c} levels of 8.8% [69]. Although youth in the metformin treatment group were able to reduce total daily insulin doses by ~0.1 U/kg/day and gained ~2.0 kg less weight than the control group, the results did not support the use of metformin with adolescents to improve glycemic control [69]. Rather than lowering HbA_{1c} levels, there was a modest increase to 9.0% in both the metformin and placebo treatment groups by the end of the 6-month study [69].

GLP-1 receptor agonists

GLP-1 is an incretin hormone released from the L cells of the distal small bowel. It suppresses glucagon, stimulates glucose induced insulin secretion, and inhibits postprandial gastric emptying. Although endogenous GLP-1 has a very short half-life, exogenous GLP-1 administration has shown similar effects, slowing gastric emptying, improving postprandial hyperglycemia, and lowering postprandial glucagon levels in people with T1DM [70–76]. Recently, a 12-week randomized, double-blind, placebo-controlled study of liraglutide, a GLP-1 receptor agonist, showed no benefit with regard to glycemic control despite those treated with liraglutide having a significant reduction in body weight (-3.13 ± 0.58 vs. $+1.12 \pm 0.42$ kg, $p < 0.0001$) with a concomitant reduction in bolus insulin doses ($p = 0.02$).

The role of GLP-1 receptor agonists in the propagation and prolongation of β-cell life is an area of investigation [77]. Additionally, this therapy has been approved for use in the treatment of obesity and studies investigating their utility in the treatment of obese children without diabetes are under way [78].

Currently, GLP-1 receptor agonists are not FDA approved for use in conjunction with insulin therapy in T1DM. Formulations currently on the market for the treatment of adults with T2DM include twice-daily injections of exenatide, daily liraglutide, and weekly albiglutide, dulaglutide, and extended-release exenatide. Common side effects are gastrointestinal symptoms including nausea and vomiting. Although postmarketing reports demonstrated rare cases of fatal and non-fatal hemorrhagic or necrotizing pancreatitis, more recent examination of the data has not borne out this concern [79].

DPP-4 inhibitors

Endogenous DPP-4 swiftly degrades GLP-1, glucose-dependent insulinotropic polypeptide (GIP), and other peptides [80]. DPP-4 inhibitors prolong the action of endogenous GLP-1, leading to multiple favorable glycemic effects; however, they have a smaller effect on weight and gastric emptying than GLP-1 receptor agonists [80].

Currently, FDA-approved DPP-4 inhibitors include sitagliptin, saxagliptin, linagliptin, and alogliptin, and comparison of these agents in people with T2DM has shown similar benefits and safety data across the different DPP-4 inhibitors [81]. Notably, these medications are oral agents and tend to have fewer gastrointestinal side effects than GLP-1 receptor agonists.

Application of DPP-4 inhibitors in addition to insulin therapy in persons with T1DM has been explored. Ellis et al. investigated the use of sitagliptin in addition to subcutaneous insulin therapy in persons with T1DM in a double-blind, placebo-controlled trial over an 8-week period [82]. They demonstrated that mean 24-h sensor glucose and postprandial glycemic control based on blinded continuous glucose monitor data were significantly improved with sitagliptin despite a reduction in prandial insulin doses. In a mechanistic study, Garg et al. examined sitagliptin in a double-blind, placebo-controlled trial in 141 participants with T1DM and demonstrated that the use of sitagliptin increased endogenous GLP-1 levels, while suppressing both GIP and glucagon [83]. However, this did not lead to a difference in HbA_{1c} levels, insulin dose, or weight after 16 weeks of treatment.

Additionally, the Restore Pancreatic Beta-Cell Function in Recent-Onset T1D Trial (REPAIR-T1D) explored whether the use of sitagliptin in conjunction with lansoprazole could lead to β-cell preservation in individuals with recent-onset T1DM based on promising findings in the non-obese diabetic (NOD) mouse [84]. However, no improvement in endogenous insulin production, as measured by C-peptide area under the curve (AUC) during a 2-h mixed-meal tolerance test, was demonstrated [84].

SGLT inhibitors

SGLT inhibitors transfer sodium down its concentration gradient while transferring glucose against its concentration gradient by acting as a cell-membrane symporter [85]. SGLT-2 is responsible for reabsorption of 90% of filtered glucose in the proximal renal tubule; whereas SGLT-1 has similar activity in the kidney, but also acts in the enterocytes of the small intestine to absorb glucose [85]. Orally active SGLT-2 inhibitors lower the renal threshold for glucose and thereby increase urinary glucose excretion [86], a mechanism for lowering glucose that is independent of insulin [86, 87].

Phase III clinical trials of SGLT-2 inhibitors in adults with T2DM have shown glucosuria of at least 50 g per day [85]. Decreases in fasting plasma glucose, postprandial glucose, and HbA_{1c} have been observed with SGLT-2 inhibitor treatment in adults with T2DM [85]. SGLT-2 inhibitors are generally well tolerated, with higher rates of genital mycotic infections compared with placebo [88].

Recent investigations have focused on the use of SGLT-2 inhibitors as an adjunct to insulin therapy in individuals with T1DM. In an 8-week proof-of-concept open-label study of empagliflozin, participants showed a lowering of their mean HbA_{1c}, fasting glucose, and total daily insulin dose while experiencing weight loss [89]. Similar results were seen in a study of 75 participants randomized to either once-daily empagliflozin 2.5, 10, or 25 mg or placebo over a 4-week period [90]. Moreover, a 24-week study of dapagliflozin in 12 participants confirmed the lowering of mean HbA_{1c} and fasting glucose; however, neither weight loss nor insulin dose reduction was observed [91].

To date, the FDA has approved the use of canagliflozin, dapagliflozin, and empagliflozin as oral SGLT-2 inhibitors for the treatment of T2DM in adults. Although the use of SGLT-2 inhibitors as agents for treatment of T2DM and T1DM is promising, total daily insulin doses may have to be reduced by 20–30% during treatment. Such decreases in insulin requirements may, in turn, increase rates of lipolysis and make insulin-requiring subjects prone to more rapid development of diabetic ketoacidosis (DKA). Indeed, the FDA has recently published a warning that people with T2DM treated with insulin may be at greater risk for DKA when treated with SGLT-2 inhibitors [17]. Further exploration of the metabolic decompensation that may occur with these agents is warranted.

Exploration of a dual SGLT-1/SGLT-2 inhibitor, sotagliflozin (LX4211), has been explored in persons with T1DM. Initial investigation of this agent demonstrated decreased fasting plasma glucose, postprandial glucose, HbA_{1c}, and insulin dose, and a reduction in body weight [92]. Additionally, sotagliflozin may have beneficial effects on increasing endogenous incretin secretion [93].

Artificial pancreas development

Despite the now widespread use of small, precise, and reliable continuous subcutaneous insulin pumps, and increasingly popular and accurate continuous subcutaneous real-time glucose sensors, the majority of people with T1DM still suffer from average glucose levels above recommended targets and/or unacceptably high rates of severe hypoglycemia [4]. Although the initial studies of an artificial pancreas began over 40 years ago with a feedback-controlled intravenous glucose sensing and insulin delivery device [94, 95], it is only recently that the accuracy, precision, miniaturization, and wireless communication of these devices have made the dream of developing truly portable, closed-loop systems to control glucose levels automatically in persons with diabetes a possibility. This section highlights some of the important studies along the pathway to a fully-automated, closed-loop treatment for people with T1DM.

Limitations of sensor-augmented pump therapy

Large-scale studies evaluating the efficacy of continuous glucose sensors (Juvenile Diabetes Research Foundation [JDRF] Continuous Glucose Monitoring Trial) and combination sensor-augmented pump therapy (Sensor Augmented Pump Therapy for A_{1c} Reduction [STAR-3]) demonstrated the benefits and also the limitations of these devices when used in an open-loop format. In the JDRF CGM trial, 322 adults and children aged 8 years and older with T1DM were randomized either to add a continuous glucose sensor to their usual diabetes management or to remain on their usual regimen of self-monitoring of blood glucose (SMBG). Whereas HbA_{1c} levels decreased by 0.5% in the adult cohort, no significant benefit of CGM over routine SMBG was seen in the child and adolescent cohorts [3]. This disappointing finding can best be explained by the inability of the two younger groups to wear the sensors effectively on a near-continuous basis: a post hoc analysis of the primary data illuminated that in every age group, those who used CGM on an average of six or more days per week had significant reductions in HbA_{1c} levels compared with control participants [96]. In the Medtronic-sponsored STAR-3 trial, which compared the use of sensor-augmented insulin pump therapy with basal-bolus regimens and SMBG, significant treatment group differences were seen at 1 year in all age groups: a 0.6% difference in the entire cohort, 0.5% in the preadolescents, and 0.7% in the adolescents [97, 98]. As in the JDRF CGM trial, the amount of sensor use correlated with the magnitude of HbA_{1c} reduction. Studies of CGM in very young children with diabetes demonstrated high degrees of parent satisfaction but little beneficial effect on HbA_{1c} levels [99, 100].

Taken together, these results suggest that sensor-augmented pump therapy in an open-loop platform has only a limited benefit in individuals with T1DM. Human control of sensor-augmented pump therapy necessitates frequent, almost continuous, surveillance of the system in order to optimize control, and human decisions regarding insulin dose administration are subject to both human judgment error and neglect. The true power of continuous glucose sensors can only be fully realized in a closed-loop platform, in which real-time feedback of current glucose levels allows for minute-to-minute modulation of insulin delivery, thereby removing (or at least relegating to the background) the attention of the user. Such systems depend on control algorithms, which determine the insulin delivery at any given point in time. Systems may be considered *completely* closed-loop if insulin delivery is determined solely by the algorithm based on the glucose levels, without any manual user interaction to the system. *Hybrid* or *partial* closed-loop systems allow for additional information to be provided to the controller algorithm based on the current activity of the user, such as initiation of a meal, exercise, or addition of manual insulin administration. The potential of closed-loop systems to improve diabetes control lies in its ability to perform the necessary functions precisely, accurately, and continuously,

allowing the user the relatively limited responsibility of ensuring the proper calibration of the sensor, patency of the infusion site, and viability of the wireless communication between devices.

Low-glucose (threshold) suspend

The simplest level of feedback control is to have the pump automatically suspend basal insulin infusion in the setting of hypoglycemia. Such a system does not require a sophisticated control algorithm to determine insulin delivery, or even to predict hypoglycemia, only to trigger a suspension of the pump when the sensor reads below a certain predetermined threshold value. These "low-glucose suspend" systems have been compared to an automobile's airbag: although the airbag does not prevent an accident, it at least mitigates the human injury. By the same token, the low-glucose suspend feature does not prevent hypoglycemia, but limits its duration and/or magnitude. Given the greater risk for severe hypoglycemia at night [2, 101, 102], identification that most people fail to wake to respond to alarms at night [103], and that seizures typically occur after a prolonged period of hypoglycemia [104], such a feature could significantly reduce the occurrence of severe nocturnal hypoglycemia and seizures, since pump suspension would be triggered automatically. Sensor-augmented pumps that automatically suspend basal insulin delivery for up to 2 h ("threshold suspend") are now widely available for people with T1DM. An in-clinic study using programmed exercise to induce a drop in blood glucose demonstrated the effectiveness of the threshold-suspend feature to reduce the magnitude and duration of hypoglycemia [105]. A subsequent 3-month in-home clinical trial involving 247 adults with T1DM demonstrated a 38% reduction in the AUC for exposure to nocturnal hypoglycemia and a 31% reduction in nocturnal hypoglycemia events with the use of a threshold-suspend system, without a deterioration in HbA_{1c} [106].

Predictive low-glucose suspend

Whereas the aforementioned low-glucose suspend systems are activated only after a hypoglycemic threshold has been achieved, a more desirable feature would be to suspend insulin delivery *before* the threshold is reached, thereby averting hypoglycemia altogether. A *predictive* pump suspension algorithm has been evaluated in several adult and pediatric studies and shown to reduce the magnitude and duration of hypoglycemia. Initial inpatient studies by Buckingham et al. with a bedside system utilizing a series of parallel prediction algorithms, a hypoglycemia threshold of 80 mg/dL, and an alarm horizon of 35 min, showed that such a system could prevent up to 75% of induced hypoglycemia [107]. More recent in-home studies incorporating a simpler hypoglycemia prediction scheme with a glucose threshold of 80 mg/dL and an alarm horizon of 30 min randomized 45 adolescents/adults and 82 children to have the predictive suspend feature randomly engaged or disengaged for up to 6 weeks of wear. It was found that episodes of sensor glucose levels <60 mg/dL were lower on suspend nights than control nights (21% compared with 33%), and that the median hypoglycemia AUC was reduced by 81% on suspend nights [108]. In children, time spent with night-time sensor glucose levels <70 mg/dL were reduced from 10.1 to 4.6% in the 11–14-year-old cohort and from 6.2 to 3.1% in the 4–10-year-old cohort (p <0.001) [109].

Closed-loop algorithm considerations

All of the studies discussed so far were conducted within an open-loop platform, with varying degrees of closed-loop intervention based on the achievement of certain clinical conditions, such as actual or predicted low sensor glucose levels. In a "true" closed-loop platform, the default condition would be automated insulin delivery based on the sensor glucose input and the control algorithm, with manual intervention at certain points to inform the controller of behavioral conditions, such as meals or exercise.

The key component of a closed-loop system is the algorithm controller; the two most commonly utilized algorithms are proportional integral derivative (PID) and model predictive control (MPC). PID algorithms determine insulin delivery solely on three components: deviation of the current glucose level from the set point (proportional); the integrated AUC between the current glucose and set point (integral); and the rate of change of the current glucose from the prior measurement (derivative) [110, 111]. PID algorithms are essentially *reactive*, responding only to glucose levels. Modifications to strict PID algorithms to account for the amount of insulin already delivered at any given moment have been incorporated into PID systems to improve performance [112–114]. MPC algorithms, on the other hand, attempt to account for many clinical variables in addition to the glucose levels, such as the delays between previously administered insulin, the rate of carbohydrate absorption, and effect of physical activity [115–118]. Insulin delivery in an MPC algorithm is iterative; calculated to achieve a target in the future based on a series of controller "moves" in a prediction window. Other algorithmic approaches to closed-loop control include "fuzzy logic" control [119], fuzzy logic combined with individualized learning algorithms [120], fading memory proportional derivative control [121], and combinations of PID and MPC controllers for dual hormonal systems [122].

Early-phase/inpatient closed-loop studies

The first human study of a closed-loop system utilizing subcutaneous glucose sensing and subcutaneous insulin delivery was performed by Steil et al. at Medtronic and UCLA [123]. In 10 adult with T1DM studied over 30 h of fully closed-loop control, 75% of glucose levels were controlled within target (70–180 mg/dL), but late postprandial hypoglycemia was common. Similar findings were observed in a follow-up pediatric study at Yale University, conducted in 17 adolescents over 36 h of closed-loop control [124]. Glucose control was excellent overall: 85% of glucose values were within the target range of 70–180 mg/dL. This study also described the effect of "hybrid" control, in which at least part of the meal insulin requirements were provided with a manual insulin bolus. Hybrid control resulted in improved postprandial glycemia,

undoubtedly due to the more rapid delivery of insulin to cover ingested carbohydrates. Most closed-loop systems in development today utilize a hybrid approach to glucose control.

Other early approaches to closed-loop control focused entirely on overnight control only. Hovorka's group at the University of Cambridge has extensively characterized the efficacy and safety of an MPC-based closed-loop system, demonstrating improved time-in-target and reduced exposure to hypoglycemia in children [125] and adults [126], and preliminary efficacy was demonstrated in studies of pregnant women [127, 128]. In a multinational study, Kovatchev et al. at the Universities of Virginia, Padova, Montpellier, and Pavia also used an MPC-based algorithm to demonstrate improved overnight blood glucose levels and reduced frequency of hypoglycemia in 20 adult with T1DM during closed-loop control compared with open-loop pump treatment [129]. Phillip et al. and the DREAM Project team used a fuzzy logic controller with an individualized learning module to control safely blood glucose levels overnight, nearly tripling the time in the target range without hypoglycemia [130, 131].

All of the systems discussed up to this point utilized only insulin. Several groups have investigated the feasibility of dual hormonal closed-loop systems employing insulin and glucagon in separate pumps, under individual algorithmic control: Damiano et al. [132], employing an MPC-based algorithm for insulin and a PID-based algorithm for glucagon; Castle et al. [133], using a fading memory proportional derivative algorithm for both insulin and glucagon; Haidar et al. [134], using a fuzzy logic model-based predictive technique; and Van Bon et al. [135], using a proportional derivative algorithm. Our group has explored the use of pramlintide and liraglutide as a means to mitigate prandial glycemic excursions in a fully automated closed-loop insulin delivery system without manual meal announcement and found reductions in prandial glucose peaks and AUC [114, 136].

Outpatient studies

The success of these inpatient feasibility studies and the development of technologies to allow for portability of the controller devices (e.g. moving the algorithms from a laptop to smartphone or tablet) have enabled closed-loop research studies to escape the confines of the clinical research facility and undergo testing in more challenging environments such as home or camp, in which meals and physical activity are less regulated and predictable.

One of the first outpatient studies of a closed-loop system was conducted by Phillip et al. in 56 children in three centers during two consecutive nights at a summer camp. Hypoglycemic episodes were reduced by 30%, without deterioration of overnight mean glucose [137]. Use of this system for up to 6 weeks in the home setting was associated with a 22% increase in time in target range, a 40% reduction in hypoglycemia, and a 50% reduction in time spent with glucose >240 mg/dL [138, 139]. Similarly, a closed-loop system developed by Kovatchev et al. and tested initially in short feasibility studies [140, 141] was also shown, in a six-night camp study, to improve time in target range from 52 to 73% and a reduction of nocturnal hypoglycemia in a cohort of 20 children and adolescents randomized to overnight closed-loop versus open-loop sensor-augmented pump therapy comparator [142].

The longest studies of closed-loop control were conducted by Hovorka's group at the University of Cambridge. Randomized controlled crossover trials of overnight closed-loop compared with sensor-augmented open-loop pump therapy were conducted in 24 adults for 4 weeks and in 16 adolescents for 3 weeks and showed an 18% increase in time in target range, lower mean glucose levels, and reduced exposure to hypoglycemia [143, 144]. Most recently, this group has demonstrated the safety and effectiveness of day *and* night closed-loop control in 33 adults and 25 adolescents over 12 weeks [145]. The adult cohort utilized closed-loop control for day- and night-time periods, with full manual meal boluses, whereas the adolescent cohort used closed-loop control at night only and open-loop sensor-augmented pump therapy during the day. In both cohorts, time in the target range was significantly improved for both overnight and full-day periods, despite the fact that adolescents were on open-loop control during day, highlighting the importance of nocturnal control in optimizing control on the subsequent day. As expected, closed-loop control also reduced hypoglycemia in both cohorts, and in the adult group it also reduced HbA_{1c} [145].

Outpatient bihormonal control with insulin and glucagon was studied by Russell et al. in two parallel studies in 20 adults and 32 adolescents in supervised hotel and camp environments, respectively, over 5-day periods. An alternative approach to meals was used in these studies, using a semiquantitative announcement that did not require exact carbohydrate counting. In both cohorts, both mean glucose and time in range were significantly improved and, in the adult cohort only, time spent in hypoglycemia was significantly reduced [146]. For these studies, aqueous glucagon was prepared fresh daily for delivery in the pump. Future studies of this system will benefit from stable liquid forms of glucagon that will not form amyloid fibrils and insoluble gels, which would occlude insulin pump catheters, after prolonged reconstitution [147].

Extended large-scale multicenter home-use studies of closed-loop systems are now being conducted by industry and academic centers across the world, which will provide the necessary safety and efficacy data for regulatory approval of these devices in the coming years. Regardless of the particular system under study, further research into human factors and long-term effects on complications and quality of life will be needed to optimize the potential of the artificial pancreas in improving the health outcomes of people with T1DM.

Improved glucagon preparations

Unlike insulin therapy, which has evolved since its discovery nearly a century ago, therapeutics directed towards correction of severe hypoglycemia have remained stagnant since injected

glucagon for treatment of severe hypoglycemia was introduced in the 1950s [148]. Current commercially available glucagon emergency kits require an eight-step process to reconstitute the lyophilized powder in a diluent immediately prior to injection given the propensity for fibril formation once the solution is mixed [149]. Recently, explorations of new formulations and modalities to deliver glucagon therapy have been explored.

Stable liquid preparations

With the development of dual hormone closed-loop delivery systems as described above, the need for a soluble formulation of glucagon for use in such systems for commercial application of this product is necessary. Recent studies have demonstrated the stability of aqueous formulations of glucagon, which show no fibril formulation after 7 days [150, 151]. Indeed, further studies have demonstrated that a stable non-aqueous glucagon formulation shows minimal chemical degradation and no fibril formulation for >18 months while stored at room temperature [152], and the use of this preparation compared with a commercially available glucagon kit in healthy people without diabetes showed therapeutic equivalence [152].

Administration of mini-dose injected glucagon has been used for the management of sick days and is being explored as an alternative to oral carbohydrate intake for the treatment of mild hypoglycemia [153, 154]. Recent evaluation of non-aqueous, mini-dose glucagon has been conducted in adults with T1DM, demonstrating beneficial effects of 75, 150, and 300 μg, and supports the development of this therapeutic agent for treatment of impending or mild hypoglycemia [155].

Dry powder intranasal preparations

Investigation of the nasal route for glucagon delivery was first reported in 1983 [156]. However, although a number of small studies yielded positive results in healthy volunteers in both adults and children with T1DM, the product was never commercialized [156–164]. Recently, this mode of glucagon delivery has made a resurgence with the development of a novel dry powder glucagon formulation. Delivery of glucagon to the nasal mucosa occurs with a single-use one-step dispensing device that discharges the powder by depressing a plunger connected to a piston. Importantly, individuals who require this therapy would not need to cooperate with its administration or inhale, as the powder is absorbed passively. Rickels et al. investigated the use of this formulation of glucagon in adults with T1DM in whom a 3 mg of dose of intranasal glucagon was found to be as effective as intramuscular glucagon in reversing insulin-induced hypoglycemia [165]. Additionally, examination of intranasal glucagon in the pediatric population has demonstrated it to have similar pharmacokinetic and safety profiles to those seen in intramuscular therapy [166]. Most importantly, based on the studies conducted, it has been concluded that a single 3 mg intranasal glucagon dose can be used in children as young as 4 years old, with no weight- or age-based dose adjustments required [166].

A recent human factors study compared the ability of 16 trained caregivers of persons with insulin treated diabetes to use intramuscular and intranasal devices to treat a simulated episode of severe hypoglycemia [167]. Intranasal glucagon was successfully administered by 94% of caregivers (average time 16 s) whereas injectable glucagon was administered by only half of the caregivers (average time more than seven times that required for intranasal administration) [167]. Two of the caregivers mistakenly injected insulin and only 12% of participants were able to administer the full injectable dose correctly [167]. These data highlight the potential benefit of a glucagon rescue therapy that does not have the same mode of delivery as insulin.

Conclusion

The care of individuals with T1DM is on the precipice of radical change. From improved insulins to the addition of adjunctive therapies, the medications used to treat this condition will better replicate physiological processes, providing people with the opportunity to reach targeted glycemic control. Mechanical solutions in the form of closed-loop delivery systems will provide the means to reach targeted glycemic control while additionally reducing the burden of the disease on the individual. New formulations of glucagon hold the potential to transform how severe hypoglycemia is managed, making the treatment of these episodes less complicated.

67 Future Drug Treatments for Type 2 Diabetes

Clifford J. Bailey
School of Life and Health Sciences, Aston University, Birmingham, UK

Key points

- Despite a variety of differently acting glucose-lowering agents, many people with type 2 diabetes do not achieve or maintain adequate glycemic control. Hence there is a continued need for new agents.
- The variable etiology and pathogenesis of type 2 diabetes requires a diversity of therapies that can be used in combination.
- Fixed-ratio combinations of glucagon-like peptide 1 (GLP-1) receptor agonists with insulin, and potential hybrid peptides of incretins and other gluco-regulatory hormones, offer the opportunity to interact with several target receptors via a single injection.
- Further incretin-based therapies in development include depot injections of GLP-1 receptor agonists, orally active GLP-1 receptor agonists, and long-acting dipeptidyl peptidase 4 (DPP-4) inhibitors.
- Novel insulin-releasing agents such as fatty acid receptor agonists could improve pancreatic β-cell responses to rising glycemia.
- Proof of principle has been shown for small molecules to mimic and potentiate insulin action.
- Glucagon receptor antagonists, selective peroxisome proliferator-activated receptor (PPAR) modulators, cellular glucocorticoid inhibitors, adiponectin receptor agonists, and fibroblast growth factor 21 analogs have been reported at various stages of development.
- Agents that directly enhance glucose metabolism or suppress glucose production have been described.
- New inhibitors of sodium-glucose co-transporters SGLT-1 and SGLT-2 are advancing in development.
- Emerging pharmacogenomics and proteomics could offer novel therapeutic opportunities.

Introduction

Despite many initiatives to prevent type 2 diabetes mellitus (T2DM), its prevalence continues to rise, accounting for ~95% of the global totality of people with diabetes (~410 million now and projected to be ~640 million by 2040) [1]. Current treatment strategies are reviewed in earlier chapters of this book, and the importance of an early, effective, individualized therapeutic approach to glycemic control is emphasized to defer the onset and reduce the severity of complications. Although many differently acting classes of glucose-lowering agents are already available (Figure 67.1), a sustained return to normal glucose homeostasis is rarely achieved, and more than one-third of people with T2DM do not attain or maintain an acceptable level of glycemic control [2–4]. This chapter reviews some of the new therapeutic approaches under consideration to improve glycemic control in T2DM, including innovative concepts in preclinical investigation through to agents advanced in clinical development.

Development of new antidiabetes agents

The highly variable etiology and pathogenesis of T2DM, which typically involves disturbances in multiple tissues and organ systems, opens the possibility of many potential approaches to blood glucose control [5]. Some of these approaches directly target underlying pathophysiological defects such as insulin resistance and pancreatic β-cell dysfunction, but interventions that improve glycemic control by any safe means should reduce the risk of complications. Because treatments are often life-long and contemporaneous with comorbidities, frailty, multiple pharmacotherapies, and lifestyle challenges, it is important that new agents offer a commendable safety profile, are well tolerated, and are compatible with a broad selection of other medications. Ideally, they will provide durable and additive glucose-lowering efficacy to existing agents through different but complementary modes of action, while carrying minimal risk of serious hypoglycemia. Additional capability to reduce adiposity and improve other modifiable cardiovascular

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

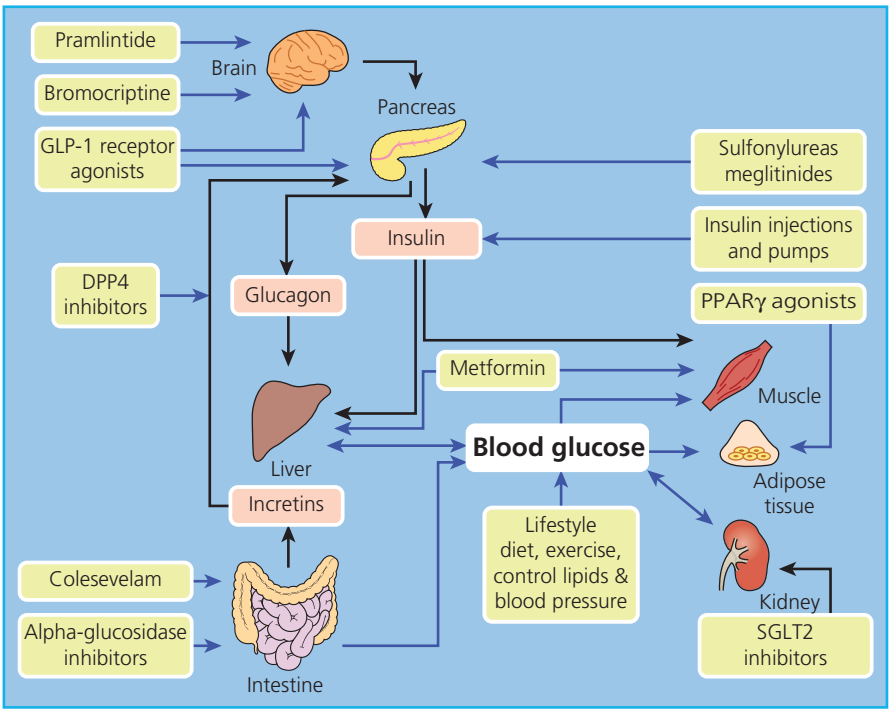

Figure 67.1 Current glucose-lowering therapies showing their main sites of action. Not all classes of therapies are indicated for the treatment of T2DM in all regions. GLP-1, glucagon-like peptide-1; PPAR, peroxisome proliferator-activated receptor; SGLT2, sodium–glucose co-transporter 2.

risk factors such as dyslipidemia and hypertension would also be preferred.

Identifying a new chemical entity and progressing it through the preclinical and clinical phases of development to marketing approval are likely to take at least 10 years (Table 67.1). The cost is expected to exceed US$1 billion, and an average cost was recently estimated to be US$2.6 billion [6]. For glucose-lowering drugs, post-authorization safety studies to monitor cardiovascular outcomes and other events may be required. Further development may be undertaken for additional indications and to produce new formulations, including single-tablet fixed-dose combinations or fixed-ratio injection combinations [7].

Modifiers of carbohydrate digestion and absorption

Dietary fiber supplements to delay the digestion and absorption of carbohydrates have generally achieved only modest reductions of postprandial hyperglycemia with small "carry-over" reductions in basal glycemia [8]. These mostly comprise soluble and/or insoluble plant polysaccharides that are not digested and form either bulky viscous gels and gums or a coarse insoluble matrix (Table 67.2). By reducing diffusion within the lumen of the small intestine. they entrap carbohydrates, impeding entry of digestive enzymes and restricting access of saccharides to the intestinal epithelium. Fiber supplements are conveniently used in conjunction with most other classes of glucose-lowering pharmacotherapies, including insulin, and the extended period of digestion can usefully reduce interprandial hypoglycemia in insulin-treated individuals.

Inhibitors of α-amylases to slow the hydrolysis of starch have not given predictable effects, and supplements containing "active" bacteria or fungal products that might modify carbohydrate digestion and absorption have not shown consistent efficacy in the limited studies to date [9]. Competitive inhibitors of brush-border α-glucosidases such as acarbose, miglitol, and voglibose are well established therapies to slow the last stages of carbohydrate digestion [10]. They require dose titration against the amount of complex carbohydrate in the diet to prevent undigested sugars from entering the large bowel, where bacterial fermentation can produce various gases, fatty acids, and osmotically active glucose, causing flatulence and diarrhea as side effects. Inhibition of sodium–glucose co-transporter 1 (SGLT-1) in the intestinal brush border provides another option to slow the absorption of glucose. This is considered further in a later section.

Supporting pancreatic β-cell function

Disturbances of pancreatic β-cell function occur early in the pathogenesis of T2DM and β-cell failure is a prominent feature of advanced stages of T2DM, making the β cell a key therapeutic target. Agents that initiate insulin secretion (sulfonylureas and meglitinides) or potentiate nutrient-induced insulin secretion (dipeptidyl peptidase 4 [DPP-4] inhibitors and glucagon-like peptide 1 [GLP-1] receptor agonists) are widely used in the treatment of T2DM (see Chapters 31 and 32). These agents partially compensate for the loss of an adequate first-phase insulin response in T2DM, while enhancing the second phase of secretion and improving the secreted proportion of insulin relative to proinsulin. However, risks of hypoglycemia and weight gain are

Table 67.1 Stages in the development of a new drug.

Preclinical stages

New chemical entity

- Identification, extraction/synthesis, chemical characterization, and patenting of compounds
- Genotoxicity testing: screening for biological activity *in vitro* and *in vivo* in animals
- Preclinical pharmacology, mode of action, pharmacodynamics (activity, safety, tolerance), pharmacokinetics (bioavailability, distribution, metabolism, elimination) and toxicity in ≥2 mammalian species

Clinical stages

Investigational new drug application: permission to begin clinical studies

Phase I

- First administration to a small number of healthy human volunteers
- Dose ranging, vital signs, pharmacodynamics, pharmacokinetics, drug interactions, safety

Phase II

- First trials in small numbers of people with the condition
- Dose ranging, efficacy, further pharmacodynamics, pharmacokinetics, and safety

Phase III

- Trials in larger numbers of people with the condition
- Multicenter trials, comparative trials with other treatments, efficacy, further pharmacodynamics and safety (including meta-analysis of cardiovascular outcomes)

New drug application: permission to market as a drug

Phase IV

- Use in medical practice
- Additional trials (similar to phase III) for long-term efficacy and safety, and use in special subgroups (e.g. elderly people), postmarketing surveillance and adverse drug reactions

frequently cited limitations of sulfonylureas and meglitinides. For DPP-4 inhibitors, the magnitude of the glucose-lowering effect may be initially less than for sulfonylureas, but there is low risk of hypoglycemia or weight gain. GLP-1 receptor agonists offer efficacy, durability, weight loss, and low risk of hypoglycemia, but present agents require subcutaneous injection and some individuals do not respond or experience nausea. Although there is preclinical evidence of β-cell preservation and increased insulin biosynthesis with GLP-1 receptor agonists, these properties have yet to be demonstrated equivocally in T2DM [4].

Table 67.2 Soluble and insoluble fiber supplements.

Soluble fiber	Insoluble fiber
Gums	Celluloses
Pectins	Wheat bran
Hemicelluloses	
Mucilages	

Many compounds with insulin-releasing properties have received preclinical and early clinical investigation, but targeting the pancreatic β cells to the exclusion of other cell types has been particularly challenging, and few lead compounds have proceeded further in development [11]. Included here are agents that increase adenosine triphosphate (ATP) production, close K^+ATP channels, depolarize the β-cell membrane, increase cytosolic calcium, enhance cyclic adenosine monophosphate (cAMP) or protein kinase C (PKC), activate imidazoline receptors, or suppress α_2-adrenergic receptors.

Glucokinase activators

Agents that allosterically activate the glucose phosphorylating enzyme glucokinase (GK) (EC 2.7.1.1) continue to attract interest as a means of initiating insulin secretion by increasing β-cell glucose metabolism (Figure 67.2). Despite many promising preclinical accounts, this approach is prone to precipitate hypoglycemia and often incurs loss of efficacy after several months of treatment in human T2DM [12, 13]. Glucokinase is also expressed in the liver, where it is regulated differently to pancreatic β cells, being activated when the influx of glucose dissociates the enzyme from a regulatory binding protein. GK in the liver does not require such rapid activation and deactivation as GK in pancreatic β-cells, and can be chronically upregulated by agents that prevent its association with or cause its dissociation from the inhibitory binding protein [14]. Several such hepato-selective GK activators are under investigation to increase hepatic glucose uptake while avoiding hypoglycemia, but the risk of excess glycogen deposition and increased lipogenesis in the liver has yet to be evaluated in human T2DM.

Fatty acid receptor agonists

Pancreatic β cells express G protein-coupled receptors for various fatty acids, notably GPR40 (FFAR1) and GPR119. Small-molecule agonists of these receptors can enhance insulin secretion in different ways [15] (Figure 67.2). Activation of GPR40 generates intracellular signals via phospholipase C, which raises cytosolic Ca^{2+} by redistribution from endoplasmic stores, and also increases isoforms of PKC that augment insulin exocytosis. Thus GPR40 agonists can partially initiate insulin secretion and also potentiate the release of insulin initiated by nutrients. Although a GPR40 agonist (TAK-875) was recently discontinued owing to hepatic side effects, the glucose-lowering efficacy of this approach was confirmed in human T2DM, and other GPR40 agonists continue in development [16]. Activation of GPR119 signals via adenylate cyclase to increase cAMP and potentiate nutrient-induced insulin secretion in a similar way to GLP-1 [17]. Both GPR40 and GPR119 are expressed by several types of enteroendocrine cells (e.g. K cells, L cells, and I cells), hence agonists for these receptors can increase the secretion of glucose-dependent insulinotropic peptide (GIP), GLP-1, polypeptide YY (PYY), oxyntomodulin, and cholecystokinin, potentially enhancing the incretin effect and promoting satiety [18]. Also, the activation of GPR40 receptors expressed by

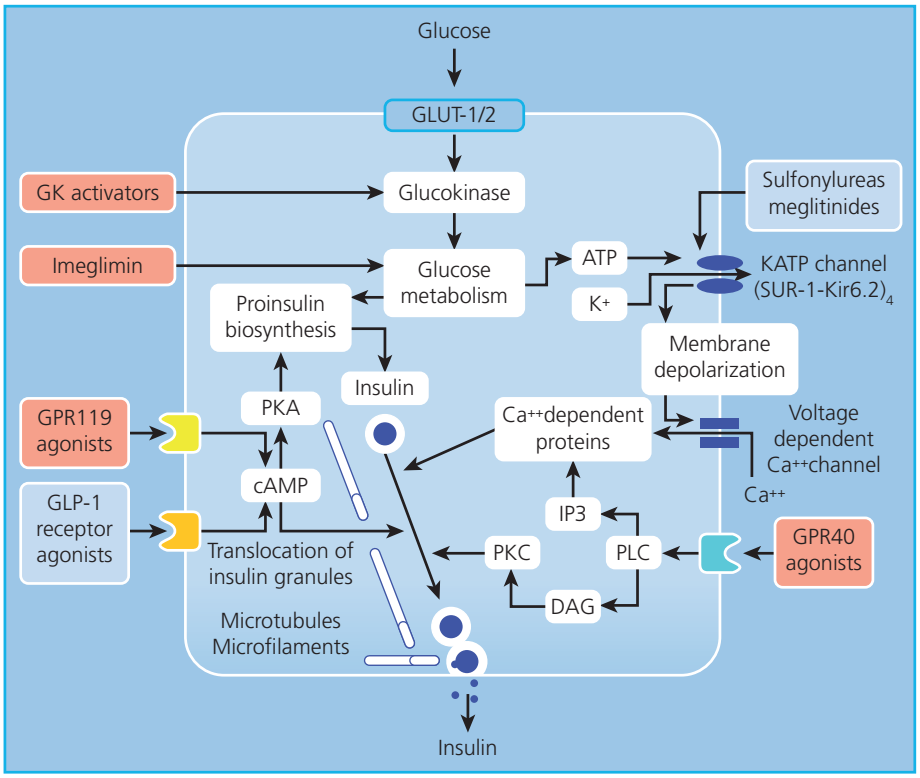

Figure 67.2 Mechanisms of action of insulin-releasing agents on pancreatic β cells. Glucose is taken up by the pancreatic β cells in proportion to the circulating concentration. The glucose is metabolized to produce ATP, which closes the Kir6.2 pores of ATP-sensitive potassium channels (K_{ATP} channels). This prevents elimination of potassium from the cell, causing localized membrane depolarization that opens voltage-dependent calcium channels. The influx of Ca^{2+} raises the cytosolic Ca^{2+} concentration, which activates calcium-dependent proteins that promote the translocation of insulin granules to the plasma membrane for exocytosis. Sulfonylureas and meglitinides initiate insulin release mainly by binding to sites on the sulfonylurea receptor-1 (SUR1), which forms part of the Kir6.2 complex. Activated GLP-1 receptors and GPR119 receptors increase adenylate cyclase activity, which raises cAMP concentrations while GPR40 receptors agonists are functionally linked to PLC. GK activators increase glucose flux into glycolysis and imeglimin acts on mitochondria. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; GK, glucokinase; GLUT, glucose transporter isoform; GLP-1, glucagon-like peptide 1; GPR, G-protein-coupled receptor; IP3, inositol trisphosphate; K_{ATP}, ATP-sensitive potassium channel; Kir, inwardly rectifying potassium channel; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; SUR, sulfonylurea receptor.

pancreatic α cells has been reported to reduce glucagon secretion, whereas GPR119 agonists may raise glucagon levels [19, 20]. Another fatty acid receptor, GPR120 (FFAR4), is expressed mainly by adipose tissue. Agonists of GPR120 promote adipogenesis and appear to improve glucose tolerance by increasing insulin sensitivity and reducing ectopic fat [21].

Imeglimin

Imeglimin is a triazine compound that alters mitochondrial energetics, possibly by delaying the opening of mitochondrial permeability transition pores. Studies in individuals with T2DM have shown it to assist glucose-induced insulin secretion and also improve insulin sensitivity and reduce hepatic glucose production [22].

Incretins

The main incretin hormone, GLP-1, potentiates nutrient-induced insulin secretion, suppresses glucagon secretion at raised glucose concentrations, delays gastric emptying, and exerts a satiety effect that assists weight control (Figure 67.3). GLP-1 is rapidly inactivated by the enzyme DPP-4, hence therapeutic GLP-1 receptor agonists are designed to protect against degradation by DPP-4. Currently available GLP-1 receptor agonists are administered by subcutaneous injection: exenatide (twice daily and weekly), liraglutide and lixisenatide (once daily), and dulaglutide and albiglutide (weekly).

Since continuously raised GLP-1 levels achieved with once-weekly administered GLP-1 receptor agonists permit substantial lowering of HbA_{1c}, a subcutaneously implanted miniature (matchstick-sized) osmotic pump has been developed to deliver exenatide continuously at up to 80 μg/day for up to 48 weeks. Trials in people with T2DM indicated that doses of ≥40 μg /day typically reduced HbA_{1c} by >1% and weight >3 kg from baseline values of ~8% and ~93 kg, respectively. Nausea was mostly transient, and antibodies that were identified in about 10% of participants did not appear to interfere with efficacy [23]. Other modes of delivery of GLP-1 receptor agonists in development include an oral tablet formulation of semaglutide: this agent

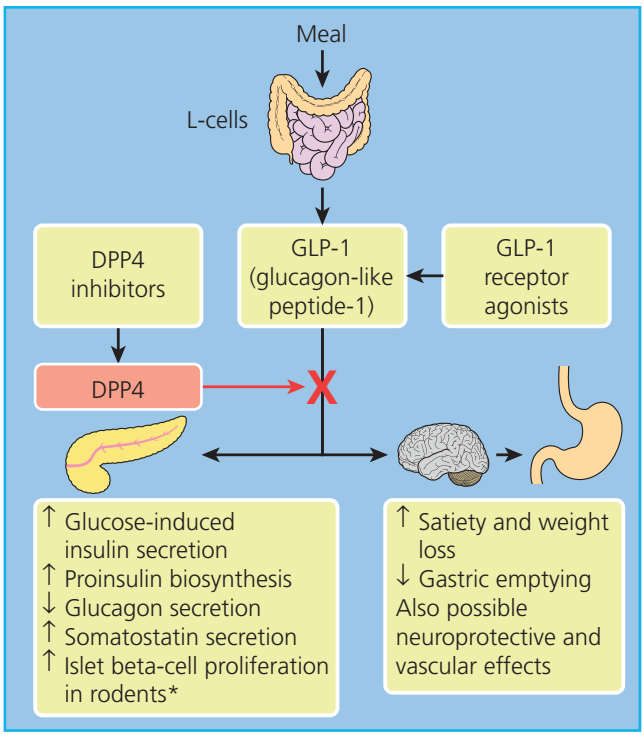

Figure 67.3 Actions of glucagon-like peptide 1 (GLP-1). GLP-1 is the main hormone responsible for the incretin effect (enhanced insulin response to enteral versus intravenous glucose). Intestinal glucose stimulates secretion of GLP-1 by L cells. The effects of GLP-1 on glucose homeostasis include pancreatic effects (increased insulin release and reduced glucagon release, each in a glucose-dependent manner), increased satiety and delayed gastric emptying. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase 4 (DPP-4). DPP-4 inhibitors prolong the activity of endogenous GLP-1. GLP-1 receptor agonists are analogs that are altered to protect against degradation by DPP-4. *Effect seen in preclinical studies but not confirmed in human T2DM.

is already in phase III trials as a once-weekly subcutaneous injection [24]. The GLP-1 receptor can also be activated by various non-peptide molecules that are undergoing preclinical investigation as templates for potential tablet formulations [25].

In view of the complementary actions of GLP-1 receptor agonists (mainly targeting postprandial hyperglycemia) and basal insulin (mainly targeting basal hyperglycemia), mixtures of the two peptides ("fixed-ratio" combinations) have been formulated into the same subcutaneous injection. The first of these combinations (IDegLira) contains liraglutide with insulin degludec in the proportions 3.6 mg : 100 units. The combination is titrated as for basal insulin, and randomized studies in people with T2DM have noted greater reductions in HbA_{1c} with the combination than with either agent alone (e.g. an average fall of 1.8% from a baseline of ~8.3%, compared with a 1.2% fall for liraglutide alone and a 1.4% fall for insulin alone) [26]. Less insulin was required with the combination (mean dose 39 units) than degludec alone (62 units), risk of hypoglycemia was reduced, and weight gain was avoided. Another "fixed-ratio" combination in development (Lixilan) contains lixisenatide with glargine in the proportions 50 μg : 100 units [27].

Hybrid peptides

The substantial improvements in glycemic control and weight reduction after bariatric surgery are associated with changes in the secretion of several gastrointestinal hormones, including increases in postprandial concentrations of hormones from intestinal L cells (GLP-1, $PYY_{3–36}$, and oxyntomodulin), a decrease in ghrelin, and inconsistent changes in GIP and gastrin [28]. In principle, therefore, it should be possible to generate similar effects by administering a comparable mix of these peptides with or without receptor antagonists for those peptides to be suppressed. The possibility of adding other peptides that affect gluco-regulation, food intake, and energy expenditure, such as glucagon and leptin, has also been considered. To avoid the problems associated with mixtures of peptides or giant combinatorial peptides, several hybrid peptides have been synthesized and tested [29, 30]. To date, these have mostly comprised selected epitopes from two or three peptides, introducing modifications to prevent degradation by DPP-4 and to provide stability. For example, hybrid peptides with agonist effects at the GLP-1, GIP, and glucagon receptors have shown glucose-lowering and weight-lowering activity in preclinical studies, and adjustments to the design may be envisaged to modify receptor binding affinities and potencies mediated through these receptors to amplify desired effects (Figure 67.4) [31, 32]. Parenthetically, to account for the inclusion of glucagon epitopes in these hybrids, it is noted that although glucagon raises blood glucose by increasing hepatic glucose output, it also affects nutrient homeostasis by increasing lipolysis, decreasing appetite, and increasing thermogenic energy expenditure [33]. Thus a hybrid might take advantage of the weight-lowering effects of glucagon if, for example, the effects of the GLP-1 moiety within the hybrid can increase insulin release and suppress endogenous glucagon secretion sufficiently to more than compensate for the hyperglycemic effect of the glucagon. Although subject to considerable physicochemical and immunological restrictions, the concept of hybrid peptides with highly selective agonist and antagonist effects at multiple receptors in a single administration offers an appealing approach to address the multiple pathogenic factors in T2DM.

DPP-4 inhibitors

Inhibitors of the enzyme DPP-4 (EC 3.4.14.5) are widely used in the treatment of T2DM to prevent the breakdown of endogenous incretins [34]. They include sitagliptin, vildagliptin, saxagliptin, linagliptin, and alogliptin, taken as once-daily (or twice-daily for vildagliptin) tablets. Although these agents extend the biological half-lives of many peptides in addition to incretins, they have been associated with relatively few adverse events, and this has encouraged the development of longer-acting DPP-4 inhibitors [35]. Omarigliptin is advanced in development as a once-weekly DPP-4 inhibitor showing similar efficacy and tolerability to sitagliptin [36]. Trelagliptin is another once-weekly DPP-4 inhibitor in development.

Bile acid receptor agonists

TGR5 (GP-BAR1) bile acid receptors are strongly expressed by intestinal L cells and brown adipose tissue, and stimulation of these receptors can enhance GLP-1 secretion, increase energy expenditure, and lower blood glucose [37]. However, excess TGR5 agonism can exert unwanted effects on gallbladder smooth muscle relaxation, causing over-filling. This has prompted studies with poorly absorbed TGR5 agonists intended to stimulate GLP-1 secretion by L cells located distally along the intestinal tract [38]. Because the TGR5 receptors are mostly located in the basolateral membranes of L cells, activation by agonists in the intestinal lumen may require large doses of these agents.

Inhibitors of glucagon secretion and action

Preclinical studies dating from the 1970s have demonstrated the glucose-lowering efficacy of glucagon antibodies, and later preclinical and clinical studies have assessed the therapeutic potential of peptide glucagon antagonists, glucagon receptor antisense oligonucleotides, and various inhibitors of α-cell glucagon secretion (e.g. somatostatin analogs and non-peptide molecules) [11]. However, none has progressed fully in development, mainly owing to an impaired counter-regulatory response to hypoglycemia. A considerable catalog of small-molecule glucagon receptor antagonists has also emerged, but compensatory hyperglucagonemia, rebound hyperglycemia if therapy is stopped, and unwanted liver effects have complicated therapeutic application [39, 40]. Although it is recognized that glucagon mediates a wide range of biological effects beyond glucose homeostasis, the suppression of glucagon action remains an interesting approach to address the relative hyperglucagonemia of T2DM [41].

Insulin mimetic agents

Insulin resistance is a prominent feature of most forms of T2DM, typically reflecting the cumulative detrimental impact of multiple pathogenic factors that disrupt the signaling activity of insulin receptors and various intermediates along the post-receptor pathways. In most presentations of T2DM other than monogenic forms, the mix of pathogenic factors will vary in make-up and severity between individuals and, during disease progression, complicating the search for agents to override or circumvent the "pinch points" [42]. The binding of insulin to extracellular regions of its receptor involves distant sites on the α subunits of the receptor, which are difficult to replicate using a small molecule [43]. However, the conformational changes produced by insulin binding may be achieved in other ways, as indicated by a monoclonal antibody that interacts with the insulin receptor at different sites to insulin but creates a conformational adjustment to the receptor that initiates some of the metabolic effects of insulin and improves glucose homeostasis in insulin-resistant diabetic animals [44]. Recently, a fungal metabolite (chaetochromin A) has been shown to interact with the extracellular portion of the insulin receptor and initiate insulin action independently of insulin binding to the receptor [45]. The metabolite was also able to synergize insulin-induced phosphorylation of the insulin receptor and reduce blood glucose in diabetic animals. This raises the possibility that small molecules might be able to elicit conformational changes at extracellular sites of the receptor other than those bound by insulin and at least partially mimic the effects of insulin. It may also be possible to by-pass the extracellular part of the receptor. For example, another fungal metabolite (demethylasterriquinone) has been reported to interact with the cytosolic region of the β subunit of the insulin receptor, activate receptor signaling without insulin binding, and control the hyperglycemia of diabetic animals [46]. This provides a further proof of concept for developing orally active small molecules to replace insulin [47].

Insulin potentiating agents

Many studies have described agents that potentiate insulin action after insulin has initiated a conformational change to the receptor and enabled tyrosine phosphorylation of the β subunit. Phosphatase enzymes normally terminate receptor signaling through receptor tyrosine dephosphorylation, and agents that inhibit these phosphatases have received special attention [46–48]. Included here are inhibitors of protein tyrosine phosphatase 1B (PTP1B) and less specific phosphatase inhibitors, notably vanadium compounds (Figure 67.5). Although some of these agents have shown efficacy during initial clinical studies, off-target effects have so far precluded their development [48–50]. Several molecules have been reported to increase tyrosine phosphorylation of insulin receptors and insulin receptor substrate (IRS) proteins, but their mechanisms are unclear and they have not been developed as glucose-lowering agents, such as the antioxidant α-lipoic acid, which is used in some regions to treat diabetic neuropathy [11].

Another approach to extend the signaling time of activated insulin receptors and IRS proteins has been to interrupt the

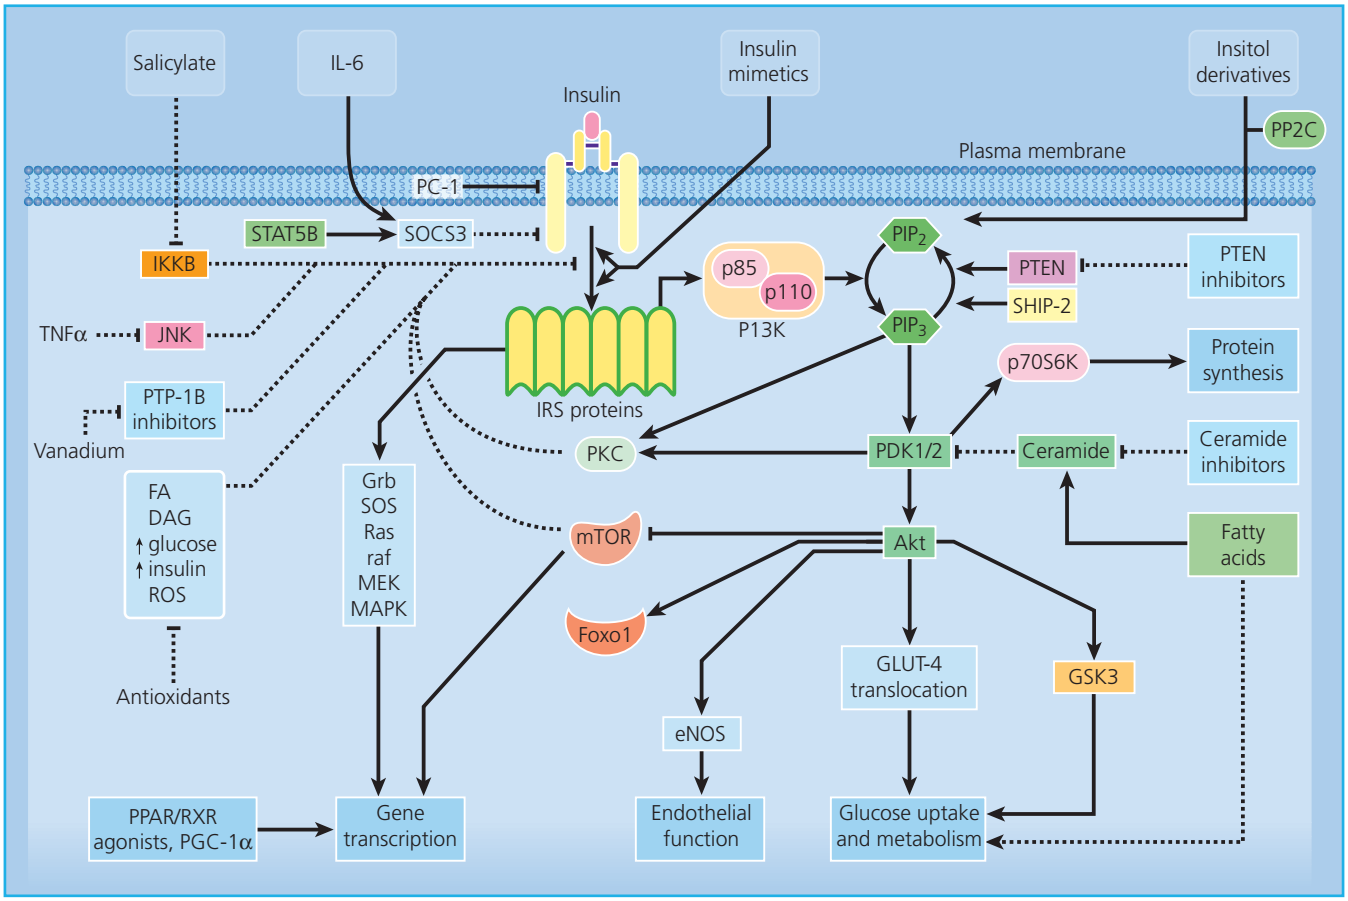

Figure 67.5 Pathways of intracellular insulin signaling illustrating potential sites for therapeutic intervention. Insulin binds to the α subunits of the extracellular region of the insulin receptor, producing a conformational change that extends to the intracellular regions and alters the conformation of the β subunits of the receptor. This allows the β subunits to be phosphorylated on tyrosine residues, which enables the β subunits to act as tyrosine kinase enzymes to phosphorylate a collection of insulin receptor substrate (IRS) proteins. The phosphorylated IRS proteins initiate signaling along the intracellular pathways that control the diverse biological effects of insulin. Many of the signaling steps are restricted ("pinch-points") by factors contributing to insulin resistance, and these steps are potential targets for therapeutic interventions. AKT, protein kinase B (PKB); AMPK, adenosine monophosphate-activated protein kinase; DAG, diacylglycerol; eNOS, endothelial nitric oxide synthase; FOXO1, forkhead box protein O1A; GLUT, glucose transporter isoform; Grb, growth factor receptor binding protein; GSK3, glycogen synthase kinase 3; IKKB, inhibitor κB kinase-β; IL6, interleukin 6; IRS, insulin receptor substrate; JNK, c-Jun N-terminal kinase; MAPK, mitogen-activated protein kinase; MEK, mitogen-activated protein kinase kinase; mTOR, mammalian target of rapamycin; PC-1/NNP1, glycoprotein 1; PDK, phosphoinositide-dependent protein kinase; PGC-1α, PPAR co-activator 1α; PI3K, phosphatidylinositol 3-kinase; PIP2, phosphatidylinositol-3,4-bisphosphate; PIP3, phosphatidylinositol-3,4,5-trisphosphate; PKC, protein kinase C; PPAR, peroxisome proliferator-activated receptor; PP2C, pyruvate dehydrogenase phosphatase (protein phosphatase 2C); PTEN, phosphatase and tensin homolog; PTP-1B, protein tyrosine phosphatase 1B; Raf, a serine-threonine protein kinase; Ras, a guanosine triphosphatase; ROS, reactive oxygen species; RXR, retinoid X receptor; SHIP-2, src homology-2-inositol phosphatase; SOCS-3, suppressor of cytokine signaling-3; SOS, sons of sevenless; STAT, signal transducer and activator of transcription; TNF-α, tumor necrosis factor α; ↑, increase.

negative feedback effects of more distal intermediates within the insulin action pathways. Certain isoforms of PKC mediate the negative effects of excess fatty acids, diacylglycerol, and products of glucotoxicity, in part by phosphorylation of the receptor and IRS proteins at serine or threonine sites [51]. Although some PKC inhibitors have increased insulin action and shown promise in the treatment of diabetic retinopathy and neuropathy, this approach has yet to prove sufficiently effective for the control of hyperglycemia in T2DM. Other signaling intermediates that inhibit the activity of insulin receptors or IRS proteins by serine phosphorylation have also been considered as potential therapeutic targets. These include inhibitor κB kinase-β (IKKβ) and c-Jun N-terminal kinase (JNK), which mediate the insulin resistance produced by certain cytokines such as tumor necrosis factor α (TNF-α), and the mammalian target of rapamycin (mTOR), which mediates a negative feedback from AKT (protein kinase B) [42]. Supplementing the availability of substrates for post-receptor steps is a further intervention to enhance insulin action, as illustrated by the administration of methylchiroinositol (pinitol), which facilitates signaling through phosphatidylinositol 3-kinase and has improved glycemic control in animal models of insulin resistance and insulin deficiency [11].

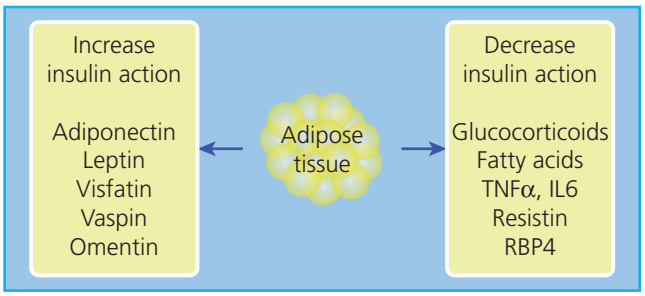

Figure 67.6 Proteins secreted from adipose tissue that can increase or decrease insulin action. These proteins or their receptors are potential targets or templates for therapeutic agents to improve glycemic control. IL6, interleukin-6; RBP4, retinol-binding protein-4; TNF-α, tumor necrosis factor α.

Adipokines

Several peptides and other substances produced by adipose tissue can affect the endocrine pancreas, insulin action, food intake, and/or energy expenditure, and some have been explored as potential therapeutic leads (Figure 67.6). For example, leptin exerts centrally mediated satiety and thermogenic effects, acts directly on tissues to improve insulin action and suppress glucagon, and facilitates weight loss. However, therapeutic doses of leptin and leptin analogs generate leptin resistance, which severely compromises long-term efficacy [52].

Adiponectin offers a range of potentially advantageous effects, including increased insulin sensitivity, improved endothelial function, and reduced inflammation, but the amounts of adiponectin released by adipose tissue are reduced in overweight and obese persons with T2DM. Supplementary adiponectin itself may not be a realistic intervention, but small-molecule agonists of the adiponectin receptors AdipoR1 and AdipoR2 could provide a suitable alternative, and initial preclinical studies have indicated that this approach can reduce insulin resistance and improve glycemic control [53, 54]. Several other adipocyte hormones have been implicated in the pathogenesis of T2DM, but their therapeutic potential remains to be determined [55–58]. For example, resistin and retinol-binding protein 4 reduce insulin sensitivity, whereas omentin and visfatin appear to improve insulin sensitivity. Many of the adipocyte peptides influence inflammatory processes, and the major proinflammatory adipokines, TNF-α, and interleukin-6 (IL-6) have been implicated in insulin resistance, but it is unclear whether these are appropriate targets for glucose-lowering purposes [59].

Fibroblast growth factors

Amongst the fibroblast growth factor (FGF) proteins, FGF21 and its analogs have been assessed as possible treatments in T2DM. FGF21 is secreted by the liver, adipose tissue, and muscle, and in preclinical studies it has improved insulin sensitivity and β-cell survival, in addition to promoting fatty acid oxidation and hepatic gluconeogenesis during fasting. However, T2DM in obese individuals appears to be associated with resistance to FGF21, and plasma concentrations of FGF21 are often raised. Nevertheless, clinical studies with FGF21 analogs have shown improvements in insulin sensitivity, glycemic control, and the blood lipid profile, and evidence is emerging that the metabolic effects of FGF21 are mediated at least in part through increased production of adiponectin [60, 61].

Peroxisome proliferator-activated receptor γ agonists

The insulin-sensitizing and other potentially beneficial metabolic effects of currently available thiazolidinediones (pioglitazone and rosiglitazone) are mostly mediated by activation of the nuclear transcription factor peroxisome proliferator-activated receptor γ (PPARγ). Other thiazolidinediones and non-thiazolidinedione PPARγ agonists have been developed, but unwanted side effects such as fluid retention, excess adiposity, and bone resorption have impinged [62]. Dual agonists of PPARγ and PPARα (known as glitazars) have also been developed to incorporate the lipid-lowering and anti-inflammatory effects of PPARα, but side effects have again precluded routine clinical use [62]. Additionally, triple PPARγ/α/δ agonists (pan-PPARs) have been studied in preclinical models to incorporate the increased energy expenditure and weight loss offered with PPARδ (Figure 67.7). However, based on structure–activity studies, it has become evident that alterations to PPAR agonist molecules can modify their receptor binding properties sufficiently to retain desired therapeutic effects and reduce side effects by altering the recruitment of coactivators and repressors [62]. This concept of selective PPAR modulators has given rise to agents in development with similar glucose-lowering efficacy but reduced side effects compared with current PPARγ agonists [63, 64].

Vitamins and minerals

Debate continues over the use of vitamins and mineral supplements as adjunct treatments in T2DM, and it is stressed that potential benefits of correcting deficiencies are very different to massive doses in individuals who already have adequate levels. Deficiencies in vitamin D are associated with insulin resistance and β-cell dysfunction and supplementation in deficient individuals has shown benefit. Low concentrations of antioxidant vitamins, notably vitamins C (ascorbic acid) and E (α-tocopherol) and β-carotene, are not uncommon in T2DM, but the value of supplements in improving glycemic control or reducing cardiovascular risk remains uncertain [11]. Thiamine (vitamin B_1) and biotin (vitamin H) have also been considered as possible supplements to improve glucose metabolism.

Reduced levels of magnesium, chromium, and zinc are frequently encountered in T2DM and supplements have been shown to improve glycemic control in deficient individuals [11]. Selenium, molybdenum, tungsten, mercury, and cadmium have also been reported to improve glucose metabolism in preclinical

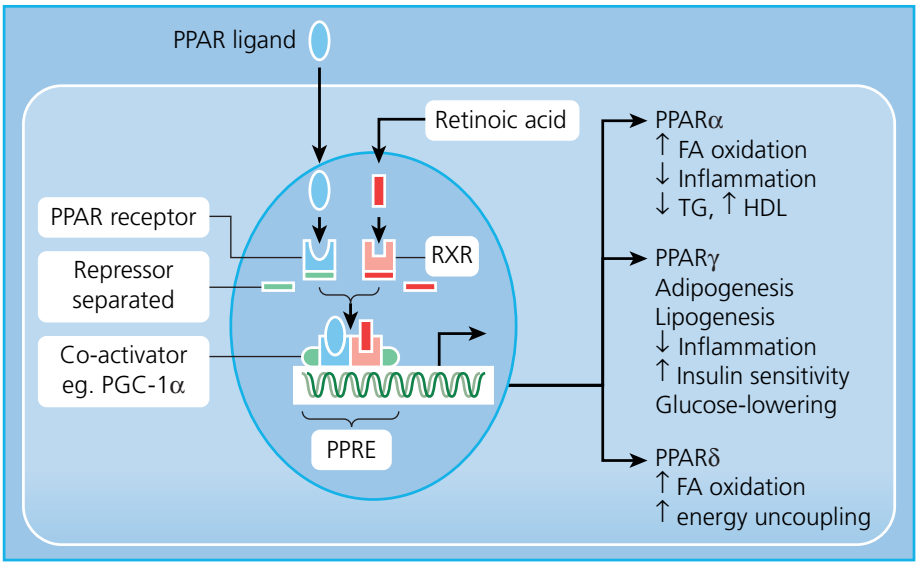

Figure 67.7 Cellular mechanism of action of a peroxisome proliferator-activated receptor (PPAR) ligand. The PPAR ligand binds to its nuclear PPAR receptor, which forms a heterodimer with the retinoid X receptor (RXR). Ligand binding releases repressors, attracts coactivators, and exposes the active site of the receptor which binds with its specific DNA nucleotide sequence—peroxisome proliferator response element (PPRE). RNA polymerase is recruited for transcription of mRNA from genes that carry the PPRE sequence in a promoter region. The mRNA is translated into the enzymes and transporters responsible for the biological effects. There are three types of the PPAR agonist: PPARγ, PPARα, and PPARδ. Each type of agonist offers a range of effects. PPARγ agonists enhance lipogenesis, adipogenesis, insulin sensitivity, and glucose lowering, PPARα agonists have lipid-lowering and anti-inflammatory effects, and PPARδ agonists promote energy expenditure. Selective structural modifications to agonist molecules provide an opportunity to retain and accentuate desired effects while reducing unwanted effects.

models, but the mechanisms are unclear, the therapeutic index is generally narrow, and toxicity risks are high. Lithium can improve insulin sensitivity, but may also decrease insulin secretion with unpredictable effects [11].

Hydroxysteroid dehydrogenase 1 inhibitors

Raised glucocorticoid concentrations can precipitate and aggravate truncal obesity, insulin resistance, and hyperglycemia, whereas interventions to reduce glucocorticoid action can prevent and reverse these effects. The enzyme 11β-hydroxysteroid dehydrogenase 1 converts cortisone to active cortisol mostly within liver and adipose tissue; hence in principle, agents that specifically inhibit this enzyme could reduce cortisol production within these tissues without substantially affecting circulating cortisol [65]. Trials with such inhibitors have shown improvements in insulin sensitivity, glycemic control, and the lipid profile of people with T2DM while enabling some weight loss, but reduction of circulating cortisol has also occurred, prompting a compensatory increase in ACTH [66, 67].

Sodium–glucose co-transporter inhibitors

SGLT activity plays an important role in the intake and elimination of glucose. Intestinal absorption of glucose is via SGLT-1 in the brush border of enterocytes, and glucose that is filtered in the kidney is reabsorbed mostly (~90%) via SGLT-2 in the initial part of the proximal tubules and the remainder by SGLT-1 in the more distal part of the proximal tubules (Figure 67.8). SGLT inhibitors in current clinical use (e.g. canagliflozin, dapagliflozin, and empagliflozin) predominantly inhibit SGLT2, lowering the renal threshold for glucose and eliminating excess glucose in the urine (glucosuria). This provides an insulin-independent mechanism to lower blood glucose and dispose of calories, thereby assisting weight loss [68]. The osmotic diuresis that accompanies the glucosuria may contribute at least in part to a lowering of blood pressure at the same time. Several additional SGLT-2 inhibitors are being developed, and there are also variants that exert a significant inhibitory effect against both SGLT2 and SGLT1 (e.g. sotagliflozin). The latter type of agent can defer glucose absorption more distally along the intestinal tract and slow the appearance of glucose in the portal circulation. However, the agent itself must either be fully absorbed, denatured along the intestinal tract, or dose adjusted to avoid unabsorbed glucose passing into the large bowel. If the passage of extra glucose along the proximal tubules leads to upregulation of SGLT-1, the inhibition of SGLT-1 may also increase glucosuric efficacy [69, 70].

Suppression of glucose production

Any intervention that suppresses hepatic gluconeogenesis and/or glycogenolysis should reduce blood glucose, but the effect must be partial and promptly reversed in hypoglycemia to avoid interference with counter-regulatory mechanisms [71]. Reducing the

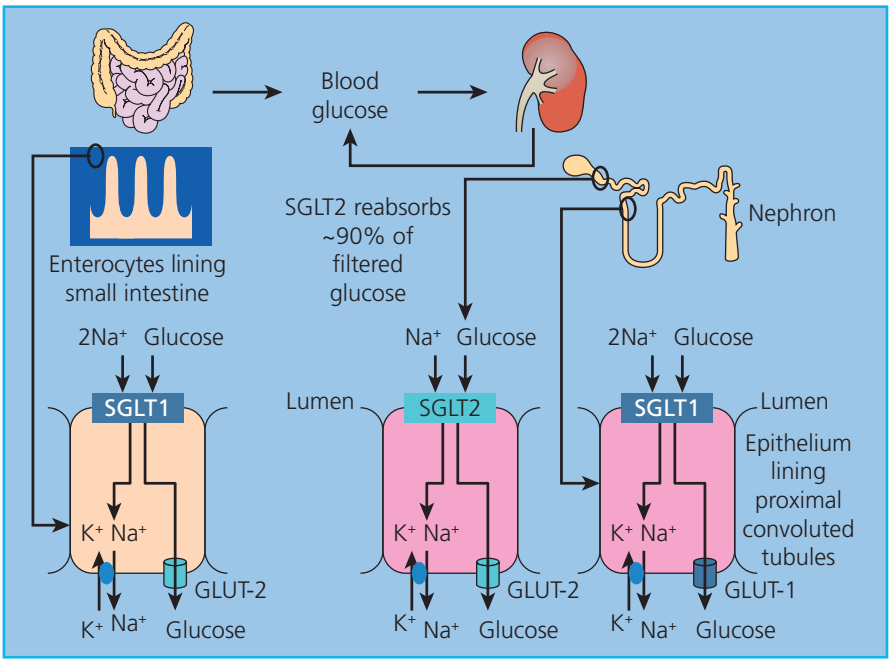

Figure 67.8 Sites of action of sodium–glucose co-transporters SGLT1 and SGLT2. SGLT1 is responsible for intestinal glucose absorption and SGLT2 is the main transporter responsible for glucose reabsorption from renal proximal convoluted tubules. SGLT1 also contributes to glucose reabsorption from the renal proximal convoluted tubules. GLUT, glucose transporter.

breakdown of glycogen stores by using inhibitors of glycogen phosphorylase has lowered blood glucose in preclinical studies. However, despite employing several different inhibitory mechanisms, clinical efficacy has been modest or not sustained. Glucose 6-phosphatase inhibitors prevent the last step in glucose output from both glycogenolysis and gluconeogenesis. Although such inhibitors can effectively lower blood glucose, their activity is not easily terminated and the risk of hypoglycemia is increased. Inhibitors of fructose 1,6-bisphosphatase prevent the dephosphorylation of fructose 1,6-bisphosphate to fructose 6-phosphate, which is the penultimate step in gluconeogenesis before glucose 6-phosphate. Studies with these inhibitors has indicated that it is possible to maintain a partial reduction of hepatic glucose output due to increased compensatory glycogenolysis, and clinical studies are ongoing [72].

Direct enhancers of glucose metabolism

Many substances are known to stimulate directly glucose uptake and utilization by muscle and adipose tissue, but few have been considered for a therapeutic application in T2DM as the magnitude of their effects is difficult to control and their side effect profiles are not suitable. Examples of agents with such effects are dichloroacetate, spermine, diamides, various peroxides, vitamin K_5, deoxyfrenolicin, okadaic acid, and several phorbol esters [11]. Inhibitors of glycogen synthase kinase have increased glycogenesis and lowered blood glucose in insulin-resistant diabetic animals, but potential adverse effects on the control of cellular division have deterred development for T2DM.

Agents that activate adenosine 5′-monophosphate-activated protein kinase (AMPK) have attracted interest as therapies for T2DM. AMPK is a key energy-regulating enzyme that appears to be one of several targets for metformin and probably PPARγ agonists and adiponectin receptor agonists. It is activated when cellular energy status declines and AMP concentrations rise, promoting the uptake and oxidation of glucose and fatty acids to restore ATP production. AMPK also reduces gluconeogenesis and lipogenesis, and may have a tumor suppressor effect [73]. Analogs of AMP such as AICAR (5-aminoimidazole-4-carboxamide-1β-D-ribofuranoside) have been shown to activate AMPK and improve glycemic control in animals with insulin-resistant diabetes. In addition, α-lipoic acid, various polyphenols, salicylates, and other small molecules have been identified as activators of AMPK [74].

Antiobesity agents

It is well recognized that the act of losing weight by reducing food intake or increasing energy dissipation, and also the longer-term achievement of reduced adiposity, improve insulin sensitivity and improve glycemic control in overweight and obese individuals with T2DM. Indeed, bariatric surgery has produced laudable results in this respect. However, there seems to have been a reluctance to approach glycemic control through pharmacological interventions primarily designed for weight loss. The intestinal lipase inhibitor orlistat is an established weight-reducing therapy, and the satiety-inducing agent phentermine is used in some regions. Several new satiety-inducing agents include a high-dose GLP-1 receptor agonist (liraglutide), a 5HT2c serotonin receptor agonist (lorcaserin), a phentermine–topiramate combination (Qsymia), and a bupropion–naltrexone combination (Contrave) [75–77]. Studies in obese individuals with T2DM indicate that these can improve glycemic control, often with results approaching comparability with some established glucose-lowering agents.

Although GLP-1 receptor agonists and SGLT-2 inhibitors already combine glucose-lowering and weight-reducing properties, it would highly advantageous if future attention could strongly target the coexisting problems of obesity and diabetes (diabesity).

Sirtuins

Sirtuins are nicotinamide adenine dinucleotide (NAD)-dependent histone deacetylases and adenosine diphosphate (ADP) ribosyltransferases that serve as epigenetic mediators. They alter histone structure and chromatin stability, enabling transcription of genes that increase mitochondrial biogenesis and energy expenditure, modulate insulin secretion and nutrient metabolism, mimic caloric restriction, and protect against weight gain, diabetes, and cardiovascular disease in animal models [78]. Several small-molecule sirtuin activators with initially encouraging effects in animal models of diabetes have been described, but these effects have not been consistently observed [79, 80].

Pharmacogenomics

Associations between gene variants and responses to glucose-lowering medications are under investigation to predict the efficacy, tolerability, and risk of adverse effects of a particular agent for the individual. Gene variants for transporter proteins that affect the absorption, cellular distribution, and elimination of drugs, and also variants encoding the enzymes involved in their metabolism, have been shown to influence responses to these drugs within the genetic constraints of the disease process itself [81, 82]. Pharmacogenomic testing for personalized medicine is in its infancy, but offers future opportunities to improve drug–patient compatibility and avoid ineffective or harmful interventions.

Using pharmacogenomics to design new drug therapies presents a particular challenge for the treatment of T2DM owing to the multivariable etiology and heterogeneous, progressive natural history of the disease [83, 84]. There is seldom a single rate-limiting protein that can be pharmacologically manipulated to reset normal glucose homeostasis, but studies are under way to map the diabetes proteome and identify prime contenders for future pharmacological intervention, especially to address the defects of β-cell function and survival as T2DM advances [85].

Safety

The long-term use of diabetes medications requires particular attention to long-term safety, and regulatory processes for the approval and subsequent surveillance of new glucose-lowering agents take thorough account of this requirement [86–88]. As noted at the start of this chapter, individuals with T2DM are prone to develop comorbidities that contraindicate some medicines, lead to drug interactions, or introduce other safety concerns. Some safety issues can take many years to emerge and necessitate revision to the label in accordance with the change in risk–benefit balance. If new medicines are to become available in a timely manner, such revisions will need to be accepted without prejudice as part of the lifespan of a medicine [89].

Conclusion

This chapter has considered glucose-lowering medications in development and potential novel therapeutic targets for T2DM. Novel insulin therapy and interventions specifically directed against type 1 diabetes are reviewed in Chapter 66. It is noted that T2DM involves such a variable mix of defects that effective management usually needs to exploit a selection of differently acting agents that can be used in combination as the disease progresses. For the future, attention to adiposity, hunger–satiety discord, energy expenditure, and inflammation may acquire greater precedence alongside more conventional approaches directed towards the secretion and actions of insulin, glucagon, and incretins. Futuristic mechanisms might incorporate very different forms of intervention such as antisense oligonucleotides and short interference RNA to modify the proteome, or pre- and probiotics to modify the microbiome. Cell-based therapies, especially glucose-sensing surrogate endocrine cells, could deliver more than insulin, and so-called "smart" drugs that are activated in accordance with the prevailing glucose concentration could obviate the problems of dose titration and hypoglycemia.

68 Stem Cell Therapy in Diabetes

Angelo Avogaro and Gian Paolo Fadini
Department of Medicine, University of Padova, Padova, Italy

Key points

- Stem cells divide asymmetrically to produce self-renewing cells and daughter cells that differentiate; they can also divide symmetrically to expand the stem cell pool.
- A β cell can be formed by an α cell following allocation towards the pancreatic lineage.
- A functional β cell can be reprogrammed from adult cell types through an inducible pluripotent stem cell (iPSC).
- Myocyte apoptosis in the normal human heart involves at least 1 in 100,000 cells at any time, which corresponds to a decrease of 2.2% of myocytes per year.
- Angiogenesis occurs as sprouting of small endothelial tubes from pre-existing capillary beds in response to local hypoxia whereas arteriogenesis is the transformation of pre-existing collateral arterioles into functional collateral arteries.

Why use stem cells in individuals with diabetes?

Major unmet clinical needs in diabetes care include the following: (1) to cure the disease by recreating physiological insulin secretion and normal blood glucose in order to avoid long-term complications; and (2) to reverse long-term complications in persons already suffering from these disabilities. The primary treatment for type 1 diabetes mellitus (T1DM) is daily intensive insulin therapy, and many individuals with type 2 diabetes mellitus (T2DM) will also require insulin therapy with time. Although multifactorial interventions have significantly decreased the incidence of complications, many people with diabetes die prematurely despite optimal medical therapy. For instance, revascularization procedures have improved in recent years, but diabetes is still an independent predictor of worse outcomes after an acute coronary syndrome. Interest in the therapeutic role of stem cells has progressively increased, especially for their potential ability to reconstruct blood vessel cells and to restore insulin secretion [1].

What is a stem cell?

Stem cells divide asymmetrically to produce self-renewing cells and daughter cells that differentiate; they can also divide symmetrically to expand the stem cell pool [2]. Stem cells usually reside in a particular environment called the niche, which controls stemness by providing short-range signals. In terms of the potential to differentiate, stem cells can be categorized into (1) totipotent, typically derived from the early embryo, which can form all tissues and organs of the body, including extraembryonic membranes (e.g. placenta); (2) pluripotent, which can form almost all tissue or cell types in the body; and (3) multipotent, which form a limited number of cellular phenotypes. Stem cell potency is recognized by typical surface or intracellular markers, and is regulated by the expression of pluripotency genes. Human embryonic stem cells (ESCs) show long-term self-renewal, while retaining a normal karyotype, and are pluripotent, as they can generate cells derived from all three germ layers. Adult stem cells can generate identical copies of themselves in a long-term self-renewal fashion; they are probably set aside during fetal development and restrained from differentiating. Before they achieve their fully differentiated state, stem cells generate intermediate cell types, called precursor or progenitor cells. Progenitor cells in fetal or adult tissues are unspecialized or partially specialized cells capable of generating specialized cells. Such cells are usually regarded as "committed" to differentiating along a particular cellular development pathway, although this characteristic may not be definitive. Mesenchymal stem cells (MSCs) give rise to bone, cartilage, muscle, tendon, and connective tissue cells. Hematopoietic stem cells (HSC) differentiate into oligo-lineage progenitor cells and gives rise to mature blood cells. Inducible pluripotent stem cells (iPSCs) are adult cells that have been reprogrammed to an embryonic stem cell-like state. Mouse iPSCs show characteristics of pluripotent stem cells, including stem cell markers, and forming tumors containing cells from all three germ layers. Several groups have shown that iPSCs can be generated from different cell types, although many obstacles remain to be resolved before being able to take full advantage of this technology in therapy [3].

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Stem cells for insulin replacement

A considerable number of protocols for efficient differentiation of stem cells into functional endocrine cells have been developed [4], but most have not been able to generate fully functional β cells [5]. Nonetheless, cells generated with these protocols secrete human C-peptide in response to glucose, and can rescue hyperglycemia in mice with streptozotocin-induced diabetes [6]. A new approach is to microencapsulate progenitor cells in an immunoisolation devise, where maturation to functional β cells would take place [7, 8]. Several studies have shown that ESCs can differentiate towards a β-cell-like phenotype (Figure 68.1). However, this approach has various limitations, such as inefficiency of differentiation, low insulin content, generation of insulin-producing neural cell lineages, and ethical concerns. D'Amour et al. developed a differentiation process that converts human ESCs into endocrine cells capable of synthesizing pancreatic hormones [9]. MSCs have also been used to generate insulin-producing cells [10], to enhance islet engraftment and survival, and to improve metabolic control in experimental diabetes [11].

Trials performed in T2DM suggest a positive impact of bone marrow–derived mononuclear cells on metabolic control in the absence of adverse events following intra-arterial injection by selective cannulation of the pancreatic vasculature [12]. Rezania et al. demonstrated that pancreatic progenitor cells can produce glucose-responsive, insulin-secreting cells and prevent or reverse diabetes in mice [13]. An alternative strategy is the reprogramming of terminally differentiated cell types into β cells. Zhou and Melton showed a direct conversion of mouse acinar cells to β cells *in vivo* via viral expression of given genes; these induced cells were able to improve glycemic control in mice with diabetes [14]. A further example of adult cell reprogramming to β cells has been described for adult mouse α cells. Following allocation towards the pancreatic lineage, the endocrine differentiation program is initiated through the expression of neurogenin3 (Ngn3), and $Ngn3^+$ cells can become α cells or bipotential β/δ precursors [15]. Combining several lineage-tracing approaches, it was demonstrated that pancreatic duct-lining precursor cells are continuously mobilized, re-express the developmental gene *Ngn3*, and successively adopt a glucagon-expressing and a β-like cell identity through mechanisms involving the reawakening of the epithelial-to-mesenchymal transition [16]. The restoration of insulin-producing cells from non-β-cell origins is enabled throughout life via spontaneous reprogramming of δ or α cells, suggesting a condition with multiple intra-islet cell interconversion events. A further approach to making functional β cells is to reprogram adult cell types towards β cells: any tissue could be reprogrammed to an inducible pluripotent state (iPSCs). Differentiation protocols can be applied to human iPSCs: cell lines derived from reprogrammed human fibroblasts have been successfully differentiated to insulin-producing cells *in vitro* [17, 18]. Maehr et al. have shown that fibroblasts obtained from skin biopsies from two people with T1DM were reprogrammed to pluripotency and differentiated to insulin-producing cells, although their functionality needs further validation [19]. In this context, Hua et al. generated iPSCs from people with maturity-onset diabetes of the young type 2 (MODY-2), which is characterized by heterozygous loss of function of the gene encoding glucokinase (GCK) [20]. These stem cells differentiated into β cells with an efficiency comparable to that of people without diabetes and expressed markers of mature β cells.

Healing the heart

During an acute myocardial infarction (MI), billions of cardiomyocytes are lost and, unfortunately, current therapies are unable to re-establish such loss. Aging also causes cardiomyocyte loss.

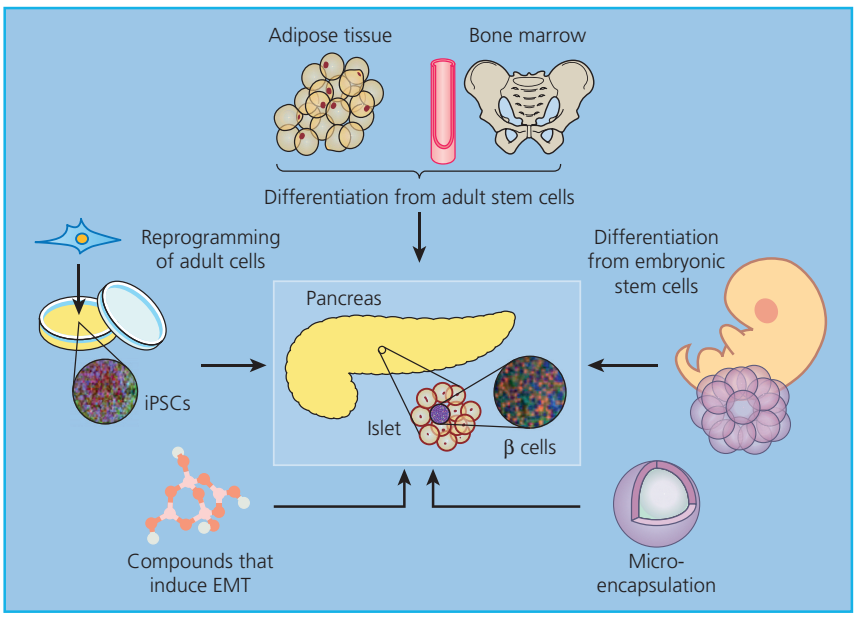

Figure 68.1 Approaches to creating insulin-producing cells. iPSCs, inducible pluripotent stem cells; EMT, endothelial-to-mesenchymal transition.

Myocyte apoptosis in the normal human heart involves at least 1 in 100,000 cells at any time, which corresponds to a decrease of 2.2% of myocytes per year.

The recognition that the adult heart harbors a compartment of multipotent c-kit$^+$ cardiac stem cells (CSCs) and other progenitor cells capable of differentiating into cardiomyocytes and coronary vessels has sparked interest in cardiac regeneration. CSCs are stored in interstitial structures with the characteristics of stem cell niches and can divide symmetrically or asymmetrically, with the ability to self-renew and form a committed progeny [21]. Recent results favor the hypothesis that cardiac development is controlled mainly by growth and differentiation of c-kit$^+$ CSCs [22]. However, the possibility that bone marrow-derived HSCs are involved in the restoration of damaged myocardium and contribute to the cardiac repair process cannot be excluded. Such cells may secrete a variety of cytokines that activate endogenous progenitors, which are actually responsible for the repair process and the restoration or preservation of ventricular function.

In 2001, Menasché et al. described the successful implantation of autologous skeletal myoblasts into the postinfarction scar of a patient with severe congestive heart failure who was undergoing coronary artery bypass surgery [23]. Five months after treatment, they concluded that treated hearts pumped blood more efficiently. Several phase I and phase II clinical trials have been conducted to test the hypothesis that cell therapy may represent a potential resource for treating heart failure. However, the mechanisms whereby stem cells promote cardiac repair remain controversial. Several cell phenotypes have been used to implement stem cell-based therapy to treat ischemic heart disease, namely unselected CD133$^+$ or CD34$^+$, circulating stem/progenitor cells, MSCs, adipose tissue-derived stem cells, resident cardiac/stem cells, and iPSCs. Intracoronary infusion of CD133$^+$ cells, an immature HSC phenotype, after recent MI was evaluated in a small, non-randomized clinical study that reported improved left ventricular ejection fraction (LVEF) with a concomitant reduction in myocardial perfusion defect after 4 months [24]. However, more coronary events, such as stent occlusion and in-stent restenosis, were observed after CD133$^+$ cell therapy. CD34$^+$ cells represent a subpopulation of cells with more endothelial-determined cells. In the randomized controlled REGENT trial, unselected and CD34$^+$CXCR4$^+$-selected bone marrow (BM) cells were administered to people with MI with reduced left ventricular (LV) function (LVEF 40%) [25]. After 6 months, the LVEF increased by 3% in individuals treated with unselected BM cells and 3% in those receiving CD34$^+$CXCR4^{+-}selected BM cells, and remained unchanged in the control group, but the differences in absolute changes of LVEF were not significant among the groups.

The intracoronary application of MSCs was assessed in two non-randomized early-phase studies by Chen et al. [26]. High-dose administration of BM-derived MSCs (6×10^{10}) resulted in a significant improvement in LVEF, whereas a lower dose (5×10^6) did not improve LV function in heart failure. Notably, MSC treatment resulted in an improved exercise capability and heart failure symptoms after 3 months. It has been proposed that expanded CSCs from self-adherent clusters, denoted cardiosphere-derived stem cells (CDCs), may represent a valid cell phenotype to rescue infarcted areas [27]. Preliminary results indicated that, in individuals with ischemic cardiomyopathy, the administration of CDCs decreased scar size, increased viable myocardium, and improved regional function of infarcted myocardium at 1 year post-treatment. In contrast to exogenous cell transfer, adult stem/progenitor cells can be mobilized from the bone marrow by systemic administration of selected cytokines (e.g. granulocyte colony-stimulating factor [G-CSF]) to augment their circulating levels in order to increase the possibility of ischemic tissue repair. However, in the MAGIC trial, G-CSF mobilization after MI was associated with a higher rate of in-stent restenosis at the culprit lesion. In a controlled, non-randomized study by Ince et al., G-CSF mobilization of CD34$^+$ BM cells shortly after angioplasty in MI improved LV function and metabolic activity and attenuated LV remodeling for up to 12 months without increasing the restenosis rate [28]. Similarly, Valgimigli et al. showed a fair safety profile for G-CSF in people with MI, although LV perfusion or function was unchanged 6 months after treatment [29]. G-CSF did not improve LV wall motion or perfusion over a period of 1 month in people with stable coronary artery disease. A meta-analysis of stem cell mobilization by G-CSF from 10 trials, including 445 participants with MI, indicated that cumulatively the data do not support efficacy of endogenous stem cell mobilization by G-CSF [30].

As an alternative to cell therapy, the use of drugs to modulate stem/progenitor cell availability and homing is being considered. Zaruba et al. proposed a combined strategy of G-CSF plus dipeptidyl peptidase 4 (DPP-4) inhibition to improve cardiac homing of mobilized stem/progenitor cells, which is currently under clinical investigation in the SITAGRAMI trial in people after MI [31]. This approach stems from the concept that inhibition of DPP-4, which cleaves the main stem cell-attracting chemokine, stromal-derived factor 1α (SDF-1α), will improve homing of mobilized stem/progenitor cells. Endogenous stem cell mobilization can be achieved also using the CXCR4 antagonist plerixafor. The cardiac stem/progenitor cell (CSPC) compartment is involved in the occurrence of diabetic cardiac dysfunction through activation of the cell death pathways and inhibition of cell replication [32]. Glucose-induced dysfunction of the pool of cardiac progenitor cells (CPCs) leads to insufficient replacement of old, dying cells, and the acquisition of the heart senescent phenotype. A protein that appears to be implicated in CPC poll damage is p66shc, an adaptor protein, which is linked to premature aging, oxidative stress, and apoptosis. Exposure of human CPCs to hydrogen peroxide results in increased caspase-3 cleavage and apoptosis, mediated by the activation of the c-jun N-terminal kinase (JNK) pathway [33]. Regarding cells bioenergetics, CSPCs exposed to a diabetic environment show remarkably reduced activity of key enzymes of the pentose phosphate pathway (glucose-6-phosphate dehydrogenase [G6PD] and transketolase), resulting in decreased antioxidant defense mechanisms and activation of apoptosis [34]. Inflammation has also been implicated [35].

Creating new vessels

Peripheral arterial disease is highly prevalent among persons with diabetes and is associated with significant morbidity and mortality. Peripheral arterial disease can lead to critical limb ischemia, resulting in major amputations and death. In people with peripheral vascular disease, both angiogenesis and arteriogenesis should represent compensatory mechanisms to increase vessel growth. Angiogenesis occurs as sprouting of small endothelial tubes from pre-existing capillary beds in response to local hypoxia; it is mainly mediated by vascular epithelial growth factor with no need for non-tissue resident cells. The resulting capillaries are small, and cannot compensate for the large occluded conduit artery. Arteriogenesis is the transformation of pre-existing collateral arterioles into functional collateral arteries; this implies an increase in diameter of existing arterial vessels capable of compensating for the loss of function of occluded arteries. Ischemia itself induces elevation of plasma stem and progenitor cell-activating cytokines, including sKitL (soluble Kit ligand) thrombopoietin, and G-CSF. Together with hypoxia, these in turn induce the release of SDF-1, thereby stimulating mobilization of proangiogenic cells that accelerate revascularization of the ischemic site. Traditional circulating endothelial progenitor cells (EPCs), as identified by Asahara et al. [36], were recently found to originate from the monocyte–macrophage lineage. Traditional cardiovascular risk factors have been associated with decreased circulating progenitor cell number and function. A number of studies have reported dysfunction of endogenous EPCs in the setting of hypertension, dyslipidemia, smoking, and diabetes. Reversal of these risk factors may overcome intrinsic deficiencies of autologous EPCs. Attention should be paid to the application of EPCs in advanced cardiovascular states, with special effort to optimize the metabolic and mechanical context of cell therapy. Standard treatment for severe cases of peripheral arterial disease is surgical or endovascular revascularization. Nonetheless, up to 30% of individuals are not candidates for such interventions, owing to the high operative risk or adverse vascular anatomy. BM-derived stem and progenitor cells have been identified as a potential new therapeutic option to induce angiogenesis. In humans, two different approaches have been proposed, based on (i) unselected autologous mononuclear BM-derived stem cells (BM-MNCs) directly sampled from BM, or (ii) autologous $CD34^+$ or $CD133^+$ BM-MNCs sampled from the peripheral circulation after G-CSF stimulation of the BM. Cells can be administered either intramuscularly, intra-arterially, or topically (Figure 68.2). The intramuscular approach is easily performed and allows a large amount of cells to be injected in the proximity of the ischemic area; theoretically, this approach may result in a cell depot, which would allow local paracrine activity.

The first clinical trial of stem cell therapy in peripheral arterial disease was the TACT (Therapeutic Angiogenesis using Cell Transplantation) study, with unselected BM-MNCs injected intramuscularly into the ischemic limbs of people with critical limb ischemia: it proved safe and able to improve rest pain, perfusion, oxygen pressure, and pain-free walking distance at 24 weeks' follow-up compared with placebo [37]. One clinical trial using

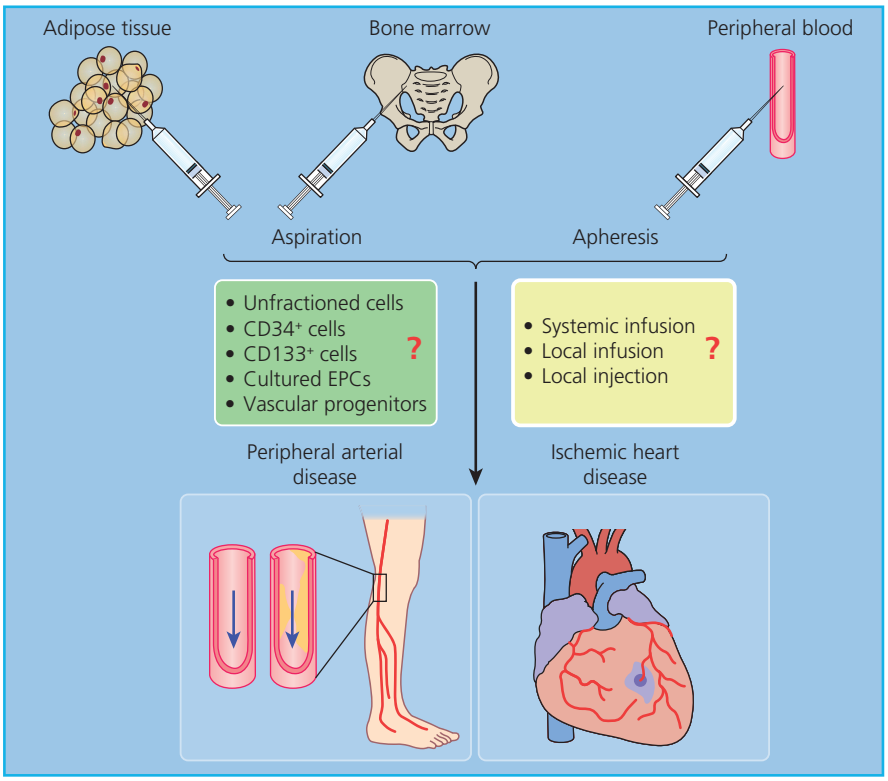

Figure 68.2 Technical approaches for the administration of stem cells to treat critical limb ischemia and heart failure.

unselected BM-MNCs delivered intra-arterially demonstrated a similar improvement in ankle brachial index (ABI) compared with previous trials of intramuscular BM-MNC administration [38]. Notably, an intra-arterial study in individuals with diabetes suggested much greater ABI improvements, and also improvements in wound healing and blood flow. The Intraarterial Progenitor Cell Transplantation of Bone Marrow Mononuclear Cells for Induction of Neovascularization in Patients with Peripheral Arterial Occlusive Disease study was a multicenter randomized trial of intra-arterial BM-MNC therapy in persons with critical limb ischemia [39]. The study reported improvements in wound healing and reductions in rest pain, despite no effect on ABI and limb salvage rates. Both intramuscular and intra-arterial injection of G-CSF-mobilized peripheral MNCs have been shown to result in a >0.1-point improvement in ABI and a twofold increase in maximum walking distance in small clinical series. A meta-analysis by Fadini et al. of 37 trials of cell therapy indicated that cell therapy is able to improve significantly ABI, total carbon dioxide (TCO_2), rest pain, pain-free walking distance, ulcer healing, and limb salvage [40]. In contrast, G-CSF monotherapy was not associated with significant improvements of these endpoints, albeit final conclusions should be deferred because the number of G-CSF testing trials was limited.

Conclusions

Important advances have been made recently in the field of stem cell biology and in the therapeutic application of stem cells in the treatment of diabetes and its complications. However, a tremendous amount of work still lies ahead in the endeavor to apply stem cell therapy to people with diabetes. Common to therapeutic strategies for the replacement of β cells, and for the rescue of blood vessels and myocardium, is the need for totally safe cellular approaches. This is particularly relevant to the deployment of the iPSC approach. However, considerable uncertainties still remain regarding which is the precise lineage to employ, and the proper conditions that need to be created to yield the optimal therapeutic approach. This is of importance for new vessel formation since, as described in detail by Fadini et al., the endothelial progenitor is a dynamic phenotype in space and time [41]. Furthermore, other phenomena such as the endothelial-to-hematopoietic or the epithelial-to-mesenchymal transitions should also be taken into account, underlying, needless to say, the major challenges that lie ahead before the definitive application of cellular treatment to persons with diabetes.

69 Islet Transplantation

Angela Koh, Peter E. Senior, and A.M. James Shapiro
Clinical Islet Transplant Program, University of Alberta, Edmonton Alberta, Canada

Key points

- Islet transplantation is a promising treatment for people with type 1 diabetes (T1DM) with severe hypoglycemia, hypoglycemia unawareness and/or glycemic lability.
- Successful islet transplantation can lead to insulin independence, but this is often not maintained in the long term.
- Graft function is preserved for several years beyond the loss of insulin independence, which results in a better glycemic control in spite of a return to insulin use.
- Current immunosuppression protocols include the use of more potent induction agents, which lead to better long-term outcomes, and improved safety and tolerability profiles.
- The side effects of maintenance immunosuppression are now clearly understood, and with appropriate dose titration, side effects are generally well tolerated.
- The long-term impact of islet transplantation on diabetes-related complications is incompletely elucidated, but there appears to be stabilization of microvascular and macrovascular disease.

Introduction

The discovery of insulin revolutionized outcomes for people with type 1 diabetes (T1DM), and the acute lethal complications of diabetes such as diabetic ketoacidosis were effectively treated. However, improved survival allowed development of secondary complications of diabetes [1]. Typically, the person with T1DM develops retinopathy, nephropathy, neuropathy, or vascular disease over time. It was not until 1993 that definitive proof for the value of good glycemic control was established. The landmark Diabetes Control and Complications Trial (DCCT) study showed that the microvascular complications of diabetes could be delayed or avoided by good glycemic control, which required intensive insulin therapy [2]. Such therapy was associated with an HbA_{1c} that was 1.9% lower than the control group. It should be noted that the HbA_{1c} was not normalized, but remained at least 1% above the upper limit of normal in the intensively treated group. Similar evidence was provided by the United Kingdom Prospective Diabetes Study (UKPDS) in type 2 diabetes (T2DM) with microvascular disease, showing significant improvement for a decline of 0.9% in the HbA_{1c} [3]. Thus, glycemic control is essential if the microvascular complications of diabetes are to be prevented.

Controlling glycemia with exogenous insulin remains a challenge. Given the non-physiological subcutaneous route of insulin administration, its inherent delay in absorption, the variability of serum levels obtained, and the systemic versus portal venous delivery, it is perhaps remarkable how well the glucose levels are actually controlled. The newer insulin analogs have removed some of the variability and delay in absorption but even with intensive therapy, it is difficult to achieve normoglycemia. Continuous subcutaneous insulin administration helps further but neither earlier nor more recent studies have managed to normalize glucose values [4, 5]. Carbohydrate counting and attention to diet aids the quest for normoglycemia but is not the complete solution. The largest study using all available tools to optimize therapy was still associated with an increased risk of hypoglycemia [2]. In the DCCT, the risk for severe hypoglycemia (defined as needing third-party assistance) was increased threefold. Concern about hypoglycemia remains the limiting factor in attempts to achieve optimal glycemic control.

Many efforts have been made to generate a closed-loop system for glucose control. The first successful efforts were with the Biostator®, which involved continuous monitoring of blood glucose and then an insulin infusion using a computer-derived algorithm [6]. Although effective for a short period, it was impractical being bulky and plagued with flow problems from the double lumen catheter used for sensing the glucose level. Insulin infusion pumps have helped (especially those using insulin analogs such as insulin lispro or aspart), but they are not closed-loop systems. Frequent glucose monitoring is required and this rarely results in normal glycemia without severe hypoglycemia. The goal of any closed-loop system is to have reliable glucose sensing linked to appropriate insulin delivery on a continuous basis. Considerable progress has been made recently with the so-called

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

"bionic pancreas" which is a wearable dual insulin and glucagon pump system. Russell and colleagues reported in 2014 that the bihormonal approach significantly improved glycemic control and protected against hypoglycemic episodes [7]. Furthermore, Ly and colleagues demonstrated that a glucose sensor-augmented insulin pump fitted with an automated low glucose suspend feature effectively reduced the incidence of severe and moderate hypoglycemic reactions [8].

Transplantation of islets of Langerhans or of the whole pancreas can achieve a biological-based and even more physiological closed-loop system, but requires life-long immunosuppression to achieve this. Choudhary et al. have recently discussed in detail the first-, second-, third-, and fourth-line current recommended options for people with T1DM with refractory glycemic control [9]. Islet or pancreas transplantation is reserved as a final step once structured education, continuous glucose monitoring, consideration of low-glucose suspend pumps, and other options have been explored and exhausted.

Background history

Transplantation of pancreatic tissue was first tried in 1890 when a surgeon in England transplanted fragments of a sheep's pancreas into a boy with diabetic ketoacidosis [10]. The immune barriers, unknown at the time, were insurmountable, especially for a xenograft. The modern era of transplantation began in the 1960s when the use of steroids, especially when combined with azathioprine, allowed successful renal transplantation [11]. The steroids block several cytokines and act as inhibitors of antigen presentation; azathioprine is an inhibitor of purine synthesis and thus impedes the generation of active T cells. Cyclosporin A, a calcineurin inhibitor, which is associated with an impaired transcription in active T cells and thus blocks interleukin 2 activation, greatly improved transplantation graft survival [8]. In 1972, Ballinger and Lacy demonstrated that chemical diabetes could be "cured" in mice with islet transplantation [12].

Many groups had been working on rodent and canine models to perfect islet isolation and maintain demonstrable β-cell insulin secretion [13, 14]. Experiments in rats and mice showed that success in transplantation of islets could be obtained in rodents and the transplanted islets had a biphasic insulin secretory response to glucose [15]. Islet allotransplantation in animals was also successfully performed [16, 17] and it has been possible to isolate human islets that would function in diabetic nude mice [18, 19]. The results of these studies highlighted the need for purified islets and the importance of the site of transplantation. Multicellular islet tissue comprises 1.5% by weight of the whole pancreas [20]. Careful digestion is necessary to achieve a purified preparation, and collagenase became the mainstay in the digestion [13]. Success with isolation from human pancreases was more problematic than in animal studies [21, 22]. Methods used for the dissociation of islets from the exocrine tissue required a combination of mechanical and enzymatic techniques.

The site of transplantation was also an issue. The pancreatic bed, because of the risk of inducing acute pancreatitis, was not a preferred option. Liver, spleen, renal subcapsule, and an omental pouch have been the primary locations tried [17, 23–25]. Work with immune privileged sites, such as the testes, has been ongoing but has not been routinely adapted [26]. A site with portal drainage has the natural advantage of mimicking the normal route of insulin delivery and is most commonly used for human islet transplantation [27]. The splenic site was associated with infarction [28] and so the liver, renal, and omental pouch have been the preferred areas for islet transplantation. All sites have disadvantages compared to the native islet bed in that oxygenation is lower [29] and the intra-islet blood pressure is elevated [30]. The vascularization of the liver gives it an advantage and may help in angiogenesis of the islets while an advantage of the omental pouch or renal site is the ability to remove the islets for histologic examination. When the liver is used, an unresolved question is whether the venous drainage of the islets is into the portal sinusoids or the systemic circulation. A possible drawback of the portal site is that it allows more exposure to high levels of immunosuppressive drugs and their potential toxicity as they are absorbed [31].

Early human studies

The first human islet transplants, were performed in the 1970s [32], with insulin independence rarely reported [33]. Up to 1998, approximately 260 people with T1DM had received an islet transplant, with only 12% remaining insulin-independent for more than 1 week [27]. The first two patients transplanted as part of an early cohort transplanted in Edmonton in 1989 [34] received approximately 260,000 islets at the same time as a renal transplantation. Exogenous insulin was used intravenously for 14 days with intensive glucose monitoring in order to maintain euglycemia, which may help preserve β-cell function [35]. The immunosuppression therapy included corticosteroids, azathioprine, cyclosporin A, and Minnesota antilymphocyte globulin. Both patients demonstrated positive C-peptide status posttransplant but both developed cytomegalovirus infection and lost islet mass, never having achieved insulin independence. The subsequent five patients had transplants using both fresh and cryopreserved islets so that the total islet mass given exceeded 10,000 islet equivalents/kg. One patient obtained insulin independence for 2 years [36]. One patient who was transplanted at this time had a liver transplant with partially purified islets infused. Complete portal vein thrombosis ensued necessitating an urgent repeat liver transplant [37]. One other patient attained insulin independence for a period but eventually all patients required insulin again. On long-term follow-up, two of these patients have continued C-peptide production, the longest being more than 9 years since her transplant. However, subsequent technical problems arose in Edmonton, particularly with the collagenase, and so purified islets could not be obtained and thus islet transplantation lapsed as an avenue for treating diabetes. Other major centers, particularly

Miami/Pittsburg, St. Louis, and Milan, also reported early success [38–41] and demonstrated that the transplanted cells may survive for a prolonged time [42, 43].

Pancreas transplantation

With improved immunosuppression the possibility of performing whole pancreas transplants, particularly at the time of renal transplantation, for end-stage diabetic nephropathy, became a possibility [44]. Initial efforts were associated with peritonitis from exocrine drainage of the pancreatic duct. These problems were surmounted by using bladder drainage [45] such that success rates reached over 80% for 1-year graft survival accompanied by low mortality rates [46–49]. With newer techniques of anastomosis connecting the transplanted duodenum to an enteric drainage site [50], fewer problems were encountered (especially with the acidosis secondary to bicarbonate loss in the urine associated with the bladder anastomosis [51]). More than 25,000 whole pancreas transplants have been carried out worldwide. The 1-year graft survival rate has improved due to reduction in technical and immunological failure rates [52]. However, the overall 10-year graft survival rate for deceased donor pancreas transplants has not substantially improved over time and was 48% for transplants between 1995–1999 [53]. Graft survival is better for simultaneous pancreas–kidney transplantation than for either pancreas transplant alone, or pancreas transplantation after kidney transplantation. The side effects are diminishing but it remains a technically challenging surgical procedure [54–56] with some morbidity and mortality. The excellent glycemic control [54] can lead to reversal of diabetic renal lesions [55], stabilization or improvement in neuropathy [57, 58], vascular status [59, 60], and stabilization but not necessarily improvement of retinopathy [61, 62].

Islet transplantation and the Edmonton Protocol in the year 2000

The unimpressive results of islet transplantation in the late 1990s, as illustrated by low rates of insulin independence [42, 63, 64], were related to the islet preparation (purity of preparations and adequate islet numbers) [65] and immunosuppression (potency and toxicity especially in terms of glucose tolerance) as has been reviewed by Hering and Ricordi [66]. The field of islet transplantation was rejuvenated with our report of seven consecutive cases who achieved insulin independence after islet transplantation, using a steroid-free immunosuppression regimen (Edmonton Protocol) [67]. Some of the factors associated with this success are discussed below.

Islet isolation

Islet mass availability remained a central issue for success. An adequate islet mass contributed to the success of the Edmonton Protocol, with >11,000 islet equivalents/kg recipient body weight being transplanted.

The normal pancreas has 1.0–1.7 million islets [68, 69] yet early studies showed only 250,000 islets being recovered for allotransplantation. Minimizing warm and cold ischemia time and other donor issues are important [70, 71]. The use of University of Wisconsin perfusate solution at the time of organ retrieval [72] enhanced the yield. In addition, the intraductal delivery of collagenase [21, 22, 73], particularly with improved collagenase preparations [74, 75], further enhanced the number of islets obtained. Great strides were made in characterizing the collagenase necessary for purified islet isolation, resulting in much better preparations. The enzyme preparation Liberase was widely used for islet isolation and is a blend of primarily collagenase type 1 and 2, but also has collagenase 3 and 4, clostripain, thermolysin, and proteases (trypsin, chymotrypsin, and elastase), and is associated with a low endotoxin load [75].

Another major advance was the development of a metal chamber by Ricordi et al. that allowed disassociation of islets with mechanical digestion and the continuous removal and harvesting of the liberated islets [76, 77]. Purification of islets using a refrigerated COBE centrifuge and Ficoll gradient is also important; while it leads to some loss of cells, it reduces the otherwise substantial risk of intraportal hypertension associated with the infusion of unpurified preparations [37, 78]. The increased purification may also have a negative effect in that ductal elements, which may be important as a source for islet neogenesis, are removed [79].

Short-term culture of the islets may lead to enhanced purity without excessive loss of islets. In addition, the newer methods of islet isolation have removed all xenoproteins from the process, and this could further reduce the risk of rejection.

Immunosuppression

The importance of the appropriate immunosuppression regimen is demonstrated by the fact that with autotransplantation once 2500 islet equivalents/kg are provided then insulin independence can usually be achieved, but three or four times this number of cells are required for insulin independence in the allotransplant environment [80]. In the Edmonton Protocol, daclizumab was used for induction, followed by maintenance immunosuppression therapy with sirolimus (target trough levels of 12–15 μg/L for first 3 months, then 10–12 μg/L) and low-dose tacrolimus (target trough levels of 3–6 μg/L) [67]. Such a combination allowed the omission of steroids from the regimen, which was a major advantage in the setting of borderline islet mass by reducing β-cell toxicity. Effective blockade of interleukin 2 with sirolimus, which inhibits T-cell expression and activation, and daclizumab, an antibody to interleukin 2 receptors, allows inhibition of T-cell activation and provides potent immunosuppression. Sirolimus can result in lipid abnormalities but was not known to affect glucose tolerance [81, 82]. Tacrolimus, a more potent calcineurin inhibitor than cyclosporin A, is associated with some diabetogenicity [12, 83–85] by inhibiting insulin release [86] in a dose-dependent manner [87], a problem shared by its predecessor cyclosporin A

[88, 89]. Hence, part of the rationale for using sirolimus as the mainstay of immunosuppression with low-dose tacrolimus was to reduce diabetogenicity of the maintenance immunosuppresion regimen.

Islet transplantation current state-of-the-art

Following this initial success, more than 1800 islet transplants have been performed worldwide using the Edmonton Protocol or variants of it, and incorporating newer advances. Indeed, islet transplantation today is quite different from 15 years ago.

Islet preparation

Pancreas preservation

The University of Wisconsin solution (UW) was effective in pancreas preservation, but prolonged storage before islet isolation led to reduced recovery of viable islets [90]. The two-layer system using perflurodecalin (PFC) and UW for whole pancreas preservation was thus advocated for rescuing ischemically damaged pancreases [88]. This was due to the ability to ensure adequate oxygenation to the pancreas during preservation, and the reduction of cold ischemic injury by promoting adenosine triphosphate production [91]. It was also found that preservation in PFC resulted in the upregulation of anti-apoptotic genes and the downregulation of pro-apoptotic genes [89].

Indeed, islet recovery from pancreases preserved with the two-layer system was double that of UW alone [91, 92]. Furthermore, PFC preservation resulted in an islet yield from pancreases procured from marginal donors that were sufficient for clinical transplantation in more cases than with UW alone [92]. However, more recently, it was shown that there was no significant difference in islet yield or transplantation outcome regardless of whether the two-layer method or UW alone was used [93]. We currently use histidine-tryptophan-ketoglutarate (HTK) solution alone for pancreas preservation, which appears to be equally effective as UW for islet isolation. However, outcomes in clinical pancreas transplantation have been reportedly inferior where HTK is used in place of UW solution.

Islet culture

Previously, islets were infused into recipients within 2 hours of isolation [67], to reduce the risk of ischemic injury to the islets. However, this gave little time for appropriate quality control measures to be completed and potential recipients had to live near the transplant center. Our current practice is to culture islets for up to 72 hours prior to transplantation. This has numerous advantages since the additional time when the islets are in culture allows for the administration of conditioning or other immunosuppressive therapies, can result in improved safety because transplants can be carried out when the entire transplant team is present, and allows for better islet characterization before transplant [94]. In addition, the decrease in total tissue volume with culture may reduce the risk of portal vein thrombosis. Furthermore, the use of regional islet processing centers has been advocated as a means of standardizing the islet product, and hence, improving transplant outcomes. Islet culture can result in better islet recovery after shipment [95], and islet culture has now become standard and routine practice at most islet transplant centers worldwide.

Enzyme preparation and digestion protocols

In 2007, it became apparent that the crude collagenase extract in Liberase, a secretion product of *Clostridium histolyticum* bacteria, could have been contaminated with bovine brain infusion extract, as this extract contains high levels of lipid, carbon and nitrogen, which apparently facilitates the proliferation and secretory capacity of the bacteria. The specific risk to an islet transplant recipient is the possibility of prion transmission from the cow brain extract through the enzyme and into the pancreas organ during digestion of the gland. The estimated risk is currently unknown, but a working number is currently less than one in ten million risk, in other words exceedingly remote. Since then, most islet isolation centers have switched to an alternative enzyme manufactured by Serva. This is a GMP grade enzyme where the potential risk of prion transmission should be dramatically lower as no bovine brain extracts are used in the manufacture process. Using HPLC and collagenase activity assay, we found that the Serva collagenase is less pure and less potent compared to Liberase. However, with modification of our digestion protocols, we have now managed to achieve a high rate of islet isolation success (defined as >300,000 islet equivalents (IEQs), >70% viability and <5 mL packed tissue volume) that is superior to historical outcomes from the Liberase era (unpublished data). Specifically, we use different digestion protocols for younger ($\leq$35 years old) versus older donors. For younger donors, we use collagenase and neutral protease simultaneously, while for older donors, a higher amount of collagenase initially, followed by sequential digestion with a lower amount of neutral protease was found to be optimal. Others have found islet isolation outcomes and islet function are similar with the two enzyme blends [96].

Transplant procedure

Once adequate pure islets are prepared, the patient is brought to radiology and percutaneous access is established under midazolam and fentanyl sedation. After infiltration of local anesthetic, a 22-gauge Cheba needle is advanced under fluoroscopic guidance into the portal vein. Others have used CT guidance or it is possible to gain access by the transjugular route or with laparoscopy [97]. A guidewire is then inserted into the main portal vein and a catheter is positioned with confirmation by portal venogram. Purified islets are then infused with frequent monitoring of portal pressure. If the portal pressure doubles or rises to greater than 22 mmHg, infusion is halted until it resolves and if it does not resolve, the infusion is discontinued. Initially we used a 60 mL syringe but quickly adopted the use of an intravenous bag that is prepared in the laboratory [98]. This aids aseptic technique and

may also pose less shear pressure on the islets and further provides some constant monitoring of portal pressure during islet infusion.

This percutaneous approach can result in the risk of bleeding from the liver, which was seen in the first report. Subsequently, gelfoam pledgets and coils were used to seal the catheter tract, and bleeding was not seen in the next 28 cases [99]. However, in 2003, there was a spate of post-procedural bleeding (defined as an acute fall in hemoglobin of 20%, associated with free fluid on ultrasound, the need for blood transfusion or surgical intervention for control of bleeding) [99, 100]. Since then, the portal tributary cannulation site has been plugged with coils, and the tract ablated using tissue glue (Tisseel) with no further recurrence of bleeds in the next 35 procedures [100]. Over the most recent 10 years, we have found that Avitene powder (1 gram) dissolved in 6 cc of solution made up of radiological contrast media and saline has been the most effective, reliable, simple, and practical sealant approach. The advantage of making this up in contrast media is that deployment can be readily visualized on fluoroscopy, and provides confidence that the entire tract has been ablated. When adequately deployed, this has eliminated bleeding risks and has the practical advantage of being clearly visible during deployment on fluoroscopy.

Before transplant, intravenous insulin and dextrose infusions are started to maintain euglycemia during transplant. Initially, insulin was discontinued after transplantation and was avoided unless hyperglycemia (serum glucose ≥11.1 mmol/L) occurred [67]. Subsequently, this threshold was lowered and insulin was given if pre-meal glucose was >6.0 mmol/L or 2-hour post-meal glucose was >8.0 mmol/L [99]. We previously showed that maintaining euglycemia in the immediate post-transplant period could contribute to better graft survival [101]. Since mid 2005, it has been our policy to maintain euglycemia (serum glucose 4.0–7.0 mmol/L) following transplant by using intravenous insulin (minimum of 1 unit/hour) with dextrose infusions for the first 48 hours, and then subcutaneous insulin thereafter.

Intravenous heparin is also infused to keep the prothombin time between 70–90 seconds for 48 hours after transplantation, to promote engraftment by reducing the immediate blood-mediated inflammatory reaction (IBMIR). Heparin is withheld if there is inadequate tract plugging with Avitene (<3 cm in length) until imaging confirms the absence of bleeding.

After the heparin infusion is discontinued, subcutaneous low molecular weight heparin (enoxaparin 30 mg twice daily) is administered for seven days and aspirin 81 mg daily for 14 days.

In addition, patients receive one tablet of sulfamethozazole 400 mg–trimethoprim 80 mg daily for 6 months; *Pneumocystis* pneumonia prophylaxis, and valganciclovir 900 mg daily for 14 weeks when there is Cytomegalovirus status mismatch between donor and recipient, and in those who have received lymphocyte-depleting induction agents.

Immunosuppression

The immunosuppressive regimen of the original Edmonton Protocol is still being used today, with some modifications. Daclizumab was initially given at a dose of 1 mg/kg every 2 weeks for five doses. After 2003, this was changed to a dose of 2 mg/kg at transplant and at 5 days post-transplant [99]. This was because the latter dosing regimen was found to be efficacious and was more convenient for patients.

Recently, induction with antithymocyte globulin (6 mg/kg) and etanercept, with maintenance immunosuppression with tacrolimus (target trough level 8–10 μg/L) and mycophenolate mofetil (1 g twice daily) is used [100]. Also, a lymphocyte depletion protocol consisting of alemtuzumab (Campath-1H), tacrolimus and mycophenolate mofetil is being evaluated. Preliminary data suggest that the use of these potent induction agents has improved short- to medium-term graft outcomes [101–103].

Many of the initial patients who were on sirolimus and tacrolimus for maintenance immunosuppression have had intolerable side effects that were attributed to sirolimus (see later), necessitating a switch of immunosuppression to tacrolimus and mycophenolate mofetil. This latter combination appears to be as efficacious and better tolerated [104]. Furthermore, sirolimus impairs β-cell regeneration, and could contribute to the observed gradual loss of graft function seen following islet transplantation [105]. Thus, the current combination of tacrolimus and mycophenolate mofetil is now our routine first-line maintenance immunsouppression choice for islet transplantation.

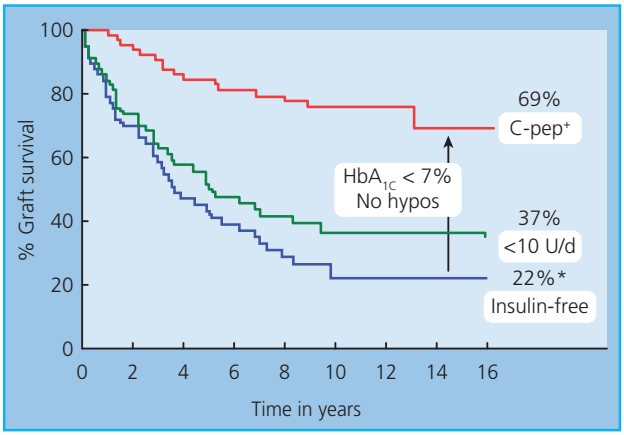
Islet transplantation outcomes

Glycemic control

Insulin independence was achieved in 11 out of the first 12 patients, after a minimum of 9000 IE/kg were transplanted [67]. HbA_{1c} levels improved in all islet recipients, and this was achieved without hypoglycemia and was accompanied by an improved stability of glucose control [67]. Unfortunately, insulin independence was not sustainable in the long term for the majority of patients. From survival analysis, only ~10% of patients remained off insulin at 5 years although most patients (~80%) still had C-peptide present [99] (Figure 69.1).

In terms of overall blood glucose control, those who remained off insulin did the best (median HbA_{1c} 6.2%), similar to the patients who were back on insulin but still had C-peptide (median HbA_{1c} 6.7%). Patients who had lost all graft function had relatively poor glucose control (median HbA_{1c} 9.0%), and required more insulin than before the transplant [96] (Figure 69.2).

The HYPO score and lability index were developed to measure the severity of hypoglycemia and glycemic lability. The HYPO score is generated using a combination of 4 weeks of self glucose monitoring results and self-reported hypoglycemic episodes over the previous year. For every episode of hypoglycemia <3 mmol/L in the 4 weeks, patients are instructed to record all symptoms felt and if assistance was required for recognition or treatment of the hypoglycemia. Higher scores were given for more severe hypoglycemic episodes (i.e. lower glucose values, absence of symptoms or neuroglycopenic symptoms, needing outside help



* Includes late retransplants

Figure 69.1 Kaplan-Meier graft survival curves over 16 years after islet transplantation. The blue line shows the overall proportion remaining completely free of insulin at 16 years, including those receiving late top-up transplant infusions (22% insulin free at 16 years). The green line shows similar survival curves for transplant recipients using less than 10 units of insulin per day, and continuing to enjoy substantial benefit from the islet procedure (37% at 16 years). The red line shows the proportion of individuals with measurable insulin release from their transplanted islets, as measured by human C-peptide release by 16 years (69% of transplant recipients). Importantly, the white box (HbA_{1C} < 7% and no hypos) shows the ongoing substantial benefit of even partially functioning islet transplants, where patients have markedly improved glucose control (HbA_{1C} < 7%) in a manner that cannot be achieved by exogenous insulin therapy, and protection from severe hypoglycemic reactions.

for recognition/treatment), while from the self-reported episodes in the past year, higher points were awarded if an ambulance was called or glucagon given. The lability index was also calculated from the 4 weeks of glucose records, using a formula that takes into the account the number of glucose readings, the glucose values, and the time interval between testing [106]. These scores are now routinely used in the assessment of suitability of a candidate for transplant, as well as for follow-up of transplant recipients. In addition, the Clarke score [107] is also frequently used, with a score of ≥4 indicating hypoglycemia unawareness.

Both the HYPO score and lability index show marked improvement post-transplant. With resumption of insulin use, there was more lability and some episodes of hypoglycemia, but both scores were still better than pre-transplant [99].

A key indication for islet transplantation is hypoglycemia unawareness. People who have received a pancreas transplant have restoration of their counter-regulatory response to hypoglycemia [108, 109]. The autonomic response and hence hypoglycemia awareness is also improved post pancreas transplant [110]. On the other hand, the same restoration in counter-regulatory responses and symptom recognition was not seen following successful islet transplantation [111]. Conversely, others have found that counter-regulatory hormonal and symptom responses to hypoglycemia do improve after islet transplantation [112–114]. The reasons for these differences are unclear, however, there may be a subset of patients who have return of hypoglycemia awareness, and/or the timing of testing could be critical. Indeed, we have noted that 85% of our cohort of islet transplant recipients reported return of symptoms of hypoglycemia, although 62% of them subsequently lost hypoglycemia awareness.

Diabetes complications

Retinopathy

Retinopathy has been reported to remain stable following islet transplantation [115, 116]. The majority of our patients (~80%) showed either no change or an improvement in retinopathy grade compared to baseline 3 years following islet transplantation. However, in our cohort, 18 of 98 (18.4%) islet transplant recipients had either vitreous hemorrhage or need for laser photocoagulation after islet transplantation, suggesting that close ophthalmologic follow-up remains necessary.

Nephropathy

We have previously reported that the estimated glomerular filtration rate (eGFR) (by MDRD study equation) declined with time. The median rate of eGFR decline was -0.39 mL/min/1.73 m^2/month with wide inter-patient variability [117]. This decline in GFR is comparable to that seen in optimally treated people with T1DM and albuminuria [118]. However, for one-third of the islet transplant recipients, the decline in eGFR exceeded that in untreated diabetic nephropathy [119]. In addition, on follow-up, progression in albuminuria was seen in 24% of patients, with regression only in 2.4% [117].

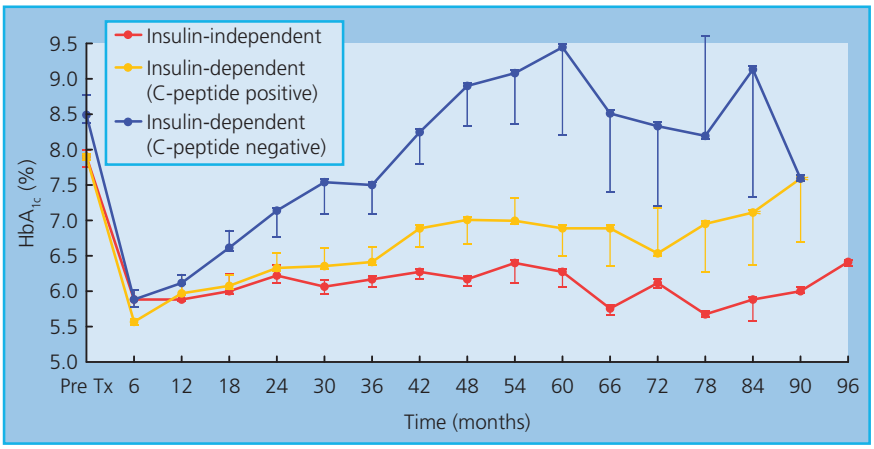


Figure 69.2 Glycemic control is related to islet graft function.

When tacrolimus and mycophenolate mofetil were used for maintenance immunosuppression, no difference in the rate of GFR decline was seen compared to either medically treated controls or the general population; nor was there any progression in albuminuria [120].

It is not clear at present whether the decline in renal function in islet alone transplants is due to progression of diabetic nephropathy or the effects of immunosuppression, in particular the combination of sirolimus and tacrolimus. Nevertheless, care should be taken during the patient selection process with regard to the assessment of renal function.

Neuropathy

There was no change in neuropathy status as assessed by vibration perception threshold or neuropathy disability score in our cohort [121], and others have shown stabilization of neuropathy [115].

Cardiovascular disease

A substantial proportion (30%) of islet transplant recipients at our center have pre-existing coronary artery disease prior to transplantation. In terms of cardiovascular risk factors, triglyceride levels increased (0.82 ± 0.04 mmol/L vs. 1.09 ± 0.06 mmol/L, $p < 0.001$, while there was a reduction in LDL-cholesterol levels (2.53 ± 0.06 mmol/L vs. 2.14 ± 0.06 mmol/L, $p < 0.001$) likely from an increase in statin use following transplantation. Blood pressure remained unchanged. Following islet transplantation, the rate of incident (new or worse) coronary artery disease was similar to the general T1DM population at 8.9 events/1000 patient-years [122].

Procedure-related complications

Complete portal vein thrombosis has not occurred with the use of purified islet allograft preparations, although partial thrombosis (of right or left branch, or peripheral segmental vein) was seen in about 5% of transplant recipients, all of whom were treated with anticoagulation without any long-term clinical sequelae [67, 99]. The risk of portal vein thrombosis has been minimized by: limiting the islet packed cell volume, careful monitoring of portal pressures during islet infusion, and intraportal dosing with heparin followed by systemic anticoagulation.

Other rare complications include gallbladder puncture and arteriovenous fistulae formation.

Liver enzymes (aspartate transaminase, alanine aminotransferase, and alkaline phosphatase) were elevated in >50% of transplants and are generally subclinical. These enzymes peak at around 1 week and normalize spontaneously within a month [123].

Changes consistent with fatty liver have also been observed on imaging post-transplantation [124]. These steatotic changes were confirmed with biopsy in some cases, and may be related to the high insulin levels the hepatocytes are exposed to following intrahepatic transplant [124]. It is unclear currently whether these changes would result in any long-term sequelae.

Side effects of immunosuppression

Most transplant recipients would have some side effects from immunosuppresion, but it is highly variable between patients.

Mouth ulcers previously occured frequently, but was entirely associated with use of sirolimus. These are usually small and self-limiting. Most respond to topical therapy, dose reduction, and switching to the tablet formulation of sirolimus [96]. Elimination of routine use of sirolimus has entirely resolved this problem.

Gastrointestinal disturbances, either constipation or diarrhea, are also common, occurring in 60% of islet transplant recipients, while acne was noted in 52%. Peripheral edema was reported by 43% of patients [100]. Peripheral edema was also closely linked to the high-dose use of sirolimus, and has similarly been largely eliminated through current use of tacrolimus and mycophenolate mofetil.

Ovarian cysts following transplant were previously commonly encountered [99]. It was also found in another small study that among women, ovarian cysts occurred in 62% of islet transplant recipients, and menstrual irregularity developed in all the six women who had regular menstrual cycles before transplant [125]. At our center, new ovarian cysts were found in 33 of 57 (57.9%) women after islet transplantation. Most cysts were asymptomatic but 14 women reported pelvic pain. Sirolimus withdrawal was associated with a reduction in cyst size and resolution of cysts in 80% of women. Also, the use of combined oral contraception appeared to be protective against ovarian cyst development [126]. Again, elimination of sirolimus from the routine regimen has largely resolved this issue.

Other complications related to immunosuppressive therapy include anemia, leukopenia, hypertension, dyslipidemia, weight loss, and fatigue [100].

Tacrolimus was associated in a dose-dependent manner with tremor and nephrotoxicity. The combination of sirolimus and tacrolimus could also worsen renal function. Indeed, two individuals in whom tacrolimus was switched to mycophenolate mofetil (MMF) had stabilization of renal impairment [127]. Also, three patients had resolution of proteinuria after sirolimus was withdrawn and replaced by a combination of cellcept and higher dose tacrolimus [128].

Mycophenolate mofetil is generally well tolerated, with the most commonly reported side effect being gastrointestinal in nature (bloating, diarrhea, abdominal cramps), which usually subside with dose reduction [129].

Pneumonia occurred in 3 patients, of which one was considered fungal in etiology [98].

Cytomegaloviral disease has not occurred, although seroconversion from negative to positive has occurred in 4 of 67 (6%) islet transplant recipients. To date, we have encountered a single incidence of post-transplant lymphoproliferative disorder in now 252 patients treated (risk 0.39%), a risk which is lower than that encountered in other solid organ transplantation.

With experience, we have learned to tailor the immunosuppression regimen and target drug levels to minimize side effects without compromising graft function, such that fewer complications are seen in those transplanted more recently as compared to earlier patients.

Thirty-four patients had undergone immunosuppression change from sirolimus+tacrolimus to tacrolimus+mycophenolate mofetil following islet transplantation. The three most frequent reasons for this change were: peripheral edema (18/34, 53%), gastrointestinal symptoms (11/34, 32%), and ovarian cysts in women (9/26, 35%). These all improved after the immunosuppression change. Importantly, there was no change in graft function or immune status following the change [104].

Immune sensitization

The percentage of panel reactive antibodies (PRA) increased in 13% of patients from levels <15% to ≥15% after transplant [99]. Recently, it has become clear to us that positive PRA does negatively impact islet transplant outcome. Indeed, pre-transplant PRA of >15% in either class I or II is an independent predictor of poor graft survival (in terms of C-peptide) after transplant [130].

For individuals with high PRA, it will be important to determine the specific antibodies causing the positive PRA and a flow cytometry-based crossmatch performed against potential donors before transplant. Our current policy is to perform prospective crossmatches for all recipients with PRA >5% and for those who have received previous transplants.

It has become apparent that high rates of broad PRA sensitization were observed in patients when immunosuppression was slowly and completely withdrawn following complete graft loss [131]. Our current approach is therefore not to withdraw all immunosuppression when a patient loses all islet function, but rather to wean down to single-agent therapy with mycophenolate (Myfortic therapy). We currently plan to continue this for at least 2 years after function is lost in order to reduce the risk of subsequent sensitization. The effectiveness of this strategy is still to be evaluated.

Indications and contraindications for islet transplantation

At our center, islet transplantation is offered to people with T1DM who have severe hypoglycemia and/or hypoglycemia unawareness, or glycemic lability, in spite of optimal medical therapy with frequent blood glucose monitoring and the use of multiple daily insulin injections or continuous subcutaneous insulin infusion. This is largely still based on clinical judgment, although the use of the HYPO score and lability index adds an objective component to the decision. Some individuals have progressive complications despite optimization of medical therapy. Although we originally considered this group, they are now the exception, as we are concerned about the potential for immunosuppression to exacerbate renal impairment.

Diabetes-related complications are not absolute contraindications for islet transplantation. For people with unstable retinopathy, we recommend waiting for 6 months from the last treatment for the disease to stabilize before islet transplantation since there is a risk of worsening following transplantation. The sirolimus and tacrolimus combination is avoided in individuals with macroalbuminuria (>300 mg/day). We prefer not to transplant people with mild to moderate reduction in GFR (<60 mL/min/1.73 m^2). We also recommend waiting for at least 6 months following myocardial infarct, revascularization procedure, or evidence of ischemia on functional cardiac testing. A severely reduced left ventricular ejection fraction <30% is a contraindication for islet transplantation.

The current accepted indications and contraindications for islet transplantation in most centers are listed in Table 69.1.

Patient evaluation

At the assessment visit for islet transplantation the person with diabetes should have a realistic expectation of the outcome. If they have frequent hypoglycemia and glycemic lability problems, then both of these are readily correctable by islet transplantation. The ability to render the person free of the risk of progression of diabetes complications is unproven at this time, although given good glycemic control this may be expected in the longer term. Those who have active infection, a history of cancer, severe vascular disease, or active foot ulceration, who abuse alcohol or drugs, or who are younger than 18 or older than 65 years are not usually considered. Once the individual meets the entry criteria and is willing to accept the risks of the procedure and immunosuppression, a full evaluation is required. This includes a thorough history and physical examination, the latter concentrating on diabetes complications: retinopathy, neuropathy (autonomic and peripheral), and vascular disease. Our laboratory evaluation includes details of these complications with an ophthalmology report required, 24-hour urine for microalbuminuria, protein, and creatinine clearance; together with a serum creatinine, ECG, stress MIBI scan, and a lipid panel. If there is any suggestion of an abnormality either clinically or on vascular testing, coronary angiogram is performed. In addition, the basic transplant screens are required, including blood group, complete blood count, coagulation screen, liver function tests, electrolytes, calcium, magnesium, phosphorus, analysis for HIV, hepatitis, Epstein-Barr virus, syphilis, cytomegalovirus, and urine culture. An ultrasound of the abdomen and liver is required to ensure that no lesions are present in the liver. A hemangioma on the right side of the liver would place a patient at increased risk of bleeding during the procedure if a percutaneous approach was used. In people older than 40 years, mammograms are performed in women and prostate-specific antigen determinations in men. Considerable time is spent reviewing the potential complications with the patients so that each individual can make a personal assessment of the risk–benefit ratio for themselves and decide if they wish to proceed. In most other transplant settings (heart and liver), the issues are life and death but in islet transplantation this is not the case, as continuing to work with other insulin regimens is possible and thus risk–benefit issues are different.

Table 69.1 Indications and contra-indications for islet transplantation.

A. Indications for islet transplantation

Clinical history compatible with T1DM, with stimulated C-peptide <0.3 μg/L on mixed meal tolerance test.

Intensive diabetes management

- Glucose testing ≥3 times/day
- ≥3 insulin injections/day or insulin pump as directed by endocrinologist, diabetologist or diabetes specialist with ≥3 clinical evaluations during the past year.

≥1 severe hypoglycemic event, defined as an event with one of the following symptoms: memory loss; confusion; uncontrollable behavior; irrational behavior; unusual difficulty in awakening; suspected seizure; seizure; loss of consciousness; or visual symptoms, in which the person was unable to treat him/herself and with blood glucose <54 mg/dL (3 mmol/L) or prompt recovery after oral carbohydrate, intravenous glucose or glucagon in the past 1 year.

One of the following:

- Reduced hypoglycemia awareness (Clarke score ≥4 or HYPO score ≥90th percentile or ≥1047) within last 6 months
- Marked glycemic lability with wide swings in glucose levels despite optimal therapy, with glycemic lability index ≥90th percentile or 433 within last 6 months
- Composite Clarke score ≥4 + HYPO score ≥75th percentile (≥423) + lability index ≥75th percentile (≥329)

B. Contraindications for islet transplantation

Glycated hemoglobin ≥10%

Untreated proliferative retinopathy

Blood pressure >160/100 mmHg

Glomerular filtration rate <80 mL/min/1.73 m^2

Presence or history of macroalbuminuria >300 mg/day

Presence or history of panel reactive anti-HLA antibodies (by flow cytometry)

Active infections, including:

- Hepatitis B, hepatitis C or HIV
- Tuberculosis requiring treatment within the previous 3 years
- Invasive aspergillus, histoplasmosis, or coccidiomycosis within 1 year

Severe cardiac disease

- Myocardial infarct within 6 months
- Evidence of ischemia on functional cardiac testing within 1 year
- Left ventricular ejection fraction <30%

Any history of malignancy except for completely resected squamous or basal cell carcinoma of the skin.

Receiving treatment for a medical condition requiring chronic use of systemic steroids except for the use of ≤5 mg prednisolone daily or equivalent.

Any medical condition that could interfere with safe participation in islet transplantation.

Desired pregnancy (female recipient)

Challenges and future directions

Islet shortage

The shortage of donor pancreases for islet transplantation remains a challenge. Most recipients require more than one islet infusion to become insulin-independent. Given the limited supply of organs, the ability to achieve insulin independence after infusion of islets from a single donor is an important goal which has been achieved by Hering et al. in carefully selected recipients given excellent islet preparations, intensive peritransplant management, and alternative induction immunosuppression [101]. Other alternative sources of islets include xenografts (e.g. porcine islets) or stem cells, but these remain in the pre-clinical experimental phase at present [132–134].

Islet engraftment

Defects in insulin secretion soon after transplantation of what should be an adequate islet mass indicates that many islets were lost at the time of engraftment. This could be due to hypoxia early post transplant [135], the toxic effects of the immunosuppressive drugs [136], and the IBMIR which results in immune destruction of islets [137]. It has been estimated that only a third of islets engraft successfully [138].

Various strategies are being tested in attempts to improve engraftment, including the use of vascular growth factors to promote re-vascularization [139], inhibitors of IBMIR [140], and anti-apoptotic peptides (e.g. caspase inhibitors) [141]. The use of low molecular weight dextran sulphate was found to block IBMIR to a greater extent than heparin, possibly by its more potent inhibition of the complement system [142]. The use of islet surface heparinization was also shown to significantly attenuate IBMIR *in vitro* and *in vivo*, without systemic side effects [143].

Monitoring the islet graft

A key barrier to understanding what happens to the islet graft after transplantation is the lack of access to the graft. Current methods of monitoring graft function are based on the measurement of markers of glucose homeostasis, which may not be disrupted in early stages of rejection [144]. Immunological monitoring is limited by the lack of standardized markers for autoimmunity and rejection [145]. Unlike other solid organ transplants, serial protocol liver biopsies may not yield sufficient islet tissue for examination. Several approaches for β-cell imaging have been proposed, but are still in various stages of development [146]. Clearly, it is of vital importance to develop methods to detect graft dysfunction in its early stages or even before it happens, so as to allow intervention in an attempt to rescue the graft.

Promoting graft survival

Islet graft function appears to decline over time, with most islet transplant recipients returning to insulin use. The glucagon-like peptide 1 (GLP-1) receptor agonist, exenatide, when used in islet transplant recipients with failing islet graft function resulted in reduction in insulin requirements, but this could not be sustained when the drug was discontinued, suggesting that there was no trophic effect on β-cell mass [147]. The lack of detectable changes in markers of allo- or auto-immunity in the majority of islet transplant recipients, together with the absence of significant inflammatory infiltrate in histological specimens of islet transplants suggest that non-immunological mechanisms

play an important role in the gradual graft loss [99, 148]. Possible culprits include increased metabolic demand and toxicity of immunosuppressants, and certainly warrant further investigation.

Immunosuppression toxicity

While newer immunosuppressant drug combinations are associated with less toxicity, the ideal situation would be the ability to withdraw immunosuppressive drugs after an initial period of use post transplant. To achieve this, tolerance to the graft must be induced. Co-stimulation blockade has shown promise for tolerance induction. There have been encouraging results with belatacept (LEA29Y), a potent new CTLA4-Ig, in primate models of islet transplants [149], and clinical trials in human are in progress. Indeed, the use of belatacept for ongoing maintenance immunosuppression, thus allowing the avoidance of calcineurin inhibitors, has been used successfully in the renal transplantation setting and may be the basis for future maintenance therapy [150].

Another strategy would be islet encapsulation, but this has been associated with limited success to date [151].

Summary and conclusions

Islet transplantation can correct problems with glycemic lability and recurrent hypoglycemia. Given its technical ease, it is particularly suitable for those with problems with glycemic control and no other major complications. The more technically difficult whole pancreas transplant provides stable glucose control and is ideal in those undergoing simultaneous renal transplant. The islet transplant procedure has some risks both acutely (particularly bleeding, and thrombosis in the portal vein circulation) and in the long term, the unknown but real risk of sepsis and neoplasms. For some people with major problems with diabetes control these risks are acceptable. Whether the good glycemic control attained will prevent complications in the long term will take years to resolve. Using the indication of progressive diabetes complications is less suitable at this time, given the problems encountered. Islet transplantation can free an individual with very difficult diabetes from the risks of frequent hypoglycemia or glycemic lability. The decision whether to proceed can only be made by an informed patient who has to cope with difficult diabetes on a daily basis.

Major steps have been taken in islet transplantation but more needs to be done. Significant changes over the past 10 years have resulted in improved outcomes, but many challenges remain. Islet transplantation has faced hurdles before and overcome them. These new challenges can be met and solved. To quote Sir Winston Churchill, "Now this is not the end. It is not even the beginning of the end. But it is, perhaps, the end of the beginning."

70 Gene Therapy for Diabetes

Virginia Haurigot, Veronica Jimenez, and Fatima Bosch

Center of Animal Biotechnology and Gene Therapy and Department of Biochemistry and Molecular Biology, School of Veterinary Medicine, Universitat Autònoma de Barcelona, Bellaterra; and Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Spain

Key points

- The term "gene therapy" defines any therapeutic strategy based on the genetic modification of a cell by introduction of exogenous genetic material in order to prevent, correct or ameliorate the symptoms of a disease.
- The selection of a gene transfer vector over another depends on the indication, the target tissue in case of *in vivo* gene therapy and the period of time during which the expression of the transferred genetic material is required.
- The use of gene transfer technologies has allowed the development of potential therapeutic strategies for the treatment of type 1 (T1DM) and 2 diabetes (T2DM), as well as the performance of proof-of-concept studies in small and large animal models to understand the pathophysiology of these diseases better.
- For T1DM, most gene therapy strategies have focused on restoring insulin production by islets or surrogate cells, enhancing glucose disposal or preventing the destruction of remaining β cells.
- For T2DM, attempts have been directed towards ameliorating insulin resistance in peripheral tissues, enhancing insulin production or increasing the functionality and/or mass of β cells.
- Extensive studies are required to demonstrate the efficacy and safety in large animal models of the approaches that have shown therapeutic potential in small diabetic animals before any of these gene therapies are brought to the clinic to treat diabetes in humans.

Introduction to gene therapy

Gene therapy is a therapeutic strategy based on the genetic modification of a cell by introduction of exogenous genetic material in order to prevent, correct, or ameliorate the symptoms of a disease. Originally, gene therapy was conceived to supplement or replace the function of a defective gene by delivering to the target cell a functional copy that could mediate the production of the desired therapeutic protein. Progress in the field has led to the broadening of gene therapy applications, and nowadays the introduction of genetic material to a cell is not only limited to gene addition but also includes induction, repression, and modulation of gene expression at transcriptional and post-transcriptional level and, more recently, genome editing. To these ends, full-length genes, cDNAs and a variety of modulatory and interfering RNA and DNA molecules, including antisense RNA, short-hairpin RNA (shRNA), microRNA (miRNA) and microRNA target sequences (miRT), have been used. Furthermore, the vast range of technologies that the field has set up over the years for therapeutic purposes are also being exploited in proof-of-concept studies to demonstrate gene function.

On the basis of the strategy used, gene therapy can be classified into the following two subtypes: *ex vivo* gene therapy, in which target cells are genetically modified *in vitro* before transplantation into the patient, and *in vivo* gene transfer, in which cells are genetically modified *in situ* in the individual [1].

The success of gene therapy depends on the existence of gene transfer vehicles capable of safely and efficiently introducing genetic material into target cells either *ex vivo* or *in vivo*. In order to achieve this goal, a wide variety of vectors has been developed over the past few years; these are generally divided in two categories: non-viral and viral vectors. Delivery systems based on non-viral vectors include both the direct administration of naked nucleic acids and the use of physico-chemical means to ferry the genetic material into the target cell, such as electrotransfer or incorporation of nucleic acids into liposomes or cationic polymers. On the other hand, the use of viral vectors exploits the natural ability of viruses to enter cells, transfer their genetic material to the nucleus and express proteins. So far the vast majority

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

of gene therapy strategies developed for the treatment of diabetes have been based on the use of viral vectors as gene transfer vehicles.

Viral vectors

Several naturally occurring viruses have been subjected to numerous genetic modifications to allow their use as safe gene transfer vehicles. For example, viral vectors cannot develop a productive infection after delivery to cells or animals due to the genetic deletion of genes essential for the life cycle of the wild-type virus. Therefore, recombinant viral particles contain a genetically modified viral genome that may be partially or completely devoid of viral genes and is unable to generate new virions upon infection. They retain, however, the infectivity of the wild-type virus and its ability to mediate introduction of the genetic material into the cell nucleus (a process known as transduction) because these functions are conferred by the capsid itself [2].

The selection of one vector over another depends on the gene transfer application, the target tissue in case of *in vivo* gene therapy and the period of time during which the expression of the transferred genetic material is required. For example, for proof-of-concept studies or if short-term expression is sufficient, adenoviral vectors (AdV) show great efficiency of transduction *in vitro* and *in vivo*. However, the immunogenicity of these vectors precludes their use for therapeutic purposes [3], particularly in the context of chronic diseases such as diabetes. For therapeutic, *in vivo* approaches in which long-term gene expression is desired, adeno-associated vectors (AAV) stand out as the vectors of choice. The wild-type virus is non-pathogenic and the different serotypes of vectors have ability to transduce a wide variety of cell types, mediating long-term expression of the gene of interest in non-dividing tissues. In addition, the simple composition of AAV vectors, and their low efficiency in transducing professional antigen-presenting cells perhaps contribute to their generally low immunogenicity [4]. These gene transfer vectors have been used in clinical trials since the mid-1990s, and no serious adverse events related to the vectors have been described so far. More than 300 participants have been enrolled in these studies, comprising adults and children affected by different pathologies, generally all serious illnesses, and administered with recombinant AAV at different doses and through different routes to target different organs, mainly liver, skeletal muscle, brain, and eye [5]. Thus, recombinant AAV vectors are regarded as having a strong safety record after both local or systemic administration [6]. Indeed, in 2012 the European Medicines Agency gave marketing approval to the first gene therapy product for the management of lipoprotein lipase deficiency (Glybera®) based on the administration of lipoprotein lipase-expressing AAV vectors of serotype 1 (AAV1) to the muscle. The only limitations to the use of these vectors are their limited cloning capacity, the presence in the general population of pre-existing anti-AAV humoral immunity due to natural infection that may preclude transduction of certain organs, and the subclinical activation of capsid-specific T cells when vectors are administered to peripheral organs that can limit expression of the therapeutic transgene but this has so far been efficiently controlled with short-course immunosuppression [7–9].

The main properties of the viral vectors most commonly used in gene therapy are summarized in Table 70.1.

Gene therapy for diabetes

Both type 1 diabetes (T1DM) and type 2 diabetes (T2DM) are characterized by hyperglycemia, which when not properly controlled, ultimately leads to the development of severe microvascular, macrovascular, and neurological complications with high morbidity and mortality. Although the control of hyperglycemia remains the main target of the strategies developed so far for diabetes, several approaches target other components of the disease pathogenesis, which are different in T1DM and T2DM, as discussed later.

Much less work has been done in the development of gene therapy approaches for diabetes long-term complications. The complexity of the mechanisms underlying the development of these diseases as well as the lack, in most cases, of appropriate animal models of human disease, in particular retinopathy, neuropathy and nephropathy, have hampered this objective.

Gene therapy for T1DM

The hyperglycemia of T1DM results from an absolute deficiency of insulin secretion due to the autoimmune destruction of the β cells of the pancreas. Therefore, the main gene therapy approaches developed for T1DM have focused on restoring insulin production by islets or surrogate cells, enhancing glucose disposal or avoiding the destruction of remaining β cells.

Ex vivo genetic engineering of islets for transplantation

Islet transplantation has demonstrated therapeutic benefit in people with T1DM, particularly with the Edmonton Protocol (see Chapter 69) [10]. However, the scarcity of cadaveric donors and the large quantities of functional islets required for amelioration of diabetes in each single individual have limited the broad clinical application of this approach. Moreover, the processes of islet isolation, purification and transplantation, together with the host's immune response, greatly impair islet function and promote islet apoptosis, limiting the long-term survival of the grafts [10]. To overcome these limitations, several studies have explored gene therapy strategies based on the *ex vivo* genetic engineering of islets prior to transplantation. Adenoviral vectors have been the most extensively used vectors to this end because of their high efficiency for *ex vivo* transduction of islets of different species, including human [11, 12]. The transgenes used to improve the outcome after transplantation can fall within three main categories:

1 Mitogenic and/or prosurvival/anti-apoptotic factors aimed at promoting islet survival, such as hepatocyte growth factor (HGF),

Table 70.1 General characteristics of the most commonly used viral vectors.

Viral vector	Retroviral (RV)	Lentiviral (LV)	Adenoviral (Ad)	Adeno-associated (AAV)	Herpes Simplex (HSV)
Family	*Retroviridae*	*Retroviridae*	*Adenoviridae*	*Parvoviridae*	*Herpesviridae*
Pathogenicity of parental virus	Yes	Yes	Yes	No	Yes
Genome	ssRNA, lineal	ssRNA, lineal	dsDNA, lineal	ssDNA, lineal	dsDNA, lineal
Maximum cloning capacity	8 kb	8 kb	36 kb	4.7 kb	150 kb
Production at high titers	Yes	No	Yes (lower titers with 3rd generation vectors)	Yes	No
Insertion in host genome	Yes, with preference for regulatory elements	Yes, but with no preference for regulatory elements	No	Yes, but randomly and with extremely low frequency Mainly episomal.	No
Innate immunity	Yes	Yes	High for 1st and 2nd generation vectors	Very limited	Yes
Target cells	Infects dividing cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells	Infects dividing and quiescent cells
Transgene expression	Long-lasting	Long lasting	Short-lived, except for 3rd generation vectors	Long-lasting	Short-lived, except for late generation vectors
Main advantages	Long-lasting expression in dividing cells Production at high titers	Long-lasting expression in dividing cells	Episomal Production at high titers (except for 3rd generation) High levels of transduction *in vivo* High cloning capacity	Episomal Production at high titers High levels of transduction *in vivo* Non-pathogenic, low immunogenicity Several serotypes with different tissue tropism	Episomal High cloning capacity
Main disadvantages	Infects only dividing cells Limited cloning capacity Risk of insertional mutagenesis	Limited cloning capacity Risk of insertional mutagenesis but lower than for retroviral vectors	Inflammatory and immune responses to the viral proteins limit persistence of transgene expression. Diminished in 3rd generation vectors. Useful only for short-term studies Unselective tropism	Limited cloning capacity	Transient expression of the transgene Non -characterized neurotoxicity

X-linked inhibitor of apoptosis (XIAP), manganese superoxide dismutase (MnSOD), B-cell lymphoma 2 (Bcl-2), and heme oxygenase-1 (HO-1) [13–15].

2 Immunoregulatory genes to counteract the immune response that destroys β cells, such as interleukin-1 receptor antagonist protein (IRAP), interleukin 10 (IL-10), interleukin 4 (IL-4), and transforming growth factor β (TGF-β) [16, 17].

3 Factors that promote vascularization, such as HGF and vascular endothelial growth factor (VEGF), given that hypovascularization has been deemed a likely culprit for the short-term survival of transplanted islets [18, 19].

In general, these strategies enhanced the viability and function of the transplanted islets and attenuated β-cell death, preventing graft failure and reversing hyperglycemia.

In addition to the *ex vivo* genetic manipulation of islets, AAV vectors have been used *in vivo* to deliver immunomodulatory genes, such as the immunosuppressive IL-10 or Epstein-Barr-derived BCRF-1, to the muscle of the recipient of the islet graft prior to the transplant [20, 21]. This strategy has been shown to prevent recurrence of autoimmunity and allogeneic rejection, resulting in prolongation of graft survival and remission of diabetes in mice [20, 21].

Ectopic production of insulin by non β cells

Other gene therapy strategies have focused on the use of surrogate cells to produce insulin. In β cells, proinsulin is processed into mature insulin by the proprotein convertases PC1/3 and PC2, which are absent in the majority of other cells. To solve this problem and enable the processing of proinsulin by surrogate cells not expressing PC1/3 and PC2, new proteolytic sites have been engineered in the proinsulin molecule which are recognized by furin, a protease present in most cells.

Several cell types have been used in *ex vivo* gene transfer approaches to achieve ectopic production of insulin, including mouse pituitary corticotroph cells [22], keratinocytes [23, 24], fibroblasts [25], myotubes [26], hepatocytes [27, 28], and gut K cells [29, 30]. For the last four engineered cell types there is evidence of amelioration of glycemia, ranging from partial to total, when transplanted into diabetic mice [25, 26, 28, 30]. However, in most of these studies the therapeutic effect was short-lived due to loss of transplanted cells [25, 26, 30].

The most noteworthy results in the attempts to achieve ectopic insulin production have been obtained by genetically engineering hepatocytes *in vivo* to produce insulin in a glucose-regulated manner. Hepatocytes are attractive target cells because they express the same glucose-sensing molecules as β cells, such as the glucose transporter type 2 (GLUT-2) that mediates the insulin-independent entry of blood glucose into the cell and the enzyme glucokinase (GK), which phosphorylates the incoming glucose molecule. In addition, hepatocytes are essential regulators of carbohydrate metabolism and several genes expressed in the liver are transcriptionally regulated by glucose or insulin, offering the possibility of engineering glucose/insulin-controlled expression cassettes that mediate the production of insulin as a function of circulating glucose/insulin levels. To this end, naturally occurring promoters such as those from the GLUT-2, phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G-6-Pase) and liver-pyruvate kinase (L-PK) genes as well as engineered hybrid and synthetic promoters have been used to mediate glucose/insulin-responsive insulin expression following *in vivo* delivery of gene transfer vectors [31–37]. None of these systems, however, managed to mimic the quick response to glucose of the insulin promoter [34], and the slow glucose-mediated transcriptional control of these promoters may result in an inadequate insulin secretory response, with postprandial episodes of hyperglycemia followed by hypoglycemia several hours later.

Enhancement of glucose disposal

As an alternative to ectopic glucose-regulated insulin expression in the liver, gene transfer of the insulin gene can be used to engineer a glucose sensor in skeletal muscle in order to enhance glucose uptake in a glucose-dependent manner in this tissue to lower diabetic hyperglycemia [38]. Several reasons support the choice of skeletal muscle as a target organ for this strategy. First, muscle can efficiently secrete proteins into the bloodstream and has a metabolism highly based on glucose consumption, accounting for about 70% of glucose disposal after a meal. Second, muscle is easily accessible by non-invasive procedures, and gene transfer by AAV vectors leads to minimal systemic biodistribution, limiting biological effects to this organ even if ubiquitous promoters are used to direct therapeutic transgene expression [39]. Moreover, gene delivery to muscle is not limited by the presence of pre-existing neutralizing antibodies against AAV [40], a key aspect given the relatively high prevalence of anti-AAV antibodies in the general population [41].

In normal conditions, insulin stimulates glucose uptake in skeletal muscle by promoting the translocation of the glucose transporter type 4 (GLUT-4) to the plasma membrane [42]. Once inside the muscle cell, glucose is phosphorylated by hexokinase II (HK-II) [43]. HK-II has a low Km for glucose and is inhibited by glucose-6-phosphate, which limits glucose uptake. In contrast to HK-II, the hepatic GK has a high Km for glucose (about 8 mM), is not inhibited by glucose 6-phosphate, and shows kinetic cooperativity with glucose [43]. During diabetes, because of the lack of insulin, the translocation of GLUT-4 to the plasma membrane and mRNA levels and activity of HKII are decreased in muscle cells [44, 45], compromising the ability of the skeletal muscle to dispose of glucose after a meal. To counteract diabetic hyperglycemia, a novel gene therapy approach has been developed based on the co-expression of the insulin and glucokinase genes in muscle cells. The rationale behind this approach is based on the following premises:

1 Expression of constant, low levels of insulin ensures translocation of GLUT-4 to the plasma membrane without the risk of causing hypoglycemia;

2 Low levels of insulin are also sufficient to inhibit lipolysis and prevent ketoacidosis; and

3 The expression of GK draws the uptake of glucose into the muscle cell only when blood glucose levels are high.

Hence, the combination of these two genes generates a "glucose sensor" in the skeletal muscle that uptakes large quantities of glucose only when circulating glucose levels rise, such as in postprandial conditions, but does not cause hypoglycemia because GK activity is shut down at physiological glucose concentrations.

As a proof of concept, this approach was first tested in transgenic animals that overexpressed the insulin and glucokinase genes specifically in skeletal muscle [38]. When made diabetic, these mice were normoglycemic and did not develop secondary complications. Afterwards, AAV1 vectors were used to transfer the insulin and glucokinase (GCK) genes to the skeletal muscle of diabetic mice. In contrast to untreated diabetic mice, in AAV1-Ins and AAV1-GCK-treated mice, long-term restoration of fed and fasted normoglycemia was achieved [38]. AAV1-treated mice also showed increased skeletal muscle glucose uptake, normalization of glucose metabolism in the liver (increased glucose uptake and glycogen synthesis and reduced hepatic glucose production) and improved glucose tolerance [38]. Moreover, these mice had normal food and fluid intake, and the weight of the abdominal fat pad and skeletal muscle was normalized [38]. This study established the proof-of-concept that a gene therapy based on the production of basal levels of insulin and the increased uptake of glucose by the skeletal muscle allowed for a tight regulation of glycemia [38].

As a next step towards the clinical translation of this approach, a pre-clinical study in diabetic dogs was undertaken to investigate feasibility, efficacy, duration of the therapeutic effect as well as safety issues. A single intramuscular administration of AAV1 vectors encoding for insulin and GCK to diabetic dogs resulted in normalization of fasting glycemia and accelerated disposal of glucose after an oral challenge for >4 years after gene transfer,

with no episodes of hypoglycemia, not even during exercise [39]. This normalization of glucose metabolism was associated with recovery of body weight, normal levels of glycated plasma proteins, and long-term survival without secondary complications. In contrast, gene transfer of either the insulin or the GCK genes alone failed to achieve complete correction of diabetes, indicating that the synergistic action of insulin and GK are needed for full therapeutic effect [39].

In vivo reprogramming of surrogate cells into β cells

The concept of β-cell reprogramming implies the transdifferentiation of a surrogate cell into a functional β cell capable of sensing glucose and releasing insulin accordingly. This is generally achieved through the use of transcription factors that are key for the differentiation of progenitor cells into β cells during pancreas development.

Most *in vivo* approaches tested so far have used adenoviral-mediated gene transfer of Pancreatic duodenal homeobox-1 (Pdx-1), NeuroD, MafA, and Neurogenin-3 (Ngn3), individually or in combination, to liver or pancreatic exocrine cells via systemic or intra-pancreatic administration, respectively [46–55]. Although this vector type generally mediates short-term expression of transgenes of interest (Table 70.1), their use here is justified because evidence suggests that, at least in the liver of mice, adenoviral transduction per se is required for efficacy [54]. When the target cells were hepatocytes, oval cells or ductal cells in the liver, hyperglycemia partially ameliorated because of the expression of insulin in these cells, but full phenotypic conversion into functional β cells could not be achieved [46–51, 53, 54]. In contrast, when cells from the exocrine pancreas were reprogrammed, the resulting cells did not exhibit a hybrid or mixed phenotype but closely resembled islet β cells at biochemical and ultrastructural level [52, 55]. Furthermore, reprogrammed cells formed islet-like structures and mediated long-term (>1 year) normalization of hyperglycemia [52]. It is worth mentioning that the formation of islet-like clusters and the acquirement of glucose-responsiveness like the one of endogenous β cells were slow processes, and full physiological maturity of the reprogrammed cells was not accomplished until several months after reprogramming induction [52].

It should be borne in mind that genetically reprogrammed β cells, like endogenous islet β cells, will be susceptible to autoimmunity [56], hence reprogramming gene therapy approaches may require concomitant immunotherapy to avoid destruction of the β-cell surrogates.

β-Cell regeneration

Another approach to restore the β-cell mass considers the regeneration of β cells from those cells that have survived the attack of the immune system. The regenerative potential of the endocrine pancreas seems to be quite high immediately after the onset of the disease [57], but it slows down as the disease progresses [58]. To induce replication of remaining β cells, genes have been transferred *in vivo* to murine and canine β cells mostly by means of adenoviral and AAV vectors, the latter having a much more efficient transduction, via different routes of delivery including intravenous and intraperitoneal systemic administration and local delivery to the pancreas through the bile-pancreatic duct [59–63]. *In vivo* gene transfer of mitogenic and anti-apoptotic/prosurvival factors such as HGF or Sirtuin 1 or downregulation of NADPH oxidase 2 (Nox2) or miR-338-3p reduced apoptosis and induced proliferation of β cells [61, 64–66]. Noticeably, delivery of glucagon-like peptide 1 (GLP-1), β-cellullin or Akt not only mediated β-cell regeneration but also reversal of diabetes [67–69]. Other genes that have been shown to promote β-cell regeneration in transgenic animal models and are therefore promising for gene therapy approaches for T1DM include insulin-like growth factor-I (IGF-I), regenerating gene 1 (Reg1), epidermal growth factor (EGF), gastrin or nerve growth factor (NGF) [70–74].

Immune modulation

The immune system is a key component of the etiopathogenesis of T1DM. The T cell–mediated destruction of β cells arises as a consequence of the breakage of tolerance to β-cell antigens. Consequently, many gene therapy approaches developed for the treatment of T1DM aim at increasing the number and/or activation of regulatory T cells (Tregs) and/or decrease the frequency of autoreactive T cells. Amongst all vectors, AAVs have been the most widely used vectors to transfer immunomodulatory genes to prevent or ameliorate T1DM in mice. AAV-mediated overexpression of the cytokines IL-2, IL-4, IL-10, or the chemokine CCL22 have demonstrated therapeutic efficacy in non-obese diabetic (NOD) mice, an animal model of spontaneous autoimmune diabetes [75–80]. IL-2 is the key cytokine supporting survival and function of Tregs [75]. Treatment with low-dose recombinant IL-2 has been recently reported to safely expand/stimulate Tregs and improve clinical condition in humans with T1DM, but multiple administrations were needed [81]. In contrast, one-time, AAV-mediated, systemic, muscular or β-cell specific delivery of the IL-2 gene increased the frequency and activation of Tregs and prevented diabetes in NOD mice [75, 76, 78]. IL-4 induces the expression of the transcription factor Forkhead box P3 (Foxp3), the defining marker of Tregs [82], in Treg precursor cells [83]. AAV-mediated expression of IL-4 in β cells prevented islet destruction and onset of diabetes in NOD mice [80]. On the other hand, IL-10 plays an important role in the development of Tregs and secretion of IL-10 by Tregs inhibits effector T-cell responses [82]. Gene transfer of IL-10 to murine muscle increased Tregs in a dose-dependent manner and abrogated diabetes development [77]. Finally, CCL22 is the ligand of the chemokine receptor CCR4, highly expressed on Tregs. Overexpression of CCL22 in β cells recruited endogenous Tregs to the islets, limiting expansion and effector activity of autoreactive T cells and conferring long-term protection from autoimmune diabetes [79].

Another strategy is based on the conversion of cytotoxic T cells, including pathogenic, β-cell-specific T cells into Tregs through *ex vivo* lentiviral or retroviral vector-mediated gene transfer of

Foxp3 [84, 85]. In addition, systemic administration of adenoviral vectors encoding a cytotoxic T-lymphocyte associated antigen 4 (CTLA4)-Fas ligand fusion protein stimulated apoptosis and blocked co-stimulation of autoreactive T cells and greatly reduced the incidence of T1DM [86].

Another group of strategies has relied on the active induction of immune tolerance, for example by expression of the preproinsulin II gene in the thymus following intrathymic administration of lentiviral vectors [87], by non-viral gene transfer of the IGF-I gene to the liver [88] or by transient, adenoviral-mediated expression of a soluble form of the immunoadhesin intercellular adhesion molecule 1 (ICAM-1) [89] soon after diabetes onset. All of these approaches resulted in suppression of autoimmune diabetes in NOD mice or transgenic mice overexpressing human interferon β in β cells [71], both of them murine models of human T1DM. Induction of antigen-specific tolerance by retroviral-mediated expression of insulin or glutamic acid decarboxylase 65 (GAD65) in B lymphocytes has also proven to be promising for T1DM (90). Likewise, the administration of viral vector- or plasmid-based gene transfer vaccines encoding the autoreactive antigens insulin, proinsulin or GAD65 has been reported to induce immune tolerance and prevent the development of T1DM in mice [91–93].

Gene therapy for T2DM

Although most of the gene therapy strategies developed so far for diabetes have focused on T1DM, as the scientific understanding of the pathophysiology of T2DM increases, a growing number of proof-of-concept gene transfer studies are being conducted in rodents to gain insight into the molecular mechanisms underlying T2DM as well as to evaluate the therapeutic efficacy of several candidate factors. The results of these studies highlight the tremendous potential of the genetic modification of metabolic tissues for the treatment of T2DM, but further work is warranted for the development of safe gene therapy approaches mediating long-term counteraction of T2DM.

T2DM results from a state of insulin resistance in peripheral tissues (mainly skeletal muscle, adipose tissue, and liver) which is not appropriately compensated by an increased insulin secretory response, likely due to a combination of decreased β-cell mass and function. Therefore, the vast majority of gene transfer studies for T2DM have either focused on ameliorating insulin resistance in peripheral tissues or on stimulating insulin secretion, with the goal of enhancing insulin production or increasing the functionality and/or mass of β cells.

Enhancement of insulin production

The systemic or intra-pancreatic gene transfer of the HGF, GLP-1, heat shock factor, adiponectin, metallothionein, or PPARα genes using adenoviral, lentiviral or AAV vectors has been proven to enhance insulin secretion, decrease endoplasmic reticulum (ER) stress-induced β-cell apoptosis and, in the case of GLP-1 and HGF, increase β-cell mass in mice with T2DM [94–98]. In a completely different approach, the engineering of the liver with adenoviral vectors to mediate glucose-responsive insulin production has been shown to improve glucose tolerance, insulin sensitivity and glycemic control in diabetic obese *db/db* mice [99].

Amelioration of insulin resistance

A growing number of *in vivo* proof-of-concept gene transfer studies have directed their efforts towards amelioration of insulin resistance and glucose intolerance via several different approaches. The systemic administration of adenoviral vectors encoding GLP-1 improved insulin sensitivity through restoration of insulin signaling in peripheral tissues and reduction of hepatic gluconeogenesis in diabetic obese *ob/ob* mice [100]. The attenuation of insulin resistance has also been achieved in T2DM high-fat diet (HFD)-fed rats through systemic AAV-mediated gene transfer of the serine protease kallikrein [101]. Kallikrein converts kininogen to the peptidic hormone bradykinin, which increases insulin sensitivity and stimulates glucose uptake *in vivo* [102]. Similarly, the AAV-mediated local gene transfer of HK-II to white adipose tissue has managed to increase glucose uptake in adipocytes [103], and may also be a promising strategy for improving insulin sensitivity in T2DM [104].

There is strong evidence that individuals with T2DM overexpress phosphoprotein enriched in diabetes/phosphoprotein enriched in astrocytes (PED/PEA-15) in skeletal muscle and adipose tissue [105], a protein that causes insulin resistance by interacting with the D4 domain of phospholipase D1 (PLD1) [106]. The disruption of the association between PLD1 and PED/PEA-15 at tissue level through adenoviral-mediated overexpression of a soluble form of D4 in the liver, pancreas, and skeletal muscle restored glucose homeostasis by improving both insulin sensitivity and secretion in diabetic transgenic mice ubiquitously overexpressing PED/PEA-15 and in obese HFD-fed wild-type mice [107].

On the other hand, recent studies support a role for cholesterol in the development of obesity, insulin resistance, and hepatic steatosis [108]. The ABCG5 ABCG8 (G5G8) sterol transporter promotes cholesterol excretion into the bile and the intestinal lumen. Following adenovirus-mediated delivery of the G5G8 genes to the liver of *db/db* mice, the levels of biliary cholesterol and fecal sterol increased, the levels of plasma glucose and triglycerides decreased and glucose tolerance improved [108]. These changes were associated with reduced expression of lipogenic genes, alleviation of ER stress, and restoration of hepatic insulin signaling [108].

Reduction of adipocity, adipocyte dysfunction, and adipose tissue inflammation

Given the strong association between T2DM and obesity, many proof-of-concept gene transfer studies have targeted adiposity, adipocyte dysfunction, and/or adipose tissue inflammation, with the aim of ultimately improving insulin sensitivity and glucose tolerance. The intra-cerebroventricular administration of AAV vectors encoding the adipokine leptin prevented HFD-induced adiposity, reduced blood glucose and insulin levels, and increased energy expenditure through thermogenesis [109]. It was

demonstrated that the effect was mediated by transduction of hypothalamic cells of the brain [110]. The administration to the muscle of AAV vectors encoding the secreted glycoprotein Wnt10b, a recently described member of the Wnt family reported to inhibit adipogenesis, decreased overall fat mass and improved glucose and energy homeostasis in obese rats [111]. In humans, mutations in Wnt10b are associated with obesity [112], and certain variants of the transcription factor 7-like 2 (*TCF7L2*, formerly *TCF4*) gene, another member of the Wnt signaling pathway, confer increased risk of T2DM [113].

AAV-mediated delivery to subcutaneous white adipose tissue of mitoNEET, a protein residing in the mitochondrial outer membrane and involved in regulation of mitochondrial iron content, resulted in benign expansion of the fat pad, reduced inflammation and preservation of insulin sensitivity in mice subjected to HFD [114]. Likewise, the adenoviral-mediated gene transfer of the secreted frizzled-related protein 5 (Sfrp5) to the liver reduced adiposity and adipose tissue inflammation in different models of obesity and diabetes, improving glucose tolerance and insulin sensitivity [115]. Sfrp5 is an anti-inflammatory adipokine linked to the Wnt signaling pathway whose expression is perturbed in models of obesity and T2DM [115]. Inhibition of macrophage infiltration and inflammation in adipose tissue has also been reported upon intravascular delivery to obese diabetic mice of adenoviral vectors encoding GLP-1 that resulted in increased circulating levels of the protein [116]. This observation suggested that the anti-inflammatory action of GLP-1 on adipose tissue might be the mechanism underlying the reported improvement in insulin sensitivity.

Interferon regulatory factor (IRF) proteins are a family of nine transcription factors involved in the mammalian regulation of type I interferon expression and innate immunity [117, 118]. These proteins also seem to play an important role in metabolism [119, 120]. For example, hepatic expression of IRF3 has been reported to be decreased in animals with diet-induced and genetic obesity [120], making IRF proteins interesting targets for gene therapy approaches to counteract T2DM. In this regard, the adenoviral-mediated liver-specific overexpression of IRF-3 or -9 improved glucose and lipid homeostasis and attenuated systemic and hepatic inflammation in diet-induced diabetic and *ob/ob* mice [119, 120].

Another promising therapeutic candidate for T2DM and obesity is adiponectin, which possesses insulin-sensitizing and anti-inflammatory properties [121]. In humans, adiponectin levels are inversely correlated with the degree of adiposity, insulin resistance and T2DM [122, 123]. Muscular or hepatic gene transfer of adiponectin by means of AAV vectors enhanced insulin sensitivity, lessened insulin-resistance, reduced obesity and downregulated hepatic gluconeogenesis, *de novo* lipogenesis and inflammation in HFD-fed diabetic rats [121, 124]. Similarly, the adenoviral-mediated expression of C1q/TNF-related protein-12, an adipokine sharing partial homology with adiponectin whose expression in adipocytes is increased by the antidiabetes drug rosiglitazone [125], improved glucose tolerance and insulin sensitivity, normalized hyperglycemia and hyperinsulinemia, and lowered postprandial insulin resistance in obese diabetic mice [125]. The effects on insulin sensitivity were mediated by the activation of insulin signaling in adipose tissue and liver [125].

Enhancement of adipose tissue vascularization

It has been postulated that the obesity-associated adipose tissue hypoxia that occurs as a result of insufficient adipose tissue blood flow could trigger insulin resistance by inducing inflammation, altering adipokine expression, and/or affecting adipocyte differentiation [126–128]. In this regard, a recent proof-of-concept study demonstrated that AAV-mediated gene transfer of the potent pro-angiogenic factor VEGF to fat pads can increase tissue vascularization in mice [103]. This may be a promising approach for the treatment of T2DM as VEGF overexpression in adipose tissue of transgenic mice has been proven to protect against obesity and insulin resistance in HFD-fed mice [129].

Conclusions and perspectives

Viral vectors have taken the lead as tools to achieve efficient *ex vivo* and *in vivo* long-term genetic modification of tissues and organs through a single vector delivery. This technological advance has opened the possibility of not only doing gene transfer studies to understand the role of a given gene in disease, but also to the development of new therapeutic strategies. In the case of diabetes there are a number of gene transfer approaches with demonstrated efficacy in lowering blood glucose that could offer an advantage over conventional treatments. Future studies are required to demonstrate the efficacy and safety in large animal models of the approaches that have demonstrated promise in small animals before any of these gene therapies are brought to the clinic to treat diabetes in humans.

71 Future Models of Diabetes Care

Sanjeev N. Mehta[1] and Robert A. Gabbay[2]

[1] Pediatric, Adolescent, and Young Adult Section, Joslin Diabetes Center; Section on Genetics and Epidemiology, Joslin Diabetes Center; Harvard Medical School, Boston, MA, USA

[2] Joslin Diabetes Center, Boston, MA; Harvard Medical School, Boston, MA, USA

Key points

- In the United States, recent legislation aims to reward healthcare systems and providers who offer value-based care representing a departure from traditional, volume-oriented fee-for-service models.
- The Chronic Care Model is a well-known framework for organizing diabetes care which has demonstrated effectiveness in a wide variety of clinical settings.
- Delivery system design emphasizing team-based care represents one of the most effective strategies for improving diabetes care.
- Primary care providers will remain central to the reorganization of chronic care, including safe and effective diabetes management.
- Self-management education and support are distinct, but important, components of effective diabetes care.
- Emerging technologies, such as telemedicine, may address important access issues for individuals with diabetes, but their cost-effectiveness warrants further investigation.

Introduction

The future of diabetes care will be shaped by projections of increased incidence, greater prevalence of complications in an aging population, and corresponding escalations in healthcare expenditures. The worldwide diabetes prevalence of 8.3% in 2014 already exceeded the 20-year projected prevalence made in 2010 (7.8%). Furthermore the number of individuals with diabetes are predicted to increase further from 415 million in 2015 to 642 million in 2040 [1]. In the United States (USA) alone, one in three persons will develop diabetes in their lifetime [2]. Current healthcare costs associated with diabetes and its complications now exceed $245 billion in the USA, and worldwide estimates are considerably higher [3]. In addition to promoting diabetes prevention, the millions of people with diabetes will require more cost-effective care models to reduce the burden of diabetes on affected individuals and society in general.

Nearly a decade after the Institute of Medicine's report describing *Crossing the Quality Chasm* [4], momentum continues to build for an implementation of better models of chronic illness care and diabetes is at the forefront of these efforts. In many ways, diabetes is the hallmark disease for studying quality improvement because of the prevalence, cost and strong evidence-base for attaining metabolic control [5]. For persons with diabetes, there is agreement about minimum goals for HbA_{1c} ≤7% (53 mmol/mol) (for youth <18 years, HbA_{1c} ≤7.5% (58 mmol/mol)); blood pressure (BP) <140/90 mmHg (for youth <18 years, BP <90th percentile for age, sex, and height); and low density lipoprotein (LDL) cholesterol <100 mg/dL (2.6 mmol/L). However, fewer than 14% of Americans with diabetes are currently achieving these goals, noting more stringent blood pressure goals (<130/80 mmHg) at the time of publication [6]. Patient, provider, and system-level factors contribute significantly to these suboptimal outcomes. As such, there is need for greater evaluation of real-world outcomes to understand optimal models of diabetes care better across the wide spectrum of care settings and cohorts of people with diabetes.

Diabetes is one of the most psychologically and behaviorally challenging chronic illnesses to manage because as much as 95% of the management relies on the individual's self-care efforts central to a person's livelihood, namely diet, exercise, and stress management [7]. With the onset of diabetes-related complications, the burden and costs increase substantially. Despite this, the current healthcare system often does not have adequate resources to foster a person's self-management. Limitations in the availability of self-management education and the lack of ongoing self-management support impair engagement with self-care. Effective diabetes self-management often requires the expertise, training, and ongoing involvement of a coordinated, multidisciplinary team of medical providers, educators, nutrition counselling, and mental health professionals. Most individuals with diabetes do not have ready access, either geographically or financially, to gain the necessary foundation for improving self-efficacy and ultimately self-management.

Textbook of Diabetes, Fifth Edition. Edited by R. Holt, C. Cockram, A. Flyvbjerg and B. Goldstein.

Providers may be similarly constrained to provide high-quality care due to constraints on time and resources. Clinical inertia is defined as the clinician's "recognition of the problem but failure to act" [8]. This refers to the situation where physicians fail to initiate or intensify therapy when faced with people who are not meeting target goals for clinical variables. This inertia certainly has many potential reasons including decreased provider visit time, lack of timely data, inadequate provider attention to patient adherence, and financial barriers. More information is ultimately needed on the basic epidemiology of clinical inertia including a careful analysis of associated patient, physician and clinic characteristics. Additionally, providers may not be up to date on rapidly evolving evidence-based guidelines, optimal approaches to medication management, and adequately trained on delivering effective encounters in time-constrained settings. Compounding these challenges is the plethora of new diabetes management data that are becoming available to the provider. The expanding use of electronic health records (and related regulatory requirements), advanced diabetes technologies such as continuous glucose monitoring devices, and greater connectivity through patient portals present the risk of overwhelming diabetes care providers. Better information technology systems are needed to provide the right information in a timely and efficient manner.

Despite the significant challenges confronting people with diabetes and their providers, it is increasingly clear that healthcare systems bear much of the responsibility for the delivery of suboptimal care and resulting outcomes. Lack of insurance remains a critical barrier to access for 12% of the US population; rates of insurance coverage vary internationally with many developed countries providing a basic level of national health insurance, in particular, coverage for primary care services. Despite the highest cost expenditure in the USA ($7000 per capita versus less than $3500 for Australia, Canada, France, Germany, The Netherlands, New Zealand, and the UK), 12% of the US population is uninsured despite federal regulation requiring health insurance coverage for all citizens [9]. In comparison to these seven high-income nations, the USA had the worst ratings for access, care coordination, and safety experiences [10].

Primary care is an important foundation of care in any health system. Starfield et al. [11, 12] have shown that residents of countries with strong primary care foundations have improved health outcomes and lower mortality, with lower costs and fewer health disparities. For people with diabetes mellitus, primary care physicians are a critical foundation of the healthcare delivery system. In the USA, individuals with diabetes consulting a primary care physician outnumber those consulting an endocrinologist by almost 10 to 1 [13]. There are well-described shortages of endocrinologists to support the management of particularly complex patients. Therefore, any reorganization of care will need to focus on the needs of primary care providers, the effectiveness of primary care settings, and coordination with ancillary support services, such as endocrinologists and community resources.

Overall, the solutions to these issues will require reorganizing and reinventing diabetes care from a systems-level approach that addresses the needs of people with diabetes and providers as well as the broader community in which they live. In the cross-national Diabetes Attitudes Wishes and Needs (DAWN) study, attitudes towards diabetes care were assessed across 13 countries from Asia, Australia, Europe, and North America [14, 15]. Although variation existed among countries in terms of both provider and patient perspectives of diabetes care, all respondents (primary care physicians, nurses, and specialists) noted lack of care coordination and implementation of chronic disease strategies as an area in need of improvement worldwide. As noted above, the payment system was also identified as a barrier in most of the countries surveyed, with the USA, Germany, and Japan leading the way. In the DAWN Study, people with diabetes reported high ease of access to providers, but ratings of team collaboration among their providers were relatively low. Primary care physicians noted a lack of multidisciplinary care and a need for more coordination of care. This chapter focuses on the safe, efficient, and effective organization of diabetes care, provides current examples, and introduces the potential of telemedicine to enhance high-value healthcare delivery.

The Chronic Care Model

Although several approaches have been utilized to translate evidence-based recommendations into clinical practice, the Chronic Care Model (CCM) has been the most widely implemented model to demonstrate effectiveness in a variety of clinical settings in the USA and internationally [16, 17]. The CCM proposes that productive interactions resulting in improved outcomes are more likely to result from prepared, adequately resourced practice teams and an informed and empowered patients (Figure 71.1).

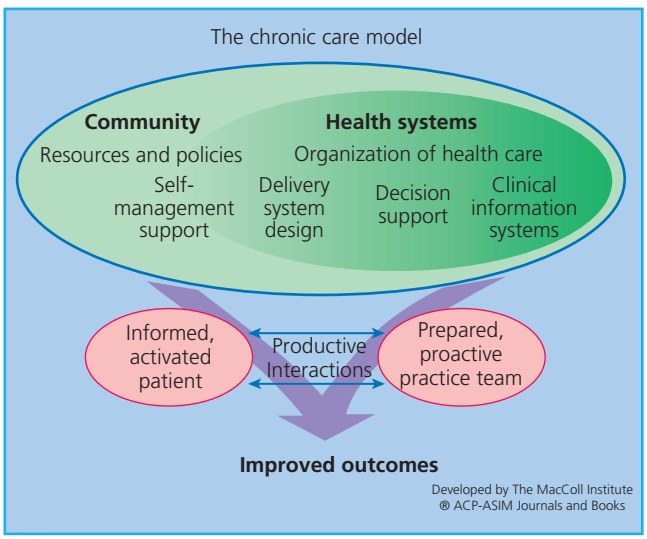

Figure 71.1 The Chronic Care Model. Source: Wagner 1998 [16]. Reproduced with permission of American College of Physicians; permission conveyed through Copyright Clearance Center, Inc.

The CCM conceptual framework highlights the organization of care that would facilitate these productive interactions with the goal of transforming the overall care delivery system from one that is reactive and organized around acute care to one which is proactive and planned around the care of individuals with chronic diseases such as diabetes. Indeed, interventions evaluating the CCM framework have often focused on more cost-effective management of diabetes.

Mounting evidence from randomized intervention trials, and evaluations of large-scale quality improvement efforts, and comparisons of high and lower performing practices have demonstrated that the implementation of the CCM is feasible across a diversity of practice settings with resultant improvements in disease outcomes [18]. The CCM has been employed for diabetes in a number of healthcare settings and has demonstrated improvement in cardiovascular risk factors [19] and reductions in HbA_{1c} [16], along with improvements in care processes, such as complication screening. Although simpler interventions would be attractive, the evidence suggests that high-performing practices do best when they incorporate multiple elements of the CCM [20–24].

The CCM focuses on six core elements summarized below, and followed by more in-depth descriptions:

1 *Health systems.* The success of reorganizing more effective care systems is contingent on the support of senior leadership responsible for setting overall priorities and allocating resources. There is often a need to better inform leadership of the unique burden diabetes places across various ambulatory and inpatient care settings. At a minimum, recognizing the financial opportunities of more cost-effective care strategies for this highly prevalent condition may need to be demonstrated given myriad demands of a health system. Senior leadership can then facilitate interventions and set policies aimed at delivering and promoting high-value diabetes care.

2 *Delivery system design.* The healthcare system must thoughtfully reorganize, and even restructure, staff and resources to deliver high-quality diabetes care. The Institute of Medicine has characterized high-quality care as safe, timely, effective, efficient, equitable, and patient-focused. In the ambulatory care setting, planned visits are more likely to result in proactive and productive patient encounters. In this setting, clinical staff take on specific roles and responsibilities in preparation for each visit. Visits themselves are structured to be efficient and patient-centered. Given time constraints, effective visits will often require targeted goal setting and addressing potential barriers to behavior change with timely follow-up by phone or in person. The delivery system should be organized to ensure that staff are engaged to their full potential to address patient needs before, during and—importantly—following routine encounters. Team-based care may also facilitate higher level care management efforts for more complex or challenging patients.

3 *Decision support.* Once healthcare teams are efficiently organized, they must be empowered to access and deliver evidence-based care in time-constrained settings. Individuals with diabetes often have multiple comorbidities resulting in competing demands for provider attention and knowledge. Given the likelihood of time-constrained encounters, high-quality systems must provide timely, easily accessible, and relevant clinical decision support around diabetes management. Guidelines are best integrated through reminder systems that can be embedded into daily care; periodic feedback and standing orders can be used to empower other practice staff to ensure that evidence-based guidelines are implemented. Embedding evidence-based guidelines into daily clinical practice and sharing those guidelines and information with people with diabetes to encourage their participation are the keys to decision support. For more complex patients (presence of significant comorbidities or diabetes-related complications) or those with more advanced needs (insulin titration, insulin pump initiation), there needs to be an effective approach to accessing support from specialists, such as endocrinologists or diabetes educators. Innovative approaches that incorporate real-time specialist-based decision support are needed.

4 *Clinical information systems.* Health information technology has the capacity to go well beyond meeting rules and regulations around medical documentation to support the delivery of high-value diabetes care. Clinical decision support systems, ideally embedded in electronic health records, may improve both diabetes care delivery and clinical outcomes [25]. These systems can provide timely information and reminders to both providers and people with diabetes and identify high-risk subpopulations for more intensive care. As practices engage with broader population health strategies (e.g. care management and outreach programs), diabetes registries that provide searchable information on diabetes populations are proliferating in many healthcare settings [26]. By tracking key process and outcomes, these registries can also provide important feedback on the overall functioning of the healthcare system.

5 *Self-management support.* Diabetes education has long been recognized as a crucial part of diabetes management, but there is increased recognition of the need for ongoing support. Self-management support goes beyond providing the knowledge needed by the individual to manage their own disease successfully. It emphasizes the person's central role in their care by involving them in establishing health priorities, identifying potential barriers to behavior change, and reflecting on personal goals at follow-up. This helps to foster the individual's personal responsibility and self-efficacy for managing their own health. Given the inadequate supply of diabetes educators, it is incumbent on primary care providers to incorporate these approaches into their daily encounters. The cost-effectiveness of using practice-based health coaches and physician extenders to improve self-management support warrants further evaluation.

6 *Community.* People with diabetes should be encouraged to participate in effective community programs, and this highlights the need of providers to partner with those within the community to fill gaps of care related to access, education, and ongoing support. Partnering becomes even more critical in limited resource environments where extending care beyond the confines of the clinic is essential. Partnerships with community advocates may also be

used to advance laws and policies at the local, state, and national level to improve benefits for those living with diabetes.

Health systems

In suggesting solutions to improve the US healthcare system, Berwick et al. [27] provide insight into important aspects of the healthcare delivery system that translate into improved outcomes. They propose that an effective healthcare system that produces outstanding health outcomes pursues three primary goals, known as the Triple Aim:

1 Improving the patient's experience of health;
2 Improving the health of a defined population;
3 Reducing the costs of care for populations.

In order to accomplish the Triple Aim goals, Berwick et al. define three preconditions. First, the healthcare system must be focused and responsible for the health of a defined population. Second, monetary and related constraints are placed on the system. The system does not have unlimited resources. The USA has experienced unrestrained healthcare costs and spends far more than any other high-income country's health system, yet its health outcomes lag behind other countries [28]. Third, there is an overarching entity that is responsible for the health of the population and pursues the goals of the Triple Aim. Health systems such as those in Canada and the UK already embody these principles. There are also several examples in the USA such as Kaiser Permanente, and Health Partners in Minneapolis and Group Health Cooperative, both closed-panel health maintenance organizations.

Accountable Care Organizations

Medicare expenditures represent 15% of all US federal spending and have risen faster than the gross domestic product for decades. The current, widely used fee-for-service payment structure incentivizes the provision of more services and has largely contributed to the unsustainable growth in healthcare spending in the USA. Perhaps most concerning, the US healthcare system is not achieving higher—or even comparable—quality care when compared to other high-income countries. Earlier efforts to control spending through capitation payments only incentivized cost reduction and risked further deterioration in patient health outcomes [29]. In 2010, the Affordable Care Act (ACA) was signed into law with the broad aims of expanding health insurance coverage and reforming the healthcare delivery system in order to improve access to high-value care [30]. Efforts to redesign care delivery have focused on strengthening the role of primary care providers and coordinating care for Medicare beneficiaries across healthcare settings [31]. This focus on primary care has been central to initiatives in a number of health systems worldwide given the pioneering work demonstrating that robust primary care helps prevent illness and death [32].

The ACA established accountable care organizations (ACOs) under the Medicare Shared Savings program (MSSP) which would serve as the cornerstone of aligning incentives and accountability for providers across the continuum of care [33]. Under these programs, provider-led organizations assume responsibility for a population of Medicare beneficiaries (typically people over the age of 65 years) attributed to it based on their patterns of primary care use [34]. For its designated population, ACOs assume responsibility for the cost and quality of care regardless of where that care is provided. ACOs that deliver high-quality care at costs that are lower than their risk-adjusted projected spending target will share in savings with Medicare [34].

Accountable care organizations continue to evolve, but the early performance of ACOs has been assessed. By the end of 2014, MSSP had 405 participating ACOs serving 14% of the Medicare population. The ACOs demonstrated improvements in healthcare quality across numerous indicators, including some beneficial impacts on patient experience (e.g. timely access to care) [35], at overall cost savings. Despite favorable initial assessments, it remains too early to evaluate the unique impact of the ACA and accountable care organizations specifically on improvements in care quality and reductions in medical expenditures. Additionally, the costs associated with establishing an efficient and well-coordinated ACO, such as a robust information technology infrastructure and timely collection of quality measure data, remain unknown [30, 36].

Concerns remain regarding the development of shared savings for ACOs under the ACA. Perhaps most importantly is whether the law will provide enough incentive to increase and engage primary care providers fully across the diversity of ACO models, especially those established by hospitals or specialty groups [30]. Some have suggested inclusion of primary care-oriented quality measures for ACOs as a means of ensuring their central role in a redesigned healthcare system [31]. Early data suggest that poorer performing ACOs and those in high-spending regions were more likely to achieve savings under MSSP [37]. While this should encourage participation and value creation for these ACOs, it has been suggested that adjusted (e.g. regional) benchmarks will incentivize lower-spending ACOs to participate in the MSSP. Quality is assessed across five domains: patient experience, care coordination, patient safety, preventive health, and health of at-risk and elderly populations. The costs associated with collecting 65 standardized measures may be significant with ACOs, especially those without a strong information technology infrastructure across their healthcare settings, and will need to be assessed when determining the overall value of ACOs [29, 37, 38]. Several diabetes quality measures have been incorporated into these measures. Finally, and not unexpectedly, there remains ongoing discussion regarding the balance of risks and rewards for providers considering participation in an ACO [29, 39].

Delivery system design

Although the best results are obtained when multiple facets of the CCM are implemented together, probably the single most effective quality improvement intervention in diabetes care involves delivery system design to incorporate a team-based approach [40]. Other key elements of delivery system design are case management and shared care.

Realistically, primary care providers have reached their limit in terms of additional tasks that they can undertake, and therefore it is inevitable that the care team needs to be expanded. In many ways, team management has been considered a central feature of superior diabetes care. Diabetes educators and dietitians have long been part of standard diabetes care and the expansion of their roles and the roles of other individuals within the healthcare system will likely continue.

Team-based care allows task distribution which includes identifying team members to:

1 track longitudinal information through flowsheets, registry data, or electronic health records;

2 deliver evidence-based process measures and conduct recommended clinical assessments;

3 ask patients about self-care goals and care barriers prior to the primary healthcare provider entering the room.

Standing orders can be used to empower office staff to order overdue laboratory screening and eye examination referral, and can even extend to algorithms for medication intensification. Appropriate communication between team members is the key, and the incorporation of clinic "huddles" at the beginning of the day can ensure that appropriately planned care is delivered to all individuals with diabetes. The goal is to ensure that every member of the team practices at "the top of their license" and utilizes their skills to improve care for people with diabetes.

Diabetes has been a fertile testing ground for care management approaches in which usually either a nurse or pharmacist meets regularly with high-risk individuals to provide intensified care [40, 41]. Care populations are segmented based on needs to ensure that appropriate care intensity is provided. Key elements of care management include:

1 Defining and identifying high-risk patients;

2 Case assessment;

3 Individualized care plans;

4 Development, implementation, and monitoring of outcomes.

Diabetes registries are an ideal source for identifying high-risk individuals either based on clinical measurements (e.g. HbA_{1c} levels), low self-management skills, or overdue visits. Intensification of therapy can be facilitated by empowering other healthcare providers through standing orders to implement changes, and by clearly assessing health management needs and support.

Care management is most effective when incorporated and embedded within the primary care clinic as opposed to "carve-out" models where an outside entity provides telephonic care management for patients and which subsequently leads to ineffective communication with the primary healthcare provider. Integration of care management with the primary care practice is needed to ensure appropriate information exchange, shared goals, and coordination of care.

Diabetes nurses are eager to increase their involvement and take on more responsibility for diabetes care, as surveyed internationally through the DAWN study [14]. Pharmacists have also been utilized to work in conjunction with primary care physicians in a case management role. Recent reimbursement changes within the US Medicare system have facilitated billing for these services based on non-randomized trials in which this care has been found to be cost-effective [42].

Care management approaches have been effective at improving glucose control, blood pressure and lipid control in many different settings in the USA and elsewhere [40, 41]. One controversy has been the extent to which case management permits medication titration. Two models have been used: one in which the case manager advises the primary care physician who then makes the medication change versus the second in which a standing order algorithm enables a case manager to intensify treatment without routinely checking with the primary care provider. Although studies suggest that standing order algorithms are more effective in lowering HbA_{1c} levels [40, 41], some physicians have concerns about nurses or pharmacists making these changes without routine provider input. As more studies and appropriate training programs are developed to allow other health professionals to assist in medication titration, this approach will continue to show promise in improving clinical outcomes while not overburdening the already overtaxed primary care system.

Shared care is defined as "the joint participation of primary care physicians and specialty care physicians in the planned delivery of care, informed by an enhanced information exchange over and above routine discharge and referral notices as the co-management of patients by primary care and subspecialty specialists" [43]. Currently, when most people with diabetes are referred to endocrinologists, care is subsumed by the specialists and true co-management is rare. In a Cochrane review which examined shared care across multiple chronic illnesses, limited data were available on effective models [44].

Decision support

The approach frequently used as decision support involves embedding evidence-based guidelines into daily practice to obtain clinical improvement. A number of organizations provide evidence-based clinical guidelines. Although there can be some discrepancies among them, most are generally disagreements on how low goals should be brought down. While these debates are important, overriding evidence suggests that the vast majority of people with diabetes are not at minimum clinical care goals. Establishing clinical goals is a first step; however, the best practices to achieve those goals are critically important to ensure positive clinical outcomes. The American Diabetes Association (ADA) and national bodies such as the National Institute for Health and Care Excellence (NICE) provide detailed guidelines [45]. This is a necessary first step, but decision support goes beyond the acceptance of consensus guidelines and focuses on the implementation of those guidelines in everyday practice. Although provider education regarding guidelines is important, these interventions typically have had limited impact beyond processes of care (i.e. ensuring that more patients are screened for complications). Effective multifaceted interventions most often include academic detailing, physician reminders, and audit and feedback to improve diabetes

outcomes. Patient tracking systems (patient registries) and nurse-led interventions are also effective [46].

Examples of guideline implementation can include incorporating decision support into electronic health records or reviewing the chart prior to a planned visit to identify gaps in care and strategies to intensify treatment plan. Although provider knowledge of guidelines is critical, these guidelines need to be shared with people with diabetes to encourage their participation. Empowering people with diabetes to "know their numbers" provides the basis for a negotiated treatment plan to achieve those goals. Ideally people with diabetes are involved in creating goals for care and incorporate "shared decision-making."

Given the evidence that blood pressure control can reduce both microvascular and macrovascular complications, future efforts will clearly focus on identifying better approaches for monitoring this outcome. Self or automated blood pressure monitoring offers many of the same advantages as glucose monitoring. An increased number of blood pressure recordings increase the accuracy of the measurement. It may also empower individuals to discuss their blood pressure with their physician [47]. Home monitoring, in conjunction with other interventions such as patient education, Internet communication, nurse or pharmacist follow-up, leads to improved blood pressure control [48, 49]. Telemonitoring may lead to reductions in both systolic and diastolic blood pressure [50].

One potential barrier to capitalizing on insights from self or automated blood glucose or blood pressure monitoring data is that clinicians may be overwhelmed by the sheer quantity of clinical information. The increasing availability of continuous glucose monitoring data, routine glucose self-monitoring results that can be shared through web portals, and ambulatory blood pressure monitoring are all at the expense of potentially overburdening the already busy clinician with much information, but inadequate—and often non-reimbursed—resources to manage this vital data. There will clearly be a need to develop more robust data filtering methodologies to analyze and package this information in clear concise summaries that can lead to appropriate clinician and patient action. Some evidence of this is already apparent in software for many of the blood glucose monitoring devices that provide ready access to glucose averages, standard deviations and other simple data analytical features. Merging this information with evidence-based decision support tools for providers is likely to increase their overall value to improve quality of care. Indeed, there has been a rapid evolution of mobile diet logbooks and "wearable devices," including pedometers, accelerometers, and other home monitoring devices that could provide objective measures of lifestyle behaviors [51].

Clinical information systems

Clinical information systems help to organize patient and population data to facilitate effective and efficient care delivery. Diabetes registries are being adopted in a variety of healthcare settings involving municipalities, academic health centers, third-party payers, the US Veterans Affairs Health System, and international registries in Europe, Canada, and elsewhere [52]. A registry is a searchable list of all people with a particular chronic disease. The well-designed registry lists all members of the patients' health team and provides key information for people with diabetes and providers. The critical impact of the registry is that it can allow timely identification of high-risk subpopulations, permitting the healthcare team to intensify treatment. A registry can also provide snapshots of care that can collate the many data elements needed for optimal care (e.g. last eye and foot examinations, nephropathy screening, HbA_{1c}, cholesterol, blood pressure) and can include prompts for care (decision support).

The primary challenges to further adoption of diabetes registries are cost and interoperability issues between different electronic health record systems. Information technology-related issues often receive the most attention by practices in the USA [22]; however, even non-technologic approaches such as incorporation of paper flowsheets can be an effective start. Furthermore, caution is needed to avoid wasting time and resources on implementing information technology solutions to diabetes care without attending to some of the more fundamental practice redesign issues. More robust results are often seen when team-based care and care management are in place.

A new challenge of information overload is entering into diabetes care. The widespread availability of the Internet makes it an attractive communication tool among people with diabetes and providers. It has been useful in multiple areas ranging from videoconferencing for diabetes education to tele-ophthalmology to patient support and education websites [53, 54]. People with diabetes desire an effective tool to communicate with their providers in order to receive responsive feedback and advice in a timely manner. Web-based management of diabetes through patient-initiated glucose meter uploads can facilitate provider treatment intensification and has demonstrated mixed results in different patient populations [55]. Glucose meter uploading is undoubtedly more accurate than patient recorded values. A potential advantage of between visit care offered by this type of telemedicine approach is an improvement in the "velocity to goal" (i.e. how fast the person reaches good diabetes control). This is particularly important because studies suggest that the average time between treatment intensification in some cases may be as long as 27–35 months [56]. Telemedicine provides a significant opportunity to give providers updated clinical data for more appropriate medication adjustments; however, enthusiasm is tempered by the data burden presented by the frequent communication between people with diabetes and providers related to blood glucose values. Reimbursement could facilitate greater adoption of this approach, and future advances could provide clinicians with treatment algorithms that can assist clinical decisions by interpreting data from glucose meter downloads.

The use of computerized glucose predicting engines shows promise in optimizing insulin management [57]. Albisser et al. [58] have demonstrated that utilizing a shared central database allowing for patient input of glucose self-monitoring values as

well as medication, diet, and exercise data, analyzed with a glucose predicting algorithm, enabled providers to reduce iatrogenic hypoglycemic events ninefold compared to that of baseline. The reduction in hypoglycemic events was accomplished without change in HbA_{1c}. Thus, the ability to predict future blood glucose levels improves glycemic stability and may also prove useful in patient self-management. Current research on closed-loop artificial pancreas systems are expected to provide more robust algorithms that will become available to guide patient self-titration of insulin and/or streamline provider titration decisions [59]. There are, however, potential regulatory issues with the widespread recommendations of these algorithms.

Self-management support

A distinction needs to be made between self-management support and self-management education. Self-management education is quite familiar in the diabetes community and encompasses the traditional role of the diabetes educator providing knowledge and skills to individuals with diabetes. Self-management support, however, need not be performed by a diabetes educator and, in fact, peer coaches have been utilized to foster self-management support. Self-management support involves the ongoing collaborative approach between coach and people with diabetes to define problems, set priorities, establish goals, and create treatment plans. Resources offered to problem-solve can include community-based organizations, peer support programs, and other groups. Individualized approaches that address the major concerns defined by the person with diabetes, typically involve a strong element of coaching with the goal of educating and empowering the individual. The challenge for the future is to make self-management support more widely available. Innovative approaches that leverage information technology to provide patient coaching are possible solutions [60].

Self-management has long been recognized as a key determinant of disease outcome. It has become increasingly clear, however, that knowledge is necessary but not sufficient to influence behavior. This has led to increased attention to determinants of patient behavior change. The overall importance of a behavior change is judged by the people with diabetes based on their values. Knowledge and education can clearly influence importance by providing the rationale for health improvement. Confidence, also referred to as self-efficacy, is the inherent confidence that a person with diabetes can be successful in making the behavior change. This can be augmented through problem-solving and discussion of alternative strategies. Adherence to diet, exercise, monitoring, and medication are required for optimal diabetes outcomes. Although many social and societal factors influence patient adherence, clinician counseling style has a profound impact on potential behavior change. Providers can either increase resistance to change, or help to facilitate readiness to change on the part of the patient. Patient empowerment and increased self-efficacy are key factors in enabling people with diabetes to feel confident in making necessary changes. Recent years have brought to the forefront behavior change approaches from the psychologic literature to be applied to diabetes. One of the most promising approaches is motivational interviewing [61, 62].

Motivational interviewing is a directive patient-centered counseling style for eliciting behavior change by helping patients to explore and resolve ambivalence. It is a collaborative patient–provider model that stresses that motivation must come from the patient, not the provider, and honors and respects the patient's autonomy. Initially utilized in the addiction field, it is now being applied to a number of chronic diseases including diabetes [63]. It is a teachable evidence-based approach that holds significant promise to improve patient adherence. Part of the attractiveness of motivational interviewing has been the well-defined set of skills that can be taught to different individuals. Certified trainers are available worldwide [64]. Brief motivational interviewing has adapted many of the skills of traditional motivational interviewing, as used by psychologists, for use in the busy time-pressured healthcare environment. Meta-analyses have shown this to be a powerful approach that can be learned by people with varying backgrounds and applied to multiple chronic illnesses [63] and the approach resonates with people with diabetes [65]. Studies in diabetes are promising [65–67] but others focused only on motivational interviewing have found mixed results. Fidelity to motivational interviewing technique and incorporating this approach with other changes in care delivery are likely to provide the most robust responses.

Several other behavior change models/theories, which can either explain or help practitioners conceptualize behavior change, have been identified. They include the health belief model, theory of reasoned action or theory of planned behavior, stages of change or transtheoretical model, social cognitive or social learning theory, community organization/building, and social marketing (See Chapter 56) [68].

Community

Community resources are often overlooked and not integrated into care for people with diabetes. Providers can become more familiar with these resources and work collaboratively to make individuals aware of opportunities. These can include safe exercise opportunities, healthy food availability, social programs, and support services that are available through non-governmental organizations. Communities can partner with healthcare organizations and governments to improve public awareness about diabetes. Overall, as prevention of diabetes and its complications becomes an increasing public focus, public awareness efforts to empower those with diabetes or at risk of diabetes to engage in appropriate diet and exercise will be needed. Social marketing provides a rationale for how this approach can be effective, and an excellent example of success is the change in tobacco use in the USA over the last three decades. Similar public health initiatives are needed to stem the epidemic of obesity that is fuelling the rise in diabetes.

Overwhelming evidence now suggests that the simultaneous incorporation of multiple components of the CCM is synergistic and more effective than traditional single intervention

approaches [22, 40]. Too much past research focused on only a single intervention and therefore missed the potential value of the concurrent implementation of multiple interventions for true "transformation of care."

Transformation of care, according to the CCM, has often been accomplished through "learning collaboratives" either through the Breakthrough Series Collaborative [69, 70] or through other similar experiences. Widespread implementation in the USA has generally occurred in large organizations, in part based on supportive reimbursement systems. Nevertheless, external support for practice transformation is being explored in several regional improvement programs [70, 71]. Position statements and guidelines from many professional societies have come out in strong support of the CCM [72, 73]. Another effective approach has been to use practice facilitators or coaches to guide clinical care teams to deliver timely, evidence-based care [74–76]. In the USA, the Primary Care Extension Program authorized by the Affordable Care Act aims to use Health extension agents to accelerate the transformation of primary care practices across the diverse practice and community settings. This service, modelled after the US Agricultural Cooperative Extension service, employs local change agents (practice facilitators) to guide practice transformation [77–79]. This concept clearly resonates with primary care providers [79], and could be utilized to spread diabetes innovations into primary care. As health systems move more towards the Institute of Medicine's model of a learning health system [80], diabetes has the opportunity to take center stage in many of the new models of care that are being proposed.

Another initiative to improve chronic disease management in the USA has focused on the patient-centered medical home. The patient-centered medical home is a concept being developed by the major primary care societies in the USA. It combines the principles of primary care (continuity of care, whole person orientation, quality/safety, prevention, timely access to care) with many of the elements of the CCM (coordinated/integrated care, teams, population health). One of the driving forces behind this concept is to revitalize primary care in the USA. Diabetes has been a common target condition of early pilots [81].

Although the concept of patient medical home has been attractive and a certification program has been established in the USA, there are concerns that this model may have limited application outside the country. In particular, many of the elements described for the National Center for Quality Assurance certification process require advanced information technology capabilities that generally necessitate an electronic health record. Despite the value of electronic health records, the mere availability of these tools is often insufficient to transform care. Often, practices and health systems can get side-tracked with the formidable information technology and interoperability challenges, losing sight of the overall goal of transforming healthcare. In comparison, the CCM elements are more easily translatable in low technology environments within the developing world.

In the USA, several states have explored integrated approaches to adopt the CCM. The foremost of these has been initial experience in Pennsylvania where insurers have agreed to provide significant reimbursement and incentives for primary care adoption of the CCM to improve diabetes care. Learning collaboratives are conducted across the state to teach clinicians and office staff the implementation aspects of the CCM. These efforts are supported by practice coaches who meet with practices individually to problem-solve implementation efforts. Clinics are required to report on clinical outcomes and care changes on a monthly basis, and payers have agreed to provide funding for needed practice changes such as case management in the hope of containing spiralling healthcare costs [82]. Evidence is accumulating that clinical outcomes improvements were associated with a concomitant reduction in healthcare utilization [83]. A national initiative is currently underway in Australia to implement the CCM through the Australian National Primary Care Collaboratives [84], and similar initiatives are being explored in Canada, Denmark, The Netherlands, New Zealand, and elsewhere.

Telemedicine

Technological advances over the last quarter century have created new opportunities for connecting people with diabetes to their healthcare providers. The established tradition of contacting on-call providers for urgent medical advice has evolved in the era of widespread internet- and phone-based connectivity. Increasingly, healthcare teams recognize the critical importance of staying connected to people with diabetes in-between routine, in-person clinical encounters in addition to improving access to people with diabetes for whom significant barriers may impede access to traditional face-to-face encounters. Telemedicine, broadly defined as the provision of medical care from a distance, may provide opportunities to serve the "triple aim" of better health and improved patient experience at reduced cost.

The promise of telemedicine relates directly to the challenges of effectively managing the epidemic of diabetes. Telemedicine may improve patient access for certain at-risk populations, such as those which are geographically (e.g. rural communities), functionally (e.g. elderly or disabled), and/ or socioeconomically isolated. Telemedicine may amplify the inadequate and concentrated supply of diabetes specialists, educators, and mental health personnel, to support primary care teams and their patients with diabetes. Telemedicine may even provide an alternative for engaging people with diabetes less motivated to visit their healthcare teams. Telemedicine has been used for a variety of chronic conditions, including diabetes and heart failure, with data suggesting increasing evaluations in both clinical and research settings [85].

Telemedicine encompasses numerous applications of established and emerging technologies. Not unexpectedly, there remains debate regarding the term "telemedicine" with ongoing efforts to standardize the definition by leading organizations such as the World Health Organization [86, 87]. Telemedicine interventions have used telephone, mobile phones, wireless devices, electronic mail, websites, or videoconferencing to deliver

care in real-time (synchronous) or using "store and forward" (asynchronous) approaches. The Food and Drug Administration has regulated the use of mobile health applications on "smart," internet-enabled mobile phones, a potential new option for telemedicine [88]. Telemedicine is often provided by medical staff, but trained, non-medical staff and automated messaging services have been used. There are many differences in published telemedicine interventions that may impact their relative cost-effectiveness for specific or more general populations living with diabetes. To date, most telemedicine evaluations occurred in addition to, not as a substitute for, traditional clinical encounters.

There have been a number of well-conducted meta-analyses and meta-regressions aimed at assessing the clinical effectiveness of dozens of telemedicine interventions for diabetes care [89–95]. The diversity of interventions has highlighted the wide range of opportunities, from diabetes education to medical care, including specialized services such as eye care and mental health support [96, 97]. These reviews have generally reported positive findings in terms of clinical outcomes (e.g. glycemic control and self-management) and patient experience (e.g. care coordination and access). However, many of the clinical improvements were modest and not consistent across studies. There were also some unintended negative findings, including challenges with technologies and diminished quality of interactions with healthcare teams. The generalizability and cost-effectiveness of telemedicine in diabetes care remains an important area for future investigation [91, 95].

In 1997, the US Government mandated the implementation and independent evaluation of the Informatics for Diabetes Education and Telemedicine (IDEATel) demonstration which would be the largest ever randomized controlled trial comparing telemedicine case management to usual care in the management of diabetes [98]. The IDEATel demonstration was delivered over two phases between 2000 and 2008 in New York State at a cost of $57 million. The trial targeted older, ethnically diverse, medically underserved Medicare beneficiaries with diabetes residing in medically underserved areas of New York State [99]. Videoconferencing by nurse case managers was enabled by a web- and camera-enabled computer, modem-based internet connectivity, and self monitoring equipment for blood glucose and blood pressure. Endocrinologists provided supervision as needed, and care recommendations were communicated to primary care physicians. Annual assessments of metabolic control were performed over the 5-year study period [100]. The trial demonstrated modest, but statistically significant, improvements in HbA_{1c}, blood pressure, and LDL cholesterol and no impact on mortality. There was significant attrition over the 5-year period much owing to challenges or frustrations with the computer. An independent evaluation demonstrated no reduction in Medicare use or costs for health services [101]. Despite sustained clinical improvements, the intervention costs were deemed "excessive" at over $8000/person annually given similar improvements noted in case management trials not using telemedicine, which occurred at a fraction of the cost. There were significant lessons learned and summarized in the final report to Congress which emphasized the need to target high-risk populations likely to benefit from telemedicine and the adoption of lower-cost, user-friendly technologies which have since entered the marketplace [102].

Telemedicine continues to evolve in the delivery of diabetes care. Short- and long-term studies have been generally favorable across a wide spectrum of measures including clinical outcomes, patient experience, and cost-effectiveness [89–94]. The IDEATel demonstration resulted in sustained clinical improvements which were likely to reduce the risk of long-term complications despite the high cost. It is conceivable that a similar trial in the current technological era could be implemented at significantly lower costs. It has been suggested that standardizing processes and outcomes (e.g. core dataset) may improve our understanding of the clinical and cost-effectiveness of telemedicine in the care of individuals with diabetes, perhaps most importantly, the absence of cost-effectiveness data may impede insurers' willingness to reimburse for telemedicine-based services [95]. State-level regulations and private insurance reimbursement are critical barriers to expanded use of telemedicine services [103]. There remains significant variation in reimbursement for telemedicine-based care in the commercial insurance market. Fortunately, there is evidence that reimbursement policies may be changing. The federal government is reimbursing telemedicine for certain at-risk populations as well as those receiving care in the Veterans Health Administration. In 2015, the Center for Medicare and Medicaid Services authorized reimbursement for telemedicince targeting rural communities faced with shortages of healthcare professionals [104].

However, standardization may also restrict the wide spectrum of telemedicine applications targeting the range of unmet needs for individuals living with diabetes. Most systematic reviews have recommended matching specific telemedicine approaches to targeted outcomes to optimize cost-effectiveness [89, 93]. That is, thoughtfully weighing the relative merits of specific patient populations, real-time versus asynchronous communication, use of medical staff versus trained non-medical professionals, individual versus group sessions, tailored versus generic feedback and education, and low versus high "dose" interventions. There is general consensus that effective telemedicine interventions, like most successful technological innovations, will benefit significantly from a participatory design approach in which people with diabetes are actively involved in identifying unmet needs and tailoring interventions to address them [89, 90, 93]. With the right design and careful implementation, telemedicine will continue to play an increasing role in supporting a healthcare system focused on delivering the right care in the right place at the right time.
